Acknowledgments.—We should like to express our sincere thanks to the Office of Naval Research for potentiating this investigation. The senior author was supported by Contract N6onr-218, Project NR-123-243.

Summary

Several derivatives of glucose-4-phosphoric acid have been obtained by an improved synthesis.

The properties of two new compounds have been reported.

(13) It should be noted that the rotation in pyridine is in good agreement with that reported by Raymond[3] but the rotation in alcohol is not. The value given here is that exhibited by several samples. For comparison, Raymond's values were −45.3 and −9.8°, respectively.

Phosvitin, the Principal Phosphoprotein of Egg Yolk

BY DALE K. MECHAM AND HAROLD S. OLCOTT

A phosphoprotein preparation containing 10% phosphorus has been isolated from egg yolk in yield sufficient to account for at least 60% of the total protein phosphorus in yolk. The proposed name "*phosvitin*" indicates both its high phosphorus content and its source in the egg yolk. Details of the isolation procedures and the results of various chemical and physical studies will be described in this paper.

A number of investigators have separated polypeptides rich in phosphorus following enzyme digestion of both vitellin and casein.[2-13] The presence of such peptides was attributed to the occurrence of groupings in these proteins resistant to digestion. In the case of vitellin at least it now appears that such polypeptides were formed from a phosphoprotein of as high phosphorus content as any of the polypeptides isolated, and that most of the phosphorus was present in the form of the phosphoprotein to be described.

Isolation

Phosphoprotein fractions containing 7% or more phosphorus[14] were first obtained by the following procedure. Fresh liquid egg yolk was extracted with chloroform to remove lipids. The residual suspension was then washed with water to remove the "livetin" fractions, and finally extracted with 10% sodium chloride in the presence of chloroform to obtain the phosphoprotein. Salt was removed by dialysis. Apparently most of the other yolk protein components were insolubilized

(14) Unless otherwise stated, phosphorus analyses are in terms of non-lipid phosphorus not removable by dialysis. Since Plimmer (*J. Physiol.*, **38**, 247 (1909)) cited in Needham[39]) and Schmidt and Thannhauser (*J. Biol. Chem.*, **161**, 83 (1945)) found in yolk considerably less nucleic acid phosphorus than phosphoprotein phosphorus (the latter report 11 mg. and 116 mg., respectively, per 100 g. yolk), no attempt was made to distinguish between the two in most yolk fractions. As described in the text, there is no detectable nucleic acid in phosvitin.

by shaking with chloroform[15]; then in the presence of salt, phosphoprotein was dissociated from them. Yields by this method were low.

Phosvitin then was obtained by the method outlined in a preliminary report.[16] The fraction which separated from diluted yolk (1 part yolk to 2 parts water) in a Sharples centrifuge[17] was lyophilized, extracted with ether and dispersed in a solution containing 5 g. of sodium sulfate per 100 ml. of water. Addition of sodium sulfate to a concentration of 36 g. per 100 ml. of water precipitated the bulk of the proteins. After dilution of the soluble fraction to a concentration of 22 g. of sodium sulfate per 100 ml. of water, copper acetate was added to precipitate the phosvitin as the copper salt. The precipitate was dissolved in *p*H 5, 0.5 *M* citrate buffer, dialyzed against several changes of the same buffer to remove copper, and finally against distilled water to remove citrate. The material isolated had essentially the same composition and properties as that prepared by the method described below but the latter was more satisfactory both in yield and in economy of operation.

It was noted that addition of magnesium sulfate in small amounts to solutions of phosvitin caused formation of a precipitate which slowly dissolved at higher salt concentrations. This behavior was then used to obtain a phosvitin-rich fraction directly from yolk. An outline of the process and the distribution of protein solids and phosphorus during the various steps is shown in Fig. 1, and details are given below.

Preparative.—Yolks of fresh eggs[18] were washed in tapwater and rolled on cheesecloth to free them from adhering white. Chalazae were cut off. The yolk membranes were then punctured and the contents allowed to drain out through a single layer of cheesecloth. To 2400 g. of yolk contents (from 13 dozen eggs) were added 1200 ml. of 1.2 *M* magnesium sulfate solution (containing 120 mg. of Merthiolate[19]) and the mixture was stirred vigorously, but without producing foam, for one hour. Addition of 12 l. of water (containing 600 mg. of Merthiolate) then was started and completed in one and one-half hours, the mixture being stirred as before. After eighteen hours at room temperature (surface covered with toluene) the soft sticky precipitate was collected by centrifugation (A, Fig. 1), and the soluble fraction (B, Fig. 1) was discarded. The original yolk was at *p*H 6.0; the 0.09 *M* magnesium sulfate supernatant solution was at *p*H 5.9.

The precipitate was dispersed in 1600 ml. of 0.4 *M* ammonium sulfate with forty-five minutes of stirring. The dispersion was brought to *p*H 4.0 by the careful addition of 6 *N* sulfuric acid, and 80 ml. of *p*H 4, *M* acetate buffer was added. The dispersion then was shaken vigorously with 1500 ml. of ethyl ether and allowed to stand overnight at room temperature. The addition of ether was necessary in order to collect the non-phosvitin residue into a separable layer; filtration in the absence of ether did not remove all of the non-phosvitin protein. The slightly opalescent aqueous layer was drawn off and the remaining

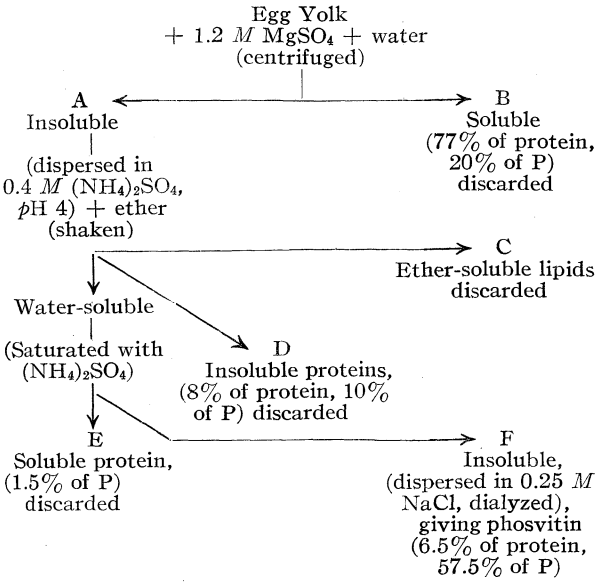

Fig. 1.—Preparation of phosvitin fraction from egg yolk. Analyses refer to dry, lipid-free protein and phosphorus of original yolk. Total recovery of protein was 92%, of phosphorus, 90%. Phosphorus contents of protein solids: original yolk, 1.09%; fraction B, 0.29%; fraction D, 1.36%; fraction F, 9.7%.

mixture was centrifuged to obtain some additional aqueous extract. The free ether layer (C, Fig. 1) was discarded. Three additional extractions of the residue (a gelatinous emulsion) were made with 0.4 *M* ammonium sulfate plus *p*H 4, *M* acetate in the ratio previously used, the successive volumes employed being 1,000, 800, and 800 ml.; 300 ml. of ether was added with the first of these, and no ether was then removed until after the final salt extraction. Only the last of these extracts was separated by centrifuging, the others being allowed to stand overnight before drawing off the aqueous layer. The gelatinous insoluble residue (D, Fig. 1) was discarded.

The *p*H 4, 0.4 *M* ammonium sulfate extracts were shaken in successive portions as obtained with one portion (approximately 200 ml.) of ethyl ether. After thirty to forty-five minutes, standing, the aqueous layers were drawn off and filtered through coarse paper. The filtrates were again shaken with 200 ml. of ethyl ether and the aqueous layers filtered through medium porosity sintered glass covered with one-half inch of Hy-flo filter aid (analytical grade).[19] The filtrate (4420 ml.; *p*H, 4.1) was perfectly clear and slightly yellow in color. It was next dialyzed overnight against two liters of saturated ammonium sulfate plus excess solid ammonium sulfate. A slow stirrer kept the solution agitated. The sacks then were transferred to two liters of saturated ammonium sulfate solution adjusted to *p*H 4 with glacial acetic acid, again with solid ammonium sulfate present.

After overnight dialysis, a white gelatinous solid had separated, most of which could be collected by centrifugation. The rest was collected by filtration through sintered glass. The saturated ammonium sulfate supernatant (E, Fig. 1) was discarded after it was found to contain only 2.5% of the phosphorus present in the 0.4 *M* ammonium sulfate extracts.

The precipitate was mixed with 50 ml. of 5 *M* sodium chloride, then diluted to 1000 ml. total volume. The viscous dispersion was dialyzed against several changes of 2 *M* sodium chloride, the first portion being made 0.01 *M* in sodium acetate to hasten solution of the precipitate, and then against water.

No systematic investigation of the effects of small variations in the separation procedures was made. In

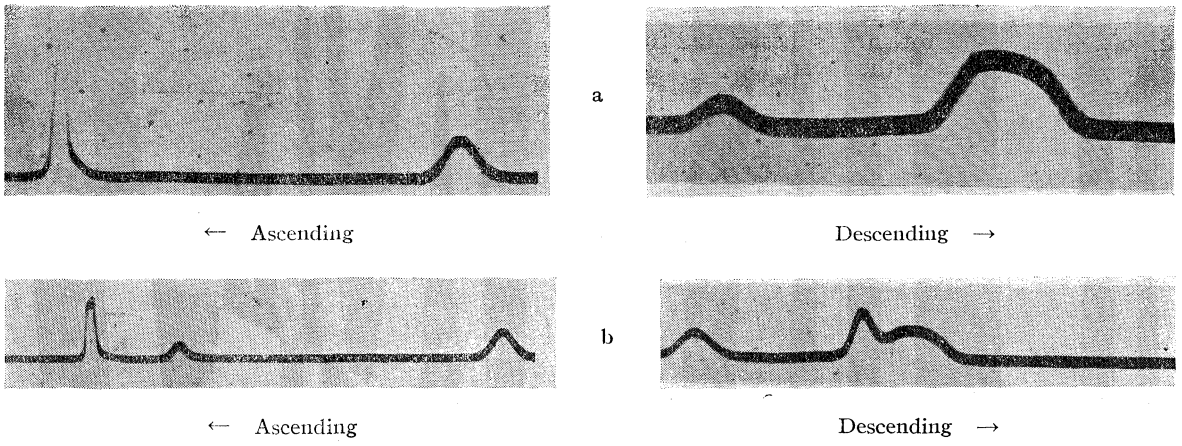

Fig. 2.—Svensson–Philpot electrophoresis records: phosvitin (citrate-dialyzed, magnesium sulfate method of preparation), 1.7% solution; "*a*" in sodium acetate buffer, *p*H 4.6, μ 0.1; mobility of rising boundary, $-12(\times 10^{-5})$ cm.^{2} volt^{-1} second^{-1} referred to 0°; delta boundary at right. Larger falling boundary represents unresolved components ranging in mobility from −8 to −10 units; epsilon boundary at left. "*b*" in sodium citrate buffer: *p*H 4.6, μ 0.1. The small slower moving rising boundary, about 25% of the whole, has a mobility of about −12 units. The faster 75%, which appears further resolvable, has a mobility of about −15 units; delta boundary at right. The slower moving falling component, comprising about 40% of the whole, has a mobility of −9 units; the faster 60%, about −12 units; epsilon boundary at left.

general, however, it was observed that in the magnesium sulfate precipitation step, dilution to 0.05 *M* concentration (instead of 0.09 *M*) caused precipitation of more non-phosvitin protein, while above about 0.3 *M* concentration, there was little precipitation of phosvitin. Also, after removal of the 0.09 *M* magnesium sulfate precipitate at a *p*H near 6, additional precipitate could be obtained by raising the *p*H to 8 or 9, but almost no phosvitin could be separated from this second precipitate. In the ammonium sulfate–ether extraction step, separation of the non-phosvitin fraction into the ether–gel layer became less complete as the *p*H was increased above 4 or the ammonium sulfate concentration was increased above 0.4 *M*. At lower salt concentrations (*ca.* 0.1 *M*) dissociation of phosvitin from the magnesium sulfate precipitate was quite incomplete.

When it was found that phosvitin preparations were apparently unaffected by heat (solutions at levels of *p*H from 4 to 8 when heated for several hours at 100° did not precipitate nor show any other evidence of change), attempts were made to devise methods of preparation in which the non-phosvitin proteins of yolk were heat-denatured. Small amounts of phosvitin could be recovered but the procedures were definitely less satisfactory than those described above.

Analyses.—The dialyzed preparation (F, Fig. 1) was at *p*H 6.05, and contained 24.4 g. of solids. The solids contained 9.7% phosphorus and 11.9% nitrogen (molar ratio N/P, 2.72). Total lipids were 0.7%; total lipid phosphorus, less than 0.03% of the lipid; total inorganic phosphorus, about 0.01% of the total solids. Neither purine nitrogen (method of Hitchings[20]) nor pentoses (orcinol–ferric chloride method[21]) were detectable. Ninety-six per cent. of the phosvitin phosphorus was removed from a sample of the preparation by 0.25 *N* sodium hydroxide at 35° in twenty-four hours. This is the method used by Plimmer[22] to characterize phosphoproteins. Thus, practically all of the phosphorus of phosvitin is present as phosphoprotein phosphorus.

Attempts to obtain products containing still lower nitrogen-to-phosphorus ratios by further fractionation procedures applied to fraction F were unsuccessful. In each case the molar ratios were within the range of 2.5–2.9.

In preparations carried out on a smaller scale with more nearly complete recovery of the starting material, the amount of yolk protein phosphorus recovered as phosvitin phosphorus was consistently between 60 and 70%. In these preparations the 0.4 *M* ammonium sulfate extracts were separated by centrifuging; more complete extraction of phosvitin was indicated by a lower phosphorus content (about 1.1%) of the insoluble protein (D, Fig. 1). The phosphorus not precipitated by 0.09 *M* magnesium sulfate (B, Fig. 1) was consistently about 20% of the total.

Characterization

Physical Properties.—Typical electrophoretic patterns obtained by W. H. Ward with phosvitin are shown in Fig. 2. In sodium citrate buffer, two main components or groups of components were present. About 40% had a falling mobility of −9, and about 60%, −12 ($\times 10^{-5}$ cm.^{2} volt^{-1} second^{-1}) at *p*H 4.6, ionic strength, 0.1. In sodium acetate buffer the boundaries were not resolved and the mobilities were less by 2 or 3 units ($\times 10^{-5}$). Such data indicate that phosvitin preparations consist of at least two groups of substances, not easily resolved electrophoretically, with high mobilities centering about the values given above. Because of the high charge on this material, the use of higher ionic strength buffers would have been desirable.

The osmotic pressure method of Bull[23] was used to estimate the molecular weight of phosvitin. Values ranging from 18,000 to 25,000 were obtained with samples prepared by the salt fractionation, copper precipitation method. The runs varied in sample concentration from 0.3 to 1.4%, in *p*H from 5.7 to 6.5, and sodium chloride concentration from 0.5 to 2.5 *M*. Observed molecular weights in the presence of 6.7 *M* urea and 0.5 *M* sodium chloride were also in the range given above.

Fig. 3.—Ultracentrifuge (Spinco) analysis of 0.8% solution of phosvitin (upper series of pictures) in 0.1 *M* sodium chloride at *p*H 5. Computed sedimentation constant, 1.84 *S* (10^{-13} second) referred to distilled water at 20°. This confirms an earlier measurement made for us by W. B. Dandliker, University of California. The lower series of records represents an analysis made in 0.1 *M* sodium chloride with 0.05 *M* magnesium chloride at *p*H 5. Computed sedimentation constant, 3.79 *S*, referred to distilled water at 20°. The discontinuity at the right of each record shows the position of the liquid surface.

The behavior of phosvitin in the ultracentrifuge (Spinco) was determined and interpreted by W. H. Ward. When magnesium ions were present, an apparent aggregation of phosvitin was observed both in the ultracentrifuge and with osmotic pressure measurements. A preparation obtained by the magnesium sulfate method and citrate-dialyzed was centrifuged at 0.8% concentration in 0.1 *M* sodium chloride, *p*H 5.0, solutions in the absence and presence of 0.05 *M* magnesium chloride. Patterns are shown in Fig. 3. Corrected sedimentation constants (S_{20}) of 1.84 and 3.79 were obtained. These correspond to minimum molecular weights of approximately 12,000 and 39,000, in the absence and presence, respectively, of magnesium. By osmotic pressure measurements the corresponding values were 21,000 and 38,000. The data suggest that, under these conditions, the protein acts as a dimer in the presence of magnesium ions. Possibly magnesium forms a bridge between phosphate groups on adjacent molecules.

The optical rotation of a 2% phosvitin solution in water was measured at *p*H 7.5 and 4.5; values for $[\alpha]^{20}D$ of −71 and −51° were found. In 2 *M* sodium chloride, corresponding values were −68 and −46°. Hewitt[24] found that the optical rotation of a serum albumin preparation (−67°) was the same at *p*H 4.9 and 7.2; Almquist and Greenberg[25] reported that the optical rotation of egg albumin (−31°), livetin (−39°) and serum albumin (−49°) did not vary in the *p*H range 4.5 to 10. The positive effect of *p*H on the rotation of phosvitin probably reflects the change of ionization state of the phosphate group.

Amino Acid Composition.—Results of amino acid determinations on a phosvitin preparation

are given in Table I. The large amount of serine and the absence of sulfur amino acids are noteworthy.

[a] With exceptions noted, all analyses are on a single preparation of the partial sodium salt (*p*H 6), moisture-free basis. Samples were hydrolyzed by refluxing sixteen hours with 6 *N* hydrochloric acid (except for tryptophan). Amino acid analyses are by microbiological methods except as noted. [b] Eighty per cent. dephosphorylated with grapefruit phosphatase. Values are expressed in terms of the original untreated phosvitin. The dephosphorylated product was not isolated; aliquots of the dephosphorylation digest were frozen and dried in vacuum in the vessels subsequently used for hydrolysis. [c] Determined by chemical methods (see methods section). [d] Observed values corrected for estimated 10% destruction of hydroxy amino acids during hydrolysis, and a corresponding increase in ammonia nitrogen. [e] Values obtained on different phosvitin preparation.

It was of particular interest to determine whether a sufficient number of serine residues were present to permit all of the phosphorus to be present as the serine phosphate ester, since the isolation by Levene and co-workers,[26,27] of phosphoserine from yolk indicated that at least part of the phosphoric acid was present in this form.

It is usually assumed that about 10% of the total serine in proteins is destroyed during acid hydrolysis.[28] Lowndes, *et al.*,[9] showed that destruction of serine in hydrochloric acid was somewhat accelerated in the presence of added phosphoric acid. However, the comparative stability in acid of peptide-linked serine and phosphoserine residues is not well established; Lipmann and Levene[26] considered residues of both kinds approximately equal in lability, while the results of Posternak and Posternak,[6] Damodaran and Ramachandran[8] and Nicolet and Shinn[29] suggest that the phosphorylated residues are more labile. Results of the determination of the total hydroxyamino acid and ammonia contents of hydrolysates of phosvitin and dephosphorylated phosvitin (see Table I) were in agreement with the latter authors in showing that phosphorylated hydroxyamino acid residues of phosvitin are somewhat less stable to acid than non-phosphorylated. Therefore, serine was determined only in enzyme dephosphorylated samples. Correction of the serine values for 10% destruction during hydrolysis brings the serine and phosphorus contents (of phosvitin) to equivalence. Microbiological determinations of serine and threonine gave values of 28–35 equivalents per 10^4 g., and traces, respectively (not corrected for destruction during hydrolysis). Although the microbiological methods were not considered completely satisfactory in the case of these two amino acids,[30] the results are in agreement with the chemical methods, in indicating both a preponderance of serine, and a serine content approximately equivalent to the phosphorus present.

The inhomogeneity of phosvitin indicated by electrophoresis (but not by the ultracentrifuge) is also suggested by the amino acid analyses. Of the amino acids determined, methionine, tyrosine and tryptophan were definitely present but in amounts too small to permit the presence of one residue in a molecule of molecular weight 21,000. Small amounts (less than 1%) of isoleucine and valine were present but were not determined accurately. Alanine was not determined, but might be expected (by elimination of other common amino acids) to be present in considerable amounts.

Subtraction of amide nitrogen (corrected for destruction of hydroxyamino acids) and of the non-α-amino nitrogen of arginine, histidine and lysine from the total nitrogen gives a value for α-amino nitrogen which on a molar basis is about double that of the phosphorus present. Consequently, there is about one phosphate group for each two amino acid residues.

Rietz, *et al.*,[31] found that when proteins are treated with cold concentrated sulfuric acid the aliphatic hydroxyl groups of serine and threonine residues form acid sulfate esters. A sample of phosvitin was treated by this technique; 86% of the original nitrogen was recovered after dialysis. In the recovered material, only one sulfur atom per thirty phosphorus atoms was present. This

result indicates that practically all of the hydroxyamino acid residues in phosvitin are phosphorylated, and that the sulfuric acid treatment does not replace phosphate with sulfate groups.

Ultraviolet Absorption.—Nicolet and Shinn[32] have presented evidence that serine in peptide linkage forms dehydroalanyl residues upon treatment with dilute alkali; phosphorylated serine residues might be expected to form dehydroalanyl residues even more readily.[29] Since Carter and Greenstein[33] reported that dehydropeptides absorb light very strongly in the ultraviolet range, the ultraviolet absorption spectra of phosvitin, enzyme-dephosphorylated phosvitin, and alkali-treated phosvitin were determined. Results are presented in Fig. 4. There was nearly a tenfold increase in density at 250 mμ with 36% dephosphorylation in four hours of treatment with 0.25 *M* potassium hydroxide at 35°. An additional twenty hours of treatment, with 95% dephosphorylation, gave a relatively small additional increase in density, possibly because of degradation beyond the dehydroalanyl stage.

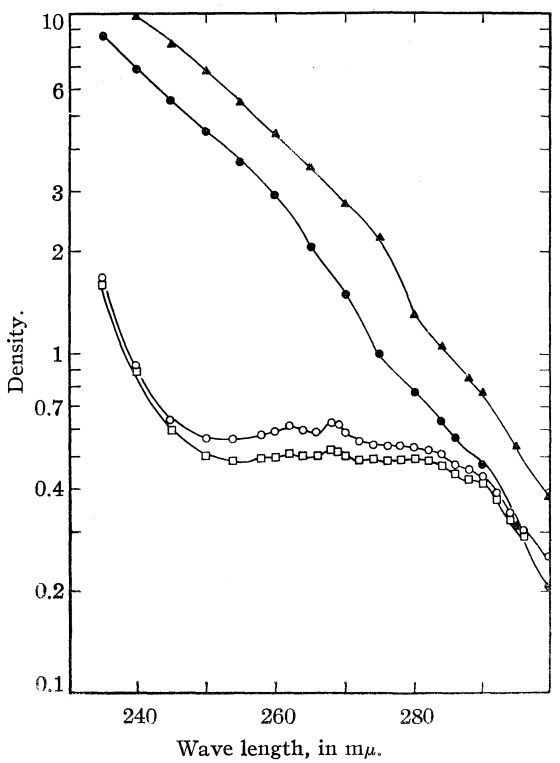

Fig. 4.—Ultraviolet absorption of phosvitin samples (density calculated to sample concentration equivalent to 165 micrograms of phosphorus per ml.; solvent, 0.1 *M* potassium chloride; samples at *p*H 6.5–6.7): □, untreated (citrate-dialyzed) phosvitin; ○, enzyme dephosphorylated (80% dephosphorylated); ●, four hours, 0.25 *M* potassium hydroxide, 35° (36% dephosphorylated); ▲, twenty-four hours, 0.25 *M* potassium hydroxide, 35° (95% dephosphorylated). Enzyme and potassium hydroxide digestions made with citrate-dialyzed phosvitin at a concentration of 825 micrograms of phosphorus per ml.

Titration.—Phosvitin samples were titrated in an attempt to determine whether all of the phosphorus was present as mono-esterified orthophosphate. Phosvitin prepared by the magnesium sulfate method was citrate-dialyzed, then electrodialyzed. Electrodialysis was very slow; ten days were required before the current through the cell failed to increase markedly from the time water was added until it was replaced (eighteen hours).

Titration curves for aliquots of the resulting solution containing 6.24 mg. of phosphorus are shown in Fig. 5. Although the inflection points (points of maximum slope) occurred at different *p*H values in the different solutions, the equivalents of alkali required to reach these points were in reasonable agreement.

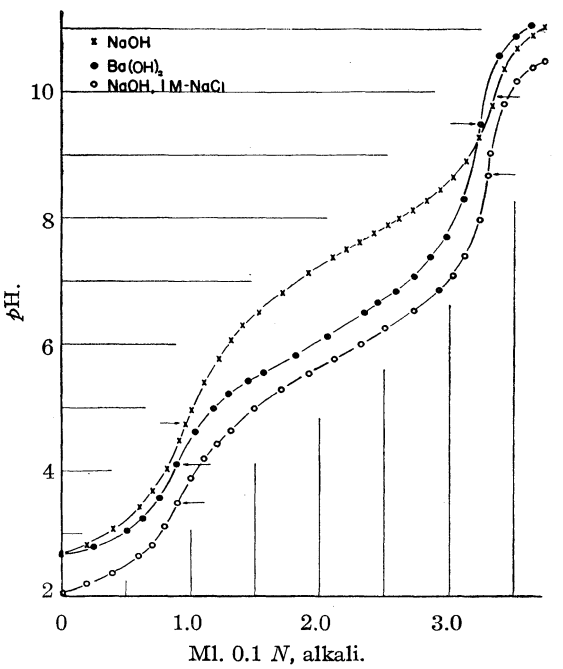

Fig. 5.—Electrodialyzed phosvitin titrations: 10-ml. solution (6.24 mg. phosphorus) titrated with 0.101 *N* sodium hydroxide (X); 0.101 *N* sodium hydroxide in the presence of 1 *M*, final concentration, sodium chloride (○); and 0.131 *N* barium hydroxide (●). Calculated to 0.100 *N* base before plotting. Arrows indicate inflection points.

The milliequivalents of the basic amino acids present with 6.24 mg. (0.201 millimole) of phosphorus, calculated from their ratio obtained from Table I were arginine 0.018, lysine 0.026 and histidine 0.020. It was assumed that all the basic amino acid residues neutralized their equivalent of acidity at *p*H values below the first inflection point, but only the arginine and about one-half the lysine ε-amino groups (of *pK* values around 12.5 and 10, respectively) did so at the *p*H of the second inflection point. The titration results expected, with all the phosphorus present as mono-esterified orthophosphate, then can be given as follows (in milliequivalents): to the first inflection point, acidity from phosphorus, 0.201, neutralized by basic residues, 0.064, net expected 0.137; total to the second inflection point from phosphorus, 0.402, neutralized by basic groups, 0.031; net expected, 0.371. Actually, only 0.092 and 0.328 milliequivalent of alkali were required. Because

(32) Nicolet and Shinn, *J. Biol. Chem.*, **142**, 609 (1942).
(33) Carter and Greenstein, *ibid.*, **165**, 725 (1946).

the discrepancy between the acidity expected and found occurred in titration to the first inflection, rather than between the first and second inflections, the results indicated failure to remove all metal ions from the sample rather than the existence of diesterified orthophosphate.[34,35]

Accordingly a 500-mg. lyophilized portion of phosvitin prepared by the magnesium sulfate method, not citrate-dialyzed, was suspended in 10 ml. of 1 *N* hydrochloric acid in absolute ethanol, let stand thirty min., centrifuged, and the extraction with acidic ethanol repeated four times more. (The first and second extracts were definitely yellow, presumably because of extraction of iron and copper (see below)). Residual solvent was removed from the solid in vacuum over potassium hydroxide at room temperature; 490 mg. of solid was recovered. Portions were weighed out, titrated (results given in Fig. 6), and phosphorus and nitrogen contents of the titrated solutions determined. Nitrogen–phosphorus ratios were not significantly changed by the acid–alcohol extractions (2.72 in the original preparations; 2.69, 2.64 in the washed solids).

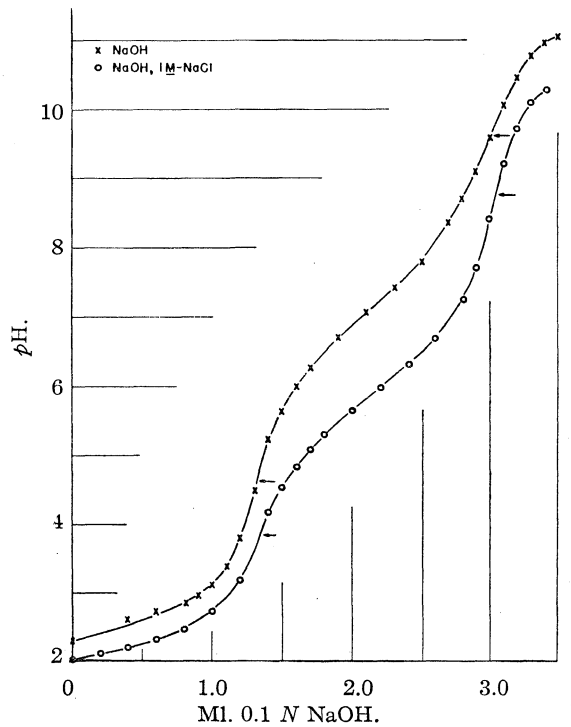

Fig. 6.—Acidic ethanol-washed phosvitin titrations: ×, 0.100 *N* sodium hydroxide, 4.2 mg. of phosphorus in sample; O, 0.100 *N* sodium hydroxide in presence of 1 *M*, final concentration, sodium chloride, 4.4 mg. of phosphorus in sample. The solid samples, suspended in 10 ml. of water at the start of the titration, did not dissolve completely until about 1.0 ml. of alkali had been added. Arrows indicate inflection points.

In the case of these samples, it was assumed that all of the basic amino acid residues would be present as hydrochlorides at the start of the titration, but that the histidine imidazole and approximately one-half the lysine ε-amino groups would, at higher *p*H values, release hydrochloric acid and cause an increase in alkali requirement over that expected; the increased requirement would occur between the first and second inflection points. Calculated to the same quantity of phosphorus as the preceding titrations, the average results then were as follows: To the first inflection, expected acidity from phosphorus, 0.201 milliequivalent; found, 0.194; total titration expected from phosphorus, 0.402, acid released from basic amino acid hydrochlorides during titration, 0.033; found, 0.436. Thus, in the case of the acid–ethanol washed samples the results are interpretable as indicating that all of the phosphorus is present as mono-esterified orthophosphate.

Heavy Metals.—Miescher,[2] Bunge[3] and Hugounenq and Morel[4] found about one-twentieth as much iron as phosphorus in the products of high phosphorus content which they separated from pepsin digests of vitellin. Phosvitin prepared by the magnesium sulfate procedure was found to contain 0.4% iron. By spectrographic examination of the ash of phosvitin, copper and calcium were found to be present in amounts approximately equal to that of iron. No other metallic elements except sodium were present in more than trace amounts. No magnesium was found, despite its use in the preparation. Samples of phosvitin then were dialyzed against *p*H 5 citrate buffer followed by water, the procedure used previously[16] for removal of copper from the copper–phosvitin precipitate. Only traces of iron, copper and calcium remained in the phosvitin. The nitrogen–phosphorus ratio was not changed by the citrate dialysis. The affinity of phosphate esters for heavy metals is well-recognized. Hence it is possible that phosvitin preparations picked up these ions not only from the yolk but also from impurities in the large amounts of salts used in the fractionation sequence.

Susceptibility to Enzyme Action.—Phosphatases in general have not been found capable of dephosphorylating intact phosphoproteins. However, Axelrod[36] showed that a purified orange phosphatase would dephosphorylate phosvitin. An unfractionated preparation of grapefruit flavedo press-juice solids subsequently was found to be a satisfactory phosphatase source for this purpose. It is of interest that casein also was dephosphorylated by the grapefruit preparation. The grapefruit and orange phosphatases therefore fall into the class of phosphoprotein phosphatases. Harris[37] demonstrated phosphoprotein phosphatase activity in frogs' eggs.

Typical results obtained using the grapefruit preparation and a bone phosphatase preparation are given in Table II. Below phosvitin concentrations of 1%, dephosphorylation occurred rapidly with citrus phosphatase preparations. A sweet potato extract fraction capable of hydrolyzing *p*-nitrophenyl phosphate rapidly was nearly inactive on phosvitin.

In some cases, amino nitrogen determinations were obtained before and after dephosphorylation of phosvitin samples with the grapefruit preparations. A slight increase occurred during dephosphorylation; typical values were 5.3% amino nitrogen of the total nitrogen originally, 7.3% after 89% dephosphorylation. Comparable values for casein digests were 5.8% of the total nitrogen originally, 10.1% after 82% dephosphorylation. Thus the grapefruit preparation appears to have caused some proteolysis, but so little that, at least with phosvitin, the dephosphorylation of a protein rather than of a peptone is indicated.

The dephosphorylated phosvitin was insoluble, separating slowly during the later stages of the re-

TABLE II

PHOSPHOPROTEIN DEPHOSPHORYLATION BY PHOSPHATASE PREPARATIONS[a]

Phosphatase Source	Concentration mg. per ml.	Substrate	Protein phosphorus, mg. per ml.	Digestion conditions Hr.	°C.	pH	Dephosphorylation, %
Bone	6.0	Phosvitin	1.86	72	25	9.1	2
Grapefruit	0.6	Phosvitin	1.84	72	25	6.7	36
	.6	Casein	0.17	48	25	6.6	71
	.26	Phosvitin	0.87	64	35	6.6	90

[a] Bone phosphatase preparation according to Martland and Robison, *Biochem. J.*, **23**, 237 (1929), from veal shank bone. Grapefruit preparation, flavedo press-juice solids. Relative activity of preparations against *p*-nitrophenyl phosphate : bone (*p*H 9.1), 12 (not changed by addition of 0.003 *M* magnesium sulfate); grapefruit (*p*H 5), 70. The bone phosphatase preparation was not completely soluble in the digestion mixtures; such digests therefore were shaken gently throughout the digestion period. Phosvitin dephosphorylation was not changed by the presence of 0.003 *M* magnesium sulfate in either grapefruit or bone preparation digests.

action as a gel. In this property it is similar to sericin, the hot-water soluble protein of silk, which it also resembles in amino acid content (high serine, absence of sulfur amino acids).

The numerous reports of isolation of phosphopeptones[2-18] from enzyme digests of both egg yolk and milk proteins indicate that peptides containing phosphorylated amino acid residues are resistant to protease activity, consequently it was thought that phosvitin might not be as rapidly digested by trypsin and pepsin as are proteins containing little or no phosphorus. A single experiment was performed (Table III) along this line.

TABLE III

DIGESTION OF PHOSVITIN BY TRYPSIN AND PEPSIN[a]

Substrate	Concn., mg. N per ml.	Original *p*H	Enzyme	Concn., mg. per ml.	Amino N as % of total N 0 hr.	4 hr.	24 hr.
Phosvitin	1.0	8.4	Trypsin	0.06	6.3	8.8	9.6
Heated phosvitin	1.0	8.4	Trypsin	.06	...	..	9.4
Dephosphorylated phosvitin	0.8	8.4	Trypsin	.06	8.4	13.6	14.8
Casein	1.1	8.5	Trypsin	.06	6.5	11.8	13.0
Phosvitin	1.0	1.9	Pepsin	.11	6.3	7.1	7.6
Dephosphorylated phosvitin	0.8	1.8	Pepsin	.11	8.6	10.1	11.0
Casein	1.1	1.9	Pepsin	.11	6.5	11.4	14.0

[a] To 8 ml. of substrate solution at the *p*H indicated, 1 ml. of enzyme solution (trypsin in 0.001 *N* hydrochloric acid, pepsin in water) was added. After the indicated period of digestion at 35°, trypsin samples were acidified with glacial acetic acid, pepsin samples were neutralized with sodium hydroxide, made to 10 ml., and analyzed. The trypsin and pepsin were crystallized preparations.

With trypsin, phosvitin was less rapidly attacked than was either casein or dephosphorylated phosvitin. Heated phosvitin was digested only to the same extent as the unheated sample, hence it appears that phosvitin resists the action of trypsin rather than inhibits it in the manner of ovomucoid, the trypsin-inhibitor of egg white.[38] The results with pepsin do not permit strict comparison between phosvitin and casein, because the former gelled shortly after being adjusted to *p*H 1.9 and after twenty-four hours had formed a fairly dense gel occupying approximately one-half the volume of the digest.

Discussion

Extensive reviews of the literature on yolk proteins are available.[39,40] It was generally considered that there were two fractions, vitellin, the water-insoluble part, accounting for about 80% of the total, and livetin, the water-soluble fraction, accounting for the remaining 20%. Vitellin was a lipoprotein and contained 0.8–1.2% protein phosphorus,[41,42,43,44] livetin contained no lipid and no phosphorus.[45] Evidence that lipovitellin is not homogeneous was furnished recently by Alderton and Fevold[17] and Fevold and Lausten,[46] who separated the lipoprotein fraction of yolk into two fractions, one containing 2% and the other, 0.4%, protein phosphorus.[47]

It has now been shown that 60 to 70% of the protein phosphorus of yolk can be obtained by mild fractionating procedures in the form of phosvitin.[48] Hence all past vitellin preparations probably contained 5–10% phosvitin, an amount sufficient to influence markedly many of the reported properties. Phosvitin shows a high affinity for other proteins,[49] presumably through electrostatic bonds. Consequently a reasonable explanation for the differing phosphorus contents reported for vitellin is that more or less phosvitin was carried down in the lipovitellin precipitation as salt was removed to differing extents and at differing rates. In fact, Alderton and Fevold[17] reduced the pro-

(47) Shepard and Hottle (*J. Biol. Chem.*, **179**, 349 (1949)) have recently shown electrophoretically that livetin contains three main components, an observation in agreement with unpublished work of this Laboratory.

(48) The results with yolk proteins suggested that the phosphorus of casein also might occur as a separable high phosphorus phosphoprotein. However, attempts to prepare a phosphorus-enriched fraction from a casein solution or from skim milk by the magnesium sulfate precipitation procedure were unsuccessful.

(49) Equal weights (100 mg.) of phosvitin and protamine sulfate in solution formed a precipitate containing 95% of the phosphorus when mixed (*p*H 6.7; total volume, 140 ml.). The precipitate could be dissolved in 2 *M* sodium chloride. When dialyzed against 2 *M* sodium chloride the protamine nitrogen was eventually all removed with no loss of phosphorus. Since sodium chloride solutions of less than 2 *M* concentration would not dissolve the precipitate completely, the electrostatic bonds must be relatively strong. Phosvitin (2 mg. per ml.) and bovine serum albumin (18 mg. per ml.) in the absence of salt formed a precipitate at *p*H 6 but not at *p*H 4. In the presence of sodium sulfate (0.25 *M*), no precipitate formed at either *p*H.

tein phosphorus content of their lipoprotein precipitate from 2 to 1% by repeated solution in 5% sodium chloride and precipitation by dialysis, a procedure which probably left some phosvitin in solution with each repetition.

Similarly, Francis and Wormall[50] reported that only 25% of the total phosphorus of a precipitate of lipovitellin–antilipovitellin was protein phosphorus, although protein phosphorus accounted for 53% of the total in the original antigen preparation. It appears likely that this difference may represent a separation of the originally antigenic lipoprotein from phosvitin.

The separation of phosphopolypeptides from yolk proteins and casein during enzyme hydrolysis has been mentioned.[2-13] Presumably the vitellinic acid preparations of Levene and Alsberg[51] were somewhat less degraded fractions, very similar in composition to phosvitin. Vitellinic acid was prepared by exposure of vitellin to 12% ammonia for two hours. The yields were low; Jukes and Kay,[40] quoting unpublished results of Kay and Marshall, state that the maximum yield was 35% of the phosphorus of vitellin (of 1% original content). The low yields, together with the fact that no evidence was ever presented indicating that the material might be of higher molecular weight than the phosphopeptones separated from enzymic digests, probably were responsible for the failure to appreciate the possible significance of such material in the yolk proteins.

Whether phosvitin functions in the egg as a storehouse for phosphate, or for metals, or whether it plays an active role during metabolism remains to be determined.[52] Chargaff[53] found that radioactive phosphorus injected into a hen as disodium phosphate was more rapidly incorporated into the vitellin fraction than into the phospholipids of yolk. He therefore suggested that phosphorylated serine residues might be involved in phospholipid synthesis.

Analytical Methods.—Total and inorganic phosphorus was determined usually by the method of Allen[54]; isobutanol extraction was used if samples became turbid in the inorganic phosphorus determination. The methods of Fontaine, Pons and Irving[55] and of Lowry and Lopez[56] also were used occasionally for the determination of inorganic phosphorus. Total nitrogen was determined by the micro-Kjeldahl method recently shown not to require lengthy digestion times,[57] or by macro-Kjeldahl. Amino nitrogen was determined by the manometric Van Slyke method[58] with a fifteen minute reaction time. In order to determine moisture content, samples were dried to constant weight at 78° *in vacuo* over phosphorus pentoxide (Abderhalden pistol heated with 95% ethanol). Total lipid was determined as follows: The material was extracted with absolute ethanol (Soxhlet) for eighteen hours followed by ethyl ether for two hours. After careful evaporation of these solvents, the residue was taken up in chloroform, filtered from insoluble material, dried and weighed. Total sulfur was determined by a sodium peroxide fusion method.[59] Iron was determined by a thiocyanate method.[60]

Dialyses were performed with Visking tubing. Protein preparations were dried by lyophilization. The glass electrode was used for *p*H determinations.

Amino acids were determined chemically as follows: serine, threonine and ammonia by periodate procedures,[61,62,63] tryptophan by the method of Horn and Jones,[64] methionine by the method of Horn, Jones and Blum,[65] cystine and cysteine by the method of Mecham,[66] arginine by the method of Brand and Kassel.[67] The microbiological determinations were carried out by methods to be described elsewhere by J. C. Lewis and N. Snell.

Acknowledgment.—We are indebted to the following associates: W. H. Ward for the electrophoresis and ultracentrifuge examinations; Miss Neva Snell and J. C. Lewis for the microbiological amino acid determinations; Bernard Axelrod for the bone phosphatase preparation and the *p*-nitrophenyl phosphate assays of phosphatase activity; E. F. Jansen for the grapefruit flavedo press-juice concentrate; E. J. Eastmond for the spectrographic analyses; G. F. Bailey for the ultraviolet absorption measurements; Miss E. A. McComb for the iron and many of the phosphorus analyses; L. M. White, A. Bevenue and G. Secor for other analytical data; R. H. Wilson for determining the blood anti-coagulating activity; H. Fraenkel-Conrat for the toxicity determination; and Mrs. Angeline Elder for valuable technical assistance. Crystalline trypsin was furnished through the courtesy of M. Kunitz; crystalline pepsin was prepared by H. C. Reitz. The large amount of egg yolk fractions furnished by G. Alderton and H. L. Fevold were useful in preliminary experiments.

Summary

Sixty to seventy % of the phosphoprotein phosphorus of egg yolk can be isolated in a protein fraction (the phosvitin fraction) representing 6.5 to 7.0% of the yolk protein and containing about 10% phosphorus. The separation is made by dispersing whole fresh yolk in 0.4 *M* magnesium sulfate solution and diluting to approximately

(52) A series of sulfated proteins[30] was found by Kazal, Spicer and Brahinsky (Abstracts, 114th Meeting, American Chemical Society Sept., 1948) to possess blood anti-clotting activity, a possibility suggested by the fact that heparin contains acid sulfate groups. It was thought that phosvitin might also possess such activity, particularly since Doyon and Sarvonat (*Compt. rend. soc. biol.*, **65**, 368 (1913)) reported that an extract of "haemotogen" (a phosphopeptone obtained from a pepsin digest of vitellin), prepared according to Hugounenq and Morel,[4] prevented coagulation of blood *in vitro*. However, a phosvitin preparation was not active in a preliminary trial. Injection of 10 mg. of phosvitin caused no apparent ill effects in mice.

0.09 *M* magnesium sulfate concentration. The 23% of the total yolk protein that precipitates contains 80% of the phosphoprotein phosphorus. Phosvitin is then extracted from the precipitate with 0.4 *M* ammonium sulfate at *p*H 4; ethyl ether is added to coagulate non-phosvitin components. A typical preparation contained 11.9% nitrogen, 9.7% phosphorus (molar ratio N/P = 2.72). The phosphorus is present as mono-esterified orthophosphate.

Amino acid analyses indicated (in equivalents per 10^4 g.): total β-hydroxy-α-amino acids, 33, and serine, 28 (not corrected for destruction during hydrolysis), compared to 31 moles of phosphorus. There is approximately one phosphoserine residue for each two amino acid residues. Basic amino acids account for nearly one-third of the remaining amino acids.

Osmotic pressure measurements indicated a molecular weight of about 21,000. The best preparations were homogeneous in the ultracentrifuge but showed appreciable boundary spreading on electrophoresis. Inhomogeneity was also indicated by the presence of small amounts (less than 1 g. equivalent per 21,000 g.) of tyrosine, methionine and tryptophan.

A pronounced aggregating effect of magnesium ions was shown by both osmotic pressure and ultracentrifuge measurements; in 0.05 *M* magnesium chloride, the molecular weight found was 38,000 and 39,000, respectively, by the two methods.

Phosvitin was dephosphorylated by citrus phosphatases but not by a bone phosphatase preparation. Alkaline dephosphorylation caused an increase in ultraviolet absorption indicative of the formation of dehydroalanyl residues. Trypsin and pepsin acted more slowly on phosvitin than on casein.

1,5-Anhydrolactitol and 1,5-Anhydromaltitol

BY HEWITT G. FLETCHER, JR., LEONORE H. KOEHLER[1] AND C. S. HUDSON

A previous publication[2] from this Laboratory described the synthesis of 1,5-anhydro-4-(β-D-glucopyranosyl)-D-glucitol (synonym, 1,5-anhydrocellobiitol) and 1,5-anhydro-6-(β-D-glucopyranosyl)-D-glucitol (synonym, 1,5-anhydrogentiobiitol) through the reductive desulfurization of the appropriate aryl 1-thioglycosides with Raney nickel. The present communication describes the extension of this synthetic method to the lactose and maltose series which was undertaken in order to obtain data for certain generalizations regarding the relationships between rotatory power and configuration among the various 1,5-anhydroglycitols and certain related compounds.[3]

Several well-characterized 1-thioglycosides suitable for the present purpose have been reported in the literature for the lactose and maltose series. Purves described phenyl 1-thio-β-lactopyranoside and its heptaacetate[4] as well as phenyl 1-thio-β-maltopyranoside heptaacetate (III).[5] Haskins, Hann and Hudson[6] prepared by the procedure of Purves, among other 1-thioglycosides, 2′-naphthyl 1-thio-β-lactopyranoside (I) and its heptaacetate as well as 2′-naphthyl 1-thio-β-maltopyranoside heptaacetate.

The reductive desulfurization by Raney nickel of 2′-naphthyl 1-thio-β-lactopyranoside (I) has now been carried out to give crystalline 1,5-anhydro-4-(β-D-galactopyranosyl)-D-glucitol (II), which may be assigned the alternative name of 1,5-anhydrolactitol. The specific rotation of this substance in water, $[\alpha]^{20}D$, proved to be +49.4°. Comparison of the molecular rotations of β-cellobiopyranose, β-lactopyranose and 1,5-anhydrocellobiitol listed in Table I shows that 1,5-anhydrolactitol would be expected to be dextrorotatory. Calculation based upon the isorotation hypothesis affords a numerical value of (7040 + 9550) ÷ 326 = +50.9°.

TABLE I

COMPARISON OF SOME MOLECULAR ROTATIONS IN THE CELLOBIOSE, LACTOSE AND MALTOSE SERIES

	Mol. wt.	$[\alpha]_D$ (H_2O)	$[M]_D$	Difference
β-Lactopyranose	342	+34.9°	+11,900	
				+ 7,040

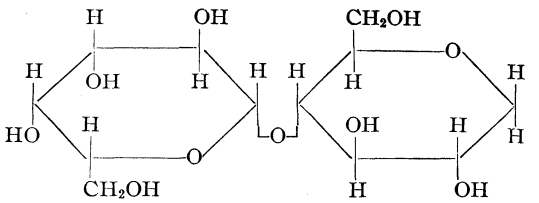
I

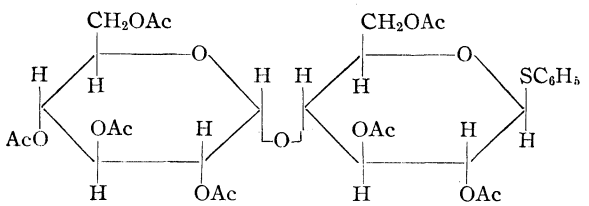
2′-Naphthyl 1-thio-β-lactopyranoside



II

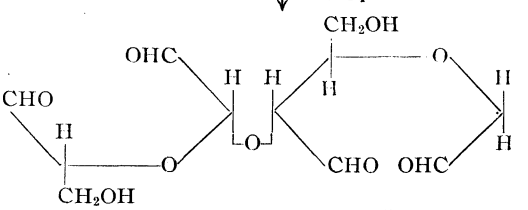
1,5-Anhydro-4-(β-D-galactopyranosyl)-D-glucitol

$\downarrow 3NaIO_4$

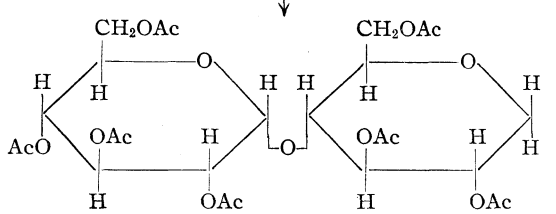


III

Phenyl 1-thio-β-maltopyranoside heptaacetate

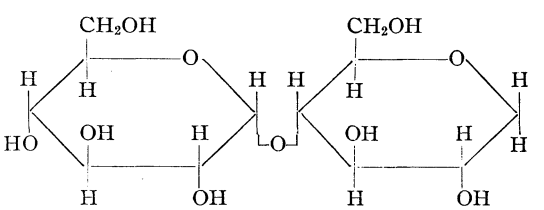


+ HCOOH



IV

1,5-Anhydro-4-(α-D-glucopyranosyl)-D-glucitol heptaacetate



V

1,5-Anhydro-4-(α-D-glucopyranosyl)-D-glucitol

Repeated attempts to prepare the heptaacetate of 1,5-anhydrolactitol in crystalline condition through the reductive desulfurization of both phenyl 1-thio-β-lactopyranoside heptaacetate and 2′-naphthyl 1-thio-β-lactopyranoside heptaacetate as well as through the direct acetylation of the anhydride itself gave only amorphous products.

The structure of the 1,5-anhydro-4-(β-D-galactopyranosyl)-D-glucitol (II) was confirmed by oxidation with periodate. As was to be expected, the substance consumed on a molar basis three moles of periodate with the concomitant formation of one mole of formic acid. As a further confirmation of its structure, the anhydride was hydrolyzed with aqueous acid and the products identified as 1,5-anhydro-D-glucitol (polygalitol) and D-galactose, the latter isolated as its α-methyl-α-phenylhydrazone.

Phenyl 1-thio-β-maltopyranoside heptaacetate (III) was reductively desulfurized with Raney nickel to yield crystalline 1,5-anhydro-4-(α-D-glucopyranosyl)-D-glucitol heptaacetate (IV) (1,5-anhydromaltitol heptaacetate) rotating +82° in chloroform. A calculation similar to that shown above for 1,5-anhydrolactitol but based upon the molecular rotations of methyl β-cellobiopyranoside heptaacetate, methyl β-maltopyranoside heptaacetate and 1,5-anhydrocellobiitol heptaacetate (Table I) leads to the prediction of a value of +87° for 1,5-anhydromaltitol heptaacetate through the isorotation hypothesis.

Catalytic deacetylation of 1,5-anhydromaltitol heptaacetate afforded the free 1,5-anhydromaltitol (V), (synonym, 1,5-anhydro-4-[α-D-glucopyranosyl]-D-glucitol), which could not be induced to crystallize. Confirmation of its structure as a derivative of polygalitol was obtained through acid hydrolysis to 1,5-anhydro-D-glucitol (*i. e.*, polygalitol) and D-glucose, identification of the latter being made through the phenylosazone and the particularly convenient D-glucose phenylosotriazole.

Acknowledgment.—We are indebted to Mrs. Margaret M. Ledyard for microanalyses and to Dr. W. T. Haskins for samples of 2′-naphthyl 1-thioglycosides. One of us (L. H. K.) held a Fellowship from the Corn Industries Research Foundation while engaged in this research.

Experimental[7]

1,5-Anhydro-4-(β-D-galactopyranosyl)-D-glucitol (II).—Two grams of pure 2′-naphthyl 1-thio-β-lactopyranoside, prepared according to the method of Haskins, Hann and Hudson,[6] was dissolved in 200 ml. of 70% aqueous alcohol, treated with approximately 25 g. of freshly prepared Raney nickel and boiled gently under reflux for one hour. The supernatant solution was then removed, the nickel washed successively with three 100-ml. portions of boiling water and the combined solution and washings concentrated *in vacuo* at 55° (bath) to a volume of approximately 2 ml.

(7) Melting points were measured with a calibrated Anschütz type thermometer completely immersed in the bath liquid. Rotations are specific rotations for sodium light at 20°; concentration is expressed in g. of substance per 100 ml. of solution.

On scratching with a glass rod at room temperature, hard, clear prismatic crystals formed; these, combined with two additional crops obtained from the mother liquor by the addition of alcohol, amounted to 850 mg. (63%). Two recrystallizations from water brought the product to a rotation of +49.4° in water (*c*, 2.512) which was unchanged by further recrystallization. 1,5-Anhydro-4-(β-D-galactopyranosyl)-D-glucitol melts with decomposition, the melting point range varying with the rate of heating. When a sample in a capillary tube was plunged into a bath whose temperature of 226° was rising uniformly at the rate of 3° per minute, a melting point of 233–237° was obtained.

1,5-Anhydrolactitol is insoluble in methanol, dioxane, methyl cellosolve and methyl ethyl ketone, difficultly soluble in boiling glacial acetic acid and readily soluble in hot water.

Anal. Calcd. for $C_{12}H_{22}O_{10}$: C, 44.17; H, 6.80. Found: C, 44.20; H, 6.82.

One gram of the anhydride was hydrolyzed by boiling for two hours in 2.5 ml. of 0.39 *N* sulfuric acid. After quantitative removal of the acid and reconcentration to a volume of 3 ml. the hydrolyzate was treated with 0.4 g. of α-methyl-α-phenylhydrazine. After three hours at room temperature 100 mg. of crystalline material was removed by filtration. Recrystallization from 30% ethanol gave colorless leaflets melting at 191–192° either alone or in admixture with an authentic sample of the α-methyl-α-phenylhydrazone of D-galactose. The remainder of the hydrolyzate was heated for several hours on the steam-bath, filtered through decolorizing carbon, and concentrated to a colorless sirup which in methanol solution gave a deposit of 200 mg. (40%) of 1,5-anhydro-D-glucitol melting at 142°. Mixed with authentic polygalitol the material melted at 142–143°. Thus the synthetic 1,5-anhydro-4-(β-D-galactopyranosyl)-D-glucitol was shown to be a derivative of polygalitol.

Sodium Metaperiodate Oxidation of 1,5-Anhydro-4-(β-D-galactopyranosyl)-D-glucitol.—The anhydride (98.1 mg.) was oxidized in aqueous solution with sodium metaperiodate, using the technique of Jackson and Hudson.[8] After twenty-six hours at room temperature, analysis showed the consumption on a molar basis of 2.98 moles of oxidant and the formation of 1.02 moles of formic acid.

1,5-Anhydro-4-(α-D-glucopyranosyl)-D-glucitol Heptaacetate, IV.—Ten grams of phenyl 1-thio-β-maltoside heptaacetate, prepared according to the method of Purves,[5] melting at 87–92° and showing a rotation of +48.7° in chloroform was suspended in 100 ml. of absolute alcohol and treated with approximately 40 g. of freshly prepared Raney nickel. The suspension was boiled for one hour and the supernatant liquor then decanted while still hot, the nickel being washed repeatedly, first with hot absolute alcohol and then with boiling acetone. Concentration of the combined decantate and washings *in vacuo* at 60–70° (bath) led to the spontaneous formation of fine, needle-like crystals amounting to 6.66 g. (78%) and melting at 127–128°. Recrystallized once from a mixture of 1.8 parts acetone and 2.3 parts of ether and then thrice from ten parts of alcohol, the substance melted at 133–134° and rotated +82.0° in chloroform (*c*, 3.4). 1,5-Anhydro-4-(α-D-glucopyranosyl)-D-glucitol heptaacetate is insoluble in water and pentane, sparingly soluble in ether and cold alcohol and readily soluble in acetone and in hot alcohol.

Anal. Calcd. for $C_{26}H_{36}O_{17}$: C, 50.32; H, 5.85. Found: C, 50.35; H, 6.03.

(8) E. L. Jackson and C. S. Hudson, THIS JOURNAL, **59**, 994 (1937).

1,5-Anhydro-4-(α-D-glucopyranosyl)-D-glucitol, V.—The catalytic deacetylation of 1,5-anhydro-4-(α-D-glucopyranosyl)-D-glucitol heptaacetate with barium methylate in the conventional manner gave a sirup which could not be induced to crystallize. On reacetylation, a sample of the amorphous material gave the original heptaacetate identified by melting point and mixed melting point, demonstrating that the catalytic deacetylation had produced no unforeseen change in the anhydride.

A portion (1.2112 g.) of the amorphous 1,5-anhydro-4-(α-D-glucopyranosyl)-D-glucitol which had been dried *in vacuo* at 45° was hydrolyzed by boiling in 3.0 ml. of 0.39 *N* sulfuric acid for two hours. One-half of the resulting solution was treated with phenylhydrazine in the usual manner to yield 60 mg. of D-glucose phenylosazone, identified by its melting point and by its inability to depress the melting point of authentic D-glucose phenylosazone. By way of confirmation the D-glucose phenylosazone was converted to D-glucose phenylosotriazole by the procedure of Hann and Hudson.[9] The 4.6 mg. of D-glucose phenylosotriazole thus obtained melted at 196–197° either alone or in admixture with authentic D-glucose phenylosotriazole. The second half of the hydrolysis solution was freed of sulfuric acid and then subjected for two days to the action of baker's yeast to remove the D-glucose. After filtration through decolorizing carbon and removal of solvent there was obtained a colorless sirup which, when diluted with methanol, gave 100 mg. (33%) of clear prismatic crystals melting at 142–143°. Mixed with authentic polygalitol these showed the same melting point.

The specific rotation of 1,5-anhydro-4-(α-D-glucopyranosyl)-D-glucitol in water was obtained by quantitative deacetylation of its pure heptaacetate in the following manner. The heptaacetate (0.6919 g.) was dissolved in a mixture of 2 ml. of chloroform and 10 ml. of methanol and treated with 0.3 ml. of approximately 1.3 *N* sodium methylate solution. After two days at room temperature the solvent was removed with a gentle stream of filtered air and the residual colorless sirup diluted with water to 25.00 ml. From the rotation of this solution a specific rotation of +132° (*c*, 1.455) for 1,5-anhydromaltitol was obtained.

Summary

1,5-Anhydro-4-(β-D-galactopyranosyl)-D-glucitol has been obtained through the reductive desulfurization with Raney nickel of 2′-naphthyl 1-thio-β-lactopyranoside. Its structure has been confirmed by periodate oxidation and by hydrolysis to 1,5-anhydro-D-glucitol (*i. e.*, polygalitol) and D-galactose.

Phenyl 1-thio-β-maltopyranoside heptaacetate has been reductively desulfurized with Raney nickel to give crystalline 1,5-anhydro-4-(α-D-glucopyranosyl)-D-glucitol heptaacetate. Catalytic deacetylation of this heptaacetate gave amorphous 1,5-anhydro-4-(α-D-glucopyranosyl)-D-glucitol the structure of which was confirmed by hydrolysis to 1,5-anhydro-D-glucitol and D-glucose.

Relations between Rotatory Power and Structure in the Sugar Group. XXXVI.[1] The 1,5-Anhydrides of the Glycitols and Related Sugar Derivatives

BY HEWITT G. FLETCHER, JR., AND C. S. HUDSON

Twelve years ago, when Werner Freudenberg and E. F. Rogers[2] published their article on "the chemistry of naturally occurring monoanhydrohexitols" it had already been determined that polygalitol and styracitol are 1,5-anhydrides of D-mannitol and D-glucitol but it was not known which of these epimeric structures applies to each anhydride. Styracitol, to be sure, had been synthesized through the catalytic hydrogenation of tetraacetyl-2-hydroxy-D-glucal by Zervas[3] but this synthesis did not distinguish between the epimeric anhydrides since carbon atom two of tetraacetyl-2-hydroxy-D-glucal is symmetric. Freudenberg and Rogers obtained two indications that styracitol is of the D-mannitol series and polygalitol of the D-glucitol series. As the first of these indications, the rate of oxidation of styracitol by lead tetraacetate was found to be much faster than that of polygalitol, from which they inferred for styracitol the *cis*-relationship of hydroxyl groups on carbon atoms two and three that occurs in the 1,5-anhydro-D-mannitol configuration in contrast to the absence of such a pair of adjacent hydroxyl groups in the 1,5-anhydro-D-glucitol pattern; their inference was based upon the previous generalization by Criegee[4] that the *cis* arrangement is attacked more rapidly than is the *trans* by this type of selective oxidation. The second indication came from their comparison of optical rotatory values by the isorotation method. The pyranose (*i. e.*, 1,5-ring) substances of the D-glucose series are much more dextrorotatory than their epimers of the D-mannose series; thus the molecular rotation of methyl α-D-glucopyranoside is +30,860 and that of methyl α-D-mannopyranoside is +15,380, and the epimeric difference is thus 30,860 − 15,380 = +15,480, a large value. For polygalitol the molecular rotation is +6,950, for styracitol it is −8340 and the epimeric difference is +15,290. The closeness of the numerical agreement may possibly be fortuitous, since a comparison of the molecular rotations of methyl β-D-glucopyranoside (−6,640) and methyl β-D-mannopyranoside (−13,550) gives +6,910 for the epimeric difference. In either case, however, the comparison of rotations indicated in a qualitative way that polygalitol belongs in the D-glucose series and styracitol in the D-mannose series, on the assumption that the isorotation hypothesis applies to the substances with sufficient approximation to exclude an actual reversal of the sign of a large epimeric difference. These two agreeing indications that were noted by Freudenberg and Rogers have been shown by the later conclusive structural and configurational chemical proofs[5] to have led them to the correct assignment of configurations to polygalitol and styracitol. Since this example shows that the isorotation comparisons gave valuable early indications of configurations, we seek in the present article to extend such comparisons to a rather large group of sugar derivatives that are related through the common possession of a tetrahydropyrane structure, with particular emphasis on the 1,5-anhydroglycitols and their 2-desoxy derivatives, the hydroglycals.

Examination of Table I will demonstrate that the isorotation hypothesis holds well for the 1,5-anhydropentitols and for the four known 1,5-anhydrohexitols as well as for the fully acetylated derivatives of all these substances. The large epimeric differences of molecular rotation are of the correct sign throughout and they range in value between 5,500 and 7,650 for the 1,5-anhydrides and between 8,480 and 13,400 for the acetates of these anhydrides. In the hexitol series the 1,5-anhydrides of allitol, altritol, gulitol and iditol are still unknown; they constitute two epimeric pairs and its seems reasonable to predict that the epimeric difference for each pair will have the sign that is shown by the known pairs of Table I. If a member of one of these epimeric pairs should be discovered through a synthetic method that does not distinguish between epimers, as for example through the catalytic reduction of an acylated 2-hydroxyglycal, is it possible to assign the full configuration through the use of isorotation hypotheses? The answer to this question may be obtained through the following considerations.

The hydroglycal that is common to the D-glucose and D-mannose series (III) is closely related to polygalitol (I) and styracitol (II); it is a 2-desoxypolygalitol, which is synonymous with 2-desoxystyracitol. If the molecular rotation of polygalitol is expressed as B + A and that of styracitol as B − A, where A represents the contribution from carbon atom two and B that from the remainder of the structure, the molecular rotation of hydroglucal, in the structure of which carbon atom two is symmetric, may be written [(B + A) + (B − A)]/2 = B, if it be assumed that iso-

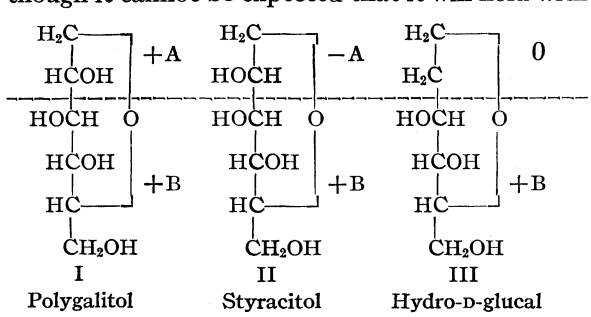
rotation holds for the three substances. Even though it cannot be expected that it will hold with



mathematical precision, it may be that the approximation will be such that the molecular rotation of hydroglucal will lie well between those of polygalitol and styracitol. Such is indeed the case, as is shown by the data in Tables I and III; polygalitol (+6,950), hydro-D-glucal (+2,440) and styracitol (−8,340). Likewise the molecular rotation of hydro-D-arabinal (−5,690) lies between those for 1,5-anhydro-D-arabitol (−13,200) and 1,5-anhydroribitol (0), the molecular rotation of hydro-D-xylal (−5,300) lies between those for 1,5-anhydro-D-lyxitol (synonym, 1,5-anhydro-D-arabitol) (−13,200) and 1,5-anhydroxylitol (0) while the molecular rotation of hydro-D-galactal (+7,120) is between those for 1,5-anhydro-D-talitol (−1,870) and 1,5-anhydro-D-galactitol (+12,600). As is to be expected, the molecular rotations of those acetates of these compounds that are known are similarly related. Thus triacetylhydro-D-glucal has a molecular rotation (+9,750) which is between the values for tetraacetylstyracitol (−13,900) and tetraacetylpolygalitol (+12,900); in the five-carbon series the molecular rotation of diacetylhydro-D-xylal (−7,840) is seen to lie between those for triacetyl-1,5-anhydro-D-lyxitol (synonym, triacetyl-1,5-anhydro-D-arabitol) (−19,300) and triacetyl-1,5-anhydroxylitol (0).

The literature reveals that an amorphous diacetylhydroarabinal having a dextrorotation in

arabinal, prepared from 2,3,4-triacetyl-D-arabinosyl bromide in 66% yield according to the method of Karrer and co-workers[7] was hydrogenated, following the directions of Gehrke and Aichner,[6] to give in 86% yield diacetylhydro-D-arabinal as a colorless, viscid liquid boiling at 0.2 mm. pressure at 90° and having $n^{20}D$ 1.4523. The specific rotation of this substance, $[\alpha]^{20}D$, in chloroform was found to be −45.1° (*c*, 3.02) and it is therefore evident that the product having a rotation of +43.1° reported by Gehrke and Aichner was diacetylhydro-L-arabinal. In agreement with the examples cited above the molecular rotation of diacetylhydro-D-arabinal (−9,110) lies well between those of the two corresponding 1,5-anhydropentitol acetates, triacetyl-1,5-anhydro-D-arabitol (−19,300) and triacetyl-1,5-anhydroribitol (0).

This relationship between the molecular rotations of a hydroglycal and its two corresponding 1,5-anhydroglycitols thus appears to be a general one in a qualitative way and it may be said that *although the molecular rotation of a hydroglycal is not the exact mathematical average of those of the corresponding epimeric 1,5-anhydroglycitols, it lies well between their greatly differing values.*

If this generalization had been known at an earlier date, which was not possible because the pertinent data upon which it is founded were not then known, one could have inferred that the 1,5-anhydrohexitol which Freudenberg and Rogers[2]

(7) P. Karrer, B. Becker, F. Benz, P. Frei, H. Salomon and K. Schöpp, *Helv. Chim. Acta*, **18**, 1435 (1935).

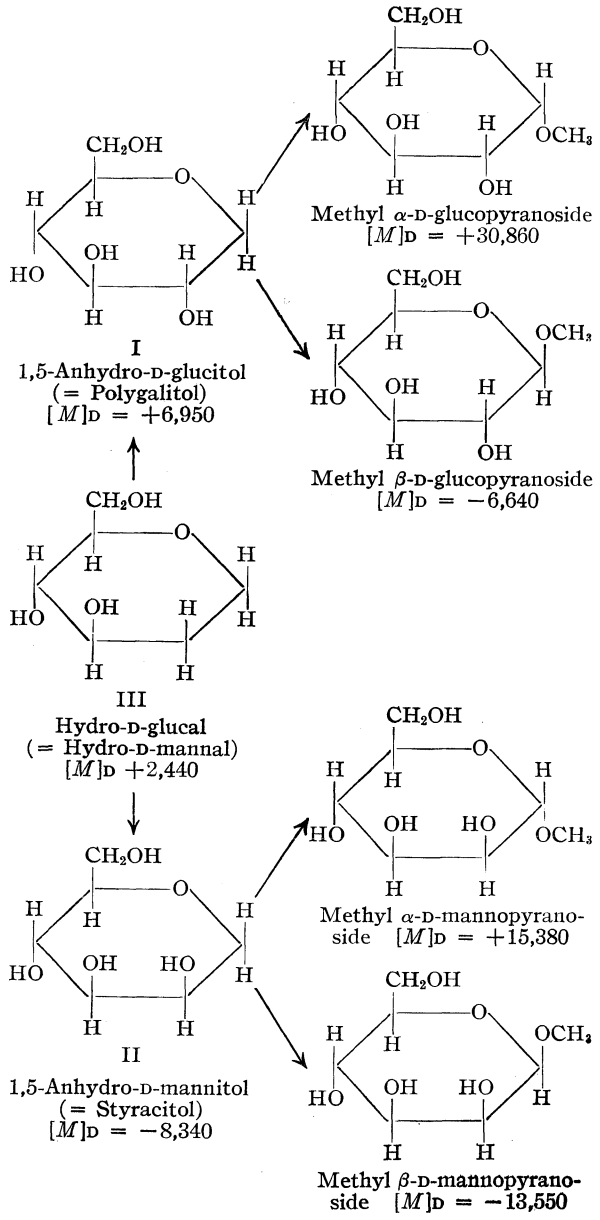

Fig. 3.—Some rotatory relations in the D-glucose and D-mannose series.

synthesized through the catalytic reduction of tetraacetyl-2-hydroxy-D-galactal (IV) was of the D-talitol rather than D-galactitol series since the 1,5-anhydroglycitol which these authors obtained had a molecular rotation of −1,870 and was thus more levorotatory than hydro-D-galactal (IV) (+7,120). Actual proof of the configuration of the substance in question as 1,5-anhydro-D-talitol finally came through unequivocal independent syntheses of 1,5-anhydro-D-talitol[8] and 1,5-anhydro-D-galactitol.[9]

From the above it is apparent that should the catalytic reduction of an acetylated 2-hydroxyglycal ever give rise to both of the expected 1,5-anhydroglycitols[10] each of the two substances may at once be assigned its proper configuration, solely on the basis of its rotation and without recourse to comparison with the rotation of the corresponding hydroglycal.

The foregoing discussion has been limited to derivatives of the monosaccharides; those of some

(10) The palladium-catalyzed reduction of tetraacetyl-2-hydroxy-D-glucal has, for instance, been shown (ref. 5c) to produce a small quantity of 1,5-anhydro-D-glucitol although 1,5-anhydro-D-mannitol is the predominating product. Hockett and Conley (ref. 5d) have indicated that the nature of the catalyst employed may influence the proportions of products formed.

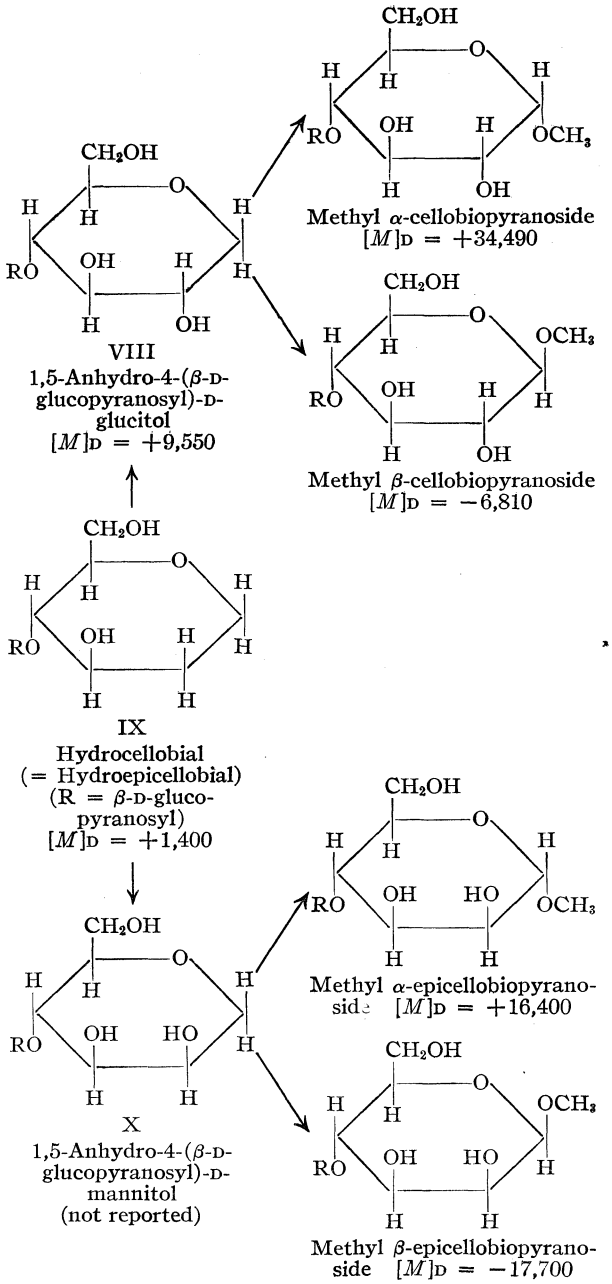

Fig. 5.—Some rotatory relations in the cellobiose and epicellobiose series.

disaccharides will now be considered. In no case are data now known for an epimeric pair of the pertinent 1,5-anhydro derivatives. The hydroglycals from cellobiose, gentiobiose and lactose were synthesized many years ago; the data concerning them are shown in Table II. Maurer and Plötner[11] synthesized 1,5-anhydro derivatives in the cellobiose and gentiobiose series through the palladium-catalyzed reduction of the respective heptaacetyl-2-hydroxyglycals, and though they designated these anhydrides as substituted styracitols (*i. e.*, as derivatives of D-mannitol by present knowledge) it is apparent that there was no just basis for excluding the possibility that they were substituted polygalitols. Indeed, a consideration of the pertinent rotatory relations as developed previously in this article leads clearly to the inference that these two 1,5-anhydro derivatives, one from cellobiose and one from gentiobiose, are substituted polygalitols. In each case the substituted 1,5-anhydride is more dextrorotatory than the corresponding hydroglycal (see Tables II and III), just as polygalitol is more dextrorotatory than hydro-D-glucal. All doubt concerning the allocations has been removed lately through the syn-

(11) K. Maurer and K. Plötner, *Ber.*, **64**, 281 (1931).

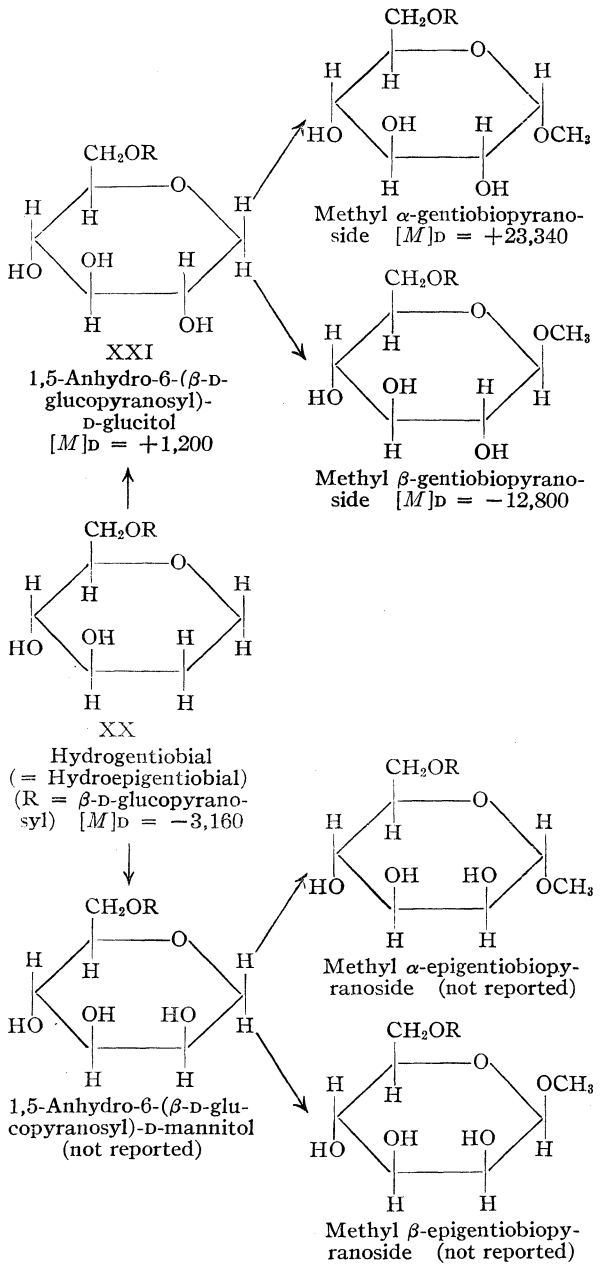

Fig. 6.—Some rotatory relations in the gentiobiose and epigentiobiose series.

thesis of authentic 1,5-anhydro-4-(β-D-glucopyranosyl)-D-glucitol by the reductive desulfurization of phenyl 1-thio-β-cellobioside heptaacetate and of 1,5-anhydro-6-(β-D-glucopyranosyl)-D-glucitol from phenyl 1-thio-β-gentiobioside heptaacetate in like manner.[9] The substances proved to be identical with those discovered by Maurer and Plötner; they are substituted polygalitols rather than substituted styracitols.

The recent preparation of an anhydride in the lactose series, 1,5-anhydro-4-(β-D-galactopyranosyl)-D-glucitol[12] affords an analogous example; as will be seen from Tables II and III the anhydride (+16,100), a substituted polygalitol, is more dextrorotatory than the long known hydrolactal (+8,800).

With the data which are available in Tables I, II and III, and assuming isorotation, it is possible to predict the sign and order of magnitude of the rotations of some 1,5-anhydrides which have not as yet been reported. Thus, using the molecular rotation of the known 1,5-anhydro-4-(β-D-glucopyranosyl)-D-glucitol (+9,550) and the molecular rotation of hydrocellobial (+1,400), it is simple to calculate the molecular rotation of the unknown epimeric anhydride, 1,5-anhydro-4-(β-D-glucopyranosyl)-D-mannitol, as 2 × 1,400–9,550 = −6,750, corresponding to a specific rotation of −21°. Alternatively, the difference between the epimers polygalitol and styracitol (+6,950 − (−8,340) = +15,290) may be used to calculate a value of 9,550 − 15,290 = −5,740, corresponding to a specific rotation of −17° for the same anhydride.

Attention is next directed to the Figs. 1–6.[13] In the left hand column of each of these figures one will observe that the arrangements portray the relationship that has been shown between the molecular rotation of a hydroglycal and those of the members of the related epimeric pair of 1,5-anhydroglycitols. An inspection of the two combined columns of these figures leads to a new generalization which may be stated as follows: *the molecular rotation of a 1,5-anhydroglycitol lies well between the molecular rotations of the anomeric methyl glycopyranosides of the corresponding aldose.* Each methyl α-D-glycopyranoside is much more dextrorotatory, and each methyl β-D-glycopyranoside is much more levorotatory, than the corresponding 1,5-anhydro-D-glycitol. This generalization is not a purely empirical one; it has the same type of basis upon the isorotation hypothesis as does the relationship between the rotation of a hydroglycal and the corresponding 1,5-anhydroglycitol. From Figs. 1–6 it will be seen that the molecular rotation of a 1,5-anhydroglycitol is not the exact mathematical mean of the molecular rotations of the corresponding methyl glycopyranosides but that it does lie so well between them that the generalization can be applied without uncertainty.

Summary

Some relationships between molecular rotation and configuration among the hydroglycals, the 1,5-anhydroglycitols and the methyl glycopyranosides have been pointed out.

Steroids. I. 3-Thio-enol Ethers of Δ^4-3-Keto Steroids

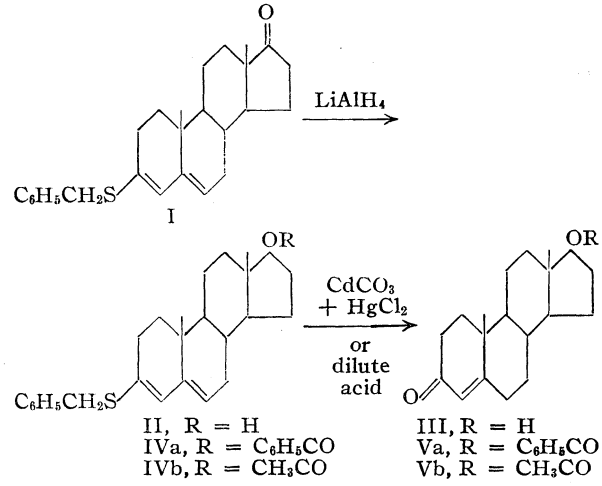
BY G. ROSENKRANZ, ST. KAUFMANN AND J. ROMO

The reaction of 3-keto steroids with alcohols in the presence of condensing agents is well known.[1a,b,c,d] In the case of Δ^4-3-keto steroids, the reaction with monohydric alcohols leads preferably to 3-enol ethers while with glycols cyclic ketals are formed.[2]

It is to be expected that analogous reactions will occur with mercaptans and thioglycols. Bernstein and Dorfman[3] and Hauptmann[4] reported some thioenol ethers and mercaptols of cholestenone, dehydrocholic acid and cholestanone.[5]

We decided to study the exact reaction conditions for the condensation of Δ^4-androstene-3,17-dione with benzyl mercaptan. In order to avoid the reaction of the 17-keto group, as it occurs in the case of dehydroisoandrosterone acetate and several mercaptans,[6,7] we carried out the condensation either at room temperature with anhydrous zinc chloride and sodium sulfate in dioxane solution or by azeotropic distillation of the benzene solution of equimolar quantities of the ketone and mercaptan in the presence of *p*-toluenesulfonic acid. In both cases the resulting product was the well-characterized 3-benzylthioenol ether of Δ^4-androstene-3,17-dione (I). This product can be reconverted easily into the parent ketone by known methods, *e. g.*, with cadmium carbonate and mercuric chloride or by acid hydrolysis.

A very important reaction of the 3-enol ethers (and also of the 3-ketals) of Δ^4-androstene-3,17-dione is their reduction to the corresponding derivatives of testosterone.[1d] The best known method for this reduction is with sodium and alcohol. Applying this method to our 3-thioenol ethers, we encountered difficulties to accomplish the reduction of the 17-keto group without altering the thioenol ether group, while the reaction of these compounds with alkyl-magnesium halides (Miescher[5]) takes place very neatly, involving only the 17-keto group and leaving the 3-grouping unaffected. We found, however, that the 17-keto group of the 3-benzylthioenol ether of Δ^4-androstene-3,17-dione (I) can be transformed into the hydroxyl group with lithium aluminum hydride[8] whereby the 3-benzylthioenol ether of testosterone (II) is obtained in good yield. This latter compound can be hydrolyzed by means of dilute mineral acids or cadmium carbonate and mercuric chloride to testosterone (III). By careful acylation of the 3-benzylthioenol ether of testosterone (II) the corresponding esters (IV) are obtained. The mild hydrolysis of these 3-thioenol-ether 17-esters with cadmium carbonate and mercuric chloride leads to the corresponding esters of testosterone (V). It is obvious that the preceding reactions represent a new synthesis for the preparation of testosterone and its esters.



The thioenol ethers described in this paper are well-crystallized substances which are fairly alkali resistant. They are stable in acid-free solvents but in presence of traces of acids they decompose rapidly with development of vile-smelling vapors. They also decompose under the influence of light and must be stored in dark containers.

As an interesting alternative we also studied the reaction between Δ^4-androstene-3,17-dione and monothioglycol since the latter compound contains simultaneously a hydroxyl and a sulfhydryl group. In analogy to the reaction of the Δ^4-3-keto-compounds with ethylene glycol[2] and dithioglycol[4,5] we expected the formation of a cyclic hemithioketal (VI).

Theoretically two other compounds might also be formed: the 3-(β-hydroxyethyl)-thioenol ether (VII) and the 3-(β-mercaptoethyl) enol ether (VIII) of androstenedione.

The formation of other theoretically possible reaction products, where the double bond of the

(5) In one of his patents which recently became available to us (U. S. Patent 2,435,013), Miescher describes the reactions of androstene-3,17-dione with ethyl mercaptan and dithio-glycol, respectively. No characteristics of the corresponding reaction product are given. After the conclusion of our work a U. S. Patent (2,451-434) of Dorfman and Bernstein became available. This patent refers to the preparation of the ethylthioenol ether of testosterone propionate by the reaction of testosterone propionate with ethyl mercaptan. The product is described as a yellow viscous oil.

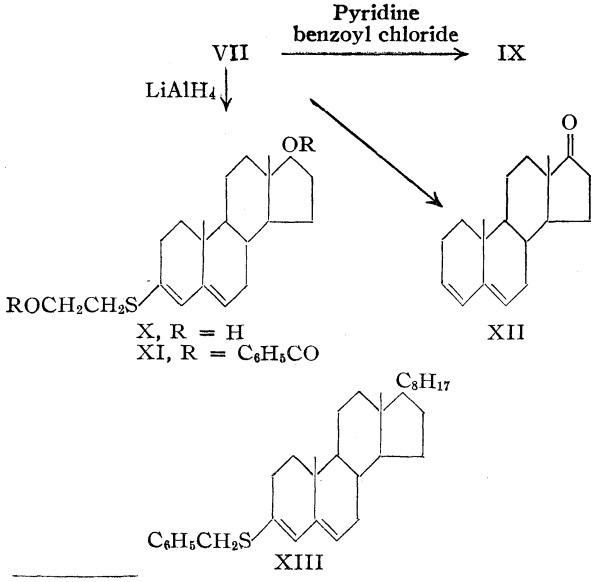
α,β-unsaturated ketone would react with the mercaptan seems remote since Hauptmann[4] was unable to obtain any sulfur-containing steroid compounds in the reaction of Δ^4-cholestene-3-one and benzyl mercaptan using as a catalyst, piperidine which is supposed to favor particularly the reaction between mercaptans and the α,β-double bond.

Working under different conditions we were able to isolate two compounds: using pyridine hydrochloride as condensing agent we isolated the thioenol ether (VII) and using zinc chloride and sodium sulfate or *p*-toluenesulfonic acid we obtained another compound which is probably the cyclic hemithioketal of the formula (VI).[9]

The thioenol ether (VII) behaves exactly as the 3-benzylthioenol ether of Δ^4-androstene-3,17-dione (I) and can be converted into the corresponding derivatives of testosterone by the same process as mentioned above. With benzoyl chloride and pyridine a monobenzoate (IX) can be prepared. The same reaction applied to the corresponding 17-hydroxy compound (X) which was obtained by the action of lithium aluminum hydride on (VII) gives a crystalline dibenzoate (XI).



In order to decide between formulas (VII) and (VIII) and for a definite proof of structure we submitted the compound to hydrogenolysis with Raney nickel. We obtained the known $\Delta^{3,5}$-androstadiene-17-one (XII), which proved beyond doubt structure (VII) for the compound obtained in the reaction of monothioglycol and androstenedione in presence of pyridine hydrochloride. Formula (VIII) can be excluded because on desulfuration one could expect a 3-ethyl ether of the androstane series. In order to establish the behavior of the double bonds of the thioenol ethers on desulfuration, it was necessary to submit several thioenol ethers of the androstane and cholestane series to hydrogenolysis under different conditions. As this reaction has not been described before we selected the following compounds for our study: 3-benzylthioenol ether of Δ^4-androstene-3,17-dione (I); 3-benzylthioenol ether of testosterone (II); 3-(β-hydroxyethyl)-thioenol ether of Δ^4-androstene-3,17-dione (VII); 3-(β-hydroxyethyl)-thioenol ether of testosterone (X) and 3-benzylthioenol ether of Δ^4-cholestenone (XIII).

This latter compound had not been prepared before. We obtained it by the reaction of equimolar quantities of benzyl mercaptan and Δ^4-cholestenone using as condensing agents either *p*-toluenesulfonic acid or zinc chloride and sodium sulfate. It seemed to us that if an excess of the mercaptan is used, the formation of the mercaptol predominates, whereas, using equimolar quantities, thioenol ethers are formed. However, Bernstein and Dorfman[3] reported the preparation of the 3-ethylthioenol ether of Δ^4-cholestenone using ethyl mercaptan in excess. We are inclined to regard this as an exception, due perhaps to the volatility of the mercaptan used. Hauptmann[4] using excess benzyl mercaptan obtained the corresponding mercaptol of Δ^4-cholestenone.

For the hydrogenolytic desulfuration, we used the method described by Wolfrom and Karabinos.[10] The hydrogenolysis was carried out in two different series: in the first series the Raney nickel was partially deactivated according to the method of Spero, McIntosh and Levin.[11] These authors refluxed the acetone suspension of the catalyst during two hours and subsequently added the compound which was to be desulfurated, completing the reaction by further refluxing. In the second series of experiments fully active Raney nickel, prepared according to the method of Mozingo,[12a,b] was used in ethanol or dioxane as reaction medium.

With the deactivated catalyst we obtained $\Delta^{3,5}$-

(9) Investigation of this compound is now on the way in our laboratories. The results will be published at some future date.

(12) (a) Mozingo, *Org. Syntheses*, **21**, 15 (1941); (b) in the classification of Adkins and Pavlic (THIS JOURNAL, **69**, 3039 (1947)) this Raney nickel is referred to as "catalyst W-2."

compounds throughout the whole series. With fully active catalyst the thioenol ethers of testosterone and cholestenone were desulfurated to the saturated compounds of the androstane and cholestane series, respectively.

When desulfurizing the thioenol ether of Δ^4-androstene-3,17-dione, a mixture of $\Delta^{3,5}$-androstadiene-17-one and androstan-17(β)-ol[13] was obtained. It is very probable that the first action of the Raney nickel on the thioenol ether molecule consists in the elimination of the sulfur atom. If the nickel catalyst is partially deactivated, its action ceases when desulfuration is complete, but with an active catalyst, and in a medium which does not exercise a deactivating action, the Raney nickel reduces the 17-keto group and then saturates the conjugated double bonds.

The simultaneous formation of the $\Delta^{3,5}$-androstadiene-17-one and androstan-17(β)-ol indicates that the carbonyl group of the thioether molecule acts as a partial deactivator of the nickel, hindering the saturation of the double bonds, but when it is reduced to the alcohol group its influence disappears and the double bonds are saturated.

The isolation of $\Delta^{3,5}$-androstadien-17-one from the desulfuration products of the thioenol ether of Δ^4-androstene-3,17-dione is the first direct evidence for this position of the double bonds in this compound, because under the extremely mild conditions of the desulfuration the shifting of the double bond is not likely to occur. That same position of the double bonds was suggested by some authors[1] for the enol ethers of the Δ^4-3-keto steroids but so far no direct proof for this assumption has been presented.

As additional evidence for the heteroannular location of the double bonds in our thioenol ethers, we may mention the fact that we failed to obtain an addition product with maleic anhydride, working in benzene solution under the usual conditions, while such an addition product would most likely have been formed in the case of a homoannular diene.

The ultraviolet absorption spectra of the thioenol ethers have an absorption maximum at 268 mμ; the corresponding enol ethers show a maximum at 240 mμ.[14] Gillam, *et al.*,[15] found a difference of 22 mμ between the absorption maxima of certain semicarbazones and thiosemicarbazones, and Bowden, *et al.*,[16] report a similar bathochromic effect of the –SR group attached to the ethylenic linkage. In the light of these findings and of the evidence presented above by ourselves, we feel justified in ascribing the Δ_λ of 28 mμ between the λ_{max} of the enol ethers and of the thioenol ethers (240–268 mμ) to the introduction of a sulfur-containing substituent, and not to any rearrangement in the steroid molecule itself.[17]

(13) We ascribe to this compound the β-configuration at C_{17} in accordance with the convention advanced in Fieser and Fieser "Natural Products Related to Phenanthrene," 3rd edition, Reinhold Publishing Corp., New York, N. Y., 1949, pp. 325–327.

Experimental[18,19,20,21]

3-Benzylthioenol Ether of Δ^4-Androstene-3,17-dione (I).—(a) Pure Δ^4-androstene-3,17-dione (4.9 g., 0.017 mole) was dissolved in 25 cc. of anhydrous dioxane; 4 g. (0.034 mole) of benzyl mercaptan, 8 g. of freshly fused and pulverized zinc chloride and 8 g. of anhydrous sodium sulfate were added under external cooling. After seventeen hours at room temperature the orange-colored mixture was diluted with benzene, washed with water to remove the inorganic salts, dried over sodium sulfate and evaporated to dryness. The residue was crystallized from acetone–methanol whereby 3 g. (45%) of small pale-yellowish needles of I, m. p. 177–179°, $[\alpha]^{20}D$ −84°, λ_{max} 268 mμ, log E_m 4.15 was obtained.

Anal. Calcd. for $C_{26}H_{32}OS$: C, 79.54; H, 8.21; S, 8.16. Found: C, 79.59; H, 8.10; S, 7.88.

(b) A solution of 10 g. (0.035 mole) of Δ^4-androstene-3,17-dione in 100 cc. of benzene to which 5.3 g. (0.043 mole) of benzyl mercaptan and 0.5 g. of *p*-toluenesulfonic acid were added was refluxed for six hours. Every two hours 15 cc. of the azeotropic mixture was distilled off. After the end of the reaction the mixture was diluted with 100 cc. of benzene, washed neutral with 5% sodium carbonate solution and water, dried over anhydrous sodium sulfate and evaporated to dryness. The residue was crystallized from acetone–methanol, whereby 7.5 g. (55%) of I, m. p. 177–179°, was obtained.

To a solution of 2 g. of I in 200 cc. of ethanol, 3 cc. of concentrated hydrochloric acid and 3 cc. of water were added. After refluxing for two hours the mixture was poured into water, extracted with ether, washed neutral with water, sodium bicarbonate solution and water, dried over sodium sulfate and evaporated to dryness.[22] The residue on crystallization from acetone–hexane gave 1.2 g. of crystals, m. p. 166–170°, $[\alpha]^{20}D$ + 190° (in ethanol). A qualitative test of sulfur was negative; mixed with an authentic sample of Δ^4-androstene-3,17-dione it gave no depression.

To a solution of 2 g. of I in 250 cc. of acetone, 3 g. of freshly prepared cadmium carbonate and 3 g. of finely pulverized mercuric chloride were added. The mixture was refluxed for eight hours, the inorganic salts were filtered off and washed with acetone. The filtrate was concentrated to a volume of 50 cc., poured into water and ex-

(17) Moreover, we calculated the differences between the molecular rotations of our thioenol ethers and of the corresponding Δ^4-3-keto steroids and found in five out of seven cases a Δ_M of -873 ± 3 (in two cases the values differed by 10% from the above mean value; see note 20). This strongly levorotatory shift supports a $\Delta^{3,5}$ rather than a $\Delta^{2,4}$ location of the double bonds (see Fieser, ref. 13, p. 210) and comes near the corresponding values for the oxygen analogs (Δ_M about −760),[18] thus suggesting once more that the oxygen-containing and the sulfur-containing enol ethers possess the same structure.

(18) The microanalyses were carried out by Dr. Carl Tiedcke, New York, N. Y., and in our microanalytical laboratory under the direction of Miss Amparo Barba.

(19) All the melting points were determined on the Kofler micro-melting point apparatus.

(20) The rotations of the sulfur-containing substances were determined in anhydrous dioxane; these compounds decompose rapidly in chloroform. The decomposition in dioxane, though somewhat slower, probably accounts for the 10% discrepancy in the molecular rotations of compounds II and VII (see note 17). Attempts to stabilize the dioxane solutions by the addition of a few drops of pyridine were not satisfactory. All determinations were carried out in appr. 2% solutions, using a 10-cm. tube of 2-cc. capacity.

(21) The ultraviolet absorption spectra were determined in alcoholic solution, using a Beckman Model DU Quartz Spectrophotometer with 1-cm. quartz cells.

(22) In the following, this procedure is briefly referred to as "usual workup."

tracted with ether. After the usual workup the residue was recrystallized from acetone–hexane. Androstenedione (1.1 g.) m. p. 167–172° was obtained, characterized by a mixed melting point with an authentic sample.

3-(β-Hydroxyethyl)-thioenol Ether of Δ⁴-Androstene-3,17-dione (VII).—A solution of 10 g. (0.035 mole) of Δ⁴-androstene-3,17-dione in 100 cc. of benzene, 3 g. (0.038 mole) of monothioglycol and 0.8 g. of pyridine hydrochloride in 10 cc. of absolute alcohol was refluxed for six hours. Every two hours 10 cc. of the azeotropic mixture was distilled off. At the end of the reaction the mixture was diluted with 100 cc. of benzene and worked up as described above. The residue was crystallized from methanol, whereby 4 g. (33%) of white prisms of VII, m. p. 166–177°, $[\alpha]^{20}D$ −113°, λ_{max} 268 mμ, log E_m 4.41 was obtained. From the mother liquors additional 2 g. (16.5%) could be collected on further standing.

Anal. Calcd. for $C_{21}H_{30}O_2S$: C, 72.78; H, 8.72; S, 9.25. Found: C, 72.74; H, 8.69; S, 9.15.

The hydrolysis of this thioenol ether was accomplished under the same conditions as described above for I. In both cases Δ⁴-androstene-3,17-dione was obtained, identified by melting points, mixed melting point and rotation.

The benzoate (IX) was prepared by dissolving 4 g. (0.011 mole) of VII in 10 cc. of anhydrous pyridine to which 5 g. (0.036 mole) of benzoyl chloride was added. The mixture was left standing at room temperature for eighteen hours, then diluted with pure chloroform and washed with 2% sulfuric acid, water, sodium carbonate solution and water until neutral, dried over sodium sulfate and concentrated to a residual volume of about 15 cc., diluted with 200 cc. of ether and quickly filtered. The filtrate was decolorized with charcoal and evaporated to dryness. The residue, after addition of methanol, became solid. After two crystallizations from chloroform–methanol, 2 g. (39%) of white plates, m. p. 209–211° was obtained; $[\alpha]^{20}D$ + 177.3°, λ_{max} 232 mμ, log E_m 4.38.[23]

Anal. Calcd. for $C_{28}H_{34}O_3S$: C, 74.62; H, 7.60; S, 7.11. Found: C, 74.59; H, 7.62; S, 7.28.

3-Benzylthioenol Ether of Δ⁴-Cholestenone (XIII).—This compound was prepared as described above under (b), using 5 g. (0.013 mole) of Δ⁴-cholestenone in 100 cc. of benzene, 2.5 g. (0.02 mole) of benzyl mercaptan and 0.3 g. of *p*-toluenesulfonic acid. Crystallization from acetone yielded 3.2 g. (50%) of white needles of XIII, m. p. 121.5–122°, $[\alpha]^{20}D$ −105°, λ_{max} 268 mμ, log E_m 4.31.

Anal. Calcd. for $C_{34}H_{50}S$: C, 83.27; H, 10.26; S, 6.53. Found: C, 83.42; H, 10.14; S, 6.66.

3-Benzylthioenol Ether of Testosterone (II).—The flask of a Soxhlet extraction apparatus was charged with a solution containing 2 g. (0.053 mole) of lithium aluminum hydride in 800 cc. of anhydrous ether and 3 g. (0.008 mole) of I was placed in the extractor thimble. The solution was warmed until all the thioenol ether had been transferred to the reaction flask. The mixture was then cooled externally with ice and, under continuous stirring, water was added dropwise to decompose the excess hydride and the complex formed during the reaction. When decomposition was complete, 300 cc. of benzene was added in order to dissolve the product completely. The benzene–ether solution was washed with water, dried over sodium sulfate and evaporated to dryness. After recrystallization from methanol with a drop of pyridine, 2 g. (66%) of white needles, m. p. 168–169°, $[\alpha]^{20}D$ −126.2°, λ_{max} 268 mμ, log E_m 4.20 was obtained.

Anal. Calcd. for $C_{26}H_{34}OS$: C, 79.12; H, 8.68; S, 8.12. Found: C, 79.22; H, 8.68; S, 8.28.

The hydrolysis of II with hydrochloric acid was carried out as described above for I: To a solution of 1 g. of II in ethanol, 3 cc. of hydrochloric acid and 3 cc. of water were added. After two hours refluxing, the mixture was poured into water, the product extracted with ether and worked up as usual. By several recrystallizations from acetone–hexane, 0.5 g. (68%) of testosterone (III) m. p. 150–152°, $[\alpha]^{20}D$ +104.2° (in methanol) was obtained. The mixed melting point with an authentic sample of testosterone gave no depression. The sulfur test was negative.

To a solution of 2 g. of II in 250 cc. of acetone, 3 g. of cadmium carbonate and 3 g. of mercuric chloride were added. The mixture was refluxed for two hours and the reaction product worked up as in previous examples. By repeated recrystallizations from acetone–hexane 0.9 g. (61%) of testosterone (III), m. p. 150–51° mixed m. p. 150–153°, $[\alpha]^{20}D$ + 103.4° (in methanol) was obtained. The sulfur test was negative.

3-Benzylthioenol Ether of Testosterone Benzoate (IVa).—To a solution of 4 g. (0.01 mole) of II in 8 cc. of anhydrous pyridine, 5 g. (0.035 mole) of benzoyl chloride was added and the mixture was left standing at room temperature for fourteen hours. It was then diluted with chloroform, washed with 2% sulfuric acid, water, sodium carbonate solution and water until neutral, dried over sodium sulfate and concentrated to a residual volume of 20 cc. Ether was added and the solution was quickly filtered, decolorized with charcoal and evaporated to dryness. After crystallization from methanol, 2 g. (40%) of white needles was obtained which, after recrystallization from acetone–methanol, melted at 160–161°, $[\alpha]^{20}D$ −59.3°, λ_{max} 228, 268 mμ; log E_m 4.46, 4.32.

Anal. Calcd. for $C_{33}H_{38}O_2S$: C, 79.47; H, 7.68; S, 6.42. Found: C, 79.59; H, 7.80; S, 6.69.

To a solution of 0.7 g. of IVa in 200 cc. of alcohol, 3 drops of concentrated hydrochloric acid and 3 cc. of water were added. After two hours of refluxing, the product was worked up as in the previous example. By crystallization from methanol, 0.35 g. (64%) of testosterone benzoate (Va), m. p. 190–192° was obtained, which gave no depression when mixed with an authentic sample.

3-Benzylthioenol Ether of Testosterone Acetate (IVb).—A flask containing a mixture of 10 cc. of anhydrous dioxane and 10 cc. of pyridine was cooled externally with ice and 9 g. (0.11 mole) of acetyl chloride was added dropwise. To this mixture, which was kept in the ice-bath, a solution of 1.5 g. (0.004 mole) of II in 20 cc. of anhydrous dioxane was added dropwise. It was left standing at room temperature during one hour and then poured into water. It was extracted with ether and the ether solution washed with 2% sulfuric acid solution and water until neutral, dried over sodium sulfate and evaporated to dryness. After crystallization from methanol with a drop of pyridine, 1 g. (60%) of white needles, m. p. 110°, $[\alpha]^{20}D$ −134° was obtained.

Anal. Calcd. for $C_{28}H_{36}O_2S$: C, 77.01; H, 8.31; S, 7.34. Found: C, 76.98; H, 8.39; S, 7.19.

To a solution of 0.6 g. of IVb in 100 cc. of ethanol, 3 drops of concentrated hydrochloric acid and 3 cc. of water were added. After two hours of refluxing, the mixture was poured into water and worked up as usual. The residue was taken up in hexane and the solution decolorized with charcoal. By crystallization, 0.2 g. (44%) of testosterone acetate (Vb) m. p. 139–140°, $[\alpha]^{20}D$ + 89° was obtained, which gave no depression when mixed with an authentic sample. The sulfur test was negative.

3-(β-Hydroxyethyl)-thioenol Ether of Testosterone (X).—Under the same conditions as described above for I, 3 g. of VII was treated in a Soxhlet apparatus with an excess of lithium aluminum hydride yielding, after crystallization from methanol with a drop of pyridine, 2 g. (66%) of white needles m. p. 175–177°, $[\alpha]^{20}D$ −161.3°.

Anal. Calcd. for $C_{21}H_{32}O_2S$: C, 72.36; H, 9.25; S, 9.19. Found: C, 72.38; H, 9.46; S, 9.09.

Following the method described above for II, 1.5 g. of X was hydrolyzed with hydrochloric acid and 1 g. (80%) of testosterone m. p. 151–153°, $[\alpha]^{20}D$ +103° (in methanol), was obtained. The mixed m. p. gave no depression. The sulfur test was negative.

On hydrolysis with cadmium carbonate and mercuric chloride under the conditions described above for II, 2 g. of X yielded 1.4 g. (85%) of testosterone m. p. 151°,

(23) In view of this unexpected dextrorotation and the absence of the typical absorption maximum at 268 mμ, we abstain from assigning a structural formula to IX.

$[\alpha]^{20}D$ + 104.6° (in methanol) which gave no melting point depression.

The **dibenzoate (XI)** was prepared by applying to a solution of 1 g. of X in 5 cc. of pyridine, to which 3 g. of benzoyl chloride was added, the treatment described for II. After crystallization from methanol, 0.5 g. (31%) of tiny plates was obtained, m. p. 131–133°, $[\alpha]^{20}D$ −58.5°, λ_{max} 230, 268 mμ, log E_m 4.57, 4.22.

Anal. Calcd. for $C_{35}H_{40}O_4S$: C, 75.50; H, 7.24; S, 5.75. Found: C, 75.60; H, 7.30; S, 5.65.

Working as described for IVa, 2 g. of dibenzoate yielded 0.4 g. (28%) of testosterone benzoate, m. p. 188–193°. Mixed with an authentic sample of m. p. 192–194° the mixture melted at 188–193°.

Probable Hemithioketal of Δ^4-Androstene-3,17-dione: First Method.—Five grams (0.017 mole) of the diketone and 1.4 g. (0.17 mole) of monothioglycol were dissolved in 10 cc. of anhydrous dioxane. Seven grams of freshly fused and pulverized zinc chloride and 7 g. of anhydrous sodium sulfate were added and the mixture was left standing at room temperature for sixteen hours. It was then diluted with benzene, washed with water, dried and evaporated to dryness, leaving 5.5 g. of an oily residue, which was subsequently chromatographed on a column of 100 g. of aluminum oxide (Alorco F-20), using portions of 300 cc. of benzene–hexane 1:1 for each fraction of the elution. Fraction 1 yielded 0.9 g. and fraction 8 yielded 0.2 g. of an oil. The combined crystalline fractions 2–7 (3.7 g.) with melting points ranging from 178 to 193°, were recrystallized several times from methanol yielding 2.5 g. (41%) of white needles, m. p. 190–193°, λ_{max} 238 mμ, log E_m 4.30.

Anal. Calcd. for $C_{21}H_{30}O_2S$: C, 72.78; H, 8.72; S, 9.25. Found: C, 73.02; H, 8.86; S, 8.93; $[\alpha]^{20}D$ +52.4°.

Second Method.—Ten grams (0.035 mole) of the diketone was dissolved in 100 cc. of benzene and 3.5 g. (0.045 mole) of monothioglycol was added. The mixture was refluxed for six hours and every two hours 10 cc. of the azeotropic mixture was distilled off. Proceeding as described in previous examples, by several crystallizations from methanol 3 g. (25%) of white needles, m. p. 190–193° was obtained. An additional crop of 2 g. (16%) was obtained from the mother liquors.

The mixed m. p. of the crystals obtained by these two methods gave no depression.

On hydrolysis with hydrochloric acid, 2 g. of this product gave 1.3 g. of Δ^4-androstene-3,17-dione, m. p. 168–170°.

On hydrolysis with cadmium carbonate and mercuric chloride, 2 g. of the product gave 1.5 g. of Δ^4-androstene-3,17-dione.

Hydrogenolysis of 3-Benzylthioenol Ether of Δ^4-Androstene-3,17-dione (I). Method A with Fully Active Raney Nickel.—To a solution of 4 g. (0.01 mole) of I in 100 cc. of dioxane, a suspension of 30 g. of Raney nickel in 100 cc. of ethanol, prepared according to Mozingo[12] was added and the whole was refluxed for eight hours. The nickel was filtered off and the solvent was removed under reduced pressure leaving 3 g. of a solid residue, which was dissolved in 38 cc. of absolute ethanol and 3.8 cc. of acetic acid; 3 g. of Girard reagent T was added. After refluxing for one hour the mixture was poured into water, containing a quantity of sodium hydroxide sufficient to neutralize $^9/_{10}$ of the acetic acid. From the aqueous mixture, the non-ketone fraction was extracted with ether, the ether solution was washed with water, dried and evaporated; by recrystallization from hexane, 0.3 g. (8%) of androstan-17(β)-ol, m. p. 163°, $[\alpha]^{20}D$ + 12° (in chloroform) was obtained. This compound has been prepared by Marker[24] who reports a m. p. 166°. Mixed with an authentic sample of 166° the mixture melted at 163–166°. The tetranitromethane test and the sulfur test were negative.

Anal. Calcd. for $C_{19}H_{32}O$: C, 82.55; H, 11.65. Found: C, 82.68; H, 11.74.

(24) Marker, THIS JOURNAL, **62**, 2523 (1940).

The androstan-17(β)-ol acetate was prepared by heating a solution of 0.5 g. of androstan-17(β)-ol in 20 cc. of acetic anhydride on a steam-bath for one hour. The excess anhydride was removed under reduced pressure and the residue crystallized from methanol–water, yielding 0.3 g. of androstan-17(β)-ol acetate, m. p. 72–75°, $[\alpha]^{20}D$ +5° (in chloroform).

Anal. Calcd. for $C_{21}H_{34}O_2$: C, 79.19; H, 10.76. Found: C, 79.48; H, 10.52.

Kuwada and Miyasaki[25] describe a 17-acetoxyandrostane melting at 82°, but we did not have an opportunity to compare their product with ours.

The androstan-17(β)-ol benzoate was prepared by adding 3 g. of benzoyl chloride to a solution of 1 g. of androstanol in 8 cc. of anhydrous pyridine. The mixture was left standing at room temperature for sixteen hours, then diluted with chloroform, washed with 2% sulfuric acid and then with water until neutral, dried and evaporated. After recrystallization from methanol and acetone–methanol, 0.8 g. of white needles, m. p. 159–161°, $[\alpha]^{20}D$ + 51.7° (in chloroform) was obtained.

Anal. Calcd. for $C_{26}H_{36}O_2$: C, 82.05; H, 9.53. Found: C, 82.04; H, 9.64.

The aqueous mixture of the hydrogenolysis of I, which still contained the ketone fraction, was acidified with hydrochloric acid and extracted with ether. After the usual workup, 2.5 g. (66%) of white plates m. p. 85–87°, $[\alpha]^{20}D$ −21° (in chloroform) was obtained by crystallization from methanol–water. Mixed with a sample of $\Delta^{3,5}$-androstadien-17-one, obtained by dehydration of dehydroisoandrosterone with phosphorus pentoxide, following the method of Burrows, *et al.*,[26] no depression of the melting point was observed. The tetranitromethane test was positive; the sulfur test was negative.

Anal. Calcd. for $C_{19}H_{26}O$: C, 84.39; H, 9.69. Found: C, 84.24; H, 9.75.

$\Delta^{3,5}$-Androstadien-17-one has been isolated by Wolfe, Fieser and Friedgood[27] who report a m. p. 88–89° and has also been prepared by other authors.[28,29]

The oxime was prepared by dissolving 0.5 g. of the ketone in 50 cc. of methanol to which 0.3 g. of hydroxylamine hydrochloride and 0.5 g. of sodium acetate were added. After refluxing for three hours, the solution was poured into water and worked up as usual. By recrystallization from methanol–water, 0.3 g. of the oxime, m. p. 165–167°, was obtained. This compound has also been prepared by Wolfe, Fieser and Friedgood,[27] who report m. p. 164–166°.

Hydrogenolysis of I. Method B, with Partially Deactivated Raney Nickel.—A suspension of 20 g. of Raney nickel in 100 cc. of acetone was refluxed for one hour, 2 g. of I in 100 cc. of acetone was added and refluxing was continued for four hours. The nickel was filtered off and washed with acetone. The solution was evaporated to dryness and the residue was recrystallized from methanol–water, yielding 0.65 g. (48%) of white plates, m. p. 87–89°, of $\Delta^{3,5}$-androstadien-17-one. The mixed melting point with the above test compound gave no depression. The tetranitromethane test was positive; the sulfur test negative.

Hydrogenolysis of 3-Benzylthioenol Ether of Testosterone (II). Method A.—Two grams of II was dissolved in 100 cc. of alcohol and 20 g. of Raney nickel was added. After refluxing for four hours, the reaction mixture was worked up as described above for I, and by crystallization from hexane, 1.2 g. (86%) of androstan-17(β)-ol, m. p. 165–166°, was obtained. The tetranitromethane test and the sulfur test were negative.

(29) Ross, *J. Chem. Soc.*, 25–27 (1945).

Method B.—Working as described for I, 3 g. of II yielded, after crystallization from ethanol, 1.8 g. (87%) of needles, m. p. 156°, $[\alpha]^{20}D$ −139° (in chloroform). The tetranitromethane test was positive and the sulfur test negative.

Anal. Calcd. for $C_{19}H_{28}O$: C, 83.76; H, 10.35. Found: C, 83.79; H, 10.40.

This is the $\Delta^{3,5}$-androstadien-17(β)-ol previously described by Butenandt[28] and also by Kuwada and Miyasaki[25] who report m. p. 153–155°.

The acetate, prepared in the usual manner, melted at 128°. Kuwada and Miyasaki[25] report m. p. 126°, $[\alpha]^{20}D$ −155° (in chloroform).

Anal. Calcd. for $C_{21}H_{30}O_2$: C, 80.20; H, 9.61. Found: C, 80.26; H, 9.64.

In order to obtain an authentic specimen for comparison, we also prepared $\Delta^{3,5}$-androstadien-17-ol by the following method, which is essentially the one followed by Butenandt[28] but with some modifications: one gram of testosterone was dissolved in 200 cc. of anhydrous ether. This solution was added dropwise to a boiling solution of 0.8 g. of lithium aluminum hydride in 200 cc. of anhydrous ether. After working up the reaction mixture as described in previous examples, a residue was obtained which was a mixture of isomeric androstenediols. These were dissolved in 300 cc. of ethanol and after addition of 10 cc. of hydrochloric acid, refluxed for two hours. The product was poured into water and worked up as usual. By crystallization from ether–hexane, 0.5 g. of $\Delta^{3,5}$-androstadien-17(β)-ol, m. p. 158° was obtained.

When mixed with a sample of the product obtained by method B (see above) the mixture melted at 156–158°.

Hydrogenolysis of the 3-(β-Hydroxyethyl)-thioenol Ether of Δ^4-Androstene-3,17-dione (VII). Method A.—Proceeding as described for I, 4 g. of VII yielded a crude reaction product of 2.7 g. (85%). After treatment with Girard reagent T, 0.7 g. (22%) of androstan-17(β)-ol, m. p. and mixed m. p. 162–164°, was obtained from the non-ketone fraction. The tetranitromethane test and the sulfur test were negative. The ketone fraction yielded 1 g. (32%) of $\Delta^{3,5}$-androstadien-17-one, m. p. 85–87°, $[\alpha]^{20}D$ −22° (in chloroform). The tetranitromethane test was positive; the sulfur test negative.

Method B.—Working as above, from 2 g. of VII, 1.3 g. (83%) of white plates of $\Delta^{3,5}$-androstadien-17-one, m. p. and mixed m. p. 87–88°, $[\alpha]^{20}D$ −21.5° (in chloroform) was obtained. The tetranitromethane test was positive; the sulfur test negative.

Hydrogenolysis of the 3-(β-Hydroxyethyl)-thioenol Ether of Testosterone (X). Method A.—Working as in previous examples, 2 g. of X yielded 1.3 g. (82%) of androstan-17(β)-ol, m. p. and mixed m. p. 164–166°. The tetranitromethane test and the sulfur test were negative.

The acetates prepared from this androstan-17(β)-ol and from the one obtained by hydrogenolysis of II were identical.

Androstan-17(β)-ol (0.5 g., 0.002 mole) was dissolved in 30 cc. of acetic acid. A solution of 1.5 g. (0.015 mole) of chromic anhydride in 10 cc. of 80% acetic acid was added. The mixture was left standing at room temperature for three hours, then poured into water and extracted with ether. After the usual workup and crystallization from methanol, 0.2 g. of white plates of androstan-17-one, m. p. 122°, $[\alpha]^{20}D$ + 103° (in chloroform) was obtained. The tetranitromethane test was negative.

Method B.—Working as in previous examples, 2 g. of X yielded 1.4 g. (90%) of needles of $\Delta^{3,5}$-androstadien-17-(β)-ol, m. p. and mixed m. p. 154–155°. The tetranitromethane test was positive, the sulfur test negative.

Hydrogenolysis of the 3-Benzylthioenol Ether of Δ^4-Cholestenone (XIII). Method A.—Working as in previous examples, 4 g. of XIII yielded after crystallization from methanol–ether, 2.5 g. (82%) of cholestane, m. p. 78–79°, $[\alpha]^{20}D$ + 23.7° (in chloroform). The tetranitromethane test and the sulfur test were negative.

Anal. Calcd. for $C_{27}H_{48}$: C, 87.01; H, 12.98. Found: C, 87.16; H, 12.72.

Method B.—Working as described above, 1.5 g. of XIII yielded 1 g. (88%) of crystals of $\Delta^{3,5}$-cholestadiene, m. p. 78–79°, $[\alpha]^{20}D$ −101° (in chloroform). The tetranitromethane test was positive and the sulfur test negative.

Anal. Calcd. for $C_{27}H_{44}$: C, 87.96; H, 12.03. Found: C, 87.82; H, 12.23.

The mixed melting point of the reaction products of method A and method B showed a marked depression.

Summary

1. Several thioenol ethers of Δ^4-3-keto steroids have been prepared.

2. The conversion of the thioenol ethers of Δ^4-androstene-3,17-dione and its esters to the corresponding testosterone derivatives has been accomplished by treatment with lithium aluminum hydride.

3. Evidence for the structure of the 3-thioenol ethers of Δ^4-3-ketosteroids has been given.

Synthetic and Degradative Studies in the Isoquinoline Series. IV

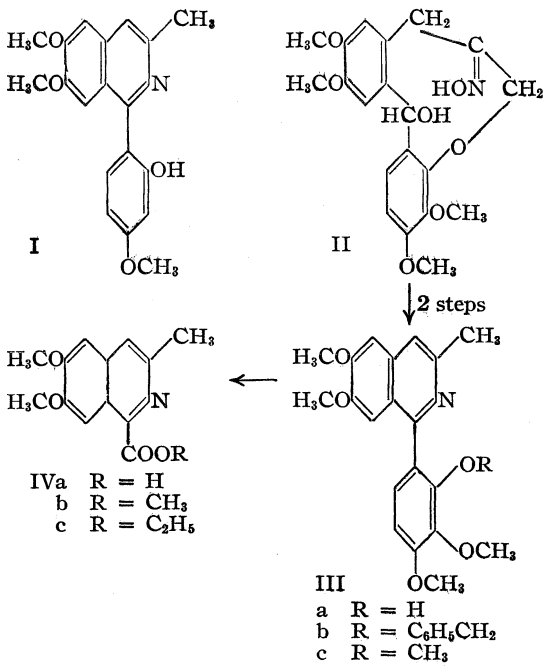
BY G. FODOR, V. BRUCKNER, J. KISS AND J. KOVÁCS

In our recent communication of this series[1] an unequivocal synthesis of I and the proof of its structure by oxidative degradation was described. This compound was isomeric, but not identical, with that prepared by Pfeiffer, *et al.*,[2] from brasilin and formulated as I; consequently the structure of their compound became doubtful.[1]

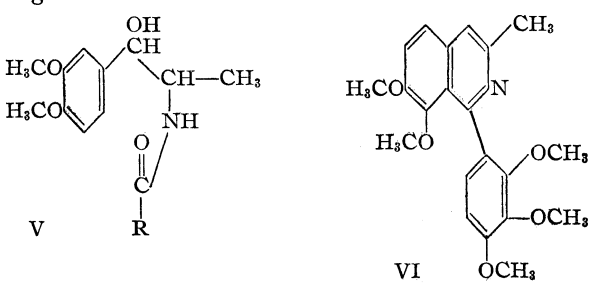
Tetramethyl hematoxylonol oxime (II) was converted by the same authors[2] in two steps into an amphoteric compound to which we will refer below as "H." Oxidation of "H" with permanganate yielded metahemipinic acid (3,4-dimethoxyphthalic acid). Degradation with nitric acid furnished an acid ("A") only isolated as picrate. Acid "A" reacted with diazomethane under formation of a monomethyl derivative, which was again only isolated as picrate. On the basis of these facts Pfeiffer, *et al.*,[2] suggested for "H" structure IIIa and for acid "A" formula IVa. These structures were not confirmed by synthesis. Although the synthesis of the methyl ether of "H" from amide Vb was attempted, the obtained synthetic

(1) Bruckner, Fodor, Kovács and Kiss, THIS JOURNAL **70**, 2697 (1948).

(2) Pfeiffer, Breitbach and Scholl, *J. prakt. Chem.*, **2**, 154, 157 (1940).



product was not identical with the methyl ether of "H," but only isomeric with it. Because of this failure Pfeiffer, *et al.*,[2] concluded that the intramolecular condensation of Vb, due to an unusual (o. m.) ring closure, led to the isoquinoline derivative (VI). However, this structure for the synthetic product was not proved by them through degradation.



The present publication deals with the synthesis and degradation of isoquinoline (IIIa) and with that of 3-methyl-6,7-dimethoxyisoquinoline-1-carboxylic acid (IVa).

The isoquinoline derivative (IIIa) was prepared by reaction of α-(3,4-dimethoxyphenyl)-β-aminopropanol with 2′-hydroxy-3,4-dimethoxybenzoyl chloride via the compound Va which was then benzylated to give Vc.[3]

This was then condensed to give the crystalline isoquinoline (IIIb). The latter was debenzylated by hydrogenolysis giving IIIa whose properties differed from "H," but which gave on treatment with diazomethane the methyl ether (IIIc) already obtained by Pfeiffer, *et al.*[2] The same compound was also obtained by us from the stereoisomeric form of Vb.[4]

The direction of the ring closure was elucidated by oxidative degradation of IIIa, leading to metahemipinic acid, so that there could be no further doubt as to the structure of the synthetic product. Obviously, the sole fact observed by Pfeiffer, *et al.*,[2] of "H" also giving an oxidative degradation metahemipinic acid, is no adequate proof for "H" possessing structure III, but only indicates the maintenance of the two carbon atoms, attached in *m, p* position to the methoxy groups of oxime II, during the two steps conversion into "H."

It remains to be decided whether the existing difference between IIIa and "H" is to be sought for in the different positions of the substituents in the aryl radical attached to carbon atom 1 of the isoquinoline system, or in the structure of the hetero ring. In the first case, both compounds ought to give on oxidation the same carboxylic acid (IVa). As we did not succeed in isolating on oxidation of IIIa with nitric acid either acid "A" or its picrate,[2] we attempted to approach the problem by a straightforward synthesis of IVa.

For this purpose the trichloroacetyl amide (Vd) was prepared which on condensation should yield a trichloromethylisoquinoline which on hydrolysis would be expected to give the desired acid (IVa) and on hydrogenolysis would give the known[5] 1,3-dimethyl-6,7-dimethoxyisoquinoline. Unfortunately, all attempts to form an isoquinoline derivative from Vd failed. Accordingly, we adopted another line of synthesis starting with the ethoxalyl derivative (Ve) preparable in good yield. Its intramolecular condensation by means of $POCl_3$ gave the 1-carbethoxyisoquinoline (IVc) and subsequent hydrolysis the crystalline acid (IVa). This acid, under the conditions reported by Pfeiffer, *et al.*,[2] did not give any precipitate with picric acid; moreover, on evaporating the solution only the picrate of 3-methyl-6,7-dimethoxyisoquinoline could be isolated, indicating the loss of the carboxylic group during the reaction. The identity of this unexpected product was shown by synthesis from the formamido compound (Vf).

Acid IVa gave with diazomethane a crystalline methyl ester (IVb, m. p. 151–153°), the picrate of which showed m. p. 168–170°. As Pfeiffer, *et al.*,[2] recorded for the picrate of their methyl ester, obtained from "A," m. p. 216°, IVa cannot be identical with "A." Furthermore, as structure IVa for our synthetic acid could be confirmed by its oxidative degradation leading to metahemipinic acid, "A" must have another structure, remaining still to be elucidated.

(3) Condensation of 2-benzyloxy-3,4-dimethoxybenzoyl chloride with the aminopropanol, in an analogous manner as described previously, did not go smoothly.

(4) The stereoisomer forms of acylamide (Vb) are in the same relation as ephedrine and ψ-ephedrine. Compare Bruckner, Fodor, Kiss and Kovács, *J. Chem. Soc.*, 885 (1948).

(5) Bruckner, Kovács and Kovács, *Ber.*, **77**, 610 (1944).

It is evident from the above facts that the difference between "H" and IIIa is not to be sought for in the difference of the aryl radicals attached to the carbon atom 1 of the isoquinoline ring, but perhaps in the difference of the position of both substituents of the hetero ring, or even in the structure of the entire hetero ring system of "H." To reach a decision in this matter the structure of "H" must be fully investigated.

Experimental

2-Benzyloxy-3,4-dimethoxybenzoic Acid.—Ten grams of methyl 2-hydroxy-3,4-dimethoxybenzoate, 1.1 g. of sodium and 6 ml. of benzyl chloride were condensed in 50 ml. of absolute ethanol[1] to yield colorless needles of the acid, melting at 95–96° after recrystallization from ethanol.

Anal. Calcd. for $C_{16}H_{16}O_5$: C, 66.66; H, 5.60. Found: C, 66.62; H, 5.30.

The acid was converted to the oily acid chloride by means of thionyl chloride.

α-(3,4-Dimethoxyphenyl)-β-(2-hydroxy-3,4-dimethoxybenzoylamino)-propanol (Va).—2-Hydroxy-3,4-dimethoxybenzoyl chloride, prepared from 11.5 g. of the acid was condensed in the usual manner[1] with 27 g. of α-(3,4-dimethoxyphenyl)-β-aminopropanol[6] to yield 18 g. of Va, m. p. 87–88°. Va, treated with ethereal diazomethane, was converted to Vb, melting at 107–108°, after recrystallization from toluene. Vb was also prepared by treating 2.2 g. of the aminopropanol with 1.06 g. of 2,3,4-trimethoxybenzoyl chloride.

Anal. Calcd. for $C_{21}H_{27}O_7N$ (Vb): C, 62.21; H, 6.71. Found: C, 62.26; H, 6.65.

Vb is stereoisomeric with the compound of Pfeiffer, m. p. 127–128°, obtained from the stereoisomeric aminopropanol.

1-(2'-Benzyloxy-3',4'-dimethoxyphenyl)-3-methyl-6,7-dimethoxyisoquinoline (IIIb).—To a solution of 18 g. of Va in 500 ml. of absolute ethanol was added a solution of 1.05 g. (0.046 mole) of sodium in 50 ml. of absolute alcohol. To this mixture was added 8 ml. (0.04 mole) of benzyl chloride and the solution refluxed for eight hours. The reaction mixture was filtered, the alcohol evaporated and the residue dissolved in 500 ml. of hot toluene. Addition of 25 ml. of phosphorus oxychloride yielded 8 g. of VIb, prisms melting at 147–148° after recrystallization from 50% ethanol.

Anal. Calcd for $C_{27}H_{27}O_5N$: C, 72.79; H, 6.09. Found: C, 72.91, 72.45; H, 6.41, 6.11.

1-(2'-Hydroxy-3',4'-dimethoxyphenyl)-3-methyl-6,7-dimethoxyisoquinoline (IIIa).—A solution of 6.5 g. of IIIb in 280 ml. of ethanol was subjected to hydrogenolysis using 2.5 g. palladium–charcoal (7% palladium). Absorption of hydrogen was quantitative in seventeen minutes and there was produced, as yellowish prisms, m. p. 158–60.5°, 5.1 g. (95.6% theoretical) of III, isolated by precipitation from alkaline solution by carbon dioxide. Recrystallization from ethanol afforded nearly colorless prisms, m. p. 168–169°.

Anal. Calcd. for $C_{20}H_{21}O_5N$: C, 67.57; H, 5.96. Found: C, 67.19; H, 6.41.

Pfeiffer[2] recorded for "H" m. p. 174°.

The **picrate** of IIIa was obtained as yellow crystals, m. p. 238–239° from ethanol.

Anal. Calcd. for $C_{26}H_{24}O_{12}N_4$: C, 53.40; H, 4.14. Found: C, 53.17; H, 4.35.

Pfeiffer[2] recorded for the picrate of "H" m. p. 210°.

The **methyl ether IIIc**, m. p. 105–107°, was obtained by treating a methanol solution of IIIa with ethereal diazomethane. Pfeiffer reported[2] the same melting point for the synthetic product from his Vb. We have obtained in the usual manner 0.76 g. of IIIc from 1 g. of our Vb (m. p. 109–110°) which is stereoisomeric with that of Pfeiffer.

The **picrate** of IIIc is obtained from methanol as yellow crystals, m. p. 184–185°.[2]

Anal. Calcd. for $C_{27}H_{26}O_{12}N_4$: C, 54.16; H, 4.38. Found: C, 54.15; H, 4.52.

Degradation of IIIa to 3,4-Dimethoxyphthalic Acid.—Three and seven-tenths grams (0.0107 mole) of IIIa dissolved in 525 ml. of hot 0.03% aqueous sodium hydroxide was treated with 23.7 g. of potassium permanganate dissolved in 475 ml. of hot water to obtain 3,4-dimethoxyphthalic acid.[1] The product weighed 200 mg. after recrystallization from water and melted at 175–177°[7] alone and when mixed with an authentic sample. The 3,4-dimethoxyphthalic acid was further characterized by converting it to metahemipinic ethylimide, m. p. 228–229°.[7]

Anal. Calcd. for $C_{12}H_{13}O_4N$: C, 61.25; H, 5.57. Found: C, 60.90; H, 5.57. Hemipinic ethylimide melts at 93°.[8]

α-(3,4-Dimethoxyphenyl)-β-N-ethoxalylaminopropanol (Ve).—Twenty-one and one-tenth grams (0.1 mole) of the corresponding aminopropanol[6] was dissolved in 100 ml. of hot chloroform, 6.8 g. (0.05 mole) of ethoxalyl chloride was added and the mixture allowed to stand overnight. The amino-propanol hydrochloride was collected, the filtrate washed with a total of 30 ml. of water, dried, the solvent blown off and the residue recrystallized from toluene; yield, 6.5 g.; m. p. 92–93°.

Anal. Calcd. for $C_{15}H_{20}O_6N$: C, 58.06; H, 6.50. Found: C, 57.93; H, 7.05.

α-(3,4-Dimethoxyphenyl)-β-N-trichloro-acetylaminopropanol (Vd).—From 2.11 g. of the amino-propanol[6] and 0.82 g. of trichloroacetyl chloride in 40 ml. of toluene, 0.8 g. of recrystallized amide (Vd) was obtained; needles from benzene–ligroin, m. p. 115–116°.

Anal. Calcd. for $C_{13}H_{16}O_4NCl_3$: C, 43.75; H, 4.52. Found: C, 43.89; H, 4.08.

3-Methyl-6,7-dimethoxyisoquinoline-1-carboxylic Acid (IVa).—To 0.94 g. of the amide Ve in 15 ml. of anhydrous toluene, 0.8 ml. of phosphorus oxychloride was added and the mixture refluxed for one hour. Then ice was added until phosphorus oxychloride decomposed, and the separated aqueous layer was made alkaline with ammonia and extracted with ether. The material recovered from the ether weighed 183 mg. and was hydrolyzed by boiling with 4 ml. of 10% sodium hydroxide solution and with 5 ml. of methanol for ninety minutes. The methanol was then evaporated, the alkaline aqueous solution extracted with ether, decolorized and acidified to congo red paper. The acid separated forming yellowish crystals; yield 57 mg., m. p. 203–204° (dec.). Recrystallized from water containing a drop of hydrochloric acid, its hydrate could be obtained (free of chlorine); from methanol the anhydrous acid could be obtained.

Anal. Calcd. for $C_{13}H_{13}O_4N \cdot H_2O$: C, 58.84; H, 5.70. Found: C, 58.80; H, 5.40. Calcd. for $C_{13}H_{13}O_4N$: C, 63.13; H, 5.30. Found: C, 62.80; H, 5.20.

Picrate.—By adding an aqueous solution of the acid to an alcoholic solution of picric acid, as reported by Pfeiffer,[2] the above acid did not give any precipitation. When a solution of 25 mg. of IVa and 23 mg. of picric acid in 1.5 ml. of methanol was heated and then allowed to stand, crystallization could not be observed. By evaporation of the solvent yellow crystals separated, m. p. 269–270° (shrinking from 200°). The analytical data showed that decarboxylation had taken place, yielding the picrate of 3-methyl-6,7-dimethoxyisoquinoline.

Anal. Calcd. for $C_{18}H_{16}O_9N_4$: C, 50.50; H, 3.76. Found: C, 50.30; H, 3.97.

3-Methyl-6,7-dimethoxyisoquinoline.—A solution of 4.5 g. of the aminopropanol[6] in 80 ml. of anhydrous formic

(6) Iwamoto and Hartung, *J. Org. Chem.*, **9**, 511 (1944).

(7) Goldschmiedt, *Monatsh.*, **9**, 722 (1888).

(8) Freund and Heim, *Ber.*, **23**, 2906 (1890).

acid was refluxed for forty-eight hours. Formic acid was then removed in a vacuum and the brownish glassy formamido compound (Vf) treated with 10 ml. of phosphorus oxychloride in 100 ml. of toluene in the usual manner. The isoquinoline was purified by repeated distillation under 1 mm. pressure; yield 1.2 g., m. p. 135–136°.

Anal. Calcd. for $C_{12}H_{13}O_2N$: C, 70.92; H, 6.45. Found: C, 71.21; H, 6.60.

Hydrochloride.—Long needles from ethanol–ether, m. p. 237–238°.

Picrate.—It is very poorly soluble in hot alcohol, m. p. 270°, and is identical with the picrate obtained from the acid (IVa).

Anal. Calcd. for $C_{18}H_{16}O_9N_4$: C, 50.5; H, 3.76. Found: C, 50.30; H, 4.02.

Decarboxylation of IVa.—Twenty-two mg. of the acid was heated under 1 mm. pressure in a Spaeth tube to 200° and the solid distillate converted into a picrate; crystals from methanol, m. p. 270°. It was identical with the picrate of the crystalline 3-methyl-6,7-dimethoxy-isoquinoline, obtained from the formamido compound, as described above.

Methyl Ester (IVb).—Five millimoles (123 mg.) of the acid (IVa) was dissolved in 23 ml. of methanol and 3 ml. of an ethereal diazomethane solution added. The solvent was evaporated under reduced pressure, the solid residue (53 mg.) treated with 10 ml. of ether and filtered. The filtrate was shaken with a dilute sodium bicarbonate solution, dried and the ether removed. The residue was 48 mg., m. p. after recrystallization from benzene–petroleum ether, m. p. 151–153°.

Anal. Calcd. for $C_{14}H_{15}O_4N$: C, 63.70; H, 5.98. Found: C, 63.80; H, 6.03.

Picrate.—Yellow needles from methanol, m. p. 168–170°. Pfeiffer recorded for the picrate of the methyl ester of the acid a melting point of 216°.

Anal. Calcd. for $C_{20}H_{18}O_8N_4$: OCH_3, 18.94. Found: OCH_3, 18.67.

1-Carbethoxy-3-methyl-6,7-dimethoxyisoquinoline (IVc).—This ester could be isolated by decomposing with absolute ethanol (instead of water) the excess of phosphoryl chloride in the mixture obtained on ring closure of the amide (Ve); yield 2.1 g. from 9.5 g. of ethoxyalylamide (Ve). Repeated distillation from a Spaeth tube under 1 mm. pressure afforded yellowish needles, m. p. 86–87°.

Anal. Calcd. for $C_{15}H_{17}O_4N$: N, 9.1. Found: N, 9.3.

Picrate.—Glistening gold-yellow needles (from 96% ethanol), m. p. 176–177°.

Anal. Calcd. for $C_{21}H_{20}O_{11}N_4$: C, 50.0; H, 4.0. Found: C, 50.1, 50.1; H, 4.4, 4.45.

Degradation of 1-Carboxy-3-methyl-6,7-dimethoxyisoquinoline (IVa) to 3,4-Dimethoxyphthalic Acid.—Two hundred and ten milligrams of potassium permanganate dissolved in 10 ml. of water was added to a solution of 247 mg. of 1-carboxy-3-methyl-6,7-dimethoxyisoquinoline in 40 ml. of dilute sodium hydroxide in fifteen minutes. The residue of evaporation (350 mg.) was extracted as described in previous degradation procedures and 144 mg. of crude crystals was obtained. Purification through the lead salt yielded 27 mg. of metahemipinic acid, m. p. after recrystallization from 0.5 ml. of water 176°, alone and mixed with an authentic specimen. The product was converted in the usual manner into its ethylimide which after sublimation and recrystallization showed m. p. 229° under the microscope.

Summary

The synthesis of 1-(2′-hydroxy-3′,4′-dimethoxyphenyl) - 3 - methyl - 6,7 - dimethoxyisoquinoline (IIIa) is described. Its structure has been confirmed by oxidative degradation. It differs from a compound obtained from hematoxyline, incorrectly assigned the same structure in the literature. The synthesis of 3-methyl-6,7-dimethoxyisoquinoline-1-carboxylic acid (IVa) and its methyl ester (IVb) was accomplished in a straightforward manner. They were found to be different from the compounds described earlier.

The recent results proved, in accordance with previous investigations, that the intramolecular condensation of acylamides of type V lead in every case to 6,7-dialkoxy isoquinoline derivatives and in no case to 7,8-dialkoxyisoquinolines, the latter possibility being assumed by earlier investigators.

Formation of Bromine Addition Compounds with Some Condensed Ring Hydrocarbons

BY JOHN R. SAMPEY, JESSIE M. COX AND ANNE B. KING

The formation of intermediate addition compounds plays a prominent role in current theories on the mechanism of bromination.[1] Crystalline dibromide addition products of phenanthrene and anthracene have been isolated,[2] while more than fifty years ago Orndorff and Moyer[3] prepared a crystalline naphthalene tetrabromide in 3% yield. In the present study we increased the yield of the latter compound to 30% by photobromination, and we found all the above and other addition compounds stable when shaken with sodium sulfite solution to remove unreacted bromine, but each readily gave a test for active bromine when treated with an acetone solution of sodium iodide.

(3) Orndorff and Moyer, *Am. Chem. J.*, **19**, 262–270 (1897).

Experimental

Preparation of Naphthalene Tetrabromide.—12.8 grams of pure naphthalene in 100 ml. of carbon tetrachloride was brominated under anhydrous conditions at 0° with one mole of bromine in 100 ml. of the same solvent during two hours with a 2″ arc at the distance of 2″; the solvent was evaporated and the product extracted with 95% alcohol and crystallized from chloroform; yield 30% of naphthalene tetrabromide, melting 111° and giving four atoms of bromine on a Rosanoff analysis. A sodium

iodide analysis[4] gave 72.4% bromine (theory 71.4%), showing all four bromines active.

Some Factors Influencing the Rate of Formation of Naphthalene Tetrabromide.—When 0.01 mole of naphthalene in 20.00 ml. of carbon tetrachloride was brominated under anhydrous conditions with 0.01 mole of bromine in 10.00 ml. of the same solvent in a darkened laboratory at room temperature, 5.1 ± 1% of the active bromine was found by the sodium iodide analysis. The presence of 0.029 g. of iodine did not change this percentage. Photobromination of 0.01 mole of the hydrocarbon in 20.00 ml. of carbon tetrachloride on a water-bath and under a 6″ mercury arc at 3″ distance with 10.00 ml. of molar bromine–carbon tetrachloride solution, during three hours, resulted in the formation of 21.1 ± 2% of active bromine; cooling the reaction to 0° and using a 2″ arc at 2″ for seventy minutes gave 61.0 ± 5% of active bromine.

With the aid of a Universal Spectrophotometer, Model 14, the effect of wave length on the formation of naphthalene tetrabromide has been determined. When 0.005 mole of naphthalene in 5.00 ml. carbon tetrachloride was brominated for twenty minutes at 41° with 10.00 ml. of half molar bromine solution in the same solvent under anhydrous conditions at 6000, 5250, 3700 Å. and no irradiation, the percentages of active bromine by sodium iodide analyses were respectively, 23.8 ± 0.2, 11.0 ± 1, 1.3 and 0%.

Rates of Formation of Bromine Addition Compounds with Other Condensed Ring Hydrocarbons.—The rates of formation of bromine addition compounds under dark-room conditions were carried out on 0.01 mole quantities of the hydrocarbons in 20.00 ml. carbon tetrachloride at 0° for a period of eighteen hours; 10.00 ml. of bromine–carbon tetrachloride solutions (molar) were added under anhydrous conditions. Sodium iodide analyses yielded the following percentages of active bromine: phenanthrene 55.2 ± 3%, naphthalene 11.2 ± 0.1% and diphenylmethane 2.0 ± 2%. Fluorene, benzene and diphenyl gave no active bromine even though the solutions were kept cold to prevent decomposition of any addition compounds during the treatment with sulfite and evaporation of the carbon tetrachloride. The addition of 0.029 g. iodine to the above reactions did not change by more than 2% the rates of bromine addition.

Since anthracene is insoluble in carbon tetrachloride 0.005 mole of this hydrocarbon was dissolved in 50.00 ml. of carbon disulfide, and the dark room brominations made with 10.00 ml. of half-molar bromine in the same solvent. Naphthalene solutions of the same strength were used for comparison. The results showed the presence of 13.0 ± 1.2% bromine with anthracene but none with naphthalene.

The photobrominations were carried out in carbon tetrachloride under anhydrous conditions at 0° with a 2″ arc at 2″ for sixty minutes; sodium iodide analyses indicated the following active bromine present: phenanthrene 84.1 ± 2%, naphthalene 55.3%, diphenyl 1% and benzene 1%. When 0.005 mole of anthracene and naphthalene were photobrominated in 50.00 ml. of carbon disulfide under similar conditions, they gave 74.0 ± 2% and 69.0% active bromine, respectively. These results demonstrate conclusively that larger amounts of active bromine addition products of the hydrocarbons are formed in photobromination than in dark room bromination.

Acknowledgments.—The authors are happy to acknowledge the helpful suggestions made by Dr. E. Emmet Reid in this research. Financial assistance was received from the Office of Naval Research.

Summary

1. Measurements have been made on the rates of formation of active bromine addition compounds under photo and dark room brominations of some condensed ring hydrocarbons.

2. Naphthalene tetrabromide has been prepared in 30% yield by photobromination.

The Structure of Diphenylthiocarbazone (Dithizone)[1]

BY ALSOPH H. CORWIN AND GEORGE R. JACKSON[2,3]

Introduction

The compound diphenylthiocarbazone, known as "dithizone," is well known in analytical chemistry because of its colorimetric reactions with traces of metals. A search of the literature will show, however, that no direct attempt has been made to prove the structure arbitrarily assigned to it by Emil Fischer.[4a,b]

Because of increasing interest in dithizone derivatives, it was deemed advisable to attempt a structural determination of diphenylthiocarbazide, from which would follow the structure of its oxidation product, dithizone.

Diphenylthiocarbazide is prepared by the reaction of phenylhydrazine with carbon disulfide. In ether or benzene, the phenylhydrazine salt of phenyldithiocarbazic acid precipitates.[5,6] Heating this salt to 90–100° drives off hydrogen sulfide and leaves behind diphenylthiocarbazide. Treating this with alcoholic potassium hydroxide produces dithizone, for which the following equation has been proposed[4a]

$$2C_6H_5NHNHCNHNHC_6H_5 \longrightarrow \underset{\text{I}}{C_6H_5N{=}NCNHNHC_6H_5} + \underset{\text{II}}{C_6H_5NH_2} + \underset{\text{III}}{C_6H_5NHNHCNH_2}$$

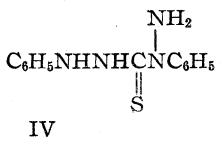
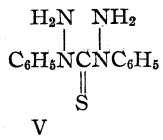
On the basis of analysis, structure I was assigned to diphenylthiocarbazide. Structures IV and V should be considered as alternatives, however.



IV



V

These differ from Fischer's structure with respect to the point of attachment of the nitrogens to the carbon. Compound IV would be formed by the α,β condensation of carbon disulfide with phenylhydrazine, compound V by the β,β condensation.

The structural investigation of diphenylthiocarbazide (I) is divided into two parts; (1) the reduction to phenylthiosemicarbazide and (2) the investigation of the structure of the latter compound which has been formulated as III but for which the alternative β formulation has not been excluded.

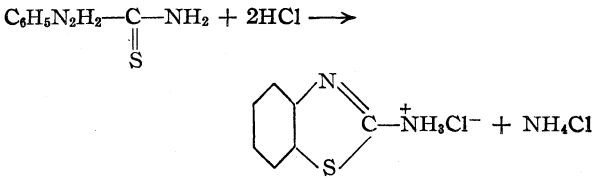
Upon reduction with stannous chloride and hydrochloric acid,[7] diphenylthiocarbazide gave one mole of aniline and one mole of phenylthiosemicarbazide. The reduction was also performed catalytically, using Raney nickel. The reaction stopped after one mole of hydrogen was consumed and additional shaking had no effect. The products were again aniline and phenylthiosemicarbazide.

Since compound V cannot yield the $S{=}C{-}NH_2$ grouping on reduction, the reductions show that one half of the diphenylthiocarbazide molecule has the structure $C_6H_5{-}NH{-}NH{-}C$, an observation which excludes formula V. The problem is thus reduced to that of ascertaining the structure of phenylthiosemicarbazide.

Phenylthiosemicarbazide was prepared from phenylhydrazine hydrochloride and ammonium thiocyanate according to the procedure given by Fischer and Besthorn,[8] but since the compound obtained from the reduction and the synthetic product both decomposed on heating, mixed melting points could not be used to establish identity. Proof of identity was obtained by the mixed solubility method, using the absorption in the ultraviolet as the criterion of solubility.

Reductions of phenylcarbazide with tin in hydrochloric acid, zinc in glacial acid, zinc in hydrochloric acid and sodium hydrosulfite were tried, but only starting material was recovered in each case.

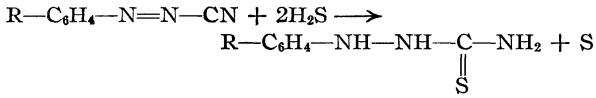
The acid used in the stannous chloride reductions was approximately 5 normal. It was found that when concentrated hydrochloric acid was used, with or without the reducing agent, 2-aminobenzothiazole hydrochloride was formed according to the equation



Thus it was found that strong reducing agents had no effect on phenylthiosemicarbazide, and concentrated hydrochloric acid converted it to 2-aminobenzothiazole, which did not conclusively prove the structure. The resistance of this class of hydrazine derivatives toward reduction will be investigated further.

Aqueous cyanide solutions will react with diazonium salts to precipitate colored compounds referred to as diazocyanides, the reaction differing from the normal coupling reaction in that the solution must remain acid during the addition.[9,10] It has generally been accepted that the structure of the aromatic diazocyanides is of the form $R{-}C_6H_4{-}N{=}N{-}CN$, and that labile and stable isomers which have been isolated represent *syn* and *anti* forms of this general structure.

The substituted benzene diazocyanides are easily converted to the thioamides by treatment with hydrogen sulfide. Either the *syn* or the *anti* form of the diazocyanide may be used



When a diazotized solution of aniline was treated with aqueous potassium cyanide at $-5°$ a red, unstable oil was obtained. The ether extract was treated with hydrogen sulfide. The product obtained melted with decomposition at 200° and had all the physical properties of the phenylthiosemicarbazide obtained from the reduction of diphenylthiocarbazide.

If the structure of benzenediazocyanide is accepted as $C_6H_5N{=}NCN$, the C–N–N–C grouping is established. From the reaction with H_2S it follows that the structure of phenyl thiosemicarbazide is $C_6H_5NHNHCNH_2$. This observation excludes formula IV and thus establishes Fischer's formulation of the structure of diphenylthiocarbazide.

A simple formulation of the mechanism of the condensation between phenylhydrazine and carbon disulfide is rendered improbable by the observation that this condensation does not proceed in the absence of air. It might be postulated that the catalytic effect of air is due to the fact that the essential reagent is a free radical.

To shed some light on the mechanism of the condensation, the reaction of cyanogen bromide with phenylhydrazine was studied in ether and in aqueous solution at different acidities.

(7) Fierz-David, "Technologie der Textilfasern," Julius Springer, Berlin, 1926, Vol. III, p. 660.

(8) Fischer and Besthorn, *Ann.*, **212**, 316 (1882).

(9) Gabriel, *Ber.*, **12**, 1637 (1879).

(10) Hantzsch and Schultze, *ibid.*, **28**, 666 (1895).

Pelazzari and Tivoli[11] have shown that cyanogen halides react with phenylhydrazine to give cyanophenylhydrazines. In ether β-cyanophenylhydrazine is formed. This is an unstable oil which forms a reasonably stable hydrochloride. Ammonium hydrosulfide converts this to β-phenylthiosemicarbazide. Water, on the other hand, converts it to β-phenylsemicarbazide. We have established the identity of the β-phenylthiosemicarbazide by intercomparison with material prepared according to Fischer's method.[8]

If the reaction between phenylhydrazine and cyanogen bromide is carried out in aqueous solution using a twofold excess of phenylhydrazine, two products are formed. The first is β-cyanophenylhydrazine. The main product is an isomer, α-cyanophenylhydrazine. This reacts with ammonium hydrosulfide to give α-phenylthiosemicarbazide, decomposing at 153°, and with water to give α-phenylsemicarbazide.

We have found that both α and β substitutions can occur in aqueous solution. At *p*H 0.6 the yield was quite low but more than half of the product was β-phenylsemicarbazide obtained from the β-isomer and less than half was α. At *p*H 3.5 the yield was higher and the proportion was much greater in favor of the α-isomer. At *p*H 5.6 the yield of α-isomer appears to be still higher but the results are complicated by the fact that a secondary reaction, perhaps polymerization, sets in. These condensations must be regarded as anomalous since the β-position of phenylhydrazine should be the more reactive in the case of the free base while increasing salt formation should either block the reaction or should favor condensation in the α-position. The contrary results observed show the need for an investigation of the mechanism of the reaction.

Experimental

Preparation and Purification of Diphenylthiocarbazide.—The procedure given by Grummitt and Stickle[5] was followed for the preparation of crude diphenylthiocarbazide. When crystallized from alcohol in the manner directed, the crystals obtained are slate-gray in color. It is necessary to wash these crystals with three portions of benzene to obtain an "almost colorless product." Attempts to purify the slate-gray material by means of further recrystallizations from alcohol do not give a better looking product.

A much more satisfactory method of purification consists of heating 95% alcohol to boiling, pouring it on the crude carbazide, and filtering hot. On cooling, the crystals are invariably snow white, except if one uses as starting material the slate-gray product referred to above. This method consumes more alcohol than the other but a product suitable for analysis is obtained.

Anal. Calcd. for $C_{13}H_{14}N_4S$: C, 60.41; H, 5.47. Found: C, 60.35; H, 5.43.

It was found that the crude diphenylthiocarbazide consists of two materials, one of which is extremely soluble in alcohol. This can be extracted from the main product by boiling with benzene, in which diphenylthiocarbazide is very slightly soluble. The suspension is filtered hot and on cooling the second product comes out as a white, amorphous mass. The yield averaged 10 g. for 54 g. of phenylhydrazine. Further investigations on this substance are in progress.

Reduction of Diphenylthiocarbazide with Stannous Chloride.—A solution of 10 g. of $SnCl_2 \cdot 2H_2O$ in 20 cc. of concentrated hydrochloric acid was added to a mixture of 10 g. of diphenylthiocarbazide and 60 cc. of water. This was stirred for fifteen minutes at room temperature, heated on the steam-bath for three hours with stirring, and then allowed to cool. The crystalline product was filtered, mixed with 50 cc. of water and filtered again. This was repeated with another 50-cc. portion of water, and finally the product was washed with 25 cc. of water. The crystals remaining were sucked as dry as possible and recrystallized once from 95% ethanol, to obtain 6.0 g. (95% of theoretical) of material melting with decomposition sharply at 200°.

To recover the aniline, hydrogen sulfide was passed into the combined filtrates from above until precipitation ceased, and the tin sulfides removed and washed with water containing a little hydrochloric acid. Ammonium sulfide was then added to complete the precipitation of tin. This was filtered and washed as before. The filtrate was made strongly basic and extracted five times with 50–75 cc. portions of ether. The ether was then removed from the combined extracts and finally pale yellow aniline was collected, b. p. 183–183.5°. This was acetylated to give a derivative melting at 113.5–114°. The yield of aniline was 3.1 cc. or 86% of the theoretical.

Catalytic Hydrogenation.—Three cubic centimeters of Raney nickel catalyst was added to 4 g. of pure diphenylthiocarbazide in 200 cc. of 95% ethanol. The diphenylthiocarbazide did not dissolve completely. The suspension was placed on the shaker and hydrogen was introduced under a pressure of 50 lb. p.s.i. After forty-five minutes no hydrogen had been absorbed. Five cubic centimeters more catalyst was added at this point and shaking was resumed. Hydrogen was absorbed rapidly and after two hours the theoretical amount for one mole had been taken up. The hydrogenation was allowed to continue overnight but no more hydrogen was absorbed.

The catalyst was filtered off and phenylthiosemicarbazide was isolated as a white crystalline solid melting with decomposition at 200°. Aniline was isolated as acetanilide, m. p. 113.5–113.8°.

Spectrophotometric Identification of Phenylthiosemicarbazide.—Saturated solutions were made of the substance prepared by reduction of diphenylthiocarbazide and by synthesis from phenylhydrazine and ammonium thiocyanate by mixing 350 mg. of material with 10 cc. of 95% ethanol. A solution saturated with respect to both compounds was also made by mixing 350 mg. of each compound with 10 cc. of 95% alcohol. These were allowed to stand for three hours before measurements were begun, to insure complete equilibration. The absorptions of the three solutions at 312 mμ were 29.2, 29.0 and 29.4, proving the identity of the two compounds.

Attempted Reductions of Phenylthiosemicarbazide.

1. **Tin and Hydrochloric Acid.**—One gram of phenylthiosemicarbazide was added to a solution of 10 cc. of concentrated hydrochloric acid and 10 cc. of water. To this was added 2 g. of mossy zinc and the mixture heated on the steam-bath. The phenylthiosemicarbazide did not go into solution and was recovered on cooling.

2. **Zinc and Glacial Acetic Acid.**—One gram of phenylthiosemicarbazide was added to 10 cc. of glacial acetic acid and warmed until it went into solution. This was heated on the steam-bath for two hours with zinc dust. The excess zinc dust was filtered off and water added to the acetic acid solution, at which time almost 1 g. of starting material crystallized.

3. **Zinc and Hydrochloric Acid.**—One gram of phenylthiosemicarbazide was mixed with 10 cc. of concentrated hydrochloric acid and 10 cc. of water, and zinc dust added. Hydrogen was evolved but the phenylthiosemicarbazide was recovered unchanged.

4. **Sodium Hydrosulfite.**—A mixture of 1 g. of phenylthiosemicarbazide, 5 cc. of water, and 2 g. of sodium hydrosulfite was heated on the steam-bath for two hours, the

(11) Pelazzari and Tivoli, *Gazz. chim. ital.*, **22**, 226 (1892); Pelazzari, *ibid.*, **37**, 611 (1907).

phenylthiosemicarbazide remaining suspended in the colorless solution the entire time. When cooled, washed with water, and dried, more than 0.9 g. of starting material was recovered.

Preparation of 2-Aminobenzothiazole from Phenylthiosemicarbazide.—Four grams of phenylthiosemicarbazide was added to 40 cc. of concentrated hydrochloric acid and heated on the steam-bath for two hours. On cooling, the hydrochloride crystallized. The free base obtained by neutralizing the hydrochloride was recrystallized from water to give white shining platelets which melted reversibly at 130–131°. Warming with acetic anhydride and recrystallizing from alcohol produced thick prisms melting sharply at 187°. The acetyl derivative of 2-aminobenzothiazole is reported as melting at 186–187° and 2-aminobenzothiazole as melting at 130–131°.[12]

Preparation of 1-Phenylthiosemicarbazide from Benzenediazocyanide.—Almost water-white aniline was prepared by fractional distillation of aniline which had been twice steam distilled, collecting the fraction coming over at 181.5–182° (uncor.). A mixture of 28 cc. of this aniline, 90 cc. of concentrated hydrochloric acid and 180 cc. of water was cooled to −5° and a solution of 21 g. of sodium nitrite in 60 cc. of water slowly added until diazotization was complete. Then 350 cc. of ether that had been freshly distilled from a weakly acidic ferrous sulfate solution to remove peroxides was slowly added, keeping the temperature below 0°. To this was slowly added a solution of 39 g. of potassium cyanide in 75 cc. of water, the mixture being well stirred and the temperature maintained below 0°. When addition was complete, the mixture was poured into a large separatory funnel and the aqueous portion separated and discarded. Preliminary tests showed that the crude diazocyanide decomposed on warming to room temperature so it was not isolated. The ether extract was quickly cooled in an ice-bath and hydrogen sulfide passed through. The red solution turned dark very slowly, and then suddenly changed to light straw color. The crude precipitate melted with decomposition over a wide range from 185–195°. After recrystallizing from alcohol once a pure product was obtained which melted with decomposition sharply at 200°.

The same product was obtained when the ether extract from the diazonium mixture was dried with sodium sulfate before introducing the hydrogen sulfide, and since there was a considerable loss due to adsorption on the sodium sulfate, this step was omitted. The best yield of pure 1-phenylthiosemicarbazide was approximately 20 g., or 40% of theoretical.

Reaction between Phenylhydrazine and Cyanogen Bromide at Various Acidities. 1. **At *p*H 0.6.**—A mixture of 2.8 g. of phenylhydrazine hydrochloride (0.02 mole), 5 g. of sodium bisulfate and 3 g. of sodium sulfate was dissolved in 50 cc. of water to give a solution whose *p*H was observed to be 0.6. Two and two-tenths grams (0.02 mole) of cyanogen bromide in 5 cc. of 95% ethanol was added slowly. After standing for fifteen minutes the solution was warmed slightly and then allowed to cool. A crop of 0.4 g. of α-cyanophenylhydrazine in the form of thin white platelets was obtained. The filtrate was again warmed for a few minutes and then thoroughly cooled. 0.4 g. of the hydrolysis product of β-cyanophenylhydrazine, β-phenylsemicarbazide, was obtained. On evaporation an additional 0.2 g. of this substance was obtained.

2. **At *p*H 3.5.**—A mixture of 2.8 g. of phenylhydrazine hydrochloride and 15 g. of sodium sulfate was dissolved in 100 cc. of water giving a solution whose *p*H was 3.5. Two and two-tenths grams of cyanogen bromide in 5 cc. of 95% ethanol was added slowly. After standing four hours the crystals of α-cyanophenylhydrazine were removed, washed with water and dried, yield 0.8 g. The filtrate was evaporated to two-thirds of its original volume and allowed to cool. The precipitate was 1.0 g. additional α-isomer. Upon further evaporation and cooling 0.7 g. of β-phenylsemicarbazide was obtained.

3. **At *p*H 5.6.**—A mixture of 2.8 g. of phenylhydrazine hydrochloride and 15 g. of sodium acetate was dissolved in 100 cc. of water to give a solution whose *p*H was 5.6. Two and two-tenths grams of cyanogen bromide was added as before. An abundant white precipitate of α-cyanophenylhydrazine came down almost immediately. Within a few minutes this started to turn yellow and after thirty minutes it was almost completely transformed to tar.

Reaction of Phenylhydrazine with Carbon Disulfide with and without Air.—A solution of 10 cc. of phenylhydrazine in 40 cc. of benzene was added to each of two 100-cc. three-neck flasks equipped with stirrers and condensers. Three and two-tenths cubic centimeters of carbon disulfide was dropped into each with stirring, producing a light-yellow, practically solid sludge. The third neck of flask A was then plugged but air was not excluded. Nitrogen was introduced through the third neck of flask B to remove air. Both were heated on steam cones and B was continually swept with nitrogen. It was necessary to make periodic additions of benzene to B to compensate for evaporation. Parallel observations are recorded.

Time, min.	Flask A (with air)	Flask B (with nitrogen)
15	Thick suspension	Yellow solution
30	H_2S being evolved	Green color. Trace of H_2S
35	H_2S	No H_2S. Removed to ice-box
50	Solution H_2S still evolved	Cooling overnight gave no ppt.
120	H_2S test negative, heavy ppt.; removed to ice-box; obtained solid mass of diphenylthiocarbazide	Next day air admitted, white ppt. formed slowly

Summary

1. Diphenylthiocarbazide has been reduced catalytically and chemically to produce aniline and phenylthiosemicarbazide, proving that one half of the molecule has the grouping C_6H_5—NH—NH—C.

2. Attempts to reduce phenylthiosemicarbazide to thiourea and aniline were unsuccessful.

3. 1-Phenylthiosemicarbazide obtained from benzene diazocyanide and hydrogen sulfide was found to be identical to the phenylthiosemicarbazide obtained from the reduction of diphenylthiocarbazide.

4. Assuming that benzene diazocyanide is $C_6H_5N{=}N{-}CN$, it follows that phenylthiosemicarbazide and therefore diphenylthiocarbazide have the C—N—NC grouping of benzene diazocyanide.

5. From this evidence it is concluded that the structure of diphenylthiocarbazide used in the preparation of dithizone is

$$C_6H_5{-}NH{-}NH{-}\underset{\underset{S}{\|}}{C}{-}NH{-}NH{-}C_6H_5.$$

Absorption Spectra of Certain α,β-Unsaturated Ketones. II.[1] Effect of Size of Ring and of Position of Double Bond

BY HELEN S. FRENCH AND LOIS WILEY

Definite and reliable rules have been formulated by Woodward[2] for the relations between structure and absorption spectrum of α,β-unsaturated cyclohexanones. These have been very useful already in determining the structures of complex naturally-occurring compounds. Comparatively little has been done for corresponding compounds of α,β-unsaturated cyclopentanones. Gillam[3] postulated a shift of 110 Å. toward the violet for the high-frequency high-intensity band of such cyclopentenones as compared with that of cyclohexenones based upon experimental results on a small number of such compounds. In our first paper of this series[1] we found indications that the shift occurred in the opposite direction, toward the red, for such α,β-unsaturated cyclopentanones with an exocyclic rather than an endocyclic double bond, and more work on such compounds was promised. Since such five-atom ring ketones also occur frequently in complex naturally-occurring compounds, it seems important to formulate any possible "rules" connecting their structures and absorption spectra.

Closely related and relatively simple derivatives of cyclohexanone and cyclopentanone, with α,β-exocyclic ethylene bonds have therefore been prepared and their absorption spectra studied.

Experimental

Preparations.—Since all the compounds were prepared according to previously published methods, references to those methods are given in Table I. All compounds were carefully purified by recrystallizations from the appropriate solvents, or by redistillations *in vacuo*, until their melting points (or boiling points) were as recorded in the literature, and until two successive purifications gave identical absorption spectra.

Absorption Measurements.—The method was the same as that previously reported from this Laboratory,[4] with the substitution of a Spekker photometer for the sector photometer. The results are recorded as curves in Figs. 1–4, and the absorption maxima are listed in Table I.

The first eleven compounds in Table I were prepared and purified as above described. For purposes of comparison, Table I also includes the previously published data for the absorption maxima of nine closely related compounds. The data in the table refer only to the short-wave length, high-intensity bands.

Discussion.—From a study of Fisher–Hirschfelder models, it is clear that 6-atom rings are very little changed by the introduction of one double bond. Cyclohexanone and cyclohexenone are both strainless to about the same degree, since both rings are non-planar. This helps account for the validity of Woodward's[2] rules, which allow very little difference in absorption for equal substitution on an exocyclic double bond and on an endocyclic double bond. The permitted regions for absorption maxima overlap in such cases, *e. g.*, 2350 ± 50 Å. for an endocyclic double bond and 2400 ± 50 Å. for an exocyclic double bond, when two substituents are on the doubly-bound carbons.[2]

Models show, however, great differences in corresponding five-atom rings. Cyclopentanone and its derivatives with α,β-exocyclic double bonds are planar, with the four conjugated atoms in the same plane. When a double bond is introduced into the ring, the struggle for the ring to be preserved at all upsets the coplanarity of the conjugated atoms. This may account for the shift of absorption maxima of 110 Å. to shorter wave lengths noted by Gillam and West.[3] The complete planarity of the four conjugated atoms in the cyclopentanones with α,β-exocyclic bonds, how-

ever (more complete than in either of the 6-atom ring types), results in a shift of the absorption toward the red. The relations among (1) co-planarity of conjugated atoms, (2) the completeness of the resonance of the system and (3) the region of maximum absorption are well-known, and have been frequently emphasized.[16] Our results show this shift to be small and to vary from 20 to 50 Å. when the substituents on the exocyclic double bonds are saturated groups. Note the corresponding cyclohexanone and cyclopentanone pairs of compounds VI and III, VII and V, XV and IV, the latter two pairs in both alcohol and hexane. The shift to the red is greater when the phenyl group is a substituent, 85 Å. for IX and VIII, 140 Å. for X and XIV, and 250 Å. for XIII and XI. The smallest shift (20 Å.) means a difference of approximately 130 Å. between the effects of an exocyclic and an endocyclic double bond in cyclopentanones, which is admittedly within the largest limit (150 Å.) allowed for cyclohexanones. However, if the absorption maxima of four corresponding compounds are considered, those of *both* cyclohexanones lie between those of the two more widely differing cyclopentanones.

An unexplained but consistent shift to the red is caused by the change from two alkyl radicals to an alicyclic ring on the exocyclic double bond in both cyclopentanones and cyclohexanones. The models show less tendency to steric interference when the alicyclic rings are present, which may be a sufficient explanation. (Compare the pairs I and III, IV and V, XV and VII.)

The very large shifts to the red caused by extending the conjugation are to be expected, and show consistent regularities. (1) When one α-sidechain is extended to include a second double bond conjugated with the first, but with only saturated substituents, the shift is about 500 Å. to the red. (Compare VI with XVI, XVII, XVIII, and XIX.) (2) When the conjugation is extended by the substitution of a phenyl group for a saturated ring, the shift to the red is 375 ± 25 Å. (Compare VI and IX, VII and XII, III and VIII.) The phenyl group has been variously described under such circumstances as being equivalent to one double bond[17] and to 1.5 double bonds.[18] From these few examples, it would seem

to be not quite equivalent to one double bond in these compounds. (3) When the conjugation is crossed by the introduction of a second exo-α,β-double bond on the other side of the ketone group, the shift to the red is 400–450 Å. (Compare IX and X, XII and XIII, VIII and XIV, XIX and XX.) This *shift* is independent of whether the substituted groups are saturated or aromatic.

Finally, several pairs of compounds (III and V, I and IV, VI and VII, IX and XII, X and XIII, XI and XIV) differ only by a methyl radical which is on the ring but not on a doubly-bound carbon. The effect of this methyl group on the absorption maxima is negligible with the exception of the last pair. The shift of 85 Å. to the red on the introduction of the methyl group into the 2,5-dibenzalcyclopentanone was surprising. The study of models shows, however, that only in this case would the phenyl group be forced to take the position toward the carbonyl oxygen. The shift of absorption may therefore be an effect of *cis–trans* isomerism. Without the methyl group, the phenyl group has more room away from the carbonyl oxygen. More evidence would certainly be needed to establish this point. The methyl group seems not in any way to inhibit the complete coplanarity of the conjugated system in these molecules.

The effect of change of solvent from alcohol to hexane is the usual one for this high-intensity band, a shift of about 70 Å.[2] to shorter wave lengths. In the curves for IV, V, VI and VII is shown the further effect of hexane in changing the "step-out" in the longer wave length region into a definite low-intensity maximum. This effect agrees with Ramart-Lucas and Hoch's[19] observation that alcohol shifts the low-intensity C=O band toward the violet and the high-intensity C=C—C=O band toward the red, resulting in a mere step-out for the former in alcohol solution instead of the definite maximum in hexane.

It will be noted that the cyclopentanone compounds III, IV, V, VIII, XI, XII and XIV all have analogous cyclohexanone compounds, VI, XV, VII, IX, XIII, XII and X. I and II are conspicuously without analogs. This emphasizes the fact, known at least since 1912,[20] that cyclopentanones and cyclohexanones react very differently with aliphatic ketones. Under the same conditions which give I with cyclopentanone and acetone, cyclohexanone and acetone form cyclohexylidene acetone.[20] Even this compound is unstable and forms an equilibrium mixture with the isomeric cyclohexenyl acetone.[21] The double bond exocyclic to a 6-atom ring is unstable by 3.5 kcal. with respect to the corresponding endocyclic compound.[22] The reason for an analog for IV is that pulegone is a naturally occurring compound! It must be emphasized in this connection that VI and VII must be prepared with great care, in order to keep the double bond exocyclic to the 6-atom ring. Reese[7] was the first to isolate the 2-cyclohexylidene cyclohexanone as a pure compound in 1942, a white crystalline solid, m. p. 57°. Before that time and even after 1942 reports of its preparation described the product as an oil boiling at 142–145° at 15 mm. (or at corresponding boiling points at various other low pressures).[23] It was the absorption spectrum of this liquid product that was reported by Evans and Gillam[24] with the comment that the low intensity of the absorption maximum indicated contamination by an unconjugated isomer. Unless kept *in vacuo*, the solid rearranges to the liquid, as would be expected from the foregoing discussion. To confirm the identity of the crystals as the conjugated α,β-unsaturated ketone, and the liquid as the unconjugated β,γ-unsaturated ketone, Reese[7] measured the molecular refractivities of both. The absorption spectra of these compounds VI and VII reported here confirm Reese's conclusions.

The benzal derivatives of cyclohexanone have the exocyclic double bond stabilized by conjugation with the aromatic ring.

In conclusion, α,β-unsaturated cyclopentanones have not been as widely investigated as the corresponding cyclohexanones. It is therefore not possible as yet to formulate for them rules such as Woodward's.[2] The following statements, however, can be made with a fair degree of confidence concerning cyclopentanones with an α,β-exocyclic double bond.

1. Their absorption is shifted farther to the red than that of the corresponding cyclohexanones, in constrast to cyclopentenones with endocyclic double bonds, whose absorption is shifted to the blue from that of the corresponding cyclohexanones.

2. Alkyl radicals on the ring carbon alpha to the exocyclic double bond cause a red shift which is unnoticeable in the cyclohexanones.

3. The exocyclic double bond is more stable and more completely conjugated with the carbonyl group than in the cyclohexanones.

4. The shifts toward the red caused by extension of conjugation by the phenyl radical are about 50 Å. greater than in the corresponding cyclohexanones.

Work is in progress in this Laboratory to determine the further effect on absorption of α,β-exocyclic double bonds on cyclic ketones already containing α,β-endocyclic double bonds.

Summary

1. The absorption spectra of seven α,β-unsaturated cyclopentanones and four α,β-unsaturated cyclohexanones are recorded in curves and a table.

(24) Evans and Gillam, *J. Chem. Soc.*, 816 (1941).

2. The results are discussed in an attempt to formulate generalizations for cyclopentanones analogous to those formulated for cyclohexanones by Woodward.[2]

3. The most important of such generalizations is that the conjugated *exo*-cyclic double bond in the cyclopentanones shifts the absorption maximum to the red from that of the corresponding cyclohexanones and in contrast to the shift to the blue of the conjugated *endo*-cyclic double bond in the cyclopentenones.

The Explosion of Nitrous Oxide–Hydrogen Mixtures

BY CHARLES P. FENIMORE AND JOHN R. KELSO

This paper presents explosive limits for the nitrous oxide–hydrogen system. When combined with Melville's[1] interpretation of his slow reaction data between these gases, the explosive data strongly indicate the presence of the radical HO_2 in the reacting system. Although a detailed reaction mechanism cannot be based on these findings, it is of some interest that the processes forming HO_2 occur at temperatures 200° or more higher in this system than they previously have been known to occur in other reaction systems.[2]

Since Melville encountered explosions in his studies of the slow reaction but did not observe reproducible limits, it is necessary to state at the outset that reproducible limits can be readily obtained. To do so, the gases must be oxygen-free, however, and their entry into the reaction vessel must be rapid. The second requirement is necessary presumably so that not much molecular oxygen can be formed by the thermal decomposition of nitrous oxide before the pressure builds up to the explosion limit. Hence, the second requirement is only a restatement of the first, that the gases must be oxygen free.

Experimental

Hydrogen and nitrous oxide, freed from oxygen by treatment with aqueous alkaline pyrogallol and dried, were mixed in a previously evacuated vessel in the desired proportions. Proportions were estimated by an attached mercury manometer. The mixing vessel communicated to the reaction vessel through a stopcock of 2-mm. bore. The reaction vessel was heated in an electric resistance furnace and fitted with two chromel alumel thermocouples whose readings did not differ by more than 1°. Adequate temperature constancy could be maintained through a Sorensen voltage regulator and variable transformers with only occasional manual control. Two cylindrical quartz reaction vessels 30 cm. long were used; one measured 0.9 cm. inside diameter, the other 2.5 cm. These two vessels were new and manufactured at the same time and place, and presumably possessed similar surfaces. In addition, runs were made in a cylindrical vycor vessel of 1.5 cm. inside diameter. The findings obtained in the vycor vessel showed the same features as those in quartz up to 830° and are not reported in detail.

After the mixing vessel had been filled at a pressure such that the pressure would rise to the desired value in the previously evacuated reaction vessel when the gas was partitioned between them, the stopcock was opened rapidly. An explosion ensued immediately or not at all. No perceptible induction period was ever noted. Explosions were indicated by a sharp click and a bright flash of light which propagated back through the stopcock into the mixing vessel. The color of the light was dependent on temperature and composition. Explosions at low temperatures or of compositions rich in hydrogen appeared reddish; those at higher temperatures or of mixtures rich in nitrous oxide yellowish or white. At 800° only compositions containing over 50% hydrogen appeared at all reddish.

At a given temperature and gas composition, observations were repeated at varying pressures until the lower pressure limit was bracketed within 1–2 mm. The measurements were taken over a fairly extended period of time and frequent returns to limits measured weeks or months before proved the values, at temperatures $\leqslant 830°$, reproducible to 3–5 mm. The results obtained in vycor between 900 and 980° were less reproducible ($\simeq \pm 10$ mm.).

Results and Discussion

In Figs. 1 and 2, the lower limiting explosion pressure for nitrous oxide–hydrogen mixtures is plotted as a function of temperature and gas composition for vessels of two different sizes. The decimal point serves a double purpose in these contour maps. In addition to pointing off tenths of a cm. of a pressure determination, each point places the temperature and composition at which that determination was made. At temperatures below 720° in the small vessel (or 670° in the larger one) the explosion pressure was too high to observe in a quartz and glass apparatus. For the same reason, the minimum explosion pressure escaped capture in either vessel above 820°. In a vycor vessel of 1.5-cm. inside diameter, very similar results

(1) Melville, *Proc. Roy. Soc.* (London), **142A**, 524 (1933); **146A**, 737, 760 (1934).

(2) For a discussion and for references, see Minkoff, *Faraday Soc. Discussions*, **2**, 151 (1947).

were obtained; the explosive region extended from 670 to 820°, the minimum explosion pressure (6.6 cm.) occurred with 69% nitrous oxide at 740°.

The most striking feature of these data is that in any section of fixed composition the pressure *versus* temperature curve possesses a minimum; although if no change occurred in the reaction mechanism, a continuous decrease of the lower limit would be anticipated with increasing temperature. The nature of the reaction which intrudes to upset a steady decrease of the explosion limit becomes evident when a small amount of oxygen is added to the reactants. We have found oxygen to be an efficient poison for the explosive reaction, although Melville found it an effective catalyst for the slow reaction. Extensive tests proved that the addition of 2 mm. of oxygen raised the explosion limit above 20 cm. wherever it was less than this value in Figs. 1 and 2. This quantity of oxygen was much greater than the amount necessary to inhibit the reaction, however. Nitrogen was prepared containing 3% of oxygen, and it was found that the addition of 5 mm. of this mixture to the reactant gas drove the explosion pressure above 20 cm. for any composition at 780 and 820° in the large reaction vessel and at 760 and 800° in the smaller vessel.

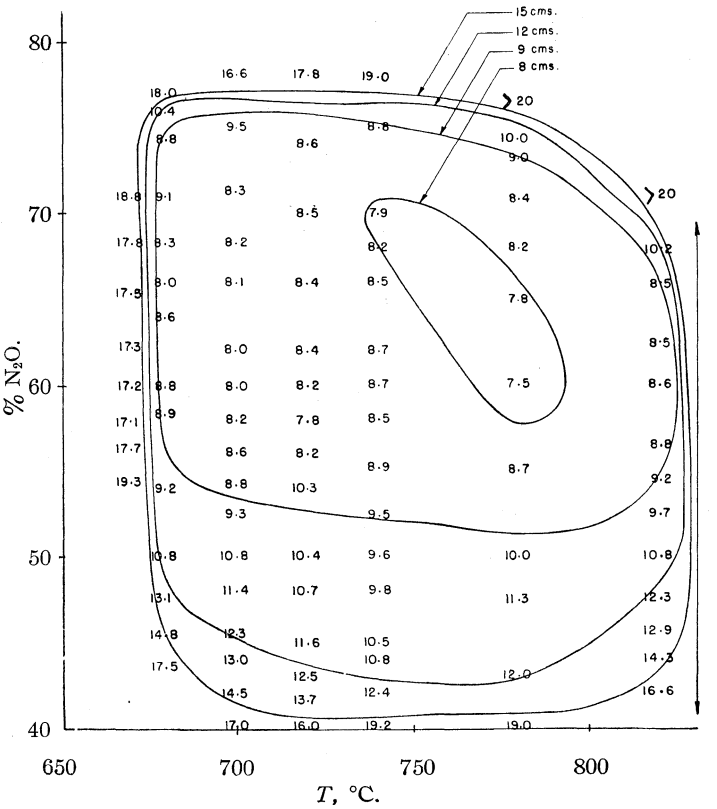

Fig. 1.—Lower explosion limit of N_2O–H_2 mixtures in 2.5-cm. i. d. quartz vessel.

The effect of added oxygen must be ascribed to the chemical nature of the additive since nitrogen (free from oxygen) did not inhibit the explosions. In general, the effect of 2–12 mm. of added nitrogen was to depress slightly or to leave unaltered the pressure of nitrous oxide plus hydrogen required for explosion. Added in still larger amounts, nitrogen increased the limiting pressure of the reactants. It might be conceived that the effect of oxygen could depend only on its paramagnetism and that nitric oxide would also inhibit the explosive reaction. This was proved false. The addition of 3 mm. of nitric oxide slightly shifted the minimum pressure toward the stoichiometric ratio, but left the main features of Fig. 1 unchanged.

The inhibition of explosions by added oxygen suggests an explanation for the existence of a minimum in the explosion limit in the absence of added oxygen. Nitrous oxide undergoes thermal decomposition to nitrogen and oxygen and the obvious conclusion is that at a high enough temperature the decomposition furnishes oxygen enough to inhibit the explosive reaction between nitrous oxide and hydrogen.

For a more detailed statement of this view, we consider the following sequence of reactions by which Melville interpreted his studies of the slow reaction and note that if these equations are valid

$$N_2O \longrightarrow N_2 + O \quad (1)$$
$$O + H_2 \longrightarrow OH + H \quad (2)$$
$$H + N_2O \longrightarrow OH + N_2 \quad (3)$$
$$OH + H_2 \longrightarrow H_2O + H \quad (4)$$
$$H \longrightarrow \text{recombination on wall or third body} \quad (5)$$

for the explosive as well as for the slow reaction, it appears inevitable that the mechanism of poisoning by added oxygen must be

$$H + O_2 + M \longrightarrow HO_2 + M \ (HO_2 \text{ is inert}) \quad (6)$$

because the hydrogen atom is the only labile particle in Melville's sequence which could react with molecular oxygen. The natural assumption is that the inhibition of the explosive reaction even without added oxygen is also caused by (6), and this because nitrous oxide decomposes to give chiefly molecular oxygen and nitrogen, although the decomposition is not allowed for in Melville's sequence.

The success of (6) as a poisoning reaction is founded on the stability of HO_2 or, more precisely, on the fact that HO_2 is destroyed without the generation of free radicals which can re-enter the gas phase reaction. While this is the only fate permitted above, it is obvious that the reaction

$$HO_2 + H_2 \longrightarrow H_2O_2 + H \quad (7)$$

might proceed in the nitrous oxide–hydrogen system since it does so in the oxygen–hydrogen system where its occurrence permits the third explo-

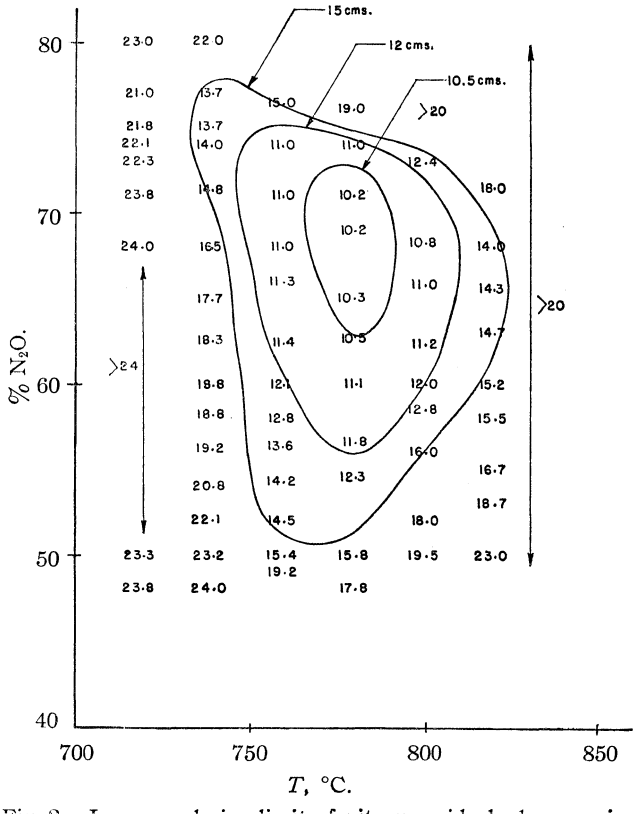

Fig. 2.—Lower explosion limit of nitrous oxide–hydrogen mixtures in 0.9-cm. i. d. quartz vessel.

sion limit.[3] A comparison of Figs. 1 and 2 hints that this reaction does in fact take place. In the larger vessel, the explosive region extends much farther toward hydrogen-rich mixtures than in the smaller vessel, while the limit toward nitrous-oxide-rich mixtures is only slightly extended. In view of the weak dependance of explosion pressure on vessel size (the minimum explosion pressure in the two vessels varies inversely with the cube root of the diameter) this strong feature could not result from a greater diffusion path alone. It might be expected, however, if reaction (7) occurred because the greater diffusion path to the wall allows greater opportunity for the regeneration of the hydrogen atom before destruction of the HO_2 radical at the wall in the larger than in the smaller vessel, and hence a greater extension of the explosive region toward hydrogen-rich mixtures is permitted.

It is of interest to ask whether HO_2 will remain a quasi-inert body as temperature is increased. In the absence of any major change of reaction mechanism, it would be expected that if HO_2 became unstable or more reactive at higher temperatures the explosion limit would decrease again because a chain-breaking mechanism would have ceased to operate. Furthermore, if such an effect were observed it should be accompanied by a cessation or at least a great diminution of the poisoning effect of added molecular oxygen. We have not been able to recapture the explosion limit in either of the quartz vessels between 830 (where it vanished) and 960°. In the vycor vessel, on the other hand, the explosion limit reappeared at 900° and slowly decreased as the temperature was raised further. At the higher temperatures (above 900°) the minimum explosion pressure occurred much nearer the stoichiometric ratio than in the lower temperature region. In Fig. 3, the explosion limit is plotted for equimolar mixtures in a 1.5-cm. inside diameter vycor vessel. The addition of 2 mm. of molecular oxygen to this mixture produced only a slight effect in the temperature range from 900 to 980° (increased the explosion pressure by an amount $\leqslant 10$ mm.) although the low temperature lobe was destroyed by a similar addition of oxygen, just as it was in either quartz vessel.

It will be recalled that the vycor vessel gave lower explosion limits than those obtained in even a larger quartz vessel in the low temperature range as well, $T < 830°$, and this may be due either to the greater facility of hydrogen atom recombination on quartz than on vycor or to a difference in the fate of HO_2 on quartz and on vycor. The first alternative appears the simpler, and it is probable that a more rugged or larger apparatus would allow the recapture of the explosion limit in quartz above 900°. The major constitutive difference between vycor and quartz is the presence of approximately 4% of boric oxide and small amounts of sodium, iron, aluminum and arsenic in the latter; and the larger quartz vessel was treated with boric oxide and with sodium borate in an attempt to force the reappearance of the explosion limit.

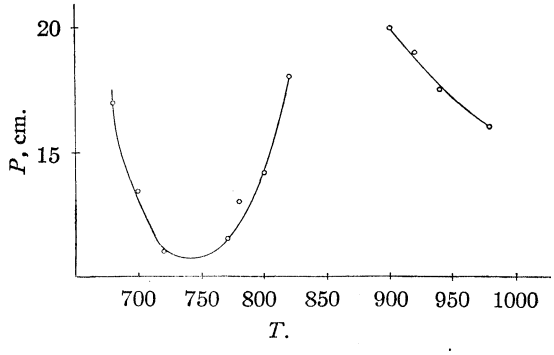

Fig. 3.—Lower explosion limit of 1:1 nitrous oxide–hydrogen mixtures in 1.5-cm. i. d. vycor vessel.

However, neither treatment was effective in promoting explosions in the temperature range 830–960° in quartz. On the contrary, the only effect observed from these surface treatments was a moderate elevation of the explosion limit in the low temperature range, $T < 830°$.

Acknowledgment.—The authors are indebted to Dr. Bernard Lewis for suggestive discussions preceding and during the course of this work.

Summary

A study of the lower explosion limit of the nitrous oxide–hydrogen system reveals the existence of a minimum in the pressure *versus* temperature curve for mixtures of any fixed compositions. The addition of molecular oxygen poisons the explosive reaction, and this suggests that the minimum is due to the poisoning of the reaction by oxygen from the thermal decomposition of nitrous oxide. In view of the results of Melville's study of the slow reaction, the mechanism of poisoning must be $H + O_2 + M \rightarrow HO_2 + M$.

After passing through the minimum, the explosion limit does not increase indefinitely as the temperature is raised. Above 900° it decreases again in a vycor vessel, but could not be observed to decrease in quartz vessels of the size employed. In vycor above 900°, the explosion is not strongly affected by added oxygen and this insensitivity would be expected from the interpretation of the low temperature results.

Studies in the Lead Chloride–Lead Bromide System[1]

BY GEORGE CALINGAERT, FRANCES W. LAMB AND FRED MEYER

The published information on the lead chloride–lead bromide system is incomplete and contradictory, and after a preliminary examination of its X-ray diffraction characteristics it became obvious that previously reported work would have to be repeated in order to arrive at a reliable description of the system. This paper covers an investigation of this system which, in addition to a thorough X-ray diffraction analysis, includes a repetition and an extension of the work of other investigators by thermal analysis, by conductivity and by aqueous preparations.

In a recently published study of the binary and ternary systems of lead halides, Mlle. Delgery,[2] contrary to the conclusions of previous investigators,[3] reported the existence of several compounds and eutectics. Her first two papers gave the results of thermal analyses on the three binary systems of lead chloride, lead bromide and lead iodide,[2a] and on the ternary system of these lead halides.[2b] These thermal analyses were supported in a third publication[2c] on six series of unsaturated aqueous solutions, each containing two of the four halides. In each series, the composition of the solute was varied from that of one halide to that of the other, while the total concentration was kept constant. All the conductivity–composition curves reported showed broad minima and sharp maxima, which latter were interpreted by the author as indicating the existence in solution of compounds of the corresponding solute compositions. Furthermore, Delgery proposed such measurements as a valuable adjunct to thermal analysis, reporting that peritectic compounds difficult to detect by thermal analysis were readily detected by such conductance measurements.[2c,2d]

For the lead chloride–lead bromide system Delgery's results indicated the existence of a stable compound, PbClBr, a peritectic compound, $PbBr_2 \cdot 3PbCl_2$, a eutectic close to $9PbBr_2 \cdot 16PbCl_2$, and several series of solid solutions, two of which had limited miscibility. These results contradicted the earlier thermal analysis of Mönkemeyer,[3a] who found that this system was one in which there was a continuous series of solid solutions with the melting (liquidus) points of all intermediate compositions lying on a straight line joining the melting points of the pure components. The work of Mönkemeyer was directly confirmed by Favorskii,[3b] and indirectly by Matthes[3c] in a study of the ternary system, lead chloride–lead bromide–lead iodide. A comparison of the results obtained by Delgery, Mönkemeyer and Favorskii is given in Fig. 1.

On the other hand, Thomas,[4] in 1898, claimed, like Delgery, to have prepared both $PbBr_2 \cdot 3PbCl_2$ and PbClBr. His evidence that $PbBr_2 \cdot 3PbCl_2$ was a compound rather than a solid solution was based on the constancy of the composition of the material crystallizing out of a hot solution of lead chloride to which potassium bromide had been added. His evidence for the existence of PbClBr was even less satisfactory, since his material was obtained only by heating PbClI in a current of bromine.

Experimental

Materials.—Except for lead bromide, these were of analytical reagent quality; all were used without further purification. Spectrographic analysis of the potassium chloride, lead chloride and lead bromide showed a total metallic impurity of less than 0.007, 0.01 and 0.01%, respectively. Chemical analysis of the lead chloride gave

the calculated composition; chemical analysis of the lead bromide indicated the presence of less than 0.8% of a basic bromide.

Thermal Analysis.—All cooling and heating curves were run *in vacuo* in a Vycor tube in which was supported a Vitreosil thermal well having a thin-walled capillary end. The runs were made on 40- to 50-g. samples which were vacuum dried for several hours before starting the run. Cooling and heating rates of 1°/minute ± 10% were maintained by manual control of the furnace voltage. Temperatures were measured with an L. & N. glass-fiber insulated iron–constantan thermocouple and a K-2 potentiometer. Throughout each run, the Vycor tube was vibrated continuously with a Burgess Vitro-Tool; this gave improved heating and cooling curves and minimized supercooling.

One cooling curve and two heating curves were obtained on each sample. One heating curve was run on an intimate mechanical mixture and the other on the solidified melt, after it had been finely ground. The two heating curves always gave comparable results; that is, in the heating curve run on the mixture, only one thermal arrest, characteristic of the solidus temperature of the corresponding solid solution, was observed. The duration of arrests obtained ordinarily varied from thirty to almost fifty minutes for a 40-g. sample.

Conductivity Measurements. A. Equipment.—Conductance measurements were made at 1000 cycles from a bridge assembled from an L & N precision type slide wire, a shielded 11,111 ohm a. c. decade resistance box, a 1000 mmf. variable air condenser, a Wagner ground and appropriate shielding. The slide wire was used as fixed unit-ratio arms by maintaining the slide wire contact at its effective a. c. center. Two Jones-type conductivity cells were made of 16-mm. Pyrex tubing with platinized electrodes approximately 10 cm. apart. The cells were calibrated at 25° with the 0.01 demal KCl solution of Jones and Bradshaw, and the measurements were made at 25.00 ± 0.01°. The *p*H was measured with a glass electrode and a Model G Beckman *p*H meter.

B. Preparation of Solutions.—Two sets of stock solutions of lead chloride and lead bromide were prepared, corresponding to the two series of solutions whose conductivities were to be measured.

In the first set, sufficient lead halides were dissolved in carbon dioxide-free, hot conductivity water, in calibrated Pyrex volumetric flasks, so that after hydrolysis products were removed, the solutions would be exactly 0.02 molar in lead ion. After solution of the halides was complete, the solutions were allowed to reach hydrolytic equilibrium at 25°, adjusted to final volume and filtered through a Jena sintered-glass filter. The final concentration of the lead bromide solution was calculated from the weight of Pb(OH)Br recovered, and the final concentration of the lead chloride solution was computed on the basis of *p*H. The second set of stock solutions was prepared by dissolving the desired amount of each lead halide in a hot dilute solution of its hydrohalic acid. The *p*H's of both hydrobromic and hydrochloric acid solutions, prepared by dilution of concentrated acids with conductivity water, were close to 3.30, this being nearly the maximum *p*H at which the more easily hydrolyzed lead bromide would dissolve completely. The compositions of both sets of stock solutions were finally confirmed by analysis.

Solutions for conductivity measurements were prepared by mixing at room temperature appropriate volumes of each stock solution from calibrated Pyrex burets into Pyrex volumetric flasks. No appreciable change in volume occurred on mixing. This method of preparation insured that both the relative composition (Cl/Br) and the actual total concentration (0.0200 molar lead halides at 25°) were accurately controlled.

C. Conductance measurements on each solution were made in both cells, and were considered satisfactory when consecutive measurements of the cell resistance were constant to 3 parts in 10,000 and the resistance ratio of the cells was within 5 parts in 10,000 of the value found in calibration.

Aqueous Preparations. A. The Preparation of $PbBr_2 \cdot 3PbCl_2$ was attempted according to the method of Thomas,[4] using four times his scale, and by collecting the entire crystalline product for three temperature intervals. A Glas-Col electrical beaker jacket was used to maintain close temperature control. Forty ml. of a 10% potassium bromide solution was added slowly with stirring at 95° to one liter of carbon dioxide-free water containing 20 g. lead chloride. The resulting clear solution was slowly cooled with constant stirring, and crystallization began at 90°. The solution was further cooled to 70°, where it was maintained for two hours before removing the first crop of crystals. A second crop of crystals was similarly obtained from the supernatant solution for the interval from 70 to 50°. The resulting supernatant solution was then allowed to cool overnight to room temperature (approx. 23°) for the last crop. Each crop of crystals was separated from adhering mother liquor by washing with 95% ethyl alcohol, transferring to a Buchner funnel and draining as completely as possible. The crystal meals were then ground, and dried overnight at 75° *in vacuo* with constant pumping.

B. Other solid solutions of lead chloride and bromide of predetermined composition were attempted. The appropriate volumes of standardized hydrochloric and hydrobromic acids (approx. 1.1 *N*) required to prepare 1.021 equivalents of mixed acid (equivalent to 900 ml. of the hydrobromic acid solution) of the desired chlorine-bromine ratio were placed in "Low-Actinic" flasks and 66.7 ml. of a 1.5 *M* lead acetate solution was added dropwise with stirring. The flasks were stoppered and kept for three weeks at room temperature (approx. 23°), with occasional shaking. The products recovered were found to be well-formed tiny crystals which were drained as completely as possible on a filter, and then vacuum-dried at 110° to remove the final traces of acids.

X-Ray Diffraction.—The following is a description of the samples used and the technique of specimen preparation:

A. Fused preparations were obtained by heating under nitrogen an intimate mixture of the appropriate weights of lead chloride and lead bromide at about 525° in fused alumina crucibles. After melting, they were stirred for ten or fifteen minutes and allowed to cool.

B. Heat-treated Preparations: H 1.—One of the 50 mole % compositions used for thermal analysis, and having a forty-minute crystallization period, was kept at 420 ± 3° for sixty hours, and then allowed to cool in air.

H 2.—This is a 50 mole % lead bromide melt which had a three-hour crystallization period and was cooled to room temperature in the furnace.

H 3.—The same as H 2 except that, following the three-hour crystallization period, the sample was annealed at 416 ± 3° for forty-six hours, after which it was cooled to 100° over a period of ten hours.

H 4.—The same as H 2 except that the crystallization and annealing times were fifteen hours each, and the cooling time three hours.

C. The preparation of specimens which would show a minimum of preferred orientation and give patterns of reproducible relative intensities was a problem of major importance, which is inherently more difficult with the Geiger-Counter Spectrometer than with camera units. Lead chloride and lead bromide crystallize in long needles along their *a* axes, and there is a tendency for these axes to line up parallel to the surface on which they are mounted. A method was developed for making reproducible collodion films of 30-mg. samples on microscope slides, as follows:

(1) The 200-mesh material was ground an additional ten minutes. Grinding is important not only for particle size reduction but also to obtain particles of equal dimensions in all three directions in order to avoid possible orientation during the drying of the collodion film.

(2) Two drops of dilute collodion (1 part collodion in 2 parts of a 3:1 absolute alcohol–ether solution) was added to 30 mg. of the fine powder placed in a small glass cone. The mixture was worked with a stirring rod (the end of which was shaped to fit the bottom of the cone) until the solvent evaporated, leaving a fine powder coated with collodion. About 0.5 ml. of dilute collodion was added, and the dried powder was suspended by stirring, forming a fine, stable suspension.

(3) This suspension was poured on a microscope slide to cover the full width of the slide for one inch of its length, and was stirred rapidly until it became tacky and formed a thick gel. After drying, the preparation was ready for use.

The reproducibility of this method of specimen preparation was checked on nine lead chloride and ten lead bromide preparations. The average deviation from the mean relative intensity of 31 of the lead chloride reflections and 29 of the lead bromide reflections was found to be approximately 10% for each of the reflections.

Collodion films are also well suited for use with the back-reflection camera, since they can be readily removed from the glass slide, are smooth, flexible and may be accurately held to the curvature of the focusing circle of the camera. For this purpose a denser film was prepared by using 100 mg. of sample and 1 ml. of dilute collodion.

D. A calibration of the goniometer was made before and after each series of 2 θ measurements, using alpha-quartz. The lattice constants, a = 4.91310 Å. and c = 5.40461 Å., given by Wilson and Lipson,[5] were used to calculate the 2 θ values of suitable lines occurring in the forward-reflection region. These are listed in Table I. The calibration of the goniometer readings showed very little variation throughout the series of measurements made in this study.

[a] Calculations were made using 1.5418 Å. as the wave length of the weighted mean of the CuKα radiation, except for the indicated reflections where 1.54050 and 1.54435 Å. were used as the wave lengths of α_1 and α_2, respectively.

E. Lattice constants were computed for each fused composition from measured angles of reflection (2 θ) found for five planes in the forward-reflection region by manual scanning measurements after correcting for systematic errors (based on the previous calibration), using a weighted least squares solution of the equation

$$d^{-2} = (2/n\lambda)^2\sin^2\theta = h^2a^{-2} + k^2b^{-2} + l^2c^{-2} \quad (1)$$

The weighting factor, determined by least squares theory, is proportional to $\csc^2 2\theta$. Since the numerical solution of simultaneous equations obtained from Eq. (1) by least squares is not sensitive to small variations in weights, it was possible to assign an average relative weight for each plane satisfactory for all compositions (Table II) and, consequently, to obtain by matrix algebra a general solution of the least squares equations for the lattice constants for all compositions.

Results

Thermal Analysis.—Liquidus and solidus temperatures were determined from cooling and heating curves, respectively, on nine compositions ranging from pure lead chloride to pure lead bromide in steps of one-eighth mole fraction except that the 37.5 mole % lead bromide was replaced by 35 mole % lead bromide which is the eutectic composition of Delgery's thermal diagram.

A summary of the data obtained is given in Table III and Fig. 2. Where more than one run

TABLE III

THERMAL ANALYSIS OF PbCl$_2$–PbBr$_2$ SYSTEM

Composition in mole % PbBr$_2$[a]	Liquidus, *T*, °C.	Solidus, *T*, °C.
0	496.3[b]	496.0[b]
12.5	478.9	474.6
25	464.0	457.5
35	452.3	443.3
50	435.9	425.0
62.5	420.7	410.2
75	403.4	394.2
87.5	386.5	381.5
100	370.1[c]	369.8[c]

[a] The compositions are based on the weights of reagents used. [b] Mönkemeyer, Favorskii and Delgery give 495, 498 and 498°, respectively. [c] Mönkemeyer, Favorskii and Delgery give 370, 373 and 366, respectively.

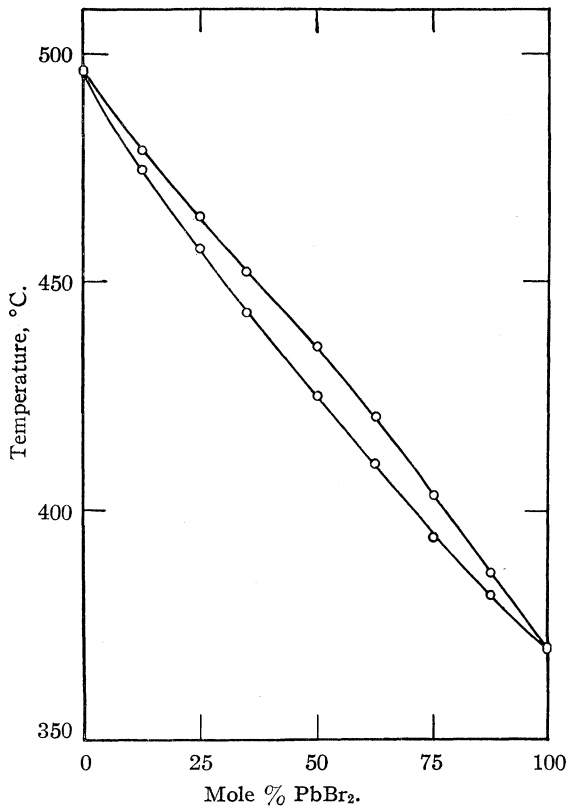

Fig. 2.—Thermal diagram of lead chloride–lead bromide system obtained in the present work.

was made, the values shown represent an average of those values for which the extrapolation of the thermal breaks was the least arbitrary. For this reason, solidus values from cooling curves and liquidus values from heating curves were ignored. The points given in this Table are believed to be precise to one degree; but judging from a calibration with zinc, they may be from zero to 2.5° low.

The thermal diagram obtained for this system is an ideal example of the diagram obtained for a binary system in which the two components form a continuous series of solid solutions, where all the melting points are intermediate between those of the pure components. As a consequence, no compounds exist in the lead chloride–lead bromide system; at least, not in the temperature–composition region above and possibly somewhat below the solidus curve of the system. This is in complete agreement with Mönkemeyer[3a] and Favorskii,[3b] and in complete disagreement with Delgery.[2a,2b]

Conductivity Measurements.—The variations in conductivity with varying anion composition which Delgery observed[2c,2d] are considerably different in character from those observed by Sandonnini[6] for similar systems in which complex compounds are known to exist, and are in such complete contradiction with accepted theories of conductivity that we decided to subject them to extremely careful experimental verification.

Because no experimental details, other than the concentrations used, were given in Delgery's brief communication,[2c] it was not possible to carry out these measurements under conditions identical with those which she employed; nor, did it seem desirable to do so on the basis of the following considerations. First, it was estimated from a study of the system $PbCl_2$–$PbBr_2$–H_2O,[7] that the minimum solubility of this system at 20° is 0.020 mole of lead halides per liter.[8] Therefore, nearly saturated solutions were avoided by using a total halide concentration of 0.020 molar at 25° rather than 0.0245 molar as used by Delgery. Second, because of the appreciable hydrolysis of both lead chloride and lead bromide, some free acid is always present in their solutions, and the solution of either halide in water is always accompanied by the separation of some insoluble hydrolysis products. Variations in the composition of the solutions and, consequently, in their conductivities would depend, therefore, on the method used to prepare the solutions.

Two methods were used; each involved mixing appropriate volumes of stock solutions of lead chloride and lead bromide. In the first, the stock solutions were prepared with the minimum amount of free acid by dissolving the proper excess of lead halide in conductivity water so that after the products of hydrolysis were removed the solutions were of the desired concentration. This method has the principal disadvantage that a solution of lead bromide is more acidic than a solution of lead chloride of the same concentration (about 1 *p*H unit for 0.020 molar solutions at 25°), so that the *p*H of a series of solutions prepared from them varies continuously. Also some investigation of the nature and degree of the hydrolysis of these lead halides was required.[9] This method was used only because it seems similar to Delgery's. Since she does not mention hydrolysis, it was assumed that her stock solutions were prepared by dilution from saturated solutions. In the second method, the lead bromide stock solution was prepared by using as the solvent the most dilute hydrobromic acid solution which would prevent the precipitation of hydrolysis products. The lead chloride stock solution was prepared by using a hydrochloric acid solution of the same *p*H as the hydrobromic acid. These lead halide solutions form a series of isohydric solutions and so do the hydrohalic acid solutions used to prepare them.

The results of the conductivity measurements

(6) Sandonnini, *Gass. chim. ital.*, **46**, II, 205–219 (1916).

(7) Meyer, *Rec. trav. chim.*, **42**, 301 (1923).

(8) The temperature of this study was not stated, but assuming that the work was done at constant temperature, it was estimated from the ratio of solubilities reported by G. Meyer for the lead halides and from the solubility–temperature data of these compounds reported in the "International Critical Tables."

(9) The products of hydrolysis were identified as the basic salts Pb(OH)X, and 0.020 molar lead bromide and lead chloride solutions were found to be 2.1 and 0.2% hydrolyzed at 25°, respectively.

are given in Table IV and are plotted against composition in Fig. 3. Series A, varying pH, is the series of solutions for which the lead halide stock solutions were prepared with water, and where the acidity, due to hydrolysis, is the minimum possible for each solution of the series. Series C, constant pH, is the series of solutions for which the lead halide stock solutions were prepared with their respective dilute acids, each of the same pH. Series B, constant pH, is a series of solutions made by mixing the hydrochloric and hydrobromic acid solutions used for preparing the stock solutions of Series C. The conductivities of all three series show very slight positive deviations from a simple additive relation with composition, and no evidence whatever of the sharp maxima reported by Delgery. The results for the two halide series can be shown to be consistent by evaluating the contribution of the acids present in each solution of each series, assuming as a first approximation that the conductivities of these solutions are an additive function of all the ions present, and that the ionization equilibria of the lead halides are independent of the acid concentration.

TABLE IV

CONDUCTIVITY MEASUREMENTS FOR THE LEAD CHLORIDE–LEAD BROMIDE AND HYDROCHLORIC–HYDROBROMIC ACID SERIES

Solution	Vol. % $PbBr_2$ soln.	Spec. cond.[a] ohm^{-1} cm.$^{-1}$ × 10^3	pH	Solution	Vol. % $PbBr_2$ soln.	Spec. cond.[a] ohm^{-1} cm.$^{-1}$ × 10^3	pH

2	20.00	2.204	3.30	7	59.99	2.209	3.30
4	29.98	2.204	3.31	8	79.97	2.217	3.34
5	39.98	2.207	3.31	9	100.00	2.217	3.30

[a] Measurements were made in each case on two cells and their average and maximum deviation from the average value shown above was 0.015 and 0.025%, respectively.

Corrections for solutions of Series C were obtained directly from the smooth curve drawn through the conductivity values obtained for Series B as in Fig. 3. The curve of these corrected values for Series C (C minus B), shown in Fig. 3 as C − B, is almost exactly parallel to the original curve C.

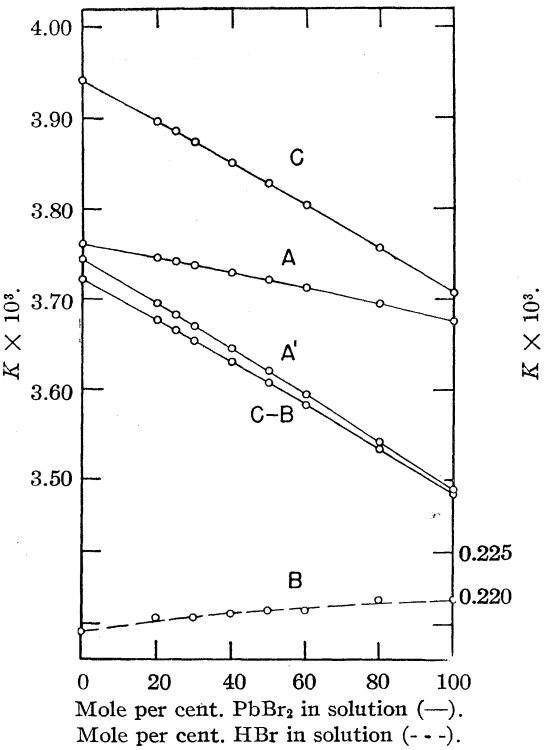

Fig. 3.—Conductivity of aqueous solutions of $PbCl_2$–$PbBr_2$ system, and of HCl–HBr system (pH 3.30).

The corresponding corrections for solutions of Series A were made from an estimate of the total acid present, using the value of 425 as a composite equivalent conductance for both acids. That no appreciable change in the amount of each acid occurred on mixing the stock solutions is shown in Table V by the agreement between the values of the pH calculated and observed for each Series A solution. The corrected conductivities for Series A are shown in Table V and in Fig. 3, as A′.

The failure of the two corrected curves, A′ and C − B, to superimpose exactly must be attributed

to the fact that the ionic equilibria involved in each series, particularly with regard to intermediate ions formed from the lead halides, are influenced by the amount of halogen acids present. The closer agreement obtained for the lead bromide end is, of course, due to the similarity of the compositions of the two lead bromide solutions, so that there is really no assurance that these corrected conductivities are a measure of the "conductivity of lead bromide" independent of the *p*H of the solutions used.

Another interesting point is that, for both series, the conductivity of the lead bromide solution was lower than that of the lead chloride solution. This was unexpected, inasmuch as the Br^- ion has a higher limiting ionic conductivity than the Cl^- ion. It is also contrary to the report of Delgery,[2c] who, strangely enough, shows the bromide to be more conducting than the chloride in the two more concentrated solutions, and less conducting in the most dilute solution she measured.

For comparison, the conductivity results reported by Delgery[2c] for the lead chloride–lead bromide system are shown in Fig. 4 for 0.0245 molar Pb, together with the present results. These results, as well as those for the other binary halide solution systems, which seemed improbable, must now be considered erroneous and should be disregarded.

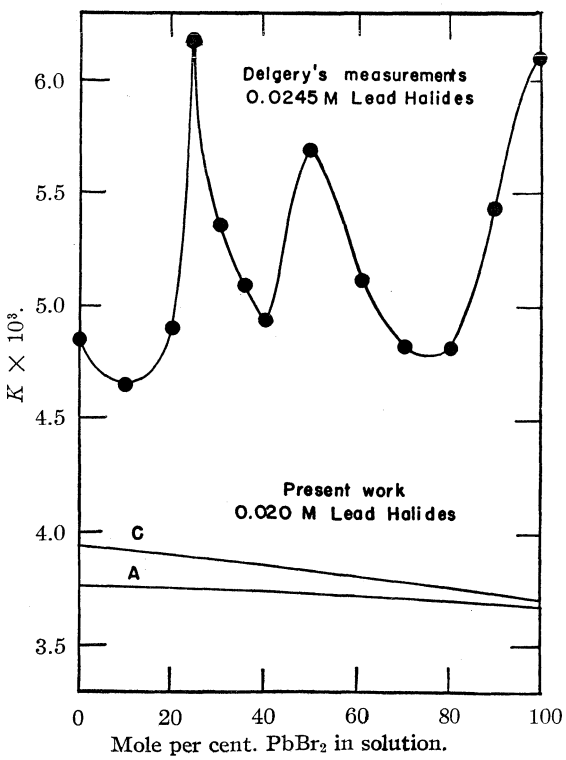

Fig. 4.—Comparison of conductivity of aqueous solutions of the lead chloride–lead bromide system.

Aqueous Preparations.—These were undertaken to check the claim by Thomas[4] that a compound $PbBr_2 \cdot 3PbCl_2$ could be prepared from an aqueous solution; to determine whether it was possible to prepare from aqueous solutions any given solid solution of this system; and to determine whether the X-ray diffraction characteristics of solid solutions of this system prepared from aqueous solution were different from those of solid solutions prepared by fusion.

A. The preparation of $PbBr_2 \cdot 3PbCl_2$ was attempted using the method of Thomas[4] but on a larger scale and by collecting the entire crystalline product for three temperature intervals (see Experimental Part). The results are given in Table VI. The estimated ranges of composition of the solid solutions are given in the last column, where the smallest figure is based on the assumption that the contaminant is entirely potassium bromide and the largest on the more plausible assumption that it is entirely potassium chloride. These results show that the composition of the solid solution crystallizing out is not constant as Thomas claimed.

TABLE VI

ATTEMPTED PREPARATION OF $PbBr_2 \cdot 3PbCl_2$ USING THOMAS' METHOD

Fraction	Temp. range, °C.	Yield, g.	Analyses, % Pb	Br	Cl	K	Composition, mole % $PbBr_2$
1	90–70	7.3	68.21	14.96	16.55	0.10	28.3–28.7
2	70–50	5.4	68.56	14.34	17.01	.08	27.0–27.3
3	50–23	4.0	69.22	12.33	18.23	.09	22.8–23.2

X-Ray diffraction patterns in the back-reflection region of these samples were among the sharpest obtained for solid solutions of this system, and a comparison of these patterns clearly showed a progressive shift in lines, again demonstrating the difference in composition of these samples. The non-existence of this "compound" is further supported by the fact that except for very slight line shifts, forward-reflection patterns of the first and third samples were identical with those of the fused 25 mole % preparation.

B. The Preparation of Solid Solutions of Predetermined Composition.—It has been shown in a study of the effect of alkali and alkaline earth chlorides and bromides on the solubility of lead chloride and lead bromide,[10] that all the solubility curves obtained possess a common minimum for a range of concentration of soluble halides from about 0.3 to about 0.7 *N*. It was therefore expected that if no compounds or favored composition existed, the addition of lead ion to a solution containing both bromide and chloride ions in this concentration range would result in the precipitation of a solid solution containing the same chlorine–bromine ratio as the solution. To simplify the problem of purification of the product, hydrobromic and hydrochloric acids were selected as the soluble halides and lead acetate as the soluble lead salt. (Even if salts were used for the

(10) Herz and Hellabrant, *Z. anorg. allgem. Chem.*, **130**, 188 (1923).

halides, some acid would have been necessary to avoid hydrolysis.) The effect of hydrochloric acid on the solubility of lead chloride[10,11] fits into the same general picture. As far as the authors are aware, no comparable data exist for the effect of hydrobromic acid on the solubility of lead bromides.

The actual preparations are described in the Experimental Part. The preparations were analyzed chemically and studied by X-ray diffraction. The results of analysis showed the products to vary in composition from 48.3 to 57.5 instead of from 35 to 65 mole % lead bromide, as expected. The data for these experiments are summarized in Table VII. The last column of Table VII gives the estimated composition of the mixed acid remaining after the addition of lead acetate and is based on the estimate made from Herz and Hellabrant's data[10] that 0.004 mole of lead ion remains in solution. That aging was not an important factor in determining composition was shown in an experiment in which the initial precipitate from a solution of the same composition as that used for Aq 1 was immediately recovered and was found, by X-ray diffraction, to be close to 50 mole % lead bromide.

TABLE VII

COMPOSITION OF SOLID SOLUTIONS OF LEAD CHLORIDE AND LEAD BROMIDE OBTAINED BY PRECIPITATION FROM MIXED HCl–HBr SOLUTIONS

Solid solution	Initial mole % HBr of mixed acid	Analysis of precipitates % Br	% Cl	Mole % $PbBr_2$ in precipitates	Calcd. mole % HBr in soln. in equil. with precipitate
Aq 1	35	23.96	11.39	48.3	32.0
Aq 2	45	25.60	10.40	52.2	43.3
Aq 3	50	25.73	10.39	52.4	49.5
Aq 4	50	25.64	10.40	52.2	49.5
Aq 5	55	26.29	10.09	53.6	55.3
Aq 6	65	27.88	9.14	57.5	66.7

The last two columns of Table VII correspond to the equilibrium compositions obtained by G. Meyer[7] for the solid solution and the solute in the system $PbCl_2$–$PbBr_2$–H_2O. For comparison, the two sets of data are shown in Fig. 5. The similarity between the two systems is striking. In fact, the only effect of the presence of 0.85 N mixed acids (considering the 0.21 N acetic acid present to be without influence) is to shift the equilibrium compositions of the solid solutions about 2% toward the lead bromide axis. This effect may in part be ascribed to the greater acid strength of hydrobromic acid, and is apparently superimposed on the tendency to form the 50 mole % lead bromide solid solution.

While G. Meyer pointed out that this relationship between the equilibrium compositions of solute and solid solution of the $PbCl_2$–$PbBr_2$–H_2O system is exactly similar to that found for the

(11) Kendall and Sloan, THIS JOURNAL, **47**, 2306 (1925).

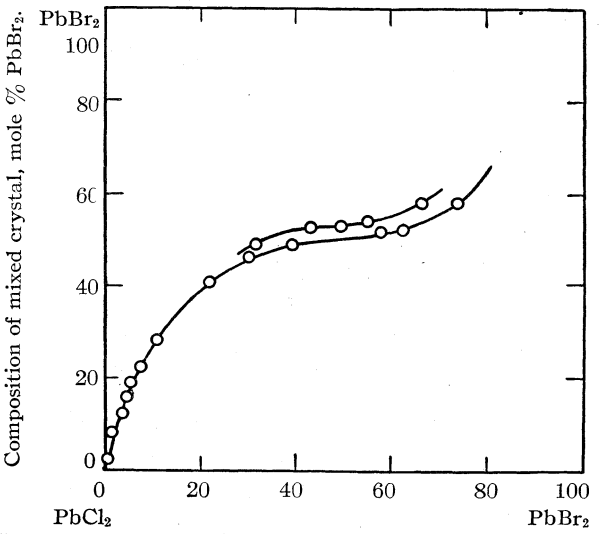

Fig. 5.—Lead chloride–lead bromide mixed crystals in equilibrium with their aqueous solution: lower curve, $PbCl_2$–$PbBr_2$–H_2O system from G. Meyer; estimated temperature, 20°; upper curve, present data for 0.85 N mixed acid; approximate temperature, 23°.

permutites by Hisschemöller[12] and was therefore explainable on the basis that a compound, $PbCl_2 \cdot PbBr_2$, existed, he felt that it could also be due to physical forces alone. The present results, however, clearly demonstrate that not all compositions of solid solutions of lead chloride and lead bromide are equally likely to form; in other words, chloride and bromide ions do not enter the crystal lattice on the basis of statistical probability alone.

The results obtained in repeating Thomas' preparation of the 25 mole % lead bromide solid solution can now be qualitatively explained on the basis of the tendency to form the 50 mole % composition, if the same relationship between the composition of the solid solution and the solute in aqueous solution is assumed to hold for the system $PbCl_2$–KBr–H_2O at the various temperatures used as for the $PbCl_2$–$PbBr_2$–H_2O system at 20°. On this basis, the composition of the solid solutions for the various fractions would have been 34.5, 28 and 19 mole %, respectively, instead of the 28.5, 27, and 23 mole % lead bromide actually obtained.

X-Ray Diffraction.—Lead chloride and lead bromide[13] are orthorhombic, with four molecules per unit cell, and belong to space group V_h^{16}, with all atoms occurring in special positions (c). Their lattice constants (Table IX) differ from their mean value by less than 3%, and they would be expected to form a continuous series of solid solutions and to obey Vegard's law for solid solutions.

An X-ray diffraction study was made of nine

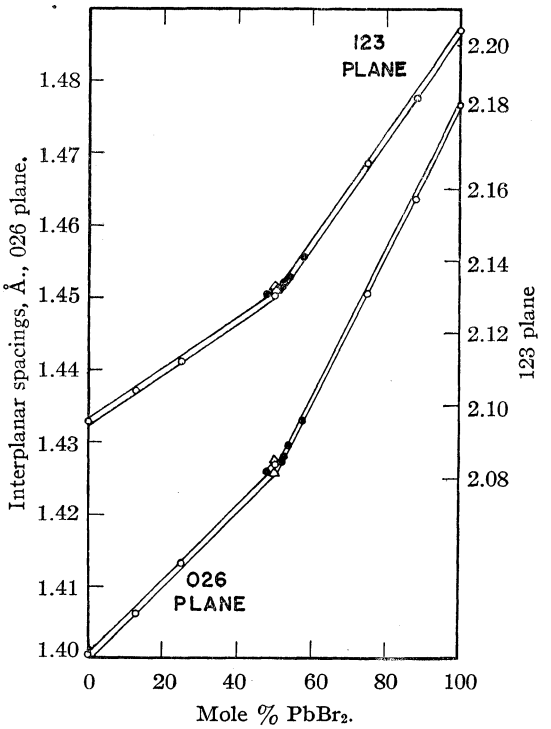

Fig. 6.—Relationship between interplanar spacings and compositions for the 123 and 026 planes in the $PbCl_2$–$PbBr_2$ system. The lines show the effect of an error of $\pm 0.02°$ in 2θ. Legend: ○, fused; ●, aqueous; △, heat-treated preparations.

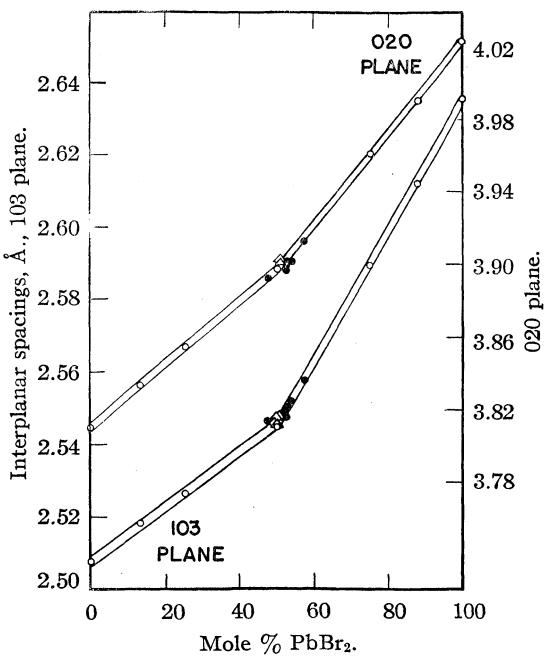

Fig. 7.—Relationship between interplanar spacings and compositions for the 020 and 103 planes in the $PbCl_2$–$PbBr_2$ system. The lines show the effect of an error of $\pm 0.02°$ in 2θ. Legend: ○, fused; ●, aqueous; △, heat-treated preparations.

fused preparations of the lead chloride–lead bromide system. In a preliminary examination of 2 r. p. m. automatic recordings in the forward-reflection region obtained with a Norelco Geiger-counter X-ray spectrometer using Cu K_α radiation, line-shift measurements showed a discontinuity at the 50 mole % composition indicative of a compound, PbClBr, isomorphic with lead chloride and lead bromide and forming a complete series of solid solutions with each of these compounds. The preliminary investigation also reveals discontinuities in the progressive changes in relative intensities of a number of lines at the 50 mole % composition, which gave further support to the above hypothesis.

In view of these unexpected results more accurate determinations of the Bragg angles were made by manual scanning measurements, which gave 2 θ values reproducible to $\pm 0.01°$. Making allowance for error in applying the calibration data, the total experimental error in 2 θ measurement should not be over $\pm 0.02°$.

Manual scanning data were obtained for the 002, 020, 026, 103, 123 and the unresolved 212, 114 planes of most of the fused preparations. The average d values in Ångström units for the first five planes are given in Table VIII. The interplanar spacings–composition data are shown in Figs. 6 and 7 for the 123, 026, 020 and 103 planes. [a] Each of the individual interplanar spacing values represents the average of 2 or 3 determinations. The average deviation for each plane is based on 18 to 20 individual determinations for the fused preparations and 24 to 29 for the heat-treated and aqueous preparations. [b] The calculated experimental error is based on a $\Delta 2\theta$ of $\pm 0.02°$.

these figures, discontinuities in interplanar spacings can be seen at the 50 mole % composition, which is in agreement with the preliminary observations made from the automatic scanning records.

In order to determine whether the results of X-ray diffraction were in any way due to a distortion of the crystal lattice in the fused preparations, an investigation was made of heat-treated and aqueous preparations. The compositions of the heat-treated preparations were held close to the 50 mole % composition, since the effect of line-shift measurements should be most pronounced at this composition. Heat treatment included slow crystallization, prolonged annealing and slow cooling. Manual scanning data were obtained for the heat-treated and aqueous preparations. The average interplanar spacing values are given in Table VIII, and Figs. 6 and 7. It is evident that any changes produced in interplanar spacing values for the 026, 123 and 020 planes by heat treatment are within the experimental error. The increases in d values noted for the 103 plane are only slightly greater than the experimental error and may or may not be real. If real, a possible explanation might be that the adjustment of the crystal lattice took place primarily along the a-axis. Preparations from aqueous solution likewise show no significant differences.

A least squares treatment was used to calculate the lattice constants for each composition from the manual scanning data obtained on the 002, 020, 026, 103 and 123 planes. The lattice constants, axial ratios and unit cell volumes are given in Table IX. The lattice constants for lead chloride and lead bromide show good agreement with the literature values.

The relationships of lattice constants and unit cell volume with composition are shown in Fig. 8.

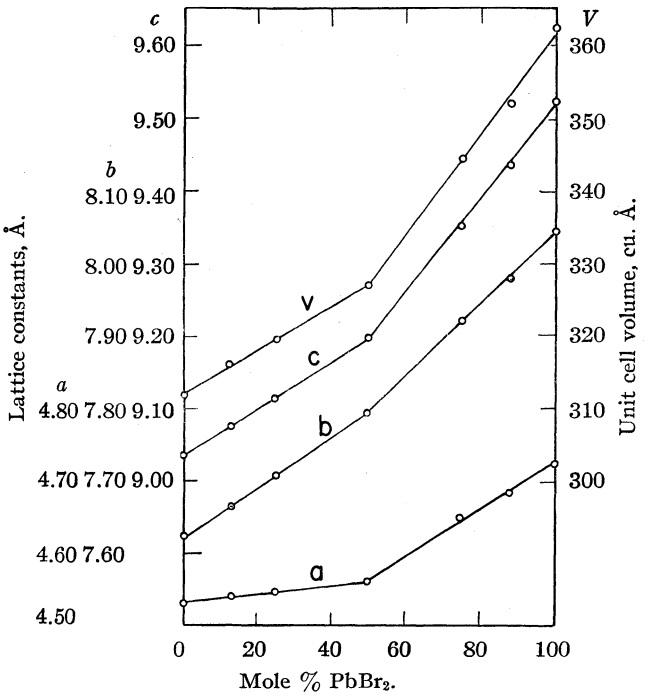

Fig. 8.—Relationship of lattice constants and unit cell volume with composition for the $PbCl_2$–$PbBr_2$ system.

As would be expected from the interplanar spacings-composition relationships, these data are best represented by two straight lines intersecting at the 50 mole % composition. From this it may be concluded: (1) that the replacement of chloride ions by bromide ions expands the crystal lattice at a slower rate from 0 to 50 than from 50 to 100 mole % lead bromide. This difference in rate of expansion is most pronounced for the a-axis and least for the b-axis (Fig. 8; also the 020 plane, Fig. 7); (2) that the compound or ordered structure at the 50 mole % composition has definite axial ratios independent of the method of preparation. These axial ratios are unique, being minimum values for the system.

According to Nieuwenkamp and Bijvoet,[13d] the halide ions of the isomorphic compounds lead chloride and lead bromide occupy two inequivalent positions in the crystal lattice, designated as X′ and X″. Also, the Cl″ and Br″ ions have a slightly larger space volume around them in their respective lattices than the Cl′ and Br′ ions. From this it was theorized that a preferential replacement of the Cl″ ions is taking place from the 0 to 50 mole % lead bromide compositions, leaving only the Cl′ ions for replacement from the 50 to 100 mole % compositions. This would explain the lower rate of expansion of the unit cell from 0 to 50, since there is more space for the larger bromide ion at the Cl″ ion positions than at the Cl′ ion positions in the crystal lattice. On the basis of this theory, the 50 mole % composition might then be considered to be a preferential-replace-

ment structure, $PbCl'Br''$, and would explain the discontinuity observed in the lattice constant–composition relationships.

As a further check on the existence of the preferential-replacement form $PbCl'Br''$, a comparison was made of calculated and experimental relative intensities of a number of the reflections. This was of particular interest since discontinuities were noted in the progressive changes in relative intensities of several lines at the 50 mole % composition. The relative intensities (I/I_1) of 11 lines were evaluated for the fused compositions from 1 r. p. m. automatic recordings taken on quadruplicate specimen preparations. A rotating sample mount was used to decrease preferred orientation effects. A summary of the average observed relative intensities for each composition is given in Table X, from which it is noted that at the 50 mole % composition there is either an actual reversal in the progressive changes of relative intensities, as for the 002 plane, or there is an abrupt change in their rate, as for the 121 plane.

Using the structure factor formula[14] for lead chloride and lead bromide, the intensities for the above 11 reflections were calculated for lead chloride, lead bromide and the three possible forms at the 50 mole % composition: namely, the form in which there is random replacement of Cl′ and Cl″ by Br′ and Br″ and the two forms in which there is preferential replacement, $PbCl'Br''$ and $PbBr'Cl''$. The calculated intensities and the experimental relative intensities are given in Table XI. The calculated intensity values for the "ordered" form, $PbCl'Br''$, fit the trend of the experimental relative intensities at the 50 mole % composition better than either the "ordered" form $PbBr'Cl''$, or the random form. This is true for each of the planes calculated except the 113 and 032 planes where the calculated intensities for the three forms are nearly the same. It is interesting to note that the sum of the calculated intensities for the 212 and 114 planes of the "ordered" form, $PbCl'Br''$, is in good agreement with the trend of the observed relative intensity for the 212, 114 plane (not resolved) at the 50 mole % composition. The results of the intensity study thus support the theory that a preferential-replacement structure occurs at the 50 mole % composition and indicate that it is $PbCl'Br''$. Thus, the line-shift and intensity data both indicate that the "ordered" form is a "compound"

(14) "Internationale Tabellen zur Bestimmung von Kristallstrukturen," Vol. I, rev. ed., The Chemical Catalog Co., New York, N. Y., 1944, p. 138.

stable at room temperature, isomorphic with lead chloride and lead bromide and forming a complete series of solid solutions with both pure components.

Discussion

The present thorough study of the lead chloride–lead bromide system shows it to be a somewhat unique salt system, containing an "ordered" structure at the 50 mole % composition, stable at room temperature. Since the lattices of the two isomorphous components possess two sets of halogen positions with different space volumes, the opportunity arises for the formation of a unique type of ordering as one halogen is replaced by the other in such a way as to cause the least dimensional change in the lattice. Consequently, as bromine is substituted for chlorine in the lead chloride lattice, it preferentially replaces the chlorine from the more spacious Cl″ positions until these are completely replaced, forming a continuous series of solid solutions culminating in the formation of the "ordered" structure, PbCl′Br″. Upon further substitution of bromine for chlorine, the less spacious Cl′ positions are occupied, and this forms another continuous series of solid solutions ending with lead bromide. In this second series, the rate of expansion of the unit cell with change in composition is necessarily greater than in the first series of solid solutions. This interpretation not only accounts for the discontinuities observed in the lattice constants–composition relationships for the system, but it has also been shown to account for the discontinuities observed in the relative intensities–composition data.

If the structure PbCl′Br″ were a compound which was at all stable in the range of temperatures defined by the thermal diagram of the system, one would expect the liquidus and solidus curves to approach or meet at the 50 mole % composition, as in the bromine–iodine system.[15] Since this is not the case (Fig. 2), it is clear that PbCl′Br″ does not exist as a compound in this temperature range. For this reason, the preferential-replacement structure may be considered a borderline compound which is stable only at lower temperatures.

The fact that no transition temperature was observed, even in the annealing and slow-cooling of the 50 mole % composition may be due either to the fact that the heat of transition is too small for detection with the present method, or to the fact that the transition occurs over a range of temperatures.[16] Furthermore, two samples of 50 mole % composition which were quenched from the solidus temperature, where they had been held for an hour, to that of a Dry-Ice–chloroform bath, showed no measurable degree of randomness at room temperature. If the transition to the preferential-replacement structure does not occur in the temperature–composition region immediately below the solidus curve for the system, it occurs rapidly and completely at lower temperatures, since the X-ray diffraction characteristics of any solid solution of this system appear to be independent of sample history.

The results obtained in the attempted preparation of solid solutions of lead chloride and lead bromide of predetermined composition by precipitation from solutions containing excess hydrochloric and hydrobromic acid, and those of G. Meyer on the lead chloride–lead bromide–water system, demonstrated the definite tendency of the 50 mole % composition to crystallize out, which appears to further support the existence of the "ordered" structure PbCl′Br″ as a borderline compound.

The results and conclusions of the present study are completely at variance with those reported by Delgery for this system.[2] Furthermore, we are unable to account for the striking differences which exist between her thermal analysis and those of other investigators[3] (Fig. 1), including the present one (Fig. 2). Based on her thermal analysis, Delgery claimed the existence of a high-temperature stable compound, PbClBr, and a peritectic compound, $PbBr_2 \cdot 3PbCl_2$, both of which Thomas[4] had previously claimed to prepare. Thomas' preparation of the first composition by heating PbClI in a current of bromine is obviously no evidence for a compound, and we were unable to confirm his preparation of the second. Likewise, we are unable to account for the striking differences which exist between Delgery's conductivities for this system and our own (Fig. 4). We have shown that hydrolysis does not account for the unexpected variations in conductivity which she reported; neither would the possible presence of excess solid phase in her lead chloride–lead bromide solutions, since the system possesses only one minimum in solubility. All her conductivity-composition curves for solutions of binary lead halide systems show sharp conductivity maxima, of a type never observed before, and not readily interpretable on the basis of accepted theories. It is also noteworthy that these maxima are reported at compositions which were precisely the same as those of compounds which she had initially observed or was able to confirm afterward by thermal analysis.

Acknowledgment.—It is a pleasure to acknowledge the assistance of Loren M. Knowles in making the thermal runs and completing several aqueous preparations, and of Gordon E. Noakes and Berol L. Robinson in securing X-ray diffraction data. We are also indebted to Profs. Lewis S. Ramsdel and A. L. Ferguson, University of Michigan, respectively for valuable suggestions in the interpretation of the X-ray diffraction data and for making electrochemical equipment available for the conductometric studies.

Summary

The lead chloride–lead bromide system has been studied by means of thermal analysis, conductivity, aqueous preparations and X-ray diffraction. No binary compounds exist in this system other than the preferential-replacement structure, PbCl′Br″, whose existence was demonstrated by the X-ray diffraction data. This "ordered" structure is stable at room temperature but not at the melting point, is isomorphous with lead chloride and lead bromide, and forms a complete series of solid solutions with both.

Vapor Pressures of Phlegmatic Liquids. I. Simple and Mixed Triglycerides[1]

BY E. S. PERRY, W. H. WEBER AND B. F. DAUBERT[2]

The vapor pressure measurements of phlegmatic[3] liquids, such as the triglycerides, require a method which imposes a minimum of thermal hazard to the substance under examination. Of the available methods capable of accommodating materials of this kind, the static method of Hickman, Hecker and Embree[4] employing the pendulum tensimeter appeared to be more promising than the dynamic methods proposed by Verhoek and Marshall[5] and Kapff and Jacobs.[6] In application, the dynamic methods have been limited to the vapor pressure measurements of plasticizer-type esters in the range of 10^{-2} to 10^{-4} mm. at 40 to 160°. The pendulum-tensimeter method, however, has been used with substances of lower volatilities which have perhaps even less thermal stability than the ester materials, such as, for example, 1,4-dipropyldiaminoanthraquinone. In addition, the method gives absolute pressure measurements in that the pressure of the vapor is measured directly as a force per unit area. In contrast to the dynamic methods, therefore, the results are independent of the theoretical equations of the kinetic theory and errors introduced by inaccuracies in accommodation coefficients are obviated. For these reasons the pendulum-tensimeter method seemed most generally applicable for the measurements reported below. In the present paper are presented the vapor pressures for a large number of triglycerides, including all of those having an even number of carbon atoms in the acid radical from tributyrin to tristearin; for mixed triglycerides, both saturated and unsaturated; and for several fractionated natural fats. In a subsequent paper[7] there will be presented the vapor pressures of a number of high molecular weight esters of the plasticizer and diffusion pump fluid types.

The theory for the pendulum-tensimeter method has been reported by the original authors,[4] therefore only the final equations will be reproduced here for convenience. The vapor pressure P is calculated from the effective weight of the pendulum M, the area of the orifice A, and the angular displacement θ, according to the relationship: $P = M/A \times \sin \theta$. For our specific apparatus the vapor pressure in mm. mercury is: $P = 1.075/8.96 \times 13.6 \times 10 \times \sin \theta = 0.0882 \times \sin \theta$.

Experimental

Apparatus.—A pendulum-tensimeter similar to that of Hickman, Hecker and Embree,[4] but incorporating the orifice heater recommended by Verhoek and Marshall,[5] was used. A small liquid trap was added to the reflux line to prevent loss of vapor from the boiler. The usual oil-bath was replaced by an air-bath so that the temperature range could be extended. This consisted of an aluminum box approximately 9″ × 9″ × 5″, lagged with asbestos paper. The first air-bath contained a single heater element wound in a flat coil and mounted just off the floor of the box. The heater was shielded and baffled to prevent irregular heating by radiation. Heat distribution in the box was examined by placing 8 thermometers at various points and recording the temperatures of each as the heat was progressively increased to 300°. A satisfactory heat distribution was not obtained by this method regardless of the baffle used and it was finally discarded in favor of one which responded better to the test. The new heater element consisted of a glass rod frame on which was wound asbestos-covered resistance wire equivalent to 1000 watts. The glass frame was cubical in shape and dimensioned so as to leave a half-inch space between it and the walls of the box on all sides. Resistance wire was wound evenly on all 12 rods of the frame. Power was controlled by a variable transformer. Air temperatures measured at various points in the box by means of thermometers as discussed above showed that the total disparity in temperatures was not over 2°. The bath was therefore used as such without any further attempts to better distribute the heat.

The aluminum box with heating element hung from a yoke which straddled the tensimeter and was supported so that it could rotate with the tensimeter. Two Pyrex windows were provided for better illumination and direct observation of the pendulum at the orifice. One window was located on the front wall of the box and the other on the rear wall. The use of the air-bath greatly facilitated the observation of the equilibrium point of the pendulum and thereby increased the reproducibility of the readings. It also extended the effective temperature range to well over 300°.

While collecting data, temperature measurements were made with a well-thermometer which protruded into the

boiler and dipped below the surface of the liquid when the usual charge of 20–30 g. of material was used. With smaller charges of 3 to 10 g., the well was slightly above the liquid surface. However, the stem was entirely within the air-bath and the temperatures of the well-thermometer were in agreement with other calibrated thermometers located in the immediate vicinity, although outside of the well. The temperature of the oil layer in the boiler was thus assumed to be at the temperature of the bath.

Materials.—Most of the simple triglycerides were obtained from the Eastman Kodak Company. The mixed triglycerides, tricaprylin and tricaprin, were synthesized and purified at the University of Pittsburgh.[8,9] The simple triglycerides were further purified by molecular distillation and in some cases the distillation was preceded by a recrystallization from solvents. Because the amounts of the mixed triglycerides available were so small, purification had to be limited to recrystallization only. Distillation in the cyclic molecular still consisted of removing three strip cuts, the first of which amounted to 5% of the original charge and the others 10% each. The 2 succeeding 25% fractions were used for the vapor pressure measurements. The natural fats were also prepared by molecular distillation. The olive oil was an imported U. S. P. grade packaged by Magnus, Mabee and Reynard, Inc. Castor oil from several sources was used; two were refined commercial grades and the third was a U. S. P. grade. The corn and soybean oils were refined commercial products. In all cases, the original oil was first distilled into four equal fractions. The two middle fractions were again molecularly distilled, first removing a 25% strip cut and then collecting the succeeding 50% for examination in the tensimeter.

Melting points for most of the triglycerides used are given in Table I.

Procedure.—Most details of the procedure were similar to those recommended by the original authors.[4] Readings were taken after the temperature had reached and maintained a constant value for at least three minutes. Best results were obtained by adjusting the pendulum until it just appeared to float on the vapor, not quite touching the orifice. When sufficient sample was available, a 20- to 30-g. portion was used. With the mixed triglycerides where only limited amounts of material were available, the measurements were made with as little as 3 g. of sample. When using the smaller samples it was necessary to make the readings rapidly so that the material would not all evaporate before the desired temperature range was covered. It was found that results obtained by taking measurements while the temperature rose at the rate of 0.5 to 1° per minute were as good as those taken after the three-minute equilibrating period. This can be verified by an inspection of the results plotted in the figures of the next section. Measurements with all mixed triglycerides were done using this method of temperature increase. Individual temperature readings were taken to 0.5° values. More accurate measurements were not warranted in view of the reproducibility obtained as shown in Figs. 1 to 5.

Results and Discussion

The experimental data for the measurement of all the triglycerides are plotted in Figs. 1 to 5 on the usual log P *vs.* $1/T$ chart. The temperature data given in Table I are not necessarily determined points. These are the temperatures at which the straight lines drawn through the experimental points for each triglyceride intersect the 1- and 50-μ pressure values. This method of listing data was chosen merely as a convenience for permitting accurate reproduction of the vapor pressure curves and thus obviating the necessity of tabulating all of the experimental data in this report. The accuracy of the data, however, can be seen from the curves. In most every case the individual temperature measurements lie on a straight line, with deviations usually not greater than 2° from the line, and in many cases 1°. Data resulting from several independent sets of measurements with the same sample showed that the reproducibility of the curve was within 1°. A 1° variation in the slope of the line corresponds

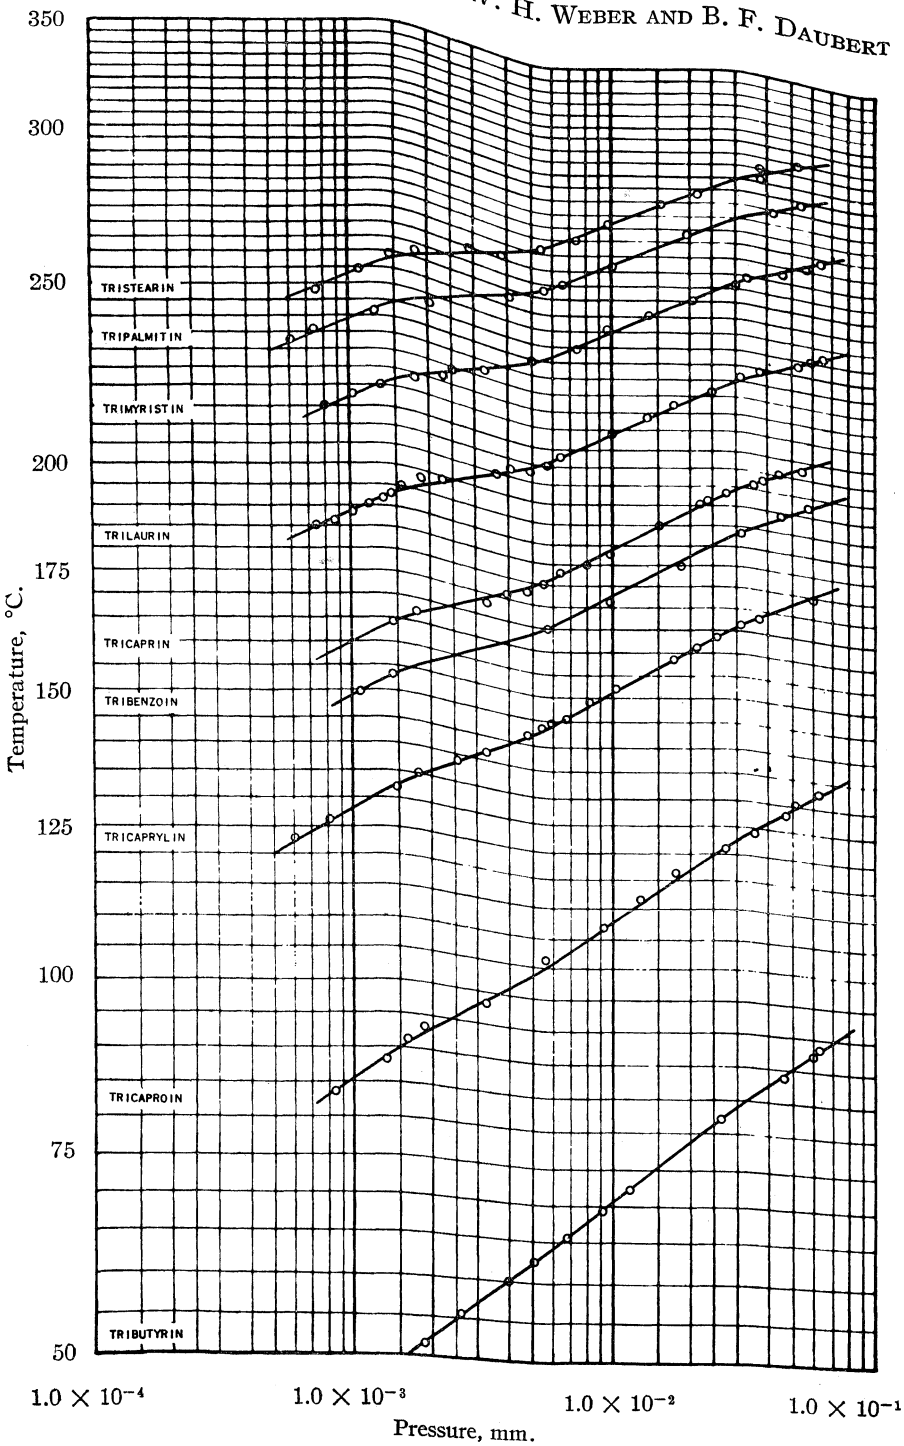

Fig. 1.—Experimental vapor pressure data.

to about a 2% change in the latent heats of vaporizations.

The curves connecting the points for each triglyceride can be expressed by the general equation: $\log P = -A/T + B$, where A represents the slope of the line and B is the y-intercept. These constants have been calculated for each material using the temperatures corresponding to pressures at 50 and 1 μ. The values are recorded in Table I. The latent heats of vaporization L in cal./mole are related to A as follows: $A = L/2.3R$, where R is the universal gas constant. The latent heats for each material have been calculated and are given in column 6 of Table I.

It will be noticed that the slopes of the curves for all triglycerides show a gradual increase as the number of carbon atoms in the acid chain increase. The degree of linearity obtained between latent heats of vaporization and molecular weight is shown by the plot of Fig. 6 in which the computed latent heats for the triglycerides are plotted against the total number of carbon atoms of the fatty acid side-chains. The points on the curve are numbered in accordance with the listing of Table I for the purpose of reference to the triglyceride in question. The adherence to straight line agreement is only fair but the general trend is clearly shown. Tribenzoin (point 4), containing 7 carbon atoms per acid group, 6 of which form an aromatic ring, shows a definite departure from the curve. This is not unexpected since it is known that aromatic groupings usually have lower vapor pressures than do the same number of carbon atoms arranged in open-chains. The vapor pressure–temperature relationship of tribenzoin lies between that for tricaprylin and tricaprin, perhaps being very close to that for an aliphatic triglyceride having 9 carbons in the acid chains.

The vapor pressure curves for the mixed triglycerides are given in Figs. 2, 3 and 4, according to the sequence of the acid groupings in each molecule. These data indicate that the vapor pressure appears to be independent of the group

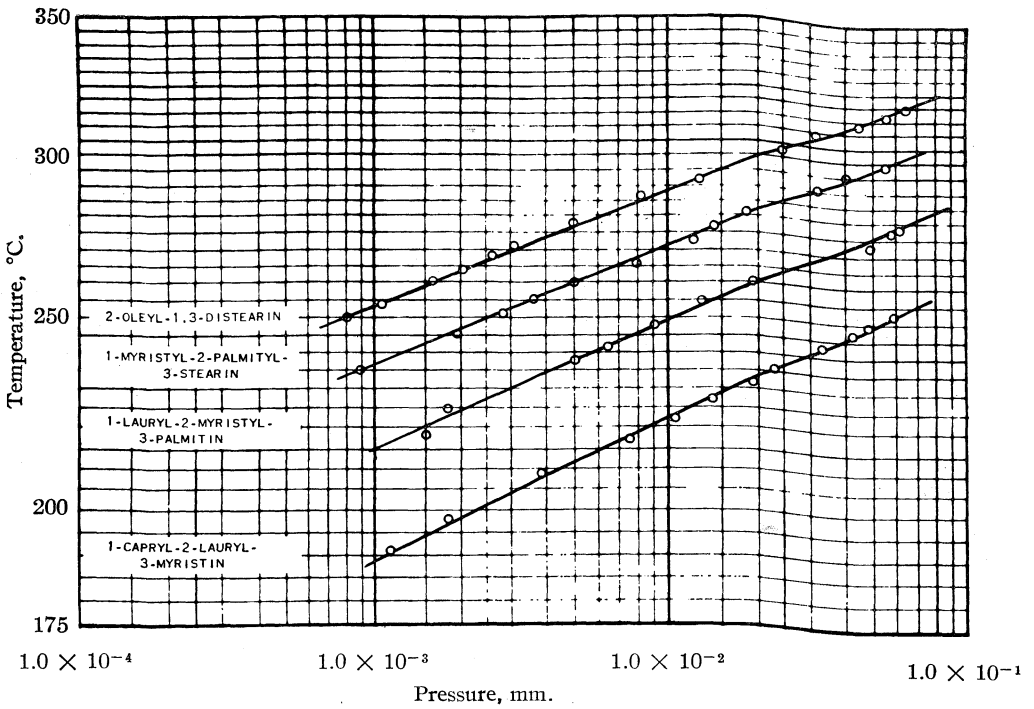

Fig. 2.—Experimental vapor pressure data.

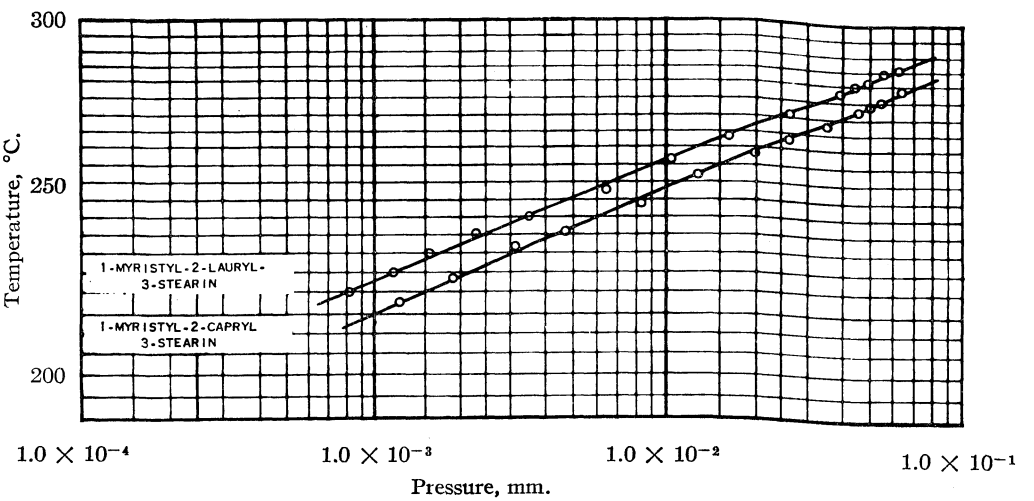

Fig. 3.—Experimental vapor pressure data.

arrangement and the individual chain-length of the acid groups. The principal influence is, perhaps, the total number of carbons in the molecule. For example, the three compounds: trimyristin, 1-lauryl-2-myristyl-3-palmitin and 1-myristyl-2-capryl, 3-stearin—all of which have a total of 42 carbon atoms in the acid groups—have comparable latent heats, as shown by the coincidence of points 7, 11 and 14 of Fig. 6. Likewise, the latent heat for tripalmitin is comparable to that for 1-myristyl-2-palmityl-3-stearin—points 8 and 12. Other correlations of this kind are evident from Fig. 6 or Table I. The effect of one double bond per triglyceride molecule has very little, if any, influence on the vapor pressure, as is shown by comparison of results for 2-oleyl-1,3-distearin with tristearin. The vapor pressure values for tristearin are very slightly higher than those for the oleyl distearin which, if significant, is at variance with the relative order of vapor pressures as would be deduced from boiling point data of saturated compounds and their unsaturated analogs. From the distillation of mixtures of quite pure methyl oleate and methyl stearate, Weitkampf and Brunstrun[10] have shown

(10) Weitkampf and Brunstrun, *Oil and Soap*, **18**, 47 (1941).

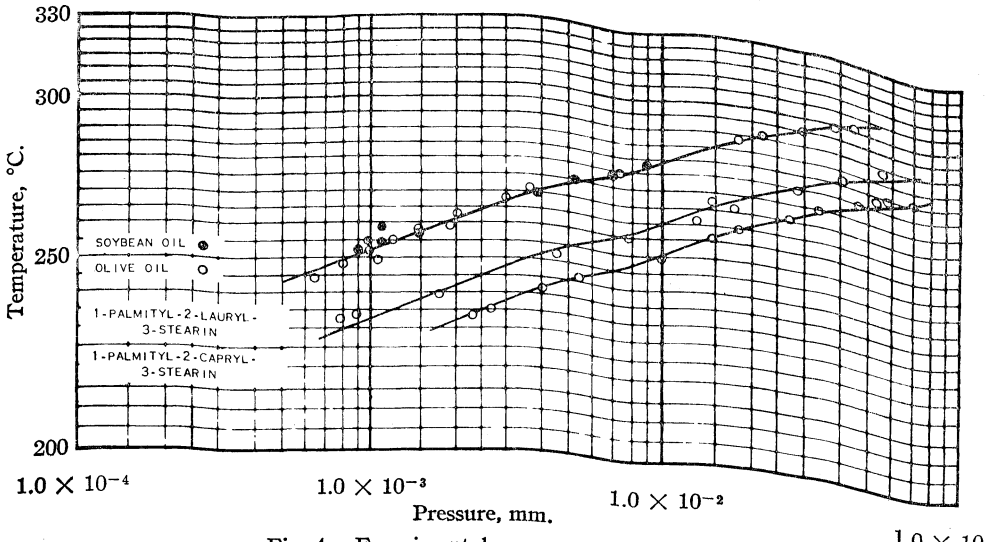

Fig. 4.—Experimental vapor pressure data.

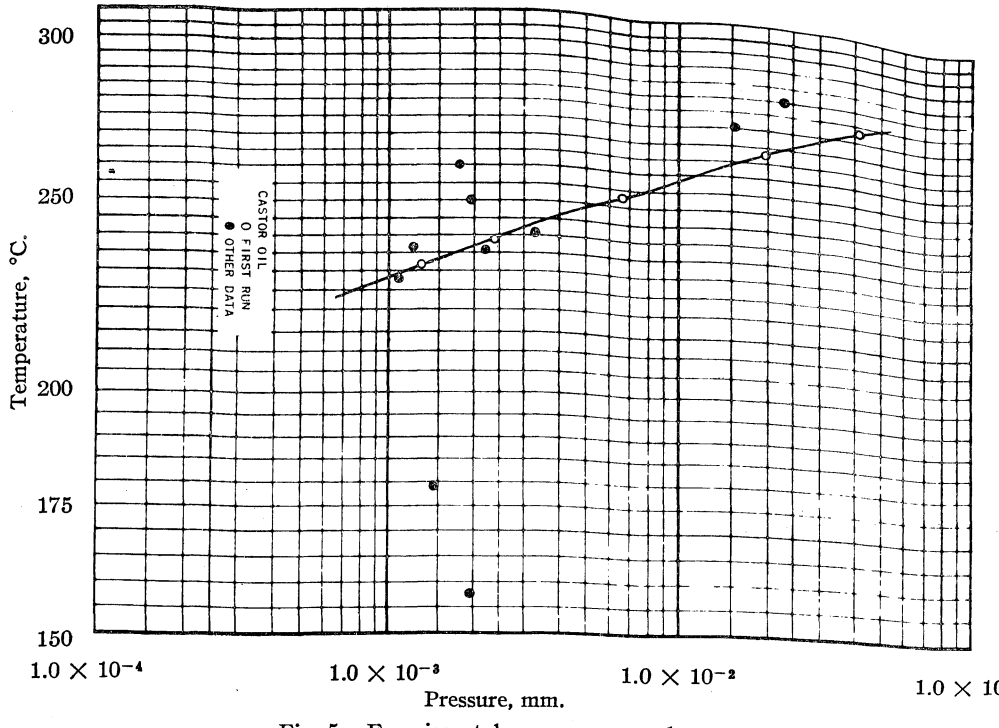

Fig. 5.—Experimental vapor pressure data.

that the boiling points of the unsaturated acids appear to be perhaps 2 to 3° lower than those of the corresponding saturated acids. The more recent work of Norris and Terry[11] shows conclusively that the vapor pressures of the methyl ester of fatty acid of equal carbon atoms increase with increasing unsaturation. For example, the vapor pressure of methyl stearate is lower than that of its unsaturated analog, methyl oleate, and the latter, in turn, is lower than that of methyl linoleate. It would be expected, therefore, that the vapor pressure of tristearin should be lower than that of the oleyl distearin. The influence of only one double bond in the large oleyl distearin molecule may not be as effective in altering its vapor pressure as one double bond would be in a smaller molecule like the fatty acid molecule.

The attempt to determine the effect of additional unsaturation on vapor pressure was not successful with synthetic triglycerides owing to the abnormal behavior encountered with triolein and its *trans*-isomer, trielaidin, in the tensimeter. Although synthesized and purified by the

(11) Norris and Terry, *Oil and Soap*, **22**, 41 (1945).

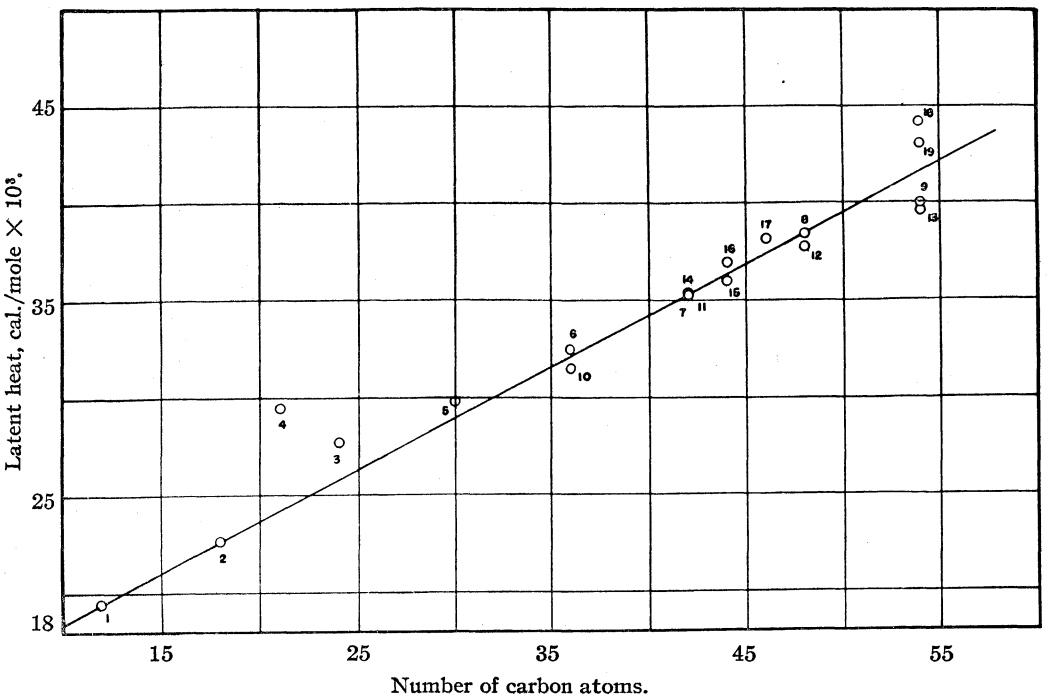

Fig. 6.—Relationship between molecular weights and latent heats.

same general methods used for the other triglycerides, these substances appeared to decompose in the tensimeter. The data followed no general trend and variations of 25 to 50° at one temperature were not uncommon. This was indeed surprising because of the known thermal stability of triolein in regard to its distillability. Since similar results were obtained from three individual preparations it appeared that the difficulty could be inherent in this type of triglyceride.

Of interest, however, is the fact that distilled olive oil responds normally to measurement by the method. Although the principal fatty acid constituent of this fat is oleic acid which makes it very similar to triolein, good reproducible vapor pressure data can be obtained with it by the tensimeter method. The pressure–temperature relationship for olive oil is plotted in Fig. 4. The regularity with which the points fall on a straight line is not only evidence of the accuracy of the data but shows that the olive oil triglycerides sustain the treatment of the tensimeter and hereby differ from the behavior of the synthetic triolein or trielaidin. The vapor pressures for olive oil are higher than those for tristearin which, on the basis of its unsaturation, is in agreement with the results of Norris and Terry.[11]

There was cause to surmise from these results that perhaps the olive oil fractions contained a natural inhibitor which protects it. Olive oil, however, is known to contain only minute quantities of tocopherols, its natural stability being due to the high percentage of stable fatty acids, such as oleic, which comprise its structure. The fractionation in the molecular still, in addition, would have completely removed any tocopherols from the fractions tested. In spite of these facts, an experiment was undertaken in which 25 mg. of tocopherols was added to 6 g. of the synthetic triolein in hopes of arresting the undesirable reactions taking place in the tensimeter. The presence of the tocopherols, however, made no improvement over the previous results.

The vapor pressures obtained with the fractionated soybean oil are also plotted in Fig. 4. The data fall on a straight line which, within experimental limits, follows the course of the olive oil line and thereby exhibits identical vapor pressures. The greater degree of unsaturation which exists in soybean oil, however, is not manifested in showing higher vapor pressures for this fat over the more saturated olive oil, which would be expected. When compared to tristearin, the two lines are not parallel but cross at the lower range and diverge 5° at 50 μ. Tristearin, in general, has lower vapor pressures over this range than soybean oil, but not of the order which would be expected from the differences in saturation. Perhaps these differences expected from pure substances are minimized in natural material where the molecules are heterogeneous combinations of many related constituents such as the number of different triglycerides which can exist in a natural fat.

Abnormal behavior was encountered with castor oil. The first experiments with a commerical grade of castor oil of unknown origin

labeled "Stripped" gave results which fell with good regularity on a straight line, as shown in Fig. 5. The position of the line, however, was some 25° below that for soybean oil or tristearin which did not seem reasonable in view of the structure of the castor oil molecule. Assuming that the sample used had received some unknown treatment either by the refiner or in stripping, several other samples were tried. A commercial grade of refined oil (Baker Castor Oil Co.) having acetyl values of 146.5 and 146.3 before and after distillation, respectively, gave very erratic results which extended over an abnormal temperature range, as can be seen from the plot in Fig. 5. After treatment in the tensimeter, the acetyl value was found to be 143 ± 2%, the uncertainty being due to errors introduced because of the small sample available for analysis. The degree of dehydration, however, seemed small to account for the large disparity in the data. Other undesirable reactions must occur, although the fact that the greatest variations are at the lower temperatures makes it difficult to offer an explanation on the basis of thermal effects. The examination of two other samples of castor oil, one a U.S.P. product and the other a refined grade, yielded similar results.

It was not possible to get data when using corn oil because of the tendency of the pendulum to stick to the orifice. Apparently the corn oil polymerized too rapidly to be successfully handled in the tensimeter and that oil which reached the orifice was sufficiently tacky to cause the diaphragm of the pendulum to stick. The orifice heater aggravated this condition perhaps by even further overheating the oil. After several attempts to collect data with fresh samples of corn oil, these measurements were abandoned.

The constants for Dühring's rule[12] for the triglycerides have been determined and are listed in the last column of Table I. The constants were computed from the absolute temperatures at the 2 pressures, 50 μ and 1 μ for contiguous members of the series in the order listed in Table I. The constant as determined is the ratio of the absolute temperature difference for one triglyceride at 2 pressures to that for the other triglyceride at the same 2 pressure values. Expressed more precisely, the relationship has the following form: $T'_A - T_A/T'_B - T_B$ = constant, where $(T'_A - T_A)$ equals the absolute temperature of one triglyceride at 50 and 1 μ, respectively, and $(T'_B - T_B)$ equals the corresponding temperatures for the other triglycerides. The Dühring constant is calculated from the temperature data of the indicated material with that of the material next lower in the list. For example, the value 0.920 is the ratio of the difference of the two temperatures for tributyrin to that for tricaproin. The constancy of this quantity is good over the entire series investigated, as can be noted from the computed values in Table I.

Summary

The vapor pressure–temperature relationships for 9 simple triglycerides, 10 mixed triglycerides and 4 natural fats have been determined by the pendulum-tensimeter method. In most every instance a straight-line relationship between temperature and pressure was obtained. Abnormal behavior with 2 unsaturated synthetic triglycerides and 2 natural fats was encountered. Latent heats of vaporizations for each material are calculated, and constants for Dühring's rule are also computed.

Vapor Pressures of Phlegmatic Liquids. II. High Molecular Weight Esters and Silicone Oils[1]

BY E. S. PERRY AND W. H. WEBER

The vapor pressures of a number of simple and mixed triglycerides have been reported in a previous paper.[2] At the time of these measurements there was available in this Laboratory a number of molecularly distilled phthalate and sebacate esters whose pressure–temperature relationships could be determined by the pendulum–tensimeter method.[3] A knowledge of the vapor pressures of this class of materials is of importance in certain aspects of their use as plasticizers and vacuum pump fluids. Therefore, the determination of their vapor pressures seemed advisable and worthy of publication.

The pressure–temperature curves for a few of these esters, particularly dibutyl phthalate, di-2-ethylhexyl phthalate, and di-2-ethylhexyl sebacate, have been obtained by others[3,4,5,5a] using both

(1) Communication No. 152 from Laboratories of Distillation Products, Inc.

(2) Perry, Weber and Daubert, THIS JOURNAL, **71**, 3720 (1949).

(3) Hickman, Hecker and Embree, *Ind. Eng. Chem.*, **9**, 264 (1937).

(4) Verhoek and Marshall, THIS JOURNAL, **61**, 2737 (1939).

(5) Kapff and Jacobs, *Rev. Sci. Instruments*, **18**, 581 (1947).

(5a) A recent publication on this subject by Small, Small and Cowley, *Trans. Faraday Soc.* (London), **44**, 810 (1948), has come to the authors' attention since the original manuscript of this paper was submitted for publication. Their dynamic method gave results which are in closer agreement than previously published results (from dynamic methods) to those of the present paper.

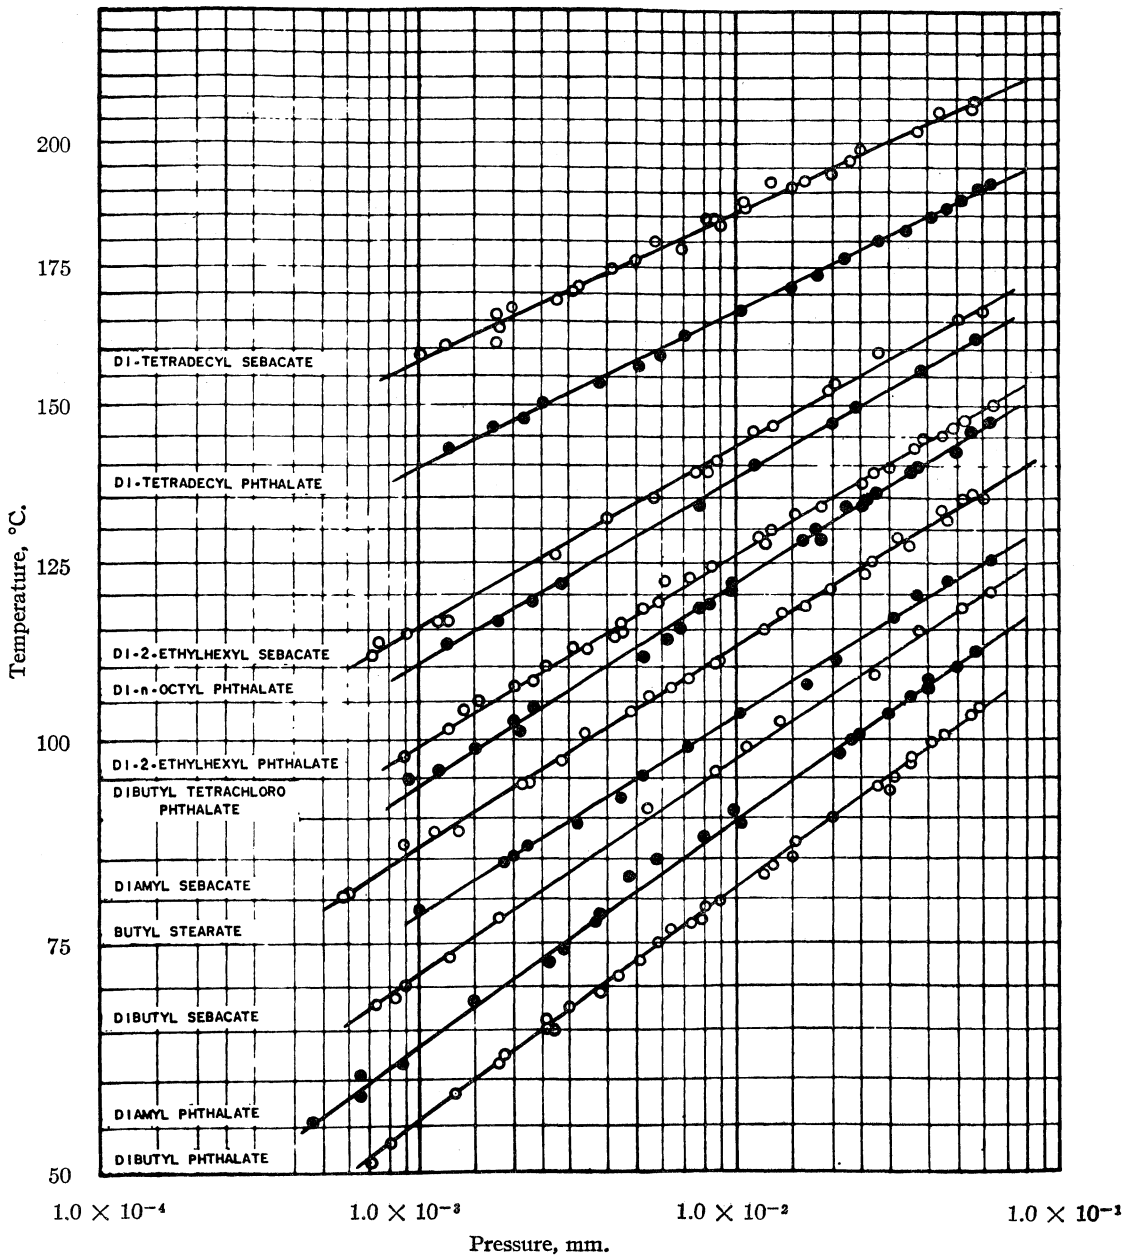

Fig. 1.—Experimental vapor pressure data.

the static pendulum-tensimeter method and dynamic methods. The agreement, however, between the methods of Verhoek and Marshall[4] and the pendulum tensimeter has been much better than that between the pendulum tensimeter and the dew-point method of Kapff and Jacobs.[5] The present results substantiate this point and definitely indicate that the dew-point method yields higher values.

In the present paper are reported the vapor pressure curves for fourteen esters, including new data for the three esters mentioned above, and for two commercial silicone fluids.

Experimental

The apparatus and procedure were identical to that described in the first paper.[2] One variation in the procedure was made in an attempt to increase the accuracy of the readings. Since these esters are fluids at room temperature, the return of the condensate to the boiler causes no difficulties. Consequently, a longer time for the establishment of equilibrium at each temperature was permissible. In spite of the additional time, the readings showed no better consistency over the methods used with the triglycerides.

The phthalates and sebacates of di-*n*-butyl, di-*n*-amyl and di-2-ethylhexyl alcohols were obtained from vacuum pump fluid stocks of Distillation Products, Inc. Di-*n*-octyl phthalate, di-*n*-tetradecyl phthalate and di-*n*-tetradecyl sebacate were synthesized in this Laboratory.

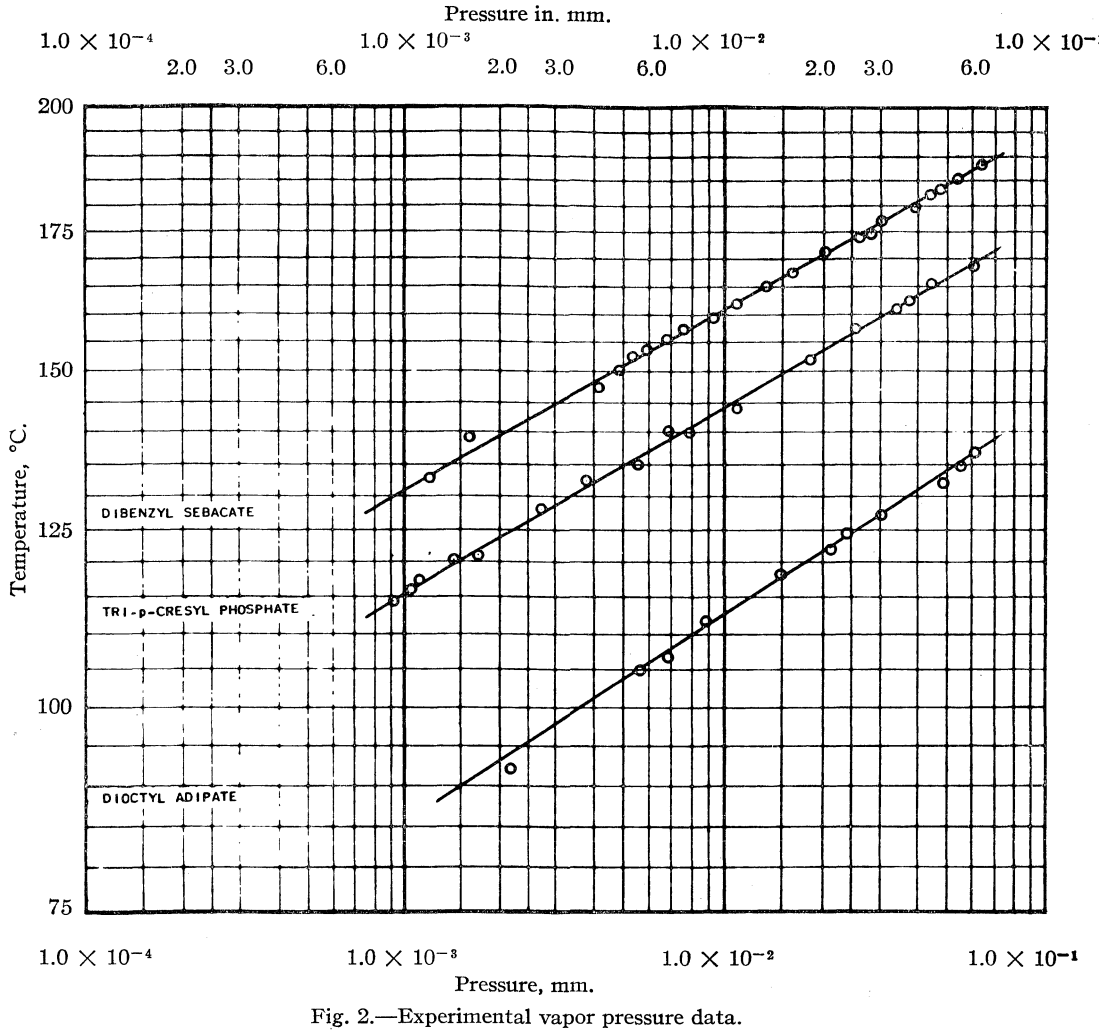

Fig. 2.—Experimental vapor pressure data.

The esterification was carried out in xylene using *p*-toluenesulfonic acid as catalyst. The tri-*p*-cresyl phosphate was a white-label quality product purchased from Eastman Kodak Company. The dibenzyl sebacate was obtained from Resinous Products and Chemical Company. The butyl stearate was a commercial-grade plasticizer sold by Commercial Solvents Corporation. The dibutyl tetrachlorophthalate was an experimental ester furnished by Commercial Solvents Corporation to whom we are grateful for the sample and permission to publish the results. The authors are indebted to the Pigments Department of E. I. du Pont de Nemours and Company, Inc., for supplying the samples of dioctyl adipate used in the measurements.

Regardless of the source or purity of these materials, each one was distilled in the cyclic molecular still before being used for the vapor pressure determinations. This consisted of removing 3 strip cuts which totaled 25% of the original charge. The 2 succeeding 25% fractions were used for the measurements. Dibenzyl sebacate, however, was first fractionated in a laboratory column equivalent to 6 theoretical plates. The distillate was then redistilled in the molecular still, as described above, to ensure complete removal of volatile constituents, if any, which could have been formed during the fractionation at the higher pressures. All of the esters were water-white with the exception of the dibutyl tetrachlorophthalate. Its amber color persisted even after treatment with a contact bleaching agent.

The silicone oils are commercial vacuum pump fluids made by the Dow Corning Corporation. These were used *per se* without the additional purification because distillation would alter their vapor pressure characteristics by removing the lower-boiling constituents. The exact nature of these fluids is not known, of course, but they are perhaps methyl and phenyl substituted polysiloxanes.

Results and Discussion

The experimental results of pressures and temperatures are plotted in Figs. 1, 2 and 3. The derived constants A and B for the Clausius–Clapeyron equation, $\log P = -A/T + B$, where $A = L/2.3R$, and the latent heats of vaporization L have been computed for each ester and are given in Table I. In all cases the experimental pressure–temperature values fall on a straight line with good regularity over the temperature range studied. There appears to be a rough linear relationship between decreasing vapor pressure and increasing molecular weights for all aliphatic esters with the exception of the chlorinated dibutyl phthalate. A plot of latent heats of vaporization as a function of the total number of carbon atoms in the alcohol side-chains for each

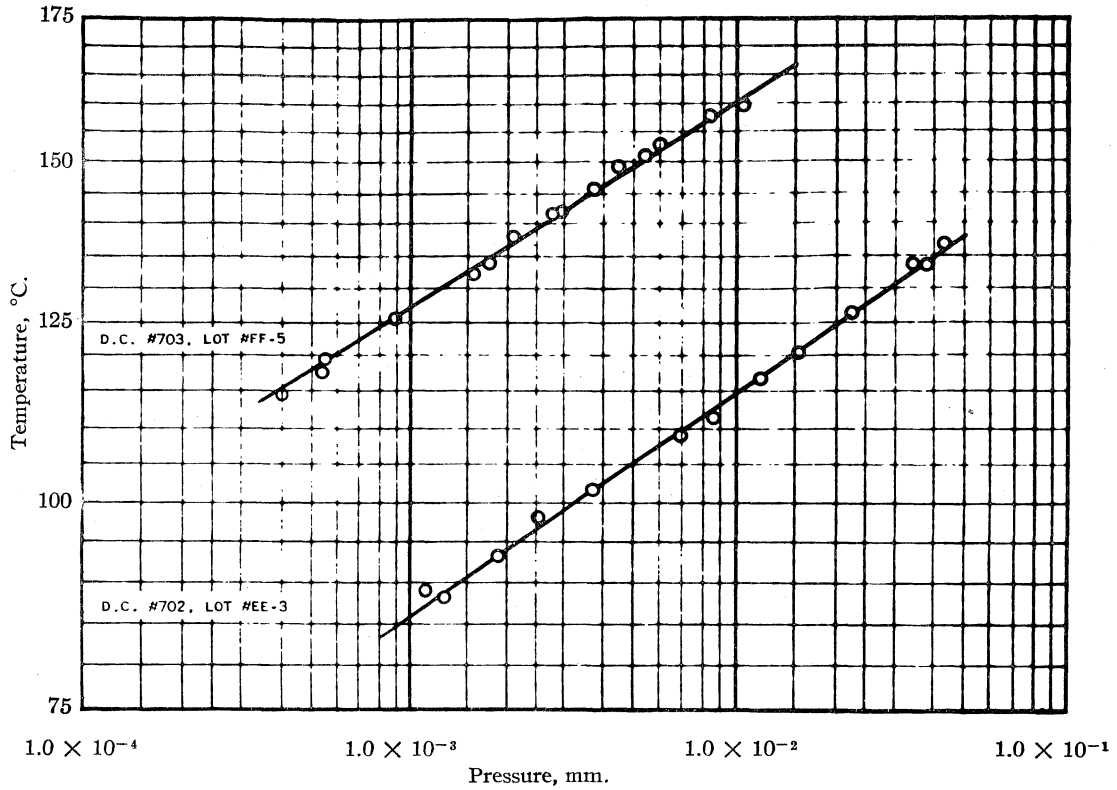

Fig. 3.—Experimental vapor pressure data.

of the phthalate and sebacate series also follows a nearly linear course, as shown in Fig. 4. The hollow circles are the points for the phthalate ester series and the solid dots represent the values for the sebacate esters. The number at each point is the order of listing of the esters in Table I. The depression of the vapor pressure by the aromatic nucleus in dibenzyl sebacate is clearly indicated in the figure. Likewise, the effect of the heavy chlorine atoms in lowering the vapor pressure of dibutyl tetrachlorophthalate over that of the parent dibutyl phthalate is evident. The lower vapor pressure of the normal octyl phthalate as compared to that for the isoöctyl phthalate is manifested in the disparity of the computed latent heats for these two isomeric esters. This is in agreement with the general behavior of aliphatic compounds in that the boiling point decreases with increased branching.

The constants for Dühring's rule, calculated as described in the previous paper,[2] are listed in Table II for each pair of adjacent members for both the phthalate and sebacate esters, excluding dibenzyl sebacate and dibutyl tetrachlorophthalate. The values of Table II are in good agreement with the theory for Dühring's rule.

The values of latent heats previously published for some of the esters are listed in Table I for comparison purposes. In every case the present values are lower than those published. Agreement is best between the values of this work and those of Hickman, Hecker and Embree[3] also using the pendulum tensimeter. Although somewhat higher, the values reported by Verhoek and Marshall[4,5a] are in consistent agreement with those of this report. The results of the dew-point method,[5] however, are considerably higher than those obtained by either of the other two methods. The results are not consistent over the range of esters studied and the values obtained for repeated determinations on the same material are at variance. For example, 2 values reported for

Amoil are 29,300 and 31,700, while 2 determinations on Amoil-S gave 29,300 and 28,700.

The latent heats of vaporization for the silicone fluids DC-702 and DC-703 are found to be much higher when calculated from present data than those reported in the commercial literature[6] of the manufacturer. Both sets of values are given in Table I. Boiling points at 10^{-2} mm. mercury for the 2 fluids taken from Fig. 3 are 115° for DC-702 and 160° for DC-703 as compared to 160 and 200°, respectively, reported in reference 6. A complete study of the vapor pressures of pure cyclic and linear methylpolysiloxanes has been made by Wilcock[7] but a comparison of his results with the present ones was not feasible because of the uncertainty of the structure of the commercial oils used in the present investigation.

(6) Dow Corning Silicone Notebook Fluid Series No. 2 issued July, 1946.

Summary

The vapor pressure–temperature relationships for five phthalate, five sebacate, 1 stearate, 1 adipate and 1 phosphate esters have been determined. Also 2 commercial silicone fluids have been examined. The latent heats of vaporization for each of these materials are computed and compared with previously published values. Constants for Dühring's rule are computed for each of the phthalate and sebacate series.

Polarographic Urea–Formaldehyde Kinetic Studies

BY GEORGE A. CROWE, JR.,[1] AND CECIL C. LYNCH

In a previous paper[2] we have shown polarographically the reaction between formaldehyde and urea to be reversible at 25° in 0.05 *N* lithium hydroxide. It seemed desirable to study the effects of change in temperature and *p*H on this reaction. Such a study is presented here.

Smythe[3] measured the urea–formaldehyde reaction rate in neutral solution between 30 and 60° and found that the reaction was bimolecular. (Crowe and Lynch[2] showed that the reaction was reversible in 0.05 *N* lithium hydroxide at 25°, and found that the reverse reaction was monomolecular.) Jahoda,[4,5] Bieber and Trümpler[6,7] and Vesely and Brdicka[7,8] observed that the electroreduction of formaldehyde at the dropping mercury electrode was very low at 25° in neutral solution. As the *p*H or temperature was increased, the rate of reduction was greatly increased. It was postulated[6,7,8] that formaldehyde was normally hydrated, and that the amount of electroreduction of formaldehyde was a measure of its dehydration rate; maximum dehydration was found to occur above 80°, or at *p*H 13.14 at 25°.[4,8]

The kinetic study described in this paper indicates that both dehydration of formaldehyde and the assumption of the formation of an anion of urea are necessary to account for the increase of urea–formaldehyde reaction rate with increase of *p*H. Increase of temperature probably affects the rate of dehydration of formaldehyde without markedly changing the rate of formation of this anion form of urea.

Experimental

The apparatus, chemicals and general technique were as described previously.[2] The supporting electrolytes consisted of 0.05 *N* lithium hydroxide (*p*H 12.7), 0.1 *M* sodium carbonate (*p*H 11.2), 0.1 *M* sodium bicarbonate (*p*H 8.7) and a buffer mixture of 0.05 *M* boric acid, 0.05 *M* lithium chloride and 0.045 *M* lithium hydroxide (*p*H 10.1). All reagents were C. P. Baker Analyzed except the lithium hydroxide which was Merck and Company lithium hydrate. The solutions were made up to twice the concentrations given above, and diluted with an equal volume of urea, formaldehyde or monomethylolurea solution to be tested.

Reaction rates for the reversible reaction of urea and formaldehyde to form monomethylolurea are given in Table I. The equilibrium constant appears to be constant within experimental error (±5% of the value determined) for changes of temperature and *p*H over the ranges tested.

TABLE I

RATES FOR THE REACTION $NH_2CONH_2 + HCHO \rightleftarrows NH_2CONHCH_2OH$, AND AVERAGE POLAROGRAPHIC CURRENT OF FORMALDEHYDE AT VARIOUS *p*H VALUES AND FOR VARIOUS TEMPERATURES

Temp., °C.	*p*H	k_f (sec.$^{-1}$)	k_r (sec.$^{-1}$)	*K* From reaction rates	*K* From equilibrium data	Av. pol. current of 0.00354 *M* formaldehyde, mma.
25	12.7	2.97×10^{-2}	1.45×10^{-3}	20	26	12.0
25	11.2	3.56×10^{-3}	6.04×10^{-5}	59	35	4.8
25	10.1	6.10×10^{-4}	1.75×10^{-5}	35	55	1.20
25	8.7	2.14×10^{-4}	1.38×10^{-5}	16	60	0.34
15	12.7	1.71×10^{-2}			18	5.97
20	12.7	2.67×10^{-2}			14	8.75
25	12.7	3.36×10^{-2}			30	12.0
25	12.7	2.97×10^{-2}	1.45×10^{-3}	20	26	12.0
30	12.7	9.80×10^{-2}			21	17.8
38	12.7	0.129			20	24.9
40	12.7	0.158			21	26.2

The average polarographic reduction current for formaldehyde with varying temperature and *p*H is also given in Table I. As can be seen from the table, for a given decrease in polarographic current, lowering the *p*H from 12.7 slows down the urea–formaldehyde reaction rate more than lowering the temperature. The amount of electroreduction of formaldehyde to methanol occurring at the dropping mercury electrode was about 0.2% of the formaldehyde in solution per hour, and occurred only when −1.65 volts or more was applied to the electrodes. Therefore the amount of reduction of formaldehyde was negligible in comparison to the amount involved in reaction with urea.

The change of the polarographic wave height of formaldehyde with temperature is shown for *p*H 8.7 and *p*H 12.7 in Fig. 1. The log of formaldehyde wave height is plotted *vs.* the reciprocal of the absolute temperature, as in an equation derived from the Arrhenius equation

$$\text{Log}\,\frac{i_2}{i_1} = \frac{\Delta E_{aa}}{2.303 \times 1.987}\left(\frac{1}{T_1} - \frac{1}{T_2}\right) \qquad (1)$$

where i_1 and i_2 are the formaldehyde wave heights for absolute temperatures T_1 and T_2, and ΔE_{aa} is the apparent energy of activation for the reduction of formaldehyde at the dropping mercury electrode. The lower, steeper slopes are limited by the rate of dehydration of formaldehyde; the upper, less steep slope is dependent only on the change of viscosity of the solution and the change of mercury mass and drop time with temperature.

(8) Vesely and Brdicka, *Coll. Czechoslov. Chem. Commun.*, **12**, 313 (1947).

The sum of the effects of change of viscosity, mercury mass and drop time would give an apparent activation energy of about 4000 cal. per mole, as compared to the upper slope of 3560 cal. per mole. This indicates that only free formaldehyde is present above 55° at *p*H 12.7, and above 81° at *p*H 8.7. This latter value is in agreement with the value of 80° found by Yahoda.[4]

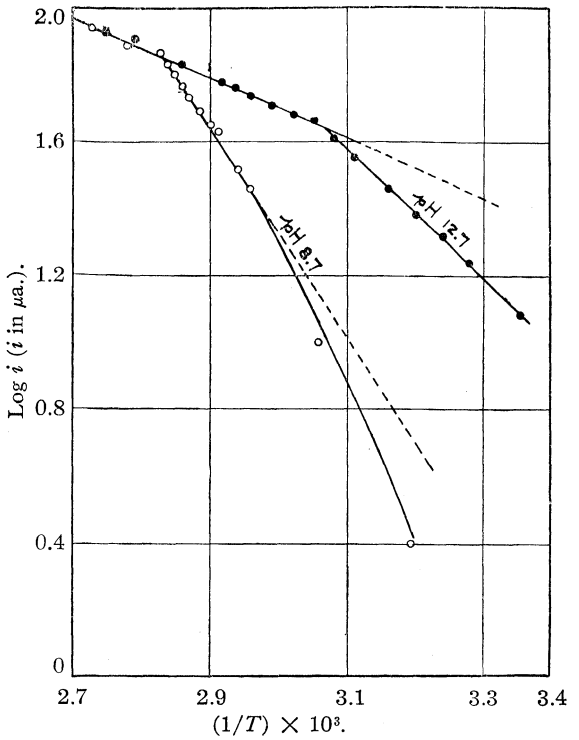

Fig. 1.—Formaldehyde dehydration with temperature.

The extent of dehydration of formaldehyde was estimated as the ratio of the actual formaldehyde wave height to the total dehydrated wave height from Fig. 1. At 25° the formaldehyde was found to be about 41% dehydrated at *p*H 12.7, and about 1.2% dehydrated at *p*H 8.7.

The forward urea–formaldehyde reaction rates were calculated with corrected formaldehyde values, and the same reaction rates were obtained as before, within experimental error. Since the extent of the reaction was small in evaluation of initial slopes, the values of the reaction rate constants obtained and the equilibrium constant should not differ significantly from the values given previously.[2] The results showed this to be true. It appeared impossible to calculate the observed effect of change in reaction rate with *p*H from the data included here, since not only does the concentration of formaldehyde in the reaction vary with *p*H, but also the concentration of the anion of urea appears to vary with *p*H.

For the change of urea–formaldehyde reaction rate with temperature in neutral solution, Smythe[3] found the energy of activation to be 14,700 cal./mole. Calculated by the Arrhenius equation from Table I, the effective energy of activation (ΔE_a) at *p*H 12.7 was 15,900 cal./mole, which is in agreement with Smythe within the limits of experimental error.

Equations were developed to relate the urea–formaldehyde reaction rate and the polarographic wave height of formaldehyde for changes of *p*H and temperature.

From the Arrhenius equation and equation (1), a relationship was found between urea–formaldehyde forward reaction rates (k_1 and k_2) at two temperatures and polarographic wave heights of formaldehyde (i_1 and i_2) at the same two temperatures, and at a constant *p*H.

$$\log \frac{k_2}{k_1} = \frac{\Delta E_a}{\Delta E_{aa}} \log \frac{i_2}{i_1} \qquad (2)$$

where ΔE_a was 15,900 cal./mole and ΔE_{aa} was 10,000 cal./mole for *p*H 12.7 over the range of 15 to 40°. Using these values, k_f was calculated from formaldehyde wave height, and at *p*H 12.7.

t, °C.	k_f (*p*H 12.7) Calcd.	Found
15	0.015	0.017
20	.028	.027
25	.045	.034
30	.085	.098
38	.14	.13
40	.16	.16

For changes of *p*H at a given temperature, the urea–formaldehyde forward reaction rate was calculated from the polarographic wave height of formaldehyde by the equation

$$k_f = iB/A(A - i) \qquad (3)$$

where k_f was the forward reaction rate, i the formaldehyde wave height, and A and B constants. Equation (3) was deduced from analogy to the second-order equation $kt = x/a(a - x)$ and consideration of the relative amount of formaldehyde available for either electroreduction or reaction with urea. From the values in Table I, at 25° with $A = 15$ and $B = 0.12$

*p*H	kt Calcd.	Found
12.7	0.032	0.030
11.2	.0038	.0036
10.1	.00070	.00061
8.7	.00019	.00021

Reverse reaction rates k_r can be calculated from the forward reaction rate k_f and the equilibrium constant K, where $K = k_f/k_r$.

The mechanism and reaction rate of the urea–formaldehyde reaction to form monomethylolurea appears to involve the dehydration of formaldehyde (the hydrated form, $H_2C(OH)_2$, does not react) and also the formation of an anion of urea. This anion is assumed to be a resonance structure

With changing *p*H, both urea and formaldehyde activation equilibria are shifted; whereas with changing temperature, the main change appears to be in the rate of dehydration of the formaldehyde. Thus for a given decrease of formaldehyde reduction current, the urea–formaldehyde reaction rate is affected more by changing the *p*H than changing the temperature, indicating that the amount of the anion of urea is affected by *p*H change more than by temperature change.

Summary

The effects of varying *p*H and temperature on the reversible reaction $HCHO + NH_2CONH_2 \rightleftarrows NH_2CONHCH_2OH$ have been studied, using the polarograph to measure formaldehyde concentration. Equations are presented to relate the urea–formaldehyde reaction rate to the polarographic current of formaldehyde for changes of *p*H or temperature.

The urea–formaldehyde reaction rate appears to be dependent both upon the rate of dehydration of formaldehyde and rate of anion formation of urea.

A method is given for estimating the fraction of dehydrated formaldehyde at various temperatures and *p*H values, based on polarographic wave heights of formaldehyde.

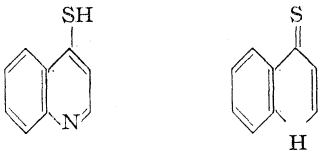
Ultraviolet and Infrared Spectra of Quinoline Derivatives: 2- and 4-Thiols

BY R. B. HANNAN, JR., J. H. LIEBLICH AND ALICE G. RENFREW

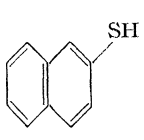
This investigation was undertaken in an attempt to determine the type of linkage between the sulfur atom and the quinoline nucleus in the substituted 2- and 4-quinolinethiols. Two structures are possible for these compounds: a thiol structure (A) and a thione structure (B).



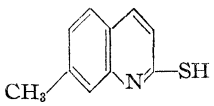
A B

(These may be in tautomeric equilibrium.) Ewing and Steck[1] have attacked the same problem in the hydroxyquinolines by the use of ultraviolet spectra, and it was hoped that their method would be successful with the sulfur analogs. The infrared spectra of these sulfur compounds have also been studied. Unfortunately neither approach has provided an answer to the problem. Since the data may be of some utility, the results will be described briefly.

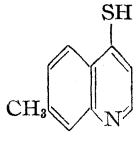
Ultraviolet and infrared absorption spectra of the following compounds are presented.



I
2-Naphthalenethiol

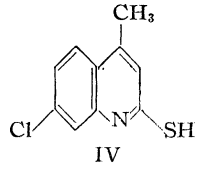


II
7-Methyl-2-quinolinethiol

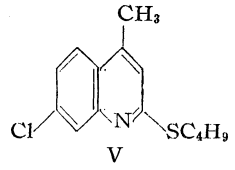


III
7-Methyl-4-quinolinethiol

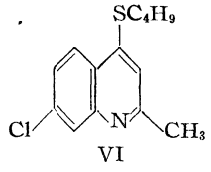
(1) Ewing and Steck, THIS JOURNAL, **68**, 2181 (1946); Steck, Ewing and Nachod, Abstracts, Washington Meeting, A. C. S., Sept. 1948, page 12L.



IV
7-Chloro-4-methyl-2-quinolinethiol



V
7-Chloro-4-methyl-2-*n*-butylthioquinoline



VI
7-Chloro-4-*n*-butylthio-2-methylquinoline

Few data for comparison are available in the literature. Morton and Stubbs[2] have reported the ultraviolet absorption spectra of 4-methyl-2-quinolinethiol and its ethers in neutral alcoholic solution only. Clinton and Suter[3] give spectrophotometric measurements for two 4-dialkylaminoalkyl sulfides of 7-chloroquinoline. The curve for 7-chloro-4-quinolylmercaptoacetic acid is given by Surrey.[4]

Experimental

The preparation and properties of the quinolinethiols (II, III and IV) have been reported by Renfrew.[5] The preparation of the two thioethers is described below.

7-Chloro-4-methyl-2-*n*-butylthioquinoline[6](V).—This sulfide was synthesized by the procedure described by

(2) Morton and Stubbs, *J. Chem. Soc.*, 1321 (1939).
(3) Clinton and Suter, THIS JOURNAL, **70**, 491 (1948).
(4) Surrey, *ibid.*, **70**, 2190 (1948).
(5) Renfrew, *ibid.*, **68**, 1433 (1946).
(6) Mrs. Pauline C. Piatt of the Department of Research in Pure Chemistry carried out much of the synthetic work.

Clinton and Suter.[3] *n*-Butylthiol (Eastman Kodak Co.) was dissolved in absolute alcohol containing an equivalent of sodium. The calculated amount of 2,7-dichloro-4-methylquinoline (0.07 mole) was added in portions during ten minutes, and the reaction mixture was refluxed four hours. After removal of alcohol, an ether solution of the sulfide was washed with dilute alkali until no further mercaptan was removed. The crude product was an oil, which crystallized first when supercooled to −30°. Samples were crystallized from methyl alcohol or ligroin (90–100°), using solvent equal to one-half the weight of the sample, and the supernatant liquid was removed by centrifuging in a cold room. Cooling curves indicated a melting point of 22.9°. The sulfide is soluble in ether, acetone, pentane and ligroin, insoluble in water, and tends to form a two-phase system with methanol and ethanol.

Anal. Calcd. for $C_{14}H_{16}NSCl$: N, 5.27; S, 12.06. Found: N, 5.22; S, 11.93.

7-Chloro-4-*n*-butylthio-2-methylquinoline (VI).—Synthesis was carried out as indicated above. Crystallization occurred during concentration of the dry ether solution and was repeated from one-half volume of pentane. Three recrystallizations from two volumes of ligroin (90–100°) gave a white solid, m. p., 53.8–54.5°. It was readily soluble in methyl alcohol and in ether but had a low solubility in hexane.

Anal. Calcd. for $C_{14}H_{16}NSCl$: N, 5.27; S, 12.06; Cl, 13.40. Found: N, 5.45; S, 12.13; Cl, 13.45.

The ultraviolet absorption spectra were obtained with a Cary recording spectrophotometer. The maximum error in the wave length calibration of the instrument was ±5 Å.

The spectrum of each compound has been obtained in acidic, basic and neutral (alcoholic) solution. These spectra are shown in Fig. 1. Intensities have been presented in terms of absorbance ($\log_{10} I_0/I$) rather than extinction coefficients because the solubilities were so low that concentrations could not be determined. For the aqueous acidic and basic solutions the solubilities were less than 5 mg./l. The solubility in 95% ethanol was higher, and the concentrations of the alcoholic solutions were: (I) 10.3 mg./l.; (II) 6.47 mg./l.; (III) 6.29 mg./l.; (IV) 6.02 mg./l.; (V) 5.36 mg./l.; (VI) 5.19 mg./l.

The infrared absorption spectra were recorded on a Baird spectrophotometer. The wave length accuracy of this instrument is better than ±0.1 micron. All of the spectra shown in Fig. 2 with

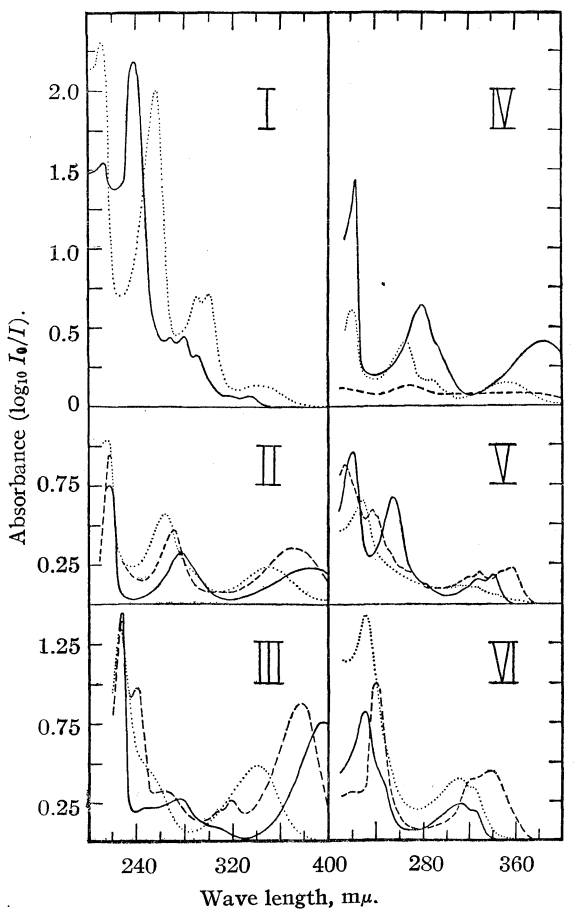


Fig. 1.—Ultraviolet spectra: — 95% ethanol; . . . . . 0.01 *N* sodium hydroxide; - - - - 0.01 *N* hydrochloric acid; I, 2-naphthalenethiol; II, 7-methyl-2-quinolinethiol; III, 7-methyl-4-quinolinethiol; IV, 7-chloro-4-methyl-2-quinolinethiol; V, 7-chloro-4-methyl-2-*n*-butylthioquinoline; VI, 7-chloro-4-*n*-butylthio-2-methylquinoline.

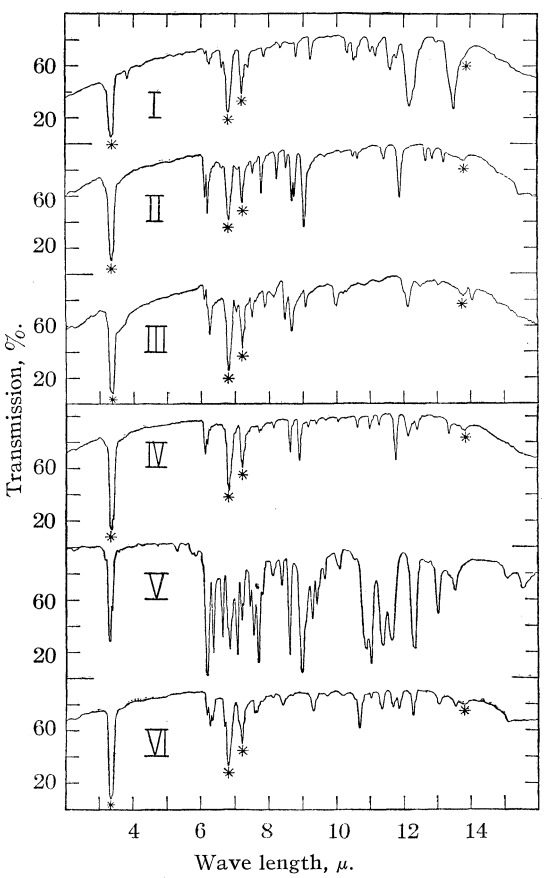

Fig. 2.—Infrared spectra, asterisks denote bands of Nujol: I, 2-naphthalenethiol; II, 7-methyl-2-quinolinethiol; III, 7-methyl-4-quinolinethiol; IV, 7-chloro-4-methyl-2-quinolinethiol; V, 7-chloro-4-methyl-2-*n*-butylthioquinoline; VI, 7-chloro-4-*n*-butylthio-2-methylquinoline.

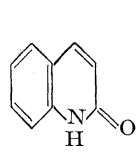
the exception of V were obtained from suspensions of the solid samples in Nujol. The spectrum of the liquid thioether (V) was obtained from a sample of capillary thickness. The spectra of several of these samples were also obtained as fluorocarbon suspensions and in carbon tetrachloride solution in an attempt to find characteristic absorption bands for S–H or N–H linkages. The spectra of the Nujol suspensions are presented as being most informative.

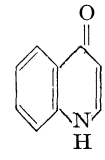
Discussion of Results

A. Ultraviolet Spectra.—Briefly, the conclusions of Ewing and Steck[1] on the hydroxyquinolines were based on the following observations and reasoning. The ultraviolet spectrum of quinoline undergoes a bathochromic shift (displacement of absorption maxima to longer wave lengths) in changing from a neutral to an acidic solvent. Similarly, the spectra of the naphthols undergo a bathochromic shift as the solvent is changed from neutral to basic in character. In either acidic or basic solvents, the spectra of the 3-, 5-, 6-, 7- and 8-quinolinols undergo bathochromic shifts, thus indicating that the oxygen retains its phenolic character and the heterocyclic ring retains its aromatic character in these particular quinolinols.

Conversely, the spectra of the 2- and 4-quinolinols do not undergo a shift in either acidic or basic media. This is explained by postulating the existence of these compounds in their respective keto forms.



2-Quinolone



4-Quinolone

In these compounds, the oxygen has lost its phenolic character and the spectrum does not undergo the bathochromic shift exhibited by the naphthols. Similarly, the heterocyclic ring has lost its aromatic character and the spectrum does not undergo the shift exhibited by quinoline.

It was hoped that the same reasoning could be applied to the sulfur analogs. The ultraviolet spectrum of 2-naphthalenethiol (I) was obtained and was found to undergo a bathochromic shift on going from neutral to basic medium (see Fig. 1). It would then be anticipated from the reasoning cited above that the spectra of the quinolinethiols would exhibit bathochromic shifts in acidic or basic media while the spectra of the quinolinethiones would remain unchanged in neutral, acid and basic media.

The spectra of 7-methyl-2-quinolinethiol (II), 7-methyl-4-quinolinethiol (III) and 7-chloro-4-methyl-2-quinolinethiol (IV) were obtained in neutral, acidic and basic media (see Fig. 1). Contrary to the anticipated results, the spectra of these three quinolinethiols exhibited hypsochromic shifts (displacements of absorption maxima to shorter wave lengths). These results cannot be explained by the reasoning applied to the bathochromic shifts observed for the quinolinols. A similar hypsochromic shift was encountered by Specker[7] and confirmed by Ewing and Steck[1] with solutions of 4-pyridone.

The spectrum of 7-chloro-4-*n*-butylthio-2-methylquinoline (VI) undergoes a bathochromic shift in an acidic medium but is not shifted in a basic medium. This is consistent with the sulfide structure in which the sulfur has lost its thiol character while the heterocyclic ring has retained its aromatic character.

7-Chloro-4-methyl-2-*n*-butylthioquinoline (V) dissolved very slowly in the aqueous solvents and it appears probable that the anomalous changes in the spectra are due to decomposition of the sulfide.

B. Infrared Spectra.—In a further attempt to confirm the structure of the mercaptoquinolines as thiols or thiones, their infrared spectra were recorded (see Fig. 2). It was hoped that the thiols would exhibit the characteristic absorption band associated with the S–H stretching vibration at 2400–2600 cm.$^{-1}$ (3.85–4.17μ). However, only the 2-naphthalenethiol spectrum showed this absorption band. The thiones would be expected to show an absorption band at about 3400 cm.$^{-1}$ (2.94μ), characteristic of the N–H stretching vibration. None of these compounds showed any absorption bands in this region. The thiones would also be expected to show a band characteristic of the C=S group in the 1400–1500 cm.$^{-1}$ region (6.67–7.13μ). However, the inherent weakness of this band and the complexity of the thioether spectra in this region indicate that this criterion will not provide any help. Therefore the infrared spectra do not offer a solution to the problem.

Summary

The ultraviolet absorption spectra of 2-naphthalenethiol, 7-methyl-2-quinolinethiol, 7-methyl-4-quinolinethiol, 7-chloro-4-methyl-2-quinolinethiol, 7-chloro-4-methyl-2-*n*-butylthioquinoline and 7-chloro-4-*n*-butylthio-2-methylquinoline were obtained in neutral, acidic and basic solvents. The observed wave length shifts are anomalous with respect to the reasoning used in establishing the structure of quinolinols and quinolones.

The infrared absorption spectra of these compounds have also been obtained but do not provide any further indication of their structure.

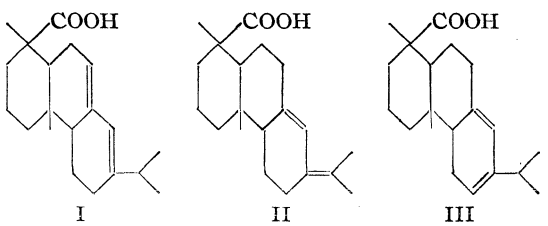
Kinetics of the Acid-catalyzed Isomerization of Levopimaric Acid in Anhydrous Ethanol

BY PAUL F. RITCHIE AND LANE F. MCBURNEY

For many years it has been known that certain constituents of wood rosin and oleoresin isomerize in the presence of strong acids or heat[1,2] and that the result of the preponderant reaction is an increase in the abietic acid content of the initial material.[3] The inadequacy of early techniques by which resin acids were isolated proved to be a serious handicap to investigators who attempted study of this isomerization reaction[4,5,6] and consequently the data acquired were incomplete or, in many cases, vitiated by the impurity of the resin acid specimens employed. Recent work established procedures by which resin acids were made available for study.[7] It is known now that the three isomeric, abietic-type acids—abietic (I), neoabietic (II), and levopimaric (III)—are the



I II III

resin acids participating in the isomerization and that the remaining components of oleoresin or rosin are relatively insensitive to strong acids or heat. The present communication is the result of an investigation, by a polarimetric method, of the kinetics of the acid-catalyzed isomerization of levopimaric acid in the solvent anhydrous ethanol.

Experimental

Preparation of Materials.—Anhydrous ethanol (Commercial Solvents Corp.) was purified from traces of aldehydes by the method of Dunlap.[8] The aldehyde-free alcohol was dried by the method of Lund and Bjerrum.[9] Levopimaric acid was isolated and purified by the method of Harris and Sanderson[7] $[\alpha]^{24}D$ −276° (C = 1%, ethanol), m. p. 150–152°. Hydrogen chloride was prepared by the method of Fieser.[10] Alcoholic hydrogen chloride was prepared by the absorption of dry hydrogen chloride in absolute ethanol until the concentration of the solution, as determined by weight, was approximately that desired. *p*-Toluenesulfonic acid was prepared from the monohydrate (Eastman Kodak Company, Eastman quality) by the methods of Gattermann[11] and Meyer,[12] melting point 105–105.5°. Methanesulfonic acid was prepared from "Indoil Methanesulfonic Acid," (Indoil Chemical Company) by the method of Smith and Hammett,[13] boiling point 136–138° at 0.4–0.6-mm. pressure. Trichloroacetic Acid (Eastman Kodak Company, Eastman quality, sulfate-free) was purified by the method of Jaeger.[14] The concentration of all ethanolic acid solutions was determined by titration of weighed samples with standard sodium hydroxide solution using methyl red as the indicator. Lithium ethylate solutions were prepared by the method of Elliott and Kilpatrick.[15] Lithium chloride (J. T. Baker Chemical Co., C.P. quality) was purified by the method of Elliott and Kilpatrick.[15]

Adequate precautions against acquisition of moisture by ethanolic solutions were taken at all stages in their preparation. In order to permit the withdrawal of a portion of a solution without exposing the bulk to the atmosphere, an all-glass apparatus—a modification of the automatic buret—was constructed and employed for the storage of solutions.

Apparatus.—A Pellin polarimeter sensitive to 0.02° was used in conjunction with a sodium-vapor lamp and a 5-dm. tube for all measurements. During experiments the temperature of the tube and contents was maintained constant within ±0.05° by water circulated from a thermostatically controlled bath through a jacket enclosing the tube.

Experimental Procedure.—Reaction mixtures were prepared by dispensing the desired volume of an ethanolic solution of levopimaric acid from an automatic buret into a 50-ml. volumetric flask, adding solutions of any other components, with the exception of the acid catalyst, from a weight buret and diluting with ethanol leaving only slightly more space than necessary to accommodate the catalyst solution. After placing the flask and contents in the water-bath at the temperature at which the experiment was to be conducted and allowing sufficient time for the attainment of thermal equilibrium, the proper amount of a solution of the acid catalyst was added from a weight

buret and the volume of the solution adjusted by the addition of ethanol. The flask was rotated to ensure thorough mixing of the contents, a portion of the solution transferred to the polarimeter tube, which had been brought to the desired temperature, and a stopper tightly fitted into the side tubulation.

Readings were taken in accordance with the directions of Guggenheim[16] and the constants of the general first order rate expression, $\log (\alpha - \alpha') = a - kt \log e$, calculated from the data by the method of averages. In Table I these methods have been applied to the data of a typical experiment for the purpose of deriving the rate constant, the calculated values of $(\alpha - \alpha')$ and the differences, $\Delta(\alpha - \alpha')$, between the observed and calculated values of $(\alpha - \alpha')$. The calculated mean deviation amounts to about 2% of the smallest observed value. Probable errors in the velocity constants were calculated and are represented by the radii of the circles in the graphs that follow. Unless otherwise noted, all measurements refer to 25°.

Results and Discussion

Preliminary investigations demonstrated that ethanolic solutions of levopimaric acid are perfectly stable for prolonged periods of time, but that in the presence of a strong acid catalyst the specific rotations of the solutions change rapidly from the initial value of −276°[7] to about −73° and, thereafter, very slowly to a final value of about −90°. The course of the rapid change was in strict accord with first order kinetics and examination of ultraviolet absorption spectra of reaction solutions of specific rotation −73° (Fig. 1) revealed that over 90% of the original levopimaric acid had been converted to abietic acid. It is not possible to determine levopimaric or neoabietic acid by absorption spectra in the presence of such large amounts of abietic acid. However, the fact that the same adduct, that of levopimaric acid, is formed when maleic anhydride reacts with either abietic or levopimaric acid in acidic media[17] is proof that levopimaric acid is present in the reaction solutions. The nature of the slow reaction is unknown although development of color in the solutions on standing for several hours may be an indication that the products of the isomerization are slowly oxidized by air under the experimental conditions. No detectable differences in the composition of the solutions of specific rotation −73° and −90° were exhibited by the ultraviolet absorption spectra. In the following discussion all measurements refer only to the rapid, relatively uncomplicated isomerization reaction.

A study of the effect of varying the initial concentration of levopimaric acid on the rate of isomerization was made using hydrogen chloride as catalyst. The results (Table II) show that the velocity of the reaction is independent of the initial concentration of levopimaric acid. Table III contains data obtained by measurement of the reaction velocity in solutions containing 1:1 trichloroacetic acid:lithium trichloroacetate buffers at 35.1°. The ionic strength of the medium was maintained constant at 7.02×10^{-2} by the addition of the proper amounts of lithium chloride.

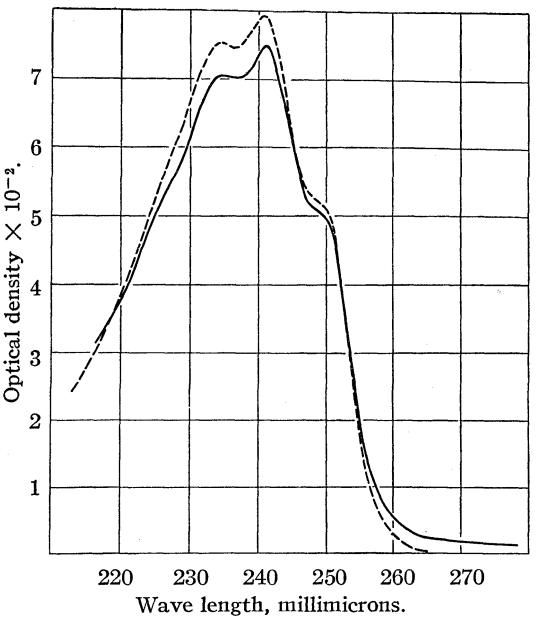

Fig. 1.—Ultraviolet absorption spectra of ethanolic solutions of resin acids: dotted curve, pure abietic acid, 10 g./liter; solid curve, acid-isomerized levopimaric acid, 10 g./liter.

Although the total buffer concentration was varied throughout a twelve-fold range, the rate of isomerization remained unaltered. Hence the reaction is catalyzed only by the solvated proton and not by undissociated acids or anions.

and c the catalyst concentration, are plotted against c. Inspection of the plots reveals that, in the case of hydrogen chloride, a large primary electrolyte effect was found. Further evidence of the existence of a primary salt effect was obtained from experiments in which varying amounts of the uni-univalent salt lithium chloride were added to solutions containing constant amounts of levopimaric acid and hydrogen chloride. The plot of the ratio of the velocities at salt concentrations c and zero, k/k_0' *versus* c is linear (Fig. 4) in agreement with the Debye–Hückel theory.[18] A primary electrolyte effect was observed in connection with *p*-toluenesulfonic acid, but the values of

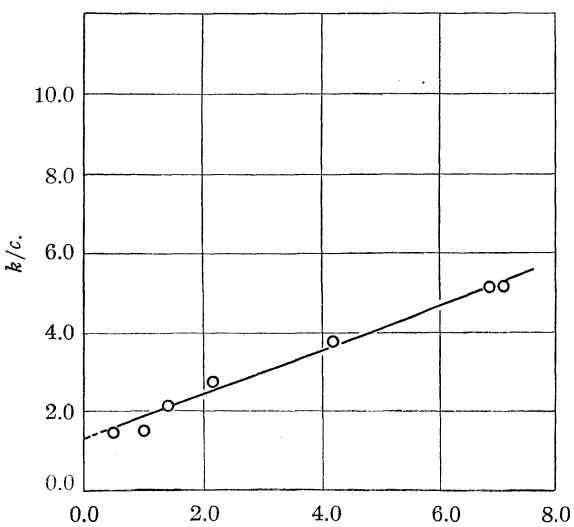

Fig. 2.—Hydrogen chloride-catalyzed isomerization of levopimaric acid: k is the reaction velocity and c the catalyst concentration in moles/liter.

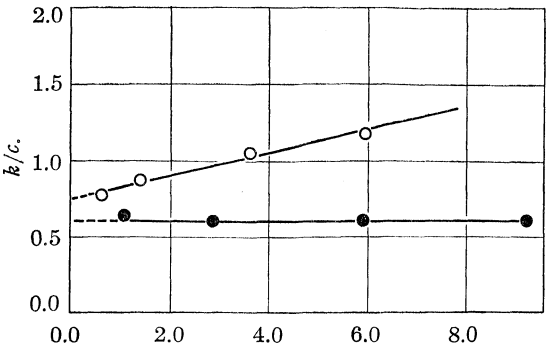

Fig. 3.—Isomerization of levopimaric acid catalyzed by (○) *p*-toluenesulfonic and (●) methanesulfonic acids. k is the reaction velocity and c the catalyst concentration in moles/liter.

k/c obtained with methanesulfonic acid were independent of the catalyst concentration.

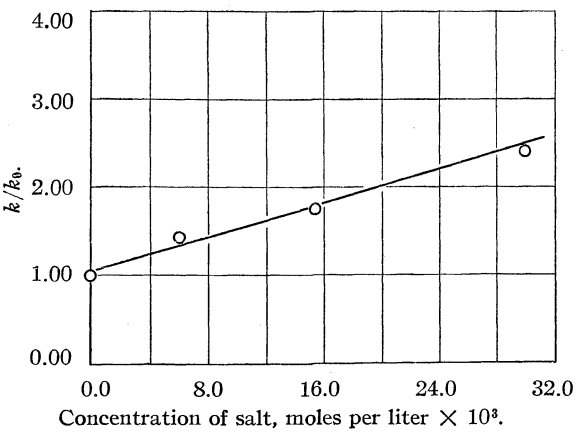

Fig. 4.—Neutral salt effect in the hydrogen chloride catalyzed isomerization of levopimaric acid: concentrations in moles/liter; hydrogen chloride, 4.62×10^{-3}; levopimaric acid, 3.33×10^{-2}; k/k_0 is the ratio of reaction velocities at salt concentrations c and zero.

Extrapolation of the curves of Figs. 2 and 3 leads to values of k/c at zero concentration with respect to each of the acid catalysts. The values thus obtained for *p*-toluenesulfonic acid (0.73) and methanesulfonic acid (0.61) are significantly lower than that corresponding to hydrogen chloride (1.23) and indicate that, at the concentrations employed, these two sulfonic acids are dissociated in ethanol to an extent less than hydrogen chloride. If it is assumed, in agreement, with the observations of Murray-Rust, and Hartley,[19] and Deyrup,[20] but contrary to the conclusions of Bezman and Verhoek[21] that hydrogen chloride is completely dissociated in ethanol, the value obtained for k/c at infinite dilution of hydrogen

(19) D. M. Murray-Rust and H. Hartley, *Proc. Roy. Soc.* (*London*), **A126**, 86 (1929).

(20) A. J. Deyrup, THIS JOURNAL, **56**, 60 (1934).

(21) I. I. Bezman and F. H. Verhoek, *ibid.*, **67**, 1330 (1945).

chloride is the catalytic coefficient $k_{C_2H_5OH_2^+}$ (in liters mole^{-1} min.$^{-1}$) of the reaction. From the catalytic coefficient and the data obtained in the experiments with trichloroacetic acid–trichloroacetate buffers (calculated to 25°) the dissociation constant of trichloroacetic acid was calculated. For purposes of comparison the dissociation constant at zero ionic strength was calculated from the Debye–Hückel limiting law, $\log_{10} K_0 = \log_{10} K_C - 5.6\sqrt{\mu}$, and found to be 6.9×10^{-6} in moderately good agreement with Deyrup's value of 3.5×10^{-6}.[20]

Both hydrogen chloride and *p*-toluenesulfonic acid were employed as catalysts in measuring the temperature coefficient of the reaction over the range 16 to 41°. The value obtained for the activation energy was 21.4 ± 0.5 kcal./mole and, as anticipated for a reaction catalyzed exclusively by solvated protons, independent of the nature of the strong acid catalyst (Fig. 5).

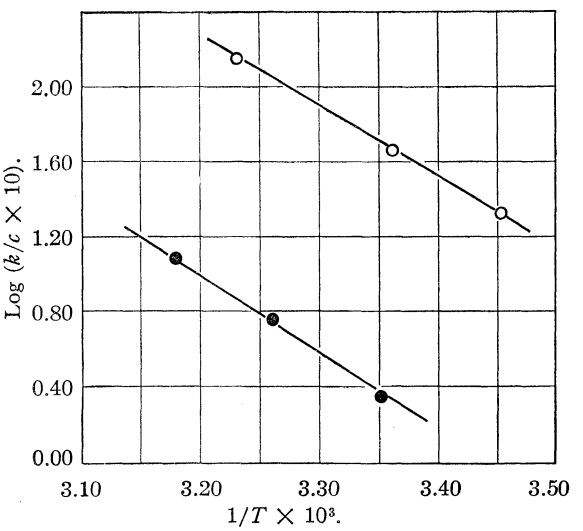

Fig. 5.—Temperature coefficient of the isomerization of levopimaric acid: concentrations in moles/liter; hydrogen chloride, ⊙, 6.01×10^{-3}; *p*-toluenesulfonic acid, ●, 2.05×10^{-2}; levopimaric acid, 3.32×10^{-2}; k is the reaction velocity; c, the catalyst concentration in moles/liter, and T the temperature (Å.).

Preliminary experiments indicated that the isomerization of levopimaric acid is retarded by the presence of even trace amounts of water in the medium. The reaction velocity was measured using solutions containing constant amounts of hydrogen chloride and levopimaric acid but varying amounts of water. Results of these experiments, collected in graphical form in Fig. 6, are very similar to those obtained by study of the inhibitive action of water in the acid-catalyzed formation of acetal,[20] in certain anionotropic rearrangements[22] and in many other reactions in anhydrous media as well as of the depressive effect of small amounts of water upon the activity coefficients of hydrogen chloride in ethanol.[23] Since water is considerably more basic than alcohols, the equilibrium

$$C_nH_{2n+1}OH_2^+ + H_2O \rightleftharpoons C_nH_{2n+1}OH + H_3O^+$$

very much favors the formation of the hydronium ion[24] which would be expected to function less efficiently as a proton donor than alkoxonium ions. A plausible explanation of the inhibitive effect of low concentrations of water upon acid-catalyzed reactions in alcoholic solution is thus afforded.

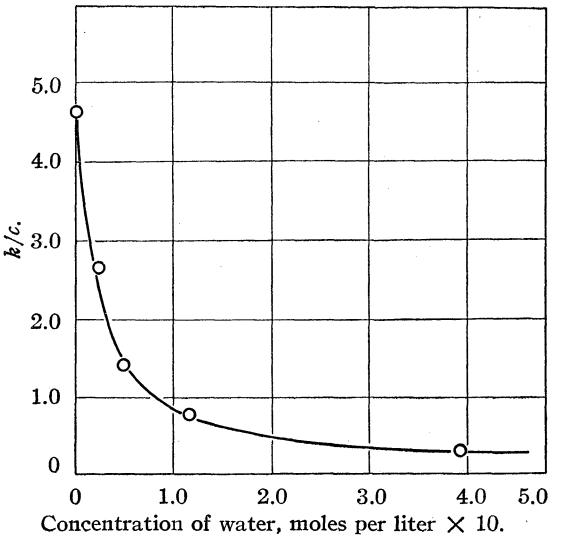

Fig. 6.—Inhibition by water of the hydrogen chloride-catalyzed isomerization of levopimaric acid: concentrations in moles/liter; levopimaric acid, 2.77×10^{-2}; hydrogen chloride, 4.46×10^{-3}; k is the reaction velocity, and c the catalyst concentration in moles/liter.

Acknowledgment.—The authors take this opportunity to thank Dr. George C. Harris of these laboratories who supplied the levopimaric acid used in this research.

Summary

Isomerization of levopimaric acid in the presence of an acid catalyst leads to reaction mixtures which contain over 90% of abietic acid and small amounts of the starting material. No evidence of the presence of the third isomer, neoabietic acid, in the reaction mixtures can be obtained from ultraviolet spectra.

The isomerization of levopimaric acid in ethanol is catalyzed exclusively by solvated protons and is first order with respect to both levopimaric acid and the catalyst. Assuming complete dissociation of hydrogen chloride in ethanol at the concentrations used, the catalytic coefficient of the reaction (in liters mole^{-1} min.$^{-1}$) is given by $k_{C_2H_5OH_2^+} = 6.3 \times 10^{15}\, e^{-21{,}450/RT}$. The reaction is inhibited by the presence of water in the medium.

The dependence of reaction velocity upon con-

centration of the catalysts hydrogen chloride and *p*-toluenesulfonic acid is in accord with the predictions of the Debye–Hückel theory, but the behavior of methanesulfonic acid is anomalous. It appears that *p*-toluenesulfonic acid and methanesulfonic acids are incompletely dissociated in ethanol at concentrations of 1×10^{-2} to 1×10^{-1} mole/liter. The value calculated for the dissociation constant of trichloroacetic acid in ethanol is 6.9×10^{-6} and in reasonable agreement with previously published values.

Alkali-sensitive Glycosides of 3-Phenyl-4-hydroxycoumarin[1]

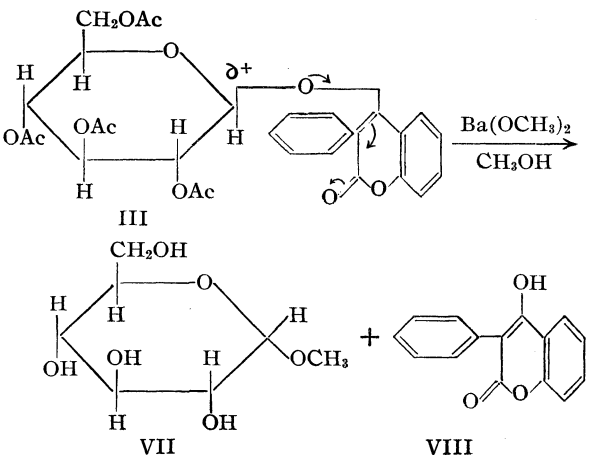
BY LEONARD SPERO,[2] CLINTON E. BALLOU AND KARL PAUL LINK

The synthesis and properties of some β-D-glucosides of 4-hydroxycoumarins were first reported from this Laboratory in 1944.[3] These compounds were made in connection with the biological studies on the hypoprothrombinemic effect of 3,3′-methylene-bis-(4-hydroxycoumarin) [Dicumarol] and related 4-hydroxycoumarins.[4] 4-Hydroxycoumarin D-glucoside tetraacetate (I), 4-hydroxy-6-methylcoumarin D-glucoside tetraacetate (II), 3-phenyl-4-hydroxycoumarin D-glucoside tetraacetate (III), and 3,3′-methylene-bis-(4-hydroxycoumarin) mono-D-glucoside tetraacetate (IV) were prepared by condensing the silver salt of the aglycon with tetraacetyl-D-glucosyl bromide. A modified Robertson method[5] was used in the preparation of 3,3′-methylene-bis-(4-hydroxycoumarin) diglucoside octaacetate (V), and 3-[6-oxo(1)-benzopyrano(4,3-b)(1)benzopyran-7-yl]-4-hydroxycoumarin D-glucoside tetraacetate (VI). Because of the method of preparation and the optical rotation of these glucosides the β-configuration was assigned.

As shown by Huebner, *et al.*,[3] these glucosides are extremely labile to alkali. Compounds I and II were deacetylated by the catalytic barium methoxide procedure. Attempts to deacetylate the glucosides in which there were substituents on position three of the coumarin residue resulted in cleavage of the glucoside linkage. This reaction is unique in that the starting compound is converted to the aglycon and methyl α-D-glucoside (VII). During attempted deacetylation of III, 80% of the starting material was converted to 3-phenyl-4-hydroxycoumarin (VIII) and VII.

Isbell's[6] interpretation of glycoside cleavage rationalizes the fact that the splitting may occur on either side of the glycosidic oxygen. An electrophilic aglycon promotes cleavage of the sugar–oxygen bond, while cleavage of the aglycon–oxygen bond occurs when the sugar residue is able to take electrons from the aglycon.

Cleavage of glycosides under anhydrous methanolic conditions could result in methanolysis, cyclization or unsaturation. This reaction demonstrates the methanolysis type. The formation of methyl α-D-glucoside (VII) indicates that a Walden inversion accompanies the cleavage of the glucosidic linkage, and this would be possible only if the sugar–oxygen bond were the one split. The following scheme, involving the indicated electronic shifts, may be used to rationalize this reaction.



A more involved mechanism is used to explain the products obtained during the alkaline cleavage of V [glucose, VII, and 3,3′-methylene-bis-(4-hydroxycoumarin) monomethyl ether]. For a detailed discussion see ref. 3.

It is conceivable that this reaction would be generally applicable to glycosides of this type.[7] One of the purposes of this study was to ascertain if the nature of the sugar residue played a role in determining the mechanism of the glycosidic cleavage. In order to study the reaction further,

(7) Dr. C. S. Hudson had originally suggested to one of us (K. P. L.) that this reaction might serve as the route through which certain inaccessible α-glycosides could be realized.

a series of glycosides of 3-phenyl-4-hydroxycoumarin (VIII) was prepared, and the methanolysis was carried out in a similar manner on each.

The silver salt of the aglycon is quite stable, and when treated with the acetylglycosyl bromide, forms the acetylated glycoside in yields of from 56–76%. The products were difficult to crystallize and purify.

The glucoside,[3] galactoside, mannoside and xyloside (all in the D series), which were assigned β-configurations because of the mode of synthesis, were cleaved to form methyl α-D-glycosides. The D-arabinoside, assigned an α-configuration by the same precedence, produced methyl β-D-arabinoside. These results corroborate the generalization of configurational assignment from mode of synthesis if a Walden inversion is assumed.

A study of the rotational changes[8] accompanying the cleavage showed a simple mutarotation curve (Figs. 1 and 2), and varying amounts of the catalytic agent increased the rate at which the reaction occurred (Fig. 3). The reactions were generally quite slow as determined by the length of time required for the rotation to stop changing. Cleavage of the glucoside required about two weeks, while cleavage of the arabinoside was not complete after six months. The concentration of the catalyst was the same in both reactions.

If concentrations of barium methoxide above 0.02 *N* were used, side reactions resulted and uncrystallizable sirups were obtained. In these cases the reaction went with extreme rapidity, the barium salt of the aglycon precipitated from the solution, and the final rotation indicated the formation of the free sugar residue. This may have been due to the presence of a small amount of barium hydroxide in the barium methoxide stock solution, and at higher concentrations of the latter, the former might have become critical.

Experimental

Preparation of the Silver Salt of 3-Phenyl-4-hydroxycoumarin[3] (IX).—Precautions were taken to work in a feeble light. VIII was dissolved in one equivalent of 1.5 *N* aqueous sodium hydroxide and one equivalent of silver nitrate plus 2% excess dissolved in a little water, was added while the solution was being vigorously stirred. The gelatinous, white silver salt which precipitated immediately, was filtered off. It was resuspended in water, collected on a funnel, pressed dry, and washed once with absolute ethanol. The salt was dried over calcium chloride *in vacuo*, finely pulverized, and dried again at 45° and 3 mm. pressure over phosphorus pentoxide. The product varied from a colorless to a light-gray powder; yield 96%.

Preparation of 3-Phenyl-4-hydroxycoumarin β-D-Galactoside Tetraacetate (X).—Pentaacetyl-β-D-galactose prepared according to Erwig and Koenigs[9] was converted to tetraacetyl-D-galactosyl bromide according to Ohle.[10] A mixture of 6.7 g. of IX, 7.2 g. of tetraacetyl-D-galactosyl bromide, 1.3 g. of Drierite and 65 ml. of dry benzene, was shaken in a dark bottle on a mechanical shaker. Upon completion of the reaction, as indicated by a negative free bromide test (no precipitate in a centrifuged sample when it was mixed with a drop of alcoholic silver nitrate and 3 volumes of absolute ethanol), the silver salts were centrifuged off and washed with hot benzene. The combined benzene solutions were concentrated *in vacuo* to a thick sirup. The sirup was taken up in hot methanol and the solution allowed to stand until crystallization was complete. Yield of the crude material was 6.9 g. Yield after one recrystallization was 76%, m. p. 91–

(8) The polarimetric studies were done with the use of a Franz Schmidt and Haensch polarimeter No. 52B with a monochromator attachment.

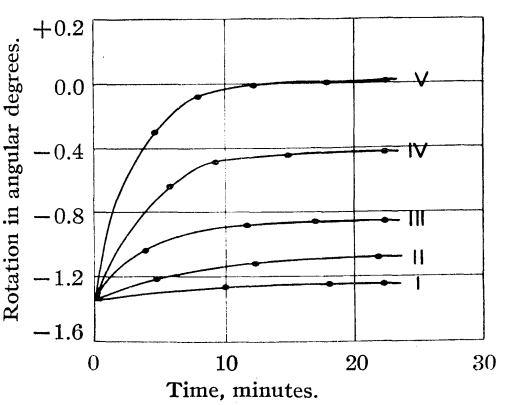

Fig. 3.—The effect of varying concentrations of barium methoxide (milliequivalents/liter of solution) on the methanolysis of 3-phenyl-4-hydroxycoumarin β-D-glucoside tetraacetate (0.058 *M*): I (1.14), II (2.28), III (4.56), IV(9.14), V(18.28).

93°; $[\alpha]^{25}D$ −39.6° (*c*, 1.2, benzene). *Anal.* Calcd. for $C_{29}H_{28}O_{12}$: C, 61.36; H, 4.94. Calcd. for $C_{29}H_{28}O_{12}$. $^1/_2H_2O$: C, 60.31; H, 5.07. Found: C, 60.19; H, 5.27.

When dried over phosphorus pentoxide at 56.5° and 2 mm. pressure for fifteen hours, 96.12 mg. of substance lost 1.52 mg. of water. Calcd. for $C_{29}H_{28}O_{12}\cdot^1/_2H_2O$: H_2O, 1.57. Found: H_2O, 1.58.

Preparation of 3-Phenyl-4-hydroxycoumarin β-D-Xyloside Triacetate (XI).—D-Xylose was acetylated to tetraacetyl-β-D-xylose according to Stone.[11] The bromosugar was made by the method of Hudson and Johnson.[12] To 150 ml. of dry benzene in a dark bottle were added 18.7 g. of IX, 16.5 g. of triacetyl-D-xylosyl bromide and 3.0 g. of Drierite. The mixture was shaken for three days or until a centrifuged portion gave the negative test for free bromide as described above.

The silver salts were centrifuged off, washed with hot benzene, and the benzene solution concentrated *in vacuo* to a thick sirup which crystallized from a mixture of ethanol and water. The crude material amounted to 17.0 g. It was recrystallized from methanol; yield 60%, m. p. 120–122°; $[\alpha]^{25}D$ −98.9° (*c*, 0.95, benzene). *Anal.* Calcd. for $C_{26}H_{24}O_{10}$: C, 62.90; H, 4.87. Found: C, 62.79; H, 4.98.

Preparation of 3-Phenyl-4-hydroxycoumarin α-D-Arabinoside Triacetate (XII).—D-Arabinose prepared by the method of Hockett and Hudson[13] was converted directly to the triacetyl-D-arabinosyl bromide according to Chavanne.[14] A mixture of 11.1 g. of the triacetyl-D-arabinosyl bromide, 12.6 g. of IX, 2.0 g. of Drierite and 110 ml. of dry benzene was shaken in a dark bottle for three days. The benzene solution obtained after centrifuging the silver salts off was concentrated to a thick sirup *in vacuo*. The product could not be obtained in a well-crystallized form. It was obtained as a white amorphous powder by pouring a methanolic solution of the sirup into a large volume of water; yield 56%, m. p. 76–96 (gradually softening); $[\alpha]^{25}D$ +43.3° (*c*, 0.9, benzene). *Anal.* Calcd. for $C_{26}H_{24}O_{10}$: C, 62.90; H, 4.87. Calcd. for $C_{26}H_{24}O_{10}\cdot^1/_2H_2O$: C, 61.8; H, 4.95. Found: C, 62.1; H, 5.07.

Preparation of 3-Phenyl-4-hydroxycoumarin β-D-Mannoside Tetraacetate (XIII).—Pentaacetyl-β-D-mannose was converted to the acetyl-D-mannosyl bromide according to Micheel.[15] The product was not crystallized, but was used as a sirup. To 100 ml. of dry benzene in a dark bottle were added 9.9 g. of the sirupy tetraacetyl-D-mannosyl bromide, 9.3 g. of IX and 2.0 g. of Drierite. After shaking for three and one-half days the reaction mixture gave a negative test with alcoholic silver nitrate. The silver salts were removed as above, and the benzene solution was concentrated *in vacuo*. The product could not be crystallized but turned to a white amorphous powder on standing. The same powder could be obtained by pouring a methanolic solution of the sirup into water; yield 72%, m. p. 68–72°; $[\alpha]^{25}D$ +29.6° (*c*, 1.4, benzene). *Anal.* Calcd. for $C_{29}H_{28}O_{12}$: C, 61.35; H, 4.94. Calcd. for $C_{29}H_{28}O_{12}\cdot^1/_2H_2O$: C, 60.3; H, 5.39. Found: C, 60.39; H, 5.39.

When dried over phosphorus pentoxide at 56.5° and 2 mm. pressure for four days, 78.46 mg. of substance lost 1.10 mg. of water. Calcd. for $C_{29}H_{28}O_{12}\cdot^1/_2H_2O$: H_2O, 1.57. Found: H_2O, 1.40.

Methanolysis of 3-Phenyl-4-hydroxycoumarin β-D-Galactoside Tetraacetate (X).—To 7.5 g. of the galactoside dissolved in 600 ml. of absolute methanol[16] was added 3.0 ml. of 0.573 *N* barium methoxide. An aliquot was taken to find the rotation at zero time, −0.98°, and the rotation was followed polarimetrically. Mutarotation ceased after ten days. The final value was +1.24°. Complete conversion to methyl α-D-galactoside would give a rotation of +1.68°.

The reaction mixture was treated with enough 0.1 *N* sulfuric acid to remove the barium. The barium sulfate was removed by filtration through an asbestos mat, and the filtrate concentrated to 50 ml. *in vacuo*. The aglycon that crystallized out during the concentration was filtered off. An equal volume of water was added and the concentration was repeated. A second crop of VIII was obtained. A total of 2.83 g. (90%) was isolated, m. p. 235°.

The filtrate was concentrated to a sirup and a small volume of ethanol added. On scratching, 1.2 g. (47%) of methyl α-D-galactoside crystallized; m. p. 109°, with no depression when mixed with an authentic sample, $[\alpha]^{25}D$ +175.3° (*c*, 1.05, water). Reported for methyl α-D-galactoside, m. p. 110°, $[\alpha]^{20}D$ +179.3° (*c*, 9.1, water). The product was acetylated to the tetraacetate with acetic anhydride and pyridine; m. p. 87°; $[\alpha]^{27}D$ +135.0° (*c*, 0.95, chloroform). Reported for methyl α-D-galactoside tetraacetate, m. p. 87°; $[\alpha]^{20}D$ +132.5° (*c*, 2.9, chloroform).

Methanolysis of 3-Phenyl-4-hydroxycoumarin β-D-Xyloside Triacetate (XI).—To 7.2 g. of the xyloside dissolved in 380 ml. of absolute methanol was added 3.0 ml. of 0.573 *N* barium methoxide. An aliquot was taken to find the rotation at zero time, −3.72°, and the reaction was followed polarimetrically. Mutarotation stopped after seven weeks. The final value was +1.21°. Some of the aglycon that crystallized in the reaction flask was filtered off. Enough 0.1 *N* sulfuric acid was added to remove the barium. The salt was removed by filtration through an asbestos mat, and the filtrate concentrated to 50 ml. *in vacuo*. The aglycon that crystallized out was collected on a funnel. An equal volume of water was added and the solution again concentrated. A third crop of the aglycon was removed to make a total of 2.2 g. (94%), m. p. 235°. The filtrate was concentrated to a sirup which did not crystallize. A small portion of the sirup was acetylated with acetic anhydride and sodium acetate. The product was crystallized from 95% ethanol; m. p. 84°, reported for methyl α-D-xyloside triacetate, m. p. 86°.

Methanolysis of 3-Phenyl-4-hydroxycoumarin α-D-Arabinoside Triacetate (XII).—One gram of the arabinoside was dissolved in 100 ml. of absolute methanol. To the solution was added 0.75 ml. of 0.387 *N* barium methoxide. The rotation at the start was +0.21°. It changed slowly over a period of six months. When it reached +0.92° the rate of mutarotation was about 0.03° per week.

To the solution was added 3.03 ml. of 0.096 *N* sulfuric acid and the barium sulfate removed as above. The filtrate was concentrated to dryness, and the white residue suspended in 5 ml. of water. The aglycon was filtered off; yield 0.5 g., after one recrystallization m. p. 235°.

The filtrate was concentrated to dryness, and the sirup taken up in absolute methanol. After three weeks in the cold, the crystals were collected by filtration; yield 30 mg., m. p. 165–169°. After one recrystallization from methanol, m. p. 167–169°; no depression with an authentic sample of methyl β-D-arabinoside; $[\alpha]^{26}D$ −239.0° (*c*, 1, water); reported for methyl β-D-arabinoside, m. p. 168°, $[\alpha]^{16}D$ −241.1° (*c*, 1, water).

Methanolysis of 3-Phenyl-4-hydroxycoumarin β-D-Mannoside Tetraacetate (XIII).—One gram of XIII was dissolved in 100 ml. of absolute methanol. The polarimetric reading at zero time was +0.36°. To this solution was added 0.75 ml. of 0.387 *N* barium methoxide. The rotation changed to +0.46° in twenty minutes. The rotation did not change for the next five days. Another milliliter of 0.387 *N* barium methoxide was added but the rotation remained constant for the next five days.

An amount of 0.1 *N* sulfuric acid equivalent to the barium was added. The barium sulfate was removed as above, and the filtrate concentrated to dryness. The white powder obtained was suspended in a few milliliters

of water and the aglycon filtered off; yield 0.2 g., 50%; m. p. 235° after one recrystallization from ethanol and water.

The aqueous filtrate was concentrated to dryness. The sirup was taken up in 1 ml. of methanol. Upon standing in the cold for a week, crystals formed; yield 64 mg., m. p. 184–188°, after one recrystallization from methanol m. p. 188°; no depression when mixed with an authentic sample of methyl α-D-mannoside; $[\alpha]^{28}D$ +86.7° (*c*, 1, methanol). Reported for methyl α-D-mannoside, m. p. 193–194°; $[\alpha]^{20}D$ +87.5° (*c*, 1, methanol).

Effect of Varying Concentrations of Barium Methoxide on the Methanolysis.—A solution of glucoside tetraacetate of VIII was made up to contain 3.33 g. per 100 ml. of methanol. To 10-ml. aliquots, 0.02, 0.04, 0.08, 0.16 and 0.32 ml. of 0.573 *N* barium methoxide was added. The rotation was followed until the change in ten minutes was less than 0.02°. The results are plotted in Fig. 3.

Summary

1. A series of glycosides of 3-phenyl-4-hydroxycoumarin (VIII) has been prepared by condensing the enol silver salt of the aglycon with the respective acetylglycosyl bromides.

2. The glycosides all undergo methanolysis when treated with catalytic amounts of barium methoxide in dry methanol. The mechanism appears to be the same in each case. A Walden inversion accompanies the cleavage. From the β-D-glycosides of VIII are formed methyl α-D-glycosides, and from the α-D-arabinoside of VIII methyl β-D-arabinoside is obtained.

3. An electronic mechanism, in which the electrophilic nature of VIII promotes electronic shifts which labilize the sugar–oxygen bond, is offered as a rationalization of the products of the alkaline cleavage.

Alkaline Methanolysis of Theobromine β-D-Glucoside Tetraacetate[1]

BY CLINTON E. BALLOU AND KARL PAUL LINK

The observations of Huebner, *et al.*,[2] and Spero, *et al.*,[3] concerning the cleavage products formed during the attempted deacetylation of 3-phenyl-4-hydroxycoumarin D-glycoside tetraacetates, have stimulated an investigation of various other alkali labile glycosides. This paper is on the alkaline methanolysis of theobromine D-glucoside tetraacetate (I).

Fischer[4] first described the difficulty of deacetylating certain purine glucoside tetraacetates without cleaving the glucosidic linkage. From theobromine D-glucoside tetraacetate (I) in aqueous alkali, Fischer obtained theobromine and glucose (II). Due to the sensitivity of this glucoside to aqueous acid and alkali, he postulated the glucosidic linkage as being to position 2 or 6 of the enol form of the purine residue.

In our studies of the cleavage of alkali sensitive glycosides the reactions are run in dry methanol[5] in the presence of catalytic amounts of barium methoxide. Under these conditions cleavage involves a methanolysis of the glycosidic linkage, and in those cases reported[2,3] a methyl glycoside and the free aglycon are formed. The cleavage is accompanied by a Walden inversion, and the products formed suggest a mechanism for the cleavage.

According to the mechanism advanced by Isbell,[6] the cleavage anion may add to either the sugar residue or the aglycon, depending upon the shift of electrons between these two parts of the molecule. During the cleavage of the glycosidic linkage under the influence of basic catalysts, a cationoid center is derived from either the sugar residue or the aglycon. If the cation comes from the sugar residue it may be attacked by an anion such as hydroxyl or methoxyl, to give the free sugar or a methyl glycoside. This sugar cation may also be attacked by an anion present within the sugar molecule with the formation of an inner anhydride. If the cationoid center derives from the aglycon it likewise may be attacked by an anion present, again hydroxyl or methoxyl, to give the free aglycon or a methoxyl derivative, or it may coördinate with an adjacent carbon atom to form a carbon–carbon double bond, a proton being expelled during the reaction.

The cleavage of 3-phenyl-4-hydroxycoumarin β-D-glucoside tetraacetate[2] with the formation of methyl α-D-glucoside represents a case in which the oxygen–sugar bond is split. This is indicated because the anion, in this reaction the methoxyl group, becomes attached to the sugar residue, and the configuration of the anomeric carbon atom changes from the β to the α form. Peat[7] has thoroughly reviewed this type of inversion as encountered in alkaline scission of anhydro sugar rings.

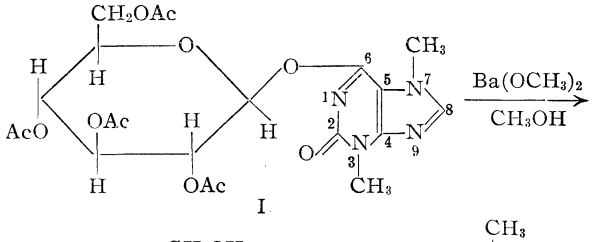
(7) Peat, *Adv. in Carbohydrate Chem.*, Vol. 2, 45 (1946).

He states, "If the carbonium cation derives from an asymmetric atom then the configuration change becomes manifest in an inversion of optical rotation (Walden inversion)." In the cleavage of the glycosides of 3-phenyl-4-hydroxycoumarin, the cationoid center derives from the anomeric carbon atom, and is attacked by the methoxyl anion. The Walden inversion is manifested by the formation of a methyl α-D-glycoside from the original β-D-glycoside.

Possibly representative of the cleavage of the oxygen–aglycon linkage is the reaction reported by Kuhn and Löw[8] for the alkaline hydrolysis of picrocrocin. In this reaction an unsaturated carbon–carbon linkage arises in the aglucon, indicating cleavage of the oxygen–aglucon bond with a simultaneous expulsion of a proton from an adjacent carbon atom. Evidence was offered to indicate that the mechanism does not follow hydrolysis of the glucoside linkage, with subsequent dehydration of the aglucon to form the unsaturated product.

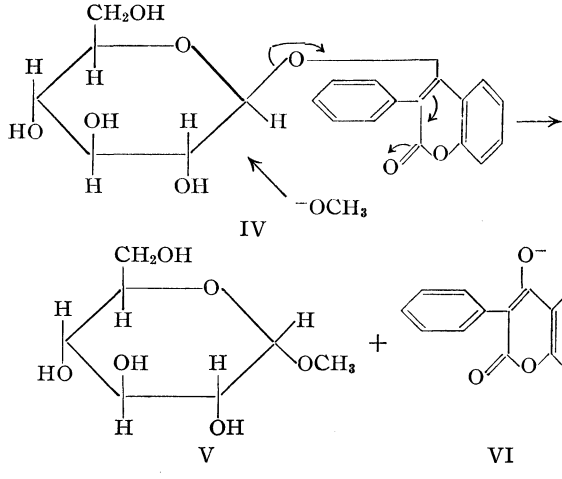
A clear-cut illustration of this second type of glycosidic cleavage is reported herewith. Theobromine D-glucoside tetraacetate (I) was cleaved in absolute methanol containing catalytic amounts of barium methoxide to form glucose (II) and a methoxy-oxy-3,7-dimethyl purine (III) in a yield of 95%. This reaction may be formulated as



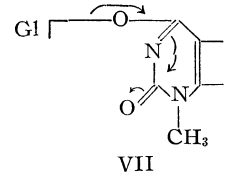
The fact that the aglucon was recovered as a methoxyl derivative indicates that the point of attack of the methoxyl anion was between the glucosidic oxygen and the aglucon. Thus the cationoid center must derive from the aglucon. This is in contrast to the cleavage of the glycosides of 3-phenyl-4-hydroxycoumarin in which the methoxyl anion attacks the anomeric carbon atom of the sugar residue.

An electronic rationalization of this reaction is not embraced by the concepts outlined by Isbell.[6] The expected electron shifts in the aglucon would tend to labilize the sugar–oxygen bond, not the aglucon–oxygen bond. It is possible that the inherent pyridinium nature of the pyrimidine portion of the purine nucleus may be involved.[9]

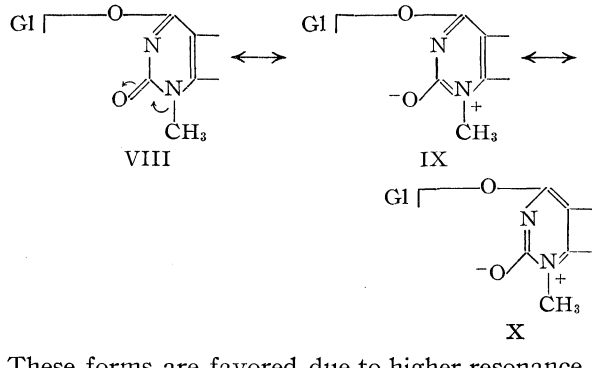
In the structure IV, the indicated "discontinuous" polarizations permit the methoxyl anion to attack the glucose portion to give V and VI.



Representing the glucoside of theobromine (I) as shown in VII, the effect of the carbonyl group would be to permit the same type of attack (weaken the glucosyl oxygen bond).



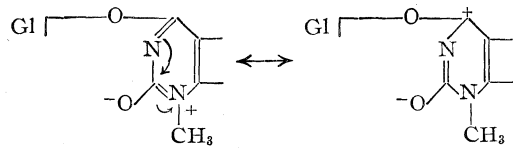
However, the products of methanolysis indicate that this is not so. As shown in VIII, the polarization of the nitrogen in position 3 could establish the continuous system IX, of which X is a resonance hybrid.



These forms are favored due to higher resonance, and would be further stabilized by the barium ions in solution. IX and X may give rise to XI as indicated

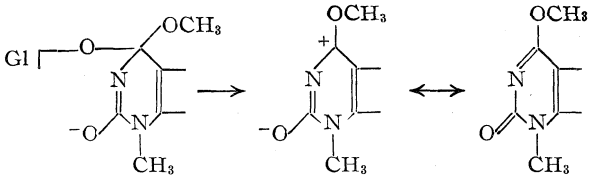
(8) Kuhn and Löw, *Ber.*, **74**, 219 (1941).

(9) We are deeply indebted to Prof. S. M. McElvain of the Chemistry Department of the University of Wisconsin for his generous suggestions concerning the electronic interpretations presented in this paper, and to Dr. H. S. Isbell of the National Bureau of Standards for reading the manuscript prior to submission for publication, and for the helpful ideas he gave.



IX XI

and upon attack by a methoxyl anion, there would be formed the intermediate XII. In methanol solution the decomposition of XII to give XIV and the glucose anion would be favored.



XII XIII XIV

This interpretation implies a fundamental difference in the activating effect upon the glycosidic linkage between the discontinuous system as represented by IV, and the continuous system formulated in IX and X. The latter permit the consideration of an aromatic type structure in which a positive center could become located on the carbon atom of the aglucon involved in the glucosidic linkage, and make this atom susceptible to attack by the methoxyl anion. Obviously the corresponding aromatic oxonium form of the 3-phenyl-4-hydroxycoumarin glycosides is not as effective a contributing structure in the alkaline cleavage of those compounds as is the ammonium cation of IX.

Whether the imidazole ring of the purine nucleus contributes to the labilizing effect of the aglucon is not known. The xyloside of 1-methyluracil is labile to alkali,[10] and it is possible that this same type of methanolysis could be duplicated with this compound.

The exact position of the methoxyl group in the theobromine residue (III) was not established. It could be either on position 2 or 6 as shown, since enolization would be possible at either carbon atom. It seems quite likely that the methoxyl group will occupy the position at which the sugar molecule was attached. The data on the ultraviolet absorption spectra indicate this (Table I).

TABLE I

ULTRAVIOLET ABSORPTION DATA OF PURINES IN METHANOL

Compound	Wave length of maxima, mμ	Mol. ext. coeff. of maxima	Wave length of minima, mμ
Methoxy-oxy-3,7-dimethylpurine (III)	245	0.36×10^4	235
	295	$.85 \times 10^4$	260
Theobromine β-D-glucoside tetraacetate (I)	245	$.33 \times 10^4$	235
	295	$.67 \times 10^4$	260
Theobromine	275	$.91 \times 10^4$	245
Caffeine	275	$.87 \times 10^4$	245

(10) Levene and Sobotka, *J. Biol. Chem.*, **65**, 469 (1925).

It is seen that the maxima and minima of I and III are identical. These are significantly different from the characteristics shown by theobromine and caffeine. By a similar study of the appropriate purine bases it should be possible to determine whether the correct linkage in the glucoside (I) is to position 2 or 6. This method has been most successfully employed by Gulland and Holiday[11] in establishing linkages in the ribosylpurines.

The methoxy-oxy-3,7-dimethylpurine (III) formed in this reaction was characterized by carbon and hydrogen analysis, by a methoxyl determination, by conversion to caffeine via the well known imidoester rearrangement,[12] and by hydrolysis to theobromine. The formation of glucose is indicated by the final rotation of the methanolysis reaction mixture, and by its reducing power.

Hydroxycaffeine D-glucoside tetraacetate, also prepared according to Fischer,[4] was treated in the same manner with dry methanol and barium methoxide. The expected 8-methoxycaffeine was not isolated, and the only substance found was the aglucon hydroxycaffeine. The structure of this glucoside is not strictly comparable to that of the theobromine glucoside, since the glycosidic linkage is to position 8 in the imidazole ring of the purine nucleus. However, it is still labile to alkali, and the methanolysis should produce definitive products. It is possible that these conditions simply effect deacetylation of the glucoside, and the process of working up the reaction, which introduces moisture, hydrolyzes the deacetylated glucoside.

Experimental

Preparation of Theobromine D-Glucoside Tetraacetate (I).—I was made from the silver salt of theobromine and tetraacetyl-D-glucosyl bromide as described by Fischer,[4] but extreme care was necessary in the preparation of the silver salt of theobromine before the reaction could be completed successfully. Thirty grams of theobromine was dissolved in 2 liters of boiling water containing an excess of ammonia, and an ammoniacal solution of silver nitrate (1 equivalent plus 2% excess) was added with stirring. The salt precipitated immediately.

To remove the last traces of ammonia, the precipitated salt was washed several times with water, and then resuspended in about a liter of water. This suspension was concentrated by boiling at atmospheric pressure until the volume was about 200 ml. This step was repeated. The salt was filtered off, washed with absolute ethanol, and dried in an oven at 130°. If this purification of the theobromine salt was not carried out, the glucoside formed in the coupling reaction was cleaved during the subsequent recrystallizations. An acetone–Skelly "B" mixture was found to be a more desirable solvent for recrystallization of the glucoside than ethyl acetate as directed by Fischer.

Methanolysis of Theobromine D-Glucoside Tetraacetate (I).—Three grams of I was dissolved in 240.4 g. of dry methanol.[5] The optical rotation of this solution was −0.37° (25°, 1 dcm.). To this solution was added 1.0 ml. of 0.387 *N* barium methoxide, and the rotation was observed until it stopped changing twelve hours later at the value +0.23° (25°, 1 dcm.). Complete conversion of the glucoside to free glucose would give a value of +0.23 (25°, 1 dcm.). To this solution was

(11) Gulland and Holiday, *Nature*, **132**, 782 (1933).

(12) Hibbert and Johnson, THIS JOURNAL, **52**, 2001 (1930).

added 4.0 ml. of 0.096 *N* sulfuric acid to precipitate the barium ions. The barium sulfate was removed by filtration through an asbestos mat. The filtrate was concentrated to dryness *in vacuo* at 50°. The white crystalline product obtained was dissolved in the minimum amount of hot absolute ethanol. The solution was filtered, and upon cooling, fine white needles separated. They were filtered off and dried in a desiccator over phosphorus pentoxide, yield 1.0 g., m. p. 244–245° when heated rapidly. Otherwise, it begins to sinter at 230° and undergoes rearrangement to caffeine. The substance is very soluble in cold water and hot alcohol. Theobromine is quite insoluble in both.

Anal. Calcd. for $C_7H_8ON_4(OCH_3)$: C, 49.5; H, 5.15; OCH_3, 15.95. Found: C, 49.7; H, 5.38; OCH_3, 15.83.

The ethanolic filtrate was diluted with water to a known volume and an aliquot was taken for the determination of the reducing power by the method of Shaffer and Somogyi.[13] Ninety per cent. of the glucose of the original glucoside was accounted for. The reducing value, the rotation of the reaction given above, and a 95% recovery of the aglucon as the methoxy derivative III establishes the formation of glucose.

Rearrangement of the Methoxy-oxy-3,7-dimethylpurine (III) to Theobromine.—Lactim ethers readily undergo rearrangement to the isomeric lactam ($-N=C-OCH_3 \rightarrow CH_3-N-C=O$) upon heating.[12] This rearrangement was employed to establish the structure of the purine residue III. About 0.2 g. of III was heated in a sealed tube at 290–300° in a lead-bath for one hour. After cooling, the tube was opened and the contents ground up in a mortar. The mixture was heated in a crucible, and the substance that sublimed was collected on the under surface of a watch glass over the crucible. The sublimate was recrystallized from absolute ethanol. It formed fine white needles, m. p. 227–231°, yield 0.15 g. One more recrystallization from the same solvent gave m. p. 230–232°. The substance showed no depression of the melting point when mixed with an authentic sample of caffeine which melted at 232–233°. A methoxyl determination was negative.

(13) Shaffer and Somogyi, *J. Biol. Chem.* **100**, 695 (1933).

The substance formed a mercuric chloride salt, m. p. 246°; reported for caffeine–mercuric chloride salt, m. p. 246°.

Conversion of III to Theobromine.—Ethers of the enolic forms of purines and pyrimidines (lactim ethers) are easily hydrolyzed by dilute acid. A small amount of III was dissolved in water and 0.1 volume of concentrated hydrochloric acid was added. The solution was boiled for five minutes. Upon cooling, it was neutralized with dilute sodium hydroxide and a white crystalline powder separated. This was filtered off and dried. The substance begins to sublime at 300° and melts at 350–355° with decomposition. An authentic sample of theobromine showed this same behavior. The material showed the characteristic solubility of theobromine, and formed an insoluble silver salt when ammoniacal silver nitrate was added to a solution of the substance in dilute ammonia water.

Anal. Calcd. for $C_7H_8O_2N_4$: C, 46.6; H, 4.45. Found: C, 46.8; H, 4.74.

Summary

1. Two purine glucosides, theobromine D-glucoside tetraacetate and hydroxycaffeine D-glucoside tetraacetate were treated with barium methoxide in dry methanol in an attempt to cleave the glucosidic linkage by methanolysis.

2. Methanolysis of theobromine D-glucoside tetraacetate occurred and the products of the cleavage were glucose and a methoxyl derivative of the aglucon. This indicates that the cleavage occurs between the glucosidic oxygen and the aglucon. The cleavage of the glucoside of hydroxycaffeine did not result in products which were indicative of the mechanism of the splitting.

3. An electronic interpretation of this reaction is offered in an attempt to rationalize the results with respect to the present concepts of the various mechanisms involved in the alkaline cleavage of the glycosidic linkage.

The Reaction of Amides with Isocyanates. II. N-Substituted Amides

BY PAUL F. WILEY

In previous studies[1,2,3] of the reaction of isocyanates with amides in which the amide nitrogen was not substituted the reaction has been shown to occur according to the equation (R′ = H).

$$RCONHR' + R''NCO \longrightarrow RCONCONHR''$$
$$\qquad\qquad\qquad\qquad\qquad\quad |$$
$$\qquad\qquad\qquad\qquad\qquad\quad R'$$

R = alkyl or aryl
R″ = alkyl or aryl

Recent investigators[4,5,6,7] who have had occasion to use the reaction of nitrogen-substituted amides with isocyanates have generally made no mention of any divergence from the above equation. However, Kühn[1,2] has reported unknown products from formanilide, acetanilide, acetnaphthalide and benznaphthalide and phenyl isocyanate as well as the formation of N,N′-diphenylbenzamidine from benzanilide. A further investigation along the lines of Kühn's[1,2] earlier work has been made in the present study.

In these experiments phenyl isocyanate was the only isocyanate used, and in addition to the amides shown in Table I, N-*n*-butylacetamide, N-isobutylundecylenamide and N-ethylbenzamide were used. The reactions were run using either boiling toluene or xylene as reaction media or no solvent at temperatures varying from 120 to 220°. Table I lists identified products obtained and

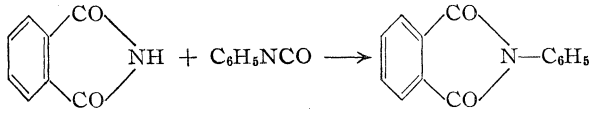
TABLE I

Amide	Solvent or temperature	Time in hours	Yield, %	Product
N-Ethylacetamide	Toluene	24	19.4	1-Acetyl-1-ethyl-3-phenylurea
ϵ-Caprolactam	Toluene	24	92	N-(Phenylcarbamyl)-ϵ-caprolactam
Succinimide	165–180°	7	1.3	1-Succinoyl-3-phenylurea
Acetanilide	Xylene	24	17.3	1-Acetyl-1,3-diphenylurea
N-Methylbenzamide	190°	2	13.2	Benzanilide
Benzanilide	200–220°	4	44	N,N'-Diphenylbenzamidine
Phthalimide	165–180°	4	14	N-Phenylphthalimide

reaction conditions. Of the products reported in Table I, the first three are new. Analyses and method of preparation were felt to be sufficient proof of structure for the first two of these compounds. However, the product obtained from succinimide and phenyl isocyanate did not give an analysis completely consistent with the proposed structure, the yield was very low, and the reaction conditions were severe. It is quite probable that the proposed structure is incorrect, but numerous attempts directed toward an independent synthesis were unsuccessful. The amides used but not listed in Table I could not be caused to react with phenyl isocyanate.

The most generally occurring reaction between substituted amides and isocyanates was the one in accord with the above equation where R′ was alkyl, aryl or acyl. This reaction occurred in all cases where reaction could be made to proceed to any detectable degree in boiling toluene or xylene. Other reactions that occurred were



$$C_6H_5CONHCH_3 + C_6H_5NCO \longrightarrow C_6H_5CONHC_6H_5$$

$$C_6H_5CONHC_6H_5 + C_6H_5NCO \longrightarrow C_6H_5C(=NC_6H_5)-NHC_6H_5$$

These three reactions appear to be quite unlike, but it is probable that the first step in each is an attachment of the isocyanate nitrogen atom to the carbon in the carbonyl group of the amide. Other products were formed in small amounts when ϵ-caprolactam and acetanilide were used at 200°, but these compounds were not identified. The product from acetanilide was a yellow solid melting above 340°. The analysis indicated a molecular formula of $C_{36}H_{28}N_5O_4$, but, due to insolubility of the compound, a molecular weight determination could not be made. The product was undoubtedly the same as that reported by Kühn[2] from the same reaction. From ϵ-caprolactam and phenyl isocyanate at 200° there was obtained a white solid for which the molecular formula $C_{13}H_{14}N_2$ seemed most likely. No satisfactory formula could be postulated for either of these compounds on a basis of the reaction of phenyl isocyanate with the amides. It is probable that they are derived from reaction of phenyl isocyanate with itself.

Reaction of substituted amides with isocyanates is much slower and more difficult to bring about than is the case with unsubstituted amides. In general the completely aliphatic amides in which the nitrogen was relatively basic and little steric hindrance was present, *i. e.*, ϵ-caprolactam, reacted best under mild conditions. Under severe conditions no clear cut pattern of reaction appeared.

Acknowledgment.—I am indebted to Messrs. W. L. Brown, H. L. Hunter and W. J. Schenck for microanalyses.

Experimental[8]

1-Acetyl-1-ethyl-3-phenylurea.—A solution of 11.9 g. (0.1 mole) of phenyl isocyanate and 8.7 g. (0.1 mole) of N-ethylacetamide in 200 cc. of dry toluene was refluxed for twenty-four hours. The solvent was removed by evaporation under reduced pressure. The residue was separated further by distillation *in vacuo* removing material boiling at 55–60° at 0.5 mm. pressure. The semi-solid substance remaining was crystallized twice from alcohol. The yield of 1-acetyl-1-ethyl-3-phenylurea, m. p. 54–58°, was 4.0 g. (19%). Three recrystallizations from alcohol changed the melting point to 55–58°.

Anal. Calcd. for $C_{11}H_{14}N_2O_2$: C, 64.08; H, 6.80; N, 13.59. Found: C, 63.86; H, 6.80; N, 13.57.

N-Phenylcarbamyl-ϵ-caprolactam.—A solution of 11.3 g. (0.1 mole) of ϵ-caprolactam and 11.9 g. (0.1 mole) of phenyl isocyanate in 200 cc. of dry toluene was refluxed for twenty-four hours. Removal of the solvent by reduced pressure evaporation left a colorless liquid residue which crystallized on cooling. The solid melted at 62–67° and weighed 22.7 g. Recrystallization of the product from alcohol gave a yield of 21.6 g. (92%) of white crystalline material, m. p. 67–69°. A small portion was recrystallized three times from alcohol, m. p. 67–69°.

Anal. Calcd. for $C_{13}H_{16}N_2O_2$: C, 67.24; H, 6.95; N, 12.06. Found: C, 67.00; H, 6.67; N, 12.03.

1,1-Succinoyl-3-phenylurea.—A mixture of 11.1 g. (0.1 mole) of succinimide and 11.9 g. (0.1 mole) of phenyl isocyanate was refluxed for seven hours. The temperature of the reaction mixture ranged from 166 to 178°. The cooled reaction mixture was dissolved in absolute alcohol, and the resulting solution was diluted with dry ether. The supernatant liquid was decanted, and the residue was dissolved in boiling alcohol, treated with charcoal, and recrystallized five times. The product crystallized in shiny white crystals, m. p. 118–120°. The yield was 0.3 g. (1.3%).

Anal. Calcd. for $C_{11}H_{10}N_2O_3$: C, 60.55; H, 4.58; N, 12.84. Found: C, 60.17; H, 4.43; N, 13.28.

1-Acetyl-1,3-diphenylurea.—A solution of 6.7 g. (0.05 mole) of acetanilide and 5.95 g. (0.05 mole) of phenyl isocyanate in 100 cc. of dry xylene was refluxed for twenty-four hours. Cooling the reaction mixture caused deposition of 4.4 g. of acetanilide, m. p. 100–105°. After the mixture was filtered, the solvent was removed from the

(8) Melting points are uncorrected.

filtrate by reduced pressure evaporation. The residue was shaken thoroughly with water, and the mixture was allowed to stand overnight. The water was poured off, and the remaining solid was crystallized from alcohol. There was obtained 2.2 g. (17%) of 1-acetyl-1,3-diphenylurea, m. p. 103–105° (lit. 105°).

N-Methylbenzamide and Phenyl Isocyanate.—A mixture of 13.5 g. (0.1 mole) of N-methylbenzamide and 11.9 g. (0.1 mole) of phenyl isocyanate was heated slowly to about 190° and maintained at that temperature for about two hours. The cooled reaction mixture solidified. Five recrystallizations from alcohol gave 2.6 g. (13%) of benzanilide, m. p. 160–162°, and no depression in melting point upon admixture with benzanilide.

N-Phenylphthalimide.—A mixture of 29.4 g. (0.2 mole) of phthalimide and 23.8 g. (0.2 mole) of phenyl isocyanate was refluxed for four hours. The cooled reaction mixture was broken up and boiled in alcohol. The alcohol was removed by filtration. The residue was dissolved in boiling acetic acid and treated with charcoal. This was followed by three recrystallizations from acetic acid. The product was a white solid, m. p. 204–206°, crystallizing in long white needles (lit. m. p. 204°). A yield of 6.2 g. (14%) was obtained.

Anal. Calcd. for $C_{14}H_9NO_2$: N, 6.28. Found: N, 6.25.

N,N'-Diphenylbenzamidine.—A mixture of 11.9 g. (0.1 mole) of phenyl isocyanate and 19.7 g. (0.1 mole) of benzanilide was heated at 200–220° for four hours. The solid obtained on cooling was recrystallized three times from absolute alcohol. The yield of white solid, m. p. 130–132°, was 12.1 g. (44%). A product melting at 140–144° was obtained after five more recrystallizations from alcohol. Kühn[2] reported a melting point of 145°.

Anal. Calcd. for $C_{19}H_{16}N_2$: N, 10.29. Found: N, 10.46.

Phenyl Isocyanate and Acetanilide at 200°.—A mixture of 13.5 g. (0.1 mole) of acetanilide and 11.9 g. (0.1 mole) of phenyl isocyanate was heated at 200–210° for four hours. The product was broken up and boiled with 150 cc. of alcohol. This mixture was cooled and filtered. There was obtained 5.3 g. of a yellow solid which melted at about 350°. This product was recrystallized four times from boiling nitrobenzene. The final compound melted at 340–375° with decomposition.

Anal. Calcd. for $C_{36}H_{28}N_5O_4$: C, 72.72; H, 4.74; N, 11.77. Found: C, 72.79; H, 4.66; N, 11.85.

Phenyl Isocyanate and ε-Caprolactam at 200°.—A mixture of 11.3 g. (0.1 mole) of ε-caprolactam and 11.9 g. (0.1 mole) of phenyl isocyanate was heated at 190–210° for four hours. The cooled reaction mixture was dissolved in boiling alcohol and filtered. The cooled filtrate deposited 1.7 g. of white crystals melting at 202–205°. Charcoaling and concentrating the filtrate gave only a black non-crystallizable oil. Five recrystallizations of the solid product from alcohol gave a sample, m. p. 209–210°.

Anal. Calcd. for $C_{13}H_{14}N_2$: C, 78.79; H, 7.07; N, 14.12; mol. wt., 198. Found: C, 78.28, 78.65, 79.21; H, 7.30, 6.48, 7.24; N, 14.53, 14.74; mol. wt., 232.

Summary

1. Under mild conditions some nitrogen substituted amides react with phenyl isocyanate to form 1,1-disubstituted-3-phenylureas, and some do not react.

2. The products obtained under severe conditions are varied and not predictable.

Chemotherapeutic Agents from Heterocyclic Amines. I. Amine Arsenicals[1]

BY DAVID FIELDING MARSH[2] AND ROBERT A. WOODBURY

The replacement of the amide NH_2 group of sulfanilamide by an NHR radical in which R represents a heterocyclic nucleus has led to compounds which are more potent and are useful for a greater variety of infections.[3] It seemed advisable to utilize these heterocyclic nuclei as substituents in other series of compounds characterized by chemotherapeutic activity.

Gough and King[4] showed the trypanocidal activity of *p*-arsenosobenzamide, and Eagle, Doak, Steinman and Hogan[5] have exhaustively investigated simple derivatives and homologs of this compound and have indicated their favorable treponemicidal activity.

The present communication reports the preparation of *p*-arsenosobenzamidoheterocycles by the reaction of *p*-dichloroarsylbenzoyl chloride with the required amine in benzene followed by hydrolysis of the *p*-arsenosobenzamidoheterocycles.

Experimental Part

Preparation of Amides.—The amine (0.2 mole), recrystallized from benzene before use, was dissolved in 250–600 ml. of warm benzene in an erlenmeyer flask and 12 ml. of freshly distilled *p*-dichloroarsylbenzoyl chloride[6] was added with shaking. The mixture was refluxed for twenty minutes to an hour and the supernatant liquid decanted into a beaker. The material which adhered to the flask was dissolved in warm 95% ethanol. On cooling, the desired *p*-arsenosobenzamide separated and was removed by filtration. Partial evaporation of the filtrate yielded some *p*-arsenosobenzoic acid. The by-product amine hydrochloride can be obtained by complete evaporation of the filtrate. The yields of amide were 35–45%, based on the amount of amine used. By recrystallizing the residual material from absolute methanol instead of 95% ethanol it was possible to prepare the dichloroarsylbenzamides. The decanted benzene contained some of the corresponding dichloroarsylbenzamide along with some unreacted amine. The products are white amorphous powders that are tinged slightly yellow or pink if

[a] Maximal tolerated dose for intraperitoneal injection in twenty gram mice, expressed as the number of milligrams/kilogram, and determined by Dr. H. J. Robinson, Merck Institute for Therapeutic Research, Rahway, N. J. [b] 2-Aminothiazole was generously supplied by Dr. D. F. Robertson, Merck & Co., Rahway, N. J. [c] 2-Aminothiazoline was generously supplied by Dr. George W. Raiziss, Dermatological Research Laboratories, Philadelphia, Pa. [d] Previously synthesized by Doak, *et al.*, ref. 5a. [e] 2-Aminopyrimidine, 2-amino-4-methylpyrimidine and 2-amino-4,6-dimethylpyrimidine were generously supplied by Dr. Jackson P. English, American Cyanamid Co., Stamford, Conn., and Dr. E. H. Northey, Calco Chemical Division of the American Cyanamid Co., Bound Brook, N. J. [f] The customary difficulties in determining the nitrogen content of pyrimidines was experienced. The values represent the average of the two highest determinations. The other nitrogen determinations and the arsenic determinations are the average of three or more determinations. [g] The dichloroarsylbenzamide compounds of pyridine, 4-methylthiazole and the pyrimidines were not isolated.

Pharmacological Activity.—We are grateful to Dr. H. J. Robinson of the Merck Institute for Therapeutic Research for carrying out preliminary tests on these compounds. Our own preliminary studies against *T. equiperdum* infections in mice have not proved encouraging. Dr. Robinson found that although the compounds are highly active *in vitro* against *T. equiperdum* and *Dirofilaria immitis*, their high toxicity *in vivo* for the host makes their use undesirable. The results with the 2-*p*-arsenosobenzamidopyridine agree with those of Eagle, *et al.*,[5c] who reported the MTD for mice as 2.3 mg./kg. and although the compound possessed a high treponemicidal activity it had a low chemotherapeutic index.

Summary

The *p*-arsenosobenzoyl derivatives of 2-aminothiazole, 2-aminothiazoline, 2-aminopyridine, 2-amino-4-methylthiazole, 2-aminopyrimidine, 2-amino-4-methylpyrimidine and 2-amino-4,6-dimethylpyrimidine were synthesized. The *p*-dichloroarsylbenzoyl derivatives of 2-aminothiazol- and 2-aminothiazoline have been prepared.

Preliminary pharmacological tests with these compounds have not indicated favorable chemotherapeutic activity.

AUGUSTA, GA. RECEIVED JUNE 16, 1949

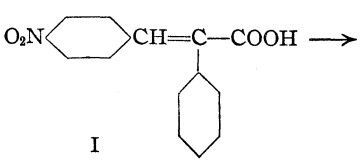
The Preparation of Three Aminodiiodophenyl-phenylpropionic Acids

BY T. R. LEWIS, MARGARET G. PRATT, E. D. HOMILLER, B. F. TULLAR AND S. ARCHER

Several years ago a program was initiated in this Laboratory the goal of which was the discovery of a superior radiopaque to be used in clinical cholecystography. As a part of this study, three isomeric aminodiiodophenylphenylpropionic acids were prepared for pharmacological evaluation. The synthesis of these acids is the subject of the present report.

A common structural feature which is shared by the cholecystographic agents examined clinically up to now is the diiodohydroxyphenyl group. It has been suggested that the presence of the hydroxyl in a gall-bladder contrast medium is necessary for visualization of this organ.[1] The utility of our compounds has been determined by Hoppe[2] who has found that the amino may replace the hydroxyl group without impairing the usefulness of the drug.[3] It is our belief that the sole function of these radicals is to facilitate the introduction of the iodine atoms into the benzene ring. The diiodo acid, III, was prepared according to the equations

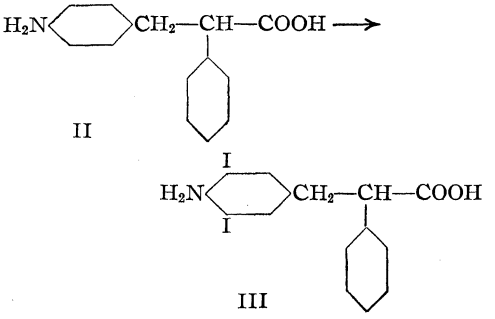


I

(1) Epstein, Natelson and Kramer, *J. Am. Roentgenol.*, **56**, 202 (1946).

(2) Hoppe and Archer, *Federation Proc.*, **8**, 303 (1949).

(3) Other work in this Laboratory has demonstrated that neither the amino nor hydroxyl group is essential for good visualization.



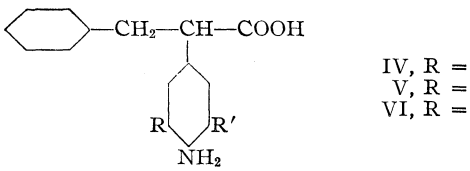
II

III

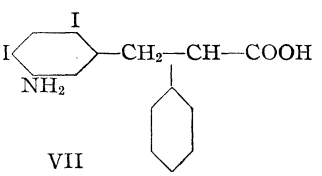
The *p*-nitrobenzaldiacetate was prepared by a slight modification of the standard method.[4] A readily separable mixture of *cis* and *trans* isomers was obtained by modification of known methods.[5,6] Under optimum conditions the combined yield of isomers was 80–85%.[7]

Reduction of the pure higher melting form of I in the presence of Raney nickel catalyst afforded the amino acid, II, in 97% yield. The crude mixed isomers yielded the same substance of comparable purity in 90% of the theoretical amount. The iodination was carried out in dilute acetic acid with iodine monochloride. Analytically pure III was obtained as tan needles after recrystallization from methanol in 64% yield. After our work had been completed the acid, III, was reported by Barnett and coworkers.[8]

The isomeric diiodo acid, V, was synthesized by a similar series of reactions. A mixture of



IV, R = R′ = H
V, R = R′ = I
VI, R = H, R′ = I



VII

isomeric *α*-*p*-nitrophenylcinnamic acids was obtained in about 80% yield. Buckles[7] obtained only one isomer in 13% yield with the aid of triethylamine. Catalytic reduction of the nitro acid resulted in a quantitative yield of the saturated amino acid, IV.

When the iodination of this compound was performed under conditions which were satisfactory for the formation of the isomeric acid, III, the product, V, was obtained in very small amounts (15–25% yield). The material was contaminated with tarry by-products which were difficult to remove. When iodinated in hydrochloric acid solution, IV gave two products which were separated by chloroform extraction. The soluble product proved to be the desired diiodo acid, V. The insoluble material, which could not be recrystallized and melted at 182°, contained ionic chlorine. When dissolved in sodium hydroxide and the solution carefully acidified a new substance separated. The analytical data indicated that this was the monoiodo acid, VI, and the substance from which it was obtained was the corresponding hydrochloride salt.

It appeared that in acetic acid solution the desired product, V, was being attacked further by the iodine monochloride thereby lowering the yield. It was hoped that removal of the diiodo acid from the reaction zone as soon as it was formed would result in improvement in both quantity and quality of the final product. Actually this proved to be the case, for when chloroform or tetrachloroethane was added to the reaction mixture iodination proceeded smoothly. The over-all yield of analytically pure material, based on *α*-nitrophenylcinnamic acid, was 64%.

It was of some pharmacological interest to obtain the optical antipodes of V. These were secured by iodination of the active forms of IV. *d*-Desoxyephedrine served as a satisfactory resolving agent for *α*-phenyl-*β*-aminophenylpropionic acid since there was a wide difference in solubility of the diastereomeric salts in ethyl acetate. The iodination of the optically active forms of IV was carried out as in the case of the *dl*-form.

The isomer VII was prepared by the same sequence that was used for III and V. The *α*-phenyl-*m*-nitrocinnamic acid was prepared by Koelsch's method.[6] No attempt was made to find optimum conditions for the iodination step. The position of the iodine atoms in the benzene ring was not determined but it is believed that the expression, VII, is the most probable structure for the compound.

Experimental[9]

α-Phenyl-*p*-nitrocinnamic Acid.—A mixture of 560 g. of *p*-nitrobenzaldiacetate, 340 g. of phenylacetic acid, 228 g. of fused sodium acetate and 560 ml. of acetic acid was refluxed for ten hours. At the end of this time the dark reaction mixture was cooled to 40° and slowly poured with stirring into three liters of water. After cooling to 5° the crystalline product was collected and the filtrate (A) reserved.

The filter cake was broken up and added to a solution of 80 g. of sodium hydroxide in four liters of water. The solution was clarified (Filtercel) and acidified with glacial acetic acid. The acid which separated was collected on a filter, washed with water and dried; yield, 387 g., m. p. 190–205°. The filtrate was combined with filtrate (A) above and acidified strongly with hydrochloric acid. In this way 40 g. of crude low melting isomer (m. p. 100–

(5) Bakunin, *Gazz. chim. ital.*, **27**, II, 36 (1897); **31**, II, 83 (1901).

(6) Koelsch and Johnson, THIS JOURNAL, **65**, 565 (1943).

(7) Buckles and Housman, *ibid.*, **70**, 414 (1948), prepared the acid, I, in 66% yield using triethylamine instead of sodium acetate. They did not report the presence of the low melting isomer.

(8) Barnett, Robinson and Wilson, *J. Chem. Soc.*, 203 (1947).

(9) All melting points unless otherwise specified are uncorrected. Analyses were carried out under the supervision of Mr. M. E. Auerbach.

110°) was obtained; total yield, 427 g. or 70% of the theoretical. When the reflux period was doubled the combined yield of the desired product was increased to 80–85%. When recrystallized from ethanol, the higher melting form melted at 208–210°. The lower melting form was crystallized from dilute ethanol, m. p. 143–145°. Bakunin[5] reported 213–214° and 147°, respectively, as the melting points of these isomers.

β-*p*-Aminophenyl-α-phenylpropionic Acid.—A water solution of 427 g. of the crude mixed acids and 66 g. of sodium hydroxide was reduced at 70° and 1,000 p.s.i. in the presence of Raney nickel catalyst. After six hours the theoretical amount of hydrogen was absorbed. The catalyst was filtered off and the filtrate made acid to congo red with 400 ml. of hydrochloric acid. The solution was cooled in ice and filtered. The crystalline hydrochloride was washed with 20% hydrochloric acid and dried *in vacuo* at 50°; yield, 400 g. (90%), m. p. >270°. Neutralization of the filtrate afforded 20 g. of the amino acid, m. p. 204–205°.

Anal. Calcd. for $C_{15}H_{15}NO_2 \cdot HCl$: Cl, 13.07. Found: Cl, 12.95.

When the pure α-phenyl-*p*-nitrocinnamic acid, m. p. 208–210°, was reduced and the filtrate from the reduction mixture made slightly acidic the free amino acid was secured in 97% of the theoretical yield, m. p. 200–203°.

β-(4-Amino-3,5-diiodophenyl)-2-phenylpropionic Acid.—A solution of 85 g. of the amino acid hydrochloride, II, in 750 ml. of acetic acid and 650 ml. of water was heated to 80°. Then a solution of 36 ml. of iodine monochloride in 120 ml. of acetic acid was added over a period of thirty minutes. After one hour more at this temperature the mixture was cooled to 60° and treated with 20 g. of sodium bisulfite. After cooling to zero degrees the whole was filtered. The product was washed with water and air-dried, wt. 110 g.

The crude acid was dissolved in 600 ml. of warm methanol, treated with 50 ml. of water previously saturated with sulfur dioxide and decolorized with Norite. Water was added to the filtrate to incipient turbidity and the solution cooled. The product was removed by filtration, washed with 70% methanol and dried; wt. 98 g. or 64% of the theoretical yield, m. p. 175–176.8° (cor.).

Anal. Calcd. for $C_{15}H_{13}I_2NO_2$: I, 51.48; N, 2.66. Found: I, 51.87; N, 2.70.

The compound obtained above was light tan. A white product was obtained in the following way. A 120-g. sample of the diiodo acid, m. p. 162–166°, was dissolved in acetone and treated with 25 g. of morpholine. The salt was collected and recrystallized from dilute ethanol. The first crop of needles was collected and dried, wt. 72 g. The melting point depended upon the rate of heating.

Anal. Calcd. for $C_{15}H_{13}I_2NO_2 \cdot C_4H_8NO$: $N_{A.P.}$, 2.44. Found: $N_{A.P.}$, 2.62.[10] The salt was dissolved in 1.5. liters of ethanol and to the solution there was added 200 ml. of 3% sodium hydrosulfite. The cloudy solution was filtered (Filtercel) and the filtrate further diluted with 750 ml. of water. It was saturated with sulfur dioxide and allowed to cool slowly. The next day the heavy white crystals of the pure acid were filtered and dried. The product, which weighed 65 g., melted at 175–176.2° (cor.).

***p*-Nitrophenylacetic Acid.**—The following is better suited for a large scale preparation than the one described in "Organic Syntheses."[11] In a 22-liter flask equipped with a stirrer and reflux condenser there was placed 7 liters of water. Then 7.5 liters of sulfuric acid was added carefully and, when the solution had cooled to 50°, 2500 g. of *p*-nitrobenzyl cyanide was added in one portion. The contents of the flask were heated (Glas-col mantle) until the inner temperature had reached 140–150° and the solution began to reflux. Heating was continued for another fifteen minutes. The total heating time was one and one-half hours. The clear solution was poured into 15 liters of water with vigorous stirring. The nitrophenylacetic acid was removed by filtration, washed with cold water and dried. The cream-colored solid weighed 2700 g. and melted at 151–153°. The yield was 97% of the theoretical.

α-*p*-Nitrophenylcinnamic Acid.—A mixture of 380 g. of *p*-nitrophenylacetic acid, 267 g. of benzaldehyde, 264 g. of fused sodium acetate and 1200 ml. of acetic anhydride was refluxed for twelve hours and poured into 3500 ml. of water. The cooled mixture was filtered and the solid (Fraction A) was saved. The filtrate was made strongly acid with hydrochloric acid and cooled. The pale yellow crystals (Fraction B) were collected.

Fraction A was heated in a sodium carbonate solution and the mixture filtered. The filtrate was extracted with benzene to remove some oily material and then acidified to give 410 g. of the higher melting acid (m. p. 210–213). After recrystallization from ethanol the product melted at 219–221°.[12]

Anal. Calcd. for $C_{15}H_{11}NO_4$: N, 5.20. Found: N, 4.92.

Fraction B, which weighed 44 g. and melted at 140–143° was crystallized from chloroform–ligroin until the melting point reached 150–152°.

Anal. Calcd. for $C_{15}H_{11}NO_4$: N, 5.20. Found: N, 5.25.

In another experiment, in which benzaldiacetate was generated *in situ* from benzaldehyde and acetic anhydride the yield of mixed *cis* and *trans* isomers was 80% after a sixteen-hour heating period. This product was reduced to the amino acid in 93% yield.

α-Aminophenyl-β-phenylpropionic Acid.—The reduction of 48.2 g. of the sodium salt of the higher melting acid was carried out at 350 p.s.i. Hydrogen was absorbed at room temperature and after the gas uptake had slackened the temperature was raised to 130° to complete the reaction. The operation required ninety minutes. The catalyst (Raney nickel) was removed and the filtrate then made faintly acidic. The solid that separated weighed 48.7 g. (98%) and melted at 200–203°. A small sample, after recrystallization from ethanol, melted at 202–204°.

Anal. Calcd. for $C_{15}H_{15}NO_2$: N, 5.81. Found: N, 5.76.

The hydrochloride was prepared by cooling a hot solution of the amino acid in 6 *N* hydrochloric acid. The white needles thus obtained melted above 250°.

Anal. Calcd. for $C_{15}H_{15}NO_2 \cdot HCl$: C, 74.66; H, 6.27. Found: C, 74.47; H, 6.08.

α-(4-Amino-3,5-diiodophenyl)-β-phenylpropionic Acid.—The filtered reduction mixture which originally contained 50 g. of α-*p*-nitrophenylcinnamic acid was acidified with 40 ml. of hydrochloric acid and maintained at 80°.

A mixture of 300 ml. of *sym*-tetrachloroethane (or an equal volume of chloroform), 67.0 g. of iodine monochloride and 180 ml. of 6 *N* hydrochloric acid was warmed to 50°. The solution of amino acid hydrochloride was added over a period of fifteen minutes at 50–55°. The mixture was heated at 55° for ten more minutes and cooled. The layers were separated and the organic phase washed with 250 ml. of 5% sodium hydrosulfite. After washing with water, 5 g. of Darco was added and the mixture stirrred at room temperature for one hour. After the charcoal was removed, the solution was diluted with three volumes of petroleum ether. The solid that separated was collected and dried. It weighed 79.6 g. and melted at 142.6–143.8° (cor.). It was taken up in a mixture of 350 ml. of ethanol and 125 ml. of water and decolorized. The filtrate deposited 65 g. of the diiodo acid, m. p. 141–145.4° (cor.). After recrystallization from benzene–ligroin there was obtained 57.4 g. of cream-colored needles, m. p. 144–146.2° (cor.). The yield was 64% based on the cinnamic acid.

Anal. Calcd. for $C_{15}H_{13}I_2NO_2$: I, 51.48. Found: I, 51.24.

A typical experiment in which the organic solvent was omitted from the reaction mixture gave a product from which two substances were isolated.

(10) Perchloric acid titration of the morpholine nitrogen. This salt was first prepared by M. E. Auerbach of this Laboratory.

(11) "Organic Syntheses," Coll. Vol. I, p. 406.

(12) Walther and Wetzlich, *J. prakt. Chem.*, [2] **61**, 181 (1900), reported the m. p. as 224.5°.

Seventy grams of the amino acid hydrochloride was added to a solution of 900 ml. of 4 *N* hydrochloric acid and 32 ml. of iodine monochloride over a period of two hours. After one-half hour 200 ml. of hydrochloric acid was added and about one hour later 950 ml. of water. The mixture was heated to 80° for one hour and diluted with 500 ml. of water. It was cooled to 35° and saturated with sulfur dioxide. The solid was filtered off and dried, wt. 107 g. It was heated with chloroform and filtered. The insoluble residue weighed 53 g. The chloroform solution was diluted with petroleum ether and cooled. A total of 35 g. of crude diiodo acid was collected which, after recrystallization from ethanol, amounted to 16.0 g. of crystals, m. p. 139–141°. The recrystallization was not smooth since a dark oil tended to separate and contaminate the product. The chloroform-insoluble fraction which melted at 182° (dec.) was probably the hydrochloride of VI.

Anal. Calcd. for $C_{15}H_{14}INO_2 \cdot HCl$: Cl, 8.80. Found: Cl, 8.63. Twenty grams of this material was dissolved in 15% sodium hydroxide and carefully neutralized. The oil that separated soon solidified. It was recrystallized from dilute methanol several times and then melted at 116.8–117.7° (cor.).

Anal. Calcd. for $C_{15}H_{14}INO_2$: I, 34.55. Found: I, 34.60.

α-(4-Acetamido-3,5-diiodophenyl)-β-phenylpropionic Acid.—Thirty grams of α-(4-amino-3,5-diiodophenyl)-β-phenylpropionic acid and 250 ml. of acetic anhydride containing 0.5 ml. of sulfuric acid was refluxed for ninety minutes and poured into water. The semi-solid product was washed with water by decantation and then dissolved in 100 ml. of 10% sodium hydroxide solution. After filtration the solution was made acid with acetic acid. The crystals were filtered and recrystallized from ethanol. There was obtained 19 g. of acetyl body, m. p. 215–217°. After another recrystallization it melted at 221.2–223.5° (cor.).

Anal. Calcd. for $C_{17}H_{15}I_2NO_3$: C, 38.16; H, 2.83; I, 47.44. Found: C, 38.37; H, 3.04; I, 47.60.

Resolution of *dl*-α-(4-Aminophenyl)-β-phenylpropionic Acid.—A solution of 240 g. of the *dl*-amino acid and 160 g. of *d*-desoxyephedrine in 2500 ml. of ethyl acetate was allowed to stand at 25° for one hour. The crystals were filtered and recrystallized from ethyl acetate. In this way 129 g. of a pure diastereomeric salt, m. p. 148–150°, was secured. A 120-g. sample was dissolved in 2500 ml. of boiling water and slowly acidified with 50 ml. of acetic acid. On cooling, 70 g. of pure *d*-α-(4-aminophenyl)-β-phenylpropionic acid deposited. The acid melted at 186–188°; $[\alpha]^{25}D$ (5% in H_2O) +102°.

Anal. Calcd. for $C_{15}H_{15}NO_2$: neutral equivalent, 241.1. Found: neutral equivalent, 240.2.

The ethyl acetate filtrate from the original crystallization was concentrated to dryness *in vacuo*. The residue was dissolved in water and made strongly basic. The desoxyephedrine was gathered with ether. In this way 100 g. of the resolving agent was recovered. The aqueous solution was acidified and the crude *l*-amino acid was filtered off.

The product was dissolved in 1600 ml. of boiling ethyl acetate and 104 g. of *l*-desoxyephedrine added. On cooling a salt separated which was recrystallized from the same solvent. It weighed 115 g. and melted at 148–150°. Thirty three grams of this salt was converted to 19 g. of the *l*-amino acid, which melted at 186–188°, $[\alpha]^{25}D$ (5% in water) −103°.

Anal. Calcd. for $C_{15}H_{15}NO_2$: neutral equivalent, 241.1. Found: neutral equivalent, 239.5.

***d*-α-(4-Amino-3,5-diiodophenyl)-β-phenylpropionic Acid.**—The *d*-amino acid (70 g.) was iodinated according to the procedure described for the *dl* compound. However, the diiodo acid was separated from the chloroform solution by extraction with ammonium hydroxide in which the ammonium salt of the diiodo acid was insoluble. It was collected, washed with acetone and dried, wt. 125 g. It was dissolved in water containing a few ml. of ammonium hydroxide and slowly acidified with acetic acid. The product was collected, dried and recrystallized from chloroform–petroleum ether. There was recovered 87 g. (63%) of pure material, m. p. 118.4–119.8° (cor.), $[\alpha]^{25}D$ (1.5% in 95% ethanol) +88.5°.

Anal. Calcd. for $C_{15}H_{13}I_2NO_2$: C, 36.54; H, 2.66; I, 51.48. Found: C, 36.39; H, 2.79; I, 51.75.

***l*-α-(4-Amino-3,5-diiodophenyl)-β-phenylpropionic Acid.**—Seventeen grams of the *l*-amino acid gave 13.0 g. of the *l*-diiodo acid, m. p. 118–120° (cor.), $[\alpha]^{25}D$ (1.5% in 95% ethanol) −88.4°. The specimen of the iodinated product which was first obtained melted at 102.5–103.5° (cor.). The rotation and analytical data were the same as that obtained for the higher melting form. Apparently this was an unstable polymorph since on standing it changed to the higher melting form. Once the latter was obtained we were unable to secure the low-melting compound.

Anal. Calcd. for $C_{15}H_{13}I_2NO_2$: C, 36.54; H, 2.66; I, 51.48. Found: C, 36.68; H, 2.70; I, 51.60.

α-Phenyl-*m*-nitrocinnamic Acid.—A mixture of 16.0 g. of *m*-nitrobenzaldehyde, 13.6 g. of phenylacetic acid, 16.0 g. of fused sodium acetate and 51 ml. of acetic anhydride was refluxed for sixteen hours. The whole was poured into water, cooled and filtered. The solid (Fraction A) was dissolved in 200 ml. of 3% sodium hydroxide solution, extracted with benzene and acidified with 11 ml. of acetic acid. In this way 21.1 g. of a crystalline solid, m. p. 130–140°, was obtained. The filtrate was combined with the one obtained above and acidified strongly with hydrochloric acid. The solid that separated weighed 2.2 g. and melted at 160–170° (Fraction B). The combined yield, 23.3 g., was 87% of the theoretical. This material was suitable for use in the reduction step.

Fraction A was twice recrystallized from ethanol. Seven grams of pure isomer, m. p. 183.8–185.2° (cor.), was obtained. Fraction B was purified in the same way, m. p. 193–196°.[13]

β-*m*-Aminophenyl-α-phenylpropionic Acid.—A solution of 48.2 g. of the nitrocinnamic acid in 500 ml. of 0.4 *N* sodium hydroxide was reduced at 70° using Raney nickel catalyst. Slight acidification of the filtrate from the catalyst resulted in the deposition of a gummy solid. The *p*H was adjusted to 7 and the suspension warmed on the steam-bath. The gum gradually solidified. It was filtered and dried. It weighed 46.4 g. (96%) and melted at 129–132°. After recrystallization from water the product melted at 131–132°.

Anal. Calcd. for $C_{15}H_{15}NO_2$: C, 74.66; H, 6.27. Found: C, 74.62; H, 6.07.

β-(5-Amino-2,4-diiodophenyl)-α-phenylpropionic Acid.—The amino acid (49.0 g.) was dissolved in 800 ml. of acetic acid and heated to 80°. A solution of 23 ml. of iodine monochloride in 150 ml. of acetic acid was added over a period of forty minutes. The mixture was heated at 80–90° for an additional hour, cooled and filtered. The filter cake was washed with acetic acid and then ether. The crude material amounted to 90 g. After two recrystallizations from dilute ethanol (sulfur dioxide was used to decolorize the solution in the first crystallization) the pure diiodo acid melted at 205–205.4° (cor.) and weighed 26.5 g.

Anal. Calcd. for $C_{15}H_{13}I_2NO_2$: I, 51.48; N, 2.84. Found: I, 51.90; N, 2.76.

Summary

1. The preparation of β-(4-amino-3,5-diiodophenyl)-α-phenylpropionic acid, α-(4-amino-3,5-diiodophenyl)-β-phenylpropionic acid and β-(5-amino-2,4-diiodophenyl)-α-phenylpropionic acid has been described.

2. The resolution of α-(4-aminophenyl)-β-phenylpropionic acid has been achieved and the resulting optical antipodes converted to the corresponding diiodo derivatives.

RENSSELAER, NEW YORK RECEIVED MARCH 14, 1949

(13) Bakunin (ref. 5) reported 181–182° and 195–196° as the melting points of the isomers.

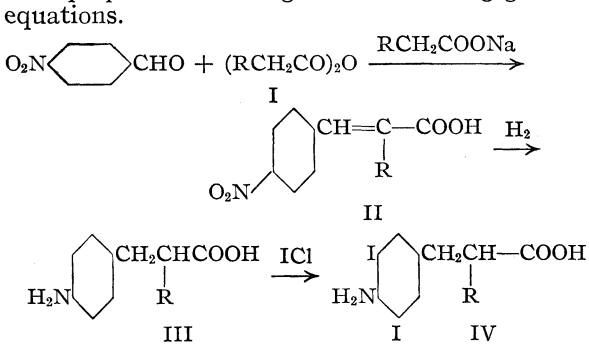
[CONTRIBUTION FROM THE STERLING-WINTHROP RESEARCH INSTITUTE]

The Preparation of Some Iodinated Aminophenylalkanoic Acids

BY T. R. LEWIS AND S. ARCHER

In a previous communication the synthesis of three isomeric (amino-diiodophenyl)-phenylpropionic acids was reported.[1] It was found that two of these concentrated sufficiently in the gall-bladder so as to render this organ opaque to X-rays.[2] It seemed advisable to determine whether one of the phenyl radicals may be replaced by another hydrocarbon group without impairing the efficiency of the compounds as contrast media. While this work was in progress two papers appeared in which it was shown that certain (diiodo-hydroxyphenyl)-alkanoic acids did provide visualization of the gall-bladder for radiological examination.[3,4] The compounds reported below were fed orally to animals and after a suitable interval cholecystograms were obtained. The compounds represented by IV produced adequate visualization of the gall-bladder except in the cases where R contained a cyclohexyl group.

The (4-amino-3,5-diiodophenyl)-alkanoic acids were prepared according to the following general equations.

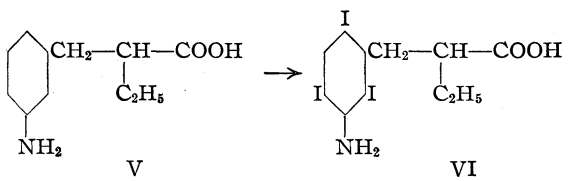


The anhydrides, I, were prepared according to the general procedure of Allen, *et al.*[5] These condensed with *p*-nitrobenzaldehyde in the presence of the sodium salt of the corresponding acid to give II in yields varying from 25–80%. In one preparation (R = *i*-amyl) we employed triethylamine in place of sodium isoheptanoate and secured the acid II (R = *i*-amyl) in 52% yield. In contrast to the aromatic series in no instance were we able to isolate more than one isomer corresponding to II.

Reduction of the unsaturated nitro acids was carried out with the aid of Raney nickel catalyst and the iodination of the resulting amino acids was carried out as described previously.[1]

Condensation of *m*-nitrobenzaldehyde with butyric anhydride in the presence of sodium butyrate resulted in the formation of α-ethyl-*m*-nitrocinnamic acid in 72% yield. When triethylamine was used as the condensing agent the yield fell off to 52% of the theoretical.

Reduction of the acid gave V, which, surprisingly, was quite low melting and difficult to obtain analytically pure. Both methods A and



B were tried but the latter did not seem to offer any advantages with respect to yield. The substance which was isolated from the reaction mixture proved to be the triiodoacid, VI. It may be recalled that when β-(*m*-aminophenyl)-α-phenylpropionic acid was iodinated only the diiodo acid was secured.[1] It is probable that the bulkier phenyl group prevented the third iodine atom from entering the remaining position ortho to the amino group.

Experimental[6]

Preparation of the Acid Anhydrides (I).—Without exception, the method described in "Organic Syntheses"[5] was used. Most of the anhydrides have been described previously.

β-Cyclohexylpropionic anhydride was obtained in 71% yield. It boiled at 154–158° at 0.5 mm., $n^{25}D$ 1.4720.

Anal. Calcd. for $C_{18}H_{30}O_3$: C, 73.43; H, 10.27. Found: C, 73.74; H, 10.15.

γ-Cyclohexylbutyric anhydride was obtained in 68% yield. It boiled at 169–172° at 0.5 mm., $n^{25}D$ 1.4730.

Anal. Calcd. for $C_{20}H_{34}O_3$: C, 74.49; H, 10.63. Found: C, 74.34; H, 10.45.

α-Ethyl-*m*-nitrocinnamic Acid.—A mixture of 100 g. of *m*-nitrobenzaldehyde, 210 g. of butyric anhydride and 73 g. of dry sodium butyrate was heated with stirring at 140° for seven hours. The red reaction mixture was cooled and then steam distilled for four hours, when crystals appeared in the flask. These were filtered and dried, wt., 130 g. The product was dissolved in 2 *N* sodium hydroxide and the solution filtered. After acidification with hydrochloric acid, the acid which separated was collected and recrystallized from dilute ethanol. In this way there was obtained 105 g. of the acid which melted at 140–142° (uncor.).

Anal. Calcd. for $C_{11}H_{11}NO_4$: N, 6.33. Found: N, 6.35.

The nitrocinnamic acids listed in Table I were prepared by essentially the same method. In the cases wherein the alkanoic acids were not volatile with steam, the hydrolyzed reaction mixture was dissolved in sodium hydroxide solution and then extracted with ether. The basic layer was acidified and the organic acids removed with ether. The solution was concentrated and the residue leached with a

[a] Details of Methods A and B are found in the Experimental Part. [b] C_6H_{11} = Cyclohexyl.

large volume of petroleum ether. The insoluble material was the desired α-alkyl-*p*-nitrocinnamic acid.

α-Ethyl-β-(*m*-aminophenyl)-propionic Acid.—Fifty grams of the nitro acid was dissolved in 500 ml. of ether containing 9.1 g. of sodium hydroxide and reduced at 70° with Raney nickel catalyst. After two hours reduction was complete. The filtered solution was made slightly acidic with acetic acid and concentrated to about 200 ml. A few ml. of acetic acid was added whereupon an oil separated which gradually solidified. It weighed 20 g. The supernatant liquid was decanted and concentrated to dryness *in vacuo*. The residue was leached with boiling ether. The leachings were concentrated to leave a viscous oil which crystallized on cooling and seeding (wt. 20 g.). The solids were combined and recrystallized from benzene–petroleum ether (Darco). The product, which melted at 67–70° weighed 34.5 g. and was suitable for use in the iodination. Further purification raised the m. p. to 78–80°.

Anal. Calcd. for $C_{11}H_{15}NO_2$: N, 7.25. Found: N, 7.21.

The amino acids listed in Table II were prepared by the same procedure. In all cases careful acidification of the filtered reduction mixture caused the compounds to separate in the yields indicated and in satisfactory condition for use in the next step. The analytical samples were obtained after one or two crystallizations from the solvents noted.

β-(Amino-2,4,6-triiodophenyl)-α-ethylpropionic Acid.—A solution of 34.0 g. of β-(*m*-aminophenyl)-α-ethylpropionic acid in 110 ml. of 6 *N* hydrochloric acid was warmed to 70°. Then a solution of 94.3 g. of iodine monochloride in 220 ml. of 6 *N* hydrochloric acid was added in one portion. A dark oil separated almost immediately. After one hour 500 ml. of water was added over a fifteen-minute period. The oil solidified. While the temperature was kept at 70°, 1000 ml. of water and 28.5 g. of iodine monochloride was added during the next five hours. The whole was cooled and filtered. The crude, dried solid which weighed 103 g. was crystallized from chloroform–ligroin. It then weighed 74 g. and melted at 147–150°. After three crystallizations from dilute methanol (Darco was used in the first two) there was obtained 42 g. of cream-colored needles melting at 155.2–157° (cor.) (42%).

Anal. Calcd. for $C_{11}H_{13}I_2NO_2$: I, 66.68. Found: I, 66.70.

β-(4-Amino-3,5-diiodophenyl)-α-propylpropionic Acid (Method A).—A solution of 26.2 g. of iodine monochloride in 200 ml. of 6 *N* hydrochloric acid was warmed to 70°. To the stirred solution there was added over a period of ninety minutes a solution of 16.0 g. of β-(*p*-aminophenyl)-α-propylpropionic acid in 440 ml. of 0.12 *N* hydrochloric acid. After one-half hour an oil separated. It gradually solidified. After one hour more at 70° the mixture was cooled, diluted with 500 ml. of water and saturated with sulfur dioxide. The product was filtered and dried. It melted at 111–113° and amounted to 32 g. It was recrystallized from dilute methanol with practically no change in melting point. The compound (29.5 g.) was dissolved in ether and treated with a slight excess of morpholine. The salt was filtered and recrystallized twice from benzene–ligroin. The pink plates melted at 130–132°. The crystals were dissolved in methanol and the solution diluted with water. It was then saturated with sulfur dioxide and further diluted to the point of incipient crystallization. On slow cooling 19.0 g. of the product separated which melted at 121–121.8° (cor.).

Anal. Calcd. for $C_{12}H_{15}I_2NO_2$: C, 31.39; H, 3.29. Found: C, 31.52; H, 3.18.

β-(4-Amino-3,5-diiodophenyl)-α-ethylpropionic Acid (Method B).—A solution of 87.4 g. of iodine monochloride in 150 ml. of 8 *N* hydrochloric acid and 300 ml. of chloroform was stirred and warmed to maintain a gentle reflux. A solution of β-(*p*-aminophenyl)-α-ethylpropionic acid in dilute hydrochloric acid prepared by acidifying the reduction mixture from 50 g. of α-ethyl-*p*-nitrocinnamic acid was added over a forty-minute period. After refluxing for forty minutes more the two-phase system was cooled and the layers separated. The aqueous portion was washed with chloroform. The combined organic layers were washed with two 150-ml. portions of water, two 120-ml. portions of 5% aqueous sodium hydrosulfite and again with water. The chloroform solution was dried over Drierite and diluted with petroleum ether. On standing 66.5 g. of the crude diiodo acid separated. After recrystallization from dilute methanol with the aid of Darco there was obtained 58.7 g. of pure product which melted at 114.2–115.1° (cor.).

Summary

1. The preparation of several β-(4-amino-3,5-diiodophenyl)-α-alkylpropionic acids has been described. These were obtained by iodination of the corresponding α-alkyl-β-(aminophenyl)-propionic acids which in turn were secured by catalytic reduction of the α-alkyl-*p*-nitrocinnamic acids.

2. α-Ethyl-β-(*m*-aminophenyl)-propionic acid gave a triiodo acid when treated with iodine monochloride.

Reaction of Aliphatic Amines with 3-Nitro-4-chlorophenylarsonic Acid

BY ROBERT L. MCGEACHIN

In the study of the preparation of organic arsenicals of possible therapeutic use against protozoa and spirochetes, it has been found[1,2,3,4] that 3-nitro-4-chlorophenylarsonic and 3-nitro-4-bromophenylarsonic acids will react with certain amines and phenols to give 3-nitro-4-alkylaminophenylarsonic and 3-nitro-4-phenoxyphenylarsonic acids. There are a number of amines that have not been used in this type reaction, however, particularly the polyethylenepolyamines, so it was decided to investigate the preparation of these substituted 4-amino compounds.

In all cases the products of these condensation reactions were yellow solids, soluble in dilute alkali giving blood-red solutions. The product obtained from tetraethylenepentamine, however, precipitated from solution as a heavy oil and resisted all attempts to crystallize it. For this reason it was isolated as the dipicrate. The products obtained from aminoethylethanolamine and aminoethylmorpholine were very soluble in water, probably due to the character of the side-chains, so that the yields here were low and the products were isolated as hydrates. In the condensation with dipropylenetriamine the product obtained constantly contained more arsenic than the theoretical amount for the product from one mole of amine and one mole of arsonic acid. Though several runs with increasing amounts of amine were tried, the desired product was not obtained.

The condensation of 2-amino-2-methyl-1-propanol with 3-nitro-4-chlorophenylarsonic acid did not proceed satisfactorily under standard conditions but was successful when an excess of the amine was heated with the arsonic acid at 160–170° for six hours. Apparently the amino group in 2-amino-2-methyl-1-propanol, which is linked to a tertiary carbon atom, is not reactive enough to allow condensation in aqueous solution at the lower temperatures. An attempt at a similar condensation using 2-amino-2-methyl-1,3-propanediol was unsuccessful.

Experimental

General Procedure for the Condensation of 3-Nitro-4-chlorophenylarsonic Acid with Amines in Aqueous Alkali.—Five grams of 3-nitro-4-chlorophenylarsonic acid, 15 ml. of 10% sodium hydroxide, 10 ml. of water and 3–5 ml. of the amine were heated, under reflux, at 135–140° for three to eight hours. The solution was cooled, made neutral to congo red with concd. hydrochloric acid. The product precipitated out as a yellow solid (except in the case of tetraethylenepentamine where the product was a thick brown oil). The product was redissolved in 5% sodium hydroxide, the solution charcoaled, filtered, and the yellow solid reprecipitated by addition of concd. hydrochloric acid to the congo red neutral point. The

[a] Arsenic was determined by a modification of the method of Cislak and Hamilton, THIS JOURNAL, **52**, 638 (1930). [b] Isolated as the dipicrate. [c] Isolated as the monopicrate. [d] Plus one molecule of water.

product was dried overnight at 90° and then *in vacuo* over concd. sulfuric acid. Yield varied from 30–50%.

Condensation of 3-Nitro-4-chlorophenylarsonic Acid with 2-Amino-2-methyl-1-propanol.—Five grams of 3-nitro-4-chlorophenylarsonic acid and 10 cc. of 2-amino-2-methyl-1-propanol were heated, under reflux, on an oil-bath at 160–170° for six hours. During this time the mixture became almost black and was very viscous. The tarry residue was *dissolved* out in 50 ml. of hot water, the solution charcoaled, filtered and then made neutral to congo red with concd. hydrochloric acid. The yellow solid that separated was purified by reprecipitation from alkaline solution with concd. hydrochloric acid, dried at 90° in an oven overnight and then *in vacuo* over concd. sulfuric acid.

General Procedure for the Preparation of the 3-Amino Derivatives.—The nitro groups in the compounds described above were reduced to amino groups using the method of Jacobs, Heidelberger and Rolf.[5] The products obtained were light-red solids, which turned dark rapidly on exposure to air; yields, 10–30%.

Summary

The preparation of a number of 3-nitro-4-substituted aminophenylarsonic acids and the corresponding 3-amino compounds has been reported.

The Synthesis of 4,5-Diethyl-*o*-phenylenediamine through the Nitration of *o*-Diethylbenzene

BY JOHN P. LAMBOOY

Until relatively recently *o*-diethylbenzene has been available in such limited quantities that it has been used for synthetic purposes by no one but its discoverer. A. Voswinkel[1] first synthesized *o*-diethylbenzene in 1888 and along with it he reported the syntheses of barium *o*-diethylbenzenesulfonate, *o* diethylbenzenesulfonamide and 1,2-diethyl-3,4,5,6-tetrabromobenzene. He was discouraged from more than preliminary efforts at nitration because of lack of starting material and the explosive nature of the product he obtained. The nature of this product as well as the position of the sulfonic acid group remain unknown.

Karabinos, Serijan and Gibbons[2] have introduced a method by which relatively large amounts of pure *o*-diethylbenzene are made available. Our need for compounds related to 4,5-diethyl-*o*-phenylenediamine made the prospect of obtaining it through successive nitrations of *o*-diethylbenzene attractive.

o-Diethylbenzene was nitrated and while it is probable that other products were produced, repeated vacuum fractional distillations yielded only one readily available product. This was shown by oxidation to the nitrophthalic acid to be exclusively 1,2-diethyl-4-nitrobenzene. The nitro compound was reduced catalytically to 3,4-diethylaniline. After carbethoxylation of the amino group the material was again subjected to nitration with the formation, for the most part, of 4,5-diethyl-2-nitrocarbethoxyaniline. Removal of the carbethoxy group to produce 4,5-diethyl-2-nitroaniline followed by deamination located the second nitro group by producing 1,2-diethyl-4-nitrobenzene. The 4,5-diethyl-2-nitroaniline was reduced catalytically to produce 4,5-diethyl-*o*-phenylenediamine.

(1) Voswinkel, *Ber.*, **21**, 3499 (1888).

(2) Karabinos, Serijan and Gibbons, THIS JOURNAL, **68**, 2107 (1946).

Experimental

1,2-Diethyl-4-nitrobenzene.—A mixture of 175 ml. of fuming nitric acid (sp. gr. 1.59–1.60) and 87.5 ml. of glacial acetic acid was cooled to 10°. While this solution was stirred vigorously, 50 g. of *o*-diethylbenzene[3] was added at a rate to maintain the temperature between 10–20°. After the last of the *o*-diethylbenzene had been added the stirring was continued for forty-five minutes at the same temperature. The reaction mixture was then poured into one liter of ice-water. The crude nitro compounds were extracted with four 125-ml. portions of ether and the ether extract washed with three 50-ml. portions of water, with six 50-ml. portions (until the reaction has become alkaline) of 10% sodium hydroxide solution and again with three 50-ml. portions of water. The ether extract was dried over anhydrous sodium sulfate and the solvent removed. After preliminary studies the following procedure was used for the separation of the desired product. The combined nitration products obtained from the nitration of 422 g. of *o*-diethylbenzene were distilled from a Claisen flask at 10 mm. pressure. Only that material collected over the temperature range 130–150°, which amounted to 380 g. or 74% yield, was fractionated. The column used was 60 cm. long, 1.5 cm. i. d., and filled with small, single-turn glass helices. The fractionating head was designed so that any desired portion of the condensate could be returned to the column. The material was fractionated three consecutive times into three degree ranges between 120–141°. The material collected in the boiling point range 139–141° at 10 mm. weighed 230.5 g., which is 41% of the theoretical amount, and was identified as 1,2-diethyl-4-nitrobenzene; yellow oil, b. p. 139–141° at 10 mm. mercury pressure, d^{22} 1.0852, $n^{25}D$ 1.5440.

Anal. Calcd. for $C_{10}H_{13}NO_2$: C, 67.02; H, 7.31; N, 7.82. Found: C, 67.22; H, 7.24; N, 8.10.

The 1,2-diethyl-4-nitrobenzene was characterized by permanganate and also nitric acid oxidation to the 4-nitrophthalic acid which was identified by the melting points of the acid, anhydride, the acid aniline salt and the anil. No evidence could be found for the presence of any of the 3-nitrophthalic acid.

3,4-Diethylaniline.—The 1,2-diethyl-4-nitrobenzene was reduced catalytically in a Parr hydrogenator at initial pressures of 60 p.s.i., using platinum oxide, platinum on zirconium or palladium on zirconium oxide. Seventeen and nine-tenths grams (0.1 mole) of 1,2-diethyl-4-nitrobenzene was dissolved in 150 ml. of absolute alcohol and

(3) The *o*-diethylbenzene used in this study was generously furnished by the National Advisory Committee for Aeronautics.

0.2 g. of platinum oxide added. At 24° the reduction was 97% complete in twenty minutes and 100% in one hour. The catalyst and solvent were removed and the 3,4-diethylaniline distilled at 10 mm. pressure to obtain 13.9–14.7 g. (93–99% yield) of product; colorless or very pale yellow oil, b. p. 116–117° at 10 mm., d^{28} 0.952, $n^{29}D$ 1.5458.

Anal. Calcd. for $C_{10}H_{15}N$: C, 80.48; H, 10.13; N, 9.39. Found: C, 80.17; H, 10.10; N, 9.4.

The material becomes discolored rapidly on exposure to air.

The **acetanilide** recrystallized from 50% alcohol as white platelets, m. p. 119°.[4]

Anal. Calcd. for $C_{12}H_{17}NO$: N, 7.33. Found: N, 7.1.

The **benzanilide** recrystallized from 70–80% alcohol as white needles, m. p. 116–117°.

Anal. Calcd. for $C_{17}H_{19}NO$: N, 5.53. Found: N, 5.5.

The **aniline hydrochloride** was prepared by passing dry hydrogen chloride into an anhydrous ether solution of the aniline. When recrystallized from a mixture of chloroform and ligroin it was obtained as white needles, m. p. 196–197°.

Anal. Calcd. for $C_{10}H_{16}NCl$: Cl, 19.10. Found: Cl, 19.17.

4,5-Diethyl-2-nitrocarbethoxyanilide.—The procedure outlined by Karrer and Becker[5] was used for the synthesis of this compound. Twenty-eight and seven-tenths grams (0.193 mole) of 3,4-diethylaniline, 73 ml. of acetone, 43 ml. of water and 34 ml. of sodium hydroxide solution (24%) and 29 g. of ethylchlorocarbonate were used to prepare the urethan. The urethan was used directly in the nitration which was accomplished in a mixture of 118 ml. of concentrated nitric acid and 43 ml. of concentrated sulfuric acid. After the product was poured onto ice and had solidified, it was dissolved in ether. The ether solution was washed with water until neutral, dried over anhydrous sodium sulfate and the solvent removed on the steam-bath. The product was recrystallized from alcohol to produce 29.8 g. (57% yield) of fine yellow needles, m. p. 60°.

Anal. Calcd. for $C_{13}H_{18}N_2O_4$: C, 58.63; H, 6.81; N, 10.52. Found: C, 58.74; H, 6.64; N, 10.2.

4,5-Diethyl-2-nitroaniline.—To a solution of 20 g. of sodium hydroxide, 50 ml. of water and 150 ml. of alcohol, 12.0 g. (0.062 mole) of 4,5-diethyl-2-nitrocarbethoxyanilide was added. While the solution was stirred the temperature was raised to 70° and held there for one hour. The alcohol was removed under diminished pressure and 100 ml. of water added. The suspension was extracted repeatedly with benzene. The benzene solution was dried over anhydrous sodium sulfate and the benzene removed under diminished pressure. The residue was recrystallized from dilute alcohol to produce 7.1 g. (81% yield) of orange prisms, m. p. 64–65°.

Anal. Calcd. for $C_{10}H_{14}N_2O_2$: C, 61.83; H, 7.26; N, 14.43. Found: C, 62.10; H, 7.33; N, 14.2.

The nitroaniline is steam distillable. The position of the nitro group was determined by deamination of 2.6 g. of the nitroaniline by the procedure outlined by Hodgson and Turner.[6] The nitro compound produced was isolated by steam distillation and the distillate extracted with ether. After the solution was dried and the ether removed the residue was distilled at reduced pressure to produce 1.4 g. (58% yield) of product. The boiling point could not be determined with certainty on this amount so it was reduced to the aniline and converted to the benzanilide, m. p. 114–115°. A mixture of this material and the benzanilide prepared from known 3,4-diethylaniline melted at 116°. This proves the nitro group to be in the 2-position.

4,5-Diethyl-*o*-phenylenediamine.—One and nine-tenths grams (0.01 mole) of 4,5-diethyl-2-nitroaniline was reduced in 75 ml. of absolute alcohol with 1.1 g. of platinum on zirconium with an initial pressure of 60 p.s.i. After removal of the catalyst and removal of the solvent the residue was recrystallized from benzene to produce 1.3 g. (81% yield) of white platelets, m. p. 114–115°.

Anal. Calcd. for $C_{10}H_{16}N_2$: C, 73.12; H, 9.82; N, 17.07. Found: C, 73.16; H, 9.66; N, 17.6, 17.7.

o-Phenylenediamine sublimes.[7] 4,5-Diethyl-*o*-phenylenediamine was found to sublime slowly at 78° at 2 mm. mercury pressure and very slowly at 100° at atmospheric pressure. 4-Methyl-*o*-phenylenediamine was prepared in 90% yield by catalytic (platinum oxide at 60 p.s.i.) reduction of a tenth mole lot of 3-nitro-4-aminotoluene to produce material of m. p. 90–92°. This material was found to sublime under the same conditions as those described above.

Summary

1. The synthesis of 4,5-diethyl-*o*-phenylenediamine through the successive nitrations of *o*-diethylbenzene has been described.

2. Several new compounds involved as intermediates in the above synthesis have been reported including 1,2-diethyl-4-nitrobenzene, 3,4-diethylaniline, 4,5-diethyl-2-nitrocarbethoxyanilide and 4,5-diethyl-2-nitroaniline.

3. The nitration of *o*-diethylbenzene has been shown to result in approximately a 40% yield of 1,2-diethyl-4-nitrobenzene.

Synthesis of 2,5-Dihydroxyphenylalanine

BY JOHN P. LAMBOOY

Theoretical consideration of the pathway of phenylalanine and tyrosine metabolism in inborn or ascorbic acid deficiency induced alcaptonuria has frequently included 2,5-dihydroxyphenylalanine as an intermediate. Hirai[1] reported its synthesis in 1927 but the yield which he obtained was poor and it now appears that the identity of his product may be subject to question. Recently Neuberger[2] reported the synthesis of this amino acid by Hirai's procedure and by a procedure similar to one of those reported here. Our two products are clearly identical and very unlike that obtained by Hirai. While this article must, in view of Neuberger's recent article, be considered primarily as confirmatory in nature, it is felt that our superior yields and considerably more convenient procedure will be of interest to investigators in the field of metabolism.

Essentially, the synthetic procedures studied were the condensations of 2,5-dihydroxybenzaldehyde or 2,5-diacetoxybenzaldehyde with either acetylglycine or benzoylglycine in the presence of acetic anhydride and sodium acetate. The products thus formed were converted directly to the amino acid by one-step reduction and hydrolysis with hydriodic acid and red phosphorus.

In the condensation between 2,5-dihydroxybenzaldehyde or 2,5-diacetoxybenzaldehyde and acetylglycine Neuberger's results differ somewhat from ours. We both obtain two compounds, a high melting, and colorless compound shown by Neuberger to be 2-keto-3-acetamino-6-acetoxycoumarin and a lower melting compound which was the true azlactone. Neuberger's optimum reaction conditions for the formation of almost exclusively the azlactone differ very slightly from ours which led to the almost exclusive formation of the acetoxycoumarin. Both compounds are converted to the desired amino acid by reduction and hydrolysis.

Our primary concern was to outline a procedure by which relatively good yields of the amino acid could be obtained with a minimum of effort. Since purification procedures led to relatively large losses of material the use of crude intermediates was investigated. This led to a considerable increase in the yield of amino acid based on starting material 2,5-dihydroxybenzaldehyde.

The best procedure was found to be the conversion of 2,5-dihydroxybenzaldehyde to 2,5-diacetoxybenzaldehyde. This material in the crude form was converted to 2-phenyl-4-(2,5-diacetoxybenzal)-5-oxazolone which in turn, in its crude form was converted to 2,5-dihydroxyphenylalanine of a high degree of purity with an over-all yield of 26% based on starting material 2,5-dihydroxybenzaldehyde. The triacetyl derivative was prepared for purposes of identification through its sharp melting point.

(2) Neuberger, *Biochem. J.*, **43**, 599 (1948).

Experimental

2,5-Diacetoxybenzaldehyde.—The method used was essentially that of Malkin and Nierenstein[3] except that the shaking time was increased to one hour and the product permitted to stand at room temperature for twenty-four hours before filtering and evaporation of the ether. From 13.8 g. (0.1 mole) of 2,5-dihydroxybenzaldehyde[4] one obtains 19.3 g. (87% yield) of crude product, m. p. 66–68°,[5] or 14.2 g. (64% yield) of material in the form of fine white needles, purified by recrystallization from 95% alcohol, m. p. 71–72°.

Anal. Calcd. for $C_{11}H_{10}O_5$: C, 59.46; H, 4.54. Found: C, 59.28; H, 4.89.

The crude material can be used advantageously for the subsequent step of either route. Acetylation in pyridine produced lower yields of purified material.

2-Keto-3-acetamino-6-acetoxycoumarin. (a) From 2,5-Diacetoxybenzaldehyde.—An intimate mixture of 21.6 g. of 2,5-diacetoxybenzaldehyde and 18.4 g. of acetylglycine was dried in a vacuum desiccator over calcium chloride for twenty-four hours. After adding 12.8 g. of freshly fused and ground sodium acetate and 60 ml. of 99–100% acetic anhydride the mixture was heated on the steam-bath for forty-five minutes and then permitted to stand at room temperature for twelve hours. The crystalline mass was triturated with 200 ml. of water and permitted to stand for approximately six hours to completely hydrolyze the excess acetic anhydride. The material was filtered, washed with water on the filter and pressed with a dam. The precipitate was placed in a beaker, broken up and suspended in about 50 ml. of ether and again filtered. The product was washed on the filter with about 20 ml. of ether and air-dried. Recrystallization from benzene produced 7.0 g. (27% yield) of purified material as colorless prisms, m. p. 230–231°.

Anal. Calcd. for $C_{13}H_{11}NO_5$: C, 59.77; H, 4.28; N, 5.36. Found: C, 59.79; H, 4.30; N, (Dumas) 5.4, 5.7, 5.5, (Kjeldahl) 5.1, 5.2, 4.9.

Before this method for the preparation of the amino acid was abandoned in favor of the more productive one which made use of benzoylglycine it was thought that this compound was the azlactone. Calcd. for $C_{15}H_{13}NO_6$: C, 59.40; H, 4.33; N, 4.62. Before the six-hour hydrolysis period was used the condensation reaction was treated with ice-water for short periods of time. The precipitate was always oily and difficult to purify but did yield small amounts of material which on purification was obtained as yellow crystals, m. p. 141–142°.[2] It seems probable that the long hydrolysis conducted at room temperature was responsible for the conversion of the true azlactone (m. p. 141–142°) to the acetoxycoumarin (m. p. 230–231°).

(b) From 2,5-Dihydroxybenzaldehyde.—The details are the same as those given in (a) above. Thus 13.8 g. (0.1 mole) of 2,5-dihydroxybenzaldehyde, 12.0 g. (0.102 mole)

(3) Malkin and Nierenstein, THIS JOURNAL, **53**, 239 (1931).

(4) Neubauer and Flatow, *Z. physiol. Chem.*, **52**, 380 (1907).

(5) Observed melting points from thermometers calibrated from U. S. P. Melting Point Reference Standards and Anschütz thermometers.

of acetylglycine, 11.2 g. (0.136 mole) of sodium acetate and 44 g. (0.43 mole) of 99–100% acetic anhydride produced 11 g. (38% yield) of the crude acetoxycoumarin, m. p. 180–201°, or 5.4 g. (21% yield) of the purified material, m. p. 230–231°.

2-Phenyl-4-(2,5-diacetoxybenzal)-5-oxazolone. (a) From 2,5-Diacetoxybenzaldehyde.—This material had previously been prepared by Neubauer and Flatow[4] from 2,5-dihydroxybenzaldehyde (method b). An intimate mixture of 25.9 g. (0.117 mole) of crude 2,5-diacetoxybenzaldehyde and 19.2 g. (0.216 mole) of benzoylglycine was dried in a vacuum desiccator over calcium chloride for twenty-four hours. One adds 12.0 g. of freshly fused, finely ground sodium acetate and 60 ml. of 99–100% acetic anhydride. The mixture was heated on the steam-bath for forty-five minutes and then during the process of cooling subjected to a partial vacuum which removed approximately 15 ml. of acetic anhydride. After standing at room temperature for a minimum of twelve hours 200 ml. of water was added, the mixture triturated and permitted to stand approximately six hours. The granular material was filtered, resuspended in 100 ml. of water and filtered again and pressed on the filter. The precipitate was suspended in about 50 ml. of ether and filtered, followed by washing on the filter with 25 ml. of ether, and air-dried. This material was light tan in color, weighed 24.1 g. (57% yield based on the crude diacetoxybenzaldehyde or 49% yield based on starting 2,5-dihydroxybenzaldehyde), m. p. 170–187°. When recrystallized from benzene the product melted 195–196°, which is somewhat higher than 190° reported before.[4]

(b) **From 2,5-Dihydroxybenzaldehyde.**—The details are the same as those used in (a) above. After the hydrolysis period the precipitate was of stiff gummy consistency, but after blotting between sheets of filter paper it could be triturated in 50 ml. of ether at which time it became sufficiently granular for successful filtration. Thus 13.8 g. of 2,5-dihydroxybenzaldehyde produced 21.8 g. (60% yield), m. p. 155–172°. When recrystallized from benzene the product weighed 10.4 g. (29% yield), m. p. 195–196°.

2,5-Dihydroxyphenylalanine.—The method used to convert any of the intermediate preparations to the amino acid was based on and made from a combination of methods found in the literature.[6,7,8] The amino acid was prepared by the use of all possible combinations of purified and crude intermediates to find the method which produced the largest amount of purified amino acid from the starting 2,5-dihydroxybenzaldehyde. Twenty-four grams (0.066 mole) of crude 2-phenyl-4-(2,5-diacetoxybenzal)-5-oxazolone (m. p. 170–187° from crude 2,5-diacetoxybenzaldehyde), 120 g. of glacial acetic acid, 120 g. of hydriodic acid (sp. gr. 1.7) and 3 g. of red phosphorus were gently refluxed for ninety minutes. While still hot the mixture was filtered through an asbestos mat and the phosphorus washed with a little hot glacial acetic acid. The filtrate was evaporated to dryness in an atmosphere of hydrogen under diminished pressure. One adds 100 ml. of water and evaporates to dryness as above. The residue was then dissolved as completely as possible in 100 ml. of water at 50° and filtered to remove undissolved benzoic acid. (When prepared from the acetoxycoumarin filtration is unnecessary.) The filtrate was cooled and extracted five times with 40-ml. portions of ether. The water phase was evaporated to approximately 80 ml., a thin layer of ligroin added followed by enough ammonium hydroxide to ensure an excess. The solution was evaporated to dryness as above, and the crude amino acid dissolved in about 150 ml. of hot water containing a little sulfur dioxide. The solution was boiled briefly with a little decolorizing charcoal, filtered and placed in the refrigerator. The amino acid is obtained in a high degree of purity after a single recrystallization from water containing a little sulfur dioxide. The yield of pure material which is obtained in the form of large, colorless crystals containing a molecule of water of crystallization was 7.4 g. (52% yield). The material melts with decomposition between 246 and 254°, depending on the rate of heating.

Anal. Calcd. for $C_9H_{13}NO_5$: C, 50.22; H, 6.09; N, 6.51; H_2O, 8.37. Found: C, 50.20; H, 5.90; N, 6.37; H_2O, 8.68.

The amino acid can be freed of its water of crystallization by drying at 100° for two hours over phosphorus pentoxide at 3 mm. The water was not lost by drying in a desiccator over calcium chloride at room temperature. The amino acid gives a positive ninhydrin reaction, xanthoproteic reaction and ferric chloride solution produces a greenish-black color. Fusion of the material with potassium hydroxide permitted the identification of ammonia. The fusion mass was dissolved in water, acidified with sulfuric acid and extracted with ether. On evaporation of the ether, acetic acid was identified. The *p*-dihydroxyphenyl compound did not survive the treatment with alkali.

When the amino acid was prepared from pure 2-keto-3-acetamino-6-acetoxycoumarin a 63% yield was obtained and from pure 2-phenyl-4-(2,5-diacetoxybenzal)-5-oxazolone the yield was 61%. These yields are equivalent to only 13 and 17%, respectively, when based on starting material 2,5-dihydroxybenzaldehyde.

N-Acetyl-2,5-diacetoxyphenylalanine.—This derivative was prepared because of the general unreliability of the decomposition points of amino acids. Neuberger reports that his product melted at 235° (uncor.). In the purified condition the triacetyl derivative consists of colorless prisms, m. p. 157–158°.

Anal. Calcd. for $C_{15}H_{17}NO_7$: N, 4.33. Found: N, 4.2.

Summary

1. 2,5-Dihydroxyphenylalanine has been prepared from 2-keto-3-acetamino-6-acetoxycoumarin and 2-phenyl-4-(2,5-diacetoxybenzal)-5-oxazolone.

2. The most productive procedure expressed in grams of product and per cent. yields based on starting 2,5-dihydroxybenzaldehyde was: 18.5 g. of 2,5-dihydroxybenzaldehyde yields 25.9 g. of crude 2,5-diacetoxybenzaldehyde (87%); which yields 24.1 g. of crude 2-phenyl-4-(2,5-diacetoxybenzal)-5-oxazolone (49%); which in turn yields 7.4 g. of 2,5-dihydroxyphenylalanine (26%).

Some Ethers Derived from Diethylaminoethyl Benzilate[1]

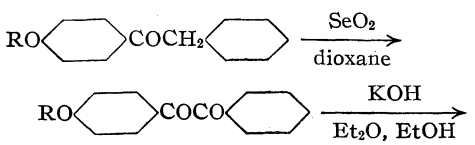
BY EARL R. BOCKSTAHLER AND DONALD L. WRIGHT

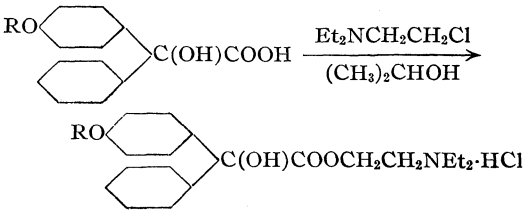
In studies of local anesthetics, it has been demonstrated repeatedly that introducing or varying an alkoxy group on a benzene ring can affect pharmacologic action markedly. For example, the introduction of a butoxy group in one recent instance[2] and of a cyclohexyloxy group in another[3] produced compounds having far greater potency and duration of anesthetic action than was possessed by the ethoxy, methoxy or unsubstituted analogs. Toxicity may or may not be correspondingly altered.

The structural resemblance of the ester type of local anesthetic to antispasmodic aminoalkyl esters suggests that similar enhancement of antispasmodic activity may be possible. Other than scattered instances of methoxy substitution, no data appear to be available in the literature for testing the validity of this conjecture. We therefore undertook the preparation of a homologous series of alkoxy-substituted esters which might be expected to be sufficiently active as antispasmodics to permit judgement on this question.

Diethylaminoethyl benzilate was selected as the parent compound. This substance is known to possess both antispasmodic[4] and local anesthetic[5] as well as mydriatic[6] properties. The 4,4′-dimethoxy derivative has been reported to be inferior to its parent as an antispasmodic.[4] Substitutions which produced the 2,2′-dimethoxy, 3,4,3′,4′-bis-(methylenedioxy), 5,5′-dibromo-2,2′-dimethoxy and 3,3′,4,4′-tetramethoxy derivatives, as ethochlorides, resulted in great reduction or abolition of mydriatic activity.[7]

As a test series, we prepared, as hydrochlorides, ten diethylaminoethyl 4-alkoxybenzilates, in which the number of carbon atoms in the alkyl group was varied from one to seven (Table I). They were obtained from appropriately substituted desoxybenzoins, by the route





For preliminary pharmacological evaluation of these compounds we are indebted to F. H. Schultz, Jr.,[8] W. M. Alexander and W. K. McDonald, of the pharmacology division of this Laboratory, with whose permission we are presenting summarized data. Their results, including additional studies, will be published in detail elsewhere.

As is shown in Table I, the supposition that it would be possible to enhance antispasmodic activity by a suitable choice of alkoxy substituent is not borne out in this series. Activity drops abruptly upon the introduction of a methoxy group, and although some of the later members return to as high a level as the parent compound, none surpass it. A peak is reached with the *n*-amoxy derivative, which possesses activity on the normal gut and against histamine equal to that of the unsubstituted benzilate. Its activity against acetyl-β-methylcholine is two-fifths of that of the parent, and its acute toxicity about half as great.

Enhancement of local anesthetic activity by appropriate alkoxy substitution is clearly apparent, however. A maximum was reached with the *n*-hexyloxy derivative, which produced anesthesia of twenty to thirty minutes duration when applied in 0.01% concentration. At a concentration of 0.25%, which caused temporary irritation (complete recovery by the following day), the duration of anesthesia was approximately three hours.

Because of this favorable finding, nine additional esters containing a variety of nuclear ether substituents were prepared and tested for local anesthetic activity. None was found to surpass the *n*-hexyloxy derivative.

It will be noted that each of the esters except the dibutoxy derivative contains an asymmetric carbon atom. No attempt to resolve these racemic mixtures was made.

Experimental[9,10]

Desoxybenzoins (Table II, A).—The monosubstituted desoxybenzoins, with the exception of the methoxy and

phenoxy, were prepared by refluxing 4-phenylacetylphenol in alcohol or acetone solution with the appropriate bromide or chloride in the presence of potassium carbonate. 4-Phenylacetylphenol was methylated by the use of dimethyl sulfate in aqueous alkaline solution. Phenoxydesoxybenzoin and the two diethoxy derivatives were prepared by Friedel–Crafts reaction of phenylacetyl chloride with appropriate phenol ethers under the usual conditions (aluminum chloride catalyst in carbon disulfide). 4,4′-Di-*n*-butoxydesoxybenzoin was obtained from 4,4′-di-*n*-butoxychalcone according to the scheme described by Rohrmann, Jones and Shonle[11] for lower homologs.

4-*n*-Butoxyacetophenone.—A mixture of 68 g. of 4-hydroxyacetophenone, 72 g. of *n*-butyl bromide, 72.5 g. of potassium carbonate, 8.4 g. of potassium iodide and 25 cc. of 95% ethanol was heated at 75–85° for forty-eight hours. It was then diluted with a little ether and enough water to dissolve the solids. The water layer was discarded. The oil layer was washed with dilute sodium hydroxide solution and with water, dried over sodium sulfate, and distilled, yielding 76 g. (79%) of colorless liquid boiling at 169–170° at 13 mm. *Anal.* Calcd. for $C_{12}H_{16}O_2$: C, 74.97; H, 8.39. Found: C, 75.09; H, 8.06.

4,4′-Di-*n*-butoxychalcone.—A mixture of 70.5 g. of 4-*n*-butoxybenzaldehyde, 76 g. of 4-*n*-butoxyacetophenone and 160 cc. of 95% ethanol was added gradually to a solution prepared from 4 g. of sodium and 40 cc. of methanol. After one hour the mixture was chilled thoroughly and filtered. The crystals were washed with water and recrystallized twice from 95% ethanol; yield, 114 g. (82%) of pale yellow crystals, m. p. 90–92°. *Anal.* Calcd. for $C_{23}H_{38}O_3$: C, 78.35; H, 8.01. Found: C, 78.05; H, 8.15.

α,β-Di-4-*n*-butoxyphenyllactic Acid.—To a stirred suspension of 112 g. of 4,4′-di-*n*-butoxychalcone in 600 cc. of 95% ethanol, 500 cc. of acetone and 41 cc. of 25% aqueous sodium hydroxide warmed to 40°, there was added gradually 98 cc. of 30% hydrogen peroxide; the temperature was kept below 45° by external cooling. After standing for one hour, the mixture was chilled and filtered. After one recrystallization from 95% ethanol, the product (63 g.) was suspended in 212 cc. of 95% ethanol and 66 cc. of 25% aqueous sodium hydroxide and boiled under reflux for three hours. The resulting solution was diluted to 2500 cc. with water and filtered. The filtrate was acidified with hydrochloric acid. The product was removed by filtration and recrystallized twice from methanol; yield, 56 g. (47%); m. p. 135–136°. *Anal.* Calcd. for $C_{23}H_{30}O_5$: C, 71.46; H, 7.82. Found: C, 71.89; H, 7.96.

4,4′-Di-*n*-butoxydesoxybenzoin.—To a stirred suspension of 55 g. of α,β-di-*n*-butoxyphenyllactic acid in 155 cc. of glacial acetic acid, there was added in small portions 99 g. of red lead oxide, at such a rate that the temperature of the mixture did not rise above 65°. The mixture was stirred for thirty minutes after addition was complete, then poured into 1500 cc. of water. The resulting precipitate was removed by filtration, washed with dilute alkali and water, and recrystallized from 95% ethanol; yield, 41 g. (85%).

Benzils (Table II, B).—The desoxybenzoin was refluxed for five to eight hours in one or two times its weight of dioxane with 1.1 molecular proportions of selenium dioxide and water. The mixture was then filtered, and the dioxane was removed by evaporation under reduced pressure. The residue solidified spontaneously, or after it had been cooled and rubbed, and was purified by recrystallization from petroleum ether or methyl, ethyl or isopropyl alcohol. Low yields in several instances are indicative, not of failure of the reaction to proceed, but rather of severe losses in recrystallization of low-melting, readily soluble substances.

Benzilic Acids (Table II, C).—A solution of the benzil in ether was allowed to stand[12] with alcoholic potash

(11) E. Rohrmann, H. G. Jones and H. A. Shonle, THIS JOURNAL, **66**, 1856 (1944).

(12) In most cases occasional shaking of the mixture sufficed for good results. A few of the benzils were not completely soluble in the specified amount of ether; in these instances, the mixture was stirred continuously.

at room temperature until rearrangement appeared complete, usually overnight. For each 0.1 mole of benzil, 320 cc. of ether, 8 g. of potassium hydroxide and 64 cc. of 95% ethanol were employed. The mixture was then extracted with water, and the extract acidified with hydrochloric acid, which precipitated the benzilic acid. Some unreacted benzil could occasionally be recovered from the ether layer; the recorded yields allow for this.

Our experience is in agreement with the statement of Ford-Moore[6] that "there is a strong tendency for the acid to separate in an obstinately gummy form." Even the purified acids crystallized extremely slowly, sometimes requiring several days for recrystallization, and the freshly precipitated crude products sometimes had to stand for several months before crystallization began spontaneously or after rubbing. The acids were recrystallized from benzene, petroleum ether or mixtures of the two.

2-Diethylaminoethyl Benzilate Hydrochlorides.—Equimolecular quantities of the benzilic acid and freshly distilled 2-diethylaminoethyl chloride were mixed in isopropyl alcohol (about 4 cc. for each gram of acid used), and refluxed for eight hours. The crude products crystallized from the cooled mixture directly or after dilution with ether. For purification, they were redissolved in a small volume of methanol, and isopropyl ether was added gradu-

ally until a permanent precipitate began to form. This, a high-melting impurity, was removed by filtration. The filtrate was diluted further with ether, and the desired product separated. Occasionally it was necessary to repeat this process several times to obtain a constant, sharply-melting product.

Summary

Ten new diethylaminoethyl 4-alkoxybenzilates have been prepared in the form of hydrochlorides and screened for antispasmodic potency. None possesses greater activity than diethylaminoethyl benzilate itself; the *n*-amoxy derivative is approximately as active as the latter, and has half its acute toxicity.

These and nine additional new diethylaminoethyl benzilate hydrochlorides containing various nuclear ether substituents have also been screened for local anesthetic potency. The *n*-hexyloxy derivative is the most active of the series.

Eighteen new benzilic acids, eighteen new benzils and eleven new desoxybenzoins were prepared as intermediates.

Relative Chloromethylation Rates of Some Aromatic Compounds[1]

BY H. HARRY SZMANT AND JOSEPH DUDEK

Apparently the only extensive study of relative chloromethylation rates of aromatic compounds is that of Vavon, Bolle and Calin[2]; the conclusions of that study are the only ones quoted in authoritative reviews of the chloromethylation reaction.[3] In this paper we wish to point out certain errors in the results of Vavon and co-workers, and to present what we believe to be more nearly correct relative chloromethylation rates of certain compounds studied by these authors. The rates for a few compounds not previously studied are also reported.

The chloromethylation reaction (I) is accompanied by several competitive reactions (II–IV). The situation may be illustrated with the chloromethylation of benzene.

$$C_6H_6 + CH_2O + HCl \longrightarrow C_6H_5CH_2Cl + H_2O \quad (I)$$

$$C_6H_5CH_2Cl + C_6H_6 \longrightarrow C_6H_5CH_2C_6H_5 + HCl \quad (II)$$

$$2C_6H_5CH_2Cl \longrightarrow C_6H_5CH_2C_6H_4CH_2Cl + HCl, \text{ etc.} \quad (III)$$

$$C_6H_5CH_2Cl + C_6H_5CH_2C_6H_5 \longrightarrow C_6H_5CH_2C_6H_4CH_2C_6H_5 + HCl, \text{ etc.} \quad (IV)$$

The course of the chloromethylation reaction can be followed by determining ionic chlorine at certain time intervals. However, the various side reactions liberate ionic chlorine from the initial chloromethylated product; hence to evaluate the chloromethylation rate, one must determine the rate of loss of chloride during the initial period of the reaction before the initial chloromethylation product has accumulated. In arriving at the relative chloromethylation rates in this study we have arbitrarily chosen to compare the time intervals required for the loss of ten per cent. of the initial ionic chlorine. In most of the cases studied, a linear relationship between the rate of chloride loss and elapsed time persisted to the point chosen for the comparison. In a few cases where the curve tended to bend ahead of time, the initial slope was extrapolated to the point chosen for the comparison. The relative chloromethylation rates obtained in this study are listed in Table I, together with the values obtained by Vavon and co-workers. Typical graphs showing per cent. loss of ionic chlorine with time are given in Figs. 1 and 2.

TABLE I

RELATIVE RATES OF CHLOROMETHYLATION

	Compound	$t10\%$[a]	Relative rate[b]	Relative rate[c] of Vavon and co-workers
1	Benzene	9.2	1.0	1
2	Toluene	3.0	3.1	3

10	Diphenyl ether	6.1	1.5	100
11	Anisole	0.4	23	1334
12	*p*-Methyl cresyl ether	1.25	7.4	1200

[a] Time (in minutes) required for a 10% decrease in initial chloride concentration. [b] Relative rate ($t10\%$ of benzene)/($t10\%$ of compound). [c] Relative rates reported in ref. 2.

Experimental

All chloromethylation experiments were carried out by allowing 0.1 mole of the aromatic starting material, 0.11 mole of paraformaldehyde and 9 ml. of concd. hydrochloric acid (equivalent to 0.11 mole hydrogen chloride) to react in 125 ml. of glacial acetic acid. In order to avoid any reaction at temperatures other than the desired one, all the formaldehyde, hydrochloric acid and 100 ml. of the acetic acid were heated with stirring in the reaction flask until the desired temperature (85°) was reached, and then (at zero time) the preheated mixture of the compound under study was added in 25 ml. of acetic acid. Samples (2 ml.) were withdrawn from the reaction mixture at desired intervals

(two to ten minutes, depending on the rate) and introduced into separatory funnels containing 50 ml. of carbon tetrachloride and 25 ml. of water. The contents of the separatory funnel were shaken for approximately thirty seconds, the two layers were allowed to separate, and the lower layer containing the chloromethylation product, starting material, and carbon tetrachloride was drained off. The chloride ion concentration of the aqueous layer was determined in the separatory funnel by means of the conventional Volhard method.[4] The chloride concentration of the reaction mixture was calculated from the relative volumes of the reaction mixture and the sample. The initial chloride concentration was determined in the same fashion by withdrawing a sample of the mixture before the addition of the compound to be chloromethylated. The results of each experiment are plotted as per cent. chloride lost from the reaction mixture against time.

Several possible sources of error resulting from the experimental procedure may be considered. The volume of the reaction mixture at any given time was calculated from the final volume, and possible changes in volume resulting from changes in the composition of the reaction mixture were ignored. This error was minimized, however, by the use of a relatively large volume of solvent. Furthermore, it may be assumed that the changes occurring in the volume of the reaction mixture during the course of the chloromethylation are similar in all the experiments and thus do not affect seriously the *relative* results. In order to check the reliability of the extraction method employed in the analysis, a mixture of the freshly distilled benzyl chloride (0.1 mole), 125 ml. of acetic acid and 9 ml. of water (in place of the hydrochloric acid) was analyzed for chloride ion. The amount of chloride ion was found to be 1–2% of the chloride ion concentration in the chloromethylation experiments. Since the critical part of the chloromethylation reaction is the initial stage during which there is relatively little chloromethylated product, it is believed that the hydrolysis of the product during the extraction does not affect seriously the results obtained.

Discussion

Inspection of Table I reveals that the results obtained in the present study are not in agreement with those of Vavon and co-workers in the cases of compounds which tend to chloromethylate very readily (as compared with benzene). These discrepancies may be accounted for, at first glance, by the fact that the reagent used by Vavon was chloromethyl ether rather than a mixture of paraformaldehyde and hydrochloric acid. Otherwise, both studies employed the same solvent, and used essentially the same method of analysis. While the absolute chloromethylation rates are, no doubt, affected by the difference in the reagent, we believe that the discrepancies in the relative rates are explained by the method by which the previous workers arrived at the relative chloromethylation rates. They chose as a point of comparison the time required for the loss of 30% of ionic chlorine at a temperature of 65°. However, in order to obtain convenient time intervals their experiments were carried out in a temperature range of 15–100°, and the time intervals required for 30% loss of ionic chlorine were then converted to time intervals corresponding to a temperature of 65°, by methods not indicated in the publication. It seems reasonable to assume that such calculations are not valid since the activation energies of the various reactions (I–IV) are not known, and since the temperature coefficients of these reactions are not necessarily the same. This view is supported by the fact that satisfactory agreement between the two sets of results is found only in the case of compounds which Vavon and co-workers studied at the same temperature. Compounds 1, 2 and 5 were all studied at 100° and since this set includes benzene, the rates obtained for these compounds agree with those of the present study. Compounds 6, 10, 11 and 12 were studied at 65° and while the relative rates reported differ from ours by a great margin, the relative rates *within* this set of compounds are in closer agreement with our results. This is brought out clearly by comparing Vavon's relative rates with ours, taking the rate of diphenyl ether[5] as unity. His relative rates then become for mesitylene, anisole and *p*-methylcresyl ether: 6, 13.3 and

(5) Additional information on the temperature coefficients of the various reactions occurring during the chloromethylation process will be presented in a forthcoming publication dealing with the chloromethylation of diphenyl sulfide.

12, as compared with our rates of 8.7, 15 and 4.9, respectively.

While the exact mechanism of chloromethylation of aromatic compounds is not known, and probably depends on the nature of the chloromethylation reagent which is employed, it can be safely assumed that the chloromethylation reaction falls into the broad class of substitution reactions brought about by electrophilic reagents.[6] Thus, the relative chloromethylation rates are in accord with those to be expected from the usual effect of substituent groups on the reactivity of the benzene ring in other substitution reactions involving an electrophilic reagent.

The initial slope of the curves depicting the change in ionic chlorine with time is directly related to the rate of chloromethylation; the actual shape of the curves, on the other hand, depends on the extent to which the competing reactions interfere with the principal chloromethylation process. Work is in progress to determine how the competing reactions are related to the chemical structure of the compound being chloromethylated. The effect of the competitive reactions on the shape of the chloromethylation curve is clearly demonstrated in the comparison of anisole and mesitylene (Fig. 2). Both compounds are very reactive in the principal chloromethylation reaction, but the initial chloromethylated product of anisole undergoes further reactions which restore ionic chlorine to the mixture. Since chloromethylmesitylene is capable of undergoing further substitution reactions[7] the lack of side-reactions in this case may be due to the relative inertness of chloromethylmesitylene as an aralkylating agent.

Acknowledgment.—The authors wish to express their appreciation to Mr. Joseph Anzenberger for his technical assistance in several of the experiments, and to Drs. T. H. Dunkelberger and O. Gawron for their interest in this work and helpful suggestions. Dr. Gawron originally suggested the kinetic approach to the chloromethylation study of diphenyl sulfide.

Summary

The relative chloromethylation rates of twelve aromatic compounds have been determined. The relative rates of six compounds have been critically compared with those previously reported, and the discrepancies between the new and old rates have been explained. The relative order of the chloromethylation rates was found to be in general agreement with that expected from the effect of the substituent on the substitution reactions of benzene involving an electrophilic reagent.

(7) Excellent yields of the dichloromethylated mesitylene can be obtained (ref. 3, p. 76).

The Catalytic Hydrogenation of Terpenes

BY HILTON A. SMITH, JOHN F. FUZEK AND HENRY T. MERIWETHER

Introduction

While a number of studies dealing with the catalytic hydrogenation of terpenes have been reported, few investigations have been concerned with the kinetics of this process. Furthermore, much of the work has been done with mixtures of terpenes, rather than with pure compounds. The present work was undertaken in order to study the kinetics of the catalytic hydrogenation of certain terpenes which could be obtained in a reasonably pure state.

Experimental

Dipentene, terpinolene, α- and β-pinenes and camphene were all furnished in relatively pure form by the Hercules Powder Company of Wilmington, Delaware. Four of these terpenes were fractionated before use through an eight-foot Vigreux column in an atmosphere of carbon dioxide. The other, β-pinene, was fractionated in the same column under vacuum. Constant boiling cuts were obtained for each material. *d*-Limonene was purchased from the Eastman Kodak Company, and carefully fractionated in an atmosphere of carbon dioxide. The constant boiling fraction used had an optical rotation $\alpha^{20}D$ of 104°. Head temperatures and refractive indices of the terpenes used are given in Table I.

Tank hydrogen[1] was used without further purification. Methanol and acetic acid, which were used as solvents, were prepared by fractionation of du Pont methanol or C. P. glacial acetic acid in a five-foot helix-packed still. Sodium oleate and palmitic acid were Merck U.S.P. and Eastman Kodak Co. best grade materials, and were used without further purification. The nickel catalyst was prepared from Raney alloy and the platinum catalyst from platinic chloride in the standard manner.[2,3] The nickel was stored under ethanol.

[a] $\alpha^{20}D$ 104°. [b] M. p. 48.7°. [c] $\alpha^{20}D$ 96°. [d] M. p. 63.5°.

High pressure hydrogenation experiments were carried out in bombs of 45-ml. capacity. These were constructed according to the directions of Adkins.[4] They were equipped with gages of 0–1000 p. s. i. range in 10 p. s. i. subdivisions, or of 0–2000 p. s. i. range in 20 p. s. i. subdivisions. Room temperatures were used except for camphene where the bomb was heated to 65° so as to have the terpene in the liquid state.

For most of the rate work a conventional shaker was used. This shaker completed 42 cycles per minute through an angle of 30° per stroke. For experiments with varying shaking speeds, a similar shaker was constructed having a Mixmaster motor for driving power. With this instrument, any shaking speed between 20 and 70 cycles per minute could be obtained. The shakers were equipped with conventional heating jackets.

In making rate studies, the nickel catalyst was placed in the hydrogenation bomb along with a small amount of the ethanol under which it was stored. This alcohol was removed by evaporation under vacuum. While the bomb was still under vacuum, the terpene was admitted in such a way that it covered the catalyst before any air entered the bomb. The bomb was then sealed, hydrogen admitted to the desired pressure, and the reaction started by shaking the bomb.

After the hydrogenation, the bomb was opened and the contents transferred to a beaker. Any catalyst remaining in the bomb was washed out by acetone. The catalyst was then filtered from the liquid and from the washings in an atmosphere of carbon dioxide, dried in a vacuum desiccator and weighed under carbon dioxide.

Low pressure hydrogenations using either nickel or platinum catalysts were carried out in a standard Parr low-pressure catalytic reduction apparatus. Platinum catalyst was weighed as platinic oxide before use. The nickel catalyst was weighed after each run in the same manner as that described for high-pressure experiments.

(4) Adkins, "Reactions of Hydrogen," The University of Wisconsin Press, Madison, Wisconsin, 1937, pp. 29–45.

Reaction Mechanisms

α-Pinene, β-pinene and camphene each absorbed one mole of hydrogen per mole of terpene to form pinane from the pinenes, and isocamphane from the camphene. Each of these products distilled through an efficient fractionating column at a constant head temperature. Their physical constants are given in Table I.

Dipentene and terpinolene each absorbed two moles of hydrogen per mole of terpene. The hydrogenation of one double bond proceeds quite readily. That of the second bond takes place more slowly. The dipentene hydrogenation proceeded first to carvomenthene and then to *p*-menthane. This was shown by use of the optically active isomer of dipentene, *d*-limonene. If the hydrogenation proceeds by the path *d*-limonene → dihydrodipentene → *p*-menthane, the absorption of one mole of hydrogen will lead to an optically inactive product. If the hydrogenation proceeds by the path *d*-limonene→carvomenthene →*p*-menthane, the absorption of one mole of hydrogen will form carvomenthene, the asymmetric carbon will not be affected, and the intermediate product, *d*-carvomenthene, should have an optical activity comparable to that of the unhydrogenated material. If both bonds are saturated simultaneously, the activity of the half-hydrogenated material should be one-half of that of the starting terpene. Figure 1 indicates that the product formed by the absorption of one mole of hydrogen per mole of terpene is definitely *d*-carvomenthene.[5]

When one equivalent of hydrogen is absorbed by terpinolene, the product would presumably be either carvomenthene or dihydroterpinolene. The half-hydrogenated terpinolene contains no carvomenthene, and it appears that the product is actually an equimolecular mixture of two *p*-menthenes. This mixture was separated by fractionation in an eight foot Vigreux column. The lower-boiling fraction was identified as 3-*p*-menthene by its physical properties, and by the formation of its nitroso derivative. The higher boiling fraction was not positively identified. It forms a low-melting solid nitroso derivative, and its physical properties conform more closely to those published for 2-*p*-menthene than for any other known *p*-menthene. A summary of such data is given in Table II. Apparently the 1,2 bond in terpinolene is first saturated, and the 4-8 bond shifts, partly to the 3-4 position, and partly in some other manner.

The mechanisms for the hydrogenation of both dipentene and terpinolene were the same whether the catalyst was platinum or nickel, whether or not

a solvent was present, and whether low or high hydrogen pressures were used. However, when nickel was used as a catalyst (with methanol as a solvent at low pressures, or with no solvent at high pressures) the hydrogenations of dipentene and terpinolene virtually ceased after one mole of hydrogen had been absorbed per mole of terpene.

[a] I. M. Heilbron, "Dictionary of Organic Compounds," Vols. I–III, Oxford University Press, London, 1934. [b] J. Zelikow, *Ber.*, **37**, 1374 (1904). [c] This value was obtained by extrapolation from a plot of log *p versus* $1/T$.

Experimental Calculations and Results

Preliminary experiments indicated that the high pressure hydrogenation reactions were independent of the amount of terpene used, and that the low pressure hydrogenations did not depend on the concentration of the hydrogen acceptor. They also showed that, for all of the reactions studied, the rate was directly proportional to the pressure of hydrogen gas, and also directly proportional to the weight of catalyst used, provided shaking equilibrium was maintained. This was true whether the hydrogenation was carried out without solvent, with methanol or acetic acid as solvent, or in the presence of certain additives. The latter are such materials as fatty acids and soaps, which greatly influenced the rate of reduction. This being true, a plot of log p_0/p against time should result in a straight line.

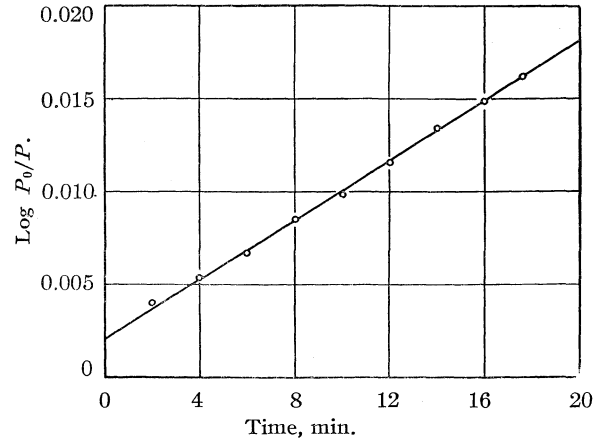

Fig. 2.—Sample hydrogenation curve for *d*-limonene on Raney nickel catalyst.

Figure 2 gives such a plot for the high pressure hydrogenation of *d*-limonene on nickel while Figs. 3 and 4 show similar plots for low pressure hydrogenations using Adams platinum catalyst and acetic acid or methanol as solvents. Since straight lines are obtained, rate constants for these hydrogenations can be calculated from the equation

$$\log p^0/p = kt/2.303\ V$$

where p is the pressure at any time t, p^0 is the initial pressure, V is the volume of the system, and k is the reaction rate constant.[6] Since k is directly proportional to the amount of catalyst used, it is divided by the weight of catalyst to give a k which represents the rate constant referred to one gram of catalyst.

Figure 5 demonstrates the necessity of maintaining shaking equilibrium. In all high pressure experiments for which rate constants are reported here, the shaking speed was maintained at 42 cycles per minute for catalyst weights of 0.3 to 0.5 g. The rate of shaking for the low pressure experiments was 180 cycles per minute, which was shown to be fast enough to maintain equilibrium conditions.

(6) Fuzek and Smith, THIS JOURNAL, **70**, 3743 (1948).

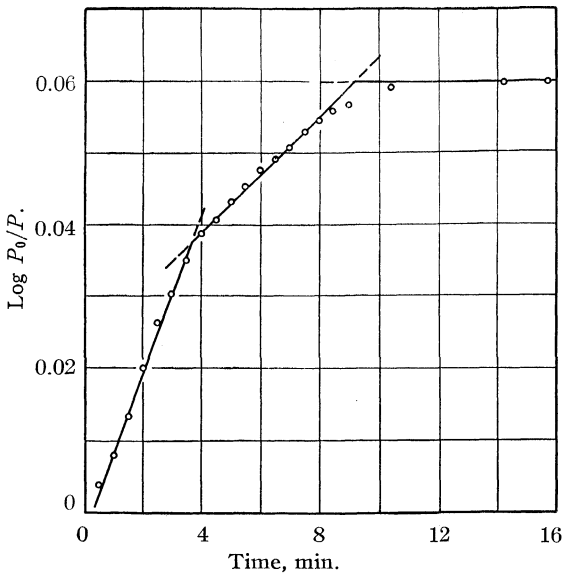

Fig. 3.—Sample hydrogenation curve for dipentene on Adams platinum catalyst in acetic acid at 64.3 p. s. i. a., t, 25°.

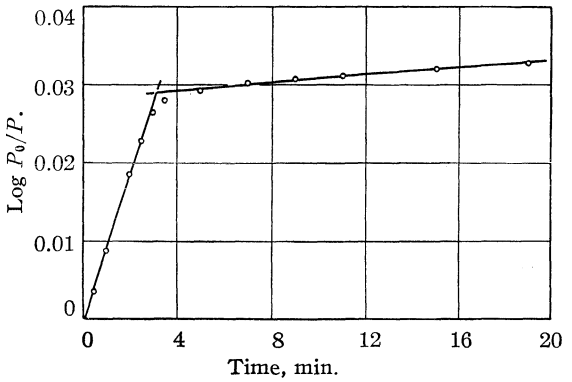

Fig. 4.—Sample hydrogenation curve for d-limonene on Adams platinum catalyst in ethanol at 64.2 p. s. i. a., t, 28°.

Tables III and IV show that the rate constants calculated from such plots are constant over a wide range of conditions. Table V gives the rate constants for the terpenes studied when they are hydrogenated over Raney nickel or Adams platinum catalyst. For the monocyclic terpenes, the rate constants are for the hydrogenation of the first bond only. Hydrogenation of the second bond over nickel is negligible under the experimental conditions employed.

β-Pinene	4.3	1.01	9.1

[a] For hydrogenation to the p-menthene only. [b] These runs were made at 65°.

Discussion

Not very much can be said concerning the effect of the structure of the terpene on its rate

of hydrogenation, other than the fact that in general those containing an exocyclic double bond undergo hydrogenation more readily than do those where all of the unsaturation is in the ring. Whether or not the terpene is monocyclic or bicyclic appears to be unimportant since there is no apparent difference in the rates of hydrogenation of the *p*-menthadienes, dipentene and terpinolene, when compared with the pinenes and camphene which are bicyclic terpenes.

It is interesting to note that the *p*-menthadienes undergo hydrogenation on either platinum or nickel more readily than do the *p*-menthenes, since it has already been shown that cyclohexene adds hydrogen much more quickly than does either the conjugated or unconjugated cyclohexadiene.[7] In this connection it would be interesting to study one of the *p*-menthadienes which has both double bonds in the ring.

(7) Smith and Meriwether, THIS JOURNAL, **71**, 413 (1949).

As would be expected, the rates of hydrogenation of dipentene and the optically active *d*-limonene are identical in all cases.

Acknowledgment.—The authors are indebted to the Hercules Powder Company for a fellowship which made this research possible.

Summary

Dipentene, *d*-limonene, terpinolene, α- and β-pinenes and camphene have been hydrogenated over Adams platinum or Raney nickel catalyst, and the results subjected to kinetic analysis. It has been shown that carvomenthene is an intermediate in the hydrogenation of dipentene or *d*-limonene, while terpinolene yields a mixture of 3-*p*-menthene and another *p*-menthene (perhaps 2-*p*-menthene) as intermediates. The factors influencing the rates of hydrogenation of these terpenes have been discussed.

The Preparation and Aging of Raney Nickel Catalysts

BY HILTON A. SMITH, WILLIAM C. BEDOIT, JR., AND JOHN F. FUZEK

Several different methods for the preparation of Raney nickel catalyst from the standard alloy have been described. Mozingo[1] describes a preparation from the nickel–aluminum alloy according to which the aluminum is dissolved in sodium hydroxide leaving the active catalyst. It is stated that the temperature during the reaction should not rise above 25°. The catalyst is then digested on a hot-plate for twelve hours, and washed by decantation. Pavlic and Adkins[2] have indicated a revision of this method, according to which the alloy is treated with caustic at 50°, and washing is accomplished by a continuous process. The catalyst is claimed to be much more active than that prepared by the method of Mozingo. In a still more recent paper, Adkins and Billica[3] described a further modification in which the washing process was carried out under about 1.5 atmospheres hydrogen pressure. This catalyst (designated as W-6) is described as the most active catalyst known to the authors.

In connection with Mozingo's preparation, it is stated that the catalyst may lose much of its activity if it is kept too long. The purpose of the research reported here was to study the activity of various Raney nickel catalysts, considering both their method of preparation and the length of time which they had been kept.

Experimental

Raney nickel catalyst was prepared by the methods of Mozingo,[1] Pavlic and Adkins[2] and Adkins and Billica.[3] Special care was taken to follow the directions explicitly as given by the authors. In addition, several modifications were introduced. The alloy was taken from a single drum of commercial product furnished by Mr. Raney of the Gilman Paint and Varnish Company, Chattanooga, Tennessee.[4]

The activity of the catalyst was determined by measuring the rate of hydrogenation of freshly distilled *d*-limonene at a hydrogen pressure of 1000 p. s. i. by the method previously described.[5] The latter material was prepared by fractionation under carbon dioxide of Eastman Kodak Co. technical grade product. In addition, the surface areas of a number of these preparations were measured by the adsorption of palmitic acid from benzene solution as previously described.[6]

Experimental Calculations and Results

The rate of hydrogenation of the *d*-limonene has been shown to follow the equation

$$\log p_0/p = k't/2.303\ V$$

where p is the hydrogen pressure at any time, t, p_0 is the initial pressure, V is the volume of hydrogen gas in the system, *i.e.*, the total void which is constant for any system, and k' is the reaction rate constant.[5] (By dividing the value of k' by the weight of catalyst employed rate constants (k) referred to one gram of catalyst

(2) Pavlic and Adkins, THIS JOURNAL, **68**, 1471 (1946).
(3) Adkins and Billica, *ibid.*, **70**, 695 (1948).
(4) According to Mr. Raney, this alloy had the following analysis: Ni, 51.06; Al, 48.19; Si, Fe, and Cu combined, 0.75. It was further stated that these latter three elements have percentages approximately as follows: Fe, 0.5; Si, 0.15; and Cu, 0.1.

may be obtained.) It was found that slight impurities in the *d*-limonene caused variation in its rate of hydrogenation, and that a simple test could be applied to tell whether the terpene was sufficiently pure. When k' is plotted against the weight of catalyst used, a straight line passing through the origin should be obtained as long as equilibrium conditions are maintained. However, when the terpene is impure, the straight line is displaced so that it no longer passes through the origin. This is shown in Fig. 1. The deviations from linearity shown when catalyst weights greater than 0.3 g. are used are caused by inability to maintain shaking equilibrium. For this reason catalyst weights were kept below 0.3 g. Figure 2 shows a typical hydrogenation plot. It gives evidence that good results may be obtained even with the active catalysts used here.

All surface areas were calculated on the assumption that, under the conditions of adsorption of palmitic acid from benzene, the catalyst surface is covered with a unimolecular layer of palmitic acid, and that the cross section of each fatty acid molecule in the layer is 20.5 square ångström units.

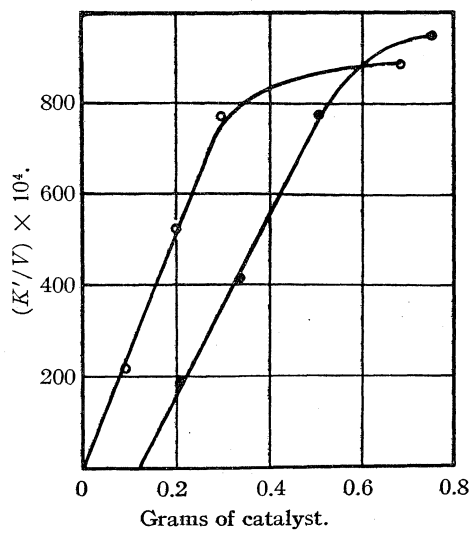

Fig. 1.—Influence of impurities on rate of hydrogenation of *d*-limonene: O, pure sample; ●, impure sample.

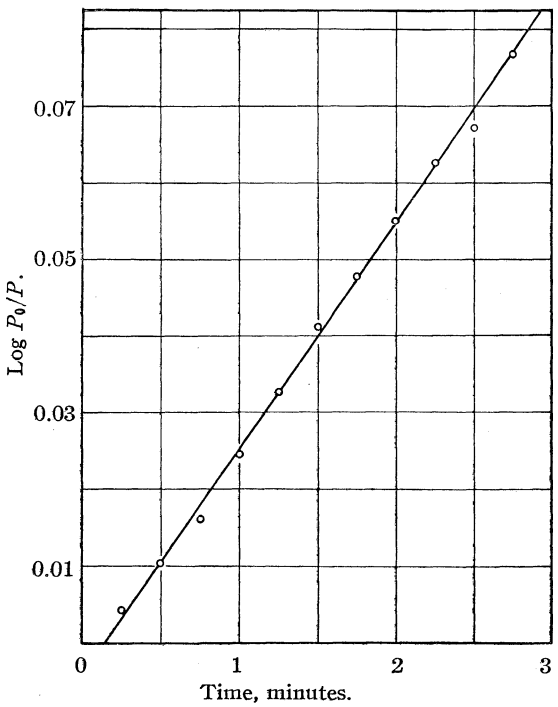

Fig. 2.—Typical hydrogenation plot for hydrogenation of *d*-limonene on an active sample of Raney nickel.

The results of both kinetic and surface measurements for a number of catalyst preparations are given in Table I. The influence of aging on the activity and surface area of such catalysts are shown in Figs. 3 and 4.

Discussion

A study of Table I shows that neither the method of reaction of the alloy with the sodium hydroxide solution, the time or temperature of the

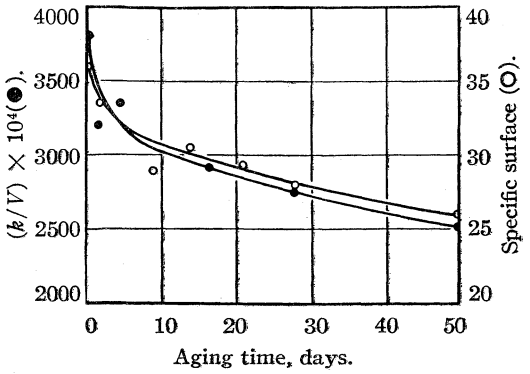

Fig. 3.—Influence of aging on surface area and catalytic activity of Raney nickel.

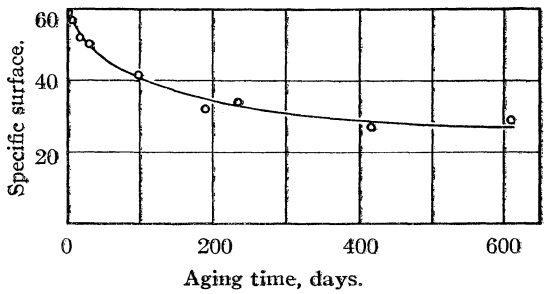

Fig. 4.—Influence of aging on surface area of Raney nickel. (These data were obtained in the course of work done under a fellowship from the Hercules Powder Company.)

digestion beyond a minimum of one hour at 50°, or the method of washing of the catalyst have any very noticeable effect on the activity of the nickel produced as measured by the rate of hydrogenation of *d*-limonene. On the other hand, differences in the original alloy may result in considerable differences in activity of the catalyst. Thus in some earlier work using different alloy rate constants much lower than those reported here were found.[6]

There seems to be no correlation whatever between surface area and initial catalyst activity. The catalyst used in connection with Fig. 4 was made from a different alloy, and had an initial activity only about 1% as great as that used for Fig. 3, although its specific surface was more than 50% greater. However, as Fig. 3 shows, there does seem to be a direct correlation between the decrease in catalytic activity and the decrease in surface area as the catalyst ages.

An examination of Figs. 3 and 4 indicates that the catalyst activity and the specific surface both decrease rather rapidly at first, but much more slowly over longer periods of time.

It has been previously shown that the activity of Raney nickel catalyst as measured by the rate of hydrogenation of *d*-limonene may be greatly affected by the presence of a small amount of additive such as palmitic acid.[7] The activity of a rather poor catalyst is increased and that of a rather good catalyst is decreased to a common value. Furthermore, the increase or decrease is proportional to the amount of fatty acid used until enough is present to cover the nickel surface, after which increasing amounts have little further effect. The catalysts prepared in connection with the work reported here were more active than those made from early samples of alloy. Therefore, a study of the influence of palmitic acid on this catalyst was undertaken. Figure 5 shows that the activity of the catalyst decreases with increasing amounts of fatty acid till it reaches about the same activity as that previously obtained, after which further addition of acid has little effect. The dotted lines in the figure are taken from earlier work[7] for comparison purposes.

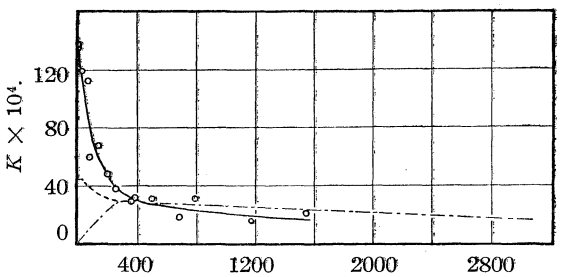

Fig. 5.—Hydrogenation of *d*-limonene on Raney nickel in the presence of palmitic acid: dotted lines represent behavior of less active catalyst samples; *cf.* Smith and Fuzek, ref. 7.

Acknowledgment.—The authors are indebted to the Office of Naval Research for financial support which made this research possible.

Summary

A study has been made of the activity of Raney nickel catalyst as affected by its method of preparation from the alloy and its age. It has been shown that different temperatures of solution of the alloy, different temperatures and times of digestion, and different methods of washing have little effect on catalytic activity as measured by the rate of hydrogenation of *d*-limonene. It has been further shown that, while the original specific surface of a catalyst has little influence on its initial activity, the change in surface with time is closely paralleled by the change in catalytic activity.

The Catalytic Hydrogenation of the Benzene Nucleus. VI. The Hydrogenation of Compounds with Two Benzene Rings

BY HILTON A. SMITH, DAVID M. ALDERMAN, JR., COMER D. SHACKLETT AND CLARK M. WELCH

In earlier publications in this series, the kinetics of the catalytic hydrogenation of the benzene nucleus in compounds containing only one phenyl group have been reported. The purpose of the present paper is to report similar studies on a number of compounds containing more than one such group. In a compound such as diphenyl or diphenylmethane, the hydrogenation curve shows no discontinuity at the half-hydrogenation point, when the reaction is carried out in acetic acid using Adams platinum catalyst. This might be due to the fact that once the compound is adsorbed on the catalyst, both rings are reduced before desorption occurs. If, on the other hand, the reaction proceeds by steps, with all of the original compound being hydrogenated to an intermediate containing one phenyl and one cyclohexyl group, and subsequently the intermediate being hydrogenated to the fully reduced product, then the lack of a break in the hydrogenation curve could only be explained if the rates of hydrogenation of the original and the intermediate compounds were the same.

The rates for diphenylacetic acid and phenylcyclohexylacetic acid have already been reported,[1] and are equal, within experimental error. The hydrogenation of methyl and ethyl diphenylacetate has also been studied by two other workers using nickel catalysts.[2,3] The hydrogenation was reported to proceed only as far as the ester of phenylcyclohexylacetic acid, although the second benzene nucleus can be reduced in the presence of platinum. Methyl benzilate could also be reduced only to the methyl ester of phenylcyclohexylacetic acid when nickel was used as a catalyst. Miescher and Hoffmann[4] have reported that benzilic acid can be hydrogenated to phenylcyclohexylglycolic and dicyclohexylglycolic acids using platinum as a catalyst. However, experimental details are not given, and there is some question as to the identity of their products.

Experimental

Diphenyl, diphenylmethane, dibenzyl, diphenylacetic acid, mandelic acid, and triphenylmethane were obtained from the Eastman Kodak Company. The diphenyl was recrystallized from methanol and then distilled through an 18-inch Vigreux column. Dibenzyl and triphenylmethane were recrystallized from ethanol. The diphenylmethane was fractionated before use. Mandelic acid and diphenylacetic acid were used directly. 1,1-Diphenylethane was obtained by the catalytic hydrogenation over nickel of 1,1-diphenylethylene, which had been prepared from bromobenzene and ethyl acetate by a Grignard reaction.[5] The diphenylethane was fractionated in an eight-foot Vigreux column. **1,6-Diphenylhexane** was prepared from γ-phenyl-*n*-propyl alcohol, which was converted to the bromide using phosphorus tribromide, and thence to the desired product by means of sodium in dry ether.[6] The product was fractionated in a small Vigreux column.

Phenylcyclohexylmethane, 1-phenyl-1-cyclohexylethane, cyclohexyldiphenylmethane, and phenylcyclohexylacetic acid were all prepared by partial hydrogenation of the corresponding diphenyl or triphenyl compound. **Phenylcyclohexane** was synthesized from cyclohexene and benzene.[7] The product was fractionated in the eight-foot column.

Benzilic acid was prepared as follows: Benzoin was prepared from benzaldehyde by the method of Adams and Marvel.[8] This was converted to benzil by oxidation with nitric acid.[9] Rearrangement to benzilic acid using alcoholic potassium hydroxide[10] with subsequent recrystallizations from benzene, water, and methanol–water mixtures gave a product which melted from 148–150°. Oxidation of the benzoin by the method of Ballard and Dehn[11] with subsequent conversion to benzilic acid and recrystallization gave a product with similar melting range. A sample of benzilic acid was converted to ethyl benzilate by the reaction of potassium benzilate with ethyl iodide. The ester was fractionated under reduced pressure in an eight-foot Vigreux column, and the middle 60% of the distillate saponified. The acid obtained from this process was treated with active charcoal (in ethanol solution), and recrystallized three times from benzene, three times from methanol–water mixtures, and twice from ligroin. The resulting material melted from 148–150° as before. It was concluded that the melting range was caused by decomposition of the acid, and not by extraneous impurities.

Phenylcyclohexylglycolic acid was prepared as follows: Benzoyl cyanide (100 g.)[12] was dissolved in 400 ml. of absolute ethanol, and the solution saturated at 10° with hydrogen chloride. After standing five days it was diluted with water, and extracted with ether. The ether layer was washed with sodium bicarbonate solution and distilled under reduced pressure, yielding 56 ml. of ethyl phenylglyoxylate, b. p. 105–106° (1 mm.). To 40 g. of this ester dissolved in dry ether was added slowly with vigorous stirring a solution of cyclohexylmagnesium bromide[13] made from one mole of bromocyclohexane and one equivalent of magnesium. The mixture was heated under reflux for one hour, poured into a mixture of ice and dilute sulfuric acid and the ether layer dried and evaporated. The remaining liquid was distilled under reduced pressure, yielding 45 ml. of ethyl phenylcyclohexylglycolate, b. p. 172–173° (10 mm.). Thirty grams of phenylcyclohexylglycolic acid was obtained from this ester by saponifica-

tion procedures. The acid, when recrystallized from benzene and methanol–water mixtures, melted from 167–168°, and had a neutral equivalent of 234. Upon hydrogenation, it yielded dicyclohexylglycolic acid.

Dicyclohexylglycolic acid was obtained in 97–99% yields by hydrogenation of either benzilic acid or the phenylcyclohexylglycolic acid using platinum catalyst and acetic acid solvent. If the recrystallized acid was heated slowly, it underwent a change of state at 160°. The crystals melted, and almost immediately recrystallized in a different modification. The resulting solid melted sharply at 173°. Miescher and Hoffmann[1] claim a melting point of 143–144° while Danilow and Venus-Danilowa[14] obtained a value of 162–163°. For proof of structure of the compound resulting from this research, the following evidence was obtained: neutral equivalent, 240 (theoretical 240); molecular weight by boiling point elevation in ethyl acetate, 239 (theoretical 240). Reaction with methylmagnesium iodide showed two active hydrogens. The product obtained by complete hydrogenation over Raney nickel at 150° was dicyclohexylacetic acid, m. p. 138°, mixed melting point with an authentic sample, 138°.

Table I gives the reactants used together with their melting points, boiling points, and neutral equivalents.

The acetic acid used as a solvent in hydrogenation runs was prepared by fractionation in a five-foot helix-packed still. The platinum catalyst was prepared by standard methods.[15] The hydrogenations were carried out in a standard low-pressure Parr catalytic reduction apparatus.

After the reaction was complete, the product was recovered either by distilling the acetic acid solvent or by diluting it with water to make the product insoluble. The product was then recrystallized or distilled. The pertinent data are given in Table II.

Experimental Calculations and Results

As in previous hydrogenation experiments dealing with the benzene nucleus, all of the reactions were zero order with respect to the hydrogen acceptor, first order with respect to hydrogen pressure, and directly proportional to the weight of catalyst used. Therefore rate constants were calculated from the equation

$$\log p^0_{H_2}/p_{H_2} = kt/2.303\ V$$

where $p^0_{H_2}$ represents the initial hydrogen pressure, p_{H_2} represents the hydrogen pressure at time t, and V is the volume of the hydrogen gas in the system. Individual values of the rate constant, k, were obtained by plotting $\log p^0_{H_2}/p_{H_2}$ against t, and multiplying the slope of the line thus ob-

tained by $2.303V$.[16] Figure 1 shows typical plots from which rate constants were calculated. These constants, all referred to one gram of standard catalyst,[1] are given in Table III. The values are given at 30°, although the actual runs were made at temperatures varying from 25 to 32.5°. Corrections to 30° were made by means of the Arrhenius equation, using an activation energy of 7400 calories per mole.[17]

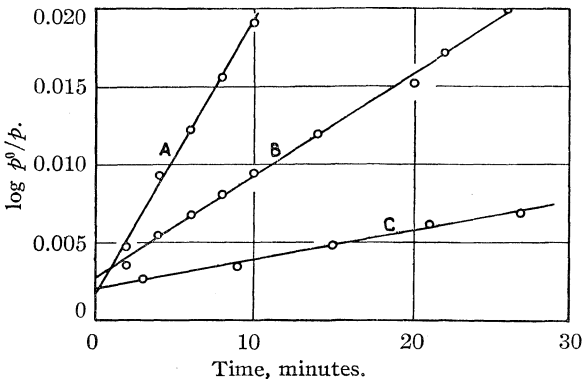

Fig. 1.—Hydrogenation plots for A, dibenzyl; B, diphenyl; and C, cyclohexyldiphenylmethane. For each run, 50 ml. of acetic acid, 0.2 g. of PtO_2 and 64 p. s. i. initial H_2 pressure were employed.

Discussion of Rate Data

An examination of the results given in Table III indicates two significant facts. First, substitution of a benzene nucleus into a molecule already containing one such nucleus usually causes a considerable decrease in the hydrogenation rate. This fact is clearly shown in Table IV. It appears that, in general, the retarding influence is reduced as the phenyl groups are removed farther away from each other.

TABLE III

RATE CONSTANTS FOR THE HYDROGENATION OF COMPOUNDS STUDIED

[a] For propylbenzenes and higher homologs. *Cf.* Smith and Pennekamp, THIS JOURNAL, **67**, 276 (1945). [b] *Cf.* Smith, Alderman and Nadig, *ibid.*, **67**, 272 (1945).

(16) Fuzek and Smith, THIS JOURNAL, **70**, 3743 (1948).
(17) Smith and Meriwether, *ibid.*, **71**, 413 (1939).

The second interesting result is shown clearly in Table V. It appears that the substitution of a cyclohexyl group for a phenyl group has essentially no influence on the rate of hydrogenation. With the exception of 1,1-diphenylethane, the substitution of a cyclohexyl for a phenyl group results in a value of the rate constant which is unchanged almost within experimental error. It is possible that a trace of catalyst poison is responsible for the one exception, although great care was taken to prevent this.

These results can be explained if one assumes that only one benzene nucleus is adsorbed on the catalyst in any of the polyphenyl compounds, and that the remaining nucleus decreases the rate because of steric factors. Thus, an increase in the number of benzene nuclei would cause a decrease in the hydrogenation rate and, in addition, the substitution of the cyclohexyl group for the phenyl group would have little influence. This suggestion is particularly interesting in reference to biphenyl, where the two benzene rings are in resonance with each other, and where one would probably expect that both of these groups would be simultaneously adsorbed on the catalyst surface in a flat position. However, it has already been suggested that resonance in a single benzene ring is destroyed when adsorption on platinum takes place,[17] and a similar condition would probably be indicated for the biphenyl molecule.

Partial Hydrogenation Experiments

In view of the previous finding that the substitution of a cyclohexyl group for one of the phenyl groups in a polyphenyl compound did not affect the rate of hydrogenation, it follows that rate measurements can give no evidence as to whether these compounds are hydrogenated completely before they are desorbed from the catalyst, or whether one phenyl is hydrogenated, the compound then desorbed, and subsequently the other phenyl or phenyls are reduced. In order to investigate the mechanism of hydrogenation of such materials, several polyphenyl compounds were hydrogenated to that point which would be equivalent to the saturation of one ring only. The hydrogenations were then stopped, and the products analyzed. Four methods of analysis were used; they were fractional distillation, spectrophotometry, esterification and identification of the products.

The half-hydrogenation products of biphenyl, diphenylmethane, 1,1-diphenylethane and 1,2-diphenylethane were analyzed by fractional distillation methods. Figure 2 shows the results for diphenylmethane and Figure 3 those for biphenyl. The fractionations were carried out in a

TABLE IV

INFLUENCE OF PHENYL SUBSTITUTION ON HYDROGENATION RATE

twenty-inch Vigreux column. The platinum catalyst was filtered from the acetic acid solution of the partially hydrogenated material, and the solvent removed by distillation in the same column. A synthetic mixture containing diphenylmethane and dicyclohexylmethane, and one containing 1,1-diphenylethane and 1,1-dicyclohexylethane were also fractionated in order to show that separation could be achieved with the apparatus employed.

The results of the fractionation experiments showed that the half-hydrogenated products of diphenylmethane and 1,1-diphenylethane were essentially pure phenylcyclohexylmethane and 1-phenyl-1-cyclohexylethane respectively. Half-hydrogenated diphenyl yielded about 60% of phenylcyclohexane. The distillation curve for 1,2-diphenylethane was unsatisfactory for analytical purposes, but indicated that a mixture was present.

Analysis of half-hydrogenated diphenylacetic acid depended on the fact that diphenylacetic acid is esterified at a measurable rate under conditions where dicyclohexylacetic acid is not esterified at all.[18] If one assumes that phenylcyclohexylacetic acid does not esterify at all, then the total esterification rate of a mixture of the three acids will be caused by any diphenylacetic acid present.

Two samples of diphenylacetic acid were hydrogenated until an amount of hydrogen gas equivalent to half that necessary to saturate both rings had been adsorbed. The catalyst was removed by filtration, and the acetic acid solvent

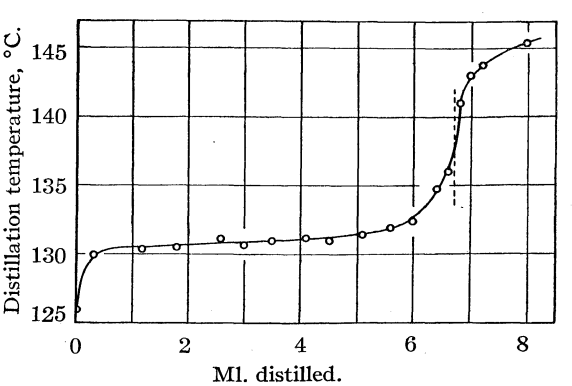

Fig. 3.—Distillation of 8.5 ml. of half-hydrogenated diphenyl; fraction between 0 and 6.7 ml. is a mixture of dicyclohexyl and phenylcyclohexane; remainder is diphenyl.

(18) Smith and Burn, THIS JOURNAL, **66**, 1494 (1944).

completely evaporated. Esterification analyses were made by treating samples from each run with methanol at 50° in the presence of hydrochloric acid catalyst. The method was essentially that used in earlier experiments,[18] except that the concentrations of organic acid and of catalyst were different from those previously used. Runs were made under comparable conditions with diphenylacetic acid, mixtures of diphenylacetic and dicyclohexylacetic acids, and with phenylcyclohexylacetic acid. The results are given in Table VI.

TABLE VI

ESTERIFICATION OF DIPHENYLACETIC ACID AND HYDROGENATED PRODUCTS IN METHANOL

For all runs, the temperature was 50.0° and the concentration of the HCl catalyst was 0.01 *M*.

Material esterified	Original concn., moles/liter	Rate constant[a]
Diphenylacetic acid	0.10	0.00957
Diphenylacetic acid plus phenylcyclohexylacetic acid	.05 .05	.00490
Half-hydrogenated diphenylacetic acid, no. 1	.10[b]	.00059
Half-hydrogenated diphenylacetic acid, no. 2	.10[b]	.00047
Phenylcyclohexylacetic acid	.10	.00054

[a] The rate constants were calculated from the equation

$$k = \frac{(r + a)\ln a/(a - x) - x}{(\text{catalyst})rt}$$

where a is the initial concentration of organic acid, x is the concentration of ester formed after time, t, and $r = 0.42$ [*cf.* Smith and Reichardt, THIS JOURNAL, **63**, 605(1941)]. The units of the rate constants are liters moles^{-1} sec.$^{-1}$

[b] These concentrations were calculated assuming a molecular weight of 218.3.

On the basis of the runs with diphenylacetic acid, it appears that the half-hydrogenated product can have a maximum of 5% of this material, and hence a minimum of 90% phenylcyclohexylacetic acid. The experiments with samples of the latter acid indicate that essentially all of the esterification rate can be accounted for by the reactivity of this material and hence the half-hydrogenated product is essentially pure phenylcyclohexylacetic acid.

When triphenylmethane was reduced with enough hydrogen to saturate only one benzene ring, the platinum filtered out, and the acetic acid solution poured into water, an oily layer separated which on standing in the refrigerator for several days became crystalline. The melting range of the crystalline material indicated that it was primarily a single compound. When recrystallized several times from methanol, the product melted at 62.0–63.6°. The literature reports a melting point of 56.5° for diphenylcyclohexylmethane.[19]

When di-(phenylpropyl)-acetic acid was half-hydrogenated, and the product recovered in the usual manner, an oily layer was obtained which could not be crystallized. This was thought to indicate that a mixture was present.

The half-hydrogenated benzilic acid was analyzed by a colorimetric method, details of which will be given later. The analysis showed that approximately 65% of the material present when enough hydrogen had been taken up to reduce one benzene nucleus was phenylcyclohexylglycolic acid.

Thus, for every compound for which satisfactory analysis was made, the partial hydrogenation product was found to be mainly a compound with only one ring saturated, and in three cases this was essentially the only material present. It would appear that the polyphenyl compound must be desorbed after one ring is saturated, and that the original material is adsorbed in preference to the partially saturated material, even though the rates of hydrogenation of the two are the same. If the differences in these adsorptions are sufficiently great, one may obtain practically pure material with only one saturated benzene nucleus.

The fact that, on nickel catalyst, the esters of diphenylacetic and benzilic acids may be hydrogenated only as far as the esters of phenylcyclohexylacetic acid[2,3] may be explained on the same basis.

Summary

The kinetics of the catalytic hydrogenation of sixteen compounds each containing more than one benzene nucleus have been investigated. All hydrogenations were carried out in acetic acid solution using Adams platinum catalyst, and first order rate constants referred to one gram of standard catalyst were tabulated.

The results indicate that, in general, the rate of hydrogenation decreases with the number of phenyl groups present. In addition, substitution of a cyclohexyl group for a phenyl group has no influence on the rate of hydrogenation.

Partial hydrogenation experiments indicate that the mechanism of the hydrogenation of compounds containing several nuclei is a stepwise reaction involving saturation of only one benzene nucleus at a time. In some cases it is possible to isolate intermediate cyclohexyl compounds in almost the theoretical quantities even though no change in rate occurs.

The Reaction between Ferrous Iron and Peroxides. I. Reaction with Hydrogen Peroxide in the Absence of Oxygen[1]

BY I. M. KOLTHOFF AND A. I. MEDALIA[1a]

In a previous paper[2] the mechanisms which have been proposed for the reaction between ferrous iron and hydrogen peroxide have been reviewed. Two mechanisms which appear equally satisfactory are those of Bray and Gorin[3] and of Haber and Weiss.[4,5] In both mechanisms the primary step is assumed to be unimolecular in ferrous iron and hydrogen peroxide, and to result in the formation of a highly active intermediate. This intermediate is ferryl iron, FeO^{++}, in the former mechanism, and the hydroxyl radical, HO·, in the latter. For simplicity, attention is focused in the present paper upon the more familiar mechanism of Haber and Weiss. The steps proposed by Haber and Weiss are

$$Fe^{++} + H_2O_2 = Fe^{+3} + OH^- + HO\cdot \quad (1)$$

$$HO\cdot + H_2O_2 = H_2O + HO_2\cdot \quad (2)$$

$$HO_2\cdot + H_2O_2 = O_2 + H_2O + HO\cdot \quad (3)$$

$$HO\cdot + Fe^{++} = Fe^{+3} + OH^- \quad (4)$$

The active intermediate (HO·) can react with ferrous iron, hydrogen peroxide or other components contained in the reaction mixture. Reaction with ferrous iron leads to the stoichiometric over-all reaction (sum of steps (1) and (4))

$$2Fe^{++} + H_2O_2 + 2H^+ = 2Fe^{+3} + 2H_2O \quad (I)$$

while reaction with hydrogen peroxide leads to induced decomposition of hydrogen peroxide (sum of steps (2) and (3))

$$2H_2O_2 = 2H_2O + O_2 \quad (II)$$

If the reaction mixture contains only ferrous iron, hydrogen peroxide, water and sulfuric acid, the free radical reaction with ferrous iron predominates, unless hydrogen peroxide is present in large excess over ferrous iron. Under the latter circumstances some of the intermediates decompose hydrogen peroxide. Consideration of the reaction in this simple system, on the basis of either mechanism mentioned above, leads to the following expression for the instantaneous consumption ratio, n

$$n = \frac{d(H_2O_2)}{d(Fe^{++})} = 0.5 + \frac{k_a}{k_b}\frac{(H_2O_2)}{(Fe^{++})} \quad (5)$$

where k_a and k_b represent the rate constants for reaction of the active intermediate with hydrogen peroxide or ferrous iron, respectively. This expression was derived theoretically and confirmed experimentally by Haber and Weiss; the value of k_a/k_b is of the order of 2×10^{-2} at 20°, depending somewhat upon the acidity.

The rate law for the *stoichiometric* reaction (I) which would be expected on the basis of either of the above mechanisms

$$-\frac{d(Fe^{++})}{dt} = \frac{2d(H_2O_2)}{dt} = k_4(Fe^{++})(H_2O_2) \quad (5a)$$

was established experimentally by Baxendale, Evans and Park,[6] who found an average value of k_4 of 62 liters mole^{-1} sec.$^{-1}$ at 25°.

The reaction between hydrogen peroxide and ferrous iron becomes of special interest when carried out in the presence of other compounds with which the active intermediate can react. The polymerization of vinyl monomers may be initiated in this way,[6] the free radical reacting with the monomer and thus initiating the polymerization. The oxidation of many organic compounds by hydrogen peroxide is induced by the ferrous iron–hydrogen peroxide reaction; this is known as a Fenton reaction. For example, it is shown in the experimental part that ethanol is oxidized to acetaldehyde when it is present in the reaction mixture of hydrogen peroxide and ferrous iron.

The reaction between ferrous iron and organic hydroperoxides is widely used for the determination of these compounds, especially when they are present in very small amounts. This reaction results in a ratio of moles of ferrous iron to hydroperoxide reacted which may be much smaller or much larger than the stoichiometric ratio dependent on whether oxygen is absent or present. Similar deviations from the stoichiometric ratio are found in the reaction between hydrogen peroxide and ferrous iron in the presence of various organic substances. The present paper deals with a study of these deviations in the absence of oxygen; in a subsequent paper the results of a similar study in the presence of oxygen will be presented. These studies have yielded insight into the side reactions which occur in the reaction between ferrous iron and organic hydroperoxides, which will be reported in a future paper.

Experimental

In adopting a technique for the study of the re-

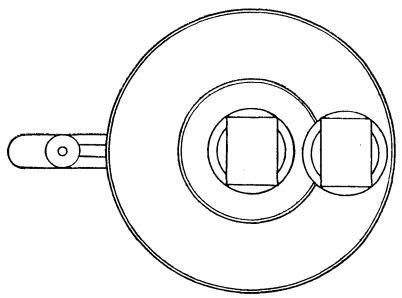
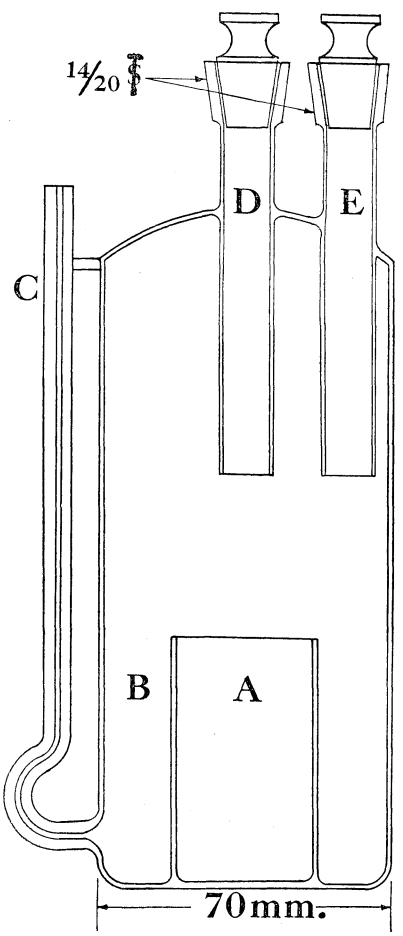
action between hydrogen peroxide and ferrous iron in the absence of oxygen, the following factors were considered: (1) exclusion of oxygen must be thorough, (2) mixing should be rapid, (3) the reaction vessel should be free from contamination by organic matter, such as stopcock grease. Reaction vessels were constructed as shown in Fig. 1. Experiments in the absence of oxygen have been carried out as follows.



Top view.



Side view.

Fig. 1.—Reaction vessel.

Procedure.—Purified nitrogen is passed through the capillary side-tube C, and through inlet tubes inserted through the tubes D and E, for at least ten minutes. The solutions which are to be added are flushed with nitrogen, in vessels provided with tubes similar to D and E, for at least thirty minutes. Aliquots are withdrawn with nitrogen-filled pipets, which are then inserted all the way through tubes D and E before draining. Solutions are introduced into compartment A through inlet tube D, and into compartment B through inlet tube E. The nitrogen inlet tube is removed from D or E immediately before inserting the pipet; however, nitrogen is continually passed through the other of these tubes, and through the capillary side-arm. When the solutions have all been added, the tubes D and E are flushed with nitrogen by keeping one tube stoppered tightly and the other loosely (alternately) while passing nitrogen through the capillary. The tubes are then stoppered tightly and the vessel is shaken vigorously for about fifteen seconds. One stopper is then loosened and nitrogen is passed through the side-arm. Aliquots are removed with a pipet, and the ferrous iron is titrated. Evidently the total volume of solution added to the vessel must be known accurately.

When the above procedure is followed, complete mixing appears to be brought about in one second (three strokes). Calculation on the basis of the rate law[4] and rate constant given above shows that in a solution initially 2×10^{-3} M in ferrous iron and 5×10^{-4} M in hydrogen peroxide (typical conditions used in the present work), the stoichiometric reaction is 11.4% complete in one second. Thus under the experimental conditions, only a minor portion of the reaction can take place before mixing is complete.

In the experiments reported in this paper, 25 ml. of acid (generally 1.5 N sulfuric) was placed in A and 75 ml. in B. Solutions of the organic substance and ferrous iron were placed in B and of hydrogen peroxide in A. The total volumes of solution were 120–130 ml., and 50-ml. aliquots were titrated ten and twenty minutes (or fifteen and thirty minutes), respectively, after mixing, with ceric sulfate solution of the proper concentration, using ferrous *o*-phenanthroline perchlorate as indicator. Good end-points were obtained with 0.001321 N cerate solution, which was the most dilute cerate solution used, using comparison flasks in the detection of the end-point. No interference in the titration of iron was found in the presence of ethanol or acetaldehyde. All experiments were carried out at room temperature (25–30°).

To test completeness of removal of oxygen by the above procedure, solutions of ferrous iron and alkali pyrophosphate were flushed with nitrogen in the separate compartments of the reaction vessel, then mixed and allowed to stand for fifteen minutes. Titration of aliquots showed that the extent of air oxidation of ferrous iron was negligible.

Reagents.—Water: Twice-distilled water was redistilled from alkaline permanganate in an all-

glass still; the middle three-fifths portion was used. Sulfuric acid was du Pont (Grasselli) reagent grade; ferrous sulfate heptahydrate, Merck reagent grade; hydrogen peroxide, Merck Superoxol (30%), C.P.; sodium perchlorate, G. F. Smith Co. Other inorganic compounds were C.P. or reagent grade. Ethanol, absolute ethanol was refluxed with aluminum and sodium hydroxide, then distilled; acetic acid, du Pont (Grasselli) reagent grade; acetone, C.P., freshly distilled; acetaldehyde, Eastman Kodak Co. "White Label" grade; methanol, C.P., freshly distilled; nitrogen, pre-purified nitrogen, obtained from Air Reduction Co. (Seaford works) and from Linde Air Co.

The dilute cerate solutions for titration were made up daily by dilution with 1 N sulfuric acid of a 0.1321 N stock solution (standardized against Bureau of Standards arsenious oxide). Both the ferrous solution and the hydrogen peroxide solution were standardized daily against the dilute cerate solution. The ferrous *o*-phenanthroline end-point was not sharp in the titration of dilute hydrogen peroxide with dilute cerate, and for this reason a known amount of ferrous solution was added after the approximate end-point, and the excess ferrous iron was back-titrated with cerate.

Results and Discussion

Results Obtained in the Presence of Sulfuric Acid and Ethanol.—In the present experiments attention is focused upon the stoichiometry of the reaction between ferrous iron and hydrogen peroxide in the presence of various other compounds, while in a later section there is described a brief study of the products formed. The stoichiometry was determined simply by titration of the ferrous iron remaining after carrying out a reaction under conditions such that the hydrogen peroxide taken was completely consumed; completeness of reaction was tested by titration of aliquots taken after two different reaction times; qualitative tests (with titanic sulfate or potassium ferricyanide) established whether ferrous iron or hydrogen peroxide remained in the mixture after completion of the reaction.

Results obtained for the reaction in sulfuric acid solutions in the presence of various concentrations of ethanol are shown in Table I. This table, as well as all other tables in this paper, gives analytical data obtained for the reaction between ferrous iron and hydrogen peroxide, in the absence of oxygen, according to the above procedure. The initial concentrations of ingredients given are those which would be present immediately after mixing if no reaction had taken place during mixing. The column headed "Molar ratio, (Fe^{++}) reacted/(H_2O_2) taken" gives the results of the titrations. Each figure given in this column is an average obtained with aliquots from a single reaction mixture after reaction times differing by a factor of two. Since in all experiments, therefore, the concentration of hydrogen peroxide taken was equal to the concentration of hydrogen peroxide reacted, this column gives the values of the overall reaction ratio, which may be designated as

$$R = \frac{\text{moles } (Fe^{++}) \text{ reacted}}{\text{moles } (H_2O_2) \text{ reacted}} = \frac{\Delta(Fe^{++})}{\Delta(H_2O_2)} = \frac{1}{\bar{n}}$$

The stoichiometric value of R is 2. The significance of the induction factor is discussed below.

[a] In 2.1 N sulfuric acid. [b] In 0.045 N sulfuric acid.

The above data show that in the presence of ethanol, less ferrous iron is oxidized than would correspond to the hydrogen peroxide initially present, on a stoichiometric basis. Thus hydrogen peroxide must be consumed by some reaction which is induced by the ferrous iron–hydrogen peroxide reaction. It is shown further in this paper that this induced reaction is principally the oxidation of ethanol to acetaldehyde; that is, a Fenton reaction. The extent of this induced reaction increases with increasing concentrations of ethanol, when the initial concentrations of iron and peroxide are kept constant. With given concentrations of ethanol and iron (10^{-3} and 0.52×10^{-3} M, respectively), the reaction ratio was found to be independent of the initial concentration of peroxide, over a fourfold range; while with a given concentration of ethanol and a given initial ratio of iron to peroxide, the reaction ratio increased (*i. e.*, the extent of the induced reaction decreased) with increasing concentrations of iron. The effect of the concentration of sulfuric acid is discussed

later. The slight deviations from the stoichiometric reaction ratio found in the absence of ethanol may be due to traces of organic impurities.

The induction factor is defined as the number of equivalents of the induced reaction divided by the number of equivalents of the primary reaction.[7] In the present experiments, R equivalents (or moles) of ferrous iron react per mole (or per 2 equivalents) of hydrogen peroxide. Thus the number of equivalents of hydrogen peroxide consumed in the primary reaction is R, and the number consumed in the induced reaction is $2 - R$; so that the induction factor is $(2 - R)/R$. The large values of the induction factor are significant from an analytical standpoint. If a determination of hydrogen peroxide with ferrous iron were attempted in the presence of ethanol, the percentage error (based on the amount of hydrogen peroxide found) would be given by 100 times the induction factor. It is seen that the error in the presence of sufficient ethanol would be over one thousand per cent.

The Fenton oxidation of ethanol may be interpreted either on the basis of the Haber and Weiss[4,5] mechanism or the Bray and Gorin[3] mechanism. On the former basis, the mechanism would be

$$Fe^{++} + H_2O_2 = Fe^{+3} + HO\cdot + OH^- \quad (1)$$
$$HO\cdot + CH_3CH_2OH = CH_3\dot{C}HOH + H_2O \quad (6)$$
$$CH_3\dot{C}HOH + Fe^{+3} = CH_3CHO + H^+ + Fe^{++} \quad (7)$$
$$Fe^{++} + HO\cdot = Fe^{+3} + OH^- \quad (4)$$

Steps (1), (6) and (7) form a chain mechanism for the reaction between hydrogen peroxide and ethanol, with ferrous iron, hydroxyl radical and hydroxyethyl radical as chain-carriers; step (4) is the termination step. The sum of steps (1), (6) and (7) gives the over-all induced oxidation of ethanol by hydrogen peroxide

$$CH_3CH_2OH + H_2O_2 = CH_3CHO + 2H_2O \quad (8)$$

In a qualitative interpretation of the results, termination by reaction between the organic radical and ferrous iron, though possible, need not be assumed for compounds, such as ethanol, which are oxidized during the course of the peroxide–iron reaction. Termination by reaction with the organic radical is found with acetic acid, as shown in step (15). Direct reaction between hydrogen peroxide and the hydroxyethyl radical may also take place, as shown in step (9), which is equivalent to the sum of steps (7) and (1).

$$CH_3\dot{C}HOH + H_2O_2 = CH_3CH(OH)_2 + HO\cdot = CH_3CHO + H_2O + HO\cdot \quad (9)$$

On the basis of the mechanism of Bray and Gorin, the pertinent steps would be

$$Fe^{++} + H_2O_2 = FeO^{++} + H_2O \quad (10)$$
$$FeO^{++} + CH_3CH_2OH = Fe^{+3} + CH_3\dot{C}HOH + OH^- \quad (11)$$
$$CH_3\dot{C}HOH + Fe^{+3} = CH_3CHO + H^+ + Fe^{++} \quad (7)$$
$$Fe^{++} + FeO^{++} + 2H^+ = 2Fe^{+3} + H_2O \quad (12)$$

Steps (10), (11) and (7) form a chain reaction with the ferryl ion as a chain-carrier; the chain is terminated by step (12). It is also possible that hydrogen peroxide is consumed by steps (16) and (17) discussed later in this paper. We are indebted to Professor M. S. Kharasch of the University of Chicago for the suggestion that acetaldehyde is the reaction product.

We have attempted to derive expressions for the stoichiometry of the reaction in the presence of ethanol, based on the above mechanisms[8]; however, agreement of any of these expressions with the experimental data of Table I is only fair. A complicating factor is the induced oxidation of acetaldehyde to acetic acid, as shown below; that is, as soon as some acetaldehyde is formed by oxidation of ethanol, it will compete with both ethanol and ferrous iron for reaction with the active intermediate (ferryl iron or hydroxyl radical), so that the kinetic treatment becomes very complicated and difficult to test experimentally.

Results Obtained in the Presence of Sulfuric Acid and Organic Compounds other than Ethanol.—Some experiments have been carried out using the apparatus and technique described above, but with acetic acid, acetone or acetaldehyde in place of ethanol. The data are given in Table II.

[a] In 0.045 N sulfuric acid.

The behavior of acetaldehyde, as indicated in Table II, is qualitatively similar to that of ethanol; that is, a significant deviation from the stoichiometric reaction is found in the presence of a small concentration of acetaldehyde. In preliminary experiments with a less refined experimental technique, methanol was also found to behave similarly.

In contrast, even relatively high concentrations of acetic acid or acetone give rise to practically no deviation from the stoichiometric reaction. In terms of the mechanisms given above, this means that these compounds either fail to react with the active intermediates, or that, if reaction does oc-

(7) I. M. Kolthoff and V. A. Stenger, "Volumetric Analysis," Vol. I, Interscience Publishers, Inc., New York, N. Y., 1942.

(8) A. I. Medalia, Ph.D. Thesis, University of Minnesota, 1948.

cur, the organic radicals thus formed react with ferrous iron in preference to ferric iron or hydrogen peroxide; this is illustrated in equations (13)–(15), with acetic acid.[9a]

$$HO\cdot + CH_3COOH = CH_3COO\cdot + H_2O \quad (13)$$

$$FeO^{++} + CH_3COOH = Fe^{+3} + CH_3COO\cdot + OH^- \quad (14)$$

$$CH_3COO\cdot + Fe^{++} = CH_3COO^- + Fe^{+3} \quad (15)$$

The sum of steps (1), (13) and (15) or of steps (10), (14) and (15), gives the stoichiometric reaction (I), which in the absence of added organic compounds results from the combination of steps (1) and (4), or (10) and (12). Thus, while the reaction between ferrous iron and hydrogen peroxide is stoichiometric in either the presence or absence of acetic acid (or acetone), the reaction may proceed through a different path in the two cases. Strong evidence that this is the correct interpretation is derived from the work described in the second paper of this series, in which it is shown that both acetic acid and acetone give rise to considerable induced oxygen oxidation of ferrous iron when the peroxide–iron reaction is carried out in the presence of dissolved oxygen. Additional evidence is given in the following section. Independent evidence that acetic acid reacts with the hydroxyl radical comes from a study of the hydrogen peroxide–ozone system, by Taube and Bray.[9b] Using the values of relative rate constants for the reaction of hydroxyl radical with acetic acid, hydrogen peroxide and ferrous iron, as determined by Taube and Bray and by Haber and Weiss, a simple kinetic treatment shows that in the experiments of Table II with 0.1 *M* acetic acid, where a reaction ratio of 1.91 was found, a reaction ratio of only 0.59 would be expected if the acetate radicals reacted with ferric iron or hydrogen peroxide rather than with ferrous iron; this is of significance, of course, only if the Haber and Weiss mechanism is adopted rather than that of Bray and Gorin.

Results Obtained in the Presence of Sulfuric Acid and Mixtures of Organic Compounds.—As shown above, it appears that when the active intermediates which are formed in the ferrous iron–hydrogen peroxide reaction react with acetic acid, then the over-all reaction is stoichiometric, while if these intermediates react with ethanol, then induced reduction of hydrogen peroxide takes place. In a mixture containing both ethanol and acetic acid, competition between these compounds (and ferrous iron) for reaction with the active intermediates would be expected to result in a reaction ratio intermediate between that found with the same concentrations of either organic compound separately. Data illustrating this are shown in Table III.

[a] Reaction medium approximately 60% acetic acid.

These data strongly support the view that acetic acid and ethanol compete for the active intermediates formed in the reaction between ferrous iron and hydrogen peroxide. The acetate free radicals do not give rise to decomposition of hydrogen peroxide (equations (13) to (15)), while the hydroxyethyl free radicals do. Thus acetic acid suppresses the induced oxidation of ethanol observed in the reaction between ferrous iron and hydrogen peroxide. Interaction between a hydroxyethyl radical and acetic acid, or an acetate radical and ethanol, while possible, need not be considered in the qualitative interpretation.

On a purely experimental basis, ethanol may be said to promote the decomposition of hydrogen peroxide during the course of the ferrous iron–hydrogen peroxide reaction, while acetic acid suppresses the promoting action of ethanol. The classification of compounds as "promoting" or "suppressing" is of great utility in considering chain reactions such as those between ferrous iron and hydrogen peroxide, organic hydroperoxides or persulfate. From an analytical standpoint, the above results are significant as indicating the use which can be made of the suppressing action of certain compounds in overcoming the induced decomposition caused by other compounds. Application of this principle to the determination of organic peroxides may be of considerable importance, as will be shown in a subsequent paper.

Reaction in the Presence of Inorganic Compounds other than Sulfuric Acid.—The experiments described above were carried out in the presence of sulfuric acid. This acid is convenient to use, since it is available in pure form and is quite stable, and extensive previous study of the ferrous iron–hydrogen peroxide reaction has been carried out in sulfuric acid medium. However, some study of the reaction in the presence of perchloric rather than sulfuric acid seemed desirable in view of the comparatively slight tendency of

(9a) If the acetate radical would decompose appreciably (to $CH_3\cdot$ and CO_2) before reacting with ferrous iron, the stoichiometry would require oxidation of ferrous iron by the methyl radical:

$$CH_3\cdot + Fe^{++} + H^+ = CH_4 + Fe^{+3} \quad (15a)$$

Because of the low concentrations of peroxide and ferrous iron used in the present experiments, no attempt was made to detect the presence of methane or carbon dioxide. Reaction between hydroxyl radical and acetic acid might form the radical $\cdot CH_2COOH$ instead of the acetate radical (step (13)); *cf.* the following paper.

(9b) H. Taube and W. C. Bray, THIS JOURNAL, **62**, 3357 (1940).

perchloric acid to form complexes with ferrous and ferric iron. Some difficulty was encountered in these experiments, apparently as a result of impurities present in several of the samples of perchloric acid which were used. In selecting a sample of perchloric acid for use in further experiments, the criterion of purity which was used was the reaction ratio of ferrous iron to hydrogen peroxide found in the presence of perchloric acid (1 *M*) in nitrogen, in the absence of other added substances. The sample which gave the reaction ratio closest to the theoretical (J. T. Baker C.P. vacuum distilled, 20%) was used in subsequent work. The reaction ratio obtained with this sample was 1.94 (theoretical, 2.0); other ratios obtained are as follows: Merck 60%, two different lots, 1.03 and 1.23; Baker and Adamson 60%, 1.82.

The reaction has also been studied in the presence of sodium perchlorate, sodium chloride, potassium nitrate and phosphoric acid. Experiments with each compound were carried out both in the absence and presence of ethanol. The data are given in Table IV.

..	10^{-3}	2.0	H_2SO_4, 0.045 *N*	3.8	.49	3.08

The above data show definitely that with perchloric acid the extent of the induced reaction in nitrogen is practically independent of the amount of acid over a fifty-fold range. The coincidence of the value obtained in perchloric acid with that obtained in dilute (0.045 *N*) sulfuric acid makes it appear that these values are limiting values, without interference by the anions. The data obtained with sodium perchlorate substantiate the conclusion that there is no salt effect upon the reaction ratio with perchlorate as the anion. The extent of the induced reaction depends upon the competition between ethanol and ferrous iron for reaction with the active intermediates. Absence of a salt effect indicates that the active intermediate is uncharged; this supports the free-radical mechanism. If ferryl iron were the active intermediate, then a salt effect would be expected for the reaction of ferryl iron with ferrous iron, but not for the reaction of ferryl iron with ethanol; thus the reaction ratio would be expected to depend upon salt concentration. It is, however, possible that hydrolysis or complex formation may obscure the expected salt effect.

Chloride ion is seen to act as a powerful suppressor, comparable with acetic acid. Reaction of hydroxyl radical with chloride ion, to form atomic chlorine, was described by Taube and Bray.[9b] From our results it follows that atomic chlorine must react more readily with ferrous iron than with ferric iron, hydrogen peroxide or ethanol.

With high concentrations of sulfuric acid, phosphoric acid or potassium nitrate, slightly higher values are found for the reaction ratio in the presence of 10^{-3} *M* ethanol than are found in dilute sulfuric acid or in perchloric acid. The effect of these compounds may be regarded as mild "suppression," either by the mechanism assumed for suppression by acetic acid, acetone and chloride ion, namely, by reaction of these compounds with the active intermediate; or possibly by protection of the ferrous ion by complex formation, resulting in a decreased rate of reaction between ferrous iron and the active intermediate.

Detection of Acetaldehyde Formed from Ethanol.—In the above presentation it has been assumed that the role of ethanol in the ferrous iron–hydrogen peroxide reaction is to reduce hydrogen peroxide. It also appeared possible that ethanol could serve simply as a chain-carrier, without itself being oxidized. A mechanism for this behavior, based on the mechanism of Haber and Weiss, would include steps (1) and (6) followed by (16) and (17).

$$CH_3\dot{C}HOH + H_2O_2 = CH_3CH_2OH + HO_2\cdot \quad (16)$$

$$HO_2\cdot + H_2O_2 = H_2O + O_2 + HO\cdot \quad (17)$$

It has been reported by Goldschmidt and Pauncz[10] that acetaldehyde, acetic acid and a small amount of oxygen are formed upon slow addition of ferrous iron to relatively concentrated solutions of hydrogen peroxide and ethanol. The conditions under which these experiments were carried out are quite different from those described in this paper. In order to decide by which mechanism hydrogen peroxide disappears when ethanol is present in the reaction mixture it was decided to determine the amount of acetaldehyde formed. It was assumed that if acetaldehyde were formed in the presence of a large amount of ethanol, ethanol would be attacked by the active intermediates rather than the small amounts of acetaldehyde. The experimental results show that the assumption is justified. The most suitable method for the detection and determination of acetaldehyde

(10) S. Goldschmidt and S. Pauncz, *Ann.*, **502**, 1 (1933).

in the presence of ferrous and ferric iron appeared to be that based on reaction with Schiff reagent.

A solution of Schiff reagent was prepared by dissolving 0.50 g. of basic fuchsin (National Aniline Co.) in 1 l. of water, together with 0.31 ml. of 6 N sulfuric acid and 0.58 g. of sodium sulfite. The solution was still pink, and sulfur dioxide was passed through very slowly until the color just turned to yellow. The solution was thus 1.5×10^{-3} M in the fuchsin reagent. Tests were carried out with various buffer solutions, using the following procedure: 5 ml. of buffer solution was mixed with 1 ml. of Schiff reagent solution, and the colors developed in various solutions after five to fifteen minutes were compared visually. At a pH of greater than 3.0, a rose color of fuchsin was visible in the absence of aldehyde. The sensitivity of the test for acetaldehyde decreased with decreasing pH below 3.0. A biphthalate buffer of pH 3.0 was unsuitable, owing to the formation of orange hydrous ferric oxide upon addition of ferric iron in a concentration of 10^{-3} M. In a phosphate buffer, at a pH of 3.0 or 2.4, a white turbidity was formed on addition of ferric iron (ferric phosphate) which did not, however, interfere with the Schiff test under the present conditions. In a phosphate buffer of pH 2.0, no precipitate was formed on addition of ferric iron, but the sensitivity of the test was lower than at the higher values of pH. Ferrous iron did not interfere with the test in the pH range 2–3. The procedure which was adopted for testing reaction mixtures was as follows.

Procedure.—To 5 ml. of reaction mixture, containing up to 0.05 N acid (sulfuric or perchloric), was added sufficient sodium dihydrogen phosphate to give a pH of 3.0 (calculated). One ml. of the solution of Schiff reagent was added and the color was observed after fifteen minutes.

By means of this test, acetaldehyde could be detected in concentrations as low as 10^{-4} M. By visual comparison with controls containing various amounts of acetaldehyde, the concentration could be estimated to $\pm 10^{-4}$ M in the range between 2 and 5×10^{-4} M. More concentrated solutions were diluted before carrying out the test.

Reactions were carried out as described previously. The conditions and results are given in Table V.

Table V

Aldehyde Determinations

Acid[a]	Initial concentrations: Ethanol, M	Initial concentrations: Fe^{++} ($M \times 10^3$)	Molar ratios: Initial $(Fe^{++})/(H_2O_2)$	Molar ratios: (Fe^{++}) reacted / Initial (H_2O_2)	Acetaldehyde found, M
Sulfuric	10^{-1}	2.9	2.1	0.13	1×10^{-3}
Perchloric	10^{-3}	2.0	3.3	.50	4×10^{-4}
Perchloric[b]	10^{-3}	2.0	3.3	.51	3×10^{-4}

[a] The sulfuric acid was 0.05 N; the perchloric acid was 0.02 N. [b] With sodium perchlorate (1 M) in addition to perchloric acid (0.02 N).

The concentration of hydrogen peroxide consumed by reaction with ethanol in the first experiment of Table V is 1.3×10^{-3} M, and in the last two experiments, 0.45×10^{-3} M. It is seen that the concentrations of acetaldehyde found correspond to the concentrations of hydrogen peroxide consumed by the induced reaction. Thus the induced reaction is, at least principally, induced oxidation of ethanol to acetaldehyde.

Acknowledgment.—The authors wish to acknowledge the advice and interest of Professor R. S. Livingston of this University.

Summary

An apparatus and procedure are described with which the reaction between ferrous iron and hydrogen peroxide has been investigated, with rapid mixing, in the absence of oxygen. Ethanol, in concentrations of 10^{-4} to 10^{-1} M, has been added to reaction mixtures in acid solution, with concentrations of the primary reactants generally of the order of 10^{-3} M; in these mixtures, the primary reaction between ferrous iron and hydrogen peroxide induces the reaction between hydrogen peroxide and ethanol, with the formation of acetaldehyde; this is known as a Fenton reaction. Mechanisms for this reaction are presented. No induced reaction is found between hydrogen peroxide and acetic acid; but when acetic acid is added to a mixture containing ethanol, the extent of the induced reduction of hydrogen peroxide by the latter is decreased. Apparently there is competition between acetic acid and ethanol for reaction with the active intermediates formed in the primary reaction; the radicals formed from the two organic compounds differ in their subsequent reactions. Ethanol is termed a promoter, and acetic acid a suppressor.

The Reaction between Ferrous Iron and Peroxides. II. Reaction with Hydrogen Peroxide, in the Presence of Oxygen[1]

BY I. M. KOLTHOFF AND A. I. MEDALIA

In the preceding paper of this series,[2] the course of the reaction between ferrous iron and hydrogen peroxide, in the absence of oxygen, but in the presence of various other compounds, was described. Evidence was given that several compounds react with active intermediates formed in the course of this reaction; thus, ethanol is believed to form the hydroxyethyl radical, and acetic acid, the acetate radical. It is known[3,4] that organic radicals are extremely reactive toward oxygen. It is shown in the present paper that not only quantitatively, but also qualitatively, quite different results are obtained in the presence of oxygen than in its absence.

Experimental

Many of the experiments described in this paper were carried out with the reaction vessel and technique described in the preceding paper,[2] but flushing the vessel with oxygen or air, in place of nitrogen, for at least ten minutes before mixing, as well as between mixing and titration. This technique will be referred to as the "shaking" procedure. Other experiments were carried out by a "stirring" procedure, described below.

"Stirring" Procedure.—The ferrous sulfate solution was added from a 10-ml. "Exax" pipet to 45 ml. of hydrogen peroxide solution in a 125-ml. erlenmeyer flask. The contents of the flask was stirred vigorously during addition of the ferrous solution by means of a flattened twisted stirring rod rotating at 1800 r. p. m. In many experiments the reverse order of mixing was used. With either order of mixing, the solution originally in the flask contained acid as well as any added substances other than the primary reactants; the ferrous sulfate solution was always acid. After standing for a short time, the entire content of the flask was titrated with ceric sulfate solution. The reaction mixtures of duplicate experiments were allowed to stand for different lengths of time (generally ten and twenty minutes) before titrating.

Reagents.—The following reagents were used in the experiments described in this paper in addition to those described in the preceding one.

t-Butyl alcohol	Laboratory supply, distilled through a fractionating column with a reflux ratio of 2:1, in all-glass apparatus
Perchloric acid	J. T. Baker C. P. (20%)
Ferrous perchlorate	Prepared by solution of pure iron wire (B and A reagent) in perchloric acid
Oxygen	Air Reduction Co. (99.5%), filtered through glass wool

Results and Discussion

Reaction in the Presence of Sulfuric Acid and Ethanol.—Results of experiments carried out by the "shaking" procedure are given in Table I. If desirable, before titration with ceric sulfate, small portions of the reaction mixtures were tested for hydrogen peroxide by addition of titanic sulfate solution. The column headed "gas" indicates the gas with which the solutions and gas space were flushed before and after mixing.

[a] These values are calculated on the incorrect assumption that all the hydrogen peroxide has been consumed by reaction with ferrous iron. [b] Calculated on the assumption that all the ferrous iron has been consumed by reaction with hydrogen peroxide.

The results given in Table I show that considerable induced oxygen oxidation of the ferrous iron can take place during the reaction between hydrogen peroxide and ferrous iron in the presence of ethanol and oxygen. The induction factor for this reaction is $(R - 2)/2$, where R is the reaction ratio

given in the fifth column of the table. In dilute solutions (0.001 M) saturated with oxygen, induction factors greater than 2 may be found. Even when the concentration of ethanol is only one-twentieth as great as that of the ferrous iron, an appreciable induced reaction is found. The mechanism of the induced oxidation of ferrous iron is discussed in the following section.

Under certain circumstances the extent of induced air oxidation of ferrous iron may be so great that hydrogen peroxide rather than ferrous iron is left after completion of the reaction. This was found to be the case in the experiments reported in the third and seventh lines of Table I. Since hydrogen peroxide can be titrated with ceric sulfate in the same manner as ferrous iron, titration values are obtained which might be mistaken as corresponding to the amount of iron present, if no test is made for hydrogen peroxide.

With higher concentrations of ferrous iron and hydrogen peroxide, lower induction factors or reaction ratios are found at the same ethanol concentrations. Comparison of the results obtained in oxygen and in air suggests that the magnitude of the reaction ratio is limited by the amount of oxygen available to the system, with initial concentrations of ferrous iron of 2×10^{-3} M or greater. The ratio of the amount of dissolved oxygen to the amount of ferrous iron becomes smaller, of course, as the concentration of ferrous iron is increased. The concentration of oxygen in a solution of 1.5 N sulfuric acid, saturated with oxygen at 25° at atmospheric pressure, is 1.07×10^{-3} M.[5] Also as the concentrations of ferrous iron and of hydrogen peroxide are increased, the ferrous iron–hydrogen peroxide reaction goes to completion more rapidly, so that less oxygen can enter the solution from the gas phase during the course of the reaction. For both reasons it is not surprising that a very low induction factor is found with 0.013 M ferrous iron and 0.0029 M peroxide in the presence of oxygen, while in the presence of air, the reaction ratio is actually lower than the stoichiometric value, with 0.0095 M ferrous iron and 0.0025 M peroxide. Apparently both induced reduction of the peroxide (*cf.* preceding paper[2]) and induced air oxidation of the ferrous iron can take place in the course of a given experiment; if relatively little oxygen is present, the reduction may predominate over the oxidation.

In Table II are given data obtained by the "stirring" technique. Hydrogen peroxide was added to ferrous iron ("reverse" addition), to prevent the error which would result, even in the absence of ethanol, from induced decomposition of hydrogen peroxide in solutions containing a large excess of hydrogen peroxide over ferrous iron.[6] All results are averages of duplicate experiments, titrated after different times, which checked closely. When more than one result is given for a given experiment each figure is the result of a single determination. In all the experiments reported, ferrous iron was in excess to hydrogen peroxide at the time of titration with ceric sulfate.

[a] In 0.046 N sulfuric acid.

Qualitatively, the deviations from the stoichiometric reaction ratio correspond to those given in Table I. With low concentrations of ethanol, ferrous iron, and hydrogen peroxide, the error is due mainly to induced air oxidation of the ferrous iron. When the concentrations of ferrous iron and peroxide are high relative to the concentration of oxygen in the solution, the induced reduction of hydrogen peroxide becomes of greater importance, leading to values of R less than the stoichiometric value of 2. Thus under typical analytical conditions, in the presence of air and ethanol, peroxide values may be found which are low, high, or by chance approximately correct, depending on the concentrations of peroxide and ferrous iron.

With an initial concentration of ferrous iron of 2×10^{-3} M, results within 5% of the stoichiometric are found over a wide range of concentrations of ethanol, due to compensation of the induced oxygen oxidation of ferrous iron and the induced reduction of the peroxide. The high values of R found with 10 M (46% by weight) ethanol may be partly due to the increased solubility of oxygen in this solvent as compared to dilute aqueous solutions.

Reaction in the Presence of Sulfuric Acid and Organic Compounds Other than Ethanol.—In

The data of Table III show that, like ethanol, acetic acid also gives rise to induced oxygen oxidation of ferrous iron in the peroxide–iron reaction. This confirms the hypothesis that acetic acid reacts with the active intermediates which are formed in the ferrous iron–hydrogen peroxide reaction. Since acetic acid itself can give rise to induced oxygen oxidation of ferrous iron, acetic acid would not be expected to suppress the induced oxygen oxidation caused by ethanol; this is brought out by comparison of the data of Tables I and III.

[a] Single experiments.

Results obtained by the "stirring" technique, in air-saturated solutions, in the presence of various organic susbstances, are given in Table IV. The "reverse" mode of addition was used throughout. All results (except as noted) are averages of duplicate experiments titrated after different times, which checked closely.

The reaction between ferrous iron and hydrogen peroxide leads to induced oxygen oxidation of ferrous iron when carried out in the presence of dissolved oxygen and any of the five organic compounds tested, as shown in the preceding tables: namely, ethanol, methanol, acetic acid, acetone and *t*-butyl alcohol. It is of particular interest that even relatively stable substances such as acetic acid and *t*-butyl alcohol can bring about considerable induced reaction. As was observed with ethanol (Table II), the extent of the induced oxidation found with a given initial concentration of ferrous iron and peroxide may vary irregularly with increasing concentrations of the added organic compound. In many of the present experiments in Table IV the extent of the induced air oxidation is limited by the amount of oxygen present, while the extent of induced decomposition of the peroxide increases with increasing concentrations of the organic compound. Thus it is seen qualitatively that the net extent of induced oxidation may be expected to pass through a maximum with increasing concentrations of the organic compound. A more exact treatment of the complex reactions involved cannot be given (*v. i.*).

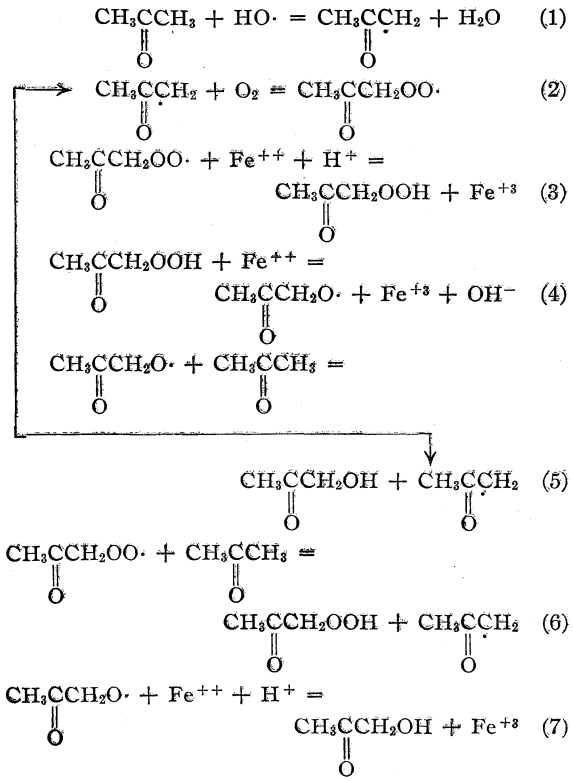
Mechanism of the Induced Oxygen Oxidation of Ferrous Iron.—When the reaction between ferrous iron and hydrogen peroxide is carried out in the presence of various organic compounds, organic radicals apparently are formed, which can react with oxygen (if present in the system), forming peroxide radicals. These can in turn react with molecules of the organic compound present, leading to a chain autoxidation of this compound, with the formation of considerable quantities of peroxides[7,8]; or the peroxide radicals may react with ferrous iron or with hydrogen peroxide; or they may decompose spontaneously. The steps which are possible in the presence of oxygen are much more numerous than in the absence of oxygen, and a detailed analysis of the results does not seem possible. As an illustration, some of the reactions which may take place are given below. For simplicity, the formation of hydroxyl radical in the primary step of the peroxide–iron reaction will be assumed.[2]

In the case of acetone, the hydrogen atoms are labilized by the keto group, so that autoxidation is facilitated. We would expect the following reactions to be possible.

Steps (3), (4) and (7) predict the oxidation of three ferrous ions by each peroxide radical formed

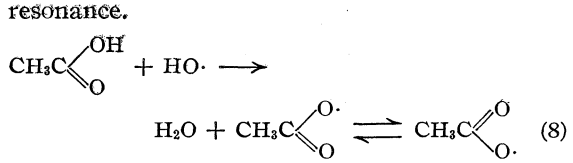
(7) J. L. Bolland, *Proc. Roy. Soc.* (*London*), **A186**, 218 (1946).

(8) E. H. Farmer and D. A. Sutton, *J. Chem. Soc.*, 119 (1943).



in step (1); however, since the initial formation of the peroxide radical (step (1)) consumes a hydroxyl radical which would otherwise oxidize a ferrous ion, only two *additional* ferrous ions are oxidized by the peroxide radical formed in this manner; so that, barring autoxidation (steps (5) and (2), or (6) and (2)), the highest possible induction factor should be unity. Induction factors greater than unity are accounted for by the chain autoxidation reactions, in which a very large number of peroxide radicals can be formed, each of which oxidizes two additional ferrous ions.

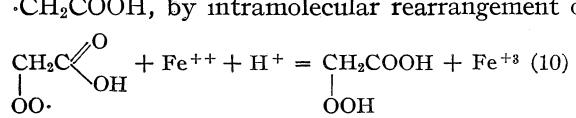
With acetic acid, removal of a hydrogen atom from the hydroxyl group leads to formation of a radical (acetate radical) which is stabilized by resonance.



Another mode of interaction between the hydroxyl radical and acetic acid would be

$$CH_3COOH + HO\cdot \longrightarrow H_2O + \cdot CH_2COOH \quad (9)$$

this radical could add molecular oxygen to form a peroxide radical, which would oxidize ferrous iron as shown in step (10). Formation of the radical, $\cdot CH_2COOH$, by intramolecular rearrangement of



the acetate radical, or by reaction of the acetate radical with acetic acid, also appears possible.

The hydroperoxide formed in step (10) could react further, in a manner similar to steps (4)–(7).

Reaction in the Presence of Various Inorganic Compounds, in the Presence and Absence of Ethanol.—Experiments have been carried out by the "stirring" technique in 1.5 *N* sulfuric acid solutions in the presence of air, with various inorganic compounds present in low concentrations, but in the absence of organic compounds. None of the inorganic compounds investigated gave rise to induced oxygen oxidation of ferrous iron in the reaction between the latter (10^{-3} *M*) and hydrogen peroxide (3×10^{-4} *M*); these compounds include $NaHCO_3$ (1.5×10^{-4} *M*), $CuSO_4$ (5×10^{-5} *M*), $(NH_4)_2SO_4$ (up to 10^{-3} *M*), KCl (10^{-4} *M*), $MnSO_4$ (5×10^{-5} *M*), and $SnCl_4$ (up to 10^{-4} *M*); C.P. or reagent grade salts were used.

A study of the effects of various common inorganic acids or salts upon the reaction in question, in the presence and absence of ethanol, has been carried out, using the "shaking" technique, with oxygen-saturated solutions. The data, given in Table V, show that with the exception of phosphoric acid, none of the compounds studied leads to any significant induced reaction, in the absence of organic compounds. The small effect found with phosphoric acid may be due to traces of impurities in the sample used, as indicated from the data obtained in the absence of oxygen,[2] or to direct reaction between oxygen and ferrous iron.

TABLE V

EFFECT OF SOME INORGANIC COMPOUNDS ON THE INDUCED OXYGEN OXIDATION. EXPERIMENTS IN OXYGEN-SATURATED SOLUTIONS, BY THE "SHAKING" TECHNIQUE

..	10^{-2}	1.5	H_3PO_4 (1 *M*)	6.5	11.7

In the presence of ethanol, the extent of induced oxygen oxidation of ferrous iron depends markedly upon the anion present. This behavior may be correlated with the suppressing action in nitrogen, except for phosphoric acid. The strong suppressing action of chloride ion in the presence of oxygen is particularly striking and may be of practical importance in the determination of peroxides by re-

action with ferrous iron; it is planned to investigate whether chloride ion exerts this suppressing action in the presence of oxygen in the reaction between ferrous iron and organic hydroperoxides. Evidently atomic chlorine, formed from the chloride ion during the course of the peroxide–iron reaction, does not react with oxygen to form reactive peroxides under the experimental conditions used. Neither do the chlorine free radicals formed activate the organic compounds present in the reaction mixture. The above reactions may be possible, but under our experimental conditions the chlorine free radicals apparently react faster with ferrous iron than with other constituents of the reaction mixture.

It is evident that traces of organic impurities in the reagents used may give rise to considerable induced reactions, especially when the concentration of the primary reactants is small (of the order of 10–3 M). In a previous paper[2] it has been shown that various samples of reagent grade perchloric acid from different sources contained impurities which caused considerable induced reduction of hydrogen peroxide. Even traces of organic impurities in the water used may exert a considerable effect on the ferrous iron–hydrogen peroxide reaction. When the present work was started we used twice-distilled water; however, no permanganate was present in the still. When this water was used reaction ratios greatly deviating from 2 were found, as shown in Table VI.

TABLE VI

EXPERIMENTS WITH IMPURE WATER IN THE PRESENCE OF AIR (EXCEPT AS NOTED). "STIRRING" TECHNIQUE

Acid and concentration, N	Initial concentration of Fe^{++} ($M \times 10^3$)	Molar ratios: Initial $\frac{(Fe^{++})}{(H_2O_2)}$ taken	Molar ratios: $\frac{(Fe^{++})\ reacted}{(H_2O_2)\ taken}$
1.5 N H_2SO_4	0.42	4.0	2.64
0.15 N H_2SO_4	.42	4.0	2.26
1 N $HClO_4$	.46	4.5	2.72
0.1 N $HClO_4$	.46	4.5	2.28
0.005 N $HClO_4$	.46	4.5	2.12
1 N $HClO_4$	.46	4.5	1.54[a]
0.005 N $HClO_4$	.46	4.5	1.72[a]

[a] Nitrogen was passed through the solutions before mixing; however, oxygen was only partially removed by the technique employed.

The impure water gave results similar to those found with pure water in the presence of small amounts of various organic compounds. Systematic investigation showed that the induced reaction could be almost completely eliminated by distillation of the water from alkaline permanganate, whereas no significant change in the extent of the induced reaction was found upon changing any of the other ingredients. Thus, similar results were found in impure water with ferrous solutions from two different sources (reagent grade $FeSO_4 \cdot 7H_2O$ and pure iron wire dissolved in perchloric acid); with three different brands of hydrogen peroxide (Merck, Baker, and Buffalo Electrochemical Co.); and with perchloric or sulfuric acid. While in the experiments of Table VI, increasing concentrations of acid led to increasing induced reaction, this effect cannot be due to impurities in the acids used, since no induced reaction was found when these same acids were used in purified water. The deviations from stoichiometric results found with the impure water must be attributed to the presence of traces of organic impurities in the water.

Summary

The reaction between hydrogen peroxide and ferrous iron in dilute solutions in the presence of oxygen and organic compounds leads to induced oxygen oxidation of ferrous iron. The extent of the induced oxidation may be quite large, particularly in oxygen-saturated solutions of the order of 10^{-3} M in peroxide and iron, in which the concentration of oxygen is relatively high. The amount of ferrous iron oxidized by the induced reaction may be two to three times as great as the amount oxidized by the stoichiometric reaction, under certain circumstances. It appears that the organic radical formed can add molecular oxygen, forming a peroxide radical, which can react with three ferrous ions, or can lead to autoxidation of the organic compound by a chain reaction. In the presence of oxygen, all the organic compounds tested show qualitatively similar behavior, without distinction between "promoting" and "suppressing" compounds. On the other hand, chloride ion is a suppressor in the presence as well as the absence of oxygen.

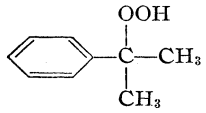
The Reaction between Ferrous Iron and Peroxides. III. Reaction with Cumene Hydroperoxide, in Aqueous Solution[1]

BY I. M. KOLTHOFF AND A. I. MEDALIA[1]

In previous publications[2,3] the authors have presented the results of an experimental study of the reaction between hydrogen peroxide and ferrous iron, in very dilute aqueous solution, in the presence of various compounds. In the absence of oxygen, it has been shown[2] that the peroxide–iron reaction induces the oxidation of certain organic compounds (termed "promoters") by hydrogen peroxide; several compounds (termed "suppressors") suppress this induced reaction. In the presence of oxygen,[3] induced oxygen oxidation of ferrous iron occurs in the presence of various organic compounds, apparently through the intermediate formation of organic peroxides; this induced oxygen oxidation is suppressed by chloride ion, but not by any of the organic compounds studied. Mechanisms for these reactions were presented in these papers, and in a review paper[4] on the reaction between ferrous iron and peroxides. It is likely that in the reaction between ferrous iron and organic peroxides, particularly hydroperoxides, active intermediates are formed, through mechanisms similar to that of the ferrous iron–hydrogen peroxide reaction. The present paper deals with a study of the reaction between ferrous iron and a hydroperoxide, under conditions similar to those used with hydrogen peroxide.[2,3] The results obtained are of particular importance in view of the wide use of the reaction between ferrous iron and organic hydroperoxides in the determination of these hydroperoxides, and in the initiation of the polymerization of vinyl monomers.

The hydroperoxide chosen for the present study is cumene hydroperoxide (phenyldimethyl methyl hydroperoxide), designated below as CHP. This compound is a typical organic hydroperoxide, of structure



The preparation of this compound from cumene (isopropylbenzene) by photochemical autoxidation at 60–70° has been described by Hock and Lang.[5] Cumene hydroperoxide is an oily liquid which is quite stable at room temperature. As shown below, its solubility in water is sufficient (0.09 *M*) to permit study of its reactions in dilute aqueous solutions. CHP is used in oxidation–reduction polymerization recipes which have proved to be of considerable practical importance.[6,7] Determination of CHP by both ferrous and iodometric methods has been studied recently.[8]

Experimental

Reagents.—The reagents used were as described previously.[2,3] The water used in all experiments was purified by distillation from alkaline permanganate. Benzene (Mallinckrodt reagent grade) and CHP (purified as below) were also used.

Purification of CHP.—A sample of CHP (Sample No. X5557–47) prepared from cumene was kindly furnished by the Hercules Powder Co. Iodometric analysis of this sample by a macro procedure (*v. i.*) corresponded to 71.4% pure CHP. It has been pointed out by Hock and Lang[5] that the impurities in a sample of cumene hydroperoxide prepared by autoxidation of cumene may consist largely of the decomposition products of cumene hydroperoxide, namely, dimethylphenylcarbinol, phenol, and acetone, in addition to the unchanged cumene.

Purification of the Hercules sample of cumene hydroperoxide was carried out by the alkali extraction procedure of Hock and Lang,[5] with the omission of the final vacuum distillation used by these authors. Iodometric analysis by the above procedure corresponded to 94.2% pure CHP. It should be pointed out that both Hock and Lang[5] and Wagner, *et al.*,[8] obtained samples of 95% purity. Further purification does not seem feasible by this method.

Iodometric Analysis of CHP.—Two methods of iodometric analysis have been investigated for use with CHP. The first of these is a macro method, developed in this Laboratory[9] for determination of *t*-butyl hydroperoxide.

Procedure.—Accurately weigh a 1.2 to 1.6 g. sample into a weighing bottle, transfer the sample to a 100-ml. volumetric flask and dilute to the mark with glacial acetic acid. Pipet a 25-ml. aliquot into a 125-ml. iodine flask, and then bubble nitrogen through the solution for five minutes. Add 2 g. of finely divided sodium iodide, flush the air space above the solution with nitrogen, and stopper the flask. Allow the solution to stand in the dark at room temperature for twenty minutes. Add 50 ml. of water, and titrate with 0.1 *N* thiosulfate solution, using starch indicator near the end-point. A blank solution should require less than about 0.02 ml. of thiosulfate solution. The reaction time of twenty minutes was found to be sufficient, by comparison with determinations carried out in sealed flasks at 100°.

The method of Kokatnur and Jelling[10] was used for the

determination of small amounts of cumene hydroperoxide. In this method the peroxide is dissolved in about 75 ml. of boiling absolute ethanol in a 150-ml. beaker; after addition of 1 ml. each of glacial acetic acid and saturated aqueous potassium iodide, boiling is continued for five minutes, and then the iodine formed is titrated immediately with 0.005 *N* thiosulfate. The accuracy of the method was improved by amperometric determination of the end-point, using the procedure developed by the late Dr. L. S. Guss of this laboratory. In this procedure a rotating platinum microelectrode at the potential of a saturated calomel electrode serves as an indicator of the iodine concentration; titration is continued until the current, which is due to reduction of iodine at the microelectrode, decreases to zero. With amounts of CHP as small as 5 mg. (0.03 millimole) in 75 ml., the accuracy and precision were found to be of the order of 2%.

Results and Discussion

Solubility of Purified Cumene Hydroxide in Water.—The solubility in water of the purified sample of cumene hydroperoxide, and its distribution between benzene and water and between benzene and aqueous alkali, have been determined. The method used was to shake various amounts of water, cumene hydroperoxide, and (in some cases) benzene for two minutes in an ungreased separatory funnel; 2-ml. portions of the filtered aqueous layer were then analyzed by the method of Kokatnur and Jelling. The results are given in Table I.

TABLE I

SOLUBILITY OF CUMENE HYDROPEROXIDE IN WATER AND AQUEOUS ALKALI AT 25°

Benzene taken,[a] ml.	Concn. of NaOH in aqueous phase initially, *N*	CHP[b] taken,[a] g.	CHP[b] diss. in 100 ml. of aqueous phase, g.	Mole % CHP in aqueous phase	Mole % CHP in organic phase[c]

28.0	.253	3.91	1.11	.132	5.51

[a] Per 100 ml. of water. [b] Based on 100% purity. [c] Corrected for the solubility of benzene in water.

The solubility of the sample of purified CHP in water does not depend upon the amount of CHP taken; this is indicative of the purity of this sample. The data for the distribution of CHP between benzene and water show that the behavior does not follow the ideal distribution equation

$$(\text{Mole \% in water}) = K\,(\text{mole \% in benzene}) \quad (1)$$

Graphical extrapolation of the data to 100% purity gives for the solubility of pure CHP in water a value of 0.165 mole %, or 0.0914 molar, or 1.39 g. per 100 ml. of solution.

From the data for the distribution of CHP between benzene and aqueous alkali the ionization constant, K_a, is calculated to be 2.6×10^{-13} (0.0506 *N* alkali) and 2.4×10^{-13} (0.253 *N* alkali), respectively, at 25°. By way of comparison, the ionization constant of hydrogen peroxide is given[11] as 2.4×10^{-12} at 25°.

Approximate Determination of the Rate of Reaction between Ferrous Iron and CHP. Procedure.—Solutions of CHP and ferrous iron in 1.5 *N* sulfuric acid (total volume, 120 ml.) were mixed in the absence of air, in a reaction vessel with two compartments, described in a previous publication.[2] After the desired time of reaction 20 ml. of air-free benzene was added to the inner compartment and the mixture was shaken for ten seconds. After standing for one to two minutes to allow separation of the phases, a 15-ml. aliquot of the benzene phase was analyzed by the procedure of Kokatnur and Jelling,[9] and 50-ml. portions of the aqueous phase were titrated with ceric sulfate. The results of experiments carried out as above are given in Table II.

TABLE II

REACTION BETWEEN FERROUS IRON AND PURIFIED CHP IN 1.5 *N* H_2SO_4 AT 27°, IN THE ABSENCE OF OXYGEN. INITIAL CONCENTRATIONS: $(Fe^{++})_0 = 5.31 \times 10^{-4}$ *M*; $(CHP)_0 = 2.21 \times 10^{-4}$ *M*

Time of reaction, sec.	Concn. remaining at given time ($M \times 10^4$) Fe^{++}	CHP	Molar reaction ratio $\frac{\Delta(Fe^{++})}{\Delta(CHP)}$	Approximate rate constant, k_1 (l. mole^{-1}sec.$^{-1}$)
30	4.52	1.38	0.95	30
40	4.36	1.36	1.15	28
75	4.10	1.00	1.00	22

In Table II the reaction times given are from the instant of mixing the ferrous iron and CHP to the midpoint of the period of shaking with benzene. In calculating the rate constant, it was assumed that, as in the reaction between hydrogen peroxide and ferrous iron, the rate-determining step is first-order in both reactants. The calculation of the rate constant is complicated by the fact that the reaction between ferrous iron and CHP is not stoichiometric, as is evident from Table II; the average reaction ratio under the experimental conditions is 1.05. The calculation of the approximate rate constant has been based upon the rate of disappearance of ferrous iron only, taking an average value of the concentration of CHP. Thus if

$$-\,d(Fe^{++})/dt = k_1(Fe^{++})(CHP) \quad (2)$$

then

$$\int_0^t \frac{-d(Fe^{++})}{(Fe^{++})} = -\ln\left[\frac{(Fe^{++})}{(Fe^{++})_0}\right] = k_1 t(CHP)_{average} \quad (3)$$

The values of k_1 given in Table II were calculated on the basis of equation (3). The agreement between the values obtained is probably as good as can be expected in view of the inaccuracy of the reaction times and the large changes in the concentrations of CHP over the ranges in which average values were taken. The average value of k_1 is 27 l. mole^{-1} sec.$^{-1}$, or slightly less than half the

(11) R. A. Joyner, *Z. anorg. Chem.*, **77**, 103 (1912).

value (62) given by Baxendale, Evans and Park[12] for the corresponding rate constant in the hydrogen peroxide–ferrous iron reaction.

Reaction in the Absence of Oxygen: Determination of Over-all Reaction Ratios.—The experiments described below were carried out using the reaction vessels and technique described previously. After rapid mixing of the ingredients, the reaction was allowed to go to completion, and then aliquots were removed after twenty and forty minutes and titrated with ceric sulfate. It was not necessary to extract the reaction mixture with benzene before the titration, since the CHP was completely consumed. Purified (94%) CHP was used throughout. Results obtained in the presence and absence of various added substances are given in Table III. Reactions were carried out at room temperature.

TABLE III

REACTION BETWEEN FERROUS IRON AND PURIFIED CHP IN 1.5 N H_2SO_4, IN THE ABSENCE OF OXYGEN

Initial concentrations				Molar ratios	
Ethanol, M	Acetic acid, M	Acetone, M	Fe^{++} ($M \times 10^3$)	Initial (Fe^{++}) / (CHP) taken	(Fe^{++}) reacted / (CHP) taken
..	..	..	0.53	2.41	1.15
..	..	..	1.9	3.28	1.12
10^{-2}	..	..	1.9	3.28	1.06
10^{-1}	..	..	1.9	3.28	0.76
..	10^{-1}	..	1.9	3.28	1.40
..	10	..	1.9	3.28	1.92
10^{-1}	10	..	1.9	3.28	1.79
..	..	10	1.9	3.28	1.93

In the absence of added substances, the molar reaction ratio is considerably less than the stoichiometric value of 2.00 (see also Table II). It is of interest that the same reaction ratio of 1:1 is found with two different initial concentrations of reactants. The results indicate that the reaction between ferrous iron and CHP induces the decomposition of CHP. In this respect the behavior is similar to that of hydrogen peroxide in its reaction with ferrous iron in the presence of an organic compound of the "promoting" type.[2]

Addition of ethanol increases the extent of the induced decomposition of CHP. The reaction ratios found with the concentrations of ethanol employed in the experiments of Table III are higher than those found in the hydrogen peroxide–ferrous iron reaction when carried out in the presence of these concentrations of ethanol, under comparable conditions.[2]

Addition of acetic acid diminishes the extent of induced decomposition of CHP, both in the presence and absence of ethanol. Qualitatively, acetic acid exerts the same "suppressing" action on the ferrous iron–CHP systems as was found in the hydrogen peroxide–ferrous iron–ethanol system.[2] With 0.1 M acetic acid, the induced decomposition of CHP is only partially suppressed, while with 10 M acetic acid (62% by weight) suppression is virtually complete, in the absence of ethanol, but only partially complete in the presence of 0.1 M ethanol. Similarly, suppression is virtually complete with 10 M acetone, in the absence of ethanol. The importance of these results from the standpoint of peroxide analysis is obvious, as will be demonstrated in a subsequent paper.

In the experiments carried out in 10 M acetic acid, it was necessary to dilute the solutions with approximately an equal volume of water before titrating, in order to obtain a sharp end-point. In the experiment with acetone, a sharp end-point was obtained by diluting the 50-ml. aliquot with 100 ml. of water before titrating. In this experiment, correction was made for loss of acetone by volatilization during the hour-long flushing with nitrogen, by weighing the vessel before and after flushing.

As has been discussed elsewhere,[4] the mechanism of the reaction between ferrous iron and hydrogen peroxide is not known with certainty, despite the extensive studies of this reaction. Much less study has been devoted to the reaction between hydroperoxides and ferrous iron, and the possible reaction steps are much more numerous. Presentation of such speculative mechanisms would be premature at this time. The course of the reaction cannot be established definitely without determination of the products. However, it is certain on the basis of the above data, together with results of reactions carried out in the presence of oxygen (*v. i.*), that in the course of the reaction between CHP and ferrous iron, some active intermediate is formed. By analogy with the mechanism of Haber and Weiss[13,14] for the reaction between hydrogen peroxide and ferrous iron, it is likely that the first step of the reaction is as shown below

$$\underset{\displaystyle\mathrm{OOH}}{\mathrm{C_6H_5\overset{}{C}(CH_3)_2}} + Fe^{++} = \underset{\displaystyle\mathrm{O\cdot}}{\mathrm{C_6H_5C(CH_3)_2}} + Fe^{+3} + OH^- \qquad (4)$$

resulting in formation of a reactive organic radical. In the absence of oxygen this free radical can react with CHP resulting in a decomposition of the hydroperoxide by a chain reaction, and also with ethanol, acetic acid, acetone, etc. The free radicals formed play a part in the induced decomposition of the CHP. In the presence of oxygen the various organic free radicals react with oxygen, giving rise to induced oxygen oxidation of ferrous iron.

Reaction in the Presence of Oxygen.—The reaction between ferrous iron and CHP in aqueous solution has been studied in the presence of oxygen by the "shaking" and "stirring" techniques described previously.[2,3] In the "shaking" technique, the same apparatus and procedure were

(12) J. H. Baxendale, M. G. Evans and G. S. Park, *Trans. Faraday Soc.*, **42**, 155 (1946).

(13) F. Haber and J. Weiss, *Naturwiss.*, **20**, 948 (1932).

(14) F. Haber and J. Weiss, *Proc. Roy. Soc.* (*London*), **A147**, 332 (1934).

used as in the experiments of Table III, except that the solutions were flushed with air or oxygen rather than nitrogen. In the "stirring" technique, one reactant is added by pipet to a solution of the other reagents, with vigorous stirring. In each experiment carried out by the "shaking" technique, the vessel was shaken for eighty seconds, to allow access of the solution to the oxygen of the gas phase during the greater part of the reaction. Aliquots of the reaction mixture were titrated with ceric sulfate after ten and twenty-five minutes reaction time. The titrations agreed closely, showing that under the conditions used, the CHP had been completely reduced within ten minutes. The results are given in Table IV.

TABLE IV

REACTION BETWEEN FERROUS IRON AND PURIFIED CHP, IN 1.5 N H_2SO_4, IN THE PRESENCE OF OXYGEN. EXPERIMENTS CARRIED OUT BY "SHAKING" TECHNIQUE

Initial concentrations				Molar ratios	
Ethanol, M	Acetic acid, M	Fe^{++} ($M \times 10^3$)	Gas	Initial $\frac{(Fe^{++})}{(CHP)}$ taken	$\frac{(Fe^{++})}{(CHP)}$ reacted
..	..	0.51	Air	3.82	3.50
..	..	.51	Air	7.64	4.64
..	..	.51	Air	12.7	4.70
..	..	.51	Oxygen	12.7	4.70
10^{-4}	..	.51	Air	12.7	4.90
10^{-3}	..	.51	Air	12.7	6.50
..	..	1.9	Oxygen	3.28	3.05
..	10	1.9	Oxygen	3.28	2.94

The results of Table IV show that considerable induced oxygen oxidation of ferrous iron takes place during the course of the reaction between ferrous iron and CHP, in the presence of oxygen. With a given initial concentration of ferrous iron, the reaction ratio is practically independent of the initial ratio of reactants, provided that ferrous iron is in sufficient excess over CHP. With 0.51×10^{-3} M ferrous iron and 0.40×10^{-4} M CHP, the same results were obtained in air as in oxygen. Addition of ethanol has a definite effect in increasing the induction factor. The addition of acetic acid (10 M) does not materially affect the extent of the reaction, in the single experiment performed. The results found for the reaction between CHP and ferrous iron in the presence of oxygen are qualitatively similar to those found for the reaction between hydrogen peroxide and ferrous iron in the presence of both oxygen and an organic compound.[3]

Results obtained by the "stirring" technique are given in Table V. The "reverse" mode of addition was used (CHP added to ferrous iron). Titrations carried out on duplicate reaction mixtures after ten and twenty minutes agreed closely; only the average values are given.

TABLE V

REACTION BETWEEN FERROUS IRON AND PURIFIED CHP, IN 1.5 N H_2SO_4. EXPERIMENTS CARRIED OUT BY "STIRRING" TECHNIQUE IN THE PRESENCE OF AIR

Initial concn. of Fe^{++} ($M \times 10^3$)	Molar ratios: Initial $\frac{(Fe^{++})}{(CHP)}$ taken	Molar ratios: $\frac{(Fe^{++})}{(CHP)}$ reacted
1.0	2.97	2.45
2.0	2.97	1.83

With 10^{-3} M ferrous iron, induced air oxidation of ferrous iron is found, while with 2×10^{-3} M ferrous iron, induced decomposition of CHP predominates over the induced air oxidation, in the experiments of Table V. This behavior is similar to that found with hydrogen peroxide in the presence of ethanol.[3]

Summary

The solubility of cumene hydroperoxide (CHP) in water at 25° is 0.0914 M. The distribution ratio of CHP between water and benzene is a function of the concentration of CHP. The ionization constant (acid dissociation constant) of CHP is 2.5×10^{-13} at 27°. The rate constant of reaction between CHP and ferrous iron in aqueous solution (1.5 N sulfuric acid) at 27°, taken as first order in each reactant, is roughly 27 l. mole^{-1} sec.$^{-1}$.

The behavior of cumene hydroperoxide in its reaction with ferrous iron is qualitatively similar to that of a mixture of hydrogen peroxide and an organic compound such as ethanol. Thus, the reaction between cumene hydroperoxide and ferrous iron in pure aqueous solution leads to considerable induced decomposition of the peroxide, in the absence of oxygen, and to considerable induced oxidation of ferrous iron, in the presence of oxygen. Addition of ethanol to the system increases the extent of both induced reactions; while addition of acetic acid suppresses the induced decomposition of peroxide in the absence of oxygen, but does not suppress the induced oxidation in the presence of oxygen.

Intramolecular Condensations in Vinyl Copolymers[1]

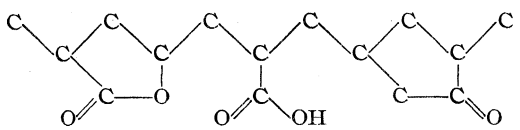
BY TURNER ALFREY, JR., CHARLES LEWIS AND BERNARD MAGEL

Intramolecular condensation reactions have been successfully employed to elucidate the structure of polymers such as polyvinyl chloride[2] polyvinyl methyl ketone[3,4,5] and polyisopropenyl methyl ketone.[6] These reactions have been subjected to statistical treatment, and the agreement between experimental results and theoretical calculations based on a 1,3-structure has established a head-to-tail addition mechanism for vinyl polymerization.

It has been suggested[7] that the copolymer of vinyl acetate and acrylic acid could be studied by hydrolyzing the acetate group and allowing the resulting hydroxyl to lactonize with the carboxyl groups present. The Flory statistical treatment[2a] is not directly applicable to such a system. It is the purpose of this paper to extend these statistics to cover the case of intramolecular condensations between unlike substituents. The example given above will be used as a model in the subsequent derivation.

We will assume a head-to-tail configuration for the copolymer, giving rise to a γ-hydroxy acid structure along the chain. We will further assume that γ-lactonization takes place to the complete exclusion of cross-linking by esterification. This is in accord with the known behavior of γ-hydroxy acids.

It is clear that lactonization cannot be quantitative since an acrylic acid segment flanked by two other acid segments is incapable of reaction. A similar situation exists for the vinyl alcohol segments. Furthermore, there exists the possibility of isolation of functions in alternating sequences. Thus we may find a carboxyl group whose neighbors are lactonized hydroxyl groups and which consequently cannot react.



In the discussion which follows we will focus our attention on the carboxyl groups, as these are the more readily determinable. We will use M_1 and M_2 to designate vinyl alcohol and acrylic acid segments, respectively. Thus an alternating sequence is of the form $M_1M_2M_1M_2M_1M_2$. Starting from a point in the chain where we find an M_1–M_2 (or an M_2–M_1) pair we advance along the chain in both directions until we reach breaks in the alternation pattern (*i. e.*, an M_1–M_1 or an M_2–M_2 pair). We next draw lines which separate the members of the like pairs thus found. By continuing this operation throughout the system, we will divide it into sequences which are either pure alternating or "straight" (*i. e.*, all M_1 or all M_2). The length of an alternating sequence is defined as the number of M_1 or M_2 groups (whichever is the smaller) that it contains.

We see that there are four possible types of alternating sequence.

I	M_1 ¦	$(M_1M_2)_nM_1$ ¦	M_1
II	M_1 ¦	$(M_1M_2)_n$ ¦	M_2
III	M_2 ¦	$(M_2M_1)_nM_2$ ¦	M_2
IV	M_2 ¦	$(M_2M_1)_n$ ¦	M_1

Let

N = total number of monomer molecules that have polymerized

m_1 = mole fraction of M_1 in copolymer

m_2 = mole fraction of M_2 in copolymer

Therefore

Nm_1 = total M_1 in copolymer

Nm_2 = total M_2 in copolymer

The total number of sequences of type I and length n is given by the product of the number of M_1 segments and the probability that an M_1 segment is followed by an alternating sequence of the desired type. Representing this quantity by A_n^{I} we have[8]

$$(1)\quad A_n^{\mathrm{I}} = Nm_1P_{11}^2P_{12}^nP_{21}^n$$

Similarly

$$(2)\quad A_n^{\mathrm{II}} = Nm_1P_{11}P_{22}P_{12}^nP_{21}^{n-1}$$

$$(3)\quad A_n^{\mathrm{III}} = Nm_2P_{22}^2P_{12}^nP_{21}^n$$

$$(4)\quad A_n^{\mathrm{IV}} = Nm_2P_{22}P_{11}P_{12}^{n-1}P_{21}^n$$

The constants P_{11}, P_{12}, etc., in the above equations are the propagation probabilities of the copolymer system. Thus P_{12} is the probability that, during the copolymerization process, a growing free radical chain of the type M^{1*} will react with a monomer molecule of type M_2.[8]

The number of alternations of type M_1M_2 must obviously be equal to the number of type M_2M_1.

(1) Presented before the High Polymer Forum at the 115th Meeting of the American Chemical Society, San Francisco, California, March–April, 1949.

(7) E. Merz, T. Alfrey and G. Goldfinger, *J. Polymer Sci.*, **1**, 75 (1946).

(8) The propagation probabilities used here refer to the system vinyl acetate–acrylic acid. P_{12} is the probability that, during the copolymerization process, a growing free radical chain of the type M_1 will react with a monomer molecule of type M_2, and similarly for the other P terms. A complete discussion of these propagation probabilities may be found in T. Alfrey, *Trans. N. Y. Acad. Sci.*, **10**, 298 (1948). An earlier paper discusses the same subject but employs a different type of symbolism, T. Alfrey and G. Goldfinger, *J. Chem. Phys.*, **12**, 205 (1944).

This is expressed mathematically by the equation

$$(5)\quad m_2P_{21} = m_1P_{12}$$

We may consequently rewrite equations (1) and (2) in the form

$$(6)\quad A_n^{\mathrm{I}} = Nm_2P_{11}P_{12}^{2}P_{12}^{n-1}P_{21}^{n+1}$$

$$(7)\quad A_n^{\mathrm{II}} = Nm_2P_{11}P_{22}P_{12}^{n-1}P_{21}^{n}$$

It is now necessary to calculate on a statistical basis the number of carboxyl groups that will be isolated in the various alternating sequences. Flory[2a] has derived an expression for the average number of chlorine atoms remaining in a sequence of v nyl chloride segments after the random removal of chlorine from 1,3-positions (*e. g.*, by the action of metallic zinc). According to this treatment, S_n chlorine atoms will remain after exhaustive dechlorination of a sequence of n vinyl chloride groups, where

$$S_n = \sum_{i=0}^{n-1} (n - i)\frac{(-2)^i}{i!}$$

Let us consider an alternating sequence of type I and length n. The lactonization of such a sequence is statistically identical with the removal of chlorine from a sequence of $2n + 1$ vinyl chloride groups. Thus S_{2n+1} gives the total number of uncombined alcohol and acid groups. Since the number of alcohol groups is greater by one than the number of acid groups both before and after lactonization, we may write for the number of remaining acid groups

$$(9)\quad S_n^{\mathrm{I}} = (S_{2n+1} - 1)/2$$

A similar treatment for the other types of alternating sequences gives

$$(10)\quad S_n^{\mathrm{II}} = S_{2n}/2$$

$$(11)\quad S_n^{\mathrm{III}} = (S_{2n+1} + 1)/2$$

$$(12)\quad S_n^{\mathrm{IV}} = S_{2n}/2$$

We may now write an expression for the total number of carboxyl groups that may be expected to be isolated in alternating sequences of all types, *viz.*

$$(13)\quad \sum_{n=1}^{\infty} (S_n^{\mathrm{I}}A_n^{\mathrm{I}} + S_n^{\mathrm{II}}A_n^{\mathrm{II}} + S_n^{\mathrm{III}}A_n^{\mathrm{III}} + S_n^{\mathrm{IV}}A_n^{\mathrm{IV}})$$

It remains to find the number of carboxyl groups that remain unlactonized because they are adjacent to other carboxyl groups. Consider such a sequence $M_1M_2M_2M_2\cdots M_2M_2M_1$. The first and last M_2 groups have already been counted in the alternating sequences flanking the sequence of M_2 groups. The remainder constitute the unlactonizable acid groups and the amount of such material is given by

$$\sum_{n=3}^{\infty} (n - 2) \times [\text{total number of } M_2 \text{ sequences of length } n]$$

In view of what has been said above, the bracketed quantity may be shown to be equal to

$$Nm_1P_{12}P_{21}P_{22}^{n-1} = Nm_2P_{21}^{2}P_{22}^{n-1}$$

so that the total number of unlactonizable acid groups of this type is given by

$$\sum_{n=3}^{\infty} (n - 2) \times Nm_2P_2^{2}P_{22}^{n-1}$$

Making use of the relationship $1 - P_{22} = P_{21}$, this reduces to

$$(14)\quad Nm_2P_{22}^{2}$$

Combining (13) and (14) we have the total number of unlactonized acid groups. Dividing by Nm_2, the total acid present initially, we have the desired quantity f, the *fraction* of the total acid that remains unlactonized.

$$(15)\quad f = \frac{1}{Nm_2}\sum_{n=1}^{\infty} (S_n^{\mathrm{I}}A_n^{\mathrm{I}} + S_n^{\mathrm{II}}A_n^{\mathrm{II}} + S_n^{\mathrm{IV}}A_n^{\mathrm{III}} + S_n^{\mathrm{IV}}A_n^{\mathrm{IV}}) + P_{22}^{2}$$

Substituting from equations (3), (4), (6), (7), (9), (10), (11) and (12)

$$f = \frac{1}{2}(P_{11}^{2}P_{21}^{2} + P_{22}^{2}P_{12}P_{21})\sum_{n=1}^{\infty}(P_{12}P_{21})^{n-1}S_{2n+1} - \frac{1}{2}(P_{11}^{2}P_{21}^{2} - P_{22}^{2}P_{12}P_{21})\sum_{n=1}^{\infty}(P_{12}P_{21})^{n-1} + (P_{11}P_{22}P_{21})\sum_{n=1}^{\infty}(P_{12}P_{21})^{n-1}S_{2n} + P_{22}^{2}$$

$$(16)\quad f = P_{22}^{2} - \frac{P_{11}^{2}P_{21}^{2}}{2(1 - P_{12}P_{21})} + \frac{P_{22}^{2}P_{12}P_{21}}{2(1 - P_{12}P_{21})} + \frac{1}{2}(P_{11}^{2}P_{21}^{2} + P_{22}^{2}P_{12}P_{21})\sum_{n=1}^{\infty}P^{n-1}S_{2n+1} + P_{11}P_{22}P_{21}\sum_{n=1}^{\infty}P^{n-1}S_{2n}$$

where we have written P for $(P_{12}P_{21})$ for simplicity in the treatment to follow.

We now have to evaluate the two summations and simplify the result. The individual constituents of the summation $\sum_{n=1}^{\infty} P^{n-1}S_{2n}$ may be expanded in a two-dimensional array

$$\left[2 + \frac{(-2)}{1!}\right]$$
$$+ P[4 + 3(-2)/1! + 2(-2)^2/2! + (-2)^3/3!]$$
$$+ P^2[6 + 5(-2)/1! + 4(-2)^2/2! + 3(-2)^3/3! + 2(-2)^4/4! + 5(-2)^5/5!]$$
$$+ P^3[8 + 7(-2)/1! + 6(-2)^2/2! + 5(-2)^3/3!\cdots\cdots]$$
$$\vdots$$

Adding the columns, we have

$$\sum_{n=1}^{\infty} P^{n-1}S_{2n} = \frac{2}{(1-P)^2} + \frac{(-2)(1+P)}{1!\,(1-P)^2} + \frac{(-2)^2 2P}{2!\,(1-P)^2} + \frac{(-2)^3P(1+P)}{3!\,(1-P)^2} + \frac{(-2)^4 2P^2}{4!\,(1-P^2)} + \cdots$$

$$= \frac{2}{(1-P)^2}\left[1 + \frac{(-2\sqrt{P})^2}{2!} + \frac{(-2\sqrt{P})^4}{4!}\cdots\right] + \frac{1+P}{\sqrt{P}(1-P)^2}\left[\frac{(-2\sqrt{P})}{1!} + \frac{(-2\sqrt{P})^3}{3!}\cdots\right]$$

$$(17)\quad = \frac{2}{(1-P)^2}\cosh 2\sqrt{P} - \frac{1+P}{\sqrt{P}(1-P)^2}\sinh 2\sqrt{P}$$

A similar treatment yields the further relationship

$$(18)\quad \sum_{n=1}^{\infty} P^{n-1} S_{2n+1} = -\frac{1}{P} - \frac{2}{\sqrt{P}(1-P)^2}\sinh 2\sqrt{P} + \frac{1+P}{P(1-P)^2}\cosh 2\sqrt{P}$$

Substituting the results of (17), and (18) in (16) and making use of the relations

$$P_{11} + P_{12} = 1$$
$$P_{21} + P_{22} = 1$$

we have

$$(19)\quad f = \frac{P_{12} - P_{21}}{2P_{12}} + \frac{P_{12} + P_{21}}{2P_{12}}\cosh 2\sqrt{P_{12}P_{21}} - \sqrt{\frac{P_{21}}{P_{12}}}\sinh 2\sqrt{P_{12}P_{21}}$$

which may be rearranged to the form

$$(20)\quad f = \left(\cosh\sqrt{P_{12}P_{21}} - \sqrt{\frac{P_{21}}{P_{12}}}\sinh\sqrt{P_{12}P_{21}}\right)^2$$

It is desirable to be able to express f as a function of the polymer composition rather than the propagation probabilities used in equation (20). This may be accomplished by making use of the relations[9]

$$\frac{P_{21}}{P_{12}} = \frac{m_1}{m_2}$$
$$\sqrt{P_{12}P_{21}} = \frac{1 - \sqrt{1 - 4m_1m_2(1 - r_1r_2)}}{2(1 - r_1r_2)\sqrt{m_1m_2}}$$

Thus we see that f is expressible in terms of the copolymer composition m_2 and the quantity $(1 - r_1r_2)$ which is a measure of the alternation tendency in copolymerization. It is possible, therefore, to plot a family of curves of f against m_2 with (r_1r_2) as parameter (see Fig. 1). In the case $r_2 = 0$ that portion of the curve for m_2 greater than 0.5 is unattainable in practice, as is that portion of the curve for m_2 less than 0.5 in the case $r_1 = 0$. The curve drawn for $r_1r_2 = 0$ may therefore be regarded as a composite of the two extreme cases.

(9) r_1 and r_2 are relative rates of propagation and are characteristic of the monomer pair used. See the references given under (8)

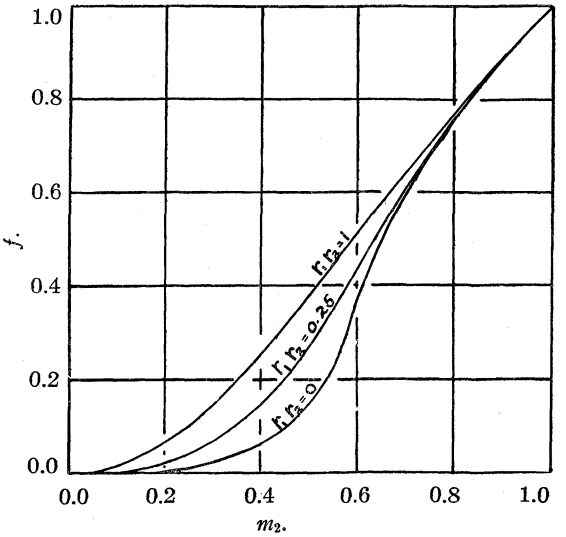

Fig. 1.—Fraction of acid remaining unlactonized as a function of mole fraction of acid in copolymer.

Summary

An expression has been derived for the amount of lactonization to be expected in a copolymer containing hydroxyl and carboxyl groups.

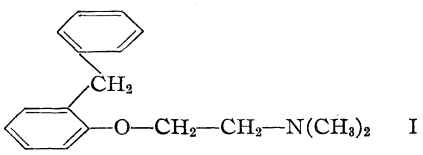
BROOKLYN, NEW YORK RECIEVED APRIL 15, 1949

[CONTRIBUTION FROM THE RESEARCH DIVISION, BRISTOL LABORATORIES, INC.]

2-Benzylphenol Derivatives. III.[1] Basic Ethers

BY WILLIAM B. WHEATLEY, LEE C. CHENEY AND S. B. BINKLEY

In previous communications the antihistaminic action of 2-benzylphenyl β-dimethylaminoethyl ether (I) and some of its analogs was reported.[1]



I

A number of other β-dimethylaminoethyl ethers related to I have been prepared in this Laboratory and submitted for pharmacological evaluation. More analogs of I are in preparation and will be the subject of a future communication.

The method of synthesis of these ethers is essentially that reported previously.[1b] The C-alkylation of phenols by halides of the benzyl type, according to the method of Claisen,[2] has been extended to heterocyclic systems. Phenol has been alkylated with 2-thenyl and 5-chloro-2-thenyl chloride to give 2-(2′-thenyl)-phenol, and 2-(5′-chloro-2′-thenyl)-phenol, respectively. In the case of alkylation of phenol with 2-thenyl chloride, the isomeric 4-(2′-thenyl)-phenol has been isolated and characterized. Alkylation of 8-hydroxyquinoline with benzyl chloride gave a compound believed to be 7-benzyl-8-hydroxyquinoline. Conversion of the various substituted phenols to the β-dimethylaminoethyl ethers proceeded smoothly via the Williamson ether synthesis.

(2) Claisen, *Ann.*, **420**, 210 (1925).

Experimental[3]

Several previously reported alkylated phenols were prepared: 4-bromo-2-benzylphenol,[4] 2-methoxy-6-benzylphenol,[2] 2-cinnamylphenol,[2] 1-benzyl-2-naphthol,[2] 2-benzyl-1-naphthol,[2] 1-allyl-2-naphthol,[5] and 2-allyl-1-naphthol.[6]

2-(4′-Fluorobenzyl)-phenol.—Alkylation of phenol with 4-fluorobenzyl chloride[7] in the manner described previously[1b] gave 2-(4′-fluorobenzyl)-phenol in 41% yield, b. p. 136–141° (3 mm.), $n^{26}D$ — 1.5728.

Anal. Calcd. for $C_{13}H_{11}OF$: C, 77.2; H, 5.5. Found: C, 76.5; H, 5.5.[8]

4-Fluoro-2-benzylphenol.—Alkylation of 4-fluorophenol (prepared by demethylation of 4-fluoroanisole with aluminum chloride according to the method described by Suter, Lawson and Smith[9]) with benzyl chloride gave 4-fluoro-2-benzylphenol in 41% yield, b. p. 117–123° (1 mm.), $n^{26}D$ — 1.5720.

Anal. Calcd. for $C_{13}H_{11}OF$: C, 77.2; H, 5.5. Found: C, 75.7, 75.7; H, 5.6, 5.5.

4-Dimethylamino-2-benzylphenol.—One hundred grams (0.268 mole) of 4-dimethylaminophenol sulfate was shaken with 500 ml. of saturated sodium bicarbonate solution and 200 ml. of chloroform until complete solution was attained. The lower layer was drawn off and the aqueous portion extracted twice with fresh chloroform. The combined extracts were dried with Drierite, an equal volume of toluene added and the solvent distilled until practically all of the chloroform was removed. Gradual addition of this solution to a stirred suspension of 12 g. (0.5 mole) of sodium hydride in 300 ml. of toluene gave a blue-green insoluble sodium salt. After refluxing for an hour to insure complete reaction, 62 g. (0.5 mole) of benzyl chloride was added dropwise over a period of two hours. Following one and one-half hours of additional refluxing, the mixture was hydrolyzed with water. The toluene layer was removed and filtered to remove a small amount of tarry material. The aqueous layer was extracted three times with chloroform and the extracts added to the toluene solution. This solution was dried, stripped and distilled *in vacuo*, the entire distillate boiling between 120 and 210° at 2–3 mm. being retained (69 g.). The distillate was then taken up in 200 ml. of Claisen alkali and extracted twice with Skellysolve D. Addition of sufficient concentrated hydrochloric acid to bring the *p*H of the aqueous solution down to 8 caused an oil to separate. It was taken into ether and the ether extracts dried and stripped. Distillation of the residue at 1 mm. gave three main fractions: (1) 7.9 g., b. p. 111–141°; (2) 16.4 g., b. p. 165–180°, $n^{25}D$ 1.6030; (3) 24.3 g., b. p. 180–217°, $n^{25}D$ 1.6194. Fraction (1) was mainly recovered starting material, (2) was assumed to be the desired 4-dimethylamino-2-benzylphenol and used as such immediately, and (3) was assumed to be 4-dimethylamino-2,6-dibenzylphenol.

2-(2′-Thenyl)-phenol and 4-(2′-Thenyl)-phenol.—A solution of 390 g. (4.16 moles) of phenol in 800 ml. of xylene was added to 90.9 g. (3.85 moles) of molten sodium under 1100 ml. of hot xylene at a rate such that refluxing was maintained. After the addition was complete, the mixture was refluxed for three hours. To the hot suspension of sodium phenolate was added over a period of thirty minutes 523 g. (3.95 moles) of 2-thenyl chloride.[10] The reaction mixture was refluxed for eighteen hours, acidified with concentrated hydrochloric acid and steam distilled until about four liters of distillate was collected. The two-phase residue was transferred to a separatory funnel and the aqueous layer withdrawn. It was extracted with 300 ml. of ether, the ether stripped and the residual oil added to the original organic layer. This material was taken up in one liter of Claisen alkali and washed three times with Skellysolve C. Acidification of the aqueous layer liberated the phenolic material, which was extracted into ether. The combined ether extracts were dried over anhydrous magnesium sulfate and stripped. Distillation of the residue gave 290 g. (39% yield) of mixed 2-thenylphenols, b. p. 137° (1.5 mm.)–190° (10 mm.). (Considerable decomposition occurred toward the end of the distillation.) The entire distillate was poured into a boiling solution of 365 g. of barium hydroxide octahydrate in 1.4 l. of water. After ten minutes of boiling, the solution was placed in the cold room. The following day the insoluble barium salt was removed by filtration, acidified and the crude 4-(2′-thenyl)-phenol recrystallized from carbon tetrachloride to give 36 g. of pure product (5% yield). An analytical sample melted sharply at 65°.

Anal. Calcd. for $C_{11}H_{10}OS$: C, 69.4; H, 5.3. Found: C, 69.6; H, 5.5.

The original aqueous filtrate containing the soluble barium salt was acidified at once, and on cooling the oily 2-(2′-thenyl)-phenol crystallized. Since this compound is easily oxidized by atmospheric oxygen, it is necessary to work rapidly to avoid undue loss during manipulations. The crude phenol was collected by filtration and the wet material dissolved in 200 ml. of hot benzene. The aqueous layer was withdrawn and benzene distilled until no more water appeared in the distillate. The solution was then diluted with one liter of Skellysolve D, cooled and seeded. The crystals were collected and recrystallized from cyclohexane. There was obtained 183 g. (24% yield) of pure 2-(2′-thenyl)-phenol, m. p. 50.0–52.0°.

Anal. Calcd. for $C_{11}H_{10}OS$: C, 69.4; H, 5.3. Found: C, 68.9; H, 5.4.

2-(5′-Chloro-2′-thenyl)-phenol.—Phenol (45.2 g., 0.482 mole) was alkylated with 85.2 g. (0.482 mole) of 5-chloro-2-thenyl chloride[11] according to the previously described procedure,[1b] giving 50.7 g. of crude product, b. p. 165–175° (5 mm.). Continued slight decomposition during distillation prevented attainment of a good vacuum, and the distillate rapidly became discolored. The distillate was therefore added to a hot solution of 53.5 g. of barium hydroxide octahydrate in 210 ml. of water and boiled ten minutes. The hot solution was cooled rapidly to 20° and filtered. Acidification of the filtrate liberated the phenol, which was removed by extraction with ether. The combined extracts were dried, stripped and the residue distilled at 1 mm. to yield 39.5 g. (39%) of 2-(5′-chloro-2′-thenyl)-phenol, b. p. 135–139°.

Anal. Calcd. for $C_{11}H_9OSCl$: C, 58.8; H, 4.0. Found: C, 58.5; H, 4.2. The phenol was immediately converted to the basic ether, which proved to be a fortunate procedure, since the next day the remainder of the analytical sample, originally a colorless liquid, had become a black solid with a strong odor of hydrogen chloride. The basic ether appeared to be perfectly stable at room temperature.

Two attempts to prepare the bromo analog from phenol and 5-bromo-2-thenyl chloride[11] were unsuccessful, as the reaction products decomposed rapidly, in one case with explosive violence.

7-Benzyl-8-hydroxyquinoline.—A solution of 100 g. (0.69 mole) of 8-hydroxyquinoline in 250 ml. of toluene was added slowly to a stirred suspension of 16.5 g. (0.69 mole) of sodium hydride in 750 ml. of toluene. A bright, yellow insoluble sodium salt formed. The reaction mixture was refluxed for thirty minutes, then, while refluxing was maintained, 79 ml. (87 g., 0.69 mole) of benzyl chloride were added dropwise over a period of five hours. The mixture was then stirred and refluxed overnight and finally hydrolyzed with dilute hydrochloric acid. Addition of sodium bicarbonate brought the *p*H of the aqueous layer up to 8. The toluene layer was removed and stripped

[k] Recrystallized from acetone.

under reduced pressure. The residue was taken up in 400 ml. of Claisen alkali and extracted twice with Skellysolve D. On adjustment of the *p*H of the aqueous layer to about 7, a brown semi-solid formed. This mixture was extracted three times with ether containing a little chloroform, the extracts combined, dried and stripped. Distillation of the residue at 3 mm. gave 27 g. of recovered 8-hydroxyquinoline, followed by 93 g. (58% yield) of material boiling at 193–205°. This material solidified in the receiver, and a portion recrystallized four times from cyclohexane melted at 96.5–97.5°. By analogy with the benzylation of α-naphthol,[2] it was assumed that the product was 7-benzyl-8-hydroxyquinoline.

Anal. Calcd. for $C_{16}H_{13}ON$: C, 81.7; H, 5.6. Found: C, 81.7; H, 5.6.

4-Iodo-2-benzylphenol.—Benzylation of 4-iodophenol[12] gave 4-iodo-2-benzylphenol in 44% yield, b. p. 163–167° (1 mm.). Considerable decomposition occurred during distillation, and the product was obtained as a violet oil which could not be crystallized. It was dissolved in toluene, freed of iodine by shaking with saturated sodium bisulfite solution and immediately converted to the β-dimethylaminoethyl ether.

Basic Ethers.—The basic ethers in Table I were prepared except as noted below, as described previously,[1b] using approximately a 30% excess of β-dimethylaminoethyl chloride hydrochloride. In the case of those phenols containing a basic function, 4-dimethylamino-2-benzylphenol and 7-benzyl-8-hydroxyquinoline, only the theoretical amount of β-dimethylaminoethyl chloride hydrochloride was used in order to minimize quaternary formation.

In general the basic ethers were converted to hydrochlorides by passing dry hydrogen chloride into cold ethereal solutions of the free bases. The monohydrochloride of 4-dimethylamino-2-benzylphenyl β-dimethylaminoethyl ether was obtained by dissolving the base in isopropyl alcohol, adding one equivalent of hydrogen chloride in ethanol and diluting with ether. The nitrate of 2-methoxy-6-benzylphenyl β-dimethylaminoethyl ether was prepared by adding one equivalent of concentrated nitric acid to an ethanol solution of the basic ether and precipitating the salt with ether.

Acknowledgment.—The authors are indebted to Mr. Richard M. Downing and Mrs. Neva Knight for the microanalyses reported herein. The assistance of Mrs. Sarah M. Tardy and Messrs. William E. Fitzgibbon, Lyman E. Lorensen and Richard R. Smith is gratefully acknowledged.

Summary

A number of β-dimethylaminoethyl ethers of various aralkylphenols has been synthesized. The Claisen alkylation of phenols by halides of the benzyl type has been extended to heterocyclic phenols and halides.

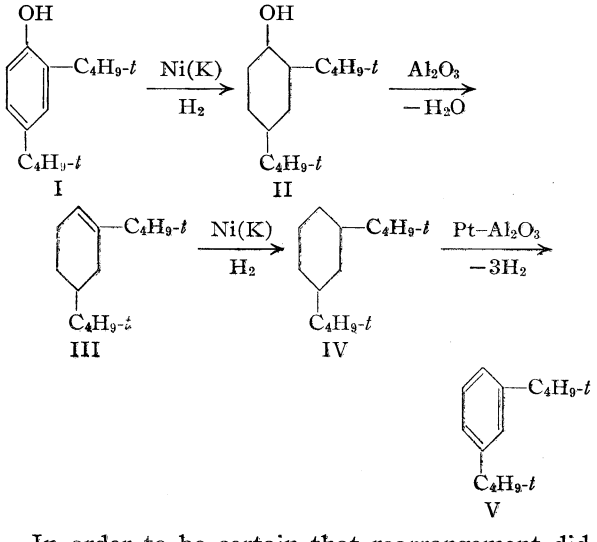
Synthesis of 1,3-Di-*t*-butylbenzene and 1,3-Di-*t*-butylcyclohexane[1]

BY HERMAN PINES, G. J. CZAJKOWSKI AND V. N. IPATIEFF

m-Di-*t*-butylbenzene has heretofore not been synthesized; this compound cannot be prepared by the alkylation of benzene with isobutylene. The present paper describes the synthesis of this hydrocarbon from 2,4-di-*t*-butylphenol. The following steps were involved in the synthesis of *m*-di-*t*-butylbenzene.



In order to be certain that rearrangement did not occur during the dehydration of 2,4-di-*t*-butylcyclohexanol (II) nor during the dehydrogenation of 1,3-di-*t*-butylcyclohexane (IV), compound V was hydrogenated and the infrared spectrum of the product was compared with the spectra of compound IV and of 1,3-di-*t*-butylcyclohexane (Graph I) prepared by the Wolff–Kishner reduction of 2,4-di-*t*-butylcyclohexanone. It was found that all the three spectra were identical with the exception of minor outside absorptions in the spectrum of the compound obtained from hydrogenation 1,3-di-*t*-butylcyclohexene. The infrared and ultraviolet spectra of *m*-di-*t*-butylbenzene are given in Graphs 2 and 3.

Experimental Part

I. Synthesis of 1,3-Di-*t*-butylbenzene

2,4-Di-*t*-butylcyclohexanol (II).—One hundred grams of 2,4-di-*t*-butylphenol (I) (Dow Chemical Co.) was hydrogenated in a 450-cc. capacity autoclave at 115–125° in the presence of nickel–kieselguhr catalyst and under 100 atmospheres of hydrogen. Three moles of hydrogen was absorbed per one mole of compound charged. The product was in the form of white crystals; it distilled at 125° (14 mm.), m. p. 107–109°; yield 92%.

Anal. Calcd. for $C_{14}H_{28}O$: C, 79.25; H, 13.20. Found: C, 78.86; H, 13.53.

1,3-Di-*t*-butyl-x-cyclohexene (III).—Compound II (48 g.) was dissolved in 50 cc. of *t*-butyl alcohol and dehydrated by passing it over activated alumina pills at 410–420°. The olefin formed was separated, dried and distilled; b. p. 114–115° at 25 mm.; $n^{20}D$ 1.4640; d^{20}_4 0.8338; yield 66%.

Anal. Calcd. for $C_{14}H_{26}$: C, 86.51; H, 13.49. Found: C, 86.65; H, 13.30.

1,3-Di-*t*-butylcyclohexane (IV).—Compound III (29.0 g.) was hydrogenated at 50° in a 125-cc., rotating autoclave in the presence of 4 g. of nickel–kieselguhr catalyst and under an initial hydrogen pressure of 100 atmospheres. Twenty-six grams of compound IV was obtained; yield 90%. The pure compound had the following properties: boiling points, 70° at 2.4 mm., 86.4° at 6.0 mm., 93.8° at 9.4 mm., 102° at 13.5 mm., 122° at 31.5 mm.; d^{20}_4 0.8312, d^{25}_4 0.8273; $n^{20}D$ 1.45727, $n^{25}D$ 1.45527; specific dispersion, ($\delta H\beta$-Hα) = 85.2 at 20°, 84.4 at 25°.

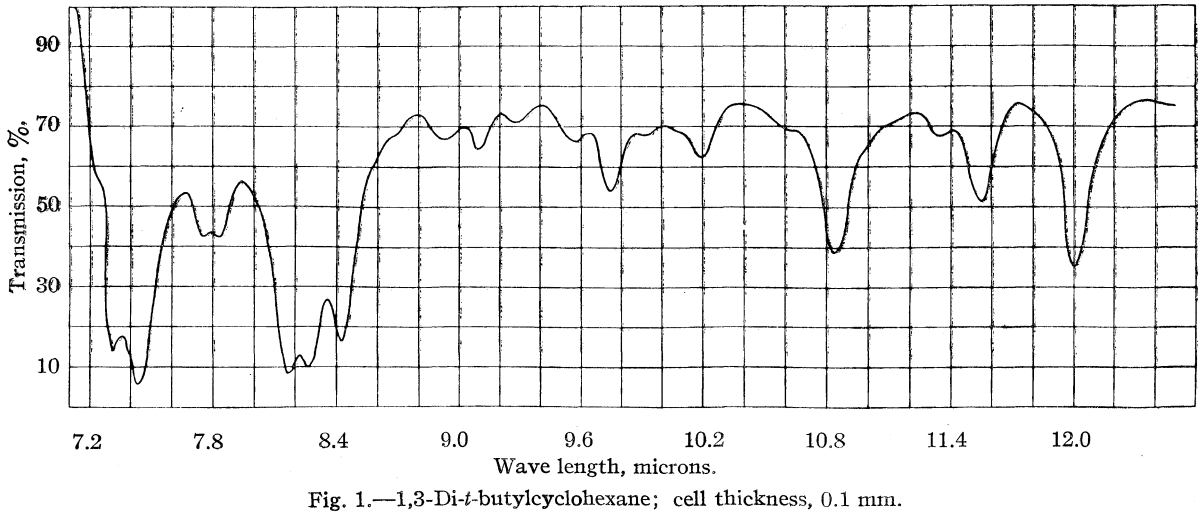


Fig. 1.—1,3-Di-*t*-butylcyclohexane; cell thickness, 0.1 mm.

(1) This work was made possible through the financial support of the Universal Oil Products Company.

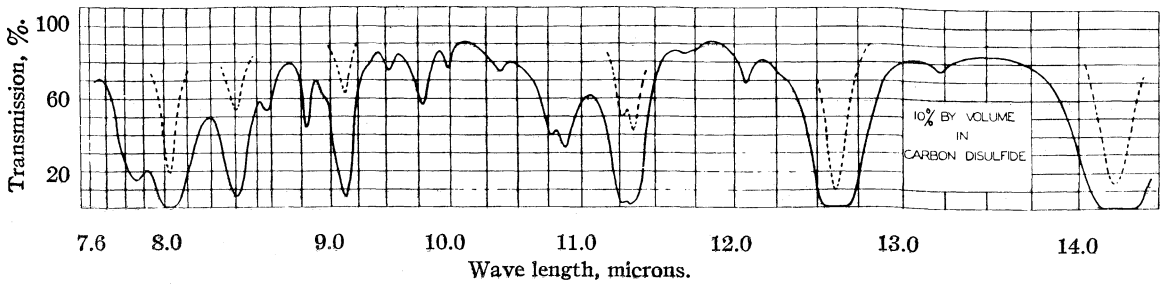

Fig. 2.—*m*-Di-*t*-butylbenzene; cell thickness, 0.1 mm.

Anal. Calcd. for $C_{14}H_{22}$: C, 85.63; H, 14.37. Found: C, 85.78; H, 14.32.

m-Di-*t*-butylbenzene (V).—Sixteen grams of (IV) was dehydrogenated by passing it three times over platinum–aluminum oxide catalyst at 275° according to the procedure described previously.[2] The aromatic hydrocarbon formed was purified chromatographically by dissolving it in four parts of pentane and passing the solution over a five-foot column of through-200 mesh silica gel.[3] This method enabled the separation of any unreacted 1,3-di-*t*-butylcyclohexane which might have remained. *m*-Di-*t*-butylbenzene thus purified had the following properties: boiling points, 73° at 2.5 mm.; 89.5 at 6.6 mm., 101° at 11.2 mm.; d^{20}_4 0.8589, d^{25}_4 0.8547; $n^{20}D$ 1.4879, $n^{25}D$ 1.4874; specific dispersion ($\delta H\beta$-$H\alpha$) = 126.6 at 20°, 126.7 at 25°.

Anal. Calcd. for $C_{14}H_{22}$: C, 88.42; H, 11.58. Found: C, 88.34; H, 11.73.

Compound V (2.2 g.) was acetylated according to the procedure described previously[4]; the 2,4-dinitrophenylhydrazone of the ketone melted at 208–210°. *Anal.* Calcd. for $C_{22}H_{28}N_4O_4$: C, 64.05; H, 6.84; N, 13.59. Found: C, 64.17; H, 6.82; N, 13.73.

II. Synthesis of 1,3-Di-*t*-butylcyclohexane from the Corresponding Ketone

1. 2,4-Di-*t*-butylcyclohexanone (VI) was prepared in 51% yield from 50 g. of 2,4-di-*t*-butylcyclohexanol (II) dissolved in 200 ml. of acetone by means of oxidation as described previously.[5] The ketone distilled at 143° at 28 mm., $n^{20}D$ 1.4645, d^{20}_4 0.8946, MR_D calculated 64.7, observed 65.1. *Anal.* Calcd. for $C_{14}H_{26}O$: C, 80.00; H, 12.34. Found: C, 79.76; H, 12.77.

The 2,4-dinitrophenylhydrazone of VI melted at 174–176°. *Anal.* Calcd. for $C_{20}H_{29}N_4O_4$: N, 14.39. Found: N, 14.37.

2. The ketone (VI) was reduced to the hydrocarbon by means of the modified Wolff–Kishner method[6]; 17.5 g. of 2,4-di-*t*-butylcyclohexanone, 8.5 ml. of hydrazine hydrate (85%), 85 ml. of 1,4-dioxane and 11.2 g. of potassium hydroxide were used. A 79% yield of hydrocarbon was obtained, $n^{20}D$ 1.4585, whose infrared spectrum was essentially the same as that of compound (IV).

(6) Huang-Minlon, *ibid.*, **68**, 2487 (1946).

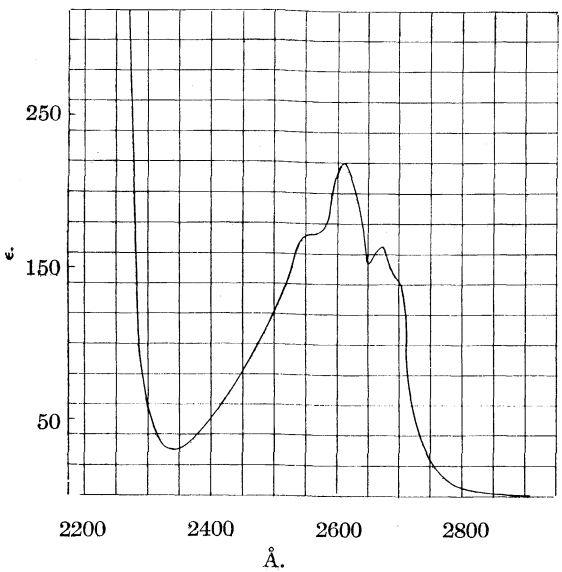

Fig. 3.—Ultraviolet absorption spectrum of 1,3-di-*t*-butylbenzene.

3. Hydrogenation of *m*-Di-*t*-butylbenzene.—Compound (V), 3.7 g., was hydrogenated in a 125-cc. autoclave at a temperature of 150° in the presence of a nickel-kieselguhr catalyst and 100 atmospheres of hydrogen pressure. The product gave a negative test for aromatics and its infrared spectrum showed it to be the same as that of compound (IV).

The test for aromatics was made by treating a few drops of the hydrocarbon with 1 ml. of 96% sulfuric acid solution containing 5% by weight of paraformaldehyde. The presence of traces of aromatics after two to three minutes causes a brown coloration of the sulfuric acid layer.

Summary

m-Di-*t*-butylbenzene was prepared by the dehydrogenation of 1,3-di-*t*-butylcyclohexane; the latter was obtained from 2,4-di-*t*-butylcyclohexanol by means of dehydration followed by hydrogenation.

The Reaction of Tobacco Mosaic Virus with Formaldehyde. II. Kinetics[2]

BY MARIE A. FISCHER[3] AND MAX A. LAUFFER

Introduction

The loss of infectivity of tobacco mosaic virus in the presence of formaldehyde was studied by Ross and Stanley.[4] It appears to be a reaction of the first order. When the inactivation is carried out at room temperature in a phosphate buffer at *p*H 7, a simultaneous decrease in the amino nitrogen content of the virus occurs and the isoelectric point of the virus is shifted toward the acid side.[5] In a previous paper[6] the authors reported that the reaction products of formaldehyde inactivation appear to be electrophoretically homogeneous but to have a different mobility than untreated virus. Therefore, it seemed desirable to study simultaneously from the kinetic point of view the effects of formaldehyde treatment at *p*H 7.0 on the electrophoretic mobility, the amino nitrogen content and the infectivity of the virus to determine the possible relationship between the three changes.

Materials and Methods

Tobacco mosaic virus, isolated by the differential centrifugation method of Stanley,[7] was treated with formaldehyde by allowing a solution of 2% virus and 2% formaldehyde in 0.1 *M* phosphate buffer, *p*H 7.0, to react at 30.0°. At suitable time intervals, 15-ml. aliquots of the reacting mixture were removed and the *p*H immediately lowered to the isoelectric *p*H of the virus (*p*H 3.5) by the addition of 20 ml. of cold 1 *M* phosphate–citrate–hydrochloric acid buffer. After centrifuging for fifteen minutes at 4,000 r.p.m., the clear supernatant fluid was discarded and the virus precipitate washed by suspending the precipitate in 30 ml. of cold 0.1 *M* phosphate–citrate–hydrochloric acid buffer, *p*H 3.5, and again centrifuging and decanting the supernatant fluid. Washing was repeated and the precipitate then was dissolved in 10 ml. of phosphate buffer, *p*H 7.00 ± 0.02, 0.20 ionic strength, and dialyzed for four days against four 250-ml. portions of the same buffer. The virus protein content was determined by micro-Kjeldahl analysis, and the preparations of formaldehyde-treated virus were stored in the refrigerator. The infectivity, amino nitrogen content and the electrophoretic mobility of each sample were then determined.

Infectivity was determined by the method of Loring,[8] using *N. Glutinosa* as the test plant. So that approximately equal numbers of local lesions could be compared, two dilutions of each preparation were made and compared by using the half-leaf method and a Latin-square pattern for inoculation. The ninhydrin method described by Miller and Stanley[9] was used to determine the amino nitrogen content of each sample and electrophoretic mobilities were determined at 1° in the apparatus described by Tiselius[10] and modified by Longsworth.[11] In preparation, the virus had already been dialyzed against phosphate buffer, *p*H 7.00 ± 0.02, 0.20 ionic strength. Therefore, a portion of each sample was diluted with this buffer to a virus concentration of 0.50% just prior to electrophoresis in the same buffer. Differences in the *p*H and the specific conductances of the protein solutions and the buffer were not detectible by the precision bridge described by Luder.[12] Migration in an electric field of 4.5 volts per cm. was allowed to proceed until the essentially homogeneous boundaries had migrated a distance of 6 cm. The current was then reversed and the boundaries brought back to their original positions. The reported mobilities were calculated from the average of the distances each boundary moved away from and back to its original position.

The observation that formaldehyde-treated virus is electrophoretically homogeneous[6] justified the use of isoelectric precipitation to stop the reaction quickly. Table I shows that the method was efficient in removing excess and reversibly bound formaldehyde, for the properties of the virus treated 0-hours with formaldehyde were essentially the same as stock and control virus. Further evidence that excess formaldehyde was probably completely removed was obtained by studying the effect of the presence

of formaldehyde on the ninhydrin reaction. To 1-ml. aliquots of stock virus, containing 5 mg. of tobacco mosaic virus, varying concentrations of formaldehyde were added, and ninhydrin determinations were carried out immediately. It is apparent from the data in Table II that small concentrations of formaldehyde inhibit the ninhydrin reaction and that the immediate reaction of excess formaldehyde affects all of the groups which are reactive to ninhydrin because color is completely absent. However, Table I shows that the immediate reaction can be reversed by the removal of the formaldehyde. This is in contrast to the Van Slyke amino nitrogen reaction which has been shown[13] to reverse partly or completely the immediate binding of formaldehyde by amino groups.

Presentation of Experimental Results

Rate of Inactivation.—Ross and Stanley[4] studied the rate at which infectivity is lost when a 2% solution of virus in 0.1 *M* phosphate buffer at *p*H 7 is allowed to react with 2% formaldehyde at room temperature. The results of similar experiments confirm the observation of Ross and Stanley that the loss of infectivity of tobacco mosaic virus in the presence of formaldehyde is a reaction of the first order. The data fit an equation of the form

$$(V) = e^{-kt} \qquad (1)$$

where (V) is virus infectivity expressed as fraction of original infectivity and t is time of contact with formaldehyde in hours. In four experiments carried out at *p*H 7 and 30°, the following values were obtained for k: 0.37, 0.44, 0.45 and 0.4 reciprocal hour.

Shift in Electrophoretic Mobility with Formaldehyde Treatment.—As was pointed out previously,[6] tobacco mosaic virus remains essentially homogeneous with respect to electrophoretic mobility after treatment with formaldehyde; however, a mobility shift occurs, because inactive virus can be separated electrophoretically from untreated virus. Since treated virus is inhomogeneous with respect to the criterion of biological activity, but homogeneous with respect to electrophoresis, it seemed desirable to study the mobility shift in more detail. In preliminary studies the kinetics of this reaction were studied by an indirect method.[14] It was first shown that a correlation could be established between the infectivity remaining, following treatment, and the electrophoretic mobility. When the logarithm of the relative activity remaining was plotted against the electrophoretic mobility of a formaldehyde-treated sample, a straight line relationship was obtained. If this proportionality is considered in relation to the logarithmic dependence of infectivity upon time, it can be deduced that the shift in electrophoretic mobility is directly proportional to the time of contact between the virus and the formaldehyde.

The experiment described in the section on materials and methods was carried out in a manner which permitted direct measurement of both time of contact with formaldehyde and electrophoretic mobility. The results are shown in Fig. 1, where electrophoretic mobility increase in a 0.1 *M* phosphate buffer at *p*H 7 is plotted as a function of time of contact with formaldehyde. The linear relationship is seen to apply only to the initial stage of the reaction. The open circles on the graph represent experimental determinations, and the smooth curve is a plot of equation (2).

$$\Delta U = 0.82(1 - e^{-0.04t}) \qquad (2)$$

ΔU in equation (2) represents the increase in anodic mobility, and t represents the time in hours during which the virus was held in contact with formaldehyde.

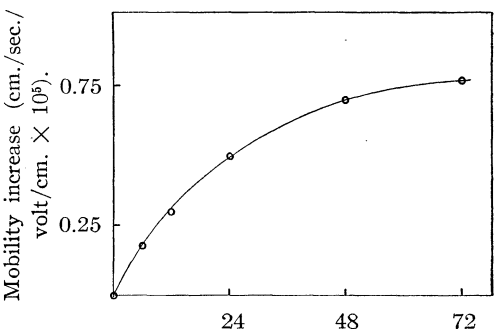

Fig. 1.—Increase in anodic electrophoretic mobility (10^5 cm.²/volt-sec.) of formaldehyde-treated tobacco-mosaic virus protein in potassium phosphate buffer, *p*H 7.00 ± 0.02, 0.2 ionic strength, plotted against time in hours of reaction at *p*H 7.0 and 30° between the protein and 2% formaldehyde.

The Decrease in Free Amino Groups.—Ross and Stanley,[4] by measuring the ninhydrin color, studied the effect of formaldehyde treatment in neutral phosphate buffer on the virus groups. In order to determine whether or not the decrease in free amino groups as shown by the ninhydrin reaction is correlated with the shift in mobility or with the decrease in infectivity, free amino groups were measured on the samples which were subjected to infectivity and electrophoretic analyses. The details of the experiment were described in the section on materials and methods. The results are presented in Fig. 2, where ninhydrin color expressed as per cent. of original is plotted against time in hours of reaction with formaldehyde. The open circles represent the experimental values obtained. If the shift in electrophoretic mobility were associated in a simple manner with the decrease in amino nitrogen, these data ought to fit the equation, $C = 100e^{-0.04t}$, where C is the color produced by ninhydrin expressed as per cent. of original, and t is the time in hours of reaction with formaldehyde. The data do not obey this equation at all. This is proof that ninhydrin does not measure exactly the

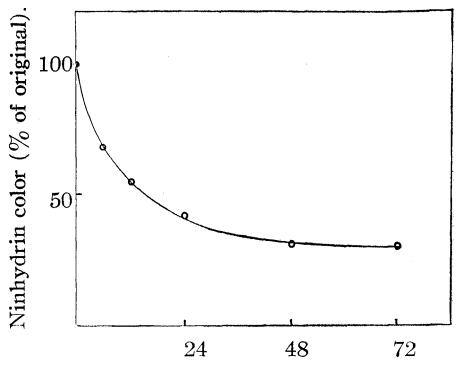

Fig. 2.—Color, expressed as per cent. of original absorption, obtained by treating formaldehyde-modified tobacco-mosaic virus protein with ninhydrin plotted against time in hours of reaction at *p*H 7.0 and 30° between the protein and 2% formaldehyde.

same thing as shift in electrophoretic mobility. The smooth curve in Fig. 2 is a plot of equation (3).

$$C = (28 + 30e^{-0.04t} + 42e^{-0.14t}) \qquad (3)$$

The parameter, 0.04, was carried over from equation (2) for reasons which will be discussed later. The other four parameters were selected to make the equation fit the data. The parameter, 28, is subject to an error of the order of magnitude of 3%. The other parameters are subject to uncertainties of the order of magnitude of 25%.

Discussion

Theoretical Considerations.—Assume that a solution contains n macromolecules per ml., each with ν groups capable of reacting with a reagent. The total concentration of groups per ml. will be $n\nu$ or N. If the reagent is present in great excess, one would expect the reaction to be first order with respect to the groups.

$$-dN/dt = kN \qquad (4)$$

$$N/N_0 = e^{-kt} \qquad (5)$$

N/N_0 is the fraction of groups unchanged after a time, t, of reaction with the reagent.

$$1 - N/N_0 = N'/N_0 = 1 - e^{-kt} \qquad (6)$$

N'/N_0 is the fraction of the groups which changed. The theory of probability leads to the expectation that the product should be inhomogeneous with respect to the number of groups per macromolecule reacted after time, t. The mean should be $\nu N'/N_0$. The distribution should be described by a standard deviation, σ.

$$\sigma = \sqrt{\nu N N'/N_0^2} \qquad (7)$$

Suppose that m of these ν groups on each macromolecule have some special significance. Then

$$n/n_0 = e^{-mkt} \qquad (8)$$

where n/n_0 is the fraction of macromolecules on which no one of the m special groups has reacted after time, t, in contact with reagent. The rate of disappearance of macromolecules with m intact special groups would be given by equation (9).

$$-dn/dt = mkt \qquad (9)$$

Types of Reaction between Formaldehyde and Proteins.—The possible reactions between formaldehyde and protein were reviewed in detail by French and Edsall[15] and by Olcott and Fraenkel-Conrat[13]. Apparently, formaldehyde is able to add reversibly to free amino groups to give groups which are weak bases and which do not produce color with ninhydrin. Further, apparently irreversible, reactions are possible by cross-linking between amino methylol groups and amide, guanidyl, imidazole, indole and phenol groups. These irreversible reactions may or may not lead to a change in charge, but do lead to change in color production with ninhydrin.

Shift in Mobility.—The negative charges on tobacco mosaic virus protein arise largely from free carboxyl groups of the dicarboxylic amino acids. These would be almost completely ionized at *p*H 7 because the *pK* is of the order of 4.0.[16] The negative charges are probably partially neutralized internally by positive charges originating from guanidine residues of arginine and the epsilon amino groups of lysine. At *p*H 7 the guanidine groups should be completely ionized; the free amino groups of lysine should be ionized to the extent of about 99.7%, since the *pK* for such groups in the polypeptide state is about 9.5, or greater.[16] Calculation from the amino acid content of tobacco mosaic virus[17] leads to the conclusion that at neutrality a tobacco mosaic virus particle should have 8,300 net charges.[18]

The mobility shift observed as a result of the reaction of the virus with formaldehyde can be interpreted as being the result of a decrease in the number of positive groups per particle, thereby increasing the net negative charge. The increase in negative charge, therefore, should be given by the quantity $\nu(N'/N_0)(\alpha_1 - \alpha_2)$, where α_1 and α_2 are the dissociation constants of the groups before and after reaction with formaldehyde, respectively. When the expression for N'/N_0 given by Equation (6) is substituted into this quantity, when it is considered that the maximum change in

(18) Unpublished acid–base binding experiments indicated that 6900 moles of acid were bound by one mole of untreated tobacco mosaic virus protein and 8200 moles of acid were bound by one mole of formaldehyde inactivated virus protein when the proteins were titrated from *p*H 3.5 (the usually accepted isoelectric point of tobacco mosaic virus protein) to *p*H 7.0. These data indicate that the theoretical valence, −8300, is of the correct order of magnitude. It should be observed that nucleic acid was omitted from consideration in arriving at the theoretical valence. This amounts to the assumption that nucleic acid does not contribute appreciably to the net charge of tobacco mosaic virus protein at *p*H 7. The reasonable agreement between the theoretical valence and that obtained by titration experiments indicates that this assumption may not be seriously in error.

charge is equal to $\nu(\alpha_1 - \alpha_2)$, and when the assumption is made that the shift in electrophoretic mobility is directly proportional to the shift in net charge, Equation (10) results.

$$\Delta U = \Delta U_{\max.} (1 - e^{-kt}) \qquad (10)$$

It is obvious that this equation is of exactly the same form as empirical Equation (2).

Experiments reported in a previous publication[6] showed that, following reaction with formaldehyde for a twenty-four-hour period, tobacco mosaic virus exhibited boundaries in the electrophoresis apparatus which were about as sharp as those exhibited by untreated virus. However, the theoretical considerations summarized by Equation (7) lead one to expect that virus treated with formaldehyde should be inhomogeneous with respect to electrophoresis. On the assumption that mobility is equal to K times the charge, Equation (11), where σ_u is the standard deviation of the distribution of mobility increments, can be derived from Equation (7).

$$\sigma_u = K \sqrt{\nu \frac{N'}{N_0} \times \frac{N}{N_0}} \qquad (11)$$

Since there are approximately 8,300 excess negative charges on a tobacco mosaic virus particle at *p*H 7, and the mobility is 7.15×10^{-5} sq. cm./volt-sec., K can be evaluated to be 0.00086×10^{-5}. Chemical analyses indicate that there are about 3,400 free amino groups on a tobacco mosaic virus particle. For reasons which will be discussed in the next section, about 30% of these can be assumed to be involved in the reaction which leads to a change in ionization. One can infer from Fig. 1 that N'/N_0 and N/N_0 are both approximately one-half for the reaction which has continued for twenty-four hours. By substituting these values into Equation (11), one can estimate that the standard deviation of the increment in mobility due to reaction of tobacco mosaic virus with formaldehyde should be of the order of magnitude of 0.014×10^{-5} cm./sec./volt/cm. Since the mobility after twenty-four hours of reaction is about 7.5×10^{-5}, the ratio of the standard deviation of the increment in mobility to the mobility is about 0.002. Inspection of electrophoresis boundary diagrams obtained with untreated tobacco mosaic virus indicates that the ratio of the standard deviation of the boundary to distance traversed is of the order of magnitude of 0.01. Therefore, the standard deviation of the boundary obtained with treated virus ought to be $\sqrt{(0.01)^2 + (0.002)^2}$, a value about 2% greater than that obtained with untreated virus. A difference of this magnitude would go undetected. Thus, the experimental observation that virus after reaction with formaldehyde is still essentially homogeneous with respect to electrophoresis is not inconsistent with the concepts used in the present case to interpret the reaction mechanism.

Decrease in Free Amino Groups.—The data presented in Fig. 2 were obtained under such conditions that they represent the irreversible change in free amino groups resulting from reaction of tobacco mosaic virus with formaldehyde. If one makes the assumption that there are three kinds of amino groups on tobacco mosaic virus particles, (a) those which do not react irreversibly with formaldehyde; (b) those which react irreversibly with formaldehyde at a relatively rapid rate; and (c) those which react with formaldehyde at a relatively slow rate, then the fraction of free amino groups remaining after time, t, would be given by a function which is the sum of a constant and two exponentials like that of Equation (5). The curved line fitting the data in Fig. 2 is a graph of Equation (3), and Equation (3) is of exactly the form described.

If the assumption is made that one of the two kinds of groups which react with formaldehyde irreversibly leads to the shift in electrophoretic mobility illustrated by the data of Fig. 1, and that the other of the two kinds of groups does not result in a shift in mobility, then it is necessary that the constant in one of the exponential terms of Equation (3) be the same as the constant in the exponential in Equation (2). Thus, the parameter, 0.04, in Equation (3) was determined from the data of Fig. 1 and not from those of Fig. 2.

It is thus evident that the results of these studies are consistent with the assumption that at least three kinds of amino groups are present on a tobacco mosaic virus particle. About 28% of the groups do not react irreversibly with formaldehyde; about 42% react irreversibly with a rate constant of about 0.14 but do not lead to a change in charge; and about 30% react irreversibly with a rate constant of 0.04 to produce a change in charge. The data of Fig. 2 are not sufficiently precise to fix these parameters with any great precision nor to rule out the possibility that more than three kinds of groups are present.

The data of Fig. 1 can be interpreted to mean that the maximum shift in mobility at *p*H 7 due to reaction of tobacco mosaic virus with formaldehyde is 0.82×10^{-5} sq. cm./volt sec. If this is divided by K, a value of 953 is obtained for the increase in net negative charge, or the decrease in positive charge per virus particle. If it is assumed that the change in charge involves free amino groups, and that $\alpha_1 = 1$ and $\alpha_2 = 0$, the shift of 953 charges would involve 953/3400 or 28% of the free amino groups. This figure agrees with the parameter, 30, in Equation (2) and constitutes evidence in favor of the reasonableness of the assumption that 30% of the amino groups react irreversibly with formaldehyde to produce a change in charge.

Kinetics of the Decrease in Infectivity.—The data of the present study and of previous studies indicate that the decrease in infectivity obtained when tobacco mosaic virus is treated with formaldehyde is a reaction of the first order. This means that the inactivation process, what-

ever it is, must be a single event phenomenon. Two possibilities exist for interpreting the decrease in infectivity. One is that the reaction is completely independent of any changes detected by chemical or electrophoretic means. The other possibility is that infectivity is lost when the first one of several particular amino groups on a virus particle has reacted irreversibly with formaldehyde. If several groups are capable of leading to inactivation, they must all be of the same sort with respect to rate of reaction with formaldehyde; otherwise, the first order law for inactivation could not be followed. If one assumes that m out of a total of ν groups of a particular sort on a virus particle can lead to loss in infectivity when irreversible reaction with formaldehyde takes place, then loss of infectivity would result when the first of these groups happened to react. Equation (9) shows that the reaction velocity constant for the loss of infectivity would be equal to m times the velocity constant for the reaction of the particular groups under study.

The reaction velocity constant for the destruction of infectivity at room temperature has been shown to be about 0.42 reciprocal hour. This is about ten times the rate constant for the change in mobility. Thus, if groups of the sort which result in shifts in mobility are responsible for the inactivation of the virus, there must be ten special groups of that sort on each virus particle. Similarly, since the rate of the reaction which leads to irreversible loss of free amino groups but not to change in charge is 0.14, there would have to be 0.42/0.14 or 3 special groups of this sort to account for the loss of infectivity.

Summary

The kinetics of the changes which take place when tobacco mosaic virus is treated with 2% formaldehyde at *p*H 7 and 30° were studied. Infectivity was found to decrease according to the law of a first order process with a rate constant of about 0.42 hour^{-1}. Electrophoretic mobility was found to increase and approach a maximum value as the time of treatment was extended indefinitely. The rate constant for this process was found to be 0.04 hour^{-1}. Free amino groups as determined by the ninhydrin color reaction were found to decrease according to a complex pattern. The results can be interpreted in terms of the assumption that 28% of the amino groups do not react irreversibly with formaldehyde; 42% react irreversibly at a rate of 0.14 reciprocal hour, and 30% react irreversibly at a rate of 0.04 reciprocal hour. These latter 30% can be assumed to be the same groups which cause shift in electrophoretic mobility. The loss of infectivity could be due either to some process entirely independent of the reactions indicated by the chemical and physical changes or to the first one of several particular amino groups of one sort reacting irreversibly with formaldehyde.

A New Synthesis of Tuberculostearic Acid[1a]

BY GUSTAV A. SCHMIDT[1b] AND DAVID A. SHIRLEY

Tuberculostearic acid or 10-methyloctadecanoic acid (compound V in Fig. 1) was isolated by Anderson and Chargaff[2] from the fatty envelope surrounding the tubercle bacillus and its structure later proved by Spielman[3] who prepared a synthetic sample. Recently Prout, Cason and Ingersoll[4] have reported preparation of the *dl*-form and the *d*- and *l*-enantiomorphs of 10-methyloctadecanoic acid, establishing that the naturally occurring isomer is the levorotatory form. The *dl*- and active forms have also been prepared by Ställberg-Stenhagen[5] by a still different method.

As a part of a study of derivatives of modified branched-chain fatty acids as potential antitubercular chemotherapeutic agents, we have undertaken the preparation of moderate amounts of tuberculostearic acid to be used in further synthetic work. We have developed a new method of synthesis of *dl*-tuberculostearic acid which appears to be an improvement over the one used by Spielman.[3] It is much shorter than the synthesis used by Prout, Cason and Ingersoll[4] and Ställberg-Stenhagen,[5] since these authors prepared the *d*- and *l*-forms which involved working with optically active intermediates and avoiding racemization in the transformations employed.

The steps in this synthesis are outlined in Fig. 1. Azelaic acid was converted to its half ethyl ester acid chloride and this was allowed to react with 2-decylzinc chloride (II), to give ethyl 9-keto-10-methyloctadecanoate (III). Reduction of the keto ester (III) by the Clemmensen method gave ethyl 10-methyloctadecanoate (IV) which was hydrolyzed to the corresponding acid (V). Purification of 10-methyloctadecanoic acid was effected by converting it to the amide (VI) followed by recrystallization of the amide and hydrolysis to the acid.

A distinctive feature of this synthesis is the use

of a secondary organometallic compound in its reaction with an acid chloride to form a ketone. The organocadmium compounds, usually found advantageous for ketone formation, are not satisfactory when secondary types are used.[6] The secondary organozinc compound used here allows formation of the ketone in 55% yield.

Experimental

2-Decanol.—Reaction of *n*-octylmagnesium bromide with acetaldehyde in customary fashion gave an 85% yield of 2-decanol, b. p. 123° (29 mm.), $n^{25}D$ 1.4326.

2-Bromodecane.—2-Decanol was converted to 2-bromodecane in essential accordance with the procedure of Hsueh and Marvel[7] except that the crude bromide was washed with cold concentrated sulfuric acid, then with water and dried and distilled. The yield of pure bromide was 88–92%. It boiled at 124–125° (30 mm.), $n^{25}D$ 1.4526.

Ethyl Hydrogen Azelate.—Pure azelaic acid and its diethyl ester were obtained from "Plastolein 9111," a commercial material reported to have the following composition of dicarboxylic acids; pimelic 4%, suberic 15%, azelaic 71% and undecandioic 10%.[8]

The mixed acids refluxed with excess ethanol, benzene and a small amount of sulfuric acid catalyst under conditions for continuous separation of the benzene, ethanol and water azeotrope allowed formation of the mixed diethyl esters in 96% yield. Diethyl azelate was separated from the mixed esters by two distillations through a fractionating column consisting of two 2 × 35-cm., helices packed, electrically heated sections on which was mounted a total condensation partial take-off head. Pure diethyl azelate obtained in 77% yield (based on the 71% azelaic acid present in the mixed starting acids) boiled at 140° (1 mm.),[9] $n^{25}D$ 1.4348. Saponification of diethyl azelate with alcoholic sodium hydroxide gave an essentially quantitative yield of azelaic acid, m. p. 105.5–106°, with no purification by recrystallization or other methods being necessary.

Diethyl azelate and azelaic acid were used for the preparation of the half ester, ethyl hydrogen azelate, in accordance with the procedure of Swann, Oehler and Buswell[10] for the preparation of ethyl hydrogen sebacate. The half ester was formed in 63% yield, b. p. 170° (1 mm.), m. p. 28–29°.[9]

ω-Carbethoxyoctanoyl Chloride.—Ethyl hydrogen azelate (224 g., 1.03 moles) was refluxed with excess thionyl chloride for one and one-half hours. Distillation gave the acid chloride in 84% yield, b. p. 155° (14 mm.). Ruzicka and Stoll[11] report this compound and give 155–158° at 15 mm. as its boiling point.

Anal. Calcd. for $C_{11}H_{19}ClO_3$: Cl, 15.1. Found: Cl, 15.0.

Ethyl 9-Keto-10-methyloctadecanoate (III).—The preparation of this ketone was carried out by reaction of 2-decylzinc chloride (II) with ω-carbethoxyoctanoyl chloride in essential accordance with the procedure used by Jones[12] for the synthesis of long-chain aliphatic ketoacids.

2-Decylmagnesium bromide (I) was prepared in customary manner from 280 g. (1.27 moles) of 2-bromodecane, 48 g. (2.0 g. atoms) of magnesium and 600 ml. of absolute ether. Titration of an aliquot with standard acid[13] showed an 80% yield of Grignard reagent. The solution of Grignard reagent was added to a solution of 136 g. (1.0 mole) of freshly fused anhydrous zinc chloride in 350 ml. of ether at such rate that gentle reflux was maintained. Reflux temperature was maintained for an additional one and one-half hours during which time the solvent was slowly distilled from the reaction mixture until the volume was approximately 600 ml. To the resulting mixture was added with stirring a solution of 170 g. (0.72 mole) of ω-carbethoxyoctanoyl chloride in 400 ml. of anhydrous benzene. After a three-hour reflux period, the mixture was treated with excess water containing a little hydrochloric acid and the organic layer separated and dried. The volatile organic material was removed by distillation until a head temperature of 150° (12 mm.) pressure was reached. It was found convenient at this point to treat the residue with ethanol under the esterification conditions described above until no more water was being removed from the system. In this way the ethyl hydrogen azelate (from unreacted acid chloride) present at this point was converted to its more volatile diethyl ester which increased the efficiency of its subsequent separation by distillation from the ethyl 9-keto-10-methyloctadecanoate. Distillation of the esterified material through the same column described above gave 78 g. of diethyl azelate boiling in the range 130–175° (95% boiled at 130°) at about 0.5 mm. pressure and 133 g. of ethyl 9-keto-10-methyloctadecanoate, b. p. 184–185° at about 0.5 mm., $n^{25}D$ 1.4470. The yield of ketoester was 55% based on the starting amount of ester acid chloride or 93% based on the acid chloride consumed.

9-Keto-10-methyloctadecanoic Acid.—Fifteen grams (0.044 mole) of ethyl 9-keto-10-methyloctadecanoate was refluxed for four hours with a solution of 20 g. of sodium hydroxide in 40 ml. of water and 60 ml. of ethanol. The alcohol was distilled off and the reaction mixture diluted to a volume of 500 ml. with water. The resulting solution was extracted with three portions of petroleum ether (b. p. 30–60°) and then acidified. The acid mixture was then extracted with petroleum ether and the combined extracts washed with dilute hydrochloric acid and then ten times with distilled water. The petroleum ether solution was dried and the solvent removed by distillation including a final heating period at 100° under a pressure of about 0.5 mm. to ensure complete removal of solvent. The residual light yellow oil (13 g. or 94% yield) was used for preparation of the semicarbazone described below. A small amount recrystallized three times from petroleum ether at −30° gave white platelets, m. p. 24–25°.

A semicarbazone derivative[14] prepared in 90% yield melted at 86–86.4° after three recrystallizations from methanol, petroleum ether and acetone in that order.

Anal. Calcd. for $C_{20}H_{39}N_3O_3$: N, 11.37. Found: N, 11.42.

Ethyl 10-Methyloctadecanoate (IV).—Using the general method of Schneider and Spielman[15] for a Clemmensen reduction, 51 g. (0.15 mole) of ethyl 9-keto-10-methyloctadecanoate dissolved in 1 l. of absolute ethanol and mixed with 420 g. of amalgamated zinc[12] was saturated with dry hydrogen chloride. The mixture was refluxed for twenty-four hours, again saturated with hydrogen chloride, and then refluxed for a second twenty-four-hour period. After removal of the unreacted zinc, the volume of the solution was reduced to one-half and excess water added. The precipitated organic layer was removed by extraction with benzene and the benzene solution distilled to remove the volatile material. Distillation of the residue gave 40 g. (83%) of ester, b. p. 175–180° (2 mm.), $n^{25}D$ 1.4440. Prout, Cason and Ingersoll[4] report $n^{25}D$ 1.4447 for this compound.

Anal. Calcd. for $C_{21}H_{42}O_2$: sapon. equiv., 326. Found: sapon. equiv., 322.

10-Methyloctadecanoic Acid (V).—A mixture of 17.5 g. (0.054 mole) of ethyl 10-methyloctadecanoate, 25 ml. of 40% aqueous sodium hydroxide solution and 100 ml. of ethanol was refluxed for twelve hours and worked up as described above for the saponification of ethyl 9-keto-10-methyloctadecanoate. There was obtained 15 g. (94%) of the acid, $n^{25}D$ 1.4513 (the literature[3,4] records $n^{25}D$ 1.4512 for 10-methyloctadecanoic acid). In view of the fact that the product had a low melting point (around 5–10° compared with literature values of 20–21°[3] and 25.4–26.1°[4]), and it was difficult to recrystallize without large loss, it was decided to convert the acid to its more easily handled amide, purify the amide by recrystallization, and hydrolyze the pure amide to the acid.

10-Methyloctadecanamide (VI).—Twelve and five-tenths grams (0.042 mole) of the 10-methyloctadecanoic acid isolated above was converted to the acid chloride by refluxing with excess thionyl chloride and the excess thionyl chloride removed by distillation. The residual acid chloride dissolved in dioxane was added dropwise with rapid stirring to cold concentrated aqueous ammonia. The precipitated amide was recrystallized once from acetone and four times from petroleum ether (b. p. 30–60°) to give 8.8 g. (70%) of pure amide, m. p. 77–78° (the literature reports 76–77°[3] and 77.5–79.2°[4]).

Hydrolysis of 10-Methyloctadecanamide.—The 8.8 g. of amide prepared above was hydrolyzed by refluxing for twelve hours with 50 ml. of 10% alcoholic sodium hydroxide. The mixture was treated as described above under saponification of ethyl 9-keto-10-methyloctadecanoate to give an essentially quantitative yield of 10-methyl octadecanoic acid, m. p. 23.5–25.8° (cor.), b. p. 200–203° (1 mm.), $n^{25}D$ 1.4512.

Anal. Calcd. for $C_{19}H_{38}O_2$: neut. equiv., 299. Found: neut. equiv., 301, 303.

Table I summarizes the physical constants of 10-methyloctadecanoic acid and its derivatives found in this work in comparison with those obtained by Spielman[3] and by Prout, Cason and Ingersoll.[4]

TABLE I

PHYSICAL CONSTANTS OF 10-METHYLOCTADECANOIC ACID AND ITS DERIVATIVES

Physical constant	This work	Spielman[3]	Prout, Cason and Ingersoll[4]
Melting point of acid, °C.	23.5–25.8 (cor.)	20–21	25.4–26.1 (cor.)
Boiling point of acid, °C.	200–203 at 1 mm.	.....	.....
Index of refraction of acid $n^{25}D$	1.4512	1.4512	1.4512
Melting point of amide, °C.	77–78	76–77	77.5–79.2
Melting point of 2,4,6-tribromoanilide, °C.	93.5–94	93–94	93.4–93.9

The Soluble Complex of Ferric Iron and 8-Hydroxyquinoline

BY E. B. SANDELL AND D. C. SPINDLER

In dilute mineral acid medium 8-hydroxyquinoline reacts with ferric ion to give a soluble green complex. A number of workers have made use of the formation of this green substance in the indirect colorimetric determination of magnesium by treating an acid solution of the magnesium hydroxyquinolate precipitate with a ferric salt. The present work deals with the composition of the green complex and its dissociation constant. The value of the dissociation constant is needed in calculating the solubility product of ferric hydroxyquinolate as well as in treating the problem of the extractability of ferric hydroxyquinolate by chloroform from aqueous solutions at various acidities.

The composition of the complex was established by applying the familiar method of continuous variations.[1] Solutions of ferric perchlorate and 8-hydroxyquinoline in perchloric acid were mixed in various ratios, the sum of molar concentrations of the two reactants being kept constant at 1.19×10^{-3} *M*. The transmittancy of the mixtures was determined at 645 mμ, the approximate wave length of maximum absorption by the iron–hydroxyquinoline complex; at this wave length, absorption by hydroxyquinolinium ion (in which form hydroxyquinoline is chiefly present at the acidities used) and ferric ion is negligibly small, at least in the concentrations employed. Transmit-

(1) P. Job, *Ann. chim.*, **9**, 113 (1928); **11**, 97 (1936).

tancy measurements were made with a Coleman spectrophotometer, Model 10, at a band width of 5 mμ. The mixtures were prepared at various *p*H's, ranging from 1.1 to 2.6, and a glass electrode was used to obtain the *p*H.

The results are shown in Fig. 1. At *p*H 1.9 and below, the curves exhibit a maximum at the value 0.5 for the ratio $[Fe^{+++}]/([Fe^{+++}] + [HOx \cdot H^+])$ and are symmetrical. At *p*H 2.1 to 2.6, the ratio for the maximum color intensity is shifted slightly to the left and lies between 0.45 and 0.5. It can be calculated that the solubility product of ferric 8-hydroxyquinolate is exceeded in solutions of higher *p*H in which the maximum is displaced from 0.5. These experiments demonstrate that in the more acidic solutions the colored product is an equimolecular compound of iron and 8-hydroxyquinoline and is therefore the ion $FeOx^{++}$.

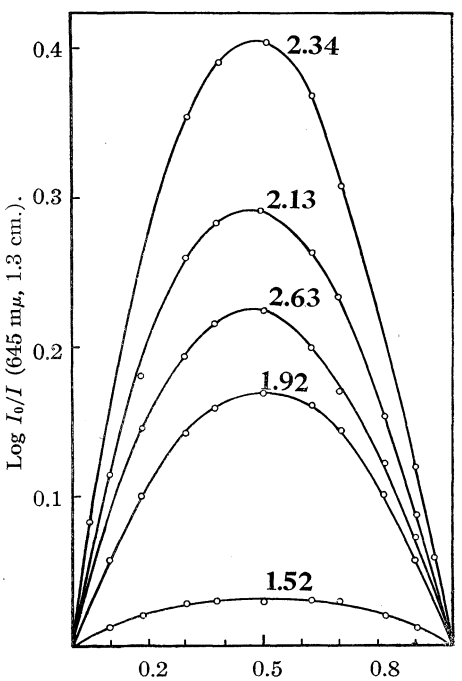

Fig. 1.—Continuous variation method applied to mixtures of ferric ion and 8-hydroxyquinoline; sum of concentrations of components 1.19×10^{-3} *M* except in *p*H 2.63 series where concentration is one-half of others. *p*H values are given on curves.

The same species is no doubt predominantly formed at higher *p*H's, but here the incipient formation of slightly soluble $FeOx_3$ is an obscuring factor. Even if the departure of the maximum color intensity from the ratio 0.5 is interpreted to mean formation of some $FeOx_2^+$, the amount of the latter is small compared to that of $FeOx^{++}$ if it can be assumed that the extinction coefficients of the two complex ions are similar in magnitude. Transmission curves of solutions in which ferric ion was present in excess, on the one hand, and 8-hydroxyquinoline in excess on the other, showed no significant difference in the range 450–700 mμ. In aqueous medium $FeOx_2^+$ cannot be formed in appreciable concentration because the increase in the hydroxyquinolate ion (Ox^-) concentration by addition of more 8-hydroxyquinoline or by raising the *p*H, required to shift the equilibrium toward $FeOx_2^+$, precipitates ferric hydroxyquinolate. In an alcoholic medium it may be expected that $FeOx_2^+$ can be formed in appreciable amount.

The maximum color intensity of acidic mixtures of ferric ion and 8-hydroxyquinoline is attained very rapidly, constancy being reached before the transmittancy of the solution can be measured. The color is moderately stable, but decreases in strength on long standing.

Dissociation Constant of $FeOx^{++}$

The extinctions of a series of mixtures, at three different *p*H values, of ferric perchlorate and 8-hydroxyquinoline, in which the concentration of the latter was constant and the concentration of excess iron was varied, were measured at 645 mμ and 25° (Fig. 2). The value of the extinction coefficient of $FeOx^{++}$ and of the dissociation constant

$$a_{Fe^{+++}} a_{Ox^-} / a_{FeOx^{++}} = K_1$$

were obtained from the relations indicated below. It is not feasible to obtain the extinction coefficient of the complex directly by adding a large excess of ferric ion.

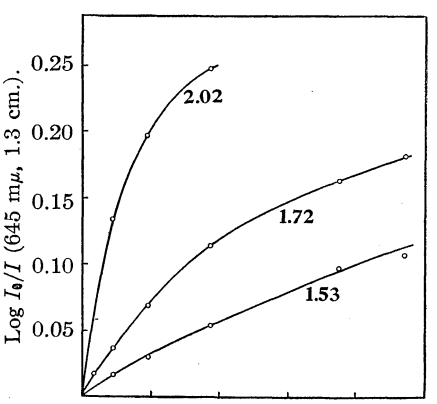

Fig. 2.—Extinction of ferric ion–8-hydroxyquinoline solutions with iron in variable excess; oxine concentration 2.38×10^{-4} *M*. *p*H values are given on curves.

The ionic strength of the mixtures was maintained constant at 0.073 by addition of sodium perchlorate. Buffer solutions were not used in the adjustment of the acidity because of the formation of complexes between ferric iron and anions. These experiments had to be carried out in a restricted range of acidity. If the solution is not sufficiently acidic, the hydrolysis of ferric ion becomes too extensive and introduces uncertainties; if the solution is too acidic, insufficient $FeOx^{++}$ is formed to allow measurement.

The following relations have been used to obtain the values of the constants mentioned

$$E = \log I_0/I = \epsilon l[\mathrm{FeOx^{++}}] \quad (1)$$

$K_1 = f_3[\mathrm{Fe^{+++}}]f_1[\mathrm{Ox^-}]/f_2\ [\mathrm{FeOx^{++}}]$, where f = activity coefficient, with valence of ion indicated by subscript (2)

Let b = total 8-hydroxyquinoline concentration

$$= [\mathrm{HOx{\cdot}H^+}] + [\mathrm{HOx}] + [\mathrm{Ox^-}] + [\mathrm{FeOx^{++}}]$$

where HOx represents 8 - hydroxyquinoline. When the pH is low, as in the present experiments, the concentration of undissociated 8-hydroxyquinoline and of hydroxyquinolate ion is small and can be neglected, and therefore

$$b = [\mathrm{HOx{\cdot}H^+}] + [\mathrm{FeOx^{++}}]$$

Now

$$[\mathrm{HOx{\cdot}H^+}] = \frac{(a\mathrm{H^+})^2[\mathrm{Ox^-}]}{K_{\mathrm{Ox}}}$$

where

$$K_{\mathrm{Ox}} = K_{1\mathrm{Ox}}K_{2\mathrm{Ox}} = \frac{a\mathrm{H^+}a\mathrm{HOx}}{a\mathrm{HOx{\cdot}H^+}} \times \frac{a\mathrm{H^+}a\mathrm{Ox^-}}{a\mathrm{HOx}} = \frac{(a\mathrm{H^+})^2a\mathrm{Ox^-}}{a\mathrm{HOx{\cdot}H^+}} = \frac{(a\mathrm{H^+})^2[\mathrm{Ox^-}]}{[\mathrm{HOx{\cdot}H^+}]} = 3.4 \times 10^{-16}$$

The value 3.4×10^{-16} for K_{Ox} is based on the values 1.2×10^{-5} and 2.86×10^{-11}, respectively, for $K_{1\mathrm{Ox}}$ and $K_{2\mathrm{Ox}}$ at 25°.[2]

$$\therefore [\mathrm{FeOx^{++}}] = b - [(a\mathrm{H^+})^2[\mathrm{Ox^-}]/K_{\mathrm{ox}}] \quad (3)$$

From (2) and (3)

$$[\mathrm{Ox^-}] = \frac{K_1f_2[\mathrm{FeOx^{++}}]}{f_1f_3[\mathrm{Fe^{+++}}]} = \frac{f_2K_1K_{\mathrm{ox}}b}{f_1f_3K_{\mathrm{ox}}[\mathrm{Fe^{+++}}] + f_2K_1(a\mathrm{H^+})^2} \quad (4)$$

From (1), (3) and (4)

$$E = \frac{\epsilon f_1f_3K_{\mathrm{ox}}[\mathrm{Fe^{+++}}]b}{f_1f_3K_{\mathrm{ox}}[\mathrm{Fe^{+++}}] + f_2K_1(a\mathrm{H^+})^2} \text{ when } l = 1 \quad (5)$$

Let C = sum of molar concentrations of ferric iron in all its forms in the solution

$$= [\mathrm{Fe^{+++}}] + [\mathrm{FeOH^{++}}] + [\mathrm{FeOx^{++}}]$$

Taking $a\mathrm{FeOH^{++}}a\mathrm{H^+}/a\mathrm{Fe^{+++}} = 6 \times 10^{-3}$ (Bray and Hershey[3]) we find

$$C = [\mathrm{Fe^{+++}}] + \frac{0.006f_3[\mathrm{Fe^{+++}}]}{f_2(a\mathrm{H^+})} + \frac{E}{\epsilon}$$

$$\therefore [\mathrm{Fe^{+++}}] = \frac{C - E/\epsilon}{Q}, \text{ where } Q = 1 + \frac{0.006f_3}{f_2(a\mathrm{H^+})} \quad (6)$$

Substituting (6) into (5)

$$E = \frac{\epsilon f_1f_3K_{\mathrm{ox}}b(C - E/\epsilon)}{f_1f_3K_{\mathrm{ox}}(C - E/\epsilon) + f_2K_1(a\mathrm{H^+})^2Q}$$

$$\therefore K_1 = \frac{(C - E/\epsilon)(\epsilon f_1f_3K_{\mathrm{ox}}b - Ef_1f_3K_{\mathrm{ox}})}{QEf_2(a\mathrm{H^+})^2}$$

(2) The value for K_2 is the converted concentration constant of K. G. Stone and L. Friedman, THIS JOURNAL, **69**, 209 (1947). The values for K_1 available when this work was begun were not considered reliable, and this constant was therefore determined by measuring the pH of mixtures of 8-hydroxyquinoline and hydrochloric acid. The value 1.2×10^{-5} was obtained. In the meantime, J. P. Phillips and L. L. Merritt, Jr., THIS JOURNAL, **70**, 410 (1948), reported the same value for K_1; their value was obtained spectrophotometrically.

(3) W. C. Bray and A. V. Hershey, THIS JOURNAL, **56**, 1889 (1934).

The values of K_1 and ϵ were obtained by fitting the equation to the curves. The following values were used for the activity coefficients[4]: $f_1 = 0.81$, $f_2 = 0.42$, $f_3 = 0.20$.

The following values for ϵ and K_1 were obtained at three different acidities

pH	ϵ	K_1
1.53	1120	3.2×10^{-15}
1.70	1020	3.2×10^{-15}
2.02	1120	2.0×10^{-15}

There appears to be no reason for giving greater weight to any particular set. The rounded averages are $\epsilon = 1090$ (645 mμ) and $K_1 = 3 \times 10^{-15}$. These figures cannot be regarded as very accurate, partly because of uncertainties in activity coefficients and the hydrolysis constant of ferric ion.

Solubility Product of Ferric Hydroxyquinolate

The approximate value of the solubility product of ferric hydroxyquinolate (needed to determine whether mixtures of ferric ion and 8-hydroxyquinoline were saturated in the experiments described above) was obtained by shaking dilute perchloric acid solutions with an excess of ferric 8-hydroxyquinolate and determining the amount of iron in solution. In some of these experiments, 8-hydroxyquinoline was added to the mixtures. The experimental work will not be described in detail, since the values obtained are considered preliminary, although adequate for the present purpose.

Difficulties were encountered in reaching equilibrium and the solid phase seemed to undergo aging which resulted in a decrease in solubility on long shaking. The values obtained varied from 1×10^{-48} to 6×10^{-47}. Account was taken of hydrolysis of ferric ion and the formation of $\mathrm{FeOx^{++}}$. The figure 10^{-47} will be taken as an average value for $a\mathrm{Fe^{+++}}(a\mathrm{Ox^-})^3$ in aqueous solution at 25°. Even though approximate, this value should be of use in analytical calculations, especially since the solubility products of the metal hydroxyquinolates vary over a wide range. The value of the solubility product of ferric hydroxyquinolate has not previously been reported. It is of interest that the solubility product of aluminum hydroxyquinolate has been reported as much larger (10^{-32}) than that of iron.[5]

Summary

1. 8-Hydroxyquinoline reacts with ferric ion in dilute mineral acid medium to give the green ion $\mathrm{FeOx^{++}}$.

2. The dissociation constant of this complex ion is $a\mathrm{Fe^{+++}}a\mathrm{Ox^-}/a\mathrm{FeOx^{++}} = 3 \times 10^{-15}$.

3. The approximate value of the solubility product of ferric hydroxyquinolate is 10^{-47}.

A Spectrophotometric Investigation of the Interaction between Antimony(III) and (V)[1a,b,c] in Hydrochloric Acid Solutions

BY JAMES E. WHITNEY[2] AND NORMAN DAVIDSON

Introduction.—The investigations described here are concerned with the nature of the abnormally deep and intense coloration that exists in some systems containing an element in two different oxidation states or in a "mixed" oxidation state. Hofman and Resencheck[3] first emphasized the general occurrence of this phenomenon in connection with studies of the ferri ferrocyanides. Earlier, Werner[4] had expressed his feeling that there was an analogy between the intense color of quinhydrone and the intense colors of various mixed compounds of platinum (II) and (IV), with cyanide, chloride, bromide, oxalate and ammonia as coördinating groups. Many authors have commented on the significance of this phenomenon for the theory of the color of inorganic compounds.[5,6,7,8,9,10]

The color of an ion is of course in general a function of its environment. However, the coloration referred to above that exists in some systems that can be said to contain an element in two different oxidation states is so much more intense than the color of either component in most other systems that it deserves recognition as a special phenomenon. We shall use the term "interaction absorption" for this effect. For purposes of illustration, we mention a few of the systems which exhibit this effect. In solution in hydrochloric acid, mixtures of the ions of copper(I) and (II),[11] of antimony(III) and (V),[12] of tin(II) and (IV),[13] and of iron(II) and (III),[11] are all much more intensely colored than are the components at the same concentration. In the solid state, the ferri ferrocyanides appear to be much more strongly colored than the brown ferri ferricyanides or the colorless ferro ferrocyanides. A mixed precipitate of iron(II) and iron(III) hydroxides is almost black, compared to the red-brown color of ferric hydroxide; similarly a mixed precipitate of cerium(III) and cerium(IV) hydroxides is blue, compared to the slight yellow color of hydrated ceric oxide. The bluish-black Cs_2SbCl_6[14] and black Rb_2SbCl_6[12] (formally compounds of antimony(IV)) are to be compared with the light yellow-green $RbSbCl_6$[15] and the colorless complex chlorides of antimony(III) with the alkali metal chlorides.[16] The black substance, cesium aurous auric chloride,[17,18] is similarly more colored than most of the complex chlorides of aurous or auric gold. The isomorphous salt $Cs_2AgAuCl_6$ which is believed to contain argentous silver and auric chloride is also jet black. This fact is included to emphasize that there are conditions other than the presence of an element in several oxidation states which can produce unusually intense coloration.

It is possible to continuously vary the composition of a solution, but seldom possible to do this for a solid. Furthermore it is much easier to carry out accurate spectrophotometric measurements for solutions than for solids. We have therefore chosen to study the effect of some of the concentration variables on the interaction absorption of hydrochloric acid solutions of antimony(III) and antimony(V). Exploratory measurements of the absorption spectra of mixed tin(II) and (IV) solutions, and of arsenic(III) and (V) solutions, were also made.

Experimental.—Absorption spectra of solutions were measured using a Beckman Model DU quartz spectrophotometer. The absorption cells were the usual rectangular right prism type of quartz cells with a 10-mm. light path. Quartz spacers were available to reduce the light path to one millimeter. In order to protect the spectrophotometer from acid vapors, the loosely fitting Beckman cell covers could be sealed to the cells with a molten one to one mixture of beeswax and rosin.[19]

The optical density, D, reported here is equal to $\log_{10} I_0/I$. Extinction coefficients are defined by $\epsilon = D/cl$, where l is the light path in centimeters and c is the concentration of the absorbing solution in volume molal units.

The antimony solutions were prepared by dissolving approximately known quantities of reagent grade antimony trichloride or pentachloride in measured quantities of concentrated hydrochloric acid of known titer to give solutions of known final volume.[20]

(20) The concentrations quoted herein are in volume formal (*F*) or volume molal (*M*) units.

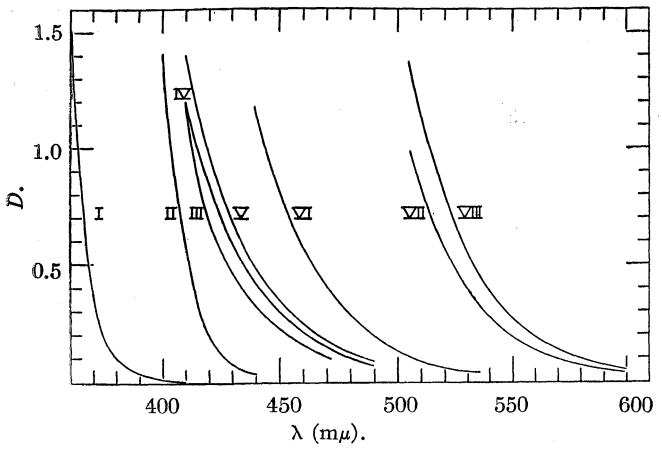

Fig. 1.—Absorption spectra of:

	I	II	III	IV	V	VI	VII	VIII
Sb(III)	0.30	0	0.068	0.22	0.16	0.03	1.17	0.745
Sb(V)	0	0.28	0.23	0.087	0.14	1.41	0.30	0.725

I–V, 11.3 *F* HCl; VI–VIII, 10.3 *F* HCl.

Aliquots (*ca.* 0.002 *F* in antimony) of the stock solutions were analyzed for antimony by a coulometric titration of antimony(III) (by means of electrolytically generated bromine).[21] Antimony(V) was determined after reduction with sulfur dioxide. Excess sulfur dioxide was removed from the solution by boiling.

For the preliminary measurements reported here, solutions of Sn(II) and Sn(IV) were obtained by dissolving reagent grade $SnCl_2 \cdot 2H_2O$ and $SnCl_4 \cdot 5H_2O$ in concentrated hydrochloric acid. Arsenic solutions were made by dissolving "primary standard" arsenious oxide, As_2O_3, in concentrated hydrochloric acid. The formal concentration of the hydrochloric acid, calculated on the assumption that the arsenious oxide was converted to the trichloride, was adjusted by the addition of weighed amounts of dry hydrogen chloride. The arsenic(V) solution was obtained from the arsenic(III) solution by oxidation with chlorine.

Spectrophotometric Results for Antimony Solutions in Concentrated Hydrochloric Acid.—Figure 1 illustrates the general nature of interaction absorption for antimony solutions in concentrated hydrochloric acid. Curves I and II are for *ca.* 0.3 *F* solutions of antimony(III) and antimony(V), respectively; curves III–V are for mixtures of these two solutions. Pure antimony(III) absorbs in the near ultraviolet and appears colorless to the eye. Antimony(V) solutions absorb on the fringe of the visible region and are a pale yellow in color. The 1:1 mixture of 0.3 *F* solutions (Curve V) is a medium yellow, and more strongly absorbing than the other mixtures for this constant total concentration. Curves VI–VIII are for antimony solutions at a total formality of 1.5. The color of the 1:1 mixture is a deep orange-brown. Comparison of Curves V and VIII reveals that for 1:1 mixtures a fivefold increase in the concentration of antimony causes a much greater increase in D at any wave length.

We define D_i, the optical density of interaction absorption, by the equation

$$D_i(\lambda, C_{III}, C_V) = D(\lambda, C_{III}, C_V) - D(\lambda, C_{III}) - D(\lambda, C_V) \quad (1)$$

In this relation, $D(\lambda, C_{III}, C_V)$ is the observed optical density (corrected to 1.00-cm. path length) of the solution containing the two oxidation states at concentrations C_{III} and C_V; $D(\lambda, C_{III})$ and $D(\lambda, C_V)$ are the absorptions due to the pure components at the same concentrations, C_{III} and C_V, in a solution of hydrochloric acid of the same concentration as the mixture.

We have found that D_i, the optical density of interaction absorption, in solutions of antimony(III) and (V) in concentrated hydrochloric acid is proportional to the product of the concentrations of the antimony(III) and (V)

$$D_i = k_i(\lambda) C_{III} C_V \quad (2)$$

In Fig. 2 it is shown that when D_i for a fixed wave length is plotted as a function of $C_{III}C_V$, a straight line going through the origin is obtained. From a survey of all the data obtained, it appeared that the values of $k_i(\lambda)$ obtained in this way are constant to better than 10% for variations of the $C_{III}C_V$ product of by a factor of 10 or more. The averaged values of $k_i(\lambda)$ obtained from all the data are plotted in Fig. 3; in obtaining these data, the $C_{III}C_V$ factor has been varied from 0.5 to 0.01. The interpretation of the result expressed by eq. (2) will be discussed in a subsequent section.

One qualitative observation that is of importance for this subsequent discussion is that when a strongly colored mixed solution of antimony(III) and (V) in concentrated hydrochloric acid is cooled to −80° it remains liquid and there is no change perceptible to the eye in the color of the system.

The extinction coefficients of antimony(V) by itself in concentrated hydrochloric acid are independent of concentration—that is, in contrast to the marked optical interaction between antimony(III) and (V) molecules, there is no interaction between antimony(V) molecules. Figure 4 is a logarithmic plot of the extinction coefficients of antimony(V) in concentrated hydrochloric acid The data in the wave-length range 380–440 mμ were obtained with 0.1 and 1.0 *F* Sb(V) solutions using 1 and 10-mm. path lengths and the observed extinction coefficients were constant to ±3%. The optical densities of 0.3 and 0.5 *F* antimony(III) solutions were also observed, and these indicate that this species also obeys Beer's law. The extinction coefficients for antimony(III) are also plotted in Fig. 4.

As reported subsequently, antimony(V) solutions in 3.5 *F* hydrochloric acid are colorless; we have examined the hypothesis that the yellow color of antimony(V) in concentrated hydrochloric acid is really interaction absorption due to the formation of some antimony(III) by the reaction

$$Sb(V) + 2Cl^- \longrightarrow Sb(III) + Cl_2 \quad (3)$$

(21) Brown and Swift, THIS JOURNAL, **71**, 2717, 2719 (1949); *cf.* Myers and Swift, *ibid.*, **70**, 1047 (1948).

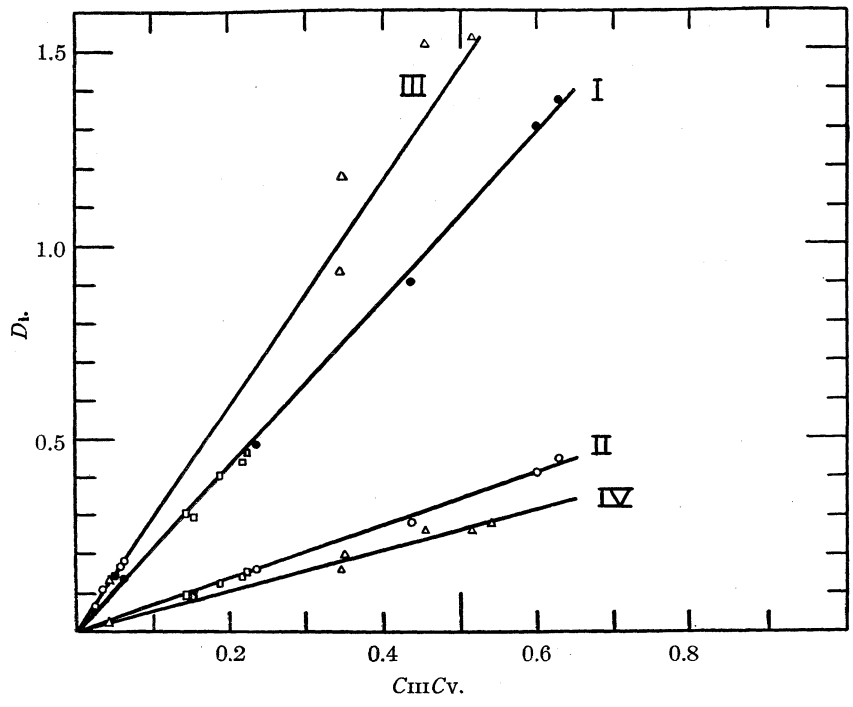

Fig. 2.—Interaction absorption, D_i, as a function of the $C_{III}C_V$ product: I, λ = 440 mμ, abscissa, 10 $C_{III}C_V$; □, total Sb = 0.3 *F*, 11.3 *F* HCl; ●, total Sb = 0.5 *F*, 10.0 *F* HCl. II, λ = 475 mμ, abscissa, 10 $C_{III}C_V$; □, total Sb = 0.3 *F*, 11.3 *F* HCl; ○, total Sb = 0.5 *F*, 10.0 *F* HCl. III, λ = 500 mμ, abscissa, $C_{III}C_V$; ○, total Sb = 0.5 *F*, 10.0 *F* HCl; △, total Sb = 1.5 *F*, 10.3 *F* HCl. IV, λ = 550 mμ, abscissa, $C_{III}C_V$; △, total Sb = 1.5 *F*, 10.3 *F* HCl.

If this were the case, the effect of the addition of chlorine would be to reverse (3), decreasing the concentration of antimony(III) and decreasing the color. Figure 5 shows that the spectrum of a 0.3 *F* antimony(V) solution saturated with chlorine is the sum of the absorption spectra of the chlorine and the antimony(V). We conclude that reaction (3) is not the cause of the color of antimony(V) in concentrated hydrochloric acid; this color is characteristic of an antimony-(V)-containing ion.

Spectrophotometric Results for Antimony Solutions in 3.5 *F* Hydrochloric Acid.—As shown in Fig. 4, the extinction coefficients of antimony(III) in 3.5 *F* hydrochloric acid are independent of the antimony concentration and the same as those observed for antimony(III) in concentrated hydrochloric acid.

The extinction coefficients of antimony(V) in 3.5 *F* hydrochloric acid are dependent on a large number of variables—the time after preparation or dilution of the solution, the concentration of the antimony(V), and the presence of other ions in the solution.

We will first present the results for antimony(V) solutions that have stood long enough so that their properties are no longer a function of time. In Fig. 6, the apparent extinction coefficients of a series of such solutions are plotted as a function of the antimony concentration. For antimony concentrations greater than 0.3 *F*, the data fit an equation of the type

$$\epsilon(\lambda) = a(\lambda)c^n \qquad (4)$$

where n has values slightly greater than 2 for the wave lengths 330, 340 and 350 mμ.

As illustrated in Fig. 6 and Table I, the extinction coefficients of antimony(V) at a concentration of 0.1–0.2 *F* are not independent of concentration but they do not change so violently with concentration as is the case at the higher concentrations.

In the same table there are presented a series of data which illustrate the effect of added ammonium perchlorate, perchloric acid and ammonium chloride. It is seen that ammonium chloride has a more marked effect on the extinction coefficients of the antimony(V) than do ammonium perchlorate or perchloric acid.

The variable extinction coefficients of antimony(V) in 3.5 *F* hydrochloric acid as a function of antimony concentration or of chloride concentration show that more than one kind of antimony(V) complex ion with water, hydroxide and chloride exists in appreciable concentration in this medium. The equilibria among the different kinds of antimony ions are established slowly.

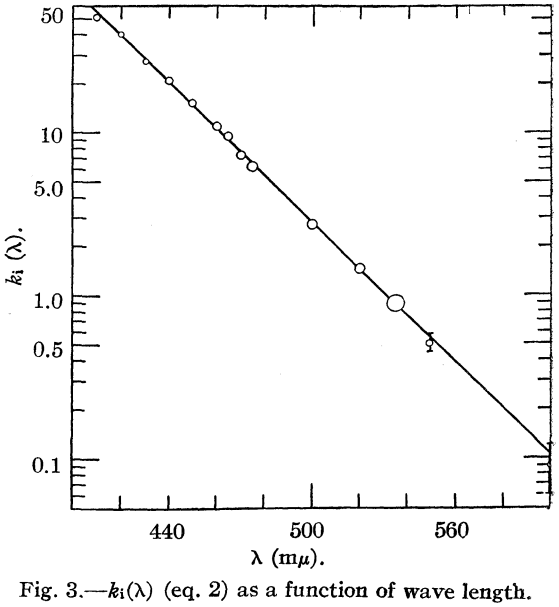

Fig. 3.—$k_i(\lambda)$ (eq. 2) as a function of wave length.

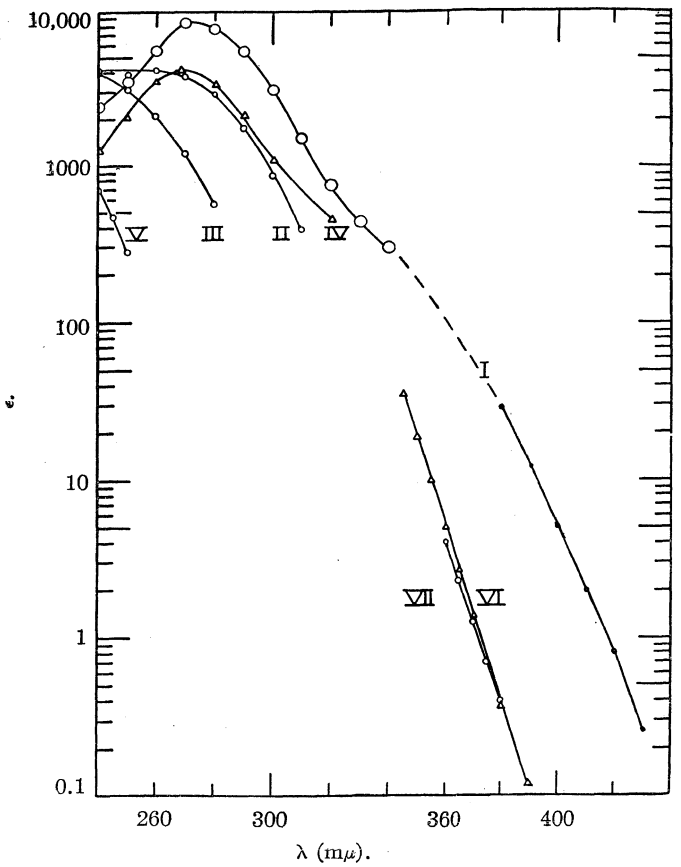

Fig. 4.—The extinction coefficients of Sb(III) and Sb(V) in various concentrations of HCl. I, Sb(V) in concentrated HCl.[a] II, 1.47×10^{-4} *F* Sb(V) in 6 *F* HCl immediately on dilution from 1.5 *F* Sb(V) in concentrated HCl. III, solution of curve II, 4 days after dilution. IV, 1.47×10^{-4} *F* Sb(V) in 3.5 *F* HCl, 3 hours after dilution from 1.5 *F* Sb(V) in concentrated HCl. V, solution of curve IV, 4 days after dilution. VI, Sb(III) in 11 *F* HCl.[b] VII, Sb(III) in 3.5 *F* HCl.[c]

[a] ○, 1.47×10^{-4} *F* Sb(V) in 11.6 *F* HCl; ●, the data were obtained for 0.10 to 1.0 *F* Sb(V) solutions in 10.5 *F* HCl, and agreed to ±3%.
[b] Data for 0.30 and 0.50 *F* Sb(III) solutions agreed to 4%.
[c] Data for 0.30 and 0.90 *F* Sb(III) solutions agreed to 10%.

When a concentrated antimony(V) solution (*ca.* 1.5 *F*) in concentrated hydrochloric acid is diluted to become a 0.5 *F* antimony solution in 3.5 *F* hydrochloric acid, the pale yellow color that is characteristic of the antimony(V) in concentrated acid slowly fades and it requires over five hours for the color to disappear completely. In Fig. 4 Curves II–V show a similar phenomenon for the dilution of antimony(V) solutions in concentrated hydrochloric acid to give *ca.* 10^{-4} *F* Sb(V) solutions in 6 and 3.5 *F* HCl. When a concentrated (1.0 *F*) antimony(V) solution in 3.5 hydrochloric acid is diluted with 3.5 *F* hydrochloric acid to an antimony formality of 0.3, the extinction coefficients observed shortly after dilution are intermediate between those of 1.0 *F* and 0.3 *F* antimony (Fig. 6). After a time of sixteen hours equilibrium apparently has been reached. We have not attempted to follow the behavior with time of these systems more closely.

Mixed solutions of antimony(V) and antimony(III) in 3.5 *F* hydrochloric acid that have stood for a while do not show the pronounced interaction absorption that occurs in concentrated acid. Table II lists some optical densities for a mixture containing 0.4 *F* antimony(V) and (III). These values are somewhat (but not spectacularly) greater than the sums of the optical densities of separate 0.4 *F* antimony(V) and (III) solutions. However, the extinction coefficients of antimony(V) are a function of the antimony(V) concentration, due perhaps to polymerization, to ionic strength effects, or to chloride supplied by hydrolysis of antimony pentachloride. In Table II, the special interaction between antimony(V) and (III) in 3.5 hydrochloric acid has been evaluated by assuming that the extinction coefficients of 0.4 *F* antimony(V) in the presence of 0.4 *F* antimony(III) are the same as the extinction coefficients of a 0.8 *F* antimony(V) solution. The resulting D_i's are quite small. We may therefore conclude that there may be weak "interaction absorption" of mixtures of antimony(V) and (III) in 3.5 *F* hydrochloric acid, but that this is of the same order of magnitude as the effect of other perturbations, such as ionic strength, added chloride, or other antimony(V)-containing molecules, on the absorption spectrum of antimony(V).

TABLE I

THE EXTINCTION COEFFICIENTS OF 0.1–0.2 *F* Sb(V) IN 3.5 *F* HCl IN THE PRESENCE OF VARIOUS OTHER IONS

λ, mμ	0.2 *F* Sb(V)	0.1 *F* Sb(V) 0.65 *F* NH_4Cl	0.1 *F* Sb(V) 0.5 *F* $HClO_4$	0.1 *F* Sb(V) 0.5 *F* NH_4ClO_4	0.1 *F* Sb(V)

330	1.36				1.12

TABLE II

THE ABSORPTION SPECTRUM OF A MIXED Sb(III) AND Sb(V) SOLUTION IN 3.5 *F* HCl

λ, mμ	D(III + V) 0.4 *F* Sb(III) 0.4 *F* Sb(V)	D(III) 0.4 *F* Sb(III)	D(V)[a]	D_i[b]
370	1.02	0.49	0.57	−0.05
375	0.66	.28	.37	+ .01
380	.45	.16	.24	+ .05
390	.228	.072	.099	+ .057
400	.133	.040	.045	+ .048

[a] D(V) are the calculated optical densities for 0.4 *F* Sb(V) using the extinction coefficients observed for 0.8 *F* Sb(V). [b] $D_i = D(\text{III} + \text{V}) - D(\text{III}) - D(\text{V})$.

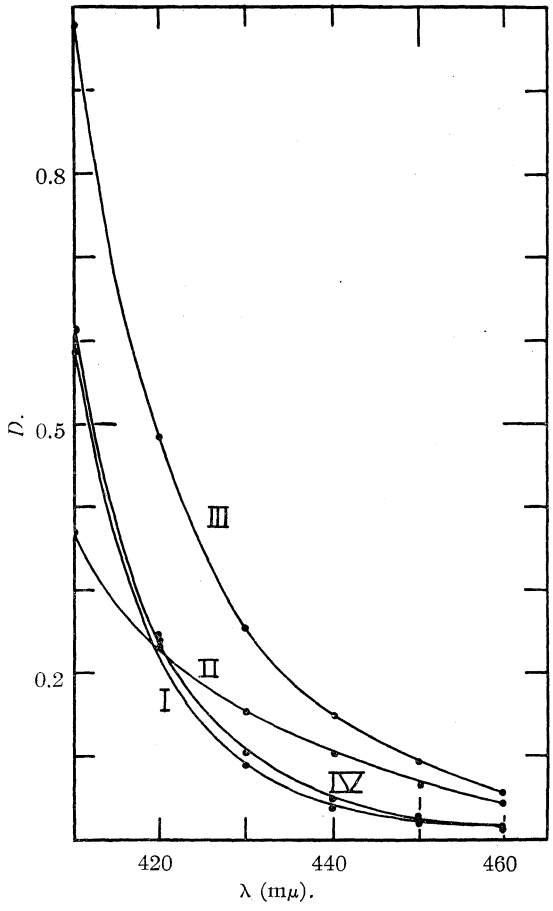

Fig. 5.—The effect of chlorine on the absorption spectrum of Sb(V) in concentrated HCl. I, 0.28 *F* Sb(V) in 11 *F* HCl; II, 11 *F* HCl saturated with Cl_2; III, 0.28 *F* Sb(V) in 11 *F* HCl, saturated with Cl_2; IV, III–II.

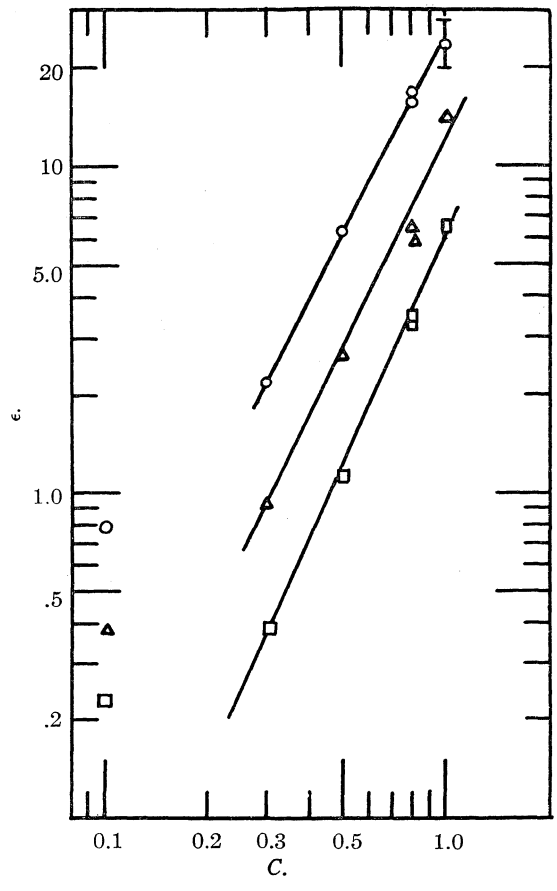

Fig. 6.—The extinction coefficients of Sb(V) in 3.5 *F* HCl as a function of antimony concentration: ○, λ = 330; △, λ = 340; □, λ = 350. The slopes of the three straight lines are: 2.06 (λ = 330), 2.16 (λ = 340), 2.28 (λ = 350).

When a 1:1 mixture of antimony(III) and (V) in concentrated hydrochloric acid at a total antimony concentration of *ca.* 1.5 *F* is diluted to become *ca.* 0.5 *F* in antimony and 3.5 *F* in hydrochloric acid, the interaction absorption color (which is much more intense than that of antimony(V) itself) does not fade immediately but loses its color in a period of about an hour. This indicates that the kind or kinds of antimony(V) molecules which exist in concentrated hydrochloric acid and which interact with the antimony(III) molecules to give rise to interaction absorption are slowly converted into "non-interacting" kinds of antimony(V) molecules in 3.5 *F* hydrochloric acid. The rate of disappearance of the intense "interaction absorption" color was greater than the rate of disappearance of the pale yellow color of antimony(V) in concentrated acid upon dilution.

Brown and Swift,[21] in these Laboratories have reported that when an antimony(III) solution in 3.5 *F* hydrochloric acid is partially oxidized with chlorine, the yellow "interaction absorption" color results but fades upon standing. This indicates that the kind of antimony(V) molecule first formed by reaction of chlorine with antimony(III) is like the antimony(V) present in concentrated hydrochloric acid in that it can give rise to "interaction absorption" and in that it is slowly hydrolyzed to a non-interacting form.

When a solution of antimony(V) in 3.5 *F* acid is warmed, a pale yellow color develops, and slowly disappears again when the solution has cooled. The more intense interaction absorption may also be reversibly generated by heating a mixed solution of antimony(III) and (V) in dilute acid.

Spectrophotometry of Tin and Arsenic Solutions.—We have investigated the absorption spectra of mixed tin(II) and (IV) and mixed arsenic(III) and (IV) solutions in concentrated hydrochloric acid. Figure 7 shows that there is marked interaction absorption for the tin mixture,[22] but that there is no marked interaction absorption for the mixed arsenic solution.

The interaction absorption for the mixed tin solution occurs in the near ultraviolet and is barely perceptible to the eye. This is presumably

(22) A more detailed study of this case has been made by Mr. C. I. Browne of these Laboratories, and will be reported shortly.

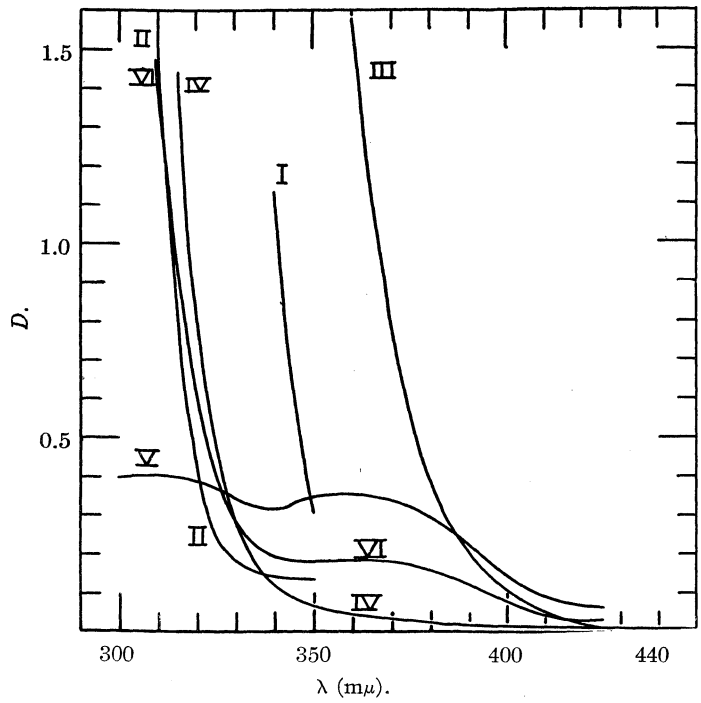

Fig. 7.—The absorption spectra of mixed As(III) and As(V), and of mixed Sn(II) and Sn(IV) solutions in concentrated HCl: I, 0.84 *F* Sn (II); II, 0.84 *F* Sn(IV); III, 0.42 *F* Sn(II), 0.42 *F* Sn(IV); I, II, III in 11.6 *F* HCl. IV, 0.76 *F* As(III); V, 0.76 *F* As(V)[a]; VI, 0.38 *F* As(III), 0.38 *F* As(V); IV, V, VI in 11.3 *F* HCl.

[a] Additional data not plotted for the As(V) solution are:

λ (mμ)	250	260	270	275
D	1.56	1.01	0.700	0.596

the reason why it has not been previously reported.

Discussion and Interpretation.—The fact expressed by equation (2) that in concentrated hydrochloric acid the optical density of interaction absorption is proportional to the product of the concentrations of the antimony(III) and (V) implies that the absorbing species is a dimeric complex containing one antimony(III) and one antimony(V). That is, the equilibrium involved in the formation of the absorbing species is of the type

$$Sb(III)Cl_4^- + Sb(V)Cl_6^- \rightleftarrows Sb_2Cl_{10}^= \quad (5)$$

$$C(Sb_2Cl_{10}^=) = KC_{III}C_V \quad (6)$$

rather than the type

$$2Cl^- + Sb(III)Cl_4^- + Sb(V)Cl_6^- \rightleftarrows 2Sb(IV)Cl_6^= \quad (7)$$

$$C(Sb(IV)Cl_6^=) = \sqrt{K'C_{III}C_V} \quad (8)$$

The equilibrium equations (6) and (8) should of course be written with activities instead of concentrations. That equation (2) fits the data so well indicates that in concentrated hydrochloric acid the appropriate activity coefficient product involving the activity coefficients of antimony(III) and (V) and of the dimer are to a good approximation independent of the total antimony concentration even when this is as high as 1.5 *F*.

The similarity of the absorption spectra of antimony(III) in 3.5 *F* and 11 *F* hydrochloric acid indicates that this component exists mainly in the same form at both acidities; this is usually assumed to be the $SbCl_4^-$ ion.

We assume that the pale yellow form of antimony(V) in concentrated hydrochloric acid is the $SbCl_6^-$ ion. The spectrophotometric data indicate that in 3.5 *F* hydrochloric acid, the $SbCl_6^-$ ion undergoes a slow hydrolysis to a less colored ion

$$SbCl_6^- + xH_2O = SbCl_{6-x}(OH)_x^- + xH^+ + xCl^- \quad (9)$$

The qualitative observation of the effect of temperature on the color of antimony(V) in 3.5 *F* hydrochloric acid suggests that reaction (9) is exothermic. As noted below, the hydrolyzed ion, $SbCl_{6-x}(OH)_x$, may be in part polymerized. It may of course also be neutralized by attachment of H^+.

The qualitative observation that on dilution from concentrated acid, interaction absorption in a mixture of antimony(III) and (V) fades more rapidly than does the pale yellow color of the $SbCl_6^-$ ion suggests that reaction (9) proceeds in several steps and that in the first of these the antimony(V) is converted to a form which is itself still colored but which is incapable of interacting with the antimony(III) to give interaction absorption; in a later step, the non-interacting but colored form of antimony(V) is further hydrolyzed to a colorless form. Because the relative rates of fading of "interaction" color and "antimony(V)" color have only been casually observed and not carefully studied, this interpretation must be regarded as a suggestion rather than a conclusion.

Brown and Swift[21] have also suggested equilibria of the type embodied in equations (5) and (9) in order to interpret their results on the electrochemical properties of the antimony(III)–(V) couple.

The variation of the optical density of antimony(V) solutions in 3.5 *F* hydrochloric acid with antimony concentration described by eq. (4) could be explained by a polymerization of the type

$$3Sb(OH)_6Cl_{6-x}^- \rightleftarrows (Sb(OH)_6Cl_{6-x})_3^{-3} \quad (10)$$

It is unlikely that this simple explanation is valid in view of the marked effect of other variables, chloride concentration, acidity, and ionic strength on the spectrum of antimony(V) in 3.5 *F* acid. It may even be that the variation with antimony concentration of the extinction coefficients of antimony(V) in 3.5 *F* hydrochloric acid is due simply to a shift in the equilibrium of eq. (9) due to changes in the free chloride concentration, the

acidity, and the ionic strength associated with changes in the antimony concentration.

The explanation of interaction absorption in terms of eq. (5) is in accordance with the properties of the intensely black solids, Rb_2SbCl_6, Cs_2SbCl_6, and $(NH_4)_2SbBr_6$.[23,24,25] These substances are formally compounds of antimony(IV). X-Ray analysis shows that they have the K_2SnCl_6 structure, and therefore contain crystallographically equivalent $SbX_6^=$ octahedra, in which each antimony atom is separated from neighboring antimony atoms by two non-bonded halogen atoms. However, these substances are diamagnetic; they do not contain independent $Sb(IV)Cl_6^=$ groups each having an odd electron and being paramagnetic. In the crystal, a $SbCl_6$ octahedron can interact with 12 equivalent neighboring octahedra. In solution, two antimonys must interact in a similar way; by analogy with the solids, we need not suppose that there is any halogen bridging involved in the dimerization in solution.

The fact that the data are satisfied by eq. (2) and do not require an equation of the type $C_D = K(C_{III} - C_D)(C_V - C_D)$ (where C_D is the concentration of interaction dimer) indicates that even in 1:1 mixed solutions that are 1.5 F in total antimony, the dimeric complex does not contain over 10–20% of the antimony. The comparatively weak color of the mixed solutions as compared to the intense black of the crystals suggests that the concentration of the dimeric "interaction" complex in solution is quite low.

It is probable that resonance between structures of the type ($Sb(V)X_6^-$, $Sb(III)X_6^=$) and ($Sb(III)X_6^=$, $Sb(V)X_6^-$) is of importance for the structure of solid M_2SbX_6 compounds and for the structure of the dimer in solution. Jensen has discussed in more detail the kinds of structure which will allow electrons to be passed back and forth between antimony atoms.[25] It is evident from the results in 3.5 F acid, that substitution of halogen coördination by oxygen coördination (of water or hydroxide) decreases the tendency for colored complexes of this type to form. This may be the reason why no interaction absorption was observed for the arsenic case—since it is generally believed that arsenic acid, H_3AsO_4, like phosphoric acid, is not converted to a chloroarsenic acid in concentrated hydrochloric acid. It is reasonable to assume that the positive effect observed for the tin solutions is due to interaction between chloro complexes of tin(II) and (IV).

The observation that cooling to −80° had no perceptible effect on the interaction absorption of a solution of antimony(III) and (V) in concentrated hydrochloric acid implies that there is very little heat for reaction (5). Since the entropy change in a dimerization reaction is usually negative, one would therefore expect the dimeric interaction complex not to be very stable. The M_2SbX_6 compounds are not very stable either and often decompose on attempted recrystallization. It may be that the interaction dimer is not at all a stable complex in solution but that it is "collision complex" which is formed for a very short period of time whenever an $Sb(V)Cl_6^-$ ion and an $Sb(III)Cl_4^-$ (or $Sb(III)Cl_6^=$??) ion come close to each other in solution.

The following calculation is intended to indicate the plausibility of this suggestion. In the crystal of Rb_2SbCl_6, the Sb–Sb distance for neighboring $SbCl_6$ octahedra is 7.25 Å.[25] This corresponds to the closest possible distance of approach of 2 $SbCl_6$ octahedra, because in the crystal the Cl–Cl distance for chlorine atoms of neighboring octahedra is 3.6 Å., which is twice the ionic or Van der Waals radius of chlorine. If now we consider that for a given $Sb(V)Cl_6^-$ in solution, any $Sb(III)Cl_4^-$ (or $Sb(III)Cl_6^=$) ion that approaches within 7.25 to 7.35 Å. will have formed a "collision complex" with the $Sb(V)Cl_6^-$ ion, the volume of solution that could be occupied by the antimony(III) molecule while interacting with the antimony(V) molecule is $4\pi \times 7.30^2 \times 0.10 = 67$ Å.^{3} The total available volume per molecule in a 1 mole/liter solution is 1660 cu. Å. (neglecting the molal volume of the solute for this rough calculation). Therefore if there were no attractive or repulsive forces between the Sb(III) and Sb(V) molecules (other than a repulsive force on contact) the fraction of 67/1660 = 0.04 of the Sb(V) molecules in a 1 F Sb(III) solution would have Sb(III) molecules within 0.1 Å. of the distance of approach of SbX_6 octahedra in the crystal. A concentration of this order of magnitude for a strongly colored dimer could account for the observed color of the mixed solutions.

If there is no marked energy of interaction in the ground state between $Sb(V)X_6^-$ and $Sb(III)X_6^=$ in the crystal or in the solution, then the marked effect on the absorption spectrum of the system can be explained as being due to a strong interaction in the optically excited states of the system. A further discussion of this idea will be contained in subsequent contributions on this general subject.

Acknowledgment.—This research has been supported in part by the Office of Naval Research. Mr. A. E. Larsh, Jr., is responsible for many of the measurements on solutions in 3.5 F acid and has assisted us in other ways. Mr. W. Wooster has generously carried out the antimony analyses. We have profited from discussions on this subject with Mr. R. Brown, Mr. H. McConnell, Professor L. Pauling and Professor E. H. Swift, all of this Laboratory. We are indebted to Professor Dan H. Campbell for many kindnesses in connection with the use of the spectrophotometer.

Summary

The absorption spectra of mixed antimony(III)

(23) Elliott, *J. Chem. Phys.*, **2**, 298 (1934).

(25) Jensen, *Z. anorg. allgem. Chem.*, **232**, 193 (1937); **252**, 317 (1944).

and antimony(V) solutions, of mixed tin(II) and tin(IV) solutions, and of mixed arsenic(III) and arsenic(V) solutions, all in hydrochloric acid, have been studied. The first two systems in solution in concentrated hydrochloric acid exhibit the phenomenon of "interaction absorption."

The optical density of interaction absorption for the mixed antimony solutions is proportional to the product of the concentrations of the antimony(III) and antimony(V) implying that the absorbing species is a dimeric complex containing one Sb(III) and one Sb(V). In 3.5 *F* hydrochloric acid, there is no marked interaction absorption.

The spectroscopic results indicate that Sb(III) exists as the same ion or molecule in concentrated and 3.5 *F* hydrochloric acid but that Sb(V) undergoes hydrolysis from an ion like $SbCl_6^-$ to an ion of the type $SbCl_x(OH)_{6-x}^-$ as the hydrochloric acid concentration is decreased from *ca.* 11 *F* to 3.5 *F*.

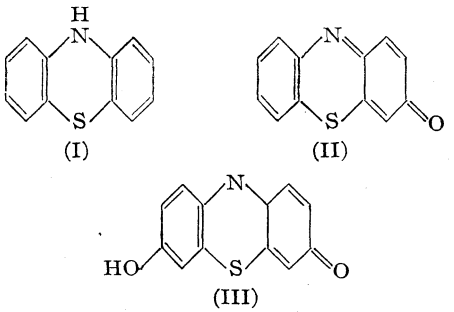
Phenothiazine Derivatives: Mono-oxygenated Compounds

BY DAVID F. HOUSTON, E. B. KESTER AND FLOYD DEEDS

Phenothiazine (I) has been shown[2] to have *in vitro* tuberculostatic action which is somewhat diminished in the presence of serum. The oxidized derivatives known as phenothiazone (II) and thionol (III) also showed a moderate inhibiting effect, and it was postulated that their lesser effectiveness might be connected with their decreased solubility in lipids. Compounds having



substituents on the nitrogen were relatively ineffective, suggesting that the nitrogen should be free to take part in oxidation–reduction effects.

The indications are, therefore, that compounds related to phenothiazine and thionol which have unsubstituted nitrogen atoms and increased lipid solubilities might show greater tuberculostatic action. A number of compounds meeting these requirements have been synthesized, and this paper reports a series of ethers related to phenothiazone.[3]

Phenothiazone-3 was first prepared as a noncrystalline compound by Bernthsen[4] by fusion of *p*-hydroxydiphenylamine with two atoms of sulfur, recovery as 3-hydroxyphenothiazine, and oxidation with ferric chloride. Kehrmann[5] later obtained it as a crystalline product, melting at 165–166°, by ferric chloride oxidation of phenothiazine in hot aqueous alcohol. A convenient modification of this method by Pummerer and Gassner[6] gave a product melting at 162–163°. A reported improvement of this process is the subject of a recent patent.[7] The crude product is recrystallized and 45% of phenothiazone-3 melting at 163–164° is obtained. Similarly, Granick, Michaelis and Schubert[8] recrystallized the product from the reaction and found a melting point of 161°. Small-scale experiments in this Laboratory have given yields up to 62.5%, though the reaction was very susceptible to changes in process conditions.

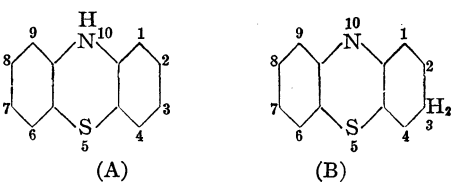
(3) The awkwardness in naming derivatives of phenothiazine and related compounds has been pointed out by Michaelis and co-workers [THIS JOURNAL, **62**, 1802 (1940), and **63**, 351 (1941)], who also emphasized that the difficulties were greater with the quinonimine or oxidized form than with the hydroxyamine or reduced form. This trouble is largely overcome, however, by basing names of reduced-from compounds on the phenothiazine skeleton A (Ring Index No. 1860) and those of oxidized-form compounds on the theoretical 3-isophenothiazine skeleton B (Ring Index No. 1859).



Although this has the disadvantage of naming the reduced and oxidized forms of a compound on the basis of two isomeric ring skeletons, it offers a systematic nomenclature for phenothiazine derivatives that conforms with the present usage of *Chemical Abstracts*. The disadvantage has been avoided, at least in part, in this paper by the common use of the term phenothiazine (Skeleton A) to denote the parent compound of derivatives of the reduced form, and phenothiazone-3 instead of 3-isophenothiazine-3-one (from Skeleton B) as the parent compound for derivatives of the oxidized form.

For the preparation of larger quantities, attention was turned to fusion experiments. Preliminary fusions of aniline, hydroquinone and sulfur[9] were unpromising. The preparation according to Bernthsen[4] proceeded rapidly and smoothly at 185–195° when catalyzed with iodine. Reaction was complete within a half hour, and phenothiazone-3 was consistently recovered in 41–47% yield. Recovery consisted in aeration of a suspension of the ground product in dilute aqueous alkali, and extraction of the phenothiazone-3 from the dried insoluble solids with hexane. Methods of recovery have been incompletely explored, and higher yields may be possible.

The isopropyl, octyl, dodecyl and hexadecyl ethers of 3-hydroxyphenothiazine were similarly prepared from the corresponding *p*-alkoxydiphenylamines, which were readily formed by etherification of *p*-hydroxydiphenylamine.[10] The methyl ether has previously been prepared by this fusion process by Baltzly, Harfenist and Webb[11] and by Gilman and Shirley.[12] Agreement between properties of the compounds so prepared with those of the product from methylation of 3-hydroxyphenothiazine by dimethyl sulfate[6] confirms the position of the ether group.

Sulfur fusions proceeded more smoothly with the ethers than with the free hydroxyl compound, and gave the *n*-alkoxyphenothiazines as light yellow solids in 80–84% yields. The 3-isopropoxy ether was obtained in 60% yields; more vigorous fusion conditions led to some decomposition.

The 3-alkoxyphenothiazines are insoluble in water and appreciably more soluble in organic solvents than is phenothiazone-3. They are readily susceptible to oxidation and tend to discolor when exposed to light and air. Their similarity in structure to that of phenothiazine is indicated from the similarity of the ultraviolet absorption curves.

Ultraviolet and visible absorptions of a number of compounds have been measured for control and comparison purposes. The differences between the absorption curves for phenothiazine (maxima at 254 and 318 mμ, inflection at 285), phenothiazine-5-oxide (228, 272, 302, 337 mμ) and phenothiazone-3 (236, 273, 357, 505 mμ)—all in methanol—are shown in Fig. 1. Substitution of a hydrocarbon or ether group for the hydrogen at the 3-position of phenothiazine caused only slight changes in the absorption in the range covered (maxima for 3-methylphenothiazine at 255 and 320 mμ; see also Table I). However, indications point to differences at lower wave lengths.

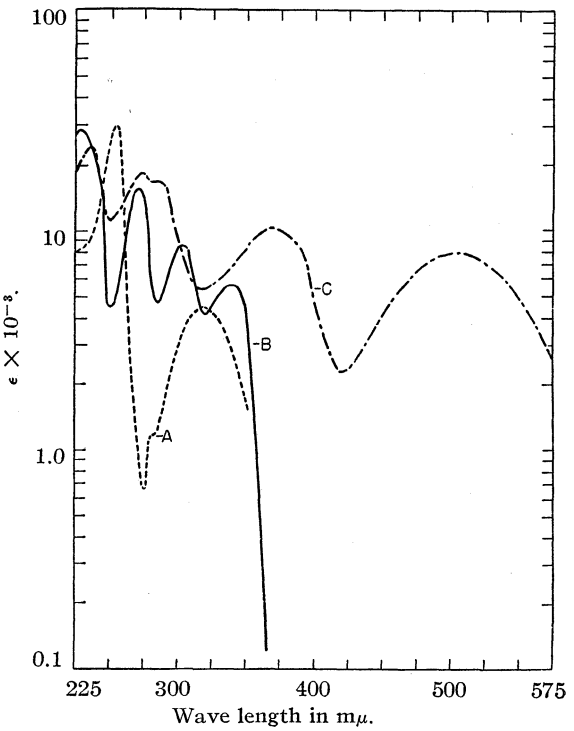

Fig. 1.—Molar extinction curves in absolute methanol (measured on solutions containing 3 to 10γ of solute per ml. of solution): (A) phenothiazine; (B) phenothiazine-5-oxide; (C) phenothiazone-3.

Phenothiazine had essentially the same maxima in isoöctane (254, 315 mμ) as in methanol. Phenothiazone-3, however, showed considerable shift with change in solvents as measured in the visible range.[13] The main absorption peak for a series of solvents was located as follows: Skellysolve B[14] (478), ether (482), benzene (490), chloroform (502), methanol (505) and water (533). The absorption of phenothiazone-3 is in agreement with the results of previous investigators.[4,8,15] The tuberculostatic properties of these compounds are the subject of other investigations, and the findings will be reported elsewhere.

Experimental[16]

A. Materials.—Phenothiazine was recrystallized from benzene and washed with commercial hexane before use.

***p*-Hydroxydiphenylamine,**[17] purified by distillation with superheated steam, followed by recrystallization from benzene–hexane,[10] consisted of pearly flakes melting at 69–70° in agreement with the reported[18] value of 70°.

(13) Measurements were made with a Hardy–General Electric Recording Spectrophotometer.

(14) Skellysolve B is named as part of the experimental conditions. Its use does not imply recommendation over other solvents having the same properties.

TABLE I

3-ALKOXYPHENOTHIAZINES

R in formula $C_{12}H_8NOSR$[a]	M. p., °C.	Empirical formula	Analytical data, % Carbon Calcd.	Carbon Found	Hydrogen Calcd.	Hydrogen Found	Nitrogen Calcd.	Nitrogen Found	Absorption maxima mμ
Isopropyl	123.0–123.7	$C_{15}H_{15}NOS$	70.00	70.2	5.88	5.88	5.44	5.46	255, 320
n-Octyl	110.1–111.5	$C_{20}H_{25}NOS$	73.35	73.1	7.70	7.52	4.28	4.31	255, 320
n-Dodecyl	101–103	$C_{24}H_{33}NOS$	75.15	75.1	8.67	8.61	3.65	3.65	.....
n-Hexadecyl	101.5–103	$C_{28}H_{41}NOS$	76.48	76.4	9.40	9.30	3.19	3.21	.....

[a] The methoxy compound, $C_{13}H_{11}NOS$, has previously been reported as melting at 158–159,[12] 159,[20] 160–161[11] and 163°.[6] It shows absorption maxima at 254 and 322 mμ in methanol.

p-**Alkoxydiphenylamines** were prepared and purified by methods previously described.[10]

Phenothiazine-5-oxide (sulfoxide) was made according to Pummerer and Gassner.[6]

B. Preparation of Phenothiazone-3 by Oxidation of Phenothiazine.—The best preparation by the method of Pummerer and Gassner[6] confirmed their results; 1.0 g. of phenothiazine yielded 0.67 g. (62.5%) of coppery granular solids that melted at 160.5–162°. The filtrate was digested for one hour on the steam-bath, cooled and filtered. Rusty purple solids weighing 0.29 g. remained.

In other experiments, differing in slight details, the purplish solids formed the main precipitate in yields of 62–96%. A composite sample (2.46 g., 76% yield) was treated by extraction with and precipitation from alcohol (210 cc.) then similarly with water (3000 cc.) according to the purification scheme of Granick, Michaelis and Schubert.[8] The yield was 0.77 g. of phenothiazone-3 (25% based on phenothiazine) melting at 160–161°.

Anal. Calcd. for $C_{12}H_7ONS$: N, 6.57. Found: N, 6.52.

C. Phenothiazone-3 by Sulfur Fusion of *p*-Hydroxydiphenylamine.—Fusion was essentially according to Bernthsen[4] except that iodine was added as catalyst. A mixture of 3.7 g. (0.02 mole) of *p*-hydroxydiphenylamine and 1.4 g. (0.044 g. atom) of sulfur was ground in a mortar and placed in a 50-cc. distilling flask carrying a bubbler tube on the side-arm. Then 0.04 g. of iodine was added, and the flask was stoppered and placed in a metal-bath preheated to 180°. Bath temperature was held at 185–195° during the fifteen to twenty minutes that gas evolution continued, and for an added ten minutes. The reaction mixture was poured into a porcelain dish and allowed to cool. It crystallized in a cake of dark greenish-brown solid which melted at 170–175° (rapid heating in capillary tube, uncorrected). DeEds and Thomas[19] reported a melting point of 172–174° for 3-hydroxyphenothiazine.

The fusion product was ground with 200 cc. of 0.5% potassium hydroxide per gram, aerated for thirty to forty-five minutes, filtered and washed with cold water. The dried solids were extracted with commercial hexane until the extracts were no longer orange. Evaporation of the solvent left a rust-red crystalline residue of phenothiazone-3. Further purification was achieved by crystallization from aqueous alcohol or—for small amounts—from water. The product melted at 161°, and was identical with the phenothiazone from the oxidation reaction. Yields varied from 40–45%.

Anal. Calcd. for $C_{12}H_7ONS$: N, 6.57. Found: N, 6.53.

Use of this recovery process has shown that the reaction is relatively insensitive to a small excess of either reactant.

Phenothiazone-3 can be separated from congeners by adsorption from hexane or benzene solutions on alumina, followed by elution with benzene containing 20% of chloroform. The phenothiazone-3 is collected in the eluate and recrystallized by concentration of the solution. It may be sublimed slowly at boiling xylene temperatures in the vacuum of a mechanical pump.

D. 3-Isopropoxyphenothiazine.—A ground mixture of 4.55 g. (0.02 mole) of *p*-isopropoxydiphenylamine[10] and 1.30 g. (0.041 g. atom) of sulfur was fused with 0.1 g. iodine at 160–170° as for phenothiazone-3. After forty-five minutes the odor of the evolving gases changed from that of hydrogen sulfide to one suggesting organic sulfides, and heating was stopped. The cooled reaction mass was an olive-brown resin which partially crystallized on mechanical working. Extraction of the solids with hexane until extracts were nearly colorless (eleven hours) left 10.5% of insoluble residue. From the solution was obtained 58.5% of clusters of yellow crystals. Evaporation left 26% of reddish oil. The crystals were purified by solution in hot benzene (5 cc./g.), addition of hexane (200 cc./g.) and cooling to 0°. The faintly tan crystalline powder melted at 123.0–123.7°. On exposure to the atmosphere it gradually becomes discolored. Vacuum sublimation at 110° first removes the colored portion. The 3-isopropoxyphenothiazine sublimes very slowly under these conditions.

Aeration for thirty minutes of a suspension of 0.5 g. of the ether in 100 cc. of 0.5% potassium hydroxide, and extraction of the dried insoluble solids with hexane, yielded 0.39 g. composed of phenothiazone-3 and the original ester.

E. 3-*n*-Alkoxyphenothiazines.—These were also prepared by iodine-catalyzed fusion of the appropriate amine with two atom-equivalents of sulfur. At temperatures of 160–170° gas evolution ended in fifty to sixty minutes. No sulfide odors developed. Extraction with and crystallization from hexane gave 80–84% of nearly white powders, and left residues of yellow oil. Melting points and analytical data are collected in Table I.

Acknowledgment.—The authors are indebted to Dr. E. J. Eastmond, Mrs. Bernice Williams and Mr. G. F. Bailey for the measurement of spectral absorptions, to Mr. L. M. White and Miss Geraldine Secor for microchemical analyses, and to Dr. F. T. Jones for microscopical examinations of numerous products.

Summary

Phenothiazone-3 has been prepared by the oxidation of phenothiazine with ferric chloride and by the iodine-catalyzed condensation of *p*-hydroxydiphenylamine with sulfur. Similar condensations of *p*-alkoxydiphenylamines and sulfur have given the isopropyl and the normal octyl, dodecyl and hexadecyl ethers of 3-hydroxyphenothiazine.

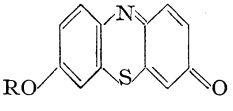
Phenothiazine Derivatives: Di-oxygenated Compounds

BY DAVID F. HOUSTON, E. B. KESTER AND FLOYD DEEDS

The synthesis of phenothiazine derivatives with possible tuberculostatic action[2] has been extended to the preparation of a series of ethers of 7-hydroxyphenothiazone-3[3] or "thionol" (I, R = H), which—from structural considerations—might have improved lipid solubility over the parent compound, and yet retain its oxidation-reduction characteristics. The investigation has been closed with the achievement of a minimum objective and the results are presented in this



I

report, although some experimental procedures are incompletely developed.

Bernthsen[4] prepared 7-hydroxyphenothiazone-3 as early as 1885 by digestion of phenothiazine with sulfuric acid. Oxidation of phenothiazine with hydrogen peroxide and hydrochloric acid[5] gave 7-hydroxyphenothiazone-3 which was found to contain difficullty removable chlorine compounds. In 1940, Granick, Michaelis and Schubert[6] called attention to the difficulty of consistently obtaining this product in suitable yields with satisfactory purity. The original Bernthsen method is exceedingly tedious, and the yields are low and variable. A recent modification[7] in which the desired product is isolated as the sparingly soluble lithium salt (I, R = Li) makes the process much more convenient.

The synthesis of 7-hydroxyphenothiazone-3 by fusion of hydroquinone, *p*-aminophenol and sulfur was patented by Vidal[8] as a dye intermediate, but practically no data on properties were recorded. A product obtained[9] by fusing sulfur with *p,p'*-dihydroxydiphenylamine at 180° did not have the properties of 7-hydroxyphenothiazone-3. The recovery of thionol from the urine of animals dosed with phenothiazine has been summarized by Collier[10] and co-workers.

In general, the high melting point (>360°) and the low solubility of thionol have hindered its purification and characterization.

Published information on ethers of 7-hydroxyphenothiazone-3 appears to be limited to the reported formation[11] of the methyl and ethyl leuco compounds by the fusion of 1:1 molar mixtures of hydroquinone and the appropriate *p*-alkoxyaniline with an excess of sulfur. The compounds were converted directly to sulfur dyestuffs.

In the present investigation, 7-hydroxyphenothiazone-3 was prepared by two methods. The first was a modification of Schneider's[9] process, in which iodine was used as a catalyst. The *p,p'*-dihydroxydiphenylamine was prepared according to Knoevenagel and Berlin[12] by condensing two molecules of *p*-aminophenol in the presence of iodine. The purified amine was then fused with sulfur, using an iodine catalyst, to form 3,7-dihydroxyphenothiazine (leucothionol). Solution of the reaction product in dilute alkali afforded the oxidized form, which was precipitated as the lithium salt and subjected to recrystallization. This material represented a 36% yield, and gave chloroform extracts having the visible absorption spectrum characteristic of 7-hydroxyphenothiazone-3. There was still present, however, a congener that was obstinately retained with the desired product. Further investigation may provide a way of capitalizing on this apparently good yield.

The second method of preparation was the lithium salt procedure of Granick and Michaelis.[7] Application of the process in this Laboratory gave somewhat lower yields of the lithium salt than the reported 8%, likely because of differences in experimental details. Further investigation showed that the yield increased as the reaction time at 160–165° was shortened, until a six-hour sulfuric acid digestion of phenothiazine gave 15% of the lithium salt. Shorter digestion periods gave very low yields. Sulfuric acid digestions at 155° with acid of various concentrations gave low yields and poor separations. At temperatures of 172–175° yields were again lower than at 160–165°, and decreased as acid concentration increased. Acid concentrations of 75 to 90% were most favorable at 160–165°, and 80% acid was generally used. The use of commercial phenothiazine melting at 174–178° gave apparently as good yields as did purified phenothiazine melting at 182.5–183.5°. However, lower yields of purified alkyl ethers resulted from the lower-melting phenothiazine. Recrystallizations of the

product from boiling glacial acetic acid yielded crystalline 7-hydroxyphenothiazone-3 which had optical and crystallographic properties in agreement with those of Granick and Michaelis' product.[13] This method was used to provide the needed amounts of 7-hydroxyphenothiazone-3 and its lithium salt.

The ethyl, amyl, octyl, dodecyl and hexadecyl ethers have been prepared by the reaction between the silver salt of thionol and the proper *n*-alkyl iodides in refluxing benzene. Bromides proved unsatisfactory. In most cases, the silver salt was made directly from the precipitated lithium salt by treatment with silver nitrate solution. Purification was achieved by chromatographing the benzene solution of the ether on alumina, eluting with benzene–chloroform mixtures, removing all volatile material (finally in vacuum), and crystallizing from hexane–benzene or acetone.

Absorption spectra of solutions of the ethers were nearly identical, though the orange-to-rust-red colors of the crystals changed appreciably with size and shape. Some evidence points toward polymorphism, although this may be induced by residual impurities. For example, crystallization of the octyl ether in one case yielded both chunky garnet-red crystals and spherulitic clusters of orange needles. Microscopical examination showed the two forms were very similar optically and crystallized from melts in apparently identical forms. The orange needles seemed to change to the darker form below the melting point.

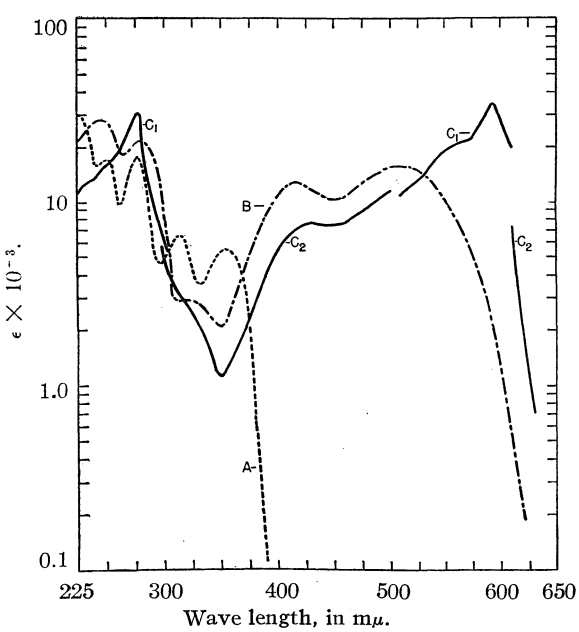

Fig. 1.—Molar extinction curves in absolute methanol: (A) 3-*n*-octoxyphenothiazine-5-oxide (2.33γ/ml.); (B) 7-*n*-octoxyphenothiazone-3 (4.33γ/ml.); (C_1 − C_2) 7-hydroxyphenothiazone-3 (C_1 = 0.588γ/ml.; C_2 = 2.94γ/ml.).

(13) A sample for comparison was kindly supplied by Dr. Granick.

An attempted formation of 7-*n*-octoxyphenothiazone-3 by ferric chloride oxidation of 3-*n*-octoxyphenothiazine[2] according to the method of preparing phenothiazone-3 from phenothiazine[14] caused hydrolysis of the ether linkage and yielded chiefly phenothiazone-3. Traces of 7-hydroxyphenothiazone-3 were noted, but no octoxy compound. Reaction of 3-octoxyphenothiazine with alkaline solutions of hydrogen peroxide effectively oxidized the sulfur atom, yielding 3-octoxyphenothiazine-5-oxide. This type of di-oxygenated derivative shows sensitivity to light and air similar to that of 3-alkoxyphenothiazines.

Spectral Absorptions.[15]—Granick and Michaelis[7] have recently published data on the spectral absorption of 7-hydroxyphenothiazone-3 and its semiquinone form. Lipson[16] has recorded absorption peaks at 552 and 500–510 mμ for an ethanol solution of 7-hydroxyphenothiazone-3, recovered from the urine of sheep treated with phenothiazine. Collier and co-workers,[10] discussing the spectrometry of phenothiazine derivatives in animal experimentation, pointed out that the peak at 552 mμ was due to the semiquinone form of phenothiazone-3.

The spectral absorption of thionol prepared in this work is in agreement with the results of Granick and Michaelis. This was conclusively shown by the identity of absorption curves obtained on methanol solutions of the two preparations. It is of further interest to note that the sharp peak at 590 mμ for these preparations in 0.01 *N* alkali is concordant with the predicted peak at 587 ± 3 mμ calculated by the rules of Lewis.[17] The visible absorption maxima of 7-hydroxyphenothiazone-3 shift with solvent (411, 502 mμ in chloroform and 424, 518 in methanol), and the absorption shows some deviation from Beer's law. This deviation is consistent with the similar characteristics of methylene blue and thionine,[18,19] amino analogs of thionol. Absorption curves for representative di-oxygenated compounds are shown in Fig. 1.

Tuberculostatic properties are being investigated by other workers and will be reported in a separate publication.

Experimental[20]

Materials.—Phenothiazine was purified by crystallization from toluene, followed by washing with hexane.

Sublimed sulfur (U. S. P.) was used in fusions. *p,p'*-Dihydroxydiphenylamine prepared according to Knoevenagel[12] melted at 167.5–168.5° in agreement with 169° reported by him. Ethyl and amyl iodides, amyl, octyl, dodecyl and hexadecyl bromides were reagent grade chemicals boiling within two-degree ranges, and were used as received. Octyl, dodecyl and hexadecyl iodides were prepared by treating the corresponding bromides with sodium iodide in refluxing acetone. The octyl and dodecyl iodides were distilled at reduced pressures, and hexadecyl iodide was recrystallized at 0° from alcohol–benzene to a melting point of 22°.

Oxidation of 3-Alkoxyphenothiazines.—(a) A 0.5-g. portion of 3-isopropoxyphenothiazine[2] was suspended in 100 cc. of 0.5% potassium hydroxide and aerated for thirty minutes. Filtration yielded rust-brown solids. A chloroform extract showed the absorption spectrum of phenothiazone-3, and recrystallization gave brick-red crystals, m. p. 158–161° (uncor.). Phenothiazone-3 melts at 161–162°. The original purple alkali solution suggested 7-hydroxyphenothiazone-3, but none was found.

(b) Oxidation of 0.5 g. of 3-*n*-octoxyphenothiazine[2] by the ferric chloride–hydrogen peroxide procedure of Pummerer and Gassner[14] resulted in a marked odor of *n*-octanol and yielded 0.34 g. of crude phenothiazone-3. Extraction with hexane gave 0.24 g. (75% on original ether) melting at 157.5–160.5° (uncor.). Chromatographing a benzene solution of this material on Alorco F-20 alumina and eluting with benzene–chloroform provided 0.2 g. of phenothiazone-3, m. p. 160–161°. Indications were obtained of a trace of 7-hydroxyphenothiazone-3.

(c) A solution of 0.5 g. of 3-octoxyphenothiazine in 20 cc. of 1% alcoholic potassium hydroxide was treated on the steam-bath with 0.5 cc. of 30% hydrogen peroxide, and with a further 0.5 cc. after one-half hour. During the two-hour heating, the original brown color changed gradually to a pale yellow with a green fluorescence. Crystallization at 0° from the reaction solution yielded 0.42 g. of light yellow solid, m. p. 166° (uncor.). Recrystallization from acetone gave 0.28 g. (53.5%) of platelets, m. p. 168.2–168.7° (dec.). This type of oxidation is common in converting sulfides to sulfoxides; the analysis corresponds to 3-*n*-octoxyphenothiazine-5-oxide.

Anal. Calcd. for $C_{20}H_{25}NO_2S$: C, 69.93; H, 7.34; N, 4.08. Found: C, 69.6; H, 7.25; N, 4.06.

7-Hydroxyphenothiazone-3. (a) Bernthsen Synthesis.[4]—The digestion of 50.0 g. of phenothiazine according to Bernthsen's original procedure provided 1.15 g. of crude 7-hydroxyphenothiazone-3. The leuco compound was extracted with ether in a carbon dioxide atmosphere, reoxidized by air in ammonia solution, and crystallized from acetic acid. The product required intensive drying, because of strong retention of moisture, before analyses approximating the theoretical were obtained.

(b) **Lithium Salt Process.**—Application of the method of Granick and Michaelis[7] to 22.0 g. of phenothiazine gave 0.98 g. of lithium thionol (3.8%) instead of the 2.01 g. reported. Liquid temperatures of 160–165° were maintained for twenty-six hours without stirring in a one-liter flask heated with a glass-cloth electric heater. These conditions may have varied from those used by Granick and Michaelis. Their recommended rapid filtration of the sodium carbonate extracts of the product was not achieved.

The lithium salt was extracted with two 100-cc. portions of boiling glacial acetic acid, which on cooling and filtration gave 0.43 g. of crystalline 7-hydroxyphenothiazone-3. Recrystallization provided rosettes of fine brownish-red needles that did not melt at 360°. Drying *in vacuo* over Anhydrone at 78° for ninety hours gave an analytical sample.

Anal. Calcd. for $C_{12}H_7NO_2S$: C, 62.87; H, 3.08; N, 6.11. Found: C, 62.7; H, 2.99; N, 6.07.

In view of the differences in yield, further exploration of reaction conditions was made. The optimum reaction conditions of digestion for about six hours at 160–165° with 75–90% acid gave 15–16% of lithium salt. Separation of hot sodium carbonate extracts with a basket centrifuge was much more convenient than filtration, though the yields were reduced slightly. Mechanical stirring did not increase the yield. The effect of changing the 4% concentration of phenothiazine in the reaction mixture was not investigated.

(c) **Sulfur Fusion Process.**—Equivalent amounts of sulfur (1.28 g., 0.04 atom) and *p,p'*-dihydroxydiphenylamine (4.06 g., 0.02 mole) ground together were placed in a long-necked flask with 0.1 g. of iodine. The flask was immersed in a metal-bath preheated to 190° and held at 195–200° until evolution of hydrogen sulfide was practically complete. This required forty-five to sixty minutes, during which time the dark reaction mixture solidified. Some ammonia and phenol were generated during the reaction. The coke-like residue, readily broken out of the flask, was digested with successive one-liter portions of 0.7 and 0.6% boiling sodium carbonate solution and filtered. The combined heated filtrates were treated with 20 g. of lithium chloride and chilled to 0°. Filtration left 0.65 g. of dark solids. Treatment of the reheated filtrate with a further 25 g. of lithium chloride gave 1.70 g. (36.3%) of lithium salt of 7-hydroxyphenothiazone-3. Recrystallizations from glacial acetic acid eventually yielded the crystalline product, though removal of persistent congeners was difficult and gave low final yields.

Anal. Calcd. for $C_{12}H_7NO_2S$: C, 62.87; H, 3.08; N, 6.11. Found: C, 62.2; H, 3.01; N, 6.18.

Ethers of 7-Hydroxyphenothiazone-3.—Preparations of the individual ethers were closely similar, and are illustrated by the details of synthesis for the amyl ether. Data on the products are collected in Table I. Excesses of alkyl iodide varied from 2.5 to 5 equivalents, but smaller amounts would likely be suitable. The vacuum treatment can be omitted in larger-scale preparations.

7-*n*-Amyloxyphenothiazone-3.—The silver salt was prepared from 2.35 g. (0.01 mole) of crude lithium salt by solution in one liter of water on the steam-bath, treatment with 2.5 g. (0.015 mole) of silver nitrate in 100 cc. of water, digestion for one hour, filtration, exhaustive washing, and drying at 105°.

The silver salt was dispersed in 500 cc. of refluxing benzene and treated with 9.9 g. of *n*-amyl iodide (5 equivalents). After seven hours reflux the liquid was cooled and filtered. The solids were washed with 200 cc. of hot benzene. Duplicate experiments showed 38 and 41% of

crude product at this point. The combined solutions were chromatographed on Alorco F-20 alumina (3.3 cm. diam., 15 cm. long), then developed and eluted with 250 cc. of benzene, 1000 cc. of 9:1 and 2500 cc. of 4:1 benzene–chloroform. The ether traveled through the column as a deep-red band, and was saved in a separate eluate. Unetherified 7-hydroxyphenothiazone-3 and some dark impurities remained strongly adsorbed at the top of the column. Evaporation of the eluate left the ethers as a partially crystalline solid. Vacuum treatment at 78° removed some volatile material, and recrystallization from hexane–benzene and from acetone provided garnet-red lath-like crystals (1) m. p. 124.5–126°. The substitution of amyl bromide for the iodide resulted in only 7% yield of the desired ether.

Repetition of this preparation with a larger amount of crude material (31.5 g.), eliminating the vacuum heating step, gave material (2) melting at 131–132°.

Acknowledgment.—The writers are indebted to Dr. E. J. Eastmond, Mrs. Bernice Williams and Mr. G. L. Bailey for the measurements of spectral absorption, to Mr. L. M. White and Miss Geraldine Secor for microchemical analyses, and to Dr. F. T. Jones for microscopical investigation of numerous products.

Summary

Thionol (7-hydroxyphenothiazone-3) has been prepared by condensation of *p,p'*-dihydroxydiphenylamine with sulfur, and by sulfuric acid oxidation of phenothiazine followed by isolation as the lithium salt. The yield from the previously reported latter process has been increased by shortening the reaction time.

The ethyl, amyl, octyl, dodecyl and hexadecyl ethers of 7-hydroxyphenothiazone-3 have been prepared by treating the silver salt with the appropriate alkyl iodides.

3-Octoxyphenothiazine-5-oxide has been made by alkaline peroxide treatment of 3-octoxyphenothiazine.

Synthesis of Inositol-5-monophosphoric Acid and Scyllitol Monophosphoric Acid[1]

BY BEAT M. ISELIN[2]

The widespread occurrence of inositol phosphoric acids in plants has long been recognized.[3] For many years inositol hexaphosphoric acid, or phytic acid was the only inositol phosphate known until Anderson,[4] in 1914, succeeded in isolating inositol monophosphoric acid from wheat bran. The same substance has been obtained by the action of the enzyme phytase on phytic acid[5,6] or by partial hydrolysis of phytic acid with dilute sulfuric acid.[7] More recent investigations have shown that inositol monophosphoric acid is a constituent of many phosphatides. Anderson has found this substance as a polysaccharide in the phosphatide fraction of tubercle bacilli.[8,9] Klenk and Sakai have described a preparation of inositol monophosphoric acid from soy bean lipositol[10] in which, as has been demonstrated by Woolley,[11] it is combined with galactose in glycosidic linkage.

The inositol monophosphoric acids isolated from natural sources are optically inactive. Their structure has not been investigated as yet. However, in the light of the present knowledge of the configuration of meso-inositol it is evident that only those mono-substituted derivatives are optically inactive in which the substituent is in position 2 or 5[12]; substitution in other positions is expected to yield products with optical activity. Assuming that the natural inositol monophosphates are not resolvable it may be concluded that the phosphoric acid residue is attached to carbon atom 2 or 5.

The synthesis of an inositol monophosphoric acid carrying the substituent on carbon atom 5 was effected by taking advantage of the known fact that *Acetobacter suboxydans* oxidizes meso-inositol specifically in position 5 yielding scyllo-meso-inosose. This substance, by acetylation and subsequent catalytic hydrogenation of the keto group with platinum oxide in glacial acetic acid, is converted to 1,2,3,4,6-pentaacetyl-meso-inositol as has been described by Posternak.[13] When the directions for the hydrogenation of scyllo-meso-inosose pentaacetate given by this author were closely followed, a product was obtained that had the recorded melting point (161–162°); acetylation to the hexaacetate and the bioassay of the hydrolyzed material with *Saccharomyces cerevisiae* revealed, however, that the product contained approximately 25% of the scyllitol isomer. It was found impossible to achieve a satisfactory separation of the two isomers by fractional crystallization. If the hydrogenation of scyllo-meso-inosose pentaacetate was carried out using methanol in-

(IV)

Attempts to phosphorylate this substance by treatment with phosphorus oxychloride were unsuccessful. Quite unexpectedly the substance also proved to be rather resistant to phosphorylation with diphenylchlorophosphonate at low temperatures though this phosphorylating agent has been shown to react very rapidly with primary or secondary hydroxyl groups of carbohydrates.[14,15,16] By increasing the reaction temperature to 80° and by the use of an excess of diphenylchlorophosphonate it was possible to obtain 1,2,3,4,6-pentaacetyl-inositol-5-diphenylphosphate (II) in 64% yield. Removal of the phenyl groups by reductive cleavage with hydrogen in the presence of platinum oxide yielded 1,2,3,4,6-pentaacetyl-inositol-5-phosphoric acid (III) (80%).

The hydrolysis of the acetyl groups could be effected by various methods. Best results were obtained by catalytic saponification with sodium methylate in methanol. The sodium salt of inositol-5-phosphoric acid formed in the course of this reaction in quantitative yield is of sufficient purity for biological purposes. Removal of the cation by means of ion exchange gave inositol-5-phosphoric acid (IV) that crystallized from aqueous ethanol in hexagonal plates melting at 198–200° with decomposition. Both the free acid and the sodium salt were optically inactive. All the salts of inositol-5-phosphoric acid, with the exception of the lead salt, were easily soluble in water. The barium salt was precipitated as a white amorphous powder from an aqueous solution by addition of ethanol. Hydrolysis of inositol-5-phosphoric acid with hydrochloric acid gave meso-inositol which, after acetylation, proved to be identical with the hexaacetate of natural meso-inositol.

Inositol-5-phosphate was not attacked by *Acetobacter suboxydans* as was to be expected since the point of attack by the bacterial enzyme, the hydroxyl group on carbon atom 5, is blocked by a substituent. In bioassays with *Saccharomyces cerevisiae* the substance had approximately 4% of the activity shown by free meso-inositol whereas in assays with *Neurospora crassa* it was about 10% as effective as inositol. This is in agreement with the finding of Woolley[17] who demonstrated that inositol monophosphate isolated from soy bean lipositol had an activity of the same order. On hydrolysis of inositol-5-phosphoric acid the calculated amount of meso-inositol was liberated as could be shown in tests with *Neurospora crassa*.

The preparation of scyllitol monophosphoric acid[18] started from the mixture of inositol- and scyllitol-pentaacetates as obtained by catalytic reduction of scyllo-meso-inosose pentaacetate in glacial acetic acid.[13] Phosphorylation with diphenylchlorophosphonate gave a mixture of pentaacetylinositol-5-diphenylphosphate and of pentaacetylscyllitol-diphenylphosphate. The two components could not be separated at this stage, but after reductive cleavage of the phenyl groups the pentaacetyl-scyllitol-phosphoric acid could be separated easily from the corresponding derivative of meso-inositol by fractional crystallization. Catalytic saponification of the acetyl groups with sodium methylate yielded the sodium salt of scyllitol phosphoric acid. Removal of the cation by means of ion exchange gave scyllitol monophosphoric acid (V) that melted at 212–214°. The acid and its salts have characteristics similar to those of inositol-5-phosphoric acid. Hydroly-

(18) Not numbered since all mono-substituted derivatives of scyllitol are identical due to the symmetric structure of the molecule.

sis with hydrochloric acid gave scyllitol in nearly quantitative yield.

Scyllitol monophosphoric acid was completely inactive in the bioassay with *Neurospora crassa* before and after hydrolysis of the phosphoric acid residue.

Experimental[19]

1,2,3,4,6-Pentaacetyl-inositol (I).—A suspension of 4 g. of scyllo-meso-inosose pentaacetate,[13] m. p. 147°, in 80 ml. of dry methanol was shaken with hydrogen at room temperature and atmospheric pressure in the presence of 0.8 g. of platinum oxide (Adams catalyst). In the course of the reduction the starting material gradually dissolved. The absorption of hydrogen stopped after five hours when 1.1 moles of hydrogen had been consumed. After removing the catalyst by filtration the solution was concentrated at reduced pressure to 25 ml. On cooling, the 1,2,3,4,6-pentaacetyl-inositol crystallized in fine needles that were filtered after standing at 0° overnight; yield 2.73 g., m. p. 174–178°. From the mother liquor, after concentration to 5 ml., an additional 0.64 g. of the product with a slightly lower melting point was obtained (total yield, 84%). After recrystallization from anhydrous ethanol the substance melted at 177–179°.

Anal. Calcd. for $C_{16}H_{22}O_{11}$: C, 49.22; H, 5.69. Found: C, 49.03; H, 5.95.

170 mg. of the substance was acetylated to the hexaacetate by treatment with 1 ml. of a mixture of 95% acetic anhydride and 5% concd. sulfuric acid; yield 180 mg. The hexaacetate, after recrystallization from ethanol, melted at 214–215°; admixture of inositol hexaacetate prepared from meso-inositol produced no depression of the melting point.

1,2,3,4,6-Pentaacetyl-inositol-5-diphenylphosphate (II).—To a solution of 5 g. of 1,2,3,4,6-pentaacetyl-inositol in 15 ml. of anhydrous pyridine, 10.35 g. (3 moles) of diphenylchlorophosphonate[14] was added. The mixture was kept at 80° for twenty hours with careful exclusion of moisture. On cooling in an ice-bath crystals of pyridine hydrochloride separated from the yellow colored solution. After dilution with 15 ml. of pyridine and addition of 0.2 ml. of ice-water to hydrolyze the excess of acid chloride the mixture was added to 1000 ml. of ice-water with vigorous stirring. From the emulsion, after about ten minutes, crystals appeared that were filtered after standing at 0° for two hours, washed with ice-water and cold ethanol, and dried *in vacuo* over sulfuric acid. Recrystallization of the crude product (5.95 g.) from 100 ml. of anhydrous ethanol gave 5.15 g. (64%) of pure 1,2,3,4,6-pentaacetyl-inositol-5-diphenylphosphate which crystallized in fine needles melting at 192–193°.

Anal. Calcd. for $C_{28}H_{31}O_{14}P$: C, 54.02; H, 5.02; P, 4.97. Found: C, 53.96; H, 5.15; P, 5.01.

The substance is easily soluble in acetone, ethyl acetate and chloroform, less soluble in methanol and ethanol, and only sparingly soluble in ether.

1,2,3,4,6-Pentaacetyl-inositol-5-phosphoric Acid (III).—A suspension of 4.5 g. of 1,2,3,4,6-pentaacetyl-inositol-5-diphenylphosphate in 90 ml. of anhydrous ethanol was hydrogenated at room temperature and atmospheric pressure in the presence of 0.2 g. of platinum oxide. The starting material went into solution as the reduction proceeded. The absorption of hydrogen stopped abruptly after ninety minutes when the theoretical quantity (8 moles) had been consumed. The catalyst was removed by filtration and the filtrate was concentrated at reduced pressure to 20 ml. On standing at 0° rapid crystallization occurred (prisms). After gradual addition of 20 ml. of petroleum ether (b. p. 50–60°) and standing at 0° for two hours the crystals were filtered and washed with a mixture of equal parts of ethanol and petroleum ether; yield 2.76 g. (80%). The substance melted at 233–234°; recrystallization did not change this melting point.

(19) All melting points are corrected.

Anal. Calcd. for $C_{16}H_{23}O_{14}P$: C, 40.85; H, 4.93; P, 6.59. Found: C, 40.99; H, 5.01; P, 6.53.

The substance is soluble in water, methanol, ethanol and acetone, insoluble in chloroform and ether. An aqueous solution reacts strongly acid.

Sodium Inositol-5-phosphate.—To 2.5 g. of 1,2,3,4,6-pentaacetyl-inositol-5-phosphoric acid dissolved in 25 ml. of cold anhydrous methanol 13.3 ml. of a 1 *N* solution of sodium methoxide in dry methanol (2.5 moles, 2 moles required for neutralization of the free acid groups) was added. After five minutes an amorphous precipitate of sodium inositol-5-phosphate appeared. The mixture was allowed to stand at 0° overnight. The product was separated by centrifuging and was washed on the centrifuge with dry methanol until the supernatant reacted neutral (four to five washings). After two additional washings with dry ether the substance was dried *in vacuo*. It weighed 1.59 g. (97%).

Anal. Calcd. for $C_6H_{11}O_9PNa_2$: P, 10.19. Found: P, 10.09.

The fine white powder is slightly hygroscopic. A 5% solution in water has a *p*H of 8.0.

Inositol-5-phosphoric Acid (IV).—This substance was prepared by passing a solution of 1 g. of the sodium salt of inositol-5-phosphoric acid in 10 ml. of water through a column containing 15 g. of moist Amberlite-IR-100-AG. The effluent was concentrated at reduced pressure to 3 ml. On addition of ethanol to incipient turbidity spontaneous crystallization occurred. After standing overnight at room temperature the crystals were collected on the filter and washed with ethanol; yield 0.70 g. (82%). For recrystallization the substance was dissolved in 2 ml. of water and 10 ml. of ethanol was added gradually. The colorless hexagonal plates melted with decomposition at 198–200° when rapidly heated and at 195–197° on slow heating.

Anal. Calcd. for $C_6H_{13}O_9P$: C, 27.69; H, 5.04; P, 11.92. Found: C, 27.63; H, 5.06; P, 11.96.

The substance showed no optical activity in concentrations up to 10%. It was very soluble in water, but insoluble in all organic solvents. A 0.2 molar aqueous solution had a *p*H value of 1.4. The salts of inositol-5-phosphoric acid were soluble in water, with the exception of the lead salt, which was formed by addition of lead acetate in excess to an aqueous solution of the free acid or its sodium salt. The barium salt was prepared by neutralizing a solution of the inositol-5-phosphoric acid with barium hydroxide (phenolphthalein) and adding an equal volume of ethanol. The amorphous precipitate was centrifuged, washed with several portions of 50% ethanol and finally with anhydrous ethanol, and dried *in vacuo*. The product contained water of crystallization which was removed only by heating at 120° and 0.1 mm. pressure for three hours.

Anal. Calcd. for $C_6H_{11}O_9PBa$: Ba, 34.7. Found: Ba, 34.6.

Cleavage of the phosphoric acid ester was effected by heating 0.25 g. of inositol-5-phosphoric acid in a sealed tube with 20 ml. of 2 *N* hydrochloric acid at 130° for twenty-four hours. After this period of time the solution was evaporated to dryness and the partly crystalline residue was dissolved in 3 ml. of water. On addition of ethanol to incipient turbidity meso-inositol crystallized spontaneously; yield 158 mg. (91%). The crude product (m. p. 222–226°), on acetylation with 1.2 ml. of a mixture of acetic anhydride (95%) and concd. sulfuric acid (5%), gave 345 mg. (91%) of inositol hexaacetate which, after recrystallization from ethanol, melted at 214–216°. Admixture of hexaacetate prepared from meso-inositol produced no depression of the melting point.

Biological Experiments

The action of *Acetobacter suboxydans* upon inositol-5-phosphoric acid was studied manometrically. Sodium inositol-5-phosphate, in quantities varying from 10 to 100 micromoles and adjusted to *p*H 6 with $^1/_{15}$ molar phosphate buffer, was not attacked by a suspension of resting

bacteria (about 10 mg. dry weight) while in experiments with meso-inositol (20 micromoles) the calculated amount of oxygen was consumed within thirty minutes.

In the bioassay with *Saccharomyces cerevisiae* the method of Jurist and Foy[20] was used. The activity of inositol-5-phosphoric acid was 4 ± 2% of that shown by free meso-inositol. In bioassays with *Neurospora crassa*, carried out according to Beadle,[21] the substance was about 10% as active as inositol. All comparisons were made on the basis of the molecular weight. Hydrolysates of inositol-5-phosphoric acid, prepared by heating the sample with 2 *N* hydrochloric acid at 130° for twenty-four hours and subsequent concentration to dryness and neutralization with dilute sodium hydroxide, showed a 100 ± 3% activity for the inositol calculated to be present in such solutions.

Pentaacetyl-scyllitol Phosphoric Acid.—The synthesis of this substance started from the mixture of inositol- and scyllitol-pentaacetates as obtained by carrying out the hydrogenation of scyllo-meso-inosose pentaacetate in acetic acid instead of methanol. The product crystallized in apparently homogeneous needles melting at 161–163°.

Anal. Calcd. for $C_{16}H_{22}O_{11}$: C, 49.22; H, 5.69. Found: C, 49.23; H, 5.52.

Acetylation of 300 mg. of this substance with 1.5 ml. of a mixture of 95% acetic anhydride and 5% concd. sulfuric acid gave 200 mg. of inositol hexaacetate which, after recrystallization from ethanol, melted at 215–216°, and 50 mg. of scyllitol hexaacetate melting at 299–300° after recrystallization from acetic anhydride. In the bioassay with *Saccharomyces cerevisiae* the mixture of meso-inositol- and scyllitol-pentaacetates, after hydrolysis with 2*N* hydrochloric acid, had only 74% of the activity shown by a hydrolysate of pure 1,2,3,4,6-pentaacetyl-inositol. These results indicate that the mixture contained about 25% scyllitol-pentaacetate. All attempts to separate scyllitol-pentaacetate from the inositol isomer failed.

Phosphorylation with diphenylchlorophosphonate, as described before, gave a mixture of pentaacetyl-inositol-diphenylphosphate and the corresponding scyllitol derivative in 65% yield. After recrystallization from ethanol the product melted at 173–181°.

Anal. Calcd. for $C_{28}H_{31}O_{14}P$: C, 54.02; H, 5.02; P, 4.97. Found: C, 53.81; H, 5.21; P, 4.96.

Attempts to separate the two isomers at this stage by fractional crystallization from ethanol or acetone–water and by fractional extraction with ether were unsuccessful.

3.1 g. of this product was hydrogenated as has been described for the pure pentaacetyl-inositol-diphenylphosphate. When the reduction neared completion fine crystals of pentaacetyl-scyllitol phosphoric acid separated. After warming to dissolve the product the catalyst was removed by filtration and the solution was concentrated at reduced pressure to 20 ml. On standing at room temperature pentaacetyl-scyllitol phosphoric acid separated in extremely fine needles; yield 0.43 g. (18%). From the mother liquor, after further concentration and standing at 0°, 1.60 g. (68%) of 1,2,3,4,6-pentaacetyl-inositol-5-phosphoric acid was obtained which was converted to free inositol-5-phosphoric acid as described before. Pentaacetyl-scyllitol phosphoric acid, after recrystallization from dry methanol, melted at 252–253° with decomposition.

Anal. Calcd. for $C_{16}H_{23}O_{14}P$: C, 40.85; H, 4.93; P, 6.59. Found: C, 41.03; H, 5.14; P, 6.50.

This substance, after removal of the substituents by hydrolysis with hydrochloric acid, was inactive in the bioassay with *Saccharomyces cerevisiae*.

Scyllitol Phosphoric Acid (V).—From 0.80 g. of pentaacetyl-scyllitol phosphoric acid, by catalytic saponification with 2.5 moles of sodium methoxide, 0.51 g. (98%) of sodium scyllitol phosphate was obtained as a white slightly hygroscopic powder.

Anal. Calcd. for $C_6H_{11}O_9PNa_2$: P, 10.19. Found: P, 9.88.

The free scyllitol-phosphoric acid was prepared from 0.4 g. of the sodium salt by removal of the cation with Amberlite-IR-100-AG. From the concentrated aqueous solution, on gradual addition of five volumes of ethanol, the free acid separated in fine crystals; yield 0.28 g. (82%). After recrystallization from water–ethanol the substance melted at 212–214° with decomposition.

Anal. Calcd. for $C_6H_{13}O_9P$: C, 27.69; H, 5.04; P, 11.92. Found: C, 27.61; H, 5.02; P, 11.89.

The substance is insoluble in all organic solvents. An aqueous solution reacts strongly acid (in 1 per cent. solution, *p*H 1.8). The lead salt is the only salt of scyllitol phosphoric acid that is insoluble in water. The barium salt is precipitated from an aqueous solution as a white amorphous powder by addition of 1 volume of ethanol.

Hydrolysis of 50 mg. of scyllitol-phosphoric acid by heating with 10 ml. of 2 *N* hydrochloric acid at 130° for twenty-four hours yielded 33 mg. (95%) of scyllitol, m. p. 345–350°. The crude product, on acetylation, gave 65 mg. (82%) of scyllitol hexaacetate that melted at 298–300°.

Acknowledgment.—The author wishes to express his gratitude to Professor H. O. L. Fischer who has made it possible for him to work on this problem. He is indebted to Dr. H. K. Mitchell, California Institute of Technology, for carrying out the bioassays with *Neurospora crassa*, and to Mr. H. C. Stancer, University of Toronto, for the bioassays with *Saccharomyces cerevisiae*.

Summary

Inositol-5-monophosphoric acid and scyllitol monophosphoric acid have been prepared in good yields by a method involving relatively few steps. Inositol-5-phosphoric acid is resistant to the attack by *Acetobacter suboxydans* and shows only a low activity in the bioassay with *Saccharomyces cerevisiae* and *Neurospora crassa*.

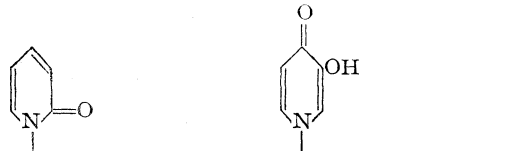
Addition and Condensation Reactions of 2-Pyridone

BY ROGER ADAMS AND VIRON V. JONES[1]

2-Pyridone was used as a model compound for the study of reactions leading to structure I, which is analogous to the proposed structure for leucenol (II). Taking advantage of the ease with which 2-pyridone adds to acrylonitrile,[2] the reaction between 2-pyridone and α-acetamidoacrylic acid was studied. The adduct was obtained and by



hydrolysis the desired product (I) resulted. By substitution of 3-methoxy-4-pyridone for 2-pyridone and using a similar series of reactions, the successful synthesis of leucenol was attained.[3]

Many reactions of 2-pyridone which might lead to structure I were explored, before a satisfactory method was discovered. Some new chemistry of 2-pyridone was uncovered which is described in this communication.

2-Pyridone and acrylonitrile react readily to form β-(N-2-pyridone)-propionitrile[2] and by hydrolysis β-(N-2-pyridone)-propionic acid results. In an attempt to prepare the corresponding α-bromo compound from which the amino compound I could be made by the action of ammonia, β-(N-2-pyridone)-propionic acid was treated with bromine and red phosphorus. The isolated product contained two unreactive atoms of bromine from which it was deduced that two bromine atoms had probably been substituted in the 3,5-positions of the pyridone ring. 2-Pyridone has been shown by Koenigs and Geigy[4] to react very readily with bromine with formation of 3,5-dibromo-2-pyridone.

2-Pyridone and chloroacetaldehyde condense to the hydrochloride of N-2-pyridone acetaldehyde. The free base could not be obtained crystalline but a crystalline oxime and semicarbazone were prepared. The methods ordinarily successful for converting an aldehyde into the corresponding amino acid, which would permit the synthesis of I, failed.

2-Pyridone and bromopyruvic acid gave a product which appeared to be the 2-pyridonium salt of N-2-pyridone pyruvic acid hydrobromide since 2-pyridone was readily removed in the cold by means of picric acid and an immediate precipitate of silver bromide with silver nitrate suggested a hydrobromide. Since the reduction of the pyridone ring in the conversion of the keto to the primary amino group seemed likely from other experiments, this possible route to I was abandoned.

2-Pyridone adds to butadienesulfone with potassium hydroxide as catalyst to give the one-to-one addition product. It does not add under similar conditions to mesityl oxide.

The reaction of sodium 2-pyridone with α,β-dibromopropionic acid in an attempt to prepare α-bromo-β-(N-2-pyridone)-propionic acid was unsuccessful. Instead, a water soluble product ($C_8H_8NO_3Br$) resulted, the constitution of which was thoroughly investigated. Its aqueous solution was acid to congo red and gave an immediate precipitate of silver bromide with aqueous silver nitrate. The same product resulted from sodium 2-pyridone and ethyl α,β-dibromopropionate, followed by hydrolysis. After some knowledge of the structure was obtained, it was discovered that it could be more conveniently prepared from 2-pyridone and α-bromoacrylic acid. α-Bromoacrylic acid was probably an intermediate in the formation of the compound when α,β-dibromopropionic acid was used as a starting material. Ethyl α-bromoacrylate also reacted with 2-pyridone and the product upon heating in aqueous solution on the steam-bath gave the 2-pyridone α-bromoacrylic acid compound.

The structure of this adduct was determined through a study of its reactions. By treatment with ammonia the halogen atom was replaced by an amino group and the product was an amino acid which was isomeric but different from I and gave no color with ninhydrin. It was, therefore, assumed to be α-(N-2-pyridone)-β-aminopropionic acid (III). Upon treatment with dry hydrogen bromide, water was eliminated and the hydrobromide of a β-lactam (IV) was formed which by means of aqueous ammonia reverted to the amino acid. The amino acid upon treatment with dilute alkali was transformed with loss of ammonia to the corresponding hydroxy acid (V), which could be obtained directly from the 2-pyridone α-bromoacrylic acid adduct by the action of dilute aqueous alkali. It was also synthesized from 2-pyridone and glycidic acid. By the action of acetic anhydride, merely acetylation of the hydroxyl group took place, and no dehydration to the corresponding acrylic acid could be detected. The hydroxy acid was stable to and unchanged by boiling with 48% hydrobromic acid.

Electrometric titration of the 2-pyridone α-

(1) From a thesis presented by Viron V. Jones to the Graduate College of the University of Illinois, May, 1949, in partial fulfillment of the requirements for the degree of Doctor of Philosophy. He held the Cincinnati Chemical Works Fellowship, 1946–1949.

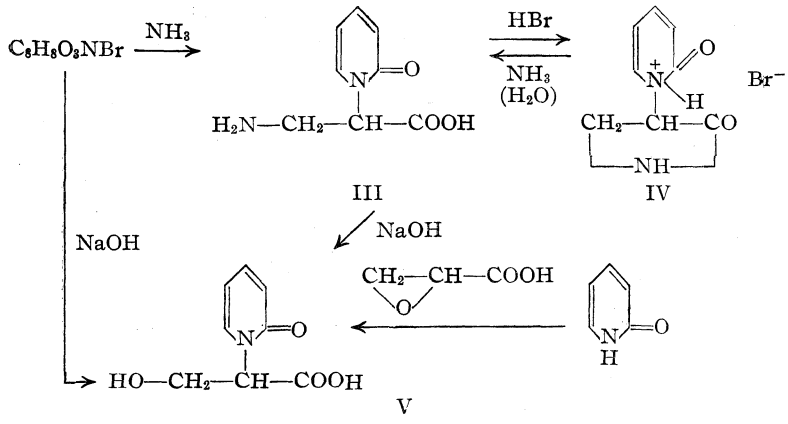
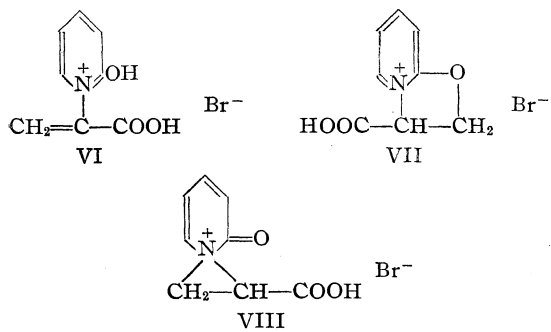
(4) Koenigs and Geigy, *Ber.*, **17**, 591 (1884).



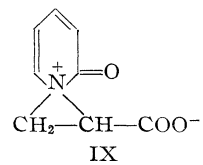
bromoacrylic acid adduct with sodium hydroxide exhibited a curve having but one end-point and typical for that of a strong monobasic acid. The strength of the acid and high activity of the halogen is comparable to that of a betaine hydrobromide $(R_3NCH_2COOH)^+(Br)^-$. Three possible structures, (VI, VII, VIII), which will serve to explain the electrometric titration, water solubility and the ionizable bromine, can be postulated for the adduct.



The infrared absorption showed two bands in the carbonyl region, one at 1760 cm.$^{-1}$, attributed to a carboxyl, and one at 1649 cm.$^{-1}$, to a pyridone carbonyl (Fig. 1). The absorption coincides well with that of β-(N-2-pyridone)-propionic acid. These data are presented as evidence against formula VI and VII. Moreover, 2-propoxypyridine has no absorption in the carbonyl region, while N-*n*-propylpyridone has a strong band at 1660 cm.$^{-1}$ (Fig. 1).

Formula VIII is in accord with the structure of similar compounds proposed by Cromwell[5] as intermediates in the reaction of amines with α-bromo-α,β-unsaturated ketones. The formation of a β-amino or β-hydroxy acid by the action of ammonia or aqueous alkali on the 2-pyridone α-bromoacrylic acid adduct may be explained on the basis of this formula by assuming cleavage in the β-position to the carboxyl group, thus leaving the pyridone residue in the α-position.

When VIII reacted in the cold with silver oxide or sodium bicarbonate, a halogen-free product resulted, insoluble in non-polar solvents, soluble in water and lower alcohols. A molecular weight determined by the freezing point depression of water showed it to be monomeric. Infrared data indicated a free carboxyl ion which must exist as an internal salt. A comparison of the infrared spectrum of a betaine hydrobromide with that of the corresponding betaine was made. A carbonyl band at 1740 cm.$^{-1}$ in the former and a carbonyl band at 1625 cm.$^{-1}$ in the latter was found, a difference of 115 cm.$^{-1}$. The absorption of the 2-pyridone α-bromoacrylic acid adduct shows a carbonyl band at 1760 cm.$^{-1}$ and that of the hydrobromide free product, a carbonyl band at 1630 cm.$^{-1}$, a difference of 130 cm.$^{-1}$. It has been shown that the carboxyl group in compounds containing zwitterions absorbs at a lower wave number than compounds containing normal carboxyl groups.[6] These results support the postulation that the hydrobromide-free product has structure IX. Another similarity to the betaines is found in the formation of a hemihydrobromide.



Stoltzenberg[7] prepared a hemihydrochloride and hemihydrobromide of the betaine of N-trimethylglycine. The 2-pyridone α-bromoacrylic acid adduct reacts with one-half mole of silver oxide to give a compound containing one atom of bromine for two pyridone residues. The same product resulted from mixing equimolar quantities of the 2-pyridone α-bromoacrylic acid adduct and the hydrohalide-free product. Structures for such hemihalides can be formulated on the basis of the assumption that a proton from the carboxyl of the betaine hydrobromide is accepted by a molecule of the betaine base with a crystalline salt resulting (X and XI).

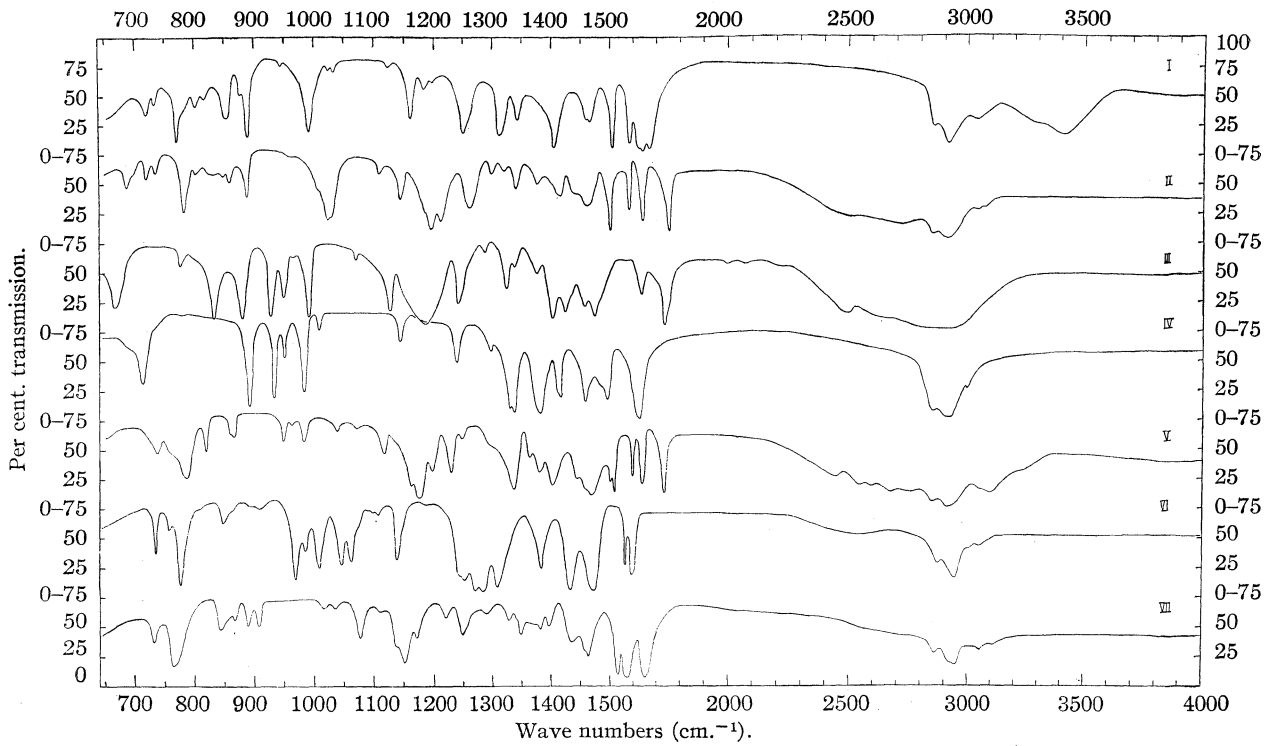

Fig. 1.—I, Hydrobromide-free 2-pyridone α-bromoacrylic acid product; II, 2-pyridone α-bromoacrylic acid adduct; III, betaine hydrobromide; IV, betaine; V, N-2-pyridonepropionic acid hydrobromide; VI, 2-propoxypyridine; VII, N-*n*-propyl-2-pyridone. Compounds I–V (inc.) were run as nujol mulls; compounds V and VI, which were liquids, were run in a 0.025 mm. cell.

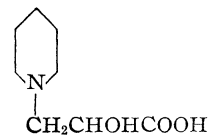
The reduction products of the 2-pyridone α-bromoacrylic acid adduct were also investigated. With palladium on charcoal as catalyst, two moles of hydrogen were absorbed and a sirup resulted which would not crystallize. It contained an ionizable bromine since a copious precipitate of silver bromide formed upon treatment with silver nitrate. By the action of ammonia, an amino acid resulted, identical with the hydrogenation product of α-(N-2-pyridone)-β-aminopropionic acid (III) in which the pyridone residue had been reduced to piperidone. The intermediate sirup is probably the piperidone analog of VIII.

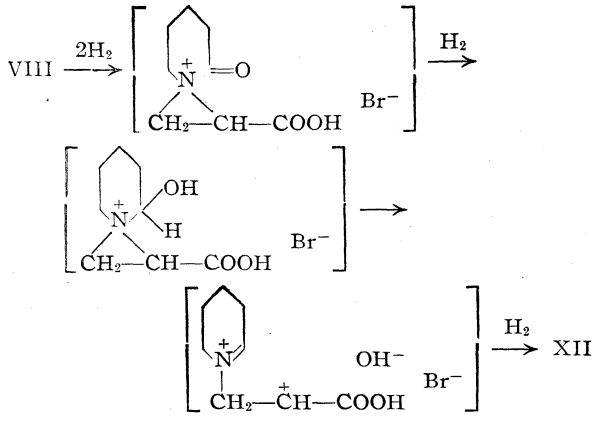
On the other hand, when platinum oxide was used as a catalyst, four moles of hydrogen were absorbed and a crystalline compound, $C_8H_{15}NO_3$·HBr, was obtained. A free base resulted upon treatment with silver oxide. Esterification to a methyl ester hydrobromide occurred when boiled in methanol but not by treatment with diazomethane. The free base was not identical with β-(N-2-piperidone)-propionic acid or α-(N-2-piperidone)-propionic acid formed by the reduction with hydrogen and platinum oxide of the corresponding pyridones. Moreover, the corresponding hydrobromide of β-(N-2-pyridone)-propionic acid absorbed only two moles of hydrogen.

A clue to the structure of this reduction product was obtained by its pyrolysis at 185° (1 mm.) in a sublimation apparatus. Piperidine hydrobromide was obtained, indicating that the oxygen in the pyridone ring in the starting compound had migrated to the propionic acid residue. The infrared spectrum of the reduction product showed no carbonyl group other than the carboxyl and a band at 3400 cm.$^{-1}$ indicative of a hydroxyl. The product proved to be α-hydroxy-β-piperidinopropionic acid (XII). It was synthesized from α-hydroxy-β-chloropropionic acid and piperidine or from piperidino-acetaldehyde hydrochloride by treatment with sodium cyanide followed by hydrolysis.



XII

The mechanism of the formation of XII probably involves first reduction of the pyridone nucleus to the piperidone since by hydrogenation of the 2-pyridone α-bromoacrylic acid adduct with palladium on charcoal as catalyst, followed by treatment with ammonia, a piperidone derivative resulted. If the piperidone carbonyl is next reduced, a pseudo base will be formed which may rearrange to a carbonium hydroxide. The latter upon reduction could yield the hydrobromide of the hydroxy acid (XII).



Ethyl α-bromo-β-ethoxypropionate and sodium 2-pyridone yielded a compound with the composition $C_{15}H_{16}O_4N_2$. The product was assumed to be ethyl α,β-di-(N-2-pyridone)-propionate. Both the ethoxy group and bromine atom appear to have been replaced by pyridone residues.

Experimental

α-Acetamido-β-(N-2-pyridone)-propionic Acid.—A mixture of 0.5 g. of α-acetamidoacrylic acid[8] and 0.5 g. of 2-pyridone[2] was heated on a metal-bath at 140° for one hour. The thick sirup which formed was dissolved in 5 ml. of chloroform and allowed to evaporate overnight. A small amount of solid separated in the sirup. This product was stirred with 5 ml. of acetone and left in the refrigerator for one day. A small amount of colorless granules was obtained. After recrystallization from methanol, the product melted at 199° (cor.) with decomposition.

Anal. Calcd. for $C_{10}H_{12}N_2O_4$: C, 53.56; H, 5.40. Found: C, 53.20; H, 5.50.

α-Amino-β-(N-2-pyridone)-propionic Acid.—A mixture of 0.3 g. of α-acetamido-β-(N-2-pyridone)-propionic acid and 5 ml. of 48% hydrobromic acid was refluxed for six hours. The excess acid was removed by distillation on the steam-cone under reduced pressure. The sirup which remained was made just basic to litmus paper with concentrated ammonia, and evaporated to dryness. The residue was crystallized from the minimum amount of water. The yield was 0.17 g. (72%) of a product melting at 236° (cor.) with decomposition. It gave a blue color with ninhydrin solution.

Anal. Calcd. for $C_8H_{10}N_2O_3$: C, 52.75; H, 5.53. Found: C, 52.75; H, 5.79.

Bromination of β-(N-2-Pyridone)-propionic Acid; β-(3,5-Dibromo-N-2-pyridone)-propionic Acid.—A mixture of 15 g. of β-(N-2-pyridone)-propionic acid,[2] 3.6 g. of red phosphorus and 30 ml. of carbon tetrachloride contained in a three-necked round-bottom flask was cooled in an ice-bath and equipped with dropping funnel, stirrer and reflux condenser. To this was added dropwise with stirring 60 g. of bromine. After completion of the addition, the mixture was gradually heated until nearly all the hydrogen bromide had been removed. The carbon tetrachloride was distilled on the steam-cone leaving a dark semi-solid material which was then boiled with a little water and diluted to 400 ml. with water. After cooling in an ice-bath, fine white granules precipitated. The yield was 10 g. (32%). The product was recrystallized from 50% ethanol and melted at 182° (cor.). It gave a negative test with boiling silver nitrate solution.

Anal. Calcd. for $C_8H_7NO_3Br_2$: C, 29.44; H, 2.22; N, 4.31. Found: C, 29.63; H, 2.23; N, 4.40.

(8) Bergmann and Grafe, *Z. physiol. Chem.*, **187**, 187 (1930).

N-2-Pyridone Acetaldehyde Hydrochloride.—A mixture of 20 g. of methyl chloroacetal and 10 g. of water containing ten drops of concentrated hydrochloric acid was refluxed until the two phases disappeared. To this hot solution was added 10 g. of 2-pyridone and the refluxing continued for one hour. All the volatile materials were distilled on a steam-cone at 20 mm. After addition of 50 ml. of acetone to the resulting sirup, it was placed in a refrigerator overnight. A solid crystalline mass resulted which upon filtration gave 12 g. (66%) of product. After recrystallization from absolute ethanol, the melting point was 139–140° (cor.).

This product upon treatment with aqueous sodium bicarbonate or sodium hydroxide yielded a sirup which would not crystallize. The sirup was soluble in ethanol and ether, but insoluble in water. It gave a positive reaction to Tollens reagent.

Anal. Calcd. for $C_7H_8NO_2Cl$: C, 48.48; H, 4.62; N, 8.17; Cl, 20.42. Found: C, 48.53; H, 4.58; N, 7.97; Cl, 20.25.

After neutralization of the hydrochloride with solid sodium bicarbonate and extraction with ether, the N-2-pyridone acetaldehyde was treated with pyridine and hydrogen cyanide and a trace of solid potassium hydroxide. After standing and subsequent treatment with ammonia, followed by hydrobromic acid hydrolysis, no amino acid could be isolated.

Similarly, ammonium carbonate and sodium cyanide did not give the desired condensation product.

N-2-Pyridone Acetaldoxime.—A solution of 20 ml. of 95% ethanol containing 1.0 g. of 2-pyridone acetaldehyde hydrochloride and 1.0 g. of hydroxylamine hydrochloride was made just basic to moist litmus paper with 10% aqueous sodium hydroxide, and evaporated to dryness on a steam-cone. The residue was extracted with 20 ml. of ether and yielded 0.75 g. (85%) of a light yellow solid upon evaporation. Recrystallization from carbon tetrachloride resulted in a product melting at 78–79° (cor.).

Anal. Calcd. for $C_7H_8N_2O_2$: C, 55.25; H, 5.33; N, 18.41. Found: C, 55.41; H, 5.14; N, 18.32.

N-2-Pyridone Acetaldehyde Semicarbazone.—A mixture of 1.0 g. of 2-pyridone acetaldehyde hydrochloride, 1.5 g. of semicarbazide hydrochloride and 1.5 g. of sodium acetate was dissolved in 20 ml. of water and heated on a steam-cone for five minutes. A white precipitate formed after cooling in an ice-bath. The yield of product was 1.1 g. (100%). After crystallization from methanol, the product melted at 155–156° (cor.).

Anal. Calcd. for $C_8H_{10}O_2N_4$: C, 49.49; H, 5.16; N, 28.87. Found: C, 49.46; H, 5.14; N, 28.80.

Reaction of 2-Pyridone and Bromopyruvic Acid.—To 75 ml. of chloroform containing 3.4 g. of bromopyruvic acid,[9] 4 g. of 2-pyridone was added and the mixture held at 55° for ten hours. After evaporation to a thick sirup, 50 ml. of acetone was added and then five drops of 48% hydrobromic acid. Upon standing in a refrigerator for twenty-four hours, a granular solid formed weighing 5.8 g. (78%). After recrystallization from 95% ethanol, the melting point was 143–145° (cor.) with decomposition.

Anal. Calcd. for $C_{13}H_{13}O_5N_2Br$: C, 43.72; H, 3.67. Found: C, 43.65; H, 3.49.

This product gave a 2-pyridone picrate from ethanol and a positive test with Tollens reagent.

Reaction of 2-Pyridone and Butadiene Sulfone.—A mixture of 5.0 g. of 2-pyridone and 7.0 g. of butadiene sulfone was refluxed for two hours in 50 ml. of absolute ethanol containing two pellets of potassium hydroxide. The ethanol was distilled off on a steam-cone using vacuum toward the end. The resulting thick sirup was stirred up with 25 ml. of acetone and placed in a refrigerator overnight. A mass of fine white crystals formed. The filtrate yielded upon evaporation a second crop of crystals, making the total yield of 8.2 g. (73%). The product was purified by recrystallization from acetone, m. p. 136–137°.

(9) Sprinson and Chargaff, *J. Biol. Chem.*, **164**, 411 (1946).

Anal. Calcd. for $C_9H_{11}NO_3S$: C, 50.70; H, 5.17; N, 6.57. Found: C, 51.00; H, 5.08; N, 6.64.

Under analogous conditions, no condensation product of 2-pyridone and mesityl oxide resulted.

Reaction of α,β-Dibromopropionic Acid and the Sodium Salt of 2-Pyridone.—A mixture of 20 g. of the dihydrate of the sodium salt of 2-pyridone and 30 g. of α,β-dibromopropionic[10] acid in 50 ml. of acetone was heated on a steam-cone until bumping became too severe. The solvent was then allowed to evaporate aided by a stream of air. The resulting thick pasty mass was extracted once with 50 ml. of hot nitromethane and filtered from the sodium bromide. Ether was added to the filtrate until faint cloudiness appeared and then placed in a refrigerator overnight. The yield of almost white granular material was 22 g. (64%). After recrystallization once from 95% ethanol and once from water, the melting point was 122–123° (cor.).

The product was soluble in water forming a solution acid to congo red paper. The very pure material was insoluble in all organic solvents, but when crude was soluble in ethanol. The aqueous solution formed instantly a voluminous precipitate with aqueous silver nitrate solution.

Anal. Calcd. for $C_8H_8O_3NBr \cdot H_2O$: C, 36.41; H, 3.79; N, 5.30. Found: C, 36.76; H, 3.81; N, 5.19.

The sample was dried in an Abderhalden at 100° and 1 mm. to constant weight.

Anal. Calcd. for $C_8H_8O_3NBr$: C, 39.04; H, 3.27; N, 5.69. Found: C, 39.18; H, 3.01; N, 5.64.

Electrometric Titration.—A solution of 0.242 g. of the adduct hydrate in 25 ml. of water was titrated electrometrically with 0.0895 *N* sodium hydroxide. The initial *p*H was 2.0 and readings were taken at regular intervals to the phenolphthalein end-point. The resulting curve was typical of that for strong acids such as hydrobromic acid, and there was but one end-point. Calcd. for $C_8H_{10}NO_4Br$: mol. wt., 264. Found: mol. wt., 267.

Reaction of Sodium 2-Pyridone and Ethyl α,β-Dibromopropionate.—To a mixture of 12 g. of anhydrous sodium 2-pyridone in 100 ml. of absolute ethanol was added 28 g. of ethyl α,β-dibromopropionate.[10] A reaction occurred with the evolution of heat. The mixture was refluxed until bumping became severe (about fifteen minutes), and filtered from an inorganic residue. The filtrate was evaporated to a sirup and after taking up in 50 ml. of isopropyl alcohol was filtered from more of the inorganic material. The isopropyl alcohol was evaporated leaving a sirup which was soluble in water and ethanol but insoluble in ether and benzene. The aqueous solution was acid to congo red paper and yielded instantly a heavy precipitate of silver bromide with cold silver nitrate solution. The sirup did not crystallize after standing in a warm place for one week, but after mixing with acetone and allowing to stand in the refrigerator for two days, 6 g. of a crystalline product, m. p. 122°, was isolated. The melting point of this mixed with a 2-pyridone bromoacrylic acid adduct showed no depression.

Reaction of 2-Pyridone and α-Bromoacrylic Acid.—A mixture of 10 g. of 2-pyridone and 16 g. of α-bromoacrylic acid[10] and 0.2 g. of water containing 0.5 g. of *t*-butylcatechol was heated on the steam-cone with occasional stirring for one hour. The resulting thick sirup was dissolved in 50 ml. of boiling isoamyl alcohol and allowed to stand at room temperature for twenty-four hours then transferred to a refrigerator overnight. The fine white crystalline solid weighed 19 g. (70%). After recrystallization from a small volume of water it melted at 122–123° (cor.). This is the preferred method of synthesis.

Reaction of 2-Pyridone and Ethyl α-Bromoacrylate.—A mixture consisting of 9.5 g. of 2-pyridone and 18 g. of ethyl α-bromoacrylate[10] was heated for four hours on the steam-cone. A thick sirup resulted which was acid to moist congo red paper, and which yielded instantly a heavy precipitate of silver bromide with silver nitrate solution. The sirup was soluble in water and ethanol, but insoluble in ether and benzene. No crystallization occurred after standing in a warm place for three days, but when stirred with 25 ml. of acetone and allowed to stand in the refrigerator twenty-four hours, a granular precipitate formed. The yield was 4.5 g. and after recrystallization from ethanol melted at 120°.

Reaction of the 2-Pyridone Bromoacrylic Adduct with Ammonia; α-(N-2-Pyridone)-β-aminopropionic Acid.—A mixture of 2.0 g. of the adduct hydrate and 20 ml. of concentrated aqueous ammonia was refluxed for one hour. The resulting solution was evaporated to a solid and a sirup on the steam-cone aided by a stream of air. It was then dissolved in 25 ml. of methanol and allowed to stand twenty-four hours in the refrigerator, after which the granular crystals were filtered. An additional amount of material was obtained by evaporating the filtrate to dryness and recrystallizing from the minimum amount of boiling methanol. The total yield was 1.0 g. (71%) and after recrystallization from 50% methanol it melted at 213–215° (cor.) with decomposition. The pure product was soluble in water, insoluble in ethanol and non-polar solvents, and gave a negative test with ninhydrin and with Nessler reagent.

Anal. Calcd. for $C_8H_{10}N_2O_3$: C, 52.74; H, 5.54; N, 15.40. Found: C, 52.89; H, 5.41; N, 15.33.

Reaction of α-(N-2-Pyridone)-β-aminopropionic Acid and Hydrobromic Acid; α-(N-2-Pyridone)-β-aminopropiolactam Hydrobromide.—Dry hydrogen bromide was passed into a suspension of 0.35 g. of the amino acid in 2 ml. of absolute ethanol until a clear solution resulted. This solution, after standing in a refrigerator overnight, yielded 0.45 g. (89%) of fine colorless crystals. After recrystallization from 95% ethanol the product melted at 298–299° (cor.) with decomposition.

Anal. Calcd. for $C_8H_9N_2O_2Br$: C, 39.20; H, 3.72; N, 11.43; Br, 32.60. Found: C, 39.36; H, 3.75; N, 11.63; Br, 32.72.

A little of this material was dissolved in 0.5 ml. of water and made basic to litmus with aqueous ammonia. After evaporating to dryness, the residue was dissolved in the minimum amount of methanol and set in an ice-bath. The white granular crystals melted at 211–213° (cor.) with decomposition and the melting point of a mixture with α-(N-2-pyridone)-β-aminopropionic acid showed no depression.

Reaction of α-(N-2-Pyridone)-β-aminopropionic Acid and Sodium Hydroxide; α-(N-2-Pyridone)-β-hydroxypropionic Acid.—A solution of 0.5 g. of sodium hydroxide in 5 ml. of water and 0.8 g. of the amino acid was refluxed for one-half hour. Ammonia was liberated. The resulting solution was made acid to congo red paper with concentrated hydrochloric acid and allowed to remain in the refrigerator overnight. The granular crystals weighed 0.42 g. (52%) and melted at 168–172°. This proved to be identical with the hydroxy acid prepared by treating the 2-pyridone-α-bromoacrylic acid adduct with alkali.

Reaction of the 2-Pyridone Bromoacrylic Adduct with Sodium Hydroxide; α-(N-2-Pyridone)-β-hydroxypropionic Acid.—A solution of 6.8 g. of the adduct hydrate and 2.0 g. of sodium hydroxide in 25 ml. of water was refluxed for one hour. After cooling somewhat, 2.5 g. of concentrated sulfuric acid was added carefully and the mixture allowed to remain in the refrigerator overnight. The yield of fine granular crystals was 3.8 g. (79%). After recrystallization from methanol, the melting point was 173–175° (cor.).

Anal. Calcd. for $C_8H_9NO_4$: C, 52.45; H, 4.97. Found: C, 52.72; H, 5.18.

A mixture of 1.5 g. of the hydroxy acid and 10 ml. of 48% hydrobromic acid was refluxed for four hours. The excess acid was distilled *in vacuo* and the semicrystalline residue was taken up in 5 ml. of water. After neutralizing with sodium carbonate to congo red, a crystalline precipitate formed which was unchanged hydroxy acid.

α-(N-2-Pyridone)-β-acetoxypropionic Acid.—Upon refluxing 1 g. of this compound with 5 ml. of acetic an-

(10) Marvel, Cook and Cowan, THIS JOURNAL, **62**, 3495 (1940).

hydride for fifteen minutes and distilling the excess anhydride *in vacuo*, a thick sirup was obtained which solidified on standing. It was washed with acetone and recrystallized from methanol. The yield of colorless flakes was 0.47 g. (39%). The pure product melts at 224–225° (cor.).

Anal. Calcd. for $C_{10}H_{11}NO_5$: C, 53.33; H, 4.93; N, 6.23. Found: C, 53.11; H, 4.99; N, 6.07.

Reaction of 2-Pyridone and Glycidic Acid; α-(N-2-Pyridone)-β-hydroxypropionic Acid.—A mixture of 1.3 g. of the potassium salt of glycidic acid[11] and 0.95 g. of 2-pyridone in 2 ml. of ethanol was heated on the steam-cone for one hour. The sirup was taken up in 10 ml. of absolute ethanol and made just acid to congo red paper with hydrochloric acid and evaporated to dryness. The residue was extracted with 1.0 ml. of glacial acetic acid to remove the inorganic residue. The acetic acid was distilled on the steam-cone using vacuum. The sirup was transferred to a vacuum desiccator containing moist sodium hydroxide and allowed to stand overnight. The material solidified and after recrystallizing from 10 ml. of absolute ethanol yielded 1.0 g. (55%) of a tan-colored solid. After recrystallizing from methanol, the product melted at 173° (cor.) and the melting point of this mixed with the product obtained from the alkali treatment of the 2-pyridone α-bromoacrylic acid adduct showed no depression.

Reaction of the 2-Pyridone α-Bromoacrylic Acid Adduct and One Mole of Silver oxide.—A solution of 2.6 g. of the very pure adduct hydrate in 20 ml. of methanol was poured into a mortar and macerated for two minutes with the silver oxide prepared from 1.7 g. of silver nitrate. The silver bromide was removed by filtration and the filtrate evaporated at room temperature aided by a stream of filtered air. The crystalline residue was stirred with 10 ml. of *n*-propyl alcohol and filtered. The yield was 1.0 g. (56%). The melting point was elevated to 105–107° (cor.) by dissolving in the minimum amount of cold methanol and repeating the evaporation and *n*-propyl alcohol treatment. The product which is merely the adduct with a molecule of hydrogen bromide eliminated was insoluble in acetone, ether and benzene. It was soluble in hot *n*-propyl alcohol but no crystalline product could be obtained by cooling.

Anal. Calcd. for $C_8H_7NO_3.H_2O$: C, 52.45; H, 4.97. Found: C, 52.98; H, 5.13.

Upon drying in an Abderhalden, the melting point was 159–165° (cor.).

Anal. Calcd. for $C_8H_7NO_3$: C, 58.17; H, 4.28. Found: C, 58.45; H, 4.41.

Upon dissolving the product in concentrated hydrobromic acid and evaporating, a sirup resulted which on standing crystallized. It proved to be the 2-pyridone α-bromoacrylic acid adduct.

Reaction of the 2-Pyridone α-Bromoacrylic Acid Adduct and One-Half Mole of Silver Oxide.—A solution of 0.2 g. of the adduct hydrate in 25 ml. of methanol was macerated in a mortar for several minutes with the silver oxide prepared from 0.67 g. of silver nitrate. After removing the silver bromide by filtration, the filtrate was evaporated at room temperature to a crystalline residue aided by a stream of air. The solid was dissolved in the minimum amount of boiling absolute ethanol and allowed to stand for forty-eight hours in a refrigerator. The yield of granular crystals was 0.8 g. (50%). Recrystallization from methanol yielded a product melting at 156° (cor.) with decomposition. This product is a hemihydrobromide. An aqueous solution gave a heavy precipitate of silver bromide with silver nitrate solution.

Anal. Calcd. for $C_{16}H_{15}N_2O_6Br$: C, 46.72; H, 3.69. Found: C, 46.49; H, 3.54.

This product was also prepared by mixing 0.45 g. of the 2-pyridone α-bromoacrylic acid adduct hydrate and 0.25 g. of the hydrobromide-free compound in 2 ml. of 50% methanol and evaporating to dryness. The residue upon recrystallizing from ethanol yielded 0.37 g. of crystals melting at 156° (cor.) with decomposition. No depression in melting point was observed when mixed with the hemihydrobromide prepared by the silver oxide method.

Hydrogenation of the 2-Pyridone α-Bromoacrylic Acid Adduct with Palladium on Charcoal and Treatment of the Product with Ammonia; α-(N-2-Piperidone)-β-aminopropionic Acid.—A solution of 2 g. of the adduct hydrate in 100 ml. of hot 95% ethanol was hydrogenated at 50° and 50 lb. hydrogen pressure using 1.0 g. of palladium–charcoal catalyst. Two moles of hydrogen were absorbed. The solution was filtered and evaporated to a sirup. A solution of 50 ml. of methanol saturated with ammonia was added to the sirup and allowed to evaporate in a warm place. The resulting sirup was placed in a vacuum desiccator for two days. A small amount of granular material formed. This was washed with acetone and recrystallized from methanol. The yield of product was 0.5 g. melting at 177–179° (cor.) with decomposition.

Anal. Calcd. for $C_8H_{14}N_2O_3 \cdot H_2O$: C, 47.04; H, 7.93; N, 13.73. Found: C, 47.10; H, 7.63; N, 13.38.

α-(N-2-Pyridone)-β-aminopropionic Acid.—A solution of 1 g. of the amino acid in 50 ml. of 50% ethanol was hydrogenated at 50-lb. pressure and at 50° using 50 mg. of platinum oxide catalyst. Twelve hours was required for complete hydrogenation during which two moles of hydrogen was absorbed. The solution was filtered to remove the catalyst and evaporated at room temperature to a thick sirup. After drying in a vacuum desiccator for one day, a hard glass formed which from isoamyl alcohol yielded 0.65 g. (59%) of a white powder. Purification was effected by recrystallization from methanol, m. p. 177–179° (cor.) with decomposition. A melting point of a mixture with the product prepared in the previous experiment showed no depression.

Hydrogenation of the 2-Pyridone α-Bromoacrylic Acid Adduct with Platinum Oxide Catalyst.—A solution of 100 ml. of 95% ethanol containing 4.0 g. of the adduct hydrate and 50 mg. of platinum oxide was hydrogenated at 50° and 50 lb. pressure. In three hours four moles of hydrogen had been taken up and no further absorption occurred. The platinum was filtered off and the filtrate evaporated at room temperature aided by a stream of air. The crystalline solid which remained was washed with acetone. The yield was 3.2 g. (83%). The melting point of the sample purified by recrystallizing from nitromethane was 173–174° (cor.).

Anal. Calcd. for $C_8H_{16}NO_3Br$: C, 37.80; H, 6.36; N, 5.52. Found: C, 38.10; H, 6.36; N, 5.45.

Maceration in a mortar of 0.9 g. of the product in 10 ml. of methanol with silver oxide prepared from 0.61 g. of silver nitrate, was continued until the brown color disappeared. The filtrate from this slurry was evaporated at room temperature aided by a stream of air. The residual solid was crystallized from methanol and weighed 0.5 g. (82%). After further purification, the product melted at 219–220° (cor.) with decomposition.

This product was soluble in water and methanol, insoluble in the higher alcohols and all non-polar solvents. When refluxed with 48% hydrobromic acid for four hours, the original hydrobromide was obtained in 86% yields.

Anal. Calcd. for $C_8H_{15}NO_3$: C, 55.46; H, 8.75; N, 8.09. Found: C, 55.33; H, 8.83; N, 8.07.

Esterification of the Hydrogenated 2-Pyridone α-Bromoacrylic Acid Adduct.—A solution of 5 g. of the hydrogenated adduct in 50 ml. of methanol and 1 ml. of 48% hydrobromic acid was refluxed for twelve hours. The volatile materials were removed by distillation on a steam-cone using vacuum toward the end. A thick sirup remained which solidified upon cooling. The yield of material, after recrystallization from isopropyl alcohol, was 4.5 g. (86%). The melting point after further recrystallization from the same solvent was 141° (cor.).

Anal. Calcd. for $C_9H_{18}NO_3Br$: C, 40.31; H, 6.79. Found: C, 40.14; H, 6.78.

(11) Freudenberg, *Ber.*, **47**, 2027, 2034 (1914).

Attempts to obtain the free ester by treatment with silver oxide and methanol resulted in hydrolysis and only the free acid could be isolated. Diazomethane in methanol failed to methylate the free acid.

Pyrolysis of the Platinum Oxide Hydrogenated 2-Pyridone α-Bromoacrylic Acid Adduct.—The pyrolysis was conducted by heating 0.62 g. of the four mole hydrogenated 2-pyridone α-bromoacrylic acid adduct in a sublimation apparatus at 175–185° (1 mm.). At first considerable bubbling occurred, but after about one hour the mass became solid, and the temperature was elevated to 205–210°. A white product sublimed onto the cold finger weighing 0.35 g. (88%). After recrystallization from nitromethane, the product melted at 236° which was identified as piperidine hydrobromide.

The same product was obtained by allowing the pyrolysis temperature to remain at 185°, and the solid mass taken up in nitromethane. Upon cooling and adding an equal volume of dioxane, the piperidine hydrobromide separated.

Reaction of Piperidine and α-Hydroxy-β-chloropropionic Acid.—A mixture of 2.0 g. of α-hydroxy-β-chloropropionic acid and 4.0 g. of piperidine was heated on a steam-cone for one hour. Upon cooling, a solid and a sirup remained. This was stirred with 15 ml. of dioxane and chilled in an ice-bath. The piperidine hydrochloride which separated was removed by filtration, and the filtrate allowed to evaporate. The resulting sirup was left in a vacuum desiccator overnight. A crystalline product was obtained after allowing to stand under 25 ml. of ether in a warm place and replacing the colored ether with fresh ether every two hours over a period of one day. The solid was washed with dioxane and weighed 1.6 g. (55%). The product was purified by recrystallizing from methanol, m. p. 219° (cor.) with decomposition. The melting point when mixed with the four mole hydrogenated 2-pyridone α-bromoacrylic acid adduct base showed no depression.

Piperidinoacetaldehyde Hydrochloride.—A mixture of 22 g. of piperidinoacetaldehyde methyl acetal[12] and 20 ml. of concentrated hydrochloric acid was refluxed for one hour. The aqueous acid was distilled on a steam-cone *in vacuo* leaving a thick sirup. After standing in a vacuum desiccator containing sodium hydroxide for twenty-four hours, the sirup became hard without crystallizing. The sirup was dissolved in 25 ml. of nitromethane and allowed to evaporate aided by a stream of air. A crystalline solid and sirup remained. About 50 ml. of acetone was stirred into the mixture and a flocculent precipitate formed. After filtering from the solution, the gummy solid was dissolved in 15 ml. of nitromethane and allowed to remain in the refrigerator overnight. The solid mass was washed with ice-cold nitromethane leaving 5 g. of an almost white material melting at 106–107°. This product checks with that prepared by Stoermer who reported a melting point of 106°. Upon evaporation, the filtrate yielded a gummy sirup which could not be induced to crystallize.

α-Hydroxy-β-piperidinopropionitrile.—A solution of 5 g. of the aldehyde hydrochloride prepared in the previous experiment in 15 ml. of water was added slowly to an ice-cold solution consisting of 1.5 g. of sodium cyanide in 25 ml. of water. A solid product precipitated immediately weighing 4.5 g. (95%). After recrystallizing from benzene, the product melted at 97–98° (cor.).

Anal. Calcd. for $C_8H_{14}N_2O$: C, 62.35; H, 9.09. Found: C, 62.50; H, 9.28.

This product could be advantageously prepared in 73% yield directly from the crude piperidinoacetaldehyde hydrochloride sirup.

α-Hydroxy-β-N-piperidinopropionic Acid.—The hydrolysis was carried out by refluxing 2.4 g. of the nitrile for four hours with 10 ml. of concentrated hydrobromic acid. The excess acid was removed by distillation at atmospheric pressure until a solid separated, then further concentration was accomplished by evaporation on the steam-cone aided by a stream of air. The solid which remained was extracted with four 15-ml. portions of boiling *n*-propyl alcohol. This solution was evaporated to a solid and recrystallized from the minimum amount of boiling-hot isopropyl alcohol. The yield was 3.7 g. (92%) and after recrystallizing melted at 173–175° (cor.) with decomposition. The melting point when mixed with the four mole hydrogenated 2-pyridone α-bromoacrylic acid adduct showed no depression.

β-(N-2-Piperidone)-propionic Acid.—A solution of 2 g. of β-(N-2-pyridone)-propionic acid in 100 ml. of 95% ethanol was hydrogenated at 40 lb. pressure and room temperature using 1.0 g. of palladium on charcoal catalyst. After eighteen hours, two moles of hydrogen were absorbed. The catalyst was filtered from the solution which was then evaporated to dryness at room temperature aided by a stream of air. The white crystalline solid was recrystallized from acetone, yielding 1.4 g. (70%) of fine white flakes. After recrystallization the melting point was 148° (cor.).

Anal. Calcd. for $C_8H_{13}NO_3$: C, 56.13; H, 7.68; N, 8.18. Found: C, 56.48; H, 7.80; N, 8.28.

An excess of dry hydrogen bromide was passed into a solution of 0.47 g. of this product contained in 10 ml. of chloroform. Upon cooling in an ice-bath, a white crystalline product separated. The yield of hydrobromide was 0.6 g. (95%). The sample was purified by recrystallizing from nitromethane, m. p. 179° (cor.), with decomposition.

Anal. Calcd. for $C_8H_{14}NO_3Br$: C, 38.11; H, 5.60; N, 5.56. Found: C, 38.25; H, 5.37; N, 5.42.

Reaction of Methyl α-Bromopropionate and the Sodium Salt of 2-Pyridone; α-(N-2-Pyridone)-propionic Acid.—A mixture of 5.8 g. of the anhydrous sodium salt of 2-pyridone, and 8.8 g. of methyl α-bromopropionate in 25 ml. of absolute ethanol was refluxed for one hour and filtered hot. The solution was distilled on the steam-cone using vacuum toward the end. The sirup remaining was soluble in water and chloroform but insoluble in ether. No crystalline product could be obtained from the sirup so it was saponified by heating for an hour on the steam-cone with a solution of 4.0 g. of sodium hydroxide in 10 ml. of water. This solution was then made acid with 25 ml. of ethanol containing 2.5 g. of concentrated sulfuric acid. An inorganic precipitate was filtered off and the filtrate evaporated to dryness. The residue was washed with 50 ml. of hot chloroform. The granular crystals remaining weighed 7.0 g. (84%). After recrystallizing from absolute ethanol, the melting point was 215–217° (cor.) with decomposition.

Anal. Calcd. for $C_8H_9NO_3$: C, 57.52; H, 5.43; N, 8.38. Found: C, 57.39; H, 5.18; N, 8.51.

α-(N-2-Piperidone)-propionic Acid.—A suspension of 2.0 g. of α-(N-2-pyridone)-propionic acid and 50 mg. of platinum oxide in 50 ml. of absolute ethanol was hydrogenated at 50-lb. pressure and 50°. Two moles of hydrogen were absorbed in two hours. After filtering from the catalyst, the filtrate was evaporated at room temperature aided by a stream of air. The crystalline solid which remained was recrystallized from benzene. The yield was 1.9 g. (93%). The melting point was elevated to 144° (cor.) after further recrystallization from the same solvent.

Anal. Calcd. for $C_8H_{12}NO_3$: C, 56.13; H, 7.67; N, 8.18. Found: C, 56.27; H, 7.41; N, 8.25.

Reaction of Sodium 2-Pyridone and Ethyl α-Bromo-β-ethoxypropionate; α,β-Di-(N-2-pyridone)-propionic Acid.—A solution of 5.0 g. of the anhydrous sodium salt of 2-pyridone and 8.0 g. of ethyl α-bromo-β-ethoxypropionate[13] in 25 ml. of absolute ethanol was refluxed for four hours. The solvent was evaporated on the steam-cone aided by a stream of air until only a sirup and a solid remained. The sirup was extracted with 25 ml. of chloroform and the solvent distilled on the steam-cone using vacuum to remove the last trace of solvent. The sirup was allowed

(12) Stoermer, *Ber.*, **31**, 2542 (1898).

(13) Wood and DuVigneaud, *J. Biol. Chem.*, **134**, 413 (1940).

to remain in a vacuum desiccator overnight then extracted with 25 ml. of boiling xylene. The resulting solution was set in a warm place and evaporated. A crystalline residue resulted weighing 1.5 g. (12%). It melted at 151° (cor.) after recrystallization from xylene. No other crystalline product could be isolated.

Anal. Calcd. for $C_{15}H_{16}N_2O_4$: C, 62.50; H, 5.56. Found: C, 62.29; H, 5.32.

Summary

1. The reactions of 2-pyridone were studied with the objective of finding the best route to α-amino-β-(N-2-pyridone)-propionic acid, an analog of leucenol. The addition of 2-pyridone to α-acetamidoacrylic acid, followed by hydrolysis of the adduct, resulted in the product desired and provided the procedure for the successful synthesis of leucenol.

2. Other reactions of 2-pyridone which were explored during this investigation were numerous. β-(N-2-Pyridone)-propionic acid upon treatment with bromine and phosphorus gave β-(3,5-dibromo-N-2-pyridone)-propionic acid. 2-Pyridone gave the expected N-substituted products upon condensation with chloroacetaldehyde and bromopyruvic acid. It added to butadiene sulfone.

3. An extensive study was made of the condensation product of sodium 2-pyridone with α,β-dibromopropionic acid. The product was water soluble and contained ionizable bromine. It could be made more advantageously from 2-pyridone and α-bromoacrylic acid.

4. The 2-pyridone α-bromoacrylic acid adduct reacted with ammonia to give α-(N-2-pyridone)-β-aminopropionic acid or with aqueous alkali to give the corresponding β-hydroxy compound. Upon reduction with hydrogen and palladium–charcoal catalyst two moles of hydrogen were absorbed and the piperidone analog resulted as shown by treatment with ammonia to give α-(N-2-piperidone)-β-aminopropionic acid which was also made by the reduction of the α-(N-2-pyridone)-β-aminopropionic acid. When the adduct was reduced with hydrogen and platinum oxide as a catalyst, four moles of hydrogen were absorbed and α-hydroxy-β-piperidinopropionic acid was the product as shown by synthesis from piperidine and α-hydroxy-β-chloropropionic acid or from piperidinoacetaldehyde through the cyanohydrin. The mechanism of these transformations is discussed.

5. The 2-pyridone α-bromoacrylic acid adduct was titrated as a monobasic acid. With one molecule of silver oxide it yielded a betaine and with one-half mole of silver oxide a betaine hemihydrobromide. The infrared spectra of betaine hydrobromide and betaine compared closely with those of the 2-pyridone α-bromoacrylic acid adduct and the hydrobromide-free analog, thus showing similar groupings. The structure of the adduct is postulated as an ethylene-immonium bromide which permits a satisfactory explanation of all the experimental facts.

An Improved Apparatus for the Study of Reactions in Liquid Ammonia[1,2]

BY GEORGE W. WATT AND C. W. KEENAN[3]

Apparatus of the type described by Johnson and Fernelius[4] and modified extensively by Watt and Moore[5] for the conduct of reactions in liquid ammonia at its boiling point involves two serious shortcomings. Neither the original nor the modified apparatus provides for (a) the possibility of conducting titrations in a closed system (a procedure frequently advantageous in establishing the stoichiometry of reactions of liquid ammonia solutions of alkali and alkaline earth metals), or (b) the substantially quantitative removal of solid reaction products following *in situ* filtration and washing, without exposure of these products to the atmosphere. Both of these objectives are realized through use of the apparatus described in the present paper.

Two relatively simple reactions were chosen to demonstrate the operability of the equipment, *i. e.*, the reduction of ammonium bromide and silver(I) bromide with liquid ammonia solutions of potassium.[6] These cases show that the equipment described below permits one to exercise close analytical control over all reactants and products, including gaseous products; the importance of so-doing has been emphasized elsewhere.[7]

Experimental

Apparatus.—The apparatus designed to meet the needs indicated above is shown in Fig. 1. In general, this equipment is similar to that described by Watt and Moore[5]; consequently only the improvements will be pointed out here.

(1) The major part of this work was done under the sponsorship of the Office of Naval Research, Contract N6onr-26610.

(2) The liquid ammonia employed in these studies was generously supplied by E. I. du Pont de Nemours and Company.

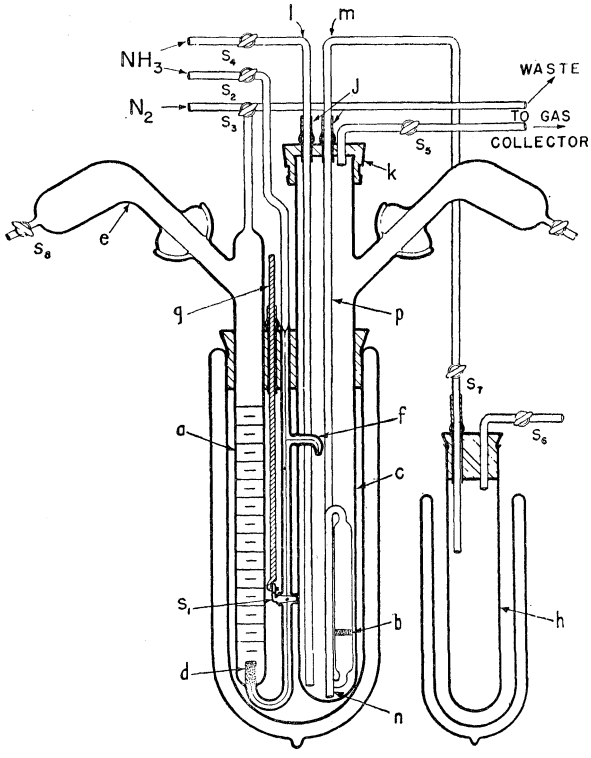

Fig. 1.

The novel features are the buret a and the internal in-line filter[8] b. Both the buret and the main reaction cell c are provided with addition bulbs connected by ball-socket joints held by spring clamps (not shown). In actual operation, ammonia is condensed in the buret until it is approximately one-half full, a known weight of alkali metal[9] is added from tube e, the solution is stirred by a stream of ammonia through the fritted glass filter[10] d, and sufficient additional ammonia is then condensed in a to give a metal solution of the desired concentration. Stopcock s_1 is closed and ammonia is condensed in c, which contains the substance which it is intended to bring into reaction with the metal solution.

Titrations with metal solutions are conducted as follows. With stopcock s_5 open, a positive pressure of dry oxygen-free nitrogen is exerted (through stopcock s_3) upon the surface of the metal solution in a. While the solution (or suspension) in c is stirred by a slow stream of ammonia gas, stopcock s_1 is opened and metal solution is delivered dropwise into c *via* the capillary delivery tip f, and at the same time the metal solution is filtered through d. Addition of metal solution may be interrupted upon the appearance in c of a color change, a precipitate, the beginning or cessation of gas evolution, or the first appearance of the characteristic blue color denoting the presence of excess metal solution.

[Stopcock s_1 is submerged in the coolant ammonia contained in the outer Dewar flask and is lubricated with Dow–Corning high vacuum grease. This stopcock is held in place by a spring clamp (not shown) and is manipulated by means of the metal rod g which is connected through a glass ring sealed onto the handle of the stopcock s_1. This rod extends through a glass sleeve in the rubber stopper and the closure between rod and sleeve is made with rubber tubing.]

Upon completion of a reaction that yields a solid product, filtration, washing, and collection of the solid are accomplished as follows. With controlled reduction of the pressure in tube h (evacuated *via* stopcock s_6), stopcock s_7 is opened and the contents of c filtered through b. The solid on the filter b is washed with fresh portions of ammonia successively condensed in c and drawn over through b as described above.[11] At the same time, the filtrate and washings are collected quantitatively in h. *While the solid on the filter is still wet with ammonia,* cap k (together with tubes l, m, and the gas exit tube) is removed from reaction cell c and, with stopcock, s_7 open, a small rubber cap (small bore pressure tubing closed at one end with a screw clamp) is quickly placed over the intake end of the filter tube, *i. e.*, at n. Tube m is then broken off at point p, attached to the vacuum line at point p, evacuated for a few minutes, and sealed off just above n. Following thorough evacuation to remove excess ammonia, tube m is sealed off between p and the top of the filter tube, and transferred to a dry box for all subsequent manipulations. Thus the solid sample is isolated without exposure to the atmosphere.[12]

The cap k is a rubber stopper bored out to fit over the tube c and held firmly in place by a metal collar (not shown) which is tightened with a screw. This type of cap obviates use of a thick stopper which would restrict the side-to-side movement of tubes l and m which are connected through k by means of rubber-to-glass seals which are kept gas-tight by means of spring clamps (not shown).

Titration of Ammonium Bromide Solution with Potassium Solution.—Weighed samples of am-

(8) Ace Glass, Inc., Cat. No. 8570, filter tube, porosity C or D.

(9) The metal is cut under dry xylene, so that only freshly cut surfaces are exposed. While still wet with xylene, the metal is transferred to tube e while a current of dry ammonia gas is admitted *via* stopcock s_8. The xylene is volatilized in the ammonia gas stream, tube e is tightly stoppered, stopcock s_8 is closed, and the tube and its contents are weighed. Thereafter, tube e is attached to the side-arm on buret a which is previously flushed out with dry ammonia gas.

(10) Ace Glass, Inc., Cat. No. 8575, filter tube, porosity C.

(11) An alternative procedure is used with very finely divided solids which tend to clog the filter medium. The initial reaction is conducted with filter b raised upward in c so that the intake tip of the filter is above the level of the solution in c. The solid is allowed to settle, filter b is lowered carefully and the supernatant solution is drawn off with minimum disturbance of the settled solid. Thereafter, the solid is washed several times by condensation of fresh ammonia, settling, and decantation, before the bulk of the solid is finally drawn over onto the filter.

(12) While this procedure may appear to involve risk of exposure of the sample to the atmosphere, samples of highly pyrophoric metals which react violently upon the slightest exposure have been handled in this manner without any evidence of atmospheric oxidation.

monium bromide dissolved in approximately 50 ml. of liquid ammonia in c were titrated with potassium solutions of known concentration delivered from the calibrated buret a. The first appearance of a permanent blue color (characteristic of solutions of metals in ammonia) was taken as the end-point. Data for two such titrations are given in Table I (Expts. 1 and 2).

[a] Calcd. on the basis of the weight of ammonium bromide or silver(I) bromide used. [b] Measured as a portion (15–20 ml.) of a known volume (25–30 ml.) of potassium solution containing a weighed quantity of potassium.

Reduction of Silver(I) Bromide with Potassium.—Solutions containing known weights of silver(I) bromide were similarly titrated with potassium solutions. In these cases, however, the end-point could not be detected as indicated above, owing to the presence of the black finely divided precipitate of elemental silver. Consequently, a calculated volume of potassium solution was added, the precipitate allowed to settle, and drops of potassium solution were added to the clear supernatant solution until there was no further evidence of reaction. The combined supernatant solution and washings gave a negative test for silver ion. The resulting data are shown as Expts. 3 and 4, Table I.

Summary

An improved apparatus for the conduct of reactions in liquid ammonia at its boiling point has been described, and its utility demonstrated. This apparatus provides for titrations employing liquid ammonia solutions of metals and permits one to carry out filtration and purification operations at the boiling point of the solvent.

It has been demonstrated that silver(I) bromide is reduced to elemental silver by reaction with solutions of potassium in liquid ammonia.

NOTES

Preparation of Radioactive Cyanide from Carbon Dioxide

BY RICHARD ABRAMS

For synthesis of labeled compounds it is often necessary to convert $BaC^{14}O_3$ to $HC^{14}N$. Available methods treat carbon dioxide with ammonia and potassium metal[1] (yield is a sensitive function of experimental conditions[2]), or treat barium carbonate with sodium azide[3] (yields are low in our experience). A method which has been found to be very satisfactory is based upon the reduction of carbon dioxide to carbon with magnesium powder,[4] and the conversion of amorphous carbon to hydrocyanic acid with ammonia gas at 1000°.[2,5,6] Yields are usually between 60 and 70% and not particularly dependent upon carbon dioxide pressure or magnesium excess.

In a typical experiment, carbon dioxide was liberated into a vacuum system from 1.1 mmoles. of barium carbonate by mixing with 1.6 g. of lead chloride and heating with a micro-burner.[7] Traces of water were removed by sublimation at −80°. The carbon dioxide was then admitted to a quartz tube containing 2.5 mmoles. of magnesium powder in a thin-walled iron thimble. The tube was heated rapidly with an oxygen flame until the thimble glowed red, and reaction began as noted by the sharp pressure drop. Intermittent heating was continued until the pressure remained constant. The contents of the thimble were washed with 1 *M* hydrochloric acid and with water, transferred as a slurry to a quartz boat, and dried under an infrared lamp. The yield was 0.76 mmole. of carbon which was 89% pure. Based upon the residual pressures of condensable and non-condensable gases and the acetylene liberated upon wetting the reaction mixture, the 30% loss consisted of approximately 5% unreacted carbon dioxide, 10% carbon monoxide, and 15% magnesium carbide.

The boat containing the carbon was placed in a quartz tube surrounded by an electric furnace. Ammonia gas was allowed to flow directly from the tank through the quartz tube and out through a wash bottle containing a 10% excess of 0.1 *M* sodium hydroxide. When all the air had been displaced by ammonia, the furnace was turned on so that the temperature rose to 1000° in thirty minutes, and stayed between 1000° and 1100° for two and one-half hours. All the hydrocyanic acid formed was carried out by the ammonia which flowed through the tube continuously at a

rate of 2 to 3 bubbles/second. The cyanide accumulated in the alkaline solution in the wash bottle which was removed at the termination of the heating period. Yields in this step were quantitative.

In a series of four runs, using approximately 1 mmole. of barium carbonate, in which the magnesium excess ranged from 14 to 48% over the stoichiometric amount, and the carbon dioxide pressure from 278 to 385 mm., the yields of cyanide obtained were 67, 69, 72 and 59%. The value of 59% was obtained by radioactivity assay, the others by silver nitrate titration.

2,4-Dinitrophenylhydrazones of Methoxy- and Methylcyclohexanones

BY HOMER ADKINS AND A. G. ROSSOW

Since the literature record of the melting points of these derivatives is confused and contradictory, we have re-examined the behavior of their ketones in the procedure described by Shriner and Fuson.[1]

2-Methoxycyclohexanone gave in our hands not the 2,4-dinitrophenylhydrazone, m. p. 135°, reported by others[2] but slowly and in low yield a red product, m. p. 218–219° uncor., whose analysis corresponded to cyclohexandione-1,2-bis-(2,4-dinitrophenyl)-osazone. *Anal.* Calcd. for $C_{18}H_{16}N_8O_8$: N, 23.72. Found: N, 23.62. This reaction is analogous to the prior[3] record for 3-methoxy-2-butanone. 3-Methoxycyclohexanone by similar treatment did not yield a 2,4-dinitrophenylhydrazone, m. p. 133.5°,[2] but instead gave rapidly in quantitative yield a product, m. p. 170–170.5° uncor., whose analysis indicated loss of methanol as well as water during the condensation. *Anal.* Calcd. for $C_{12}H_{12}N_4O_4$: C, 52.17; H, 4.38; N, 20.28. Found: C, 52.30; H, 4.42; N, 20.54. Our product may therefore be either a ring-closed derivative or cyclohexen-2-one 2,4-dinitrophenylhydrazone; the latter has previously been reported as m. p. 163[4] and 117°.[5] From the 4-methoxy ketone we obtained 4-methoxycyclohexanone 2,4-dinitrophenylhydrazone, orange crystals from ethanol, m. p. 142.5–143.5° uncor. *Anal.* Calcd. for $C_{13}H_{16}N_4O_5$: N, 18.18. Found: N, 18.20. This accords with the m. p. of 141.5–142.5°[6] but disagrees with the values of 150°[2,7] from the prior literature.

The behavior of 2-methylcyclohexanone was not examined, but its position isomers gave conventional results. 3-Methylcyclohexanone gave an orange-yellow 3-methylcyclohexanone 2,4-dinitrophenylhydrazone, m. p. 153.5–155.0° uncor., which appeared to be a mixture of stereoisomers. *Anal.* Calcd. for $C_{13}H_{16}N_4O_4$: N, 19.17. Found: N, 19.22. The same procedure on 4-methylcyclohexanone gave 4-methylcyclohexanone 2,4-dinitrophenylhydrazone, golden yellow crystals from ethanol, m. p. 134.7–135.1° uncor. *Anal.* Found: N, 19.47.

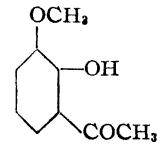
The Reaction of *o*-Veratronitrile with Methylmagnesium Iodide

BY E. D. AMSTUTZ

In the course of other work to be reported later relatively large quantities of *o*-acetovanillone (I) were required.



I

The usual method of synthesis involves the successive conversion of *o*-veratric aldehyde to the methylcarbinol,[1] acetophenone,[2] and demethylation.[3] It has now been found that several of these steps may be obviated with improvement in yield and facility. Although ether splitting is by no means new, the reaction of *o*-veratronitrile with methylmagnesium iodide has previously been reported[4] to yield the dimethoxyketone. Apparently the phenol formed escaped attention.

The present work has shown that the 2,3-dimethoxyacetophenone may be the main product of the reaction but also that conditions may be so arranged that it appears only as a minor product with 2-demethylated ketone assuming major importance. For example, using double the calculated quantity of Grignard reagent over a total reaction time of sixty hours the yield of *o*-acetovanillone rises to about 75% and the yield of non-phenolic ketone drops to about 18%.

Since the methoxyl group ortho to the acetyl is vinylogous with methyl acetate it is not inconceivable that it could have suffered hydrolysis during the acid treatment to destroy the magnesium complex. A sample of the solid magnesium-containing complex was therefore removed from the reaction mixture and rapidly decomposed with cold ammonium chloride solution. Ether extraction removed a yellow material which exhibited (in alc. soln.) a definitely positive test for the phenolic group with ferric chloride. Since it is hardly likely that the hydrolysis could have occurred under these mild conditions and in such a short interval of time, it appears necessary to suppose that the splitting occurred during the reaction of the Grignard reagent. The same conclusion is indicated by the fact that 2,3-dimethoxyacetophenone (in ether soln.) did not yield phenolic bodies on gentle warming and stirring for three hours with dilute hydrochloric acid, although it was obvious other changes were taking place. Also Fuson and Chadwick[5] have

(1) Pauly, *et al.*, *Ann.*, **383**, 317 (1911).

(2) Krannichfeldt, *Ber.*, **46**, 4016 (1913).

(5) Fuson and Chadwick, *J. Org. Chem.*, **13**, 484 (1948).

shown that such hydrolysis is quite liable to remove the acyl group. The production of *o*-acetovanillone therefore appears to be analogous to the formation of isobutyl 3,5-dimethoxy-4-hydroxyphenyl ketone from 3,4,5-trimethoxybenzonitrile and isobutylmagnesium bromide.[6] It differs, however, in the fact that methylmagnesium iodide does not require high temperatures and apparently does not alkylate at the position of attachment of the *o*- or *p*-methoxyl group.

Similar observations have been made on 2-benzyloxy-3-methoxybenzonitrile in which the benzyl ether is split. Since there is no preparative advantage accruing to the use of the benzyl ether rather than the methyl ether, details of these experiments are omitted.

Experimental

An ether solution of 16.3 g. (0.1 mole) of *o*-veratronitrile was added rapidly to an ether solution of Grignard reagent prepared from 28.4 g. (0.2 mole) of methyl iodide and 4.8 g. (0.2 g.-atom) of magnesium. No refluxing was observed and no precipitate formed for about one hour. The solution was therefore refluxed and stirred for eight hours during a total time of about sixty hours. Although a small amount of Grignard reagent was still present the mixture was then worked up in the usual way with water, ammonium chloride solution and finally dilute hydrochloric acid. Phenolic material, removed from the ethereal solution with dilute alkali, proved to be almost pure *o*-acetovanillone and amounted to 12.36 g. (74.5%), m. p. 50–53.1°, mixed with authentic *o*-acetovanillone, m. p. 51.8–53°. The crude neutral material amounted to 3.25 g. (18%), $n^{30.5}D$ 1.5282, observed for authentic *o*-acetoveratrone $n^{26.5}D$ 1.5368. Starting material unaccounted for above was obtained as a water-, ether- and alkali-insoluble resinous gum.

A second run of the same size using a nitrile to Grignard ratio of 1:1.5, refluxing for one hour and standing overnight yielded some tar and 25.6% of *o*-acetovanillone (m. p. 51.8–53°; mixed with authentic, m. p. 51.8–53°) and 32.2% of *o*-acetoveratrone, $n^{26.5}D$ 1.5368. The neutral fraction yielded iodoform (m. p. 121–123°) and an acid, m. p. 118–120.4° (reported for *o*-veratric acid, m. p. 122°).[7] It also formed a 2,4-dinitrophenylhydrazone, m. p. 150–151.8° which did not depress the melting point of an authentic specimen.

Purification of Xanthopterin[1]

BY A. G. ANDERSON, JR., AND JERRY A. NELSON

In connection with the studies on the physiological properties of xanthopterin in this Laboratory,[2] xanthopterin free of other pterin impurities was desired. A purification procedure satisfactory as a routine method for this purpose was not found in the literature. In this investigation xanthopterin has been purified *via* a new crystalline derivative, xanthopterin hydrochloride. Crystalline xanthopterin sulfate has also been prepared. The hydrochloride salt affords a simple, effective means for the purification of synthetic xanthopterin as prepared in this Laboratory. Purification was also effected by sublimation *in vacuo*. This procedure gave poor yields and thus was not practical.

(1) This investigation was supported in part by a research grant from the Division of Research Grants and Fellowships of the National Institute of Health, U. S. Public Health Service.

Experimental

Xanthopterin.—Leucopterin and, from it, xanthopterin were prepared by the procedures of Purrmann[3] and Totter,[4] respectively, as modified by Dauben and Goheen,[5] the modified procedure being similar to that recently reported by Hitchings and co-workers.[6] The xanthopterin so obtained was used in the experiments described below.

Xanthopterin Hydrochloride.—To 100 mg. of finely powdered xanthopterin was added 20 ml. of concentrated hydrochloric acid and the mixture heated on a steam-bath for ten minutes and filtered by suction while hot. The insoluble material (approximately 20 mg.) was largely xanthopterin hydrochloride and to this was added 5 ml. of hydrochloric acid and the mixture heated and filtered as before. The small quantity (5 mg.) of insoluble material was discarded. The two filtrates were placed in a refrigerator at −5° overnight. The hydrochloride precipitated as tiny, tan hexagonal plates which were separated by filtration, washed with a few ml. of cold alcohol, then with ether and dried. The yield from the first filtrate was 86 mg. (71.5%) and from the second filtrate 10 mg. (8.4%); total yield 96 mg. (79.9%). The salt was recrystallized from hydrochloric acid in corresponding yield. It was soluble in hot water or hot dilute hydrochloric acid but the hydrochloride could not be recovered from these solutions by cooling or concentration. On heating the crystals darkened at 200° and above but no melting point was observed up to 320°.

Anal. Calcd. for $C_6H_6O_2N_5Cl$: N, 32.48. Found: N, 32.41.

Amorphous xanthopterin was recovered quantitatively as a yellow solid on treatment of the hydrochloride with just sufficient 0.1 *N* ammonium hydroxide to effect solution (the xanthopterin began to precipitate a few seconds after the salt had dissolved) and then adjustment of the acidity to *p*H 5–6 by addition of dilute hydrochloric acid. The mixture was cooled, filtered and the collected precipitate washed with a few ml. of cold water, then acetone and dried.

Xanthopterin Sulfate.—Eighty-six mg. of finely powdered xanthopterin was dissolved in 2.3 ml. of sulfuric acid–water (1:1) solution by heating on a steam-bath. As the xanthopterin dissolved the solution became orange in color. On cooling the solution in tap water and scratching the sides of the flask, crystallization occurred and, after standing overnight in a refrigerator, the tiny, tan boat-shaped crystals were separated by filtration, washed with a few ml. of cold alcohol, then with ether and dried; yield 45 mg. (36%). The crystals gradually darkened and decomposed above 200° leaving a black residue at 280°. The sulfate could be recrystallized from the same sulfuric acid solution in corresponding yield. Attempts to obtain a second crop from the filtrate were unsuccessful. Xanthopterin sulfate is quite soluble in dilute or concentrated sulfuric acid and undergoes hydrolysis with water to precipitate amorphous xanthopterin. Recovery of xanthopterin from the sulfate was best effected in the manner described for the hydrochloride.

Anal. Calcd. for $C_6H_7O_6N_5S$: N, 25.27. Found: N, 25.80.

Chromatographic Analysis of Purified Xanthopterin.—Paper chromatographs of the xanthopterin purified *via* the hydrochloride and by sublimation *in vacuo* were obtained by the method of Good and Johnson[7] who employed the *n*-butanol–acetic acid–water mixture of Partridge.[8] Under ultraviolet light the chromatographs showed only one fluorescent spot (Rf = 0.35–0.38) which was in agreement with the value (Rf = 0.38) reported by Good and Johnson.[7] The material was thus free of leucopterin (Rf = 0.12), dihydroxanthopterin (Rf = 0.26) and other fluorescent pterin impurities. It should be noted that some samples of synthetic xanthopterin prepared as indicated did not contain these impurities and thus required no further purification.

Absorption Spectra of Purified Xanthopterin.—Ultraviolet absorption spectra of an aqueous solution (*p*H of 11.25) of the xanthopterin purified by sublimation and *via* the hydrochloride showed absorption maxima at 255 mμ. ($E_m \times 10^{-3} = 18.2$) and 392 mμ; ($E_m \times 10^{-3} = 7.0$) in agreement with other reported spectra.[4,9]

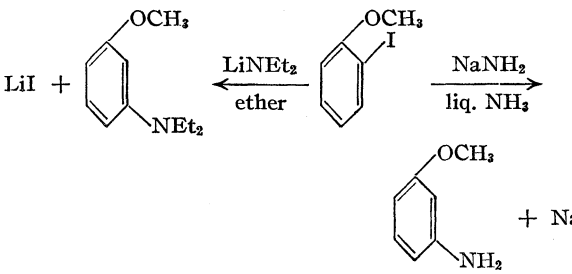
The Reaction of Sodium Amide with *o*- and *m*-Chlorotrifluoromethylbenzene

BY ROBERT A. BENKESER AND ROLAND G. SEVERSON[1]

Recently it was reported that certain aryl halides react with a liquid ammonia solution of sodium[2] or potassium amide.[3] It has also been found that ether solutions of aryl halides are attacked by lithium dialkylamides.[4] When the aryl halide has an ether, sulfide or dialkylamino group ortho to the halogen, it was observed that the amino or dialkylamino group does not take up the position which the halogen originally occupied, but rather a meta-substituted product[5,6,7] is formed



The corresponding *p*-haloethers also exhibit this tendency to undergo rearrangement when treated with lithium dialkylamides in ether, but to a somewhat lesser extent.[8]

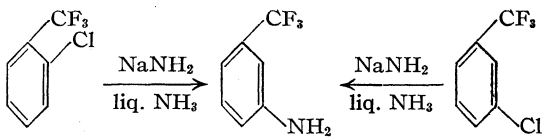
(6) Gilman, *et al.*, *ibid.*, **67**, 2106 (1945).
(7) Gilman, Kyle and Benkeser, *ibid.*, **68**, 143 (1946).
(8) Gilman and Kyle, *ibid.*, **70**, 3945 (1948).

It has now been observed that the same rearrangement occurs even when the halogen is ortho to a strong meta-directing group. Thus, *o*-chlorotrifluoromethylbenzene upon treatment with sodium amide in liquid ammonia for five hours at −33° gives a 52% yield of pure *m*-aminotrifluoromethylbenzene. Efforts to isolate any of the ortho isomer have been unsuccessful. In contrast, *m*-chlorotrifluoromethylbenzene gives the expected *m*-aminotrifluoromethylbenzene. It is noteworthy that the yield here is only 35%.



Experimental

***m*-Aminotrifluoromethylbenzene.** (a) **From *o*-Chlorotrifluoromethylbenzene.**—Sodium amide[9] was prepared from 16.1 g. (0.7 g. atom) of sodium and 750 ml. of liquid ammonia containing 0.4 g. of hydrated ferric nitrate. To this mixture was added 90.3 g. (0.5 mole) of *o*-chlorotrifluoromethylbenzene[10,11] (b. p. 149–150°) during a period of one hour. After stirring for an additional four hours, ammonium chloride was added and the solvent was allowed to evaporate. The residue was dissolved in ether, filtered and treated with anhydrous hydrogen chloride which precipitated 62 g. of a brown hydrochloride. From the ether filtrate 14.4 g. of *o*-chlorotrifluoromethylbenzene (b. p. 149–150°) was recovered. Crystallization of the crude hydrochloride from an ethanol–ether mixture gave 53 g. of white crystals from which the free base was obtained by adding concentrated ammonium hydroxide. After extracting the basic solution with ether, drying the ether extract over Drierite, removing the solvent, and fractionating the product through a small helices-packed column, there was obtained 35.1 g. (52% yield) of *m*-aminotrifluoromethylbenzene boiling at 86° (20 mm.), $n^{20}D$ 1.4801, $n^{25}D$ 1.4775.

The acetyl derivative[12] melted at 103–104° and the benzoyl derivative[13] at 110–111°. A mixed melting point between this acetyl derivative and that obtained from an authentic sample of *m*-aminotrifluoromethylbenzene[10] showed no depression.[14]

(b) **From *m*-Chlorotrifluoromethylbenzene.**—This procedure was identical with that described above. From 90.3 g. (0.5 mole) of *m*-chlorotrifluoromethylbenzene,[10] 47.8 g. of crude hydrochloride was obtained. This gave 36 g. of pure salt when crystallized from an ethanol–ether mixture and 23.9 g. (35% yield) of the free base boiling at 86° (20 mm.), $n^{20}D$ 1.4800. The acetyl and benzoyl derivatives melted at 103–104° and 110–111°, respectively.

Preparation of Wüstite

BY R. W. BLUE AND H. H. CLAASSEN

For X-ray diffraction studies of iron oxides it is frequently helpful to have diffraction patterns of the pure oxides for purposes of comparison. Samples of magnetite, ferric oxide and iron are readily obtained but a sample having the ferrous oxide structure is less easily prepared. Fusion of higher oxides with iron often results in samples which do not give clean diffraction patterns.

Previous work[1] indicates that the lower limit for oxygen content of this sodium chloride-type structure is 23.1% oxygen as compared with 22.27% for ferrous oxide. The name wüstite has been given to the material in the composition range, 23.1 to 25.6% oxygen, in which the sodium chloride-type of structure occurs.

A convenient way to prepare a sample of wüstite is to take advantage of the simultaneous reactions

$$\text{Iron} + H_2O \longrightarrow \text{wüstite} + H_2$$
$$\text{Magnetite} + H_2 \longrightarrow \text{wüstite} + H_2O$$
$$\text{Iron} + \text{magnetite} \longrightarrow \text{wüstite}$$

When equimolal amounts of iron and magnetite are placed in an atmosphere of water vapor in the temperature region 750 to 900°, some hydrogen is immediately formed and the water hydrogen ratio is automatically regulated for conversion of both iron and magnetite to wüstite. By keeping the iron and magnetite in separate boats one can use an excess of either reactant; the reactant not in excess is converted to material giving a clean diffraction pattern of the sodium chloride-type of structure but there is a slight difference between the diffraction patterns of the two samples which may be described as follows:

In practice magnetite obtained by burning pure iron at fusion temperatures contains 10 to 50% ferrous oxide.[2] The ferrous oxide diffraction lines obtained with these ferrous oxide–magnetite samples are doublets which become single lines when reduction occurs. When the samples are reduced in a stream of hydrogen the line in each doublet which corresponds to the smaller lattice disappears first. When reduction is carried out by the double-boat method described above, the line corresponding to the larger lattice disappears first; and when wüstite is formed from iron by the double-boat method the diffraction lines are in the mean position between the doublet positions. The latter differences correspond to only a few thousandths of an ångström but they can be clearly seen by comparing XRD patterns of samples prepared simultaneously by the double-boat method.

Oxides in the composition range 23.2 to 24.3% oxygen have been prepared under various conditions. All samples in this composition range give the same XRD pattern with the exceptions noted above depending on the source material.

In a typical experiment magnetite containing about 40% wüstite was prepared by burning Armco iron in an atmosphere of oxygen. Some of this material, after crushing and screening to 60 to 120 mesh, was reduced with hydrogen at 450° to iron. Thirty-three and one-quarter grams of the magnetite and 3.0 g. of the iron were weighed into separate alundum boats and placed in a quartz tube closed at one end and joined at the other end by a wax seal to a Pyrex tube equipped with a side tube and vacuum connection. A few cc. of water was placed in the side tube and, after the apparatus was assembled, the side tube was cooled in liquid air. The apparatus was then evacuated and the side tube was warmed to room temperature. That part of the tube containing magnetite and iron was then heated to 900°. After seventy-two hours the tube was cooled in a stream of air and the iron oxide samples were removed. (Cooling to room temperature required about five minutes.) Examination by X-ray diffraction revealed that both the wüstite from the iron and that from magnetite contained no other crystalline materials. Reduction in a stream of hydrogen at 450° showed that the wüstite from the oxide contained 23.2% oxygen.

N-(Dialkylaminoalkyl)-amides

BY R. O. CLINTON, U. J. SALVADOR AND S. C. LASKOWSKI

Since only a few simple aromatic amide derivatives have been tested as local anesthetics,[1] it seemed desirable to extend these types to include 4-aminobenzamides and related compounds. However, the initially prepared compounds proved relatively inactive in comparison with their ester analogs, and the investigation was terminated after the preparation of only a few compounds.

Attempts were also made to prepare 4-aminobenzamides derived from imino-interrupted side chains, analogous to those derived from sulfur- and oxygen-interrupted side chains.[2] Because of the complex mixtures formed, we were unable to prepare pure 4-aminobenzamides of this type.

Experimental[3]

Nitriles.—The reaction of a primary or secondary amine with acrylonitrile was carried out by the method of Whitmore, *et al.*[4]

4-Nitrobenzamides and 4-Aminobenzamides.—The 4-nitrobenzamides were prepared from 4-nitrobenzoyl chloride and the amine by the sodium bicarbonate–chloroform–water procedure.[2] The yields were good, but the compounds derived from the tribasic amines proved extremely difficult to purify. The 4-aminobenzamides were obtained by reduction with ferrous sulfate and ammonia. Purification proved difficult in most cases, and with the more complex imino-interrupted side-chain compounds a pure base or characteristic derivative could not be obtained. The 4-nitro- and 4-aminobenzamides are listed in Table I.

Note on the Arc Spectrum of Element 61[1]

BY CYRUS FELDMAN

An examination has been made of the arc emission spectra of three samples of the chloride of element 61 prepared by Paul Lantz. This material was separated from a mixture of uranium fission products by fractionation and concentration on a series of Amberlite IR-I and Dowex resin columns.[1a] Detailed accounts of the isolation of milligram amounts of element 61 are to be reported elsewhere by G. W. Parker and P. Lantz of this Laboratory. The amount of element 61 present in these samples was estimated on the basis of published values[1a] of the half-life and energy of the β-radiation of this element. The characterization of material which is radiochemically and spectrographically identical with these samples as element 61 has been confirmed by X-ray emission work.[2]

Once isolated, the material was prepared in the form of approximately 0.05 ml. of a hydrochloric acid solution. A thin layer of Zapon lacquer was deposited on a flat-topped $^1/_4''$ diam. high purity graphite electrode; the sample solution was deposited atop this and dried under an infrared lamp. This electrode was made the anode of a 220-volt, 9-ampere d.c. arc. A $^1/_8''$ diameter high purity graphite rod served as cathode. The arc gap was 4 mm. The burning took place inside a chamber which permitted light to enter the spectrograph without allowing the vapor containing element 61, which is highly radioactive, to escape into the laboratory.

The light was focused on the slit of a 21-foot (6.5-meter) Jarrel-Ash spectrograph. Further details of dispersion, etc., are given in Table A.

When sample 1 was exposed, spectra of iron, neodymium, element 61, and samarium were obtained in juxtaposition in the order mentioned; in the other two cases, only the spectra of iron, and element 61 were photographed. The placement of the spectra on the plate was effected by means of a Hartmann diaphragm at the slit; the camera was not moved at any time during the exposure. The exposure conditions were essentially the same as those used by Harris, Yntema and Hopkins.[3]

A search was made for the five lines specifically mentioned by them as being common to the spectra of the neodymium and samarium fractions and being somewhat more intense in the fractions intermediate between them.[3,4] Wave lengths were located by interpolation between iron lines of known wave length; observations were made on an ARL–Dietert projection comparator, which gives an enlargement of twenty-one-fold.

In all, three samples were tested; the results are summarized in Table A.

	3378.0	Absent	Absent	(see text)
	3379.2	Absent	Absent	Absent

Sample 1 was received on February 20, 1948; its spectrum showed the presence of comparatively large amounts of calcium and magnesium, moderate amounts of iron, nickel, sodium and chromium, and small amounts of neodymium. Calcium was easily the major metallic constituent of this sample.

Although no definite line was seen in its spectrum at 3305.8, the proximity of iron 3305.98, which was present, might have masked a weak line at 3305.8. A line was observed at 3342.5, but this line may have been chromium 3342.586.

Two highly purified samples were received from the same source on March 7, 1949. The two samples contained 50 and 100 micrograms, respectively, of element 61. Arc spectra of these samples were taken under the same conditions as used for sample 1, except that higher dispersion was used. The spectrum of sample 3 is shown in Fig. 1.

The results are summarized in Table A. A weak line, not assignable to any known element, was found at 3377.64 ± 0.03 Å. in the high dispersion spectra, but in view of the fact that Yntema's observations were also made in the second order of a 6.5-meter spectrograph,[4] this line cannot be assumed to be identical with 3378.0. It was the weakest of several lines believed due to element 61 which were observed in the 3000–3450 Å. region of spectra 2 and 3. Seven such lines are listed in Table B; although these lines are fairly close to minor lines of various elements listed in the M. I. T. Wavelength Tables, qualitative examination of the spectrum showed that the only impurities present in samples 2 and 3 were faint traces of copper and calcium, and these did not interfere with the lines listed. A detailed study of the arc spectrum of element 61 is being made by W. F. Meggers and B. F. Scribner, Jr., of the National Bureau of Standards.

TABLE B

STRONGEST ARC LINES OF ELEMENT 61 IN THE 3000–3450 Å. REGION

Wave length, Å.	Relative intensity
3366.05 ± 0.03	Weak
3377.64 ± .03	Weak
3391.25 ± .03	Medium
3418.67 ± .03	Weak
3427.42 ± .03	Strong
3441.09 ± .03	Weak
3449.81 ± .03	Medium

Unfortunately, it was impossible to compare these (arc) spectra with the (spark) spectrum observed by Timma.[5] His observations covered the 3630–4400 Å. region; aside from the fact that the methods of excitation used were different, his principal lines could not be looked for in the present arc spectrum with any hope of success because of interference by C_2 and CN bands. However, the spark lines he mentioned as due to element 61 were observed in the spectrum of aliquots of samples 1, 2 and 3 when excited by the copper spark technique.

A Convenient Synthesis of Phenaceturic Acid[1]

BY JARED H. FORD

Phenaceturic acid was required as a starting material in numerous experiments directed toward the synthesis of benzylpenicillin.[2] The following method which employs methyl phenylacetate as the starting material was found to be more convenient than the literature method[3] in which phenylacetyl chloride was used.

Experimental

Glycine (75.1 g.) was added to a solution of 23 g. of sodium in 850 ml. of anhydrous methanol, and the mixture was boiled under reflux a few minutes to obtain a clear solution. One hundred fifty grams of methyl phenylacetate was then added and the solution was boiled under reflux for three days. The methanol was distilled off and the residue was dissolved in 400 ml. of cold water which contained 20 g. of sodium bicarbonate. The resulting solution was twice extracted with ether to remove unchanged methyl phenylacetate, and then acidified to *p*H 2 with concentrated hydrochloric acid. After standing overnight in a refrigerator, the product was filtered, washed with cold water and dried in a vacuum oven. The resulting white crystals melted at 139–141° (lit.,[3] 143°); yield, 122.6 g. (63.5%). One recrystallization from hot water (400 ml.) gave 114.2 g. of product which melted at 143–144°. From the ether extracts were obtained 42.1 g. (28%) of methyl phenylacetate; b. p. 96–98° (14 mm.).

A longer period of heating did not increase the yield and it appears likely that an equilibrium is involved

$$C_6H_5CH_2COOCH_3 + NH_2CH_2COONa \rightleftharpoons C_6H_5CH_2CONHCH_2COONa + CH_3OH$$

Alkyl Derivatives of Ethylenediamine

BY ALBERT E. FROST, JR., STANLEY CHABEREK, JR., AND ARTHUR E. MARTELL

In the course of other work a number of symmetrical dialkyl ethylenediamines have recently been prepared and characterized. A number of other amines, containing a smaller or larger number of alkyl groups, and a few dialkyl piperazines were obtained as by-products. The by-products not previously reported for this method and their properties are listed in Table I. The method of preparation, which involved the reaction of ethylene dichloride with an excess of primary amine, has been described by others.[1,2,3,4,5] The main products were characterized as the dipicrates and as the phenylureas, which are listed in Table II. Attempts to prepare the phenylurea from tribenzylethylenediamine were unsuccessful, and it was found that picrates could not be formed readily from dioctylpiperazine, tetraoctylethylenediamine, didodecylpiperazine and tribenzylethylenediamine. The picrate obtained with dibenzylethylenediamine was shown by analysis to be the monopicrate. Repeated recrystallization from various solvents did not change the melting point or the analysis.

Acetyldesoxycellulose Quaternary Salts

BY F. N. HAYES AND CHAO-HAN LIN

A cellulose acetate tosylate was prepared by the method of Malm, Tanghe and Laird.[1] Separate portions of it were heated with pyridine, 3-picoline and isoquinoline to give quaternary salts, resulting from displacement of tosylate ions. Similar reactions of *p*-toluenesulfonate esters with tertiary amines are well known.[2,3] Table I gives analytical data and the calculated values for free hydroxyls, unreacted tosylate ester groups, and quaternary salt groups per glucose unit for each of the three products.

The average over-all percentage conversion of the original hydroxyl groups to quaternary salt groups may be used as an estimate of the per cent. primary free hydroxyl in the original cellulose acetate. Our value of 28% compares favorably with a reported value of 25% on a similar sample,[1] determined by the method of tosylation and iodination.

TABLE I

Sample	Percentage N[a]	Percentage S[a]	Amount per g. u. Free[b] OH	Amount per g. u. Tos.[b] ester	Amount per g. u. Quat.[b] salts	Tos. replaced	Percentage Conv. of OH to quat. salt

[a] Analyses by Micro-Tech Laboratories, Skokie, Ill. [b] Calculated from the analyses, assuming that the acetyl content remains unchanged.

A sample of cellulose acetate, EK-102893,[4] was tosylated[1] and the product (I) was reprecipitated from acetone by alcohol. Pyridine, 3-picoline and isoquinoline were dried and redistilled.

A solution of 6.0 g. of cellulose acetate tosylate in 60 ml. of pyridine was heated on a steam-bath for twenty-four hours, at the end of which time, it was diluted with 40 ml. of acetone and treated with just enough water to obtain a homogeneous solution. This was slowly poured into excess acetone with good stirring. The precipitated product was filtered, washed with acetone and twice reprecipitated from hot alcohol by ether. The yield of the purified product (II) was 5.5 g.

In a similar manner, 3.0 g. of the tosyl ester gave 2.8 g. of a 3-picolinium salt (III) and 8.0 g. yielded 7.8 g. of an isoquinolinium salt (IV).

Separation of Hafnium and Zirconium by a Fractional Distillational Procedure

BY D. M. GRUEN AND J. J. KATZ

In view of current interest in hafnium–zirconium separations,[1] we have investigated a separation method first reported by van Arkel and De Boer.[2] This method involves fractional distillation at atmospheric pressure of the volatile complex compounds formed by reaction of zirconium and hafnium tetrachlorides with either phosphorus pentachloride or phosphorus oxychloride. Although van Arkel and De Boer showed that distillation resulted in considerable separation of hafnium and zirconium they gave no quantitative data on the relative volatilities of the zirconium and hafnium compounds.

The present work is concerned chiefly with the phosphorus oxychloride complexes, since these have lower boiling points and greater thermal stability than the corresponding phosphorus

(1) K. Street and G. T. Seaborg, THIS JOURNAL, **70**, 4268 (1948).
(2) A. E. van Arkel and J. H. De Boer, *Z. anorg. Chem.*, **141**, 289–296 (1924).

pentachloride compounds. van Arkel and De Boer assigned the formula 2 $ZrCl_4 \cdot POCl_3$ on the basis of zirconium and chlorine analyses. However, analyses for phosphorus, a more sensitive criterion of composition, indicate a more probable formula $3ZrCl_4 \cdot 2POCl_3$ (phosphorus: Calcd. 6.17%; found, 6 27, 6.12, 6.10%).

The vapor pressures of pure $3ZrCl_4 \cdot 2POCl_3$ and $3HfCl_4 \cdot 2POCl_3$ have been determined in the range 0.1–1.0 atmosphere and are represented graphically in Fig. 1. The boiling points are 360 and 355° for the zirconium and hafnium compounds, respectively; the 5° difference in boiling points (which we feel is accurate to ±1°) leads to a calculated value of $\alpha_0 = 1.14$ for the ratio of the vapor pressures at the boiling points. The heat of vaporization for both complexes is 20.5 ± 0.5 kcal.

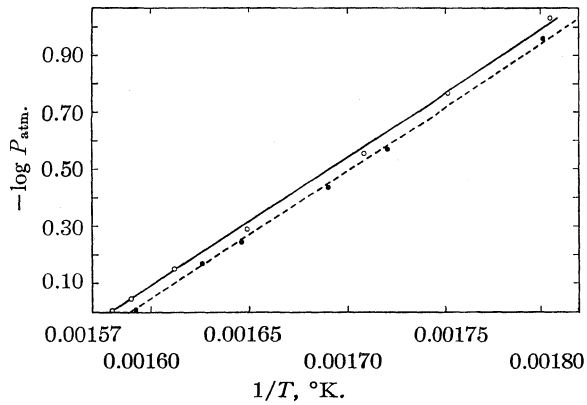

Fig. 1.—Vapor pressure of $HfCl_4$–$POCl_3$ and $ZrCl_4$–$POCl_3$ complexes: —, Zr complex; - - -, Hf complex.

A glass perforated plate column[3] with 50 physical plates was used in the distillation. In a typical experiment $3ZrCl_4 \cdot 2POCl_3$ containing 2.5% hafnium (on the weight of zirconium) yielded a first fraction (5%) containing 16% hafnium. The residue, after distilling 40% away, contained <0.2% hafnium.

Calculation shows the column can also be operated to yield essentially pure hafnium. This aspect, as well as further studies of the chemical and physical properties of these interesting compounds, is presently being investigated.

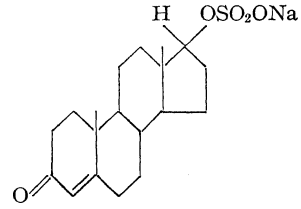
Sodium Testosterone Sulfate

BY G. W. HOLDEN, I. LEVI AND R. BROMLEY

Sodium testosterone sulfate has been prepared with the object of comparing its androgenic activity with that of testosterone and other of its derivatives. The results of the biological tests will be reported later.

With the exception of the use of charcoal in the purification procedure, the method followed was that described by Butenandt and Hofstetter[1] for the preparation of sodium estrone sulfate.

In alcohol, sodium testosterone sulfate exhibits an absorption maximum at 241 mμ, characteristic of testosterone. In water the maximum is shifted to 248–249 mμ.



A solution of chlorosulfonic acid, prepared by dissolving chlorosulfonic acid (1 ml.) in dry chloroform (30 ml.), cooling to 0° and adding pyridine (15 ml.), was added to a solution of testosterone (1.5 g.) in dry pyridine (20 ml.) and dry chloroform (50 ml.). After forty-eight hours at room temperature the solvent was removed *in vacuo* with a water-bath temperature of 40–50°. The solid residue was dissolved in methanol and the acidic solution almost neutralized (litmus) by the addition of methanolic sodium hydroxide. Aqueous sodium bicarbonate was then added to make the solution alkaline and the methanol removed *in vacuo* in the presence of water. The final volume of about 50 ml. was quite clear. This solution was shaken occasionally with Nuchar C (3 g.) at room temperature during one day. The Nuchar was filtered, washed several times with water (negative test for chloride) and eluted by suspending in methanol while still moist. Sodium testosterone sulfate (714.8 mg., 35%) was obtained by concentrating the methanol to small volume, clarifying by filtration using a little Nuchar to remove some yellow color, and precipitating with several volumes of ether. The product, thus obtained, is almost colorless. The m. p. (Fisher–Johns) is quite sharp at 215° with a green color changing to a clear brown at practically the same temperature; $[\alpha]^{25}D$ +74.5° (1% in water), +68° (1% in ethanol); $\epsilon_{(248-249)}$ 20,300 (in water): $\epsilon_{(240.5-241)}$ 17,700 (in ethanol). *Anal.* Calcd. for $C_{19}H_{27}O_5SNa$: C, 58.43; H, 6.97; Na, 5.88. Found: C, 58.54; H, 6.38; Na, 6.03. The semicarbazone precipitated at once on addition of semicarbazide hydrochloride to an aqueous solution of sodium testosterone sulfate. It does not melt up to 300° but starts to darken at 240° becoming slate-gray and finally chocolate-brown. For the determination of testosterone, 53.4 mg. of sodium testosterone sulfate was added to the barium chloride sodium acetate solution described by Talbot[2] for the hydrolysis of sodium dehydroisoandrosterone sulfate. After four hours heating on the steam-bath the solution was extracted with ether. Only 6.5% of the theoretical weight of residue was obtained. Fifty milligrams of sodium testosterone sulfate was then hydrolyzed by refluxing one hour with a mixture of 100 ml. of water and 15 ml. of concd. hydrochloric acid in the presence of 75 ml. of toluene. The toluene was separated, the aqueous solution further extracted with ether and the combined extracts distilled after washing with sodium bicarbonate and water. The yellowish gummy residue weighed 26.8 mg. (68%). It was crystallized by means of aqueous acetone to yield 9.3 mg. (25.3%) of testosterone m. p. 153.5° and mixed m. p. with pure testosterone undepressed.

Mechanism of the Polymerization of Propylene with Aluminum Bromide-Hydrogen Bromide Catalyst[1]

BY FRANK R. MAYO AND CHEVES WALLING

The recent excellent experimental work of Fontana and Kidder[2] on the kinetics of the polymerization of propylene by aluminum bromide-hydrogen bromide at about $-80°$ showed that, after the steady rate is obtained, the rate of polymerization is consistent with the equation

$$\frac{-d[m]}{dt} = \frac{kKc[m]}{1 + K[m]}$$

where [m] is the monomer concentration, c is the total concentration of catalyst in all forms, K is the equilibrium constant for the reversible formation of a postulated complex formed from a catalyst–monomer complex plus additional monomer, and k is the rate constant for chain lengthening, considered to be rearrangement of the catalyst–polymer–monomer complex into a stable form.

The object of this communication is to present an alternative interpretation of their data. Our scheme assumes (1) that essentially all of the catalyst (or promoter) is bound to the polymer as an un-ionized complex such as $H(-CH_2-\overset{H}{\underset{CH_3}{C}}-)_n-Br\cdot AlBr_3$, (2) that the first rate determining step in the propagation reaction is the dissociation of this complex into $H(-CH_2-\overset{H}{\underset{CH_3}{C}}-)_n^+$ and $AlBr_4^-$, (3) that actual chain propagation involves addition of the carbonium ion and anion to the propylene before recombination of the original ions occurs. Since, in a solvent of low dielectric constant, the dissociated complex will exist as an *ion pair* surrounded by a cage of solvent and propylene molecules, recombination will be kinetically first order, and the situation parallels that suggested by Matheson[3] for peroxide-initiated polymerizations. Thus, the fraction of the dissociations in which the carbonium ion will add a propylene unit before recombining with the negative ion will be $K'[m]/(1 + K'[m])$ where K' is the ratio of the rate constant for the reaction of the ion pair with propylene divided by the rate constant for recombination of the ion pair. The over-all rate of polymerization is then

$$\frac{-d[m]}{dt} = \frac{k'K'c\ [m]}{1 + k'\ [m]}$$

where k' is the rate of dissociation of the catalyst-polymer complex, c.

The form of the equation shows that an appreciable fraction of the dissociations are accompanied by growth, and also that only one growth step occurs at a time. These requirements are easily met if both ions simultaneously add to the propylene. Experiments with scale models indicate the probability of this course; they also show that the two mechanisms here considered differ only in details. When this interpretation is applied to isobutylene[4], styrene[5] and vinyl ethers[6] the integral orders of these polymerizations with respect to monomer suggest that the fraction of ionizations resulting in chain growth is lower, a result to be expected if the respective complexes ionize more readily but give less reactive carbonium ions.

Our proposed interpretation provides a mechanism for carbonium ion polymerizations in solvents of low dielectric constant similar to that proposed for the polymerization of alkenes by sulfuric acid, the solvolyses of alkyl halides, and the Friedel–Crafts reaction. Further, it accounts more readily than the mechanism of Fontana and Kidder for observations[5,6] that the rates of carbonium ion polymerizations increase very rapidly with the dielectric constant of the solvent. However, our interpretation is inconsistent with one conclusion of Fontana and Kidder, that ΔH for reversible addition of monomer to complex is 8.9 kcal./mole and that K decreases with increasing temperature. In our scheme, this corresponds to the anomaly that the activation energy for simple recombination of two ions is 8.9 kcal./mole *larger* than for addition of propylene to a carbonium ion. Since, in the experiments cited, an appreciable but unknown proportion of catalyst precipitated in an inactive form from each reaction mixture, we suggest that experiments at different temperatures have not yielded correct temperature coefficients, a point which is a critical test of our proposal.

Investigation of Possible Interactions between Thallium(I) and Thallium(III) in Solution and in the Crystalline Thallium Sesqui-halides

BY HARDEN MCCONNELL AND NORMAN DAVIDSON

The discovery[1] that the rate of radioactive exchange between Tl(I) and Tl(III) in aqueous solutions is slow has prompted us to: (1) examine, by a radiochemical method, whether or not the substances Tl_2Cl_3 and Tl_2Br_3 contain non-equivalent Tl(I) and Tl(III) ions; (2) look for non-additive light absorption[2] in some aqueous solutions containing Tl(I) and Tl(III). Problems (1) and (2) are related because the Tl_2X_3 compounds are more colored than the corresponding TlX or TlX_3 compounds.[3]

(1) Harbottle and Dodson, THIS JOURNAL, **70**, 880 (1948); Prestwood and Wahl, *ibid.*, **71**, 3137 (1949); see also pp. 226, 205 of "Isotopic Exchange Reactions and Chemical Kinetics," Brookhaven National Laboratory, Patchogue, New York, Dec., 1948.

(3) Benrath, *Z. anorg. Chem.*, **93**, 161 (1915); **136**, 358 (1924).

(1) For the exchange experiment with Tl_2Cl_3, 4 ml. of dilute HCl solution containing 5.2 mg. of dissolved Tl_2Cl_3 and 1.46 mg. of active $TlCl_3$ (containing Tl^{204}) were evaporated nearly but not quite to dryness by evacuation at room temperature for forty-five minutes. It follows from the data of Benrath that under these conditions essentially all of the Tl(I) was initially precipitated as Tl_2Cl_3, and there might be small amounts of $TlCl_2$ or hydrated $TlCl_3$ formed subsequently, depending on the completeness of evaporation.[3] (Furthermore by visual inspection of the precipitate one saw only the characteristic hexagonal yellow flakes of Tl_2Cl_3.)[4] This entire residue, the yellow solid Tl_2Cl_3 and the adhering excess of $TlCl_2$ or $TlCl_3$ (solid or solution), was redissolved in water and divided into two 2-ml. samples. Thallous chromate was precipitated from one portion, using the conditions developed by Harbottle and Dodson,[1] washed, and slurried onto a counting plate. The second sample was reduced with sulfur dioxide so that all the thallium could be precipitated as the chromate and the total activity counted. There was no appreciable self absorption in the samples.

A blank experiment was performed which was identical to the above except that the evaporation to give solid Tl_2Cl_3 was omitted, and the sample was allowed to stand for twenty minutes.

For the Tl_2Br_3 experiment, 30 ml. of a solution containing 1.2 g. of $TlBr_3$ was saturated with inactive TlBr at room temperature to insure the absence of bromine. The solution was then saturated with active TlBr at 50°. Two 10-ml. aliquots of this solution were allowed to cool to room temperature, and the red Tl_2Br_3 precipitated out.[5] The thallous activity was determined with one sample and the total activity with the other. For control measurements, the thallous and total activities of 1-ml. aliquots of the solution at 50° were determined.

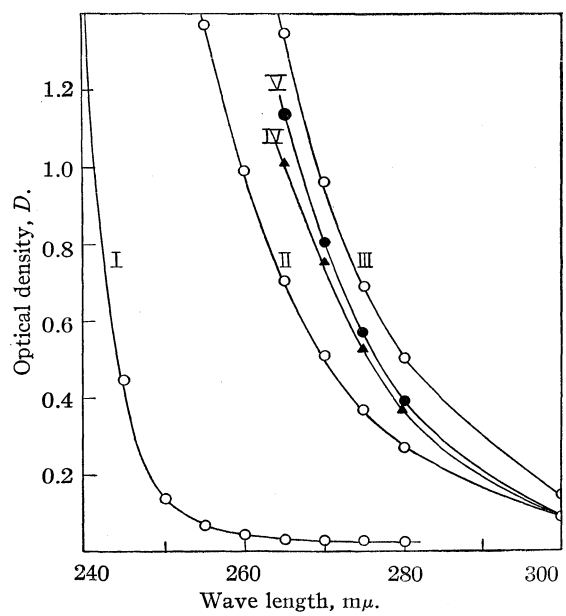

Fig. 1.—The absorption spectra of some thallium(I) and (III) solutions in perchloric acid: I, Tl(I) 0.068 *F*; II, Tl(I) 0.034 *F*, Tl(III) 0.079 *F*; III, Tl(III) 0.157 *F*, I, II, III in 3.2 *F* $HClO_4$; IV, Tl(III) 0.079 *F*; V, Tl(I) 0.113 *F*, Tl(III) 0.079 *F*; IV, V in 1.6 *F* $HClO_4$.

(4) Another sample of Tl_2Cl_3 was further identified by a thallium analysis; for a description of the crystalline form, *cf.* Meyer, *Z. anorg. Chem.*, **24**, 354 (1900).

(5) The identification of this substance as Tl_2Br_3 is based on its color and crystalline form corresponding to the descriptions given by Benrath[3] and Meyer[4] and on the solubility data determined by Benrath.

TABLE I

EXCHANGE EXPERIMENTS WITH THALLIUM SESQUI-HALIDES

Experiment	Composition of exchange mixture, mg. Tl(I)	Tl(III)	Specific activities,[a] c./min. mg. Tl(I)	Tl(III)	Ratio of specific activities of Tl(III) and Tl(I)
Solid Tl_2Cl_3	3.12	2.00[b]	31.5	321	10 (±1)
Tl_2Cl_3 control	3.12	2.00[b]	18.6	241	13 (±1)
Solid Tl_2Br_3	32.4[c]	10.8[c]	102	27.8	0.27 ± (0.05)
Tl_2Br_3 control	6.1	18.4	87.7	20.2	0.23 ± (.05)

[a] For the Tl_2Cl_3 experiment, the specific activities were calculated on the basis of the amounts of Tl(I) and Tl(III) added; for the Tl_2Br_3 experiment, see footnote (c). [b] Including 0.96 mg. of active Tl(III). [c] These numbers, estimated from the solubility data of Benrath, are included to indicate the probable size of the Tl_2Br_3 precipitate; only the ratio of activities is important for the interpretation of the experiment.

The experimental results (Table I) are that within the uncertainties of the experiments there is no exchange in the solid state. These uncertainties are due to experimental errors and due to the possibilities of differences between the control experiments and the experiments in which solid Tl_2X_3 compounds were separated as to: (a) degree of homogeneous exchange in solution, (b) degree of induced exchange on precipitation of thallous chromate. For the Tl_2Cl_3 experiment, the calculated ratio of specific activities of Tl(III) and Tl(I) for complete equivalence in the solid is 2.1 accepting the validity of the control experiment (and assuming no exchange between the solid Tl_2Cl_3 and the excess adhering Tl(III)). For the Tl_2Br_3 experiment this ratio is 1.0. Because of the evidence that Tl_2Cl_3 has 64 thallium atoms per unit cell,[6] it is worthwhile to emphasize that our data are not sufficiently accurate to exclude the possibility that a small fraction of the Tl(I) and Tl(III) atoms occupy equivalent positions in the Tl_2X_3 lattice.

(2) Figure 1 exhibits the absorption spectra of some thallium (I) perchlorate, thallium (III) perchlorate, and mixed solutions in 3.2 and 1.6 *F* perchloric acid. Thallium (III) is more colored than Tl(I) and there is no appreciable non-additive absorption in the mixed solutions. The extinction coefficients of Tl(III) calculated from these data (Table II) show that Tl(III) is more colored at lower acidities, suggesting an increased hydrolysis of Tl^{+++} to $Tl(OH)^{++}$ or $Tl(OH)_2^{+}$. Harbottle and Dodson[1] and Prestwood and Wahl[1] have previously suggested such a hydrolysis to explain the variation of the rate of exchange between Tl(I) and Tl(III) with acidity.

TABLE II

EXTINCTION COEFFICIENTS OF Tl(III) AS A FUNCTION OF ACIDITY

λ (mμ)	290	280	270	265
ε (Tl(III))(1.6 *F* $HClO_4$)	2.25	4.6	9.5	13.3
ε (Tl(III))(3.2 *F* $HClO_4$)	1.8	3.25	6.1	8.5

Most of the known cases of interaction absorption in solution are in media containing excess

(6) Jerslev and Hägg, *Experientia*, **2**, 495 (1946).

chloride ions. The insolubility of thallous chloride in water and dilute solutions of thallic chloride, and the presence of free chlorine in concentrated thallic chloride solutions (3.5 *F*) in which thallous chloride has an appreciable solubility[3] prevented an exact spectrophotometric study of solutions having significant concentrations of thallous and thallic chlorides. We can report however that as successive portions of solid thallous chloride were added to a 3.4 *F* thallic chloride solution containing some (*ca.* 0.03 *F*) free chlorine, the optical density of the resulting solutions decreased (as the chlorine was removed) and became constant at the values: $\lambda = 380$ mμ, $D = 0.065$; $\mu = 360$ mμ, $D = 0.66$, for a solution that contained 0.04 *F* excess Tl(I). Since the optical densities of the solutions never increased as the TlCl was added, there was probably no significant interaction absorption in the solution.

This work has been supported by the Office of Naval Research. We are grateful to Dr. German Harbottle for communicating to us his excellent method of separating thallous and thallic ions.

The Lactal Ring Structures of Some Synthetic Pyrimidine Nucleosides[1]

BY MARJORIE ZEIGER NEWMARK, IRVING GOODMAN AND KARL DITTMER[2]

The ribosyl, arabinosyl, glucosyl and galactosyl nucleosides of uracil and thymine and the corresponding 5-bromo-uracil derivatives were prepared in our laboratories[3,4] and tested for biological activity[5] on two strains of *Escherichia coli*, two strains of *Neurospora crassa*, a strain of *Lactobacillus casei*, and one of *Streptococcus faecalis* R.

A uracil-requiring mutant of *E. coli* was unaffected by any of the synthetic nucleosides although uracil or natural uridine produced good growth. A uracil-less mutant of *N. crassa* which was shown by Loring to grow well on uracil, uridine or uridylic acid was also unaffected by the synthetic products. Results of studies of *L. casei* and *S. faecalis* R showed a similar lack of biological activity. These studies emphasized the need for complete elucidation of the detailed structure of these synthetic nucleosides.

In order to establish the nature of a possible relationship between structure and activity, a number of naturally occurring and synthetic nucleosides were analyzed by the periodate method as adapted by Davoll, Lythgoe and Todd[6] to determine the ring structures of the sugar component of the nucleosides. In this method glycofuranosyl nucleosides of the pentoses require one mole of periodate per mole of nucleoside for oxidation, whereas glycopyranosides of this type require two moles of periodate. Aldohexoses in the pyranoside form require two moles of periodate for oxidation and liberate one mole of formic acid during the course of the reaction; aldohexoses in the furanoside form also require two moles of periodate for oxidation but liberate no formic acid.

Table I summarizes the results of the periodate oxidation of a number of synthetic pyrimidine nucleosides as well as the naturally occurring pyrimidine nucleosides, uridine and cytidine. All of the synthetic nucleosides here reported possess the pyranoside structure. These results would indicate in part that the known biological activity of uridine and cytidine are dependent upon the furanoside structure.

TABLE I

PERIODATE OXIDATION OF SOME PYRIMIDINE NUCLEOSIDES

N-Glycoside	Moles IO_4^- / Mole glycoside	Moles HCOOH / Mole glycoside

A Complex Praseodymium Fluoride Readily Soluble in Dilute Acids[1]

BY THEODORE P. PERROS AND CHARLES R. NAESER

The insolubility of praseodymium trifluoride in dilute mineral acids is well known. In the course of investigations concerning this compound a complex potassium–praseodymium–fluoride compound, possibly new, which was easily soluble in dilute acids was prepared.

(1) From the thesis for the M.S. degree of T. Perros, The George Washington University.

Experimental

About 10 g. of technical grade potassium hydrogen fluoride was placed in a platinum crucible and heated over a burner until molten. Approximately 0.5 g. of praseodymium trifluoride was placed in the melt and stirred with a platinum rod. Within five minutes the praseodymium fluoride had dissolved completely, giving a pale yellow-green color to the melt. After the melt had cooled and solidified to a hard, brittle mass, it was placed in a beaker and water (containing a few drops of ammonium hydroxide solution) was added to dissolve the excess potassium fluoride and potassium hydrogen fluoride. After several leachings with water, a pale green residue mixed with dark particles of impurities from the potassium hydrogen fluoride remained. The washings, even after concentration, gave no evidence for the presence of praseodymium ions. However, light reflected from the green residue gave the characteristic absorption spectrum of praseodymium ions.

This green residue, but not the black particles, was readily soluble in 3 *N* hydrochloric acid when slightly warmed. This behavior is quite different from that of praseodymium trifluoride.

Purification of potassium hydrogen fluoride by crystallization eliminated the dark impurities. The purified material with praseodymium trifluoride gave a residue completely soluble in the 3 *N* hydrochloric acid. This marked difference in solubility of the two praseodymium–fluoride compounds indicates the formation of a complex ion containing both praseodymium and fluorine.

When Pr_6O_{11} was added to fused potassium hydrogen fluoride a vigorous reaction took place, and the final green residue showed the same characteristics as that obtained by treatment of the praseodymium trifluoride with potassium hydrogen fluoride.

Investigations to determine whether the composition of this substance is similar to the $KLaF_4$ described by W. H. Zachariasen[2] and also to determine the properties of this substance are being continued.

Acid Catalyzed Reaction of Diarylformamidines with Ethyl Orthoformate

BY ROYSTON M. ROBERTS

Ethyl N-phenylformimidate (I) was first prepared by Comstock and Clapp[1] from ethyl iodide and the silver salt of formanilide; the yield was low, and although it has been improved by Smith and Nichols[2] the procedure is expensive and tedious. Claisen[3] prepared this compound from aniline and ethyl orthoformate. He reported that the preparation was accomplished only after numerous unsuccessful attempts and that his directions must be followed exactly; even so, the yield he obtained was only 44% from a reaction mixture heated nine hours. Our attempt to repeat this work resulted in a yield of 11%. Claisen postulated a two-step mechanism for the reaction: first, the formation of N,N′-diphenylformamidine (rapid), and second, reaction of this compound with a second mole of ethyl orthoformate (much slower).

$$2C_6H_5NH_2 + (C_2H_5O)_3CH \longrightarrow C_6H_5N{=}CH{-}NH{-}C_6H_5 + 3C_2H_5OH \quad (A)$$

$$C_6H_5{-}N{=}CH{-}NH{-}C_6H_5 + (C_2H_5O)_3CH \rightleftharpoons 2C_6H_5N{=}CHOC_2H_5 + C_2H_5OH \quad (B)$$

I

There is no doubt regarding the ease with which the first step (A) takes place, but we have found that the second step (B), is practically completely dependent on acid catalysis. This undoubtedly explains the many unsuccessful experiments mentioned by Claisen and also our first attempt in which we took some care to avoid traces of acid. When we heated pure N,N′-diphenylformamidine with ethyl orthoformate containing a little anhydrous potassium carbonate for twenty-four hours, we found practically no alcohol was produced and the N,N′-diphenylformamidine was recovered unchanged. Prompted by the observation of acid catalysis in the reaction of ethyl N-phenylformimidate with amines (to be published separately) we added a small amount of aniline hydrochloride to the ethyl orthoformate and N,N′-diphenylformamidine and found that the calculated amount of ethanol was evolved rapidly and a 96% yield of ethyl N-phenylformimidate was produced. Other acids are also effective in catalyzing the reaction; sulfuric and *p*-toluenesulfonic acids gave comparable results and even acetic acid was fairly effective. Ethyl N-*p*-tolylformimidate[4] was produced from *p*-toluidine or N,N′-di-*p*-tolylformamidine under similar conditions. The formamidines need not be isolated when the aromatic amine is the starting material. In fact, the acid catalyzed reaction of orthoformate with aromatic amine may not proceed by intermediate formamidine formation but may be more direct. The mechanism of this reaction will be discussed more completely in a subsequent paper. It is interesting to note that reaction (B) is apparently reversible and has previously been described as it occurs in the opposite direction from that reported here! Knott[5] treated ethyl N-phenylformimidate in alcoholic solution with carboxylic and sulfonic acids; he obtained N,N′-diphenylformamidine salts and was able to identify ethyl orthoformate as the other product in one case.

Recently Hamer, Rathbone and Winton have reported modifying Claisen's procedure obtaining yields of 81–85% by "including aniline hydrochloride to inhibit the formation of carbylamine."[6] Their reason for choosing aniline hydrochloride for this function is not given and there is no mention of acid catalysis.

It is perhaps pertinent to recall attention to the fact that in 1941 Smith and Nichols[2] showed that the reaction of Grignard reagents with ethyl N-phenylformimidate was the most satisfactory general method for the synthesis of aromatic

aldehydes from the corresponding halides except for the difficulty of obtaining the ethyl N-phenylformimidate, a reagent which is now easily available.

Experimental

Materials.—Ethyl orthoformate, Eastman Kodak Co., redistilled, b. p. 142–144°; N,N′-diphenylformamidine (m. p. 138.5–139.5°, cor.), N,N′-di-*p*-tolylformamidine (m. p. 141.4–142.8°, cor.), prepared from the amines and ethyl orthoformate[7]; aniline hydrochloride, *p*-toluidine hydrochloride, prepared from the amines and concentrated hydrochloric acid, dried in a vacuum desiccator.

N,N′-Diphenylformamidine and Ethyl Orthoformate. A. Aniline Hydrochloride as Catalyst.—In a 200-ml. flask was placed 19.6 g. (0.10 mole) of N,N′-diphenylformamidine, 29.6 g. (0.20 mole) of ethyl orthoformate and 1.0 g. (0.008 mole) of dry aniline hydrochloride. An efficient 40-cm. distilling column having a total reflux partial take-off type head was attached and the reaction mixture was heated. Ethanol began to reflux immediately. After one hour of reflux the ethanol was distilled; 6.7 ml. was collected in about fifteen minutes. Anhydrous potassium carbonate (2.0 g.) was added and the mixture was shaken and allowed to stand two hours. The reaction mixture was then distilled through the same column under reduced pressure. Excess ethyl orthoformate was first recovered, 12.3 g., b. p. 83–85° (93 mm.). The pressure was then lowered to 40 mm. and colorless ethyl N-phenylformimidate distilled constantly at 117° (40 mm.); 28.7 g. or 96% of the theoretical amount was obtained.

The difference in the conditions under which the two steps of the reaction take place is illustrated by the following experiment. A mixture of 0.40 mole of aniline and 0.60 mole of ethyl orthoformate was heated in a flask to which was attached a 40-cm. distilling column. During one and one-quarter hours 36 ml. of ethanol distilled and then the distillation practically stopped. Aniline hydrochloride (1.30 g., 0.01 mole) was added to the reaction mixture and heating was resumed; distillation of ethanol now took place again at a rapid rate and 11.5 ml. was collected in thirty minutes, then the evolution practically stopped again. Anhydrous potassium carbonate (2.60 g.) was added and the mixture was distilled under reduced pressure. The excess ethyl orthoformate (27.2 g.) was removed first, b. p. 83° (90 mm.), then the product was distilled at 10-mm. pressure; 53.2 g. (89% of the amount calculated from aniline was obtained, b. p. 87–88° (10 mm.), $n^{25}D$ 1.5275 (lit., 1.52787[8]).

B. Sulfuric Acid as Catalyst.—Aniline (1 mole), ethyl orthoformate (1.5 moles) and sulfuric acid (10 drops, *ca.* 0.04 mole) were heated under reflux thirty minutes and then 117 ml. of ethanol was distilled through a short column. The catalyst was neutralized with 3.5 g. of dry sodium *t*-butoxide and the mixture was distilled under reduced pressure. After the excess ethyl orthoformate was recovered, 121.6 g. (82% of the theoretical amount) of ethyl N-phenylformimidate was obtained, b. p. 117–119° (40 mm.).

C. Acetic Acid as Catalyst.—N,N′-Diphenylformamidine (0.10 mole), ethyl orthoformate (0.20 mole) and glacial acetic acid (0.6 ml., 0.01 mole) were heated under reflux for one hour, then 4.5 g. of distillate, b. p. 76–80°, was collected during forty minutes; the distillation temperature then began to rise sharply. Ethyl orthoformate (*ca.* 17 g.) was recovered at 82–83° (90 mm.), and 14.6 g. (55% of the theoretical amount calculated from 0.09 mole of N,N′-diphenylformamidine) of ethyl N-phenylformimidate was obtained, b. p. 117–118° (40 mm.).

N,N′-Di-*p*-tolylformamidine and Ethyl Orthoformate; *p*-Toluenesulfonic Acid as Catalyst.—N,N′-Di-*p*-tolylformamidine (0.10 mole), ethyl orthoformate (0.20 mole) and *p*-toluenesulfonic acid (0.001 mole) were heated in a 100-ml. flask to which was attached a 15-cm. Vigreux column with a total reflux partial take-off head. After one hour of reflux 5.8 ml. of ethanol, b. p. 75–79°, was removed. Calcium carbonate was added and the mixture was stirred overnight. Distillation of the filtered reaction mixture gave *ca.* 12 ml. of ethyl orthoformate, b. p. 83° (93 mm.), and 24.0 g. of ethyl N-*p*-tolylformimidate,[4] b. p. 133.5–134° (40 mm.). This was 74% of the calculated amount of product.

Treatment of *p*-toluidine or N,N′-di-*p*-tolylformamidine with ethyl orthoformate in the presence of *p*-toluidine hydrochloride or sulfuric acid as described above gave similar results—yields of 74–76% of ethyl N-*p*-tolylformimidate.

Acknowledgment.—The author gratefully acknowledges the assistance of Mr. Robert H. DeWolfe, who carried out some of the experiments, and a grant from the University of Texas Research Institute which made this assistance possible.

Chemistry of Epoxy Compounds. X.[1] Polymerization of the Isomeric 9,10-Epoxyoctadecanols

BY DANIEL SWERN AND GERALDINE N. BILLEN

The thermal polymerization of the isomeric 9,10-epoxystearic acids was recently reported.[2] The present note reports the results of the thermal polymerization of the isomeric 9,10-epoxyoctadecanols (I), m. p. 54 and 48°, respectively, in

$$CH_3—(CH_2)_7—\underset{\diagdown\,\diagup}{\underset{O}{CH—CH}}—(CH_2)_7—CH_2OH \quad (I)$$

the presence of naphthalene-2-sulfonic acid as catalyst.

Starting Materials.—The isomeric 9,10-epoxyoctadecanols, m. p. 54 and 48°, were prepared from oleyl[3] and elaidyl[4] alcohols, respectively, by epoxidation with peracetic[5] or perbenzoic acid.[6] Calcd. for $C_{18}H_{36}O_2$, oxirane oxygen,[7] 5.62%; found, 5.62%.

Polymerization Procedures.—9,10-Epoxyoctadecanol (either isomer) and the required quantity of naphthalene-2-sulfonic acid were mixed and then ground until the catalyst was uniformly distributed. Approximately 5-g. portions of the mixture were then weighed into a series of test-tubes which had been flushed with nitrogen or carbon dioxide. After being filled, the tubes were again flushed with inert gas, stoppered tightly, and then immersed in a constant-temperature oil-bath which maintained the desired temperature to ±0.2°. Fifteen minutes was allowed for the establishment of temperature equilibrium before the polymerization time was counted. During the equilibration period, the tubes were shaken occasionally to ensure homogeneity. At selected time intervals, a tube was removed from the oil-bath, cooled rapidly to room temperature, and then analyzed within twenty-four hours.

Analytical Procedures.—Analyses were carried out as previously reported.[2] Carbonyl oxygen was determined by the procedure reported by Knight and Swern.[8]

Discussion

Figure 1 shows the course of the catalyzed polymerization of 9,10-epoxyoctadecanol (ol), m. p. 54°, at 60, 80, 90 and 100°. Figure 2

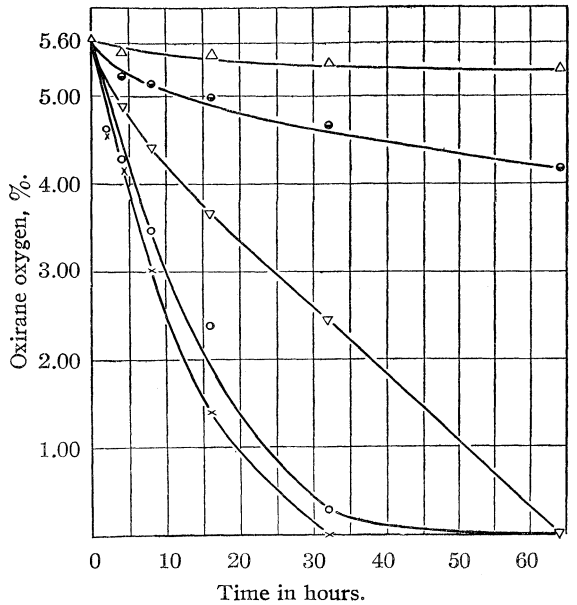

Fig. 1.—Thermal polymerization of 9,10-epoxyoctadecanol(ol), m. p. 54°, with naphthalene-2-sulfonic acid as catalyst: O, 90°, 2% catalyst; △, 60°, 0.75% catalyst; ×, 100°, 2% catalyst; ◒, 80°, 0.75% catalyst; ▽, 100°, 0.75% catalyst.

shows the course of the catalyzed polymerization of 9,10-epoxyoctadecanol (el), m. p. 48°, at 80, 90, 100, 120 and 140°. These data may be briefly summarized as follows: (a) under identical conditions, the high-melting epoxyoctadecanol (ol) polymerizes at a more rapid rate than does the low-melting isomer (el); (b) both isomers can be converted to viscous liquids if the polymerization is permitted to proceed far enough; (c) when the oxirane oxygen value is substantially zero, the molecular weight is about 900, or approximately that of a trimer; (d) in all the polymerizations except the one at 60°, about 20 to 30% of the reduction in oxirane oxygen can be accounted for by isomerization to the carbonyl group; (e) in two cases in which the comparison has been made, molecular weights determined ebulliosopically in benzene differ from those calculated from the oxirane oxygen analyses by only 7 to 15%; (f) the isomerization of the oxirane group to the carbonyl group is a function of both the temperature and the percentage of catalyst, although there appears to be no simple relationship involved; and (g) the refractive index of the polymers levels off at 1.462 to 1.464 (60°).

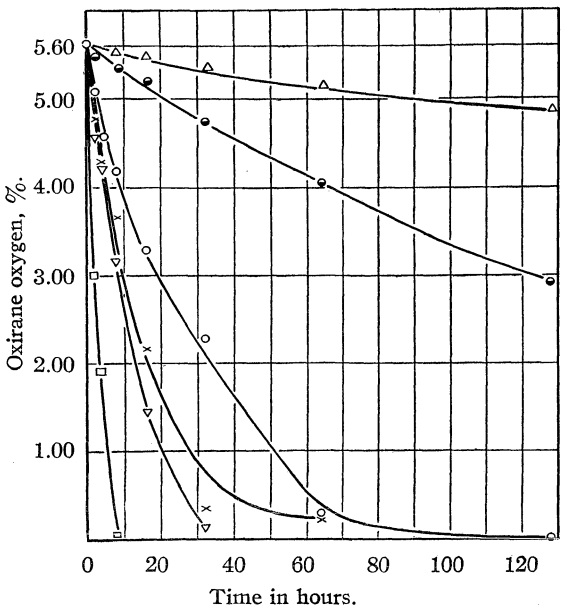

Fig. 2.—Thermal polymerization of 9,10-epoxyoctadecanol(el), m. p. 48°, with naphthalene-2-sulfonic acid as catalyst: O, 90°, 2% catalyst; △, 80°, 0.75% catalyst; ▽, 120°, 0.75% catalyst; ×, 100°, 2% catalyst; ◒, 100°, 0.75% catalyst; □, 140°, 0.75% catalyst.

On the basis of the data reported here and the known reactions of oxirane groups, it can be concluded that the main reactions which occur during the thermal polymerization of the 9,10-epoxyoctadecanols are (a) a condensation reaction between the oxirane and primary hydroxyl groups, yielding a polyether, as shown in Equation I, and (b) isomerization of the oxirane group to the carbonyl group. All the polymers are readily soluble in the common organic solvents, with the exception of petroleum naphtha, thus indicating that cross-linking reactions occur only to a limited extent, if at all.

Some Derivatives of Benzylvanillin and Benzylvanillic Acid

The benzyl ethers of the monochloro and monobromo derivatives of vanillin and benzyl-2-nitrovanillin were prepared by the alkylation of the appropriate vanillin derivative and benzyl chloride in the presence of sodium hydroxide.[1]

Benzyl Ethers of Derivatives of Vanillic Acid.—Five grams of the benzyl ether of the requisite vanillin derivative was dissolved in 50 cc. of pyridine and the solution heated to 60–70°. A hot (90–100°), concentrated aqueous solution of 5 g. of potassium permanganate was added in small portions. A vigorous reaction ensued with the immediate precipitation of manganese dioxide. The mixture was cooled and filtered. The residue was washed with a little pyridine and the filtrate and washing were combined. The manganese dioxide in the residue was dissolved in sodium bisulfite solution and dilute hydrochloric acid. A white precipitate remained which was extracted with ethyl ether. The pyridine was removed from the filtrate by steam distillation and the residue was extracted with the ether previously used. The ether layer was repeatedly extracted with sodium hydroxide solution until acidification gave no precipitate. The aqueous extracts were combined, acidified and the resultant precipitate filtered, washed with water and dried. It was then recrystallized from the appropriate solvent (either aqueous ethanol or aqueous acetic acid). The properties of some benzyl ethers of derivatives of vanillin and vanillic acid are listed in the accompanying table. The ethers crystallized as colorless needles except where otherwise noted.

COMMUNICATIONS TO THE EDITOR

RELATIONSHIP OF THE FOLINIC ACID GROUP AND THE LEUCONOSTOC CITROVORUM FACTORS

Sir:

The reported nutritional requirement of *Leuconostoc citrovorum* 8081 for thymidine[1] or a factor(s) in refined liver extracts[2] suggested the possibility that the organism required an antipernicious anemia principle. In the isolation of thymidine,[3] this factor and erythrotin,[4] a member of the vitamin B_{12} group and probably identical with vitamin B_{12}, were separated quantitatively. While neither of these fractions possess the activity of the original liver extract for *Leuconostoc citrovorum* in a previously described medium[5] supplemented with pyridoxine, the two fractions on recombination possessed the full activity. The thymidine containing fraction could be replaced by 0.03–0.1 γ per cc. of crystalline thymidine while the erythrotin-containing fraction could not be replaced by crystalline erythrotin. However, concentrates of the folinic acid[6] were found to be highly effective in replacing the erythrotin fraction, and the relative potencies of these fractions determined by *Lactobacillus casei* test and this modified test parallelled closely.

A concentrate of folinic acid 200,000 times as active as an enzymatic digest of liver in the *Lactobacillus casei* test, elicited a half-maximal response in the *Leuconostoc citrovorum* test at 0.0001–0.0002 γ per cc. In the absence of thymidine, 0.001 γ per cc. of this factor was required for the same response. Thymidine at a concentration of 10–20 γ per cc. can also replace the folinic acid group; consequently, the synergistic action of the folinic acid group and thymidine in stimulating the growth of the organism resulted in the high activity of purified liver extracts which we have previously found to contain large amounts of thymidine.[3]

Other factors associated with the folinic acid appear to be effective for this organism, but folic acid is essentially inactive under our testing conditions. Very mild acid hydrolysis destroys folinic acid but forms a compound with biological activities corresponding to folic acid.

This synergistic action and interchangeability of thymidine and the folinic acid group indicate the functioning of this group in the biosynthesis of thymidine as well as further involvement of thymidine concerning the biosynthesis of the active coenzyme form of folinic acid for this organism.

THE FOLINIC ACID GROUP, A SERIES OF NEW VITAMINS RELATED TO FOLIC ACID

Sir:

By application of *inhibition analysis* to a study of factors functionally related to *p*-aminobenzoic and folic acids, testing procedures for a wide variety of new factors occurring in refined liver extracts have been developed.[1,2] One of these methods developed about two years ago, involved the prevention of the toxicity of methylfolic acid for *Lactobacillus casei* in a previously described medium[3] supplemented with thymine, purines, folic acid (0.001 γ per cc.) and methylfolic acid (1 γ per cc.). Under these conditions, only the folic acid group was known to prevent competitively the toxicity of methylfolic acid. However, liver extracts, both crude and refined, which prevent the toxicity in a competitive manner, are approximately 15 times as active as can be accounted for on the basis of their folic acid content determined by assay with *Lactobacillus casei* in the absence of the inhibitor. A similar technique has been employed with *Streptococcus faecalis* R in demonstrating an unusual activity for formylfolic acid.[4]

With the aid of this assay based on this differential in activity, one of the active principles has been concentrated more than 200,000 fold from enzymatic digests of hog liver. A half-maximal response of *Lactobacillus casei* is obtained in the presence of 0.002 γ per cc. of the concentrate which is somewhat more active than folic acid under these testing conditions. Depending upon the time of incubation and response at which the comparison is made, the concentrate is from 10 to 100 times as active as folic acid in preventing the toxicity of methylfolic acid (1 γ per cc.) for *Streptococcus faecalis* R. On the basis of structure and functional relationship to folic acid, this active principle has been termed folinic acid. On the basis of estimated purity of the concentrate, folinic acid does not appear to be less active than folic acid in promoting the growth of either organism in the absence of the inhibitor.

(1) Shive, *et al.*, THIS JOURNAL, **70**, 2299 (1948).
(2) Shive, *Ann. New York Acad. Science*, in press, presented before the New York Acad. of Science, Feb., 1949.
(3) Rogers and Shive, *J. Biol. Chem.*, **172**, 100, 751 (1947).
(4) Gordon, *et al.*, THIS JOURNAL, **70**, 878 (1948).

While folinic acid accounts for the major portion of the activity of extracts of hog liver, another factor with similar physical and biological properties occurs in these extracts. At least two other substances possessing activity in the assay have been detected by means of paper chromatography. Consequently, it appears that a group of compounds, the folinic acid group, possess activity similar to that of folinic acid.

Since the folinic acid group is utilized more effectively than folic acid for several organisms, the possibility exists that it may be more active than folic acid in the treatment of sprue, nutritional and pernicious anemia, and other nutritional deficiencies related to the folic acid and vitamin B_{12} groups.

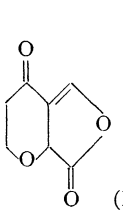
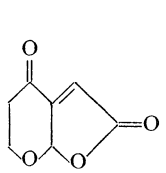
THE STRUCTURE OF PATULIN

Sir:

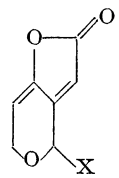
Recent evidence has required revision of the accepted structure (I)[1] of the antibiotic mold metabolite, patulin, and two new formulations, (II)[2] and (III, X = OH),[3] have been advanced. The following data now afford additional strong support for (III, X = OH) as the structure of patulin.



(I)



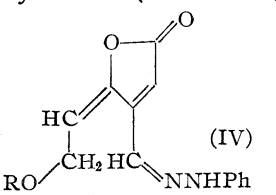
(II)



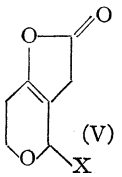
(III)

Structure (III, X = OH) possesses three structural characteristics: free hydroxyl group, lactal ring and doubly-unsaturated lactone system. Presence of a free O–H band (2.73μ), in the infrared spectrum of patulin and its absence in patulyl acetate (III, X = OAc) and in patulyl chloride (III, X = Cl), retention of the characteristic double bond ultraviolet and infrared spectra of patulin in these derivatives (Patulin: u.v., 275 mμ, log ϵ 4.22; ir., 5.58μ, 5.94μ, 6.11μ. Acetate: u.v., 277 mμ, log ϵ 4.24; ir., 5.58μ, 5.93μ, 6.11μ. Chloride: u.v., 277 mμ, log ϵ 4.18; ir., 5.61μ, 5.94μ, 6.13μ), and conversion of each in high yield to patulin phenylhydrazone by aqueous phenylhydrazine indicate the presence of a non-enolic hydroxyl group and exclude occurrence of enolization or isomerization during their preparation.

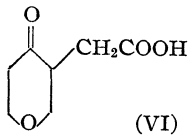
Patulin shows reactions (negative Schiff, positive Tollens, positive Fehling)[1] characteristic of a lactal ring. Lactal ring opening by phenylhydrazone formation usually unmasks a hydroxyl group and the conversion of patulin phenylhydrazone (IV, R = H) by treatment with sodium



(IV)



(V)



(VI)

acetate–acetic anhydride to patulin phenylhydrazone acetate (IV, R = Ac), m. p. 143° (calcd. for $C_{15}H_{14}O_4N_2$: C, 63.00; H, 4.93. Found: C, 63.40; H, 5.27) fits this interpretation. Infrared spectra of patulin phenylhydrazone (5.86μ, 6.04μ, 6.23μ) and its acetate (5.84μ, 6.00μ, 6.22μ) indicate retention of the doubly-unsaturated lactone system in these derivatives. Demonstration of a lactone ring in the phenylhydrazone and its acetate is shown by consumption of 1.05 and 1.92 equivalents, respectively, of sodium hydroxide. Dihydropatulin (V, X = OH) phenylhydrazone[4] contains only a singly-unsaturated lactone system (u.v., 380 mμ, log ϵ 4.55; 1.07 equivalents sodium hydroxide).

Treatment of patulin with warm excess thionyl chloride followed by sublimation furnishes unstable patulyl chloride (III, X = Cl) in 78% yield, m. p. 92–94° (calcd. for $C_7H_5O_3Cl$: C, 48.70; H, 2.92; Cl, 20.55. Found: C, 48.94; H, 2.63; Cl, 20.43); structural evidence given above. Patulyl chloride in anhydrous dioxane with palladium–barium sulfate catalyst absorbs 2.0 of moles hydrogen in two hours to give a neutral fraction which furnishes on distillation oily dihydrodesoxypatulin (V, X = H) in 34% yield, b. p. 90–95° (0.5 mm.). (Calcd. for $C_7H_8O_3$: sapon. equiv. 140.1. Found: 141.2); immediate Legal test; u.v., at 212 mμ, log ϵ 3.93; ir., 5.57μ, 6.01μ. Accordingly, dihydrodesoxypatulin contains a β,γ-unsaturated-γ-lactone system and its exact structure is established by hydrolysis in aqueous alcoholic sodium hydroxide to dihydrodesoxypatulinic acid (VI), identified by its well-known derivatives[2,3,4,5]: 2,4-dinitrophenylhydrazone, m. p. 193–195°; methyl ester 2,4-dinitrophenylhydrazone, m. p. and m. m. p. 149–150° (calcd. for $C_{14}H_{16}O_7N_4$: C, 47.70; H, 4.58. Found: C, 47.50; H, 5.02); *p*-phenylphenacyl ester, m. p. 124–127°.

POLARIZED INFRARED SPECTRA FOR SILKWORM-GUT AND OTHER FIBROUS PROTEINS

Sir:

Infrared spectra observed with anisotropic specimens in polarized light depend upon their orientations relative to both direction of incidence and plane of polarization of the light. Spectra for different orientations of the same specimen can be correlated with structure and arrangement of its molecules. We have been employing this technique to study fibrous proteins. A recent account[1] of results obtained in this way by others encourages us to report some of our own findings at this time.

Polarized spectra for silkworm-gut, a material giving[2] the X-ray diffraction pattern characteristic of fibroin, are shown in Fig. 1. Each spectrum was traced from original instrumental records of *per cent.* transmission through two different samples, one about twenty, another about five microns thick, at left and right, respectively.

These spectra indicate an arrangement that is highly ordered in some respects. The degree of polarization exhibited by several bands approaches the best observed here for single crystals of favorably arranged, simple molecules, exceeding that for the other fibrous proteins we have examined.

The *rachis* of seagull feather exhibited many features appearing in Fig. 1 while quill from pigeon feather was polarized perceptibly at the lower frequencies only. Several natural collagens gave spectra similar to ones described above, with polarizations varying vicariously like ones for feather keratins. Films of rabbit myosin, oriented[3] so as to produce the α-keratin structure, and porcupine quill, showed only small effects of different sort.

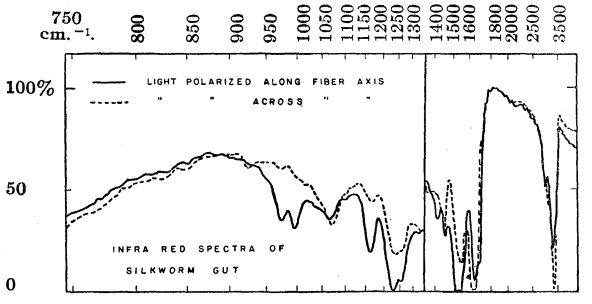

Fig. 1.

Our findings are confirmed in part by those of Ambrose, Elliott and Temple,[1] who worked just in the limited spectral range between 2800 and 3500 cm.$^{-1}$. There they found only slight differences for myosin (91% *vs.* 87% absorption, recalculated from their optical densities) and even smaller ones for porcupine quill and tropomyosin. They report larger effects, however, with feather keratin, as do we.

A full report will be submitted when our work has been completed.

USE OF *p*H INDICATORS WITH ION EXCHANGE RESINS

Sir:

I wish to report the use of *p*H indicators as a means of detecting acids adsorbed on a strong base type resin, Amberlite I.R.A 400.[1]

When the basic form of this resin is treated with phenolphthalein the indicator is quantitatively removed from solution and the resin becomes the characteristic deep pink. Washing has no effect and even strong acid or base will not elute the indicator. Acid decolorizes the resin but base restores the color. If the resin is left for a few days in neutral solution, however, the color is destroyed and base will not restore it. When methyl orange is adsorbed the characteristic color is given with hydrogen ion. Washing removes the color. Again neither strong acid or base will elute the indicator.

The following experiment on the determination of I.R.A 400 capacity for aspartic acid will serve to illustrate the use of a column indicator: Aspartic acid solution was exchanged on the basic form of the resin. The column was washed and 50–100 drops of 1% phenolphthalein passed through. The top of the column remained colorless and a pink zone formed at the junction of the aspartic acid and unreacted resins. The columns were micro burets containing 5–6 g. of 20–30 mesh resin. The acid was 4 mg./ml. and a flow rate of 0.2 ml./min. was used. The value obtained was: 1.5 cc. wet R:NOH resin = 100 mg. aspartic acid.

The method gave a visual illustration of resin efficiency. Not one colored particle was located in the aspartic resin. The pink zone was perfectly even. There was no measurable displacement of aspartic by phenolphthalein.

THE HYDROLYSIS OF NICOTINYL-L-TYROSYL-HYDRAZIDE BY CHYMOTRYPSIN

Sir:

The recent report that benzoyl-L-tyrosylhydrazide is ineffective as an inhibitor in the chymotrypsin catalyzed hydrolysis of benzoyl-L-tyrosylamide or ethyl ester[1] would lead one to infer

(1) S. Kaufman, H. Neurath and G. W. Schwert, *J. Biol. Chem.*, **177**, 793 (1949).

that the hydrazide analogs of the specific chymotrypsin amide or ester type substrates[2-5] are not hydrolyzed by this enzyme. We therefore wish to point out that at least one of the acylated α-amino acid hydrazides possessing the structural characteristics required of ester or amide type specific chymotrypsin substrates,[2-5] *i. e.*, nicotinyl-L-tyrosylhydrazide is hydrolyzed by this enzyme (Table I).

TABLE I

SEPARATION OF COLUMBIUM AND TANTALUM WITH ANION EXCHANGE RESINS[1]

Sir:

In a previous communication[2] an experiment was described indicating a partial separation of zirconium and hafnium on an anion exchange column in HCl–HF mixtures. While this separation was unusually difficult, the separation of the adjacent elements columbium and tantalum by the same method, under similar conditions, was very efficient.

The experiments were carried out with a 12.5-cm. column (0.0226 sq. cm. cross-section) of the anion exchange resin Dowex-1 using columbium[95] (β-emitter $T_{1/2}$ = 35 days[3]) and tantalum[182] (β-emitter $T_{1/2}$ = 117 days[3]). The columbium was carrier-free fission product and the tantalum was prepared by a neutron bombardment of tantalum metal. In a typical experiment, the tracers were added to the column in a mixture of 9 *M* HCl and 0.05 *M* HF and elution carried out in the same medium at an average flow rate of *ca.* 0.3 ml./sq.cm./min.

The results are shown in Fig. 1 which represents a transcribed continuous record of the activity of the eluent. The bands were identified by standard radiochemical procedures.

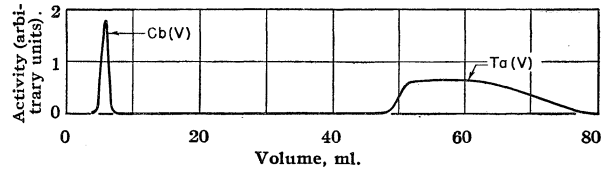

Fig. 1.—Separation of columbium (V) and tantalum (V) by anion exchange: dowex-1 column 12.5 cm. length 0.0226 sq. cm. cross-section, average flow rate; 0.3 ml./sq. cm./min.

Columbium eluted relatively rapidly in a sharp, well-shaped band and the tantalum very much more slowly in a somewhat diffuse band with a sharp front edge. The separation appears to be complete and could probably be achieved with better than 99% purity of the fractions using columns of considerably shorter length.

The experiments prove that both columbium and tantalum can form negatively charged complexes in this medium with probable negative charge minus two or greater. From the slower elution rate of the tantalum one can conclude that the average negative charge on this element is greater than that on columbium.

The very large difference in elution behavior of these two elements is somewhat surprising since both elements, in some complexes at least, show practically the same size. Thus Hoard[4] found no significant difference in the lattice constants of the complex fluorides K_2CbF_7 and K_2TaF_7. The rather large difference in the behavior of these elements on anion-exchangers may thus be due to comparatively large differences in their polarizability, causing considerable differences in the chloride complex constants, or to small differences in the value of each stability constant with a resulting large difference in the negatively charged series due to the fact that for these the product of a considerable number of such constants is involved.

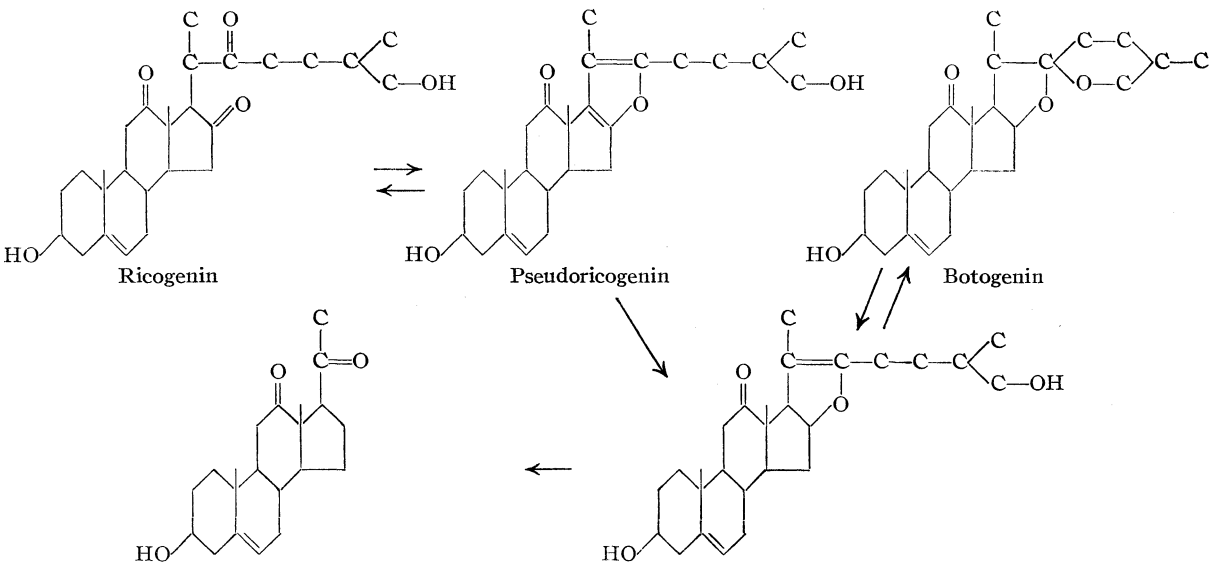
STEROIDAL SAPOGENINS, 173. 16-DEHYDROPREGNEN-5-OL-3-DIONE-12,20 FROM RICOGENIN, A NEW STEROIDAL SAPOGENIN

Sir:

In an extensive search for naturally occurring steroidal sapogenins having substituents in ring C which may be utilized for the synthesis of cortisone, the anti-arthritic hormone, a new saponide, riconin, m.p. 285–289° dec., was isolated from the mixture of glycosides occurring in *Dioscorea Macrostachya.*



Hydrolysis of riconin with alcoholic hydrochloric acid gave ricogenin, m.p. 225–227°. *Anal.* Calcd. for $C_{27}H_{40}O_5$: C, 72,9; H, 9.1. Found: C, 72.9; H, 9.1.

Ricogenin formed a diacetate, m.p. 195–197°, and contains three ketonic groups having the same side-chain structure as kryptogenin. *Anal.* Calcd. for $C_{31}H_{44}O_7$: C, 70.4; H, 8.4. Found: C, 70.2; H, 8.2.

Treatment of ricogenin with acetic anhydride at 195° for eight hours followed by hydrolysis gave pseudoricogenin, m.p. 220–222°. *Anal.* Calcd. for $C_{27}H_{38}O_4$: C, 76.0; H, 9.0. Found: C, 76.2; H, 9.0.

When heated with alcoholic hydrochloric acid for fifteen minutes, pseudoricogenin was converted into ricogenin, m.p. and mixed m.p. 225–227°. Catalytic reduction of the diacetate of pseudoricogenin, using palladium-on-barium sulfate as catalyst, saturated only the conjugated double bond in ring D, giving the diacetate of pseudobotogenin. This product upon alkaline hydrolysis followed by isomerization with alcoholic hydrochloric acid gave botogenin, m.p. and mixed m.p. 260–262°. *Anal.* Calcd. for $C_{27}H_{40}O_4$: C, 75.7; H, 9.4. Found: C, 75.5; H, 9.4.

Acetylation of this product gave botogenin acetate, m.p. and mixed m.p. 246–248°. *Anal.* Calcd. for $C_{29}H_{42}O_5$: C, 74.0; H, 9.0. Found: C, 74.1; H, 9.3.

The pseudobotogenin diacetate produced by the catalytic reduction of the diacetate of pseudoricogenin was oxidized with chromic anhydride in acetic acid, followed by hydrolysis,[1] giving 16-dehydropregnen-5-ol-3-dione-12,20 acetate, m.p. and mixed m.p. with the product prepared from naturally occurring botogenin, 225–227°. *Anal.* Calcd. for $C_{23}H_{30}O_4$: C, 74.8; H, 8.2. Found: C, 74.6; H, 81.

ALLO-PREGNAN-3,12,20-TRIONE

Sir:

The current interest in Kendall's substance E for rheumatoid arthritis has stimulated great interest in the search for starting materials for its synthesis. Recently, Marker reported the possibility of utilizing a steroidal sapogenin, botogenin, isolated from *Dioscorea Mexicana.*[1] Its degradation product was 5-pregnen-3(β)-ol-12,20-dione, characterized by conversion to *allo*-pregnan-3,12,-20-trione, m.p. 264°. The latter was identical with *allo*-pregnan-3,12,20-trione[2] from the degradation of hecogenin.

We have prepared an authentic sample of *allo*-pregnan-3,12,20-trione by an entirely different route and have found it completely different from the trione from hecogenin. Desoxycholic acid has been degraded to 12(α)-acetoxyprogesterone (I), m.p. 181°, $[\alpha]^{26}D$ +215°, $[\alpha]^{26}_{5461}$ +259° (chloroform), absorption maximum at 240mμ(log ϵ 4.14 in ethanol).[3] This compound (I) upon sodium–alcohol reduction followed by chromic acid oxidation furnished *allo*-pregnan-3,12,20-trione (II), m.p. 206–208°, $[\alpha]^{23}D$ +184°, $[\alpha]^{23}_{5461}$ +224° (chloroform), no maximum at 240mμ. *Anal.* Calcd. for $C_{21}H_{30}O_3$: C, 76.3; H, 9.2. Found: C, 76.0; H, 8.9. The reduction was also accomplished with hydrogen and Adams catalyst in acetic acid; subsequent hydrolysis and oxidation gave the same product (II). The course of these methods of reduction has been shown previously[4]

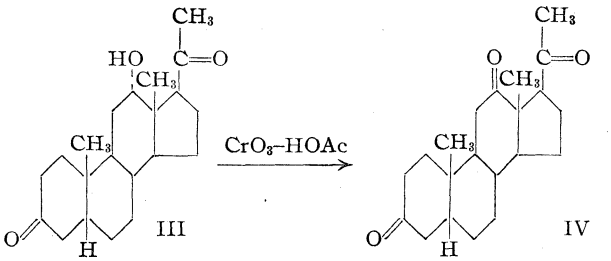
12(α)-Acetoxyprogesterone

allo-Pregnan-3,12,20-trione



12(α)-Hydroxypregnan-3,20-dione

Pregnan-3,12,20-trione

to lead to the *allo*-configuration at C-5. Nevertheless, we have prepared the corresponding isomer, pregnan-3,12,20-trione (IV), by the mild oxidation of an authentic sample of 12(α)-hydroxypregnan-3,20-dione (III). It had the following properties: m.p. 204–206°, $[\alpha]^{26}D$ +181°, $[\alpha]^{26}_{5461}$ +225° (chloroform). *Anal.* Calcd. for $C_{21}H_{30}O_3$: C, 76.3; H, 9.2. Found: C, 76.0; H, 9.1. Reichstein and von Arx[5] report for pregnan-3,12,20-trione: m.p. 201–202°; $[\alpha]^{17}D$ +182 ± 7, $[\alpha]^{17}_{5461}$ +219 ± 8 (ethanol). A mixture of IV with II showed a melting point depression of 36°. The melting point of each of these compounds was depressed 10–20° by the trione from hecogenin.

Since the properties of *allo*-pregnan-3,12,20-trione (II) are different from those of the samples derived from hecogenin and botogenin, some doubt must be entertained as to the structures of the degradation products from both of these sapogenins.

We thank Parke, Davis and Company for their help.

SYNTHESES IN THE DIRECTION OF MORPHINE. I. 7-METHOXY- AND 7,8-DIMETHOXY-2-TETRALONE.

Sir:

We wish to report the synthesis of 7,8-dimethoxy-2-tetralone, which may serve as a useful intermediate for elaboration in the direction of morphine and certain of its degradation products,[1] and may open a way for the preparation of physiologically active substances oxygenated at points corresponding to the 3 and 4 positions in morphine. 7-Methoxy-2-tetralone may serve in the syntheses of substances similarly substituted in the 3 position; and is of particular interest in view of the recent report that 3-hydroxymorphinane is a powerful analgesic surpassing morphine in clinical tests[2].

1,2,7-Trimethoxynaphthalene,[3] m.p. 38.5–39.5°, b.p. 133° at 1 mm. (picrate[3], m.p. 113°), gave by reduction[4] with sodium and alcohol, the crystalline ketone, m.p. 76° (*anal.* calcd. for $C_{10}H_8O(OCH_3)_2$: OCH_3, 30.1. Found: OCH_3, 29.5, 29.3), characterized as the semicarbazone, m.p. 191–191.5°, and the 2,4-dinitrophenylhydrazone, m.p. 167° dec. (*anal.* calcd. for $C_{18}H_{18}O_8N_4$: C, 56.0; H, 4.7; N, 14.5. Found: C, 55.7; H, 4.6; N, 15.0, 14.8). The structure of the ketone was shown by oxidation, with alkaline permanganate, to hemipinic acid, identified by its m.p.[5] (177–179°) and by the m.p.[6] (166–167°) and characteristic fluorescence[6] of the pure anhydride.

2,7-Dimethoxynaphthalene similarly[4] gave on reduction 7-methoxy-2-tetralone, m.p. 27–28°, b.p. 124–126° (1.5 mm.); semicarbazone, m.p. 174–176° (*anal.* calcd. for $C_{12}H_{15}O_2N_3$: C, 61.8; H, 6.5. Found: C, 62.1, 62.1; H, 6.4, 6.4); 2,4-dinitrophenylhydrazone m.p. 177–181° (*anal.* calcd. for $C_{17}H_{16}N_4O_5$: C, 57.3; H, 4.5. Found: C, 57.2, 57.5; H, 4.4, 4.6).

DEGRADATION OF GLYCOGEN TO ISOMALTOSE

Sir:

Methylation studies[1] have indicated that the glycogen molecule has a highly ramified structure composed of α-D-glucopyranosyl units joined 1,4 with branching at C6 on one out of twelve units. As additional evidence in support of this structure we report the isolation of crystalline 6-α-D-glucopyranosyl-β-D-glucopyranose octaacetate (β-D-isomaltose octaacetate)[2] from an acetylated acid hydrolysate of glycogen.

Animal (rabbit liver) glycogen (5.00 g., $[\alpha]^{25}D$ +200°, *c* 0.92, water) in 2% concentration was hydrolyzed at 100° in 0.05 *N* sulfuric acid for nine hours (degree of hydrolysis *ca.* 75%). After acid neutralization with barium carbonate and ion removal with exchange resins (Amberlite IR-100 and IR-4), the amorphous solid obtained on solvent removal was acetylated with hot acetic anhydride and sodium acetate. The resultant sugar acetate mixture (6.08 g.) was chromatographed[2] on Magnesol–Celite under such developmental conditions that monosaccharides were removed from the column. β-D-Glucose pentaacetate was identified,

ERYTHEIN AND APOERYTHEIN AND THEIR RELATION TO THE ANTIPERNICIOUS ANEMIA PRINCIPLE

Sir:

Normal gastric juice has been found to contain a non-dialyzable, heat labile substance which combines, apparently stoichiometrically, with erythrotin,[1] (vitamin B_{12})[2] to form a complex (erythein) which is non-dialyzable and not dissociated by dialysis. Erythrotin in this combination is not available to microörganisms (*Escherichia coli, Lactobacillus lactis Dorner, Lactobacillus leichmannii*), but is released by heat, much as biotin is released from avidin, whereupon it is again microbiologically active. Heated gastric juice contains no principle capable of combining with erythrotin.

Quantitative determination of heat labile principle (apoerythein) is readily performed by measuring in an erythrotin assay (*Escherichia coli*)[1] the inhibition of growth resulting when aliquots of the juice are added (unheated) to cultures containing just sufficient erythrotin to elicit a maximum response. The erythrotin combining capacities (millimicrograms of erythrotin per ml. of secretion) of samples of gastric juice from normal and anemic subjects were found to be respectively, 20, 60[3], 60, 15; and 5, <5,[3] <1, <1 >15.

Commercial preparations of hog gastric mucosa made for therapeutic use have been found to be rich in a principle which appears on the basis of chemical and biological properties to be analogous to the apoerythein in gastric juice. Other biological materials tested, including commercial pepsins, contain very little or none of the active substance. Less than 2000 parts by weight of a concentrate prepared from hog gastric mucosa completely counteracted consistently the microbiological growth stimulation of one part of erythrotin.

For preparative purposes hog gastric mucosa has been used, and the principle can be precipitated from an aqueous extract by alcohol, acetone or ammonium sulfate (80% saturation). The principle is highly selective in its action and inactivates erythrotin but does not diminish the biological action of the end-products of erythrotin-catalyzed processes which can substitute for this vitamin in microbiological assays—methionine (*Escherichia coli* test)[1] and desoxyribosides (*Lactobacilli* tests).[4]

The complex formed when erythrotin combines with apoerythein decomposes upon heating (120° fifteen minutes) into erythrotin (or a compound which cannot be distinguished from it biologically or chromatographically), and a residue no longer possessing the ability to bind erythrotin. In combined form erythrotin is not as susceptible to destruction by alkaline or oxidative treatments which inactivate the unbound vitamin, since heat liberation following such treatment of the complex yields the original erythrotin activity.

These experiments point to the probability that apoerythein is the intrinsic factor of Castle or an important component thereof. Clinical trials are now in progress to test this conclusion.

We are deeply indebted to Dr. William Shive for generous supplies of erythrotin before vitamin B_{12} was available and for prepublication disclosures concerning erythrotin tests, and to Dr. Edward Campbell, Eli Lilly and Company, who furnished biological preparations and gastric samples.

NEW BOOKS

The Optical Principles of the Diffraction of X-Rays. By R. W. JAMES, M.A., B.Sc., F.Inst.P., Professor of Physics in the University of Cape Town. (The Crystalline State. Vol. II. Editor: Sir Lawrence Bragg.) The Macmillan Company, 60 Fifth Ave., New York, N. Y., 1948. xv + 623 pp. 15 × 23.5 cm. Price, $17.50.

To serious students of X-ray diffraction, the publication of this book is an important event, for it is unquestionably one of the great books in this field. It has been awaited ever since it was announced in 1933 in the first volume of the three volume series on "The Crystalline State," edited by Sir Lawrence Bragg. The fifteen year period that elapsed between the appearance of the two volumes is accounted for in part by the war, of course, and in part by the author's moving and taking up new duties in a new country; but no small part must be ascribed simply to the magnitude of the task of writing the book. It is twice the size of Vol. I, and is filled with detailed mathematical treatments, careful comparisons of different theories with each other and with experimental results, and a great many carefully worded discussions, all of which must have required a great amount of effort on the part of the author.

Seldom are advanced scientific books written with such clear presentation of material. Because of this and because of its completeness and authoritativeness, it is sure to become a great favorite with students, as well as with teachers; and for the same reasons it is very unfortunate that the book is so expensive—many students will feel they cannot afford it. The high quality and the pleasing nature of the book is to be expected, of course, from an author who has made fundamental contributions to the subject for over twenty-five years, and at the same time has possessed the faculty of presenting crystallographic matters clearly and concisely, as demonstrated by his little monograph "X-Ray Crystallography" (Dutton & Co., 1930) that has helped many a student pass his examinations.

The book logically begins in the appendices in which are presented principles of vector algebra that are used throughout the book, and the various reciprocal lattice relations of such importance in X-ray crystallography. There is probably no more convenient derivation of these relations published anywhere than this one. In the early chapters the author derives the geometrical theory of diffraction, with intensity formulas for the case of no appreciable rescattering or absorption of radiation in the crystal. The treatment of the case with re-scattering of the waves in the crystal is based on Darwin's treatment; this is followed by Ewald's dynamical theory, which is presented with emphasis on the physics and with a minimum of the mathematical detail, so as to keep the main lines of the argument clear. Later in the book the dynamical theory is extended from the case of dipoles at lattice points to scattering matter distributed uniformly through the crystal (Laue's theory) and to the theory and observation of Kossel lines, Kikuchi lines in electron diffraction, and divergent beam X-ray photography.

The atomic scattering factor, dispersion and the influence of temperature on the diffraction of X-rays takes up a quarter of the book. In the treatment of diffuse scattering arising from thermal vibration of the atoms in crystals, a subject that has seen more than its share of controversy in the past, each party is given his "day in court." The author points out the true conclusions along with the mistakes and shortcomings of the contributors to the field, and continually compares theory with experiment. Few would have objected if less space had been devoted to certain early theories that are now superseded, but the author includes them because "they have had an important place in the development of the subject." This summary and the other brief historical summaries in the book, which are well documented with references, are very effective and interesting guides to a complex literature.

Although the book is not devoted to methods of crystal analysis, an excellent treatise is included on the use of Fourier series in crystal analysis, including Patterson and Patterson–Harker series, as well as the older series, and discussions of the determination of phases and the optical synthesis of series.

Electron diffraction receives little attention, and molecular and neutron scattering none. The last chapters cover the theory of scattering of X-rays by gases, liquids, amorphous solids, small crystallites with different shapes, lattices with faulty stacking and with periodic disturbances, and fibrous materials.

C. S. BARRETT

The Electronic Theory of Organic Chemistry. BY M. J. S. DEWAR. Oxford University Press, 114 Fifth Avenue, New York 11, N. Y. (Oxford at the Clarendon Press). 1949. x + 324 pp. Illustrated. 15.5 × 24.5 cm. Price, $7.50.

On the advanced level in a field such as theoretical organic chemistry, books should be written by only two classes of authors—mature scholars bent on accuracy and young enthusiasts with fresh viewpoints. The claims of Dr. Dewar to a hearing are under the second classification. In a clearly and vigorously written book, he sweeps across theoretical organic chemistry with a point of view which, while by no means revolutionary, is fresh enough to be stimulating.

"The Electronic Theory of Organic Chemistry" is the first general discussion of the problems of organic structure and mechanisms in the language of molecular orbitals. The resonance approach, Dewar says, "is most unsuitable from the organic chemist's point of view since it involves a new symbolism and a novel and uncongenial outlook." The hope of better things which this statement raises is, in the reviewer's opinion, not fulfilled in the book; for no general operational superiority is demonstrated for the rather nebulous notation of molecular orbitals as an instrument of correlation and prediction, in comparison to the well-developed qualitative resonance scheme. It is healthy, nevertheless, to have this substantial reminder that resonance is not a phenomenon of nature.

As those familiar with Dewar's research papers would anticipate, the so-called π-complexes occupy a prominent place in his discussions of structure and reaction mechanisms. The π-complexes are not as new as the reader might conclude from their presentation here; the economical representation  implies no more, and perhaps no less, than the equivalent representation in terms of resonance given by Winstein and Lucas in 1938. The fact that the π-complex notation is a matter of language is often lost sight of in the discussion, as where it is said that the bromonium ion "was originally formulated with a three-membered ring but it is more probably a π-complex." At several points the fertility of the notation is demonstrated, notably by anticipation, in the discussion of the Wagner–Meerwein rearrangement, of current developments indicating the mesomeric nature of the intermediate carbonium ions.

One who expresses forthright and unreserved opinions on many things is sure to share, from time to time, the position of Mr. Gallup on the day after election. While page 86 was being printed, devoted to an explanation of why a bimolecular allylic rearrangement (S_N2') will probably never

be found, a paper appeared by Kepner, Winstein and Young proving the existence of this mechanism. Even without such experimental work, it would be hard to credit Dewar's transition state involving five collinear atoms in view of the ease of the ortho Claisen rearrangement and consideration of models.

The book shows broad interest in fundamentals and an unusual feeling for reaction mechanisms. However, the problems are often not simple and the facts are not treated in as careful a manner as is usually necessary for reliable conclusions to be reached. For example, few of the mechanisms given for prototropy and carbonyl reactions would retain their simple beauty if the facts of general acid-base catalysis were considered. References are provided unevenly; of the ideas discussed, the disapproved ones are credited to their authors with more regularity than those which are believed to be correct. The contents of some cited papers are ignored to the point of presenting a superficial conclusion already recognized as untenable. Internal evidence suggests that the author has not had time to become familiar with the details of all the problems he discusses. These facts impose a serious limitation on the use of the book; for it is not an authoritative review of the status of the numerous problems considered. It is, as Sir Robert Robinson says in the foreword, a "connected series of original essays." As such, it promises to start many discussions and to stimulate a number of researches.

PAUL D. BARTLETT

Recent Advances in Analytical Chemistry. Editors: R. E. BURK, Plastics Dept., E. I. du Pont de Nemours and Co., Wilmington, Delaware, and OLIVER GRUMMITT, Morley Chemical Laboratory, Western Reserve University, Cleveland, Ohio. (Frontiers in Chemistry, Vol. VII.) Interscience Publishers, Inc., 215 Fourth Ave., New York 15, N.Y., 1949. v + 209 pp. Illustrated. 15.5 × 23.5 cm. Price, $4.50.

Like previous volumes of the "Frontiers" series, the current volume includes reports by the authorities who presented the specific lectures. The reports are in the form of summaries of the seven lectures presented which, for this series, included the following phases of analytical chemistry: Voltammetry (polarography) and amperometric titrations (I. M. Kolthoff); inorganic analysis with organic reagents, and some recent colorimetric and gravimetric organic reagents (John H. Yoe); application of infrared spectroscopy in analysis (Otto Buck); electron microscopy and microanalysis—new methods in chemistry (James Hillier); fractionation, analysis and purification of hydrocarbons (Frederick D. Rossini); and applications of the mass spectrometer (J. A. Hipple).

Each chapter includes a brief historical and theoretical introduction, a discussion of the principles involved and equipment (where pertinent) used and available, typical applications and usefulness of the technique. The lectures are not designed to add to the knowledge of the specialist in a specific field, but rather to present a comprehensive picture of current knowledge which will enable the nonspecialist to understand and evaluate the possibilities of each technique. Copious illustrations, together with data, diagrams and typical graphs help to give a clear cut picture of the capabilities of the specialty covered. The two chapters by Yoe deal with the general qualifications required of suitable organic reagents and with the use of specific recent reagents for silver, palladium, iron, titanium and tungsten.

The chapter on infrared includes the history, origin of infrared spectra, design and development of some instruments, applicability to quantitative analysis with particular emphasis on the hydrocarbons and usefulness in structure studies. The other instrumental chapters are similar in purpose, all being supplied with a small, though sufficient, number of literature references.

Each chapter comprises a readily understandable comprehensive outline of the subject covered in somewhat greater detail than could be assimilated by merely listening to the lectures.

H. A. FREDIANI

Isotopic Carbon. Techniques in Its Measurement and Chemical Manipulation. By MELVIN CALVIN, Professor of Chemistry, CHARLES HEIDELBERGER, JAMES C. REID, BERT M. TOLBERT, and PETER F. YANKWICH, Instructor in Chemistry. All members of the Scientific Staff of the Radiation Laboratory, University of California, Berkeley. John Wiley and Sons, Inc., 440–4th Avenue, New York 16, N. Y., 1949. xiii + 376 pp. 107 figs. 15 × 24 cm. Price, $5.50.

In this book are collected the personal and vicarious experiences of Professor Calvin and his associates at the University of California with the carbon isotopes. Also included is an exhaustive digest of the literature on methods of synthesis of labelled molecules and techniques of measurement of these isotopes. The dust jacket offers this book as "A complete manual . . . for those who wish to use the isotopes of carbon as tracers in chemistry and biology. . .," and while the book could hardly be expected to fulfil such a broad claim, it will be of great value to anyone involved in problems of measurement of any of the low energy activities such as that of C-14, or in problems of synthesis of labelled molecules from the available chemical forms of the carbon isotopes. The table of contents shows the topics treated: Chap. 1. Production and Properties of Isotopic Carbon; 2. Measurement of Carbon-13; 3. Characteristics of Carbon Tracer Radiations; 4. Instruments for Radioactivity Measurement; 5. Detectors for Radioactivity Measurement; 6. Sample Preparation I; 7. Sample Preparation II; 8. Vacuum Techniques in Organic Chemistry; 9. Synthesis of Carbon Labelled Compounds; 10. Criteria of Purity; 11. Degradation Procedures; 12. Biosynthetic Methods; Appendix I. Isotope Dilution Methods; II. Statistical Treatment of Counting Data; III. Determination of Coincidence Corrections; IV. Determination of Counter Efficiency; V. Self Absorption Data; VI. Numerical Examples; VII. Flow in Vacuum Systems; VIII. Vacuum Gauges and Manometers; IX. Induction Stirrer for Use with Vacuum or Closed Systems.

Because the authors are personally familiar with a large fraction of the experimental procedures, many of them having been developed in their own laboratories, the book offers a wealth of detail which is usually omitted in journal publications. This value is lacking in those sections which merely reprint the literature without comment. Chapters 3 to 7 and Appendices II, III and V treat in considerable detail the procedures for preparing and measuring sample of C-14. Many of these minor, but quite important, points of technique are either new or have been available only as hearsay. Much of this material is directly applicable to other low energy β activities such as S^{35}. Chapter 9 presents all, apparently, of the methods that have been used in the synthesis of carbon labelled compounds.

Stable tracer carbon has been here treated as a stepchild. Syntheses with C-13 are presented along with those with C-14, and justifiably, since the problems are almost identical. But while there are more than one hundred pages devoted to the various problems associated with measuring the radioactive isotopes, the measurement of C-13 is reviewed in less than six. This ratio is not a measure either of the relative importance or of the relative complexity of handling stable and radioactive carbon. The authors do not examine the factors that determine the unique applicability of one method or the other to certain types of problems nor do they emphasize the complementary function, so nicely demonstrable with the carbon isotopes, of stable and radioactive tracer methods.

The authors might well have included a discussion of the various experimental conditions that must be considered in designing an experiment involving the use of carbon tracers. These conditions determine the particular isotope, the method of measurement and the necessary pre-

cision, and the isotopic concentration of the labelled compounds. This last determines the scale of the synthesis of the compounds. Particularly when a micromole scale is demanded to maintain a high tracer concentration the synthesis may be the most difficult hurdle met.

The exposition is generally clear and lucid and considering the large number of authors the style is quite uniform. The errors introduced are few and those are not seriously misleading. The book is well made but the price is high for one with such a rapid rate of obsolescence. Had the extraneous material, such as the chapters on vacuum methods and some of the introductory and survey material, been left out, the book could have been published in pamphlet form under the title "Techniques in the Use of Radioactive Carbon" without appreciably impairing its value which, on the topics appropriate to that title, is quite considerable.

WARREN W. MILLER

Advances in Carbohydrate Chemistry. Vol. 3. Edited by W. W. PIGMAN, The Institute of Paper Chemistry, Appleton, Wisconsin, and M. L. WOLFROM, The Ohio State University, Columbus, Ohio. Academic Press, Inc., Publishers, 125 East 23rd Street, New York 10, N. Y. 1948. xxiii + 424 pp. 15 × 23 cm. Price, $8.50.

The third volume of the "Advances" appeared in 1948, and by now will be found on the desks, on the shelves, in the mountains and at the beaches, wherever carbohydrate chemists are at work or play throughout the world. For those chemists who are not yet familiar with the excellent historical and critical up-to-date reviews comprising this series, a brief glance at the contents of the new volume will show the wide range of topics and indicate their appeal especially to the teacher and the research chemist in the many fields in which carbohydrates play major roles.

The book opens with a short obituary of Dr. R. Max Goepp, Jr., a former member of the Executive Committee of the "Advances."

The titles and authors of the reviews are as follows.

"Historical Aspects of Emil Fischer's Fundamental Conventions for Writing Stereo-Formulas in a Plane," (22 pp.), by C. S. Hudson, National Institutes of Health, U. S. Public Health Service, Bethesda, Maryland.

"The Structure and Reactivity of the Hydrazone and Osazone Derivatives of the Sugars," (22 pp.), by E. G. V. Percival, The University of Edinburgh, Scotland.

"The Chemistry and Configuration of the Cyclitols," (33 pp.), by Hewitt G. Fletcher, Jr., National Institutes of Health, U. S. Public Health Service, Bethesda, Maryland.

"Trityl Ethers of Carbohydrates," (33 pp.), by Burckhardt Helferich, Chemisches Institut der Universität, Bonn am Rhein, Germany.

"Glutose and the Unfermentable Reducing Substances in Cane Molasses," (16 pp.), by Louis Sattler, Department of Chemistry, Brooklyn College, Brooklyn, N. Y., and the New York Sugar Trade Laboratory, New York, N. Y.

"The Halogen Oxidation of Simple Carbohydrates, Excluding the Action of Periodic Acid," (56 pp.), by John W. Green, The Institute of Paper Chemistry, Appleton, Wisconsin.

"The Molecular Constitution of Cellulose," (44 pp.), by Jack Compton, Viscose Research Department, Celanese Corporation of America, Rome, Georgia.

"Isotopic Tracers in the Study of Carbohydrate Metabolism," (22 pp.), by Samuel Gurin, Department of Physiological Chemistry, School of Medicine, University of Pennsylvania, Philadelphia, Pennsylvania.

"Products of the Enzymic Degradation of Starch and Glycogen," (60 pp.), by Karl Myrbäck, Biokemiska Institutet, Stockholms Högskola, Stockholm, Sweden.

"The Polysaccharides of *Mycobacterium tuberculosis*," (26 pp.), by M. Stacey and P. W. Kent, Chemistry Department, The University, Birmingham, England.

"The Chemistry of Streptomycin," (48 pp.), by R. U. Lemieux and M. L. Wolfrom, The Ohio State University, Columbus, Ohio.

NELSON K. RICHTMYER

Some Aspects of the Luminescence of Solids. By F. A. KROGER, Natuurkundig Laboratorium, N. V. Philips Gloeilampenfabrieken, Eindhoven (Netherlands). Elsevier Publishing Company, Inc., 215 Fourth Avenue, New York 3, N. Y., 1948. xi + 310 pp. Illustrated. 15.5 × 21 cm. Price $5.50.

This monograph on inorganic luminescent solids, based on experimental work by Kroger and associates at the Philips Lamp Company in Holland, does not pretend to give a comprehensive account of the present status of solid-state luminescence, nor does it present a general survey.

The emphasis is largely on luminescent efficiency, absorption, excitation and emission phenomena, and their temperature dependence. After an elementary, descriptive presentation of the theoretical basis for luminescence in solids, the properties of aluminate, molybdate, silicate and tungstate phosphors, and of manganese, titanium and uranium as activators are discussed in detail. Much of the work is reported for the first time. The experimental data are largely semi-quantitative with no indication of probable errors, and the correlations, in many cases, are only qualitative, *e.g.*, the correlation of absorption edge and the maximum of emission. The relevant published researches of other investigators are briefly mentioned. A tabulation, complete with emission color and original references, of 949 different phosphors according to 43 activators is extremely useful for reference purposes.

Kroger has an easy and enthusiastic style of presentation that occasionally reverts to the first person. A few odd expressions such as "cheap transition" denoting the transition requiring the least energy indicate that English is not the native language of the author and in general add to the charm of the presentation.

Investigators in luminescence can most painlessly become familiar with the work of one of the currently most active groups in phosphor research by reading this book.

FERD E. WILLIAMS

Max Planck in seinen Akademie-Ansprachen. Erinnerungsschrift der Deutschen Akademie der Wissenschaften zu Berlin, Akademie-Verlag, Berlin, 1948. 204 pp. 1 illustration. 15 × 24 cm. Price, DM 8.75.

Max Planck was a member of the German Academy of Sciences in Berlin from 1894 to his death in 1947 and its permanent secretary for mathematics and the natural sciences from 1912 to 1938. As a memorial to him the Academy has published this little book containing some of the addresses he made to the Academy, whether upon his admission or upon some festive or memorial occasion or when welcoming newly elected members in response to their remarks at the time of their admission; and when necessary to make Planck's response intelligible to the reader, the address of the newly elected member is also reproduced.

In his acceptance speech on admission Planck made clear his own philosophy of the rôle of the theoretical as contrasted with the experimental physicist, and not the least interesting of his later responses to new members are those in which the member expressed a different philosophy, as in the case of Einstein. The last essay was a Leibniz-day address of 1935. The little volume begins with a picture of Planck and closes with a list of 235 titles of his articles published between 1879 and 1948 (a seventy-year span) assembled by Max von Laue.

Studies in Stereochemistry. I. The Stereospecific Wagner–Meerwein Rearrangement of the Isomers of 3-Phenyl-2-butanol[1]

BY DONALD J. CRAM[2]

A considerable amount of our more intimate knowledge of the mechanisms of molecular rearrangements rests on the use of stereochemical relationships which exist between particular groups of carbon atoms in reactants and products of a given reaction. Thus Wallis and co-workers[3] and others have unequivocally demonstrated in their fundamental researches on the subject that in the Curtius, Hofmann, Lossen and Wolff rearrangements the migrating species when asymmetric is capable of maintaining optical configuration throughout the course of the reaction. There is good reason to expect that this stereospecificity with regard to the migrating group can be equally well applied to the pinacol and Wagner–Meerwein rearrangements.

Bartlett and Pöckel[4] called attention to evidence that in the Wagner–Meerwein rearrangement the carbon atom where replacement occurs undergoes a Walden inversion. Bernstein and Whitmore[5] in their elegant study of the semipinacolic deamination reaction of optically active 1,1-diphenyl-2-amino-1-propanol have demonstrated that a Walden inversion of the carbon atom originally bearing the amino group accompanies the reaction.

The Wagner–Meerwein reaction is unique, in that the stereochemistry of all three of the carbon atoms involved in the bond-making and breaking processes can be examined through the use of the proper systems. This rearrangement has been studied extensively in bicyclic systems with the use of such reactions as the conversion of camphene hydrochloride to isobornyl chloride,[4,6,7,8] and the reverse reaction of the conversion of isobornyl chloride to camphene hydrate.[9] In these and other examples investigated that involve asymmetric carbon atoms at both sites of reaction (the carbon atoms *from which* and *to which* migration of a methylene group occurs), the complete stereochemical structures of both starting material and product were not known.[10] In every case the starting materials as well as the products are bicyclic compounds, and the reactions are limited to the methylene group as the migrating species.

Wallis, *et al.*,[11] have studied the migration of a phenyl group in optically active 2-methyl-2-phenyl-1-butanol when this compound is treated with thionyl chloride. These authors have suggested on the basis of changes in sign of rotatory power during rearrangement that inversion occurred at the carbon atom originally bearing the phenyl group. They also considered the existence of any true carbonium ions during the course of the reaction to be very doubtful, and looked upon their reaction as taking place by a concerted mechanism in which all bond-making and bond-breaking processes occurred at the same time, once the thionyl chloride derivative of the starting carbinol

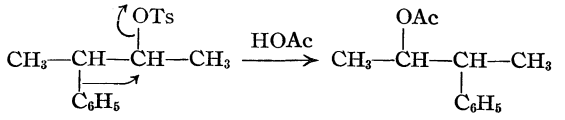
was formed. This work, however, represents the only attempt to study the stereochemistry of the Wagner–Meerwein rearrangement in an acyclic system.

Among others, Wilson, *et al.*,[8] have postulated an ionic intermediate in the Wagner–Meerwein rearrangement, but more concrete evidence for an ionic intermediate is found in the work of Winstein, *et al.*,[12] on the *i*-cholesteryl system which involves a pair of electrons as the migrating species.

In contrast to the findings of the above authors, the present investigation (see papers I, II, III and IV in this series) will unequivocally demonstrate for the first time the existence of a *discrete molecular species*, a carbocyclic three-membered carbonium ion as an intermediate in a Wagner–Meerwein rearrangement in an acyclic system.[13] It should be stated, however, that the results of this work are in a sense not unlike the demonstration of the existence of a bromonium ion by Winstein and Lucas,[14] whose work has served as an inspiring model in the present investigation.

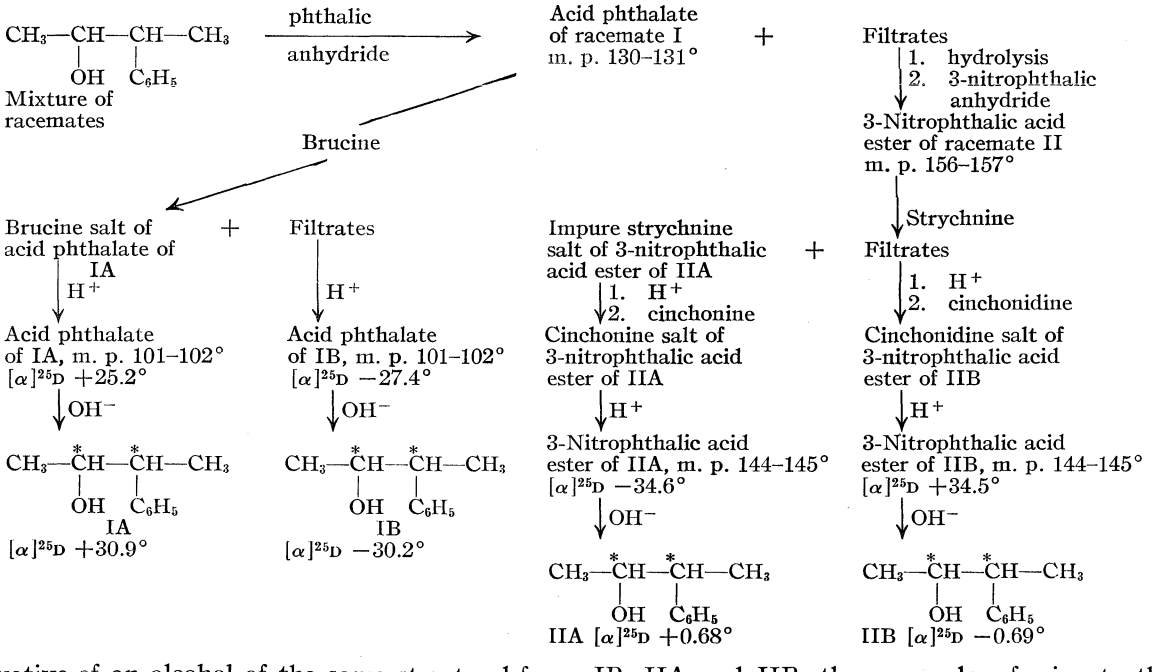
Paper I in the present series is devoted to an investigation of the mechanism of the Wagner–Meerwein reaction which takes place during the acetolysis of the *p*-toluenesulfonates of the stereoisomers of 3-phenyl-2-butanol. When rearrangement occurs in the molecule, the product is a derivative of an alcohol of the same structural formula as is the reactant, but not necessarily the same stereochemical formula. This fact simplifies the



procedures of isolation and identification of products as well as giving some information in regard to the possible existence of symmetrical intermediates. This system also allows a study at the same time of the stereochemical transformations that occur at both the carbon atoms *from which* and *to which* migration takes place; these carbon atoms are free to rotate, and the substituents attached to them are not held in a definite position in space with respect to each other.

Preparation and Resolution of 3-Phenyl-2-butanol

A mixture of the two racemates of 3-phenyl-2-butanol[15] was obtained by the treatment of 2-phenylpropionaldehyde (this compound was prepared by the procedure of Claisen[16]) with the methyl Grignard reagent. The resolution of this carbinol into the four optically pure stereoisomers was accomplished according to the scheme indicated. The four alcohols are designated as IA, IB, IIA and IIB, the numerals referring to the racemate series and the letters to the enantiomorphs within the series.



The acid phthalates of II, IIA and IIB were prepared as well as the 3-nitrophthalic acid esters of I, IA and IB, and in each case where an enanti-

omorphic pair was obtained, the magnitude of the rotation of the one is in good agreement with that of the other. The melting points of the solid derivatives also coincide. These data indicate that complete resolution was accomplished. The *p*-toluenesulfonates of IA and IIA were prepared by treating the corresponding alcohols with *p*-toluenesulfonyl chloride in a pyridine solution. Table I records the physical constants, analytical data and yields pertaining to these compounds.

Acetolysis of the *p*-Toluenesulfonates of the Stereoisomers of 3-Phenyl-2-butanol

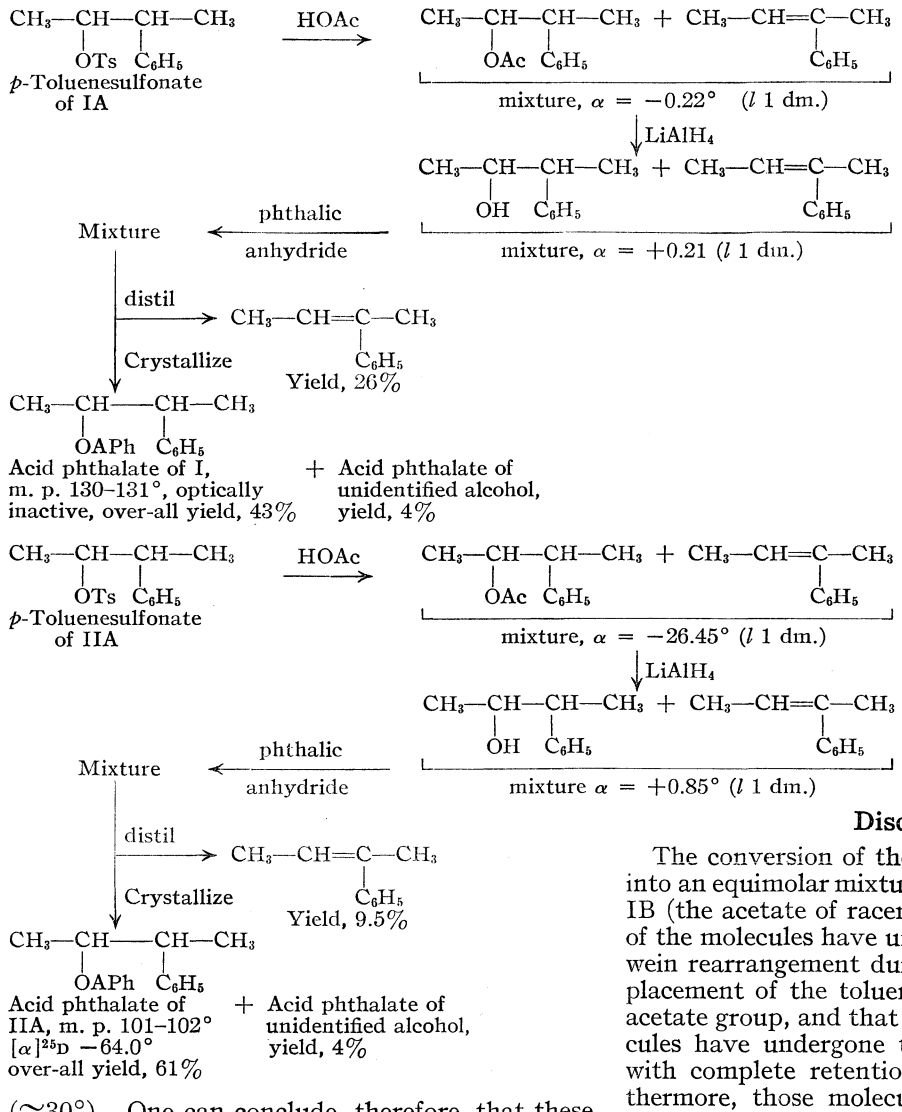
The *p*-toluenesulfonates of IA and IIA were prepared and heated at 70° for thirty hours[17] in a solution of glacial acetic acid which contained 1% of acetic anhydride and enough potassium acetate to neutralize the toluenesulfonic acid produced in the reaction.[18] The following formulations indicate the procedures used for isolation of the products, the yields and rotations. The alcohol IIA was isolated as the acid phthalate because this derivative possesses more desirable crystallization properties than the corresponding 3-nitrophthalic acid ester.

The observed rotation of the liquid acetate–olefin mixture obtained from the acetolysis of the *p*-toluenesulfonate of IA is very small (−0.22°) indicating that almost complete racemization took place. Had simple inversion of the carbon atom bearing the *p*-toluenesulfonate group occurred to any extent, one would have expected a corresponding increase in this rotation since the magnitude of the rotation of the acetate of IIA or IIB is quite high (>26°). The magnitude of the rotation obtained by the reduction of this mixture is also very low (+0.21°) indicating that there is little, if any, predominance of the amount of IA over IB, or *vice versa*.

The observed rotation of the liquid acetate–olefin mixture obtained from the acetolysis of the *p*-toluenesulfonate of IIA is quite large (−26.45°), which indicates that there is a considerable amount of optically active compound present. When reduced to the carbinol–olefin mixture, however, the rotation drops to +0.85°, a fact consistent with the large amount of IIA alcohol ($[\alpha]^{25}D$ +0.68°) present in this mixture There can be little if any of either IA or IB present, however, (products of simple inversion), because these alcohols have a high magnitude of rotation

(17) This period of heating is equal to about six half-lives of the starting material under these conditions, as calculated from the kinetic data obtained for acetolysis of these compounds by S. Winstein and B. Friess[23] (unpublished work).

(18) Experiments run without the potassium acetate gave a slightly lower yield of product and more tar.



(≅30°). One can conclude, therefore, that these acetolysis reactions proceeded with little, if any, *simple inversion* of the carbon atom bearing the *p*-toluenesulfonate group.

Another interesting point that should be noted is that the sum of the yields of the final carbinol derivative and the olefin in the I series (≅70%) is just about equal to the sum of the yields of the carbinol derivative and the olefin obtained in the II series, even though the relative amounts of olefin and carbinol differ.

Walden Inversion of the *p*-Toluenesulfonate of IIA

It seemed desirable to relate the configurations of the two asymmetric carbon atoms of one of the enantiomorphs of racemate I to those of one of the enantiomorphs of racemate II. This relationship could be established if a simple inversion without rearrangement could be performed on the carbon atom bearing the oxygen of one of the stereoisomers of 3-phenyl-2-butanol or a derivative. Accordingly, one of the diastereoisomers would be converted into another without altering the stereochemistry of the carbon atom bearing the phenyl group. Simple inversion was accomplished through the use of the method that Phillips[19] employed for the inversion of the *p*-toluenesulfonate of 1-phenylpropanol-2. Treatment of the *p*-toluenesulfonate of IA with a solution of a large amount of potassium acetate dissolved in absolute ethanol produced a small amount of the acetate of IIA (most of the *p*-toluenesulfonate was converted to the ethyl ether). This acetate was converted to the acid phthalate for identification purposes.

Discussion

The conversion of the *p*-toluenesulfonate of IA into an equimolar mixture of the acetates of IA and IB (the acetate of racemate I) indicates that half of the molecules have undergone a Wagner–Meerwein rearrangement during the course of the displacement of the toluenesulfonate groups by the acetate group, and that the other half of the molecules have undergone the displacement reaction with complete retention of configuration. Furthermore, those molecules that have undergone rearrangement have done so in a highly stereospecific manner.[20] In the acetolysis of IIA there is no concrete proof that any rearrangement has taken place, but it would seem highly probable that since rearrangement took place in the I series, the same occurred in the II series. If the analogy between systems I and II is maintained, half of the molecules of *p*-toluenesulfonate of IIA must rearrange to IIA acetate, and half of the molecules produce IIA acetate without rearrangement.[21]

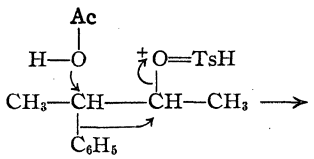
The isolation of the acetates of IA and IB in equimolar proportion from the acetolysis with

(19) Phillips, *J. Chem. Soc.*, **123**, 44 (1923).

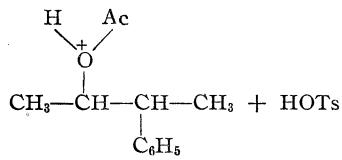
(20) The reaction giving rise to the acetates was at least 90% stereospecific since the ratio of the yield of the acid phthalate of racemate I to the yield of the acid phthalates of other alcohols was ten to one. Stereospecificity of even a higher degree was found in the II series.

(21) Strong evidence for this suggestion is found in paper III of this series. The *p*-toluenesulfonates of the two racemates series of 3-phenyl-2-pentanol were submitted to acetolysis, and in both cases the product was a mixture of the acetate of starting material and the acetate of rearranged material (2-phenyl-3-pentanol acetate).

glacial acetic acid of the *p*-toluenesulfonate of IA is strong evidence that both products arose from a symmetrical intermediate ion, and that the reaction was *not* completely concerted. Had the latter been the case, only rearranged product (IB) would have been obtained. The acetate group would have entered the molecule at the same time that the phenyl group migrated and the *p*-toluenesulfonate group left.[22]



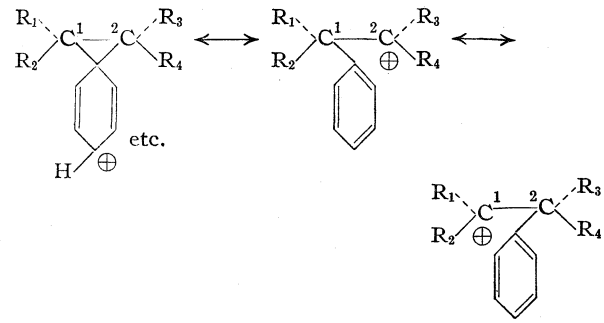
IA configuration



IB configuration

In the acetolysis experiments with glacial acetic acid the lack of products belonging to the II racemate series when the starting materials belong to the I racemate series and *vice versa* indicates that any intermediate ions formed during the reaction are capable of maintaining their optical integrity. Furthermore, very little, if any, simple bimolecular displacement of the *p*-toluenesulfonate group by acetic acid molecules could have taken place under these conditions. When the reaction was conducted in ethanol containing acetate ion, simple bimolecular displacement was the only reaction encountered exclusive of the reaction with ethanol, the nature which was not examined.

These facts can be rationalized in the following manner. The first step in the rearrangement is probably the transfer of a proton from a glacial acetic acid molecule to one of the two negative oxygens of the *p*-toluenesulfonate group placing a positive charge on the sulfur that can be distributed through resonance on the oxygen bearing the carbon. The carbon–oxygen bond is thus weakened and the second step is the departure of a molecule of *p*-toluenesulfonic acid, leaving a carbonium ion that must in some way be capable of maintaining optical and hence tetrahedral character. A cyclic ion existing as a resonance hybrid as shown below fulfills this requirement and offers an attractive hypothesis for explaining the racemization of the *p*-toluenesulfonate of IA on the one hand, and the maintenance of configuration of the same derivative of IIA on the other, during acetolysis with acetic acid. If R_1 and R_3 are methyl groups and R_2 and R_4 are hydrogens, this intermediate possesses a plane of symmetry, and the cycle could be opened by an acetic acid molecule

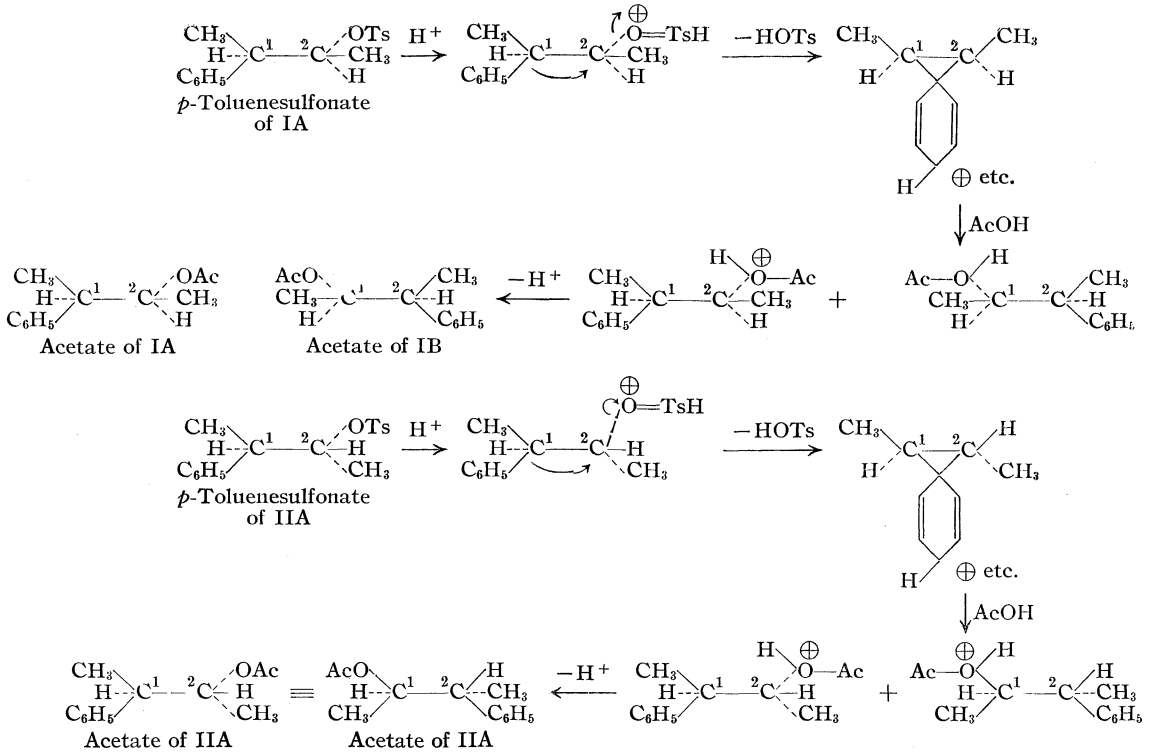


at either carbon atoms 1 or 2 (with equal probability), giving rise to racemic acetate after the departure of a proton from the molecule. If R_1 and R_4 are methyl groups and R_2 and R_3 are hydrogens, the intermediate is asymmetric, and when the cycle is opened at either carbon atoms 1 or 2 (with equal probability), optically active product is obtained. Since there are no cases known of simple front-side displacement unattended by the possibility of reaction by a cyclic mechanism, it is logical to assume that the cycle was formed with inversion of the carbon atom bearing the *p*-toluenesulfonate group, and that when the cycle is opened, the carbon atom hit by the acetic acid molecule is inverted. The latter reaction is probably bimolecular. The question as to whether the cycle is formed by a concerted displacement of the *p*-toluenesulfonate by the phenyl group is difficult to settle. The stereospecificity of the reaction would seem to demand that this step is concerted. On the other hand, kinetic determinations[23] of the comparative rates of the liberation of *p*-toluenesulfonic acid from the *p*-toluenesulfonates of I, II and 2-butanol in glacial acetic acid showed that these reactions all take place with very little difference in rate. Since the butanol derivative does not and the derivatives of I and II do rearrange, the breaking of the carbon–oxygen bond in the latter molecules cannot be much aided energetically by the formation of a new carbon–carbon bond in a cycle, or there would be divergence in the activation energies and hence the rates of the reactions in the two types of molecules. These data suggest that either intermediate ions of other than a cyclic nature exist, or that the loss of the *p*-toluenesulfonate group and the formation of the intermediate cycle take place in concert with one another, but that the energy gained by the formation of a new carbon–carbon bond of the cycle approximately cancels the energy needed to compensate for the decrease of resonance energy and for the energy needed to distort the bond angles into a three-membered ring. The latter explanation is preferred because the stereochemistry of the reaction is not compatible with the existence of intermediates of a non-cyclic character.

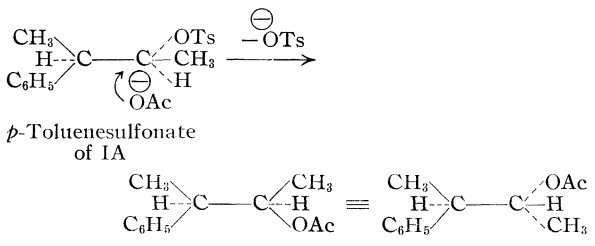
The hypothesis favored for the mechanism is summarized in the formulations.

(22) This evidence is in accord with the suggestion of C. G. Swain [THIS JOURNAL, **70**, 1126 (1948); **70**, 2989 (1948)] that Wagner-Meerwein rearrangements are concerted processes as far as the carbonium ion intermediates.

(23) Private communication from S. Winstein and B. Friess of work carried out in connection with a general investigation of the Wagner–Meerwein rearrangement.



In presenting this mechanism, IA has been assumed to have a certain stereochemical configuration. This assumption was made because it leads to a symmetrical intermediate cyclic ion which in turn gives equal molecular amounts of IA and IB acetates. The assignment of IA to the configuration shown and not to that assumed for IB was purely arbitrary. Having assigned the configuration of IA, the configuration of IIA is determined through the conversion of the *p*-toluenesulfonate of IA to the acetate of IIA by acetate ion through simple inversion of the carbon atom bearing the oxygen bond. The configurations of IB and IIB



become fixed through their enantiomorphic relationship to IA and IIA, respectively. The configurations of IIA and IIB are such that each would give rise to an asymmetric cyclic intermediate, these two intermediates being enantiomorphic in relationship. This type of intermediate for the II series is just what the results of the acetolysis experiments demand. Thus this series of experiments not only provides a certain insight into the mechanism of the Wagner–Meerwein rearrangement, but also presents a unique method of determining the stereochemical structure of this type of compound. The results of an independent determination of the stereochemical structure of each of these four isomers is presented in the fourth paper in this series, and the results are in full agreement with the above assignments. A discussion of the mechanism of the formation and the configuration of the olefin formed in the acetolysis experiments will also be found in the fourth paper of this series.

It is interesting to note in regard to the studies of the inversion by acetate ion in ethanol of the *p*-toluenesulfonates of 1-phenyl-2-propanol[19] and 3-phenyl-2-butanol that the yields of acetate product decreased respectively and that the yields of ether increased. Since the rate-determining step in the reaction with acetate ion is in each case bimolecular, the rate is more sensitive to steric hindrance than is the rate of the reaction with the ethanol, which probably proceeds by a different mechanism.

Experimental

Separation of the Mixture of Isomers of 3-Phenyl-2-butanol into Racemates I and II.—The mixture of the isomers of 3-phenyl-2-butanol[15] (112 g.) obtained from the action of methylmagnesium bromide on 2-phenylpropionaldehyde was heated to 100° for one hour with 112 g. of phthalic anhydride and 125 g. of pyridine. The resulting mixture was cooled, dissolved in benzene, extracted twice with excess dilute sulfuric acid, washed with water, dried, evaporated, dissolved in two volumes of ethyl acetate, and low-boiling petroleum ether added until the solution became slightly turbid. The product that crystallized was recrystallized from ethyl acetate and petroleum ether to give 35.5 g. of pure phthalic acid ester of racemate I, m. p. 130–131° (white flat needles).

The filtrates from the crystallization and purification of the above substance were combined, evaporated to an oil, and brought to reflux for fifteen hours in a solution of 80 g. of sodium hydroxide dissolved in 400 ml. of water. The mixture was then cooled, extracted with petroleum ether, and the organic layer was separated, washed with water, dried, evaporated to an oil and distilled. This alcohol (90.0 g.) was mixed with 116 g. of 3-nitrophthalic anhydride and 120 g. of pyridine and heated to 100° for one hour. The mixture was then cooled, dissolved in benzene, and this solution was extracted with excess dilute sulfuric acid, washed with water, dried and evaporated to an oil. This oil was dissolved in two volumes of ethyl acetate and low-boiling petroleum ether added until the solution became turbid. On standing, a solid separated which, when recrystallized from ethyl acetate and petroleum ether, produced 91 g. of the 3-nitrophthalic acid ester of racemate II, m. p. 156–157° (fine white needles).

The filtrates from the above crystallizations were combined, evaporated, and hydrolyzed to the alcohol in the same manner as described above, weight 46 g. This mixture of racemates was submitted to the same cycle as described above to produce 25 g. of additional acid phthalate of racemate I (m. p. 130–131°) and 28 g. of additional 3-nitrophthalic acid ester of racemate II (m. p. 156–157°).

Resolution of the Phthalic Acid Ester of Racemate I.—A mixture of 52 g. of the acid phthalate of racemate I, 40 g. of brucine and 900 ml. of acetone was brought to boiling, filtered and allowed to cool. The needles that separated were recrystallized from acetone to give 70.5 g. of salt which was shaken with ether and excess 2 *N* sulfuric acid. The ether layer was washed with water, dried and evaporated to an oil, and this oil crystallized from ethyl acetate and petroleum ether to give 18.2 g. of white square plates of the acid phthalate of IA, m. p. 101–102°, which was depressed by admixture with a small amount of the acid phthalate of racemate I.

The filtrates from the crystallizations of the above brucine salt were combined and shaken with excess 2 *N* sulfuric acid and ether, the ether layer washed several times with water, dried and evaporated to an oil. This oil was taken up in two volumes of ethyl acetate and a slight turbidity produced by the addition of petroleum ether. The mixture was carefully seeded with the acid phthalate of racemate I and allowed to crystallize until an estimated one-third of the total amount of solid in the solution had crystallized. The mixture was filtered, 10.4 g., m. p. 128–131°. This material when submitted to the procedure recorded above produced an additional 3.8 g. (m. p. 130–131°) of the acid phthalate of IA, m. p. 101–102°.

The combined filtrates from the crystallization of racemate I were diluted with low-boiling petroleum ether, and when allowed to stand, 17.5 g. of square plates were deposited. This material was recrystallized from ethyl acetate and petroleum ether and the product collected in two crops, the first amounting to 4.2 g. (m. p. 103–106°) and the second to 11.7 g., m. p. 101–102° (square plates) of the acid phthalate of IB. An additional 3.3 g. (m. p. 101–102°) of pure acid phthalate of IB was obtained by fractional recrystallization of the other fractions of impure material.

Resolution of the 3-Nitrophthalic Acid Ester of Racemate II.—A solution of 90 g. of the 3-nitrophthalic acid ester of racemate II, 53 g. of strychnine, 300 ml. of chloroform and 100 ml. of acetone was allowed to stand overnight and the solid deposited was collected. The filtrate was shaken with a mixture of excess 2 *N* hydrochloric acid solution and ether. The ether layer was washed with water, dried, evaporated to an oil and mixed with 43 g. of cinchonidine and 300 ml. of acetone. The clear solution deposited fine white needles on standing, which were collected and recrystallized twice from acetone to give 58 g. of salt. This material was shaken with a mixture of ether and excess 2 *N* sulfuric acid, the ether layer was washed with water, dried, and evaporated to an oil, and the 3-nitrophthalic acid ester of IIB was crystallized and recrystallized from an ethyl acetate–petroleum ether mixture to give 28 g. of white needles, m. p. 144–145°, of pure 3-nitrophthalic acid ester of IIB.

The filtrates from the crystallization of the cinchonidine salt were combined with the strychnine salt and shaken with excess 2 *N* hydrochloric acid and ether, the ether layer was separated, washed with water, dried and evaporated to an oil. This oil was dissolved in 350 ml. of acetone and mixed with 43 g. of cinchonine and the resulting solution cooled. After standing for two days at 0°, the white needles that separated were collected and recrystallized twice from acetone to give 55 g. of cinchonine salt. This material was shaken with an excess of 2 *N* hydrochloric acid and ether, the ether layer was separated, washed with water, dried and evaporated to an oil which crystallized from ethyl acetate and petroleum ether. This compound (white needles) when recrystallized from ethyl acetate and petroleum ether amounted to 24.2 g., m. p. 144–145°, of pure 3-nitrophthalic acid ester of IIA.

The filtrates from the crystallization of the cinchonine salt were converted to a mixture of 3-nitrophthalic acid esters, which, when submitted to the same resolution procedure, produced 8.5 g. (m. p. 144–145°) of additional ester of IIB and 6.3 g. (m. p. 144–145°) of additional ester of IIA.

Conversion of the Phthalic Acid Esters of I, IA and IB and the 3-Nitrophthalic Acid Esters of II, IIA and IIB into the Corresponding Alcohols.—The procedure for the hydrolysis of the above esters to the corresponding alcohols is illustrated by the conversion of the acid phthalate of IA to IA. A mixture of 22 g. of this ester, 8 g. of sodium hydroxide, 8 g. of potassium hydroxide and 80 ml. of water was refluxed for sixteen hours, cooled and extracted twice with low boiling petroleum ether. The extracts were combined, washed once with water, dried, evaporated to an oil, and the oil distilled to produce 10.3 g. of IA, b. p. 118° (25 mm.).

Conversion of I, IA and IB to the Corresponding 3-Nitrophthalic Acid Esters and the Conversion of II, IIA and IIB to the Corresponding Phthalic Acid Esters.—The procedures for the above introconversions is illustrated by the preparation of the 3-nitrophthalic acid ester of IA. A mixture of 2.2 g. of IA, 2.83 g. of 3-nitrophthalic anhydride and 5 ml. of pyridine was heated to 100° for one hour, cooled and shaken with a mixture of ether and excess 2 *N* sulfuric acid. The ether layer was washed with water, dried and evaporated to an oil. This material was crystallized from one volume of ethyl acetate and two volumes of low-boiling petroleum and the product recrystallized from the same solvents to give 4.3 g. of fine white needles, m. p. 150–151°.

Preparation of the *p*-Toluenesulfonates of IA and IIA.—The procedure for the above preparations is illustrated by the conversion of IA to the *p*-toluenesulfonate of IA. A mixture of 10.3 g. of IA, 12.8 g. of pure *p*-toluenesulfonyl chloride and 20 ml. of pure pyridine was allowed to stand at room temperature for twenty-four hours. The mixture was then shaken with a cold mixture of excess 2 *N* sulfuric acid, ether and petroleum ether. The organic layer was separated, washed with water, with a dilute alkaline solution, and again with water. The solution was then dried, evaporated to an oil under reduced pressure and crystallized and recrystallized from a mixture of one volume of benzene and five volumes of low boiling petroleum ether to give 17.5 g. of white needles, m. p. 62–63°.

Acetolysis of the *p*-Toluenesulfonate of IA.—The *p*-toluenesulfonate of IA (5.0 g.) was dissolved in 100 ml. of a mixture of 1 ml. of acetic anhydride, 100 ml. of dry glacial acetic acid and 1.96 g. of freshly fused potassium acetate. The resulting solution was held at 70° for thirty hours, cooled, and shaken with a mixture of 300 ml. of low boiling petroleum ether and one liter of water. The layers were separated, the organic layer washed with water, with a dilute alkaline solution, again with water, and dried, evaporated to an oil and the oil distilled; weight 2.70 g., observed rotation on the liquid ($l = 1$, $\lambda = D$), $-0.22°$. This distillate was added dropwise to a solution of 3 g. of lithium aluminum hydride in ether, the excess reagent was decomposed with ethanol and the mixture shaken with a mixture of petroleum ether and dilute sulfuric acid. The organic layer was washed with water, dried, evaporated to

an oil and the oil distilled, weight 2.05 g., observed rotation on the liquid ($l = 1$, $\lambda = D$), +0.21°. This liquid was mixed with 2.05 g. of phthalic anhydride and 3 g. of pyridine and heated to 100° for one hour, cooled, and shaken with a mixture of benzene and excess 2 *N* sulfuric acid. The benzene layer was washed with water, dried, evaporated to an oil, and this oil distilled at 130° at 20 mm. of pressure. The olefin that distilled amounted to 0.55 g. The residue was crystallized from ethyl acetate and low boiling petroleum ether and the product recrystallized from the same solvents to give 2.10 g. of the acid phthalate of racemate I, m. p. 130–131°, not depressed by admixture with an authentic sample of racemate I acid phthalate, $[\alpha]^{25}D$ 0° ($c = 3.12$) in absolute ethanol. The filtrates were combined and evaporated to give 0.11 g. of residue.

Acetolysis of the *p*-Toluenesulfonate of IIA.—This reaction was carried out in exactly the same manner as described above for the acetolysis of the *p*-toluenesulfonate of IA. From 2.9 g. of the *p*-toluenesulfonate of IIA was obtained 1.67 g. of a mixture of acetate and olefin, observed rotation ($l = 1$, $\lambda = D$), −26.5°. Reduction with lithium aluminum hydride produced 1.26 g. of a mixture of alcohol and olefin, observed rotation ($l = 1$, $\lambda = D$), +0.85°. Treatment of this liquid with phthalic anhydride gave a mixture from which was isolated 0.12 g. of olefin and 1.33 g. of the acid phthalate of IIA, m. p. 101–102°, m. m. p. with an authentic sample, 101–102°, $[\alpha]^{25}D$ −64.0°. The filtrates from the crystallizations were combined, evaporated and fractionated on a small column of acid-washed alumina. The material was absorbed from a benzene solution, and the column was developed with a 30% acetone–70% benzene mixture. From the 1st fraction coming through the column was isolated 0.4 g. more of the acid phthalate of IIA, m. p. 101–102°, m. m. p. with an authentic sample, 101–102°. No crystalline compounds were obtained from the other fractions. The column was flushed with methanol and all residues combined to give 0.11 g. of unidentified material.

Inversion of the *p*-Toluenesulfonate of IA with Acetate Ion to Produce the Acetate of IIA.—A mixture of 1.0 g. of the *p*-toluenesulfonate of IA, 5 ml. of absolute ethanol and 0.70 g. of freshly fused potassium acetate was heated to reflux for twenty-four hours. The material was then cooled and shaken with a mixture of water and petroleum ether, the layers separated and the organic layer was washed twice with water, dried, evaporated to an oil and distilled; 0.42 g. This oil was added dropwise to a solution of 0.5 g. of lithium aluminum hydride dissolved in dry ether, and at the end of the addition the excess hydride was decomposed with ethanol. The resulting mixture was shaken with petroleum ether and dilute sulfuric acid, the organic layer was washed with water, dried, evaporated to an oil and distilled; 0.35 g. This mixture of alcohol and ether was heated at 100° with 0.35 g. of phthalic anhydride and 1 ml. of pyridine. This resulting mixture was cooled, shaken with benzene and excess 2 *N* sulfuric acid, and the organic layer was washed with water, dried and evaporated. The resulting oil was distilled at 1 mm. and 130°, the ether distilling first and the excess phthalic anhydride coming over last. The residue was crystallized from ethyl acetate and low-boiling petroleum ether, and two recrystallizations of the product from the same solvents produced 120 mg. of the acid phthalate of IIA, m. p. 100–101°, m. p. with an authentic sample, 101–102°. This melting point was depressed 25° by the acid phthalates of either IA or IB. Crystallization of the above product with an equal amount of the acid phthalate of IIB produced the acid phthalate of racemic II, m. p. 83–84°, not depressed by admixture with an authentic sample.

Acknowledgments.—It is a pleasure to express appreciation to Drs. S. Winstein, T. A. Geissman and G. Hammond for their many important and helpful suggestions regarding the work presented in this paper. The author is indebted to Mr. Welton Burney for the analytical data.

Summary

1. The compound 3-phenyl-2-butanol has been completely resolved into its four optically pure stereoisomers, IA, IB, IIA and IIB, and a series of derivatives of the isomers prepared.

2. When the *p*-toluenesulfonate of IA was submitted to acetolysis, the acetate of racemic I was obtained whereas when the *p*-toluenesulfonate of IIA was submitted to acetolysis, the acetate of IIA was obtained. These results are interpreted as evidence for an intermediate cyclic carbonium ion in a Wagner–Meerwein rearrangement, this ion being symmetrical in the I series and asymmetrical in the II series. The carbon atom bearing the bond to oxygen is inverted when the cycle is formed and another inversion takes place on the carbon atom whose bond is broken when the cycle is opened.

3. These reactions provide a unique proof of stereochemical structure with respect to the configuration of racemate I and racemate II.

4. The configuration of IA has been related to IIA by the simple inversion by acetate ion of the carbon atom bearing the oxygen in the *p*-toluenesulfonate of IA.

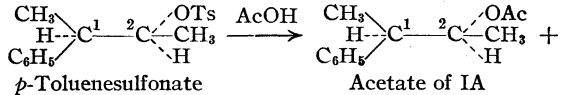
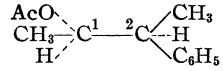
Studies in Stereochemistry. II. The Preparation and Complete Resolution of 3-Phenyl-2-pentanol and 2-Phenyl-3-pentanol

BY DONALD J. CRAM AND ROBERT DAVIS[1]

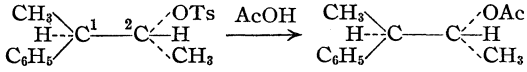
The first paper of this series reported the stereospecific Wagner–Meerwein rearrangement of the *p*-toluenesulfonates of the stereoisomers of 3-phenyl-2-butanol during acetolysis. Good evidence was provided that the *p*-toluenesulfonate of IA rearranged to I acetate; however, since the *p*-toluenesulfonate of IIA gave the acetate of IIA, there was no concrete proof of any disturbance of the carbon chain even though rearrangement was very probable.



p-Toluenesulfonate of IA — Acetate of IA

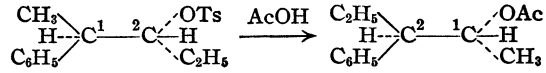


Acetate of IB



p-Toluenesulfonate of IIA — Acetate of IIA

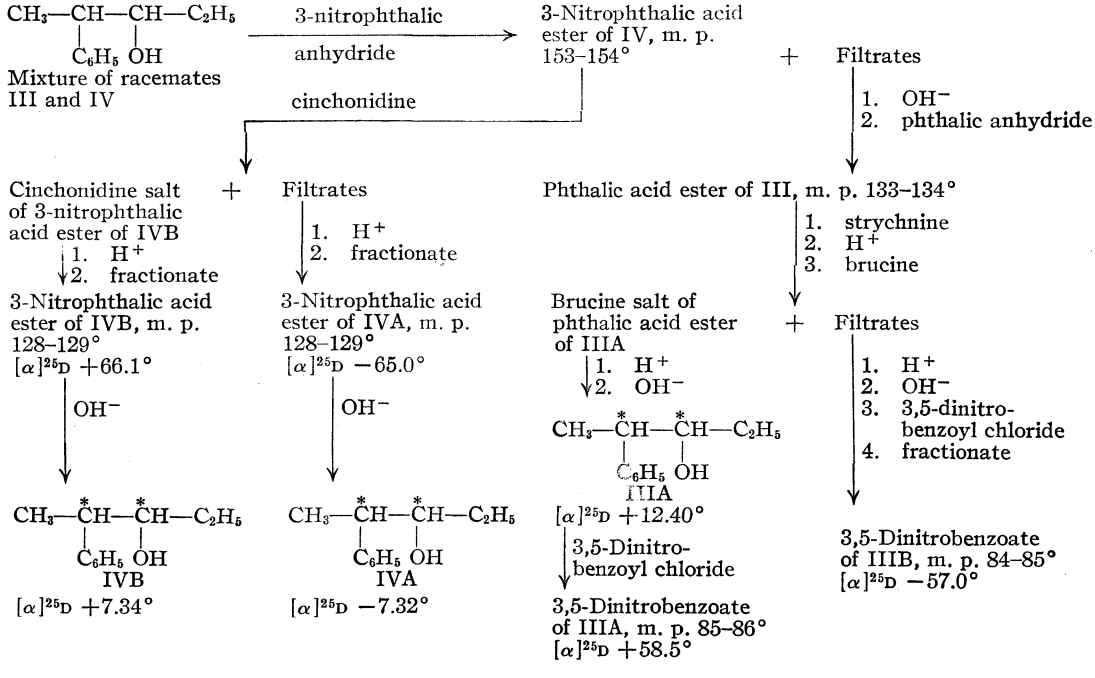
In the similar treatment of the *p*-toluenesulfonate of the isomer of 2-phenyl-3-pentanol that is sterically analogous to IIA, if rearrangement occurs, the relative positions of the methyl and ethyl groups in the product will be reversed, and the substance will be a derivative of 3-phenyl-2-pentanol. This system should also provide additional facts concerning the postulated existence of a cyclic intermediate carbonium ion.



This paper deals with the preparation and resolution of 2-phenyl-3-pentanol and 3-phenyl-2-pentanol into the eight stereoisomers of these two structural isomers, and with a correlation of the probable configuration of these isomers with their physical properties and modes of resolution. Paper III in this series will report the results of the rearrangement studies to which these isomers were submitted.

Results

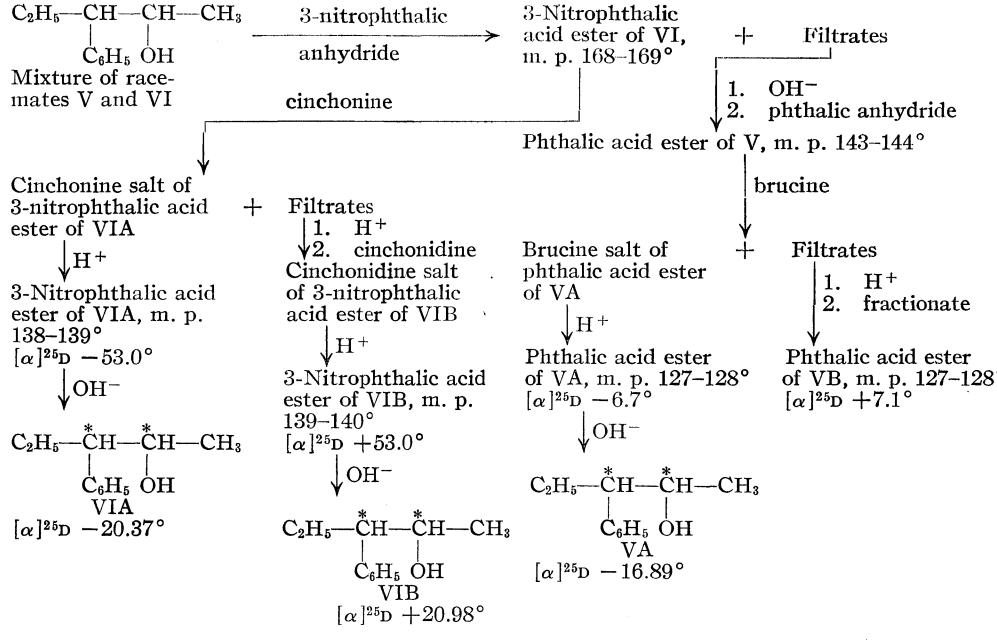
A mixture of the two racemates of 2-phenyl-3-pentanol was prepared by the treatment of 2-phenylpropionaldehyde[2] with ethylmagnesium bromide. The method used for the resolution is outlined below.



(1) Present address: Medical School, University of California, Los Angeles 24, California.

(2) This compound was prepared by the method that Dutta [*J. Indian Chem. Soc.*, **18**, 233 (1941)] used for the preparation of 2-*p*-tolylpropionaldehyde. Claisen [*Ber.*, **38**, 705 (1905)] prepared 2-phenylpropionaldehyde previously by a different method.

The compound 2-phenylbutyraldehyde[3] was prepared by a method analogous to that used for the preparation of 2-phenylpropionaldehyde.[2] The former substance was treated with methylmagnesium bromide to give a mixture of the two racemates of 3-phenyl-2-pentanol. Resolution of this mixture was affected by the following method.



The magnitude of the rotations and the melting points of the enantiomorphically related substances in the two series are in agreement, which indicates that optical purity was obtained in each case. The acid phthalates of IIIA and IIIB were never obtained in a crystalline condition, and therefore the 3,5-dinitrobenzoate derivative was prepared for identification purposes.

Table I records the physical properties and the yields of the above compounds.

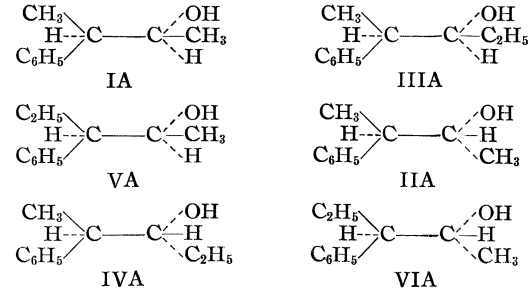
Discussion

The analogy between the methods used for the resolution of 3-phenyl-2-butanol[4] and the resolutions of 2-phenyl-3-pentanol and 3-phenyl-2-pentanol is so clear cut as to provide a clue to the relative configuration of the isomers of the two latter compounds. In all three cases the two racemates were split through the preparation of the acid phthalate and 3-nitrophthalic acid ester derivatives. In each case the latter derivative was obtained in greater quantity. The racemic mixtures of the acid phthalates of I, III and V were each resolved through the brucine salt, giving in each case a crystalline salt of only one of the enantiomorphs. The racemic mixtures of the 3-nitrophthalic acid esters of II, IV and VI were each resolved through the cinchonidine salts, and in each case one of the enantiomorphic pair formed a crystalline cinchonidine salt, and in two of the three cases the other member of the enantiomorphic pair formed a crystalline cinchonine salt.[5]

A comparison of the melting points of the derivatives of the above alcohols also points to analogous configurational relationships along the lines suggested above. Thus the acid phthalates of racemates I, III and V melt at 130–131°, 133–134°, 143–144°, and the 3-nitrophthalic acid esters of racemates II, IV and VI melt at 156–157°, 153–154° and 168–169°, respectively.

Finally, comparisons of the specific rotations of the stereoisomers themselves strengthen the analogy. Thus the specific rotation of IA is more positive than that of IIA, IIIA more positive than IVA, and VA is more positive than VIA.

The above argument provides a basis for the following assignments of relative configurations for the stereoisomers of 3-phenyl-2-butanol, 2-phenyl-3-pentanol and 3-phenyl-2-pentanol. Since



(3) This substance has been reported by Stoermer, *Ber.*, **39**, 2300 (1906).

(4) See paper I in this series.

(5) Attempts to form crystalline brucine salts of the acid phthalates of IB, IIIB and VB failed; attempts to form crystalline cinchonine salts of the 3-nitrophthalic acid esters of IIB and VIB failed; attempts to form crystalline cinchonidine salts of IIA and VIA failed. Crystalline cinchonine salts of IVA and IVB and crystalline cinchonidine salts of IVA and IVB were obtained.

the structures of IA and IIA were determined in the first paper of this series, the following assignments can be made. The respective enantiomorphic relationships of the above compounds to IB, IIB, IIIB, IVB, VB and VIB determines the structures of the B series.[6]

The above configurational assignments are consistent with further evidence that is presented in papers III and IV in this series.

Experimental

Preparation and Separation of the Racemates of 2-Phenyl-3-pentanol.—A mixture of 126 g. of 2-phenylpropionaldehyde[7] and 500 ml. of dry ether was added over a period of an hour to a cooled stirred solution of ethylmagnesium bromide (made from 24.1 g. of magnesium and 110 g. of ethyl bromide) dissolved in 1000 ml. of dry ether. After warming the mixture for one hour, the flask was cooled and the product decomposed by pouring into a mixture of ice and excess 2 *N* sulfuric acid. The two layers that resulted were separated, the organic layer washed with water, dried, and the product distilled to give 130 g. of alcohol, b. p. 123–125° at 18 mm. pressure.

A mixture of this alcohol (130 g.), 155 g. of 3-nitrophthalic anhydride and 150 g. of pyridine was heated at 100° for one hour, cooled and shaken with a mixture of excess of 2 *N* sulfuric acid and benzene. The layers were separated and the organic layer was washed with water, dried, evaporated to an oil, and this oil was crystallized from a mixture of three volumes of ethyl acetate and enough low-boiling petroleum ether to make the solution turbid. The crystalline product that separated was recrystallized from ethyl acetate and petroleum ether to give 68 g. of 3-nitrophthalic acid ester of racemate IV, m. p. 153–154° (fine needles).

The combined filtrates were evaporated and hydrolyzed by heating at reflux with a solution of 102 g. of potassium hydroxide in 500 ml. of water for fifteen hours. At the end of this time the mixture was cooled, extracted with petroleum ether, and the organic layer was washed with water, dried, evaporated and the resulting oil distilled, 75 g.

This alcohol (70 g.) was heated at 100° with a mixture of 64 g. of phthalic anhydride and 75 g. of pyridine for one hour. This mixture was then cooled, shaken with a mixture of excess 2 *N* sulfuric acid and benzene, the layers separated and the organic layer washed with water, dried, and evaporated to an oil. This oil was crystallized from two volumes of ethyl acetate and enough petroleum ether to make the solution slightly turbid. The solid that deposited was recrystallized from ethyl acetate and petroleum ether to give 24.7 g. of the acid phthalate of racemate III, m. p. 133–134° (wedge-shaped needles).

The filtrates from the above crystallizations were combined and put through the same cycle as that described above to give 33 g. of additional 3-nitrophthalic acid ester of racemate II, m. p. 153–154°, and 10.5 g. of additional

(6) This type of nomenclature has been adopted until the configuration of one of the two asymmetric carbon atoms of one of these isomers has been related to *d*-glyceraldehyde.

(7) This aldehyde[2] was prepared by the same procedure described further on for the preparation of 2-phenylbutyraldehyde.

phthalic acid ester of racemate I, m. p. 133–134°. A total of 19 g. of unresolved 2-phenyl-3-pentanol was recovered from these operations.

Preparation of 2-Phenylbutyraldehyde.[2]—A mixture of 87.2 g. of sodium and 872 ml. of absolute ethanol was refluxed until the sodium disappeared. The solution was cooled and 872 ml. of dry low-boiling petroleum ether was added and the mixture cooled in an ice-bath. To this mixture was added a cooled solution of 410 g. of ethyl chloroacetate and 448 g. of propiophenone, the resulting mixture was stirred to break up all the lumps and then allowed to stand for twenty hours in an ice-bath. At the end of this time the dark solution was brought to reflux and the petroleum ether allowed to gradually escape through the partial condenser over a period of eight hours (this material was collected through the use of a second condenser). The contents of the flask were diluted with sufficient water, ice and ethyl ether to produce two layers which were separated; the water layer was extracted with ether and discarded. The two organic solutions were combined, washed five times with a 1 *N* sodium hydroxide solution, three times with water, dried, and evaporated to an oil which was distilled under reduced pressure. The first fraction, 203.6 g., distilled at about 90° (8 mm.), and the product (a glycidic ester) was collected at 127–133° (5 mm.), weight 314.5 g.

This material was added to a solution of 34.4 g. of sodium which had been decomposed in 560 ml. of 95% ethanol. The mixture formed a red homogeneous solution which was allowed to stand about twenty hours. A white solid formed at first but dissolved when more water was added. This solution was acidified with 330 ml. of 6 *N* hydrochloric acid at a temperature below 10°, and the oil that separated was extracted with ether. The extract was dried, the ether evaporated, and the resulting oil was added to a mixture of 1300 ml. of 6 *N* sulfuric acid and 1300 g. of ice. After standing overnight the mixture was steam distilled until about 2 l. of distillate was obtained. The oily aldehyde was extracted with ether, the resulting solution was washed twice with 3 *N* sodium carbonate solution and twice with water, dried, evaporated to an oil which was distilled to give 165.5 g. of 2-phenylbutyraldehyde, b. p. 97–99° (15 mm.).

Preparation and Separation of the Racemates of 3-Phenyl-2-pentanol.—To a Grignard solution prepared from 30 g. of magnesium, 177 g. of methyl iodide and 500 ml. of ether was added slowly 165.5 g. of 2-phenylbutyraldehyde. The mixture was then refluxed for an hour, cooled, and decomposed on a mixture of ice and excess 2 *N* sulfuric acid. The oil that separated was extracted with ether, the extract was washed with water, dried and evaporated to an oil and distilled to give 142 g. of 3-phenyl-2-pentanol, b. p. 128–131° (30 mm.).

A mixture of 142 g. of this carbinol, 168 g. of 3-nitrophthalic anhydride and 190 g. of dry pyridine was warmed to 100° for one hour, cooled and shaken in a mixture of benzene and excess 2 *N* sulfuric acid. The organic layer was washed first with 2 *N* sulfuric acid, then with water, dried and the benzene was evaporated. The oil crystallized from a mixture of ethyl acetate and petroleum ether and recrystallization of the product from the same solvents gave 96 g. of fine white needles (m. p. 167–168°) of the 3-nitrophthalic acid ester of VI.

The filtrates were combined, the solvent evaporated and the oil held at reflux for twelve hours in a mixture of 40 g. of sodium hydroxide, 40 g. of potassium hydroxide and 400 ml. of water. The resulting mixture was cooled, extracted with petroleum ether and the extract was washed with water, dried, evaporated and the oil distilled to give 70 g. of alcohol. This material was heated to 100° for one hour with 63 g. of phthalic anhydride and 85 ml. of pyridine, cooled, and shaken with a mixture of benzene and excess *N* sulfuric acid. The organic layer was washed, first with 2 *N* sulfuric acid, then with water, the solution was dried, evaporated and the oil crystallized from ethyl acetate and petroleum ether. Recrystallization of the product from the same solvents produced 39 g. of the phthalic acid ester of V, m. p. 143–144° (heavy prisms).

A second cycle similar to that described above produced 33 additional grams of 3-nitrophthalic acid ester of VI, m. p. 167–168°, and 9 additional grams of the phthalic acid ester of V, m. p. 143–144°. A total of 12.5 g. of unresolved alcohol was recovered.

Resolution of the Phthalic Acid Ester of III.—A solution of 13.5 g. of the racemic ester and 10 g. of strychnine in 100 ml. of acetone was brought to boiling and slowly cooled. The solid that separated was collected and shaken with a mixture of ether and excess 2 *N* hydrochloric acid. The organic layer was washed with water, dried, evaporated and the resulting oil was mixed with 7 g. of brucine and 50 ml. of acetone. The material that separated was collected and recrystallized from acetone to give 7.0 g. of salt. The combined filtrates from all the above crystallizations were concentrated and shaken with ether and 2 *N* hydrochloric acid. The organic layer was washed with water, dried, evaporated and crystallized from ethyl acetate and petroleum ether to give 5 g. of racemic starting material. This material was put through the same cycle of operations and an additional 4 g. of recrystallized brucine salt obtained. The combined 11 g. of brucine salt was shaken with excess 2 *N* sulfuric acid and ether, the organic layer washed with water, dried and evaporated to an oil. This oil (4.5 g.) could not be crystallized and was hydrolyzed directly to IIIA by heating at reflux for twelve hours with 3.5 g. of sodium hydroxide and 20 ml. of water. The resulting oil was extracted with petroleum ether, the organic layer was washed with water, dried, evaporated and distilled to give 2.27 g. of IIIA, b. p. 125° (23 mm.).

A small sample of this alcohol was converted to the 3,5-dinitrobenzoate in the usual manner, m. p. 85–86° (needles from ether and petroleum ether).

The combined filtrates from the crystallizations of the brucine salt were concentrated and converted to the acid phthalate of impure IIIB. Crystallization of this oil from ethyl acetate and petroleum ether produced 2.0 g. of the acid phthalate of racemic III. The filtrate from this crystallization was hydrolyzed in the usual manner and the alcohol converted to the 3,5-dinitrobenzoate. Five crystallizations of this material from an ether–petroleum ether mixture produced 400 mg. of the 3,5-dinitrobenzoate of IIIB, m. p. 84–85° (needles from an ether–petroleum ether mixture).

Resolution of the 3-Nitrophthalic Acid Ester of IV.—A mixture of 50 g. of the 3-nitrophthalic acid ester of IV, 41 g. of cinchonidine and 400 ml. of 95% ethanol was heated to reflux temperature and slowly cooled. The material that separated was recrystallized twice from 95% ethanol to give 18 g. of salt which was converted to the 3-nitrophthalic acid ester of IVB by the usual method; weight 8.5 g., m. p. 128–129°, rosettes from ethyl acetate and petroleum ether.[8]

The combined filtrates were concentrated and converted to the 3-nitrophthalic acid ester which crystallized slowly from ethyl acetate and petroleum ether when seeded with racemic 3-nitrophthalic acid ester of IV. A first crop was harvested when about half of the material had crystallized, weight 26 g. (racemic material). This substance was put through the same resolution cycle and an additional 7.5 g. of 3-nitrophthalic acid ester of IVB was obtained, m. p. 128–129°.

The combined filtrates were concentrated and converted to the acid ester and this material was submitted to fractional crystallization (four cycles) from ethyl acetate and petroleum ether, in each case the derivative of IVA crystallizing last. A total of 7.2 g. of the 3-nitrophthalic acid ester of IVA was obtained, m. p. 128–129° (rosettes)[8] from ethyl acetate and petroleum ether.

Resolution of the Phthalic Acid Ester of V.—A mixture of 30 g. of the phthalic acid ester of V, 25 g. of brucine and 200 ml. of acetone was brought to boiling and cooled slowly. The plates that separated were collected and recrystallized from acetone and the 23 g. obtained was con-

(8) This substance crystallizes in two different forms, needles, which if heated rapidly partially melt at 117°, resolidify and melt at 128–129°, and rosettes, m. p. 128–129°.

verted to the phthalic acid ester of VA; weight 9.2 g., m. p. 127–128° (flakes from ethyl acetate and petroleum ether). The filtrates were combined, concentrated and converted to the acid ester which was allowed to crystallize from ethyl acetate and petroleum ether until about half of the material had appeared. This substance was collected (weight 5 g.) and submitted to the resolution procedure described above to give 1.5 additional grams of acid phthalate of VA.

The combined filtrates were concentrated and converted to the free acid ester which was submitted to a four-cycle fractional crystallization procedure with ethyl acetate and petroleum ether as solvent. In each case the material that first crystallized was rich in racemate. A total of 4.5 g. of the phthalic acid ester of VB was obtained, m. p. 127–128° (flakes).

Resolution of the 3-Nitrophthalic Acid Ester of VI.—A mixture of 100 g. of the 3-nitrophthalic acid ester of VI, 65 g. of cinchonine and 500 ml. of acetone was heated to the boiling point and slowly cooled. The needles that separated were collected and twice recrystallized from a mixture of chloroform and acetone. The salt (55 g.) was converted to the 3-nitrophthalic acid ester of VIA; weight 30 g., m. p. 138–139° (needles from ethyl ether and petroleum ether).

The filtrates were combined, concentrated and converted to the acid ester which was mixed with 50 g. of cinchonidine and 300 ml. of acetone. The needles that separated were recrystallized twice from acetone to give 25 g. of salt which was converted to 13 g. of white needles (from ether and petroleum ether) of the 3-nitrophthalic acid ester of VIB, m. p. 139–140°.

The filtrates were combined, concentrated and converted to the acid ester which was subjected to the resolution procedure described above to produce 9 additional grams of the 3-nitrophthalic acid ester of VIA (m. p. 139–140°) and 13 additional grams of the 3-nitrophthalic acid ester of VIB, m. p. 139–140°.

Hydrolysis of the Phthalic Acid Esters of III, V and VA to III, V and VA, Respectively, and the 3-Nitrophthalic Acid Esters of IV, VI, IVA, IVB, VIA, and VIB to IV, VI, IVA, IVB, VIA and VIB, Respectively.—The procedure used for the above introconversions is illustrated by the hydrolysis of the 3-nitrophthalic acid ester of VIA to VIA alcohol. A mixture of 36 g. of the ester, 10 g. of potassium hydroxide, 10 g. of sodium hydroxide and 100 ml. of water was heated at reflux for twelve hours. The mixture was then cooled, extracted twice with petroleum ether, the extracts combined and washed with water, dried and evaporated to an oil. This oil was distilled to give 15.6 g. of VIA, b. p. 121° (17 mm.).

Acknowledgment.—The author wishes to express his thanks to Welton Burney, who performed the analysis of the compounds reported in this paper.

Summary

1. The compounds 2-phenyl-3-pentanol and 3-phenyl-2-pentanol have been prepared and completely resolved into the eight optically pure stereoisomers.

2. Tentative stereochemical structures have been assigned to each isomer.

Studies in Stereochemistry. III. The Wagner–Meerwein Rearrangement in the 2-Phenyl-3-pentanol and 3-Phenyl-2-pentanol Systems[1]

BY DONALD J. CRAM

Paper II[2] of this series reported the primary resolutions of 2-phenyl-3-pentanol into racemates III[3] and IV followed by the secondary resolution of each of these racemates into IIIA, IIIB and IVA and IVB, respectively. The structural isomer, 3-phenyl-2-pentanol, was also resolved to give racemates V and VI, and subsequently VA, VB and VIA and VIB, respectively. Tentative assignments of configuration for each of these isomers were suggested. This paper reports the results of an investigation of the acetolyses of the *p*-toluenesulfonates of III, IV, V, VI, IIIA, IVA, VA and VIA.

Results

Table I records the physical properties, analyses and yields of the *p*-toluenesulfonates of III, IV, V, VI, IIIA, IVA, IVB, VA, VIA and VIB. In each case the acetolysis of these substances was conducted at 70° and for thirty hours in anhydrous glacial acetic acid containing enough potassium acetate to neutralize the *p*-toluenesulfonic acid as it formed. The mixtures of acetate products were hydrolyzed to the corresponding mix-

[a] All of the compounds except VI crystallized as needles from low-boiling petroleum ether. [b] This compound was never obtained in a crystalline state. Purification was accomplished through repeated precipitation of the substance from low-boiling petroleum ether at Dry Ice temperature followed by high vacuum drying of the oil at room temperature.

[e] A mixed melting point determination of this substance with the 3-nitrophthalic acid ester obtained from the acetolysis of the *p*-toluenesulfonate of VI produced no depression.

tures of alcohols which were converted to mixtures of solid derivatives.

Table II records the yields and compositions of the products of the acetolysis experiments performed on the racemic *p*-toluenesulfonates of III, V, IV and VI. The products were identified in the first two experiments (III and V) by conversion to the phthalic acid ester mixtures, which melted at 129–131° and 128–130°, respectively (mixed melting point, 128–130°). Figure 1 records the plot of composition against melting point of known mixtures of phthalic acid esters of III and V, and mixed melting point determinations of the unknown and known mixtures served to identify the unknown mixture from both a qualitative and quantitative point of view.

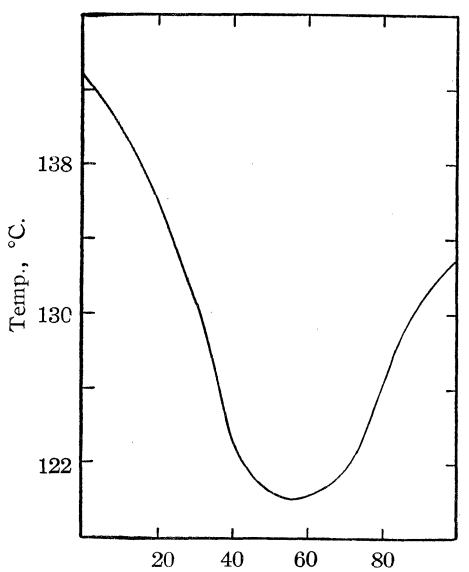

Fig. 1.—Melting point–composition diagram of the acid phthalates of III and V.

The products of the acetolysis experiments performed on the racemic *p*-toluenesulfonates of IV and VI were converted to mixtures of 3-nitrophthalic acid esters which melted at 147–149° and 148–150°, respectively (mixed melting point, 148–150°). Figure 2 records the plot of composition against melting point of known mixtures of the 3-nitrophthalic acid esters of IV and VI, and mixed melting point determinations of the unknown mixtures served to identify both quantitatively and qualitatively the compositions of the unknowns.

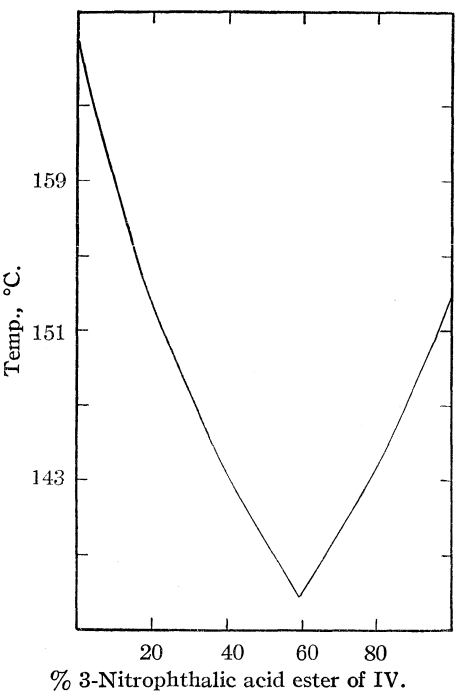

Fig. 2.—Melting point–composition diagram of the 3-nitrophthalic acid esters of IV and VI.

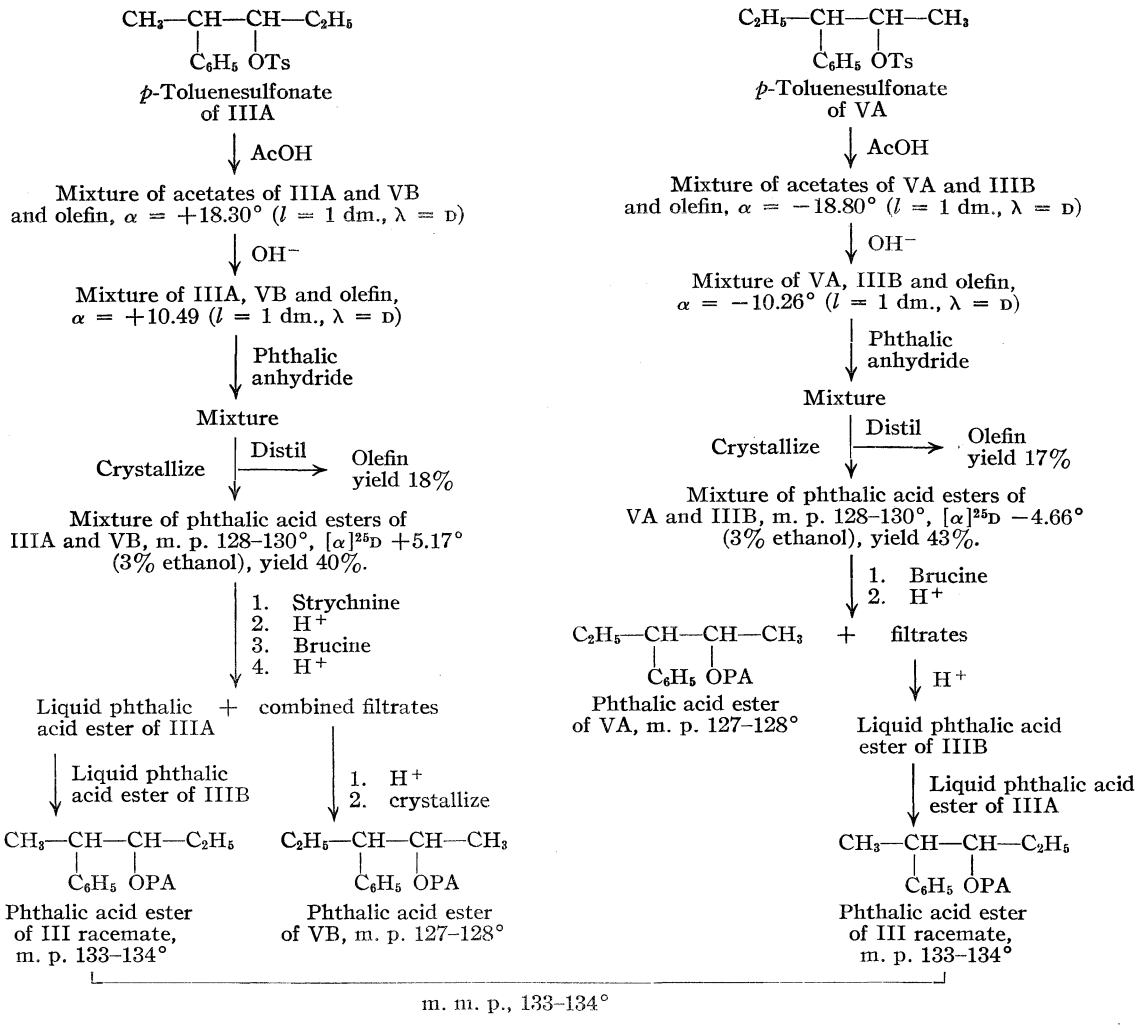
The methods employed for the determination of the products of the acetolysis experiments performed on the *p*-toluenesulfonates of IIIA and VA are outlined below. Special isolation procedures had to be used to demonstrate the qualitative composition of the products of each reaction, because the phthalic acid esters of IIIA and IIIB are liquids and hence a melting point–composition plot of mixtures of this derivative of IIIA and VB on the one hand and VA and IIIB on the other was impossible.



The procedure used for the determination of the compositions of the products of the acetolysis experiments performed on the *p*-toluenesulfonates of IVA and VIA is outlined in the following scheme. Figure 3 plots the variation of melting point with composition of mixtures of the 3-nitrophthalic acid esters of IVA and VIA. The qualitative and quantitative determinations of the compositions of the unknown mixtures were made through the use of mixed melting point determinations between the known and unknown mixtures.

For purposes of relating the configurations of VIA to VA, the *p*-toluenesulfonate of VIA was subjected to the action of potassium acetate[4] dissolved in absolute ethyl alcohol. The product (mixture of acetate and ether) was hydrolyzed and converted to the phthalic acid ester which proved to be the ester of VA.

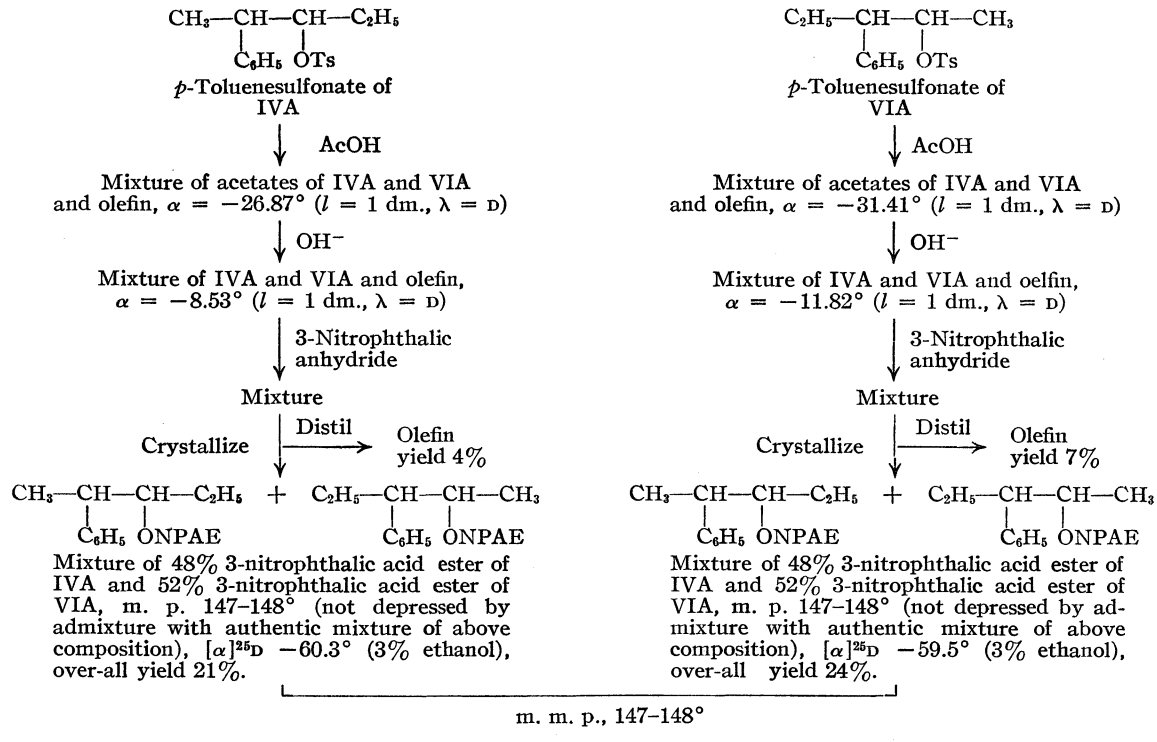
Discussion

The above results clearly indicate that a partial rearrangement of the carbon skeleton has taken place during the acetolysis of the *p*-toluenesulfonates of the isomers of 2-phenyl-3-pentanol and 3-phenyl-2-pentanol (p. 3879).

This rearrangement appears to be stereospecific, at least as far as the main products of the reaction are concerned. The material that did not rearrange underwent a displacement reaction with complete retention of configuration. Thus in each case a mixture of rearranged and unrearranged acetate was obtained. These results are in complete agreement with what would be predicted from the interpretation given to the behavior of the analogous 3-phenyl-2-butanol system reported in paper I of this series.[5] The fact that rearrangement was found in both racemate series of the 2-phenyl-3-pentanol and 3-phenyl-2-pentanol systems provides strong evidence that rearrangement also took place in *both* racemate series of the 3-phenyl-2-butanol system. The *p*-toluenesulfonate of IIA must then have given acetate of IIA by two routes, one involving rearrangement, and the other not, even though there is no way of distin-

(4) This reaction results in simple inversion of the carbon atom bearing the oxygen and is analogous to the reaction reported in paper I (THIS JOURNAL, **71**, 3863 (1949)) of this series in which the *p*-toluenesulfonate of IA was converted to the acetate of IIA.

(5) Cram, THIS JOURNAL, **71**, 3863 (1949).



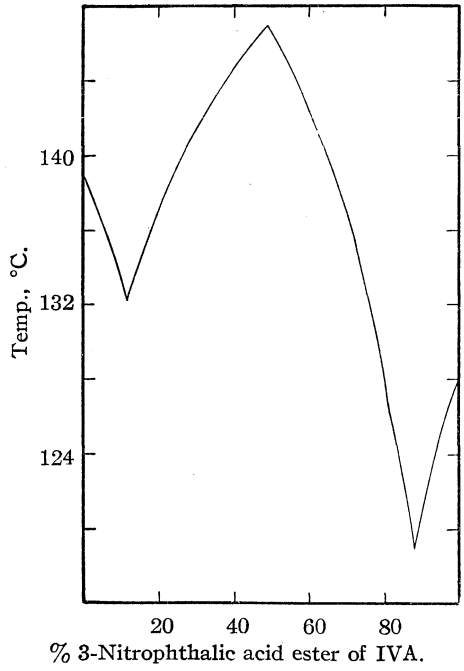


Fig. 3.—Melting point–composition diagram of the 3-nitrophthalic acid esters of IVA and VIA.

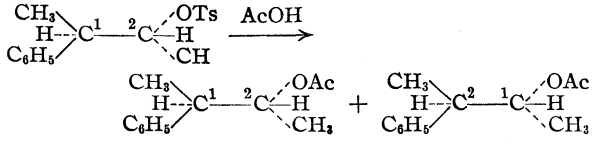
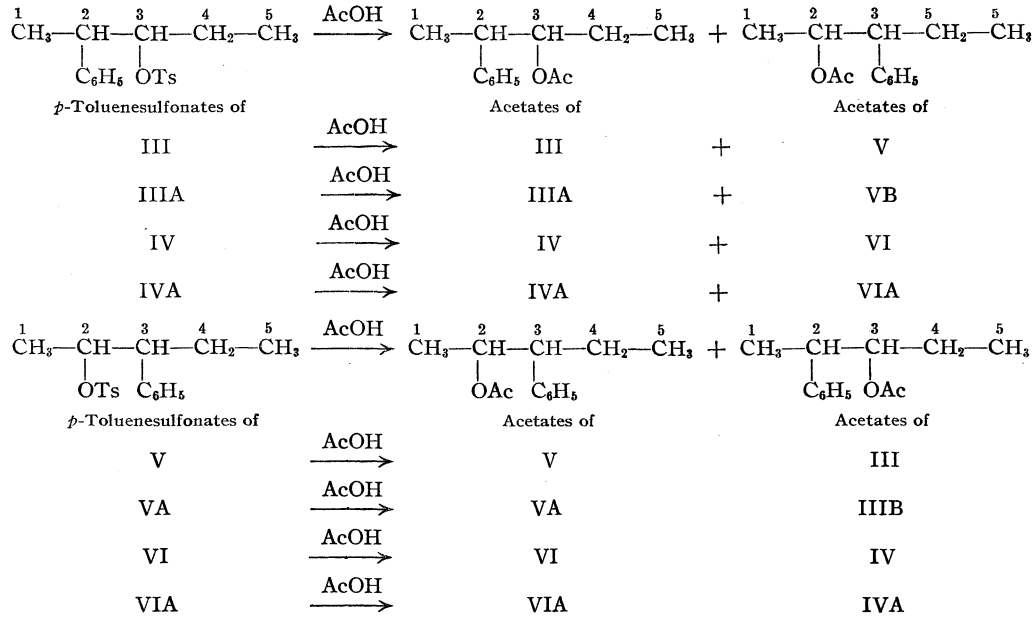
guishing between the products coming from the two paths.



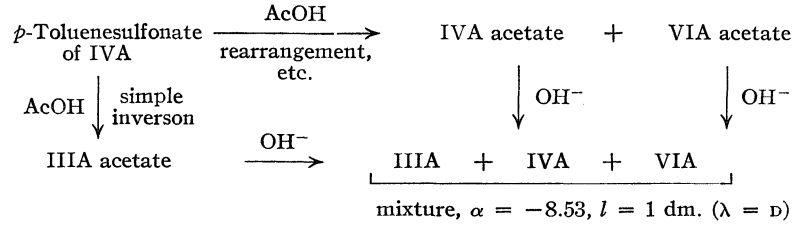
From an experimental point of view, the 3-phenyl-2-pentanol and 2-phenyl-3-pentanol systems are much more difficult to study because the products of the reactions are mixtures of two structural isomers whose properties are very similar. As a result, the products were identified as mixtures of solid derivatives, and in only two cases were the two components separated. This method of analysis served well for a qualitative determination of the isomeric products, but is indicative in only a crude way of the relative amounts of each isomer produced in the reaction. Thus from the acetolysis of the *p*-toluenesulfonates of racemates III, IV, V and VI was ultimately obtained in each case approximately a seven to three ratio of 3-phenyl-2-pentanol derivative to 2-phenyl-3-pentanol derivative. When IVA and VIA esters were employed, however, the ratio was about one to one. This discrepancy is probably due to the interesting fact that the 3-nitrophthalic acid esters of IVA and VIA form a molecular compound in a one to one ratio (see Fig. 3), and that this molecular compound is more insoluble in the crystallization solvent than the VIA component (the melting point of the molecular compound is higher than either pure component). Hence the molecular compound crystallized preferentially.

The good agreement between the relative amounts of each isomer produced (see Table II) from the reactions of the III, V, IV, and VI esters, however, was probably not fortuitous, and can safely be interpreted as meaning that the 3-phenyl-2-pentanol isomer was produced in somewhat larger quantities than was the 2-phenyl-3-pentanol isomer, regardless of which series the starting mate-

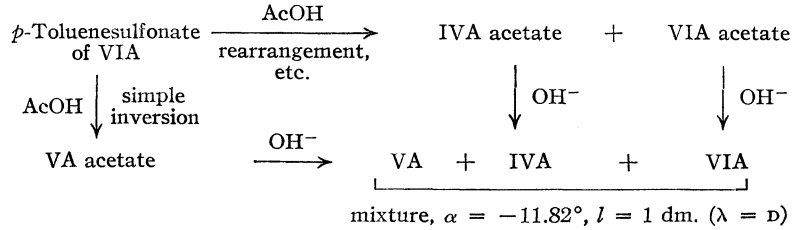


rial belonged to. The striking fact about the data is that the *p*-toluenesulfonates of the structural isomers, III and V, produced the same products in the same ratios, and that the *p*-toluenesulfonates of the structural isomers IV and VI gave analogous results. When the optically active *p*-toluenesulfonates of IIIA and VA were used, the rotations of the whole samples of the acetate products were taken and the values proved to be of almost equal magnitude but of opposite sign (+18.30 and −18.80°, respectively). This relationship of the rotations was maintained through the conversions of the acetates to the alcohols, and the subsequent conversions to the phthalic acid esters. These data are excellent evidence that in these two runs the products were qualitatively and quantitatively the same but of opposite configurations.

The data obtained for the acetolysis of the *p*-toluenesulfonates of the optically active isomers, IVA and VIA, are not as conclusive. The yields of the solid derivatives are only about half of the yields obtained in the runs involving the esters of IIIA and VA as starting materials. Undoubtedly more material was lost during the purification of the solid derivatives in the former cases due to the formation of a molecular compound between the two components. However, the poor agreement between the rotations of the impure acetate products of the IVA and VIA runs suggests that small amounts of side reactions interfered. A plausible explanation for the direction which the rotations took is to assume that a small amount of direct displacement took place with simple inversion at the carbon atom bearing the oxygen during the acetolysis of the *p*-toluenesulfonates of IVA and VIA. Thus the ester of IVA would give small amounts of acetate of IIIA and subsequently the alcohol, IIIA, and the ester of VIA would give small amounts of acetate of VA and subsequently the alcohol, VA.



mixture, $\alpha = -8.53$, $l = 1$ dm. (λ = D)
(IIIA, $[\alpha]^{25}D$ +12.40°; IVA, $[\alpha]^{25}D$ −7.32°; VIA, $[\alpha]^{25}D$ −20.37°)[6]



mixture, $\alpha = -11.82°$, $l = 1$ dm. (λ = D)
(VA), $[\alpha]^{25}D$ −16.89°; IVA, $[\alpha]^{25}D$ −7.32°; VIA, $[\alpha]^{25}D$ −20.37°)[6]

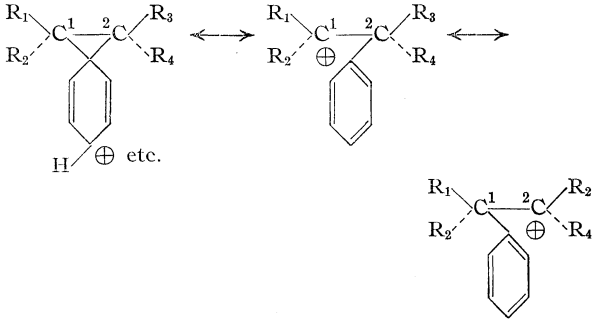
The positive rotation of IIIA would tend to cancel some of the negative rotation of the mixture of IVA and VIA, whereas the negative rotation of VA would not affect very much the negative rotation of the mixture of IVA and VIA.

The relative yields of olefin obtained from the acetolysis reactions are consistent with the con-

(6) These rotations of the pure alcohols were reported in paper II of this series (THIS JOURNAL, 71, 3871 (1949)).

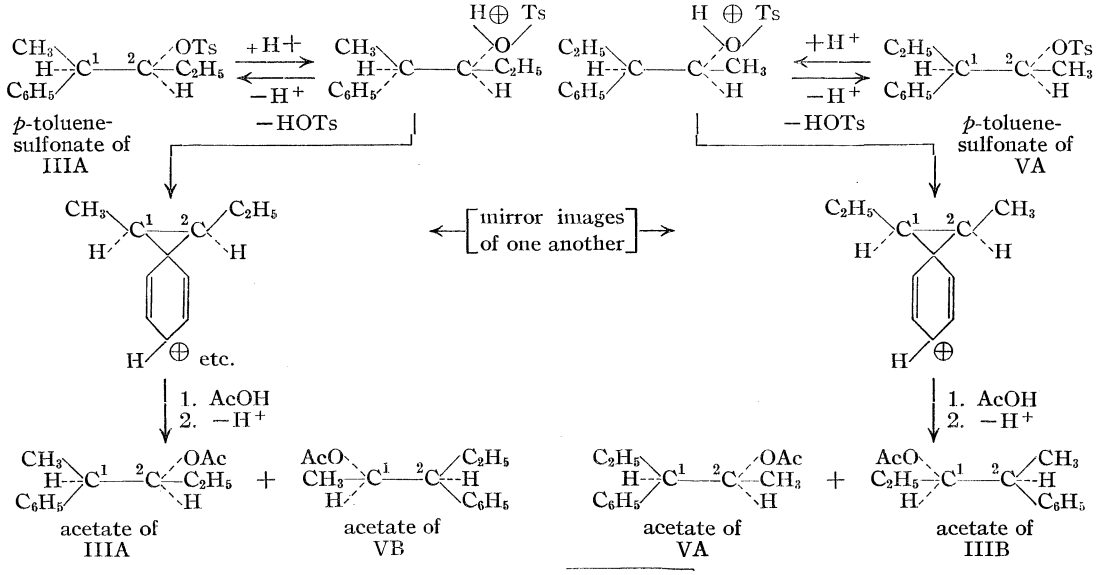
figurational assignments of III, IV, V, and VI (racemic alcohols) made in part II[2] of this series. The yield of olefin obtained from the acetolysis of the *p*-toluenesulfonate of IA (see paper I[5] of this series) was 26% as compared to a yield of 9.5% obtained from the *p*-toluenesulfonate of IIA. Since the *p*-toluenesulfonates of III and V gave yields of olefin amounting to 31 and 29%, respectively, and the *p*-toluenesulfonates of IV and VI, yields of 14 and 11%, respectively, it seems probable that the configurations of III and V are analogous to I on the one hand, and the configurations of IV and VI are analogous to II on the other. Further evidence for this analogy is found in paper IV of this series, along with definite proof that IVA possesses a configuration analogous to that of IIA.

Enough information is now at hand to rationalize the experimental results and the deductions based on these results in terms of a mechanistic interpretation of the acetolysis reaction of the *p*-toluenesulfonates of IIIA, IVA, VA and VIA. In the generalized cyclic ionic species shown, if R_1 and R_3 are methyl groups and R_2 and R_4 are hydrogens, the cycle possesses a plane of symmetry.

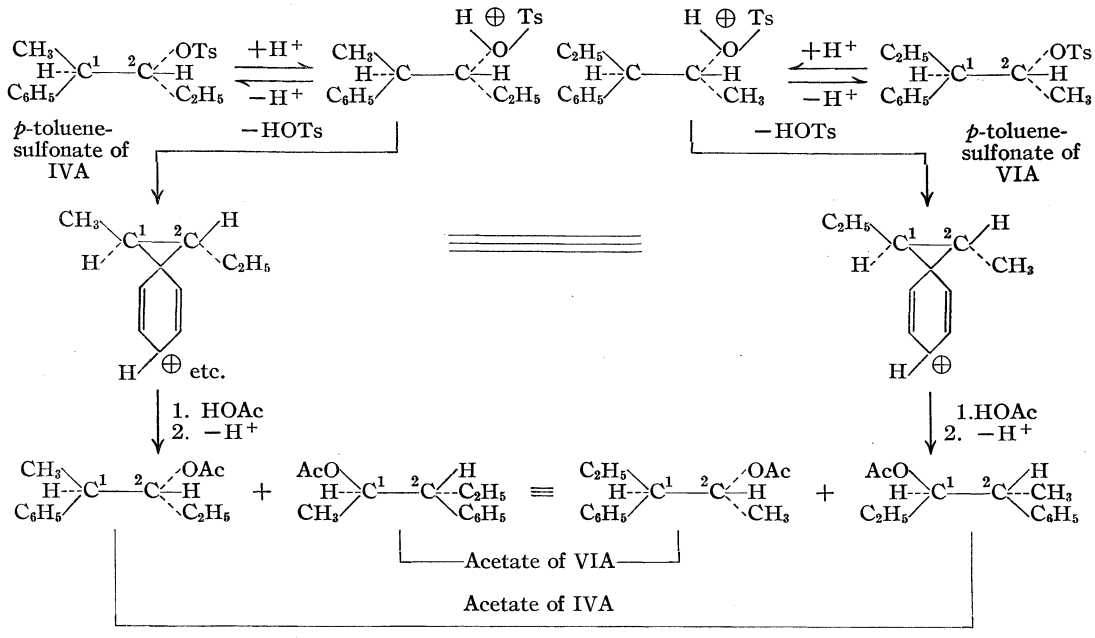


This intermediate was postulated as being formed during the acetolysis of the *p*-toluenesulfonates of either IA or IB.[5] Opening of the cycle at carbon atoms 1 or 2 (with equal probability) leads to racemic I acetate.[7] If R_1 and R_4 are methyl groups and R_2 and R_3 are hydrogens, the cycle is asymmetric, and can be formed only from the *p*-toluenesulfonate of IIA. When such a cycle is opened, the same product (acetate of IIA) is obtained whether the cycle is opened at carbon atoms 1 or 2. Such an intermediate was postulated in the acetolysis of the *p*-toluenesulfonate of IIA. If R_1 is a methyl group, R_3 an ethyl group, and R_2 and R_4 are hydrogens, the cycle is asymmetric, and would be formed from the *p*-toluenesulfonates of either IIIA or VB, these two structural isomers possessing a pseudo-enantiomorphic configurational relationship to one another. Furthermore, when the cycle is opened at carbon atom 2, acetate of IIIA would be obtained, and when the cycle is opened at carbon atom 1, acetate of VB is produced. If both reactions occur, a mixture would be obtained. The composition of the mixture would be independent of whether the starting material was one or the other isomer (IIIA or VB configuration) if no competing side reactions interfered. If R_1 is a methyl group, R_4 an ethyl group and R_2 and R_3 are hydrogens, the cycle is asymmetric, and would be formed from the *p*-toluenesulfonates of either IVA or VIA, these two structural isomers possessing an analogous configurational relationship to one another. When this cycle is opened at carbon atom 2, the acetate of IVA is obtained, and when opened at carbon atom 1, the acetate of VIA is produced. When both reactions occur, a mixture would result, the composition of which would be independent of which of the two starting materials the cycle came from.

The following scheme summarizes the argument.

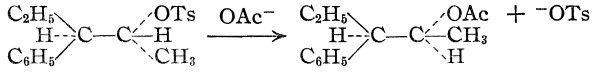


(7) The reasonable assumption has been made that inversion occurs at the carbon atom bearing the oxygen when the cycle closes, and that a second inversion occurs at the point where the cycle is opened.



The interesting fact that a small excess of 3-phenyl-2-pentanol derivative over 2-phenyl-3-pentanol derivative was obtained in each case (see Table II) independent of which racemate series was involved is explainable on the hypothesis that the cyclic intermediate ions are always asymmetric. The cycle is opened by a collision with an acetic acid molecule more often at the carbon atom bearing a methyl group than at the carbon atom bearing an ethyl group because of the slightly greater steric hindrance an ethyl group offers over that of a methyl group in the nucleophylic bimolecular displacement reaction.

The assignments of relative configurations of VA and VIA were substantiated by the inversion of the carbon bearing the oxygen bond of the *p*-toluenesulfonate of VIA by acetate ion in absolute ethanol. Although ether of undetermined configuration was the main product of the reaction, a small amount of solid derivative of VA was isolated.



p-Toluenesulfonate of VIA — Acetate of VA

Although any one experimental observation in the series of investigations reported in the first three papers of this series does not substantiate the general hypothesis of a carbocyclic ionic intermediate, the long sequence of facts become coherent only in terms of such a hypothesis. The formulation of the fundamental ideas early in the work was of great help not only in designing systems to broaden the experimental evidence but also in predicting products of reactions and thereby aiding in the experimental work. However, there has been no evidence obtained that the mechanism presented above applies to Wagner–Meerwein rearrangements in systems that are not closely similar to the one at hand. Since, in a sense, the reactions studied above amount to an aromatic substitution of an alkyl group for an alkyl group in a benzene ring, the results of this study should be relevant to the general question of the mechanism of aromatic substitution.

Experimental

Syntheses of the *p*-Toluenesulfonates of III, IV, V, VI, IIIA, IVA, IVB, VA, VIA and VIB.—The procedure used for the above syntheses is illustrated by the conversion of III to the *p*-toluenesulfonate of III. A mixture of 3.85 g. of III, 4.46 g. of pure *p*-toluenesulfonyl chloride and 10 ml. of pure dry pyridine was allowed to stand at room temperature for twenty-four hours. The mixture was then shaken with a cooled mixture of benzene and excess 2 *N* sulfuric acid, and the organic layer was washed successively with 2 *N* sulfuric acid, water, dilute alkaline solution and water. The organic layer was then dried, the solvent was evaporated under reduced pressure and at room temperature, and the resulting oil was crystallized and recrystallized from a low boiling petroleum ether and benzene mixture to give 5.0 g. of ester, m. p. 90–91° (white needles).

Acetolysis of the *p*-Toluenesulfonates of III, V, IV, VI, IVA, VIA, IIIA and VA.—The same procedure was used for the acetolyses of the *p*-toluenesulfonates of all of the above isomers. The acetates produced were hydrolyzed to the respective alcohols and solid derivatives were prepared by completely analogous methods. The following procedure is representative.

The *p*-toluenesulfonate of III (3.45 g.), 79 ml. of glacial acetic acid, 0.79 ml. of acetic anhydride and 1.5 g. of freshly fused potassium acetate was heated at 70° for thirty hours, cooled, and shaken with a mixture of petroleum ether and a large volume of water. The organic layer was separated, washed first with water, then with dilute alkaline solution and again with water. The solvent was evaporated and distilled to give 1.91 g. of mixture of acetate and olefin. This mixture was hydrolyzed by heating at reflux temperature for twenty-four hours in a mixture of 10 ml. of water and 1.91 g. of potassium hydroxide. The mixture was then cooled, extracted with

petroleum ether, the extract was washed with water, dried, evaporated and distilled. The 1.50 g. of the mixture of alcohols and olefin obtained was heated at 100° for one hour with 1.50 g. of phthalic anhydride and 2 ml. of pyridine. This mixture was cooled, shaken with a mixture of ethyl ether and excess of 2 *N* sulfuric acid, the ether layer was washed with water, dried and evaporated to an oil. This oil was crystallized from ethyl acetate and petroleum ether and recrystallized from these same solvents to produce 1.00 g. of acid phthalate, m. p. 129–131°, m. m. p. with a mixture of 32% acid phthalate of III and 68% acid phthalate of V (m. p. 129–132°), 129–132°, m. m. p. with an equal weight of the acid phthalate of III, 121–127°, m. m. p. with an equal weight of the acid phthalate of V, 137–142°.

The combined filtrates were evaporated to an oil and this oil was subjected to distillation under 18 mm. of pressure to give 0.50 g. of olefin.

When the *p*-toluenesulfonate of V (6.8 g.) was subjected to the above procedures, 3.8 g. of a mixture of acetate and olefin was obtained which was converted to 3.0 g. of a mixture of olefin and alcohol. Conversion of the mixture to the acid phthalate gave 2.22 g. of a recrystallized mixture of acid esters, m. p. 128–130°, m. m. p. with a mixture of 33% acid phthalate of III and 67% acid phthalate of V (m. p. 128–130°), 128–130°, m. m. p. with an equal weight of the acid phthalate of III, 121–126°, m. m. p. with an equal weight of acid phthalate of V, 136–141°. Olefin (0.90 g.) was recovered from the filtrates.

Acetolysis of the *p*-toluenesulfonate of IV (3.71 g.) produced 2.0 g. of a mixture of acetate and olefin which on hydrolysis gave 1.55 g. of a mixture of alcohol and olefin. Treatment of this mixture with 3-nitrophthalic acid ester produced 1.40 g. of a recrystallized mixture of acid esters, m. p. 147–149°, m. m. p. with a mixture of 31% 3-nitrophthalic acid ester of IV and 69% 3-nitrophthalic acid ester of VI (m. p. 147–149°) 147–149°, m. m. p. with an equal weight of the 3-nitrophthalic acid ester of IV, 139–145°, m. m. p. with an equal weight of the 3-nitrophthalic acid ester of VI, 152–161°. A total of 0.24 g. of olefin was recovered from the filtrates.

Acetolysis of the *p*-toluenesulfonate of VI (3.90 g.) produced 2.45 g. of a mixture of acetates and olefin which upon hydrolysis gave 1.75 g. of a mixture of alcohols and olefin. Conversion of the mixture of the 3-nitrophthalic acid ester produced 1.55 g. of recrystallized material, m. p. 148–150°, m. m. p. with a mixture of 29% 3-nitrophthalic acid ester of IV and 71% of the same derivative of VI (m. p. 148–150°), 148–150°, m. m. p. with an equal weight of the 3-nitrophthalic acid ester of IV, 139–146°, m. m. p. with an equal weight of the same derivative of VI, 154–163°. A total of 0.20 g. of olefin was obtained from the filtrates.

When the *p*-toluenesulfonate of IVA (2.4 g.) was subjected to acetolysis, 1.32 g. of a mixture of acetate and olefin was obtained, $\alpha = -26.87°$ ($l = 1$ dm.) and hydrolysis of the mixture produced 0.88 g. of a mixture of olefin and alcohol, $\alpha = -8.53°$ ($l = 1$ dm.). Conversion of this material to the 3-nitrophthalic acid ester produced 0.58 g. of recrystallized product, m. p. 147–148°, $[\alpha]^{25}D$ −60.3° (3% in ethanol), m. m. p. with a mixture of 48% of the 3-nitrophthalic acid ester of IVA and 52% of the 3-nitrophthalic acid ester of VIA (m. p. 147–148°), 147–148°, m. m. p. with an equal weight of IVA, 134–141°, m. m. p. with an equal weight of VIA, 138–142°. From the filtrates was isolated 0.05 g. of olefin.

Acetolysis of the *p*-toluenesulfonate of VIA (5.0 g.) produced 2.90 g. of a mixture of alcohol and olefin, $\alpha = -31.41°$ ($l = 1$ dm.), which when hydrolyzed gave 2.20 g. of a mixture of alcohol and olefin, $\alpha = -11.82°$ ($l = 1$ dm.). This material was converted to the 3-nitrophthalic acid ester derivative to give 1.33 g. of recrystallized material, m. p. 147–148°, $[\alpha]^{25}D$ −59.5° (3% in ethanol), m. m. p. with a mixture of 48% 3-nitrophthalic acid ester of IVA and 52% 3-nitrophthalic acid ester of VIA (m. p. 147–148°), 147–148°, m. m. p. with an equal weight of 3-nitrophthalic acid ester, of IVA, 131–136°, m. m. p. with an equal weight of the same derivative of VIA, 137–142°. A total of 0.15 g. of olefin was obtained from the filtrate.

Acetolysis of the *p*-toluenesulfonate of IIIA (2.4 g.) produced 1.26 g. of a mixture of acetate and olefin, $\alpha = +18.30°$ ($l = 1$ dm.) which when hydrolyzed gave 0.94 g. of a mixture of alcohol and olefin, $\alpha = +10.49°$ ($l = 1$ dm.). Conversion of this material to the acid phthalate gave 0.96 g. of recrystallized derivative, m. p. 128–130°, $[\alpha]^{25}D$ +5.17° (3% in ethanol). Olefin (0.19 g.) was obtained in the usual way from the filtrates.

A mixture of 0.80 g. of the above mixture, 0.70 g. of strychnine and 10 ml. of acetone was allowed to stand and the material that separated was recrystallized from acetone and shaken with a mixture of ethyl ether and excess dilute sulfuric acid. The organic layer was washed with water, dried, the solvent was evaporated and the resulting oil mixed with 0.50 g. of brucine and 5 ml. of acetone. The material that separated was recrystallized from acetone and shaken with a mixture of ether and excess dilute sulfuric acid, the organic layer was washed with water, dried and evaporated to an oil, weight, 155 mg. This material was mixed with 155 mg. of the acid phthalate of IIIB (this material is an oil and was prepared by hydrolysis of the pure 3,5-dinitrobenzoate of IIIB[2] with subsequent esterification of the alcohol obtained). When dissolved in an equal volume of ethyl acetate and a small amount of petroleum ether added, the oil crystallized to give 250 mg. of the acid phthalate of III, m. p. 133–134°, mixed melting point with an authentic sample, 133–134°.

The filtrates from the crystallizations of the strychnine and brucine salts were evaporated to dryness, shaken with an excess of dilute sulfuric acid and ether, the ether layer was washed with water, dried and evaporated to an oil. Crystallization of this material from ethyl acetate and petroleum ether and recrystallization of the product from the same solvents gave 0.54 g. of the acid phthalate of VB, m. p. 127–128°, m. m. p. with an authentic sample, 127–128°. A sample of this material was mixed with an equal weight of the acid phthalate of VA and the mixture recrystallized from ethyl acetate and petroleum ether, m. p. 143–144°, m. m. p. with an authentic sample of the acid phthalate of V, 143–144°.

Acetolysis of the *p*-toluenesulfonate of VA (5.0 g.) produced 2.80 g. of a mixture of acetate and olefin, $\alpha = -18.80°$ ($l = 1$ dm.), which on hydrolysis gave 2.17 g. of a mixture of olefin and alcohol, $\alpha = -10.26°$ ($l = 1$ dm.). Conversion of this material to the acid phthalate gave 2.11 g. of recrystallized material, m. p. 128–130°, $[\alpha]^{25}D$ −4.66° (3% in ethanol). Olefin (0.40 g.) was obtained from the filtrate in the usual way.

A solution of 1.5 g. of the above material and 1.8 g. of brucine dissolved in 10 ml. of acetone was allowed to stand and the salt that separated was recrystallized and converted back to the phthalic acid ester; weight 0.70, m. p. 128–129°, m. m. p. with an authentic sample of the acid phthalate of VA, 128–129°. A small amount of this material was mixed with an equal weight of the same derivative of VB and recrystallized from ethyl acetate and petroleum ether, m. p. 143–144°, m. m. p. with an authentic sample of the acid phthalate of V, 143–144°.

The filtrates from the crystallization of the salt were concentrated and shaken with a mixture of excess dilute sulfuric acid solution and ether, the organic layer was washed with water, dried, and evaporated to an oil, weight 0.52 g. A small amount of this oil (50 mg.) was mixed with an equal amount of the oil obtained by treatment of IIIA with phthalic anhydride (the non-crystalline phthalic acid ester of IIIA), and the mixture was crystallized and recrystallized from ethyl acetate and petroleum ether; weight 55 mg., m. p. 133–134°, m. m. p. with an authentic sample of the phthalic acid ester of III, 133–134°.

Inversion of the *p*-Toluenesulfonate of VIB to Produce the Acetate of VB.—A solution of 10 ml. of absolute ethanol, 1.0 g. of *p*-toluenesulfonate of VIB and 3.0 g. of freshly fused potassium acetate was held at reflux for fifteen hours. The mixture was then cooled and shaken with a mixture of water and petroleum ether (low boiling).

The organic layer was washed three times with water, dried, evaporated to an oil and distilled to give 0.40 g. of oil. This material was treated with 0.20 g. of phthalic anhydride and 2 ml. of pyridine at 100° for one hour, cooled and shaken with a mixture of benzene and dilute sulfuric acid (excess). The organic layer was washed with water, dried, evaporated and the oil submitted to distillation; weight of ether 0.27 g.

The material that did not distil was crystallized and recrystallized three times from a mixture of ethyl acetate and petroleum ether to give 32 mg. of acid phthalate of VB; m. p. 126–128°, m. m. p. with an authentic sample, 127–129°.

A sample of this material was mixed with an equal weight of the acid phthalate of VA and the mixture crystallized from ethyl acetate and petroleum ether; m. p. 143–144°, m. m. p. with an authentic sample, 143–144°.

Acknowledgment.—The author wishes to thank Welton Burney for the analyses reported in this paper.

Summary

1. The *p*-toluenesulfonates of the isomers of 3-phenyl-2-pentanol and 2-phenyl-3-pentanol (III, IV, V, VI, IIIA, IVA, VA and VIA) were prepared and submitted to acetolysis, and the mixtures of acetates obtained were hydrolyzed to the respective mixtures of alcohols, of which solid derivatives were prepared. From the *p*-toluenesulfonate of either III or V was obtained a mixture of III and V derivatives, from the *p*-toluenesulfonate of either IV or VI was obtained a mixture of derivatives of IV and VI, from the *p*-toluenesulfonate of either IVA or VIA was obtained a mixture of derivatives of IVA and VIA, from the *p*-toluenesulfonate of IIIA was obtained a mixture of derivatives of IIIA and VB, and from the *p*-toluenesulfonate of VA was obtained a mixture of derivatives of IIIB and VA. These results have been interpreted as constituting evidence that a Wagner–Meerwein rearrangement takes place in each system and in a highly stereospecific manner, and that the stereochemistry of these reactions can be explained only on the basis of carbocyclic, asymmetric ionic intermediates.

2. Additional evidence has been obtained for the relative configurations of the above isomers.

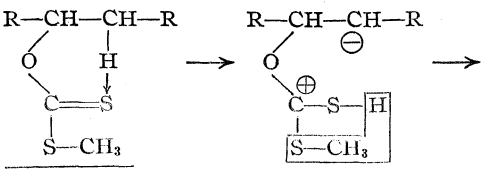
Studies in Stereochemistry. IV. The Chugaev Reaction in the Determination of Configuration of Certain Alcohols

BY DONALD J. CRAM

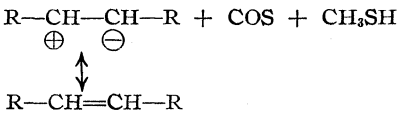
The results of rearrangement studies of the *p*-toluenesulfonates of the isomers of 3-phenyl-2-butanol led in paper I[1] of this series to an assignment of relative configurations to the four stereoisomers. The determination of the relative configurations by an independent method is desirable, and the use of the Chugaev reaction offers not only an attractive and unique method of accomplishing this end, but also offers a means of extending our knowledge of the steric course and mechanism of the Chugaev reaction itself. Since these two problems are completely interdependent, the purpose of this investigation is to show consistency between what is already known about the configurations of the starting material, and what is already known about the stereochemistry of the Chugaev reaction.

Stevens and Richmond[2] have suggested that the lack of rearranged olefins as products of this reaction can be explained by assuming that intramolecular hydrogen bonding prior to the proton elimination takes place, and that the reaction can be pictured as follows.



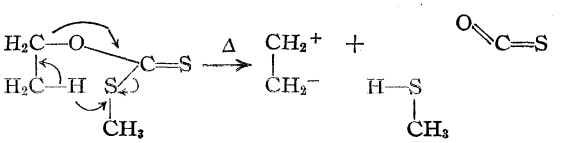
(1) Cram, THIS JOURNAL, **71**, 3863 (1949).

(2) Stevens and Richmond, *ibid.*, **63**, 3132 (1941).



These authors did not state whether the proton was pulled from the carbon before or during the breaking of the carbon oxygen bond, but the diagram implies the former.

Hückel, *et al.*,[3] found that decomposition of the xanthate of *l*-menthol produced about 30% Δ^2-menthene and 70% Δ^3-menthene, and the xanthate of *d*-neomenthol decomposed to give 80% Δ^2-menthene and 20% Δ^3-menthene. Since the hydrogen, loss of which leads to Δ^3-menthene, lies *cis* to the carbon–oxygen bond in the xanthate of *l*-menthol, and *trans* in the xanthate of *d*-neomenthol, the 70% Δ^3-menthene produced by the xanthate of *l*-menthol represents in effect a *cis* elimination reaction, and the 20% Δ^3-menthene obtained from the xanthate of *d*-neomenthol a *trans* elimination reaction. The stereochemistry of the reactions that produced Δ^2-menthene are not clear. These authors interpret the reaction as taking place by a completely concerted proc-



(3) Hückel, Tapp and Legutke, *Ann.*, **543**, 191 (1940).

ess, in which the sulfur bearing the methyl group plucks a proton from the carbon atom adjacent to the carbon atom bearing the oxygen at the same time that the carbon–oxygen and carbon–sulfur bonds break. Such a mechanism can, of course, only apply to a *cis* elimination reaction.

In the present investigation, each of the two racemate series of 3-phenyl-2-butanol when submitted to the Chugaev reaction should give a different geometric isomer of 2-phenyl-2-butene, determination of the structures of which should provide evidence for the relative configurations of the starting carbinols.

Discussion

Preparation, Identification and Characterization of the Isomers of 2-Phenyl-2-butene.—A mixture of the two geometric isomers[4] of 2-phenyl-2-butene was produced by the acid-catalyzed dehydration of 2-phenyl-2-butanol, and the large difference in boiling points permitted separation of the isomers by fractional distillation. If a small amount of *p*-toluenesulfonic acid is added to the pot during fractional distillation, pure *trans* compound[5] can be obtained.

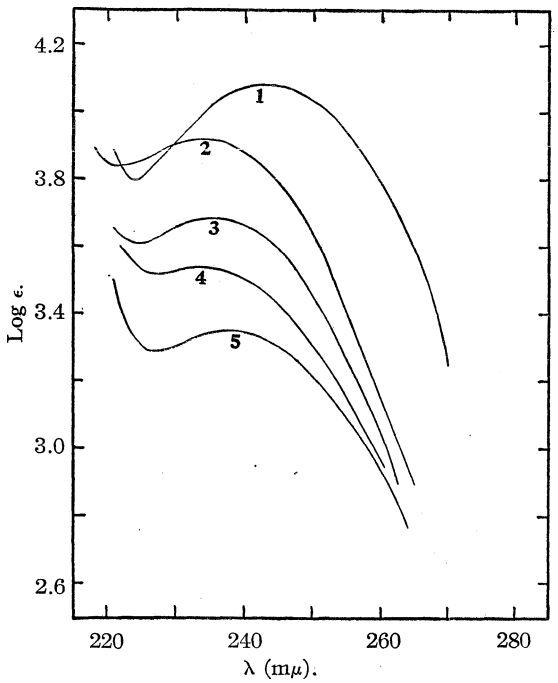


Fig. 1.—Ultraviolet absorption spectra (Beckman quartz spectrophotometer) run in cyclohexane: curve 1, *cis*-2-phenyl-2-butene; curve 2, *trans*-2-phenyl-2-butene; curve 3, fraction A of olefin obtained from xanthate of II; curve 4, fraction A of olefin obtained from xanthate of IV; curve 5, fraction A of olefin obtained from xanthate of I.

(4) If one assumes that the index of refraction of mixtures of these two components is a linear function of the composition, the ratio of the *cis* to *trans* isomer is 4 to 1. This value is roughly verified by the yield data.

(5) This substance, which is the lower boiling isomer, can be distilled from the continually equilibrating mixture.

The molecular structure of each olefin was confirmed by ozonolysis experiments, and the assignment of relative configuration was made on the basis of a comparison of the difference in the ultraviolet absorption spectra (see Fig. 1), and the difference in steric requirements for resonance involving the double bond and the benzene ring that exists between the two substances. Examination of Fisher–Hirschfelder models of each isomer indicates that when the benzene ring and methyl group are on the same side of the double bond (*trans* isomer), rotation of the benzene ring through the position corresponding to coplanarity with the double bond is resisted by interference between the methyl group and the hydrogen at the *o*-position of the ring. When the methyl group is on the opposite side of the double bond (*cis* isomer), this particular resistance to coplanarity is absent. Therefore, a certain amount of steric inhibition of resonance must exist in the *trans* isomer that would not be found in the *cis* compound, and this difference should lead to a divergence in the physical properties of the two substances. Thus the *cis* compound would be expected to be more polar (there should be a greater contribution to the resonance hybrid of dipolar forms in the *cis* than *trans* forms), to boil higher, to have a higher index of refraction and to absorb light at a longer wave length and at higher intensities.[6] Examination of the physical properties (see Experimental) of the two olefins obtained would indicate that the higher boiling substance corresponds to a *cis* (the two methyl groups *cis* to each other) and the lower boiling to a *trans* configuration. The presence of a much higher concentration of the *cis* isomer in an acid equilibrated mixture is consistent with the greater resonance of stabilization expected for the *cis* over the *trans* structure. The difference in free energy amounts to about 520 cal. based on the amounts of each obtained from an equilibrated mixture (the same mixture was obtained from each pure component).

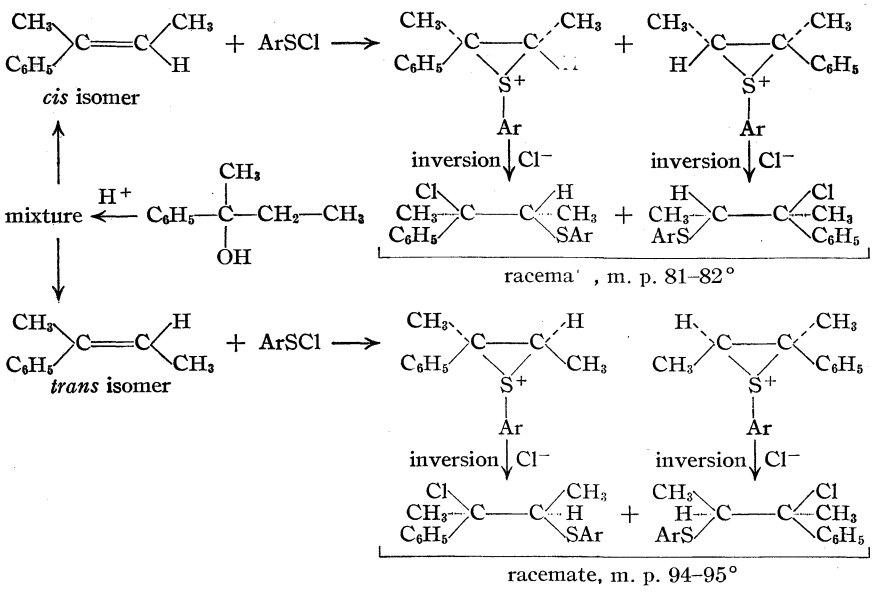
The addition of 2,4-dinitrobenzenesulfenyl chloride[7] to each isomer produced different crystalline derivatives (presumably different racemates), indicating that the addition reaction proceeds in a stereospecific manner. N. Kharasch and Buess[8] have demonstrated that the addition proceeds predominantly according to Markownikoff's rule when conducted in glacial acetic acid, and these authors have suggested a three-membered cyclic cation as an intermediate in the reaction, formed by the addition of 2,4-dinitrobenzenesulfenyl cation to the double bond. The stereospecificity of the reaction found in the present investi-

(6) An example of the effect of steric inhibitions of resonance on absorption spectrum is found in the study of the spectra of *cis*- and *trans*-stilbene by Smakula and Wassermann, *Z. physik. Chem.*, **A155**, 353 (1931).

(7) This reagent, directions for its use and suggestions as to its mode of addition were kindly supplied by Dr. N. Kharasch, University of Southern California.

(8) Kharasch and Buess, THIS JOURNAL, **71**, 2724 (1949).

gation would support this hypothesis, and the course of the reaction can be tentatively formulated as



The Products of the Chugaev Reaction.—The xanthates of racemate I[9] (rich in IB), racemate II (rich in IIA), and racemate IV (rich in IVA) were prepared and decomposed to produce mixtures of olefins, the compositions of which are summarized in Table I. The methods of analysis of the olefins are indicated in the footnotes of Table I and in the experimental section.

It is clear from these results that each reaction produced three products. The xanthates of the isomers of 3-phenyl-2-butanol each gave *cis*- and *trans*-2-phenyl-2-butene and 3-phenyl-1-butene. The presence of the last compound in the olefinic products was demonstrated in each case by the optical activity of the mixtures, and by the preparation and isolation of the racemic crystalline 2,4-dinitrobenzenesulfenyl chloride addition compound of this olefin. The production of this olefin from the two xanthates is to be expected, since a hydrogen can be lost from either carbon atom 1 or carbon atom 3 of the xanthate. The estimated amount of 3-phenyl-1-butene present in the mixture came to 30–40% in each case.

The relative amounts of *cis* and *trans* isomers obtained from the two xanthates indicate that the Chugaev reaction proceeds for the most part but not completely in a stereospecific manner. Thus 36% of the purified olefin mixture obtained from the xanthate of I proved to be *cis*-2-phenyl-2-butene, whereas 11–14% of the *trans* isomer was found. From the xanthate of II was obtained hydrocarbon of which 49–52% proved to be *trans*-2-phenyl-2-butene and only a trace of the *cis* isomer was detected. There is no way of determining the stereochemistry of the reaction which gives rise to 3-phenyl-1-butene. If one assumes on the basis of the findings of Hückel, *et al.*,[3] that the Chugaev reaction is predominantly a *cis* elimination, the above results are substantial proof of the correctness of the configurational assignments of racemates I and II. If one assumes that the configurations of racemates I and II were previously demonstrated by the rearrangement studies (see paper I of this series), then the above results demonstrate that the Chugaev reaction goes predominantly by a *cis* elimination mechanism. In any case, these experiments have linked the two chains of stereochemical evidence together in an internally consistent manner, thereby strengthening each argument.

(9) The numbering system has been maintained throughout papers I, II, III and IV of this series.

TABLE I

PRODUCTS OF THE CHUGAEV REACTION

Compos., start. alc., %		Yields, % Xanthate	Yields, % Tot. olef.	Compn. of olef. mix., % Cis isom.	Compn. of olef. mix., % Trans. isom.	Compn. of olef. mix., % Struct. isom.	Obs. rot., Olef. fract.	Obs. rot., Ald. mix.
80	IB				11[e]	40[f]		
20	IA	80	76	36	11[g]	37[h]	−2.02	+75.80
72	IIA				52[e]	32[f]

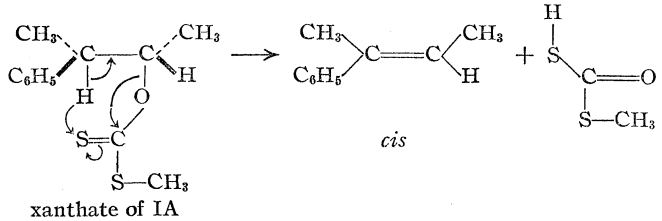
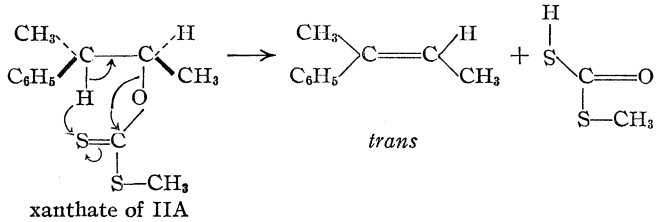
[a] The relative amounts of each isomer were estimated from the rotation of the mixture. [b] This yield is based in each case on the sum of the olefin fractions obtained by fractional distillation. [c] Sum of the fractions obtained by fractional distillation = 100%. [d] l = 1 dm. [e] The mixture of the *trans* isomer and the structural isomer (the olefin whose double bond is not in conjugation with the benzene ring) were never separated. Estimates of the amounts of *trans* isomer obtained were made from the amounts of acetophenone isolated from the ozonolysis mixtures (these values were corrected for the small manipulative losses found in a control experiment involving the separation of acetophenone from 2-phenylpropionaldehyde, the other ozonolysis product). [f] These values were obtained by difference, utilizing the estimates of the amounts of the *trans* olefin which were based on the isolation of acetophenone. [g] This estimate is based on the molar extinction coefficients of the spectrum of this mixture (see Fig. 1) at λ = max. The absorption of the olefin whose double bond is not in conjugation with the benzene ring is negligible in this region. A pure sample of 3-phenyl-1-butene was never obtained; however, the spectrum of this substance should simulate that of toluene, which exhibits very weak absorption ($\epsilon > 50$) in the region of 230–240 mμ and should not interfere (see Jones, *Chem. Revs.*, **32**, 1 (1943), and Braude, *et al.*, *J. Chem. Soc.*, 1087 (1947), and Murry, *et al.*, THIS JOURNAL, **70**, 3867 (1948)). [h] These values were obtained by difference, using the estimates of the amounts of *trans* olefin in the mixture, which estimates were based on spectral data.

The Chugaev reaction is considered in the present investigation to go predominantly by the following mechanism. The elimination reaction

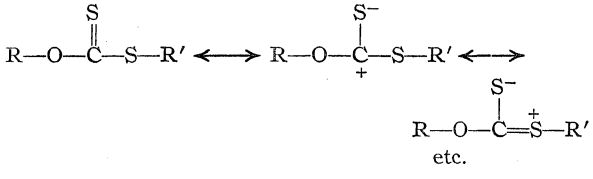


xanthate of IA



xanthate of IIA

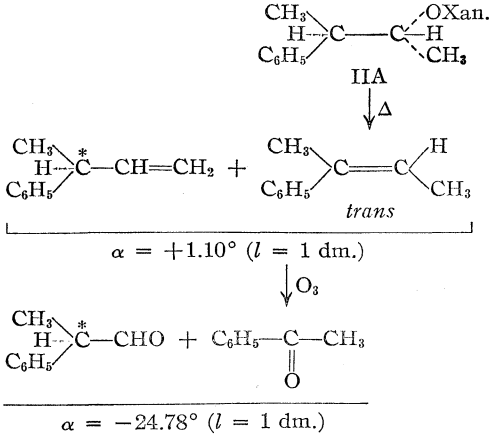
is pictured as being completely concerted, the hydrogen–carbon and the carbon–oxygen bonds breaking at the same time. The decomposition of the thiomethyl carbonate product is considered to be a second and independent reaction, the course of which is not pertinent. The above mechanism differs from that of Stevens and Richmond[2] only insofar as the reaction is thought to be completely concerted, rather than as taking

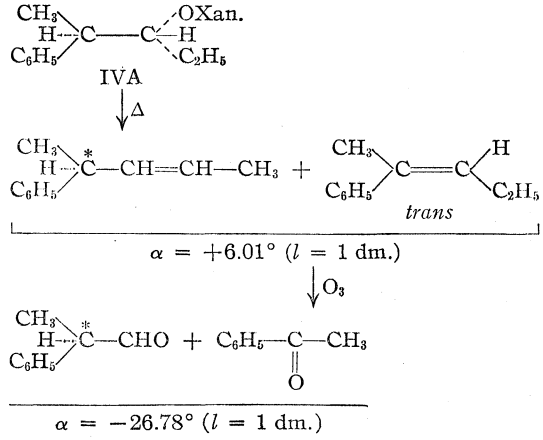


place in steps. This picture of the reaction is preferred over that of Hückel's[3] because the resonance inherent in the xanthate group would tend to increase the nucleophilic character of the sulfur of the thiocarbonyl group over that of the sulfide group. Furthermore, the steric requirements for the attack of the thiocarbonyl group on the hydrogen are less than those of the sulfur bearing a methyl group. The small amount of olefin that arises as a result of a *trans* elimination reaction is considered to be produced by an independent intermolecular mechanism.

The preparation and decomposition of the xanthate of IV (rich in IVA) was carried out for purposes of establishing the configuration of IVA relative to that of the I and II series of alcohols. Production of a large predominance of the *trans* (40–52%) over that of *cis* product (6%) is proof that IV possesses a configuration analogous to that of II.[10] Furthermore, the ozonolysis experiments, the results of which are outlined below, establish that IVA possesses a configuration analogous to IIA. The use of starting materials containing considerable amounts of the corresponding enantiomorphs (IIB and IVB, respectively) in no way modifies the argument. The opposite directions of the rotations of the olefin mixtures obtained from IIA and IB as well as of their respective ozonolysis products (see Table I) confirms the configurational assignments given to these isomeric alcohols in paper I[1] of this series, which were made on the basis of the simple inversion of the *p*-toluenesulfonate of IA by acetate ion to produce the acetate of IIA. The above experiment has demonstrated that the configurations about carbon atom 3 of IB and IIA are enantiomorphically related, and hence the configurations about that carbon atom in IA and IIB must be similarly related, in conformity with the previous argument.

Enough evidence is now available to place the configurational relationships of the four stereoisomers of 3-phenyl-2-butanol and the eight isomers of 2-phenyl-3-pentanol and 3-phenyl-2-pentanol on a secure basis. The configurations of I and II have been established through re-





(10) In making the estimate based on spectral data of the amount of *trans*-2-phenyl-2-pentene obtained from the xanthate of IV (see Table I), the assumption has been made that the spectrum of this substance should be very similar to that of *trans* 2-phenyl-2-butene. The positions of $\lambda_{max.}$ for the curve of the latter compound and the curve of the mixture of *trans* 2-phenyl-2-pentane and 4-phenyl-2-pentene (see Fig. 1) would tend to make this assumption valid.

arrangement studies and through the Chugaev reaction. If one assumes an absolute configuration for IA (this is the only assumption that has to be made), the structures of IB, IIA and IIB become fixed. The structure of IV was related to that of II through the Chugaev reaction, and the configurations of IVA and IIA related to one another by the degradative experiments, thereby fixing the structure of IVB. The *p*-toluenesulfonate of IVA was rearranged (acetolysis) in a stereospecific and predictable fashion to give acetate VIA, thereby fixing the structures of VIA and VIB. The structure of VIA was related to that of VA through simple inversion of the *p*-toluensulfonate of VIA by acetate ion to give acetate of VA, thereby fixing the structure of VA and VB. The *p*-toluenesulfonate of VA upon acetolysis produced IIIB acetate in a stereospecific and predictable manner thereby fixing the structure of IIIA and IIIB. Thus the assignments of configuration made earlier in the work and based for the most part on analogies between physical properties have been substantiated through the use of chemical introconversions and degradative experiments.

The olefinic products of the acetolysis of the *p*-toluenesulfonates of IA and IIA reported in paper I of this series were identified through the preparation of their addition compounds with 2,4-dinitrobenzenesulfenyl chloride. In each case the product obtained proved to be the derivative of *cis*-2-phenyl-2-butene. This fact suggests that the olefin arises from a non-asymmetric intermediate, possibly a free carbonium ion. Such an ion could be formed while the relative rotational positions of the two asymmetric carbon atoms with respect to each other was not conducive to the ring closure that leads to the acetate product.

Experimental

Preparation of *cis*- and *trans*-2-Phenyl-2-butene.—Methylethylphenylcarbinol (260 g.) was prepared according to the method of Klages,[11] and this material was held at reflux temperature mixed with 750 ml. of 4 *N* sulfuric acid. The olefin produced was isolated and distilled in the usual manner; weight 208 g., b. p. 80–84° (18 mm.), $n^{25}D$ 1.5347. This material was submitted to fractionation on a center rod column (55 theoretical plates at the highest operating efficiency) at 29.5 mm. of pressure and three fractions were taken: 1st, wt. 52 g., b. p. 82–88°; 2nd, wt. 85 g., b. p. 88–93.8°; 3rd, wt. 48 g., b. p. 93.8–94.0°. The second fraction was submitted to the same procedure to give 25 g. of material boiling below 93.8° and 58 g., b. p. 93.8–94.0°. All the fractions boiling below 88° were combined and treated by the same procedure to produce 22 g. of olefin, b. p. 77–78°, 45 g., b. p. 78–83°, and 30 g., b. p. 83–94°. Several refractionations of the middle boiling portions finally produced a total of 33 g. of material, b. p. 77–78°, and 128 g. of material, b. p. 93.8–94°. Careful redistillation of the higher boiling olefin gave 124 g. of pure *cis* isomer, b. p. 93.9–94.0° (p = 29.5 mm.), b. p. 194° (p = 1 atm.), $n^{25}D$ 1.5393, d^{25}_4 0.9799, MR_D 45.08, $\lambda_{max.}$ 243 mμ, log ε 4.082. The physical properties of this substance were unaltered by distillation at atmospheric pressure.

Anal. Calcd. for $C_{10}H_{12}$: C, 90.84; H, 9.15. Found: C, 90.92; H, 9.39.

Careful redistillation of the lower boiling olefin produced 29 g. of pure *trans* isomer, b. p. 77.0–77.1° (p = 29.5 mm.), b. p. 174° (p = 1 atm.), $n^{25}D$ 1.5192, d^{25}_4 0.9191, MR_D 45.01, $\lambda_{max.}$ 235 mμ, log ε 3.912. The physical properties of this substance were unchanged by distillation at atmospheric pressure.

Anal. Calcd. for $C_{10}H_{12}$: C, 90.84; H, 9.15. Found: C, 90.72; H, 9.18.

The *cis* isomer (13.5 g.) was mixed with 0.10 g. of pure toluenesulfonic acid and the mixture submitted to slow fractionation at 29.5 mm. to produce 11.4 g. of *trans* isomer, b. p. 77–79° (slight fluctuation), $n^{25}D$ 1.5197.

Equilibration of *cis* and *trans* 2-Phenyl-2-butene.—Pure *cis* isomer (5.0 g.) was heated to 100° with 0.05 g. of *p*-toluenesulfonic acid for three hours, the mixture cooled, shaken with a mixture of petroleum ether and water. The organic layer was washed with alkali, with water, dried, evaporated and distilled; wt. 4.1 g., $n^{25}D$ 1.5334.

Pure *trans* isomer (5.0 g.) when submitted to the same procedure gave 3.6 g. of product, $n^{25}D$ 1.5320.

2,4-Dinitrobenzenesulfenyl Chloride Addition Compounds of *cis*- and *trans*-2-Phenyl-2-butene.—A mixture of 0.50 g. of *cis*-2-phenyl-2-butene, 0.875 g. of 2,4-dinitrobenzenesulfenyl chloride and 2 ml. of glacial acetic acid was stirred until homogeneous and allowed to stand overnight. The heavy prisms that separated were recrystallized from a small amount of glacial acetic acid and petroleum ether; wt., 0.94 g., m. p. 81–82° (rich yellow prisms),[12] mixed m. p. with 2,4-dinitrobenzenesulfenyl chloride, 55–76°.

Anal. Calcd. for $C_{16}H_{15}SN_2O_4Cl$: C, 52.38; H, 4.12. Found: C, 52.27; H, 4.37.

Using the procedure described above, 0.50 g. of *trans*-2-phenyl-2-butene was converted into its addition compound with 2,4-dinitrobenzenesulfenyl chloride to give 0.97 g. of yellow rectangular plates (material recrystallized from ethyl acetate and petroleum ether), m. p. 94–95°, mixed m. p. with same derivative of the *cis* isomer, 59–73°, mixed m. p. with 2,4-dinitrobenzenesulfenyl chloride, 61–81°.

Anal. Calcd. for $C_{16}H_{15}SN_2O_4Cl$: C, 52.38; H, 4.12. Found: C, 52.21; H, 4.12.

Ozonolysis of *cis*- and *trans*-2-Phenyl-2-butene.—Ozone was passed into a mixture of 0.50 g. of *cis* isomer and 10 ml. of ethyl acetate at 0° until no more ozone was absorbed (twenty minutes). The resulting solution was added dropwise to a stirred boiling mixture of 50 ml. of water, 1.0 g. of zinc dust, a trace of silver nitrate and a trace of hydroquinone. After the addition was complete the mixture was cooled and extracted three times with ether, the combined extracts were washed with water, dried and evaporated to an oil, and the oil distilled to give 350 mg. of acetophenone, b. p. (micro) 202.5°. A small sample was converted to the oxime, m. p. 57–58°, mixture m. p. with an authentic sample 58–59°. Another sample was converted to the 2,4-dinitrophenylhydrazone, m. p. 248–249°, mixed m. p. with an authentic sample 248–249°.

From 0.50 g. of the *trans* isomer was obtained by the same procedure 310 mg. of acetophenone, b. p. (micro) 202°. Oxime was prepared from this material, m. p. 57–58°, mixed m. p. with an authentic sample, 58–59°. The 2,4-dinitrophenylhydrazone melted at 248–249°, mixed m. p. with an authentic sample, 248–249°.

Xanthates of I (rich in IB), II (rich in IIA) and IV (rich in IVA).—A mixture of 14.8 g. of II rich in IIA ($[\alpha]^{25}D$ +0.29), 3.85 g. of potassium and 60 ml. of dry toluene were heated at reflux for sixteen hours, cooled and the

(12) The melting point of this substance is sensitive to the rate of heating of the melting point bath; the substance melts at 81–82° if the rate of increase is normal, at 85–86° if very slow. If the substance is recrystallized from ethyl acetate and petroleum ether, the melting point decreases. Material recrystallized after having been melted shows the same characteristics.

small lump of potassium removed with a wire. A large excess (20 ml.) of carbon disulfide was added and the resulting mixture stirred at reflux temperature overnight. The mixture was again cooled and 12 ml. of methyl iodide added, the mixture was held at reflux temperature for four hours, cooled and shaken with a mixture of ether and water. The organic layer was washed with water, dried and the solvent evaporated to a low volume on a steam-bath, and the resulting concentrated solution was submitted to distillation at 15 mm. to remove the toluene. The remaining oil was distilled to give 20.2 g. of xanthate (yellow oil), b. p. 134–135° (p = 3 mm.), $n^{25}D$ 1.5746.

Anal. Calcd. for $C_{12}H_{16}OS_2$: C, 59.96; H, 6.71. Found: C, 60.23; H, 6.83.

The xanthate of I (rich in IB) was prepared by the procedure described above. From 22.0 g. of I rich in IB ($[\alpha]^{25}D$ −18.9°) was obtained 28.8 g. of yellow oil, b. p. 122–123° (p = 1 mm.), $n^{25}D$ 1.5749.

Anal. Calcd. for $C_{12}H_{16}OS_2$: C, 59.96; H, 6.71. Found: C, 60.18; H, 6.81.

The same procedure was used for the preparation of the xanthate of IV (rich in IVA). From 9.5 g. of IV (rich in IVA) ($[\alpha]^{25}D$ −2.64°) was obtained 11.0 g. of xanthate (yellow oil), b. p. 131–132° (p = 2 mm.), $n^{25}D$ 1.5680.

Anal. Calcd. for $C_{13}H_{18}OS_2$: C, 61.37; H, 7.13. Found: C, 61.73; H, 7.45.

Decomposition of the Xanthate of I.—The xanthate of I (rich in IB) (28.8 g.) was heated at 180° in a Wood's metal bath, and the olefin formed was collected as it distilled from the mixture, wt. 16.9 g. of crude yellow material. This material was distilled at reduced pressure (20 mm.) to get rid of low boiling impurities and undecomposed xanthate, wt. 13.7 g. Fractional distillation of this mixture of olefins through a center rod column (55 theoretical plates at the highest operating efficiency) at 29.5 mm. gave three fractions: fraction A, wt. 6.12 g., $n^{25}D$ 1.5093, d^{25}_4 0.8841, MR_D 44.67, b. p. 79.5–80.5°, α −2.01 (l = 1 dm., λ = D); fraction B, wt. 1.55 g., b. p. 80.5–93.8°; and fraction C, wt. 4.32 g., b. p. 93.8–94.0°, $n^{25}D$ 1.5387. Fraction A was analyzed, and Fig. 1 records the ultraviolet absorption spectrum of this mixture.

Anal. Calcd. for $C_{10}H_{12}$: C, 90.84; H, 9.15. Found: C, 90.82; H, 9.38.

Fraction A (1.40 g.) was submitted to ozonolysis (the procedure described earlier for the ozonolysis of *cis*-2-phenyl-2-butene was employed) to produce 0.91 g. of a mixture of acetophenone and 2-phenylpropionaldehyde, α +75.80° (l = 1 dm., λ = D). This mixture (0.50 g.) was dissolved in 5 ml. of ethyl alcohol and added to a suspension of silver oxide in 10 ml. of water (this reagent was prepared just before use by dissolving 1.5 g. of silver nitrate in 10 ml. of water and adding a dilute alkaline solution until no more precipitate formed). The resulting mixture was heated at reflux temperature for half-an-hour, cooled and extracted three times with ether, the extracts were combined, washed with dilute alkaline solution and then with water, dried, evaporated to an oil, and the oil was distilled to give 90 mg. of acetophenone, b. p. (micro) 200°. The 2,4-dinitrophenylhydrazone was prepared, m. p. 248–249°, mixed m. p. with an authentic sample 248–249°.

A known mixture of 250 mg. of acetophenone and 250 mg. 2-phenylpropionaldehyde[1] was submitted to the procedure described above and 230 mg. of acetophenone was obtained, b. p. (micro) 201°, m. p. of the 2,4-dinitrophenylhydrazone, 248–249°, mixed m. p. with an authentic sample, 248–249°.

A mixture of fraction A (325 mg.), 560 mg. of 2,4-dinitrobenzenesulfenyl chloride and 1 ml. of glacial acetic acid was allowed to stand overnight and the resulting oil was dissolved in 3 ml. of benzene and submitted to chromatographic absorption on a small alumina column. The first band to filter through (benzene was used to develop the column) was collected, evaporated under reduced pressure and crystallized and recrystallized from ethyl acetate and petroleum ether to give 110 mg. of optically inactive yellow needles, m. p. 123–124°, depressed by admixture with the 2,4-dinitrobenzenesulfenyl chloride addition products of either *cis*- or *trans*-2-phenyl-2-butene. No other crystalline products could be isolated.

Anal. Calcd. for $C_{16}H_{15}SN_2O_4Cl$: C, 52.38; H, 4.12. Found: C, 52.59; H, 4.39.

Fraction B from the original distillation was discarded. Fraction C (200 mg.) was mixed with 350 mg. of 2,4-dinitrobenzenesulfenyl chloride and 0.5 ml. of glacial acetic acid. The addition compound was isolated and purified in the usual manner; wt. 330 mg., m. p. 81–82°, mixed m. p. with the authentic derivative of *cis*-2-phenyl-2-butene, 81–82°.

Decomposition of the Xanthate of II.—The xanthate of II (rich in IIA) (20.2 g.) was decomposed by the procedure described above to give 12.89 g. of crude olefin, distillation of which produced 11.2 g. of material which was submitted to fractional distillation at 29.5 mm. to give two fractions: fraction A, wt. 8.72 g., b. p. 79–80°, $n^{25}D$ 1.5120, d^{25}_4 0.8831, MR_D 44.92, α +1.10° (l = 1 dm., λ = D); and fraction B, wt. 1.54 g., b. p. 80–84°. Fraction A was analyzed, and Fig. 1 records its ultraviolet absorption spectrum.

Anal. Calcd. for $C_{10}H_{12}$: C, 90.84; H, 9.15. Found: C, 90.42; H, 9.30.

Fraction A (500 mg.) was treated with 2,4-dinitrobenzenesulfenyl chloride in the usual manner and 350 mg. of recrystallized derivative was obtained, m. p. 94–95°, mixed m. p. with an authentic sample of the addition product of 2,4-dinitrobenzenesulfenyl chloride with *trans*-2-phenyl-2-butene, 94–95°. The filtrates from the crystallization and recrystallization of the above substance were concentrated, dissolved in a small amount of benzene, and submitted to chromatographic absorption on a small column of alumina. The column was developed with benzene and the first band to filter through the column was collected, concentrated and the resulting oil crystallized and recrystallized from ethyl acetate and petroleum ether to give 20 mg. of yellow needles, m. p. 124–125°, not depressed by admixture with the corresponding derivative prepared from fraction A obtained from the decomposition of the xanthate of I.

Fraction A (4.4 g.) was submitted to ozonolysis to give 2.7 g. of a mixture of acetophenone and 2-phenylpropionaldehyde, α −24.78° (l = 1 dm., λ = D). This mixture (500 mg.) was oxidized with silver oxide, and the acetophenone was isolated in the usual manner (see above), wt. 302 mg., b. p. 202° (micro), m. p. of the 2,4-dinitrophenylhydrazone, 248–249°.

Fraction B was submitted to fractional distillation, and the material that boiled above 85° (p = 29.5 mm.) and the material held in the column at the end were combined (total wt., 450 mg.) and converted to the 2,4-dinitrobenzenesulfenyl chloride addition product, wt. 640 mg., m. p. 81–82°, not depressed by admixture with an authentic sample of the addition product of 2,4-dinitrobenzenesulfenyl chloride with *cis*-2-phenyl-2-butene.

Decomposition of the Xanthate of IV.—The xanthate of IV (rich in IVA) (10.5 g.) when pyrolyzed at 200° gave crude olefin (5.9 g.) which on distillation produced 4.7 g. of material. This mixture was submitted to fractional distillation at 29.5 mm. and two fractions were taken: fraction A, wt. 3.8 g., b. p. 94.4–98.0°, α +6.01 (l = 1 dm., λ = D); and fraction B, wt. 0.23 g., b. p. 98–101°. Fraction A was analyzed, and Fig. 1 records its ultraviolet absorption spectrum.

Anal. Calcd. for $C_{11}H_{14}$: C, 90.35; H, 9.65. Found: C, 90.18; H, 9.91.

Fraction A (1.5 g.) was submitted to ozonolysis to produce 0.83 g. of a mixture of acetophenone and 2-phenylpropionaldehyde, α −26.51° (l = 1 dm., λ = D). This mixture (500 mg.) was oxidized with silver oxide by the procedure reported above and 240 mg. of acetophenone was isolated, b. p. 201° (micro). The 2,4-dinitrophenylhydrazone of this substance melted at 248–249°, not depressed by admixture with an authentic sample.

Identification of Olefin from Rearrangement Studies.—The olefin (0.55 g.) obtained from the acetolysis of the *p*-toluenesulfonate of IA (see paper I of this series) was treated in the usual manner with 2,4-dinitrobenzenesulfenyl chloride, and 0.65 g. of recrystallized product obtained, m. p. 81–82°, not depressed by admixture with the same derivative of an authentic sample of *cis*-2-phenyl-2-butene.

In the same way the olefin (0.12 g.) obtained from the acetolysis of the *p*-toluenesulfonate of IIA (see paper I of this series) was converted to the 2,4-dinitrobenzenesulfenyl chloride addition compound, wt. 90 mg. (recrystallized material), m. p. 81–82°, not depressed by admixture with an authentic sample of the same derivative of *cis*-2-phenyl-2-butene.

Acknowledgments.—The author wishes to thank Welton Burney for the analyses reported in this paper. The use of the reagent, 2,4-dinitrobenzenesulfenyl chloride was made possible through the kindness of N. Kharasch, who provided a sample of the substance and directions for its use, and who also made information available as to the direction of addition of the reagent to the carbon–carbon double bond.

Summary

1. The geometric isomers of 2-phenyl-2-butene have been prepared, configurational assignments have been made on the basis of physical properties, and solid derivatives have been prepared.

2. Evidence has been adduced for the stereospecific addition of 2,4-dinitrobenzenesulfenyl chloride to the carbon–carbon double bond.

3. The Chugaev reaction has been shown to be predominantly a *cis* elimination reaction in an acyclic system.

4. Evidence has been obtained for the relative configurations of all the stereoisomers of 3-phenyl-2-butanol, 2-phenyl-3-pentanol and 3-phenyl-2-pentanol.

5. The formation of olefin during the acetolysis of the *p*-toluenesulfonates of IA and IIA has been shown to be a non-stereospecific reaction.

The Synthesis of Phellandral[1,2]

BY ROBERT L. FRANK, ROBERT E. BERRY AND ODETTE L. SHOTWELL

Most of the evidence concerning the structure of the terpene phellandral has indicated that this naturally occurring aldehyde is best represented by Structure X.[3,4,5] Cooke, Macbeth and Swanson[5b] have established the structure of the carbon skeleton by hydrogenation of phellandric acid to the known *cis*- and *trans*-hexahydrocuminic acids, and ultraviolet absorption spectra have located the double bond in the position α,β to the carbonyl group.[5a,6] This structure has now been confirmed by the synthesis of *dl*-phellandral through *dl*-phellandric acid, and the resolution of the racemic acid to the *d*-form corresponding to the acid obtained by oxidation of *d*-phellandral. The steps to the aldehyde are represented by Structures I–X.

The starting material, *p*-isopropylphenol (I), was best prepared by sulfonation of cumene, followed by alkali fusion. Methods involving nitration, reduction and diazotization or the alkylation of phenol resulted in mixtures of *o*- and *p*-isopropylphenols.

The hydrogenation and oxidation steps (I–II–III) were straightforward and gave yields of 96 and 82%, respectively.

In the preparation of the cyanohydrin acetate of 4-isopropylcyclohexanone (V) it was expected that treatment of the ketone with acetic anhydride and aqueous potassium cyanide[7] would lead directly to the cyanohydrin acetate. The reaction was tried on cyclohexanone as a model compound, and it was found to yield not the acetate but the cyanohydrin itself. The latter is resistant to acetylation by acetic anhydride, giving only 19% acetylation even in an excess of the reagent. Subsequent experiments showed that if one adds a trace of acetyl chloride to the acetic anhydride, the acetylation proceeds smoothly in good yields (64% with cyclohexanone). The conversion of 4-isopropylcyclohexanone (III) to the cyanohydrin acetate (V) was then carried out in two stages, but without purification of the intermediate cyanohydrin (IV), in a yield of 70%.

The method of Burns, Jones and Ritchie[8] and others[9] for the pyrolysis of esters gave excellent results with 4-isopropylcyclohexanone cyanohydrin acetate (V). The optimum temperature for our ester was 575–600°, which resulted in a small amount of charring in the pyrolysis tube, but nevertheless gave the highest yields (74%) of 4-isopropyl-1-cyano-1-cyclo-

hexene (*dl*-phellandronitrile, VI). The nitrile (VI) was assumed to have its unsaturation in the position α,β to the cyano group on the basis of its ultraviolet absorption spectrum (maxima at 212 mμ, log ϵ 3.95, and 271 mμ, log ϵ 2.01)[10,11] and on the basis of previous reports that rearrangement of the double bond seldom occurs in this type of pyrolysis.[12]

Hydrolysis of *dl*-phellandronitrile (VI) was accomplished under both alkaline and acidic conditions. In either case, however, mixtures resulted due to α,β–β,γ shifting of the double bond.[13] Saponification with 10% aqueous potassium hydroxide gave a mixture of solid acids, presumably VII and VIII, of m. p. 119–142°. Recrystallization from numerous solvents failed to effect separation. Hydrolysis with 75% sulfuric acid gave a similar mixture from which phellandric acid (VII) could not be isolated but which did give a 44% yield of an isomer we believe on the basis of infrared data to be the Δ^2 acid (VIII).

Various means, described in the Experimental Part, were used to obtain pure *dl*-phellandric acid (VII) from the mixture. Best results were obtained by refluxing the mixture in ethanolic sodium ethoxide to give an 80% yield of the pure Δ^1 acid (VII).

Reduction of *dl*-phellandric acid to *dl*-phellandral was accomplished readily, although in low yield (16% from the anilide), by the von Braun and Rudolph modification of the Sonn–Müller reduction.[14] The *dl*-phellandral was characterized by means of its physical properties and formation of its oxime, semicarbazone and 2,4-dinitrophenylhydrazone. Ultraviolet absorption spectra of the synthetic aldehyde and its semicarbazone corresponded with those reported for natural phellandral by Cooke and Macbeth[5a] and Evans and Gillam[6] (Fig. 1).

We were particularly interested in the properties of the oxime because of the structural similarity between phellandral and perilla-aldehyde. The *anti*-oxime of the latter has been reported to be 2000 times as sweet as sucrose.[15] We obtained only one oxime of *dl*-phellandral; it was not sweet.

Resolution of *dl*-phellandric acid (VII) was partially accomplished through its quinine salt. This salt reached constant rotation when the acid was about 56% resolved, and the resolution was completed by means of *l*-α-phenylethylamine.

(10) Braude, *Ann. Repts. Chem. Soc.*, **42**, 122 (1945).

(11) Ultraviolet absorption spectra were kindly carried out by Mrs. Calvin Brantley using a Model D Beckmann spectrophotometer. The nitrile was dissolved in 95% ethanol, concentration 0.0192 g. per liter of solution.

(12) For example, the pyrolysis at 575° of the diacetate of pentamethylene glycol yields only 1,4-pentadiene, with apparently no shifting of the unsaturation into conjugation to form piperylene (see reference 9a).

(13) Boorman and Linstead, *J. Chem. Soc.*, 261 (1935).

(14) v. Braun and Rudolph, *Ber.*, **67**, 269 (1934).

(15) Kurukawa and Tomizawa, *J. Chem. Ind. Japan*, **23**, 342 (1920); (*C. A.*, **14**, 2839 (1920)).

The *d*-acid thus obtained was essentially identical in m. p. (143–144°) and rotation ($[\alpha]D^{26}$ + 112.2°) with that obtained by oxidation of *d*-phellandral.[5b]

Experimental

All melting points are corrected.

p-Isopropylphenol (I).—Ninety grams (104 ml., 0.75 mole) of cumene and 83 g. (0.85 mole) of 95% sulfuric acid were heated with stirring for three hours on a steam-cone. The warm mixture was poured into 250 ml. of water, and 40 g. of sodium bicarbonate was added in small portions, followed by 105 g. of sodium chloride. Crude sodium *p*-cumenesulfonate, which precipitated on cooling, was collected on a suction filter, washed with 40 ml. of saturated aqueous sodium chloride, and dried for two days at 80°. It weighed 109 g.

A mixture of 960 g. (17.1 moles) of potassium hydroxide and 40 ml. of water was heated to 250° in a 3-l. iron pot fitted with a stirrer. To this was added with constant stirring over a period of one-half hour 360 g. (1.62 moles) of the impure sodium *p*-cumenesulfonate. The temperature was raised to 325° for ten minutes, then the contents immediately poured onto 3 l. of cracked ice. The resulting water solution was neutralized with concentrated sulfuric acid and steam distilled. Colorless crystals of *p*-isopropylphenol formed in the distillate. After drying in a vacuum desiccator for two days these weighed 118 g. (35% based on cumene), m. p. 58–59° (lit.,[16] 61°).

4-Isopropylcyclohexanol (II).—A solution of 187 g. (1.37 moles) of *p*-isopropylphenol in 250 ml. of ethanol (purified by stirring for three hours with 2 g. of Raney nickel) was hydrogenated over 6.0 g. of Raney nickel at 190° and 125-atm. pressure. Fractional distillation gave 189 g. (96%) of 4-isopropylcyclohexanol, b. p. 123–124° (40 mm.), $n^{20}D$ 1.4660 (lit.,[17] 1.4661).

4-Isopropylcyclohexanone (III).—To a solution of 59 g. (0.20 mole) of potassium dichromate in 455 ml. of water in a 1-l., three-necked flask fitted with a dropping funnel, a reflux condenser, a thermometer and a stirrer was added 80 g. (0.56 mole) of 4-isopropylcyclohexanol. Concentrated sulfuric acid (52 ml.) was added dropwise with stirring at such a rate that the temperature was kept between 55° and 60° (about 10 ml. of acid was added before the temperature began to rise). The reaction mixture was cooled to room temperature, the oily layer separated, and the aqueous layer extracted with ether. The oily layer and the extracts were combined, washed with 5% aqueous sodium hydroxide, then water, and dried over anhydrous magnesium sulfate. Fractional distillation in a 12-in. Fenske-type column gave 64.6 g. (82%) of 4-isopropylcyclohexanone, b. p. 90–91° (13 mm.), $n^{20}D$ 1.4560 (lit.,[17] 1.4552^{25}°). The semicarbazone, prepared according to the method of Shriner and Fuson,[18a] melted at 187–188° (lit.,[19] 187–188°).

Cyclohexanone Cyanohydrin.—A solution of 65 g. (1.00 mole) of potassium cyanide in 125 ml. of water was added dropwise with stirring to a mixture of 94 ml. (102 g., 1.00 mole) of acetic anhydride and 52 ml. (49 g., 0.50 mole) of cyclohexanone in a 1-l. flask fitted with a mechanical stirrer, a dropping funnel and a reflux condenser. During the addition the mixture was cooled in an ice-bath. Stirring was continued for fourteen hours at room temperature, after which the reaction mixture was homogeneous. Saturated aqueous sodium carbonate was added until the mixture was alkaline to litmus. A red oil separated during this time; it was removed, and the water layer extracted with three 50-ml. portions of benzene. The extracts and oil were combined, washed with three 50-ml. portions of 30% aqueous sodium bisulfite, dried over magnesium sulfate, and the benzene distilled at 15-mm. pressure. The residual oil crystallized when a spot on the flask was cooled with Dry Ice. It was purified by rapid distillation at 91–95° (2 mm.) from a Claisen flask to yield 47.7 g. (76%) of colorless liquid, $n^{20}D$ 1.4643, which crystallized on chilling. An analytical sample was prepared by washing these crystals with chloroform, ether and acetone; m. p. 35°.

Anal.[20] Calcd. for $C_7H_{11}ON$: C, 67.17; H, 8.86. Found: C, 67.21; H, 8.88.

Cyclohexanone Cyanohydrin Acetate.—To 68 ml. (73 g., 0.75 mole) of acetic anhydride and 0.8 ml. of acetyl chloride heated to boiling was slowly added 85.0 g. (0.68 mole) of cyclohexanone cyanohydrin. The mixture was refluxed for one hour after the end of the addition; it turned dark red during this time. Direct fractional distillation gave 91.0 g. (80%) of product, b. p. 125° (13 mm.), which crystallized on cooling; m. p. 48° (lit.,[8] 48–49°).

The same experiment, carried out with acetic anhydride containing no acetyl chloride, yielded 19% of the cyanohydrin acetate.

4-Isopropylcyclohexanone Cyanohydrin Acetate (V).—Crude 4-isopropylcyclohexanone cyanohydrin was prepared by the method for cyclohexanone cyanohydrin, with the use of 90 ml. (98 g., 0.96 mole) of acetic anhydride, 60 g. (0.43 mole) of 4-isopropylcyclohexanone and 62 g. (0.96 mole) of potassium cyanide in 192 ml. of water. After removal of the benzene at 15 mm. from the extract of the product, the oil was refluxed for one hour with 41 ml. (44.0 g., 0.43 mole) of acetic anhydride and 0.5 g. of acetyl chloride. Fractional distillation then gave 65.5 g. (70%) of product, b. p. 145–147° (14 mm.). It crystallized on cooling; m. p. 43–44°. An analytical sample was prepared by four recrystallizations from methanol–water to yield colorless mica-like plates, m. p. 50.5–52.5°.

Anal. Calcd. for $C_{12}H_{19}O_2N$: C, 68.85; H, 9.15. Found: C, 68.86; H, 9.20.

4-Isopropyl-1-cyano-1-cyclohexene (*dl*-**Phellandronitrile, VI**).—Three hundred and fifty-seven grams (1.71

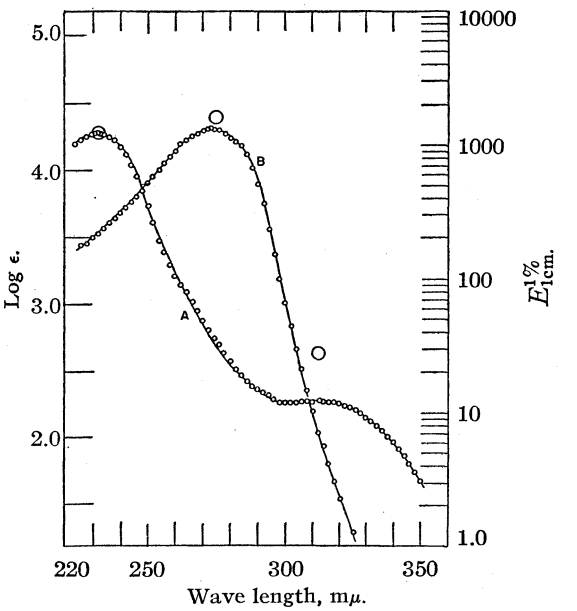

Fig. 1.—Ultraviolet absorption of *dl*-phellandral (A) (0.00418 g. per liter of ethanol solution) and its semicarbazone (B) (0.600 g. per liter of ethanol solution). The large circles represent the literature values (references 5a and 6).

(19) Vavon and Callier, *Bull. soc. chim.*, [4] **41**, 677 (1927).

(20) Microanalyses were carried out by Misses Emily Davis, Betty Alice Snyder and Theta Spoor, Mr. Maurice Dare and the Clark Microanalytical Laboratory.

moles) of the cyanohydrin acetate of 4-isopropylcyclohexanone was pyrolyzed by passing it through a vertical 18-mm. Pyrex tube filled with eight inches of glass beads. The temperature of the reaction was 575–600°; the ester was passed through the tube over a period of twelve hours at a rate of one drop every 3.5 seconds. There was some charring in the pyrolysis tube. Direct distillation of the product in a ten-inch Fenske-type column yielded 188 g. (74%) of colorless liquid, b. p. 118–120° (15 mm.); $n^{20}D$ 1.4786; sp. gr. $\frac{20}{20}$ 0.914; *MR* calcd. (using exaltation of 0.7): 46.2, found: 46.3.

Anal. Calcd. for $C_{10}H_{15}N$: C, 80.53; H, 10.14. Found: C, 80.37; H, 9.88.

Pyrolysis of a similar amount at 500° gave a 60% yield (based on unrecovered starting material) and a 31% recovery of starting material; at 565–575° the yield was 62% with no recovery of starting material.

Hydrolysis of 4-Isopropyl-1-cyano-1-cyclohexene. A. With Potassium Hydroxide.—A mixture of 188 g. (1.26 moles) of the nitrile, 141 g. (2.52 moles) of potassium hydroxide, and 3 ml. of 1-octanol (to prevent foaming) in 1271 ml. of water was refluxed for forty-eight hours. After forty hours most of the nitrile layer had disappeared. After cooling and filtration, the solution was acidified with concentrated hydrochloric acid. A light brown precipitate formed. This was dissolved in 1500 ml. of hot nitromethane. The mother liquor was extracted with 300 ml of nitromethane and the extract combined with the main hot solution. On cooling 136 g. of white platelets deposited; m. p. 119–142°. A second crop, 18.5 g., m. p. 83–118°, raised the total yield of mixed Δ^1- and Δ^2-4-isopropyltetrahydrobenzoic acids (VII and VIII) to 73%. Crystallizations from ethanol–water mixtures and from nitromethane did not raise nor narrow the m. p. range.

Anal. Calcd. for $C_{10}H_{16}O_2$: C, 71.39; H, 9.59. Found: C, 71.57; H, 9.52.

B. With Sulfuric Acid.—To 25 g. of 75% sulfuric acid at 120° in a 200-ml. flask equipped with a stirrer, a dropping funnel and a reflux condenser was added dropwise 6.0 g. (0.04 mole) of 4-isopropyl-1-cyano-1-cyclohexene. The mixture was stirred at 110–120° for three hours, then poured into ice-water to give a brown precipitate. Two recrystallizations from ethanol–water, with the use of Darco, and one from dioxane–water (60:40) yielded 3.0 g. (44%) of colorless needles, m. p. 105°.

Anal. Calcd. for $C_{10}H_{16}O_2$: C, 71.39; H, 9.59. Found: C, 71.46; H, 9.73.

On the basis of its neutral equivalent, 172, and its infrared spectrum, kindly furnished by Mrs. J. L. Johnson, this acid is assumed to be Δ^2-4-isopropyltetrahydrobenzoic acid (VIII). The spectrum, obtained in Nujol suspension using a Perkin–Elmer Model 12B infrared spectrometer with rock salt optics, showed weak absorption bands at 702, 736, 1071, 1086, 1109, 1178, 1217, 1274, 1286, 1301, 1314 and 1371 cm.$^{-1}$ and strong bands at 1649 (unconjugated double bond) and 1680 cm.$^{-1}$ (carboxylic carbonyl group). No absorption was observed in the region of 1750–1800 cm.$^{-1}$, characteristic of γ-lactones.[21]

***dl*-Phellandric Acid (VII).**—Thirty-eight grams (1.6 gram-atoms) of sodium was dissolved in 1400 ml. of absolute ethanol in a 3-l. flask fitted with a reflux condenser. To this was added 136 g. (0.810 mole) of the mixture of acids, m. p. 119–142°, obtained by the alkaline hydrolysis above. A lumpy precipitate formed; the mixture was refluxed for three hours and allowed to stand overnight. About half the alcohol was removed by distillation, ice-water was added to the residue and the latter then carefully acidified with concentrated hydrochloric acid. Crystals formed in the mixture, which now had a total volume of 5 l. One recrystallization from 1400 ml. of nitromethane gave 109 g. (80% from the mixture, 58% from the nitrile) of colorless needles, m. p. 142–144° (lit.,[5b] 143–144°).

Anal. Calcd. for $C_{10}H_{16}O_2$: C, 71.39; H, 9.59. Found: C, 71.03; H, 9.31.

(21) Thompson, *J. Chem. Soc.*, 328 (1948).

Attempted lactonization of the Δ^2 acid[22] by heating a mixture of 10 ml. of 60% sulfuric acid with 0.5 g. of a sample of the mixed acids nearly to boiling for five minutes gave a recovery of the mixture, m. p. 104–135°.

In an experiment to esterify the Δ^2 acid[13] 3.0 g. (0.02 mole) of the same mixture was dissolved in 36 ml. of absolute ethanol, and 18 ml. of 1 *N* ethanolic hydrogen chloride was added. After five hours at room temperature and one-half hour of refluxing, the mixture was poured into ice-water, extracted with benzene, the benzene removed at 15 mm. pressure, and the residue recrystallized twice from nitromethane. The product, m. p. 142–143°, was the desired *dl*-phellandric acid, but weighed only 0.3 g. (10% from the mixture).

One milliliter (1.5 g.) of thionyl chloride was added to 0.57 g. of the mixture of Δ^1 and Δ^2 acids, and the resulting acid chloride mixture heated at 100–105° for two hours, then hydrolyzed by stirring in water at room temperature for three hours. The crystals, recrystallized from nitromethane, melted at 134–143°, indicating some concentration of the Δ^1 acid, but the recovery was less than 0.1 g.

***dl*-Phellandric Acid Anilide.**—One hundred grams (0.59 mole) of *dl*-phellandric acid, 500 ml. of dry benzene and 65 ml. (106 g., 1.50 moles) of thionyl chloride, connected to a suitable trap, were allowed to stand for forty-five hours. The benzene and excess thionyl chloride were removed *in vacuo*. The residual acid chloride was dissolved in 1800 ml. of dry benzene in a 3-l. flask and 163 ml. (166 g., 1.78 moles) of aniline was added directly. Some heat was evolved and a white precipitate of aniline hydrochloride formed. After four hours at room temperature, the mixture was filtered to remove the precipitate, and the filtrate evaporated in stages to yield successive crops of crystalline anilide. These were washed in turn with dilute hydrochloric acid, dilute aqueous sodium hydroxide and water. Recrystallization from 4.5 l. of high-boiling petroleum ether yielded 122 g. (84%) of product in the form of fine needles, m. p. 131–132°.

Anal. Calcd. for $C_{16}H_{21}NO$: C, 78.96; H, 8.70; N, 5.76. Found: C, 79.20; H, 8.48; N, 5.87.

***dl*-Phellandral.**—The method of von Braun and Rudolph[14] was followed closely. The imino chloride of *dl*-phellandric acid anilide was prepared from 50 g. (0.21 mole) of the anilide and 43 g. (0.21 mole) of phosphorus pentachloride. Chromous chloride solution was prepared in an atmosphere of carbon dioxide from 70 g. (0.41 mole) of red chromous acetate, kindly prepared by Messrs. Aaron Herrick and Marshall Hatfield,[23] and 275 ml. of 3 *N* hydrogen chloride in absolute ether. Addition of the imino chloride in 100 ml. of dry benzene to the chromous chloride solution gave a brown chromic chloride complex as described by von Braun and Rudolph. After hydrolysis of this and extraction of the aqueous layer with ether, the combined ether–benzene solutions were united with those of a second identical reduction. Evaporation at 15-mm. pressure yielded the Schiff base of *dl*-phellandral as a light brown residue. This was decomposed by means of 1 l. of 10% aqueous oxalic acid, and the *dl*-phellandral steam distilled in about 5 l. of water. The distillate, divided into convenient portions, was extracted four times with a total of 4 l. of ether. The extracts were dried over magnesium sulfate and fractionally distilled under nitrogen in a modified Claisen flask to give 10.4 g. (16%) of *dl*-phellandral, b. p. 103–105° (9 mm.); $n^{20}D$ 1.4896 (lit. for *l*-isomer,[5a] 1.4897); sp. gr. $\frac{20}{20}$ 0.944 (lit. for *d*-isomer,[3] 0.9412[20]); *MR* calcd. (using exaltation of 0.77):[24] 46.5, found: 46.6.

Anal.[25] Calcd. for $C_{10}H_{16}O$: C, 78.88; H, 10.60. Found: C, 77.62, 77.64, 77.48; H, 9.79, 9.90, 10.28.

(24) v. Auwers and Eisenlohr, *J. prakt. Chem.*, **84**, 15 (1911).

(25) The analysis indicates the presence of phellandric acid, an expected result considering the ease of oxidation of phellandral (ref. 3).

The oxime, prepared according to the directions of Shriner and Fuson,[18b] melted at 76–77° when recrystallized as plates from ethanol–water.

Anal. Calcd. for $C_{10}H_{17}NO$: C, 71.80; H, 10.25. Found: C, 72.03; H, 10.42.

Ultraviolet irradiation of the oxime in benzene solution for thirty-six hours resulted in complete recovery of the material melting at 76–77°.

The semicarbazone,[18a] shiny flakes when recrystallized from methanol, melted at 199.5–200.5°.

Anal. Calcd. for $C_{11}H_{19}N_3O$: C, 63.16; H, 9.09. Found: C, 63.17; H, 9.12.

The 2,4-dinitrophenylhydrazone, prepared by the method of Shriner and Fuson,[18c] formed red microcrystals from absolute ethanol, m. p. 194.5–196°.

Anal. Calcd. for $C_{16}H_{20}N_4O_4$: N, 16.87. Found: N, 16.80.

d-Phellandric Acid.—To a mixture of 2920 ml. of petroleum ether (80–110°) and 488 ml. of *n*-butyl alcohol were added 45 g. (0.27 mole) of *dl*-phellandric acid and 101 g. (0.27 mole) of quinine trihydrate. The solution was heated to 60°, filtered hot, allowed to cool slowly to room temperature and finally chilled overnight in an icebox. The precipitated salt was filtered and recrystallized from the same solvent mixture. A second 45-g. portion of acid was treated in the same manner, and the two batches of salt combined and recrystallized seven times. The rotation did not change during the last two crystallizations. There was obtained 24 g. of quinine salt, m. p. 141–143°, $[\alpha]^{25}D$ −100° (0.0288 g./ml. of methanol).

Anal. Calcd. for $C_{30}H_{40}N_2O_4$: C, 73.14; H, 8.18. Found: C, 73.34; H, 8.43.

The quinine salt was dissolved in chloroform and decomposed by shaking with 12 ml. of 5% aqueous potassium hydroxide. The chloroform layer was discarded. The aqueous layer was washed twice with chloroform and then acidified. The precipitated acid was collected on a filter, washed with water and air-dried. It weighed 6.4 g., $[\alpha]^{25}D$ +63° (0.0223 g./ml. of methanol).

The partially resolved acid was dissolved in 300 ml. of a mixture of 1 volume of *n*-butyl alcohol to 20 volumes of petroleum ether (80–110°), and an excess of *l*-α-phenylethylamine was added. The mixture was heated on a steam-cone, then allowed to cool slowly as before. After eighteen recrystallizations from the same solvent mixture the rotation of the salt remained constant. There was obtained 1.27 g. of salt, m. p. 151–152°; $[\alpha]^{25}D$ +70.0° (0.0266 g./ml. of methanol solution).

Anal. Calcd. for $C_{18}H_{27}NO_2 \cdot H_2O$: C, 70.32; H, 9.51. Found: C, 70.66; H, 9.58.

This salt was decomposed in the same manner as the quinine salt to yield optically pure *d*-phellandric acid, m. p. 143–144°, $[\alpha]^{26}D$ +112.2° (0.02054 g./ml. of methanol solution) (lit.,[5b] m. p. 144–145°, $[\alpha]^{20}D$ +112.8° (0.02083 g./ml. of methanol solution)).

Anal. Calcd. for $C_{10}H_{16}O_2$: C, 71.39; H, 9.59. Found: C, 71.25; H, 9.62.

Summary

The structure of the terpene phellandral has been confirmed by the total synthesis of *dl*-phellandral and the resolution of *dl*-phellandric acid.

Flavanones and Related Compounds. VI. The Polarographic Reduction of Some Substituted Chalcones, Flavones and Flavanones

BY T. A. GEISSMAN AND S. L. FRIESS[1]

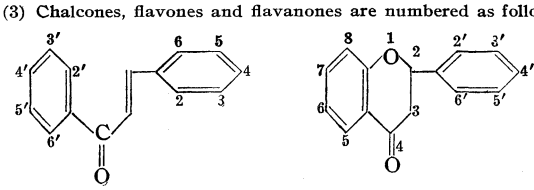
The study of the behavior at the dropping-mercury electrode of substances belonging to the C_6–C_3–C_6 (flavonoid) group of naturally occurring plant substances[2] has been continued. A more detailed examination has been made of some of the questions raised in the earlier part of this work, and a study has now been made of a group of flavones having hydroxyl and acetoxyl groups in the 5-, 7- and 4′-positions.[3] In addition, fourteen flavanones and sixteen chalcones, containing hydroxyl, methoxyl and acetoxyl groups in various positions in both aromatic rings, were examined. In each group the parent compound was included.

The objectives of this study included (1) a correlation between the kind and degree of substitution and the resulting variation in the ease of reduction at the electrode; (2) an evaluation of the most probable electrode mechanism; and (3) an attempt to account for the observed $E_{1/2}$ values on the basis of the proposed electrode reaction and the relative degrees of resonance stabilization of the reactants and products of the electrode reaction.

(1) du Pont Fellow in Chemistry, 1946–1947. Present address: University of Rochester, Rochester, N. Y.

(2) Engelkemeir, Geissman, Crowell and Friess, THIS JOURNAL, **69**, 155 (1947).

(3) Chalcones, flavones and flavanones are numbered as follows:



Experimental

The polarographic runs were made in 50% buffer–50% isopropyl alcohol mixtures at a temperature of 25 ± 0.1°, the $E_{1/2}$ values being measured against the saturated calomel electrode (S.C.E.). The *p*H values recorded for the various buffer mixtures used in the polarographic runs are the nominal ones given by the Beckman *p*H meter. They are in general about 1 *p*H unit higher than those of the aqueous buffer solutions alone.

In the case of the chalcones, the polarograph, buffers and dropping-mercury electrode were those used in the earlier study. Later, a Fisher Electropode was used, the runs with the flavones and flavanones being made with this instrument.

The capillary used for the runs on the flavones

and flavanones had the following characteristics: drop time at zero applied voltage = 3.78 sec.; m = 1.63 mg./sec.; $m^{2/3}t^{1/6}$ = 1.73. In the case of these series the buffers were all acetic acid–tetramethylammonium hydroxide mixtures. This buffer was adopted as a standard despite its poor buffering power at the higher *p*H values, since it was felt best to avoid possible complexities which the use of different (acetate, phosphate and borate) buffers might involve.[4]

Each run was carried out in duplicate, using in most cases different amounts of compound for each polarogram. The curves obtained for such duplicate runs gave reproducible half-wave potentials and wave heights proportional (by measurement, or estimation by inspection) to the sample weights.

In order to compare the Elecdropode with the instrument formerly used, a run was made on flavonol (3-hydroxyflavone), a compound not otherwise included in the present discussion. The value of the half-wave potential for this compound was found in the previous work to be −1.33 volts at *p*H 7.7; the value on the Elecdropode was −1.30 volts at *p*H 7.5. No systematic correction was applied, however, to the values found on either instrument since attention was chiefly directed to the differences observed within each group of related substances.

Since it was considered possible that certain chalcones having 2′-hydroxyl groups might be converted in solution into equilibrium mixtures containing some of the isomeric flavanone, particularly since a thirty-minute deoxygenation period preceded each run, a run was made using a mixture of 2′-hydroxychalcone and flavanone, at *p*H 7.5. The $E_{1/2}$ value for flavanone (−1.37 v.) was unaffected by the presence of the chalcone, and no wave was observed to occur at this point when 2′-hydroxychalcone was run alone under identical conditions. At no time was there any evidence that a flavanone gave rise to the corresponding chalcone, or *vice versa*, under the conditions of the polarographic runs carried out in this work.

Most of the compounds used were on hand or were prepared by known methods.[5]

Each compound was purified before use by recrystallization from an appropriate solvent. **5-Acetoxyflavone** was prepared by the acetylation of the hydroxy compound with acetic anhydride–pyridine. It formed white needles from alcohol, m. p. 121–122°. This changed on recrystallization to the value of 145° reported by Sugasawa.[6] In view of this behavior the compound was analyzed: Calcd. for $C_{17}H_{12}O_4$: C, 72.85; H, 4.32. Found: C, 72.96; H, 4.52.

(4) Furman and Stone, THIS JOURNAL, **70**, 3055 (1948), in a polarographic study of some anthraquinones, found differences in the nature and position of the wave exhibited by a given compound when buffers of the same *p*H but different composition were used.

(5) Geissman and Clinton, *ibid.*, **68**, 597 (1946).

(6) Sugasawa, *J. Chem. Soc.*, 1483 (1934).

Naringenin triacetate was prepared from purified naringenin by Asahina's method.[7] The colorless needles, recrystallized from ethyl acetate–petroleum ether, melted at 82–84°.

Anal. Calcd. for $C_{21}H_{18}O_8$: C, 63.32; H, 5.55; OAc, 32.4. Found: C, 63.28; H, 5.10; OAc, 31.3.

Flavanone was prepared by refluxing 2′-hydroxychalcone in alcoholic hydrochloric acid solution.[8]

Results

In Table I are given summaries of the half-wave potentials and i_d/c values (i_d in microamperes, c in millimoles/liter) for the compounds studied. In general, i_d/c values were measured only for those curves which were clearly separated from adjoining waves. In a number of cases the amount of compound selected for a run proved to be incompletely soluble in the standard volume of buffer–isopropyl alcohol used in the polarograph cell; in such cases the concentration was not known with certainty and no i_d/c value is reported. Enough examples of i_d/c are given, however, to establish the range within which these values fall for each class of compounds studied. It is seen that most of the flavanones give single-wave, the flavones double-wave and the chalcones triple-wave polarograms. Some exceptions to this are observed, and this is regarded in most cases to be the result of the fusion of two waves into a single one. The results can most conveniently be discussed by directing attention to each class of compound separately.

Flavones.—In Fig. 1 are shown polarograms (plotted from Elecdropode readings) for 4′-hydroxyflavone, its acetate and its methyl ether. The two-step nature of the waves is evident, and is in contrast to the single wave of more highly substituted flavones[2] (*e. g.*, quercetin). This point was re-examined by repeating one of the earlier runs on kampferol (3,5,7,4′-tetrahydroxyflavone). This compound showed a single well-defined wave at −1.49 v. in a buffer of *p*H 6.1.[8a] Although some of the compounds show but one wave, it seems likely that this may be the result of the fusion of two steps which occur closely enough together to obscure the plateau between them. This is indicated by the

(7) Asahina and Inubuse, *Ber.*, **61B**, 1514 (1928).

(8) Kostanecki and Szabranksi, *ibid.*, **37**, 2635 (1904).

(8a) The single-wave polarograms of quercetin, kampferol and some related substances were interpreted in the earlier work[2] as indicating a single-electron reduction of these substances, a conclusion which was supported by wave analyses which gave "n" values of about 1. It appears from the present results that this conclusion was incorrect, and that in the case of these compounds the polarograms were actually those of two-electron processes in which two, one electron waves appeared as a single fused wave. An inspection of the diffusion current constants supports this view. In at least one case reported in that paper[2] a double wave was noted (quercetin tetramethyl ether), and it is noteworthy that when the "break" in this curve was ignored, and it was treated as a single wave, the diffusion current constant calculated from the total wave height was in line with those calculated for waves which did not show a distinct "break."

observation that in some series of runs at increasing *p*H the separation between the waves progressively decreases before the fusion into a simple wave occurs.

[a] Half-wave potentials are measured *vs.* the saturated calomel electrode; i_d/c values are in microamperes/millimole/liter. [b] Very small wave. [c] Triple wave with small breaks. [d] Single (fused) wave. [e] Small symmetrical wave. [f] Slight maximum in wave.

Figure 2 shows the variation in half-wave potential with *p*H for a number of the compounds examined. The abrupt shift in $E_{1/2}$ at *p*H values in the region 8–9 has been observed not only in this series but also in the case of similarly substituted chalcones and flavanones. A similar behavior has been used in the case of a series of substituted benzaldehydes by Baker, Davies and Hemming.[9] The same effect was noted in the first part of this study.[2]

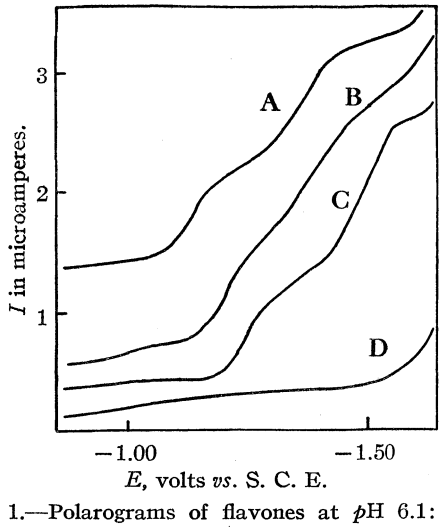

Fig. 1.—Polarograms of flavones at *p*H 6.1: A, 4′-acetoxyflavone; B, 4′-methoxyflavone; C, 4′-hydroxyflavone; D, buffer blank.

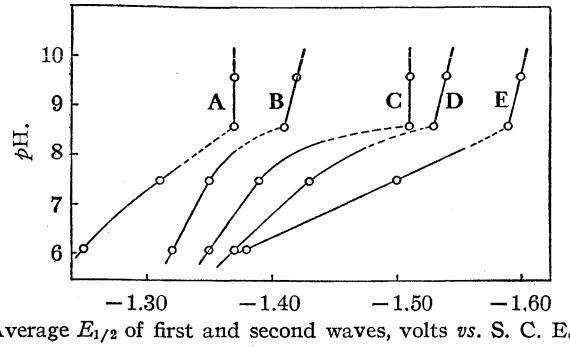

Fig. 2.—Variation of half-wave potential with *p*H: A, 4′-acetoxyflavone; B, flavone; C, 5-hydroxyflavone; D, 4′-hydroxyflavone; E, 7-hydroxyflavone.

Compared with flavone itself, the 5-, 7- and 4′-hydroxy compounds are more difficultly reducible and the corresponding acetyl derivatives more readily reducible. Since the presence of two waves makes it possible to base comparisons on

TABLE II

AVERAGE $E_{1/2}$ VALUES OF FIRST AND SECOND WAVES

either wave or on their average value, the effects of the substituents are best seen when the latter basis is adopted (Table II), although at *p*H 7.5 and 8.6 the effects are clearly apparent on either basis (Table I). 4′- and 7-hydroxyflavone show substantially the same values of $E_{1/2}$ in the range below *p*H 8.6, while 5-hydroxyflavone shows lower $E_{1/2}$ values at all *p*H's. A series of studies by Scaramelli[10,11] on hydroxybenzaldehydes and their ethers has shown a similar relationship between the effects of an ortho-(corresponding to 5- in the flavones) and a para-(corresponding to 7-) hydroxyl group, *p*- and *o*-hydroxybenzaldehydes being more difficultly reducible than benzaldehyde, but the ortho- compound being more easily reduced than the para-. Similar results are reported for the corresponding hydroxyacetophenones.[12,13]

Although the differences in $E_{1/2}$ values for the three hydroxyflavones and their derivatives are small, their reproducibility and the essential simplicity of the structures of these compounds is such that these effects are properly subject to interpretation. The decreased acidity of the 5-hydroxyl group in chromone derivatives (and in general, of hydroxyl groups *peri* to carbonyl groups in other systems) is a well-known property manifested by its greater difficulty of methylation with diazomethane and in the diminished solubility of 5-hydroxyflavone derivatives in aqueous alkali. It is to be expected, then, that throughout the *p*H range used in this work the anionic character of the 5-hydroxyl group would be less than that of the 7- or the 4′-hydroxyl group. Since, as will be shown in the sequel, there is good reason to ascribe the effects of these hydroxyl groups upon the ease of reduction of the carbonyl group to their ability to release electrons into the ring, the greater anionic character of the 7-hydroxyl group would allow it to have a greater effect upon the reducibility of the carbonyl group than the 5-hydroxyl group. The greater (negative) $E_{1/2}$ value of 7-hydroxyflavone than of 4′-hydroxyflavone at *p*H 9.6 may be ascribed to the greater acidity of the 7-hydroxyl group and its assumption of a greater degree of anionic character at this *p*H. Although at lower *p*H values, where the effects of un-ionized hydroxyl groups are probably predominant, very small differences in *pK* values would not be apparent, at higher *p*H values the increasing role of the anionic oxygen atoms should cause an increasingly wider separation of their effects. On the basis of these considerations the $E_{1/2}$ values of the hydroxylated flavones are in accord with expectations.

At a low *p*H (6.1) the hydroxyflavones and flavone itself show almost identical $E_{1/2}$ values for the first wave, the second wave only showing the greater ease of reduction of the parent compound. Since flavone contains the same heterocyclic oxygen atom as the hydroxyl-substituted derivatives, it is probable that this oxygen atom is of the greatest influence in affecting the ease of carbonyl reduction in all of these compounds, the effects of the nuclear hydroxyl groups superimposing themselves markedly upon this effect only at *p*H values which permit them to assume an appreciable amount of anionic character.

An examination of the diffusion current constants (i_d/c) for the flavones (Table I) shows that these are of about the same order of magnitude. The approximately twofold variation over all the values measured follows no consistent pattern. The values appear to be those of one-electron steps, since they correspond closely in order of magnitude with those observed by Pasternak[14] for a group of related substances. For example, Pasternak finds i_d/c values of approximately 2, with variations of about ± 0.3, in most cases, for steps involving one-electron electrode reactions of a number of carbonyl compounds. An inspection of Table I shows that for the flavones examined, i_d/c values of comparable magnitude were found. Closer agreement than is actually found need not be expected in view of the considerable structural differences in the compounds examined by Pasternak and in this work. Smith and his co-workers[15] likewise found diffusion current constants of approximately the same magnitude (*ca.* 4, for two-electron steps) for a series of hydroxychromanes and -coumaranes.[15a]

Wave analyses, by means of the equation

$$E = \text{constant} - \frac{0.059}{n} \log \frac{i}{i_d - i}$$

for a number of the compounds studied give n values of about 1 for each wave. This result, while not a demonstration that these are actually one-electron steps, since it is not known whether these are reversible processes, is at least consistent with the view that each wave represents a one-electron process. Müller[16] takes the view that while such wave analyses may not be strictly valid for irreversible processes, the n values so obtained may be regarded as approximations to the nearest integer of the number of electrons involved in the wave. In Figs. 3 and 4 are shown

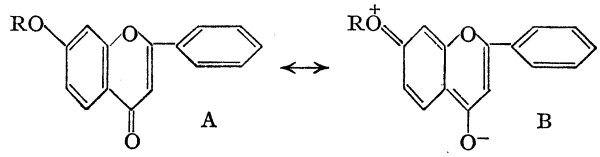
wave analyses for both waves of 7-hydroxyflavone. The values of n found from these and several other such wave analyses are given in Table III.

TABLE III

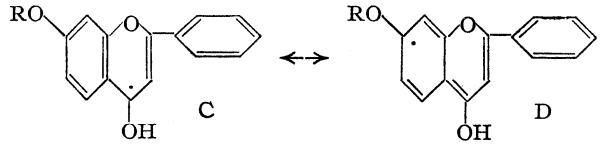
Flavone	*p*H	1/slope of E *vs.* log $i/(i_d - i)$	n
7-OH (1)	6.1	−0.055	1.1
7-OH (2)	6.1	− .081	0.7
7-OH	9.6	− .112	.5
3-OH	7.5	− .064	.9
4′-OAc	8.6	− .070	.8

The polarographic reduction of organic compounds in distinct one-electron steps has been interpreted in a number of cases[14,16,17,18,19] as indicating the intermediate existence of a "semiquinone," or free radical, at the electrode. The behavior of the flavonoid compounds (of all three classes) studied in the course of the present work, can be accounted for in the light of the effects of structure upon the stabilization of the free radical produced in an initial, one-electron, electrode reaction. It is possible to arrive at a consistent treatment of the observed results if it is assumed that a greater degree of stabilization of the free radical as compared with the unreduced form (the oxidant) should result in a greater ease of reduction, as compared with another substance in which the substituents reduce the relative stabilization of the radical with respect to the oxidant.

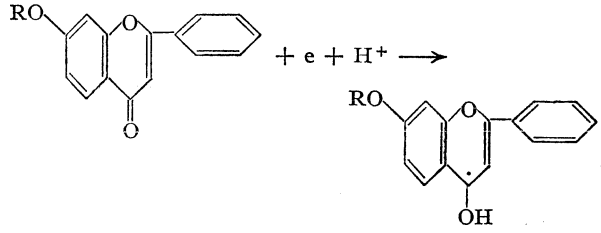
For illustration, consider the 7-substituted flavones. The forms A⟷B are among those contributing to the structure of the resonance hybrid of the unreduced form



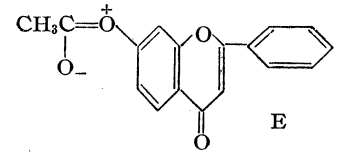
and forms C⟷D may be considered among those contributing to the structure of the one-electron-reduced product (the free radical), where forms



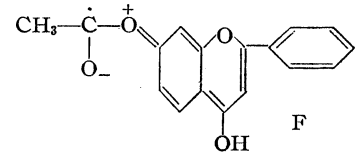
C, etc., may be considered to be the immediate product of the initial electrode reaction, according to the equation



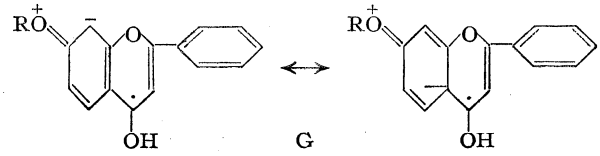
In the acetoxy compound (R = CH_3CO–), the stabilization of the oxidant will be diminished as a result of contributions from the opposing effect E



while that of the radical will be enhanced by a form F



It is apparent that when R = CH_3, form B will be relatively more effective than form D, since the latter will be opposed by forms G



(17) Brdička, *Z. Elektrochem.*, **47**, 314 (1941).

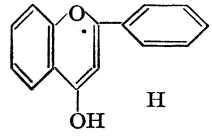
and consequently it is to be expected that the acetoxy compound should be more easily reduced than the methyl ether.

It is seen from Table I and Fig. 5 that flavanones show single-wave polarograms, and undergo an initial electrode reaction involving one electron. A reason for two-step waves in the case of flavones can therefore be suggested. The greater stabilization of a form such as C⟷D, through participation of the chromone ring as in H



allows it to persist at the electrode and to be reduced further in a second electrode reaction. A flavanone, on the other hand, lacks the added possibilities for stabilization of the radical through the participation of such forms as H, and consequently undergoes disproportionation or dimerization in the free radical stage before a second electrode step can ensue, giving rise to a product which is not reducible at the electrode in the range of voltage used.

Flavanones.—An examination of the diffusion current constants for the flavanones studied shows that these are in most cases somewhat greater than those characteristic of a one-electron potential-determining electrode reaction. An unusual and unexplained feature of the i_d/c values for some of the flavanones is the sharp drop (from about 2 microamperes/mmole./liter to less than 1) noticed at high *p*H values. Wave analyses for a representative number of the compounds give n values of about 1, but the E *vs.* log $(i/i_d - i)$ plots showed a tendency to deviate from straight lines, vitiating even the approximate nature of this check on the number of electrons involved in the wave being analyzed.

The relative ease of reducibility of each flavanone can be related to the unsubstituted compound (9) as a standard. With increasingly more negative $E_{1/2}$ values, indicating increasing difficulty of reduction, the $E_{1/2}$ values of Table I may be used directly as a measure of the ease of reduction, and a correlation can be found between these values and particular kinds of nuclear substitution present.

It is seen by a comparison of the $E_{1/2}$ values at a *p*H of 6.1 for the flavanones 9, 10, 16 and 17 that the introduction at the 4′-position of the electron-supplying groups hydroxyl or methoxyl, or of the electron-withdrawing acetoxyl group, leads to no significant effect upon the ease of reduction relative to the unsubstituted flavanone. In view of the manner in which such substituents act to affect the ease of reduction of the flavones discussed above, this comparison demonstrates that substitution in a position not conjugated with the carbonyl group, and therefore incapable of affecting it by resonance, leads

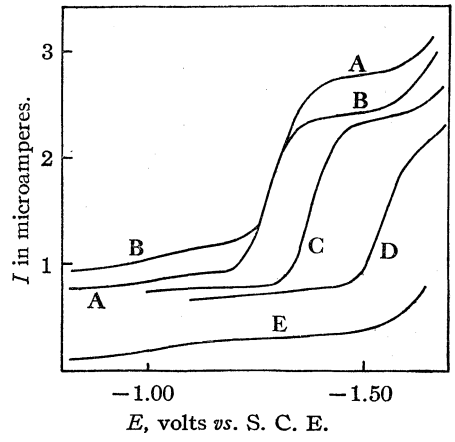


Fig. 5.—Flavanone polarograms at *p*H 6.1: A, flavanone; B, 4′-hydroxyflavanone; C, 4′,5-dihydroxyflavanone; D, 4′,5,7-trihydroxyflavanone; E, buffer blank.

to no influence on the ease of reduction of such substituted compounds. The non-effectiveness of substitution in the 2-phenyl group is further illustrated by a comparison of the $E_{1/2}$ values for compounds 14 and 15.

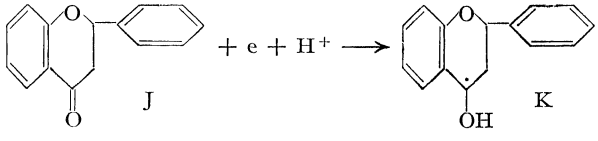
In the resonance-effective (*i. e.*, with respect to the carbonyl group) 5- and 7-positions, however, the effect of varying substitution is marked. The effect of substitution in the 5-position is shown by comparing the $E_{1/2}$ values for 9 (−1.29), 10 (−1.39), and the first wave of 21 (−1.22). Since a substituent in the 4′-position is ineffective, it is seen from this comparison that for the carbonyl-conjugated 5-position, substitution of an electron-supplying hydroxyl group increased the difficulty of reduction while an electron-withdrawing acetoxyl group decreases the difficulty of reduction as compared with flavanone (9).

The relative effectiveness of electron supply by the hydroxyl and methoxyl groups, so far as these reductions are concerned, is shown (with reference to position 7) by a comparison of the $E_{1/2}$ values for compounds 9 (−1.29), 12 (−1.45) and 17 (−1.40). Here, the order of electron supply, interpreted from the relative ease of reducibility, is OH > OMe > H, as would be expected.

The effect of the acetoxyl group with respect to electron supply is shown, for example, by a comparison of flavanone 9 with 13, 18 and 22. The acetoxyl group is evidently electron-attractive relative to hydrogen, an effect clearly shown by the behavior of flavanone 22 in this series.

It is further evident from an inspection of the $E_{1/2}$ values for the flavanones examined that a multiplicity of substituents in resonance-important positions leads to additivity of their effects upon the ease of reduction. Among the comparisons that can be cited to show this are: (1) increasing difficulty of reduction in the series 10, 11, 12, 13 (see Fig. 5), and (2) increasing ease of reduction in the series 20, 21, 22. The

magnitude of the i_d/c values indicates that the electrode reaction involves a two-electron change, although the n values from wave analyses indicate one-electron steps. An examination of the change in $E_{1/2}$ with pH shows that (Fig. 6) hydrogen ion also participates in this reaction. It is therefore likely that the electrode process involves the potential-determining reaction



The occurrence of only a single step of reduction can be ascribed to the instability of the primary electrode product K, which lacks the stabilization from the (unconjugated) 2-phenyl group found with the fully conjugated flavones and chalcones, and which immediately adds a second electron in a rapid second stage to yield a single-wave polarogram with a wave height corresponding to a two-electron reduction.

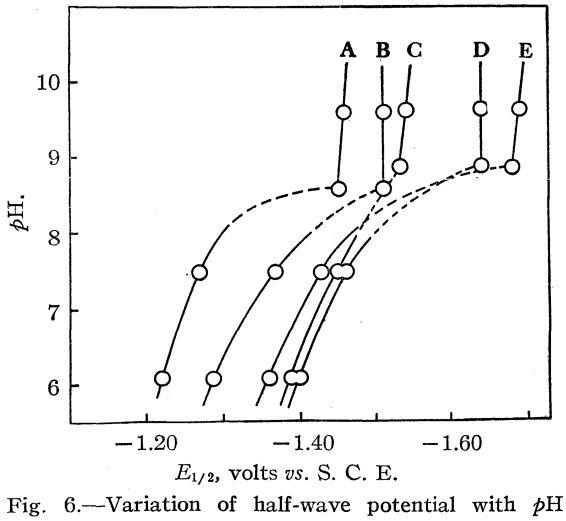


Fig. 6.—Variation of half-wave potential with pH: A, 4′,5-diacetoxyflavanone; B, flavanone; C, 4′,5-dihydroxyflavanone; D, 4′,7-dimethoxyflavanone; E, 4′,5,7-trimethoxyflavanone.

The arguments, based upon substitution effects, that favor this mechanism are virtually the same as those previously advanced in the discussion of the flavones. The substitution of electron-releasing groups such as hydroxyl or methoxyl in positions conjugated with the carbonyl group causes increased resonance stabilization in form J, relative to the unsubstituted state, but no increased (or decreased) stabilization of the reaction product K. Hence, this kind of substitution leads to increasing difficulty of the production of K by electrode reduction, as compared to the unsubstituted molecule, and is reflected in a shift of the half-wave potentials to the more negative values observed.

Chalcones.—The complex nature of the waves given by the chalcones studied is apparent from the data given in Table I. Figure 7 shows clearly the kind of curves from which these values were obtained. These polarograms are those of chalcone and of three chalcones carrying one, two and three hydroxyl groups in positions joined by conjugation with the carbonyl group.

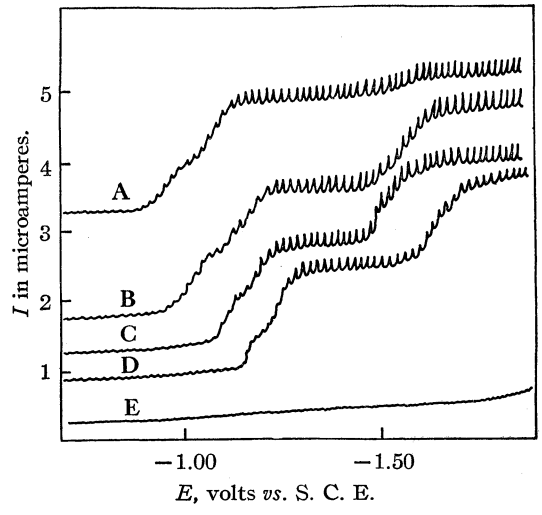

Fig. 7.—Chalcone polarograms (at pH 7.7): A, chalcone; B, 2′-hydroxychalcone; C, 2′,4-dihydroxychalcone; D, 2′,4′,4-trihydroxychalcone; E, buffer blank.

The diffusion current constants (i_d/c), while somewhat more variable than those found for the flavones and flavanones, appear to fall in the range typical of one-electron electrode reactions; the values for chalcones are in the majority of cases in the range of 1–2. Wave analyses have been carried out for a number of the polarograms, the values found for n being summarized in Table IV. In Fig. 8 are shown plots of E *vs.* log $(i/i_d - 1)$ for the three waves of chalcone (23). The agreement between the evaluation of n by this method and by estimation from diffusion current constants is shown by the data of Table IV, in which the n values range from 0.7–1.4 for the

TABLE IV

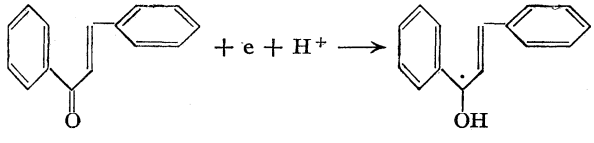
fourteen cases listed. It appears that the conclusion is a sound one that the waves of the chalcone polarograms represent one-electron potential-determining reactions.

Of the three waves, the first two appear to depend upon the degree of hydroxylation of the chalcones. The third shows no such regular dependence upon structure. These relationships are shown more clearly in Figs. 9 and 10, in which are plotted $E_{1/2}$ values as functions of the *p*H at which they were measured (Fig. 9, averaged first and second waves; Fig. 10, third waves). The $E_{1/2}$ values become essentially *p*H-independent above *p*H values of about 8–9; and between *p*H 6–8 the slopes of the curves are reasonable approximations to 0.06 v./*p*H unit. This indicates the participation of hydrogen ions in the electrode reactions.

The dependence of the half-wave potentials upon the degree of hydroxylation resembles that observed in the cases of flavone and flavanone derivatives. The following initial electrode reaction is suggested



The free radical produced can be stabilized by resonance involving a number of contributing forms, the important ones being represented by structures having the free electron on the β-carbon atom or at three positions in each of the aromatic rings. As in the case of the flavones, the considerable stabilization afforded by the participation of a number of structures makes it possible for a second electrode reaction to occur

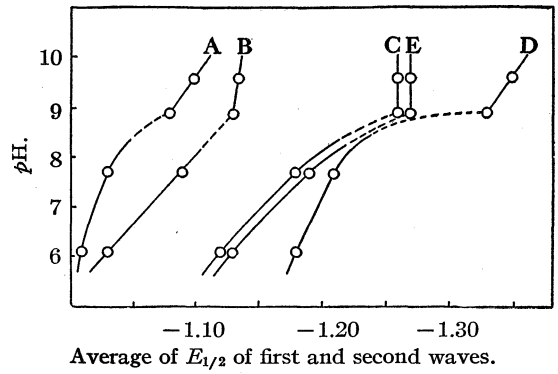


Fig. 9.—Variation of half-wave potential with *p*H: A, chalcone; B, 2′-hydroxychalcone; C, 2′,4-dihydroxychalcone; D, 2′,4′,4-trihydroxychalcone; E, 2′-hydroxy-4′,6′,4-trimethoxychalcone.

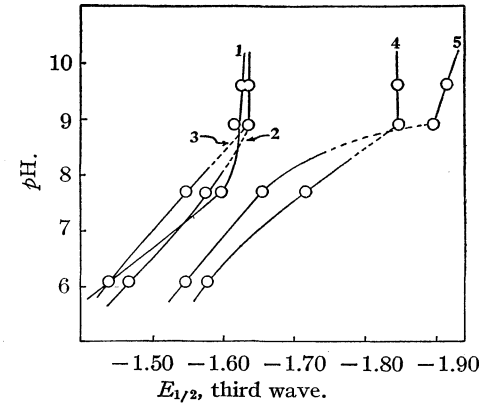

Fig. 10.—1, chalcone; 2, 2′-hydroxychalcone; 3, 2′,4-dihydroxychalcone; 4, 2′-hydroxy-4′,6′,4-trimethoxychalcone; 5, 2′,4′,4-trihydroxychalcone.

at higher potentials, leading to further reduction rather than to dimerization or disproportionation. The second wave can be the result of more than one kind of reduction of the free radical, but appears to be subject to the same kind of structural influences as affect the first wave. This is shown by the nature of the dependence of its half-wave potential upon structure and the fact that the effects of *p*H changes upon the first wave are also shown by the second wave.

The third waves show what appear at first sight to be erratic variation with those changes in substitution which cause regular variations in the first two waves. The data suggest the possibility

TABLE V

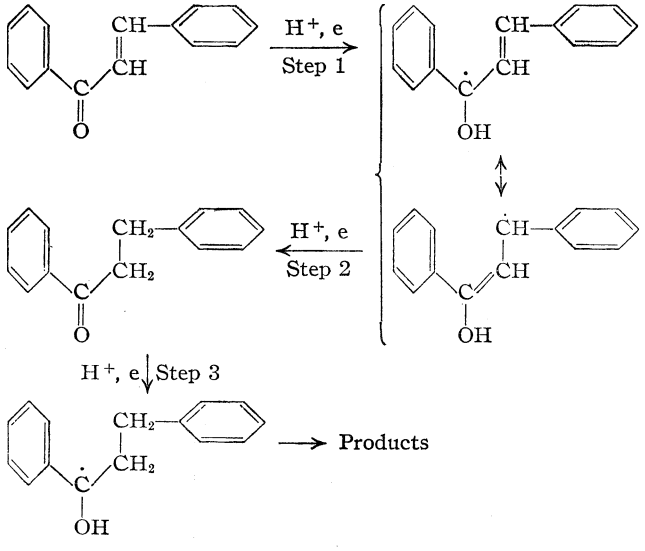
that the third wave represents the reduction of a substance which no longer possesses an α,β-unsaturated carbonyl system, but which contains a structural element such as a carbonyl group attached to an aromatic ring. This supposition is supported by the observation that the third wave occurs at $E_{1/2}$ values in the range of those reported by Scaramelli[12] for hydroxylated acetophenone derivatives. The values in Table V show this correspondence.

From the considerations of the foregoing discussion, the following sequence of steps at the electrode can be suggested (using chalcone as a typical example).



This sequence of electrode reactions makes it possible to account for the occurrence of three waves, and also for the considerably greater ease of reduction of chalcones than of similarly substituted flavones and flavanones. If one compares the considerably greater possibility for resonance stabilization of the initial free radical, as compared with the original chalcone, with the corresponding differences between the unreduced and free-radical forms of flavones and flavanones, it is seen that the chalcone free radical is *preferentially* stabilized to the greatest degree, that of a flavone next, and that of a flavanone least. This is completely in accord with the relative ease of reduction at the electrode of chalcone > flavone > flavanone.

Summary

A study has been made of the effect of substitution of hydroxyl, alkoxyl and acetoxyl groups upon the ease of reduction of a group of flavones, flavanones and chalcones at the dropping-mercury electrode. When these groups are present in positions conjugated with the carbonyl groups in these compounds, hydroxyl and methoxyl groups decrease, and acetoxyl groups increase, the ease of reduction.

The results have been interpreted in terms of one-electron electrode reactions and the relative stabilities of the unreduced compounds and the initial free radicals produced in the first stage of the electrode process.

Flavanones give single-wave, flavones double-wave and chalcones triple-wave polarograms. It is suggested that these behaviors are due to the successive reduction at the electrode of the unreduced compound and one-electron-reduced intermediates.

Experimental Vapor Heat Capacities and Heats of Vaporization of 2-Methylpentane, 3-Methylpentane and 2,3-Dimethylbutane[1]

BY GUY WADDINGTON, J. C. SMITH,[2] D. W. SCOTT AND H. M. HUFFMAN

This paper is a further contribution from the thermodynamic research program of the Petroleum and Natural-Gas Branch of the Bureau of Mines. The vapor heat capacities and heats of vaporization of 2,2-dimethylbutane and *n*-hexane have already been measured in this Laboratory.[3] Similar data for the three remaining hexanes are presented here. In the case of the heat-capacity measurements, the temperature range was from approximately the normal boiling point of the compound to 200°. Heats of vaporization were determined at temperatures corresponding to saturated pressures of about one-quarter, one-half and one atmosphere.

Experimental

Apparatus and Method.—Since the apparatus and experimental procedures used were essentially as described in detail in an earlier paper,[4] only a brief account of them will be given here.

A measured, constant flow of hydrocarbon vapor was produced by electrical heating in a cycling vaporizer. This was passed through a flow calorim-

eter in which the temperature rise, produced in the vapor by a measured power input, was measured by means of platinum resistance thermometers. The apparent heat capacity of the vapor, $C_{p(\text{app.})}$ is given by $W/F\Delta T$ where W is the power supplied to the calorimeter, F is the flow per unit of time and ΔT is the observed temperature rise. Heat losses from the calorimeter are such that $C_{p(\text{app.})} = C_p + k/F$ where C_p is the true heat capacity. Hence, by measuring apparent heat capacities at several flow rates, then plotting $C_{p(\text{app.})}$ *vs.* $1/F$ and extrapolating to zero value of $1/F$, corrected values of C_p are obtained. The heat-capacity data are believed accurate to $\pm 0.2\%$. By measuring heat capacities at two or more pressures and extrapolating linearly to zero pressure the heat capacity of the ideal gas is obtained.

The proportionality between flow of vapor and electrical energy supplied to the vaporizer was determined by condensing and weighing the vapor produced, by a measured power input, during a measured time interval. This measurement, when properly corrected,[4] yields heats of vaporization believed to be accurate to about $\pm 0.1\%$.

The apparatus, as originally described,[4] has been modified slightly. The *aneroid* manostat[5] now used gives good control, and with it small or large changes of the pressure setting can be made very conveniently. The measurement of time has been made more accurate by use of fifty cycle alternating current obtained from a General Radio 816A Precision Tuning Fork Unit and a special power amplifier.

Materials.—The 2-methylpentane was Phillips Technical Grade, which, by a preliminary distillation for other purposes, had been brought to a purity of approximately 98 mole per cent. Further distillation in a 100-plate column, at an initial reflux ratio of 140:1 and a final reflux ratio of 90:1, resulted in a material having the following properties: d^{20}_4 0.6531, $n^{20}D$ 1.37145. The purity, determined from a melting curve, assuming liquid-soluble, solid-insoluble impurities, was 99.88 mole per cent.

The 3-methylpentane was also Phillips Technical Grade, which was purified by distillation at the Laramie Station of the Petroleum and Natural-Gas Branch of the Bureau of Mines. Since attempts to crystallize 3-methylpentane have not been successful, an analysis by means of the freezing behavior was impossible. By analogy with a sample of 2-methylpentane having a similar history, it is believed that the material used had a purity greater than 98 mole per cent. It had the following properties: d^{20}_4 0.6644, $n^{20}D$ 1.37647.

The 2,3-dimethylbutane was Phillips Pure Grade. It was purified further by distillation in a 100-plate column at a reflux ratio of 100:1. The purity estimated from a freezing curve was 99.87 mole %. It had the constants d^{20}_4 0.6616, $n^{20}D$ 1.37501. Whenever air had access to this compound, it was protected from peroxide formation by the addition of about 0.02 per cent. of a commercial anti-oxidant known as "tri-alkyl phenol."

Heats of Vaporization.—Table I gives a summary of the heats of vaporization of the three compounds investigated. For each compound, there is available for comparison an accurate value at 25° from the work of Osborne and Ginnings.[6] The largest difference observed, six calories at 25° for 2-methylpentane, is within the estimated $\pm 0.1\%$ uncertainty of the present work. The values reported by Lemons with Felsing[7] tend, as in the case of *n*-hexane, to be approximately 1% lower than the values here reported.

TABLE I

HEATS OF VAPORIZATION OF 2-METHYLPENTANE, 3-METHYLPENTANE AND 2,3-DIMETHYLBUTANE

29.87	2	6900 ± 2	6899
39.97	3	6769 ± 5	6770
57.99	3	6519 ± 6	6521

[a] 1 cal. = 4.1833 int. joules; at. wt. carbon = 12.01; at. wt. hydrogen = 1.008. [b] Maximum deviations from the mean.

For interpolation to intermediate temperatures, the following equations may be used without significant loss of accuracy:

2-methylpentane: $\Delta H_{\text{vap.}} = 9173 - 0.2673T - 0.02196T^2$
3-methylpentane: $\Delta H_{\text{vap.}} = 9688 - 3.366T - 0.01629T^2$
2,3-dimethylbutane:
$\Delta H_{\text{vap.}} = 8461 + 2.233T - 0.02438T^2$

The last column of Table I lists values calculated with these equations.

Vapor Heat Capacities.—The molal vapor heat capacity of each compound was measured at five temperatures ranging from slightly below the normal boiling point to approximately 200°. At each temperature, measurements were made at two and, in some cases, three pressures. Table II summarizes the experimental values.

Heat Capacity in the Ideal Gas State.—From the data given in Table II, values of the heat capacity of the ideal gas were obtained at each temperature by plotting C_p *vs.* P and extrapolating to zero pressure. The validity of the linear extrapolation over the pressure range studied has been verified by determining heat capacities at three different pressures for *n*-hexane,[3] *n*-heptane[4] and benzene[8] in addition to two of the three compounds reported here. Wacker, Cheney and Scott[9] have also demonstrated this point in the case of isobutane at −30.0°.

Values of C_p°, the heat capacity of the ideal gas, are summarized for the three compounds in Table III. Over the temperature range of the experiments, the following empirical equations represent the experimental results without significant loss of accuracy. The maximum deviations of the experimental points from the empirical equations are given in parentheses.

2-methylpentane: (±0.06% 341 − 471°K.)

$$C_p^\circ = 1.55 + 0.11963\ T - 3.478 \times 10^{-5}\ T^2$$

3-methylpentane: (±0.04% 332 − 471°K.)

$$C_p^\circ = 1.40 + 0.11776\ T - 3.291 \times 10^{-5}\ T^2$$

2,3-dimethylbutane: (±0.02% 325 − 471° K.)

$$C_p^\circ = -2.65 + 0.13692\ T - 5.433 \times 10^{-5}\ T^2$$

Figure 1 shows differences between the ideal gas heat capacities of the isomeric hexanes. Data used in this plot are from the present work and from earlier published work[3] from this Laboratory. Over the temperature range studied, differences between the heat capacities of the isomers do not exceed 2%.

Pitzer and Kilpatrick[10] have calculated heat capacities of the ideal gas for the isomeric hexanes by approximate statistical methods. The results so obtained have received wide distribution in the tables published under the auspices of API Project 44[11]; hence it is of interest to compare the calculated values with those obtained experimentally. Table IV makes this comparison at two temperatures. In most cases the calculated results are higher than the experimental values by amounts larger than the estimated accuracy uncertainty of the latter. However, the absence of any gross discrepancies will increase confidence in the extensive compilations of statistically calculated vapor heat capacities[11] where no experimental checks exist.

Second Virial Coefficients from Thermal Data.—From the heats of vaporization and from published vapor-pressure data[12] molal volumes of the vapor were calculated at several temperatures for each compound by use of the exact Clapeyron equation $\Delta H_{vap.} = T(V_g - V_l)\ dP/dT$, in which V_g and V_l indicate molal volumes of vapor and liquid, respectively. Further information concerning vapor volumes as a function of tempera-

[a] Heat of vaporization from ref. 6.

ture was supplied by the fact that the experimentally determined values of $(\partial Cp/\partial P)_T$ are equal to $-T(\partial^2 V/\partial T^2)_P$. The two types of thermal data were correlated by means of the following empirical relations for the second virial coefficient B (defined by $PV = RT + BP$).

2-Methylpentane; $B = -390 - 40.26e^{1050/T}$ cc.
3-Methylpentane; $B = -318 - 91.9e^{800/T}$ cc.
2,3-Dimethylbutane; $B = -526 - 21.9e^{1150/T}$ cc.

The parameters were evaluated by previously reported methods.[8]

Table V gives data for 2-methylpentane, 3-methylpentane and 2,3-dimethylbutane which illustrate the correlations obtainable by use of these expressions for the second virial coefficients. In all cases differences between the observed and calculated values of B correspond to combined errors in the experimental values of $\Delta H_{vap.}$ and dP/dT of less than 0.1%. Reference to the last three columns of Table III further illustrates the correlations obtainable with the expressions for the second virial coefficients and also calls attention to the errors to which the Berthelot equation of state leads in calculating $C'_p - C^\circ_p$ in the region of the normal boiling point.

Kay[13] has made direct determinations of the densities of the isomeric hexanes from the normal boiling points to the critical temperatures. Table VI makes a comparison, at two temperatures, of Kay's data and vapor densities calculated from second virial coefficients. At the lower temperature, which is slightly above the normal boiling point, the agreement is within the ±0.0002 g./cc. which Kay[14] assigns to his work. In this region the use of the second virial coefficient might be expected to give more accurate results. The results at the higher temperature involve a considerable extrapolation of both temperature and pressure in the use of the second virial coefficients and yet the agreement is fair. The available evidence (see also ref. 8) suggests that second virial coefficients

derived from thermal and vapor-pressure data give an accurate and convenient method of determining volumes and related properties within the temperature and pressure range prescribed by their experimental bases.

Entropies.—The entropies of gaseous 2-methylpentane and 2,3-dimethylbutane at 298.16°K. have been computed by Pitzer and Kilpatrick.[10] The heat of vaporization and second virial coefficient data of this paper made it possible to calculate the entropies at other temperatures up to the normal boiling point and to refine the values at 298.16° K. by taking account of gas imperfection. These entropy calculations are summarized in Table VII. The values for the entropy of the liquids are from the work of Douslin and Huffman[15]; at the two higher temperatures moderate extrapolations of the heat-capacity curves for the liquids were required. The vapor-pressure equations of ref. 12 were used.

Since 3-methylpentane has never been frozen, the entropy of the liquid has not been obtained from low-temperature studies. For this compound, values for the entropy of vaporization to the ideal gas at atmospheric pressure were computed, and these calculations are included in Table VII.

Acknowledgments.—We wish to thank Mr. J. W. Tooke of the Phillips Petroleum Company for help in obtaining the hydrocarbon samples. We are also indebted to Mr. B. H. Eccleston and Mr. H. J. Coleman for the distillations and purity determinations on the three samples.

Summary

The vapor heat capacities of 2-methylpentane, 3-methylpentane and 2,3-dimethylbutane have been measured over the temperature range 325 to 471°K. Values of the heat capacity of the ideal gases are given by the following empirical equations.

2-Methylpentane:
$$C_p^\circ = 1.55 + 0.11963T - 3.478 \times 10^{-5}T^2$$
3-Methylpentane:
$$C_p^\circ = 1.40 + 0.11776T - 3.291 \times 10^{-5}T^2$$
2,3-Dimethylbutane:
$$C_p^\circ = -2.65 + 0.13692T - 5.433 \times 10^{-5}T^2$$

Heats of vaporization for the three compounds were measured at three temperatures ranging from about 25° to the normal boiling point. For interpolation the following equations may be used:

2-Methylpentane:
$$\Delta H_{vap.} = 9173 - 0.2673T - 0.02196T^2$$
3-Methylpentane: $\Delta H_{vap.} = 9688 - 3.366T - 0.01629T^2$
2,3-Dimethylbutane:
$$\Delta H_{vap.} = 8461 - 2.233T - 0.02438T^2$$

Entropies of 2-methylpentane and 2,3-dimethylbutane in the ideal gas state are given at the normal boiling points, at 298.16°K. and at an intermediate temperature.

Second virial coefficients derived from the thermal data are shown to be consistent with literature data on vapor densities.

The Solubility of Cuprous Chloride and Silver Bromate in Aqueous Solutions of Unsaturated Alcohols[1a]

BY R. M. KEEFER, L. J. ANDREWS AND R. E. KEPNER

Extensive information concerning the reactions of allyl alcohol and certain unsaturated acids to form water-soluble complexes with cuprous ion and cuprous chloride has been accumulated.[1b,c,d,e,f]

By solubility measurements of the type used in previous investigations data have now been obtained concerning the tendency for certain allylic alcohols to form cuprous complexes. The equilibrium constants for these metalation reactions are reported here and are compared with those obtained for the unsaturated acids. Measurements of the solubility of silver bromate in aqueous solutions of certain of these alcohols and of a few other compounds of interest are also reported, the results of which may be explained satisfactorily on the assumption that a 1:1 complex between silver ion and the unsaturate is formed.[2] Thus data are available for a comparison of the relative tendencies for cuprous and silver ions to coördinate with a carbon–carbon double bond.

The Solubility Measurements.—The method of determining the solubility of cuprous chloride in aqueous solutions of unsaturated compounds has been described previously.[1d,e,f] All solutions were prepared and saturated with cuprous chloride or silver bromate at 25.0°. For the cuprous chloride series the chloride-ion concentration was varied by addition of hydrochloric acid and the ionic strength maintained at 0.100 by addition of perchloric acid prior to addition of solid cuprous chloride. In the silver bromate experiments potassium nitrate was added to the aqueous solutions of the unsaturated compounds to adjust the ionic strength to 0.10 prior to addition of solid silver bromate. Aliquots of the solutions saturated with silver bromate were analyzed for total silver ion by adding a measured excess of 0.0500 M

sodium chloride solution and back titrating the excess chloride ion using 0.0250 *M* silver nitrate with dichlorofluorescein as an indicator. High concentrations of alcohol interfere with the action of the indicator. In the case of 4-methyl-4-penten-2-ol, γ,γ-dimethylallyl alcohol, 3-methyl-3-buten-2-ol and 2-methyl-2-buten-1-ol the low solubility of the alcohols in water did not allow a wide variation in alcohol concentrations. With vinylacetic acid (μ = 1.0 using perchloric acid) and phenol (μ = 0.10 using potassium nitrate) the saturated solutions were analyzed for total silver ion by adding excess sodium bromide and weighing the silver bromide formed. The solubility product of silver bromate was determined in 1.00 *N* perchloric acid and in 0.100 *N* potassium nitrate. High concentrations of β-chloroallyl alcohol were needed in aqueous solution to dissolve measureable amounts of cuprous chloride. The equilibrium constants for this compound were found to vary somewhat with alcohol concentration of the medium. The results reported for this compound are thus significant only as regards the relative magnitude of the equilibrium constants as compared to those for the other alcohols studied.

Cuprous Chloride and Silver Bromate.—Cuprous chloride was prepared as described previously.[1b] Silver bromate was prepared according to the directions of Neuman.[3] The product was dried for two hours at 110°, powdered and analyzed for silver content.[4] Found: Ag, 45.90. Calcd.: Ag, 45.75.

The Unsaturated Alcohols.—The crotyl alcohol (b. p. 121.0–121.2°) was prepared from crotonaldehyde.[5] Methylvinylcarbinol (b. p. 97.3°) was prepared by hydrolysis of a butenyl chloride mixture.[6] Ethylvinylcarbinol (b. p. 113.8–114.0°) was prepared from ethylmagnesium bromide and acrolein.[7] Samples of β-methallyl alcohol (b. p. 142°), β-chloroallyl alcohol (b. p. 134.0°) and 4-methyl-4-penten-2-ol (b. p. 130.3°), furnished through the courtesy of the Shell Chemical Corporation, were dried and fractionated before use. Small samples of 3-methyl-3-buten-2-ol (b. p. 115–117°), 2-methyl-2-buten-1-ol (b. p. 138.0°), α,α-dimethylallyl alcohol (b. p. 96.0–96.5°) and γ,γ-dimethylallyl alcohol (b. p. 142–143°), kindly furnished by Professor W. G. Young and Mr. J. Rule of the University of California at Los Angeles, were dried and fractionated. J. T. Baker C. P. phenol was distilled and a fraction of b. p. 177–178° (uncor.) was collected. The preparation of the sample of vinylacetic acid has been described previously.[1e]

Results

The solubility of cuprous chloride in aqueous solutions of unsaturated alcohols is given in Table I. As in the studies of unsaturated acids[1e,f] the following equations may be shown to account for the formation of water soluble cuprous species in the experiments reported in this communication.

$$CuCl = Cu^+ + Cl^- \quad S.P. = 1.85 \times 10^{-7} \quad (1)$$

$$Cu^+ + 2Cl^- = CuCl_2^- \qquad K_2 = (CuCl_2^-)/(Cu^+)(Cl^-)^2 = 3.51 \times 10^5 \quad (2)$$

$$Cu^+ + Un = Un{\cdot}Cu^+ \qquad K_3 = (Un{\cdot}Cu^+)/(Un)(Cu^+) \quad (3)$$

$$Cu^+ + Cl^- + Un = Un{\cdot}CuCl \qquad K_4 = (Un{\cdot}CuCl)/(Un)(Cu^+)(Cl^-) \quad (4)$$

The unsaturated compound has been designated as Un and the water soluble complexes formed as Un·Cu$^+$ and Un·CuCl. The detailed procedure for evaluating K_3 and K_4 is the same as that used in previous work. The values of K_3 and K_4 are given in Table III. Table I gives the calculated

[a] Analysis by silver bromide precipitation method. [b] μ adjusted to 1 using perchloric acid.

The concentrations of substances needed to calculate K_6 were readily obtained by use of equation (5) and equations (7) and (8) in which ($Ag^{+}{}_{T}$) represents the total molar concentration of free and complexed silver ion in solution at equilibrium, and (Un_i) is the initial molar concentration of the unsaturate in aqueous solution before the addition of silver bromate. The values of K_6 calculated are given in Table II and some of these are summarized in Table III to permit comparison with the K_3 values obtained for the formation of the corresponding cuprous complexes.

$$(Ag^{+}{}_{T}) = (BrO_3^-) = (Ag^+) + (Un\cdot Ag^+) \quad (7)$$

$$(Un) = (Un_i) - (Un\cdot Ag^+) \quad (8)$$

[a] Calculated from data of Ref. 1d.

Structures of the type previously proposed for silver or cuprous complexes of compounds containing carbon–carbon double bonds[1,2] seem appropriate to describe the complexes formed by the unsaturated alcohols investigated in the present study. In general the K_3 and K_4 values for cuprous complex formation of the α,β-unsaturated alcohols are somewhat higher than those observed for the α,β-unsaturated acids investigated previously. Since a carboxyl group conjugated with a carbon–carbon double bond should markedly decrease the electron density at the double bond through both resonance and inductive effects, this observation seems reasonable. As in the case of the unsaturated acids, replacement of hydrogen atoms by methyl substituents at the double bond in the unsaturated alcohols reduces the magnitude of K_3 and K_4. As previously noted this may result from steric effects of the methyl substituents. It is interesting to note that α-alkyl-substituted allyl alcohols (*cf.* crotyl alcohol and methylvinylcarbinol) also show lower K_3 and K_4 values than does allyl alcohol. Molecular models show that such alkyl substituents might inhibit the tendency for cation complexing at the double bond because of steric effects. In the case of β-chloroallyl alcohol low values of K_3 and K_4 were found as compared to those for allyl alcohol, as might be expected in view of the inductive effect of a chlorine substituent.

The values of K_3/K_4, representing the equilibrium constant for the ionization of Un·CuCl to produce Un·Cu^+ and chloride ion, vary from 2.4 × 10^{-2} for allyl alcohol to 0.6 × 10^{-2} for 2-methyl-2-buten-1-ol and β-chloroallyl alcohol. These

(8) The value for the solubility product of silver bromate is based on measurements of the solubility of silver bromate in 0.1 *N* potassium nitrate solution by titration procedures and is in good agreement with the results of Dalton, Pomeroy and Weymouth, THIS JOURNAL, **46**, 60 (1924). In the experiments with phenol using a gravimetric method of analysis for silver a solubility product of 0.978 × 10^{-4} was obtained for silver bromate in 0.1 *N* potassium nitrate solution. For the runs using vinylacetic acid the silver bromate solubility product was determined for 1 *N* perchloric acid solution by the gravimetric method as 1.029 × 10^{-4}.

values are of the same order of magnitude as were obtained for the corresponding equilibrium constants determined in the studies of the unsaturated acids.[1f] It is interesting to note that the earlier observation[1e] that the magnitude of K_3/K_4 is much less affected by changes in structure of the unsaturate than are the K_3 and K_4 values is upheld in the present investigation.

The equilibrium constants for the silver complexes of phenol, crotyl alcohol and allyl alcohol reported in Table II agree favorably with those obtained by somewhat different procedures by Winstein and Lucas[2] (2.19, 5.17 and 12, respectively) for solutions of ionic strength equal to 1. The change in ionic strength should have little effect on the equilibrium constants so that the values may be compared directly. Structures of the type previously proposed for silver ion and aromatic compounds would seem appropriate for the silver ion–phenol complex.[2,9] In general the values of K_6 follow the same trends as do the values of K_3. However, the effect of varying substituents at the double bond does not produce as marked an effect on K_6 as on K_3. It is interesting to note that the cuprous complexes are much more stable than the silver complexes as may be seen by comparing the values of K_3 and K_6 given in Table III. As in the case of the cuprous complexes, silver ion complexes vinylacetic acid to about the same extent as it does allyl alcohol. Even with saturated solutions of maleic and fumaric acid no indication of complex formation with silver ion could be obtained. This again would be in agreement with the results obtained with cuprous ion which indicated that the maleic and fumaric acid complexes were much less stable than the vinylacetic acid complex.

(9) Keefer and Andrews, THIS JOURNAL, **71**, 3644 (1949).

Summary

By measurement of the solubility of cuprous chloride or silver bromate in aqueous solutions of unsaturated alcohols, equilibrium constants for the reactions to form the complexes Un·Cu$^+$, Un·CuCl and Un·Ag$^+$ at 25° have been determined. The cuprous ion complexes are considerably more stable than the corresponding silver ion complexes. α,β-Unsaturated alcohols show a somewhat greater tendency for this type of complex formation than do α,β-unsaturated acids. When hydrogen atoms at the double bond are replaced by methyl groups, the tendency for the unsaturated alcohols to undergo cuprous complex formation is reduced.

The Exchange Reaction between Antimony(III) and Antimony(V) in Hydrochloric Acid Solutions

BY NORMAN A. BONNER

This paper deals with a preliminary study of the exchange reaction between antimony(III) and antimony(V) in hydrochloric acid solutions. The kinetics of the exchange have been studied in 6 *f* hydrochloric acid, and in addition, the rates of exchange have been measured in 3 *f* and 12 *f* hydrochloric acid. In 6 *f* acid, half-times in the neighborhood of sixty hours were observed and the rate was found to depend critically on the hydrochloric acid concentration.

Experimental

Tracers.—The 60-day Sb^{124} tracer was obtained from the Atomic Energy Commission in the form of 200 mg. of metallic antimony which had been irradiated in the Clinton Pile. The metal was boiled with a small amount of aqua regia, the resulting oxide dissolved in concentrated hydrochloric acid, and the solution boiled to remove chlorine and nitrogen oxides. Stock +3 tracer solutions were made by diluting aliquots of the above solution to about 3 *f* hydrochloric acid and passing hydrogen sulfide into the boiling solution until the antimony sulfide turned black. The sulfide was filtered off, washed, dissolved in 6 *f* hydrochloric acid, boiled to remove hydrogen sulfide and diluted to a known volume with 6 *f* hydrochloric acid.

The +5 tracer solutions were prepared in the same manner except that after the sulfide precipitate had been dissolved and the hydrogen sulfide removed, the 6 *f* hydrochloric acid solution was diluted with an equal volume of distilled water and chlorine gas bubbled through the hot solution for several hours. The solution was then boiled to remove chlorine and bring the hydrochloric acid concentration to 6 *f*. The final, known volume was obtained by dilution with 6 *f* hydrochloric acid.

As a check on the radiochemical purity of the tracer, a sample was sealed in a test-tube and the γ-radiation counted at intervals in a standard geometry with the same brass-wall Geiger–Mueller counter. The counter itself was checked against a similar 5.3-year Co^{60} standard and found to give the same corrected counting rate, within the statistical counting error, at all times.

The antimony sample decayed with a 60 ± 1-day half-life over a period of five half-lives in satisfactory agreement with the previously determined value.[1] The antimony had been received from Oak Ridge more than a month before these particular experiments were started and the standard was prepared so the activity of the 2.8-day Sb^{122} (and any short-lived impurities) had decreased to an immeasurably small value.

Reagents.—Analytical reagents were used.

The +3 and +5 antimony carriers were made up in the same manner as the corresponding tracers, but the starting material was an accurately weighed sample of antimony trioxide instead of antimony metal. The trioxide was analyzed by triiodide titration and found to be 99.9% pure.

The carrier, tracer and hydrochloric acid solutions were all analyzed gravimetrically for total chloride by the pre-

(1) Seaborg and Perlman, *Rev. Modern Phys.*, **20**, 585 (1948), list the half-life as sixty days.

cipitation of silver chloride. The precipitation was carried out in the presence of tartaric acid in the case of the carrier and tracer solutions in order to prevent the precipitation of antimony.

The hydrogen ion and chloride ion concentrations were calculated from the known total antimony and chloride concentration with the assumption that the principal forms of the +3 and +5 complexes in 6 *f* hydrochloric acid are $SbCl_4^-$ and $SbCl_6^-$, respectively. If these formulas are wrong (as is easily possible) the hydrogen ion and chloride ion concentrations will be correspondingly slightly in error.

Reaction mixtures were prepared by adding the proper amounts of carrier, hydrochloric acid and tracer solutions in the order mentioned to a 25-ml. volumetric flask. The time at which the tracer solution was added to the other reagents was taken as the time origin for the exchange reaction. At temperatures other than 25°, the carrier mixture was allowed to come to temperature equilibrium with the thermostat before the tracer was added.

The isopropyl ether used in the separation procedure was freed from peroxides by repeated shakings with ferrous ammonium sulfate solution acidified with sulfuric acid. The ether was stored over an acidified solution of ferrous ammonium sulfate. This purification step was found necessary in order to prevent the oxidation of antimony (III) to antimony(V) by the peroxides. No other purification was carried out.

Separation Procedures.—For the 6 *f* and 12 *f* runs, ether extraction was used as the separation method, the only difference between the two cases being that the aliquots from the 12 *f* run were diluted with an equal volume of water before proceeding.

An aqueous solution 2.14 *f* in magnesium chloride, 6.0 *f* in hydrochloric acid was prepared and saturated with isopropyl ether. An 11.7-ml. portion of this solution was mixed with 16.7 ml. of isopropyl ether. To carry out the separation, 5.0 ml. of the reaction mixture was added to the above two-phase system. The mixture was shaken vigorously for one minute in a centrifuge tube fitted with a ground-glass top, then centrifuged for five minutes. For the 9.8 and 25.0°-runs in 6 *f* hydrochloric acid the time at which centrifugation was started was taken as the time of separation. In the 34.6°-run, the time at which the aliquot was added to the other reagents was taken as the time of separation. In the 12.0 *f* experiment, the time of separation was considered to be the time at which the aliquot was diluted with water. Aliquots of the two phases were pipetted off, weighed to the nearest 0.02 g. and the γ-radiation counted. The total activity in each phase was calculated from the known density and with the assumption that the total volume of each phase did not change when the ether and the hydrochloric acid solutions were mixed. Semi-quantitative experiments indicated that this assumption was justified. It was further justified by the fact that the sum of the activities of the two fractions always equalled, within experimental error, the activity of a standard containing the same total amount of tracer.

Under the above conditions it was found that 98% of the antimony(V) went into the ether phase and 98% of the antimony(III) remained in the aqueous phase. No exchange (0 ± 2%) was observed during the separation.

The separation procedure used in the experiment in 3 *f* hydrochloric acid involved the precipitation of antimony (III) with 8-hydroxyquinoline. The reaction mixture (20 ml.) was added to several ml. of solution containing a total of 1 g. of citric acid. To this was added about 25 ml. of 7 *f* ammonium hydroxide and 4 ml. of a 2% solution of 8-hydroxyquinoline in 2 *f* acetic acid. The resulting mixture was heated on a steam-bath for about one and one-half hours and then filtered. The precipitate was mounted on filter paper and the β-radiation counted under cellophane. The filtrate was acidified and antimony sulfide precipitated with hydrogen sulfide. The precipitate was filtered and the β-radiation counted. Each of the two samples was analyzed for antimony.

Less than 2% exchange occurred during this separation procedure.

Counting Procedures.—Gamma radiation was counted directly from the solutions by placing a test-tube containing the sample in a standard geometry near a brass-wall Geiger–Mueller counter. The test-tubes were always filled to the same height and were calibrated so that corrections could be made for slight differences in counting rate due to differences in the dimensions of individual tubes. A correction was also applied for the difference in counting rate of the same size sample in ether and in aqueous solution. The counting rate in ether was found to be 2% higher than in the hydrochloric acid–magnesium chloride solution used.

For β-counting the sulfide or 8-hydroxyquinoline precipitates were mounted under cellophane on cards which could be placed in a standard position under an 8 mg./sq. cm. dural window in the side of a brass Geiger–Mueller counter.

No coincidence corrections were applied to either γ- or β-counting rates, since the highest counting rate used was about 2000 c./min. and the usual rate was 1000 or less. The coincidence correction on the counters used amounted to less than 2% at a counting rate of 2000 c./min.

Results

The reaction studied is $Sb^{III\prime} + Sb^{V} = Sb^{III} + Sb^{V\prime}$, where the primes indicate radioactive atoms. For this particular reaction, the logarithmic form of the first order exchange law[2] is

$$-\ln(1 - F) = \frac{R[(Sb^{III}) + (Sb^{V})]t}{(Sb^{III})(Sb^{V})}$$

where

(Sb^{III}) = total concentration (active + inactive) of Sb^{III}

(Sb^{V}) = total concentration (active + inactive) of Sb^{V}

$F = (Sb^{V})'/(Sb^{V})'_{\infty}$ = fraction exchange at time, t, when $(Sb^{V})' = 0$ at $t = 0$

($F = (Sb^{III})'/(Sb^{III})'_{\infty}$ if $(Sb^{III})' = 0$ at $t = 0$)

$(Sb^{V})'_{\infty} = (Sb^{V})'$ at time, $t = \infty$

R = actual rate at which exchange of antimony atoms occurs between Sb^{III} and Sb^{V}. R will be constant during any one experiment, since (Sb^{III}) and (Sb^{V}) are then constant.

According to this equation, a plot of log $(1 - F)$ *vs.* time should give a straight line regardless of the mechanism of the reaction. The only requirements are that the exchange reaction be homogeneous[3] and all conditions (including the concentrations of reactants and products) be kept constant. Further, if one (or both) of the reacting chemical species contains more than one antimony atom, the atoms must be chemically equivalent.

In general, a set of four measurements of F, the fraction exchange, were made at different times for each experiment. In all cases a straight line passing through the origin was obtained when log $(1 - F)$ was plotted *vs.* time. Figure 1 is a typical example of such a plot.

When 50% exchange has occurred, $F = 1/2$, $(1 - F) = 1/2$ and $t = T_{1/2}$ by definition. At this point

$$R = \frac{(Sb^{III})(Sb^{V})\ln 2}{[(Sb^{III}) + (Sb^{V})]T_{1/2}}$$

(2) Duffield and Calvin, THIS JOURNAL, **68**, 557 (1946), or Friedlander and Kennedy, "Introduction to Radiochemistry," John Wiley and Sons, Inc., New York, N. Y., 1949.

(3) In this situation the meaning of "homogeneous" includes the possibility that the reaction is heterogeneously catalyzed. It is necessary, however, that the reactants and products exist principally in one, homogeneous medium.

[a] $R = (Sb^{III})(Sb^V)\ 0.693/[(Sb^{III}) + (Sb^V)]T_{1/2}$. [b] $R' = R/(H^+)^4(Cl^-)^9$. [c] $k = R'/(Sb^{III})^{0.6}(Sb^V)^{1.1}$. [d] The solution also contained 0.834 mole/l. of Na^+. [e] The solution also contained 0.3336 mole/l. of Na^+. [f] Only one point obtained on the exchange curve. [g] Low activity. β-counting used. [h] Flask packed with glass beads. [i] 9.8°. [j] 34.6°.

In any given experiment the antimony(III) and antimony(V) concentrations are known, and $T_{1/2}$ can be obtained from the plot of log $(1 - F)$ *vs.* t. It is then possible to calculate the value of R, the rate of exchange, for each experiment.

Effect of Hydrochloric Acid Concentration.—The hydrochloric acid concentration varied from one experiment to the next as the antimony concentrations were changed, so it was necessary to determine the effect of this variation. In addition, the dependence of the rate of exchange on the hydrochloric acid concentration is of interest in itself.

By a process of trial and error, with the first approximations based on experiments 1–4 (see Table I in which the data for all experiments are summarized) it was found that the best values of the dependences on hydrogen ion and chloride ion concentrations were 4.0 ± 0.5 and 9.0 ± 0.5, respectively. In other words, in a series of experiments in which the antimony concentrations are kept constant and the hydrogen ion and chloride ion concentrations are varied, the expression $R/[(H^+)^4(Cl^-)^9]$ is essentially constant. R is the measured rate of the reaction. Any other values of the exponents give a less constant result.

The total variation in the hydrogen ion concentration was from 4.7 f to 6.1 f, and the chloride ion concentration varied from 5.4 f to 6.1 f. In experiments 3 and 4 Na^+ was added, as sodium chloride solution, to allow independent variation of (H^+) and (Cl^-).

The actual numbers 4 and 9 have no fundamental significance under these circumstances since the activity coefficients of hydrogen ion, chloride ion and the antimony ions undoubtedly suffer large changes with small changes in the hydrochloric acid concentration.

The function $R' = R/[(H^+)^4(Cl^-)^9]$ is thus an empirical expression which corrects the measured rates for changes in the concentrations of hydrogen ion and chloride ion. Furthermore, it corrects the rate for variations in the activity coefficients of hydrogen ion, chloride ion and the antimony ions resulting from changes in the hydrochloric acid concentration.

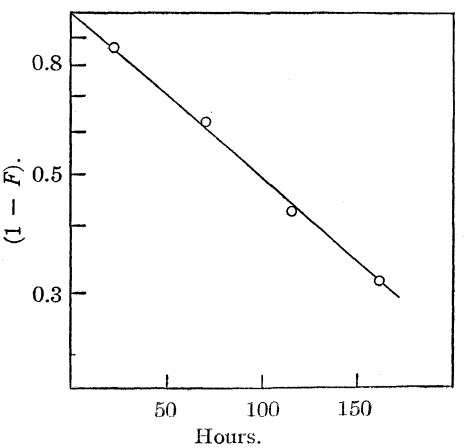

Fig. 1.—Semi-logarithmic plot of (1-fraction exchange) *vs.* time for run 1: $T_{1/2}$ = 97.2 hr.

In addition to the series of experiments in 6 *f* hydrochloric acid, one experiment was carried out in 3 *f* and one in 12 *f* hydrochloric acid. Both experiments were done at 25.0°.

In the 3 *f* experiment (No. 5), only one point was measured on the exchange curve. At 191.5 hours, exchange was 9.3% complete with antimony(III) and antimony(V) concentrations of 0.0039 *f* and 0.0022 *f*, respectively. The half-time is thus approximately 1400 hours. The 8-hydroxyquinoline precipitation method was used for the separation.

In 12.0 *f* hydrochloric acid with antimony(III) and antimony(V) concentrations of 0.0235 *f* and 0.0198 *f*, respectively, the half-time was 36.2 min. (Expt. no. 6). A plot of the values of log $(1 - F)$ *vs.* *t* for the four points obtained gave a straight line passing through the origin.

Effect of Antimony Concentrations.—Figure 2 is a plot of log $R' = R/(Cl^-)^9(H^+)^4]$ *vs.* log (Sb^V) with the antimony(III) concentration held at 0.0219 *f* (Experiments 7–10). In two cases the concentrations were slightly different from 0.0219 and the rates were adjusted according to the correction discussed in the next paragraph. The slope of the line, and therefore the dependence of the rate on the antimony(V) concentration, is 1.1 ± 0.1.

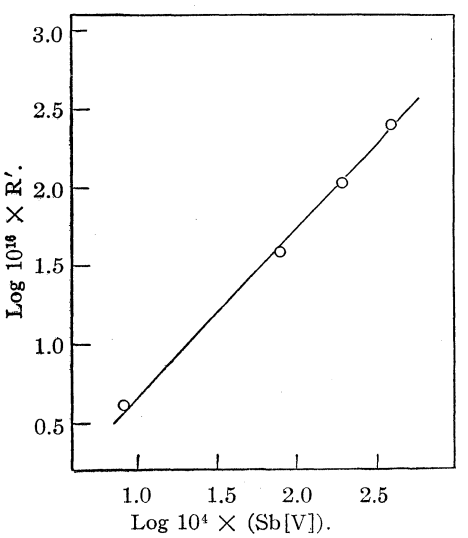

Fig. 2.—Dependence of rate of exchange on antimony(V) concentration: antimony(III) concentration = 0.0219 *f*; slope = 1.1 ± 0.1.

Figure 3 is a similar plot of log R' *vs.* log (Sb^{III}), the antimony(V) concentration being 0.0198 *f*. Also included is a point corresponding to an antimony(V) concentration of 0.0396 *f* which has been corrected to 0.0198 *f* (Experiments 11–14). The slope of the line is 0.60 ± 0.05.

An inspection of Table I shows that the rates are the same within experimental error regardless of whether the tracer is added in the form of antimony(III) or antimony(V).

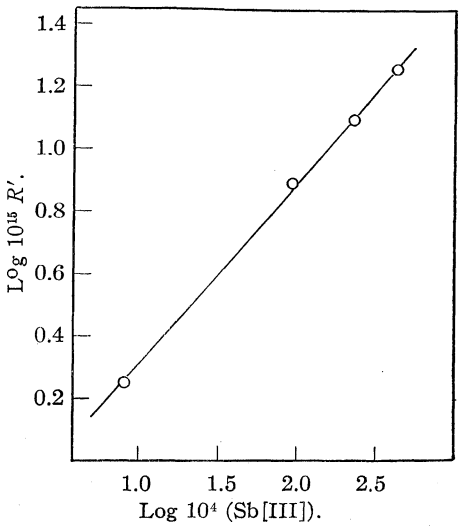

Fig. 3.—Dependence of rate of exchange on antimony (III) concentration: antimony(V) concentration = 0.0198 *f*; slope = 0.6 ± 0.05.

It should be emphasized at this point that the values 0.6 and 1.1 for the antimony(III) and antimony(V) concentration dependences are much less arbitrary than are the values for the hydrogen ion and chloride ion concentration dependences. The corrected rate, R', includes empirical corrections for changes in the activity coefficients of the antimony ions caused by changes in the hydrochloric acid concentration.

As a result, the values 0.6 and 1.1 are probably very nearly the correct ones. It seems likely that the true values are 0.5 and 1.0.

One effect has not been allowed for, however. No corrections have been made for variations in the activity coefficients of the antimony ions resulting from changes in their own concentrations. At an ionic strength of about 6, one might expect these particular changes to be small.[4] Since no accurate method is known for making corrections of this type, it has been assumed for the present that the effect is small.

Effects of β-Radiation.—In order to eliminate the possibility that β-radiation was affecting the rate of exchange a run was made in which the amount of active antimony was approximately $^1/_{80}$ of the maximum amount used. In this experiment the separation was carried out by ether extraction as usual, but the antimony in the samples was precipitated as sulfide and β-counted. The value of the rate constant for this run (no. 15) was, within experimental error, the same as the average value. Therefore, any effect of radiation is negligible.

Effect of Surface Area of the Reaction Vessel.—A run was made in a 100-ml. volumetric

(4) Nachtrieb and Fryxell, THIS JOURNAL, **70**, 3552 (1948), in studies of the distribution of iron(III) between ether and hydrochloric acid solutions have found effects which can be explained by assuming that a change in the (small) iron concentration causes an appreciable change in the activity coefficient in spite of the fact that the hydrochloric acid concentration is kept constan .

flask packed with soft glass beads instead of in the usual 25-ml. flask. The flask was rotated in the thermostat in such a way that the solution was continuously flowing over the beads. The rate constant for this run (no. 16) was the same as the average, within experimental error.

The Rate Law.—From the foregoing discussion, it appears that the empirical rate law for the antimony(III)–antimony(V) exchange reaction at 25.0° is

$$R = (8.8 \pm 0.9) \times 10^{-11} (Sb^{III})^{0.6} (Sb^{V})^{1.1} (H^+)^4 (Cl^-)^9$$

where all concentrations are uncorrected formal concentrations, and the units of R are moles $\times$ liters^{-1} $\times$ hr.$^{-1}$.

The chloride ion concentrations were calculated by analyzing for total chloride and subtracting the amount of chloride complexed with antimony, assuming the formulas $SbCl_4^-$ and $SbCl_6^-$ for the +3 and +5 states, respectively. The hydrogen ion concentrations are then the sum of the chloride ion and the total antimony concentrations. (Except in the case where Na^+ was present, when in addition an analysis of the added sodium chloride solution was necessary.)

This rate law is valid in the ranges of concentration (H^+) = 4.7 f to 6.1 f, (Cl^-) = 5.4 f to 6.1 f, antimony(III) = 0.0008 f to 0.040 f antimony(V) = 0.0008 f to 0.040 f, and (Na^+) = 0.0 f to 0.8 f.

Most of the variation in the value of the rate constant is probably due to slight uncertainties in the hydrochloric acid concentration. A difference of 1% in the hydrochloric acid concentration would lead to a difference of almost 15% in the rate.

The Activation Energy.—Three experiments were carried out at temperatures of 9.8, 25.0 and 34.6°, respectively (Expts. 20–22). The solutions were all made up at the same time, using the same pipets in order that differences in the concentrations of the various ions be minimized.

The experimental activation energy calculated from this set of data is 27 ± 2 kcal./mole.

Discussion of Results

At the present time there appears to be a considerable lack of knowledge concerning the nature of the ions existing in solutions of antimony in hydrochloric acid. There is a large amount of experimental information on the behavior of antimony solutions,[5] but it is mostly not applicable to a determination of the true nature of the ions in 6 f hydrochloric acid.

Lingane[6] presents some polarographic evidence that the formula of the antimony(V) ion in 6 f hydrochloric acid is $SbCl_6^-$. In addition, the acid $HSbCl_6$ and its salts have been prepared.[7] The evidence is admittedly far from conclusive, but since there appears to be no particular reason to doubt this formula, it is the generally accepted one.

The case of the antimony(III) ion (or ions) is even more uncertain. Either of the formulas $SbCl_4^-$ or $SbCl_6^{=}$ is generally assumed,[8] but formulas such as $SbOCl_2^-$ are not necessarily excluded.[9] In the case of solutions in hydrobromic acid there is even a small amount of evidence for the ion $Sb_3Br_{11}^{=}$.[10]

Probably the most interesting result of the exchange experiments is that the rate of exchange does not depend on the first power of the antimony(III) concentration. If the activated complex for the exchange is an ion such as $Sb_2Cl_{12}^{=}$[4] ($SbCl_6^{=}$ + $SbCl_6^-$) in which the two antimony atoms are equivalent, one would expect the rate to be first order with respect to the concentrations of antimony(III) and of antimony(V). Since the rate actually depends on the ~1/2 power of the antimony(III) concentration, it is possible that an ion such as $Sb_2Cl_n^{-(n-6)}$ might be the principal antimony(III) ion in solution and be in equilibrium with $SbCl_6^{=}$.

There is some evidence for the existence of the antimony(III)–antimony(V) complex $Sb_2Cl_{12}^{-4}$. The salts of the type Rb_2SbCl_6 are diamagnetic,[11] indicating that the antimony atoms are alternately in the (+3) and (+5) oxidation state, and not in the (+4) state. In addition Whitney and Davidson[12] have obtained spectrophotometric evidence for a +3–+5 complex ion in 11.3 f hydrochloric acid. The concentration of the complex, however, is proportional to the first power of each of the antimony oxidation states.

Furthermore, the experiment in 12.0 f hydrochloric acid (No. 6) would be expected to indicate extremely rapid exchange if the complex observed by Whitney and Davidson were the activated complex. The half-time at 25° was actually 36.2 minutes.

It thus appears that the complex observed by Whitney and Davidson is not the activated complex of the exchange reaction.

Whitney, *et al.*,[13] have found the same effect in the case of the tin(II)–tin(IV) system in hydrochloric acid. A colored complex is formed, but the exchange reaction is relatively slow. Their tentative explanation is that either the slow step in the reaction is the exchange of tin atoms between two different complexes of tin in the same oxidation state (the complex which is

responsible for the optical interaction and the exchange reaction is then assumed to be present at very low concentration), or the colored complex is not the activated complex for the exchange.

As a result of the lack of accurate knowledge concerning the nature of the ions in solution, it seems rather futile to attempt to decide definitely on the mechanism of the exchange reaction at present.

Further experiments designed to obtain more information about the nature of the antimony ions are planned.

Summary

1. A method has been developed for the separation of antimony(V) from antimony(III) by means of an ether extraction from hydrochloric acid solution.

2. A study of the rate of the exchange reaction between antimony(III) and antimony(V) shows that the rate law at 25.0°, with hydrogen ion concentrations from 4.7 f to 6.1 f, chloride ion concentration from 5.4 f to 6.1 f, antimony(III) concentrations from 0.0008 f to 0.040 f, antimony (V) concentrations from 0.0008 f to 0.0040 f and Na^+ concentrations from 0.0 f to 0.8 f is $R = (8.8 \pm 0.9) \times 10^{-11}\ (Sb(III))^{0.6}\ (Sb(V))^{1.1}\ (H^+)^4\ (Cl^-)^9$ mole $\times$ liter^{-1} $\times$ hr.$^{-1}$.

3. In the same ranges of concentrations the experimental activation energy is 27 ± 2 kcal./mole (measurement made at 9.8, 25.0 and 34.6°).

4. In 12.0 f hydrochloric acid at 25.0° the half-time for exchange is 36.2 minutes with an antimony(III) concentration of 0.0235 f and an antimony(V) concentration of 0.0198 f.

Polarography of Calcium, Strontium and Barium in Liquid Ammonia

BY C. J. NYMAN

The polarographic characteristics of several ions in liquid ammonia have been previously reported.[1] The present paper deals with the reduction of calcium, strontium and barium salts in this solvent.

Experimental

The electrolysis cells and apparatus for preparing the anhydrous liquid ammonia solutions have been described previously.[1] The cell with the internal reference electrode was used in all cases.

The dropping mercury electrode had the following characteristics in a saturated solution (0.021 M) of tetraethylammonium iodide in liquid ammonia at −36°. At a pressure of 20 cm., the drop time t was 5.1 sec. (open circuit) and the mass of mercury m flowing through the capillary was 1.184 mg./sec.

A Fisher Elecdropode, calibrated in the usual manner, was used in this investigation. All applied potentials were checked by means of a student type potentiometer.

The ammonia, barium nitrate and strontium nitrate were C. P. materials of commerce. Calcium iodide was prepared in the following way: 3 g. of calcium hydroxide was made into a slurry with 100 cc. of water, and then ammonium iodide was added until all the calcium hydroxide dissolved. The solution was filtered, and an additional 15 g. of ammonium iodide was added. The solution was evaporated almost to dryness on a hot-plate, and the resulting paste was transferred to porcelain boats. These were placed in a Pyrex combustion tube and heated by means of a tube furnace. A stream of dry hydrogen was used to sweep the water vapor and excess ammonium iodide from the region of the boats. The temperature was raised slowly to about 150° and held for two hours, when it was increased to 400° for two hours. The material was allowed to cool with the stream of hydrogen still passing through the tube. On analysis, the calcium iodide contained less than 0.5% impurity. The purification of the tetraalkylammonium salts has been described previously.[1]

(1) For previous papers, see H. A. Laitinen and C. J. Nyman, THIS JOURNAL, **70**, 2241, 3002 (1948).

Data and Discussion

Figure 1 shows typical polarograms obtained on electrolysis of calcium iodide solutions when using tetraethylammonium iodide as indifferent electrolyte. A maximum was observed even with low concentrations of calcium ion, and it was only partially suppressed by traces of methyl red. Higher concentrations of methyl red did not completely eliminate the maximum. A similar behavior was exhibited by the strontium ion (see Fig. 2), but the barium ion did not show a maximum when using tetraethylammonium iodide as the indifferent electrolyte (see curve II, Fig. 3). With tetrapropylammonium iodide, barium exhibits a maximum which is not suppressed by either methyl red or methyl cellulose (see curve I, Fig. 3).

TABLE I

DIFFUSION CURRENTS OF CALCIUM, STRONTIUM AND BARIUM IN LIQUID AMMONIA AT −36°

Ion	C	D	$m^{2/3}t^{1/6}$	i_d, microamp. Calcd.	Obs.	% Δ
Ca	0.38	1.91×10^{-5}	1.019	2.05	2.0	−2.5

Sr	.78		1.185	4.94	5.21	+6
Ba	.43	1.77×10^{-5}	1.249	2.72	2.65	−3
Ba	.63		1.249	4.00	3.90	−3

The diffusion currents for various concentrations of the alkaline earth metal ions, as measured in liquid ammonia at −36°, are recorded in Table I. Tetraethylammonium iodide served

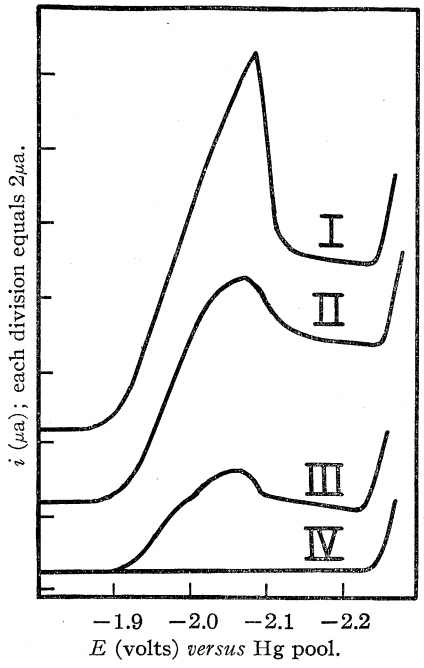

Fig. 1.—Polarograms of calcium iodide in saturated tetraethylammonium iodide: curve I, 8.2×10^{-4} *M;* curve II, 8.2×10^{-4} *M* plus a trace of methyl red; curve III, 3.8×10^{-4} *M* plus a trace of methyl red; curve IV, saturated solution of tetraethylammonium iodide.

as the supporting electrolyte. Theoretical values were calculated by means of the Ilkovic equation[2,3]

$$i_d = 605nCD^{1/2}m^{2/3}t^{1/6}$$

which relates the diffusion current i_d (microamperes) of an ion to n, the number of faradays of electricity required per mole of electrode reaction, to its concentration C (millimoles per liter), to its ionic diffusion coefficient D (sq. cm./sec.), and to the capillary characteristics m (mg./sec.) and t (sec.). The ionic diffusion coefficient D can be evaluated by means of the expression[4,5]

$$D = RT\lambda^0/zF^2$$

where R is 8.317 volt-coulombs per degree, T is the absolute temperature, λ^0 is the equivalent conductance of the ion at infinite dilution (ohm^{-1}-sq. cm.-equiv.$^{-1}$), z is the charge of ion, and F is 96,500 coulombs. Most of these terms are experimental quantities which can be easily evaluated. Gurjanowa and Pleskov[6] reported the equivalent ionic conductance at −40° of calcium, strontium and barium at infinite dilution as 180, 183 and 167 ohm^{-1}-sq. cm.-equiv.$^{-1}$, respectively.

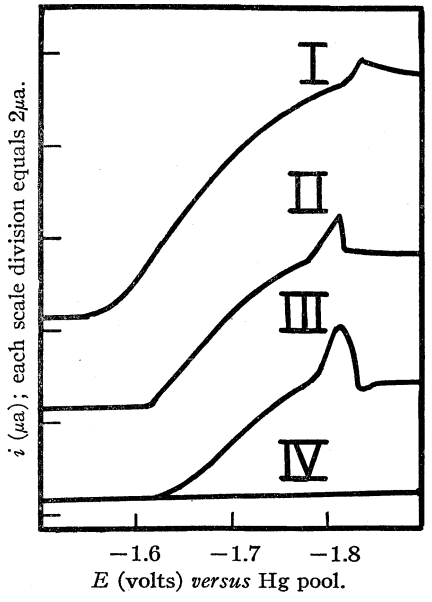

Fig. 2.—Polarograms of strontium nitrate in saturated tetraethylammonium iodide: curve I, 7.8×10^{-4} *M* plus a trace of methyl red; curve II, 5.2×10^{-4} *M* plus a trace of methyl red; curve III, 3.7×10^{-4} *M;* curve IV, saturated solution of tetraethylammonium iodide.

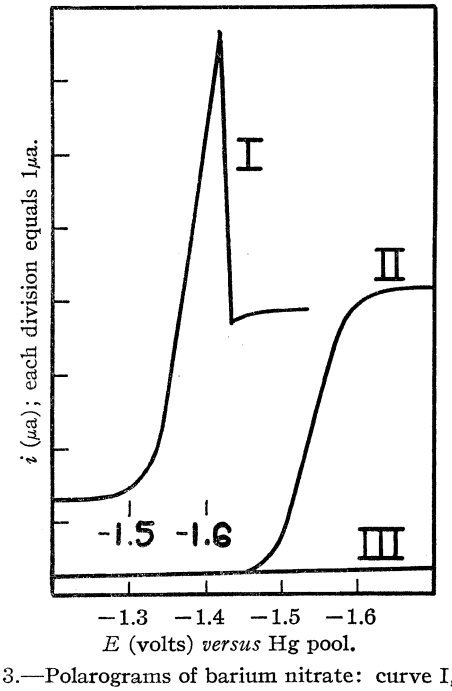

Fig. 3.—Polarograms of barium nitrate: curve I, 4.3×10^{-4} *M* in saturated tetrapropylammonium iodide; curve II, 6.3×10^{-4} *M* in saturated tetraethylammonium iodide; curve III, saturated solution of tetraethylammonium iodide.

As can be seen, the agreement between the observed and calculated values of i_d is good, and it is considerably better than that observed in the case of the alkali metal ions[1] where the ob-

served values were higher by 10%. This is attributed to the fact that the migration current has been markedly reduced by the higher relative concentration of indifferent electrolyte. The solubility of tetraethylammonium iodide, which was used in this investigation, is about four times as great as that of tetrabutylammonium iodide, which was used in the investigation of the alkali metal ions.

TABLE II

$E_{1/2}$ IN LIQUID AMMONIA AT −36° *versus* MERCURY POOL

Ion	*C.* mmole/l.	$E_{1/2}$, volts	Slope of $E_{d.e.}$ *vs.* log $\left(\frac{i_d - i}{i}\right)$
Ca	0.38	−1.96	0.058
Ca	.82	−1.96	.044
Sr	.37	−1.69	.061
Sr	.52	−1.68	.078
Sr	.78	−1.67	.117
Ba	.58	−1.54	.033
Ba	.63	−1.54	.040

Since the shape of a polarographic reduction wave, when the metal is soluble in mercury, is given by the expression[7]

$$E_{d.e.} = E_{1/2} + \frac{2.303RT}{nF} \log \frac{(i_d - i)}{i}$$

(7) J. Heyrovsky and D. Ilkovic, *Coll. Czech. Chem. Commun.*, **7**, 198 (1935).

the slope of a plot of $E_{d.e.}$ *versus* log $(i_d - i)/i$ can be used as a test for reversibility. $E_{d.e.}$ is the potential of the dropping mercury electrode; $E_{1/2}$ is the half-wave potential; i_d is the diffusion current; and i is the current flowing at a potential $E_{d.e.}$. A reversible two-electron reduction would give a slope of 0.024.

In Table II are recorded values for the half-wave potentials of calcium, strontium and barium in liquid ammonia at −36° and also the slope of $E_{d.e.}$ *vs.* log $(i_d - i)/i$. The approach of the reduction to reversibility is not so close in the case of the alkaline earth ions as it is in the case of the alkali metal ions.[1] There is a parallel behavior between these ions and the alkali metal ions in that the largest ion is the most readily reduced to the amalgam. Insufficient data are available to calculate theoretical values of the half-wave potentials.

Summary

The diffusion currents of calcium, strontium and barium ions were measured and found to agree with those calculated by the Ilkovic equation.

The half-wave potentials were determined, and the reduction was found to be less reversible than in the case of the alkali metal ions.

Polarographic Behavior of Organic Compounds. I. The Maleate and Fumarate Species

BY PHILIP J. ELVING* AND CHARLES TEITELBAUM

Although extensive polarographic investigations of maleic and fumaric acids have been carried out, there was felt to be a need for a thorough study of the acids with a more careful control of the factors affecting polarographic reduction.

Insufficient attention was paid in much of the previous work[1] to such factors as buffering, electrolyte concentration, capillary characteristics, temperature control and concentration. The most thorough previous work is that of Vopicka,[1c] although the concentrations he used were somewhat high, capillary characteristics were not given, buffering at the ends of the *p*H range studied was not satisfactory, no measurements were made between *p*H 5.3 and 9.0, and no temperature control was attempted. He developed an equation to express the effect of *p*H on half-wave potential. Herasymenko[1e] interpreted Vopicka's results on the basis of a new equation, which gave slightly better agreement with the experimental results. The only previous work on the calculation of the "*n*" values (apparent electron change per molecule reduced) is that of Furman and Bricker[1k] for maleic acid where values of 1.17 and 1.22 were obtained. No clear relationship between diffusion current and *p*H has been established; Vopicka[1c] indicates a straight line relation between half-wave potential, $E_{0.5}$, and *p*H. No previous report has been found of the appearance of double waves in buffered solution. No previously reported polarographic investigation of the esters has been located.

Experimental

Buffer solutions of varying *p*H (Table I) were prepared from reagent grade chemicals by weighing out one mole of the first named buffer constituent, diluting to approximately 800 ml., adding enough of the second component to reach the approximate *p*H desired, diluting to 1 liter and determining the exact *p*H.

Maleic acid (Pfanstiehl C. P., m. p. 133–136°) was used as received. Fumaric acid (Eastman Kodak Co. practical grade) was recrystallized three times from 1 *N* hydrochloric acid and decolorized with Norit; the white solid melted at 282–284° in a sealed tube. Solutions, 0.1 *M*, of the acids were prepared; 4 g. of sodium fluoride was added to each liter to inhibit mold growth. The diethyl maleate and diethyl fumarate were Eastman Kodak Co. White Label grade; diethyl maleate, $n^{20}D$ 1.4400 (literature value[2] 1.4407) and diethyl fumarate, $n^{20}D$ 1.4405 (literature value[3] 1.4410). The purified[4] 1,4-dioxane had $n^{20}D$ 1.4221 in exact agreement with the literature value.[3] Since aqueous solutions of the esters would hydrolyze, 0.5 *M* stock solutions were prepared in 1,4-dioxane; only 1 ml. of stock solution was used in making 100 ml. of test solution. The absence of additional polarographic waves due to impurities supports the adequacy of the purity of the materials used.

A Sargent Polarograph Model XXI was used. Potential measurements were checked with a potentiometer. A Beckman Model G *p*H meter was used for all *p*H measurements. An H-type polarographic cell was used with a water-jacket around the sample leg and a saturated calomel electrode in the other half of the cell. Water at 25 ± 0.2° was circulated through the water-jacket.

The operations involved in the measurements were the usual ones used in polarographic studies. All solutions were degassed by a stream of oxygen-free nitrogen. The *p*H was determined after the solution had been degassed and the curves determined so that any effect of the degassing on the *p*H would not be ignored.

Calculation of the resistance through the cell with the concentrations of buffers used indicated that any correction for the potential drop would be within the experimental error. Confirmation for this view was received in the polarographing of solutions of cadmium chloride in 0.1 *M* potassium chloride where satisfactory agreement with the literature values was obtained. Since the buffers used had a higher conductivity than 0.1 *M* potassium chloride, no correction was considered necessary. The accuracy of the potential measurements were periodically checked by measurement of cadmium chloride solutions.

Experiments and Data

The "*m*" value for the capillary into distilled water was 2.17 mg. per second.

The effect of buffer concentration on the polarographic waves for maleic acid was determined at *p*H 5.9, where very clear waves were obtained. In solutions of low buffer concentration two waves were obtained; as the concentration of buffer was increased, the two waves gradually merged (Table II, Nos. 1 to 4). Where a reasonable distinction could be made, the $E_{0.5}$ values of both waves and of the whole, composite wave were measured. Although the significance of $E_{0.5}$ for a whole wave is perhaps doubtful in those cases where the waves consist of two separate and distinct parts, such values are included for comparison with the cases where the waves were not resolvable and were reported as one wave. To test whether the effect was due to the change in buffer capacity or to the change in ionic strength, varying concentrations of potassium chloride were added to a fixed concentration of buffer (Table II, nos. 5 and 6). Finally, to test the constancy of $E_{0.5}$ at varying concentrations of reducible species and to demonstrate further the optimum concentration of buffer, the concentration of maleic acid was varied in two buffer concentrations (Table II, nos. 7 to 10).

The effect of *p*H on $E_{0.5}$ of maleic acid was studied over the *p*H range of 2 to 9 using buffer solutions which were 0.1 *M* or 0.9 *M* in the major buffer constituent. The values obtained in 0.1 *M* solution showed an irregular relation between $E_{0.5}$ and *p*H; the values for 0.9 *M* solution are given in Table III. Similar studies on fumaric acid and the diethyl esters in solutions of varying concentration of buffer constituent and reducible

species indicated that low concentrations of buffer constituent such as 0.1 *M* are inadequate but that 0.9 *M* is adequate. The results for fumaric acid and the two esters in the latter type solution are given in Tables IV, V and VI. The effect of the dioxane from the stock solutions of the esters was shown to be negligible by taking equal quantities of diethyl maleate with and without dioxane; the curves obtained were identical within the experimental accuracy. A second wave was obtained for both esters in buffer 9 (Table VII). The relation between $E_{0.5}$ and *p*H for all compounds studied is shown in Fig. 1.

Discussion

Effect of Buffer Concentration.—Low concentrations of buffer were definitely indicated as not adequate. Ordinarily, it is expected that a molar ratio of buffer to reducible species of 100:1 is adequate for the desired constancy of *p*H throughout the solution. Considering that the usual concentration of reducible species used was 0.5 mM, a buffer concentration of 0.05 *M* should be adequate. However, the inadequacy of buffer solutions of low electrolyte concentration becomes more understandable if we consider the role of the buffer in the reduction. The reduction of the acids may be written as

$$C_4H_4O_4 + 2H^+ + 2e \longrightarrow C_4H_6O_4$$

Since the reaction tends to use up hydrogen ions and make the solution more basic, only the acidic

(5) Kolthoff and Lingane, "Polarography," Interscience Publishers, Inc., New York, N. Y., 1946, p. 145.

component of the buffer is effective in maintaining a constant *p*H. In the case of the sodium acetate–acetic acid buffer of *p*H 5.9, only the basic component, sodium acetate, was measured. The approximate concentration of the acidic form, acetic acid, can be calculated from the known *p*H and the concentration of the acetate.[6] Such a calculation indicates that the ratio of sodium acetate to acetic acid is approximately 18:1. Hence, the 0.1 *M* concentration of buffer gives a ratio of acidic form of buffer to reducible species of only 56:1; the 0.3 *M*, 160:1; the 0.7 *M*, 390:1; and the 0.9 *M*, 500:1. These facts explain the $E_{0.5}$ data for fumaric acid at *p*H 5.9 at different buffer concentrations: −1.242 (0.1 *M*), −1.224 (0.3 *M*), −1.213 (0.7 *M*), and −1.210 (0.9 *M*). This would indicate that there is inadequate buffering at the lower values and that, in this case, the minimum sufficient concentration of sodium acetate is between 0.3 and 0.7 *M*. In terms of the ratio of the acid component of the buffer to reducible species, a ratio of between 160:1 and 390:1 is required. The $E_{0.5}$ would be expected to be constant at varying concentrations of reducible species only if there were adequate buffering. The data for maleic acid in 0.1 *M* concentrations of measured buffer constituent give a very irregular relation when $E_{0.5}$ is plotted against *p*H while the relation for the 0.9 *M* buffer is quite regular; the former, apparently, is due to the irregularly inadequate buffering. It may be noted that Vopicka[1c] used a sodium acetate–acetic acid buffer at *p*H 9, in which the concentration of acidic form must have been negligible.

The foregoing comments on buffering capacity have applied only to buffer 4 which had the highest *p*H of any of the acetic acid buffers (2, 3 and 4) and thus the smallest concentration of acetic acid. If a 0.9 *M* concentration in measured constituent of this buffer was sufficient, then a similar concentration of the other buffers should most certainly be sufficient since the concentration of the acid component of the other buffers would be still higher. For buffer 5, the concentration of acetic acid is 0.9 *M*, which should be sufficient. For buffers 6 to 9, the acidic form, ammonium chloride or potassium hydrogen phosphate, is also fixed at 0.9 *M*. In buffer 1, the buffering capacity is admittedly dubious but since the results obtained were consistent with the others, it may be concluded that either the buffering was adequate or that good buffering was not necessary in this *p*H range.

An anomaly which seems difficult to interpret is the effect of buffer concentration on the polarographic waves of maleic acid. Two waves are obtained at *p*H 5.90 when low concentrations of buffer are used; these waves gradually merge as the concentration of buffer is increased. The addition of a presumably inert electrolyte, such as potassium chloride, has, to some degree, the same effect as the increase of buffer concentration. Two waves appear only at low *p*H. As previously noted, incomplete buffering should lead to more basic conditions. The appearance of two waves only at a low concentration of buffer of *p*H 5.9 might indicate that a high *p*H favors the appearance of two waves; however, two waves appear only in buffers of low *p*H. To explain the effect of the addition of a presumably inert electrolyte, one can only postulate that the phenomenon observed is at least partially caused by an ionic strength effect and that the appearance of two waves is not an indication of a varying ratio of different dissociated forms. The polarographic reduction of fumaric acid yielded only one wave in all buffers.

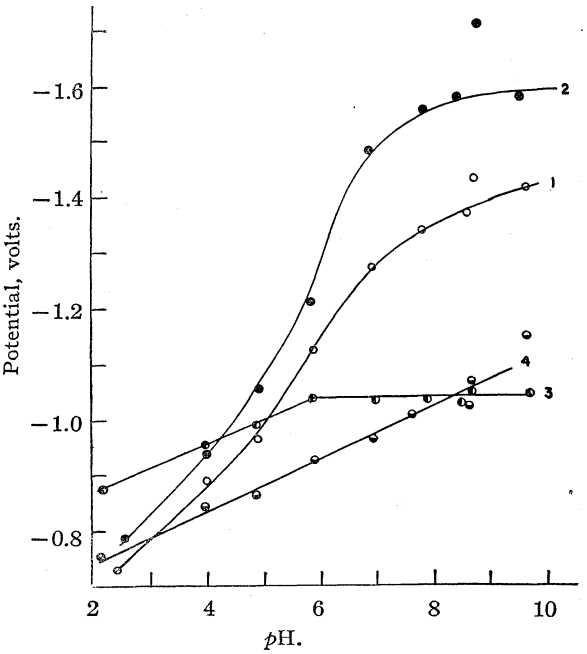

Fig. 1.—Variation of half-wave potential with *p*H: 1, maleic acid; 2, fumaric acid; 3, diethyl maleate; 4, diethyl fumarate.

Polarography of the Esters.—Freshly prepared stock solutions of diethyl fumarate gave curves with a distinct maximum while solutions which had been allowed to stand for some time did not. Since the addition of very small amounts of fumaric acid also suppressed the maximum, its disappearance was attributed to the slow partial hydrolysis of the ester in the stock solution by traces of water.

The appearance of two waves in the reduction of the diethyl esters can only be attributed to a two-step reduction since only one form of the reducible species exists. This might, by analogy, indicate that the two waves for maleic acid might be due to a two-step reduction and not to the reduction of two different forms. However, in the

(6) Clark, "The Determination of Hydrogen Ions," 3rd ed., Williams and Wilkins Co., Baltimore, Md., 1928, p. 220.

case of the esters two waves occur only at high pH values while for the maleic acid it happens only at low pH, indicating a fundamental difference in the two phenomena. It certainly indicates that a proof by analogy would be dubious.

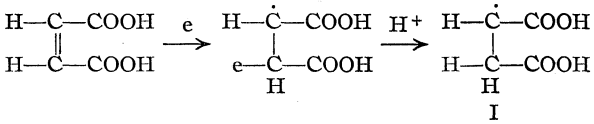
Interpretation of $E_{0.5}$–pH Curves for Maleic and Fumaric Acids.—The curves for maleic and fumaric acids, relating $E_{0.5}$ to pH, are of similar flattened S-shapes (Fig. 1). The fumaric acid curve is more negative at all points. The greater thermodynamic stability of fumaric acid would lead us to expect it to have the more negative $E_{0.5}$ values since the more stable of two compounds yielding the same product on reduction would be expected to be the less easily reduced. The facts, that at most pH values a single wave is obtained for the reduction and that a smooth curve is obtained when $E_{0.5}$ is plotted against pH, lead to the assumption that we may treat the curve as representing the composite behavior of the three possible forms of the acid: undissociated, half-dissociated and fully dissociated. The observed $E_{0.5}$ is a function of the ease of reduction of all of the forms present and their relative concentrations; the effect of pH on half-wave potential will be considered in this light.

The fact that maleic acid becomes still less stable at high pH values may be due to the electrostatic repulsion of the two negatively charged carboxylate groups in close proximity to one another. In the first ionization stage, maleic ($K_{a_1} = 1.5 \times 10^{-2}$) is a stronger acid than fumaric ($K_{a_1} = 1 \times 10^{-3}$); on the other hand, in the second ionization stage, maleic ($K_{a_2} = 2.6 \times 10^{-7}$) is a much weaker acid than fumaric ($K_{a_2} = 3 \times 10^{-5}$). This may be explained as being due to the difficulty of removal of the second positively charged proton in such close proximity to the negative charge of the carboxylate group. Roberts and Kimball[7] account for the anomalous *cis*-addition of bromine to maleic acid in basic solution on the basis of rupture of the three-membered ring of the primary addition product and rotation to the fumaroid configuration in which configuration the electrostatic repulsion is considerably less because of the wider separation of charge. This evidence also indicates that the close proximity of the two carboxylate groups causes a decreased stability of the doubly-charged maleate ion. These lines of evidence agree with the observations of this study, that the difference in stability between fumaric and maleic acids, as reflected by their $E_{0.5}$ values, is greatest at high pH values.

This explanation says nothing about the $E_{0.5}$ of each acid individually; the curve for each acid is difficult to interpret because there is involved in the effect of pH upon $E_{0.5}$ not only the activity of hydrogen ion but also the presence of three different forms of the reducible species and three different forms of the presumed product of reduction, succinic acid. However, one would predict that the change in the difference in $E_{0.5}$ should be greatest at the same pH as where the greatest change in the concentration of the doubly-charged maleate ion occurs. If the first ionization of maleic acid, which is very largely complete at the pH values considered, is neglected, it is found that $p\mathrm{H} = pK_{a_2} + \log [A^=]/[HA^-]$, so that the ratio, $[A^=]/[HA^-]$, changes one hundred-fold when the pH changes from $(pK_{a_2} + 1)$ to $(pK_{a_2} - 1)$. This, then, is the pH region (5.3 to 7.3) where one would expect to find the greatest change in concentration of doubly-charged maleate ion and, correspondingly, the greatest difference in $E_{0.5}$ values. That this prediction is at least roughly realized is shown in Fig. 1. The presence of the points for buffer 7 above the rest of the curve suggests the possibility of some sort of complex formation between the phosphate and the acid.

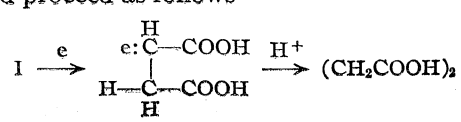
The calculated electron changes (Table VIII) involved in the reduction of both acids gave values of close to one. The wide variance of the diffusion current in varying pH led to the conclusion that calculations of the n value by the Ilkovic equation would be meaningless.

The previously mentioned interpretation of the $E_{0.5}$–pH curve stated that the difference in $E_{0.5}$ is explicable by the difference in thermodynamic stability. If this explanation is valid, then it seems likely that the potential-determining step in both cases leads to the same product, for the differences in energy of the two acids can have significance only if they are referred to a common standard. An electron change of one in the potential-determining step indicates that succinic acid cannot be the product of the potential-determining step since formation of succinic acid involves a two-electron change. The production of nascent hydrogen does not seem likely as the step since this should give a $E_{0.5}$–pH relationship unaffected by the nature of the acid and the two acids should give identical $E_{0.5}$ values. What seems more likely as the potential-determining, probably reversible step is the formation of a radical ion which would, perhaps simultaneously, acquire a proton



I

I would be expected to have free rotation about the central bond and thus be the same for maleic and fumaric acids. The pH dependence of the reduction seems to indicate a proton being added before the second step. The further reduction of I would then not be potential-determining and would proceed as follows



(7) Roberts and Kimball, THIS JOURNAL, 59, 947 (1937).

Interpretation of $E_{0.5}$–pH Curves for Diethyl Maleate and Diethyl Fumarate.—The diethyl esters were chosen for study in the belief that the factors influencing the polarographic reduction would be simplified. Since the ethyl groups are not as labile as protons and the hydrolysis of the esters is relatively slow, one need only consider one form of the reducible species and one form of the reduced product. The expectation that the curves of $E_{0.5}$ *vs.* pH would be considerably simpler to interpret, was not realized. Generally, the change in $E_{0.5}$ with varying pH is smaller for the esters than for the acids, but the variations in this change are actually less easily understandable for the esters than for the acids.

The curve of $E_{0.5}$ *vs.* pH for diethyl maleate consists of two straight lines (Fig. 1), intersecting at pH 5.8 and crossing the single straight line for diethyl fumarate at pH 8.4. As in the case of the acids, the greater stability of the fumarate should cause it to have the more negative $E_{0.5}$ value; this expectation is realized at high pH values.

The distinct break in the $E_{0.5}$–pH curve for diethyl maleate indicates two distinct mechanisms for the polarographic reduction, a pH-dependent mechanism at low pH and a pH-independent mechanism at high pH. It seems clear that the mechanism for the reduction of diethyl maleate at high pH differs from the mechanism for diethyl fumarate. At low pH values, the similarity of mechanisms for both esters seen in the parallel lines of the $E_{0.5}$–pH curve, whose slope lies between that expected for a reaction involving one proton and one involving two protons.

The "n" values calculated for diethyl maleate (Table VIII) seem to indicate an irreversible reaction at low pH values and a possible electron change of one for the potential-determining step at high pH values. The "n" values calculated for diethyl fumarate imply a mechanism of reduction similar to the acids, that is, a potential-determining reduction to a radical ion simultaneously with or immediately followed by a proton addition. Another electron and another proton would then be added to complete the reduction. This is supported by the appearance of a double wave at high pH values, indicating a two-step reduction.

There are two observed anomalies for which possible causes should be discussed, the higher $E_{0.5}$ of the less stable diethyl maleate at low pH and the change in mechanism of its reduction. Price[8] has explained anomalous effects in the reactivity of the two esters in copolymerization on stereochemical grounds. Based on relative stabilities diethyl maleate should copolymerize more readily than diethyl fumarate. However, the reactivity of the latter toward copolymerization is almost 12.5 times that of the former. On the other hand, the reactivity of maleic anhydride is almost 10 times that of diethyl fumarate. Price postulates that at some step in the copolymerization one of the intermediates is stabilized by resonance which requires a copolar configuration. Construction of molecular models indicates that there is steric strain involved in the assumption of a coplanar configuration by diethyl maleate but no such strain for diethyl fumarate or maleic anhydride. If one assumes that a planar intermediate is involved in the potential-determining step of the pH-dependent mechanism but not in the pH-independent mechanism, the two anomalies mentioned become understandable. For the similar pH-dependent mechanisms of the two esters, the steric strain in the intermediate makes the diethyl maleate more difficultly reducible. This does not necessarily mean that the product of the addition of the first electron is not the same but may merely imply that a higher energy barrier must be crossed in the change from diethyl maleate to the first product than in the case of diethyl fumarate. As the pH is raised, the reduction becomes more difficult. Finally, the reduction becomes so difficult by the pH-dependent mechanism as the hydrogen ion activity is decreased that another mechanism is favored. This does not happen for diethyl fumarate because there is no steric strain to make the pH-dependent mechanism a difficult one and also because the increased thermodynamic stability of the fumarate would make the pH-independent mechanism more difficult for it as opposed to diethyl maleate.

Acknowledgment.—This work was made possible by the award of a Frederick Gardner Cottrell Grant by the Research Corporation to whom the authors wish to express their gratitude.

Summary

The polarographic curves for maleic acid, fumaric acid, diethyl maleate and diethyl fumarate have been determined over a pH range of 2 to 9. A concentration of major buffer constituent exceeding 0.5 M was found necessary for adequate buffering action. Mechanisms of reduction consistent with the half-wave potential–pH curves and other related data have been proposed.

Maleic acid gave two waves at low pH in solutions of low concentration of buffer; increase in concentration of buffer constituents caused gradual merging of the waves into one. The same effect could be caused by adding potassium chloride to a fixed concentration of buffer, indicating the cause of the merging of the two waves to be probably a change in ionic strength and excluding as the cause of the two waves the successive reduction of different dissociated forms of the acid.

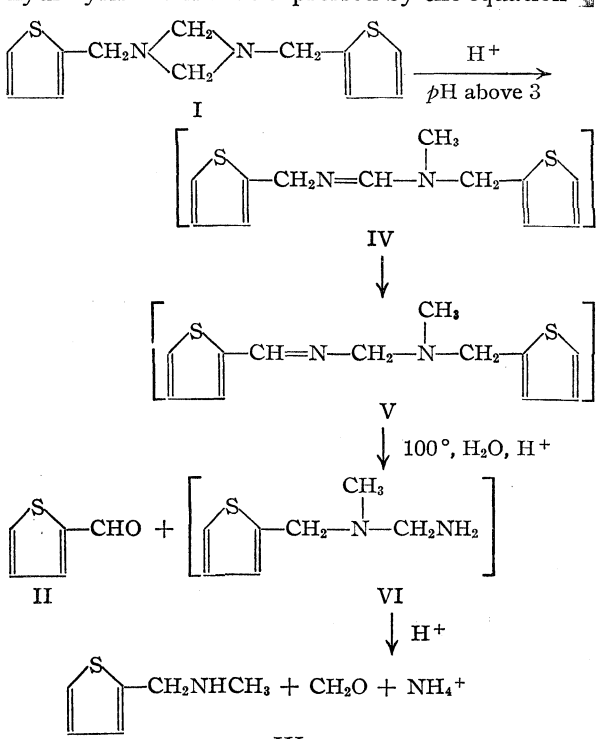
Aminomethylation of Thiophene. IV. Preparation of 2-Thiophenaldehydes from the N-(2-Thenyl)-formaldimines

BY HOWARD D. HARTOUGH AND JOSEPH J. DICKERT, JR.

Prior articles in this series[1,2,3] have dealt with reaction factors in the aminomethylation of thiophene, with preparation of the N-(2-thenyl)-formaldimines and with their reactions.

It has now been found that N,N'-di-(2-thenyl)-1,3-diazacyclobutane, I, can be hydrolyzed in dilute acid solution at a *p*H of 3 to 6.8 to give a 48% yield of 2-thiophenealdehyde, II, and a 47% yield of N-methyl-2-thenylamine, III. Ninety-five per cent. of the sulfur in I appears in the two products. At a lower *p*H than 3, formaldehyde is evolved and resinification occurs; at a *p*H above 7, no hydrolysis occurs. The hydrolysis of I is best expressed by the equation



Based upon the above postulated mechanism of hydrolysis, the yields of II and III become 96 and 94%, respectively.

In postulating the above mechanism the authors have assumed from data previously published[2,3] that the structure of I contains the diazacyclobutane ring and that structures IV and V are irreversible structures formed by rupture of the four-membered ring. I has previously been shown to exist in a dynamic equilibrium with N-(2-thenyl)-formaldimine, VII. The actual form depends upon the *p*H of the solution. At *p*H of 1 to 2, the existence of the monomer, VII, has been demonstrated.[3] Above *p*H of 3, I appears to exist and it has been isolated directly from a solution of *p*H 6 by extraction with ether.

Further positive evidence that I is the active intermediate in the hydrolysis to II and III is indicated by the fact that N,N',N''-tris-(5-methyl-2-thenyl)-tetrahydro-1,3,5-triazine, VIII, does not yield 5-methyl-2-thiophenealdehyde under hydrolytic conditions. The dimeric form of N-(5-methyl-2-thenyl)-formaldimine corresponding to I could not be isolated in a prior work.[2]

A number of possible reaction courses are conceivable in this hydrolysis and should be considered. Analogy with the mechanism proposed by Sommelet[4] for production of benzaldehyde would suggest that VII was the active intermediate and a prototropic shift occurred in that compound to form N-methyl-2-thenaldimine, IX, which would subsequently be hydrolyzed to II. However, this mechanism does not account for the formation of III. IX has been prepared and characterized to substantiate that it could not be isolated in these hydrolysis experiments. Its inherent instability, however, would militate against its isolation under the drastic hydrolysis conditions applied.

Since this article was originally submitted for publication, Angyal and Rassack[5] have briefly reported a study of the reaction of benzylamine hydrochloride and formaldehyde to form benzaldehyde, N-methylbenzylamine and ammonia. A thiophene, formaldehyde and ammonium chloride mixture will form a 2-thenylamine[1] and, therefore, a reaction similar to that proposed by Angyal and Rassack should be considered. Their mechanism would postulate the reaction of formaldehyde with the 2-thenylamine to form the formaldimine and subsequent reaction of equimolar amounts of the amine and the formaldimine to yield the 2-thiophenealdehyde, ammonia and an N-methyl-2-thenylamine. It will be noted that this mechanism gives the same products and in the same ratios as that involving the dimer, I, of the formaldimine as a reactant. Angyal and Rassack[5] discuss oxidation of benzylamine by formaldimine, $CH_2{=}NH$ (from hexamethylenetetramine), to yield benzaldehyde, methylamine and ammonia. Graymore and Davies[6] describe

the similar oxidation of benzylformaldimine, and assume aminomethyl alcohol (from hexamethylenetetramine) to be the oxidizing agent. If such reactions occur in the thiophene series they produce one mole of 2-thiophenealdehyde from each mole of amine or formaldimine—twice the amount resulting from the mechanisms above. In addition to this oxidizing action, formaldehyde may cause a stepwise reduction of formaldimines to secondary or tertiary amines.[5,7]

Related to the hydrolysis of I is the treatment of 2-thenylamine and N-(2-thenyl)-formaldimine with hexamethylenetetramine, **X**, and hydrochloric acid. Angyal and Rassack[5] discussed treatment of benzylamine with **X** to form benzaldehyde, and Graymore and Davies[6] described the similar reaction of benzylformaldimine with X, with suitable concentrations of hydrochloric acid, to give the aldehyde. By analogy, similar reactions might be expected with thiophene isologs. When carefully acidified 2-thenylamine (sufficient acid to form the hydrochloride was employed) was added to X, the aldehyde, II, was formed. The reaction was not allowed to go to completion and the results definitely indicated that I was an intermediate since it was isolated by extraction with ether from the hydrolysis mixture at a *p*H of 4. Therefore, it appears that the mechanism of Angyal and Rassack[4] is not applicable to the present case.

2-Thiophenealdehyde, II, can also be obtained in 20–25% yield by warming I with formaldehyde and ammonium chloride. The remainder of I presumably reacts with formaldehyde and ammonium chloride to give a product containing a greater percentage of nitrogen than I. The product probably contains about 50% of bis-2,5-(methyleneiminomethyl)-thiophene, since it can be oxidized to a mixture of 2,5-thiophenedicarboxylic acid and 2-thiophenecarboxylic acid.

The formation of II and III does not require the prior separation of I. If the reaction mixture of thiophene, formaldehyde and ammonium chloride having a *p*H of 1.5 is adjusted to a *p*H of 3 to 6.8 and the mixture steam distilled, II can be obtained in 35–45% yield and III in 10–25% yield. If the *p*H is left at 1.5, only a trace of II is obtained. The *p*H dependence is probably associated with the fact[2] that I exists as the monomeric hydrochloride in solutions of *p*H 1 to 2 and as the dimer in more alkaline solutions. The yields of III were lower at higher *p*H values and the residual high boiling amines increased substantially. One would anticipate that at the lower *p*H value of about 6, the compound VI would hydrolyze more slowly to III.

The products obtained by hydrolysis of a reaction mixture from 2-methylthiophene, formaldehyde and ammonium chloride are not strictly analogous to those from thiophene. While 5-methyl-2-thiophenealdehyde, XI, was recovered it was not possible to isolate any N-methyl-5-methyl-2-thenylamine or, for that matter, any amine but the unhydrolyzed N-(5-methyl-2-thenyl)-formaldimine. The formaldimine produced from the reaction of 2-methylthiophene, formaldehyde and ammonium chloride[2] is a trimer of N-(5-methyl-2-thenyl)-formaldimine, VIII. Attempts to hydrolyze an isolated sample of VIII gave no aldehyde, XI. Polymerization of VIII occurred. The experimental observations might well be explained by the Sommelet mechanism, assuming that the formaldimine reacts as the monomer in acid solution. There is no experimental evidence of the existence of a dimer when 2-methylthiophene is employed.[2] Graymore and Davies[6] decided that, in the case of benzylformaldimine, trimerization to tribenzyltrimethylenetriamine precluded the prototropic shift and subsequent reaction and, to obtain the aldehyde, conditions avoiding polymerization were required.

When a reaction mixture obtained from 3-methylthiophene is hydrolyzed, products corresponding to those from thiophene are obtained at a *p*H of about 3 but at a *p*H of 6 no N-methyl-3-methyl-2-thenylamine was isolated. Instead, the amine N,N-dimethyl-3-methyl-2-thenylamine was isolated in low yield. Similarly, 2-chlorothiophene and *t*-butylthiophene produced N,N-dimethylamines but no N-methyl-2-thenylamines were isolated. Experimental work was not sufficiently extensive in these cases nor in the case of 2-methylthiophene to define the reaction courses. Formation of the N,N-dimethyl derivatives may take place stepwise through the reducing action of formaldehyde on the formaldimine.[5,7]

Experimental

The purity of thiophene, 2- and 3-methyl-, and 2-chlorothiophene, as determined by infrared analysis, was greater than 99 mole per cent. The *t*-butylthiophene used was later found to contain almost equimolar portions of 2-*t*-butyl- and 3-*t*-butylthiophene.[8] All melting points are corrected; boiling points are uncorrected.

General Procedure.—To the aqueous reaction mixture containing the N-(2-thenyl)-formaldimines as described in prior references[2,3] was added enough 10% sodium hydroxide solution to raise the *p*H of the solution to about 6 as determined by Hydrion paper. Normally a heavy oil separated from the reaction mixture. The well-stirred mixture was steam distilled (still temperature 105–110°) until no trace of the characteristic odor of thiophenealdehydes was noted in the distillate. The distillate, slightly basic, was neutralized with a little hydrochloric acid and extracted three times with ether. The extract was dried over anhydrous calcium sulfate, the ether evaporated and the product distilled *in vacuo*.

In the case of 5-chloro-2-thiophenealdehyde and the *t*-butyl-2-thiophenealdehyde the products were not sufficiently volatile with steam to be collected readily in that

(7) Werner, *J. Chem. Soc.*, **111**, 844 (1917).

(8) This material was previously thought to be pure 2-*t*-butylthiophene but was reinvestigated after Appleby, Sartor, Lee and Kapranos reported formation of isomers in alkylation of thiophene at the 112th Meeting of the American Chemical Society, New York City, September, 1947. This information was later published: THIS JOURNAL, **70**, 1552 (1948).

[a] Yield from hydrolysis of pure IV was 48%. Yields from hydrolysis of reaction mixtures generally ranged from 10–25%. [b] Isolated from the reaction mixture as the amine hydrochloride, m. p. 196–199° dec., by extracting the concentrated steam hydrolysate with chloroform. [c] Sample lost before check analyses could be obtained. [d] Obtained in low yields—generally below 10%. [e] Product not distilled. Identified as the methiodide. [f] Calcd.: H, 3.37. Found: H, 3.37. [g] Calcd.: H, 5.39. Found: H, 5.42. [h] Calcd.: H, 4.09. Found: H, 3.80.

manner. The hydrolysate, after boiling for two hours, was cooled and extracted with ether. After drying, the aldehydes were obtained by distillation *in vacuo*.

Isolation of the amine fraction was carried out in the following manner. Any oily or semi-resinous water-insoluble material was separated by decantation and discarded. The aqueous layer was neutralized with 40% sodium hydroxide, the amines were extracted with ether and dried, the ether was evaporated, and the amines were distilled *in vacuo* from a Claisen flask. Higher boiling complex amine mixtures were also noted from continued distillation but no simple products could be isolated.

Distillation of the insoluble oil obtained by the decantation step above, which normally was discarded, yielded, in the case of thiophene, only a small amount of aldehyde and higher boiling complex oxygen-containing products containing no active alcohol, aldehyde or acid components. These materials resinified in concd. hydrochloric acid indicating them to be methylene thenyl ethers. One relatively pure product from thiophene, b. p. 110° at 0.5 mm., $n^{20}D$ 1.5780, analyzed as follows: C, 55.65; H, 5.65; S, 26.78. These analyses indicate an empirical formula of $C_{11}H_{18}O_2S_2$. The product was oxidized with alkaline permanganate to 2,5-thiophenedicarboxylic acid, m. p. 358.5–359.5° (sealed tube on melting point block). No simple structure that oxidizes to this acid can be reconciled with the empirical formula $C_{11}H_{18}O_2S_2$.

Any significant departure from the above general procedure can be found in footnotes to the tables.

Hydrolysis of N,N'-Di-(2-thenyl)-1,3-diazacyclobutane, I.—To 21 g. (0.164 mole) of I obtained by a method previously described,[2] was added 12 g. of concd. hydrochloric acid in 200 ml. of water. This mixture was heated at the reflux temperature for one hour and then steam distilled. 2-Thiophenealdehyde, 9.0 g. (48%), was obtained by extraction of the distillate with ether. Caustic neutralization of the hydrolysate mixture, followed by ether extraction, yielded 10.0 g. (47%) of N-methyl-2-thenylamine, b. p. 184–185° (uncor.).

Reaction of I with Formaldehyde and Ammonium Chloride.—To 25 g. of N-(2-thenyl)-formaldimine dimer, I, were added 13 g. of ammonium chloride and 42 g. of 36% formaldehyde. The temperature fell to 18° and then slowly rose to 40°. I dissolved in the aqueous solution during the temperature rise. When the heat of reaction was no longer noticeable the reaction mixture was warmed to 70–80° for two hours. After cooling, 5.5 g. (20%) of 2-thiophenealdehyde was extracted from the mixture with ethyl ether and identified as the semicarbazone, m. p. 223–224°.

The amine portion of the reaction product, obtained in the usual manner by caustic neutralization,[2] contained 13.63% nitrogen. A 5-g. sample slurried with 10 g. of sodium hydroxide in 125 ml. of water was oxidized slowly by adding 10 g. of potassium permanganate in 150 ml. of water at 40° to the slurry. After obtaining the crystalline acids (3.2 g.) in the conventional manner, there were obtained 2.2 g. of 2,5-thiophenedicarboxylic acid, m. p. 358.5–359.5° and 1.0 g. of 2-thiophenecarboxylic acid, m. p. 128–129°. These acids are conveniently separated by digesting in benzene, the 2,5-thiophenedicarboxylic acid being very insoluble.

N-Methyl-2-thenaldimine was prepared by a modification of the method used for the preparation of N-methylpyrrolaldimine.[9] To 36 g. (0.3 mole) of 25% ethylamine was added with stirring 34 g. (0.3 mole) of 2-thiophenealdehyde during the course of one hour. The temperature rose to 35° after the addition was completed following which the mixture was heated at a temperature of 60° for two hours.

The mixture was then washed three times with 50-ml. portions of water. About 120 ml. of 17% hydrochloric acid was added and the mixture extracted with ether. Evaporation of the ether layer yielded 21 g. of unreacted 2-thiophenealdehyde. The residue was neutralized with caustic and the imine extracted with ether. The ether solution was dried and the ether was removed by evaporation; the residue of N-methyl-2-thenaldimine (9 g.) boiled at 48–49° (1.5 mm.); $n^{20}D$ 1.5864.

Anal. Calcd. for C_6H_7NS: N, 11.2; S, 25.6. Found: N, 11.4; S, 26.0.

This compound must be analyzed immediately since it is hydrolyzed rapidly by the moisture in the air. One sample which was allowed to stand for two days had only 9.73% nitrogen. This same sample was allowed to stand for several weeks and at that time had only 5.07% nitrogen.

An attempt to prepare a picrate of this compound gave only the picrate of methylamine, m. p. and mixed m. p. 209–211° uncor.

Anal. Calcd. for $C_7H_8N_4O_7$: C, 32.31; H, 2.96. Found: C, 32.01; H, 3.07.

Reaction of 2-Thenylamine Hydrochloride and Hexamethylenetetramine.—One mole (140 g.) of hexamethylenetetramine in 500 ml. of water was heated to boiling in a flask equipped for distillation. To this boiling mixture, one mole, 113 g., of 2-thenylamine[3] in 100 g. of 36% hydrochloric acid and 200 ml. of water was added dropwise over a period of approximately ninety minutes. 2-Thiophenealdehyde, 15 g., was obtained from the distillate after this period of time. The reaction was stopped at this point, not because the aldehyde formation had stopped, but in order that the insoluble yellow oily layer could be investigated. The *p*H of the reaction mixture was approximately 6 at this point as determined by Hydrion paper. After cooling to 20°, 150 ml. of concd. hydrochloric acid was added. The *p*H changed from 6 to approximately 4 during this addition but the yellow oil did not dissolve. Extraction with ether yielded 90 g. of a bright yellow oil which when distilled gave 10 g. of 2-thiophenealdehyde. The remaining material, b. p. 116–124.5 (0.8 mm.), was identified as I, N,N'-di-(2-thenyl)-1,3-diazacyclobutane.[2]

Acknowledgment.—The authors are grateful to Dr. D. E. Badertscher for his advice and interest in this problem and to Dr. Seymour L. Meisel for the preparation of N-methyl-2-thenaldimine and determination of its properties in connection with another phase of this problem.

Summary

A convenient synthesis of several 2-thiophenealdehydes is described in which the aminomethylation intermediates, the N-(2-thenyl)-formaldimines, undergo a prototropic shift and are hydrolyzed to the corresponding aldehydes. The reaction is complicated by side reactions and N-methyl- and N,N-dimethyl-2-thenylamines are also isolated.

Small-Ring Compounds. III. Synthesis of Cyclobutanone, Cyclobutanol, Cyclobutene and Cyclobutane[1]

BY JOHN D. ROBERTS AND CHARLES W. SAUER[2,3]

The formation of methylenecyclobutane from the reaction of pentaerythrityl bromide with zinc represents one of the simplest methods for the synthesis of a cyclobutane derivative in good yield from readily available starting materials. This reaction, which was discovered by Gustavson[4] and studied by a large number of other investigators,[5] gives methylenecyclobutane along with lesser amounts of 2-methyl-1-butene and spiropentane. Derfer, Greenlee and Boord[6] have extended the scope of the reaction considerably by showing that 1,1,1-tri-(bromomethyl)-alkanes react with zinc to give alkenyl- and alkylidenecyclobutanes.

Methylenecyclobutane has been converted to cyclobutanone in 30–36% yield by ozonization[7] and in small yield by oxidation with potassium permanganate in aqueous acetone[8] or *via* reduction of the corresponding nitrosite.[9] Other methods for the preparation of cyclobutanone, with the exception of the reaction of ketene with diazomethane,[10] involve at least five steps from available starting materials and give over-all yields of less than 10%.[11]

In the present work, methods for the preparation of cyclobutanone from methylenecyclobutane were investigated. Ozonization was not attempted because of the relative difficulty of adapting this procedure to large-scale laboratory operation. Satisfactory yields of cyclobutanone were obtained from methylenecyclobutane by oxidation to 1-(hydroxymethyl)-1-cyclobutanol and cleavage of the glycol with lead tetraacetate. Gustavson[4] has previously obtained 1-(hydroxymethyl)-1-cyclobutanol in 40% yield by oxidation of methylenecyclobutane with dilute aqueous potassium permanganate. In the present investigation, 80–83% yields were achieved by performic acid oxida-

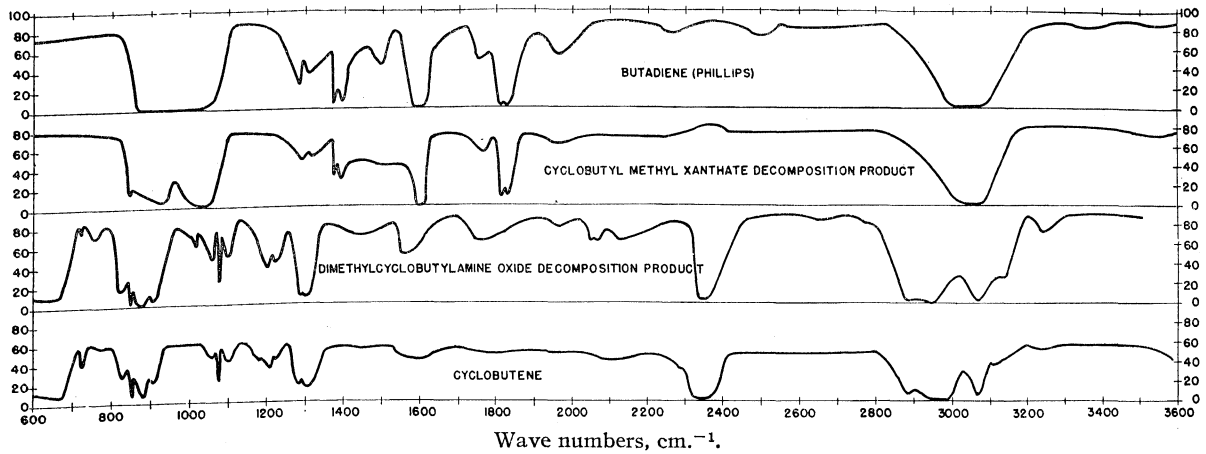

Fig. 1.—Infrared spectra.

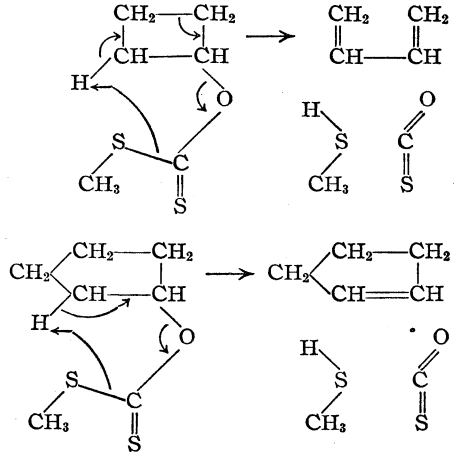
tion using a modification of the procedure employed by Roebuck and Adkins[12] for the preparation of *trans*-cyclohexandiol-1,2. A 39% yield was obtained in a single experiment using hydrogen peroxide in *t*-butyl alcohol.[13] Oxidation of the glycol with lead tetraacetate in methylene chloride solution gave yields of cyclobutanone up to 90%. Periodate oxidation of the glycol was not successful. The over-all yield of cyclobutanone from pentaerythritol was 40%.

Cyclobutane was obtained from cyclobutanone in 82% yield by the Huang-Minlon[14] modification of the Wolff–Kishner reduction.[15] Reduction of cyclobutanone to cyclobutanol was achieved in 90–100% yields using lithium aluminum hydride.[16]

The direct dehydration of cyclobutanol to cyclobutene does not appear to be feasible. Dojarenko[17] has reported that cyclobutanol is converted largely to propylene and butadiene over alumina at 360–390°. In the present work the indirect Tschugaeff method was investigated since this procedure has been shown to give olefins from alcohols in many cases with little skeletal rearrangement.[18] Cyclobutanol was converted to O-cyclobutyl S-methyl xanthate by successive treatments in diethyl ether with sodium hydride,[19] carbon disulfide and methyl iodide. The xanthate ester was pyrolyzed by dropwise addition to boiling diphenyl. The sodium hydroxide-insoluble gaseous product was shown to be quite pure 1,3-butadiene by comparison of its infrared spectrum (Fig. 1) with the infrared spectra of authentic samples of cyclobutene (prepared by the method of Willstätter and von Schmaedel[20]) and 1,3-butadiene. Application of the Tschugaeff method to cyclopentanol, investigated as a model case, resulted in a 70% yield of the normal dehydration product, cyclopentene, which was isolated as the dibromide. The abnormal behavior of the cyclobutyl xanthate ester as compared with the corresponding cyclopentyl ester on pyrolysis may be due to a different mode of reaction available only to the former ester. In this formulation the 2,3-bond of the cyclobutane ring is considered to be cleaved as an integral part of the pyrolysis reaction.



For the preparation of cyclobutene, cyclobutanone was converted to cyclobutyldimethylamine by reductive amination with excess methylamine followed by methylation of the resulting cyclobutylmethylamine with formaldehyde and formic acid. The procedure for the reductive amination was similar to that used by Hancock and Cope[21] for the preparation of isopropylaminoethanol while the methylation procedure was that of

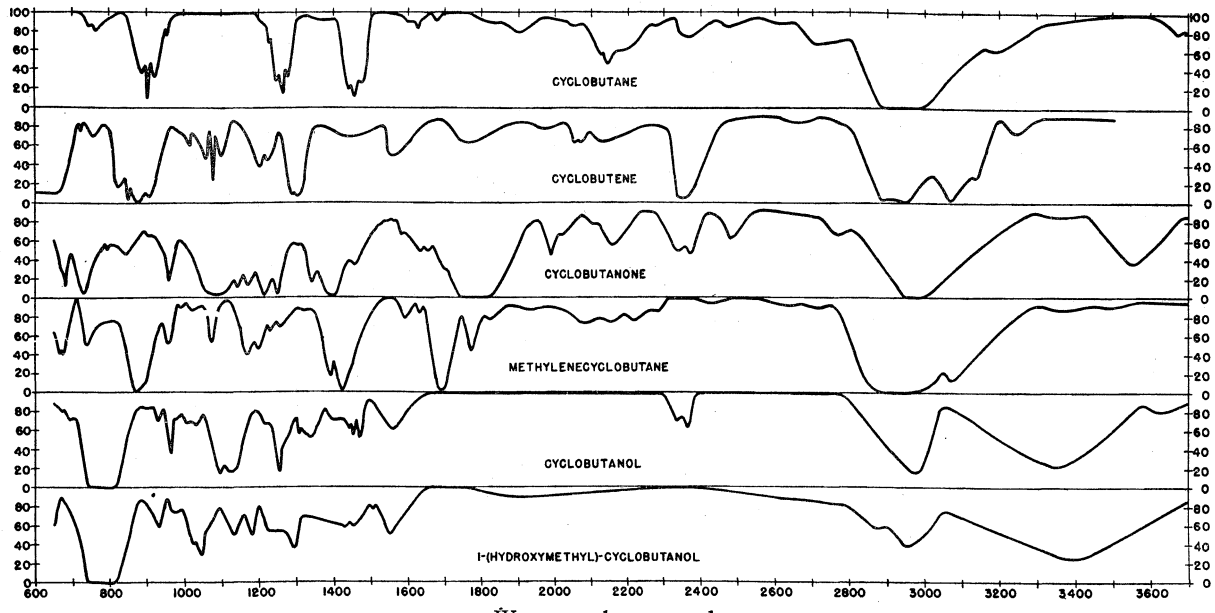

Fig. 2.—Infrared spectra.

Clarke, Gillespie and Weishaus.[22] Part of the cyclobutyldimethylamine was converted to cyclobutene through the quaternary iodide by the method of Willstätter.[20] Contrary to earlier reports[20,23] the cyclobutene obtained in this ways contained no appreciable amount of 1,3-butadiene (*cf.* infrared curves of Fig. 1). Cyclobutene, free of 1,3-butadiene, was also obtained from the pyrolysis of cyclobutyldimethylamine oxide by the method of Cope, Towle and Foster.[24] The amine oxide was prepared by oxidation of dimethylcyclobutylamine with 10% hydrogen peroxide. Cyclobutene was obtained by this method in 50–60% yields with recoveries of 28–30% of the starting material as cyclobutyldimethylamine. The yield of cyclobutene from the quaternary iodide is somewhat better (70%) and about 30% of cyclobutyldimethylamine is recovered.

Acknowledgment.—We are indebted to Dr. R. C. Lord, Jr., Mr. R. S. McDonald and Mr. E. Slowinski for the infrared determinations.

Experimental

Methylenecyclobutane.—The reaction of pentaerythrityl bromide with zinc is more easily controlled using the following procedure than the one described by Shand, Schomaker and Fischer.[25]

A solution of 10 g. of zinc bromide and 30 ml. of ethanol in 700 ml. of water was placed in a 3-l. three-necked creased flask equipped with a stainless-steel stirrer driven by a 1/4-h. p. 10,000 r. p. m. motor. One neck of the flask was equipped with a thermometer which extended into the solution and a 30-cm. air-cooled reflux condenser with a Claisen head at the top connected to a water-cooled spiral condenser. The receiver at the bottom of the spiral condenser was fitted with a Dry Ice-cooled condenser. Stirring was begun and 476 g. (7.3 gram atom) of zinc dust added. Purified pentaerythrityl bromide[26] (678 g., 1.75 moles) was placed in a 1-l. Erlenmeyer flask attached to the third neck of the creased flask by a rubber tube.[27] The contents of the reaction flask were heated to 90° and a portion of the bromide was added. The reaction began immediately and the remainder of the bromide was added portionwise as rapidly as permitted by the foaming of the mixture. The temperature was maintained at 90 ± 1° during the addition of the bromide and afterwards at 95° for one-half hour. The hydrocarbon which steam-distilled was washed with ice water and dried over calcium chloride. The yield of crude product was 102 g. (86%). Fractionation of the material from several runs through a 2 × 60 cm. glass-helix packed column gave a 70% yield (based on pentaerythrityl bromide) of methylenecyclobutane, b. p. 41.5–42°. No spiropentane could be isolated from the reaction products. The infrared spectrum of the methylenecyclobutane is given in Fig. 2.

Pentaerythrityl benzenesulfonate failed to react with zinc dust in boiling 50% absolute ethanol in the presence of sodium iodide or sodium bromide.

1-(Hydroxymethyl)-1-cyclobutanol.—**A.** To an ice-cooled solution of 12 g. (0.176 mole) of crude methylenecyclobutane, 88 ml. (0.194 mole) of 7.5% hydrogen peroxide in *t*-butyl alcohol was added 1 ml. of a 0.5% solution of osmium tetroxide in *t*-butyl alcohol. The mixture was kept in a refrigerator for two days. At the end of this period, the solution gave a negative test for peroxide. The *t*-butyl alcohol was removed by distillation and the residue distilled under reduced pressure. The yield of the glycol, b. p. 78–85° (2 mm.), was 7.0 g. (39%).

Anal. Calcd. for $C_5H_8O_2$: C, 58.80; H, 9.86. Found: C, 59.10; H, 9.79.

B. To a stirred mixture of 600 ml. (13.4 moles) of 87% formic acid and 120 ml. (1.1 moles) of 35% hydrogen peroxide was added slowly 68 g. (1.0 mole) of purified methylenecyclobutane. The temperature of the reaction mixture was maintained at 20–30° with an ice-bath. The mixture was then allowed to stand at room temperature

overnight. The formic acid and water were removed by distillation on a steam-bath at water-pump pressure. The residue was treated with an ice-cold solution of 80 g. (2.0 moles) of sodium hydroxide in 150 ml. of water. The alkaline solution was warmed to 45°, allowed to cool and then extracted with methylene chloride in a continuous extractor for twenty-four hours. The methylene chloride was removed and the residue distilled. The yield of the glycol, b. p. 93° (5 mm.), was 83.2 g. (83%); $n^{25}D$ 1.4715. The infrared spectrum of the liquid product is shown in Fig. 2.

Cyclobutanone.—In a 1-liter creased flask equipped with a stainless-steel stirrer was placed 85.0 g. (0.833 mole) of 1-(hydroxymethyl)-1-cyclobutanol and 500 ml. of methylene chloride. One neck of the flask was closed with a stopper while the other was fitted with a vertical vapor extractor topped by a reflux condenser. The extractor tube held a large Soxhlet thimble containing 420 g. (0.948 mole) of crude lead tetraacetate. The stirrer was started and the mixture heated to reflux. The lead tetraacetate was extracted by the methylene chloride and carried into the solution of the glycol. When the extraction was complete, the mixture was refluxed and stirred for an hour and then allowed to stand overnight. Water (250 ml.) was added and the mixture steam-distilled until about 1 liter of steam-distillate was collected. The distillate was cooled in ice and neutralized with 40% sodium hydroxide solution and then continuously extracted with methylene chloride. Distillation through a 1.6 × 25 cm. glass-helix packed column 52.8 g. (90.5%) of cyclobutanone, b. p. 98–100°, $n^{25}D$ 1.4189. The infrared spectrum of the pure material (liquid) is given in Fig. 2. The product was identified by its 2,4-dinitrophenylhydrazone, m. p. 146–146.5° (lit., 132–133°,[10a] 146.3–146.7°,[6] 147–147.2°[28]) and semicarbazone, m. p. 206–207° dec. (lit., 201°[11b], 202°[29,11d], 202.6–203°,[6] 211–212°,[10a,11e,i] 212–212.5°,[28] 216°,[30] 221°).[11a]

Anal. (semicarbazone). Calcd. for $C_5H_9ON_3$: C, 47.23; H, 7.13. Found: C, 47.08; H, 7.25.

Cyclobutane.—A 200-ml. flask containing a mixture of 7.0 g. (0.1 mole) of cyclobutanone, 10 ml. of 85% hydrazine hydrate, 50 ml. of Carbitol and a solution of 14 g. (0.3 mole) of potassium hydroxide in 50 ml. of Carbitol was attached to a 12 × 250 mm. Vigreux column the top of which was connected to a Dry Ice-cooled trap. The flask was heated in an oil-bath and the evolved cyclobutane collected in the trap. The heating was continued until no water distilled from the reaction mixture with the bath at 200°. The cyclobutane was distilled through a short Vigreux column with an ice-cooled reflux condenser, b. p. 12.5°; yield 4.6 g. (82%). The infrared spectrum of the gaseous material is shown in Fig. 2. A similar procedure gave an 86% yield of cyclopentane from cyclopentanone.

Cyclobutanol.—Cyclobutanone (30 g., 0.43 mole) was added dropwise to a stirred suspension of 5 g. (0.125 mole) of lithium aluminum hydride in 200 ml. of dry ether. After the addition was complete the mixture was refluxed for one hour. Sufficient 10% sulfuric acid was added slowly with stirring to dissolve the solids and the cyclobutanol was extracted with ether. Distillation through a 16 × 250 mm. glass-helix packed column, gave, other than diethyl ether: 8.6 g., b. p. 121–125°, and 19.1 g., b. p. 125°, of cyclobutanol. The combined yield was 90%. The pure material showed $n^{25}D$ 1.4347. The infrared spectrum of the liquid is shown in Fig. 2.

Cyclobutyl phenylurethan was prepared from cyclobutanol and phenyl isocyanate; m. p. 130.6–131.2° (lit.,[31] 110–111°) after recrystallization from hexane.

Anal. Calcd. for $C_{11}H_{13}O_2N$: C, 69.09; H, 6.85. Found: C, 69.35; H, 6.78.

A similar lithium aluminum hydride reduction of cyclopentanone gave an 85% yield of cyclopentanol.

O-Cyclobutyl S-Methyl Xanthate.—The procedure for this preparation was similar to that employed by Whitmore and Simpson.[32]

To a stirred suspension of 3.5 g. (0.146 mole) of sodium hydride in 100 ml. of dry ether was added dropwise 8 g. (0.11 mole) of cyclobutanol. The mixture was refluxed for three hours and then treated successively with 9.7 g. (0.135 mole) of carbon disulfide and 19.2 g. (0.135 mole) of methyl iodide. After each addition, the mixture was refluxed for three hours. Water was added to dissolve the solids, the ether layer was separated and dried over magnesium sulfate. The ether, excess carbon disulfide and methyl iodide were removed and the cyclobutyl methyl xanthate distilled under reduced pressure. The yield was 14.3 g. (84%), b. p. 67° (1.5 mm.).

Anal. Calcd. for $C_6H_{10}OS_2$: C, 44.41; H, 6.21. Found: C, 44.37; H, 6.43.

O-Cyclopentyl S-methyl xanthate, b. p. 88° (2.5 mm.), was prepared by a similar procedure in 90% yield.

Anal. Calcd. for $C_7H_{12}OS_2$: C, 47.69; H, 6.86. Found: C, 47.66; H, 6.93.

Pyrolysis of O-Cyclobutyl S-Methyl Xanthate.—The xanthate ester (1.84 g., 0.011 mole) was added to boiling diphenyl and the evolved gases collected over concentrated sodium hydroxide solution to dissolve the carbon oxysulfide and methyl mercaptan formed in the pyrolysis. The residual gas amounted to 250 ml. Comparison of the infrared spectrum (Fig. 1) of the gas with that of a sample of 1,3-butadiene (Phillips Petroleum Company, "Special Purity") showed the product to be apparently pure 1,3-butadiene. Pyrolysis of 13.5 g. (0.077 mole) of O-cyclopentyl S-methyl xanthate by the same procedure gave cyclopentene which was isolated as the dibromide, b. p. 75° (17 mm.). The yield of the dibromide was 12.2 g. (70%).

Cyclobutyldimethylamine—Cyclobutanone (21 g., 0.30 mole) was dissolved in 102 ml. of a 5.9 *M* solution of methylamine in absolute alcohol. The mixture was allowed to stand overnight and then shaken with hydrogen at 10–35 lb. per sq. in. over previously reduced platinum oxide catalyst. The theoretical quantity of hydrogen was absorbed in two hours. The excess methylamine was removed by distillation and the residue cooled, then acidified with 45 ml. of concentrated hydrochloric acid. The hydrogenation catalyst was separated by filtration and the alcohol and water removed from the filtrate by distillation under reduced pressure. The sirupy residue was heated with 75 ml. of 87% formic acid and 75 ml. of 35% formaldehyde solution on a steam-bath until a vigorous evolution of carbon dioxide began. The flask was removed from the bath until the gas evolution subsided, after which heating was continued overnight. The next day, 15 ml. more of 35% formaldehyde solution was added and the mixture was heated under reflux for four hours. The excess formaldehyde and formic acid were removed under reduced pressure and the residue was dissolved in 75 ml. of water. A solution of 40 g. of sodium hydroxide in 60 ml. of water was added dropwise with stirring and the liberated amine extracted with xylene. The xylene extracts were combined, dried over sodium hydroxide and distilled from sodium. The yield of cyclobutyldimethylamine, b. p. 97–100°, was 22.4 g. (75.5%).

In an attempt to isolate **cyclobutylmethylamine** from a reductive amination using 35 g. (0.5 mole) of cyclobutanone and methyl Cellosolve instead of ethyl alcohol as solvent, 29.7 g. of product, b. p. 84.5–88°, was isolated which was apparently a stable hydrate of the amine.

Anal. Calcd. for $C_5H_{11}N \cdot H_2O$: C, 58.21; H, 12.70; neut. eq., 103.1. Found: C, 57.62; H, 12.74; neut. eq., 105.8.

Methylation of the hydrated amine with formic acid and formaldehyde gave dimethylcyclobutylamine, b. p. 98–100°, in good yield.

Cyclobutyldimethylamine picrate was prepared from the amine and picric acid in benzene and recrystallized from isopropyl alcohol; m. p. 193.5–195° (dec.).

Cyclobutene from Cyclobutyltrimethylammonium Hydroxide.—Willstätter and von Schmaedel[20] prepared cyclobutene from cyclobutyltrimethylammonium hydroxide but did not give experimental details.

To 10 g. (0.1 mole) of cyclobutyldimethylamine dissolved in 100 ml. of ether was added 16.5 g. (0.11 mole) of methyl iodide. Heat was evolved and the quaternary iodide began to crystallize at once. The mixture was allowed to stand in a refrigerator overnight. The yield of the quaternary iodide was quantitative.

A solution of 25 g. (0.1 mole) of the quaternary salt in 100 ml. of water was shaken with 0.30 mole of freshly prepared silver oxide for two hours. The mixture was filtered and concentrated under reduced pressure. The sirupy quaternary hydroxide was added dropwise to a flask heated to 140° with an oil-bath. The pressure within the flask was maintained at 50 mm. The evolved gases were bubbled through a 1 *N* solution of hydrochloric acid and then condensed in a Dry Ice-cooled trap. The contents of the trap were allowed to evaporate into a gas holder. The yield of cyclobutene calculated from the gas volume was 0.073 mole (73%). The infrared spectrum of the product is shown in Figs. 1 and 2.

The contents of the hydrochloric acid bubbler were made basic and extracted with xylene. The xylene extracts were dried over sodium hydroxide and distilled from sodium. The recovery of cyclobutyldimethylamine, b. p. 98–102° was 2.8 g. (23%).

Cyclobutene from Cyclobutyldimethylamine Oxide.—To an ice-cooled stirred mixture of 20 ml. of 35% hydrogen peroxide and 50 ml. of water was added 10 g. (0.1 mole) of cyclobutyldimethylamine at such a rate as to keep the temperature of the reaction mixture below 10°. The solution was allowed to warm to room temperature and left overnight. Platinum foil was added to decompose the excess peroxide and the solution was concentrated under reduced pressure.

The sirupy amine oxide was decomposed at 160° as described above for cyclobutyltrimethylammonium hydroxide. The yields of cyclobutene were 50–60%. From 28–32% of cyclobutyldimethylamine, b. p. 98–102°, was recovered from the hydrochloric acid bubbler. The infrared spectrum of the cyclobutene prepared from the amine oxide pyrolysis is shown in Fig. 1.

Cyclobutyldimethylamine oxide picrylsulfonate was prepared from the amine oxide and picrylsulfonic acid in isopropyl alcohol; m. p. 168.8–169.5°, after recrystallization from isopropyl alcohol.

Anal. Calcd. for $C_{12}H_{16}O_{10}N_4S$: C, 35.29; H, 3.95. Found: C, 35.24; H, 4.06.

Summary

Cyclobutanone has been prepared in good yield by hydroxylation of methylenecyclobutane with performic acid and cleavage of the resulting glycol with lead tetraacetate.

Cyclobutanone has been converted to cyclobutane by the Wolff–Kishner reaction, cyclobutanol by reduction with lithium aluminum hydride, and cyclobutyldimethylamine by reductive amination with methylamine followed by methylation with formaldehyde and formic acid.

O-Cyclobutyl S-methyl xanthate on pyrolysis gives 1,3-butadiene. Under similar conditions, O-cyclopentyl S-methyl xanthate gives cyclopentene.

Cyclobutene, free of 1,3-butadiene, was prepared by the pyrolysis of cyclobutyltrimethylammonium hydroxide and cyclobutyldimethylamine oxide.

Thermal Decomposition of Amine Oxides to Olefins and Dialkylhydroxylamines[1,2]

BY ARTHUR C. COPE, THEODORE T. FOSTER AND PHILIP H. TOWLE

A number of allyldialkylamine oxides and benzyldimethylamine oxide recently have been shown to rearrange to trialkylhydroxylamine derivatives on heating at temperatures of 80 to 165°, with migration of the allyl and benzyl groups from nitrogen to oxygen.[3] In extending this work, it has

$$R_2N(C_3H_5)\rightarrow O \longrightarrow R_2NOC_3H_5$$

$$(CH_3)_2N(CH_2C_6H_5)\rightarrow O \longrightarrow (CH_3)_2NOCH_2C_6H_5$$

been found that N,N-dimethyl-(α-phenylethyl)-amine oxide (I) does not rearrange in this manner on heating, but undergoes an entirely different type of reaction, forming styrene and N,N-dimethylhydroxylamine. This paper reports an investigation of the thermal decomposition of several amine oxides, homologs of I, which was undertaken to obtain information concerning the scope and nature of the elimination reaction leading to olefins. Mamlock and Wolffenstein[4] have reported that tri-*n*-propylamine oxide decomposes on heating into propylene and N,N-di-*n*-propylhydroxylamine, but the reaction has received little attention.

N,N-Dimethyl-(α-phenylethyl)-amine oxide (I) was prepared by oxidation of the tertiary amine with 35% aqueous hydrogen peroxide at room temperature, and the excess hydrogen peroxide was decomposed catalytically in the presence of platinum foil. Preparation of the picrate of I from an aliquot of the aqueous solution showed that the

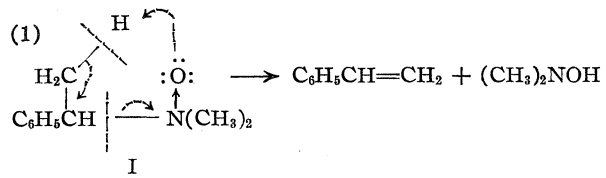
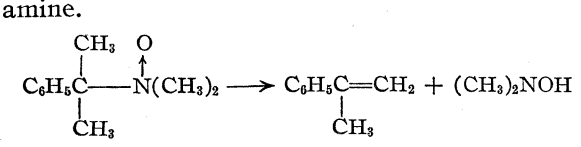
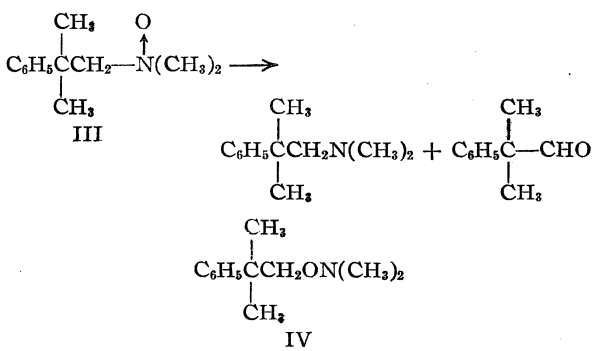
yield of I obtained by oxidation was 98%. After removal of the water from the solution of I by distillation under reduced pressure, the non-volatile amine oxide on heating at 85–115° and 5 mm. pressure was converted into volatile products which collected as a distillate. The distillate was separated by extraction with hydrochloric acid into N,N-dimethylhydroxylamine (isolated in 94% yield as the hydrochloride) and styrene (isolated in 70% yield and characterized as the dibromide). There was no evidence of partial isomerization of I into the rearrangement product, O-(α-phenylethyl)-N,N-dimethylhydroxylamine. This elimination reaction resembles the thermal decomposition of trimethylalkylammonium hydroxides into olefins, trimethylamine and water (Hofmann exhaustive methylation), which proceeds by attack of hydroxyl ion on hydrogens beta to the nitrogen linkage.[5] The conversion of I to styrene can be formulated in a similar way. The process is represented as intramolecular, but an equivalent intermolecular route is equally in accord with the facts known at present.



In order to obtain evidence concerning the validity of this interpretation, homologs of I containing no α- and no β-hydrogen atoms were investigated. N,N-Dimethyl-(α,α-dimethylbenzyl)-amine was prepared from benzyl cyanide by methylation, hydrolysis of the α,α-dimethylbenzyl cyanide to α,α,α-dimethylphenylacetamide, and degradation of the amide to α,α-dimethylbenzylamine by the Hofmann reaction, followed by methylation with formaldehyde and formic acid. Oxidation of the tertiary amine with 35% hydrogen peroxide gave N,N-dimethyl-(α,α-dimethylbenzyl)-amine oxide (II), from which the crystalline picrate was obtained in 96% yield (based on the tertiary amine). II decomposed readily on heating at 75–85° into α-methylstyrene (isolated in 78% yield and characterized as the nitrolpiperidine derivative) and N,N-dimethylhydroxylamine (isolated in 63% yield as the hydrochloride). Occurrence of the elimination with II indicates that α-hydrogen atoms are unnecessary for the reaction. There was no evidence of partial rearrangement of II into O-(α,α-dimethylbenzyl)-N,N-dimethylhydroxylamine.



A related amine with no β-hydrogens, N,N-dimethyl-(β-phenylisobutyl)-amine, was prepared by the Friedel–Crafts alkylation of benzene with β-methylallyldimethylamine.[6] N,N-Dimethyl-(β-phenylisobutyl)-amine oxide (III) was prepared by oxidation of the tertiary amine with 35% hydrogen peroxide. III was isolated as a crystalline hydrate, and proved to be much more stable than I or II. It did not decompose on heating until a temperature of 148° was reached, at which temperature exothermic decomposition occurred. From the decomposition products were isolated 39% of the original tertiary amine, N,N-dimethyl-(β-phenylisobutyl)-amine, and 7.7% of α,α-dimethylphenylacetaldehyde, identified as the semicarbazone and by oxidation to α,α-dimethylphenylacetic acid. A smaller amount (4.4%) of a weakly basic compound was isolated, which was not obtained completely pure, but from an approximate analysis, solubility characteristics and physical properties was probably the rearrangement product, O-(β-phenylisobutyl)-N,N-dimethylhydroxylamine (IV). The formation of IV by



rearrangement could occur in a manner analogous to the rearrangement of benzyldimethylamine oxide,[3] even though the α-carbon of the β-phenylisobutyl group is less electron attracting than the α-carbon of a benzyl group, because the elimination reaction is blocked by the absence of β-hydrogens. Decomposition of samples of III at atmospheric pressure produced relatively small amounts of gas, which contained carbon dioxide and oxygen. Other products must have been formed to account for the remainder of III, but they were not isolated. The relative stability of III (compared to I and II) and the fact that III did not decompose to yield an olefin (possible only with rearrangement such as occurs in the dehydration of neopentyl alcohol) furnishes evidence that the elimination proceeds by attack of the amine oxide oxygen on a β-hydrogen atom, as shown in equation (1). A similar decomposition of N-methyl and N-ethyltetrahydroquinoline oxides has been reported by Dodonov[7] to yield tetrahydroquinoline and formaldehyde and acetaldehyde, respectively.

The behavior of benzyldiethylamine oxide (V) on heating proved to be interesting in that both

elimination and rearrangement occurred as competitive reactions. Five products were isolated from the decomposition of V. N-Benzyl-N-ethylhydroxylamine (VI), the olefin elimination product, was isolated in 34% yield, and in a separate decomposition at atmospheric pressure the ethylene formed was collected and characterized as ethylene dibromide (14% yield). The rearrangement product, O-benzyl-N,N-diethylhydroxylamine (VII), was isolated in 31% yield (equation 3). Finally, 21% of N,N-diethylhydroxylamine

benzyldimethylphenylammonium chloride as the alkylating agent,[8] and aryl allyl ethers have been prepared with allyldimethylphenylammonium hydroxide as the alkylating agent.[9] The similarity of the bond between the benzyl group and nitrogen in benzyldialkylamine oxides and quaternary ammonium salts and bases containing a benzyl group is apparent, and the ease with which the bond is broken in a nucleophilic displacement reaction presumably accounts for the occurrence of the alkylation reaction (equation 4).

The structures of the products formed by the decomposition and rearrangement of V were determined as follows. N-Benzyl-N-ethylhydroxylamine (VI) was reduced with stannous chloride and hydrochloric acid to benzylethylamine, which was characterized as the hydrochloride and picrate. O-Benzyl-N,N-diethylhydroxylamine (VII) was hydrogenated in the presence of palladium and yielded diethylamine (isolated as the picrate) and benzyl alcohol, which was identified by conversion to benzyl chloride and subsequently to benzylisothiouronium picrate. O,N-Dibenzyl-N-ethylhydroxylamine (IX) was hydrolyzed in the presence of hydrochloric acid and yielded N-benzyl-N-ethylhydroxylamine (isolated as the picrate) and benzyl chloride, which was converted to benzylisothiouronium picrate. N,N-Diethylhydroxylamine (VIII) was characterized by its physical properties, analysis, analysis of the picrate and conversion to the known hydrochloride and neutral oxalate.

Work is in progress to determine the usefulness of the decomposition of alkyldimethylamine oxides to olefins and dimethylhydroxylamine as a method for the synthesis of olefins compared to the Hofmann exhaustive methylation reaction, and to determine whether the elimination is intramolecular as represented in equation (1), or intermolecular.

Experimental[10]

N,N-Dimethyl-(α-phenylethyl)-amine.—α-Phenylethylamine[11] was methylated by treatment with formaldehyde and formic acid[12] in 69% yield to N,N-dimethyl-(α-phenylethyl)-amine; b. p. 71° (11 mm.), $n^{25}D$ 1.5000, d^{25}_4 0.8989; M_D calcd., 48.72; found, 48.83; m. p. of the picrate 140–140.5°.

N,N-Dimethyl-(α-phenylethyl)-amine Oxide (I).—N,N-Dimethyl-(α-phenylethyl)-amine (11.0 g.) was stirred with 18.3 g. (150% excess) of 35% aqueous hydrogen peroxide for eleven hours at room temperature. The excess hydrogen peroxide was decomposed by stirring the mixture with 8 sq. cm. of clean platinum foil until the evolution of oxygen ceased. Most of the water was removed by distillation at 35 mm. pressure and a bath temperature of 45–55°; the distillate and material which condensed in a trap cooled with a mixture of Dry Ice and trichloroethylene in the vacuum line were saved. The residual sirup was diluted with 25 ml. of absolute ethanol, reconcentrated under reduced pressure while nitrogen was admitted through a capillary ebulliator inlet, and the process was repeated twice to remove as much water as possible. The amine oxide remained as a viscous sirup, which from its odor contained a small amount of styrene.

N,N-Dimethyl-(α-phenylethyl)-amine oxide picrate was prepared in 98% yield by treating an aliquot of the aqueous solution of the amine oxide with an equivalent amount of picric acid in aqueous solution, and was recrystallized to constant m. p. from 95% ethanol, m. p. 155.5–156.5°.

Anal. Calcd. for $C_{16}H_{18}N_4O_8$: C, 48.73; H, 4.60; N, 14.21. Found: C, 48.76; H, 4.77; N, 14.19.

Decomposition of N,N-Dimethyl-(α-phenylethyl)-amine Oxide (I).—A 100-ml. round-bottomed flask fitted with a capillary nitrogen inlet and containing the amine oxide was connected by a large-diameter tube to a condenser set for distillation, which led to two receivers in series cooled in a mixture of Dry Ice and trichloroethylene. The system was evacuated to 5 mm. and the flask was immersed in an oil-bath at 85°. The bath temperature was raised slowly to 115° during thirty-five minutes, at which time almost all of the material had distilled. The bath temperature was raised to 150° to complete the distillation; 0.35 g. of a tarry residue remained. The distillate was combined with the distillate obtained in concentration of the amine oxide solution, pentane was added as a solvent, and the mixture was washed with dilute hydrochloric acid. The acid solu-

tion was extracted with pentane, and the pentane solutions were washed with water until neutral.

The combined aqueous layers containing hydrochloric acid were concentrated under reduced pressure to a crystalline residue, which was dried by adding absolute alcohol and reconcentrating under reduced pressure, and placed in a vacuum desiccator over phosphorus pentoxide. The yield of N,N-dimethylhydroxylamine hydrochloride was 6.73 g. (94%), m. p. 101–104° (sealed capillary). A sample which was recrystallized several times from a mixture of absolute ethanol and ether was obtained as hygroscopic white needles, m. p. 106.5–109° (sealed capillary).[13]

Anal. Calcd. for C_2H_8NOCl: C, 24.62; H, 8.27; N, 14.36; Cl, 36.35. Found: C, 24.96; H, 8.24; N, 14.12; Cl, 35.99.

The pentane solution containing the neutral product was dried over magnesium sulfate and concentrated at atmospheric pressure, after addition of a crystal of picric acid as a polymerization inhibitor. Distillation of the residue yielded 5.34 g. (70%) of styrene; b. p. 82–83° (102 mm.), $n^{25}D$ 1.5424–1.5428. The styrene was identified by conversion to the dibromide, which after recrystallization from 80% ethanol had m. p. and mixed m. p. with a known sample 72.5–73°.

α,α-Dimethylbenzyl Cyanide.—The general procedure of Haller and Bauer[14] was used, except that both methyl groups were introduced in a single alkylation. Benzyl cyanide (1 mole) in 250 ml. of dry ether was added during thirty minutes to a suspension of 2 moles of freshly prepared sodamide in 1 l. of dry ether, with stirring in a 3-l. three-necked flask equipped with a reflux condenser, dropping funnel and slip-sealed Hershberg stirrer. The mixture was heated under reflux and stirred for one hour, after which 2.2 moles of methyl iodide in 350 ml. of dry ether was added during forty minutes, while the mixture was cooled in an ice-bath. An additional 750 ml. of dry ether was added and the mixture was heated under reflux and stirred for one hour. The mixture was allowed to stand overnight, heated under reflux for one additional hour, and cooled. Ethanol was added to destroy small amounts of sodamide above the surface of the liquid, followed by water to dissolve the precipitated sodium iodide. The product was washed with dilute sodium bisulfite and sodium carbonate solutions and water, dried over sodium sulfate, and distilled through a 20 × 1.6 cm. column packed with glass helices; yield 113.5 g. (78%), b. p. 81–82° (2.2 mm.), $n^{25}D$ 1.5043–1.5055.

α,α,α-Dimethylphenylacetamide was prepared in 74% yield by warming α,α-dimethylbenzyl cyanide with 85% sulfuric acid for three hours,[14] m. p. 150–153°. A sample recrystallized to constant m. p. from absolute ethanol had m. p. 160–161.5° (ref. 14 reports m. p. 160°).

α,α-Dimethylbenzylamine.—Use of a reported procedure for the Hofmann degradation of α,α,α-dimethylphenylacetamide[15] led to recovery of part of the amide, and the following procedure[16] gave a better yield. A solution of 117 g. of sodium hydroxide in 975 ml. of water was placed in a 2-l. three-necked flask and cooled to 0° in an ice–salt bath. Bromine (46.9 g.) was added in portions with stirring, followed by 79.6 g. of α,α,α-dimethylphenylacetamide (m. p. 157.5–159.5°) in small portions during ten minutes, while the solution was at 0°. The suspension was stirred at 0° for seven hours, packed in ice, and allowed to come to room temperature overnight. The mixture was stirred and warmed on a steam-bath for thirty minutes. The product was extracted with ether, the ether solution was dried over sodium sulfate, and the amine hydrochloride was precipitated by introducing dry hydrogen chloride; yield 79.8 g. (95%), m. p. 240–241° (ref. 15 reports m. p. 240°). The amine was liberated with 6 *N* sodium hydroxide, extracted with ether, dried over sodium sulfate and distilled through a 20 × 1.6 cm. helix-packed column; yield 55 g. (83.5%), b. p. 72–73° (8 mm.); $n^{25}D$ 1.5175–1.5185.

N,N-Dimethyl-(α,α-dimethylbenzyl)-amine.—N,N-Dimethyl-(α,α-dimethylbenzyl)-amine was prepared from 55 g. of α,α-dimethylbenzylamine, 108 g. of 87% formic acid and 92 ml. of 37% formaldehyde solution by a general procedure previously described.[12] The amine was liberated from its hydrochloride, extracted with ether, and distilled through a 20 × 1.6 cm. helix-packed column; yield 62 g. (94%), b. p. 84–87° (11 mm.), $n^{25}D$ 1.5071, d^{25}_4 0.9176; M_D calcd., 53.35; found, 52.96.

Anal. Calcd. for $C_{11}H_{17}N$: C, 80.92; H, 10.50; N, 8.58. Found: C, 80.94; H, 10.51; N, 8.84.

A picrate prepared from a sample of this amine and an equivalent amount of picric acid in 95% ethanol was recrystallized from a mixture of chloroform and ether, m. p. 210–212° (dec.).[17]

Anal. Calcd. for $C_{17}H_{20}N_4O_7$: C, 52.04; H, 5.14; N, 14.28. Found: C, 51.86; H, 5.37; N, 14.36.

N,N-Dimethyl-(α,α-dimethylbenzyl)-amine Oxide (II).—N,N-Dimethyl-(α,α-dimethylbenzyl)-amine (20 g.) was oxidized with 35% aqueous hydrogen peroxide (36 g.) during twenty-two hours. After decomposition of the excess hydrogen peroxide in the presence of 8 sq. cm. of platinum foil, an aliquot of the aqueous solution was extracted with ether to remove any remaining amine and treated with an equivalent quantity of picric acid in 95% ethanol. The picrate of II precipitated in 96% yield, m. p. 142–143°. It decomposed partially on attempted recrystallization from absolute ethanol, but was analytically pure as originally precipitated.

Anal. Calcd. for $C_{17}H_{20}N_4O_8$: C, 50.00; H, 4.94; N, 13.72. Found: C, 50.23; H, 5.12; N, 13.53.

N,N-Dimethyl-(α,α-dimethylbenzyl)-amine oxide remained as a viscous sirup after concentration in the manner described for preparation of I. II was decomposed in the same manner as I by heating in a nitrogen atmosphere at 3 mm. pressure and a bath temperature of 75–85° for one and one-half hours. The distillation of the volatile products was completed by raising the temperature to 200° briefly; the residue amounted to 1.2 g. The distillate was separated into a neutral and basic fraction in the manner described for isolating the decomposition products of I. The basic fraction yielded 7.5 g. (63%) of N,N-dimethylhydroxylamine hydrochloride. Fractionation of the dried pentane extracts yielded 11.3 g. (78%) of α-methylstyrene, b. p. 59–60° (15 mm.). A sample of the α-methylstyrene was characterized by treatment with isoamyl nitrite and hydrochloric acid, which yielded the nitrosochloride, which in turn was treated with an excess of piperidine in benzene. The nitrolpiperidine derivative of α-methylstyrene so obtained was recrystallized from hexane; m. p. and mixed m. p. with a known sample[18] 121–122°.

β-Methylallyldimethylamine and N,N-Dimethyl-(β-phenylisobutyl)-amine.—β-Methylallyl chloride (1 mole) was added dropwise with stirring to 4 moles of 25% aqueous dimethylamine solution during two and seven-tenths hours. The temperature of the reaction mixture rose from 24 to 39° from the heat of reaction. The mixture was stirred for two hours, allowed to stand overnight, and made strongly alkaline with 6 *N* sodium hydroxide. The amine was extracted with ether, the ether solution was dried over sodium sulfate, and distilled through a 20 × 1.6 cm. helix-packed column. The yield of β-methylallyldimethylamine[6] was 81 g. (82%), b. p. 82–83.5°, $n^{25}D$ 1.4055. Reaction of 49.5 g. of β-methylallyldimethylamine with benzene in the presence of anhydrous aluminum chloride yielded 60.7 g. (69%) of N,N-dimethyl-(β-phenylisobutyl)-amine[6]; b. p. 89–90° (9 mm.), $n^{25}D$ 1.4973–1.4983. A picrate prepared from this amine in 95% ethanol and recrystallized from absolute ethanol had m. p. 176–178.5°.

Anal. Calcd. for $C_{18}H_{22}N_4O_7$: C, 53.20; H, 5.46; N, 13.79. Found: C, 53.31; H, 5.49; N, 13.59.

N,N-Dimethyl-(β-phenylisobutyl)-amine Oxide (III).—N,N-Dimethyl-(β-phenylisobutyl)-amine (25 g.) was stirred with 33.5 g. of 35% aqueous hydrogen peroxide at room temperature until a clear solution was obtained (forty-eight hours). The excess hydrogen peroxide was destroyed by periodic addition of single drops of Catalase Sarett[19] until no more oxygen was evolved. The aqueous solution was extracted with ether to remove any unreacted amine and concentrated at 25 mm. pressure and a bath temperature of 45–55°. A portion of the white, crystalline solid residue was recrystallized from a mixture of absolute ethanol and ether with considerable loss. Analysis indicated that the solid so obtained was N,N-dimethyl-(β-phenylisobutyl)-amine oxide monohydrate.

Anal. Calcd. for $C_{12}H_{19}NO \cdot H_2O$: C, 68.21; H, 10.02; N, 6.63. Found: C, 67.95; H, 9.68; N, 6.49.

Equivalent quantities of III in water and picric acid in 95% ethanol yielded 98% of the picrate of III, m. p. after recrystallization from absolute ethanol as fine yellow needles 171–172° (dec.).

Anal. Calcd. for $C_{18}H_{22}N_4O_8$: C, 51.18; H, 5.25; N, 13.27. Found: C, 51.01; H, 5.32; N, 13.38.

III prepared from 25 g. of N,N-dimethyl-(β-phenylisobutyl)-amine was decomposed in the apparatus described for decomposition of I, except that a trap cooled with liquid nitrogen was placed between the second receiver and the vacuum pump. The flask containing the amine oxide was immersed in an oil-bath at 95° and then evacuated. The bath was heated slowly to 148° during thirty minutes, at which time decomposition of the amine oxide began and the pressure rose to 30 mm. The heating bath was removed rapidly and replaced after five minutes, when the vigorous decomposition had subsided and the pressure in the system had again fallen to 3 mm. (In other experiments the sudden decomposition blew the wide-bore tube connecting the flask and condenser out of the flask, and it presumably would be safer to conduct the decomposition in an inert, high-boiling solvent to dissipate the heat of reaction.) The oil-bath was heated to 220° during two hours; the residue amounted to 1.6 g. The trap cooled with liquid nitrogen contained only a few drops of condensate, from which no dimethylamine picrate could be isolated.

The distillate was separated into neutral and basic fractions as described under decomposition of I. The residue obtained on concentration of the hydrochloric acid solution was made strongly basic with 6 *N* sodium hydroxide and extracted with ether. The ether extracts were dried over sodium sulfate and distilled through a 20 × 1.0 cm. helix-packed column. N,N-Dimethyl-(β-phenylisobutyl)-amine was recovered in a yield of 9.7 g. (39%), b. p. 91–94° (12.5 mm.), and identified by the m. p. of its picrate and mixed m. p. with a known sample, which was not depressed.

The residues from distillation of the recovered amine and from the neutral fraction described below appeared to be identical from preliminary distillations, and were combined and refractionated through a 30 × 0.8 cm. semimicro column.[20] In this way 1.19 g. of a compound was obtained; b. p. 111–115.5° (0.85 mm.), $n^{25}D$ 1.5322–1.5332. The compound was weakly basic and formed salts with picric acid and picrylsulfonic acid which crystallized poorly and could not be purified. Analytical results were in poor agreement with the formula for O-(β-phenylisobutyl)-N,N-dimethylhydroxylamine (IV), indicating the presence of an impurity if that structure is correct.

Anal. Calcd. for $C_{12}H_{19}NO$: C, 74.56; H, 9.91; N, 7.25. Found: C, 74.69; H, 8.66; N, 7.57.

The pentane solution of the neutral product was dried over magnesium sulfate, concentrated, and distilled through a 20 × 1.0 cm. helix-packed column. α,α-Dimethylphenylacetaldehyde[21] was obtained in a yield of 1.6 g. (7.7%); b. p. 98.5° (17 mm.), 217–218° (Siwoloboff); $n^{25}D$ 1.5101, d^{25}_4 0.9854; M_D calcd., 44.80; found, 44.99.

Anal. Calcd. for $C_{10}H_{12}O$: C, 81.04; H, 8.16. Found: C, 80.74; H, 8.11.

The semicarbazone prepared from the aldehyde had m. p. 169–173°, and a sample of the aldehyde which was oxidized with silver oxide yielded α,α-dimethylphenylacetic acid,[22] m. p. 76.5–78°. Mixed m. p. of the acid with an authentic sample, m. p. 77.5–78.5°, obtained by the alkaline hydrolysis of α,α,α-dimethylphenylacetamide, was not depressed.

Small samples of N,N-dimethyl-(β-phenylisobutyl)-amine oxide hydrate were decomposed by heating at atmospheric pressure and the relatively small amount of gas which was evolved was collected. It proved to contain carbon dioxide and oxygen, and not to contain dimethylamine (picric acid did not precipitate a picrate).

Benzyldiethylamine Oxide (V).—Benzyldiethylamine (50 g.) was stirred with 75 g. of 35% aqueous hydrogen peroxide for seventeen hours, until a homogeneous solution was obtained. Excess hydrogen peroxide was decomposed by stirring the solution with platinum foil. Benzyldiethylamine oxide picrate, prepared in 95% yield from an aliquot of a similar preparation and picric acid in 95% ethanol and recrystallized from the same solvent, had m. p. 124.5–125°.

Anal. Calcd. for $C_{17}H_{20}N_4O_8$: C, 50.00; H, 4.94; N, 13.72. Found: C, 49.71; H, 5.07; N, 13.70.

The residual sirup of benzyldiethylamine oxide obtained on concentration was dried and decomposed by heating at 1 mm. in an oil-bath heated from 100 to 180° during one and one-half hours, in the manner described for decomposition of I. In a few cases the amine oxide crystallized before decomposition started. In such cases the flask containing the solid was heated momentarily with a free flame near the edge of the solid until decomposition started, as indicated by a pressure increase from 1 to 30 mm., to prevent a sudden decomposition. The temperature of the oil-bath was raised to 200° briefly; a residue of 1.5 g. remained. The distillate was combined with the material which was distilled during concentration of the amine oxide solution, and pentane was added. The dilute hydrochloric acid extract of the mixture was concentrated, made alkaline with 6 *N* sodium hydroxide, and extracted with ether, which was dried over sodium sulfate and distilled through a 20 × 1.0 cm. helix-packed column. The distillation yielded 2.7 g. (21%) of N,N-diethylhydroxylamine (VIII), 9.6 g. (19%) of O-benzyl-N,N-diethylhydroxylamine (VII) and 14.5 g. (34%) of N-benzyl-N-ethylhydroxylamine (VI).

The N,N-diethylhydroxylamine[23] had b. p. 48° (15 mm.), $n^{25}D$ 1.4173, d^{25}_4 0.8612; M_D calcd., 25.78; found, 26.04.

N,N-Diethylhydroxylamine picrate was prepared in 95% yield in 95% ethanol and recrystallized from benzene, m. p. 95–98°.

Anal. Calcd. for $C_{10}H_{14}N_4O_8$: C, 37.74; H, 4.43; N, 17.61. Found: C, 37.90; H, 4.76; N, 17.53.

N,N-Diethylhydroxylamine hydrochloride proved to be very hygroscopic and was not recrystallized satisfactorily. A sample prepared from VIII in ether and dry hydrogen chloride had m. p. 65–69.5° (sealed capillary).[24] The neutral oxalate had m. p. 137–140° after recrystallization from absolute ethanol.[25]

O-Benzyl-N,N-diethylhydroxylamine (VII) had b. p.

The picrate of O,N-dibenzyl-N-ethylhydroxylamine was prepared in 95% ethanol and recrystallized from absolute ethanol, m. p. 108.5–109.5°.

Anal. Calcd. for $C_{22}H_{22}N_4O_8$: C, 56.17; H, 4.72; N, 11.91. Found: C, 56.16; H, 4.83; N, 12.01.

A sample of benzyldiethylamine oxide, prepared from 20 g. of benzyldiethylamine and hydrogen peroxide, was decomposed by heating at atmospheric pressure in an oil-bath at 110–180° during one and eight-tenths hours. The ethylene which was formed was collected over sodium chloride solution in a gas buret, and amounted to 1.5 l. The ethylene was bubbled through bromine water and converted to ethylene dibromide, which was washed with water, dried over calcium chloride and distilled; yield 3.26 g. (14%), b. p. 128–130°.

Structure Proof of Compounds Formed by Decomposition of Benzyldiethylamine Oxide. (a) N-Benzyl-N-ethylhydroxylamine (VI).—A solution of 1.19 g. of VI in 10 ml. of 3 *N* hydrochloric acid was treated with 1.77 g. of stannous chloride dihydrate in 5 ml. of concentrated hydrochloric acid. The mixture was warmed on a steam-bath for six hours, diluted with water, and saturated with hydrogen sulfide. The precipitated tin sulfides were separated by filtration, and the filtrate and washings were concentrated under reduced pressure to yield 1.37 g. (102%) of benzylethylamine hydrochloride, m. p. 183–184°. Recrystallization from a mixture of absolute ethanol and ether gave white plates of the hydrochloride, m. p. and mixed m. p. with a known sample[26] 184–185°. A portion of the benzylethylamine hydrochloride was converted into the picrate, which after crystallization from aqueous ethanol had m. p. and mixed m. p. with a known sample[27] 122–123°.

(b) O-Benzyl-N,N-diethylhydroxylamine (VII).—A solution of 0.311 g. of VII in 10 ml. of absolute ethanol was hydrogenated in the presence of 0.3 g. of 10% palladium-on-Norite catalyst for thirty hours, in which time 1.45 molar equivalents of hydrogen was absorbed. The catalyst was separated by filtration, washed with ethanol and the filtrate and washings were distilled at atmospheric pressure until only a small residue remained. Addition of a solution of 0.40 g. of picric acid in 5 ml. of ethanol to the distillate precipitated diethylamine picrate as an oil which was crystallized from benzene. The yield of diethylamine picrate, m. p. 71–73°, was 0.412 g. (79%). A sample which was recrystallized from benzene had m. p. 73.5–74.5° and a mixed m. p. with a known sample was not depressed.

The residue remaining after distillation of the ethanol and diethylamine was warmed on a steam-bath for five minutes with 1 ml. of concentrated hydrochloric acid. The oil which separated was extracted with ether, dried over sodium sulfate and concentrated. Thiourea (0.13 g.) was added to a solution of the residue in 2 ml. of ethanol, and the mixture was warmed on a steam-bath for two minutes. Picric acid (0.4 g.) was added, and the mixture was cooled and diluted with water. Benzylisothiouronium picrate separated in a yield of 0.148 g. (22%), m. p. after recrystallization from aqueous ethanol 187–188.5°, which was not depressed on mixture with a known sample. The low yield of this derivative and the high hydrogen uptake in the catalytic reduction are presumed to be due to partial hydrogenolysis of the initially formed benzyl alcohol to toluene.

(c) O,N-Dibenzyl-N-ethylhydroxylamine (IX).—IX (0.13 g.) was heated under reflux with 25 ml. of 6 *N* hydrochloric acid for one and eight-tenths hours. The aqueous acid was distilled under reduced pressure, and the oily residue was treated with 0.13 g. of picric acid in 5 ml. of ethanol. After dilution with water to the point of turbidity, the picrate of O,N-dibenzyl-N-ethylhydroxylamine separated. Further dilution of the filtrate precipitated 0.062 g. (20%) of a second picrate, which after recrystallization melted at 76.5–79° and was identified as N-benzyl-N-ethylhydroxylamine picrate monohydrate by mixed m. p. with a known sample, which showed no depression.

In another similar hydrolysis of 0.38 g. of IX, the distillate of aqueous hydrochloric acid was extracted with ether. The extract was dried over sodium sulfate, concentrated, and the residue was warmed on a steam-bath with concentrated hydrochloric acid in the manner described under (b) above. Subsequent treatment with thiourea followed by picric acid as described in (b) yielded 0.10 g. (25%) of benzylisothiouronium picrate, m. p. 186.5–187.5°, which was not depressed by an authentic sample.

Summary

N,N-Dimethyl-(α-phenylethyl)-amine oxide (I) and N,N-dimethyl-(α,α-dimethylbenzyl)-amine oxide (II) undergo an elimination reaction rather than rearrangement on heating at 75–115°, forming N,N-dimethylhydroxylamine in both cases and styrene and α-methylstyrene, respectively. N,N-Dimethyl-(β-phenylisobutyl)-amine oxide (III) does not form an olefin on heating, indicating that the elimination reaction probably proceeds in a manner similar to the Hofmann reaction by attack of the amine oxide oxygen on β-hydrogen atoms (equation 1). Benzyldiethylamine oxide (V) rearranges in part on heating into O-benzyl-N,N-diethylhydroxylamine (VII), and also forms products of the elimination reaction, ethylene and N-benzyl-N-ethylhydroxylamine (VI). Additional products which are formed in this case

(26) Hoover and Hass [*J. Org. Chem.*, **12**, 508 (1947)] report m. p. 184°.

(27) Graymore *J. Chem. Soc.*, 41 (1941), reports m. p. 122–123°.

by the bimolecular alkylation of VI by V (equation 4) are O,N-dibenzyl-N-ethylhydroxylamine (IX) and N,N-diethylhydroxylamine (VIII).

Selective Oxidation with N-Bromosuccinimide. I. Cholic Acid[1]

BY LOUIS F. FIESER AND SRINIVASA RAJAGOPALAN[2]

The first objective of this work was to find an improved method for the conversion of cholic acid, the preponderant acid of available biles, into desoxycholic acid, the starting material for the only known synthetic routes to Kendall's Compound E, for which an important therapeutic use requiring greatly expanded supplies has recently been announced.[3] Wieland and Dane[4] discovered that 7α,12α-dihydroxycholanic acid can be converted into the 7-keto derivative in good yield by partial oxidation with chromic acid and thereby established the first of several instances of disparity between susceptibility of steroid alcoholic groups to acylation and to oxidation (except in Oppenauer oxidation, in which the first step is analogous to an acylation[5]). Iwasaki[6] effected the selective chromic acid oxidation of both 3α,7α- and 3α,7β-dihydroxycholanic acid to 3α-hydroxy-7-ketocholanic acid, and Kaziro and Shimada[7] demonstrated the selective oxidation of desoxycholic acid to 3α-hydroxy-12-ketocholanic acid. These Japanese workers thus established the order of susceptibility as $C_7 > C_{12} > C_3$ and correctly inferred that cholic acid should be convertible by chromic acid oxidation into the 7-keto derivative[7]; the failure of their own attempts to demonstrate the conversion is possibly attributable partly to the unfavorable melting point behavior of the 3α-hydroxy-7,12-diketocholanic acid that they isolated, as suggested by Gallagher and Long,[8] and partly to the difficulty in isolation of 3α,12α-dihydroxy-7-ketocholanic acid with high recovery even as the ester (Experimental part).

Haslewood[9] was the first to report the partial oxidation of cholic acid at C_7; by addition of aqueous chromate to cholic acid in acetic acid buffered with sodium acetate and Wolff–Kishner reduction of the crude oxidation mixture he obtained desoxycholic acid in yield of about 40%. Oxidation with chromic acid in acetic acid was studied by Gallagher and Long,[8] who isolated the 7-keto derivative as the methyl ester diacetate in 40% yield by chromatography, and by Hoehn and co-workers,[10] who obtained the ethyl ester in 41% yield; the latter workers report a yield of 41% (as ethyl ester) by oxidation of cholic acid with bromine in alkali at −5°.

As a means of evaluating various processes of partial oxidation, we adopted a standard procedure of conducting Wolff–Kishner reduction of the total oxidation mixture by the Huang-Minlon procedure[11] and isolating desoxycholic acid as the ether complex, from which pure desoxycholic acid can be quantitatively recovered.[12] The oxidation procedure of Haslewood[9] seemed the most promising, but in our experience the over-all yield from cholic acid was only 29.6%. Improved yields were obtained on applying the chromate oxidation procedure to the following pure derivatives: methyl cholate (47.5%); methyl cholate 3-acetate (85% yield); methyl 3-carbethoxycholate (83%). These derivatives were obtained in yields of 85, 39 and 80%, respectively, and hence the best route is through the methyl ester and its carbethoxy derivative, but the over-all yield is only 54%.

We then investigated with promising results oxidation with N-bromoacetamide in an aqueous medium, a method briefly applied in other instances by Reich and Reichstein.[13] The over-all yield of desoxycholic acid etherate from cholic acid by use of N-bromoacetamide in aqueous acetone was 57%, and the yields from various 3-derivatives were not sufficiently higher to compensate for the losses attending their preparation.

We then turned to the more readily prepared and commercially available N-bromosuccinimide which as far as we are aware has not been employed for the oxidation of secondary alcohols,[14] and found that it is a superior reagent for selective oxidations of substantially different character from N-bromoacetamide. Initial oxidations of cholic acid in aqueous acetone afforded, after usual reduction, pure desoxycholic acid etherate

in 70% yield. We then found that the process can be simplified by conducting the oxidation in aqueous sodium bicarbonate solution. The best yields (68%) were obtained with 1.25–1.5 moles of N-bromosuccinimide, but a still larger excess had little deleterious effect. We then submitted pure desoxycholic acid to treatment with 1.25 moles of reagent under the same conditions and recovered the starting material unchanged. The reagent thus does not merely attack cholic acid preferentially at C_7 but attacks this position and leaves C_3 and C_{12} untouched. Chromic acid effects preferential oxidation at C_7 but effects successive oxidations at C_{12} and then C_3, and the same is true of bromine in aqueous alkali,[15] and even of microbiological oxidation.[16] Lardon[17] found that methyl etiocholate can be oxidized selectively to the 7-keto derivative with N-bromoacetamide in aqueous acetone in "good yield," but Reich and Reichstein[13] cite experiments showing that the same reagent (in aqueous *t*-butanol) effects oxidation of the following alcoholic groups at room temperature: 3α-, 12α-, 12β-, 17β-; thus desoxycholic acid was oxidized to the diketo acid. Sarett[18] observed the smooth oxidation of a 3α-hydroxysteroid with N-bromoacetamide in pyridine–*t*-butanol. The lack of reactivity of N-bromosuccinimide for 3α- and 12α-hydroxyl groups under the conditions that we have employed suggests a fundamental difference between the seemingly similar reagents. Direct comparison of the specificities of the various oxidizing agents under comparable conditions is in progress.

The unique specificity of the new oxidation procedure suggested an expedient for further increasing the availability of desoxycholic acid from bile. Since the desoxycholic acid present in the total acids from a bile hydrolyzate is not attacked by N-bromosuccinimide, and since adequate purification is accomplished in the course of the oxidation–reduction–etherate process outlined, the separation and purification of the component bile acids can be dispensed with and the total crude bile acids oxidized with excess N-bromosuccinimide in aqueous soda solution and the oxidation mixture reduced and processed as before. Lithocholic acid and other contaminants are removed in the ether solution, and pure desoxycholic acid is obtained very easily in yield estimated to be 34% higher than obtainable by separating the components by the usual procedures and processing the cholic acid by the present method, or in over twice the yield realizable by previous methods.

We are indebted to Dr. Max Tishler and his group at the Merck Laboratories for supplies and for friendly coöoperation.

Experimental[19]

Methyl Cholate.—The melting points recorded for this ester differ widely: 147°,[20,21] 141–142°,[22] 156–158°,[23] 160–162°.[24] We prepared the ester by a combination of previous procedures[22,24] as follows: 100 g. of technical grade cholic acid (m. p. 195–197°) was dissolved by warming in 400 cc. of methanol containing 1 g. of hydrogen chloride per 100 cc. and the mixture allowed to stand overnight and then cooled in ice. The crystalline product that separated was found to be solvated; it was collected, air-dried, and dissolved in 250 cc. of toluene, and 200 cc. of solvent was removed by distillation with a free flame. Enough benzene was added to bring the solid into solution at the boiling point, and the solution was filtered and diluted with ether to the point of distinct turbidity and let stand overnight. The methyl cholate that crystallized was washed freely with ether and amounted to 73 g., m. p. 155–156°. The methanol and ethereal solutions afforded a further 15 g. of ester, m. p. 155–156°; yield 85%. A sample recrystallized from toluene–ether formed colorless needles, m. p. 155–156°.

Anal. Calcd. for $C_{25}H_{42}O_5$: C, 71.06; H, 10.01. Found: C, 71.00; H, 10.00.

Methyl Cholate 3-Acetate.—Although Meystre and Miescher[24] report difficulties in preparing this derivative, we found the directions of Grand and Reichstein[22] satisfactory and obtained nearly the yield specified; thus 88 g. of methyl cholate afforded 37.5 g. (39%) of the pure acetate, m. p. 149–150°. Attempts to raise the yield by conducting the acetylation with limited amounts of acetic anhydride in pyridine were unsuccessful.

Methyl 3-Carbethoxycholate.—This derivative was found to melt considerably higher than reported by Borsche,[25] who records the m. p. 147°. A solution of 42 g. of methyl cholate in 100 cc. of pyridine was treated gradually with 50 g. of ethyl choloformate with occasional cooling under the tap. The mixture was allowed to stand overnight, diluted with water, and the precipitated solid collected and washed. The yield of crude product, m. p. 173–175°, was 46 g. Crystallization from methanol afforded 39 g. (80%) of product, m. p. 176–177°, with slight shrinking at 148°.

Anal. Calcd. for $C_{28}H_{46}O_7$: C, 67.98; H, 9.38. Found: C, 67.95; H, 9.25.

Oxidation with Chromate.—Oxidations were conducted by the procedure of Haslewood,[9] the crude oxidation mixture was reduced according to Huang-Minlon,[11] and the desoxycholic acid was isolated as the etherate as described below and this derivative was dried at 90–100° in vacuum for one-half hour. Although the etherate is described as a 1:1 complex,[12] recovery experiments such as that cited below indicate that material dried in this manner is more nearly a 1:6 complex and we have calculated yields on the basis of the empirically determined molecular weight 400; the yields from 5-g. samples were: cholic acid, 1.45 g. (29.6%); methyl cholate, 2.25 g. (47.5%); methyl cholate 3-acetate, 3.66 g. (85%); methyl 3-carbethoxycholate, 3.2 g. (83%). The free desoxycholic acid melted at 171–173°.

Oxidation of N-Bromoacetamide.—A solution of 5 g. of cholic acid in 150 cc. of pure acetone was diluted with 50 cc. of water and treated at 25° with 2 g. of N-bromoacetamide (m. p. 108°) and 10 cc. of acetic acid. The solution turned yellow and then brown and in about fifteen minutes became colorless. After about three hours 50 cc. of water was added, solvent was removed at reduced pressure to the point of distinct turbidity, and a large volume of water was added to precipitate the product as a gum. This crude

material was reduced and the desoxycholic acid isolated as the etherate (mol. wt. assumed, 400) as described in detail below; yield 2.8 g. (57%). Yields of etherate from 5-g. samples of pure derivatives were as follows: methyl cholate, 3.3 g. (69%); methyl cholate 3-acetate, 3.0 g. (70%); methyl 3-carbethoxycholate, 3.1 g. (77%).

Methyl 3α-Acetoxy-7-keto-12α-hydroxycholanate.—The oxidation product from methyl cholate 3-acetate was a granular solid that on crystallization from methanol afforded colorless platelets, m. p. 175–176°.

Anal. Calcd. for $C_{27}H_{42}O_6$: C, 69.93; H, 9.15. Found: C, 70.01; H, 9.25.

Methyl 3-carbethoxy-7-keto-12α-hydroxycholanate also separated as a solid on dilution; it crystallized from methanol as either plates or needles, m. p. 181–182°.

Anal. Calcd. for $C_{28}H_{44}O_7$: C, 68.26; H, 9.00. Found: C, 68.57; H, 9.24.

Oxidation with N-Bromosuccinimide[26]; Preferred Procedure.—Eighty grams of technical cholic acid (Armour Laboratories, m. p. 195–197°) was dissolved by warming in a solution of 50 g. of sodium bicarbonate in 1.6 l. of tap water and the solution was cooled to 25°, treated with 43.7 g. (1.25 equiv.) of N-bromosuccinimide, and shaken occasionally until the reagent had all dissolved (about one and one-half hours). The yellow solution was allowed to stand at 25° for about seventeen hours, heated on the steam-bath for one hour, cooled in ice and acidified with dilute hydrochloric acid (1:2), added slowly with vigorous stirring and scratching. The keto acid separated as a white, granular solid and after cooling in ice for one-half hour it was collected, washed well with water, dried superficially between filter papers, transferred to a 1-l. round-bottomed flask with a ground joint and dried by evaporation to dryness with methanol (500 cc.; this saves time in the next step).

The flask was then charged with 600 cc. of triethylene glycol, 90 cc. of 86% hydrazine solution (the amount can be reduced to about 2 equivs.) and 70 g. of potassium hydroxide pellets, and heated cautiously under reflux in an oil-bath to a temperature of about 130° (thermometer suspended through condenser), when a vigorous exothermic reaction sometimes sets in (*e. g.*, when the starting acid is very impure). The flask was removed from the bath a few times until the frothing had subsided and then the mixture was refluxed gently for one-half hour; the condenser was removed and distillation conducted until the temperature had risen to 190°, and refluxing was continued for two to three hours at 190–200°. The solution was cooled, diluted with tap water to about 2 l., and acidified with 1:2 hydrochloric acid. On standing overnight the crude desoxycholic acid became granular and could be filtered easily. It was washed well, dried between filter papers, and then dried by evaporation with 500 cc. of methanol nearly to dryness (toward the end with a current of air). The residue while still warm was dissolved in 500 cc. of warm absolute ethanol and the solution allowed to stand at room temperature for one-half hour for separation of a trace of impurity, and filtered by gravity (100 cc. of ethanol for washing). The clear yellowish filtrate was evaporated to dryness as before (air current) and the slightly brown residual sirup was treated with 400 cc. of dry ether and alternately shaken and briefly heated until the gum had dissolved and given rise to a precipitate of desoxycholic acid etherate (unreacted lumps can be broken up with a flattened rod). After three or four hours with occasional shaking, the white etherate was collected, washed with 150–200 cc. of dry ether, and dried at 90–100° in vacuum for one-half hour. The etherate melts unsharply above 145°; some samples partly melted, resolidified, and remelted to a clear liquid at 170–173°. The average yield in three concordant experiments was 53 g. (68%, calculated for mol. wt. 400).

For conversion to free desoxycholic acid the above complex was heated on the steam-bath with 2.5 l. of tap water with stirring for one and one-half hours, when the solid partly melted and then resolidified. The mixture was cooled and the acid collected, triturated with cold water in a mortar, collected, and dried in vacuum at 100–110° for two hours. The white solid melted at 170–172°; average yield 51.8 g. (68%).

Ethyl 3α,12α-Dihydroxy-7-ketocholanate.[27]—The crude oxidation mixture from 80 g. of cholic acid was dehydrated by evaporation with 400 cc. of methanol, refluxed with 400 cc. of absolute ethanol and 12 cc. of boron fluoride etherate for three hours, and the solution concentrated to half its volume and poured into water. The dark-brown gummy product that separated was washed and rubbed repeatedly with water and with bicarbonate solution and evaporated with 300 cc. of methanol. The resulting solid was dissolved in 300 cc. of methanol, and the solution slowly deposited a crop of small crystals of the keto ester of high purity, m. p. 158–159°; yield 34 g. (40%).

The dark mother liquor and washings were evaporated and the dark-red gummy residue reduced according to Huang-Minlon and the mixture processed for recovery of desoxycholic acid etherate by the usual procedure. The yield of pure complex was 27 g. (34.5%). The combined yield corresponds to that of the above oxidation–reduction process and the experiment shows that the 7-keto acid can be isolated easily in a pure form as the ethyl ester but only in yield slightly better than half the amount actually present.

Other Oxidation Conditions.—Oxidation of cholic acid (40 g.) in acetone (1 l.)–water (400 cc.) with N-bromosuccinimide (21.8 g.) and processing as usual afforded 27.4 g. (70%) of desoxycholic acid etherate. Oxidation of methyl cholate in the same way with 1.25, 1.5 and 2.0 equivalents of the bromoimide gave the etherate in yields of 68, 68 and 63%, respectively; with 1.0 equivalent of reagent the product was contaminated with traces of cholic acid. Oxidation of methyl cholate in aqueous acetone with 1.25 equivalents of N-bromophthalimide gave the etherate in 68% yield. Attempted oxidation with chloramine-T was unsuccessful. Oxidation of cholic acid (5 g.) in aqueous bicarbonate solution at 25° as above but with use of 1.2 equivalents of bromine resulted in a lower yield of etherate (2.4 g., 49%).

Resistance of Desoxycholic Acid to N-Bromosuccinimide.—Five grams of technical desoxycholic acid or of the etherate (dried as above) was treated in 150 cc. of acetone and 50 cc. of water with 2.5 g. of N-bromosuccinimide and 10 cc. of acetic acid. The solution was allowed to stand for sixteen hours (the usual color changes occurred) and processed exactly as above, including Wolff–Kishner reduction. Desoxycholic acid etherate of usual purity was the only product recovered; yields 5.0 g. and 4.7 g.

Desoxycholic Acid from Total Bile Acids.—One hundred grams of the total acid precipitate prepared by saponification of 198 g. of a 75% sheep bile concentrate with refluxing alkali for eighteen hours and acidification was dissolved in 1.5 l. of water containing 65 g. of sodium bicarbonate and treated with 56 g. of N-bromosuccinimide at 25°. The initially dark solution improved in color as the oxidation progressed. After twenty-four hours the light greenish-yellow solution was filtered by gravity from a fine gray solid and acidified, and the rubbery precipitate was kneaded with water and submitted to reduction with 110 cc. of 85% hydrazine, 700 cc. of triethylene glycol and 85 g. of potassium hydroxide. The rest of the processing was done in the usual way except that the desoxycholic acid etherate was ground in a mortar with ether before the final collection. The complex was nearly colorless and melted at 175–177°, after shrinking at 145–155°; yield 41.5 g. The reddish-brown ethereal mother liquor was not worked up further. The yield corresponds

(26) Commercial material was most conveniently purified by adding 300 g. to 3 l. of boiling water, filtering the hot solution quickly through a conical funnel fitted with a small plug of absorbent cotton, and cooling the filtrate; the colorless plates that separated melted at 178–179°; yield 210 g.

(27) Haslewood, *Biochem. J.*, **38**, 108 (1944).

to 21.7 g. of free desoxycholic acid per 100 g. of sheep bile concentrate. By the usual methods of separation, 100 g. of concentrate yields about 4.4 g. of desoxycholic acid and 16.8 g. of cholic acid, convertible into 10.9 g. of desoxycholic acid by our process to give a total of 15.3 g. of the acid.

Summary

An improved method for the conversion of cholic acid into desoxycholic acid has been found in oxidation of the free acid at C_7 with N-bromosuccinimide in aqueous bicarbonate solution, followed by Wolff–Kishner reduction according to Huang-Minlon; the over-all yield is 68%. The oxidizing agent is more selective than chromic acid, bromine or even N-bromoacetamide, for the alcoholic groups at C_3 and C_{12} remain unattacked in the presence of an excess. In consequence, desoxycholic acid can be prepared with greater efficiency and ease than heretofore by direct application of the procedure to the total crude acids of saponified bile.

Selective Oxidation with N-Bromosuccinimide. II. Cholestane-3β,5α,6β-triol[1]

BY LOUIS F. FIESER AND SRINIVASA RAJAGOPALAN[1]

On exploring further possible applications of a method of oxidation found particularly effective for the selective oxidation of the 7α-hydroxyl group of cholic acid, we found that cholesterol (I) on oxidation with N-bromosuccinimide in aqueous acetone is converted in moderate yield into cholestane-3β,5α-diol-6-one (III).[2] The reaction could conceivably proceed through an intermediate oxide, but cholesterol α-oxide (Va) under the same conditions was found to yield a mixture containing only a small amount of the diolone III together with cholesterol 5,6-dibromide, and a bromo α,β-unsaturated ketone of analysis and absorption spectrum consistent with formula VI. We then found that cholestane-3β,5α,6β-triol can be oxidized to the diolone III in extraordinarily high yield in aqueous dioxane, acetone, or even methanol–ether or methanol. The triol II is known to be attacked preferentially at C_6 on chromic acid oxidation,[3] but an oxidation conducted by adding the reagent gradually over a ten-hour period afforded the 6-ketone as 3-acetate in only 65% yield, for without careful control the 3,6-diketone is easily formed.[2] No control is required in the present procedure, for the same high yield was obtained with 2.1 as with 1.05 equivalents of N-bromosuccinimide.

The best previous methods for preparation of cholestane-3β,5α,6β-triol are by reaction of cholesterol on the 3-acetate with hydrogen peroxide in acetic acid over a period of four days and saponification of the resulting acetate mixture, or hydrolysis of cholesterol α,β-oxide mixture.[2,4,5] Cleavage of the oxides by acetolysis with organic acids and hydrolysis with dilute sulfuric acid are attended with extensive or partial ester formation. An interesting incidental observation is that both cholesterol α-oxide and cholesteryl α,β-oxide acetate can be cleaved in high yield to the triol II or its 3-acetate by the action of periodic acid in refluxing aqueous acetone. This acid apparently functions as a satisfactory catalyst but is incapable of forming esters; the *trans*-triol suffers no appreciable glycol cleavage under the mild conditions required for hydrolysis (one-half hour).

Of more practical importance is the development of a reliable procedure for hydroxylating the double bond of cholesterol with hydrogen peroxide and formic acid.[6] Brief heating of cholesterol with 88% formic acid produces the 3-formyl derivative, and on addition of hydrogen peroxide to the resulting suspension a clear solution soon results and precipitation with water gives a mixture of esters from which cholestane-3β,5α,6β-triol 3,6-diformate can be isolated by crystallization. Brief saponification of the total mixture affords the pure triol in 91% yield.

Since cholestane-3β,5α-diol-6-one (III) can thus be prepared very easily in quantity from cholesterol in 85.5% over-all yield, it may serve as a useful intermediate to steroids of importance. However, two possible routes from this substance to 7-dehydrocholesterol have been investigated with negative results. The 3,5-diacetate (IV), known as a by-product of the chromic acid oxidation of cholesteryl acetate,[7] can be prepared readily by treatment of the diolone III with acetic anhydride and boron fluoride at room temperature. Since the tertiary acetoxyl group at C_5 when once formed is very resistant to saponification,[7] it seems possible that the ready acylation at this position may be the consequence of enol acetate formation and migration of the acetyl

group from C_6 to C_5 through a cyclic acetal.[8] Attempts to introduce a Δ^7-double bond into the diacetate IV by reaction with selenium dioxide in refluxing acetic acid or nitrobenzene were unsuccessful. All attempts to brominate IV at C_7 with N-bromosuccinimide or pyridine hydrobromide perbromide[9] resulted only in recovery of starting material. Bromination finally was accomplished with use of bromine in hot acetic acid with boron fluoride as catalyst, but the chief product was contaminated with a difficultly separable isomer. More homogeneous material was obtained by similar bromination of cholestane-3β,5α-diol-6-one 3-acetate (VII), easily available by partial acetylation of the diolone (III) in pyridine. The bromo monoacetate (IX) on acetylation in the presence of boron fluoride yielded a pure diacetate (VIII) identical with the chief product of bromination of IV. This diacetate proved to be resistant to attempted dehydrobromination with triethylamine or pyridine, and hence the 7-bromo atom must have the β-configuration, *cis* to the hydrogen at C_8. The 3-monoacetate IX suffered slow dehydrobromination in refluxing triethylamine to give a mixture from which two isomers were isolated of composition corresponding to replacement of bromine by hydroxyl. The more abundant isomer, however, is acidic and probably results from a rearrangement, as in formula X. Such a rearrangement is analogous to that established[10] in the dehydrohalogenation of 5,7-dibromocholestane-3β-ol-6-one.[11] Further applications of the hydroxylation and oxidation procedures are under investigation.

Experimental[12]

Cholestane-3β,5α-diol-6-one[2] from Cholesterol (S.R.).—A suspension of 4.5 g. of cholesterol in 200 cc. of acetone and 25 cc. of water was treated with 2.5 g. (1.25 equiv.) of N-bromosuccinimide and 2.5 cc. of acetic acid and shaken occasionally at room temperature. In the course of forty-five minutes the mixture became yellow, orange, and then colorless and the solid all went into solution. After standing overnight the solution was diluted and extracted with ether, and the extract was washed with water and alkali, dried, and concentrated until crystals began separating. The material was collected and further small crops obtained by concentration of the mother liquor. Crystallization from chloroform gave colorless needles that separated in a fibrous mat and melted at 231–232°; yield 2.4 g. (49%).

Anal. Calcd. for $C_{27}H_{46}O_3$: C, 77.45; H, 11.08. Found: C, 77.63, 77.75; H, 10.99, 10.76.

The identity was established by conversion to the *phenylhydrazone*,[2] m. p. 163–164°, and to the mono and diacetates as described below. When the oxidation was conducted with 3.25 equivalents of N-bromosuccinimide the yield dropped to 23%. The yield was also lower when dioxane was substituted for acetone or when no acetic acid was added. Processing of the combined ethereal mother liquors afforded a small amount of a substance that separated from ethanol in colorless needles, m. p. 122°, dec., that was identified as **5,6-dibromocholesterol** by mixed m. p. determination.

Oxidation of cholesteryl acetate (5 g.) by the same procedure gave an oil that when triturated with petroleum ether afforded 1.2 g. of crude solid, m. p. 160–170° (positive test for bromine). Several crystallizations from ligroin and methanol eventually gave a small crop of needles, m. p. 230–231°, identified as **cholestane-3β,5α-diol-6-one 3-acetate**[2] by mixed melting point comparison.

(12) Melting points are uncorrected.

Cholestane-3β,5α,6β-triol (S.R.).—A suspension of 20 g. of technical cholesterol in 200 cc. of 88% formic acid was heated to 70–80° with stirring for five minutes to form a derivative that is evidently the 3-formate, which separated as an oily layer, and cooled to 25°. The resulting thick paste of solidified formate was treated with 20 cc. of 30% hydrogen peroxide and shaken occasionally. The temperature usually rose to 35–40°; sometimes there was an even more pronounced heat effect and in this case the temperature was controlled to 40° by cooling. After about forty-five minutes the solid dissolved, the foam subsided, and a blue fluorescent solution resulted, but the temperature remained a few degrees above that of the room for about four hours longer. After a total reaction time of six to fifteen hours, the mixture was treated with 300 cc. of boiling water, stirred, allowed to cool, and the granular white solid collected, dried superficially, dissolved in 600 cc. of methanol, and the solution treated with 20 cc. of 25% sodium hydroxide, warmed on the steam-bath for ten minutes, filtered, acidified and diluted with 200 cc. of water. The white solid that precipitated was collected after cooling, washed well with water and thoroughly dried. The triol so obtained was of high purity, m. p. 236–238°, and the yield, duplicated in several experiments, was 19.7 g. (91%). Crystallization from methanol gave needles, m. p. 237–239°.

Cholestane-3β,5α,6β-triol-3,6-diformate was isolated as the chief product of the reaction of cholesterol with performic acid by crystallization of the solid material prior to saponification. Several crystallizations from methanol gave colorless needles, m. p. 180–181°, $[\alpha]^{28}D$ − 47.5° (dioxane).

Anal. Calcd. for $C_{29}H_{46}O_5$: C, 73.38; H, 9.77. Found: C, 73.54; H, 10.05.

Cholestane-3β,5α,6β-triol-3-acetate-6-formate (S.R.).—Hydroxylation of cholesteryl acetate with hydrogen peroxide in formic acid suspension as above proceeded sluggishly. There was little heat effect, and the solid did not go into solution on stirring the mixture at 40–50° for about eight hours. The precipitated product afforded triol of poor quality (m. p. 218–225°) in low yield (65%) on saponification; repeated crystallization of the unsaponified precipitate from methanol afforded colorless needles, m. p. 201–202°, $[\alpha]^{28}D$ − 43.9° (dioxane).

Anal. Calcd. for $C_{30}H_{48}O_5$: C, 73.74; H, 9.90. Found: C, 73.72; H, 9.97.

Reaction of Cholesterol α-Oxide with N-Bromosuccinimide (L.F.F.).—The α-oxide[13] was prepared by reaction of cholesterol with perphthalic acid in ether solution at room temperature. The precipitation of phthalic acid was complete in about two hours; the alkali-washed filtrate was dried, evaporated to a small volume and diluted with petroleum ether, and the α-oxide, m. p. 138–139.5°, separated in yield of 59%; recrystallized material melted at 147–148°.

A solution of 2 g. of the oxide in 80 cc. of acetone was treated with 2 cc. of acetic acid and 10 cc. of water, the precipitated material was brought into solution by gentle warming, and 1.07 g. (1.2 equiv.) of N-bromosuccinimide was added. This soon dissolved to a yellow solution and after a time long needles of the oxide separated and then, within about five hours, began to dissolve. Brief shaking resulted in a clear solution, and in a few hours a total of 0.7 g. of crystals of a different form separated. Recrystallization of this material from ethyl acetate gave large rectangular prisms, m. p. 158° dec. On further crystallization from benzene the substance, which is provisionally regarded as **7-bromo-Δ⁴-cholestene-3β-ol-6-one (VI)**, formed clusters of cottony needles, m. p. 158–159°, dec., $[\alpha]^{28}D$ −33.3° (dioxane), λ_{alc}^{max} 238–243 mμ (log ε 4.2).

Anal. Calcd. for $C_{27}H_{43}O_2Br$: C, 67.62; H, 9.04. Found: C, 67.39; H, 8.84.

The mother liquor on concentration and addition of water afforded a total of 0.88 g. of material melting above 200°, but a component of constant m. p. was obtained only after several crystallizations from methanol in yield of 0.2 g. This substance formed large, flat needles, m. p. 231–232°, and gave no depression when mixed with **cholestane-3β,5α-diol-6-one.**

Cleavage of 5,6-Oxides with Periodic Acid (L.F.F.).—A solution of 1 g. of cholesterol α-oxide in 30 cc. of hot acetone was treated with a solution of 0.625 g. of periodic acid dihydrate in 10 cc. of water. Before all of the precipitated oxide had redissolved, thin plates of the cleavage product began to separate. The mixture was refluxed for one-half hour, cooled, and the product collected and washed with acetone–water (1:1). The thoroughly dried material (0.83 g.) melted at 231–232° and showed no depression when mixed with cholestane-3β,5α,6β-triol. Dilution of the mother liquor at the boiling point afforded a second crop of 0.14 g. of crystals, m. p. 225–226° (total yield, 94%). Recrystallization of the combined crops from methanol afforded flat needles, m. p. 234–235°.

Cholesteryl α,β-oxide acetate (8 g.) was refluxed for one hour in acetone solution (140 cc.) with 2 g. of periodic acid dihydrate in 20 cc. of water and the solution was filtered and concentrated to the point of saturation. A first crop of cholestane-3β,5α,6β-triol-3-acetate, m. p. 205–206°, amounted to 5.93 g. Concentration of the mother liquor afforded three further crops that separated either as plates or prisms and melted in the range 203–206°. The total yield of 3-acetate was 7.24 g. (87%).

Cholestane-3β,5α-diol-6-one (III) from the *trans*-Triol (S.R. and L.F.F.).—The selective oxidation of the triol at C_6 by N-bromosuccinimide proceeds readily in aqueous acetone or methanol with either a small or large excess of reagent. The following procedures were found particularly satisfactory.

(a) **In Aqueous Dioxane.**—A solution of 10 g. of triol in 90 cc. of dioxane was diluted with 10 cc. of water, cooled to 25° and treated with 4.5 g. (1.05 equiv.) of N-bromosuccinimide, which promptly dissolved. In the course of three to four minutes the color changed to yellow, deep orange, light yellow, and colorless, and the reaction product began to separate. The temperature was kept at 25° by cooling, and after ten minutes the mixture was cooled in ice and the diolone collected and washed with 50% methanol; the fully dried material weighed 6.7 g., m. p. 232–233°, dec. The mother liquor was diluted with water and extracted with ether, and the washed and dried solution was concentrated until crystals of the diolone began to separate, and a further crop of 2.5 g. of ketone of satisfactory purity was obtained; total yield of material, m. p. 231–233°, dec., 9.2 g. (93%).

In an experiment conducted without the addition of water the reaction was slow and the reaction product was obtained in low yield and very inferior quality.

(b) **In Aqueous Methanol–Ether.**—A 1-liter separatory funnel was charged with 23 g. of the triol, 450 cc. of ether, 75 cc. of methanol, 75 cc. of water and 10.8 g. (1.05 equiv.) of N-bromosuccinimide and shaken to effect solution. Oxidation was over in a few minutes and gave an orange-yellow solution. On addition of water the color became lighter and the bulk of the diolone separated from the organic phase as colorless, shiny needles. The water phase was tapped off and the suspension in ether washed with bisulfite solution, with alkali and with water. The ketone was then collected on a Buchner funnel and washed with ether to give a first crop of 19 g., m. p. 232–233°, dec. Successive concentrations of the mother liquor afforded two additional crops amounting to 3 g., m. p. 232–233°, dec.; total yield 22 g. (96.5%).

In parallel experiments on one-tenth the above scale with 1.05 and with 2.1 equivalents of N-bromosuccinimide, the yield of product in the first crop was 1.94 g. (m. p. 231–232°) and 1.91 g. (m. p. 231–232°), respectively.

Cholestane-3β,5α-diol-6-one 3-Acetate.[2] **(a) By Acetylation (S.R.).**—A mixture of 10 g. of the diolone, 50 cc. of acetic anhydride and seven drops of pyridine was heated to the boiling point, allowed to cool to room temperature and treated with water. The reaction product consisting

(13) Hattori, *J. Pharm. Soc., Japan*, **60**, 334 (1940) (*C. A.*, 7294 (1940)).

of colorless needles was washed with a little methanol and dried; yield 10.7 g. (91%). Material recrystallized from methanol melted at 232–233° and did not depress the sample (b).

(b) **By Oxidation (L.F.F.).**—A mixture of 400 mg. of cholestane-3β,5α,6β-triol 3-acetate and 200 mg. (1.3 equiv.) of N-bromosuccinimide was dissolved in 15 cc. of acetone by slight warming, cooled to 25° and treated with 1 cc. of water. The solution turned pale yellow in one or two minutes, crystals began to separate in ten minutes and the yellow color disappeared in twenty-five minutes. After a total of one and one-half hours 10 cc. of water was added and the precipitated solid collected; yield 370 mg. (93%), m. p. 229–230°; recrystallized: m. p. 232–233°.

Cholestane-3β,5α-diol-6-one 3,5-Diacetate[2,3] **(L.F.F. and S.R.).**—A suspension of 10 g. of the diolone in 50 cc. of acetic anhydride was treated with six drops of boron fluoride etherate, stirred, and the lumps broken up with a stirring rod. The bulk of the solid rapidly dissolved with a slight rise in temperature, and complete solution was effected by brief warming on the steam-bath. After fifteen minutes water was added and the crystalline yellow solid that soon separated was collected and the color removed by washing with a little methanol. Crystallization from methanol afforded 8.5 g. (71.5%) of the diacetate as prismatic needles, m. p. 170–171°.

Anal. Calcd. for $C_{31}H_{50}O_5$: C, 74.04; H, 10.02. Found: C, 74.25; H, 10.14.

A sample of the diacetate (5 g.) was refluxed with selenium dioxide (2.5 g.) in acetic acid (50 cc.) for six hours, but was recovered unchanged (4.7 g.). A similar experiment conducted in refluxing nitrobenzene (2 g. diacetate, seven hours) led to extensive tar formation, and the only product isolated was starting material (0.8 g., m. p. 169–170°).

7β-Bromocholestane-3β,5α-diol-6-one 3-acetate (L.F.F.).—A solution of 3.23 g. of cholestane-3β,5α-diol-6-one 3-acetate in 70 cc. of acetic acid was treated at 60° with a solution of 1.23 g. of bromine in 35 cc. of acetic acid and 1 cc. of boron fluoride etherate, kept at 60° for fifteen minutes, when the solution had become light yellow, let stand for one hour and diluted with 100 cc. of water. The dried precipitate (3.71 g., m. p. 88–100°) was ground in a mortar with a little methanol, when initially a part dissolved and a part formed a gum. Further trituration produced a thick paste of white solid, which when collected, washed and dried weighed 2.90 g. (71%).

The bromo derivative is very readily soluble in ether, fairly soluble in petroleum ether and moderately soluble in hot methanol (about 30 cc./g.). On repeated crystallization from methanol it formed a cottony mat of fine needles of the constant m. p. 170–171°; $[\alpha]^{28}D$ +7.5° (dioxane).

Anal. Calcd. for $C_{29}H_{47}O_4Br$: C, 64.55; H, 8.78. Found: C, 64.60; H, 8.63.

Dehydrobromination was accomplished by refluxing a solution of 1 g. of the 3-acetate in 10 cc. of triethylamine. The amine hydrobromide is insoluble in the boiling amine; the amount collected after seven hours and washed with ether represented 28% of the theory, and after twenty-four hours of refluxing the total yield of salt was 267 mg. (93%). The only slightly discolored filtrate and washing were evaporated at reduced pressure and the residue was washed in ether with acid and water and the solution dried and evaporated. The resulting light brown gum was chromatographed in petroleum ether (30–60°) by Dr. Huang-Minlon. Elution with petroleum ether–benzene (1:3; 1:1; 2:1) and with pure benzene gave fourteen fractions, the first five of which were oily. The next three fractions melted in the range 150–172° and were halogen-free, and crystallization of the total from acetone–ligroin (70–90°) afforded a few milligrams of isomer A, m. p. 173–175°.

Fraction 11 afforded 125 mg. of halogen-free crystals, m. p. 167–168°. Recrystallization from methanol (m. p. 168–169°) and then from acetone–petroleum ether gave isomer B (probably X), m. p. 170–171°. The substance is only slightly soluble in boiling dilute soda solution, but the cooled and filtered solution gives a definite precipitate on acidification.

Anal. Calcd. for $C_{29}H_{48}O_5$: C, 72.97; H, 10.19. Found, A: C, 73.36, 73.28; H, 10.00, 10.15. B: C, 73.24; H, 10.30.

7β-Bromocholestane-3β,5α-diol-6-one 3,5-Diacetate (L.F.F.).—A solution of 1.5 g. of the 7β-bromo 3-acetate in 13 cc. of hot acetic anhydride was treated with five drops of boron fluoride etherate and let cool, when 1.5 g. (79.5%) of the diacetate separated in crystalline form, m. p. 214–216°. Recrystallization from 250 cc. of methanol afforded 1.29 g. of needles, m. p. 216.5–217.5°, $[\alpha]^{25}D$ +37.0° (dioxane).

Anal. Calcd. for $C_{31}H_{49}O_5Br$: C, 64.01, H, 8.49. Found: C, 64.09; H, 8.42.

Attempts to brominate the diolone 3,5-diacetate with N-bromosuccinimide with and without irradiation and peroxide resulted only in recovery of unchanged starting material. Bromination of the diacetate (503 mg.) in acetic acid (5 cc.) with a solution of bromine (0.176 g.) in acetic acid (5 cc.) was effected by adding boron fluoride etherate (6 drops) and warming the solution to 75° for twenty-five minutes, when the color had faded to light yellow. On addition of 3 cc. of water and cooling a solid product was obtained; 450 mg., m. p. 201–203°, dec. One crystallization from 45 cc. of methanol gave long spars, m. p. 205–207°, dec. (325 mg.), and further purification gave material of the expected composition; m. p. 210–211°, dec., $[\alpha]^{25}D$ +27° (dioxane).

Anal. Calcd. for $C_{31}H_{49}O_5Br$: C, 64.01; H, 8.49. Found: C, 63.74; H, 8.44.

This material apparently consists chiefly of the above 7β-bromo diacetate containing a small amount of a less dextrorotatory isomer (7α-epimer ?), but several further crystallizations raised the m. p. only to 213–214°; a mixture of this with the 216.5–217.5° material melted at 214–215°.

The 216.5–217.5° diacetate (1.3 g.) was refluxed with triethylamine (80 cc.) for fifty-eight hours, but only about 100 mg. of triethylamine hydrobromide separated and the only product encountered was starting material (0.6 g.). The 210–211° product was recovered unchanged after being boiled with pyridine for six hours; this was also true when silver benzoate was added, but the recovery was in this case lower.

Summary

1. A procedure for the hydroxylation of the double bond of cholesterol by brief treatment with performic acid and saponification affords cholestane-3β,5α,6β-triol in 91% yield.

2. The above triol can be selectively oxidized to the 6-ketone with N-bromosuccinimide in 94% yield, even in the presence of methanol.

3. The 5,6-oxido derivatives of cholesterol and cholesteryl acetate can be cleaved to the glycols by reaction with periodic acid in acetone.

4. Bromination of the mono- or diacetate of cholestane-3β,5α-diol-6-one was accomplished with use of boron fluoride catalyst, but the chief products are evidently the 7β-bromo derivatives, since that from the diacetate resists dehydrohalogenation and that from the 3-monoacetate yields an acidic product of rearrangement.

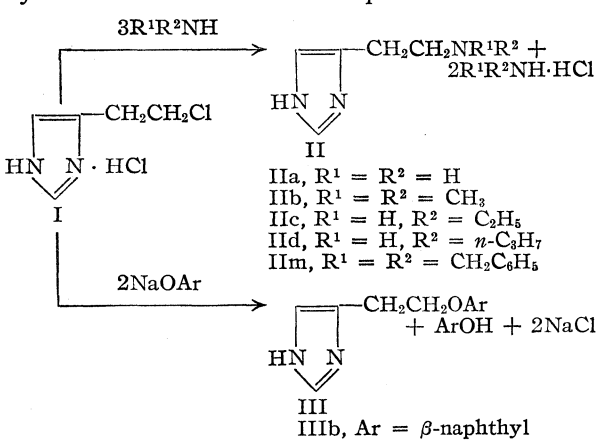
Studies of Imidazole Compounds. IV. Derivatives of 4-Ethylimidazole

BY CHARLES F. HUEBNER, ROBERT A. TURNER AND CAESAR R. SCHOLZ

In the first paper of this series certain derivatives of 4-methylimidazole[1] were discussed; a practicable synthesis of 4-(2-chloroethyl)-imidazole hydrochloride (I)[2] was reported in a later paper. In the present paper derivatives of 4-ethylimidazole related to histamine and prepared from I are described.

Several histamine derivatives bearing alkyl substituents on the side chain nitrogen-atom have been prepared, thus extending the work of Garforth and Pyman[3] who described three lower members of the series. The 4-(2-alkylaminoethyl)-imidazoles (II) were prepared by the addition of I to an excess of an amine in boiling anhydrous *n*-propanol. Some of the condensation products could then be isolated as the dihydrochloride or dihydrobromide. Usually, however, this procedure was not possible; instead, the sirupy dihydrochloride was converted into the crystalline dipicrate, which after suitable purification was reconverted into the crystalline dihydrochloride.

Two substituted 4-ethyl-imidazoles containing oxygen in the side chain (III) were synthesized by reaction of I with a sodium phenolate.



A detailed report on the pharmacology of these imidazoles will be published elsewhere. However, a few remarks in regard to their activity may be in order. In group II, the larger the N-alkyl substituent, the smaller is the histamine activity as measured by the spasm produced on the isolated guinea-pig ileum strip. Following this generalization, the most potent derivatives are 4-(2-dimethylaminoethyl)-imidazole (IIb) and 4-(2-ethylaminoethyl)-imidazole (IIc), each being 75% as active as histamine (IIa).[4] A compound of intermediate activity is IId with 5% of the activity of histamine, whereas IIm, containing the N-benzyl substituent, the largest in the series, is totally inactive at the levels tested (200 times the level at which histamine gave a standard response). Moreover, an interesting example of competitive inhibition is presented by IIm, since it possesses weak but definite antihistaminic activity [0.5% of the activity of N,N-dimethyl-N'-benzyl-N'-(2-pyridyl)-ethylenediamine hydrochloride].

In the series containing an oxygen substituent in the side chain, the pharmacological properties of 4-[2-(2-naphthoxy)-ethyl]-imidazole (IIIb) are worthy of note. It displays a high histamine-like activity, 50% that of histamine, but unlike the latter's action the spasm produced on the ileum strip is only momentary.

Acknowledgment.—The authors take pleasure in expressing appreciation to Dr. B. N. Craver for the pharmacological data and to Mrs. Katheryn Oney for assistance in the laboratory.

Experimental[5]

Physical and analytical data and the methods of preparation are summarized in Table I.

4-(2-Ethylaminoethyl)-imidazole Dihydrochloride (IIc). Procedure A.—A solution of 3.5 g. of I[2] in 30 ml. of a 30% ethanolic ethylamine solution was heated in a sealed tube at 100° for fourteen hours. The product was treated with a solution of 5 g. of sodium carbonate in 25 ml. of water and concentrated *in vacuo*. The residue was heated at 90° *in vacuo* for one hour and then digested with 50 ml. of absolute ethanol and filtered. After several more digestions the combined alcohol solutions were concentrated *in vacuo*. The resulting brown sirup was acidified (congo paper) with 1 *N* hydrochloric acid and added with stirring to a solution of 11.5 g. of picric acid in 150 ml. of water. The crystalline picrate which formed on cooling was recrystallized from water after a treatment with charcoal (Nuchar); yield 8.0 g.; m. p. 185°, with loss of water of crystallization at 104°.

The picrate was converted into the hydrochloride by treating it with 20 ml. of 5 *N* hydrochloric acid and removing the picric acid by repeated extractions with ether. The aqueous layer was concentrated *in vacuo* to a sirup, which after solution in hot methanol crystallized as platelets on careful addition of methyl ethyl ketone; after another crystallization the dihydrochloride weighed 1.5 g., m. p. 162–163°.

4-(2-Diethylaminoethyl)-imidazole Dihydrochloride. Procedure B.—To a stirred solution of 13.4 g. of anhydrous diethylamine in 25 ml. of anhydrous *n*-propanol, boiling under reflux, was added a solution of 3.4 g. of I in 25 ml. of *n*-propanol during one-half hour with exclusion of moisture. After further boiling under reflux for six hours, a solution of 5 g. of sodium carbonate in 25 ml. of water was added and the crude, brown sirupy base isolated as described above. It was treated with a 3 *N* solution of hydrogen chloride in absolute ethanol until strongly acid and crystallization induced by the slow addition of dry ethyl acetate. Recrystallization from dry ethanol–ethyl acetate yielded 0.60 g. of the dihydrochloride, m. p. 219–220°.

4-(2-Benzylmethylaminoethyl)-imidazole Dihydrobromide. Procedure C.—The mixture resulting from the reaction of 3.4 g. of I with 10.0 g. of benzylmethylamine, carried out as described under procedure B, was concentrated *in vacuo*. The residue was treated with 50 ml. of 10% aqueous sodium carbonate and extracted with 100 ml. of ether. The ether was removed and the resulting oil distilled at 15 mm. in a bath held at 140–150°. This served to remove most of the benzylmethylamine. A solution of the residue in 10 ml. of 48% hydrobromic acid was taken to dryness *in vacuo*, then dissolved in a few ml. of hot absolute ethanol. The crystalline dihydrobromide obtained after several days in the cold was recrystallized from anhydrous *n*-propanol to yield 1.5 g., m. p. 178–179°.

4-(2-Dibenzylaminoethyl)-imidazole Dihydrochloride Procedure D.—The reaction mixture obtained from 3.4 g. of I and 12.0 g. of dibenzylamine according to procedure B was boiled under reflux for twenty-four hours. The cooled solution ultimately deposited 6.2 g. of dibenzylamine hydrochloride (m. p. 257–258°), which was filtered. After evaporation of the filtrate to dryness, the residue was digested briefly with 1.86 g. of sodium carbonate in 30 ml. of water. Repeated extraction of the aqueous suspension with petroleum ether removed dibenzylamine, and the crude imidazole was extracted with diethyl ether. Following distillation of the ether, the residue was dissolved in 10 ml. of concentrated hydrochloric acid, evaporated to dryness, and dissolved in 10 ml. of ethanol. When this solution was left in the cold for several hours, it deposited 1.4 g. of dibenzylamine hydrochloride, which was filtered. The evaporated filtrate was taken up in 5 ml. of hot anhydrous *n*-propanol. The solution yielded 1.5 g. of crude 4-(2-dibenzylaminoethyl)-imidazole dihydrochloride; after two more recrystallizations 0.36 g. of the pure hydrochloride remained, m. p. 155–156°.

4-(2-Phenoxyethyl)-imidazole Dihydrochloride. Procedure E.—To a solution of 2.8 g. of phenol in 23.0 ml. of 1.30 *N* methanolic sodium methoxide, boiling under reflux, was slowly added a solution of 2.5 g. of I in 25 ml. of *n*-propanol. After six hours the cooled reaction mixture was treated with an excess of 3 *N* hydrogen chloride in ethanol, the precipitated sodium chloride was collected, and the filtrate was taken to dryness *in vacuo*. The residue was suspended in water and extracted several times with ether to remove excess phenol. The aqueous phase was added to a boiling solution of 8.5 g. of picric acid in 130 ml. of water. The picrate was filtered and recrystallized from water; yield 4.2 g., m. p. 118–120°. The picrate was converted into the hydrochloride by treating it with 12 *N* hydrochloric acid and extracting with ether in the usual manner. The sirupy hydrochloride was recrystallized from absolute ethanol–ether; m. p. 129–131°; yield 1.3 g.

Summary

A series of 4-(2-alkylaminoethyl)-imidazoles

related to histamine and two 4-(2-aryloxyethyl)-imidazoles have been prepared from 4-(2-chloroethyl)-imidazole hydrochloride. A few of these substances resembled histamine in their pharmacodynamic actions but all were less active. Weak antihistaminic activity was shown by 4-(2-dibenzylaminoethyl)-imidazole.

Polyglycerols. III.[1] Synthesis of Triglycerol[2]

BY J. ROBERT ROACH AND HAROLD WITTCOFF

The synthesis of a crystalline isomer of linear triglycerol[3] is described in this paper.

Probably the first reference to triglycerol was made by Lourenco[4] who reported it as a distillable reaction product from the interaction of glycerol and gaseous hydrogen chloride. Levene and Walti[5] hydrolyzed the reaction products resulting from the action of potassium acetate on epichlorohydrin to obtain several distillable products including a small quantity of triglycerol (b. p. 200–205° (0.1 mm.)). The same boiling range was reported by Istin[6] who distilled triglycerol directly from a polyglycerol mixture. Isolation of crude triglycerol from a polyglycerol mixture by distillation of the acetates[7,8] and the allyl ethers[3] has also been reported. In none of this work has the crystalline pentahydric triglycerol been isolated.

The present synthesis involves the hydroxylation of O-α,α'-diallylglycerol[9] by action of either performic acid or potassium permanganate. The requisite diallylglycerol was prepared by the interaction of allyl alcohol and glycerol-α,α'-dichlorohydrin in the presence of sodium hydroxide. The homogeneity of this product, on which depends the linear structure of the triglycerol, follows from the oft-recorded observation that chlorohydrins such as glycerol dichlorohydrin are dehydrohalogenated in strong basic medium to epoxides. These, in turn, react with alcohols to yield ethers in which the ether linkage is primary.[10] Furthermore, it was not possible by careful fractional distillation to detect the presence of any isomeric substance.

Since the triglycerol could not be readily distilled from the reaction mixtures in which it was formed, acetonation was employed. On treatment of the crude mixtures with acidic acetone, there resulted a mixture of isopropylidenetriglycerol and diisopropylidenetriglycerol which on hydrolysis yielded the pure triglycerol.

Separation of isopropylidenetriglycerol and diisopropylidenetriglycerol was difficult. By careful fractional distillation, however, samples which analyzed properly were obtained.

The triglycerol obtained by hydrolysis of the isopropylidene derivatives was probably a sirupy mixture of stereoisomers. Crystallization from anhydrous *n*-butanol of the product resulting from performic acid hydroxylation yielded 25–33% of a crystalline isomer of melting point 98–99°. The sirup from the mother liquor could not be induced to crystallize. For linear triglycerol there are theoretically possible a *dl*-mixture and two *meso*-forms. The presence of isomers was perhaps indicated by the fact that the sirupy triglycerol from the performic acid hydroxylation demonstrated proper elementary analyses. That permanganate hydroxylation provided a different ratio of isomers was inferred from the observation that the sirupy triglycerol yielded, on crystallization, 50% of crystalline isomer of identical melting point.

The solid triglycerol was converted to the penta-(*p*-nitrobenzoate) derivative. Attempts to prepare similar derivatives of the sirupy isomers from which the crystalline triglycerol had been removed led only to uncrystallizable oils.

Experimental

O-α,α'-Diallylglycerol.—Allyl alcohol (1161 g., 20 moles) was added, with stirring, to 50% aqueous sodium hydroxide (880 g., 11 moles) whereupon the temperature rose spontaneously to 52°. Glycerol dichlorohydrin (644.8 g., 5 moles) was added dropwise over a period of three and one-fourth hours, while the temperature was maintained at 70–80° by the exothermic reaction. After completion of the addition, stirring was continued at 70–80° for one and one-fourth hours, whereupon the excess allyl alcohol was removed by distillation *in vacuo*. The product was washed successively with water, dilute acetic acid, and again with water until the washings were neutral. All of the aqueous solutions were combined and extracted with ether, after which the ether solution was washed with water and was combined with the product. The mixture was dried (sodium sulfate) and after removal of the ether, the product was distilled through a 15-inch Vigreux column. No forerun was obtained. The material of constant refractive index (n^{25}D 1.4520, d^{25}_4 0.9810) distilled at 112–113° (14 mm.) and weighed 524.4 g. (60.8%). Redistillation at high reflux ratio through a 12-inch column packed with stainless steel helices gave a series of

fractions, all of which boiled at 68–69° (0.9–1.0 mm.) and 93% of which possessed a $n^{25}D$ of 1.4510.

Anal. Calcd. for $C_9H_{16}O_3$: I_2 number, 294.8; hydroxyl %, 9.87. Found: I_2 number, 293.9; hydroxyl %, 9.7.

In addition of the diallylglycerol there was obtained an unidentified higher boiling product (93 g.) which distilled at approximately 135° (0.6 mm.).

Isopropylidenetriglycerol and Diisopropylidenetriglycerol from the Oxidation of O-α,α'-Diallylglycerol with Performic Acid.—A mixture of O-α,α'-diallylglycerol (172 g., 1 mole), formic acid (87%, 700 cc.) and hydrogen peroxide (28%, 229 g., 2 moles) was stirred mechanically (safety glass shield). The temperature rose to 40° in twenty minutes and was maintained there first by external cooling and then by heating for a total time of five hours. The mixture was allowed to stand overnight whereupon titration of a test sample indicated the presence of about 0.5 g. of hydrogen peroxide. This was destroyed with sodium bisulfite (20 g.) and the mixture was evaporated *in vacuo* to a thick sirup. A methanol solution of the sirup was filtered and evaporated, and the sirup was dissolved in absolute ethanol (300 cc.). The solution was made slightly alkaline with alcoholic sodium hydroxide and the ethyl alcohol and ethyl formate were removed by slow distillation. The residue was dissolved in methanol (200 cc.) which contained sodium hydroxide (15 g.), and the solution was heated on the steam-bath for one hour to saponify any formate groups not removed by the alcoholysis. The mixture was made slightly acid with concentrated hydrochloric acid, after which it was concentrated. Most of the sodium chloride was removed by dissolving the residue in methanol, filtering and removing the solvent under reduced pressure. This sequence of operations was carried out twice. Thereupon the residue was dissolved in absolute ethanol (200 cc.) and the solution was allowed to stand twelve hours over sodium sulfate. Concentration of the ethanol solution yielded a theoretical quantity (240 g.) of sirup.

The hydroxylation product (240 g.) together with a solution of hydrogen chloride (9.0 g.) in acetone (1500 cc.) was stirred overnight with anhydrous sodium sulfate (90 g.). After the reaction mixture was made slightly basic with alcoholic sodium hydroxide, it was filtered and concentrated. The acetonated product (113 g.) was obtained in low yield, indicating that much of the original product had not been acetonated. Accordingly, the sodium sulfate was extracted well with methanol, and from the alcohol solution there was obtained 90 g. of sirup. This was subjected to acetonation as above (500 cc. of acetone, 9 g. of hydrogen chloride, 100 g. of sodium sulfate) to obtain more product (98 g.). The total yield of acetonated derivative was thus 211 g. (approximately 70% overall yield). This was a mixture of isopropylidene- and diisopropylidenetriglycerol. For purposes of preparing triglycerol, the distilled product was hydrolyzed directly according to the procedure indicated below.

In order to separate the isopropylidene derivatives, 70 g. of the mixture was distilled through a short column, and the course of the distillation was followed by refractive index measurements.

Sixty-three grams of distillate was obtained in two fractions. The second fraction will be discussed below. The first fraction (47 g.) distilled at 146–196° (0.3 mm.) (major portion 150–165° (0.3 mm.)). As already indicated, it was difficult to separate pure diisopropylidenetriglycerol from small amounts of isopropylidenetriglycerol by fractional distillation.

In one experiment a material which analyzed properly was obtained by distilling the diisopropylidene fraction several times, at high reflux ratio, through a 12-inch, monel metal helices-packed column. The product distilled at 157–158° (0.6 mm.) and had a $n^{25}D$ of 1.4530.

Anal.[11] Calcd. for $C_{15}H_{28}O_7$: C, 56.24; H, 8.75. Found: C, 55.9, 55.9; H, 8.7, 9.0.

(11) The authors are indebted to Mr. James Kerns for micro carbon and hydrogen analyses.

The second fraction (16 g.) referred to above, distilling at 196–240° (0.3 mm.), was fractionally distilled to yield isopropylidenetriglycerol of boiling point 172–175° (0.25 mm.) and $n^{25}D$ of 1.4691.

Anal. Calcd. for $C_{12}H_{24}O_7$: C, 51.41; H, 8.63. Found: C, 51.6, 51.4; H, 8.6, 8.9.

Sirupy Triglycerols from Isopropylidene- and Diisopropylidenetriglycerol.—The first fraction of the preceding experiment (30 g.) was dissolved in water (30 cc.) and concentrated hydrochloric acid (3 cc.). The solution was heated on the steam-bath for one-half hour. During this time acetone (12 cc. of the theoretical 13.5 cc.) distilled. The solution was then concentrated *in vacuo* to obtain a theoretical quantity (22.5 g.) of sirup. This was distilled to yield sirupy triglycerol (20 g.) which collected over a range of 190–230° (0.1 mm.), although most of the product distilled at 215–220° (0.1 mm.). The product had a $n^{25}D$ of 1.4902. This value varies with the ratio of isomers obtained by the different preparative procedures used, as shown by subsequent data.

Anal. Calcd. for $C_9H_{20}O_7$: C, 44.99; H, 8.39. Found: C, 45.1, 44.9; H, 8.7, 8.7.

Crystalline Triglycerol from the Performic Acid Hydroxylation.—The sirupy triglycerol described above (8 g.) was dissolved in warm anhydrous *n*-butanol (8 cc.). After several days of refrigeration there resulted 2 g. of crystalline triglycerol which, after three crystallizations from butanol, melted at 98–99°. Accordingly, from this and other experiments it appears that 25–33% of the crystalline isomer is present in the triglycerol which results from the hydroxylation of O-α,α'-diallylglycerol with performic acid.

Anal. Calcd. for $C_9H_{20}O_7$: C, 44.99; H, 8.39. Found: C, 45.1, 44.9; H, 8.1, 8.3.

The sirup remaining in the mother liquor, when distilled at about 225° (0.3 mm.), yielded fractions varying in $n^{25}D$ from 1.4758 to 1.4870. These values are considerably lower than the value of 1.4902 demonstrated by the original mixture from which the crystalline triglycerol was removed. None of these fractions could be crystallized, nor could they be converted to crystalline *p*-nitrobenzoates.

In an attempt to gain further insight into the composition of the unfractionated sirupy triglycerol, a quantity of it was separated by distillation at 206–275° (1 mm.) into 4 fractions. The first, second and fourth fractions weighed 4.0 g. each and had $n^{25}D$ of 1.4855, 1.4899 and 1.4935, respectively. The third fraction weighed 21.5 g. and had a $n^{25}D$ of 1.4920. The last two fractions crystallized readily to yield a total of 13 g. of crystalline product. The first two fractions and the sirupy portions of the last two could be induced neither to crystallize nor to yield solid *p*-nitrobenzoates. The crystalline triglycerol, on the other hand, could be converted to a solid *p*-nitrobenzoate. These data show that it is possible to obtain partial separation of the diastereoisomers of triglycerol by fractional distillation.

Penta-(*p*-nitrobenzoate) of the Crystalline Isomer of Triglycerol.—This derivative could be prepared either from crystalline triglycerol or from the unfractionated sirupy mixture of triglycerols. The melting point of the product was 134–134.5° regardless of its source, although the yield from the sirupy mixture was considerably lower and the product was purified with greater difficulty, as would be expected. Mixed melting points of the samples of *p*-nitrobenzoate derivative prepared from sirupy or crystalline triglycerol demonstrated no depression.

The unfractionated sirupy triglycerol was converted to the *p*-nitrobenzoate derivative by the conventional procedure employing anhydrous pyridine. The amorphous solid obtained by precipitation from water was crystallized from acetone to obtain the impure derivative melting at 95–102°. The product was crystallized once more from acetone, three times from mixtures of acetone and absolute ethanol (1:1) and twice from ethyl acetate. The resulting white needles melted sharply at 134–134.5°.

Anal. Calcd. for $C_{44}H_{35}O_{22}N_6$: C, 53.60; H, 3.57; N, 7.10. Found: C, 53.6, 53.7; H, 3.6, 3.6; N, 7.4, 7.5.

Triglycerol from the Oxidation of O-α,α'-Diallylglycerol with Potassium Permanganate.—To a mixture of O-α,α'-diallylglycerol (86.0 g., 0.5 mole) and water (600 cc.) cooled to 3° was added, with stirring, a solution of potassium permanganate (160 g., 1.01 mole) in water (3200 cc.) over a period of five hours. The temperature was kept at 3–5°. At the end of the addition the mixture was allowed to stand at room temperature for one and one-half hours, during which time the reaction temperature rose to 10°. The mixture was subsequently warmed to 25° and allowed to stand one hour longer after which the manganese dioxide was removed and the filtrate and washings were neutralized with concentrated hydrochloric acid (21.8 cc.). The aqueous solution was evaporated *in vacuo* to dryness and the residue was extracted with methanol. Removal of the methanol yielded a viscous sirup which was dissolved in ethyl alcohol. Benzene was added and the solvents were distilled in an attempt to remove the last trace of water azeotropically. A solution of the resulting sirup in absolute methanol was dried over anhydrous sodium sulfate. Filtration and removal of the methanol from the filtrate yielded 126.1 g. of a viscous water-white sirup (theoretical yield 121.1 g.). Undoubtedly impurities such as higher oxidation products were present as evidenced by the yield of isopropylidene derivatives.

The crude triglycerol (90 g.) was acetonated according to the procedure described above (750 cc. of acetone, 7.5 g. of anhydrous hydrogen chloride, 100 g. of anhydrous sodium sulfate). There resulted 75 g. (65.6% over-all yield based on diallylglycerol) of crude material which on distillation yielded 54 g. (approximately 47.2%) of a mixture of isopropylidene- and diisopropylidenetriglycerols. The mixture of isopropylidene derivatives was separated by fractional distillation into one fraction which was chiefly diisopropylidenetriglycerol (b. p. 162° (2 mm.)) and a higher boiling fraction (distillation range 190–220° (4–9 mm.)) which was primarily isopropylidenetriglycerol.

The first fraction (29 g.) was hydrolyzed to triglycerol as described above, yielding a viscous liquid (21.7 g., 100%) which on distillation gave 16.2 g. of sirupy triglycerol having a $n^{25}D$ of 1.4931. This value was higher than that shown by the sirupy triglycerol from the performic acid hydroxylation, probably because the proportion of isomers present was different, as shown by the following crystallization studies. The isolation of the crystalline isomer was effected as detailed above. Approximately 50% of the triglycerol prepared by this procedure was isolated as crystalline material as compared to 25–33% isolated from the sirupy triglycerol mixture resulting from the performic acid hydroxylation. The crystalline triglycerol prepared by the two methods had identical melting points (98–99°) which were not depressed on admixture. In this preparation, as in the previous one, the sirupy residue isolated from the mother liquor ($n^{25}D$ 1.4800) could not be induced to crystallize, nor could it be converted to a crystalline derivative.

Anal. Calcd. for $C_9H_{20}O_7$: C, 44.99; H, 8.39. Found: C, 45.1, 44.9; H, 8.1, 8.2.

Summary

1. Triglycerol has been synthesized by the hydroxylation of O-α,α'-diallylglycerol by the action of performic acid and by the action of permanganate.

2. Crystalline triglycerol of melting point 98–99° has been isolated and identified.

3. Triglycerol was isolated from the reaction mixtures by conversion to its isopropylidene derivatives and subsequent distillation.

Steroid Analogs Lacking Ring C. I. The Synthesis of 6-Cyclohexyl-Δ^{1-9}-octalone-2 by the Robinson–Mannich Base Method

BY CLIFFORD H. SHUNK[1,2] AND A. L. WILDS

For some time we have been interested in the synthesis of certain analogs of the steroid hormones progesterone, desoxycorticosterone and testosterone lacking ring C. The first stage in this work, started in 1941 and interrupted during the war, has been to apply the Robinson–Mannich base synthesis[3] of cyclic α,β-unsaturated ketones to 4-cyclohexylcyclohexanone (I), obtaining 6-cyclohexyl-Δ^{1-9}-octalone-2 (VIII). Since we were interested in extending the reactions to less readily available derivatives of the ketone I, we have looked in some detail into several methods of applying this synthesis.

The best yields in the Robinson–Mannich base synthesis have been obtained with ketones having the adjacent methylene group activated, and accordingly we first investigated the carbomethoxy derivative III, as in our previous work in the chrysene series.[4] This was prepared from the ketone I *via* the glyoxylate II, although in poor yield (*ca.* 12%) primarily because of the decarbonylation step. The next reaction with the methiodide of 1-diethylaminobutanone-3 proceeded in good yield to the diketo ester IV, and the latter could be cyclized to 6-cyclohexyl-Δ^{1-9} octalone-2 (VIII) in fair yield (48%) with aqueous alkali or acid. With sodium methoxide the carbomethoxy group was retained giving IX.

Because of the poor over-all yields by this method, and particularly in the decarbonylation of the glyoxylate II, the latter derivative itself was used for condensation with the Mannich base methiodide. However, cyclization of the resulting product gave the octalone VIII in less than 20% yield.

It seemed attractive to try the hydroxymethyl-

ene derivative VII, since this group can be introduced into ketones in excellent yield[5] and after alkylation is very easily eliminated.[6] Apparently hydroxymethylene ketones have not been employed previously in the Mannich base condensation. As high as 87% of the derivative VII could be obtained from the ketone I employing an excess of ethyl formate and sodium methoxide. There was no indication of any bis-hydroxymethylene derivative being formed[7]; the ultraviolet absorption spectrum showed a single maximum at 281 mμ.[8]

Reaction of the hydroxymethylene ketone VII with 1-diethylaminobutanone-3 methiodide resulted in introduction of the γ-ketobutyl group in excellent yield; the product consisted of V, in which the formyl group was retained, and VI in which this had been eliminated, the ratio of the two varying with the reaction conditions. Each was cyclized smoothly with acid, or preferably with dilute methanolic alkali at room temperature for two to three hours. The over-all yield of 6-cyclohexyl-Δ^{1-9}-octalone-2 from 4-cyclohexylcyclohexanone was about 60–65%. By following the ultraviolet absorption spectrum it was possible to determine rather easily the relative effectiveness of various cyclizing reagents and the optimum conditions for maximum yield.[9]

(6) *Cf.* Wilds and Djerassi, *ibid.*, **68**, 1715 (1946).

(7) This is in agreement with the findings of Prelog and Metzler with cyclopentanone, *Helv. Chim. Acta.*, **30**, 878 (1947).

(8) This illustrates the fact that a β-OH group results in a greater shift of the maximum for α,β-unsaturated ketones than an alkyl group [*cf.* Woodward, THIS JOURNAL, **63**, 1123 (1941); **64**, 76 (1942)], amounting to about 50 mμ compared to 35 mμ for an α-OH [Fieser, Fieser and Rajagopalan, *J. Org. Chem.*, **13**, 800 (1948)].

(9) Although the octalone VIII can exist in two racemic isomers which would be expected to be in equilibrium under the conditions of cyclization (due to ready shift of the double bond), only one isomer could be obtained, with no direct evidence for the presence of the other form.

Evidence confirming the structure of the octalone was obtained by dehydrogenation to 2-phenylnaphthalene (X) and 6-phenyl-2-naphthol (XI).

Experimental[10]

4-Cyclohexylcyclohexanone (I).—4-Hydroxybiphenyl was hydrogenated[11] in absolute ethanol at 140° and 2000 p. s. i. using W-6 Raney nickel catalyst[12]; the mixture of isomeric 4-cyclohexylcyclohexanols was obtained in 96% yield, m. p. in the range 80–105°. Forty grams of this mixture was dissolved in 500 ml. of glacial acetic acid and stirred at 15–18° while a solution of 30 g. of chromium trioxide in 40 ml. of water and 100 ml. of acetic acid was added slowly over a period of one hour. After an additional hour at the same temperature 50 ml. of methanol was added, the mixture allowed to stand one-half hour and then the solvent was removed under reduced pressure. The gummy residue was dissolved in dilute hydrochloric acid and ether, and the ether layer washed thoroughly with acid, dilute sodium hydroxide and water. From the ether extract was obtained 34.6 g. (87%) of the ketone, b. p. 98–100° (0.1 mm.), m. p. 30–31° (reported,[13] 31°). The semicarbazone melted at 215–216° (reported[13] 216°).

From the alkaline extract was obtained an oily acid which crystallized from ether–petroleum ether, 0.97 g. (2%), m. p. 92–93°. Further recrystallization from carbon tetrachloride did not change the m. p. of the product, evidently β-cyclohexyladipic acid. The yield of this acid was increased using higher temperatures during the oxidation.

Anal. Calcd. for $C_{12}H_{20}O_4$: C, 63.1; H, 8.8. Found: C, 62.9; H, 8.8.

2-Hydroxymethylene-4-cyclohexylcyclohexanone (VII).—The following modification of the general procedure of Johnson, Anderson and Shelberg,[5] employing three moles of sodium methoxide and five moles of ethyl formate per mole of ketone, gave the best yields. The sodium methoxide prepared from 4.8 g. of sodium and 50 ml. of dry methanol was freed of excess solvent, finally heating at 160° under reduced pressure for one-half hour, cooled under nitrogen, 25 ml. of dry benzene added and distilled again to dryness. The solid was broken up, suspended in 50 ml. of dry, thiophene-free benzene and stirred while 30 ml. of dry ethyl formate was added. After one-half hour at room temperature the mixture was cooled in an ice-bath, a solution of 13.0 g. of 4-cyclohexylcyclohexanone in 100 ml. of benzene was added and the ice-bath removed. To the yellow gelatinous mixture was then added 150 ml. of benzene and stirring was continued overnight at room temperature. Ice-cold water was added and the benzene layer extracted with two portions of cold 2% sodium hydroxide. After washing the combined alkaline layers with ether and acidifying, the resulting oil was extracted thoroughly with chloroform, washed and dried over sodium sulfate. The light orange oil remaining after the chloroform was removed under reduced pressure was distilled (capillary tube attached to a source of nitrogen) giving 13.1 g. (87%) of nearly colorless hydroxymethylene derivative, b. p. 114–116° (0.1 mm.).[14] Redistillation gave material, b. p. 113° (0.1 mm.), which had an absorption maximum at 281 mμ (E = 8,690).[15,16] The compound, which gave a purple color with alcoholic ferric chloride, was unstable and decomposed after a few days even when sealed in an ampule.

(10) All melting points are corrected.

(11) *Cf.* Musser and Adkins, THIS JOURNAL, **60**, 664 (1938).

(12) Adkins and Billica, *ibid.*, **70**, 695 (1948).

(13) v. Braun, *Ann.*, **472**, 60 (1929).

(14) When equivalent amounts of sodium methoxide, ethyl formate and ketone were used the yield was only 66%.

(15) Absorption spectra were determined in 95% ethanol using a Beckman quartz spectrophotometer; E = molecular extinction coefficient.

(16) There was no indication of a peak at longer wave lengths corresponding to the bis-hydroxymethylene derivative.

Anal. Calcd. for $C_{13}H_{20}O_2$: C, 75.0; H, 9.7. Found: C, 74.6; H, 9.5.

The **copper enolate**, prepared in 88% yield by shaking an ether solution of the hydroxymethylene ketone with a saturated solution of cupric acetate, was recrystallized from benzene to give clusters of fine green needles that decomposed at 228–229°.

Anal. Calcd. for $C_{26}H_{38}O_4Cu$: C, 65.3; H, 8.0; Cu, 13.3. Found: C, 65.7; H, 8.1; Cu,[17] 13.4.

The **aniline derivative** was prepared by adding 90 mg. of aniline to 100 mg. of hydroxymethylene ketone in 1 ml. of methanol. After one hour at room temperature 99 mg. (73%) of solid was obtained, m. p. 114–118°. Recrystallization from methanol gave light yellow prisms, m. p. 115–117°.

Anal. Calcd. for $C_{19}H_{25}ON$: C, 80.5; H, 8.9. Found: C, 80.5; H, 8.9.

2-Formyl-2-(γ-ketobutyl)-4-cyclohexylcyclohexanone (V).—To a solution of 1.45 g. of sodium in 50 ml. of dry methanol was added 13.07 g. of the hydroxymethylene ketone VII dissolved in 50 ml. of methanol. The solution was cooled in an ice-bath and then treated with 50 ml. of methanol containing the methiodide prepared from 18 g. of 1-diethylaminobutanone-3.[18] The solution was allowed to come to room temperature as the ice melted and after standing overnight 12.94 g. (67%) of white needles was collected, washing with methanol. This material, m. p. 121–123° (gas evol.), was found to contain one molecule of methanol even after drying at 65° (0.1 mm.) overnight; the melting point was not changed by further recrystallization.[19]

Anal. Calcd. for $C_{17}H_{26}O_3 \cdot CH_3OH$: C, 69.7; H, 9.7. Found: C, 69.7; H, 9.7.

After the above solid was filtered from the reaction mixture, the filtrate was poured into ice-cold dilute sodium hydroxide, extracted with benzene–ether, washed with cold dilute acid, water and dried over sodium sulfate. Distillation gave 4.84 g. of an oil, b. p. 140–155° (0.1 mm.), which from analysis appeared to consist of approximately two parts of VI, from which the formyl group had been eliminated (21%) to one part of V retaining the formyl group (9%), corresponding to a total yield of 97%.

Anal. Calcd. for $C_{16}H_{26}O_2$ (formyl group eliminated): C, 76.7; H, 10.5. Calcd. for $C_{17}H_{26}O_3$: C, 73.3; H, 9.4. Found: C, 75.6, 75.4; H, 10.2, 10.2.

The ratio of solid to oily product varied in different experiments. In one run using two parts methanol to one of benzene for the solvent, there resulted 7% of the solid, m. p. 112–114°, and 92% of oil, evaporatively distilling below 170° (0.1 mm.), corresponding in analysis to the solvent-free formyl derivative V.

Found: C, 73.2, 73.1; H, 9.5, 9.5.

6-Cyclohexyl-Δ^{1-9}-octalone-2 (VIII) from 2-Formyl-2-(γ-ketobutyl)-4-cyclohexanone (V). (a) Acid Cyclization.—Preliminary cyclization experiments were carried out by dissolving 100 mg. of the formyl derivative (V, containing one molecule of methanol) in 25 ml. of acetic acid, adding 5 ml. of concentrated hydrochloric acid and allowing to stand at room temperature. At intervals samples were withdrawn, evaporated under reduced pressure and the extent of cyclization determined from the ultraviolet absorption in ethanol at 239 mμ, with the following results: one hour, 45%; two hours, 59%; four hours, 70%; six and one-half hours, 80%; thirty-seven hours, 82%. At reflux, the cyclization appeared to be complete in less than one-half hour (one-half hour, 82%; one and one-half hour, 82%; two and one-half hours, 78%).

On the basis of these preliminary results, a solution of 2.0 g. of the solid formyl derivative V in 190 ml. of acetic acid was treated with 40 ml. of concentrated hydrochloric acid and allowed to stand at room temperature for sixteen hours. The solvent was then removed under reduced pressure followed by several portions of alcohol, leaving 1.55 g. of a red oil, E_{239} = 12,900 (corresponding to a 79% yield). The oil was partially crystallized from 10 ml. of petroleum ether (40–60°) by cooling with Dry Ice, giving 0.29 g., m. p. 37–39°. Evaporative distillation of the filtrate at 145° (0.1 mm.) gave 1.13 g. of colorless distillate which yielded another 0.25 g. of the solid, m. p. 34–37°. Chromatographic adsorption of the remaining oil on alumina gave in the ether–petroleum ether (1:4 and 2:3) eluates an additional 0.16 g. of solid, m. p. 36–39° and 0.097 g. of oily ketone (E_{239} = 10,700). The total yield of solid ketone was 47%. Further recrystallization yielded colorless prisms, m. p. 41.5–42.5°, with an absorption maximum at 239 mμ, E = 17,000.[15]

Anal. Calcd. for $C_{16}H_{24}O$: C, 82.7; H, 10.4. Found: C, 82.8; H, 10.5.

The **semicarbazone**, prepared in 95% yield by the alcohol–pyridine procedure, was recrystallized from ethanol, m. p. 223–224°. The same semicarbazone was obtained whether the solid ketone or the oily filtrates were used.

Anal. Calcd. for $C_{17}H_{27}ON_3$: C, 70.6; H, 9.4. Found: C, 70.7; H, 9.2.

The **2,4-dinitrophenylhydrazone**, prepared in methanol containing a drop of hydrochloric acid, crystallized from ethyl acetate–ethanol as a red solid, m. p. 202–203°.

Anal. Calcd. for $C_{22}H_{28}O_4N_4$: C, 64.1; H, 6.8. Found: C, 63.8; H, 6.7.

In another run as above, acid cyclization of 2 g. of the solid formyl derivative gave 1.55 g. of oil (E_{239} = 12,800, indicating a 78% yield) which was converted directly to the semicarbazone. Digestion of the crude derivative (1.57 g., m. p. 210–215°) gave with hot alcohol 1.34 g., m. p. 223–224°, corresponding to a 72% yield.

(b) **Alkaline Cyclization.**—Preliminary experiments with 200 mg. of the solid formyl derivative V in 50 ml. of methanol and 4 ml. of water containing 2 g. of potassium hydroxide (nitrogen atmosphere), indicated alkaline cyclization to be rapid at room temperature (fifteen minutes, 55%; one hour, 84%; two and one-half hours, 90%; three and one-half hours, 88%; five hours, 81%).

On this basis, to 500 ml. of methanol through which nitrogen was bubbling was added 20 g. of potassium hydroxide in 40 ml. of water followed by 5.29 g. of the solid formyl derivative V (containing methanol). After two and one-quarter hours at room temperature the slightly yellow solution was poured into 1500 ml. of saturated sodium chloride solution and extracted with four portions of ether, washing the latter with water and drying over sodium sulfate. Removal of the solvent left 3.83 g. of light yellow oil, E_{239} = 14,400, which corresponded to an 82% yield. By crystallization from petroleum ether using Dry Ice 2.68 g. (68%) of solid, m. p. 35–37°, was obtained. Evaporative distillation of the filtrate at 165° (0.1 mm.) yielded 0.96 g. of oil. Conversion of the latter to the semicarbazone, m. p. 215–217°, indicated it contained 0.55 g. of the ketone, bringing the total yield to 82%.

A similar alkaline cyclization of 3.87 g. of the oil (found above to correspond to two parts of the formyl derivative V to one part of the derivative VI with the formyl group eliminated) gave 3.17 g. of oily ketone (E_{239} = 12,000 or 65% yield) from which 2.03 g. (59%) of the crystalline ketone, m. p. 33–36°, could be obtained.

Dehydrogenation of 6-Cyclohexyl-Δ^{1-9}-octalone-2.—A solution of 1 g. of the octalone derivative VIII in 6 ml. of *p*-cymene and 0.2 g. of 30% palladium on carbon[20] was

(17) Determined by weighing residual cupric oxide in boat after carbon–hydrogen analysis.

(18) The methiodide was prepared as described previously (ref. 4) adding the methyl iodide in small portions with cooling (vigorous reaction) and allowing each to react before adding more.

(19) When 200 mg. of the solid was heated at 150°, 17 mg. of distillate was obtained and shown to be methanol by conversion to methyl 3,5-dinitrobenzoate, m. p. 106–107°, undepressed when mixed with a known sample. That the methanol might not be merely solvent of crystallization was indicated by repeated failure to induce the solvent-free compound (see below) to crystallize from methanol.

(20) Linstead and Thomas, *J. Chem. Soc.*, 1130 (1940).

heated to reflux under nitrogen. After nineteen hours an additional 0.1 g. of catalyst was added and heating continued for a total of forty-three hours. Since only 182 ml. of hydrogen had been evolved, the mixture was filtered after diluting with benzene, evaporated and the residue heated with 0.1 g. of fresh catalyst at 320° for one hour (260 ml. of hydrogen evolved). The product was dissolved in ether and extracted with several portions of 10% potassium hydroxide. The residue from the ether was evaporatively distilled at 160° (0.1 mm.) and crystallized from methanol to give 0.04 g. (5%) of **2-phenylnaphthalene** (X), m. p. 96–98°. The m. p. was raised to 101–102° by further recrystallization (reported,[21] 101.5°). From the alkaline extracts after evaporative distillation at 150–165° (0.1 mm.) and crystallization from benzene was obtained 0.27 g. (28%) of **6-phenyl-2-naphthol (XI)**, m. p. 176–177°. Recrystallization from benzene raised the m. p. to 177–178° (reported,[22] 175–176°).

Anal. Calcd. for $C_{16}H_{12}O$: C, 87.2; H, 5.5. Found: C, 87.1; H, 5.3.

The **methyl ether of 6-phenyl-2-naphthol**, prepared with alkali and methyl sulfate and recrystallized from methanol, melted at 148–149° (reported,[22] 148°).

2-Methoxalyl-4-cyclohexylcyclohexanone (II).—To the methanol-free sodium methoxide prepared from 0.86 g. of sodium was added 30 ml. of dry benzene and 4.4 g. of dimethyl oxalate. The mixture was refluxed for ten minutes under nitrogen with stirring, then cooled in an ice-bath and 6.72 g. of 4-cyclohexylcyclohexanone (I) added in 20 ml. of benzene. After standing at room temperature for one and one-half hours, the light orange solution was extracted with three portions of ice-cold 2% sodium hydroxide, the latter acidified and extracted with ether. The ether extract was washed with sodium bicarbonate solution, water, dried over sodium sulfate and evaporated, leaving 6.0 g. (60%) of a light yellow oil which gave a purple color with alcoholic ferric chloride solution.

One gram of this oil in 10 ml. of ether gave 0.66 g. (59%) of the green **copper enolate derivative** (dec. at 220–222°). Recrystallization from benzene raised the decomposition point to 224–225°.

Anal. Calcd. for $C_{30}H_{42}O_8Cu$: C, 60.6; H, 7.1; Cu, 10.7. Found: C, 60.5; H, 7.1; Cu,[17] 10.6.

From the bicarbonate extract of the crude glyoxylate was obtained 1.3 g. of a viscous red oil from which was crystallized 0.28 g. of a solid, m. p. 110–114°, using carbon tetrachloride–petroleum ether. Triturating this solid with hot benzene and filtering gave 0.03 g. of material m. p. 213–215°.[23] From the filtrate was obtained 0.19 g. of a different compound, m. p. 115–116°. Recrystallization of the lower melting compound from benzene did not change its melting point. The analysis of compound, which gave a red color with alcoholic ferric chloride, indicated it to be the free glyoxylic acid derivative (corresponding to II).

Anal. Calcd. for $C_{14}H_{20}O_4$: C, 66.6; H, 8.0. Found: C, 66.3; H, 8.1.

2-Carbomethoxy-4-cyclohexylcyclohexanone (III).—A 11.4-g. sample of the 2-methoxalyl derivative II, not purified by extraction with bicarbonate, was heated at 180° with 10 g. of powdered soft glass for thirty minutes. The red oil was dissolved in ether and extracted with cold dilute sodium hydroxide. From the ether after washing and drying was obtained 6.3 g. of a red oil from which was obtained 4.85 g. (48%) of colorless distillate boiling below 140° (0.5 mm.). Redistillation gave 1.2 g., b. p. 84–90° (0.1 mm.), which proved to be largely 4-cyclohexylcyclohexanone, 1.1 g., b. p. 90–115° (0.1 mm.), and 2.3 g. (23%) of the carbomethoxy derivative, b. p. 115–118° (0.1 mm.), or b. p. 134° (0.6 mm.).

Anal. Calcd. for $C_{14}H_{22}O_3$: C, 70.6; H, 9.3. Found: C, 70.9; H, 9.2.

When methoxalyl derivative which had been washed with bicarbonate was employed, 37% of crude material distilling below 160° (0.5 mm.) was obtained.

The **pyrazolone derivative, 5-cyclohexyl-4,5,6,7-tetrahydro-3-indazolone** was prepared by heating 1.0 g. of the crude undistilled oil with 0.8 g. of hydrazine sulfate, 1 ml. of pyridine and 10 ml. of methanol for four hours. Treatment with water and ether yielded 0.44 g. of white solid, m. p. 234–238°. Recrystallization of the derivative from ethyl acetate–acetic acid raised the m. p. to 239–243°.

Anal. Calcd. for $C_{13}H_{20}ON_2$: C, 70.9; H, 9.2. Found: C, 70.9; H, 9.2.

2-Carbomethoxy-2-(γ-ketobutyl)-4-cyclohexylcyclohexanone (IV).—To 0.23 g. of sodium dissolved in 10 ml. of methanol was added 2.4 g. of the 2-carbomethoxy derivative III in 10 ml. of benzene. After refluxing for ten minutes the solution was cooled in ice and a solution of the methiodide from 2.90 g. of 1-diethylaminobutanone-3 in 10 ml. of methanol was added. After standing overnight at room temperature and refluxing for one hour, the cooled mixture was diluted with water and extracted with ether, washing the latter with dilute acid and drying over sodium sulfate. The oil (2.90 g.) remaining after removal of the solvent solidified after standing for three months. Recrystallization from ether–petroleum ether (40–60°) gave colorless platelets, m. p. 74–75°.

Anal. Calcd. for $C_{18}H_{28}O_4$: C, 70.1; H, 9.2. Found: C, 70.3; H, 8.9.

10-Carbomethoxy-6-cyclohexyl-Δ^{1-9}-octalone-2 (IX).—To a solution of 250 mg. of sodium in 25 ml. of methanol was added 149 mg. of the above oily 2-carbomethoxy diketone IV, and the mixture was refluxed under nitrogen for two hours, cooled, diluted with water and extracted with benzene-ether. From the washed and dried extract was obtained a yellow oil which was evaporatively distilled at 165° (0.05 mm.) giving 86 mg. of oil which yielded 24 mg. (17%) of colorless needles, m. p. 110–111°. Recrystallization from methanol did not raise the m. p.

Anal. Calcd. for $C_{18}H_{26}O_3$: C, 74.4; H, 9.0. Found: C, 74.4; H, 8.9.

The **semicarbazone** was prepared by the alcohol-pyridine procedure and recrystallized from chloroform–methanol, m. p. 204–206°.

Anal. Calcd. for $C_{19}H_{29}O_3N_3$: C, 65.7; H, 8.4. Found: C, 65.3; H, 8.6.

6-Cyclohexyl-Δ^{1-9}-octalone-2 (VIII) from 2-Carbomethoxy-2-(γ-ketobutyl)-4-cyclohexylcyclohexanone (IV).—Alkaline cyclization[24] of 250 mg. of the oily carbomethoxy derivative IV was carried out by refluxing and stirring under nitrogen with 25 ml. of 5% aqueous potassium hydroxide for twenty hours. After isolation and evaporative distillation at 165° (0.1 mm.), 110 mg. of distillate was obtained which yielded 113 mg. of crude semicarbazone of the octalone derivative, m. p. 209–211°, mixed m. p. 210–213°. This corresponds to a 48% yield.

Acid cyclization[24] of 270 mg. of the carbomethoxy derivative IV by heating at reflux for twenty hours with 25 ml. of acetic acid and 5 ml. of hydrochloric acid gave 220 mg. of oily octalone after evaporative distillation.

When 2.0 g. of the 2-methoxalyl derivative II was allowed to react with the methiodide of 1-diethylaminobutanone-3 and a 240-mg. portion of the product (1.67 g. of neutral oil) cyclized[24] by refluxing with 25 ml. of methanol containing 2.5 ml. of 45% potassium hydroxide for four hours, 60 mg. of evaporatively distilled, oily octalone derivative VIII was obtained, which yielded 39

(21) Chattaway and Lewis, *J. Chem. Soc.*, **65**, 872 (1894).

(22) Hey and Lawton, *J. Chem. Soc.*, 383 (1940).

(23) Recrystallization of this higher melting compound from acetone–benzene raised the m. p. to 214–215°. The compound gave an orange color with alcoholic ferric chloride; from the analysis it is suggested, tentatively, that it may be 5-phenyl-2-ketosuberic acid, arising from a trace of 4-phenylcyclohexanone in the starting ketone. Calcd. for $C_{14}H_{16}O_5$: C, 63.6; H, 6.1. Found: C, 63.6; H, 6.2.

(24) These undoubtedly are not the best conditions for cyclization.

mg. of semicarbazone, m. p. 219–221° (mixed m. p. undepressed), and 22 mg., m. p. 185–190°. The total amount of crude semicarbazone corresponded to a 12–20% over-all yield.

Summary

6-Cyclohexyl-Δ^{1-9}-octalone-2 (VIII) has been prepared from 4-cyclohexylcyclohexanone by the Robinson–Mannich base synthesis. The use of hydroxymethylene ketones in this synthesis has been found to be advantageous, with over-all yields of 60–65% in this example.

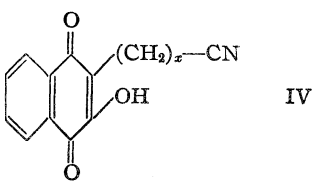
Synthesis of 2-Alkyl-3-hydroxy-1,4-naphthoquinones with Oxygenated Side Chains[1]

BY DONALD J. CRAM[2]

The syntheses and testing of a large number of naphthoquinones[3] as antimalarials has shown that the potency of the drug is a function of the lipophilic character of the molecule, and that resistance to metabolic degradation of the side chain is dependent on the presence of oxygen in the side chain. The present study is concerned with the development of methods of synthesis of 2-alkyl-3-hydroxy-1,4-naphthoquinones of structures I, II and III, in which x, y and z can be varied independently. Such methods would permit a systematic approach to the balance of lipophilic character of the quinone against resistance to metabolic degradation of the molecule, these two variables working in opposition to each other.



IV

The synthesis of IV ($x = 10$) by Fieser, *et al.*,[4] suggested the approach to the problem which has been worked out in the following fashion. Treatment of reductively acetylated nitrile quinones (V) with Grignard reagents produced ketones (I) in which x and y could be varied independently: x, by either starting with different nitriles or by applying the Hooker oxidation[5] to the ketones themselves; y, by using Grignard reagents prepared from different alkyl halides. The ketones were reductively acetylated and the ketonic group of the side chain reduced with aluminum isopropoxide to produce II, in which x could be reduced one unit at a time through the Hooker oxidation. Alternately, the reductively acetylated ketones were treated with Grignard reagents of varying types to produce tertiary alcohols of type III.

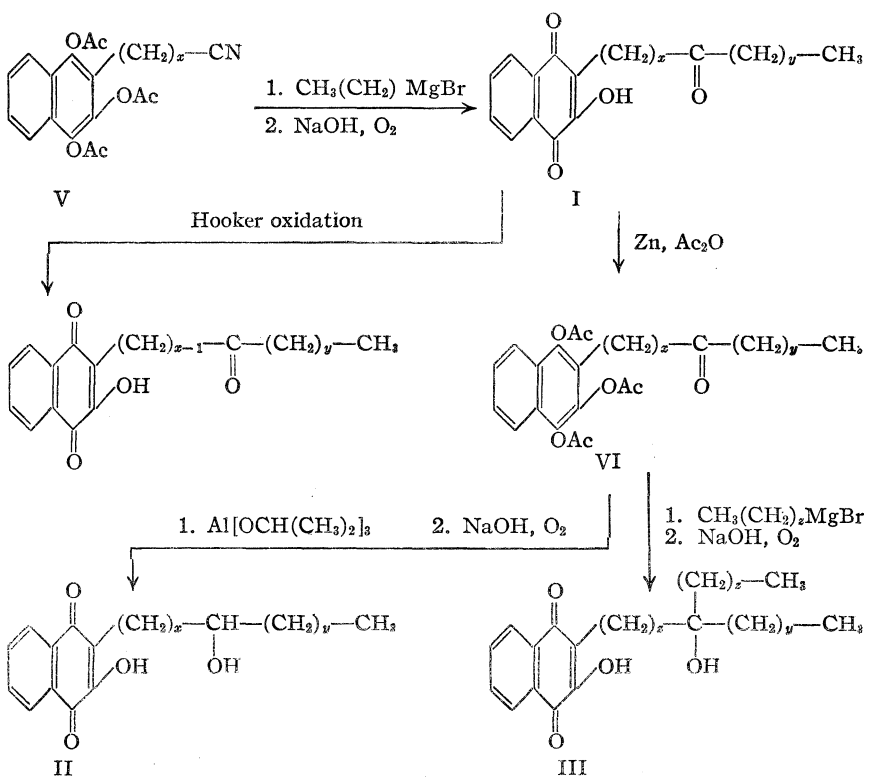


Table I records the physical properties and analytical data obtained for the new compounds that were prepared as well as a reference to the procedure employed (typical procedures are given in the experimental section). All of the quinones were prepared from compound of type IV as a

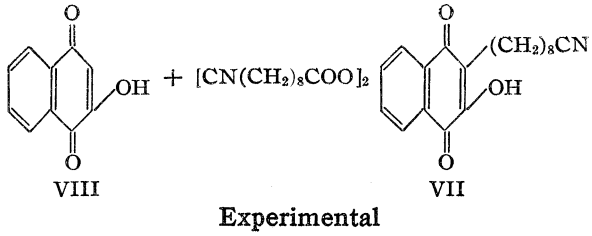
[a] Also prepared by D, yield 53%, m. p. 106–107°. [b] Prepared by the action of octylmagnesium bromide on VI, $x = 9, y = 0$.

primary starting material. Compound VII was synthesized by methods analogous to the preparation of IV ($x = 10$).[4] The compound 9-amidononanoic acid,[6] was dehydrated and the product hydrolysed to give 9-cyanononanoic acid. This substance was converted to its solid peroxide (VIII), which was used to alkylate lawsone by procedures that have been developed by Fieser, *et al.*[3]



VIII VII

Experimental

9-Cyanononanoic Acid.—A mixture of 50 g. of the ethyl ester[6] of 9-amidononanoic acid and 25 g. of phosphorus pentachloride were heated at 100° under reduced pressure for one-half hour. The liquid was cooled, dissolved in benzene, and the solution was washed first with water, then with sodium carbonate solution, and again with water. The organic layer was dried, and evaporated under reduced pressure to an oil, which was dissolved in 245 cc. of a 0.78 *N* barium hydroxide solution in methanol; the mixture was allowed to stand for fifteen hours. The barium salt was then collected, dissolved in a minimum amount of water, and acidified with an excess of acetic acid. The product was crystallized from an ether–petroleum ether mixture; yield of half acid, 26 g., m. p. 49–50°. The melting point did not change on recrystallization.

Anal. Calcd. for $C_{10}H_{17}O_2N$: C, 65.54; H, 9.35. Found: C, 65.72; H, 9.22.

(6) This substance was prepared according to the procedure of Flaschentrager, *Z. physiol. Chem.*, **159**, 297–308 (1926).

2-(8′-Cyanoöctyl)-3-hydroxy-1,4-naphthoquinone (Procedure A).—A solution of 72 g. of 9-cyanononanoic acid, 70 g. of thionyl chloride (Eastman White Label), and two drops of pyridine in 300 cc. of dry ether was refluxed for three hours. The solution was evaporated to an oil under reduced pressure. Dry ether (300 cc.) was added to the oil, and the mixture was again evaporated to an oil, which was dissolved in 300 cc. of dry ether, treated with 10 g. of Darco and filtered.

The filtrate was cooled to −15°, and to the chilled solution, 97 g. of a cold solution of 33% hydrogen peroxide was added. The temperature was again brought to −15°, and a solution of 34 g. of sodium hydroxide in 165 cc. of water was added at such a rate that the temperature of the stirred mixture never went above −5°. When the addition was complete, the mixture was stirred for one-half hour at −10°, and the white solid that separated was collected, washed with cold water, and pressed as dry as possible. This substance was dissolved in a minimum amount of chloroform, the solution dried with magnesium sulfate and filtered. The filtrate was evaporated to one-third of the original volume, and five volumes of low-boiling petroleum ether was added. The peroxide that separated was dried (45 g.).

The peroxide was mixed with 23 g. of lawsone and 450 cc. of glacial acetic acid, and the mixture was heated to 95° for two hours. The solvent was then evaporated under reduced pressure, and the residue was dissolved in ether. The ether solution was washed first with a solution of sodium bicarbonate, then with water, and the quinone was extracted into a 2% sodium hydroxide solution, which was washed with petroleum ether and acidified. Crystallization of the quinone that separated (glacial acetic acid) produced 22.5 g. of yellow needles, m. p. 99–100°. The substance formed yellow staffs, m. p. 100–101°, when crystallized from ethanol.

This quinone formed a red color in alkaline solution (addition of sodium hydrosulfite dispelled the color), and a red-orange color in a solution of concentrated sulfuric acid.

2-(10′-Cyanodecyl)-1,3,4-triacetoxynaphthalene (Procedure B).—A mixture of 22.5 g. of 2-(10′-cyanodecyl)-3-hydroxy-1,4-naphthoquinone, 22.5 g. of zinc dust,

135 cc. of acetic anhydride and two drops of triethylamine were mixed, and allowed to stand for two days at room temperature. The mixture was warmed to 50°, filtered, and the cake was washed with boiling acetic acid. To the combined filtrates was added enough water to decompose the excess acetic anhydride, the mixture was cooled, and the product was crystallized; 27.5 g. of hard white granules, m. p. 101°.

2-(11′-Ketononadecyl)-3-hydroxy-1,4-naphthoquinone (Procedure C).—Octylmagnesium bromide Grignard reagent was made in the usual way from 21.2 g. of magnesium turnings, 170 g. of octyl bromide, and 300 cc. of dry ether. To this mixture, stirred in an atmosphere of nitrogen, 27.5 g. of 2-(10′-cyanodecyl)-1,3,4-triacetoxynaphthalene (dissolved in 300 cc. of dry benzene) was added over a period of one-half hour. Ether was distilled from the reaction mixture until the volume had dropped to 400 cc. and the solution was refluxed for three hours, cooled, and poured into a mixture of ice and 50% hydrochloric acid. The two layers were well mixed, separated, and the ether–benzene layer was extracted with a sodium hydroxide-saturated solution of 50% methanol and water. The aqueous layer was washed with petroleum ether, and an excess of brine was added. The sodium salt that separated was collected, washed with water and suspended in glacial acetic acid; 20 g. of canary-yellow needles separated: m. p. 107–108°. Further crystallization of the quinone did not alter the melting point. The color reactions of this substance are identical with those of other 2-alkyl-3-hydroxy-1,4-naphthoquinones.

2-(10′-Ketoöctadecyl)-3-hydroxy-1,4-naphthoquinone (Procedure D).—This procedure is modeled after that developed by Fieser[5] as an improvement of the Hooker reaction.

A solution of 1.2 g. of sodium carbonate in 25 cc. of water was mixed with 50 cc. of dioxane, the solution was warmed to 70°, and 4.54 g. of 2-(11′-ketononadecyl)-3-hydroxy-1,4-naphthoquinone was added. Nitrogen was swept over the surface of the liquid, and after five minutes, 2 cc. of a 33% solution of hydrogen peroxide was added. The solution was held at 70° with nitrogen sweeping over the surface until it turned colorless. The solution was then cooled, acidified with 30% hydrochloric acid (3 cc.), mixed with 3 cc. of water saturated with sulfur dioxide, and the excess sulfur dioxide was removed by bubbling nitrogen through the mixture. Ethanol (100 cc.), 35 cc. of 25% sodium hydroxide solution, and 10 g. of cupric sulfate dissolved in 50 cc. of water were added. This mixture was stirred for one hour, heated to 60° for ten minutes, filtered and acidified with acetic acid. The product was crystallized twice from glacial acetic acid; 3.0 g. (fine canary-yellow needles), m. p. 108–109°.

2-(11′-Hydroxynonadecyl)-3-hydroxy-1,4-naphthoquinone (Procedure E).—To a solution (130 cc.) of 1 *M* aluminum isopropoxide through which nitrogen was bubbling, 13 g. of 2-(11′-ketononadecyl)-1,3,4-triacetoxynaphthalene was added. The solution was heated to the boiling point and then slowly fractionated through a short column. Both acetone and isopropyl acetate, as well as some isopropyl alcohol, distilled. A total of 50 cc. of distillate was collected in a period of six hours. At the end of that time the solution in the flask was cooled, and poured into a mixture of 35 cc. of concentrated hydrochloric acid, 100 cc. of water and 100 g. of ice. After the aluminum salt had decomposed, the mixture was extracted with 150 cc. of ether, and the ether layer was washed with water. To the ether layer, 100 cc. of a 50% ethanol–water mixture saturated with sodium hydroxide was then added. Oxygen was bubbled through the solution for one-half hour, an excess of glacial acetic acid was added, and the product that separated was crystallized (glacial acetic acid); 8.7 g. (86% yield) of fine yellow needles of product was obtained; m. p. 95–96°. Further recrystallization of the compound did not alter the melting point. The color reactions of the substance are the same as those of other 2-alkyl-3-hydroxy-1,4-naphthoquinones.

2-(9′-Hydroxy-9′-methylheptadecyl)-3-hydroxy-1,4-naphthoquinone (Procedure F).—The methyl Grignard reagent was prepared in the usual way from 2 g. of magnesium turnings, 12 g. of methyl iodide and 200 cc. of dry ether. To this solution (stirred in an atmosphere of nitrogen), 3 g. of 2-(9′-ketoheptadecyl)-1,3,4-triacetoxynaphthalene dissolved in 200 cc. of dry benzene was added over a period of one-half hour. The mixture was refluxed for four hours, cooled and poured slowly into a mixture of saturated ammonium chloride solution and ice. The two layers were well shaken, and the ether–benzene layer was washed with dilute alkaline solution. The ether–benzene solution was then extracted with several portions of a 65% ethanol–water mixture saturated with sodium carbonate. The extracts were combined and washed three times with low-boiling petroleum ether. To this alkaline solution was then added two volumes of brine, and the quinone was extracted into pure ethyl ether. The ether layer was washed twice with distilled water, then with two portions of 5% sulfuric acid solution, and finally with four portions of distilled water. The solution was dried thoroughly with magnesium sulfate and filtered through hard paper into a weighed flask. The ether was evaporated under reduced pressure, and the last traces of solvent were removed by heating the oil under 1 mm. of pressure at 50° for three hours. The product (2.2 g.) was obtained in the form of a viscous yellow-orange oil. The color reactions of this compound are the same as those of other 2-alkyl-3-hydroxy-1,4-naphthoquinones.

Acknowledgment.—The author is indebted to Dr. L. F. Fieser for many suggestions regarding this problem.

Summary

Procedures have been developed for the preparation of 2-alkyl-3-hydroxy-1,4-naphthoquinones in which ketonic carbonyl groups, and secondary and tertiary hydroxyl groups can be placed in the alkyl side chains in any desired position, the alkyl side chains being of any desired length.

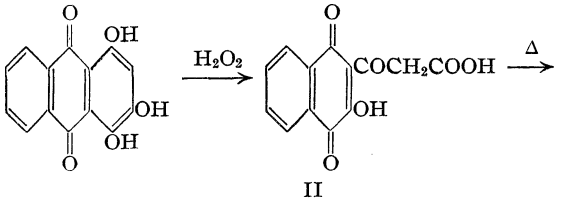
Preparation and Reactions of 2-Acyl-3-hydroxy-1,4-naphthoquinones[1]

BY DONALD J. CRAM[2]

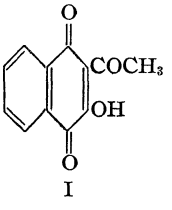
The growing importance of quinones as compounds of pharmaceutical and biological interest stimulated the present investigation of the preparation and reactions of 2-acyl-3-hydroxy-1,4-naphthoquinones. These substances, as well as compounds from which they are prepared, offer starting points from which a large variety of other quinones can be prepared, and the polyfunctional character of these substances has led in some cases to unexpected and interesting chemical reactions.

After the present study had been completed, several methods of synthesis of this type of compound were reported.[3] Previous to this work, only the simplest member, 2-acetyl-3-hydroxy-1,4-naphthoquinone (I), was known and had been prepared by the oxidation of purpurin.[4]

Repetition of the oxidation of purpurin resulted in a small yield of quinone I, as well as one of the precursors of this substance, the acid, II, which was converted to I through the action of heat.



II



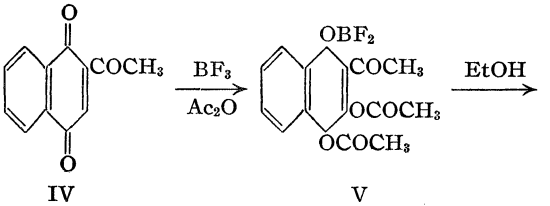
I

Treatment of 1,2,4-triacetoxynaphthalene with aluminum chloride resulted in a small yield of 2-acetyl-3-acetoxy-1,4-naphthohydroquinone (III), whose structure was demonstrated by synthesis from I. The hydroxyl group in I was acetylated by treatment of the silver salt with acetyl chloride to give 2-acetyl-3-acetoxy-1,4-naphthoquinone, reduction of which produced III. Compound III was also produced by reduction of I to 2-acetyl-3-hydroxy-1,4-naphthohydroquinone, which in turn was partially acetylated to give III. Further acetylation of III as well as the reductive acetylation of I produced 2-acetyl-1,3,4-triacetoxynaphthalene.

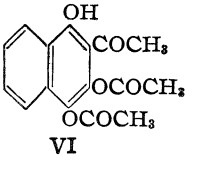
A Fries rearrangement of 1,4-diacetoxynaphthalene resulted in a poor yield of 2-acetyl-4-acetoxy-1-naphthol, which was also synthesized by the reduction of 2-acetyl-1,4-naphthoquinone[5] (IV) and partial acetylation of the product. Complete acetylation of 2-acetyl-4-acetoxy-1-naphthol produced 2-acetyl-1,4-diacetoxynaphthalene, which was also obtained by the reductive acetylation of 2-acetyl-1,4-naphthoquinone.

The most generally applicable approach to the synthesis of 2-acyl-3-hydroxy-1,4-naphthoquinones is illustrated by the following series of reactions. The compound 2-acetyl-4-acetylamino-1-naphthol[6] was oxidized with concentrated nitric acid in glacial acetic acid solution to produce good yields of 2-acetyl-1,4-naphthoquinone (IV).[7] An attempt was made to introduce a hydroxyl group into quinone IV by oxidation with hydrogen peroxide, but the oxide was obtained in only poor yields.

A new and general procedure for the introduction of a hydroxyl group into the 3-position of 2-acyl-1,4-naphthoquinones has been developed. When IV was subjected to a modified Thiele[8] reaction (boron trifluoride etherate as catalyst), the boron fluoride containing compound V separated from the reaction mixture, and was converted



IV V



VI

with boiling ethanol into VI. The structure of this diacetate was demonstrated in the following manner. Acetylation of 2-acetyl-3-acetoxy-1,4-naphthohydroquinone under mild conditions pro-

(4) Dimroth and Schultz, *Ann.*, **411**, 343 (1916); see also Kuhn and Wallenfels, *Ber.*, **74**, 1594 (1941).

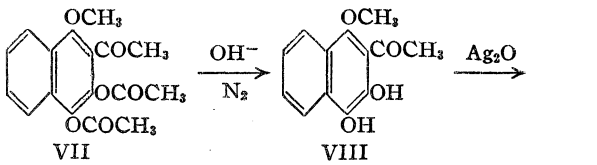
(5) The preparation of this substance is described further on in the investigation.

(6) Friedlaender, *Ber.*, **28**, 1950 (1895).

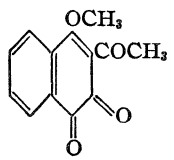
(7) This substance was obtained by Friedlaender[6] by the oxidation of 2-acetyl-4-amino-1-naphthol with ferric chloride, but the yield was poor and the product difficult to purify.

(8) This reaction has been used with sulfuric acid as catalyst for the conversion of naphthoquinone to 1,2,4-triacetoxynaphthalene [Thiele and Winter, *Ann.*, **311**, 347 (1900)], and more recently Fieser [THIS JOURNAL, **70**, 3165 (1948)] employed boron trifluoride as catalyst.

duced VI, indicating that one of the acetoxyl groups of the diacetate is in the 3-position. Methylation of VI with either dimethyl sulfate and sodium carbonate or diazomethane produced a monomethylated diacetate VII, which when hydrolyzed under carefully controlled conditions produced VIII. This substance was oxidized with silver oxide under anhydrous conditions (dry ether) to the *o*-quinone IX. Although unstable to acid or base, IX reacted with *o*-phenylenediamine to yield a diazine X.



VII VIII

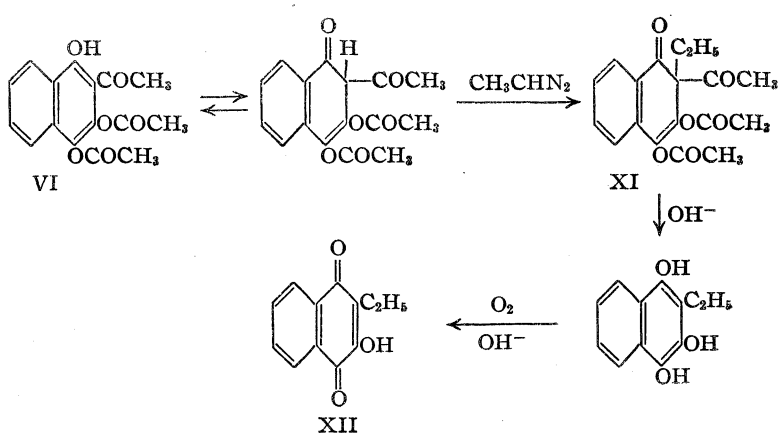


IX

Condensation of I with *o*-phenylenediamine produced an azine, which on methylation yielded X.

The above series of reactions proves that the diacetate VI contains two acetoxyl groups in the 3- and 4-positions and a free hydroxyl group in the 1-position.

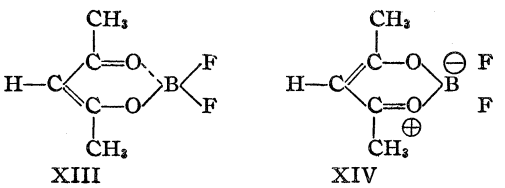
It is interesting to note that on treating VI with diazoethane, carbon alkylation occurred to give XI, possibly *via* the ketonic tautomer of VI. The structure of XI was demonstrated by hydrolysis and oxidation to 2-ethyl-3-hydroxy-1,4-naphthoquinone (XII) which was shown to be identical with an authentic sample.[9]



VI XI XII

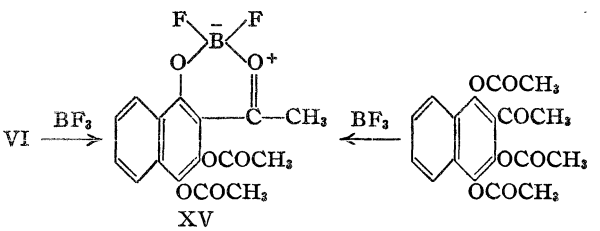
The structure of the boron fluoride containing compound V was established in the following way. The analytical values for carbon and hydrogen were high, probably owing to the passage of volatile boron fluoride compounds into the absorption train. Therefore, a method of fluorine analysis was developed, based on the conversion of fluorine to fluoride ion by fusion of the compound with alkali, and determination of the ion by the usual procedure.[10]

The analysis indicated that V contained a BF_2-group in place of a proton. There are several cases in the literature where a BF_2-group replaced a phenolic or enolic hydrogen. Morgan, *et al.*,[11] and Sugden, *et al.*,[12] prepared the boron difluoride derivative of acetylacetone by the addition of boron trifluoride to a solution of acetylacetone in benzene. The former authors assigned structure XIII to the compound, whereas the latter authors, on the basis of parachor determinations, advanced the structure XIV.



XIII XIV

By analogy with the above observations the structure of the boron-difluoride-containing product of the Thiele reaction (V) was assigned the dipolar structure XV, which is preferred over the



XV

alternate non-polar structure because of the strong electrophilic character of the boron atom, and because of the resonance of stabilization inherent in the dipolar form, and because of the energy gained by the formation of a new bond. Compound XV was also prepared by the addition of boron trifluoride to VI or to 2-acetyl-1,-3,4-triacetoxynaphthalene. The identity of the products of the three methods of preparation of XV was proved by (a) fluorine analysis, (b) decomposition points and (c) ultraviolet absorption spectra comparisons. To prove that the acetoxyl groups in the 3- and 4-positions of XV were not involved in the fixation of the BF_2-groups in the molecule, 2-acetyl-1-naphthol was allowed to react with boron trifluoride etherate in glacial acetic acid solution to give a com-

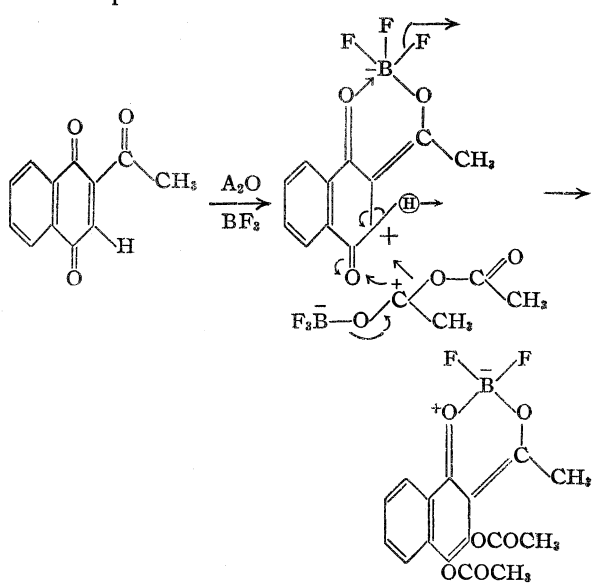
pound containing a boron difluoride group in place of a hydrogen. Treatment of this substance with warm ethanol produced starting material.

Figure 1 records the ultraviolet absorption spectra of 2-acetyl-1-naphthol and its boron difluoride derivative, and Fig. 2 records the ultraviolet absorption spectra of VI and its boron difluoride derivative, XV. Examination of these spectra indicates a marked similarity between all four curves.

The elucidation of the structure of V demonstrates that 2-acyl-1,4-naphthoquinones undergo a modified Thiele reaction to give not the expected triacetate but a diacetate containing a BF_2-group on the phenolic oxygen in the 1-position. Although 1,4-naphthoquinone undergoes the normal Thiele reaction, 2-methyl-1,4-naphthoquinone does not. This fact suggests that the addition of acetic anhydride to quinone IV is a reaction involving the acetyl group in the side-chain. A possible mechanism for the reaction is presented.



The hydrolysis and subsequent oxidation of diacetate VI was carried out by procedures developed by Fieser,[13] and quinone I was the final product.

The procedures discussed above proved to be general, and were used in the present investigation for the preparation of 2-(4′-cyclohexylbutyryl)-3-hydroxy-1,4-naphthoquinone and 2-(3′-phenylpropionyl)-3-hydroxy-1,4-naphthoquinone. The substance, 2-benzalacetyl-3-hydroxy-1,4-naphthoquonine, was prepared through the base catalyzed condensation of 2-acetyl-3-hydroxy-1,4-naphthoquinone with benzaldehyde.

When compound VI was treated with a large excess of cetyl magnesium bromide in benzene solution, the two acetoxyl groups were cleaved, and the acetyl group reacted normally with the

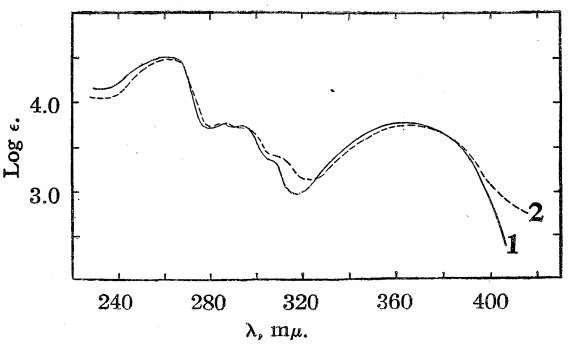

Fig. 1.—The ultraviolet absorption spectra (Beckman quartz spectrophotometer) in dioxane of: 2-acetyl-1-naphthol, curve 1; and the boron difluoride derivative of 2-acetyl-1-naphthol, curve 2.

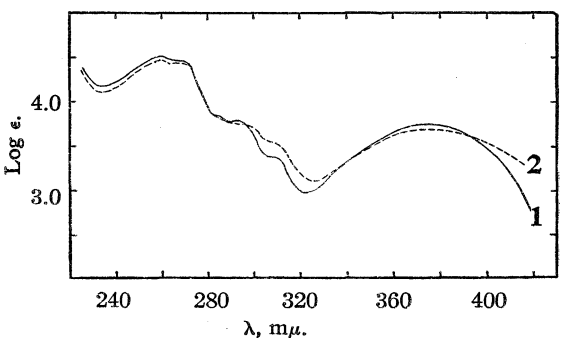

Fig. 2.—The ultraviolet absorption spectra (Beckman quartz spectrophotometer) in dioxane of: 2-acetyl-3,4-diacetoxy-1-naphthol, curve 1; and the boron difluoride derivative of 2-acetyl-3,4-diacetoxy-1-naphthol, curve 2.

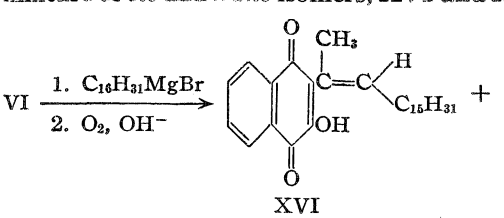
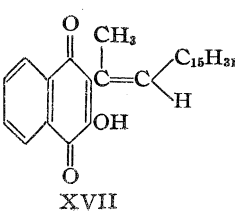
Grignard reagent. When the reaction mixture was decomposed, the tertiary alcohol lost a molecule of water, and the product proved to be a mixture of *cis* and *trans* isomers, XVI and XVII.

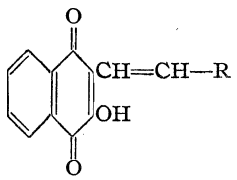




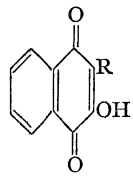
Each isomer was converted into a mixture of the two isomers when heated at 120° for half an hour. The structures of the two compounds were confirmed by oxidation to palmitic aldehyde which was identified as the *p*-nitrophenylhydrazone.

Quinones of structure XVIII give a purple color in alkaline solution, and compounds of structure XIX produce a red color.[9] Compounds

XVI and XVII both give a red color in alkaline solution.



XVIII



XIX

The steric inhibition of resonance implicit in structures XVI and XVII (the bulk of the methyl and methylene groups of the side-chain forbid coplanarity) provides an explanation for the similarity of the color reactions of these molecules and XIX.

Careful examination of Fisher-Hershfelder models of XVI indicates that the planar configuration of this molecule involves interference between the bulk of the C_{15} side-chain and the hydroxyl group in the 3-position, whereas this particular interference is absent in XVII. Determinations of the ultraviolet absorption spectra of the two isomers show that the positions of the maxima and minima as well as the extinction coefficients are all comparable, except for the maxima that occur at the longest wave length. The isomer melting at 91–92° has a maximum at 405 mμ, whereas the isomer melting at 82° has a maximum at 395 mμ. Since the isomer that presents the lesser hindrance to coplanarity of the two unsaturated systems should absorb light at the longer wave length, and since models indicate that configuration XVII gives less hindrance to coplanarity than XVI, formula XVII is assigned to the isomer melting at 91–92°, and XVI to the isomer melting at 82°.

Table I records the wave lengths and logarithms of the molecular extinction coefficients of the maxima and minima of the ultraviolet absorption spectra of isomers XVI and XVII in ethanol.

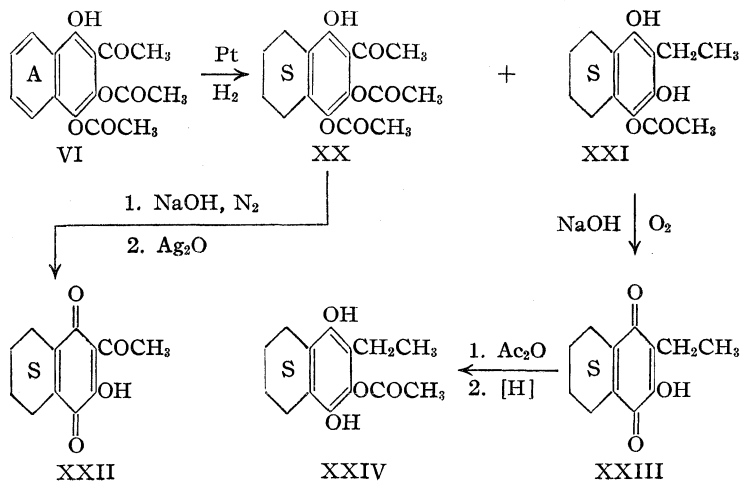
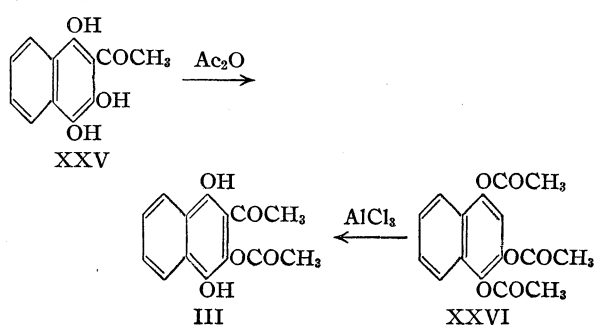
In an attempt to reduce the ketone in the side-chain of VI to the corresponding alcohol, VI was submitted to hydrogenation in a solution of glacial acetic acid with platinum oxide catalyst. Two compounds, XX and XXI, were isolated and converted to the corresponding quinones, XXII and XXIII. The position of the acetoxyl group in XXI was demonstrated by synthesis of the other possible isomer, XXIV.

The structures of these substances indicate that the reduction of VI took place in three directions: (a) ring A of the nucleus was reduced; (b) the ketonic group in the side-chain was reduced to a methylene group; (c) the acetoxyl group in the 3-position was removed by reduction. The removal by reduction of the acetoxyl group from position three of VI contrasts with the preferential acetylation of the hydroxyl group in the 3-position



of XXV, and with the selective deacetylation that must take place in the conversion of XXVI to III.



In an attempt to avoid the complications experienced in the reduction of 2-acyl-3,4-diacetoxy-1-naphthols with platinum oxide and hydrogen, compound XXVII was reduced over copper chromite catalyst in dioxane at 150° under 150 atmospheres of hydrogen. In this reduction the carbonyl group of the side-chain was reduced to a methylene group, and conversion of the substance XXVIII to quinone XXIX, a known compound,[14] confirmed the identity of the substance.

Table II records the physical properties and analyses of those of the above compounds whose detailed preparation can be adequately described by reference to the procedure used for an anal-

[1] In all cases where two different methods of preparation of the same compound are reported, admixture of samples produced no depression of melting point. [2] y. = yellow, n. = needles, w. = white, pr. = prisms, o. = orange, r. = red, pl. = plates, gr. = granules, l = light. [3] Forms a deep purple color in alkaline sol., deep red color in concd. sulfuric acid. [4] The procedure was modified by not heating the reaction mixture, but allowing it to stand ten hours at room temp. [5] Admixture with same substance produced from Fries rearrangement (see expl.) gave no m. p. depression. [6] Friedlaender (ref. 6) prepared this compound by a different procedure but reported neither melting point nor yield. [7] The sodium acetate and heating period were unnecessary. [8] Friedlaender (ref. 6) reported a m. p. of 107° for a monoacetylated amine, and Torrey and Cardarelli [THIS JOURNAL, 32, 1477 (1910)] reported a m. p. of 212°. [9] Friedlaender (ref. 6) reported a m. p. of 78° for this compound prepared by a different procedure. [10] This substance when warmed with ethanol reverts to the starting material. [11] Hooker reported a m. p. of 138–139° for this compound. The m. p. of a mixture of the two samples is 138–139°. [12] This substance [Torrey and Cardarelli (ref. 18) reported m. p. 202–208°] was prepared in a 92% yield, m. p. 210°. [13] The double bond in the side-chain was also reduced. [14] In this reaction the BF_2-derivative was treated directly with ethanol to give the phenol. [15] When crystallized from glacial acetic acid this quinone contains one mole of acetic acid of crystallization (yellow needles, m. p. 85–86 (dec.)). [16] 2-Ethyl-3-hydroxy-4-acetyl-5,6,7,8-tetrahydro-1-naphthol was isolated as a by-product (see expl.). [17] The intermediate hydroquinone was not isolated.

ogous reaction described in the experimental section.

Experimental

2-Acetyl-3-hydroxy-1,4-naphthoquinone (I) from Purpurin.—The reaction was run according to the procedure of Dimroth and Schultze,[4] but since the products were isolated from the reaction mixture by a method different than that reported by these workers, the procedure is repeated here.

To a cooled solution of 6 g. of purpurin in 150 cc. of water and 18 cc. of 5 *N* sodium hydroxide solution, 15 drops of a 1% cobalt sulfate solution and 10 cc. of a 30% hydrogen peroxide solution were added. The temperature rose to 40° in about three minutes and was maintained by placing the mixture in an ice-bath. After five minutes the solution turned red-brown, and 7.5 cc. of concentrated hydrochloric acid was added; the precipitate was collected and washed with water. The solid was triturated twice with saturated sodium carbonate solution and filtered. From the solid residue 2 g. of purpurin was recovered. The filtrate was acidified; the yellow precipitate was collected, dissolved in ethanol and passed through a small alumina column. The filtrate was evaporated to a small volume, and 50 mg. (11% yield) of I was obtained as yellow plates by crystallization of the oil from glacial acetic acid; m. p. 134–135°.

This quinone gives an orange color in alkaline solution, a yellow color in concentrated sulfuric acid solution, and a deep purple color in alkaline sodium hydrosulfite solution. Dimroth and Schultze[4] reported a yield of 79% and a melting point of 128–129°.

The original filtrate of the reaction mixture was extracted with ether, and the ether solution was dried and evaporated to a small volume from which yellow crystals slowly separated. Two recrystallizations from acetone and petroleum ether furnished 100 mg. of 2-(2′-carboxyacetyl)-3-hydroxy-1,4-naphthoquinone (II) in the form of orange needles; m. p. 119–120°. This substance produces a yellow color in alkaline solution, a yellow color in concentrated sulfuric acid solution and a purple color in alkaline sodium hydrosulfite solution.

Anal. Calcd. for $C_{13}H_8O_6$: C, 60.01; H, 3.10. Found: C, 60.20; H, 3.38.

The carboxylic acid II (50 mg.) was dissolved in 2 cc. of glacial acetic acid, and the solution was heated to 90° for five minutes. When cooled and diluted with water, the yellow quinone I crystallized; m. p. 134–135°. The melting point was not depressed by the addition of an authentic sample of I.

2-Acetyl-3-acetoxy-1,4-naphthohydroquinone (III).—A mixture of 1,3,4-triacetoxynaphthalene, 5 g. of anhydrous aluminum chloride and 100 cc. of *o*-dichlorobenzene was stirred at 80° for four hours, cooled, and mixed with 200 g. of ice and 50 cc. of 50% hydrochloric acid. A yellow solid was collected, and three recrystallizations (ethanol) produced 0.15 g. (3% yield) of III in the form of yellow needles, m. p. 196–197°. The compound forms an orange color changing to purple in alkaline solution, and a green color changing to yellow in an ethanol solution containing a drop of ferric chloride solution.

Anal. Calcd. for $C_{14}H_{12}O_5$: C, 64.61; H, 4.65. Found: C, 64.37; H, 4.66.

The substance 2-hydroxy-1,4-naphthoquinone[13] (2.5 g.) was recovered from the filtrate.

Procedure A. 2-Acetyl-1,3,4-triacetoxynaphthalene from 2-Acetyl-3-acetoxy-1,4-naphthohydroquinone (III).—To 25 mg. of III, 1.0 g. of acetic anhydride and a trace of sodium acetate were added. The mixture was warmed to 100° and diluted with 100 cc. of water, cooled, and two recrystallizations (ethanol) of the substance that separated afforded 10 mg. of white prisms; m. p. 138–139°.

Procedure B. 2-Acetyl-1,3,4-triacetoxynaphthalene from 2-Acetyl-3-hydroxy-1,4-naphthoquinone (I).—A mixture of 100 mg. of I, 200 mg. of zinc dust,[15] 2 g. of acetic anhydride and a trace of sodium acetate was heated on a steam-bath for one-half hour, filtered and the filtrate was stirred into 10 cc. of water. The product that separated was crystallized from ethanol; 105 mg., m. p. 138–139°.

2-Acetyl-3-acetoxy-1,4-naphthoquinone.—To 10 cc. of a solution of 2% ammonia in a 50% water–ethanol mixture 0.4 g. of I was added. The ammonium salt crystallized immediately. An excess of 50% silver nitrate solution was added to the mixture; the silver salt was filtered, digested with ethanol, and thoroughly dried. This salt was suspended in dry ether, and acetyl chloride was added drop by drop until all the quinone salt was decomposed. The precipitated silver chloride was collected; the filtrate was evaporated to a small volume in vacuum, cooled, and the quinone acetate was collected. Two recrystallizations of the product from dry ether produced 0.32 g. of light-yellow needles; m. p. 123–124°. This acetate hydrolyzes readily into the free quinone, and for this reason cannot be crystallized from ethanol.

Anal. Calcd. for $C_{14}H_{10}O_5$: C, 65.12; H, 3.90. Found: C, 65.28; H, 4.09.

Procedure C. 2-Acetyl-3-acetoxy-1,4-naphthohydroquinone (III) from 2-Acetyl-3-acetoxy-1,4-naphthoquinone.—An ether solution of 0.20 g. of 2-acetyl-3-acetoxy-1,4-naphthoquinone was shaken successively with three fresh portions of a solution of sodium hydrosulfite in water.[16] The ether solution was thoroughly washed with water, dried, and filtered through a small mat of Darco that had been washed with ether. The filtrate was evaporated to a small volume, cooled, and the product collected. Recrystallization of the substance from ethanol furnished 0.10 g. of yellow needles, m. p. 196–197°.

2-Acetyl-4-acetoxy-1-naphthol and 2-Acetyl-1,4-naphthohydroquinone.—A mixture of 3.0 g. of 1,4-diacetoxynaphthalene, 3.0 g. of anhydrous aluminum chloride and 30 cc. of nitrobenzene was heated for two hours at 70°, cooled, and decomposed with a mixture of ice and hydrochloric acid. The nitrobenzene was steam distilled, the black tar that remained was extracted into ether, and a brown insoluble precipitate was collected. The filtrate was dried, evaporated to dryness, and the residue repeatedly extracted with low-boiling petroleum ether. The extracts were combined, treated with Darco, evaporated to a small volume, and cooled. The product crystallized, and two recrystallizations (ethanol) furnished 0.25 g. (8.4% yield) of light yellow needles of 2-acetyl-4-

(15) This procedure is patterned after that described by Fieser, "Experiments in Organic Chemistry," 2nd Edition, D. C. Heath and Co., New York, N. Y., 1941, p. 399.

(16) This procedure is patterned after that developed by Fieser, *loc. cit.*, p. 190.

acetoxy-1-naphthol, m. p. 103–104°. The acetate forms a red solution with concentrated sulfuric acid, an orange solution with aqueous alkali, and a green solution with ethanol containing a drop of ferric chloride solution.

Anal. Calcd. for $C_{14}H_{12}O_4$: C, 68.84; H, 4.95. Found: C, 68.56; H, 4.71.

The material left from the petroleum ether extractions was dissolved in ether and shaken with sodium hydrosulfite solution, washed with water, dried, and filtered through a small ether-washed pad of Darco. When the filtrate was evaporated to a small volume and cooled, a solid separated, which after two recrystallizations from ether afforded 0.2 g. (8.1% yield) of 2-acetyl-1,4-naphthohydroquinone, m. p. 216–217°. The compound forms a red solution with concentrated sulfuric acid, an orange solution (which darkens) in aqueous alkali, and a green color changing to red in an ethanol solution containing a drop of ferric chloride solution.

Anal. Calcd. for $C_{12}H_{10}O_3$: C, 71.28; H, 4.99. Found: C, 71.20; H, 5.04.

Procedure D. 2-Acetyl-4-amino-1-naphthol.—A mixture of 10 g. of 2-acetyl-4-nitro-1-naphthol,[17] 0.10 g. of platinum oxide, 100 cc. of methanol and 5 cc. of concentrated hydrochloric acid was shaken under 25 lb. of hydrogen until six equivalents of hydrogen had been absorbed (four hours). The salt that separated was filtered and washed with methanol. This substance was mixed with 50 cc. of ethanol, and 10 cc. of a saturated sodium bicarbonate solution was added. The free amine was collected and recrystallized from ethanol; 7.3 g. (83% yield), m. p. 126–127°. Friedlaender prepared this substance by a different procedure, but he did not report a melting point or a yield.

Procedure E. 2-Acetyl-1,4-naphthoquinone (IV).—To a mixture of 16 g. of 2-acetyl-4-acetylamino-1-naphthol[18] and 140 cc. of glacial acetic acid at 15°, 6 g. of 70% nitric acid dissolved in 20 cc. of glacial acetic acid was added. The solid dissolved when the mixture was stirred. When 200 cc. of water was added to the solution, IV crystallized in fine yellow needles; 10.2 g. (88% yield), m. p. 80–81°.

2-Acetyl-1,4-naphthoquinone Oxide.—A solution made up of 0.1 g. of sodium carbonate, 0.4 cc. of dioxane, 2.5 cc. of dioxane, 2.5 cc. of water and 0.5 cc. of 30% hydrogen peroxide solution was added to 0.5 g. of IV dissolved in 15 cc. of ethanol. The mixture turned black. After ten minutes 100 cc. of water was added, and the precipitated solid collected. Two recrystallizations of the product from ethanol produced white needles of the oxide; 0.2 g. (37% yield), m. p. 125–126°.

Anal. Calcd. for $C_{12}H_{18}O_4$: C, 66.67; H, 3.73. Found: C, 66.52; H, 3.96.

Boron Difluoride Derivative (V) of 2-Acetyl-3,4-diacetoxy-1-naphthol (VI)

Procedure F. From 2-Acetyl-1,4-naphthoquinone (IV).—A mixture of 4.0 g. of IV, 12.0 g. of acetic anhydride and 2.0 g. of a solution of boron trifluoride in ether (45% by weight) was allowed to stand for twenty-four hours at room temperature.[19] Brilliant yellow needles of V separated, were collected and washed with cold glacial acetic acid; 6.0 g. (82% yield), m. p. 232–236° dec. Recrystallization of the substance from glacial acetic acid did not alter the melting properties.

This compound burns with a green flame and leaves a black ash; it is insoluble in water, decomposes in alkali and shows only a slight solubility in non-polar organic solvents. If heated with any organic solvent containing water, it decomposes. Solutions fluoresce strongly in the sunlight.

Procedure G. From 2-Acetyl-3,4-diacetoxy-1-naphthol (VI).—To a saturated solution of 5.0 g. of VI in glacial acetic acid, 3 g. of boron trifluoride etherate was added. A heavy precipitate of fine, yellow crystals separated immediately.[19] Recrystallization of the substance from glacial acetic acid furnished 4.2 g. of yellow needles, m. p. 232–236° dec.

Procedure H. 2-Acetyl-3,4-diacetoxy-1-naphthol (VI).—When 10 g. of V and 100 cc. of a 90% ethanol–water mixture were boiled for one-half hour, the boron fluoride compound decomposed to give orange-yellow crystals of VI. The mixture was cooled, the product collected and recrystallized from glacial acetic acid to yield 7.3 g. of lustrous yellow needles, m. p. 184–185°. This substance forms an orange solution with concentrated sulfuric acid, a yellow solution changing to deep red and finally to brown with aqueous alkali, and a green color in a solution of ethanol containing a drop of ferric chloride.

Procedure I. 2-Acetyl-3-hydroxy-1,4-naphthoquinone (I).—A solution (10 cc.) of a 30% potassium hydroxide was added to a mixture of 4 g. of VI and 40 cc. of ethanol (both mixtures had been previously flushed with nitrogen).[13] The mixture was allowed to stand for one-half hour. At the end of this time the purple solution was cooled, acidified with a cold solution of 8 cc. of concentrated hydrochloric acid in 25 cc. of water, and a cold solution of 8.7 g. of ferric chloride hexahydrate in 2.5 cc. of concentrated hydrochloric acid and 12 cc. of water was added. A crop of yellow needles separated, which crystallized from glacial acetic acid as gold-colored plates; 2.0 g. (70% yield), m. p. 134–135°. Admixture of the substance with an authentic sample of I (prepared from purpurin) did not depress the melting point.

1-Methoxy-2-acetyl-3,4-diacetoxynaphthalene (VII).—To a solution of 4.0 g. of VI in 300 cc. of dry benzene, an ether solution of diazomethane prepared from 10 g. of N-methyl-N-nitrosourea was added. The mixture after standing at room temperature for three hours, was evaporated in vacuum to an oil, which was dissolved in 30 cc. of ethanol, treated with charcoal and cooled in a Dry Ice–acetone mixture for several hours. The white solid that separated was filtered, washed with cold ethanol, and recrystallized twice from glacial acetic acid; 1.8 g. (white prisms), m. p. 106–107°.

Anal. Calcd. for $C_{17}H_{16}O_6$: C, 64.55; H, 5.10. Found: C, 64.33; H, 5.21.

Compound VII was also prepared in the usual manner by the action of dimethyl sulfate on VI, but the yield was inferior.

1-Methoxy-2-acetyl-3,4-dihydroxynaphthalene (VIII).—Solutions of 2.2 g. of VII in 30 cc. of ethanol and 7.5 cc. of 20% potassium hydroxide were flushed with nitrogen, mixed, and allowed to stand under nitrogen for two and one-half hours (the mixture was shaken frequently). Acidification with acetic acid yielded yellow crystals which, after thorough washing with water and recrystallization from glacial acetic acid afforded 0.65 g. of light yellow needles, m. p. 227–228°. The compound formed a green solution with ethanol containing a drop of ferric chloride solution, and a red solution with concentrated sulfuric acid, and an orange solution turning to brown with aqueous alkali. The substance was not identified.

Anal. Found: C, 69.84; H, 4.38.

The mother liquors of the original reaction mixture were saturated with sodium chloride, and cooled to 0° for twelve hours. The substance that separated was recrystallized twice from an ether–petroleum ether mixture; 0.4 g. of deep red-orange needles, m. p. 92–93°. The substance produced an orange solution with aqueous alkali, and a green color changing quickly to orange with an aqueous solution containing a drop of ferric chloride.

Anal. Calcd. for $C_{13}H_{12}O_4$: C, 67.23; H, 5.21. Found: C, 67.15; H, 5.38.

1-Methoxy-2-acetyl-3,4-naphthoquinone (IX).—A solution of 0.15 g. of VIII in 20 cc. of anhydrous ether was stirred for one hour with 0.25 g. of anhydrous magnesium

(17) Acetylation of 1-naphthol (Friedlaender, ref. 6, reported a quantitative yield and a m. p. of 103°) gave an 80% yield of 2-acetyl-1-naphthol, m. p. 101–102°. Nitration of this compound produced an 82% yield, m. p. 157–158°, of 2-acetyl-4-nitro-1-naphthol (Friedlaender, ref. 6, reported no yield and m. p. 157°).

(18) Torrey and Cardarelli, THIS JOURNAL, **32**, 1477 (1910).

(19) A small amount of etching of the glass of the reaction flask occurred.

sulfate and 0.25 g. of silver oxide. The solid was collected, and the quinone that had crystallized during the oxidation was dissolved in dry acetone and filtered. The combined filtrates were evaporated to a small volume under reduced pressure, and cooled. The solid when recrystallized twice from acetone formed rich orange-yellow needles; 75 mg., m. p. 166–167°. This ortho quinone is slightly soluble in ether and soluble in acetone. The substance forms a yellow solution with sulfuric acid, a deep red solution with aqueous alkali (after two minutes) and a deep purple solution with a mixture of aqueous alkali and sodium hydrosulfite, if the alkali is added first and allowed to stand for two minutes before the hydrosulfite is added. If sodium hydrosulfite is added first, and then the alkali, a deep red solution results.

Anal. Calcd. for $C_{13}H_{10}O_4$: C, 67.82; H, 4.38. Found: C, 67.72; H, 4.67.

O-Methyl-2-acetyl-1-naphtheurhodol.—A mixture of 50 mg. of IX, 35 mg. of *o*-phenylenediamine, and 1 cc. of glacial acetic acid was allowed to stand at room temperature for one-half hour. When the solution was cooled, a solid separated which was crystallized from ethanol; 20 mg. (light yellow needles), m. p. 157–158°.

Anal. Calcd. for $C_{19}H_{14}O_2N_2$: C, 75.48; H, 4.67. Found: C, 75.51; H, 4.65.

2-Acetyl-1-naphtheurhodol.—A solution of 0.5 g. of I and 0.18 g. of *o*-phenylenediamine in 2 cc. of glacial acetic acid was heated to the boiling point for one minute, and cooled. The product that separated was recrystallized twice from glacial acetic acid; 0.45 g. of orange needles, m. p. 206–207°.

Anal. Calcd. for $C_{18}H_{12}O_2N_2$: C, 74.99; H, 4.20. Found: C, 74.83; H, 3.90.

O-Methyl-2-acetyl-1-naphtheurhodol from 2-Acetyl-1-naphtheurhodol.—To a solution of 0.2 g. of 2-acetyl-1-naphtheurhodol in 20 cc. of a 50% acetone–water solution saturated with sodium carbonate, 2 cc. of dimethyl sulfate was added over a period of one-half hour. The mixture was stirred and kept basic by the addition of more sodium carbonate. Crystallization of the substance that separated (ethanol and water) produced light yellow needles; 0.15 g., m. p. alone and mixed with an authentic sample (see above), 157–158°.

2-Acetyl-2-ethyl-3,4-diacetoxy-1-naphthone (XI).—An ethereal solution of diazoethane was prepared from 15 g. of N-ethyl-N-nitrosourea, and added to a solution of 8 g. of VI in one liter of dry benzene. The reaction mixture was allowed to stand overnight at room temperature, and was concentrated under reduced pressure to a volume of 100 cc. The solution was then filtered through a heavy mat of Darco, and when the filtrate was cooled, 4 g. of starting material crystallized. The mixture was filtered, and the filtrate was concentrated to an oil, which was dissolved in a small amount of ethanol, mixed with a generous portion of Darco, and filtered; the filtrate was allowed to stand in an ice-chest for forty-eight hours. At the end of this period the substance that precipitated was crystallized twice from ethanol; 1.2 g. of white needles, m. p. 130–131°. This product forms a red color when allowed to stand in an aqueous alcoholic alkaline solution, and an orange color in concentrated sulfuric acid.

Anal. Calcd. for $C_{18}H_{18}O_6$: C, 65.45; H, 5.49. Found: C, 65.47; H, 5.68.

Procedure J. 2-(3′-Phenylpropionyl)-1,4-naphthoquinone by a Condensed Procedure.—Glacial acetic acid (200 cc.), acetic anhydride (100 cc.), 0.35 g. of platinum oxide and 34 g. of 2-benzalacetyl-4-nitro-1-naphthol were mixed and shaken under twenty-five pounds of hydrogen until eight equivalents had been absorbed (eighteen hours). To the mixture 6 g. of 70% nitric acid was then added. The suspended solid went into solution in about two minutes, and the catalyst was collected. Water (one volume) was added to the filtrate, the mixture was cooled, and a crop of fine yellow needles was collected; 21 g. (68% yield), m. p. 94–95°, not depressed by addition of an authentic sample of the quinone.

2-Benzalacetyl-3-hydroxy-1,4-naphthoquinone.—A mixture of quinone I (1 g.), 0.8 g. of benzaldehyde, 10 cc. of ethanol and 5 cc. of a 30% sodium hydroxide solution was stirred for twelve hours (the mixture turned black as soon as the components were added to one another). The solution was then acidified with acetic acid and oxidized with a solution of 1 g. of ferric chloride hexahydrate in 5 cc. of water and 1 cc. of concentrated hydrochloric acid. The oil that separated was dissolved in glacial acetic acid and set aside for several days. A small crop of crystals separated, and three recrystallizations from glacial acetic acid produced 0.1 g. of tan needles, m. p. 181–182°. The quinone formed a yellow solution with aqueous alcoholic alkali, a red-orange solution with concentrated sulfuric acid, a blue solution changing to purple and finally to red with an alkaline sodium hydrosulfite solution, and a yellow-orange solution with ethanol containing a drop of ferric chloride solution.

Anal. Calcd. for $C_{19}H_{12}O_4$: C, 74.99; H, 3.98. Found: C, 74.67; H, 4.09.

2-(4′-Cyclohexylbutyryl)-1-naphthol.—Freshly fused and ground zinc chloride (160 g.) was mixed with 100 g. of 4-cyclohexylbutyric acid and 85 g. of 1-naphthol.[20] The mixture was rapidly brought to 140–145°, held there for twenty minutes, cooled to 100°, and poured into water. The oily product was boiled with ethanol, collected, and recrystallized from glacial acetic acid; 72 g. (44% yield) of white needles, m. p. 103–104°.

Anal. Calcd. for $C_{20}H_{24}O_2$: C, 81.04; H, 8.16. Found: C, 81.30; H, 8.27.

2-(4′-Cyclohexylbutyryl)-4-nitro-1-naphthol.—Over a period of twelve hours a solution of 14 g. of 70% nitric acid in 50 cc. of glacial acetic acid was added to a mixture of 40 g. of 2-(4′-cyclohexylbutyryl)-1-naphthol and 150 cc. of glacial acetic acid at 15°.[20] The product that separated was washed with glacial acetic acid and dried; 32 g. (70% yield of nitro compound in the form of granules with a slight-yellow tinge), m. p. 121–122°.

Anal. Calcd. for $C_{20}H_{23}O_4N$: C, 70.36; H, 6.79. Found: C, 70.66; H, 6.75.

***cis* and *trans*-2-(1′-Methylheptadecen-1-yl)-3-hydroxy-1,4-naphthoquinone (XVI and XVII).**—To a stirred mixture of 6.5 g. of magnesium turnings and 50 cc. of dry ether in an atmosphere of nitrogen, 73 g. of cetyl bromide (dissolved in 200 cc. of dry ether) was added over a period of one-half hour. When the addition was complete, the mixture was refluxed for two hours, and a mixture of 7.3 g. of the diacetate VI and 300 cc. of dry benzene was added in portions. The reaction mixture was then refluxed for four hours, cooled and poured into a mixture of ice and ammonium chloride. The two layers were well shaken, separated, and the ether–benzene layer was shaken with a 5% solution of sodium hydroxide in a 50% alcohol–water mixture for about one-half hour. The solution was then acidified with acetic acid, and the layers separated. The ether–benzene layer was washed twice with water, dried, and evaporated under reduced pressure to an oil, which was dissolved in an equal volume of dry ether, and chilled for two days. The product that separated was dissolved in a small amount of boiling glacial acetic acid, and the solution was cooled as slowly as possible; care was taken not to disturb the flask during the crystallization. After twelve hours the product was carefully collected, and spread out on a piece of white paper. There were two kinds of crystals present in the mixture, relatively large dense packets of rich-orange needles and scattered light-yellow needles. The crystals of each component were separated manually, and submitted to alternate crystallization from glacial acetic acid and ethyl ether solutions until the melting points no longer changed. In this manner 1.7 g. of rich orange needles of the *trans* isomer (XVII), m. p. 91–92°, and 1.2 g. of fine yellow needles of the *cis* isomer (XVI), m. p. 82°, were obtained.

(20) These procedures are modeled after those of Friedlaender (ref. 6) in the preparation of 2-acetyl-4-nitro-1-naphthol.

Both compounds formed a red solution with an alkaline ethanol–water mixture, and an orange solution changing through brown, green and blue to a dirty purple with concentrated sulfuric acid. A mixed melting point determination of the two substances gave 86–89°.

Anal. Calcd. for $C_{28}H_{40}O_3$: C, 79.20; H, 9.50. Found for the *cis* isomer: C, 79.14; H, 9.68. Found for the *trans* isomer: C, 79.14; H, 9.50.

Ozonolysis of *cis*- and *trans*-2-(1′-Methylheptadecen-1-yl)-3-hydroxy-1,4-naphthoquinone (XVI and XVII).—Ozone was passed into a solution of 0.3 g. of the *trans* isomer in 30 cc. of ethyl acetate till the color was discharged. The solution was then dripped into boiling water; the water was cooled and extracted twice with petroleum ether. The extracts were combined, and the solution was washed once with dilute alkali, once with water, dried, and evaporated to a volume of 10 cc. This solution was run through a small column of acid-washed alumina, and the alumina was washed well with petroleum ether. The column filtrate was evaporated to a small volume and cooled to Dry-Ice temperature. The white solid that separated was crystallized from petroleum ether; 90 mg. of palmitic aldehyde[21] (white needles), m. p. 33–34°. The *p*-nitrophenylhydrazone[21] was prepared by the usual method, m. p. 95–96°.

The *cis* isomer (100 mg.) was oxidized by the same procedure, and 25 mg. of the *p*-nitrophenylhydrazone of palmitic aldehyde was isolated, m. p. 95–96°. A mixed melting point of the two samples of this substance showed no depression.

Conversion of *trans*-2-(1′-Methylheptadecen-1-yl)-3-hydroxy-1,4-naphthoquinone (XVII) into the *cis* Isomer (XVI).—The *trans* isomer (220 mg.) was heated at 120° for one-half hour. The melt was dissolved in a small amount of glacial acetic acid, and the solution was seeded with a crystal of the *cis* isomer. The product that separated was recrystallized twice from ethyl ether to give 63 mg. of the *cis* isomer, m. p. 82°. A mixed melting point with an authentic sample of XVI gave no depression. Starting material (105 mg.) was recovered from the combined filtrates.

A similar experiment, carried out on 130 mg. of the *cis* isomer (XVI), produced 30 mg. of the *trans* isomer XVII; m. p. 91–92°, not depressed by the addition of an authentic sample.

Procedure K. Reduction of 2-Acetyl-3,4-diacetoxy-1-naphthol (VI) to 2-Acetyl-3,4-diacetoxy-5,6,7,8-tetrahydro-1-naphthol (XX) and 2-Ethyl-3-hydroxy-4-acetoxy-5,6,7,8-tetrahydro-1-naphthol (XXI).—A mixture of 5 g. of the diacetate VI, 0.1 g. of platinum oxide and 100 cc. of glacial acetic acid was shaken under a pressure of twenty-five pounds of hydrogen till all the diacetate had dissolved (two hours). The mixture was filtered, and two volumes of water were added to the filtrate. The solid that precipitated was recrystallized twice (ethanol); 2.3 g. (light brown granules), m. p. 124–125°.

This substance (XX) dissolved in dilute alkali, and gave a yellow solution that turned quickly to orange, and finally to red. (Procedure K terminates here.)

The initial filtrate from the reaction mixture was extracted with ether, and the ether layer was well washed with water, dried, and evaporated to an oil. The oil was dissolved in a small amount of ether; an equal volume of petroleum ether was added, and the solution was cooled. The product that separated was crystallized from benzene; 0.7 g. (white needles), m. p. 144–145°.

This substance (XXI), when dissolved in aqueous alkali, gives a yellow solution that changes to brown, then to amber, to red, and finally to purple.

Anal. Calcd. for $C_{14}H_{18}O_4$: C, 67.18; H, 7.25. Found: C, 67.33; H, 7.20.

(21) A melting point of 34° for palmitic aldehyde and 95.5–96.5° for the *p*-nitrophenylhydrazone is reported in Heilbron, "Dictionary of Organic Compounds," Vol. 3, Oxford University Press, New York, N. Y., 1943, p. 329.

Procedure L. 2-Acetyl-3,4-dihydroxy-5,6,7,8-tetrahydro-1-naphthol.—Diacetate XX (2.0 g.) and sodium hydroxide (20 cc. of a 5% solution) were mixed in an atmosphere of nitrogen and stirred for one-half hour. The solution was acidified, and the solid that separated was recrystallized twice from ether; 1.3 g. (canary-yellow needles), m. p. 180–182° dec. This hydroquinone gives a red solution with aqueous alkali, a yellow solution with concentrated sulfuric acid, and an orange color in an aqueous solution containing a drop of ferric chloride solution.

Procedure M. 2-Acetyl-3-hydroxy-5,6,7,8-tetrahydro-1,4-naphthoquinone (XXII).—A solution of 1.0 g. of 2-acetyl-3,4-dihydroxy-5,6,7,8-tetrahydro-1-naphthol in 25 cc. of ether was treated with 1.5 g. of silver oxide and a small amount of magnesium sulfate. The mixture was stirred for two hours and filtered; the solid was warmed with glacial acetic acid and filtered. Two parts of water were added to the combined filtrates, the solution was cooled, and a crystalline solid separated. Two recrystallizations of the quinone from ether gave 0.6 g. of orange plates of quinone XXII, m. p. 87–88°. This quinone forms an orange solution in aqueous alkali that turns red upon the addition of sodium hydrosulfite, and a yellow solution in concentrated sulfuric acid.

2-Ethyl-3-hydroxy-5,6,7,8-tetrahydro-1,4-naphthoquinone (XXIII).—Air was passed into a solution of 0.5 g. of XXI in 5 cc. of 1 *N* sodium hydroxide solution for ten minutes. The solution was acidified and the product that separated was crystallized twice from an ether–petroleum ether mixture; flat deep-orange rods, 0.3 g., m. p. 102–103°. This quinone (XXIII) forms a deep purple color in alkaline solution, as well as in concentrated sulfuric acid solution, and in ethanol solution containing a drop of ferric chloride solution. The alkaline solution turns colorless when sodium hydrosulfite is added.

Anal. Calcd. for $C_{12}H_{14}O_3$: C, 69.88; H, 6.84. Found: C, 69.61; H, 6.91.

2-Ethyl-3-acetoxy-4-hydroxy-5,6,7,8-tetrahydro-1-naphthol (XXIV).—A mixture of 0.2 g. of XXIII, 1 cc. of acetic anhydride and a trace of sodium acetate was warmed on the steam-bath for one hour, cooled, and 3 cc. of water was added. After the excess acetic anhydride had decomposed, the mixture was extracted with ether, and the ether layer was washed with water. The ether solution was then shaken with a solution of sodium hydrosulfite in water, washed with water, dried, filtered through an ether-washed pad of Darco, and evaporated to an oil, which crystallized when cooled. Recrystallization of the solid from an ether–petroleum ether mixture gave 0.15 g. of white needles, m. p. 128–129°. The color reactions of this substance were similar to those of XXI.

Anal. Calcd. for $C_{14}H_{18}O_4$: C, 67.18; H, 7.25. Found: C, 67.47; H, 7.48.

Reduction of 2-(4′-Cyclohexylbutyryl)-3,4-diacetoxy-1-naphthol (XXVII) to 2-(4′-Cyclohexylbutyl)-3,4-diacetoxy-1-naphthol (XXVIII).—Diacetate XXVII (10 g.) was dissolved in 50 cc. of purified dioxane and reduced at 150–160° for five hours under a pressure of 3900 lb. of hydrogen in the presence of 2.0 g. of copper chromite catalyst. The reaction mixture was then filtered, excess water was added to the filtrate, and the solution was extracted with ether. The ether layer was washed with water, dried, evaporated to a small volume and cooled. The product that separated was crystallized from glacial acetic acid; 3.0 g. of white prisms, m. p. 117–118°.

Anal. Calcd. for $C_{24}H_{30}O_5$: C, 72.33; H, 7.59. Found: C, 72.39; H, 7.73.

To the mother liquors from the original crystallization of the diacetate, 100 cc. of ethanol and 50 cc. of 1 *N* sodium hydroxide were added. Air was bubbled through this mixture for three hours, and the solution was acidified. The oily product that separated was crystallized from glacial acetic acid; 3.1 g. of quinone XXIX, m. p., alone and mixed with an authentic sample (ref. 14), 108–109°.

A small sample of the diacetate XXVIII was hydrolyzed

and oxidized by procedure I. From 500 mg. of the diacetate XXVIII, 390 mg. of the quinone was isolated; m. p., alone and mixed with an authentic sample, 108–109°.

Acknowledgment.—The author is indebted to Dr. L. F. Fieser for his many helpful suggestions concerning this study, and to Margaret M. Racich for many of the analyses reported in these papers.

Summary

1. Several new methods for the preparation of 2-acyl-3-hydroxynaphthoquinones have been developed.

2. A new boron-trifluoride-catalyzed Thiele type of reaction has been found to take place between acetic anhydride and 2-acyl-1,4-naphthoquinones; the structures of the products have been elucidated.

3. The abnormal C-alkylation of a 2-acyl-1-naphthol type of compound with diazoethane has been investigated.

4. The reaction of 2-acetyl-3,4-diacetoxy-1-naphthol with a Grignard reagent has resulted in the preparation of two *cis–trans* isomeric olefins, whose ultraviolet absorption spectra were taken, and structural assignments based on these data were made.

5. The course of reduction of 2-acyl-3,4-diacetoxy-1-naphthol type compounds was investigated.

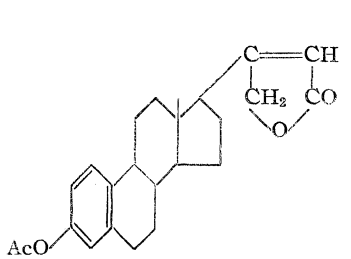
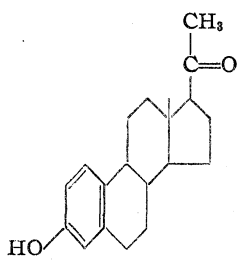
The Preparation of Two Aromatic Analogs of Desoxycorticosterone Acetate

BY CARL DJERASSI[1] AND CAESAR R. SCHOLZ

The biological testing of compounds containing both the nucleus of the estrogens and the functional side-chain of other physiologically active steroids is of considerable interest. Oettel[1a] reported on a pharmacological investigation of a cardiac aglucone derivative I, which contained an aromatic ring A, without disclosing the method of preparation, while Velluz and Muller[2] described the synthesis of an aromatic analog (II) of progesterone. The biological activity of the latter was unfortunately not indicated. The present paper summarizes our work on two independent syntheses of 3-methoxy-17-(β-acetoxyacetyl)-1,3,5-estratriene (III), as well as the preparation of the corresponding 1-methyl derivative XI. III and XI represent aromatic analogs of desoxycorticosterone acetate.



I



II

The starting material for the first synthesis (Flowsheet I) was 17-ethynylestradiol (IV), which has previously been converted[3] in unspecified yield by Rupe–Nickel reduction to 17-vinylestradiol (Va). The use of a palladium–calcium carbonate catalyst in pyridine solution[4] in the present instance led in 88% yield to the desired 17-vinyl derivative, which was converted into its methyl ether Vb with dimethyl sulfate. Hydroxylation of Vb with osmium tetroxide, followed by acetylation gave 50% of 3-methoxy-10-nor-1,3,5-pregnatriene-17,20,21-triol 20,21-diacetate (VI), which was subjected to a modified Serini reaction[5] in toluene solution and thus furnished directly the desired cortical hormone derivative III in 63% yield.

The aromatic analog III could also be prepared from methyl 3-ketoetiochola-1,4-dienate (VII) (Flowsheet II), which has been synthesized from cholesterol.[6] Aromatization with elimination of the angular methyl group of the dienone ester VII in tetralin solution at 650° by the general procedure of Inhoffen[7] led in 44% yield to the phenolic ester VIIIa which proved to be insoluble in 10% aqueous alkali. This methyl ester (VIIIa) as well as the 3-methyl ether 17-methyl ester (VIIIb) required drastic conditions for saponification (refluxing in 20% alcoholic potassium hydroxide solution for eighteen hours). This behavior is in marked contrast to the relative ease of saponification of the dienone ester VII or the aromatic

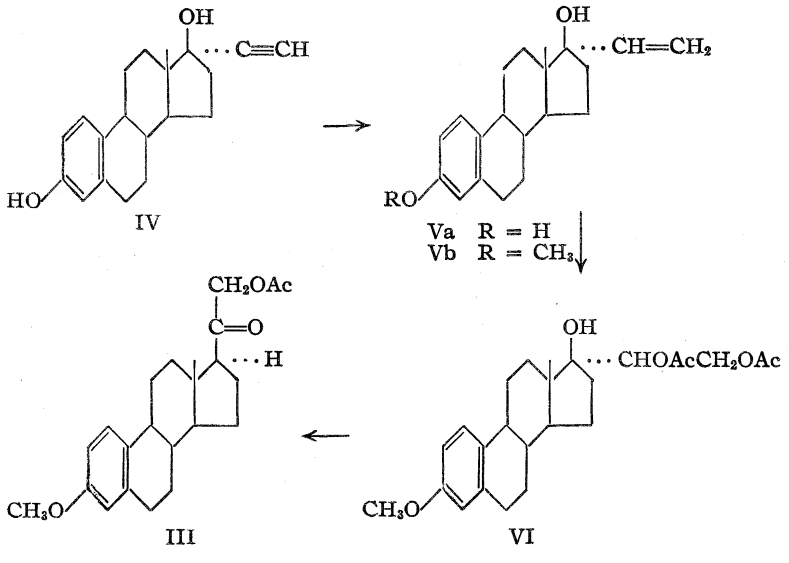
FLOWSHEET I



ester Xa,[6,8] which required only 5–10% alkali for *ca.* five hours. If it is assumed that the estrogens have a relatively planar all-*trans* configuration just as the other steroid hormones, then it is not possible to explain this anomalous behavior on steric grounds. An inversion at carbon atom 17 during the high temperature aromatization may be considered improbable, since the final product (III) in both syntheses proved to be the same.

The 3-methyl ether 17-carboxylic acid (VIIIc) was converted by the Wilds–Shunk procedure[9] to the acid chloride and thence to the crystalline diazoketone IX in 61% yield (based on VIIIc). Decomposition in boiling acetic acid solution gave 56% of the ketol acetate III, which was shown to be identical with the specimen synthesized by the first procedure by analysis, rotation, mixed melting point determination, ultraviolet and infrared absorption spectra. The infrared spectra were taken in carbon disulfide solution and showed maxima at 1733 and 1756 cm.$^{-1}$ characteristic of the ketol acetate grouping.[10]

The configuration of the ethynyl group in 17-ethynylestradiol (IV) is generally believed to be α by analogy to the corresponding reaction in the androstane series[11] and since the Serini reaction is known to involve inversion,[5] the final product III should have the ketol side-chain in the β-configuration as is the case with the naturally occurring cortical hormones. The satisfactory agreement in the

FLOWSHEET II

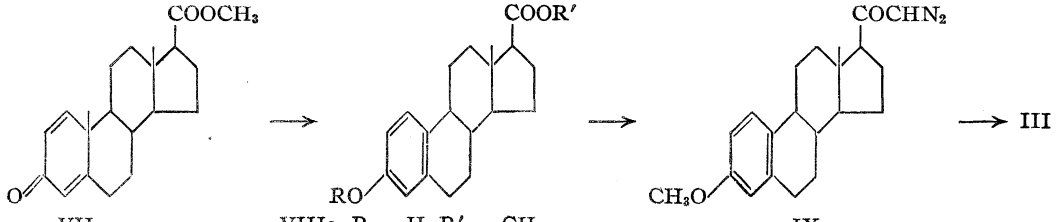


TABLE I

EVIDENCE FOR β-CONFIGURATION OF SIDE-CHAIN BY MOLECULAR ROTATION DIFFERENCES

Compound	$[\alpha]_D$ Anhydr. ethanol	$[M]_D$[a]	$\Delta[M]_D$
3-Methoxy-17-(β-acetoxyacetyl)-1,3,5-estratriene (III)	+160°	592	+372
3-Methoxy-1,3,5-estratriene[b]	+ 81°	220	
Desoxycorticosterone acetate[c]	+181°	673	+382
Δ^4-Androsten-3-one[d]	+107°	291	
17-Isodesoxycorticosterone acetate[e]	− 26°	−97	−388

[a] $[M]_D$ = $[\alpha]_D$ × mol. wt./100. [b] A. Butenandt, I. Störmer and U. Westphal, *Z. physiol. Chem.*, 208, 149 (1932). [c] In 95% ethanol, $[\alpha]^{25}D$ was +188°. [d] Kindly furnished by Dr. A. F. St. André of our laboratories. [e] C. W. Shoppee, *Helv. chim. acta*, **23**, 930 (1940); this rotation was determined in acetone solution.

(8) The 1-methyl-3-hydroxy-1,3,5-triene structure of the acid X and of all the other products arising from dienone-phenol rearrangements studied by us [THIS JOURNAL, **68**, 1712, 2125 (1946); **69**, 2404 (1947); **70**, 1911 (1948); *J. Org. Chem.*, **13**, 697, 848 (1948)] was assigned by analogy to an unequivocal case in the chrysene series [Wilds and Djerassi, THIS JOURNAL, **68**, 1715 (1946)] in which the structure of both the dienone and the rearrangement product was proven by total synthesis. Recent work in Prof. R. B. Woodward's laboratory at Harvard (private communication to C. D.) with simple model compounds has indicated that in the steroid series the following two structures are equally plausible: 1-methyl-4-hydroxy-1,3,5-triene or 1-hydroxy-4-methyl-1,3,5-triene. For simplicity's sake, the 1-methyl-3-hydroxy structure is used until unequivocal evidence is presented for an example in the steroid series.

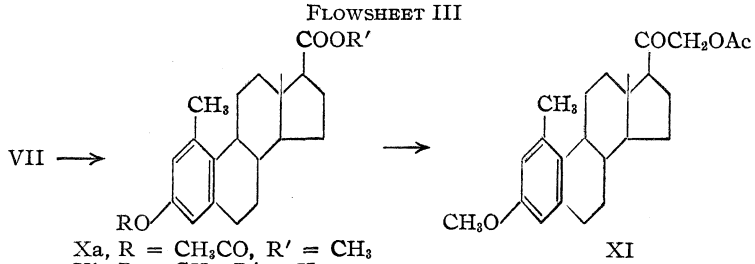
(11) Ref. 5, p. 328.

calculation of the molecular rotation differences (Table I) lends considerable support to this statement.

The diazoketone synthesis was also employed in the preparation of the aromatic desoxycorticosterone analog XI with a methyl group at C-1[8] (Flowsheet III). Methyl 1-methyl-3-acetoxy-1,3,5-estratriene-17-carboxylate (Xa), previously obtained[6] in high yield by dienone–phenol rearrangement of VII, was converted to 1-methyl-3-methoxy-1,3,5-estratriene-17-carboxylic acid (Xb) in 76% over-all yield. Treatment of its acid chloride (prepared by the Wilds–Shunk procedure)[9] with diazomethane led to an oily diazoketone which on decomposition with acetic acid afforded the desired 1-methyl-3-methoxy-17-(β-acetoxyacetyl)-1,3,5-estratriene (XI).

FLOWSHEET III



Xa, R = CH_3CO, R′ = CH_3
Xb, R = CH_3, R′ = H

XI

Preliminary results of the biological investigation by Dr. James H. Leathem of the Bureau of Biological Research, Rutgers University, indicate that the aromatic analogs III and XI of desoxycorticosterone acetate when administered in oil solution are inactive as estrogens in 1-mg. doses (uterine weight increase in rats) and do not maintain the life of adrenalectomized rats in 0.5-mg. doses (desoxycorticosterone acetate under the same conditions is effective at a 0.05-mg. level).

Acknowledgment.—The authors are indebted to the Misses Frances Hoffmann and Edwina Leathem for their capable assistance, to Miss Verda Powell for the rotations and ultraviolet absorption spectra and to Dr. A. F. St. André for furnishing the palladium catalyst and a sample of Δ^4-androsten-3-one. The infrared spectra were determined at the Sloan–Kettering Institute for Cancer Research, New York City, through the courtesy of Dr. K. Dobriner and Mrs. P. Humphries.

Experimental[12]

17-Vinylestradiol (Va).—A solution of 2.50 g. of 17-ethynylestradiol (IV)[3] in 50 ml. of C.P. pyridine was shaken at room temperature with hydrogen in the presence of 0.4 g. of 2% palladium–calcium carbonate catalyst.[1] After an initial lag of ten to thirty minutes, the hydrogen uptake proceeded smoothly and stopped after *ca.* forty minutes (one mole of hydrogen), whereupon the catalyst was filtered and solvent was removed *in vacuo*. Trituration with ether and hexane afforded 2.22 g. (88%) of colorless crystals with m. p. 142–147°, $[\alpha]^{25}D$ +59.5° (dioxane), which were satisfactory for the next step; lit.,[3] m. p. 148–150°, $[\alpha]D$ +57.3° (dioxane).

The 3-monoacetate crystallized in colorless prisms from hexane, m. p. 126–127.5°, $[\alpha]^{25}D$ +61.2° (dioxane).

Anal. Calcd. for $C_{22}H_{28}O_3$: C, 77.61; H, 8.29. Found: C, 77.25; H, 8.19.

17-Vinylestradiol 3-Methyl Ether (Vb).—Methylation was accomplished by treating 2.22 g. of the above phenol (Va) in 50 ml. of ethanol over a period of ten minutes on the steam-bath four times alternately with 4-ml. portions each of 50% aqueous potassium hydroxide and dimethyl sulfate. The alkaline solution was heated for an additional ten minutes, then cooled and acidified with dilute acid. The precipitate (2.20 g., m. p. 90–95°) was collected and recrystallized from a mixture of hexane and acetone, whereupon it was obtained as colorless crystals with m. p. 98–100°, $[\alpha]^{25}D$ +60° (chloroform); yield 1.89 g. (82%).

Anal. Calcd. for $C_{21}H_{28}O_2$: C, 80.73; H, 9.03. Found: C, 80.84; H, 9.37.

3-Methoxy-10-nor-1,3,5-pregnatriene-17,20,21-triol 20,21-Diacetate (VI).—A mixture of 1.85 g. of the methyl ether Vb, 2 g. of osmium tetroxide and 160 ml. of anhydrous ether was allowed to stand in a closed flask at room temperature for five days. The ether was decanted and the black residue was refluxed for three and one-half hours with 50 ml. of ethanol, 100 ml. of water and 14 g. of sodium sulfite heptahydrate. After filtration and boiling of the precipitate repeatedly with ethanol, the combined extract and filtrate were concentrated, diluted with water, extracted with ether and the washed and dried ether solution was evaporated to a small volume. The colorless crystals (1.29 g., m. p. 136–143°) of the triol were filtered and directly acetylated by heating for three and one-half hours at 65° with 15 ml. of acetic anhydride and 25 ml. of pyridine. Evaporation of the solution to dryness under reduced pressure and trituration of the residue with hexane yielded 1.28 g. (50% over-all) of diacetate with m. p. 109–113°, which was satisfactory for the Serini reaction. The analytical sample, obtained from hexane, had m. p. 111–113°, $[\alpha]^{25}D$ +19° (chloroform).

Anal. Calcd. for $C_{29}H_{34}O_6$: C, 69.74; H, 7.96; methoxyl, 7.21; acetyl, 19.99. Found: C, 69.57; H, 8.02; methoxyl, 7.67; acetyl, 19.68.

3-Methoxy-17-(β-acetoxyacetyl)-1,3,5-estratriene (III) from Serini Reaction on Diacetate VI.—A solution of 400 mg. of the above diacetate VI in 80 ml. of dry toluene was refluxed for forty-eight hours with 8 g. of zinc dust, then filtered while still hot and the solvent removed under reduced pressure. The residue was chromatographed on 8 g. of dil. sulfuric-acid-washed alumina (Aluminum Company of America, Grade F-20, 80–200 mesh) and the product was eluted with a mixture of hexane and benzene (60/40). Recrystallization from hexane gave 215 mg. (63%) of colorless, prismatic needles of the ketol acetate III with the following physical constants: m. p. 118–119°, $[\alpha]^{25}D$ +157 ± 0.5° (chloroform), +160° (ethanol), maximum at 278 mμ (log E 3.39) and minimum at 246 mμ (log E 2.72); the infrared spectrum showed carbonyl peaks at 1733 and 1756 cm.$^{-1}$ typical of the cortical hormone side-chain.[10]

Anal. Calcd. for $C_{23}H_{30}O_4$: C, 74.56; H, 8.16; acetyl, 11.62; methoxyl, 8.38. Found: C, 74.79; H, 8.34; acetyl, 12.27; methoxyl, 8.85.

(12) All melting points are corrected unless noted otherwise. Rotations were determined on 5–10-mg. of sample in 1.2 ml. of solvent in a 1-dcm. polarimeter tube of 1-ml. capacity. All ultraviolet absorption spectra measurements were carried out in ethanol solution on a Beckman quartz photoelectric spectrophotometer, while the infrared spectra were measured in carbon disulfide solution at the Sloan–Kettering Institute on a Perkin–Elmer infrared spectrometer. The microanalyses were carried out by Mr. Joseph F. Alicino, Metuchen, N. J.

(13) Busch and Stöve, *Ber.*, **49**, 1064 (1916).

Methyl 3-Hydroxy-1,3,5-estratriene-17-carboxylate (VIIIa).[14]—A 44% yield of material of satisfactory purity (m. p. 212–216°) was realized by using the same reaction conditions for the aromatization of methyl 3-ketoetiochola-1,4-dienate (VII)[6] as were reported by Inhoffen[7] for the conversion of 1,4-androstadien-17-ol-3-one to estradiol. Recrystallization from ethanol afforded colorless crystals of the methyl ester VIIIa; m. p. 219–220°, $[\alpha]^{24}D$ +107° (acetone), which exhibited the typical ultraviolet absorption spectrum of a phenol: maximum at 280 mμ (log E 3.39) and minimum at 247.5 mμ (log E 2.63).

Anal. Calcd. for $C_{20}H_{26}O_3$: C, 76.40; H, 8.34; methoxyl, 9.87. Found: C, 76.29; H, 8.33; methoxyl, 9.61.

The 3-acetate 17-methyl ester (VIIIe), prepared by heating the phenol VIIIa for one hour with acetic anhydride and pyridine, was obtained as colorless needles from a mixture of hexane and acetone, m. p. 146–147.5°, $[\alpha]^{24}D$ +79.7° (acetone).

Anal. Calcd. for $C_{22}H_{28}O_4$: C, 74.13; H, 7.92; acetyl, 12.07. Found: C, 74.43; H, 7.73; acetyl, 12.37.

3-Hydroxy-1,3,5-estratriene-17-carboxylic Acid (VIIId).—The 3-hydroxy 17-methyl ester VIIIa could be saponified only with difficulty. When 150 mg. of the methyl ester was refluxed with 500 mg. of potassium hydroxide and 20 ml. of methanol for eighteen hours, less than 30% of the material was saponified. By contrast, the dienone ester VII was saponified readily under these conditions. Complete hydrolysis was accomplished by refluxing 100 mg. of the ester with either 1 g. of potassium hydroxide and 5 ml. of methanol, or 10 ml. of a hydrobromic acid–acetic acid mixture (30 ml. of glacial acetic acid, 20 ml. of 48% hydrobromic acid and 10 ml. of water)[15] for eighteen hours. The crude acid, which is readily removed from ether with sodium carbonate solution, although the sodium salt is not too soluble in water, melted at approximately 256–263° (dec., uncor.). After recrystallization from hexane–acetone, the following constants were observed: m. p. 270–274° (dec., uncor.), $[\alpha]^{25}D$ +98.4° (acetone), maximum at 280 mμ (log E 3.32) and minimum at 248 mμ (log E 2.81). A sample was dried at 120° under vacuum for twelve hours before analysis.

Anal. Calcd. for $C_{19}H_{24}O_3$: C, 75.97; H, 8.05; neut. equiv., 300. Found: C, 76.37; H, 8.15; neut. equiv., 304.

Methyl 3-Methoxy-1,3,5-estratriene-17-carboxylate (VIIIb).—The methylation of the phenolic methyl ester VIIIa was carried out with dimethyl sulfate exactly as described for 17-vinylestradiol (Va) and afforded 94% of material of m. p. 160–163° suitable for the saponification step. The analytical sample crystallized from ethanol as long needles, m. p. 163–164°, $[\alpha]^{26}D$ +47.6° (chloroform).

Anal. Calcd. for $C_{21}H_{28}O_3$: C, 76.79; H, 8.59; methoxyl, 18.90. Found: C, 76.57; H, 8.43; methoxyl, 18.93.

3-Methoxy-1,3,5-estratriene-17-carboxylic Acid (VIIIc).—The above ester VIIIb was saponified by refluxing 2.56 g. for eighteen hours with 25 g. of potassium hydroxide and 125 ml. of methanol. Acidification with dilute acid, followed by filtration and digestion with boiling ethanol gave 2.14 g. (87%) of the desired acid VIIIc with m. p. 217–218°. Recrystallization from ethanol raised the m. p. to 219–220°, $[\alpha]^{26}D$ +102° (dioxane).

Anal. Calcd. for $C_{20}H_{26}O_3$: C, 76.40; H, 8.34; methoxyl, 9.87. Found: C, 76.56; H, 8.28; methoxyl, 10.05.

3-Methoxy-17-(β-diazoacetyl)-1,3,5-estratriene (IX).—Six hundred milligrams of the acid VIIIc was converted into the sodium salt by dissolving in hot ethanol, adding 80 mg. of sodium hydroxide and evaporating to dryness in a current of air. The nearly colorless sodium salt was dried at 100° and 30 mm. for eighteen hours and then suspended in 15 ml. of dry benzene and 3 drops of pyridine. Oxalyl chloride (3 ml.) was added while cooling in ice and after five minutes at 10°, the yellow solution was distilled to dryness at room temperature *in vacuo*. After adding benzene twice and evaporating, the residue was stirred with benzene, filtered through sintered glass and the nearly colorless filtrate was added to an undistilled ethereal solution of diazomethane (from 7.5 g. of nitroso methylurea) kept at −10° and previously dried for two hours over solid potassium hydroxide. After one hour in ice, the solvent was removed under reduced pressure at 20° and the solid residue was recrystallized from a mixture of hexane and acetone yielding 390 mg. (61%) of the light yellow diazoketone IX with m. p. 126–128° (gas evolution complete at 135°). Extremely slow burning was necessary to obtain even fair analytical results.

Anal. Calcd. for $C_{21}H_{26}N_2O_2$: C, 74.52; H, 7.74; N, 8.28. Found: C, 73.87; H, 7.96; N, 8.57.

3-Methoxy-17-(β-acetoxyacetyl)-1,3,5-estratriene (III) from the Diazoketone IX.—The solid diazoketone (390 mg.) was dropped slowly into 20 ml. of boiling glacial acetic acid[9] and heating was continued for an additional five minutes. The yellow solution was evaporated to dryness and the residue was chromatographed as described above yielding 240 mg. (56%) of the ketol acetate III with m. p. 113–115°, $[\alpha]^{25}D$ +158° (chloroform). Further recrystallization raised the m. p. to 117–118° and no depression was observed on admixture with a specimen prepared by the first method from 17-vinylestradiol. The ultraviolet and infrared spectra of the two samples were identical.

1-Methyl-3-methoxy-1,3,5-estratriene-17-carboxylic Acid (Xb).—A solution of 1.90 g. of the 3-acetoxy 17-methyl ester Xa[6] in 80 ml. of methanol was refluxed with 8 g. of potassium hydroxide for three hours and acidified. The precipitate was collected, dried and then treated in ether solution with diazomethane.[16] The solvent was removed after a few minutes, the residue was dissolved in ethanol and methylated with dimethyl sulfate in the presence of 50% aqueous potassium hydroxide solution as described previously. The crude 3-methoxy 17-methyl ester was not purified, but was saponified directly by refluxing with 5 g. of potassium hydroxide and 60 ml. of methanol for four hours. After dilution with water and extraction with ether, the alkaline solution was acidified, and afforded 1.27 g. (76%) of the desired 3-methoxy-17-carboxylic acid (Xb) melting at 237–245°. The analytical sample crystallized from acetone; m. p. 245–246°, $[\alpha]^{23}D$ +242° (chloroform), minimum at 251 mμ (log E 2.77) and broad maximum at 278–284 mμ (log E 3.32).

Anal. Calcd. for $C_{21}H_{28}O_3$: C, 76.79; H, 8.59; methoxyl, 9.45. Found: C, 76.41; H, 8.47; methoxyl, 9.33.

1-Methyl-3-methoxy-17-(β-acetoxyacetyl)-1,3,5-estratriene (XI).—The diazoketone synthesis was carried out exactly as described above for the acid VIIIc, except that the diazoketone was obtained as an oil, and was therefore treated with acetic acid without purification. The desired ketol acetate XI was obtained in 27% yield with m. p. 152–154° after crystallization from a mixture of hexane and acetone. Further recrystallization afforded rosettes of colorless prisms with m. p. 154–156°, $[\alpha]^{24}D$ +276° (chloroform). The infrared spectrum showed the characteristic peaks[10] at 1733 and 1756 cm.$^{-1}$, while the ultraviolet absorption spectrum exhibited a broad maximum at 278–284 mμ (log E 3.33), already observed with the precursor Xb, and a minimum at 248 mμ (log E 2.34).

Anal. Calcd. for $C_{24}H_{32}O_4$: C, 74.96; H, 8.39; acetyl, 11.19. Found: C, 74.72; H, 8.24; acetyl, 11.09.

Summary

Two syntheses of 3-methoxy-17-(β-acetoxyacetyl)-1,3,5-estratriene (III), an aromatic analog of desoxycorticosterone acetate, are described. The first procedure involved hydroxylation of 17-

(14) The identical methyl ester (mixed melting point determination) was isolated recently from strophanthidin by Ehrenstein and co-workers (*J. Org. Chem.*, in press).

(15) Johnson, Petersen and Schneider, THIS JOURNAL, **69**, 75 (1947).

(16) The intermediate methylation with diazomethane was essential for a good yield.

vinylestradiol methyl ether (Vb) with osmium tetroxide followed by acetylation and Serini reaction of the 20,21-diacetate (VI). The second method consisted of partial aromatization of ring A with the elimination of the angular methyl group of an appropriately substituted etiocholanic acid derivative (VII) and subsequent introduction of the ketol side-chain *via* the diazoketone.

The diazoketone synthesis was also employed in the preparation of an aromatic cortical hormone analog (XI) with a methyl group at C-1. Neither product showed estrogenic or life maintenance activity in rats at the dosage tested.

Beta Acetylenic Grignard Reagents. I. Hydrolysis and Carbonation of γ-Phenylpropargylmagnesium Bromide

BY GERALD R. LAPPIN*

An earlier investigation of the reaction of β-acetylenic halides with magnesium[1] reportedly showed that no Grignard reagent was formed and only coupling occurred. It has now been found that certain of these halides do yield an organometallic derivative with magnesium, at least one, γ-phenylpropargyl bromide, giving an excellent yield under the ordinary conditions of this reaction.[2]

The structural similarity of β-acetylenic Grignard reagents to those derived from allylic halides led to the question of whether the former would undergo rearrangement similar to the well-known rearrangement of allylmagnesium halides, yielding both acetylenic and allenic products. Rearrangement of β-acetylenic compounds to allenes has been observed[3] but under conditions totally unlike those of the Grignard reaction. When it was found that these new organomagnesium compounds could be prepared it was decided to investigate this possible rearrangement. Because it required no special method and was obtained in high yield γ-phenylpropargylmagnesium bromide was chosen for this study[4] and the reactions chosen were hydrolysis and carbonation.

$$R{-}C{\equiv}C{-}CH_2MgBr + XY \longrightarrow R{-}C{\equiv}C{-}CH_2{-}X + R{-}\underset{\displaystyle X}{\underset{|}{C}}{=}C{=}CH_2 + MgBrY$$

Discussion of Results

Hydrolysis.—The hydrolysis of γ-phenylpropargylmagnesium bromide (I) under oxygen and peroxide free conditions gave up to an 87% yield of monomeric hydrocarbon product. On distillation through a high efficiency fractionating column this gave phenylpropadiene (II) as well as 1-phenyl-1-propyne (III) along with a considerable amount of polymeric residue. Both products were identified by comparison with the previously reported characteristics, II being identified by its boiling point,[5,6] refractive index,[6] rapid polymerization[5,6] and rapid uptake of oxygen from the air to form a ketone, presumably methyl phenyl diketone.[5] Identification of III was made through its boiling point and refractive index.[7] Final confirmation was obtained from the oxidation of these hydrocarbons with potassium permanganate in pyridine solution,[8] II yielding only benzoic acid while III gave both benzoic and acetic acids.

An attempt was made to determine the ratio of acetylene to allene formed by oxidation followed by analysis for the ratio of benzoic to acetic acid formed.[8] Because of the rapid polymerization of II consistent results were not obtained, the amount of II present in the monomeric product ranging from 6 to 37% in various experiments. However, in those experiments which gave a low yield of monomeric II a high yield of polymer was obtained and if the polymer consisted only of phenylpropadiene this must have made up more than half of the total hydrolysis product. Since in at least one experiment practically no volatile monomer was obtained it is evident that copolymerization between II and III can occur so that any estimate of the composition of the total reaction mixture is very doubtful. It was clearly shown, nevertheless, that an allylic-like rearrangement did occur, whether during the formation of the organomagnesium bromide or during the subsequent hydrolysis it is, at present, impossible to say.

(2) Since the completion of the work herein described, Newman and Wotiz, THIS JOURNAL, **71**, 1292 (1949), have briefly mentioned the preparation in 95% yield of a Grignard reagent from 1-bromo-2-heptyne using a special "high dilution technique" which was not described. Carbonation was said to yield an unidentified mixture of acids. In this Laboratory the Grignard reagent has been prepared from 1-bromo-2-octyne in about 30% yield by a method which will be described in a subsequent publication.

(3) For a summary of such rearrangements see Johnson, "Acetylenic Compounds," Edward Arnold and Company, London, 1946, Vol. I, p. 63 ff.

(4) Later results have shown this choice to be a poor one for the phenylpropadiene derivatives polymerize much more rapidly than purely aliphatic allenic compounds. Further work on these rearrangements is being carried out with octynylmagnesium bromide.

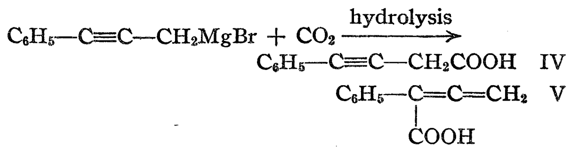
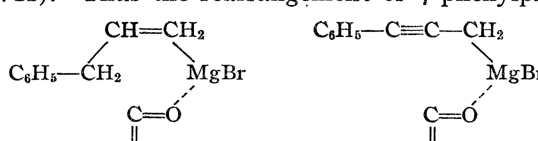
Carbonation.—The carbonation of I was carried out in the usual fashion but in the absence of oxygen and peroxides. An acidic product was obtained but all attempts to isolate either of the expected products, 1-phenyl-1-propyne-3-carboxylic acid (IV) or 1-phenylpropadiene-1-carboxylic acid (V), failed because of complete poly-



merization of the product either on distillation or even on standing in the refrigerator for a few hours. Oxidation of a portion of the acidic product gave benzoic acid and malonic acid derived from IV but no phenylglyoxylic acid from V. However, a positive qualitative test for the presence of ketone in the oxidation product was obtained. When the unsaturated acidic product was subjected to low pressure hydrogenation over palladium catalyst before distillation, it was possible to obtain in low yield the two corresponding saturated acids, 4-phenylbutanoic acid and 2-phenylbutanoic acid, though only about 40% of the theoretical hydrogen uptake was observed indicating that extensive polymerization must have occurred. However, here again it was clearly evident that an allylic-like rearrangement had taken place.

One of the possible mechanisms suggested by Young[9] for the rearrangement of allylic Grignard reagents in their reactions with carbonyl compounds involves the formation of a six-membered ring in an intermediate complex (VI). It seems structurally impossible for a β-acetylenic Grignard reagent to react through a similar mechanism (VII). Thus the rearrangement of γ-phenylpro-



VI VII

pargylmagnesium bromide on carbonation may constitute some evidence against this mechanism. However, considerably more study will be required before it can be known whether this new type of rearrangement is fundamentally or only superficially similar to that of allylic Grignard reagents.

Experimental[10]

Preparation and Hydrolysis of γ-Phenylpropargylmagnesium Bromide.—The reaction was carried out in a special indented flask fitted with a high speed stirrer giving extremely vigorous agitation and under the usual anhydrous conditions using an atmosphere of dry nitrogen throughout the entire experiment. To 2.88 g. (0.12 g. atom) of magnesium turnings in 150 ml. of dry ether was added dropwise over a period of four hours a solution of 24 g. (0.12 mole) of γ-phenylpropargyl bromide[11] in 200 ml. of anhydrous ether. After addition of all the bromide the solution was warmed on the water-bath for one hour. Titration of a 1-ml. aliquot with standard acid indicated a yield of 92% of RMgBr. Hydrolysis was carried out by adding to the ether solution dropwise a cold 5% sulfuric acid solution while cooling the flask in an ice–salt-bath. The ethereal layer was separated, washed with water, 5% sodium bicarbonate solution, and with water again. After drying over Drierite the ether was removed under reduced pressure at 20° and the residue was flash distilled at 1 mm. pressure and an oil-bath temperature of 65° to separate the monomeric product from polymerization products. The yield of volatile product was 12.9 g. (87% based on the product being C_9H_8). The non-volatile residue was a soft brown material resembling closely the description of phenylpropadiene polymer.[5]

Fractionation of the Volatile Product.—Still maintaining the atmosphere of dry nitrogen, 10 g. of the volatile product was distilled through a 50-plate distilling column[12] at 15 mm. pressure. Three fractions were collected. The first, b. p. 68–69°, n^{20}D 1.563, 1.7 g., was colorless when first collected but rapidly turned deep yellow on exposure to air and polymerized to a soft brown solid on standing for a few hours. The freshly distilled material gave a scarlet sodium salt when warmed with sodium in dry benzene. This is a reported reaction of phenylpropadiene.[6] After short exposure to air this fraction gave a positive carbonyl test with 2,4-dinitrophenylhydrazine and alcoholic potassium hydroxide.[13] These properties and reactions agree well with those reported for phenylpropadiene.[5,6] The second fraction, b. p. 69–72°, n^{20}D 1.561, 3.8 g., was colorless when collected, slowly turned pale yellow on standing for a few hours, but did not polymerize after being exposed to air for several weeks. A weak positive test for carbonyl was obtained from the yellowed fraction. This was presumed to be a mixture of II and III. The third fraction, b. p. 72–73°, n^{20}D 1.560, 2.8 g., was colorless even after standing exposed to air for several hours and gave a negative ketone test after being exposed to the air for two days. Its properties agree well with those of 1-phenyl-1-propyne (III).[7] A soft polymeric residue of about 1.5 g. remained in the pot.

Oxidation of the Volatile Product and the Fractions from Distillation.—Samples (0.3–0.5 g.) of the volatile product and of each of the above-mentioned fractions were oxidized in pyridine solution with potassium permanganate by the method of Young, Ballou and Nozaki.[8] The oxidation products were analyzed for the ratio of benzoic acid to acetic acid produced as described by these authors. The volatile product analyzed for a mixture of 37% II and 63% III, but the volatile products from other similar reactions ranged from a low of 6% II to this high value. However, in those experiments which gave a low proportion of II the amount of non-volatile product was larger indicating that, while the allene was formed, it had polymerized before the flash distillation. The first fraction from the distillation analyzed for 93% II and 7% III, the second fraction for 25% II and 75% III, the third for 98% III and 2% II thus confirming the identity of these fractions.

Carbonation of γ-Phenylpropargylmagnesium Bromide.—The Grignard reagent was prepared as previously described from 24 g. (0.12 mole) of the bromide and 2.88 g.

(9) Young and Roberts, THIS JOURNAL, **68**, 649 (1946).

(10) The ether used herein was carefully freed from peroxides and stored under nitrogen. The use of ether containing 0.005% peroxide in a carbonation experiment resulted in complete polymerization of the product.

(11) This was prepared from the corresponding alcohol by reaction with phosphorus tribromide using the method of Lai [*Bull. soc. chim.*, **53**, 1533 (1933)]. However, yields of 90–95% were obtained consistently in contrast to the reported yield of about 70%.

(0.12 g. atom) of magnesium turnings in 250 ml. of anhydrous ether using a nitrogen atmosphere. Titration of a 1-ml. aliquot indicated an 81% yield of RMgX. A large excess of air-free carbon dioxide, dried by bubbling through sulfuric acid followed by passing through anhydrous alumina, was passed into the solution of the organomagnesium bromide while cooling the reaction flask in an ice-bath. Hydrolysis was carried out immediately by adding dropwise about 50 ml. of cold 5% sulfuric acid to the cooled reaction mixture. All subsequent operations were carried out under a carbon dioxide atmosphere. The ether layer was separated and washed three times with 20-ml. portions of cold water. The acidic product was extracted with three 20-ml. portions of ice-cold 5% aqueous sodium hydroxide solution and the basic extract was washed twice with small portions of ether. The basic extract was covered with 50 ml. of ether and, while cooling in an ice-bath, acidified with cold dilute sulfuric acid. After separating the ether layer the aqueous layer was again extracted with a 25-ml. portion of ether. The combined ether extracts were dried over Drierite and the ether was removed under reduced pressure. The sirupy residue was dissolved in 100 ml. of absolute ethanol and the solution was filtered through a 1-cm. bed of decolorizing charcoal. To it was added 0.5 g. of 5% palladium-on-charcoal and hydrogenation was carried out at 60 lb. pressure and room temperature in a Parr low pressure hydrogenation apparatus. The hydrogen uptake was 6 lb. over a period of three hours, theory requiring 15.2 lb. assuming a quantitative yield of C_3H_7COOH from the organomagnesium bromide. After removal of the catalyst and distillation of the ethanol the brown sirupy residue was distilled through a small spiral-packed column at atmospheric pressure. No decomposition occurred and two main fractions were collected. The first, b. p. 268–272°, 0.8 g., was a thick yellow sirup which would not crystallize even after long standing in the refrigerator. The second, b. p. 290–294°, 3.1 g., was a thick sirup which crystallized after several weeks at 0°, m. p. 49–50° after two recrystallizations from ethanol. The reported properties of the two expected isomeric phenylbutanoic acids are: 2-phenylbutanoic acid,[14] b. p. 270–272°, m. p. 41–42°; 4-phenylbutanoic acid,[15] b. p. 290°, m. p. 51°, m. p. of amide 84–85°. Inasmuch as no solid derivative was reported for 2-phenylbutanoic acid and time did not permit the preparation of an authentic sample of this substance the neutral equivalent and molecular weight of the first fraction were determined. Calcd. for $C_{10}H_{12}O_2$: neut. equiv., 164; mol. wt., 164. Found: neut. equiv., 168; mol. wt., (cryoscopic in benzene) 170. On the basis of its boiling point, neutral equivalent and molecular weight fraction one was identified with reasonable certainty as 2-phenylbutanoic acid. Fraction two was converted to the amide in the usual manner, m. p. 83–85°, thus confirming its identity as 4-phenylbutanoic acid.

In another identical experiment an attempt was made to separate the expected acetylenic and allenic acids before hydrogenation by distillation at 0.1 mm. pressure. No distillate was obtained and the material became hard and resinous. A 3-g. sample of the unsaturated acidic product was oxidized in pyridine solution with potassium permanganate at 50° for four hours. To the mixture was added 50 ml. of water and the precipitated manganese dioxide was removed by filtration. The solution was evaporated to dryness under vacuum and the residue was redissolved in 50 ml. of water. A small portion was neutralized with dilute sulfuric acid and tested for presence of ketone,[13] a strongly positive test being obtained. However, all attempts to isolate a derivative of phenylglyoxylic acid failed. The basic solution was cooled to 5° and passed through a cation exchange resin column to convert the salts to the free acids. Evaporation of the solution to 5 ml. *in vacuo* resulted in the crystallization of 1.1 g. of benzoic acid, identified by mixture melting point with an authentic sample. The filtrate was evaporated to dryness and the residue taken up in ether. Evaporation of the ether solution to a volume of about 3 ml. *in vacuo* resulted in the crystallization of 0.3 g. of malonic acid, identified by mixture melting point with an authentic sample. No phenylglyoxylic acid was isolated.

Summary

1. The preparation of a Grignard reagent from a β-acetylenic halide, γ-phenylpropargyl bromide, is described for the first time.

2. Hydrolysis of γ-phenylpropargylmagnesium bromide has been shown to give not only the expected 1-phenyl-1propyne but also phenylpropadiene, indicating that an allylic-like rearrangement occurred.

3. Carbonation of this Grignard reagent gave a mixture of unsaturated acids which could not be separated because of the rapid polymerization which occurred. However, immediate hydrogenation of this mixture gave a low yield of both 4-phenylbutanoic acid and 2-phenylbutanoic acid, indicating that here, too, rearrangement of an allylic nature had occurred.

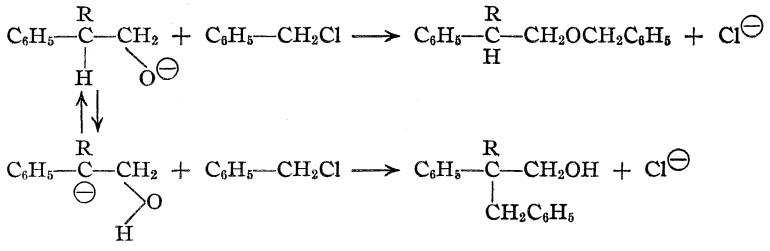
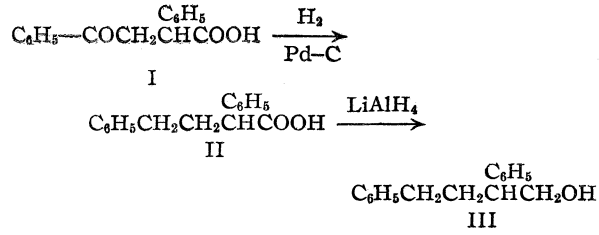
The Preparation and Attempted Racemization of Optically Active 2,4-Diphenylbutanol

BY ROBERT H. BAKER AND SIDNEY H. JENKINS, JR.

Recently it has been shown that the reaction of sodium 2-phenylethoxide with benzyl chloride in toluene produces not only the ether but also a surprising quantity of the carbon-alkylation product, 2-benzyl-2,4-diphenylpropanol.[1] Among the possible modes of formation of this unusual product is one involving successive alkylations of the carbanion tautomers of the phenethylate and substituted phenethylate ions. These reactions, where R is first H and then benzyl, would be



Although the existence of such carbanions seemed highly improbable, the possibility was easily brought to test by attempting the racemization of a suitable optically active alcohol. For this purpose the enantiomorphic forms of 2,4-diphenylbutanol were synthesized and heated at 100° with sodium in toluene. No racemization was observed and thus the possibility of the tautomeric anion is eliminated. This result might have been anticipated from those of Doering and Aschner[2] on 2-methylbutanol but it was felt that the acid-strengthening phenyl group on the 2-carbon atom would increase the probability of C-anion formation.



In a less critical test sodium 2-phenylethoxide in toluene was treated with carbon dioxide. Critical examination of the alkali-soluble hydrolysis product revealed the presence of a trace of benzoic acid, but no tropic acid could be isolated.

2,4-Diphenylbutanol was chosen for the racemization studies because it was needed in another problem and an easy synthesis was indicated. 2-Phenyl-3-benzoylpropanoic acid was resolved and the active forms were reduced catalytically to the 2,4-diphenylbutanoic acids.[3] These acids were then reduced with lithium aluminum hydride to the 2,4-diphenylbutanols, Table I. The ratios of the rotations of the (+) and (−) isomers is sufficiently constant to suggest that little or no racemization accompanies the reductions. Some attempts were made to resolve 2,4-diphenylbutanoic acid but the results were not promising.

[a] Microanalyses by Margaret Hines. [b] Mr. Martin Knell of these laboratories reports the m. p. of the racemic material is 102–103°. [c] The optical purity of this compound may have been increased by its extensive crystallization preparatory to analysis.

Solid derivatives of the alcohols are presented

(1) Baker, THIS JOURNAL, **70**, 3857 (1948).

(2) Doering and Aschner, *ibid.*, **71**, 838 (1949).

(3) Baker and Jenkins, *ibid.*, **68**, 2102 (1946).

in Table II. It is observed that the dinitrobenzoates have signs of rotation opposite to the alcohols from which they are derived.

Experimental

Resolution of 2-Phenyl-3-benzoylpropanoic Acid.—A solution of the acid, 50.8 g. (0.2 mole) in 1 l. of ethyl acetate was mixed with 64.8 g. (0.2 mole) of (−) quinine in 1 l. of ethyl acetate and the mixture was allowed to crystallize at 8° overnight.[4] The first crop of crystals was alternately crystallized from methanol and ethyl acetate and decomposed by sodium hydroxide to produce the acid which was crystallized from ether, $[\alpha]^{27}D$ +136° (*c*, 1.03 in ethyl acetate). This acid was 86% optically pure as judged by Hann and Lapworth's values.[4]

The ethyl acetate-soluble salt gave 13 g. (51%) of acid, $[\alpha]^{27}D$ −111° (*c*, 1.40 in ethyl acetate).

(+) and (−)2,4-Diphenylbutanoic Acids.—The keto acid, I, was reduced over palladium-charcoal in glacial acetic acid containing perchloric acid as previously described for the racemic acid.[3] The acids were crystallized once from 60–70° petroleum ether to give the results shown in Table I.

(+) and (−)2,4-Diphenylbutanols.—The active diphenylbutanoic acids were reduced in ethyl ether by lithium aluminum hydride following the directions of Nystrom and Brown.[5] After the addition of the acid the mixture was refluxed for one-half hour and then hydrolyzed with 10% hydrochloric acid. The alcohols were distilled, b. p. 178–180° (1 mm.).[6] Rotations and yields are summarized in Table I.

The α-Naphthylcarbamates and 3,5-dinitrobenzoates of the active alcohols were crystallized from petroleum ether and ethanol, respectively. Their constants are presented in Table II.

Attempted Racemizations of 2,4-Diphenylbutanols.—The procedure and essentially the apparatus which Doering and Aschner[2] had shown to be capable of excluding the effects of oxidants were used. The freshly prepared alcohols, 2 millimoles, were added to equivalent amounts of powdered sodium under toluene and allowed to react until hydrogen evolution had ceased. The suspension was then heated at 100° for a time and the alcohol recovered by washing the toluene with acid, then water, and distilling finally *in vacuo*. The specific rotations of the alcohols at comparable temperatures and concentrations before and after heating for specified times were

−15.1°	5 hr.	−14.6°
−14.6	8 hr.	−13.3
+24.3	8 hr.	+24.1

(4) These are more specific directions than those of Hann and Lapworth, *J. Chem. Soc.*, **85**, 1355 (1904).

(5) Nystrom and Brown, THIS JOURNAL, **69**, 2548 (1947).

(6) Marion, *Canadian J. Res.*, **16B**, 213 (1938), gives 174–180° at 1 mm. for the racemic alcohol.

EVANSTON, ILLINOIS RECEIVED JULY 5, 1949

Summary

Optically active forms of 2,4-diphenylbutanoic acid and 2,4-diphenylbutanol have been prepared by convenient methods. The latter compound is not racemized by heating of its sodium derivative at 100° for eight hours.

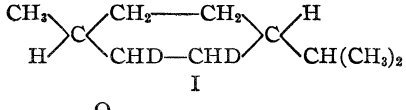
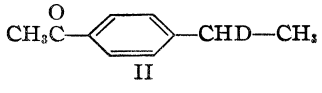
The Reduction of Optically Active Phenylmethylcarbinyl Chloride with Lithium Aluminum Deuteride[1]

BY ERNEST L. ELIEL

Recently Alexander and Pinkus[1a] showed that the reduction of optically active *trans*-2-menthene gives rise to *active* 2,3-dideutero-*trans*-menthane (I) thus demonstrating that a compound of type R_1R_2CHD is capable of rotating the plane of polarized light.



I



II

Compound I has four asymmetric centers (not all of which, however, necessarily contribute towards its rotation[1a]) and it seemed desirable to investigate again the possibility of optical activity in the case of a compound having only one carbon atom of the R_1R_2CHD-type. Such a compound is α-deuteroethylbenzene, $C_6H_5CHDCH_3$. This hydrocarbon was expected to be accessible by the reduction of phenylmethylcarbinyl chloride, $C_6H_5CHClCH_3$, with lithium aluminum deuteride–lithium deuteride according to a method recently described[2] for reductions of alkyl halides to alkanes. The fact that primary halides are reduced more easily by lithium aluminum hydride than secondary, while tertiary ones are not reduced at all,[2,3] might lead one to believe that the reaction is of the nucleophilic displacement (S_N2) type and that the reduction of optically active α-phenethyl chloride with lithium aluminum deuteride might proceed with Walden inversion and give rise to an active product. Walden inversion has been demonstrated for the reduction of epoxides with lithium aluminum hydride.[3]

The reduction of (−)-α-chloroethylbenzene with lithium aluminum deuteride–lithium deuteride in tetrahydrofuran yielded about 80% of the theoretical amount of α-deuteroethylbenzene which was free of chlorine-containing impurities

(1) Presented before the Organic Division of the American Chemical Society at Atlantic City, N. J., September 20, 1949.

(1a) Alexander and Pinkus, THIS JOURNAL, **71**, 1786 (1949). This publication reviews earlier unsuccessful attempts to synthesize optically active compounds of the R_1R_2CHD type. The present author is indebted to Dr. Elliot R. Alexander for information regarding the results of his investigation several months in advance of publication.

(2) Johnson, Blizzard and Carhart, *ibid.*, **70**, 3644 (1948).

(3) Trevoy and Brown, *ibid.*, **71**, 1675 (1949). At the time this paper appeared, the present investigation was almost complete.

and showed optical rotation far in excess of possible observational errors. Its deuterium content, calculated on the basis of density by the formula of McLean and Adams[4] appeared to be very close to the theoretical. Acetylation of the active hydrocarbon by the Friedel–Crafts procedure yielded active *p*-acetyl-α-deuteroethylbenzene (II) which, in turn, gave rise to an optically active crystalline oxime. The activity of the once-recrystallized oxime was not affected by further recrystallizations and the active ketone was regenerated by acid hydrolysis of its crystalline derivative.

It is thus established beyond doubt that α-deuteroethylbenzene is capable of rotating the plane of polarized light. The degree of optical purity and the configuration of the deuterated hydrocarbon are not known, but on the basis of the work of Trevoy and Brown[3] it seems likely that the reduction involves Walden inversion.

2,3-Diphenylbutane was obtained as a by-product in the reduction of α-chloroethylbenzene by either lithium aluminum deuteride–lithium deuteride or lithium aluminum hydride–lithium hydride. The origin of this by-product is under investigation.

Experimental

dl-**Phenylmethylcarbinol.**[5]—Acetophenone was distilled *in vacuo* from Raney nickel. One mole (120 g.) of the distillate was reduced in the presence of about 5 g. of copper chromite[6] at a temperature of 110–120° and an initial hydrogen pressure of 2500 lb. Reduction was complete in three hours. The catalyst was separated by filtration and the liner of the bomb and catalyst were rinsed with ether. The filtrate was fractionated, *dl*-phenylmethylcarbinol being collected at 92.5–93.5° (16 mm.). The purity of the product, as established by titration of the hydroxyl group,[7] was 99%, yield 118 g. (97%).

(+) **and** (−)-**Phenylmethylcarbinol.**—*dl*-Phenylmethylcarbinol was converted to its acid phthalate by the method of Houssa and Kenyon.[8] The product precipitated as an oil when its pyridine solution was poured into dilute hydrochloric acid. It was extracted with ether and the extract was washed with water, dried over sodium sulfate and freed of solvent by distillation. The residue was crystallized from benzene and melted at 107–108° (lit.[8] 108°). The acid phthalate (300 g.) was resolved *via* its brucine salt as described in the literature.[9] Crystallization of the diasteroisomeric salts proved quite tedious until seed crystals were obtained, but once the laboratory was nucleated, crystallization proceeded with great ease and in one case part of the more soluble salt precipitated along with the less soluble. Decomposition of the salts was effected by dissolving them in methanol, pouring the solution into an excess of dilute hydrochloric acid and extracting the precipitated oily phthalate with ether. The ether was washed with water, dried over sodium sulfate and distilled and the residue was crystallized as described.[9] Basic hydrolysis[9] of the resolved phthalates yielded 33 g. of the (+)-carbinol, $[\alpha]_D$ +39.7°, and 35 g. of the (−)-carbinol b. p. 93° (14 mm.), $[\alpha]_D$ −43.6°. Since Downer and Kenyon report[9] a specific rotation of −43.5°, the (−)-carbinol obtained in this work was presumably optically pure and the (+)-carbinol about 93% pure.

(+) **and** (−)-**Phenylmethylcarbinyl Chlorides.**—The chlorides were obtained from the corresponding alcohols by treatment with purified thionyl chloride in the cold followed by fractional distillation.[10] The (−)-alcohol yielded a chloride of $[\alpha]^{25}_D$ −49.2°, boiling at 74–75° (14 mm.), while the (+)-carbinol yielded a halide of $[\alpha]^{25}_D$ +45.2°. Since McKenzie and Clough[10] consistently obtained material whose specific rotation was +50.6°, and Ott[11] reports a specific rotation for α-chloroethylbenzene of −50.3°, it is estimated that the (−)-chloride obtained here was 97–98% pure while the purity of the (+)-chloride was between 89 and 90%.

(−)-α-**Deuteroethylbenzene.**—The general method of Johnson, *et al.*,[2] was followed. To a well-stirred mixture of 75 ml. of tetrahydrofuran[12] (distilled first over potassium hydroxide, then over lithium aluminum hydride), 1 g. of lithium aluminum deuteride[13] and 3 g. of finely-ground (100 mesh) lithium deuteride,[13] 33.5 g. of phenylmethylcarbinyl chloride, $[\alpha]^{25}_D$ −49.2°, was added rapidly. The reaction was not markedly exothermic. The mixture was refluxed with efficient stirring for four hours, without stirring for nine and one-half hours, and with stirring for ten more hours. It was then cooled, excess deuteride was destroyed by the addition of a solution of 20 ml. of water in 30 ml. of tetrahydrofuran, and the mixture was poured onto ice-water containing 20 ml. of sulfuric acid. The product was extracted with two portions of *ca.* 100 ml. of pentane[12] and the pentane solution was washed twice with water, four times with 85% phosphoric acid, twice with water, once with 10% sodium carbonate solution and once with water. It was dried over calcium chloride and fractionated through a Vigreux column. α-Deuteroethylbenzene was collected at 133–135° (747 mm.) and weighed 20.7 g. (79%). Its rotation was α^{25}_D −0.51 ± 0.01° (l = 2 dm., no solvent).

When the distillation residue was taken up in acetone, the solution was found to be weakly dextrorotatory. Removal of the acetone left 0.77 g. of a semisolid material, presumably a mixture of *meso* and active 2,3-diphenylbutane. In a model experiment in which *dl*-α-chloroethylbenzene was reduced with lithium aluminum hydride–lithium hydride, the solid *meso*-form was recrystallized from 95% ethanol; it then melted at 124.5–125° and did not depress the melting point of an authentic sample of *meso*-2,3-diphenylbutane.[11]

The active α-deuteroethylbenzene was fractionated through an eight-inch helix-packed column the following fractions being obtained[14]

Fraction	Weight, g.	n^{25}_D	α^{25}_D deg.
1	5.5	1.4921	−0.47 ± 0.02
2	3.9	1.4925	− .48 ± .02
3	4.4	1.4923	− .53 ± .02
4	4.6	1.4922	− .52 ± .02
5	0.9	1.4922	Not observed

Fractions 1 through 4 were recombined and their rotation was found to be α^{25}_D −0.52 ± 0.01° (l = 2 dm., no sol-

(11) Ott, *Ber.*, **61**, 2124 (1928).

(12) All solvents used in this work were checked for optical rotation which in no case was found to exceed 0.01° in a 2-dm. tube.

(13) Metal Hydrides, Inc., Beverly, Mass., isotopic purity 99+%.

(14) Rotations observed in a 2-dm. capillary tube of 2-ml. capacity. All other rotations were observed in a wide-bore 2-dm. tube of 13-ml. capacity.

vent) whence, taking $d = 0.87$,[15] $[\alpha]^{25}D$ $-0.30°$. The compound gave negative halogen tests both by the Beilstein method and with alcoholic silver nitrate.[16]

The reduction of 9 g. of (+)-α-phenethyl chloride by means of 0.35 g. of lithium aluminum hydride and 1.0 g. of lithium hydride in 30 ml. of tetrahydrofuran gave rise to 3.9 g. of ethylbenzene boiling at 132.5–134.5° (742 mm.) whose rotation was αD $-0.03 \pm 0.02°$ ($l = 2$ dm., no solvent).[14]

(−)-α-Deuteroethyl-*p*-acetylbenzene (II).—The method of Klages[17] was followed. To a solution of 14.5 g. of (−)-α-deuteroethylbenzene and 18 g. of acetyl chloride in 60 ml. of petroleum ether[12] (b. p. 30–60°), 19 g. of aluminum chloride was added gradually with efficient stirring. The mixture was refluxed for one-half hour and poured onto ice and hydrochloric acid. The layers were separated and the aqueous layer was extracted once with ether.[12] The petroleum ether and ether layers were successively washed with dilute hydrochloric acid, water, 10% sodium carbonate solution and water and then dried over sodium sulfate. Fractionation of the solvents followed by distillation *in vacuo* yielded 1.3 g. of unchanged α-deuteroethylbenzene,[18] b. p. 37–38° (17 mm.), and 14.5 g. (72%) of the desired ketone collected at 123–126.5° (18 mm.). The ketone had $n^{25}D$ 1.5260[19] and $\alpha^{23}D$ $-0.54 \pm 0.01°$ ($l = 2$ dm., no solvent), whence, assuming a density of 0.99 (see below), $[\alpha]^{23}D$ $-0.27°$.

Oxime of II.—Sodium acetate trihydrate (29 g.) and hydroxylamine hydrochloride (14.5 g.) were ground together in a mortar and the resultant slurry was extracted three times with 50-ml. portions of ethanol.[12] The filtered ethanol solution was added to a solution of 14 g. of II in 15 ml. of ethanol and refluxed for twelve hours. Part of the ethanol was then distilled and crystallization induced by the addition of water to the cloud point and cooling. The crystalline oxime was collected, washed with dilute ethanol and dried; it weighed 13.2 g. (85% and melted in 82.5–84°. The optical rotation of a solution of 5 g. of oxime in benzene[12] (total volume 15 ml.) was $-0.16 \pm 0.01°$ ($l = 2$ dm., $t = 23°$).[20] Recrystallization of the oxime from dilute ethanol raised the melting point to 83–84°[21] and changed $\alpha^{27}D$ to $-0.11 \pm 0.01°$ ($l = 2$ cm., in benzene). Further recrystallization from the same solvent did not change the melting point; $\alpha^{28}D$ $-0.12 \pm 0.01°$ ($l = 2$ dm., in benzene). Recrystallization from benzene–petroleum ether left the melting point unchanged, $\alpha^{29}D$ $-0.11 \pm 0.01°$ ($l = 2$ dm., in benzene), whence $[\alpha]^{28}D$ $-0.17°$ in benzene.

Recovery of the Ketone II from its Oxime.—A suspension of 7 g. of the oxime of II in 100 ml. of *ca.* 1 *N* hydrochloric acid was steam distilled. The distillate was extracted twice with ether and the ether layers were washed with 5% sodium carbonate solution and then three times with water. Drying over sodium sulfate followed by concentration and distillation *in vacuo* yielded 5.5 g. (86%) of the recovered ketone (II) collected at 127–129° (25 mm.). Its physical constants were as follows: $n^{25}D$ 1.5261, d^{25}_4 0.9915[22]; $\alpha^{30}D$ $-0.50 \pm 0.02°$[14] ($l = 2$ dm., no solvent). The rotation of the ketone was unaffected by eleven hours of refluxing with 1 *N* aqueous hydrochloric acid.

Acknowledgments.—The author wishes to express his appreciation to Dr. Charles C. Price for helpful advice, to Mr. Erwin Kohn for carrying out the high-pressure hydrogenation of acetophenone and to the Electrochemicals Department of the du Pont Company for a generous supply of tetrahydrofuran.

Summary

1. The reduction of (−)-phenylmethylcarbinyl chloride of $[\alpha]^{25}D$ $-49.2°$ with lithium deuteride–lithium aluminum deuteride yields active α-deuteroethylbenzene of $[\alpha]^{25}D$ $-0.30°$.

2. The active α-deuteroethylbenzene has been converted into optically active *p*-acetyl-α-deuteroethylbenzene whose crystalline oxime retained its activity through several recrystallizations and regenerated the active ketone upon hydrolysis.

NOTRE DAME, INDIANA RECEIVED JULY 16, 1949

(15) The values for d^{25}_4 found were 0.8628 for ethylbenzene and 0.8712 for deuteroethylbenzene. Application of the formula of McLean and Adams (ref. 4) to the ethylbenzene value gives an expected density of 0.8710 for the deuterium compound.

(16) The silver nitrate test was shown to be sensitive to a solution containing one part of α-phenethyl chloride in 700 of ethylbenzene.

(17) Klages, *Ber.*, **32**, 1558 (1899).

(18) The rotation of the recovered hydrocarbon was determined by diluting 0.8 ml. with 2.4 ml. of ordinary ethylbenzene and taking readings in a 2-dm. capillary tube (*cf.* ref. 14). The observed rotation was $-0.13 \pm 0.01°$, corresponding to a rotation of $-0.52°$ for the undiluted material.

(19) The data reported by Klages, ref. 16, for the hydrogen compound are: b. p. 130° (23 mm.), $n^{20}D$ 1.5310, d^{20}_4 0.991. Here observed: b. p. 114–116° (13 mm.), $n^{25}D$ 1.5269, d^{25}_4 0.9851.

(20) This reading may have been affected by a systematic error; the field was very much distorted.

(21) Klages, *Ber.*, **35**, 2245 (1902), reports a melting point of 82–83° for the hydrogen compound while the present author observed 83–84°.

(22) The expected density on the basis of the corresponding value for the hydrogen compound (ref. 19) and the formula of McLean and Adams (ref. 4) is 0.9917.

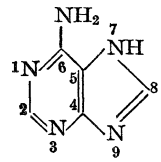
Degradations in the Purine Series Studied with Isotopes of Nitrogen and Carbon[1]

BY LIEBE F. CAVALIERI, JOHN F. TINKER AND GEORGE BOSWORTH BROWN

Tracer studies concerned with the metabolism of purines have evoked the need for methods suitable for determining the location of isotopes in purines isolated from tissue constituents. Oxidative and hydrolytic degradations of the purines adenine,[2,3,4] guanine,[5,6] xanthine,[7] hypoxanthine[2] and uric acid have been reported but only in the case of guanine[6] has the mechanism been clarified by the degradation of samples labeled with isotopes in known positions. The availability in this laboratory of several synthetic purines variously labeled with the isotopes of nitrogen (N^{15}) and carbon (C^{13} or C^{14}) has permitted the study of a number of such degradations.

The action of concentrated hydrochloric acid on the purines, adenine, guanine, xanthine, hypoxanthine and uric acid leads to the formation of glycine, ammonia, carbon monoxide and carbon dioxide. By analogy to the results with 7-methyl uric acid, which yields sarcosine under these conditions,[8] it has been assumed for both uric acid[9,10] and guanine[11] that the glycine arises from the 4- and 5-carbon atoms and the 7-nitrogen. However, no direct proof of this assumption has been presented.



I

tained excess C^{13}. Decarboxylation of a sample of *p*-tosylglycine revealed that the C^{13} was present only in the carboxyl group of the glycine (Table I). Further, since the isotope concentration in the carbon dioxide was equal to that originally present in either the 4- or 6-carbons, dilution had not occurred. That no excess N^{15} was found in the glycine indicates that the amino group must have arisen from the 7- or 9-nitrogens or the 6-amino group of adenine, but not from the 1- or 3-nitrogens. Origin of the amino group of glycine from the 6- or 9-nitrogens would require the carboxyl group to come from the 5-carbon, but since it was the carboxyl carbon of the isolated glycine which contained the excess C^{13}, it follows that the amino group of the glycine originated from the 7-nitrogen.

In the case of guanine a sample was hydrolyzed which contained C^{13} in the 4-position only.[12] This led to the formation of glycine with the C^{13} in the carboxyl group and this decisively confirms the origin of the carboxyl carbon of glycine from this purine.

Uric acid	N^{15} in 1, 3	$C_5H_4O_3N_4$	33.3	33.7	N^{15}, 0.50	$C_9H_{11}O_4NS$	6.1	6.2	N^{15}, 0.00	0.02[c]

[a] Atom % excess. [b] In all cases glycine was isolated as the *p*-tosyl derivative. [c] These values represent about 1% of the N^{15} present in either the 1- or 3-positions. This N^{15} probably arises from *p*-toluenesulfonamide which is formed from traces of ammonia remaining in the residue of the reaction mixture. [d] Sulfur analysis. [e] This carbon dioxide was obtained by the decarboxylation of the *p*-tosylglycine.

Adenine (I), labeled with C^{13} in the 4- and 6-positions and with N^{15} in the 1- and 3-positions, was hydrolyzed with concentrated hydrochloric acid and the glycine which was isolated con-

The acid hydrolysis of guanine, labeled with N^{15} in the 1- and 3-positions and in the 2-amino group, and of xanthine and uric acid, each labeled in the 1- and 3-positions, yielded glycine with no excess N^{15}. This is in conformity with the origin of the glycine from the 4, 5 and 7 atoms.

Under milder conditions, the acid hydrolysis of adenine led to the formation of 4(5)-amino-5(4)-imidazolecarboxamidine (II). Since II exhibits a distribution constant (0.12 *n*-butanol phosphate, *p*H 6.5) different from that of adenine

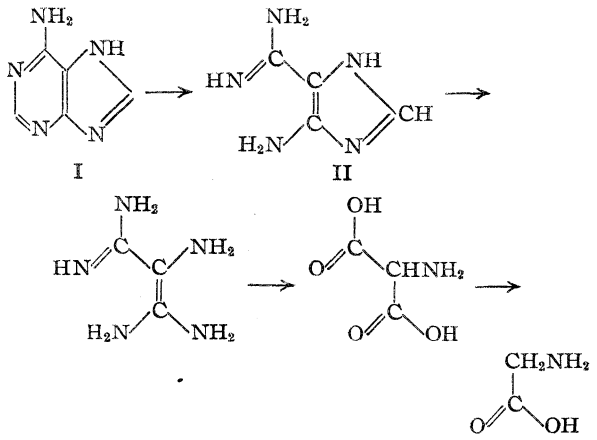
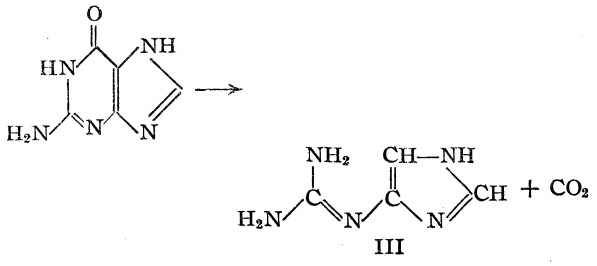
(2.2) reaction mixtures were readily analyzed and optimum conditions for the formation of II from adenine were thus easily found. The production of this carboxamidine is consistent with the observed production of formic acid in the hydrolysis of adenine or of nucleic acids.[13] This degradation permits a differentiation between the 2- and 8-carbons of adenine.

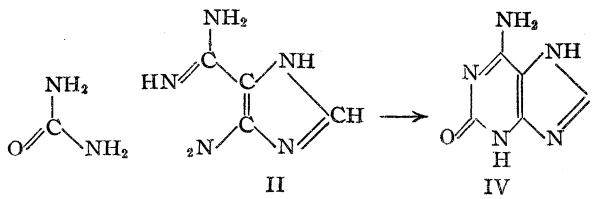
On the basis that the amidine (II) is an intermediate, it can be postulated that the formation of glycine from adenine proceeds according to the scheme shown.



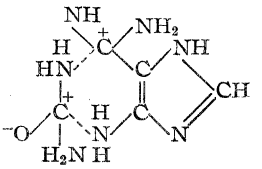
The sequence of steps involving the degradation of II may not necessarily be the one shown, but the over-all mechanism is consistent with the data. It is of interest to note that 4(5)-guanidinoimidazole (III) has been isolated by Hunter[14] after subjecting guanine to very nearly the same hydrolytic conditions.



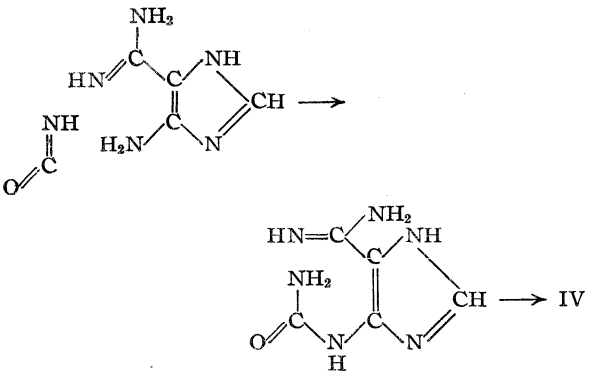
Proof of structure of the amidine (II) is found in the conversion to isoguanine (IV) by the



action of either urea or phosgene. When the fusion with urea was carried out on a sample of II containing N^{15} in both the amino and amidine groups (prepared from 1,3 labeled adenine), the N^{15} of the resulting isoguanine (III)[15] was 88% of that originally present in the II. Since it is likely that the 4(5)-amino group is a nucleophilic center attacking the electrophilic carbon of the urea, it is reasonable to assume that the N^{15}



was not eliminated from the amino substituent, but rather from the amidine grouping which can act both as a nucleophilic and electrophilic entity. Indeed, the 12% loss of N^{15} may be taken as a measure of the electrophilic character of the amidine unit in this molecule. An alternative but similar mechanism involves the addition of cyanic acid which is present in the reaction mixture.



Oxidative degradations of the purines have been carried out employing acid and alkaline permanganate, perchlorate,[6] nitric acid,[16,17] and various other oxidizing agents. The oxidation of uric acid with alkaline permanganate yields allantoin (V) via a symmetrical intermediate (VI), while

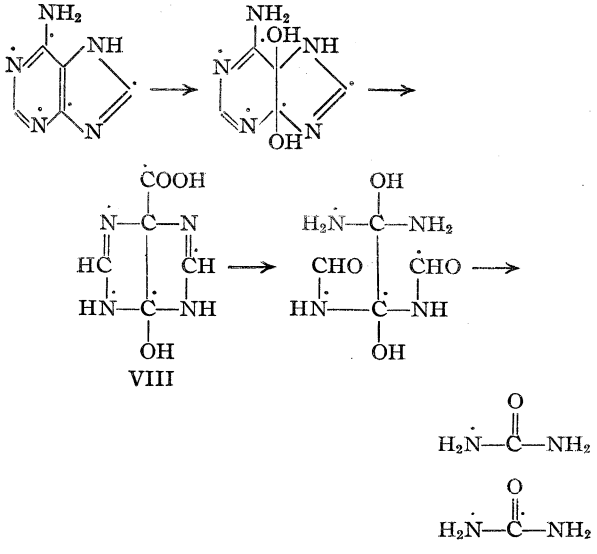
[a] The C^{13} and N^{15} values are expressed as atom % excess over the normal abundance. [b] Adenine may be obtained as the mono sulfate depending upon the rate of crystallization. [c] Sufficient adenine was burned to give a value of 4500 c. p. m. over background. [d] Sufficient dixanthydrol urea was burned to give a value of 150 c. p. m. over background.

with nitric acid the imidazolone ring is cleaved to produce alloxan (VII).[18]

The oxidation of adenine with permanganate in acid solution has been reported[3,4] to yield one mole of glycine, two moles of urea, and one mole of carbon dioxide. In our hands, this reaction did not result in the formation of glycine. The mechanism of this reaction was studied employing adenine which was labeled with N^{15} in the 1- and 3-positions, C^{14} in the 4- and 6-positions and C^{13} in the 8-position.[19] The oxidation was carried out by the use of potassium permanganate in sulfuric acid solution. Urea was isolated as dixanthydrol urea, and the ammonia and carbon dioxide collected. Since the isotope values of the ammonia and carbon dioxide evolved were essentially equal to those of the parent adenine, it is clear that complete degradation of a large portion of the sample occurred.

The isotope analyses (Table II) reveal that the N^{15} content of the urea isolated was appreciably higher than the average N^{15} content of the adenine and was one-half (47%) of that contained in either the 1 or 3 nitrogens. Since only 0.01 atom % of C^{13} was found in the urea, the 7-, 8- and 9-atom unit contributed but to a small extent to the urea found. The ratio of C^{14}:C^{12} in the urea was 0.6:1.0 and it was constant upon repeated recrystallization of the dixanthydrol urea.

Upon examination of the adenine molecule it is evident that, if no rearrangement occurs, the urea can arise in four ways, *viz.*, from the (1,3), (1,6), (3,9) or (7,9) positions. No one of these four possibilities or any combination of them is consistent with the isotope analyses. On this basis it appears necessary to postulate a rearrangement similar to that occurring in the permanganate oxidation of uric acid in alkaline solution. In this case, however, it is required that preponderant cleavage of the proposed intermediate (VIII) takes place as shown, although the C^{13} value, together with the low C^{14}:C^{12} ratio, indicates some cleavage similar to that of VI to V. Since a sample of urea under the conditions of the experiment was oxidized to the extent of only 5 to 10%, it can be assumed that once the urea is formed in the reaction it remains for the most part intact. Thus each molecule of the urea



VIII

contained one atom of N^{15} originally present in the 1- or 3-position and one normal nitrogen from the 7- or 9-position. Appreciably less than half of the urea molecules must have contained C^{14}, arising chiefly from the 4-carbon.

Experimental

Isotope Analyses.—All N^{15} and C^{13} determinations were carried out with a Consolidated–Nier mass spectrometer, Model 21-201. The average error in the N^{15} determinations was ±0.002; in the C^{13} determinations ±0.005. For the C^{14} measurements the samples were converted to barium carbonate and the analyses were carried out on carbon dioxide.[20]

Materials.—Adenine containing N^{15} in the 1- and 3-positions and C^{13} (or C^{14}) in the 4- and 6-positions was synthesized according to Cavalieri, Tinker and Bendich[21] and adenine labeled with C^{13} in the 8-position was prepared according to Cavalieri and Brown.[19] Guanine, xanthine[2,22] and uric acid[23] with N^{15} in the 1- and 3-positions were prepared as in previous communications. C^{13} was introduced into the 4-position of guanine by employing methyl cyanoacetate ($C^{13}NCH_2COOCH_3$) obtained by a previous procedure.[21]

4(5)-Amino-5(4)-imidazolecarboxamidine Hydrochloride (II).—Adenine sulfate (2 g.) was heated in a sealed tube containing 30 cc. of 6 *N* hydrochloric acid at 150 ± 2° for two hours. The solution was evaporated to dryness and extracted with two 10-cc. portions of warm concentrated hydrochloric acid. To this filtrate was added 30 cc. of ethanol and the solution cooled to induce crystallization. The crystalline deposit was recrystallized three times by dissolving it in warm concentrated hydrochloric acid (*ca.* 2 cc.) and adding alcohol (15 cc.). The yield of pure material was 200 mg. (10%); distribution constant, 0.12 (*n*-butanol–phosphate buffer, *p*H 6.5); ultraviolet absorption spectrum: λ_{max} 287 mμ, log ε 4.03.

Anal. Calcd. for $C_5H_7N_5 \cdot 2HCl$: N, 35.3. Found: N, 35.3.

Conversion of II to Isoguanine. (a) Phosgene Method.—Fifty milligrams of II was dissolved in 5 cc. of *N* sodium hydroxide and phosgene passed through the solution for one hour, during which time three 4-cc. portions of 40% sodium hydroxide were added. The mixture was then aerated for one hour. One cubic centimeter of 2 *N* sulfuric acid was added and the solution heated, decolorized and filtered. On cooling 14 mg. (26%) of material was obtained which was recrystallized from 2 *N* sulfuric acid. The ultraviolet absorption spectrum[24] at various *p*H values was identical with that of isoguanine prepared by another synthesis.[15]

Anal. Calcd. for $(C_5H_5ON_5)_2 \cdot H_2SO_4 \cdot H_2O$: S, 7.6. Found: S, 7.7.

(b) **Urea Fusion Method.**—Seventy-five milligrams of II (containing 0.97 atom % excess N^{15}) was fused with 410 mg. of urea at 180° for one hour. The cooled melt was extracted with 5 cc. of boiling water and the extract discarded. The residue was recrystallized twice from 2 *N* sulfuric acid; yield 37 mg. (47%). The N^{15} content of this isoguanine sulfate was 0.85 or 88% of that present in II.

Anal. Calcd. for $(C_5H_5ON_5)_2 \cdot H_2SO_4 \cdot H_2O$: S, 7.6. Found: 7.8.

Hydrolytic Degradation.—The hydrolyses of adenine, guanine, xanthine and uric acid were carried out by heating about 1 g. of the purine in 15 cc. of concentrated hydrochloric acid at 180° in a sealed tube for eighteen hours (Table I).

Isolation of Glycine.—The mixture from the above hydrolysis was evaporated to dryness and to the residue was added 10 cc. of 5% sodium hydroxide. The ammonia was removed by aeration, while warming the mixture. One gram of *p*-toluenesulfonyl chloride was added to the alkaline solution and the mixture stirred for six hours at room temperature. The solution was filtered and acidified. The precipitation of *p*-tosylglycine was complete in two hours and the product was collected by filtration. Two recrystallizations from ethyl acetate–petroleum ether gave 30–50 mg. of pure *p*-tosylglycine (Table I).

Decarboxylation of *p*-Tosylglycine.—*p*-Tosylglycine (20 mg.) was mixed intimately with copper powder and heated to 200 ± 5° for one-half hour in a stream of nitrogen. The carbon dioxide was collected in saturated barium hydroxide; yield $BaCO_3$, 14–16 mg. (81–92%).

Oxidation of Adenine (Table II).—Adenine sulfate (400 mg.) was dissolved in 80 cc. of water containing 4 cc. of concentrated sulfuric acid. To the boiling solution was added dropwise over a period of five minutes 2.6 g. of potassium permanganate in 35 cc. of water. Carbon dioxide was collected in saturated barium hydroxide during this time. After the outlet tube had been disconnected the excess permanganate was destroyed with oxalic acid. The solution was filtered, and 160 cc. of glacial acetic acid was added followed by 2 g. of xanthydrol (in 20 cc. methanol). Precipitation of dixanthydrol urea began after one-half hour and was complete after standing overnight. The product was recrystallized three times from glacial acetic acid; yield 120 mg. A sample of ammonia was obtained from the original oxidation mixture (after treatment with oxalic acid) by adding excess alkali and collecting the ammonia in boric acid.

Acknowledgment.—The authors wish to thank Dr. Maxwell Leigh Eidinoff for performing the C^{14} determinations, Roscoe C. Funk, Jr., and John Deonarine for the microanalyses and the N^{15} and C^{13} determinations.

Summary

The acid hydrolysis of purines has been studied by means of tracer elements, and it has been confirmed that glycine arises from the 4,5- and 7-atoms. The oxidation of adenine with potassium permanganate produces urea which is postulated to arise from the 1,7- and 3,9-nitrogen atoms.

The preparation and characterization of 4(5)-amino-5(4)-imidazolecarboximidine are described.

A new synthesis of isoguanine is described.

A New Method for the Isolation of Histamine

BY ALEXANDER GALAT AND HARRIS L. FRIEDMAN

Histamine is usually prepared by the bacterial decarboxylation of histidine in solution, and it is isolated in the form of its dipicrate. The decarboxylation of histidine proceeds readily and in good yield but the isolation of pure histamine by the picrate method offers a number of disadvantages. The purification of the dipicrate by recrystallization from water or dilute alcohol requires large volumes of solvent since the compound is sparingly soluble even at the boiling point. The conversion of the dipicrate into histamine salts, such as the dihydrochloride, involves the treatment of the dipicrate with an excess of hydrochloric acid, removal of the bulk of picric acid by filtration and extraction with an organic solvent to free the product from the last traces of this reagent. Because of the low solubility of the dipicrate these operations must be conducted in hot, dilute solutions which finally must be evaporated to dryness. This method is quite inconvenient for the preparation of relatively large amounts of histamine.

Recently, Vickery described a method for the isolation of histidine involving the precipitation of

this amino acid with *o*-dichlorobenzenesulfonic acid.[1] It seemed of interest to investigate the use of the same reagent for the isolation of histamine. We have found that when an excess of *o*-dichlorobenzenesulfonic acid is added to solutions containing histamine, the disulfonate of this base precipitates in the form of white, well-formed crystals. A nearly quantitative yield was obtained when *o*-dichlorobenzenesulfonic acid was added to solutions of histidine fermented by the method of Ackermann.[2] The new compound is readily soluble in hot water and very sparingly in cold, so that purification was effected conveniently and in good yield. The conversion of the disulfonate into histamine base and its salts was effected with equal ease, as described in the experimental part.

Experimental

Histamine Bis-*o*-dichlorobenzenesulfonate.—Twenty grams of histidine monohydrochloride monohydrate was fermented with *B. coli* organisms according to the method of Ackermann.[2] To the mixture there was added 120 g. of *o*-dichlorobenzenesulfonic acid, prepared by the method of Vickery,[1] and the precipitation completed by allowing the mixture to stand overnight. The crystals of histamine bis-*o*-dichlorobenzenesulfonate were filtered off, washed with water and recrystallized from 400 ml. of boiling water with the addition of activated charcoal. The product, dried at 100°, weighed 47 g. (87%) and melted at 225–227° (cor.).

Anal. Calcd. for $C_{17}H_{17}O_6Cl_4N_3S_2$: C, 36.10; H, 3.00; N, 7.43. Found: C, 36.35; H, 3.05; N, 7.35.

(1) Vickery, *J. Biol. Chem.*, **143**, 77 (1942).

(2) Ackermann, *Z. physiol. Chem.*, **65**, 505 (1910).

Histamine Di-hydrochloride.—A solution of 11.3 g. (0.02 mole) of histamine bis-*o*-dichlorobenzenesulfonate in 100 ml. of boiling *n*-butanol was saturated with hydrogen chloride and cooled to room temperature. The precipitate of histamine dihydrochloride was filtered off, washed with *n*-butanol followed by benzene and finally dried *in vacuo;* yield 3.4 g. (92%), m. p. 242–246° (cor.).

Histamine Diphosphate.—A hot solution of 11.3 g. (0.02 mole) of histamine bis-*o*-dichlorobenzenesulfonate in 50 ml. of water was treated with a hot solution of 6.3 g. (0.01 mole) of barium hydroxide octahydrate in 25 ml. of water. The mixture was cooled and the precipitate of barium *o*-dichlorobenzenesulfonate filtered off and washed with water. To the filtrate was added 6.0 g. of 85% phosphoric acid diluted with 10 ml. of water. The solution was then concentrated *in vacuo* to a small volume and histamine diphosphate precipitated by the gradual addition of methanol; yield 5.5 g. (90%), m. p. 130°.

Histamine Base.—A hot solution of 11.3 g. (0.02 mole) of histamine bis-*o*-dichlorobenzenesulfonate in 50 ml. of water was mixed with a hot solution of 6.3 g. (0.01 mole) of barium hydroxide octahydrate in 25 ml. of water, the mixture cooled and the precipitate filtered off and washed with cold water. The filtrate was concentrated to a small volume, cooled and a small additional amount of the barium salt removed by filtration. The filtrate was evaporated to dryness *in vacuo*, the sirup dissolved in 50 ml. of absolute isopropyl alcohol, treated with charcoal, filtered and evaporated *in vacuo* to dryness. The residue crystallized on cooling and seeding; yield: 1.90–1.95 g. (85–87%), m. p. 82–85° (sealed tube).

Summary

A new method for the isolation of histamine is described. Histamine is precipitated as bis-*o*-dichlorobenzenesulfonate which is readily converted in good yield into the histamine base or its salts.

Studies in Pterine Chemistry. I. 2-Amino-4-hydroxy-6-polyhydroxyalkylpterines

BY H. G. PETERING AND J. A. SCHMITT

Karrer, Schwyzer, Erden and Siegwart[1] reported that aldoses (IIa) and ketoses (IIb) may be condensed with 2,4,5-triamino-6-hydroxypyrimidine (I) to form 7- and/or 6-polyhydroxyalkylpterines (IV). These authors did not clearly indicate which of the isomers was obtained in any case, but they did appear to accept the hypothesis that aldoses formed 7-isomers and ketoses formed 6-isomers. The fact that D-glucose forms a 7-isomer with I was confirmed by Petering and Weisblat,[2] but neither the latter authors nor Karrer, *et al.*,[1] offered proof which could gainsay the claim of Weygand, *et al.*,[3] that the product of D-fructose (IIb) and (I) is 2-amino-4-hydroxy-7-(2′, 3′, 4′)-trihydroxybutylpterine (V) and not 2-amino-4-hydroxy-7-tetrahydroxybutyl-(D-arabo)-pterine. Thus the method of Karrer, *et al.*,[1] and that of Petering and Weisblat[2] yields 7-isomers rather than the 6-isomer, and the nature of the condensation product of D-glucose or D-fructose and I is still in doubt.

Forrest and Walker[4] have reported the synthesis of 2-amino-4-hydroxy-6-tetrahydroxybutyl-(D-arabo)-pterine from D-glucose or D-fructose and I in the presence of hydrazine (III) and boric acid by the application of the method of Ohle and Hielscher[5] for the preparation of 2-tetrahydroxybutylquinoxaline. We also have studied this method and wish to present our findings which extend the reports of Forrest and Walker in a number of ways and which are in disagreement with the latter in some respects. The data presented here depend on the fact that the authors have found that the absorption spectra of 6- and 7-alkyl-

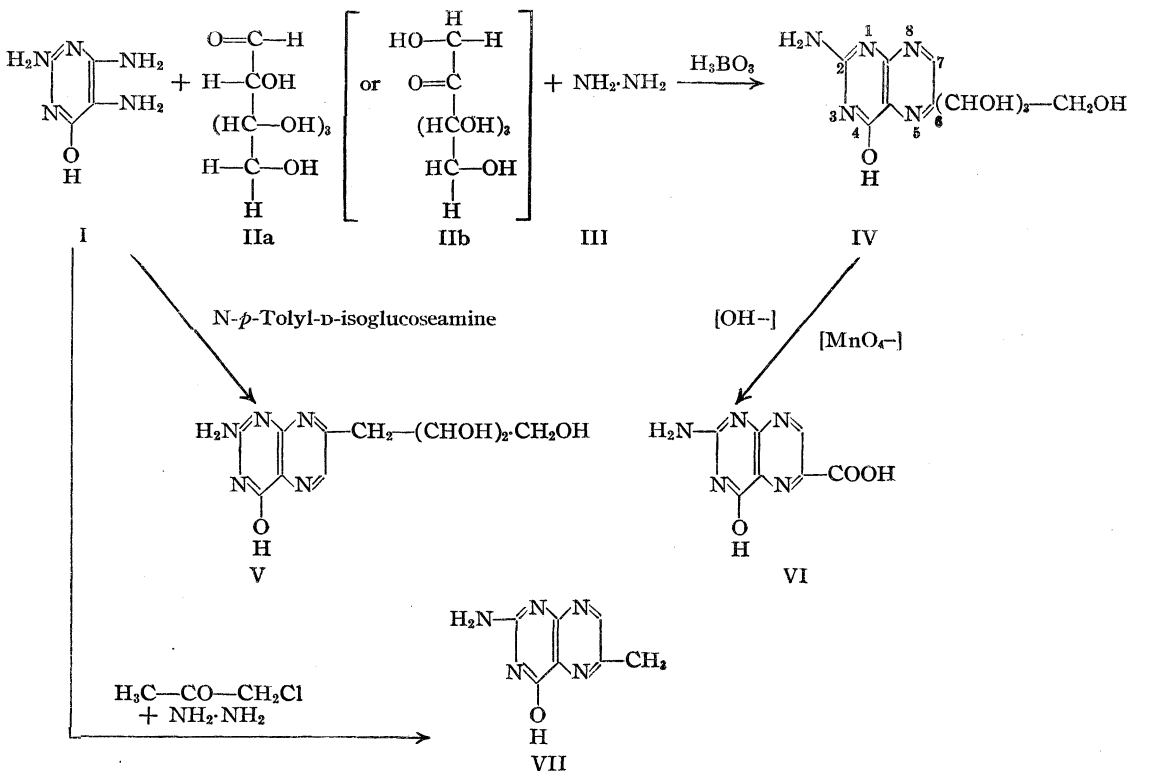
(3) Weygand, Wacker, and Schmied-Kowarzik, *Experientia*, **IV**, 427 (1948).

(4) Forrest and Walker, *Nature*, **161**, 308 (1948); *J. Chem. Soc.*, 79 (1949).

(5) Ohle and Hielscher, *Ber.*, **74**, 13 (1941).



pterines differ both qualitatively and quantitatively to such a marked extent that crude isomer mixtures can be directly analyzed, and the conditions governing the course of the synthesis can be readily determined. Some of the conditions necessary for the preparation of the 6-isomer in high purity have been defined.

Experimental

Materials.—2,4,5-Triamino-6-hydroxypyrimidine (I) was prepared according to the method of Traube[6] with the modification that the reduction of 2,4-diamino-5-nitroso-6-hydroxypyrimidine was carried out with zinc in hydrochloric acid solution, with the result that I-dihydrochloride was obtained. I-hydrosulfate was prepared from a solution of I or I-dihydrochloride by the addition of dilute sulfuric acid. Hydrazine hydrate (85%) was obtained from Eastman Kodak Co. and used without further purification. D-Glucose was used as the commercial hydrate Cerelose. D-Fructose was obtained from Eastman Kodak Co. L-Sorbose was prepared by the oxidation of sorbitol with *Acetobacter suboxydans* according to the method of Wells, *et al.*[7]

Ultraviolet Absorption Spectra.—Ultraviolet spectra were obtained with a Beckman spectrophotometer. Solvents were 0.1 *N* sodium hydroxide, and 0.08 *N* hydrochloric acid. The latter solvent was chosen because it was found easier to dissolve the materials in acidic media if the 0.1 *N* sodium hydroxide solution was diluted 1:10 with 0.1 *N* hydrochloric acid than to make a solution directly in 0.1 *N* hydrochloric acid. The ratio of the maxima was used as an intrinsic property of the molecule and in the case of crude products it was valuable as an analytical tool regardless of the content of inorganic or other non-absorbing impurities. It was found to be characteristic of the 7- or 6-isomer. *E* 252 mμ/*E* 360 mμ for 7-polyhydroxyalkylpterines in 0.1 *N* sodium hydroxide has been found to be 2.2, and *E* 255 mμ/*E* 365 mμ for 6-polyhydroxyalkylpterines in the same solvent has been found to be 3.2.

In studying the condensation of sugars with I in the presence of an oxidizing agent such as hydrazine three general types of conditions were suggested, based primarily on the observations of Ohle and Hielscher[5]: namely, (a) the condensation in the presence of boric acid, (b) the condensation in the absence of boric acid, and (c) the condensation in the presence of oxidizing agents other than hydrazine. The results with other oxidizing agents—*i. e.*, (c)—can be summarized very briefly in the statement that no good substitute was found, although hydrogen peroxide, benzoyl peroxide, hydroxylamine, methylhydrazine, phenylhydrazine and semicarbazide were tried. Pterines were only obtained with hydroxylamine and the hydrazine derivatives, but the yields were no better than if no oxidizing agent had been used. Hydroxylamine seemed to be useful in directing the synthesis to the 6-form, but it did not affect the

(6) Traube, *Ber.*, **33**, 1371 (1900).

(7) Wells, Stubbs, Lockwood and Roe, *Ind. Eng. Chem.*, **29**, 1385 (1937); **31**, 1518 (1939).

yield over the condensation without any oxidizing agent.

Condensation of 2,4,5-Triamino-6-hydroxypyrimidine with Hexoses in the Presence of Boric Acid and Hydrazine.—Since hydrazine is a reducing agent in alkaline solution, there seemed no reason to study its action above *p*H 7. Therefore the *p*H range was kept at 4.5–7.0, since it was found that strongly acidic solution caused the formation of unreactive salts of I. Three moles of boric acid were always used for one mole of hexose and two moles for one mole of pentose. Its role was not studied in any detail when it was found that it could be eliminated. The volume and type of solvent, the concentration of reactants, and the molar ratio of sugar and hydrazine to pyrimidine were studied. After the identity of the products was proved by careful analysis and alkaline permanganate degradation studies the absorption spectra of the polyhydroxyalkylpterines themselves were relied upon to determine the purity of the products and the isomer composition of the mixture.

It was found that maximum yield was only obtained at *p*H less than 7.0. The reaction at *p*H 5.0 was complete in less than two hours, and was adversely affected by dilution. Using a molar ratio of pyrimidine:sugar:hydrazine of 1:1:1 the yield of product with D-glucose was 38% and with D-fructose and D-sorbose 55–60%. The aqueous ethanol condensation method improved the purity of the 6-isomer obtained from D-glucose, but did not affect the yield of product in the case of any of the hexoses used.

Condensation of 2,4,5-Triaminopyrimidine with Hexoses in the Absence of Boric Acid and Presence of Hydrazine.—The same conditions of study as described above apply to this phase of the work. Figure 1 shows graphically the relationship of the molar ratio of sugar × hydrazine/(pyrimidine)^2 *vs.* yield for D-glucose and L-sorbose. In most cases the reactants were mixed in water at a definite *p*H and then heated at 95°. However in the case where the solvent was aqueous alcohol, the procedure used was to dissolve the reactant in the boiling alcoholic solution and then to carry out the reaction by distillation of the solvent at atmospheric pressure until the volume had been brought to a very small amount, at which time a voluminous precipitate appeared. Since this procedure did not increase the yield, but in the case of the hexose aldoses it did increase the purity of the 6-isomer obtained, it is thought that the condensation reaction was slowed up to the point where the aldose could be converted into a ketose or some common intermediate rapidly enough to prevent the formation of appreciable 7-isomer. This seems to be a logical basis for explaining why ketoses were not appreciably affected by this latter method. Something like an Amadori rearrangement appeared to change the aldose to a ketose.

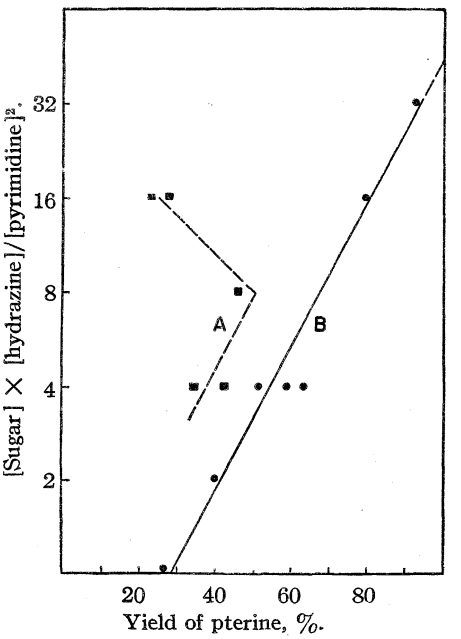


Fig. 1.—Relationship of reactants to yield in reaction without boric acid, time forty-five minutes, temp. 95°: (A), D(+)glucose; (B), L(−)sorbose.

D-Fructose was found to behave in the same manner as L-sorbose, and D-galactose similar to D-glucose in respect to the effect of the conditions described on yield and purity of 6-isomer. Pentose aldoses yielded mixtures of 6- and 7-isomer by the methods described.

The data shown in Fig. 1 were obtained at *p*H 4.5–5.5 and at a reaction time of forty-five minutes. It was found that at 95° the reaction without boric acid required thirty to forty-five minutes for completion. Analytical data together with specific illustration of the methods of preparation and purification of the compounds are given below.

2-Amino-4-hydroxy-6-tetrahydroxybutyl-(D-arabo)-pterine.—2.13 grams of I-dihydrochloride, 1.7 g. of sodium bicarbonate and 4.0 g. of D-glucose monohydrate were mixed with 17 ml. of water; 2.5 ml. of glacial acetic acid and 1.3 ml. of hydrazine hydrate (85%) in 8 ml. of water were added to this solution. The solution in a small erlenmeyer flask was allowed to react on a steam-bath at 90–95° for forty-five minutes. (After twelve minutes of heating a precipitate began to form.) The mixture was cooled and centrifuged, and the precipitate was washed with cold water, hot ethanol and ether (*p*H of mother liquor, 4.9); yield was 1.17 g. Ultraviolet ratio of 0.1 *N* sodium hydroxide solution was 2.99 indicating a product of high 6-isomer content.

One gram of this product was added to 100 ml. of water at 90° and enough ammonia was added dropwise to effect solution; 0.20 g. of Darco G60 was added and the mixture heated fifteen minutes, after which the charcoal was removed by filtration through filter-aid. The filtrate was brought to *p*H 5.0 with acetic acid and cooled to 15°. The precipitate was collected and washed with hot ethanol and ether. The product was dried *in vacuo;* yield 880 mg. *Anal.* Calcd. for $C_{10}H_{13}N_5O_5$: C, 42.4; H, 4.59; N, 24.75. Found: C, 41.2; H, 4.86; N, 24.39. $[\alpha]_D$ −97.26 (0.323% in 0.1 *N* NaOH; *E* 255 mμ/*E* 365 mμ (0.1 *N* NaOH), 2.9.

The ratios of these preparations varied from 2.9 to 3.1 and $E^{g/l.}_{1\ cm.}$ (0.1 *N* NaOH) for similar preparations varied from 71.1–76.7 at 254 mμ and 24.3–24.7 at 365 mμ.

2-Amino-4-hydroxy-6-tetrahydroxybutyl-(L-xylo)-pterine.—2.13 grams of I-dihydrochloride, 1.7 g. of sodium bicarbonate and 3.6 g. of L-sorbose were dissolved in 25 ml. of water. To this solution 2.5 ml. of acetic acid and 1.3 ml. of hydrazine hydrate (85%) were added. The mixture was heated on the steam-bath at 90° for forty-five minutes, after which it was cooled and the precipitate was collected. It was washed well with water and hot ethanol and dried; yield 1.78 g.; ultraviolet ratio in 0.1 *N* sodium hydroxide was 3.0.

One gram of this product was extracted in a Bailey–Walker extraction unit with 110 ml. of water for three and one-half hours. The extract was made alkaline with ammonia to *p*H 11 and the resulting solution was decolorized with 0.2 g. of Darco G60.

The filtrate was brought to *p*H 5.0 with acetic acid and cooled. The precipitate was collected and washed with hot ethanol and ether. The precipitate was dried *in vacuo;* yield 640 mg.; ultraviolet ratio in 0.1 *N* sodium hydroxide = 3.0. *Anal.* Calcd. for $C_{10}H_{13}N_5O_5$: C, 42.4; H, 4.59; N, 24.75. Found: C, 41.3; H, 5.10; N, 23.08. $[\alpha]_D$, −69.0 (0.393% in 0.1 *N* sodsum hydroxide; *E* 354 mμ/*E* 365 mμ (0.1 *N* sodium hydroxide), 3.0. In general this ratio has been found to vary from 2.9–3.2 and the $E^{g/l.}_{1\ cm.}$ in a manner similar to those found for 6-tetrahydroxybutyl-(D-arabo)-pterine preparations.

Oxidation with Alkaline Permanganate

To indicate the basis of the analysis of the ultraviolet absorption spectra for isomer composition the following data obtained by oxidative degradation to the corresponding 6-(or 7)- carboxypterine are presented.

a. 6.1 mg. of 2-amino-4-hydroxy-7-tetrahydroxybutyl-(D-arabo)-pterine was dissolved in 50.0 ml. of 0.1 *N* sodium hydroxide and the solution heated to 70°. A concentrated solution of barium permanganate was added dropwise until a permanent purple color remained after one hour of heating at 70°. The solution was cooled and to it formaldehyde was added dropwise to discharge the purple color. The mixture was filtered through filter-aid and the filter-cake was washed with a small amount of 0.1 *N* sodium hydroxide. The volume was made to 60.0 ml. and the ultraviolet absorption spectrum of a 1:10 dilution was analyzed. The original compound had an ultraviolet ratio of 2.4.

b. In a similar way 6.05 mg. of a preparation with ultraviolet ratio of 3.2 was oxidized and the ultraviolet absorption spectrum of the oxidized product analyzed.

The ultraviolet curves for the carboxypterines described above are given in Fig. 3, and show the variations in the spectra between the 7-isomer and the 6-isomer. These curves check very well with those reported for 7-carboxypterine and 6-carboxypterine by Mowat, *et al.*,[8] and Wittle, *et al.*[9] The oxidation product of a mixture of 6- and 7-tetrahydroxybutylpterines gives ultraviolet curves intermediate between **a** and **b**.

2-Amino-4-hydroxy-6-methylpterine.—Two and four-tenths grams of I-hydrosulfate and 1.06 g. of sodium carbonate were mixed in 25 ml. of water. To this solution were added 1.0 ml. of glacial acetic acid and 1.2 ml. of hydrazine hydrate (85%). The mixture was cooled in an ice-bath. To this cool mixture was added 2.0 g. of monochloroacetone in 5 ml. of alcohol. The mixture was kept cool (25°) during the ensuing reaction, and the *p*H was kept at 6.0 with small additions of solid sodium bicarbonate. A rapid reaction continued and the mixture was kept cool until a red-colored precipitate began to form. It was then heated on a steam-bath for forty-five minutes and cooled. An equal volume of ethanol was added and the mixture centrifuged. The precipitate was washed well with methanol and finally dissolved in 45 ml. of 10% ammonia water. The solution was warmed to 75° and the dark residue was removed by centrifugation. The solution was decolorized with 0.2 g. of Darco G60, and the filtrate brought to *p*H 5.0 with acetic acid. The cooled mixture was centrifuged and the precipitate washed with warm methanol. It was dried with acetone and ether and *in vacuo;* yield 700 mg.

Anal. Calcd. for $C_7H_7N_5O$: N, 39.6. Found: N, 39.3. *E* 252 mμ/*E* 360 mμ (0.1 *N* sodium hydroxide), 3.2.

Discussion

In view of the fact that the $[\alpha]_D$ of the pterine obtained by the condensation of I and D-glucose in the presence of hydrazine is identical with that obtained by the condensation of I and D-glucosone,[6] there seems little doubt that the side-chain is 1′,2′,3′,4′-tetrahydroxybutyl. This means that hydrazine must act as an oxidizing agent and there is no chance for the formation of CH_2 at C_1′.

It has been found that the reaction of I and IIa or IIb in the presence of hydrazine does not require boric acid as an assisting agent. The data obtained also suggest that the reaction requires equimolar quantities of the sugar and hydrazine, and that the action of hydrazine is more rapid and complete with ketoses than with aldoses. The fact that the reaction can be made to go to the 6-isomers with aldoses indicates a possible Amadori rearrangement. In fact it has been found that D-xylose if first treated with aniline or toluidine to give D-arylaminoxyloketose the reaction proceeds smoothly to a 6-isomer, whereas D-xylose or any other pentose yields only a mixture of isomers by any of the methods which were satisfactory for D-glucose. Similarly the preparation of 2-amino-4-hydroxy-6-methylpterine indicates that simple 6-alkylpterines may be readily prepared by the condensation of a suitable ketone and pyrimidine in the presence of hydrazine.

If the data for the aldoses and ketoses are analyzed in such a way that the expression log [sugar × hydrazine/(pyrimidine)^2] is plotted against % yield, the striking difference in behavior of the ketoses and aldoses is shown (Fig. 1).

Increasing either sugar or hydrazine increases the percentage yield based on the pyrimidine for L-sorbose or D-fructose, but for D-glucose this is not true. In the latter case an excess of either component beyond the value where sugar × hydrazine/(pyrimidine)^2 is greater than 8 results in a lowering of the yield.

The conditions for directing the synthesis to the 6-isomer for ketose are broad. In general the *p*H should be kept at 4–7, and the temperature above 90° for rapid reaction. Small volume of aqueous medium is desirable, for it facilitates isolation since the 6-isomer is more soluble than the 7-isomer. Boric acid is of no value.

The conditions for the synthesis of 6-isomer from I and aldose hexoses in the presence of hydrazine include low volume of aqueous medium—*i. e.*, high concentration of reactants—and a slight excess of hydrazine and/or sugar; the molar ra-

tio of sugar × hydrazine/(pyrimidine)[2] should not exceed 8. The *p*H should be kept at 4–7 as in the case of ketoses. An alternate method of preparing 6-isomers of high purity involves the use of aqueous ethanolic medium, the reaction being carried out during the distillation of the solvent at atmospheric pressure.

Under any condition it seems that hydrazine acts as an oxidizing agent with the probable formation of ammonia in the reaction. We have found that all hexoses studied react normally, while all pentose aldoses do not. If, however, the pentoses are converted to ketoses, then the directed synthesis to 6-isomer proceeds smoothly.

The value of the absorption spectra of the polyhydroxyalkylpterines in elucidating the isomer problem can readily be seen from the data of Figs. 2 and 3. More details of the physical properties of pterines will be published later.

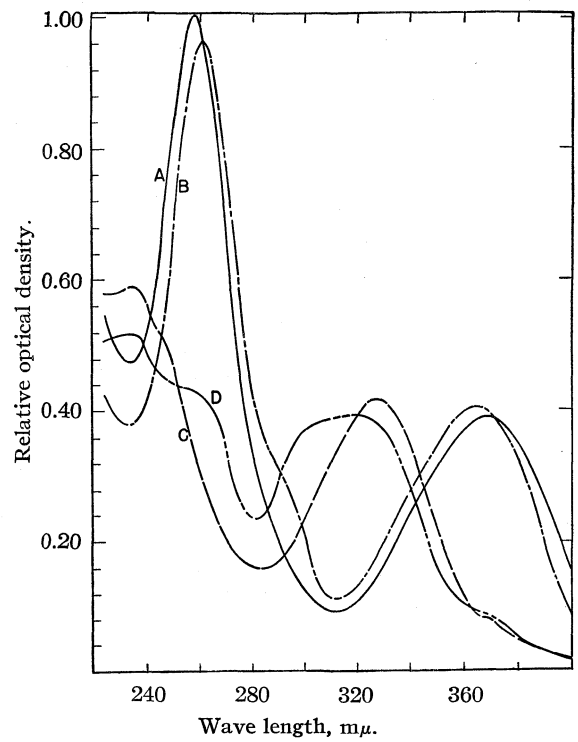

Fig. 3.—Ultraviolet absorption spectra of permanganate oxidation products from polyhydroxyalkylpterine: 2-amino-4-hydroxy-7-tetrahydroxybutylpterine (A) in 0.1 *N* sodium hydroxide, (C) in 0.08 *N* hydrochloric acid: 2-amino-4-hydroxy-6-tetrahydroxybutylpterine, (B) in 0.1 *N* sodium hydroxide and (D) in 0.08 *N* hydrochloric acid.

Summary

Methods for the direct synthesis of 2-amino-4-hydroxy-6-tetrahydroxyalkylpterines from the corresponding aldo- and ketohexoses are described and discussed.

Evidence is presented to show that the ratio *E* 255 mμ/*E* 365 mμ in 0.1 *N* sodium hydroxide of 6-tetrahydroxybutylpterines is 3.2 and is characteristic of these compounds. This fact is used in studying conditions affecting the isomer composition of the products obtained.

Condensation of 2-Pyrrolealdehyde with Hippuric Acid: Isolation of *cis* and *trans* Isomers

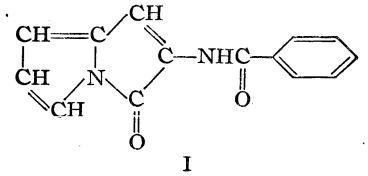
BY WERNER HERZ[1]

In the course of work which had as its objective the synthesis of β-2-pyrrolealanine,[2] the condensation of 2-pyrrolealdehyde with several compounds containing active methylene groups was investigated.[3] Complications were encountered when attempts were made to repeat earlier work[4] dealing with the reaction of pyrrolealdehyde and hippuric acid. It has now been found that these difficulties may be attributed to the formation of geometric isomers of the expected azlactone.

Erlenmeyer[5] first suggested the possibility of *cis–trans* isomerism in the azlactone series when condensing cinnamaldehyde with hippuric acid, although he was unable to isolate the two forms. Carter and co-workers[6] obtained *cis* and *trans* isomers of α-benzoylaminocrotonic azlactone and of α-benzoylaminocinnamic azlactone on heating the α-benzoylamino-β-methoxy acids with acetic anhydride. It is interesting to note that the condensation of 2-indolealdehyde with hippuric acid[7] is not reported to result in the formation of a mixture, nor were two products obtained from the few substituted pyrrolealdehydes subjected to the azlactone synthesis.[8]

Asahina and Mitsunaga[4] reported that 2-pyrrolealdehyde condenses with hippuric acid to give a product which sinters at 155° and melts at 163°. Hydrolysis with 1% sodium hydroxide resulted in two distinct acids, m. p. 173° and m. p. 235°. The only empirical formula given, that of the higher-melting acid, corresponds to the composition of the expected α-benzoylamino-β-(2-pyrrole)-acrylic acid.

The data reported in this article differ markedly from the results reported by these authors. Recrystallization of the crude product from most solvents yielded crystals melting in the range 145–163° which indicated the presence of a mixture. Crystals obtained by recrystallization from benzene melted sharply at 173°; in the following this compound will be referred to as azlactone II. From the mother liquors, fractions with considerably lower melting points were obtained. All fractions gave analyses correct for the predicted azlactone. The existence of *cis* and *trans* isomers of 2-phenyl-4-pyrrolal-5-oxazolone was therefore suspected. Another possibility, the formation of a lactam (I) in a manner similar to the formation of a coumarin from salicylaldehyde and hippuric acid,[9] was ruled out by the deep color of all fractions and by the fact that the infrared spectra



I

which would be expected to differ widely if the lactam were present showed only minor variations.

Hydrolysis of the low-melting mixture with 0.4 *N* sodium hydroxide yielded two isomeric acids of the composition expected for α-benzoylamino-β-(2-pyrrole)-acrylic acid. Acid I, dec. 192°, precipitated immediately and gave a methyl ester of m. p. 153°. Acid II, dec. 239–240°, separated on standing and was characterized by a methyl ester of m. p. 179°. Undoubtedly it is identical with the high-melting acid of Asahina and Mitsunaga.[4]

Dehydration of acid I with acetic anhydride yielded an azlactone, 2-phenyl-4-pyrrolal-5-oxazolone I, different from azlactone II. Acid II on treatment with acetic anhydride regenerated azlactone II. The infrared spectra of the pure azlactones were similar, but not identical. In the double-bond region, azlactone I exhibited two strong bands at 1740 cm.$^{-1}$ (lactone frequency) and at 1637 cm.$^{-1}$ (C=N frequency); in azlactone II these bands occur at 1751 and 1649 cm.$^{-1}$,[10]

The alkaline hydrolysis of the azlactones was further complicated by the formation of a third product arising from the reaction of acid II with alkali. This compound, an acid of formula $C_{14}H_{10}N_2O_2$, could be obtained from acid II or directly from azlactone II by hydrolysis with 1% sodium hydroxide; it frequently contaminated preparations of acids I or II when base was in excess. The absence of NH frequencies from the infrared

spectrum of the acid and its methyl ester as well as the solubility of both compounds in dilute acid suggests the formula of 4-phenyl-pyrrolo[1,2-*C*]-pyrimidine-2-carboxylic acid (II), the product of an intramolecular condensation between the benzoyl radical and the pyrrole nitrogen. If this interpretation is correct, configurations may be assigned to azlactones I and II and the acids resulting from their hydrolysis. Because the pyrrolopyrimidine could not be obtained from acid I or azlactone I, the pyrrole nitrogen and the benzoyl group in these compounds must be *trans* to each other, whereas the *cis* configuration of acid II permits ring closure to occur. It is intended to investigate the applicability of this reaction to other compounds of this type.

Experimental

2-Phenyl-4-pyrrolal-5-oxazolone, II.—An intimate mixture of 9 g. of 2-pyrrolealdehyde,[12] 18 g. of hippuric acid and 18 g. of anhydrous sodium acetate was heated on the steam-bath with 45 ml. of acetic anhydride. After one hour, the mixture was cooled, broken up with a stirring rod, triturated with water, filtered, washed with water and dried. The yield of dark-brown material was 16.5 g. Eleven grams of the crude product was extracted with 200 ml. of boiling benzene. The benzene solution was treated with charcoal and deposited 1.5 g. of orange plates, m. p. 173°. The melting point was not raised by further recrystallizations from benzene. This fraction had the analysis given below. On evaporation of the benzene mother liquor to 125 ml. and cooling, 1.1 g. of material, m. p. 172°, precipitated. Further evaporation and cooling yielded 3.5 g. of material melting in the range 135–145°.

Anal.[13] Calcd. for $C_{14}H_{10}N_2O_2$: C, 70.58; H, 4.23; N, 11.76. Found: C, 71.10; H, 4.49; N, 11.76.

Five grams of the crude condensation product was extracted with two 50-ml. portions of boiling ethanol. The combined extracts were treated with charcoal and on cooling deposited 1.5 g. of yellow crystals, m. p. 148–163°. On evaporation of the filtrate to smaller volume, 0.6 g. of material melting in the same range was obtained. Dilution of the mother liquor with water yielded 1.6 g. of lower-melting material. Hydrolysis experiments showed that the first two fractions consisted almost exclusively of azlactone II in spite of the melting point range. Reprecipitation from pyridine solution with water raised the m. p. to 173°.

α-Benzoylamino-β-(2-pyrrole)-acrylic Acids I and II.—The crude product resulting from the condensation of 9 g. of 2-pyrrolealdehyde and 18 g. of hippuric acid was stirred with one portion of 50 ml. and one portion of 25 ml. of cold ethanol. This removed a considerable portion of azlactone II. The undissolved material was recrystallized from acetone–water and weighed 4.5 g., m. p. 155–160°. Four grams was heated on the steam-bath with 200 ml. of 0.4 *N* sodium hydroxide. After three hours, the solution was acidified with concd. hydrochloric acid. A light-yellow precipitate which appeared to decompose rapidly was filtered immediately and washed with water. The filtrate deposited 1.4 g. of grey-blue needles on standing. Five recrystallizations of the first precipitate from dilute ethanol, accompanied each time by treatment with charcoal, gave 0.23 g. of slightly-colored crystals (acid I) which decomposed at 192° when the capillary was immersed at a bath temperature of 185°.

Anal. Calcd. for $C_{14}H_{12}N_2O_3$: C, 65.61; H, 4.72; N, 10.94. Found: C, 65.74; H, 4.94; N, 10.80.

The second product was dissolved in dilute sodium hydroxide and filtered from insoluble material. The precipitate obtained on acidification was recrystallized three times from dilute ethanol, each recrystallization being accompanied by treatment with charcoal. The almost white needles weighed 0.25 g. and decomposed at 239–240° when the capillary was immersed at 230° and the bath was heated up rapidly.

Anal. Calcd. for $C_{14}H_{12}N_2O_3$: C, 65.61; H, 4.72; N, 10.94. Found: C, 65.86; H, 4.90; N, 10.96.

Hydrolysis of 2 g. of the low-melting material obtained from the benzene mother liquors of azlactone II, using 80 ml. of 0.5 *N* sodium hydroxide, yielded 0.85 g. of crude acid I, contaminated by acid II.

Methyl Ester of Acid I.—A solution of 95 mg. of acid I in 5 ml. of methanol was treated with an ethereal solution of diazomethane. After removal of the ether, the solution was diluted with water and deposited 79 mg. of ester. Recrystallization from dilute methanol gave needles melting at 153°.

Anal. Calcd. for $C_{15}H_{14}N_2O_3$: C, 66.65; H, 5.22; N, 10.37. Found: C, 66.85; H, 5.44; N, 10.46.

Methyl Ester of Acid II.—In the same way, 93 mg. of acid II gave 87 mg. of light-yellow crystals melting at 179°. The ester was also obtained in 70% yield when azlactone II was treated with sodium methoxide in methanol, following the procedure of Fischer and Hofmann.[8]

Anal. Calcd. for $C_{15}H_{14}N_2O_3$: C, 66.65; H, 5.22; N, 10.37. Found: C, 66.88; H, 5.41; N, 10.11.

2-Phenyl-4-pyrrolal-5-oxazolone I.—A mixture of 27 mg. of pure acid I and 1 ml. of acetic anhydride was warmed on the steam-bath for ten minutes. Dilution with water caused the separation of a light-brown precipitate weighing 24 mg. Repeated slow crystallization from ethanol yielded golden needles, m. p. 186°, mixed m. p. with azlactone II 145–155°.

Anal. Calcd. for $C_{14}H_{10}N_2O_2$: C, 70.58; H, 4.23; N, 11.76. Found: C, 70.41; H, 4.16; N, 11.63.

Treatment of 38 mg. of acid II with acetic anhydride gave 33 mg. of orange crystals, m. p. 173°, showing no depression on admixture of azlactone II.

Hydrolysis of Azlactone II with 1% Sodium Hydroxide.—A mixture of 300 mg. of azlactone II and 15 ml. of 1% sodium hydroxide solution was warmed on the steam-bath for one hour until the azlactone was dissolved completely. The red solution was cooled and made barely acid to congo-red paper. A light-green precipitate separated. It was filtered and washed rapidly to prevent decomposition. The mother liquor on chilling deposited a small amount of acid II. The precipitate was recrystallized three times from 10 ml. of ethanol, using charcoal. The light-green needles were soluble in dilute base and acid, insoluble in water, m. p. 182–183° with decomposition. The infrared spectrum showed the complete absence of any —NH and C=O frequencies other than those ascribed to conjugated carboxyl at 1680 cm.$^{-1}$ and acid —OH. In ethanol solution the compound gave a carmine-red color with ferric chloride.

Anal. Calcd. for $C_{14}H_{10}O_2N_2$: C, 70.58; H, 4.23; N, 11.76. Found: C, 70.59; H, 4.25; N, 11.71.

This acid was also obtained by warming acid II with 1% sodium hydroxide solution on the steam-bath.

The methyl ester was prepared by dissolving 150 mg. of the acid in methanol and adding an ether solution of diazomethane. Removal of the ether followed by dilution with water yielded a yellow oil which solidified on standing. Three recrystallizations from methanol–water gave yellow needles, m. p. 107°, soluble in dilute acid, insoluble in base. The infrared spectrum contained a strong band at 1718 cm.$^{-1}$ which can be ascribed to a conjugated ester group.

Anal. Calcd. for $C_{15}H_{12}O_2N_2$: C, 71.44; H, 4.84; N, 11.11. Found: C, 71.35; H, 5.06; N, 11.13.

Summary

The condensation of 2-pyrrolealdehyde with hippuric acid and acetic anhydride gives rise to two isomeric azlactones. Configurations have been tentatively assigned to these isomers on the basis of an intramolecular condensation which only one of them appears to undergo.

Comparative Properties of Some Methyl Substituted 8-Quinolinols

BY JOHN P. PHILLIPS[1] AND LYNNE L. MERRITT, JR.

As part of an investigation in this Laboratory of some new analytical reagents of the 8-quinolinol series, the 2- and 4-methyl derivatives were studied.[2,3] Because these derivatives showed some rather interesting differences from each other and from 8-quinolinol, the properties here described were determined and the results compared.

Experimental

Purification of Materials.—The substituted 8-quinolinols were prepared and purified as previously described.[3,4] A further check on the purity of the 8-quinolinol and 2-methyl-8-quinolinol used was obtained through their quantitative bromination[5] with standard potassium bromate, both analyzing better than 99.7%.

Infrared Spectra.—All spectra were obtained with a Beckman IR-2 instrument with automatic recording. The intensity curves for solvent and solution were recorded on the same graph and the ratios of the two curves calculated at corresponding wave lengths in order to get per cent. transmission. The assignment of wave lengths was calculated from the known absorption bands of carbon tetrachloride, carbon dioxide and water vapor with an estimated accuracy of $\pm 0.05\mu$ over most of the range studied.

Approximately saturated solutions in carbon tetrachloride in 0.1 mm. thick salt cells were used throughout.

Ultraviolet Spectra.—Curves were recorded with a Beckman Model DU Quartz Spectrophotometer using 1.00 cm. cells and slit widths from 0.1–2.0 mm. as required. Readings were made every one millimicron in the vicinity of an absorption maximum and at somewhat wider intervals elsewhere. All compounds obeyed Beer's law satisfactorily in the concentration range studied. Molecular extinctions are considered accurate to two significant figures.

Powder Diffraction Lines.—The finely powdered samples, mounted on a rotating hard glass fiber coated with vaseline, were exposed for five hours to filtered copper X-ray radiation. The "*d*" values, calculated in the usual way, are the average values from two or more photographs for each compound. Relative intensities were estimated visually.

Quantitative Precipitations of Metals.—The procedure was the same as previously described[2] except that, owing to coprecipitation of the excess substituted quinolinol, it was usually necessary to ignite the precipitates to the oxides for weighing.

The standard solutions of Cu^{++}, Zn^{++}, Mg^{++}, Co^{++}, Mn^{++}, Fe^{+++} and Al^{+++} were prepared by standard methods from weighed quantities of reagent grade chemicals and further analyzed by precipitation with 8-quinolinol. Determinations were made at 0.2 *p*H unit intervals to obtain the *p*H values at which precipitation begins and is complete.

Reactions with Diazomethane.—A 100–200% excess of an ether solution of diazomethane was added to an ether solution of the substituted 8-quinolinol. Red precipitates formed with 8-quinolinol, 4-methyl-8-quinolinol and 5,7-dibromo-8-quinolinol but did not form with 2-methyl- or 2,4-dimethyl-8-quinolinol. The red products were filtered and recrystallized from benzene; they had indefinite decomposition points and were, therefore, characterized by their ultraviolet and visible absorption spectra. Nitrogen analyses on the product from 8-quinolinol (7.20%) do not conform to that calculated (8.80%) from the structure proposed by Schenkel-Rudin.[6]

Results and Discussion

The infrared absorption spectra (Figs. 1–4) from 2–11μ of these four quinolinols in approximately saturated solutions show several bands that can be correlated with known structural features of all the compounds, but few characteristics capable of distinguishing the compounds from each other. (It is evident from the graphs that 4-methyl-8-quinolinol has a low solubility in carbon tetrachloride compared to its 2-methyl isomer.)

The absorption band at 2.8μ is evidently the O–H stretching band; it is completely absent in the 8-methoxy derivatives of these compounds.[7] The bands at approximately 3.2–3.3μ are due to C–H stretching and vary somewhat in wave length and structure probably because of the different kinds of C–H linkages in the different compounds. (The absence of these bands in 4-methyl-8-quinolinol can be attributed to the low concentration of the solution.) The strong absorption maxima at about 6.35, 6.65 and 6.8μ are fundamental frequencies of the aromatic ring system. The bands at 7.1, 7.3 and 7.5μ are probably due to C–H bending, the one at 7.5μ perhaps being caused by the C–H bond in the active 2-methyl group since it is lacking in 8-quinolinol and 4-methyl-8-quinolinol. Maxima at 7.9–8.1μ are perhaps associated with C–O or C–N stretching vibrations.

No maxima identifiable with a C=O linkage could be found in any of these compounds, although the existence of a considerable proportion of the keto tautomer of 8-quinolinol in non-

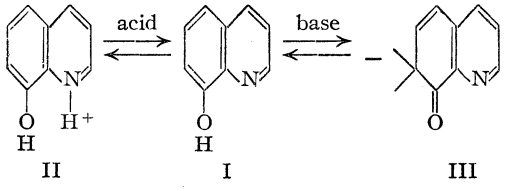
polar solvents appears probable from other considerations.[8]

The above conclusions should be viewed with caution, however, since overlapping can obscure many absorption maxima and lead to erroneous correlation of structural features with observed spectra.

The maxima in the ultraviolet absorption spectra of these compounds from 225–400 mμ (Table I) furnish additional information about their structure. (It was not considered necessary to graph these spectra since they are all very similar in shape to the curves for 8-quinolinol already recorded in the literature.[9])

The considerable change in the spectra in acidic and basic solvents is probably caused by structure changes of the following sort[10]



The spectra of the copper chelates is of interest because of the complete similarity, except for a large bathochromic shift, of their spectra to those of the parent compounds, which suggests that the role of the copper in the chelate is the same as that of the acidic hydrogen in 8-quinolinol. Similar spectra were observed with the chelates of other divalent metals.

For characterization purposes, the X-ray powder diffraction lines of these compounds and a few derivatives were measured (Table II).

same properties with the important exception that 2-methyl- and 2,4-dimethyl-8-quinolinol will not form insoluble chelate compounds with aluminum, the smallest ion of the group tested. Since 4-methyl-8-quinolinol will precipitate aluminum, it seems probable that the 2-methyl group prevents reaction with aluminum by steric hindrance. Further evidence of steric effects by the 2-methyl group is the observation that 2-methyl- and 2,4-dimethyl-8-quinolinol do not give the red addition products with diazomethane that are obtained from 8-quinolinol and 4-methyl-8-quinolinol under comparable conditions.

Quantitative data on the precipitation behavior of these compounds with metals are presented in Table III; the similar results for 8-quinolinol as determined by Goto[11] are included for comparison.

TABLE III

THE *p*H OF PRECIPITATION OF METAL CHELATES OF SUBSTITUTED 8-QUINOLINOLS

Substituent ion	None[d] Start[a]	None[d] End[b]	4-CH_3 Start	4-CH_3 End	2-CH_3 Start	2-CH_3 End	2,4-$(CH_3)_2$ Start	2,4-$(CH_3)_2$ End

Cd^{+2}	2.2	2.7	...	3.4	2.9[c]	4.5[c]	2.4	4.8

[a] The highest *p*H without any precipitation. [b] The lowest *p*H at which the metal is wholly precipitated. [c] Previously determined.[2] [d] Previously determined.[11]

It is interesting that the order of increasing *p*H at which a given metal ion is precipitated by these four compounds is roughly the order of decreasing acidity of the substituted 8-quinolinols (the ionization constants have been previously reported[3]).

8-Quinolinol — increasing K_a ↓
4-Methyl-8-quinolinol ↑
2-Methyl-8-quinolinol
2,4-Dimethyl-8-quinolinol — increasing *p*H ↓

This is explained by noting that, although the weaker acids should form more stable complexes with metallic ions[12] and should, therefore, form precipitates in more acid solutions, it is necessary to go to more basic solutions in order to obtain comparable amounts of the active chelating ion. The latter effect is apparently the predominant one.

Summary

1. The ultraviolet and infrared absorption spectra of the 2- and 4-methyl derivatives of 8-quinolinol have been measured and their correlation with structure discussed.

2. The precipitation behavior of these compounds with metal ions has been determined and evidence for steric hindrance by the 2-methyl group in such reactions presented.

3. The possible relation of the function of the acidic hydrogen in 8-quinolinol to that of the metal ion in the corresponding chelate, as shown by the relation of K_a to *p*H of precipitation, has been pointed out.

Preparation of Some Substituted 8-Hydroxy- and 8-Methoxyquinolines

BY JOHN P. PHILLIPS,[1] REBECCA LEASH ELBINGER[1,2] AND LYNNE L. MERRITT, JR.

As a result of the discovery[3] that 8-hydroxyquinaldine differed in its analytical behavior from 8-hydroxyquinoline, the compounds here described were synthesized with the hope of obtaining more selective analytical reagents of the 8-hydroxyquinoline series.

The steric nature of the failure of 8-hydroxyquinaldine to react with aluminum was demonstrated by the observation that all the 8-quinolinols studied having alkyl groups in the 2-position would not react with aluminum while the isomeric compounds with substituents in the 3- and 4-positions would react. With the expectation that larger groups in the 2-position would create greater steric hindrance, perhaps enough to prevent reaction with other metal ions besides aluminum, a series of 2-aryl- and 2-styryl 8-quinolinols was prepared, but qualitative tests with several representative metal ions indicated no improvement in selectivity.

All alkyl substituted 8-hydroxy- and 8-methoxyquinolines (Table I) were made by the Doebner–

von Miller reaction[4] between α,β-unsaturated carbonyl compounds and *o*-aminophenol or *o*-anisidine. No effective oxidizing agent for these reactions was found. (Nitrobenzene, *o*-nitrophenol and picric acid were tried.) This probably accounts, in part, for the very low yields obtained.

The 2-aryl-8-quinolinols (Table I)' were prepared by the reaction of an excess of the proper lithium aryl with 8-quinolinol according to the method of Gilman.[5] The preparation of the corresponding 8-methoxy derivatives from 8-methoxyquinoline could be effected with greater economy of the lithium aryl, but it was not found possible to cleave the resulting ethers by the usual procedures at ordinary pressures using hydriodic acid, hydrobromic acid or potassium hydroxide and ethylene glycol.

2-Styryl-8-quinolinol and some related compounds (Table I) were made by the condensation, by heating, of 8-hydroxyquinaldine with benzaldehydes.

Most of the 8-quinolinols prepared showed little or no fluorescence under ultraviolet light, while the corresponding 8-methoxy compounds generally had a strong blue-white fluorescence.

Data on the ultraviolet and infrared absorption spectra, X-ray powder diffraction patterns and quantitative reactions with metal ions of these compounds will be reported later.

Experimental

A. The general procedure used to make the alkyl substituted 8-quinolinols was as follows:

One-quarter of a mole (27.3 g.) of *o*-aminophenol was added to 100 ml. of concentrated hydrochloric acid in a flask fitted with condenser, stirrer and dropping funnel. The flask was heated to about 100° and a 30–100% excess of the appropriate α,β-unsaturated carbonyl compound added dropwise over a period of thirty to forty-five minutes. After stirring for six hours at 100–120°, the mixture was allowed to stand overnight and then steam distilled briefly to remove volatile impurities. It was then made slightly alkaline to litmus and steam distilled until all the product had come over. The products were recrystallized from alcohol–water mixtures.

The procedure used to make the 8-methoxyquinolines from *o*-anisidine differed from the above in that, after making the solution alkaline to litmus with sodium hydroxide, a gummy solid separated which was distilled under reduced pressure to obtain the product. The 8-methoxyquinolines were recrystallized from petroleum ether or cyclohexane.

In several cases it was possible to prepare the equivalent of the α,β-unsaturated carbonyl compounds by saturating a mixture of the aldehyde and ketone which were to be condensed with dry hydrogen chloride and using the resulting chloroketone without isolation, as suggested by Bauer and Engler.[7] This procedure naturally gave lower yields than when the intermediate unsaturated carbonyl compounds were isolated before use, as was usually done. Aldol condensation type reactions recorded in the literature were used to make these compounds.

B. The general method for making the 2-aryl-8-quinolinols was the following:

In a three-necked flask fitted with stirrer, dropping funnel, and condenser protected from moisture, the whole system being swept with dry nitrogen, were placed 300 ml. of dry ether and 3.5 g. (0.5 mole) of lithium metal cut into thin shavings. One quarter of a mole of the required aryl bromide was added dropwise, a vigorous reaction occurring. After the reaction was over, 0.05 mole (7.3 g.) of 8-quinolinol dissolved in ether was added over five to ten minutes. Stirring was continued for forty-five minutes and the mixture was then poured over ice and the ether layer separated. After removal of the ether by distillation, the residue was dissolved in hot dilute hydrochloric acid and then neutralized with sodium carbonate. An oil (or sometimes a solid) separated which was distilled under reduced pressure. The products generally boiled between 240 and 320° at approximately 25 mm. They were recrystallized from 95% alcohol.

The corresponding 8-methoxy compounds were prepared similarly from 8-methoxyquinoline except that, after removing the ether, vacuum distillation gave the desired products directly. These were recrystallized from petroleum ether.

The use of nitrogen was later found to be an unnecessary precaution since refluxing ether served to keep air out of the reaction flask.

C. The condensation of 8-hydroxyquinaldine or 8-methoxyquinaldine with aromatic aldehydes was effected by this general procedure:

One-tenth of a mole (15.9 g.) of 8-hydroxyquinaldine was refluxed with 30–40 g. of the required aldehyde if it boiled below 180° or heated at 150–175° if the aldehyde was high boiling, for five hours. The mixture was then

vacuum distilled to obtain the products, which were all light yellow solids. These compounds were recrystallized from 95% alcohol.

Acknowledgment.—One of the authors (J. P. P.) wishes to acknowledge the help of a du Pont Fellowship in Chemistry for the year 1948–1949. The authors also wish to acknowledge the assistance of Mrs. B. Jarvis who performed the microanalyses.

Summary

Several new 8-quinolinols substituted in the pyridine ring have been prepared. Several new substituted 8-methoxyquinolines have also been prepared. The steric hindrance of substitution of 8-quinolinol in the 2-position on the reaction with aluminum ion is shown by the fact that shifting the substituent to the 3- or 4-position permits reaction.

Antispasmodics. II. Tertiary Aminoalkane Thiol Esters of Disubstituted Acetic Acids

BY H. G. KOLLOFF, JAMES H. HUNTER, E. H. WOODRUFF AND ROBERT BRUCE MOFFETT

Studies of synthetic spasmolytic agents of the type described in a recent report from this Laboratory[1] have been extended to the preparation of a series of analogous thiol esters for the purpose of comparative evaluation of their antispasmodic activity. This investigation appeared desirable since data on such thiol esters are relatively limited.[2,3]

In the synthesis of the thiol esters whose salts are listed in Table II, disubstituted acetic acid chlorides were condensed with 2-diethylaminoethanethiol[4] and various pyrrolidylalkanethiols. The latter were prepared from the corresponding alcohols,[5] via the intermediate pyrrolidylalkane chloride hydrochlorides and isothiouronium chloride hydrochlorides recorded in Table I, by the general procedure of Albertson and Clinton.[4] In order to suppress spontaneous oxidation of these thiols, the ethereal extract from the alkaline decomposition of the pyrrolidylalkane isothiouronium salts was dried and treated with the appropriate acid chloride immediately.

Preliminary pharmacological assays by Dr. Milton J. Vander Brook of our Department of Pharmacology indicate that these thiol esters have less activity against acetylcholine chloride induced spasms than the corresponding oxygen esters.

Experimental[6,7]

The examples below illustrate the procedures used for the preparation of the various intermediates and thiol ester salts.

2-(2-Methyl-1-pyrrolidyl)-ethyl Chloride Hydrochloride.—Hydrogen chloride gas was passed into a cooled solution of 51.8 g. (0.4 mole) of 2-(2-methyl-1-pyrrolidyl)-ethanol[5] in 200 ml. of dry benzene until strongly acid. Then 36.3 ml. (0.5 mole) of thionyl chloride was added slowly with cooling in an ice–water-bath. When the addition was complete the solution was heated on a steam-bath for two hours during which time hydrogen chloride and sulfur dioxide were evolved. The chloride hydrochloride crystallized and, after cooling, was collected and washed first with benzene, then with absolute ether, and dried giving a quantitative yield of nearly white crystals, m. p. 183.5–185°. This was used without further purification for the preparation of the isothiouronium salt. An analytical specimen was prepared by recrystallization from isopropyl alcohol using decolorizing charcoal; m. p. 184–185.5°.

2-(2-Methyl-1-pyrrolidyl)-ethyl-isothiouronium Chloride Hydrochloride.—A solution of 46.0 g. (0.25 mole) of the above chloride hydrochloride and 19.0 g. (0.25 mole) of thiourea in 50 ml. of 95% ethanol was refluxed on a steam-bath for twenty hours. The product which separated after cooling was collected, washed successively with ethanol and acetone, and recrystallized from about 250 ml. of 95% ethanol giving 43.3 g. of nearly white crystals, m. p. 216–218°. Dilution of the filtrate with acetone gave an additional 7.9 g., m. p. 215–217°.

2-(2-Methyl-1-pyrrolidyl)-ethyl Phenyl-Δ^2-cyclopentenylthiolacetate Hydrochloride.—In an apparatus designed for continuous extraction[8] of an aqueous solution by ether was placed a solution of 16.9 g. (0.065 mole) of the above isothiouronium salt in 30 ml. of water and the air in the apparatus displaced with nitrogen. A solution of 5.3 g. of sodium hydroxide in 20 ml. of water was added and the mixture extracted continuously with peroxide-free ether for six hours. The ether extract was dried over Drierite, filtered and added to a solution of 13.3 g. (0.06 mole) of phenyl-Δ^2-cyclopentenylacetyl chloride[9] in 50 ml. of dry benzene. The mixture became warm and an oil separated. After refluxing for two hours, the mixture was shaken with ice-water containing a small amount of hydrochloric acid. The ether layer was extracted again with water and the combined aqueous solution washed with ether and made basic with sodium hydroxide. The oily ester which separated was taken up in ether, washed well with water and dried first over sodium sulfate and then over Drierite. The solution was filtered and hydrogen chloride gas introduced until strongly acidic. The hydrochloride separated as a viscous oil which crystallized partly on standing. After decanting the ether, the crude hydrochloride was dissolved in warm ethyl acetate. On cooling it crystallized and was collected, washed with ethyl acetate and dried. It was recrystallized from ethyl acetate giving 7.0 g. of white crystals, m. p. 111–115°.

2-(2-Methyl-1-pyrrolidyl)-ethyl-Δ^2-cyclopentenyl-*n*-propylthiolacetate Acid Citrate.—The hydrochloride cor-

[a] This compound was prepared by Dr. William Bradley Reid, Jr., in this Laboratory. [b] Yield after recrystallization from methyl ethyl ketone. [c] This yield represents the first crop of pure crystals. An additional yield of 32% of material melting at 170–175° was obtained from the filtrate. [d] Yield after recrystallization from a mixture of methyl ethyl ketone and ethyl acetate. [e] Crystallized from ethanol with the aid of decolorizing charcoal. [f] The yield reported was obtained by diluting the reaction mixture with absolute ether. It was nicely crystalline material melting at 156–161° and was used without further purification. A small sample for melting point and analysis was recrystallized from a mixture of methyl ethyl ketone and a little ethyl acetate. [g] Yield of material, m. p. 214–217°, obtained directly from the reaction mixture. A small sample was recrystallized from ethanol for melting point and analysis.

responding to this compound, prepared by a method similar to that described above, was an intractable oil. It was reconverted to the free base, and a solution of 10.7 g. (0.036 mole) of this basic ester in 50 ml. of ethyl acetate was treated with 7.66 g. (0.04 mole) of citric acid in 10 ml. of absolute ethanol. The product which separated was recrystallized from a mixture of methyl ethyl ketone and ethyl acetate giving 14.2 g. of white crystalline powder with the properties listed in Table II.

Phenylisobutylacetyl Chloride.—Crude phenylisobutylacetic acid[10] was prepared by alkylation of diethyl phenylmalonate with isobutyl bromide, followed by hydrolysis and decarboxylation. Although the crude product was contaminated with phenylacetic acid, it was converted to

(10) This acid has been prepared by Bodroux and Taboury [*Bull. soc. chim.*, 7, 668 (1910)] by the alkylation of benzyl cyanide, followed by hydrolysis.

the acid chloride with thionyl chloride, and the resulting mixture of acid chlorides separated by distillation through a 12-in. column packed with 1/8-in. glass helices. After removing the phenylacetyl chloride, a sharp cut of the desired acid chloride was obtained; b. p. 115° (14 mm.), $n^{25}D$ 1.5071.

Anal. Calcd. for $C_{12}H_{15}ClO$: Cl, 16.83. Found: Cl, 16.50.

Phenyl-Δ²-cyclohexenylacetyl Chloride.—A solution of 125.7 g. (0.615 mole) of phenyl-Δ²-cyclohexenylacetic acid[1] in 100 ml. of dry benzene and 73 ml. of thionyl chloride was heated on a steam-bath for one hour. After removal of the solvent the product was distilled through a short column giving 111 g. (77%) of yellow product, b. p. 97° (0.04 mm.), $n^{25}D$ 1.5478.

Anal. Calcd. for $C_{14}H_{15}ClO$: Cl, 15.11. Found: Cl, 15.24.

Summary

Ten new pyrrolidylalkyl and diethylaminoethyl thiol esters of disubstituted acetic acids have been prepared.

Several new intermediate pyrrolidylalkyl chloride hydrochlorides and isothiouronium salts are reported.

Methoxysubstituted Benzamidines as Local Anesthetics[1]

BY N. J. SINTOV,[2a] J. S. RODIA, J. A. TURSICH,[2b] H. L. DAVIS AND G. L. WEBSTER

The hydrochlorides of certain amidines, derived from both aliphatic and aromatic acids, have been shown to exhibit local anesthetic activity.

Most, if not all, of the fatty acid amidines fall into three categories: (1) homologs of Holocaine, $CH_3 \cdot C(NC_6H_4OC_2H_5)(NHC_6H_4OC_2H_5)$, (2) Holocaine or its homologs in which different substituents appear on the N-substituted phenyl groups, and (3) compounds of the type of Holocaine or its homologs in which one or both of the substituents on the nitrogen atoms are varied.

Taube[3] prepared a number of amidines of the Holocaine type in which the two phenyl groups were substituted with methoxy or ethoxy groups, ortho (or para) in one phenyl group and para (or ortho) in the other.

Goldschmidt[4] prepared a series of similarly substituted formamidines which showed local anesthetic activity. He also prepared formamidines in which the two N-substituted phenyl groups were substituted in the para-position with either carbethoxy or carbomethoxy groups.

Hill and Rabinowitz[5] attempted to overcome the undesirable characteristics of Holocaine by substituting for the methyl group the ethyl, propyl, butyl, isobutyl and benzyl radicals. In the amidines containing the two latter radicals one of the phenetidyl groups was replaced by an amino group and one phenetidyl radical in Holocaine was replaced by a diethylamino group. Hill and Cox[6] modified the lower homologs of Holocaine by substituting for one or both of the phenetidyl groups the *p*-carbethoxyphenyl group.

The substituted and unsubstituted benzamidines have not generally exhibited local anesthetic activity. Easson and Pyman[7] prepared and tested meta and para aminobenzamidine and 3,4-dimethoxybenzamidine, none of which showed local anesthetic properties, but they found slight anesthetic activity in both *p*-carbethoxybenzamidine and *p*-carbethoxyphenylguanidine. These authors, reasoning from the structure and properties of Holocaine, prepared and tested N-veratrylbenzamidine and found that it "had well-marked" local anesthetic character.

With the results of this previous work in mind, the purpose of these experiments was to prepare and test pharmacologically N,N'-diphenylbenzamidines in which one or more of the three phenyl groups were substituted with one or more methoxy groups.

These amidines, listed in Table I, were prepared by a modification of the method of Hill and Cox[6] in yields ranging from 32 to 62%.

In the preparation of these compounds it made no difference in the yield or purity of the product if the imidyl chloride was formed first and then it reacted with the appropriate amine or if the anilide and amine were at once added to the benzene solution of phosphorus pentachloride and the reaction completed in one operation.

The hydrochlorides of amidines numbered 1, 2, 5, 6, 8, 9 and 10 in Table I precipitated as a cream-colored powder during refluxing and no yield of hydrochloride was obtained from the benzene filtrates.

Since the disubstituted amidines are tautomeric[8] those having two different substituents on

[a] Duration in minutes. [b] The pharmacological tests were made by Mr. Rodia under the direction of Dr. C. C. Peiffer Head of the Department of Pharmacology, University of Illinois College of Medicine. [c] All solutions were in contact with the rabbit cornea for thirty seconds. [d] 0.2 ml. aqueous solution was used, at least two effective intradermal wheals were produced on the back of a guinea pig. [e] The LD. 50 dose for mice of compounds 2, 9, 6 and 10 was, respectively, in mg./kg., 153, 328, 105 and 123. [f] Compounds 1, 3, 5 and 8. produced sloughing of the skin.

the two nitrogen atoms may be made by starting with an anilide prepared from either amine. N,N′-Veratrylphenylbenzamidine was prepared from benzanilide and veratrylamine and from benzoylveratryl amide and aniline to learn if the hydrochloride of the amidine would precipitate during formation. It did not precipitate in either case. N,N′-*p*-Anisylphenylbenzamidine was prepared by starting with benzoyl-*p*-anisidide and also with benzanilide. The melting point of veratroyl anilide was found by us to be 166° but is given by Shriner and Fuson[9] to be 154°. The analysis of our anilide and of the amidine prepared from it, using *p*-anisidine, prove the composition of this anilide. The proof of the structure of this amidine was shown by the fact that the identical amidine was prepared from veratroyl-*p*-anisidide and aniline.

Preliminary experiments to determine which amine should be converted into the anilide for best results in the preparation of the amidine showed that better yields were obtained from anilides prepared from the amines which have the most substituents. It was also observed that when the more highly substituted free amine was added to the imidyl chloride a greater amount of undesirable side-reaction occurred and a considerable amount of unreacted anilide was recovered. Comparative yields are illustrated by the preparation of N,N′-veratrylphenetylbenzamidine. When prepared from benzoylveratryl anilide and phenetidine the yield of amidine was 42%, while the combination of benzoyl-*p*-phenetidide and veratrylamine yielded only 17% of theoretical.

Intradermal wheals produced by injection of 0.1 ml. of 0.025% solutions of compounds 2, 6, 9 and 10 into the human arm gave immediate anesthesia that lasted for 39, 26, 34 and twenty-eight minutes, respectively. Each of these injections produced sloughing of the skin.

Experimental

4-Aminoveratrole.—It is very important that this amine be as pure as possible. The best product was obtained in the best yields by using the directions given in "Organic Syntheses."[10]

Preparation of Monosubstituted Amides.—The procedure of Kuehn and McElvain[11] was modified for the preparation of these amides. In the preparation of the acid chlorides 5 molecular proportions of thionyl chloride were mixed with one molecular proportion of acid, the solution was refluxed for four hours and the excess thionyl chloride removed by vacuum distillation. The acid chloride was used immediately.

Veratroyl-*p*-anisidide.—Prepared by the above method in 75% yield, m. p. 173°.

Anal. Calcd. for $C_{16}H_{17}O_4N$: N, 4.88. Found: N, 4.85.

Veratroyl Anilide.[9]—Prepared by the above method in 65% yield, m. p. 166°.

Anal. Calcd. for $C_{15}H_{15}O_3N$: N, 5.45. Found: N, 5.45.

Preparation of the Amidines.—This procedure was a modification of that used by Hill and Cox.[6] Ten per cent. more than one molecular proportion (6.9 g.) of phosphorus pentachloride in 50 ml. of sodium-dried benzene was heated on a water-bath under reflux until the evolution of hydrogen chloride had ceased. The solution was then cooled. At this point the procedure was varied in two different ways with the same final result. (1) One molecular proportion of the anilide was added and the imidyl chloride formed by refluxing the mixture until no more hydrogen chloride was evolved (about thirty minutes). The solution was cooled and one molecular proportion of the amine was added. (2) One molecular proportion each of the anilide and amine were added, in this order. Following either procedure (1) or (2) the mixture was heated for six hours, or, if the amidine hydrochloride precipitated during the reaction, until no more precipitation occurred.

If the amidine hydrochloride precipitated during the re-

action the reaction mixture was worked up by cooling it and filtering off the amidine hydrochloride. The filtrates did not yield more product. The dried crude hydrochloride was stirred for fifteen minutes with 200 ml. of water, the mixture filtered and the amidine precipitated by the addition of concentrated ammonia water or solid potassium carbonate to complete precipitation. The undissolved residue from the crude hydrochloride was repeatedly extracted with water until the extracts yielded no more amidine.

The amidines numbered 3, 4 and 7 in Table I did not precipitate as the hydrochloride during refluxing, although the time of refluxing was extended to ten hours. After refluxing, the solution in each case was distilled under reduced pressure until the benzene and phosphorus oxychloride were removed. The brown, viscous residue was thoroughly stirred with 10–15 ml. of 5% hydrochloric acid and the latter decanted. The viscous paste solidified after this treatment to a soft solid. This mass was extracted, at room temperature, with 60 ml. of 5% hydrochloric acid and the amidine precipitated from the filtered extract with concentrated ammonia water. Repeated extractions were required to remove all the amidine from the residue. The first extracts yielded a brown product which became a pale ivory in color when reprecipitated from 5% hydrochloric acid. The crude amidine crystallized from 75% alcohol as a white or slightly ivory-colored, finely-divided solid.

Preparation of Amidine Hydrochlorides.—Five grams of amidine was dissolved in the least amount of ether (because of the solubility of their hydrochlorides benzene was used with the amidines numbered 3, 8, 9 and 10 in Table I) and dry hydrogen chloride gas was passed into the solution until complete precipitation of the hydrochloride, when the solution was immediately filtered by suction. The crude hydrochlorides crystallized in white needles from an alcohol–ether mixture.

Summary

Ten new amidines have been prepared and their hydrochlorides have been tested for local anesthetic activity.

All of the amidine hydrochlorides produced local anesthesia. Their solution produced sloughing of tissue at the site of injection.

[CONTRIBUTION FROM THE WELLCOME RESEARCH LABORATORIES]

N,N-Disubstituted Amidines. II. Benzamidines. The Effect of Substitution on Basicity[1]

BY EMIL LORZ AND RICHARD BALTZLY

By means of the synthetic method recently reported from these laboratories[2] a series of N,N-disubstituted benzamidines has been prepared. The primary object herein was to determine on relatively accessible compounds the effect of substitutions in the ring on the local anesthetic potency. Taken together with the benzamidines previously reported (Compounds I–VII, XIII and XXI–XXIV in our first paper)[2] the series suffices for the prediction with reasonable accuracy of the influence of convenient substitutions on the physiological properties of amidines of this type. While none of the substances reported in this paper and none of the benzamidines described earlier are of exceptional merit, the regularities observed have been found transferable to other series of greater inherent potency.

The new amidines prepared are shown together with analytical data in Table I, the numbering being consecutive with that of our earlier paper.[2] N,N-Di-*n*-butylbenzamidine (I) has a toxicity about four times that of cocaine (LD_{50} = 26.5 mg./kg. administered intraperitoneally) in mice and a potency as a surface anesthetic about one-half that of cocaine (by the method of application to the cornea of a guinea pig). Substitution of the ring by methyl, methoxyl or dimethylamino groups or by chlorine increased the potency; substitution by hydroxyl eliminated it. The most pronounced effect here was that of *p*-chlorine substitution: *p*-chloro-N,N-di-*n*-butylbenzamidine having 7.4 times the potency of cocaine. In general, the potencies run from two to five times that of cocaine.

Chlorine substitution tends to increase toxicity though not very markedly and with little selective action in respect to position. Methoxyl substitution, on the other hand, diminishes toxicity considerably in the meta and para positions and increases it markedly in the ortho: the LD_{50} for the *o*-, *m*- and *p*-methoxy-N,N-di-*n*-butylbenzamidines are 9, 30 and 36 mg./kg., respectively. This phenomenon is quite consistent, the 2,5-dimethoxy and 2,6-dimethoxy compounds (XXXI and XXXII) having LD_{50} = 13.5 and 7, respectively, while the 3,4-dimethoxy and 3,4,5-trimethoxy analogs (XXXIII and XXXV) have LD_{50} = 38 and 52.

The presence of an aromatic radical on the amidine nitrogen confers lower toxicity but increases the potency only a little.

There was a distinct possibility that these variations might be correlated with the basicity of the amidines. Since amidines have not been studied very extensively from this standpoint and amidines of the present type were formerly rather rare, a number of the hydrochlorides sufficient to indicate the effect of substitutions on basicity, were titrated in 50% methanol. Use of a partly organic solvent is necessary to prevent serious error due to precipitation of base; Hall and Sprinkle[3] showed that this device gives satis-

(1) The work here reported is part of a joint research carried out in collaboration with a Pharmacological group in these laboratories.

[a] Two pK_a values observed, at 4.46 and 10.54. The former must be that of the tertiary benzylamino nitrogen. [b] Two pK_a values observed, at 8.80 and 12.05. The former is obviously that of the hydroxyl group whose acidity should be increased by the presence of the cationic amidinium portion. [c] pK_a values were calculated according to the formula given in Clark, ref. 6, Chapter I, p. 16.

At first sight it appears surprising that an aromatic group on the amidine nitrogen diminishes the basicity so little (compare I with XXII and XXV also XXVI with XXVII), less than one unit in the pK scale. Actually, this corresponds very closely with the observations in the guanidine series[3,4] it having been shown that pK_a diminishes in the series: guanidine > phenylguanidine > N,N′-diphenylguanidine from 13.65 to 10.77 to 10.12. It would seem that the resonance possibilities in the benzamidinium ion are very close to those in the phenylguanidinium ion while compound XXII is comparable to *sym*-diphenylguanidine.

The influence of ring substitution on the basicity is in general consistent with theoretical expectations. The very high basicity observed with the 4-hydroxy derivative is obviously correlated with the fact that the hydroxyl group has been titrated first and the oxygen is anionic in the *p*H range involved in the titration of the amidinium moiety. It is to be noted that the three coöperative methyl groups of the mesityl derivative (XXI) exercise an influence greater than that of a para methoxyl or dimethylamino group. This may be partly due to steric inhibition of resonance between the amidine moiety and the ring which probably has an over-all tendency to diminish the basicity of the amidine. Schwarzenbach and Lutz[5] report pK_a for acetamidine hydrochloride as 12.40 (in water) which is significantly above the value for any of these aromatic amidines.

Experimental

Compound XXX, 4-hydroxy-N,N-di-*n*-butylbenzamidine hydrochloride was prepared by hydrogenolysis of its benzyl ether (XXIX) with palladized charcoal. With this exception all the amidines here reported were obtained by the addition of the appropriate bromomagnesium amide to a benzonitrile.[2] The nitriles employed are all described in the older literature. Most of the significant information is presented in Table I, the method of isolation being indicated by the letters A, A′, B, B′ and C, in the column

(4) Davis and Elderfield, THIS JOURNAL, **54**, 1499 (1932).

(5) Schwarzenbach and Lutz, *Helv. Chim. Acta*, **23**, 1162 (1940).

headed "Method of isolation." Methods A, B and C have been described previously.[2]

Method B′ is a modification of B in which steam distillation of the basic material is omitted and the amidine is separated from secondary amine by extraction from ethereal solution by successive portions of dilute hydrochloric acid. This is to be preferred with N-arylamidines since the secondary amine is feebly basic and the amidine base may undergo some decomposition during a prolonged steam distillation.

Method A′ differs from A only in that the amidine base is not itself distilled. The secondary amine is volatilized by heating *in vacuo* to a temperature preferably not over 160°. In some cases more drastic heating (up to 200° at 1 mm.) was employed with no apparent decomposition but it is believed that the yield of pure amidine hydrochloride suffered from such treatment.

The amidine hydrochlorides were purified by crystallization from ethanol–ether mixtures.

Electrometric Titrations.—These were performed at 0.02 molar initial concentration of amidine hydrochloride in 50% methanol, adding 0.1 *N* sodium hydroxide solution. The apparatus was a Beckman *p*H meter, Model G. Determinations of the *p*H range 6–9 were accomplished with a glass electrode 960 standardized at *p*H 4 and *p*H 7 with potassium acid phthalate and phosphate buffers, respectively. Above *p*H 9 a high *p*H glass electrode 960 E standardized at *p*H 9 and *p*H 12 with sodium chloride–glycine[6] buffers was employed.

Direct comparison of titrations in water and in 50% methanol is not possible with most of these amidines. The most accurate but laborious procedure is to perform a series of titrations in diminishing concentrations of methanol so as to permit extrapolation to zero per cent.—as was done by Hall and Sprinkle.[3] From observations on certain quinoline amidines we believe that in the range 9.5–11, the pK_a observed in 50% methanol runs about 0.3 unit above that in water. Compound XXX was titrated both in 50% methanol and in water. The two curves were roughly parallel, that for methanol being above that for water except at high *p*H (at 11.9 the curves cross). The first two pK_a values, at 8.65 in water and 8.80 in 50% methanol, presumably are due to the phenolic hydroxyl group. The higher pK_a values, relating to the amidine portion were at 12.05 in 50% methanol and 12.15 in water.

Summary

1. A number of N,N-disubstituted benzamidines have been prepared.

2. The effect of substitutions upon the basicity of unsymmetrically disubstituted benzamidines is discussed.

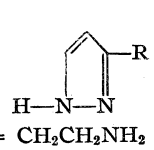
[CONTRIBUTION FROM THE LILLY RESEARCH LABORATORIES]

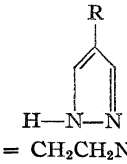
The Synthesis of Some Amines and Amino Acids Containing the Pyrazole Nucleus

BY REUBEN G. JONES

As part of a study concerned with the biological activity of certain amines and amino acids[1] the two isomeric β-aminoethylpyrazoles, I and II, and the two corresponding pyrazolealanines, III and IV, were prepared.



I, R = $CH_2CH_2NH_2$

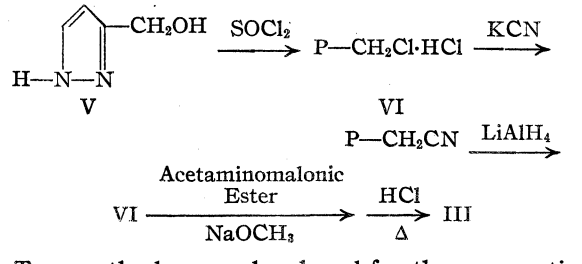


II, R = $CH_2CH_2NH_2$

III, R = $CH_2CHNH_2CO_2H$ IV, R = $CH_2CHNH_2CO_2H$

These pyrazole compounds were of particular interest because of their apparently close structural resemblance to the imidazole derivatives, histamine and histidine.

Compounds I and III were synthesized by straightforward procedures as indicated in the accompanying reactions.



Two methods were developed for the preparation of the starting material, 3-hydroxymethylpyrazole, V. Reduction of ethyl 3-pyrazolecarboxylate[2] with lithium aluminum hydride in ether gave V in 84% yield. Compound V was also prepared by the condensation of diazomethane with propargyl alcohol. It has been observed that substituted acetylenes of the type R—C≡CH undergo reaction with diazomethane to yield predominately 3-substituted pyrazoles,[3]

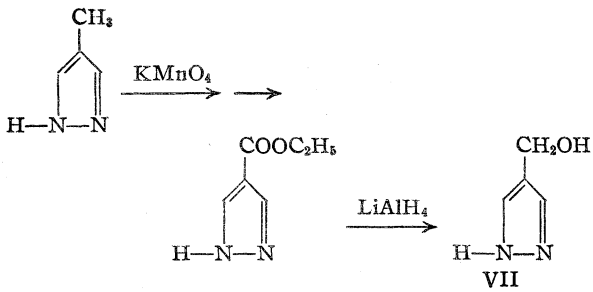
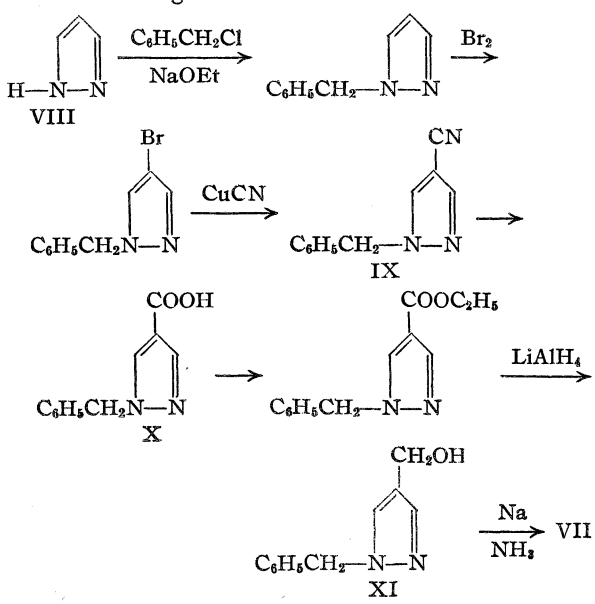
and only insignificant amounts of the alternative 4-substituted isomers. In the present case the yield of 3-hydroxymethylpyrazole was about 50% and that of 4-hydroxymethylpyrazole about 2%.

A number of unforseen difficulties were encountered in the preparation of the 4-substituted pyrazole compounds, II and IV. It was at first supposed that these could be synthesized readily from 4-hydroxymethylpyrazole by the same methods as outlined above for the corresponding 3-isomers. Consequently the preparation of 4-hydroxymethylpyrazole, VII, was undertaken. One series of reactions by which VII was obtained consisted of the permanganate oxidation of 4-methylpyrazole[4] to yield 4-pyrazolecarboxylic acid,[5] which was esterified, and the resulting ester was then reduced with lithium aluminum hydride.



An alternative method of preparing VII is outlined in the following series of reactions.



Pyrazole VIII, the starting material for these latter reactions, was conveniently obtained by the condensation of hydrazine hydrochloride with the recently available 1,1,3,3-tetraethoxypropane.[6]

The reaction of 1-benzyl-4-bromopyrazole with cuprous cyanide required a very careful control of experimental conditions in order to obtain satisfactory yields of IX. Several attempts to carry out a similar reaction between 4-bromopyrazole and cuprous cyanide resulted in failure to obtain any of the desired 4-cyanopyrazole. Sodium in liquid ammonia smoothly cleaved the benzyl group from XI to yield VII. Likewise, the acid X underwent facile cleavage to yield 4-pyrazolecarboxylic acid. Thus the 1-benzylpyrazoles behave in the same way as the 1-benzylimidazoles toward sodium in liquid ammonia.[1a]

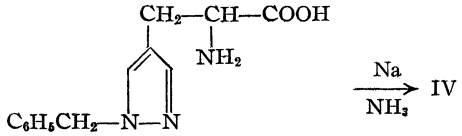
4-Hydroxymethylpyrazole reacted vigorously with thionyl chloride but the resulting 4-chloromethylpyrazole hydrochloride, unlike the isomeric 3-chloromethyl compound, was completely insoluble in thionyl chloride. Furthermore, 4-chloromethylpyrazole proved to be a highly reactive and unstable substance, and no analytically pure sample was isolated. It appeared to react rapidly with ice-water to form 4-hydroxymethylpyrazole. From the reaction of a cold absolute alcohol solution of 4-chloromethylpyrazole hydrochloride with excess potassium cyanide there was obtained a small yield of 4-cyanomethylpyrazole. This was treated with lithium aluminum hydride in ether solution, but none of the expected 4-(β-aminoethyl)-pyrazole (II) could be isolated from the reaction mixture.

In view of these disappointing results, attention was turned to the reactions of 1-benzyl-4-hydroxymethylpyrazole, XI. With thionyl chloride, this yielded 1-benzyl-4-chloromethylpyrazole hydrochloride which could not be induced to crystallize, and an analytically pure sample was not obtained. This chloromethyl compound likewise was highly reactive. An absolute alcohol solution was allowed to react with aqueous potassium cyanide, and there was obtained a liquid product which appeared to consist of a mixture of 1-benzyl-4-cyanomethylpyrazole and 1-benzyl-4-ethoxymethylpyrazole. These could not be separated by distillation, and so the mixture was subjected to the action of lithium aluminum hydride. From this reaction there was isolated a liquid mixture of 1-benzyl-4-(β-aminoethyl)-pyrazole and the unchanged 1-benzyl-4-ethoxymethylpyrazole. When this mixture in dry ether solution was treated with carbon dioxide the β-aminoethyl compound was precipitated as a white crystalline solid which was apparently the ammonium carbamate salt.[7] The dihydrochloride of 1-benzyl-4-(β-aminoethyl)-pyrazole was obtained by treating the carbamate salt with hydrogen chloride in absolute alcohol. The benzyl group was removed from 1-benzyl-4-(β-aminoethyl)-pyrazole carbamate salt by sodium in liquid ammonia to yield compound II.

The condensation of 1-benzyl-4-chloromethyl-

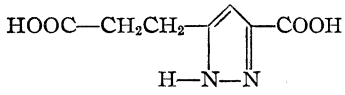
(7) For a recent discussion of ammonium carbamate salts of this type see Wright and Moore, THIS JOURNAL, **70**, 3865 (1948).

pyrazole hydrochloride with sodium acetaminomalonic ester led to the preparation of 1-benzyl-4-pyrazolealanine, XIII. This was converted through the agency of sodium in liquid ammonia to IV, which was purified by precipitation as an insoluble mercuric chloride complex.



XIII

In the early part of this work, another possible approach to the synthesis of the 3-substituted pyrazole compounds was considered. Diethyl α,γ-diketopimelate[8] was allowed to react with hydrazine to yield 5-(β-carbethoxyethyl)-3-pyrazolecarboxylate which was saponified to form the acid XIV.



XIV

When XIV was heated to about 200° in vacuum it sublimed unchanged. No method was discovered by which XIV could be decarboxylated to yield β-(3-pyrazole)-propionic acid which would have been a suitable intermediate for the synthesis of other 3-substituted pyrazoles.

Neither 3- nor 4-(β-aminoethyl)-pyrazole possessed any histamine-like action[9] or other observable pharmacological activity. 3-Pyrazolealanine was not inhibitory to *E. coli, L. arabinosis, Leuconostoc mesenteroides, Strep. viridans, Influenza virus or E. coli phages* T_2 and T_7.

Experimental[10]

3-Hydroxymethylpyrazole. (a) Reaction of Diazomethane with Propargyl Alcohol.—The diazomethane solution prepared in 1500 ml. of ether from 103 g. (1 mole) of nitrosomethylurea[11] was dried over potassium hydroxide pellets for three hours and then decanted into a dry two-liter flask. To the solution was added 56 g. (1.0 mole) of freshly distilled propargyl alcohol (b. p. 110–111°). The solution was allowed to stand at room temperature, and after sixty hours it had become colorless. The ether was evaporated, and the sirupy residue was distilled *in vacuo*. After a forerun of 31 g. (55%) of unreacted propargyl alcohol there was obtained 30 g. of viscous liquid, b. p. 120–150° (0.5 mm.), and about 2 g. of higher boiling material which partially crystallized upon cooling. After several recrystallizations from acetone–petroleum ether mixtures the crystalline substance melted at 121–122° and was identified by mixed melting point as 4-hydroxymethylpyrazole (see below).

The 30 g. of viscous liquid was dissolved in 50 ml. of water and added to a boiling-hot solution of 80 g. of picric acid in 1200 ml. of water. The resulting solution was boiled with 5 g. of decolorizing carbon, filtered and cooled to 40°. The yellow, crystalline precipitate of 3-hydroxymethylpyrazole picrate was collected, washed with a little absolute alcohol and air-dried. The yield was 78 g. (53% based upon unrecovered propargyl alcohol). It melted at 183.5–184.5°, and the melting point remained unchanged after recrystallization from water.

Anal. Calcd. for $C_{10}H_9N_5O_8$: N, 21.41. Found: N, 21.43.

The picrate, 75 g., was suspended in 200 ml. of nitrobenzene, and the mixture was vigorously shaken with 50 ml. of 12 *N* hydrochloric acid (6 *N* hydrochloric acid did not decompose the picrate). The hydrochloric acid layer was washed with three 50-ml. portions of chloroform, and then the nitrobenzene and chloroform solutions were extracted with a fresh 50-ml. portion of 12 *N* hydrochloric acid. After the total acid solution had been filtered, it was evaporated in vacuum to dryness. The residual solid was taken up in absolute alcohol, and the solution was evaporated to dryness in vacuum, leaving the 3-hydroxymethylpyrazole hydrochloride as a very hygroscopic, white, crystalline solid. It was dried in vacuum over potassium hydroxide, and the yield was 30 g. (97%); m. p. 113–115°. A sample recrystallized from absolute alcohol–ether and dried in vacuum melted at 117–118°.

To 0.5 g. (0.005 mole) of the crude 3-hydroxymethylpyrazole in 30 ml. of distilled water was added 1.05 g. (0.0067 mole) of potassium permanganate. The mixture was shaken and heated for one-half hour and then filtered. The colorless filtrate together with about 30 ml. of water used to wash the manganese dioxide was evaporated to a volume of about 5 ml. This solution was brought to *p*H 2 with hydrochloric acid and, after scratching, 0.35 g. of white crystalline precipitate separated, m. p. 216–217°. The product was identified as 3-pyrazolecarboxylic acid by a mixed melting point with an authentic sample,[12] m. p. 216–217°.

Anal. Calcd. for $C_4H_4N_2O_2$: C, 41.98; H, 3.60. Found: C, 42.16; H, 3.92.

(b) Reduction of Ethyl 3-Pyrazolecarboxylate with Lithium Aluminum Hydride.—3-Pyrazolecarboxylic acid[12] was esterified with ethanol and hydrogen chloride. The ethyl ester, obtained in 89% yield, melted[2] at 158°. In a Soxhlet thimble above a refluxing solution of 15 g. of lithium aluminum hydride[13] in 1 l. of ether was placed 28 g. (0.20 mole) of ethyl 3-pyrazolecarboxylate. After fifteen hours all of the ester had been dissolved and carried down into the lithium aluminum hydride solution. Very cautiously and with stirring, 50 ml. of water was added dropwise to the reaction mixture, and then the ether was almost all removed by evaporation. The residual, white, granular solid was treated with 300 ml. of methanol, and the mixture was thoroughly saturated with carbon dioxide. After the mixture had been heated to boiling it was filtered, and the solid was extracted with two more 300-ml. portions of boiling methanol. The total filtrate was evaporated in vacuum, and the residual sirup containing some solid was extracted with 50 ml. of dry methanol. This methanol solution was again filtered and evaporated, and the residual sirup was distilled in vacuum to yield 16.5 g. (84%) of pure 3-hydroxymethylpyrazole; b. p. 137–140° (0.5 mm.), $n^{25}D$ 1.5340, d^{25}_{25} 1.225.

Anal. Calcd. for $C_4H_6N_2O$: N, 28.56. Found: N, 28.42.

The 3-hydroxymethylpyrazole was a colorless, very viscous liquid which could not be induced to crystallize. It was highly soluble in water or alcohol, moderately soluble in ether, and it could not be extracted from its water solution with organic solvents. The picrate melted at 184–185°, and the melting point was not depressed when mixed with the picrate described above under (a).

3-Chloromethylpyrazole Hydrochloride.—To 40 ml. of thionyl chloride was added in small portions 30 g. (0.22 mole) of 3-hydroxymethylpyrazole hydrochloride. Reaction took place immediately, and a clear solution was formed. After the solution had been warmed on the steam-bath for fifteen minutes, the excess thionyl chloride

(12) Knorr, *Ann.*, **279**, 231 (1894).

(13) Obtained from Metal Hydrides Inc., Beverly, Mass.

was removed by evaporation in vacuum. The white, crystalline 3-chloromethylpyrazole hydrochloride was washed with anhydrous ether and stored in a vacuum desiccator over potassium hydroxide. The yield was 34 g. (100%), m. p. 155–156° dec. It was deliquescent.

Anal. Calcd. for $C_4H_5N_2Cl \cdot HCl$: N, 18.31. Found: N, 18.20.

3-Cyanomethylpyrazole.—To a well-stirred solution of 60 g. of potassium cyanide in 65 ml. of water cooled in an ice-bath was added a solution of 15.3 g. (0.10 mole) of 3-chloromethylpyrazole hydrochloride in 200 ml. of absolute alcohol over a period of one hour. The reaction mixture was removed from the cooling bath and stirred at room temperature for four hours. It was then filtered, the salts were washed with two 200-ml. portions of 95% alcohol and the total filtrate was evaporated in vacuum to a volume of about 100 ml. After the addition of a little water to bring some precipitated salts into solution, the mixture was extracted with four 100-ml. portions of chloroform. The chloroform extract was evaporated in vacuum leaving 9.5 g. of liquid residue. This was distilled in vacuum. It all came over at 117–120° (0.4 mm.) as a colorless liquid. The yield was 8.5 g. (80%) of 3-cyanomethylpyrazole; $n^{25}D$ 1.5138.

Anal. Calcd. for $C_5H_5N_3$: N, 39.23. Found: N, 38.94.

The picrate, m. p. 63–64°, was appreciably water soluble.

3-(β-Aminoethyl)-pyrazole.—A solution of 7.5 g. (0.07 mole) of 3-cyanomethylpyrazole in 50 ml. of dry ether was added dropwise to a solution of 5 g. of lithium aluminum hydride in 150 ml. of ether. After the mixture had stood for about one-half hour, 25 ml. of water was added dropwise through the condenser. The ether was then evaporated and 200 ml. of methanol was added. The mixture was saturated with carbon dioxide, heated to boiling and filtered. The solid was extracted with four additional 300-ml. portions of hot methanol, and the total methanol filtrate was evaporated in vacuum to dryness. The residue was dissolved in 200 ml. of warm methanol and the solution filtered and evaporated. The solid residue which appeared to be a 3-(β-aminoethyl)-pyrazole salt with carbon dioxide was dissolved in 50 ml. of water and the solution added to a hot solution of 35 g. of picric acid in 600 ml. of water. After cooling to 10° the crystalline solid was collected and recrystallized from 250 ml. of water to yield 21 g. (53%) of 3-(β-aminoethyl)-pyrazole dipicrate; m. p. 195–197°.

Anal. Calcd. for $C_{17}H_{15}N_9O_{14}$: N, 22.20. Found: N, 22.90.

The dipicrate, 20 g., was treated with concentrated hydrochloric acid in nitrobenzene and the mixture worked up as described above to yield 6.2 g. (96%) of 3-(β-aminoethyl)-pyrazole dihydrochloride; m. p. 223–224°. It was deliquescent, but only sparingly soluble in hot absolute alcohol.

Anal. Calcd. for $C_5H_9N_3 \cdot 2HCl$: N, 22.83; Cl, 38.52. Found: N, 23.21; Cl, 38.16.

3-Pyrazolealanine.—In a 500-ml. three-necked flask provided with a stirrer and dropping funnel was placed 150 ml. of absolute alcohol. In the alcohol was dissolved 6.9 g. (0.3 g. atom) of sodium. To the solution was added 43 g. (0.2 mole) of acetaminomalonic ester, and then the flask was surrounded with an ice-bath. With stirring a solution of 15.3 g. (0.1 mole) of 3-chloromethylpyrazole hydrochloride in 100 ml. of absolute alcohol was added. The ice-bath was removed, and the mixture was stirred at room temperature for one hour after which most of the alcohol was removed by evaporation in vacuum on the steam-bath. The residue was taken into 400 ml. of 2 *N* hydrochloric acid, the solution was extracted with ethyl acetate to remove unreacted acetaminomalonic ester, and then the aqueous solution was made basic with sodium carbonate and extracted with ether. Evaporation of the dried ether solution left a glass which did not crystallize. It was heated on the steam-bath for five hours with 100 ml. of concentrated hydrochloric acid. The solution was evaporated, the residual glass was taken up in water, and the solution was freed of chloride ion with silver carbonate and hydrogen sulfide in the usual way. The resulting aqueous solution was evaporated to small volume and alcohol was added to precipitate 13 g. (84% yield) of 3-pyrazolealanine as a white crystalline powder, m. p. 226–228° dec.

Anal. Calcd. for $C_6H_9N_3O_2$: C, 46.45; H, 5.85; N, 27.08. Found: C, 46.50; H, 6.38; N, 27.00.

Pyrazole.—A mixture of 220 g. (1 mole) of 1,1,3,3-tetraethoxypropane,[6] 105 g. (1 mole) of hydrazine dihydrochloride, 150 ml. of water and 100 ml. of alcohol was heated on the steam-bath for two hours. The solution was evaporated in vacuum to remove the alcohol. The brown residual sirup was taken up in 200 ml. of water, and 200 g. of sodium carbonate was added. The mixture was filtered and the salts were thoroughly washed with two 200-ml. portions of ether which were then used to extract the filtrate. The dried ether solution was evaporated and the residue was distilled in vacuum to yield 59–63 g. (87–93%) of very pure pyrazole; b. p. 95–97° (20 mm.); m. p. 70°.

1-Benzylpyrazole.—To a solution prepared by dissolving 14 g. (0.6 g. atom) of sodium in 500 ml. of absolute alcohol was added 34 g. (0.5 mole) of pyrazole. The solution was heated to gentle boiling under reflux and 150 g. (1.2 moles) of benzyl chloride was added slowly from a dropping funnel. After a few minutes the mixture had become neutral. It was filtered, and the filtrate was evaporated in vacuum to remove the alcohol. The residual liquid was poured into 100 ml. of 6 *N* hydrochloric acid. The aqueous layer was separated, washed with ether and then made basic with excess sodium hydroxide, cooled, and extracted with two 100-ml. portions of ether. After evaporation of the ether the residual 1-benzylpyrazole was distilled; b. p. 255–257° (750 mm.), 134–136° (15 mm.); $n^{25}D$ 1.5558; d^{25}_{25} 1.078. The yield was 62–68 g. (79–86%).

Anal. Calcd. for $C_{10}H_{10}N_2$: N, 17.71. Found: N, 17.59.

1-Benzylpyrazole failed to react with excess formalin. After heating the two together in a sealed tube at 120° for nine hours 95% of the 1-benzylpyrazole was recovered unchanged.

1-Benzyl-4-bromopyrazole.—A solution of 104 g. (0.65 mole) of 1-benzylpyrazole in 200 ml. of chloroform was cooled in an ice-bath and stirred well while 104 g. (0.65 mole) of bromine in 100 ml. of chloroform was slowly poured in. The chloroform solution was then shaken with excess aqueous sodium carbonate solution, dried over anhydrous sodium carbonate, and, after removal of the chloroform, the 1-benzyl-4-bromopyrazole was distilled in vacuum. It all came over at 169–170° (20 mm.) as a colorless liquid, which crystallized after cooling, m. p. 44–45°. The yield was 148–154 g. (94–98%).

Anal. Calcd. for $C_{10}H_9N_2Br$: N, 11.82. Found: N, 11.45.

1-Benzyl-4-cyanopyrazole.—A 200-ml. round-bottom flask was provided with a short Claisen head and wide-bore condenser set for distillation with a receiver attached to a vacuum line in such a way that the system could be immediately evacuated. In the flask was placed 23.7 g. (0.1 mole) of 1-benzyl-4-bromopyrazole and 13.4 g. (0.15 mole) of cuprous cyanide. The mixture was slowly and carefully heated with a soft flame and occasionally swirled until it had all melted. Local heating was avoided. As soon as the contents had become homogeneous the heating was stopped and the liquid was closely watched. Usually, at this point a slight bubbling of the liquid became evident indicating that an exothermic reaction had begun. If there was no evidence within about thirty seconds that the exothermic reaction was starting a little more heat was applied. At the first sign of spontaneous bubbling the vacuum of about 20 mm. was *immediately* applied being careful not to cause the material to bump over into the condenser. The mixture was then distilled as rapidly as possible at about 20 mm. using a flame until no more liquid

came over. The distillate of crude 1-benzyl-4-cyanopyrazole solidified upon cooling. The product was triturated with a little warm petroleum ether and then filtered and air-dried. The yield was 11–14 g. (60–76%). It was soluble in ether, alcohol, benzene or ethyl acetate, sparingly soluble in petroleum ether and insoluble in water. A sample for analysis was recrystallized from petroleum ether, m. p. 63–64°.

Anal. Calcd. for $C_{11}H_9N_3$: N, 22.21. Found: N, 22.33.

This experiment was carried out many times and it was possible to get satisfactory yields consistently. With larger-sized runs the yields were lower. If the distillation was begun as soon as the mixture had melted and before the exothermic reaction started then the distillate consisted mostly of unchanged 1-benzyl-4-bromopyrazole. However, it was essential to start the vacuum distillation just as soon as the exothermic reaction had become evident. On one or two occasions, a delay of only five or ten seconds resulted in the reaction getting out of control and leaving only charred decomposition products.

1-Benzyl-4-cyanopyrazole did not form a hydrochloride. A solution in ether was saturated with dry hydrogen chloride, but nothing precipitated. When the solution was evaporated pure, unchanged 1-benzyl-4-cyanopyrazole, m. p. 63–64°, remained.

1-Benzyl-4-pyrazolecarboxylic Acid.—1-Benzyl-4-cyanopyrazole was boiled with aqueous sodium hydroxide and alcohol until no more ammonia was evolved. The alcohol was removed by evaporation and the aqueous solution was acidified with hydrochloric acid to precipitate 1-benzyl-4-pyrazolecarboxylic acid in 94% yield. A sample was recrystallized from water containing a little alcohol, m. p. 151–152°.

Anal. Calcd. for $C_{11}H_{10}N_2O_2$: N, 13.86. Found: N, 13.88.

Ethyl 1-Benzyl-4-pyrazolecarboxylate.—A solution of 1-benzyl-4-pyrazolecarboxylic acid in ten parts of absolute alcohol was saturated with hydrogen chloride, refluxed for eighteen hours and then worked up in the usual way to give the ethyl ester in 94% yield. A sample recrystallized from petroleum ether melted at 62–63°.

Anal. Calcd. for $C_{13}H_{14}N_2O_2$: N, 12.17. Found: N, 12.27.

1-Benzyl-4-aminomethylpyrazole Hydrochloride.—A solution of 5 g. of 1-benzyl-4-cyanopyrazole in 50 ml. of dry ether was added to a stirred solution of 1.5 g. of lithium aluminum hydride in 100 ml. of ether. After one-half hour, 10 ml. of water was added dropwise. The mixture was filtered, and the solid was washed by suspension in another 50 ml. of ether. The combined ether filtrate was dried and saturated with dry hydrogen chloride. Recrystallization of the resulting precipitate from absolute alcohol–ether gave 5.0 g. (72% yield) of the monohydrochloride, m. p. 232–233°.

Anal. Calcd. for $C_{11}H_{13}N_3 \cdot HCl$: N, 18.78; Cl, 15.85. Found: N, 18.94; Cl, 16.28.

4-Pyrazolecarboxylic Acid. (a) Cleavage of 1-Benzyl-4-pyrazolecarboxylic Acid with Sodium in Liquid Ammonia.—A suspension of 2.02 g. (0.01 mole) of 1-benzyl-4-pyrazolecarboxylic acid in 30 ml. of liquid ammonia was treated with sodium in small pieces until a permanent blue color was formed (0.5 g. of sodium). The ammonia was allowed to evaporate, and then the residue was taken up in 20 ml. of water. After the aqueous solution had been washed with ether it was acidified to *p*H 2 with hydrochloric acid to precipitate 0.89 g. (80% yield) of 4-pyrazolecarboxylic acid. A sample was recrystallized from water; m. p. 279–280° dec. (lit.[5] 275 dec.).

Anal. Calcd. for $C_4H_4N_2O_2$: N, 25.00. Found: N, 25.20.

(b) Oxidation of 4-Methylpyrazole.—4-Methyl-3-pyrazolecarboxylic acid was prepared in a yield of about 50% by the condensation of methyl crotonate with diazomethane, followed by oxidation of the intermediate pyrazoline with bromine and saponification of the ester according to the method of v. Pechmann and Burkard.[14] The acid was decarboxylated by heating, to give a 70% yield of 4-methylpyrazole,[4] b. p. 202–203° (730 mm.).

4-Methylpyrazole was oxidized with potassium permanganate in the same way as has been described for the oxidation of the corresponding 3-isomer.[12] The yield of 4-pyrazolecarboxylic acid was 50–53%, m. p. 278–279° dec.

Ethyl 4-Pyrazolecarboxylate.—4-Pyrazolecarboxylic acid was esterified with ethanol and sulfuric acid, and the yield of ethyl ester was 70%; b. p. 138–140° (3 mm.), m. p. 78–79° from petroleum ether–ethyl acetate mixture.

Anal. Calcd. for $C_6H_8N_2O_2$: N, 19.99. Found: N, 20.18.

Methyl 4-Pyrazolecarboxylate.—This was prepared from the acid and diazomethane in methanol, m. p. 136–137°.

Anal. Calcd. for $C_5H_6N_2O_2$: N, 22.22. Found: N, 21.69.

1-Benzyl-4-hydroxymethylpyrazole.—A solution of 58 g. (0.25 mole) of ethyl 1-benzyl-4-pyrazolecarboxylate in 600 ml. of anhydrous ether was added dropwise to a solution of 15 g. of lithium aluminum hydride in 300 ml. of ether. After a few hours 50 ml. of water was added dropwise. The resulting mixture was filtered and the solid was extracted with three 400-ml. portions of hot methanol. The methanol and ether filtrates were evaporated in vacuum, the residue was extracted with three 200-ml. portions of dry ether, and the filtered ether solution was evaporated. Distillation of the residual liquid gave 43.5–45.3 g. (92–96% yield) of 1-benzyl-4-hydroxymethylpyrazole as a colorless, viscous liquid; b. p. 146–148° (0.2 mm.), $n^{25}D$ 1.5742, d^{25}_{25} 1.155.

Anal. Calcd. for $C_{11}H_{12}N_2O$: N, 14.89. Found: N, 14.60.

4-Hydroxymethylpyrazole. (a) Reduction of Ethyl 4-Pyrazolecarboxylate with Lithium Aluminum Hydride.—Ethyl 4-pyrazolecarboxylate was reduced with lithium aluminum hydride in ether and the mixture worked up in the manner described above for the corresponding ethyl 3-pyrazolecarboxylate. The 4-hydroxymethylpyrazole obtained in a yield of 86% was a solid. It was purified by dissolving in absolute alcohol, filtering and evaporating the solution, m. p. 120–122°. A sample was recrystallized from a mixture of absolute alcohol and chloroform, m. p. 126.5–127°. It was very soluble in water or alcohol, very sparingly soluble in chloroform and insoluble in ether.

Anal. Calcd. for $C_4H_6N_2O$: N, 28.56. Found: N, 28.25.

(b) Cleavage of 1-Benzyl-4-hydroxymethylpyrazole with Sodium in Liquid Ammonia.—To a solution of 9.4 g. (0.05 mole) of 1-benzyl-4-hydroxymethylpyrazole in 75 ml. of liquid ammonia was added small pieces of sodium (2.3 g.) until a permanent blue color was formed. Ammonium chloride, 6 g., was then added and the ammonia was allowed to evaporate. The residue was extracted with 300 ml. of hot acetone. The solution was filtered, evaporated to small volume, and 100 ml. of petroleum ether was added. There was thus obtained 4.5 g. (92% yield) of 4-hydroxymethylpyrazole; m. p. 125–126° and mixed with a sample prepared as described under (a), m. p. 126–127°. The picrate, recrystallized from water, melted at 149–150° dec.

1-Benzyl-4-(β-aminoethyl)-pyrazole.—Dry hydrogen chloride was passed into a mixture of 9.4 g. (0.05 mole) of 1-benzyl-4-hydroxymethylpyrazole and 75 ml. of anhydrous ether. The resulting oily hydrochloride could not be induced to crystallize. Therefore, the ether was removed by evaporation and 25 ml. of thionyl chloride was added. Reaction took place immediately. The resulting clear solution was warmed on the steam-bath for a short time, and then the excess thionyl chloride was evaporated in vacuum. The residual oily product, presumably 1-benzyl-4-chloromethylpyrazole hydrochloride, would not crystallize. It was readily soluble in absolute alcohol and was precipitated as an oil by the addition of dry ether.

(14) v. Pechmann and Burkard, *Ber.*, **33**, 3590 (1900).

A solution of the crude 1-benzyl-4-chloromethylpyrazole hydrochloride in 100 ml. of cold absolute alcohol was added to aqueous potassium cyanide and the mixture worked up as described above for the preparation of 3-cyanomethylpyrazole. The liquid reaction product distilled at 130–150° (0.2 mm.), and it proved to be a mixture containing the desired 1-benzyl-4-cyanomethylpyrazole together with 1-benzyl-4-ethoxymethylpyrazole (see below) which resulted from the reaction of the chloro compound with alcohol.

The liquid, 8.5 g., in 50 ml. of ether was added to a solution of 3 g. of lithium aluminum hydride in 200 ml. of ether. After this reaction mixture had been decomposed with 10 ml. of water it was filtered and the solid was extracted with three 200-ml. portions of ether. The liquid obtained after evaporation of the dried ether extract was distilled in vacuum, b. p. 110–140° (0.1 mm.). It weighed 6.2 g. This liquid was dissolved in 100 ml. of dry ether and the solution was saturated with carbon dioxide to precipitate a white, non-hygroscopic, crystalline solid. The product appeared to be the carbamate[7] formed by the reaction of one molecule of carbon dioxide with two molecules of 1-benzyl-4-(β-aminoethyl)-pyrazole. It melted with decomposition over the range 100–115°. The yield was 2.7 g. (24% based on 1-benzyl-4-hydroxymethylpyrazole).

Anal. Calcd. for $C_{25}H_{30}N_6O_2$: N, 18.83. Found: N, 18.65.

A solution of 2.0 g. of the carbamate in 20 ml. of absolute alcohol was saturated with dry hydrogen chloride; and after the addition of 30 ml. of dry ether, 2.3 g. (94% yield) of white, crystalline 1-benzyl-4-(β-aminoethyl)-pyrazole dihydrochloride separated, m. p. 177–179°. It was not hygroscopic. A sample was recrystallized from absolute alcohol, m. p. 179–180°.

Anal. Calcd. for $C_{12}H_{15}N_3 \cdot 2HCl$: C, 52.56; H, 6.25; N, 15.33. Found: C, 52.45; H, 6.51; N, 15.42.

The ether filtrate from the above carbamate was evaporated and the residual liquid was distilled in vacuum. After a small forerun 2 g. of colorless liquid was obtained, b. p. 115–117° (0.1 mm.). This was believed to be 1-benzyl-4-ethoxymethylpyrazole.

Anal. Calcd. for $C_{13}H_{16}N_2O$: C, 72.19; H, 7.46; N, 12.96. Found: C, 71.94; H, 7.52; N, 13.31.

4-(β-Aminoethyl)-pyrazole.—To a suspension of 4.0 g. of the above carbamate of 1-benzyl-4-(β-aminoethyl)-pyrazole in 150 ml. of liquid ammonia was added small pieces of sodium until a permanent blue color was formed. This required 1.1 g. of sodium, and the reaction was very slow toward the end. After evaporation of the ammonia the residue was treated with 100 ml. of warm absolute alcohol, and the mixture was saturated with carbon dioxide and filtered. The filtrate was boiled for a few minutes, again filtered, then evaporated to dryness in vacuum. The residue, dissolved in 20 ml. of water, was added to a hot solution of 9 g. of picric acid in 150 ml. of water. The product which separated after cooling was recrystallized from 100 ml. of water to yield 8.1 g. (83%) of 4-(β-aminoethyl)-pyrazole dipicrate, m. p. 190–191°.

Anal. Calcd. for $C_{17}H_{15}N_9O_{14}$: N, 22.14. Found: N, 22.03.

The dipicrate, 7.0 g., was decomposed with hydrochloric acid and the reaction worked up as described above for the preparation of 3-(β-aminoethyl)-pyrazole dihydrochloride. There was thus obtained 1.72 g. (76% yield) of 4-(β-aminoethyl)-pyrazole dihydrochloride, m. p. 227–228°.

Anal. Calcd. for $C_5H_9N_3 \cdot 2HCl$: N, 22.83. Found: N, 22.82.

It was only sparingly soluble in hot absolute alcohol and was not deliquescent.

1-Benzyl-4-pyrazolealanine.—An absolute alcohol solution of crude 1-benzyl-4-chloromethylpyrazole hydrochloride (prepared from 0.1 mole of 1-benzyl-4-hydroxymethylpyrazole) was caused to react with sodium acetaminomalonic ester. The reaction was carried out and worked up as described above for the preparation of 3-pyrazolealanine except that the evaporated mixture was treated with 6 *N* instead of 2 *N* hydrochloric acid. The 1-benzyl-4-pyrazolealanine was rather sparingly soluble in water and, therefore, the precipitate formed by the addition of silver carbonate to the hydrochloride solution was washed several times with hot water before the treatment of the filtrate with hydrogen sulfide. There was obtained 5.4 g. (22%) of 1-benzyl-4-pyrazolealanine, m. p. 243–244° dec.

Anal. Calcd. for $C_{13}H_{15}N_3O_2$: N, 17.13. Found: N, 16.93.

4-Pyrazolealanine.—1-Benzyl-4-pyrazolealanine, 1.0 g. (0.004 mole), in 50 ml. of liquid ammonia was treated with small pieces of sodium until a permanent blue color was formed (0.30 g. sodium). Then 0.70 g. (0.013 mole) of ammonium chloride was added. After the ammonia had evaporated the residue was taken up in 25 ml. of hot water and to the solution was added 5 g. of mercuric acetate dissolved in 25 ml. of water. The resulting white precipitate was thoroughly washed by suspension in two 50-ml. portions of fresh water, and then it was suspended in 100 ml. of water and hydrogen sulfide was bubbled in until the mixture was saturated. The precipitate of mercuric sulfide was separated by filtration, and the filtrate was evaporated in vacuum to a sirup. This was taken up in 50 ml. of absolute alcohol and 100 ml. of dry ether was added, whereupon a white crystalline precipitate separated which proved to be a mixture of the mono- and dihydrochlorides of 4-pyrazolealanine, m. p. 235–236° dec. The yield was 0.60 g. (72%).

Anal. Calcd. for $C_6H_9N_3O_2 \cdot 1.44HCl$: C, 34.6; H, 5.1; N, 20.4; Cl, 24.7. Found: C, 34.2; H, 5.2; N, 21.0; Cl, 24.0.

The above hydrochloride, 0.40 g. (0.0019 mole) was dissolved in 25 ml. of water and 0.40 g. (one equivalent) of silver carbonate was added. The mixture was digested on the steam-bath for one hour, filtered, and the filtrate was saturated with hydrogen sulfide. The solution was clarified with carbon, filtered and evaporated to dryness in vacuum leaving 0.25 g. (80% yield) of white crystalline 4-pyrazolealanine. It was insoluble in alcohol and only sparingly soluble in water. A solution of the product in 4 ml. of hot water was filtered and the filtrate diluted with 8 ml. of alcohol to precipitate 0.15 g. of pure 4-pyrazolealanine, m. p. 304–306° dec.

Anal. Calcd. for $C_6H_9N_3O_2$: C, 46.45; H, 5.85; N, 27.08. Found: C, 46.23; H, 6.17; N, 26.81.

4-Cyanomethylpyrazole.—To 50 ml. of thionyl chloride was added 13 g. of powdered 4-hydroxymethylpyrazole. A vigorous reaction took place, but the resulting product, presumably 4-chloromethylpyrazole hydrochloride, was insoluble in the thionyl chloride. The excess thionyl chloride was evaporated in vacuum and the solid was washed with dry ether. It was extremely hygroscopic and no satisfactory analysis was obtained. A sample, dissolved in ice-water, appeared to be quickly hydrolyzed to form 4-hydroxymethylpyrazole which was obtained after evaporation of the water solution and identified by melting point and mixed melting point.

A cold absolute alcohol solution of the crude 4-chloromethylpyrazole hydrochloride was allowed to react with potassium cyanide and the reaction was worked up as described for the preparation of 3-cyanomethylpyrazole. There was obtained 4.0 g. (28% yield) of crude 4-cyanomethylpyrazole, b. p. 125–130° (0.2 mm.) which crystallized after cooling, m. p. 73–77°. A sample was recrystallized from a mixture of chloroform–petroleum ether and then from benzene–petroleum ether, m. p. 83–84°.

Anal. Calcd. for $C_5H_5N_3$: N, 39.23. Found: N, 38.68.

5-(β-Carboxyethyl)-3-pyrazolecarboxylic Acid and its Diethyl Ester.—Diethyl α,γ-diketopimelate, b. p. 183–185° (14 mm.), was prepared in 27% yield from ethyl levulinate and diethyl oxalate according to the procedure of Wislicenus.[8]

To a solution of 61 g. (0.25 mole) of the above diketo ester in 200 ml. of methanol was added 12.5 g. (0.25 mole) of 100% hydrazine hydrate. Heat was evolved, and the solution boiled spontaneously. After removal of the methanol the ethyl 5-(β-carbethoxyethyl)-3-pyrazolecarboxylate was distilled in vacuum to yield 56 g. (93.5%) of viscous colorless liquid which soon crystallized; b. p. 180° (0.5 mm.), m. p. 70–72°. A sample was recrystallized from petroleum ether, m. p. 72–73°.

Anal. Calcd. for $C_{11}H_{16}N_2O_4$: N, 11.66. Found: N, 12.17.

The above ester, 55 g., was saponified with sodium hydroxide solution and the 5-(β-carboxyethyl)-3-pyrazolecarboxylic acid was precipitated with hydrochloric acid. The yield was 42.5 g. (100%). A sample, recrystallized from water, melted at 243–244° dec.

Anal. Calcd. for $C_7H_8N_2O_4$: N, 15.23. Found: N, 15.15.

A sample of the acid was sublimed twice in vacuum at a temperature of about 200–230°. It remained unchanged, m. p. 243–244° dec.

Anal. Calcd. for $C_7H_8N_2O_4$: neut. equiv., 92.08. Found: neut. equiv., 93.57.

A sample of the acid was boiled for several hours in quinoline and another sample was boiled in glacial acetic acid. In neither case was there any evidence of decarboxylation.

Acknowledgment.—The author is indebted to W. L. Brown, H. L. Hunter and W. J. Schenck for the microanalyses reported here, and to Frank Streightoff and Dr. H. M. Lee for the biological tests.

Summary

3-Pyrazolealanine, 3-β-aminoethylpyrazole, 4-pyrazolealanine and 4-β-aminoethylpyrazole have been synthesized.

These pyrazole compounds appear to have no significant biological activity.

INDIANAPOLIS, INDIANA RECEIVED JUNE 2, 1949

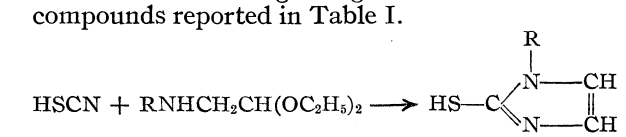
Studies on Imidazoles. IV.[1] The Synthesis and Antithyroid Activity of Some 1-Substituted-2-mercaptoimidazoles

BY REUBEN G. JONES, EDMUND C. KORNFELD, KEITH C. MCLAUGHLIN AND ROBERT C. ANDERSON

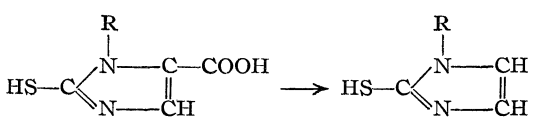
A large amount of synthetic work on antithyroid drugs appears to have been directed toward the preparation of 2-thiouracil types.[2] However, in 1945, Astwood[3] showed that 2-mercaptoimidazole had antithyroid activity about one and one-half times that of thiouracil when tested in rats. In connection with other work a number of 1-substituted-2-mercaptoimidazoles became available, and it appeared to be worthwhile to prepare others of this series and submit them to pharmacological testing.

Easson and Pyman have described a general method of preparing 1-substituted-2-mercaptoimidazoles by the reaction of primary amines with acetalylisothiocyanate.[4] Earlier, Marckwald and others had synthesized compounds of this type from isothiocyanates and aminoacetal.[5] The reaction of thiocyanic acid with N-substituted aminoacetals has proved to be a most useful method for obtaining the greater number of the compounds reported in Table I.



This is designated as method A in the table. The requisite N-substituted aminoacetals were readily prepared by heating chloro- or bromoacetal with primary amines.

Another satisfactory method (B) of synthesizing some of the compounds of Table I consisted of the decarboxylation of 1-substituted 2-mercapto-5-imidazolecarboxylic acids.



The acids were heated to about 250° at which temperature the decarboxylation was rapid, and the yields of the desired products were practically quantitative. Surprisingly the resulting 2-mercaptoimidazoles, in the absence of air, appeared to be quite stable at these elevated temperatures.

The antithyroid activities of a number of the compounds of Table I as determined by the rat test[6] are recorded in the last column. Although 2-mercaptoimidazole appears to be somewhat less active in rats than is propylthiouracil, Astwood has recently found[7] that in man 2-mercaptoimidazole and 1-methyl-2-mercaptoimidazole are much more active.

In addition to the compounds of Table I, three related members were synthesized (see Experimental) and tested. These together with their activities were: 4(or 5)-methyl-2-mercaptoimidazole,[8] 0.05; 4(or 5)-ethyl-2-mercaptoimidazole, 0.1; and 1-methyl-5-ethyl-2-mercaptoimidazole, 0.5. After the completion of this work

Experimental

N-Substituted Aminoacetals.—The preparation of the compounds presented in Table II consisted of heating diethyl chloro- or bromoacetal with an excess of the appropriate primary amine as de-

scribed by Knorr,[11] Paal and Gember[12] and others.[13] The following is a description of a typical experiment.

In a pressure vessel (autoclave or sealed tube) was placed 60 g. (0.3 mole) of bromoacetal and 88 g. (1.0 mole) of N,N-dimethylethylenediamine,[14] and the mixture was heated at 120° for sixteen hours. The product was removed from the reaction vessel, shaken with 100 ml. of 50% aqueous potassium hydroxide, and the organic layer was dried with potassium carbonate. Distillation of this liquid gave 35 g. of unreacted N,N-dimethylethylenediamine and 42 g. of dimethylaminoethylaminoacetal, b. p. 104–106° (12 mm.). The sample for analysis distilled at 105° (12 mm.).

1-Substituted-2-mercapto-5-imidazolecarboxylic Acids.—These acids, presented in Table III, were obtained by saponification of the corresponding methyl or ethyl esters[10] as has been described previously.[10]

[a] Melting points dec. are not corrected. [b] Cyclohexyl.

1-Substituted-2-mercaptoimidazoles. A. From Substituted Aminoacetals and Thiocyanic Acid.—The following example is illustrative of method A used for preparing the compounds of Table I.

To a solution of 19 g. (0.1 mole) of N-*n*-butylaminoacetal in 100 ml. of alcohol was added 12 g. (0.12 mole) of potassium thiocyanate and 55 ml. (0.11 mole) of 2 *N* hydrochloric acid. The mixture was heated on the steam-bath overnight and then evaporated to dryness *in vacuo*. The residue was extracted with hot acetone which, after evaporation, left the crude 1-*n*-butyl-2-mercaptoimidazole.

The crude products were purified in a number of ways. Those which were not too soluble in water, including the butyl and higher homologs, were taken up in dilute aqueous sodium hydroxide. The solution was treated with carbon, filtered and acidified to precipitate the product. Acetone, ethyl acetate or mixtures of one of these with petroleum ether were good solvents for recrystallizing the compounds.

B. Decarboxylation of 1-Substituted-2-mercapto-5-imidazolecarboxylic Acids.—Method B for the preparation of compounds in Table I is illustrated by the following typical experiment.

In a two-liter round-bottom flask was placed 300 g. of 2-mercapto-4(or 5)-imidazolecarboxylic acid. This was heated with a soft flame and stirred with a glass rod until all had melted and foaming had stopped. The melt was cooled under nitrogen or carbon dioxide and the solid was taken up in 2.5 l. of boiling absolute alcohol. The alcohol solution was boiled with a liberal quantity of decolorizing carbon, filtered, evaporated almost to dryness *in vacuo*, and 1 l. of petroleum ether was added to the residue. The white crystalline solid was collected on a filter and air-dried. It was analytically pure.

α-Bromobutyraldehydediethylacetal.—The method described by Kuhn and Grundmann[15] for the preparation of α-bromo-*n*-valeraldehydediethylacetal was employed using freshly distilled *n*-butyraldehyde. The product was obtained in 58% yield; b. p. 88–91° (21 mm.).

Anal. Calcd. for $C_8H_{17}BrO_2$: Br, 35.50. Found: Br, 35.59.

α-Aminobutyraldehydediethylacetal.—α-Bromobutyraldehydediethylacetal, 200 g., was mixed with 100 ml. of methanol in a 1-l. high pressure autoclave, and the bomb was cooled in Dry Ice–methanol. About 450 ml. of liquid ammonia was then added, and the bomb was closed. The reaction mixture was heated for seven hours at 120–130°. After the autoclave had been opened the ammonia was allowed to evaporate, and the methanol was distilled *in vacuo*. The mixture was diluted with ether, and a concentrated aqueous solution containing 70 g. of potassium hydroxide was added slowly with stirring. The ether solution was decanted, and the remaining sludge was extracted twice with ether. The extracts (600 ml.) were dried over potassium hydroxide, and the ether was evaporated. The residue was distilled *in vacuo;* b. p. 79–84° (24 mm.); yield, 98 g. (68%).

Anal. Calcd. for $C_8H_{19}NO_2$: N, 8.69. Found: N, 8.47.

2-Mercapto-4(5)-ethylimidazole.—This was prepared from butyraldehydediethylacetal and thiocyanate as described above. The yield was 38 g. (84%), and the product was recrystallized from either dilute ethanol or water; m. p. 165–167°.

Anal. Calcd. for $C_5H_8N_2S$: N, 21.86. Found: N, 21.26.

α-Methylaminobutyraldehydediethylacetal.—α-Bromobutyraldehydediethylacetal, 341 g., was charged into a cold 1-l. autoclave with 450 ml. of liquid methylamine, and the mixture was heated for seventeen hours at 115°. The product was isolated as described above for the amino homolog; b. p. 85–90° (25 mm.); yield, 189 g. (71%). The acetal contained a trace of the bromide starting material which was not removed by fractionation; however, it was adequately pure for conversion to the mercaptoimidazole.

2-Mercapto-1-methyl-5-ethylimidazole.—This compound was prepared as described above for the other 2-mercaptoimidazoles. The yield was 71%; m. p. 208–210°.

Anal. Calcd. for $C_6H_{10}N_2S$: N, 19.70. Found: N, 19.01.

Summary

A series of 1-substituted-2-mercaptoimidazoles has been synthesized, and some of the compounds have been tested for antithyroid activity in rats.

Hantzsch's Pyridine Synthesis

BY ARTHUR P. PHILLIPS

The Hantzsch pyridine synthesis[1] has been run using cinchoninaldehyde,[2] *m*-nitrobenzaldehyde, *p*-dimethylamino- and *p*-diethylaminobenzaldehydes as the aromatic aldehydic reactants, and with a variety of alkyl acetoacetates as the ester components. The first products obtained by this synthesis were all of the normal dihydropyridine type, and manifested weak analgesic and curare-like activities in laboratory animals.

A series of quaternary salts has been prepared from each of the original basic Hantzsch products (including the *m*-aminophenyl ones obtained by reduction of the *m*-nitrophenyl derivatives) by the addition of alkyl halides to the quinoline (or aminophenyl) nitrogen, (the dihydropyridine nitrogen being relatively non-basic[1,3]) hoping in this way to attain products with increased water solubility and enhanced curariform activity. The correlation of curare-like activity with quaternary ammonium salt structure represents one of the oldest and best examples of a relationship between chemical constitution and physiological action.

Many of the quaternary ammonium iodides were very sparingly soluble in water and some of the more active substances were converted to different salts, chlorides and ethanesulfonates, by reaction with the appropriate silver salts. The chlorides so obtained were not significantly more soluble in water than the iodides, but the ethanesulfonates were very readily soluble.

The chlorides, obtained from analytically pure iodides with silver chloride, after careful purification by repeated recrystallizations gave consistently low analyses for carbon, though the hydrogen, nitrogen and chloride results agreed well with the calculated figures.

Attempts at catalytic hydrogenations of I, Table I, with the object of reducing the dihydropyridine ring to a piperidine ring, using either palladium charcoal or Adams catalyst and hydrogen at three atm. overpressure, and temperatures from 30–70°, gave back only the unchanged starting material.

The pronounced steric hindrance to be expected in the quinoline dihydropyridine I, Table I, was confirmed by the almost complete lack of hydrolysis of the carbethoxy groups during prolonged refluxing with either aqueous or alcoholic alkali. Furthermore, treatment of the diethyl ester, I, Table I, with excess methanol containing hydrogen chloride gave no evidence of ester interchange. Resistance to saponification in this type of compound was reported by Hantzsch[1] in his original studies, and is surprising only because the true pyridine derivatives, resulting on mild oxidation of the dihydropyridines, are smoothly saponified by alcoholic alkali, even though steric effects of a similar order of magnitude should prevail here, too.

It is felt that the physiological activity observed in this series may be related to the particular steric structure involved here. Because of the saturated nature of the 4-carbon of the dihydropyridine ring to which the quinoline ring is attached the quinoline and dihydropyridine rings will be non-coaxial. Because of the substitution *ortho* to the 4-position of the pyridine ring of quinoline and the *di-ortho* substitution with respect to the 4-position of the dihydropyridine nucleus (by carbethoxy groups buttressed by methyl groups) free rotation about the quinoline-dihydropyridine juncture would be restricted to a marked degree (as in various *ortho*-substituted biphenyls) and the two rings would be distorted still further from anything approaching coplanarity by rotation of one ring about its not quite coaxial axis to the extent of approximately 90°. This property of non-coplanarity of rings is a feature held in common with morphine.

The *m*-nitrophenyl derivatives were reduced rapidly by Adams catalyst and hydrogen to the free primary aminophenyl compounds. The aminophenyldihydropyridines on treatment with excess alkyl iodide (methyl or ethyl) in the presence of potassium carbonate, to neutralize the hydrogen iodide formed, gave in nearly all cases the quaternary ammonium salt directly. In one case alkylation of the aminophenyl with ethyl iodide gave as the principal product the tertiary amine, the diethylaminophenyl compound VIII, Table II, which was then purified and subsequently converted to quaternary salts IX and XI, Table II, with methyl iodide and ethyl iodide in separate experiments.

The aminophenyl dihydropyridine V, Table II (R = C_2H_5) when heated for some time with acetonylacetone gave the 4-(3′-(2″,5″-dimethylpyrryl-1″)-phenyl) dihydropyridine XII, Table II.

Reaction of the *p*-dimethylaminophenyl compounds with a series of alkyl (methyl through *n*-butyl) iodides gave excellent yields of the corresponding quaternary salts. With the *p*-diethylaminophenyl series, as might be expected, the alkyl iodides above methyl iodide reacted very much more slowly, if at all, because of enhanced steric hindrance. Yields with these higher iodides were usually much poorer and in certain

[a] All melting points are uncorrected. [b] A = ethanol; Æ = ethyl acetate; Aq = water; Ac = acetone; E = ether; H = hexane; M = methanol. [c] True pyridine structure obtained by nitric oxidation of I. [d] Dimethyl ester. [e] Calcd.: I, 23.69. Found: I, 23.68.

cases some side-product of the original tertiary amine hydroiodide resulted.

Curare-like action seems to be enhanced, within these series, by accumulation of large alkyl groups both on the quaternary nitrogen and in the ester positions. Interest in these types of compounds has diminished with the noting of undesirable side effects during clinical trials, and with the advent of new and more potent drugs in the fields for which these were being evaluated.

Experimental

Most of these compounds were made by more or less uniform procedures. Thus experimental details are supplied for only one representative of a particular type of compound, while pertinent data for all are included in Tables I–III.

Part I (Table I)

Preparation of the Dihydropyridine, I.—(A) One mol of cinchoninaldehyde and two mols of acetoacetic ester were dissolved in an equal volume of ethyl alcohol. Two mols of concentrated aqueous ammonia were added and the mixture was heated for two hours on the steam-bath. Cooling of the reaction mixture gave I, yield 60%. (B) Alternatively two mols of β-aminocrotonic ester could be used in place of the acetoacetic ester and ammonia of (A); or (C). One mol of acetoacetic ester and one mol of β-aminocrotonic ester could be used with the cinchoninaldehyde. Yields by routes (B) or (C) were never as good as by route (A).

Oxidation of I to the True Pyridine, III.—One mol of I warmed with an excess of 3–6 *N* nitric acid gave a rapid solution of the originally suspended solid accompanied by evolution of oxides of nitrogen. When reaction was complete, in less than an hour, the mixture was cooled and basified with aqueous alkali precipitating the base III in quantitative yield.

Preparation of the Quaternary Salts.—In general one mol of I was dissolved in a little ethanol and heated several hours in presence of excess of the alkyl halide. Finally, the mixture was cooled and the product precipitated with ethyl acetate or ether.

Details concerning individual compounds are included in Table I.

Part II (Table II)

Preparation of the *m*-Nitrophenyl Compound, XIII.—A mixture of 16 g. of *m*-nitrobenzaldehyde, 34 cc. of *n*-butyl acetoacetate, 60 cc. of ethanol, and 10 cc. of concentrated aqueous ammonia was heated for three hours on the steam-bath, allowing alcohol to evaporate. Chilling and scratching converted the originally viscous oil to yellow crystals, yield 29 g. (68%). After recrystallization from benzene–hexane the yellow needles melted at 109–110°.

Hydrogenation of the Nitrophenyl Compound, XIII, to the Amino Compound, XIV.—A suspension of 8 g. of the nitro compound XIII in 50 cc. of methanol was hydrogenated in the presence of platinic oxide at room temperature and one to three atmospheres of hydrogen overpressure. Reduction was rapid, and the calculated amount of hydrogen was absorbed within an hour. After removal of the platinum by filtration, the methanol was evaporated to a small volume. All attempts to obtain this particular aminophenyl derivative crystalline, either as the base, the hydrochloride, oxalate or picrate failed. Thus it never was analyzed or characterized as such, but samples of the viscous, oily base were used directly for alkylations. Alkylations with methyl or ethyl iodides gave essentially quantitative yields of the corresponding quaternary ammonium salts, verifying in this way both the purity and identity of the otherwise uncharacterized oil.

Preparation of the Quaternary Salt, XV, from XIV.—A sample of unpurified base XIV from the preceding experiment, 6 g., dissolved in 100 cc. of benzene, plus 10 cc. of methyl iodide was combined with a concentrated solution of 15 g. of potassium carbonate in 40 cc. of water. The mixture was refluxed on a steam-bath for ten hours. A third oily layer formed, during the reaction, insoluble in either benzene or the carbonate solution. Cooling and scratching converted this oily precipitate to a mass of white crystals; yield 8.3 g. (95%). After washing with water and recrystallization from methanol–ether these crystals melted at 178–179°.

Preparation of the *m*-Pyrrylphenyl Compound, XII.—A mixture of 3.3 g. of the aminophenyldihydropyridine V, 1.3 g. of acetonylacetone and 20 cc. of ethanol was heated

[a] All melting points are uncorrected. [b] A = ethanol; Ac = acetone; Aq = water; B = benzene; E = ether; H = Skelly B; M = methanol. [c] Known compound; Lepetit, *Ber.*, **20**, 1338 (1887); German Patent 42,295, *Friedl.*, **1**, 195. [d] This salt obtained from the iodide and the appropriate silver salt as described in Part II (see ref. 1). [e] Not analyzed; see experimental part for details.

for sixteen hours on the steam-bath, allowing solvent to evaporate. The crystalline residue after recrystallization from ethanol gave 2.5 g. (60%) of white crystals melting at 164–165°.

Other experimental details are to be found in Table II.

Part III (Table III)

Preparation of 2,6-Dimethyl-3,5-dicarbomethoxy-4-(4′-dimethylaminophenyl)-1,4-dihydropyridine (Compound II, Table III).—A mixture of 30 g. (1 mol) of *p*-dimethylaminobenzaldehyde, 50 g. (2.2 mols) of methyl acetoacetate, 20 cc. (excess) of concentrated aqueous ammonium hydroxide, and 60 cc. of methanol was allowed to stand one hour at room temperature. Next in a closed bottle, wired tight, the reaction mixture was heated for seven hours in a steam-bath. After cooling, scratching gave a yellow crystalline product. The yield was 30 g. (43%) of yellow crystals from methanol, m. p. 193–194°. Evaporation of the methanol mother liquors gave 12 g. more of product melting at 192°; total yield 42 g. (61%).

Preparation of the *n*-Butyl Iodide Adduct of II (Compound VI).—A suspension of 6 g. of the above tertiary base (II) in 10 cc. of methanol and 6 cc. of *n*-butyl iodide was refluxed on a steam-bath for sixty-four hours. The crystalline product, 10 g. (100%), was precipitated from the reaction mixture by addition of excess ether, and scratching to induce crystallization. After recrystallization from methanol–ether mixtures it melted at 186–187°.

Preparation of the Chloride, VII, from the Iodide, VI.—A solution of 4 g. of the iodide (VI) in 200 cc. of methanol was digested for two hours on a steam-bath with 6 g. of freshly prepared silver chloride (washed well previously first with water, then with methanol). The mixture of insoluble silver chloride and silver iodide was then filtered off and the clear methanol filtrate was concentrated to about 20 cc. Addition of excess ether, with scratching, gave a white crystalline precipitate, 3 g. (94%) which after recrystallization from methanol–ether melted at 198–199°.

Preparation of the Ethanesulfonate, XXI, from the Iodide, XX.—Exactly equimolecular quantities of the quaternary iodide (XX) and silver ethanesulfonate were dissolved separately in methanol and the clear solutions were mixed. After digesting the mixture for about an hour on the steam-bath the precipitated silver iodide was removed by filtration and the clear filtrate was concentrated by evaporation. The quaternary ethanesulfonate was recovered by precipitation with ether, and was purified by recrystallization from ethanol–ether.

Preparation of the Oxidized, True Pyridine Compound, XIX.—The dihydropyridine quaternary salt, compound XVIII, 1.5 g. was heated for one hour on the steam-bath with 8 *N* nitric acid. Copious fumes of oxides of nitrogen

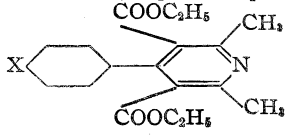
[a] All melting points are uncorrected. [b] A = ethanol; Æ = ethyl acetate; Aq = water; B = benzene; E = ether; H = Skelly B; M = methanol. [c] Based on tertiary amine used; recovered 75% of unused tertiary amine [d] Known, compound; see ref. 3 of text. [e] Isolated from the reaction of compound XIV with benzyl chloride. Hinkel and Cremer, reference 3, report m. p. 201° for this. [f] Hinkel and Cremer report m. p. 182–183°. [g] True pyridine structure



were evolved, and free iodine was liberated and steam distilled or sublimed out of the reaction mixture. The product, presumably the quaternary nitrate of the true pyridine structure, was isolated by reconversion to the iodide. The aqueous acid reaction mixture was basified to *p*H 8 with 40% aqueous potassium hydroxide, and 4 g. of potassium iodide was added precipitating the quaternary iodide. After purification by crystallization from water, then from ethanol–ether the yield of white crystals was 1.2 g. (80%), m. p. 177–178°.

The success of this nitric acid oxidation of the dihydro to the true pyridine structure gives evidence of stabilization of the molecule in the quaternary salt from. Hinkel and Cremer[4] reported that the tertiary amino derivative, compound XIV, could not be oxidized by nitrous fumes to the corresponding tertiary aminophenyl true pyridine, for under these conditions they observed decomposition of the molecule to form *p*-nitrosodimethylaniline nitrate.

Summary

A series of quaternary ammonium salts has been made for examination as potential curare substitutes. These were all derived from the Hantzsch pyridine synthesis employing aromatic aldehydes containing basic salt-forming groups or containing other substituents readily convertible to salt-forming groups.

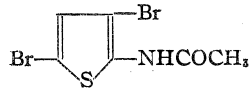
The 2-Aminothiazoles

BY CHARLES D. HURD AND H. L. WEHRMEISTER[1]

Some relationships were developed in the thiophene series, in particular with aceto-2-thiophenamide (I) and its derivatives, which were of an unexpected nature.[2] The 3,5-dibromo derivative (II), for example, underwent nitration to yield the same 3,5-dinitro derivative that was obtained by nitration of I. This substitution

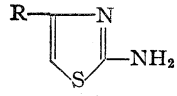
I



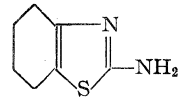
II

of bromine atoms by nitro groups is most unusual. Then again, II was found to couple readily with *p*-nitrobenzenediazonium chloride to form a dye with replacement of the 5-bromo group by azo. Coupling of I even occurred while the solution was strongly acidic. It is remarkable, as a matter of fact, that either I or II should yield azo dyes, since an amine group (not amide) is usually required to activate an aromatic molecule sufficiently for coupling.

The study of substitution reactions of amino and acetamido heterocyclic compounds now has been extended to the thiazoles. The 4-methyl- and 4-phenyl-2-aminothiazoles (III) were prepared by the reaction of thiourea with either the chloro ketone ($RCOCH_2Cl$) or with a mixture of the ketone ($RCOCH_3$) and iodine.[3] A similar procedure, using cyclohexanone, thiourea and iodine, was developed for the preparation of 2-amino-4,5,6,7-tetrahydrobenzothiazole (IV). The preparation of IV from 2-chlorocyclohexanone has been reported.[4]

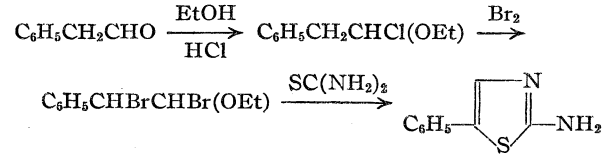


III



IV

5-Phenyl-2-aminothiazole was prepared from phenylacetaldehyde as outlined



The conventional procedure in the first step is to add the hydrogen chloride gas slowly with as little agitation as possible to avoid mixing of the water layer (formed in the reaction) with the organic layer. In the present work emulsions always were encountered, probably because of nearly identical densities of the two phases. Very dark products resulted. Some investigators[5] have designed special apparatus to perform this type of reaction so as to avoid the difficulty mentioned. In the present work, the addition of anhydrous sodium sulfate to the reaction mixture was found to be a simple solution to the problem. With this modification light colored products were obtained even when hydrogen chloride was introduced rapidly and with stirring.

Nitration of 2-acetamidothiazole is known[6] to yield 5-nitro-2-acetamidothiazole. The same compound was obtained in the present study by nitration of 5-bromo-2-acetamidothiazole, thus demonstrating that replacement of halogen does occur in the thiazole as in the thiophene series. Since the structure of the 5-bromo-2-acetamidothiazole is known,[7] the replacement reaction serves to establish the structure of the nitro compound as 5-nitro-2-acetamidothiazole.

Monomercuration of 2-acetamidothiazole occurred in position 5 with mercuric chloride in water, whereas 4,5-dimercuration took place with mercuric acetate in acetic acid. The position of the chloromercuri group in the first of these compounds (V) was established by cleavage with bromine to the known 5-bromo-2-acetamidothiazole. Conversion of V into 5-iodo-2-acetamidothiazole by reaction with iodine also proceeded

readily.[8] Similar cleavage with thiocyanogen (sodium thiocyanate and bromine) yielded 5-thiocyanato-2-acetamidothiazole (VI). 4,5-Diiodo-2-acetamidothiazole was prepared from VII by use of iodine.

Direct thiocyanation of the 2-aminothiazoles (III, R = H, CH_3, or C_6H_5) or the corresponding acetamidothiazoles was readily achieved. Yields were highest for the 4-phenyl derivative.

That thiocyanation occurred in position 5 was established, since the compound from 2-acetamidothiazole was identical to that obtained from V. As might be expected, no product was obtained on attempted thiocyanation of 2-amino-4,5,6,7-tetrahydrobenzothiazole.

No sulfonate was obtained on oxidation of VI with either dilute nitric acid or hydrogen peroxide. Sulfate ion was identified.

Reduction of the thiocyanato group to the mercapto group (RSCN → RSH) was achieved by use of zinc and acetic acid, or of potassium sulfite. The melting point of the 5-mercapto-2-acetamidothiazole so produced differed from that reported by Faith[9] for the reduction product of the compound obtained by the action of chlorosulfonic acid on 2-acetamidothiazole. The assumption that this latter reaction yielded 2-acetamido-5-thiazolesulfonyl chloride evidently is not warranted. The similar reaction of chlorosulfonic acid with 4-methyl-2-acetamidothiazole is stated in one report[10] to yield N-acetyl-4-methyl-2-thiazolylsulfamyl chloride, while in another report[11] the product is described as 2-acetamido-4-methyl-5-thiazolesulfonyl chloride. The reported melting points are 156–157° and 159–160°, respectively. It seems possible that these two substances are identical and that the assignment of structure was in error in one of the papers. The assignment of a sulfamyl chloride was based on the hydrolysis of the compound to the known 4-methyl-2-thiazolylsulfamic acid. The assignment of the sulfonyl chloride structure was based on analogy with other electrophilic reactions (bromination, chlorination) and is probably in error.

Experimental

2-Amino-4,5,6,7-tetrahydrobenzothiazole (IV).—A mixture of 39 g. of cyclohexanone, 61 g. of thiourea and 102 g. of iodine was heated overnight at 100°, then dissolved in 200 ml. of hot water and filtered through Celite. The filter cake was rinsed with 100 ml. of boiling water. Chilling of the combined filtrates in an ice-bath yielded 63 g. of the hydroiodide of IV. Twenty grams of this salt was heated with 150 ml. of water and the mixture was filtered through Celite. The filtrate was cooled and 20 ml. of aqueous 28% ammonia was added. The precipitated solid, after recrystallization from ligroin, appeared as white needles, m. p. 90–90.5°. It was shown to be IV by analysis. The reported[4] m. p. is 87.5–88.5°.

Anal. Calcd. for $C_7H_{10}N_2S$: N, 18.2. Found: N, 18.2.

2-Acetamido-4,5,6,7-tetrahydrobenzothiazole.—Five grams of acetic anhydride and 1.7 g. of IV, after heating for twenty minutes at 100° and diluting with 50 ml. of water, yielded a solid of m. p. 141–142°. Repeated crystallization from ligroin yielded a product melting at 144.5–145°.

Anal. Calcd. for $C_9H_{12}N_2OS$: N, 14.27. Found: N, 14.28.

2-Phenyl-1-chloroethyl Ethyl Ether.—Dry hydrogen chloride (11.5 g.) was introduced rapidly into a chilled, stirred mixture of phenylacetaldehyde (32.5 g.), ethanol (12.5 g.) and anhydrous sodium sulfate (30 g.). The liquid product was decanted from the solid and calcium chloride (16 g.) was added. The mixture was then maintained at 20 mm. pressure for forty-five minutes to remove excess hydrogen chloride. The yield of crude chloro ether was 47 g., or 94%.

Bromination.—Thirty-five grams of the crude ether was cooled and stirred while 30.4 g. of bromine was added during twenty minutes. The yellow crystalline solid which formed was 2-phenyl-1,2-dibromoethyl ethyl ether.

5-Phenyl-2-aminothiazole.—The above yellow solid, stirred with 50 ml. of absolute alcohol, gradually dissolved to a homogeneous, dark green solution. A suspension of 14.5 g. of thiourea in 200 ml. of absolute alcohol containing 10.3 g. of sodium methoxide was then added. The mixture was stirred for two hours and set aside overnight. Most of the solvent was distilled off, it being replaced by 200 g. of water and 20 ml. of concd. hydrochloric acid. The mixture was heated. A green oily layer appeared which was separated and further removed by extraction with ether. The aqueous layer, containing the desired thiazole salt, was cooled in an ice-bath and 100 ml. of aqueous 28% ammonia was added. The precipitate was collected, washed with water and dried; yield, 9.5 g. This crude 5-phenyl-2-aminothiazole was recrystallized thrice from dilute alcohol to yield 6 to 7 g. of product of m. p. 207.5–208.5°.

Anal. Calcd. for $C_9H_8N_2S$: N, 15.9. Found: N, 15.4.

5-Phenyl-2-acetamidothiazole.—Acetylation of the amino compound with acetic anhydride produced the amide, m. p. 244–244.5° after crystallization from alcohol.

Anal. Calcd. for $C_{11}H_{10}N_2OS$: N, 12.8. Found: N, 12.6.

5-Nitro-2-acetamidothiazole.—2-Aminothiazole was brominated and acetylated, forming 5-bromo-2-acetamidothiazole.[7] A mixture of 1.2 ml. of red fuming nitric acid (sp. gr. 1.6) and 5 g. of acetic anhydride was added to a cold solution of 3.2 g. of 5-bromo-2-acetamidothiazole in 55 g. of glacial acetic acid. A 0.3-g. precipitate was separated after ten minutes. The yellow filtrate was evaporated to dryness, taken up in 100 ml. of hot absolute alcohol, decolorized (Norit), filtered and cooled to −10°. After several hours, 0.7 g. of solid was collected, m. p. 260–262°. Recrystallization from alcohol brought the m. p. to 264–265°. Halogen was absent by test.

Anal. Calcd. for $C_5H_5N_3O_3S$: C, 32.08; H, 2.69. Found: C, 32.13; H, 2.73.

5-Nitro-2-acetamidothiazole, m. p. 262–265°, was made for purposes of comparison, by nitration[6] of 2-acetamidothiazole. The mixed m. p. was 262–265°.

(8) The preparation of several monomercurated 2-acetamidothiazoles and their conversion to iodo compounds has been reported recently by Travagli, *Gazz. chim. ital.*, **78**, 592 (1948).

(11) Backer and Jonge, *Rec. trav. chim.*, **62**, 163 (1943).

2-Acetamido-5-thiazolemercuric Chloride[8] **(V).**—To a hot solution of 7.1 g. of 2-acetamidothiazole in 200 ml. of water there was added 250 ml. of an aqueous solution containing 16 g. of mercuric chloride and 32 g. of sodium acetate trihydrate. The mixture was boiled for fifteen minutes, cooled and filtered. The filter cake was washed with 100 ml. of water, 50 ml. of methanol and 50 ml. of ether; yield, 16.7 g. or 88%. The material did not melt below 300°.

Anal. Calcd. for $C_5H_5ClHgN_2OS$: N, 7.43. Found: N, 8.09.

5-Bromo-2-acetamidothiazole.—A mixture of 1 g. of V in 20 ml. of methanol saturated with sodium bromide was treated with 1 g. of bromine. After fifteen minutes some sodium sulfite was added and the mixture was heated to boiling and filtered. The filtrate was diluted with an equal volume of water and concentrated to about 5 ml. Water was added and the solid which separated was recrystallized from dilute acetic acid; yield, 0.24 g. (42%), m. p. 210–212°. Recrystallization from dilute acetic acid brought the m. p. up to 218–220°. A mixture of this product and an authentic sample of 5-bromo-2-acetamidothiazole, m. p. 225–226°, melted at 218–220°.

The authentic sample was prepared both by bromination of 2-aminothiazole[7] and of 2-acetamidothiazole.[12] The once recrystallized product melted at 218–220°. Reported melting points are 224–225°[7] and 229–231°.[12] Our samples melted at 225–226°.

2-Acetamido-4,5-thiazolebis-(mercuric Acetate) (VII).—Forty grams of mercuric acetate, 7.1 g. of 2-acetamidothiazole and 170 ml. of glacial acetic acid were heated together at 100° for eighteen hours. The hot mixture was filtered and the solid product was washed with acetic acid, water, methanol and acetone; yield 23.4 g. (74%). This material did not melt.

Anal. Calcd. for $C_9H_{10}Hg_2N_2O_5S$: N, 4.24. Found: N, 3.46.

5-Iodo-2-acetamidothiazole.—A mixture of 1 g. of V, 1.5 g. of potassium iodide, 10 g. of water and 0.5 g. of iodine was triturated and filtered. The solid was rinsed with water and treated with 30 ml. of alcohol. The mixture was filtered and the filtrate evaporated to 15 ml. On cooling, 0.4 g. (56% yield) of crystals separated; m. p. 210–212°. A constant melting point of 225–226° was achieved after five recrystallizations from dilute alcohol. The recorded m. p. for the 5-iodo-2-acetamidothiazole obtained[8] by a similar approach is 228°.

Anal. Calcd. for $C_5H_5IN_2OS$: C, 22.36; H, 1.88. Found: C, 22.42; H, 1.90.

2-Acetamido-5-thiocyanatothiazole (VI).—To a mixture of 1.2 g. of V and 0.65 g. of sodium thiocyanate in 20 ml. of acetic acid, there was added a solution of 0.58 g. of bromine in 10 ml. of acetic acid. After standing at room temperature overnight, the mixture was filtered and the solid was washed with 10 ml. of acetic acid. Approximately 35 ml. of water was added to the filtrate, and the mixture was evaporated to dryness. The solid residue was recrystallized from methanol. The product weighed 0.32 g. (50% yield) and melted at 195–198°. This material was twice recrystallized from methanol yielding 0.2 g. of a product melting at 212–214°. A mixture of this material and the product of direct thiocyanation of 2-acetamidothiazole melted at 212–214°.

2-Acetamido-4,5-diiodothiazole.—To 20.5 g. of VII there was added a solution of 15 g. of sodium chloride in 150 ml. of water. The stirred mixture was heated at 100° for five hours, cooled and filtered. The solid obtained was washed with 1 l. of water, 50 ml. of methanol and 50 ml. of acetone. The dried product weighed 18.5 g.

A mixture of 3.1 g. of this material, 7 g. of potassium iodide, 2.9 g. of iodine and 25 ml. of water was triturated for a few minutes. The solid obtained was washed with potassium iodide solution until free of iodine. This product was washed with water and dried; yield 1.6 g. A 1.2-g. portion of this material was heated with 60 ml. of 95% alcohol, decolorizing carbon was added, and the mixture was filtered through Celite. The filtrate was concentrated to 30 ml. and 20 ml. of water was added to yield a nearly saturated hot solution. On cooling, there was deposited 0.5 g. of crystalline material. This material decomposed at 222–232° when heated from 100°. When heated from 230°, the sample decomposed at 239–240°. The product was recrystallized from dilute alcohol yielding a sample which decomposed at 240° when inserted in an oil-bath at an initial temperature of 239°. Violet vapors were observed when the sample decomposed.

Anal. Calcd. for $C_5H_4I_2N_2OS$: C, 15.24; H, 1.02. Found: C, 15.20, 15.22; H, 1.08, 1.00.

5-Thiocyanato-4-phenyl-2-aminothiazole.—To a cooled (ice-bath) and stirred mixture of 2-amino-4-phenylthiazole (19 g.), sodium thiocyanate (27 g.) and methanol (100 ml.), there was added a solution of 17.3 g. of bromine in 25 ml. of methanol saturated with sodium bromide. The addition time was twelve minutes. After stirring the reaction mixture for two and one-quarter hours, it was poured onto 200 g. of crushed ice. Approximately 100 ml. of water was used to complete the transfer. A yellow solid was present. Twenty milliliters of concd. ammonium hydroxide was added and the solid was collected by suction filtration, washed with water and dried; weight 24.8 g., m. p. 168–173°.

A part of this product was dissolved in 550 ml. of boiling absolute alcohol to yield an almost saturated solution. The solution was cooled to room temperature and the precipitated solid was collected by filtration. The filtrate was used to dissolve a further portion of the product. This process was repeated a total of five times until all the material had been recrystallized. The recrystallized material weighed 19.5 g. (78% yield) and melted at 171–174°. A sample for analysis was recrystallized repeatedly from absolute alcohol to yield a product with a melting point of 186–187°.

Anal. Calcd. for $C_{10}H_7N_3S_2$: C, 51.48; H, 3.03. Found: C, 51.51; H, 3.11.

This identical procedure was used in the thiocyanation of the other 2-aminothiazoles and 2-acetamidothiazoles. Pertinent data are assembled in Table I. Yields refer to once-crystallized material. The m. p. listed in the table is for material which was crystallized two or more times to constancy. Crystallization was from ethanol, 2-propanol or benzene.

TABLE I

THIOCYANATION EXPERIMENTS

Compound formed: 5-thiocyanato deriv. of	Yield, %	M. p., °C.	Formula	Nitrogen, % Calcd.	Found
2-Aminothiazole	32	142.5–143.5	$C_4H_3N_3S_2$	26.7	27.5
4-Methyl-2-aminothiazole	47	164.0–164.5	$C_5H_5N_3S_2$	24.5	24.5
4-Phenyl-2-acetamidothiazole	100	198–199	$C_{12}H_9N_3OS_2$	15.2	15.0
4-Methyl-2-acetamidothiazole	73	176–176.5	$C_7H_7N_3OS_2$	19.7	19.9
2-Acetamidothiazole	49	212–214	$C_6H_5N_3OS_2$	21.1	21.1

The acetylation of the thiocyanated 2-aminothiazoles with acetic anhydride gave the same products as were obtained by thiocyanation of the analogous 2-acetamidothiazoles. These acetamido compounds were soluble in alkali.

5-Mercapto-2-acetamidothiazole.—One and a half grams of zinc dust was added to a filtered solution of 2 g. of 5-thiocyanato-2-acetamidothiazole in 20–30 ml. of glacial acetic acid. The mixture was heated at 100° for an hour with stirring, then was cooled, poured into 100 ml. of water and evaporated to 40 ml. Then 100 ml. of glacial acetic acid and 20 ml. of water were added and the mixture was heated to 100° and filtered. The gray insoluble material was dissolved in 40 ml. of water and 10 ml. of concd. hydrochloric acid. After filtration, 40 ml. of concd. am-

(12) Backer and Buisman, *ibid.*, **63**, 226 (1944).

monium hydroxide was added to the filtrate. The initially-formed precipitate redissolved. After several hours 1.42 g. of solid separated. It was recrystallized from dilute acetic acid, using Norit, to yield 0.70 g. of 5-mercapto-2-acetamidothiazole, m. p. 255–257°. It decolorized iodine in warm acetic acid solution.

Anal. Calcd. for $C_5H_6N_2OS_2$: C, 34.46; H, 3.47; N, 16.08. Found: C, 34.61; H, 3.17; N, 16.11.

5-Mercapto-4-methyl-2-acetamidothiazole.—The synthesis was essentially by the above procedure. The yield of crude product was 1.15 g. from 2 g. It melted at 252–253° (dec.) after several crystallizations from acetic acid. It also decolorized iodine. Reduction with hot aqueous potassium sulfite also yielded the same product.

Anal. Calcd. for $C_6H_8N_2OS_2$: C, 38.07; H, 4.26. Found: C, 38.15; H, 3.94.

S-*p*-Chlorobenzylisothiuronium Sulfate.—This compound was obtained by adding an excess of an alcoholic solution of S-*p*-chlorobenzylisothiuronium chloride to aqueous sulfuric acid. The sulfate crystallized readily on cooling. It may be crystallized from water; m. p. 223–224° (dec.).

Anal. Calcd. for $C_{16}H_{20}Cl_2N_4O_4S_3$: N, 11.22. Found: N, 11.20.

Oxidation of the Thiocyanates to Sulfate Ion.—Heating of 2 g. of 5-thiocyanato-4-methyl-2-acetamidothiazole for one hour at 100° with 50 ml. of water and 10 ml. of concd. nitric acid produced a clear yellow solution. It was evaporated to dryness. A yellow oil remained. A test portion precipitated strongly with barium chloride solution. The bulk of the oil, dissolved in 15 ml. of water, was filtered and treated with 15 ml. of a 15% solution of S-*p*-chlorobenzylisothiuronium chloride in alcohol. There was formed 0.7 g. of S-*p*-chlorobenzylisothiuronium sulfate, m. p. 221–223°, or 223–224° after recrystallization from water. The mixed m. p. was also 223–224°.

Acknowledgments.—The several combustion analyses were performed by Misses J. Anderson, N. Mold, V. Hobbs and M. Hines.

Summary

Several 2-aminothiazoles and 2-acetamidothiazoles were prepared. Reactions of mercuration, halogenation, nitration and thiocyanation are reported. The bromine in 5-bromo-2-acetamidothiazole is replaced by nitro during nitration. Reduction of the 5-thiocyanato derivatives produces the 5-mercapto derivatives, but oxidation caused cleavage to sulfuric acid. S-*p*-Chlorobenzylisothiuronium sulfate is a new derivative of sulfuric acid.

Derivatives of Thianaphthene. III[1]

BY F. F. BLICKE AND DON G. SHEETS[2]

It was reported in a previous communication[3] that when thianaphthene-2-carboxylic, thianaphthene-2-acetic and thianaphthene-3-acetic acids were heated, in sodium carbonate solution, with Raney nickel for a short time, they were transformed into β-phenylpropionic (93%), γ-phenylbutyric (85%) and β-phenylbutyric acid (98%), respectively. These conversions offer simple, direct and conclusive proof of the structures of the original acids.

During this investigation we determined the suitability of this process for the determination of the structures of other derivatives of thianaphthene, thiophene and dibenzothiophene. The products obtained by the Raney nickel degradation are shown in Table I.

Compounds which contained a carboxyl group were dissolved in sodium carbonate solution, and then treated with Raney nickel. In other instances, methanol or ethanol was found to be a satisfactory solvent although methanol formed an azeotrope with one degradation product, namely, ethylbenzene.

The procedure was used to determine the structure of a product which had been obtained by Ancizar-Sordo and Bistrzycki[4] from the condensation of thianaphthene with benzilic acid. Although it might be expected that a 3-thianaphthenyl derivative would have been formed, at least one instance is known in which a substituent, other than a metal, entered the thianaphthene ring at the 2 position.[5] It was found that the condensation product was diphenyl-(3-thianaphthenyl)-acetic acid since, after degradation, α,α,β-triphenylbutyric acid was obtained.

From 3-hydroxythianaphthene (3-keto-2,3-dihydrothianaphthene) we expected to obtain either

TABLE I

DEGRADATION PRODUCTS OF DERIVATIVES OF THIANAPHTHENE, THIOPHENE AND DIBENZOTHIOPHENE

	Degradation product	Yield, %
Thianaphthene	Ethylbenzene	75.0
3-Hydroxythianaphthene	Ethylbenzene	86.0
Thianaphthene-3-carboxylic acid	α-Phenylpropionic acid	93.4
Diphenyl-(3-thianaphthenyl)-acetic acid	α,α,β-Triphenylbutyric acid	82.5
Thiophene-2-carboxylic acid	Valeric acid	70.0
2-Benzoylthiophene	Valerophenone	75.0
Dibenzothiophene	Biphenyl	97.5
Methylphenylcarbinol	Ethylbenzene	95.3
Acetophenone	Ethylbenzene	93.0

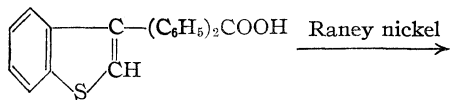
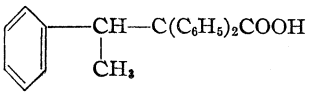
(5) Thianaphthene and phthalic anhydride condense, in the presence of aluminum chloride, to form 2-(*o*-carboxybenzyl)-thianaphthene (Mayer, Mombour, Lassmann, Werner, Landmann and Schneider, *Ann.*, **488**, 259 (1931)).



Diphenyl-(3-thianaphthenyl)-acetic acid



α,α,β-Triphenylbutyric acid

methylphenylcarbinol or acetophenone. The reaction product proved to be ethylbenzene. In separate experiments it was shown that, under the conditions employed, the carbinol, as well as the ketone, was converted into ethylbenzene. Mozingo, *et al.*,[6] found that benzaldehyde, under very similar experimental conditions, was reduced to toluene.

Experimental Part

Ethylbenzene from Thianaphthene, 3-Hydroxythianaphthene, Methylphenylcarbinol and Acetophenone.—A solution of 4.0 g. (0.03 mole) of thianaphthene in 250 cc. of methanol was refluxed for one-half hour with 45 g. of Raney nickel.[7] The cold mixture was filtered, and the catalyst washed with methanol. The filtrate and washings were diluted with 1.5 liters of water and extracted with three 100-cc. portions of chloroform. The chloroform extract was dried and fractionated. There was obtained 2.4 g. of ethylbenzene, b. p. 133–135°.[8]

The ethylbenzene was identified as *p*-ethylbenzenesulfonamide, m. p. and mixed m. p. 109°[9] after recrystallization from water.

Ethylbenzene was obtained from 3-hydroxythianaphthene, methylphenylcarbinol and acetophenone by the process described above, and, in each case, it was identified by the boiling point and by the melting point of the *p*-ethylbenzenesulfonamide. However, for the reduction of 0.04 mole of the carbinol and also of the ketone, only 35 g. of Raney nickel was used.

α-Phenylpropionic Acid from Thianaphthene-3-carboxylic Acid.—By the use of the procedure described previously[3] for the removal of sulfur from thianaphthene-2-carboxylic acid, 1.8 g. (0.01 mole) of thianaphthene-3-carboxylic acid was converted into 1.4 g. of α-phenylpropionic acid.

Anal. Calcd. for $C_9H_{10}O_2$: neut. equiv., 150.2. Found: neut. equiv., 150.0.

The amide, prepared by interaction of the acid chloride with ammonia water, melted at 91–92°[10] after recrystallization from dilute alcohol.

α,α,β-Triphenylbutyric Acid from Diphenyl-(3-thianaphthenyl)-acetic Acid.—By the use of the described procedure,[3] 3.4 g. (0.01 mole) of the diphenylthianaphthenylacetic acid, obtained by the method of Ancizar-Sordo and Bistrzycki,[4] and 40 g. of Raney nickel yielded 2.6 g. of α,α,β-triphenylbutyric acid, m. p. 157–158°[11] after recrystallization from petroleum ether (60–75°).

Anal. Calcd. for $C_{22}H_{20}O_2$: neut. equiv., 316.4. Found: neut. equiv., 315.1.

Valeric Acid from Thiophene-2-carboxylic Acid.—Subjected to the same process,[3] 2.6 g. (0.02 mole) of thiophene-2-carboxylic acid and 40 g. of Raney nickel yielded 1.4 g. of valeric acid, b. p. 180–186°.[12]

Anal. Calcd. for $C_5H_{10}O_2$: neut. equiv., 102.1. Found: neut. equiv., 104.0.

The *p*-bromoanilide, obtained from the acid chloride and *p*-bromoaniline, melted at 107–108°[13] after recrystallization from dilute alcohol; mixed m. p. 107–108°.

Valerophenone from 2-Benzoylthiophene.—A solution of 3.8 g. (0.02 mole) of 2-benzoylthiophene in 600 cc. of ethanol was refluxed for one-half hour with 40 g. of Raney nickel catalyst. The cold mixture was filtered, and the catalyst washed with ethanol. The filtrate and washings were fractionated. There was obtained 2.4 g. of valerophenone, b. p. 117–118° (10 mm.); semicarbazone, m. p. 165–166°[14] after recrystallization from dilute alcohol; 2,4-dinitrophenylhydrazone, m. p. 165–166°[15] after recrystallization from ethanol.

Biphenyl from Dibenzothiophene.—A mixture of 1.8 g. (0.01 mole) of dibenzothiophene, 500 cc. of ethanol and 35 g. of Raney nickel was refluxed for one-half hour. The mixture was cooled, filtered, and the catalyst washed with ethanol. The filtrate was concentrated to a volume of about 15 cc., and water was added until the solution became slightly turbid. Crystalline biphenyl (1.5 g.) separated from the cold solution; m. p. and mixed m. p. with an authentic sample 69–70°[16] after recrystallization from dilute alcohol.

Summary

It has been found that when thianaphthene, certain substituted thianaphthenes, dibenzothiophene and derivatives of thiophene are treated with Raney nickel, the nuclear sulfur atom is replaced by hydrogen, and a simple benzene derivative, which contains a saturated side chain, is formed. This process seems to represent a simple procedure for the determination of the structures of derivatives of these heterocycles.

Alkamine Esters of Phenyl-2-thienylacetic Acid and Phenyl-2-thienylglycolic Acid[1]

BY R. F. FELDKAMP[2a] AND JOHN A. FAUST[2b]

A series of alkamine esters of substituted 2-thienylacetic acid and 2-thienylglycolic acid have been prepared by Blicke and Tsao[3] and the antispasmodic activity determined by Lands and co-workers.[3,4,5] This former study of basic alkyl esters included 2-thienyl, phenyl, 2-naphthyl, benzyl and 4-xenyl substituted 2-thienylacetic and 2-thienylglycolic acids. Of this group, the basic esters of the phenyl substituted acids showed the greatest diversity of activity and an enlarged series of esters of these acids have been prepared for pharmacological evaluation.

Both phenyl-2-thienylglycolic acid and phenyl-2-thienylacetic acid were prepared by the method previously described.[3]

The necessary basic alkyl chloride hydrochlorides were prepared by the action of thionyl chloride upon the corresponding basic alkanols in benzene solution. The bromide hydrobromides were prepared by the action of 48% hydrobromic acid on the alcohols in aqueous solution. In order to retard the cyclization of the free halides, ether extracts were used directly with subsequent solvent exchange as required. Most of the basic alkyl ester salts were obtained by refluxing the basic alkyl halide and acid in isopropyl alcohol for fifteen hours[6]; however, some of the esters required special methods as indicated.

We are indebted to Dr. A. M. Lands and coworkers in the Pharmacological Research Laboratories for the preliminary antispasmodic screening data reported herein. The compounds were tested by the Magnus technique against acetylcholine and barium chloride induced spasms in isolated strips of rabbit jejunum. In general, the glycolate esters were more anticholinergic than the corresponding acetates, whereas none of the compounds showed any appreciable activity against barium chloride. The modifications of the ester group produced approximately the same degree of difference in activity in each series. Some conclusions on the relationship between structure and activity, which refer equally well throughout each series, can best be summarized in the higher range of the glycolate series.

1. Quaternary salts increase the activity. The methobromides 21 and 27 are more active than the corresponding hydrochlorides 20 and 26.

2. Increasing the length of the carbon chain between the nitrogen and the carbonyl decreases the activity. Compound 20 is more active than compound 23. This relationship, however, is offset by branching. Actually compound 28 is more active than compound 26.

3. Alkyl substitutions on the nitrogen larger than ethyl diminish the activity as shown by comparing compound 20 with 25. Groups larger than isopropyl cause almost complete loss of activity. The four compounds 20, 25, 29 and 34 show this relationship.

4. The over-all effect of the ester group can best be shown by indicating the diminishing activity of compounds 28, 20, 23, 26, 25, 22, 30, 31 and 29. It is interesting that compound 31 with one methyl group on the nitrogen still retained appreciable activity.

Experimental

Phenyl-2-thienylacetyl Chloride.—Phenyl-2-thienylacetic acid was dissolved in ten times the theoretical quantity of purified thionyl chloride. The clear solution was refluxed for fifteen minutes during which time a deep purple color developed. Excess thionyl chloride was removed first by distillation under reduced pressure and finally by the successive addition and distillation of three 5–10-cc. portions of anhydrous benzene. The resulting deeply colored residual oil was used directly without further purification. Several attempts to purify the product by distillation resulted in total decomposition.

Methyl Phenyl-2-thienylacetate.—A solution of 28.2 g. (0.12 mole) of phenyl-2-thienylacetic acid, 400 cc. of anhydrous methanol and 2.0 cc. of 98% sulfuric acid was refluxed for five hours. The solvent was removed by distillation and the residual oil treated with water. The ester was extracted with ether and the extract washed with dilute sodium bicarbonate solution. The extract was dried with anhydrous magnesium sulfate, the solvent removed and the ester distilled; yield 24.6 g. (82.5%), b. p. 157–161° (0.8 mm.), m. p. 71–73° after recrystallization from *n*-heptane.

Anal. Calcd. for $C_{13}H_{12}O_2S$: S, 13.80. Found: S, 13.96.

N-Methyl-N-(2-hydroxyethyl)-phenyl-2-thienylacetamide.—A mixture of 23.2 g. (0.1 mole) of methyl phenyl-2-thienylacetate, 15.0 g. (0.2 mole) of 2-methylaminoethanol and 0.2 g. of sodium methoxide was heated in an oil-bath for two hours at 140–150°. The reaction mixture was dissolved in hot ethanol, cooled, the crystals collected and washed with cold alcohol; yield 20.4 g. (74.2%), m. p. 153–154° after recrystallization from the same solvent.

Anal. Calcd. for $C_{15}H_{17}NO_2S$: N, 5.09. Found: N, 4.83.

2-Methylaminoethyl Phenyl-2-thienylacetate Hydrochloride.—Hydrogen chloride was bubbled into a suspension of 15.2 g. (0.055 mole) of N-methyl-N-(2-hydroxyethyl)-phenyl-2-thienylacetamide in 400 cc. of isopropyl alcohol until all solid had dissolved. The solvent was removed by distillation and the residual gum solidified by rubbing several times with fresh portions of anhydrous ether; yield 10.55 g. (61.5%). (Analysis and properties in Table I.)

[a] Prepared by Blicke and Tsao.[3] [b] We are indebted to Elizabeth B. Macks for the analytical data on these compounds. [c] These figures are preliminary results only but are sufficiently accurate to permit a relative comparison of the compounds [d] 1:4,000,000 dilution. [e] 1:200,000–400,000 dilution. [f] $C_5H_{10}N$ = 1-Piperidyl. Compounds 3, 17, 18 and 25 were recrystallized from isopropyl alcohol; compounds 16, 27, 32, 33 and 35 from anhydrous ethanol; compound 4 from anhydrous ethanol and anhydrous ethyl acetate; compounds 8, 19, 21, 28, 31 and 34 from isopropyl alcohol and isopropyl ether; compounds 9, 26 and 30 from anhydrous ethanol and ethyl ether; compounds 11, 12 and 15 from anhydrous ethyl acetate; and compound 29 from ethyl acetate and isopropyl alcohol. [g] Alternative structure $[(C_2H_5)_2NCH(CH_3)\text{-}CH_2\text{-}]$ not excluded. Compounds 9, 12, 13, 14, 19, 25, 26, 28, 29, 30, 31, 32, 33, 34 and 35 were prepared by Method I; compounds 8, 10, 11, 16 and 18 by Method II; compound 17 by Method III; compound 3 by Method IV and compounds 4, 21 and 27 by Method V.

Preparation of Basic Esters and Salts

I. From Basic Alkyl Halides.[6]—Equimolar quantities of basic alkyl halide and acid were dissolved in an appropriate volume of isopropyl alcohol and the solution refluxed for fifteen hours. The solvent was removed by evaporation and the solid or gummy residue rubbed with anhydrous ether. The resulting solid was recrystallized from a suitable solvent as indicated in the tables.

II. From Phenyl-2-thienylacetyl Chloride.—The crude acid chloride from above was dissolved in anhydrous benzene and treated with an equivalent of the basic alcohol in the same solvent. After refluxing for one hour, the benzene was removed from the slurry by distillation and the residue dissolved in dilute hydrochloric acid. Insoluble material was extracted with ether. The clear solution was made alkaline to litmus with 10% sodium carbonate solution and the liberated basic-ester extracted with ether. The ether extract was dried with anhydrous magnesium sulfate. After filtration the ether was removed by distillation and the residual oil purified by distillation under reduced pressure. Hydrochlorides were obtained either by treating the dried ether extract or an ether solution of the distilled base with dry hydrogen chloride gas.

III. By Ester Exchange.—Equivalent amounts of methyl phenyl-2-thienylacetate and the basic alcohol were mixed with 0.1 g. of sodium methoxide and heated at 200° for twenty-four hours. The reaction mixture was cooled, dissolved in isopropyl alcohol and the solution treated with an equivalent amount of 48% hydrobromic acid. The product was worked up as in II.

IV. Hydrobromides.—A purified base was dissolved in isopropyl alcohol and treated with the theoretical quantity of 48% hydrobromic acid. The solvent was removed by distillation and the product purified as under I.

V. Methobromides.[7]—Either a purified base or a crude base obtained by neutralizing an aqueous solution of a hydrochloride with 10% sodium carbonate was dissolved in anhydrous ethanol. The solution was placed in a pressure bottle, cooled and treated with four to six equivalents of methyl bromide. After standing at room temperature for twenty-four hours the reaction mixture was worked up as under I.

Summary

Twenty-four new alkamine esters of phenyl-2-

(7) Blicke and Maxwell, THIS JOURNAL, **64**, 430 (1942).

thienylacetic acid and phenyl-2-thienylglycolic acid were prepared and characterized. From the results of some preliminary antispasmodic screening, brief conclusions are drawn on the relationship between structure and activity.

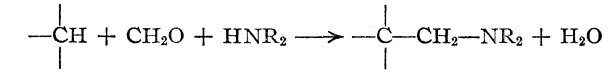
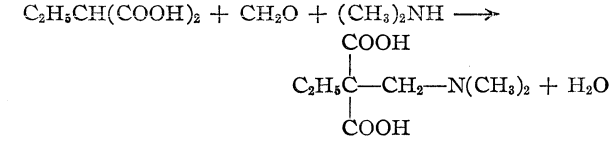
Studies on the Mechanism of the Mannich Reaction. I. Ethylmalonic Acid, A Methynyl Compound

BY ELLIOT R. ALEXANDER AND ELIZABETH J. UNDERHILL

When a compound containing an active hydrogen atom is treated with formaldehyde and ammonia or a primary or secondary amine, the active hydrogen atom is replaced by an aminomethyl group.



This reaction is commonly called the Mannich reaction,[1] and it has been used widely in synthesis. Its mechanism, however, has not been elucidated. Many types of active methylene and methynyl compounds undergo the reaction and it has been run in both acidic and basic media. The purpose of this investigation was to study the kinetics of the reaction of ethylmalonic acid with formaldehyde and dimethylamine.



Ethylmalonic acid, it will be observed, is a compound with only one replaceable hydrogen atom.

Experimental

Materials

Ethylmalonic Acid.—The ethylmalonic acid (m. p. 110–110.5°) used in this investigation was prepared by the saponification of commercial ethyl ethylmalonate.[2] Before commencing the preparation, however, the ester was shaken with half its volume of 25% aqueous potassium hydroxide for one half hour in order to remove any ethyl malonate which might have been present.

Formaldehyde.—In order to depolymerize any polyoxymethylenes present,[3a] commercial 37% formalin was diluted twenty-fold to give a solution approximately 2% in formaldehyde, which was allowed to stand for at least two days. The solution was standardized by the method outlined below.

Dimethylamine.—A solution, 2.616 *N* in dimethylamine, was made up by diluting commercial 25% aqueous dimethylamine. It was standardized with normal hydrochloric acid, using methyl orange as an indicator.

Nessler reagent (K_2HgI_4) was prepared according to the procedure given in the "Handbook of Chemistry and Physics."[4] It was found convenient to prepare it in quantities of 16 liters.

Dimethylaminomethylethylmalonic Acid.—The method used for the preparation of this acid was essentially that of Mannich and Ganz.[5] From 6.6 g. (0.05 mole) of ethylmalonic acid, 10 ml. (0.05 mole) of 22.5% dimethylamine solution, and 4.1 ml. (0.05 mole) of 37% formalin, was obtained 7.3 g. (77%) of the amino-acid, m. p. 100.5–101° (dec.).

Dimethylaminomethanol.—For the preparation of dimethylaminomethanol the procedure of Henry[6] was modified as follows. To 114 ml. (1.5 moles) of 37% formalin cooled in an ice–salt-bath, 270 ml. (1.5 moles) of 25% dimethylamine solution was added dropwise with stirring. The stirring was continued for two and one-half hours after addition was complete. Anhydrous potassium carbonate was then added in small portions until an oily layer formed. This was separated and dried over anhydrous potassium carbonate. During the entire preparation the temperature was kept below 5°, and the product was kept in a refrigerator. The yield of crude, undistilled material was 79 g. (70%), $n^{20}D$ 1.4060 (The refractive index changed to 1.4050 over a period of twenty four hours and then remained constant.). This substance was dissolved in water and analyzed as described for formaldehyde and dimethylamine.

Anal. Calcd. for C_3H_9NO: CH_2O, 40.0; $(CH_3)_2NH$, 60.0. Found: CH_2O, 36.8; $(CH_3)_2NH$, 61.2.

The infrared absorption spectrum of the substance showed only a very weak absorption band in the region characteristic of the OH group.

Procedures

Determination of Formaldehyde.—The determination of formaldehyde was carried out by a modification of the mercurimetric method of Bougault and Gros.[7] To 50 ml. of Nessler reagent was added a sample containing 0.0002 to 0.0006 equivalent of formaldehyde. A precipitate formed at once, the resulting mixture was shaken for five minutes, and it was then acidified by the addition of 30–40 ml. of 2 *N* acetic acid. Twenty-five ml. of 0.1 *N* iodine solution was added immediately and the precipitate was dissolved by agitation. The excess iodine was titrated with 0.1 *N* sodium thiosulfate solution. Care was taken to keep the mixture alkaline until the addition of the acetic acid by adding to the Nessler reagent 2–6 ml. of 10% sodium hydroxide solution in cases where the formaldehyde sample was strongly acidic. Blanks were run and corrections made for the effects of Nessler reagent, buffer, amine, ethylmalonic acid and dimethylaminomethylethylmalonic acid, on the thiosulfate titer. The corrections were not more than a few tenths of a ml. and were in such directions that they tended to cancel each other.

Determination of the Order of Reaction.—To study the kinetics of the formation of dimethylaminomethylethyl-

malonic acid from ethylmalonic acid, dimethylamine, and formaldehyde, the reaction was run in a solution kept at *p*H 4.20 ± 0.08 by the use of a buffer consisting of 4.102 g. of sodium acetate and 8–11 ml. of 12.56 *N* acetic acid, depending on the relative concentrations of amine and ethylmalonic acid.[8] The buffer, formaldehyde and amine were mixed in a 50-ml. volumetric flask, diluted to about 40 ml., and allowed to stand at room temperature for at least twelve hours. The solution was then cooled to 0°, ethylmalonic acid was added, the solution was made up to the mark, and the flask was immersed in a bath maintained at 0.09 ± 0.27°. Aliquots containing 0.0002 to 0.0006 equivalent of formaldehyde were withdrawn from time to time and analyzed immediately for formaldehyde in order to determine the extent of reaction. In each run the reaction was allowed to proceed to 52–80% of completion. The results are summarized in Table I and a typical reaction curve is shown in Fig. 1. Included in Table I is one run (54) in which the ionic strength was approximately doubled by adding 5.0 g. of potassium chloride.[9] When the reaction was run without allowing the amine and formaldehyde to stand at room temperature, complex curves (Fig. 1) were obtained.

51	4.18	.2238	.2616	.3942	.370
53	4.18	.1119	.2616	.3942	.337
54[c]	4.16	.2210	.2616	.3942	.360
				Average[d]	.360 ± 0.033

[a] Temperature is 0.48 ± 0.17°. [b] Formaldehyde and dimethylamine in the form of dimethylaminomethanol. [c] Ionic strength doubled by the addition of 5.0 g. of potassium chloride. [d] Excluding runs 44 and 49.

To investigate the reversibility of the reaction, a solution made up of the buffer and 3.78 g. (0.02 mole) of dimethylaminomethylethylmalonic acid was diluted to 50 ml. After maintaining this solution at 0° for one week, no precipitate characteristic of formaldehyde was formed upon analysis of an aliquot. Control runs were also made to discover whether there was an independent reaction between formaldehyde and either dimethylamine or ethylmalonic acid. A 50-ml. solution containing 0.02 mole of ethylmalonic acid, 0.01 mole of formaldehyde and the buffer was left at 0° for three days, and the loss in formaldehyde content was found to be 3%. In another run the acid was replaced by 0.013 mole of dimethylamine, and the formaldehyde content decreased by only 1.5% in three days.

In order to ascertain that ethylmalonic acid did not react with formaldehyde to form a compound which was decomposed under the basic conditions of the formaldehyde analysis, hydroxymethylethylmalonic ester was prepared[10] and tested for formaldehyde with Nessler reagent and also with methone.[3b] In the former case it gave formaldehyde quantitatively, but in the latter case, under acidic conditions, only a negligibly small trace of formaldehyde was detected. The control with ethylmalonic acid and formaldehyde was repeated at 0–5°, and when followed by the methone analysis it was found that 5% reaction occurred in three days.

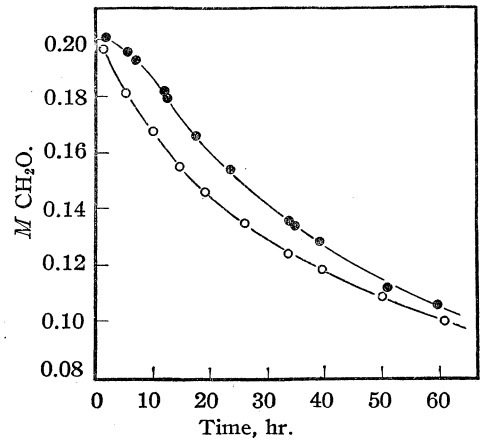

Fig. 1.—Course of the Mannich reaction at 0.16 ± 0.10° using solutions 0.2056 *M* in formaldehyde, 0.2616 *M* in dimethylamine and 0.1971 *M* in ethylmalonic acid: ⊙, Run 27, in which the formaldehyde and amine were mixed twelve hours before the addition of the ethylmalonic acid; ●, all the reagents mixed at once.

Dependence of the Specific Rate Constant, *k*, on *p*H.—By following the procedure outlined above, the dependence of the specific rate constant on *p*H was determined. In all cases the quantities of reagents used were: 2.6011 g. (0.01971 mole) of ethylmalonic acid, 5.00 ml. (0.01308 mole) of 2.616 *N* dimethylamine solution, 16.25 ml. 0.01028 mole) of 0.6324 *M* formaldehyde solution. The *p*H was varied by changing the composition of the buffer, and the temperature was held at 0.48 ± 0.04°. The buffers used and the rate constants calculated are summarized in Table II and Fig. 3. Control runs were made to determine the extent of the independent reactions of formaldehyde with dimethylamine and with ethylmalonic

TABLE II

DEPENDENCE OF REACTION RATE ON *p*H

Run	*p*H	Buffer	*k*, (liter²/mole² hr.)
39	2.90	3.728 g. KCl	0.342
40	3.95	4.102 g. NaOAc + 16.1 ml. 12.56 *N* HOAc	.455
41	4.60	4.102 g. NaOAc + 2.5 ml. 12.56 *N* HOAc	.306
42	5.03	4.102 g. NaOAc	.222
46	5.50	4.102 g. NaOAc + 4 ml. 10% NaOH	.121
47	1.00	4.102 g. NaOAc +16 ml. 5 *N* HCl	No reaction
59	11.57	20 ml. 10% NaOH	No reaction[a]
62	8.37	10 ml. 10% NaOH	0.007[b]

[a] No reaction in excess of the reaction between formaldehyde and dimethylamine. [b] Calculated roughly from the extent of reaction after three days.

(8) The volumes of acetic acid necessary to attain a *p*H of 4.2 were determined by previous experiments.

(9) The ionic strength was calculated by assuming that the sodium acetate and potassium chloride were completely dissociated, and that the dissociation constants of ethylmalonic acid and dimethylamine are 1.09×10^{-4} and 5.2×10^{-4}, respectively. The second dissociation constant of ethylmalonic acid was assumed to be negligible.

(10) Welch, *J. Chem. Soc.*, 257 (1930).

acid over the *p*H range investigated. In acid solutions these reactions were found to be negligible, but in strongly basic solutions there was a noticeable reaction between formaldehyde and the amine.

Reaction of Dimethylaminomethanol with Ethylmalonic Acid.—The buffer, 2.6011 g. (0.01971 mole) of ethylmalonic acid, and 1.0 ml. of dimethylaminomethanol (corresponding to 0.01045 mole of formaldehyde and 0.01162 mole of dimethylamine), were mixed and diluted to 50 ml. at 0°. The reaction was followed in the usual way, and the results are included in Table I. Identical results were obtained when an induction period of twelve hours was allowed before the addition of the ethylmalonic acid.

Results

By plotting the function

$$\frac{2.303}{(a-b)(b-c)(c-a)}\left[(b-c)\log\frac{a-x}{a}+(c-a)\log\frac{b-x}{b}+(a-b)\log\frac{c-x}{c}\right]$$

against the time for the runs listed in Table I, straight lines were obtained. A typical line is shown in Fig. 2. In the above expression,

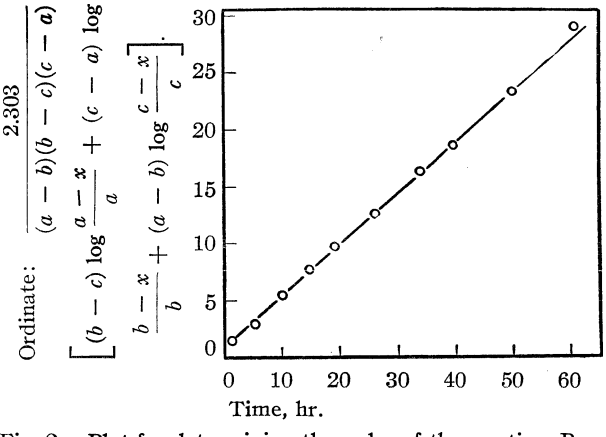

Fig. 2.—Plot for determining the order of the reaction, Run 27(see Fig. 1).

a is the initial concentration of formaldehyde, b the initial concentration of dimethylamine, c the initial concentration of ethylmalonic acid, and x is the change in concentration of any of these components as calculated from the formaldehyde remaining in the solution. All concentrations are expressed in moles per liter. In no case was the scattering of points from the straight lines greater than experimental error, or was there a trend away from these lines as the reaction proceeded, even in the case where it was allowed to proceed to 80% of completion. This relationship indicates that at constant *p*H the reaction obeys the rate equation

$$dx/dt = k(a-x)(b-x)(c-x)$$

where t is the time in hours and k is the specific rate constant in liters^2/mole^2 hr. The kinetics of the reaction is, therefore, first order in each of the components and third order over-all. A value of 0.360 ± 0.033 was obtained for k at 0.09 ± 0.27°. Third order kinetics was followed only when the formaldehyde and amine were mixed and allowed to stand for twelve hours before the addition of the ethylmalonic acid. When all three components were mixed at once, complex reaction curves were obtained (Fig. 1). Although the ionic strength in these runs varied from 1.16 to 1.39, it can be seen that the rate constant is independent of ionic strength over this range, since an increase from 1.26 (runs 30 and 51) to 2.60 (run 54) in otherwise similar runs had no effect upon k. The ionic strength was not increased further because of the insolubility of potassium chloride, the neutral salt added. The reaction is non-reversible, and since no appreciable reaction was detected between formaldehyde and either dimethylamine or ethylmalonic acid in the *p*H range of 3 to 8, the disappearance of formaldehyde from the reaction solution was taken as a true measure of the extent of the Mannich reaction under these conditions.

In Table II are listed the third order rate constants calculated for runs at various *p*H values. It can be seen that the rate is critically dependent on *p*H, and passed through a maximum at about *p*H 3.8. In Fig. 3 the specific rate constant, k, is plotted against *p*H.

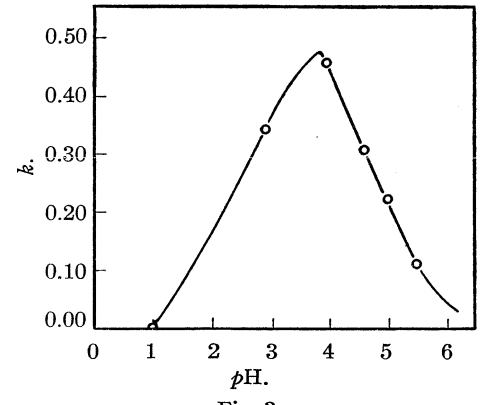

Fig. 3.

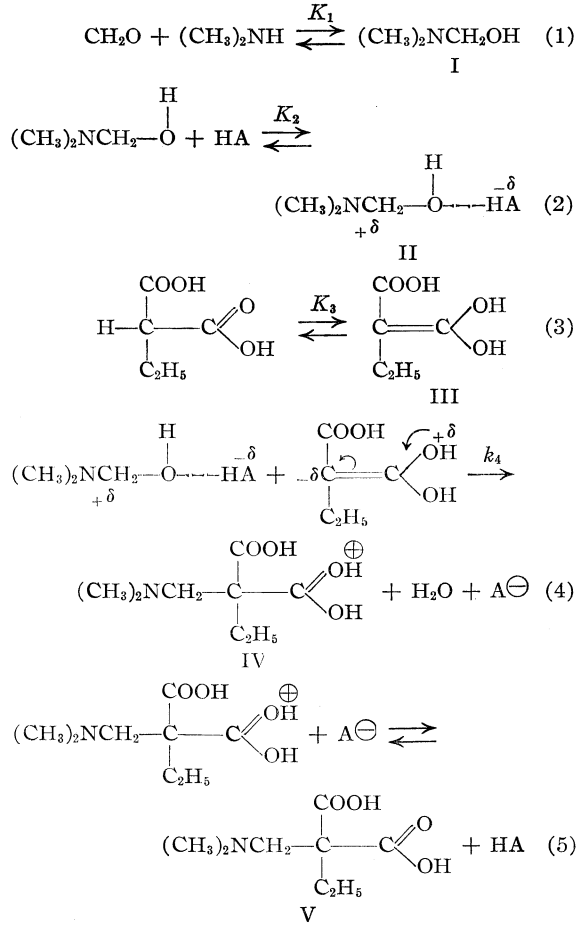
From runs 44 and 49 made at 0.48 ± 0.17°, it can be seen that the use of dimethylaminomethanol in place of formaldehyde and dimethylamine has no effect on the kinetics or on the rate constant of the reaction. The third order rate constants obtained were 0.431 (run 44) in which dimethylaminomethanol was used) and 0.410 (run 49 in which formaldehyde and dimethylamine were used), and these values are within the limits of experimental variation.

Discussion

Since it is quite possible that the Mannich reaction proceeds by different mechanisms depending on the number of replaceable hydrogen atoms and on the experimental conditions, this phase of our study was limited to an investigation of the behavior of a compound containing a methynyl group. Several compounds were tested in attempting to find one suitable for kinetic studies. In acid solution, antipyrine and indole

condense with formaldehyde even in the absence of dimethylamine. Isobutyraldehyde interferes with the formaldehyde determination, and phenylacetylene reacts best in a non-aqueous, heterogeneous system. Ethylmalonic acid was used since it has none of these disadvantages, and it reacts in good yields under mild conditions. The temperature was kept at 0° to avoid decarboxylation of the dimethylaminomethylethylmalonic acid.

The most striking feature of the experimental data is that the Mannich reaction of ethylmalonic acid follows third order kinetics. Any mechanism must take this fact into consideration. While there are other reaction sequences which follow third order kinetics, two of which will be mentioned later, one mechanism consistent with our results is



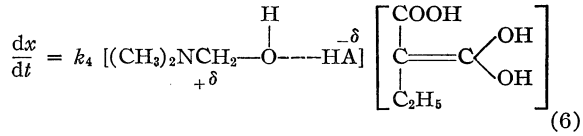
In these equations HA represents any acid present in the system.

Thus the reaction may be considered to be initiated by the reversible addition of dimethylamine and formaldehyde to give dimethylaminomethanol (I). In the presence of an acid HA, a reactive, hydrogen bonded addition complex (II) could be formed. A properly oriented collision of II with ethylmalonic acid, probably in the transitory enol form (III), would produce water, the conjugate base $A^{\ominus}$ and a protonated molecule of dimethylaminomethylethylmalonic acid (IV). Reaction of IV with the conjugate base $A^{\ominus}$ would give the free amino acid V.

The rate determining step of the over-all process is that represented by equation 4 since the rate is dependent upon the concentration of all three components and upon the concentration of acid present in the reaction mixture (Fig. 3).

Apparently, however, the rate of the establishment of the equilibrium of equation 1 is faster than but still in the same range as that of equation 4 since the initial over-all rate of the reaction was slower when all of the reagents were mixed at once than when the amine and formaldehyde were allowed to stand together for twelve hours before adding the ethylmalonic acid (Fig. 1). Presumably, in those reactions in which the amine and formaldehyde were not allowed to come to equilibrium, the initial concentration of complex II was small. Once equilibrium was established, however, it was not disturbed by the reaction of II with ethylmalonic acid. In order to obtain pure third order kinetics all of the equilibria must be established and maintained throughout the reaction.

From the above scheme it can be seen that



(6)

and, making the appropriate substitutions

$$dx/dt = K_1K_2K_3k_4[CH_2O][(CH_3)_2NH][C_2H_5CH(COOH)_2][HA] \quad (7)$$

At constant acid concentration this reduces to:

$$dx/dt = k[CH_2O][(CH_3)_2NH][C_2H_5CH(COOH)_2] \quad (8)$$

The complex variation of the rate of reaction upon *p*H indicates general acid catalysis.[11] Qualitatively, the reaction is acid catalyzed as shown by equation 7, but an increase in acid concentration decreases the concentration of the free amine and the free amine also enters into the reaction. It is presumably a superposition of these two effects which gives rise to the type of curve illustrated in Fig. 3). General acid catalysis explains the spread in rate constants at constant *p*H as the concentrations of ethylmalonic acid and dimethylamine are varied. To maintain a *p*H of 4.2 the amount of acetic acid in the buffer was varied, and thus the concentration of at least one of the acid catalysts was changed without being considered in the rate equation. It is therefore not surprising that there is a small spread in the rate constants (Table I).

While third order kinetics for the Mannich reaction merely supports the mechanism which was

(11) Hammett, "Physical Organic Chemistry," McGraw-Hill Book Co., Inc., New York, N. Y., 1940, pp. 329–333.

proposed in equations 1–5, two facts strongly imply the formation of dimethylaminomethanol as an intermediate. First, under the experimental conditions employed, the reaction of formaldehyde with ethylmalonic acid was found to be negligible when followed by the methone method of analysis for formaldehyde. Since this method gave a negative test for formaldehyde in the presence of ethyl hydroxymethylethylmalonate, it is probable that any reaction between formaldehyde and ethylmalonic acid to form the corresponding hydroxymethyl acid would be detected by this method. Consequently, mechanisms based upon the preliminary condensation between these two components have been eliminated from consideration. Second, not only is the formation of some necessary intermediate between the amine and formaldehyde indicated (Fig. 1), but also it appears to be of the methylolamine type. It is particularly significant that smooth third order curves are obtained from formaldehyde, dimethylamine and ethylmalonic acid only after allowing the amine and formaldehyde to stand together for twelve hours. With dimethylaminomethanol, however, the preliminary equilibration may be omitted and the rate constant is identical with that obtained from dimethylamine, formaldehyde and ethylmalonic acid. It is clear, therefore, that dimethylaminomethanol does not react by a preliminary hydrolysis to dimethylamine and formaldehyde, and the identity of the rate constants suggests that dimethylaminomethanol is an actual intermediate in the process. Equations 2–5 illustrate the sequence which seems to be the most probable for the reaction of dimethylaminomethanol with ethylmalonic acid.

There are a number of other mechanisms which we have considered and rejected. The reaction may be assumed to proceed by the attack of a free carbonium ion upon the enol form of ethylmalonic acid

$$(CH_3)_2NH + CH_2O \underset{}{\overset{K_1}{\rightleftharpoons}} (CH_3)_2NCH_2OH \quad (9)$$

$$(CH_3)_2NCH_2OH + HA \overset{K_4}{\rightleftharpoons} (CH_3)_2\overset{\oplus}{N}CH_2 + H_2O + A^{\ominus} \quad (10)$$

$$(CH_3)_2\overset{\oplus}{N}CH_2 + \begin{matrix} COOH \\ | \\ C \\ \| \\ C \\ | \\ C_2H_5 \end{matrix}\!\!\begin{matrix} \\ \\ OH \\ \\ OH \end{matrix} \overset{K_5}{\rightleftharpoons} (CH_3)_2NCH_2\text{—}\begin{matrix} COOH \\ | \\ C \\ | \\ C_2H_5 \end{matrix}\!\!\begin{matrix} \\ \\ \oplus OH \\ \\ OH \end{matrix} \quad (11)$$

$$(CH_3)_2NCH_2\text{—}\begin{matrix} COOH \\ | \\ C \\ | \\ C_2H_5 \end{matrix}\!\!\begin{matrix} \\ \\ \oplus OH \\ \\ OH \end{matrix} + A^{\ominus} \xrightarrow{k_6} (CH_3)_2NCH_2\text{—}\begin{matrix} COOH \\ | \\ C \\ \| \\ C \\ | \\ C_2H_5 \end{matrix}\!\!\begin{matrix} \\ \\ O \\ \\ OH \end{matrix} + HA \quad (12)$$

This series of equations, however, requires equation 12 to be the slowest step in the sequence for if equation 11 were non-reversible and rate determining the over-all rate equations would be

$$\frac{dx}{dt} = k_5[(CH_3)_2\overset{\oplus}{N}CH_2]\left[\begin{matrix} COOH \\ | \\ C \\ \| \\ C \\ | \\ C_2H_5 \end{matrix}\!\!\begin{matrix} \\ \\ OH \\ \\ OH \end{matrix}\right]$$

$$= k_5K_1K_3K_4[CH_2O][(CH_3)_2NH][C_2H_5CH(COOH)_2]\frac{[HA]}{[A^{\ominus}]}$$

and since

$$[OH_3^{\oplus}][A^{\ominus}]/[HA] = Ka$$

this reduces to specific oxonium ion catalysis which does not explain the complex variation of rate constant with pH which was found. It seems improbable that reaction 12 could be considered the rate determining step of the entire sequence since this involves a reaction between the conjugate acid of a carboxylic acid group (presumably a very strong acid) and a base such as acetate ion.

Another attractive mechanism[12] suggests that reaction occurs between a carbanion formed from ethylmalonic acid and the carbonium ion shown in equation 10. This hypothesis also has certain disadvantages. First, if the transition complex of the rate determining step involves the neutralization of unit charges, an increase in ionic strength should decrease strongly the rate of reaction.[13] This was not observed (run 54, Table I). Second, if carbanion formation exhibits general acid-base catalysis

$$H\text{—}\begin{matrix} C_2H_5 \\ | \\ C \\ | \\ COOH \end{matrix}\!\!\text{—}COOH + A^{\ominus} \underset{}{\overset{K_7}{\rightleftharpoons}}$$

$$HA + \left[\begin{matrix} \ominus C_2H_5 \\ | \\ :C \\ | \\ COOH \end{matrix}\!\!\text{—}COOH \leftrightarrow \begin{matrix} C_2H_5 \\ | \\ C \\ \| \\ C \\ | \\ COOH \end{matrix}\!\!\begin{matrix} \\ \\ O \\ \\ OH \end{matrix}^{\ominus}\right]$$

and if the rate determining step is between a carbonium ion and a carbanion

$$(CH_3)_2\text{—}\overset{\oplus}{N}\text{—}CH_2 + \begin{matrix} \ominus C_2H_5 \\ | \\ :C \\ | \\ COOH \end{matrix}\!\!\text{—}COOH \xrightarrow{k_8}$$

$$(CH_3)_2N\text{—}CH_2\text{—}\begin{matrix} C_2H_5 \\ | \\ C \\ | \\ COOH \end{matrix}\!\!\text{—}COOH$$

then the rate of reaction can be expressed by the equation

$$\frac{dx}{dt} = k_8[(CH_3)_2\overset{\oplus}{N}CH_2]\left[\begin{matrix} \ominus C_2H_5 \\ | \\ :C \\ | \\ COOH \end{matrix}\!\!\text{—}COOH\right]$$

(12) Lieberman and Wagner, Abstracts of Papers, Third Meeting-in-Miniature of the American Chemical Society, Philadelphia, Pennsylvania, 1949, p. 49.

(13) Hughes, *Trans. Faraday Soc.*, **37**, 609 (1941).

Upon making the appropriate substitutions the expression becomes independent of the concentration of acid HA. This is also contrary to fact.

The mechanism outlined in equations 1–5 is interesting in view of the fact that in basic solution antipyrine has been reported to give a poorer yield of 4-dimethylaminomethylantipyrine with dimethylaminomethanol than with dimethylamine and formaldehyde under similar conditions.[14] This was interpreted to mean that the reaction did not proceed through the primary condensation of the amine with formaldehyde. We have repeated the experiments and have verified these results. While we do not, as yet, understand their significance to the base catalyzed transformation, it is clear that they have no bearing on our reaction carried out in acid solution. We have shown that the kinetics is unchanged when formaldehyde and dimethylamine are replaced by dimethylaminomethanol.

(14) Bodendorf and Koralewski, *Arch. Pharm.*, **271**, 101 (1933).

Summary

1. In acid solution the Mannich reaction of ethylmalonic acid, formaldehyde and dimethylamine, follows third order kinetics, first order in each of the three components.

2. The rate of reaction shows a critical dependence on *p*H. It passes through a maximum at about *p*H 3.8.

3. Under the conditions of our experiments, no reaction takes place between ethylmalonic acid and formaldehyde.

4. Smooth, third order curves are obtained for the reaction only if the amine and formaldehyde are mixed and allowed to stand for twelve hours before adding the ethylmalonic acid, but if the formaldehyde and dimethylamine are replaced by dimethylaminomethanol, the reagents may all be mixed at once.

These facts are in agreement with an ionic mechanism for the Mannich reaction of methynyl compounds, based upon a primary condensation of formaldehyde with the amine.

The Preparation of 5,5′- and 7,7′-Difluoroindigo

BY ARTHUR ROE AND CLAUDE E. TEAGUE, JR.

The preparation of several fluoroindigos was undertaken as part of a study of aromatic and heterocyclic fluorine compounds being carried out in this Laboratory. The method of Sandmeyer[1] was found to be the most satisfactory way to prepare these compounds; 5,5′- and 7,7′-difluoroindigo were prepared from *p*-fluoroaniline and *o*-fluoroaniline, respectively, by this method. The preparation of 5,5′-difluoroindigo is outlined in the accompanying equations.

TABLE I

	Compound	Formula	M. p., °C.	Yield, %	Nitrogen, % Calcd.	Found
1	*s*-Di-*p*-fluorophenylthiourea[2,3]	$C_{13}H_{10}F_2N_2S$	187.5	94	10.6	10.7
2	*s*-Di-*o*-fluorophenylthiourea	$C_{13}H_{10}F_2N_2S$	188	97	10.6	10.6
3	N,N′-bis-(*p*-Fluorophenyl)-cyanoformamidine	$C_{14}H_9F_2N_3$	128	99	16.3	16.3
4	N,N′-bis-(*o*-Fluorophenyl)-cyanoformamidine	$C_{14}H_9F_2N_3$	128	98	16.3	16.3
5	α-(N,N′-Di-*p*-fluorophenylguanyl)-thioformamide	$C_{14}H_{11}F_2N_3S$	119	73	14.4	14.5
6	α-(N,N′-Di-*o*-fluorophenylguanyl)-thioformamide	$C_{14}H_{11}F_2N_3S$	106	98	14.4	14.6, 14.7
7	5,5′-Difluoroindigo	$C_{16}H_8F_2N_2O_2$	...	28[a]	9.4	9.3, 9.4
8	7,7′-Difluoroindigo	$C_{16}H_8F_2N_2O_2$	...	37[b]	9.4	9.3

[a] Yield based on compound (5). [b] Yield based on Compound (6).

The attempted preparation of 4,4′- or 6,6′-difluoroindigo starting with *m*-fluoroaniline was not possible because *m*-fluoroaniline would not react with carbon disulfide to form a difluorodiphenylthiourea; after one hundred and fifty hours refluxing the *m*-fluoroaniline was recovered almost quantitatively. The reaction of carbon disulfide with *o*- and *p*-fluoroaniline was complete in forty and seventy hours, respectively.

The *s*-di-*p*-fluorophenylthiourea formed by the action of carbon disulfide on *p*-fluoroaniline is not a new compound; conflicting reports of its melting point appear in the literature, however. Browne and Dyson[2] prepared it from *p*-fluoroaniline and thiocarbonyl chloride, and reported a melting point of 145°; Lubs and Fox[3] prepared it by the reaction of *p*-fluorophenyl isothiocyanate with *p*-fluoroaniline and report a melting point of 186.5–188°. The third synthesis here reported gives a product melting at 187.5°.

Attempts to prepare 5,5′-difluoroindigo by Baeyer's method[4] were not too successful. The preparation of 5-fluoro-α-isatin chloride from *p*-fluoroaniline was accomplished satisfactorily; attempted conversion of this to the fluoroindigo, however, resulted in the formation of large amounts of a difluoroindirubin contaminated with traces of 5,5′-difluoroindigo.

Attempts to use the Heumann method[5] starting with *p*-fluorophenylglycine were not too satisfactory; very poor yields of 5,5′-difluoroindigo were obtained in this way.

A comparison of the two new difluoroindigos with 5,5′-dibromoindigo[6] was made. No difference in the ease of vatting with hydrosulfite and the stability of the reduced form of the three dyes was noted. The dibromoindigo was absorbed on cotton cloth more rapidly than either of the difluoroindigos; both difluoroindigos were markedly more light-fast than was the dibromo derivative, however.

Experimental[6]

Directions given[1a,b] for the preparation of indigo were followed in the synthesis of 5,5′- and 7,7′-difluoroindigo; compounds involved in the synthesis which were stable enough to be analyzed are shown in the table below along with the final products. The fluoroanilines used as starting materials were prepared by the Schiemann reaction.[7]

Vatting of the dyes was carried out as follows: 0.15 g. of the dye was placed in a beaker with 100 ml. of 10% sodium hydroxide and the solution warmed to about 90°; 1 g. of sodium hydrosulfite was added with stirring. The dyes went into solution immediately, forming a light yellow solution.

Summary

The synthesis of 5,5′- and 7,7′-difluoroindigo is reported.

Orientation in Aromatic Compounds of Phosphorus. II. Nitration of Diethyl Benzenephosphonate

BY GENNADY M. KOSOLAPOFF

Although the results of nitration of benzenephosphonic acid have been reported,[1,2] the esters of this acid have not been subjected to this reaction. A study of the aromatic reactions of such esters is of importance because of the ready availability of these derivatives by the modified Friedel–Crafts reaction.[3] In addition, the observations on the possible effect of the ester grouping, in comparison with the free acid, may be expected to be of interest.

Nitration of benzenephosphonic acid with fuming nitric acid has been reported to yield the *m*-nitro isomer.[2] The early work of Michaelis and his co-workers,[1] in which the product was separated from the unreacted material by a tedious crystallization of its barium salt, indicated the formation of a product, which melted at 140°, described as the para-derivative, without further proof of structure. Nijk,[2] in making a more thorough investigation, showed that the compound reported by Michaelis was the *m*-isomer; it should be noted that the yield of the purified product was only 50–60%.[2]

Preliminary experiments indicated that diethyl benzenephosphonate nitrates much more sluggishly than dibutyl benzylphosphonate[4] in the cold with either fuming nitric acid or with mixed acid. Satisfactory nitration was performed, however, with fuming nitric acid at somewhat above room temperature. Separation of the nitrated product from the original material was readily accomplished by fractional distillation. The boiling point spread of more than thirty degrees permitted a much more rapid and convenient method for the separation of unreacted material than the previously reported procedures.[1,2] The product of nitration showed a boiling range of several degrees, which indicated the presence of isomeric nitro derivatives; this range was much too narrow, however, for a practical separation of the isomers by distillation. The nitrated product, therefore, was either hydrolyzed to the free acid (mixture) and the latter reduced to the amino derivative, or first reduced to the amino acid ester (mixture) and then hydrolyzed. The results were identical in either case: 3-aminobenzenephosphonic acid was isolated in pure state along with the 2-amino isomer, which could not be obtained completely free from the 3-isomer. The over-all yield of the amino acid mixture from the nitro ester averaged 86%. Although the *p*-amino isomer was not detected, the formation of the *p*-nitro compound in the nitration mixture is not excluded, because of the possibility of decomposition of the phosphanilic acid. Unfortunately, no data on such decomposition are available at this time; however, it has been noted that the yields of phosphanilic acid are severely reduced if the ammonolysis, used in its synthesis, is unduly prolonged. It is of interest to note that the mixture of the nitrobenzenephosphonic acids melts at the same temperature as the *m*-nitro isomer, as reported by Nijk,[2] and several attempts to separate this mixture by crystallization (from water or from organic solvents), were fruitless. This fact calls for a re-examination of the nitration products of the free acid, particularly in view of the fact that the total yield of positively identified products from such nitrations has been far below the theoretical.

Experimental Part

Nitration of Diethyl Benzenephosphonate.—Nitration of the ester under previously reported conditions[4] gave but 15–20% conversions. However, addition of 42.8 g. (0.2 mole) of diethyl benzenephosphonate to 130 ml. of fuming nitric acid (d. 1.5) over one hour at 30–35° and stirring at this temperature for one hour, followed by quenching with ice-water, washing with water and dilute sodium carbonate solution (after dilution with 300 ml. of benzene), and distillation *in vacuo*, resulted in isolation of the nitration products in the form of a pale yellow liquid, which boiled at 135–145° at 0.5 mm.; the original ester boils at 99–100° at 0.5 mm. In several experiments the average yield of the product was 35 g. (67.5%), with recovery of 7 g. of unreacted ester.

Identification of the Products.—Reduction of the nitrated product (15 g.) by addition to a mixture of 38 g. of iron filings and 45 ml. of 8% acetic acid with vigorous stirring at 60–70°, followed by stirring at 80° for forty-five minutes, resulted in isolation, after neutralization with sodium carbonate, extraction with benzene and washing with water, of the isomer mixture of diethyl aminobenzenephosphonates in the form of an oil, which could not be distilled or crystallized. Hydrolysis of this mixture by boiling concentrated hydrochloric acid (150 ml.) for four hours, followed by the removal of the bulk of hydrochloric acid *in vacuo* and careful neutralization of the residue to a weak congo red end-point by means of sodium carbonate, gave 8.6 g. (86%) of the mixed 2- and 3-aminobenzenephosphonic acids, in the form of a colorless, very sparingly soluble, crystalline powder. The decomposition range, 290–296°, of this material indicates the absence of appreciable amounts of the para isomer, which develops a characteristic blue decomposition color at lower temperatures. In addition, its characteristic acetyl derivative could not be detected following Bauer's method of preparation.[5]

Treatment of this mixture (1.73 g.), in water containing just enough hydrochloric acid to give a clear solution, with bromine resulted in isolation of 0.9 g. of 2,4,6-tribromoaniline (27%), m. p. 118°, and 2.5 g. of 2,4,6-tribromo-3-aminobenzenephosphonic acid (61%), which decomposed at 222–223° (Nijk[2] reports 222°). The former substance forms as a result of dephosphonation of

2-aminobenzenephosphonic acid. Repeated fractional crystallization of the amino acid mixture from water resulted in isolation of the 3-isomer, in the form of colorless needles, which decomposed at 290–292° (heated block); this product gave no detectable amounts of tribromoaniline on treatment with bromine water. The 2-isomer could not be freed of the 3-isomer completely and the material always gave small amounts of the above-mentioned tribromoaminobenzenephosphonic acid with bromine water, in addition to the normally expected tribromoaniline; this imperfect material showed a decomposition range of 294–296° (heated block).

Hydrolysis of the mixed diethyl nitrobenzenephosphonates (20 g., 0.0775 mole) by boiling with concentrated hydrochloric acid (175 ml.) for five hours resulted in isolation of 11–12.5 g. (78.5–89.5%) of the free acid mixture, which after crystallization from benzene–ether–ligroin mixture melted at 138–139°. This mixture, in the form of fine, almost colorless needles, could not be resolved into its components by crystallization. Reduction with alkaline sulfide, according to the previously described procedure,[6] gave the amino acid mixture similar to the one described above.

Acknowledgment.—The writer wishes to express his gratitude to Professor R. L. Shriner, who pointed out some time ago the possibility of non-homogeneous nature of Nijk's nitrobenzenephosphonic acid.

Summary

Nitration of diethyl benzenephosphonate results in the formation of appreciable amounts of the *o*-nitro isomer, along with the *m*-nitro isomer.

Some Steric Effects of the Cyclohexyl Group in Organosilicon Compounds

BY W. H. NEBERGALL[1,2] AND O. H. JOHNSON

In earlier studies[3,4] the writers found that chlorotricyclohexylgermane, $(C_6H_{11})_3GeCl$, was the sole product of the action of a large excess of cyclohexyllithium upon germanium tetrachloride, no tetracyclohexylgermane apparently being formed. However, the halogen atom of this substituted germane was found to be replaceable by normal alkyl, benzyl and phenyl groups. Attempts to substitute the chlorine atom by the sterically hindered isopropyl, cyclohexyl and *o*-tolyl groups were unsuccessful.

Efforts to prepare tricyclohexylphenylsilane, $(C_6H_{11})_3SiC_6H_5$, by the action of a large excess of cyclohexylmagnesium bromide on phenyltrichlorosilane were reported as unsuccessful by Cusa and Kipping.[5] Instead of the expected tricyclohexyl derivative, they obtained dicyclohexylphenylsilane, $(C_6H_{11})_2SiH{\cdot}C_6H_5$. This compound was brominated and then alkylated, using ethylmagnesium bromide at 160–180° to form dicyclohexylphenylethylsilane. The failure to obtain tricyclohexylphenylsilane was attributed to the steric effect associated with the cyclohexyl group.

These results led the authors to investigate the extent of substitution of the cyclohexyl group in the silane molecule by the use of cyclohexyllithium upon silicon tetrachloride. Under conventional experimental conditions three cyclohexyl groups are substituted for chlorine atoms in the reaction of cyclohexyllithium in large excess with silicon tetrachloride.

$$3C_6H_{11}Li + SiCl_4 \longrightarrow (C_6H_{11})_3SiCl + 3LiCl$$

The reaction of the tricyclohexylsilicon compound, however, differed from its germanium analog in that efforts to replace the chlorine atom by methyl, ethyl and phenyl groups were unsuccessful.

$$(C_6H_{11})_3SiCl + RLi \longrightarrow \text{No reaction}$$

Both Grignard and organolithium compounds were employed as alkylating agents and the ether was replaced by higher boiling solvents in an endeavor to force the reaction. In addition, since the Si–Br bond is reported[6] as weaker than the Si–Cl bond, bromotricyclohexylsilane was prepared and its alkylation attempted but still no evidence of further substitution was observed.

Chlorotricyclohexylsilane failed to respond to sodium condensation in boiling toluene, whereas bromotricyclohexylgermane condensed to form hexacyclohexylgermane,[3] $(C_6H_{11})_3Ge{-}Ge(C_6H_{11})_3$, under similar conditions.

Chlorotricyclohexylsilane was reduced to tricyclohexylsilane, $(C_6H_{11})_3SiH$, by lithium aluminum hydride in ether solution. This silane was brominated and iodinated to form the corresponding halides. Hydrolysis of the chloride yielded tricyclohexylsilanol, $(C_6H_{11})_3SiOH$, which was esterified by boiling with acetic anhydride to form acetoxytricyclohexylsilane.

Experimental

Synthesis of Chlorotricyclohexylsilane Using Cyclohexyllithium.—Cyclohexyllithium was prepared by adding, over a period of four hours, 95 g. (0.8 mole) of chlorocyclohexane to 500 ml. of low-boiling petroleum ether containing an excess of lithium metal shot in a one-liter, three-necked flask fitted with a mercury-sealed, air-driven stirrer, a reflux condenser protected by a calcium chloride tube, and a dropping funnel containing the chlorocyclohexane. The reaction mixture was stirred and heated on a warm water-bath to initiate the reaction, after which

(1) Part II from a thesis submitted by W. H. Nebergall to the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of Doctor of Philosophy. See THIS JOURNAL, 71, 1720 (1949), for Part I.

(2) Present address: Indiana University.

(3) Johnson and Nebergall, THIS JOURNAL, 70, 1706 (1948).

(5) Cusa and Kipping, *J. Chem. Soc.*, 1040 (1933).

(6) Linus Pauling, "The Nature of the Chemical Bond," 2d ed., Cornell University Press, Ithaca, New York, 1940, p. 53.

the heat of reaction caused continuous refluxing for two hours after all of the chlorocyclohexane had been added. Without filtering out the lithium chloride and excess lithium, 17.0 g. (0.1 mole) of silicon tetrachloride in 50 ml. of petroleum ether was added dropwise to the solution of cyclohexyllithium which was stirred and cooled in an ice–water-bath during the entire addition. After allowing the reaction mixture to stand overnight at room temperature, the lithium chloride and excess lithium were filtered out and the excess cyclohexyllithium was destroyed with 6 *N* hydrochloric acid while the reaction mixture was stirred and cooled in an ice–water-bath. The organic layer was separated, dried over anhydrous calcium chloride, and the solvent was removed by distillation leaving a viscous oily liquid. The product which was crystallized from glacial acetic acid and recrystallized from petroleum ether proved to be chlorotricyclohexylsilane, $(C_6H_{11})_3SiCl$, m. p. 101–102°,[7] yield 15 g. (60%).

Anal. Calcd.: Si, 8.97. Found: Si, 8.8.

Attempted Preparation of Methyltricyclohexylsilane by the Grignard Method.—Methylmagnesium iodide was prepared by treating 3 g. (0.13 mole) of magnesium turnings with 14.2 g. (0.1 mole) of methyl iodide in 150 ml. of absolute ether. On completion of the reaction, 3.1 g. (0.01 mole) of chlorotricyclohexylsilane dissolved in 20 ml. of dry toluene was added to the Grignard reagent. The reaction mixture was refluxed for one hour and then the uncombined ether was replaced by dry toluene. After heating the mixture on a steam-bath for three hours, the Grignard reagent was destroyed by pouring the reaction mixture into a mixture of cracked ice and dilute hydrochloric acid. The organic layer was separated and dried over anhydrous calcium chloride. The toluene was removed by air evaporation, yielding 2.5 g. of colorless crystals, which were recrystallized from low-boiling petroleum ether; m. p. 100–101°. A test for the chloride ion following hydrolysis with alcoholic potassium hydroxide was positive, indicating that the original chlorotricyclohexylsilane had undergone no change.

Attempted Substitution of Chlorotricyclohexylsilane Using Organolithium Compounds.—Methyllithium was prepared from 14.2 g. (0.1 mole) of methyl iodide and an excess of lithium metal shot in 150 ml. of anhydrous ethyl ether by the general procedure outlined for the preparation of cyclohexyllithium. On completion of the reaction, 3.1 g. (0.01 mole) of chlorotricyclohexylsilane dissolved in 25 ml. of ether was added to the solution of methyllithium. The mixture was brought to the reflux temperature and held there for two hours. The ethyl ether was replaced by petroleum ether (50–60°) and the reaction mixture was refluxed overnight. After hydrolyzing the methyllithium with dilute hydrochloric acid, the ether layer was separated and the ether was removed by evaporation. The product, recrystallized from glacial acetic acid, melted at 100–101°; test for the chloride ion was positive following hydrolysis with alcoholic potassium hydroxide. Again the methyl group failed to replace the chlorine atom of chlorotricyclohexylsilane.

Using similar procedures, attempts were made to replace the chlorine atom with ethyl and phenyl groups by the organolithium method. In each case, failure was encountered.

Suspecting that the resistance of the chlorine to substitution might be due to the stability of the Si–Cl bond, the less stable bromo derivative was prepared and an attempt was made to alkylate it, using ethyllithium. Once again, bromotricyclohexylsilane was reclaimed, unaltered, at the end of the experiment.

An Attempt to Synthesize Hexacyclohexyldisilane.—A solution of 6 g. of chlorotricyclohexylsilane in 100 ml. of dry toluene was heated with an excess of metallic sodium in a 200-ml., three-necked flask, fitted with a reflux condenser and adapted for flushing with nitrogen. The mixture was held at the reflux temperature for four hours during which time no indications of a reaction were apparent. The toluene solution was then removed from the sodium and upon evaporation of the solvent, 5.8 g. of the original chlorotricyclohexylsilane was reclaimed; m. p. 100–101°; test for the chloride ion was positive.

Reduction of Chlorotricyclohexylsilane by Lithium Aluminum Hydride.—A solution of 6 g. (0.019 mole) of chlorotricyclohexylsilane in 50 ml. of anhydrous ethyl ether was added dropwise to an excess of lithium aluminum hydride in 100 ml. of ethyl ether contained in an apparatus adapted for refluxing and excluding moisture. The reaction mixture was refluxed for one-half hour and then the ethyl ether was replaced by low-boiling petroleum ether. The excess lithium aluminum hydride and the chlorides of lithium and aluminum as products of the reaction are insoluble in petroleum ether, whereas the desired product, tricyclohexylsilane is soluble. After warming the petroleum ether solution, the insoluble substances were filtered out and most of the petroleum ether was removed by distillation at atmospheric pressure and the rest of the ether was taken off under reduced pressure. The tricyclohexylsilane, $(C_6H_{11})_3SiH$, obtained was an oily liquid which boiled at 183–185° (9 mm.), $n^{25}D$ 1.5132, yield 5 g. (90%). The compound did not freeze in a bath of Dry Ice and ethanol.

Anal. Calcd.: Si, 10.08. Found: Si, 10.0.

Bromination of Tricyclohexylsilane.—A solution of 1 g. of this silane in 50 ml. of carbon tetrachloride was treated with a slight excess of bromine. A carbon tetrachloride solution of the bromine was added dropwise to the silane solution until the bromine color no longer disappeared and the formation of hydrogen bromide ceased. The reaction mixture was heated to boiling for a few minutes and then the product was crystallized by air evaporation of the solvent. The yield of bromotricyclohexylsilane, $(C_6H_{11})_3SiBr$, m. p. 112–113°, was quantitative.

Anal. Calcd.: Si, 7.85. Found: Si, 7.9.

Iodination of Tricyclohexylsilane.—A sample of 2.8 g. of this compound was dissolved in 50 ml. of carbon tetrachloride and a slight excess of iodine crystals was added to the solution. The reaction mixture was refluxed for two hours, at the end of which time hydrogen iodide ceased to be evolved. The excess iodine was removed by combining it with powdered antimony and filtering. The carbon tetrachloride was replaced by low-boiling petroleum ether and the product, $(C_6H_{11})_3SiI$, was crystallized from this solvent and recrystallized from absolute ethanol; m. p. 97–98°, yield 2.1 g. (52%).

Anal. Calcd.: Si, 6.94. Found: Si, 7.0.

Iodotricyclohexylsilane appears to be quite unstable in view of the fact that samples of the crystalline product soon turn brown and its solutions take on a violet coloration on exposure to the air.

The Hydrolysis of Chlorotricyclohexylsilane.—A sample of 10 g. (0.032 mole) of this chloride was dissolved in 200 ml. of boiling, 5% alcoholic potassium hydroxide. Immediately a white precipitate of potassium chloride began to form and the reaction was complete in a few minutes. An equal volume of water was added to the solution which caused the formation of a white precipitate of tricyclohexylsilanol, $(C_6H_{11})_3SiOH$. This product was filtered out, crystallized from ethyl ether, and recrystallized from low-boiling petroleum ether; m. p. 176–177°, yield 8.2 g. (87%).

Anal. Calcd.: Si, 9.53. Found: Si, 9.4.

The Esterification of Tricyclohexylsilanol.—A solution of 3 g. (0.01 mole) of this silanol in 20 ml. of acetic anhydride was held at the reflux temperature for two hours. The solution was then cooled in an ice–water-bath and upon agitation of the mixture, a crop of colorless crystals formed. The product was collected on a sintered-glass filter crucible and washed with ethanol. The dried crystals melted at 82–83° and analysis indicated acetoxytricyclohexylsilane, $(C_6H_{11})_3Si—OCOCH_3$, yield 2.7 g. (80%).

Anal. Calcd.: Si, 8.34. Found: Si, 8.5.

(7) All melting points are uncorrected.

Summary

1. It has been found that cyclohexyllithium in large excess reacts with silicon tetrachloride to form chlorotricyclohexylsilane but no tetracyclohexylsilane.

2. Attempts to replace the chlorine atom of chlorotricyclohexylsilane by methyl, ethyl and phenyl groups using both Grignard and organolithium compounds as alkylating agents failed. In addition, this chlorosilane failed to respond to sodium condensation to give the disilane. These results may be due to the steric properties of the three cyclohexyl groups attached to the silicon atom in chlorotricyclohexylsilane.

3. Six new compounds have been prepared and some of their properties described. These compounds are: chlorotricyclohexylsilane, bromotricyclohexylsilane, iodotricyclohexylsilane, acetoxytricyclohexylsilane, tricyclohexylsilane and tricyclohexylsilanol.

Photochemical Studies of the Porphyrins. II. The Photoöxidation of Chlorins by Various Quinones

BY FRANK M. HUENNEKENS[1] AND M. CALVIN

Calvin and Dorough[2] have previously established that zinc tetraphenylchlorin is photooxidized in the presence of quinones to zinc tetraphenylporphin. This reaction was studied in great detail for 1,2-naphthoquinone and the following observations made: (1) There is no dark complex formed between the quinone and chlorin. (2) Light adsorbed by the chlorin (6225 Å.) is required. (3) Oxygen inhibits the reaction. (4) The reaction rate is directly independent to the light intensity and inversely related to the temperature. (5) The reaction rate is independent of the naphthoquinone concentration in the range 10^{-3} to 10^{-6} M. (The chlorin concentration is initially about 10^{-5} M.) (6) A function of the chlorin concentration gives a straight line when plotted against time.

This work has now been extended to include both ortho- and para-quinones (eight in all), as well as measurements on magnesium tetraphenylchlorin.

Experimental

Part 1. Apparatus.—The apparatus and methods were essentially the same as those employed by Calvin and Dorough. The reader is referred to the preceding paper in this series for complete details.[2]

Light Source.—The actinic light was obtained from the tungsten filament lamp (operated at 9 volts) and the monochromator system of a Beckman Quartz Spectrophotometer, Model DU. With the wave length set at 6225 Å. and the slit width at 0.8 mm. the spectral segment was 28.8 Å. In the case of certain para-quinones the reaction was slow; this necessitated focussing the Beckman lamp with great care so that an appreciable reaction could be observed in a matter of a few hours.

Light Intensity Measurements.—After the lamp had been on for at least thirty minutes, the thermostatted cell compartment and phototube housing were removed and a small thermopile (without window) was placed at a fixed, reproducible distance from the front face of the Beckman. At this distance the light beam had an area of 1.77 sq. cm.; the opening of the thermopile was centered in this beam. The intensity of the beam was determined at the beginning and end of each run and the average computed for the mid-point of that run. The thermopile and galvanometer were calibrated with a U. S. Bureau of Standards radiation lamp; the sensitivity was found to be 119.4 watts/sq. cm./cm. deflection. Using the same principles as in the previous paper[2] but with slightly different constants I_0 (in photons/sec.) may be calculated from the galvanometer deflection, D (in cm.), by the following equation: $I_0 = 6.56 \times 10^{14} \times D$.

Reaction Vessel.—The reaction vessel was an ordinary 1-cm. square Pyrex mandrel cell with a magnetic stirrer and an evacuation stopcock built into the cell top (see Fig. 6, reference (2)).

Temperature Control.—Scrupulously clean water, maintained in a large thermostat at 25.0 ± 0.1°, was circulated slowly through the modified Beckman cell compartment with quartz windows. The top of the reaction cell above the water was enclosed in a light-proof cover and heated by a stream of hot air to *ca.* 40°; the heating prevented the benzene solution in the evacuated cell from distilling and condensing on the stirring motor in the upper part of the cell.

Routine Procedure.—In the dark the quinone and chlorin solutions in benzene were mixed: 2.56 cc. of the resultant solution was delivered via a calibrated overflow cup to the reaction cell. The ground glass connection between the top and the bottom of the cell was susceptible to leaks due to striations in the grease caused by the heat and mechanical vibrations of the stirrer. This was remedied by using Cello-Grease No. 14-637, manufactured by the Fisher Scientific Company; the product is guaranteed to maintain its consistency up to 120°. Perfect seals were obtained as follows: The ground glass surfaces at the joint were heated and a thin film of melted grease applied with a brush. The joint was clamped together under light pressure and allowed to cool for thirty minutes. The cell and solution were de-oxygenated by the method of freezing the assembly in liquid nitrogen and evacuating the cell. After thawing the solution, purified hydrogen (passed over hot copper according to the method of Michaelis)[3] was admixed with the vapor phase and the process repeated. Six sweepings with hydrogen were used.

Photo-oxidation of Zinc Tetraphenylchlorin by 1,2-Naphthoquinone

Analytical Method.—After the light intensity had been measured and temperature equilibria established, the cell was illuminated with stirring for several time intervals. At the end of an illumination period the slit width was closed to 0.02 mm., the stirring motor stopped, and the log $1/T$[4] of the solution read for the wave lengths 6225, 5510 and 4650 Å.

Part 2. Materials.—Pure crystalline tetraphenylporphin, tetraphenylchlorin and the corresponding zinc salts were prepared by the methods of Ball, Dorough and Calvin.[5]

Magnesium Tetraphenylchlorin and Porphin.—The reaction was carried out in a standard Grignard apparatus with a bubbler system to remove traces of oxygen in the nitrogen.[6] The reaction flask was charged with 2.5 g. of pure magnesium turnings and the assembly gently heated and swept with nitrogen. Fifteen cc. of an absolute ether solution containing 6.9 cc. of methyl iodide was placed in the separatory funnel and 5 cc. admitted to the flask with gentle stirring. As soon as the reaction began, the remainder of the ethereal solution was added slowly enough to keep the reaction under control. Ten cc. of carefully purified dioxane[7] containing about 1 mg. of tetraphenylporphin was added dropwise through the separatory funnel. The reaction went smoothly, the porphin being converted quantitatively to the magnesium complex and the dioxane causing the magnesium iodide to precipitate. At the conclusion of the reaction 50 cc. of 1 *M* ammonium chloride was added in small portions to decompose the unused Grignard reagent (caution—violent evolution of methane!). The mixture was quantitatively transferred to a separatory funnel, shaken with 35 cc. of benzene and the benzene layer washed three times with 1 *M* ammonium chloride, twice with water and dried over anhydrous sodium sulfate. The benzene solution was concentrated under reduced pressure to about one-third its original volume to remove any residual methyl iodide, ether or dimethylmagnesium and then diluted to 50 cc.

Magnesium tetraphenylchlorin was prepared in the same manner except that all reactions were carried out in near darkness and the product, being photosensitive, had to be stored in a dark-box. Both magnesium porphin and chlorin decompose readily in the presence of acids, or even upon being evaporated to dryness. In addition, the chlorin complex decomposes spontaneously, even in

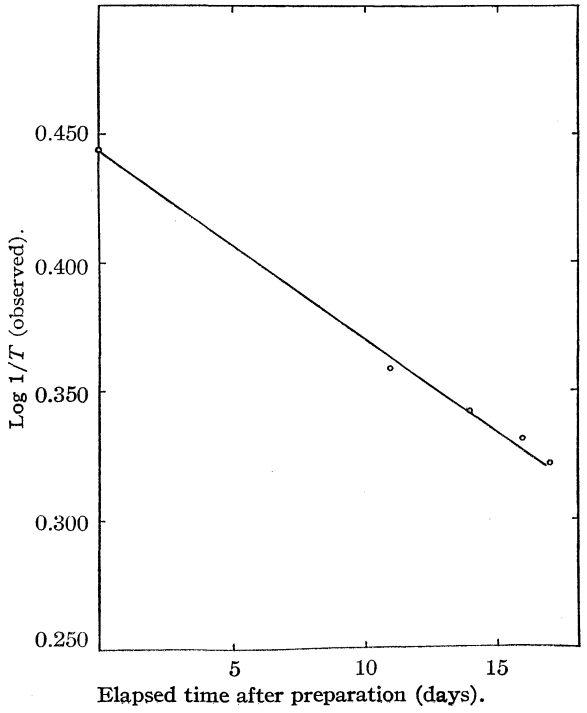

Fig. 1.—Decay of magnesium tetraphenylchlorin as a function of time.

(4) If T is the fraction of light transmitted and I_0 and I are the incident and outgoing light intensities, respectively, the value of log I_0/I read directly from the Beckman Spectrophotometer is equivalent to log $1/T$.

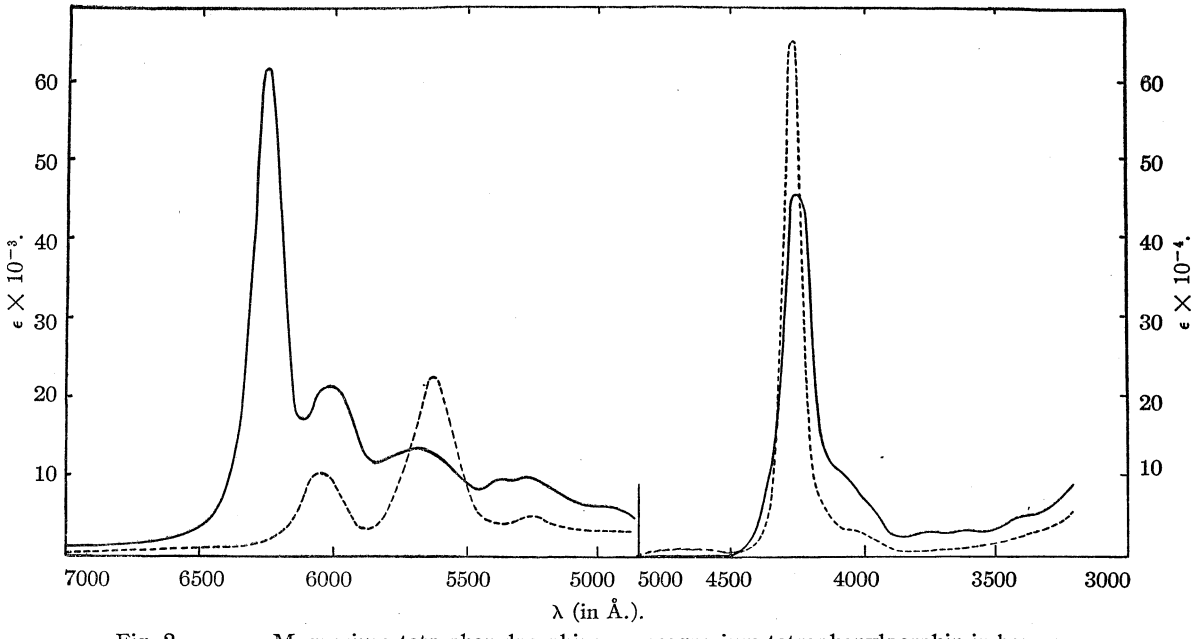

Fig. 2.—- - - Magnesium tetraphenylporphin; — magnesium tetraphenylporphin in benzene.

the dark. The almost linear decrease of concentration with time is shown in Fig. 1. For rate runs the solutions were used within two days after preparation and the initial concentration of magnesium chlorin determined spectrophotometrically.

The concentrations of the magnesium metal complexes were determined by converting an aliquot to the free base. Five cc. of the benzene solution was placed in a separatory funnel and extracted with two 1-cc. portions of concentrated hydrochloric acid. The benzene layer was then washed twice with 5 cc. of water, twice with 5 cc. of concentrated ammonium hydroxide and finally three times with 5 cc. of water. After drying over sodium sulfate, the benzene solution was diluted to 10 cc. The concentration of the free base was determined spectrophotometrically. The absorption spectra of the magnesium complexes are shown in Fig. 2.

Quinones.—9,10-Anthraquinone, 1,2-benz-9,10-anthraquinone, 9,10-phenanthraquinone, 1,4-benzoquinone and 1,4-naphthoquinone were all obtained as stock substances recrystallized from ether or ethyl alcohol.

1,2-Benzoquinone was prepared by oxidizing pyrocatechol with freshly prepared silver oxide in anhydrous ether.[8] The product was a red crystalline powder which decomposed without melting in the range 60–80°. The compound was unstable and decomposed in hydroxylated solvents within a few hours. A solution in anhydrous benzene at 0° stood for several days without decomposition.

1,2-Naphthoquinone (Sample A) was prepared by oxidizing 1-amino-2-naphthol hydrochloride with ferric chloride.[9] The dark golden product was kept as an amorphous cake as recommended by Fieser. At 110–114° the substance darkened and complete decomposition occurred in the region 135–140°.

1,2-Naphthoquinone (Sample B).—The Eastman Kodak product was purified by two sublimations *in vacuo*. The orange needles darkened and decomposed at 110–115°.

Diphenoquinone.—A suspension of 1.0 g. of 4,4′-dihydroxydiphenyl and 20.0 g. of lead dioxide in 50 cc. of anhydrous benzene was boiled gently for five minutes and filtered. The filtrate evaporated to about one-third its original volume, and cooled in an ice-bath yielded crystals of diphenoquinone which were removed by filtration and dried *in vacuo*. Recrystallized once from benzene, the product consisted of orange-red needles with a steely luster and melted at 163–165°.

Part 3. Calculations.—At various times during a rate run log $1/T$ values for three different wave lengths were read from the spectrophotometer. The band at 6225 Å. is characteristic of the zinc chlorin, the band at 5510 Å. is characteristic of the zinc porphin and the band at 4650 Å. is due to the zinc chlorin–oxygen product. The extinction coefficients of these complexes are given in Table I. From the 6225 and 5510 Å.

TABLE I

MOLAL EXTINCTION COEFFICIENTS OF ZINC COMPLEXES

Substance	ε × 10⁻³ 6225 Å.	5510 Å.	4650 Å.
Zinc chlorin	54.9	5.9	2.0
Zinc porphin	1.0	22.2	1.8
Zinc chlorin–oxygen product	1.9	7.5	38.7

bands the decrease in chlorin concentration (or, conversely, the increase in porphin concentration) may be calculated. A rise in the 4650 Å. band indicates that oxygen is present and competing with the quinone for the chlorin. This effect can be corrected for and the true rate for the quinone–chlorin reaction can be determined. The oxygen–chlorin reaction is treated in another paper.[10]

Any proposed mechanism for the reaction must be consistent with the observations of Calvin and Dorough as set forth in the first section of this paper. Furthermore, anticipating the experimental results, the mechanism must explain why the quantum yield does not vary with quin-

(8) Willstätter and Pfannenstiel, *Ber.*, **37**, 4745 (1904); Willstätter and Muller, *Ber.*, **44**, 2171 (1911).

(10) Huennekens and Calvin, THIS JOURNAL, **71**, 4031 (1949).

one concentration over a wide range, but, nevertheless, is different for each particular quinone. The key step in the mechanism (No. 6) was suggested to one of the authors (F. H.) by Prof. G. K. Rollefson. The symbols have the following significance: CH_2 = zinc chlorin in the ground state, CH_2^* = zinc chlorin in the excited singlet state, $CH_2^{\pm}$ = zinc chlorin in the triplet state, C = zinc porphin, Q = quinone, QH_2 = hydroquinone, S = solvent and wall.

$$CH_2 + h\nu = CH_2^* \quad (1)$$

$$CH_2^* = CH_2 + h\nu_f \quad (2)$$

$$CH_2^* + S = CH_2 + (S + kT) \quad (3)$$

$$CH = CH_2^{\pm} \quad (4)$$

$$CH_2^{\pm} + Q = C + QH_2 \quad (5)$$

$$CH_2^{\pm} + Q = CH_2 + (Q + kT) \quad (6)$$

Making the usual assumptions about the existence of steady states for both the excited singlet and triplet state molecules, we may write for the disappearance of zinc chlorin

$$\frac{d(CH_2)}{dt} = -\frac{k_5}{k_5 + k_6} \times \frac{k_4}{k_2 + k_3(S) + k_4} \times k_1 I_{abs.} \quad (7)$$

since the rate of formation of (CH_2^*) is dependent solely on the rate of absorption of light, *i. e.*

$$r_1 = d(CH_2^*)/dt = k_1 I_{abs.} \quad (8)$$

The conversion factor k_1 must transform photons absorbed per second into moles per liter per second of photons absorbed.

$$k_1 = 10^3/NV \quad (9)$$

where N is Avogadro's number and V is the volume of the solution (in cc.) The apparent volume delivered to the cell is 2.56 cc.; during pumping some of the solvent is evaporated and the true volume is obtained by employing the equation

$$V = 2.56 \times (C_m/C_0) \quad (10)$$

where C_m = theoretical concentration of the chlorin solution (allowing for dilution by the quinone solution) and C_0 = the concentration actually determined by the initial reading before illumination.

$I_{abs.}$ may be determined from I_0, the intensity from the Beckman, and an experimental molal extinction coefficient, Σ, of the chlorin

$$I_{abs.} = I_0 (1 - 10^{-\Sigma(CH_2)d}) = I_0 A \quad (11)$$

As previously, (CH_2) = the concentration of zinc chlorin and d = the thickness of the cell = 1 cm.

The quantum yield, γ, is expressed by the product of the fractions

$$\gamma = \frac{k_6}{k_5 + k_6} \times \frac{k_4}{k_2 + k_3(S) + k_4} \quad (12)$$

Substituting equations (8) and (12), equation (7) becomes

$$-d(CH_2)/dt = \gamma k_1 I_0 A \quad (13)$$

Transposing and integrating, letting π represent the integration constant

$$(CH_2) + (1/\Sigma) \log A = -k_1 \gamma I_0 t + \pi \quad (14)$$

The values of (CH_2) are determined from the readings at 6225 Å. Since neither the porphin nor the oxygenated product have any appreciable absorption at this wave length

$$(CH_2) = (\log 1/T)_{obs.}/54.9 \times 10^3 \quad (15)$$

The values of $(CH_2) + (1/\Sigma) \log A$ are plotted as a function of time and a straight line is obtained. Let M be the slope of the line.

The quantum yield is obtained from the slope of the concentration function–time curve by the equation

$$\gamma = -M/k_1 I_0 \quad (16)$$

The apparent molal extinction coefficient, Σ, was measured from a chlorin solution with the thermopile–galvanometer under conditions identical with those prevailing during the rate run. The value obtained, $\Sigma = 20.3 \times 10^3$, is smaller than would be expected simply by changing logarithmic bases

$$\Sigma = 54.9 \times 10^3/2.303 = 23.8 \times 10^3$$

The low experimental value is due to the method of measurement. $\epsilon = 54.9 \times 10^3$ was obtained in the usual manner on the spectrophotometer with the slit width set at 0.025 mm. admitting the incident light as a spectral segment of 0.9 Å. When Σ was measured, the slit was opened to 0.8 mm. corresponding to a segment of 28.8 Å. The sharpness of the absorption band and the width of the illuminating band gave rise to the low value of the apparent extinction coefficient.

In the case of magnesium tetraphenylchlorin Σ was 20.5×10^3.

A correction factor of 0.98 was applied to I_0 to compensate for light lost through absorption and scattering by the quartz windows and water of the thermostatted cell compartment.

Part 4. Tabulation of Data.—To avoid unnecessary repetition only one run, no. 54, will be considered in detail. Table II illustrates the data obtained when zinc chlorin was photooxidized by 9,10-phenanthraquinone. The plot of the function $(CH_2) + (1/\Sigma) \log A$ against time is shown in Fig. 3. The results of all runs are summarized in Table III. It is estimated that the quantum yields are accurate to 5–10%, hence the results are expressed only to two significant figures.

Discussion

The energy levels involved in this photochemical transformation may be represented by a Jablonski diagram (Fig. 4). The ground state of the chlorin molecule is a singlet since there are no unpaired electrons; the excited level, due to absorption at 6225 Å., is also a singlet as evidenced by the high transition probability ($\epsilon = 54.9 \times 10^3$). Calvin and Dorough[2] have shown that the chlorin molecules could not be reacting from the S′ state, for not only is the lifetime of this state too short (*ca.* 10^{-9} sec.) compared to the mean time between chlorin–quinone collisions (*ca.* 10^{-5} sec.), but also the chlorin–quinone reaction would compete against fluorescence and solvent deactivation and the quantum yields, therefore, should increase with increasing quinone concentration. Their identification of the triplet as the reactive level was based upon agreement with the kinetic data, direct demonstration of the triplet or phosphorescent state and the greatly reduced quantum yield in the case of the paramagnetic copper chlorin.

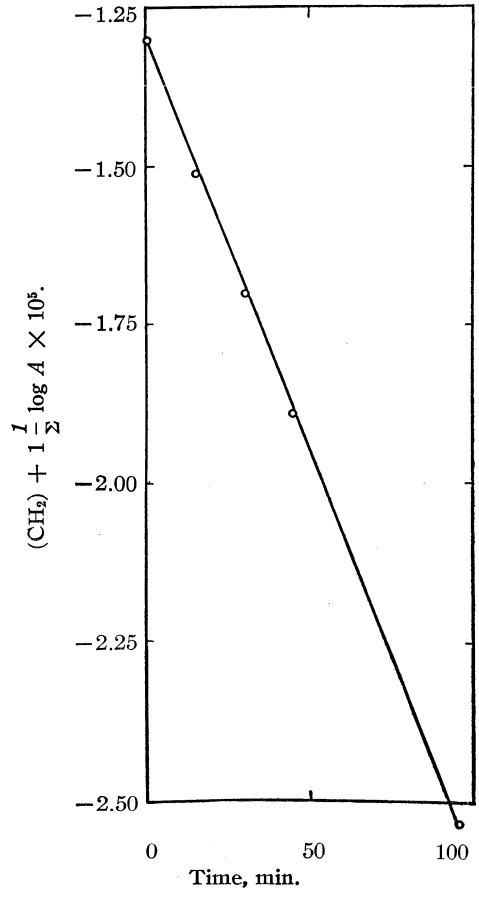

Fig. 3.—Run no. 54.

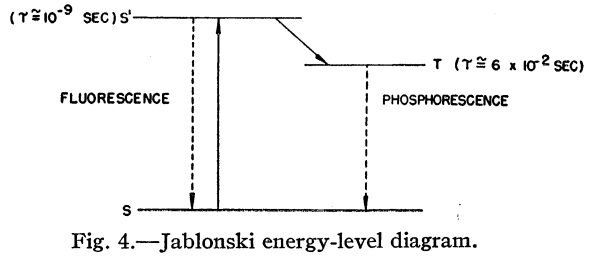

Fig. 4.—Jablonski energy-level diagram.

A very interesting observation, made by these authors, was that the reaction had a negative temperature coefficient. The average quantum yield of four runs at 25° was 0.021 whereas the average of two runs made at 10° was 0.024. In

[a] Quinone potentials are taken from G. E. K. Branch and M. Calvin, "The Theory of Organic Chemistry," Prentice–Hall, Inc., New York, N. Y., 1941, pp. 311–312. The values are those of E^0 (cor.) rather than E^0 (exp.). The potential is negative when the half-reaction is written: $H_2Q = Q + 2H^+ + 2e^-$.

a later section it will be shown that the absolute value of these quantum yields reported for 1,2-naphthoquinone are subject to an uncertainty. Nevertheless, we shall assume that these relative quantum yields reflect the true behavior of the system and that the magnitude of the temperature effect is beyond normal experimental error.

Kasha and Powell,[11] from an analysis of the rates of the various processes which could occur in the S′ state, have shown that for a maximum probability of interaction between the S′ and T states the "crossing over" must occur at the lowest point of the S′ curve (Fig. 5). Molecules excited to the S′ state may arrive at high vibrational levels but the cascade downward is rapid until a Boltzmann temperature distribution is established among the lower vibrational levels. Since lowering the temperature results in increased quantum yields, it follows that the crossing over point in this case must be located near the bottom of the S′ curve.

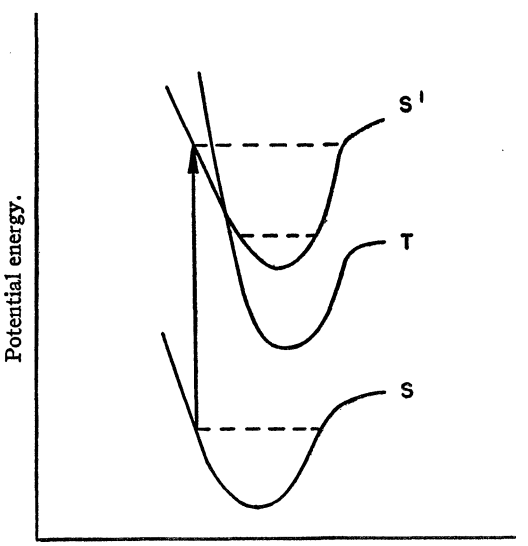

Fig. 5.—Potential energy diagram.

Another effect of lowering the temperature would be to decrease the probability of the back reaction caused by long-lived molecules in the triplet state being thermally reactivated to the S′ state. The separation of the S′ and T minima, estimated from the spectral data, is about 10 kcal.

As illustrated by Table III each quinone has a different quantum efficiency in the photo-oxidation of zinc chlorin. The photo-activation of the chlorin molecules to the triplet level merely loosens the two hydrogen atoms on the β-positions of the pyrrole nucleus. The quinone, which functions as the hydrogen acceptor, removes the hydrogens during collisions with the chlorin. Each quinone–triplet chlorin collision is not effective but the relative efficiency of this process among the various quinones should depend upon the decrease of free energy involved in the reduction of the quinone to the hydroquinone. Thus, the quantum yields should be proportional to some function of the free energy changes. In Table IV a tabulation has been made of the quantum yields and the standard oxidation potentials of the quinones. Plotting these quantities against each other, as in Fig. 6, two straight lines are obtained, one for the ortho-quinones and one for the para-quinones.

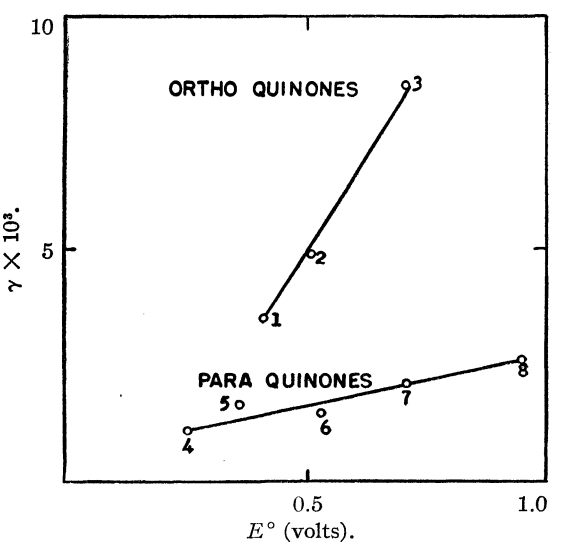

Fig. 6.—Plot of γ *vs.* E° for quinones.

The fact that there are two lines rather than one indicates that the ortho and para-quinones react by different mechanisms. An ortho-quinone may be capable of removing both hydrogens, even in a stepwise manner, during one energetically effective collision, whereas a para-quinone, unable

(11) Kasha and Powell, THIS JOURNAL, **69**, 2909 (1947).

to re-orient during the life-time of the activated complex, would require several collisions.

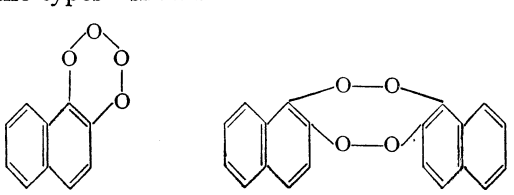
Previous work by Calvin and Dorough[2] on 1,2-naphthoquinone had given a quantum yield of about 0.021. The disagreement between this value and the present results was investigated briefly. The 1,2-naphthoquinone used in the early work had been prepared by the ferric chloride oxidation of 1-amino-2-naphthol hydrochloride. A portion of this material, labeled Sample A, was purified by vacuum sublimation and employed in run no. 53. The quantum yield of 0.023 is in good agreement with the previous value. Next, a sample of Eastman Kodak Co. 1,2-naphthoquinone, labeled Sample B, was purified by vacuum sublimation and, in run no. 74, gave a quantum yield of 0.0049. This value fitted in the *o*-quinone curve of Fig. 6. Samples A and B were compared further on the basis of melting point, analysis and absorption spectra. The results, listed in Table V, indicate only that A had partially decomposed. Sample A was the only quinone, in the series of eight, that was prepared in an aqueous medium. Traces of occluded ferric compounds or quinone peroxides of the types[12] shown

TABLE V

COMPARISON OF PHYSICAL PROPERTIES OF 1,2-NAPHTHOQUINONE

	Sample A	Sample B
Preparation	Ferric chloride oxidation of 1-amino-2-naphthol. Crystallization from water solution	Eastman Kodak Co. stock purified by two sublimations *in vacuo*
Melting point	Darkens at 110–114°, decomposes (to a black oil) 135–140°	Darkens and decomposes 113–114°
Analysis[a]	Calcd. for $C_{10}H_6O_2$ (m. w. 158.2): C, 75.8; H, 3.79%. Found: C, 71.38; H, 4.02; residue, 10.1	Found: C, 76.17; H, 4.29
Absorption spectrum (in benzene)	In the visible region (7000–3500 Å.) both samples displayed the same spectrum. The extinction coefficients were slightly higher for Sample B	

[a] Analysis performed by Mr. C. Koch.



could possibly account for the "enhanced" quantum yields obtained with Sample A.

Less extensive experiments were carried out with magnesium tetraphenylchlorin because of its unstability and the low quantum yields which were difficult to measure.

Runs no. 64 and 65 made with 1,2-naphthoquinone (Sample A) and magnesium chlorin exhibited a curved line plot of $(CH_2) + (1/\Sigma)$ log A against time. At these quinone concentrations (*ca.* 5×10^{-4} *M*) an insufficient number of collisions occurred during the triplet lifetime of the magnesium chlorin causing the rate to deviate from the expected straight-line plot. When the concentration was increased to *ca.* 5×10^{-3} *M* as in run no. 56, the rate curve was once again a straight line. In the case of zinc chlorin this concentration "breakdown" did not occur until the quinone concentration had been reduced to about 10^{-6} *M*. Hence, either the lifetime of the magnesium chlorin in the triplet state is shorter than the 10^{-2} sec. observed for zinc chlorin or the quantum efficiency of phosphorescence is less for the magnesium complex, *i. e.*, fewer of the molecules reach the triplet state.

A comparison of magnesium and zinc chlorins may be seen in Table VI. The discrepancy of the ratio for 1,4-benzoquinone could be explained simply as a difference between the two classes of quinones or the quantum yield for the reaction with the magnesium chlorin could be in error since the rate was so slow and irregular, in that one run, that the assignment of a slope to the individual points was only an approximation.

TABLE VI

COMPARISON OF ZINC AND MAGNESIUM CHLORINS

Oxidant	γ_{Zn}	γ_{Mg}	Ratio γ_{Zn}/γ_{Mg}
1,4-Benzoquinone	0.0021	0.00072	2.9
1,2-Naphthoquinone (Sample A)	.023	.0030	7.7
Oxygen[10]	.0074	.00094	7.9

An attempt was made to determine the lifetime of the phosphorescent state for magnesium chlorin using a rotating shutter phosphoroscope in conjunction with a photomultiplier tube and an oscilloscope. No decay curve could be observed corroborating the above conclusions regarding the phosphorescence life-time or phosphorescence efficiency of the magnesium chlorin. However, the magnesium chlorin does have a phosphorescent state, for when a sample was placed in a rotating shutter phosphoroscope and exposed to an ammonia-sensitized plate for three hours, a phosphorescence spectrum was obtained qualitatively similar to that of zinc chlorin.[13]

Acknowledgment.—The authors appreciate the many helpful suggestions made by their colleagues, notably Professors G. K. Rollefson and J. Cason and Drs. G. D. Dorough, M. Kasha, D. McClure, W. Simpson and H. W. Alter.

Summary

1. The zinc and magnesium complexes of tetraphenylchlorin may be photoöxidized to the corresponding porphins by both *o*- and *p*-quinones.

2. Plotting the standard oxidation potential of the quinone against the quantum yield produces one straight line for the *o*-quinones and

(12) Goldschmidt and Graef, *Ber.*, **61**, 1858 (1928).

(13) These measurements were made in the laboratory of Drs. M. Kasha and D. McClure.

another straight line for the *p*-quinones.

3. The rates of photoöxidation for magnesium tetraphenylchlorin are lower than the corresponding zinc chlorin reactions by a factor of almost eight.

Photochemical Studies of the Porphyrins. III. The Photoöxidation of Chlorins by Oxygen

BY FRANK M. HUENNEKENS[1] AND M. CALVIN

In the previous paper of this series[1a] it was established that the zinc and magnesium complexes of tetraphenylchlorin may be photooxidized to the corresponding porphin utilizing various ortho- and para-quinones as the hydrogen acceptors. Traces of oxygen were found to interfere with the normal quinone–chlorin reaction and a method of de-oxygenating the solution with purified hydrogen was devised. From a biological point of view, molecular oxygen is of great importance for although it possesses a high oxidation potential and is the final electron acceptor in aerobic systems it is, nevertheless, unable to directly oxidize certain compounds; *e. g.*, reduced pyridinoproteins or cytochrome c. It was of interest to ascertain whether in this case oxygen might be competing with the quinone as an oxidant for the photoactivated zinc chlorin.

Experimental

Part 1. Apparatus and Materials.—The apparatus and materials used in these experiments were the same as described in the previous two papers of this series.[1,2]

The ultimate reaction product, called the zinc chlorin–oxygen complex, obtained when oxygen reacts with photo-activated zinc chlorin, was not isolated in pure form. For absorption spectra purposes a known solution of zinc chlorin, in a sealed Pyrex 1-cm. square cuvette, was exposed to bright sunlight for five minutes. The absorption spectrum of this "unbleached," straw-yellow solution was determined as rapidly as possible (within five minutes) using a Cary Recording Spectrophotometer. The molal extinction coefficients were calculated on the basis that conversion of the initial chlorin was quantitative. The "bleached" product was quite stable since the absorption spectrum of a solution, exposed to diffuse laboratory light for several days, did not change appreciably; furthermore, several different zinc chlorin solutions exposed to light under a variety of conditions yielded the identical product.

The absorption spectrum of the metal-free chlorin–oxygen product was obtained by removing the zinc from a known solution of the "bleached" complex by means of the hydrochloric acid–ammonium hydroxide treatment described in a previous paper.[1]

Rate runs in the presence of both oxygen and a quinone were made inadvertently during the early part of this investigation when imperfectly sealed reaction cells permitted small quantities of oxygen to enter. Since the reaction rate is independent of the concentration of the oxidant provided it exceeds a certain minimum (*ca.* 10^{-6} *M* for zinc chlorin), it is, therefore, unnecessary to know the exact amount of oxygen present.

When oxygen alone was the oxidant, 2 cc. of the chlorin solution and 1 cc. of benzene were delivered directly to the reaction vessel and since the solution was not de-oxygenated by freezing, evacuating and sweeping with hydrogen, no volume correction was required.

Part 2. Calculations.—As will be discussed more thoroughly in a later section, oxygen differs from the quinones in that after the primary oxidation of the chlorin to the porphin a secondary reaction takes place in which the hydrogen peroxide reacts further with the porphin to produce a "bleached" yellow product. This does not interfere with the normal measurement of the quantum yield, since of all the substances in solution only the chlorin absorbs the irradiating light (6225 Å.) and the method of following the reaction depends only upon the disappearance of the chlorin.

In the case of 1,4-benzoquinone and 9,10-phenanthraquinone several runs were made in the presence of oxygen. For these runs, the observed quantum yields (γ) has been multiplied by a correction factor (f) to give the hypothetical quantum yield (γ') which would have been obtained if the quinone alone had reacted with the porphin. This correction factor is derived as follows: consider an entire rate run and let

n = total number of chlorin molecules that have reacted (with quinone and oxygen)
n' = number of chlorin molecules that have reacted with oxygen alone
Q = total number of quanta absorbed
γ = measured quantum yield
γ' = quantum yield of the quinone–chlorin reaction only
$A_0 - A$ = change in the log $1/T$ (the usual log I_0/I from the Beckman Spectrophotometer) reading at 6225 Å. for the entire run

(1a) Huennekens and Calvin, THIS JOURNAL, **71**, 4024 (1949).

(2) Calvin and Dorough, *ibid.*, **70**, 699 (1948).

$C - C_0$ = change in the log $1/T$ reading at 4650 Å. (the expression is written as $C - C_0$ to keep it positive since $C > C_0$)
ϵ_a = extinction coefficient of zinc chlorin at 6225 Å.
ϵ_c = extinction coefficient of the zinc chlorin–oxygen product at 4650 Å.
$K = V \times N \times 10^3$, a conversion factor, which when multiplied by a concentration change, will give the change in number of molecules. (V is the volume of the solution in cc., N is Avogadro's number)

Now

$$\gamma = n/Q \text{ by definition} \quad (1)$$
$$n = [(A_0 - A) \times K]/\epsilon_a \quad (2)$$

Let us assume, as a first approximation, that the oxygen merely reacted with the chlorin to give the chlorin–oxygen product whose absorption spectrum has been measured and characterized by a band at 4650 Å. and, furthermore, that the rise in the 4650 Å. band is a measure of the oxygenation. Then

$$n' = (C - C_0) \times K/\epsilon_c \quad (3)$$
$$\gamma' = (n - n')/Q \quad (4)$$

Substituting Q from equation (1)

$$\gamma' = \frac{(n - n')}{n} \times \gamma \quad (5)$$

Replacing n and n' from equations (2) and (3) and cancelling K

$$\gamma = \gamma' = \left\{\frac{[(A - A_0)/\epsilon_a] - [(C - C_0)/\epsilon_c]}{(A_0 - A)/\epsilon_a}\right\} \times \gamma \quad (6)$$

This simple correction, applied to oxygenated runs, will give a corrected quantum yield approaching that of a run made in the absence of oxygen. A further improvement is possible. We have assumed that in the absence of oxygen, the 4650 Å. band should remain stationary. Since the extinction coefficient is greater for zinc chlorin than zinc porphin (*ca.* 2.0×10^3 compared to 1.8×10^3) a change from chlorin to porphin, without considering oxygenation, should result in a slight decrease of the 4650 Å. band. Thus, the term $(C - C_0)/\epsilon_c$ should be amended to read $[(C - C_0) + P]/\epsilon_c$ where P represents the number of log $1/T$ units that have been lost through the chlorin going to porphin. P is obviously some function of $(A - A_0)$ and we may let $P = f'(A_0 - A)$. f' is very difficult to evaluate since a rigorously derived expression must take into account not only the change in all three bands (6225, 5510 and 4650 Å.), but also the extinction coefficients of the chlorin, porphin and oxygenated product at these three wave lengths. Because of the complexity of this expression and the uncertainty of the numerical values for several of the nine extinction coefficients, it was decided to accept an empirical value of 0.037 for f'. Inserting this correction and knowing that $\epsilon_a = 54.9 \times 10^3$ and $\epsilon_c = 38.7 \times 10^3$, equation (6) becomes

$$\gamma' = \left\{\frac{\frac{(A_0 - A)}{54.9 \times 10^3} - \frac{(C - C_0) + 0.037\,(A_0 - A)}{38.7 \times 10^3}}{\frac{(A_0 - A)}{54.9 \times 10^3}}\right\} \times \gamma \quad (7)$$

which reduces to

$$\gamma' = \{0.948 - [1.42\,(C - C_0)/(A_0 - A)]\} \times \gamma \quad (8)$$

Part 3. Tabulation of Results.—Table I lists the data for a typical run, No. 48, in which both oxygen and 1,4-benzoquinone were present. The symbols are the same as those employed in the preceding paper.[1] The rate curve for this run, shown in Fig. 1, is essentially a straight line even though two competing reactions are being summed.

TABLE I

RUN NO. 48—ZINC CHLORIN WITH 1,4-BENZOQUINONE AND OXYGEN

Time	Log 1/T 6225 Å.	5510 Å.	4650 Å.	Chlorin concn.	$(CH_2) + 1/\Sigma$ log A
0	0.484	..	0.046	0.881×10^{-5}	−1.43
12	.465	..	.053	.845	−1.54
22	.448	..	.059	.817	−1.63
52	.408	..	.086	.744	−1.87

A summary of all the oxygenated runs, showing the correction factor (f) is presented in Table II. For comparison, a non-oxygenated run, indicated by a blank in the correction factor column, has been included for each quinone.

Summarized data and quantum yields for rate runs made with oxygen alone are listed in Table III.

Discussion

The experimental data suggest that as an oxidant for zinc and magnesium chlorins oxygen is similar in nature to the quinones. Oxygen is reduced to hydrogen peroxide, corresponding to the reduction of a quinone to the hydroquinone. Using 0.68 volt[3] as the standard oxidation potential of the latter couple and 0.0074 as the quantum yield for the oxidation of zinc chlorin by molecular oxygen a comparison is made, in Fig. 2, of oxygen with the ortho-quinones. The quinone values are taken from the preceding paper in this series.[1] While some doubt exists as to the accuracy of the value for the oxygen–peroxide couple, it would seem, nevertheless, that the agreement of oxygen with the ortho-quinone line is too good to be accidental.

In the case of oxygen, a secondary reaction takes place between the hydrogen peroxide and porphin in which the porphin is probably attacked at one of the methine bridges causing the great ring to open to a tetrapyrrole.

In addition to being above to act as a hydrogen acceptor, oxygen, because of its paramagnetism, might conceivably exert another effect upon the reaction. The selection rule which prohibits transitions from the triplet to the ground singlet state is easily broken down in the presence of inhomogeneous magnetic fields or heavy atoms. The non-reactivity of copper chlorin toward

(3) W. M. Latimer, "Oxidation Potentials," Prentice-Hall Inc., New York, N. Y., 1938, p. 38.

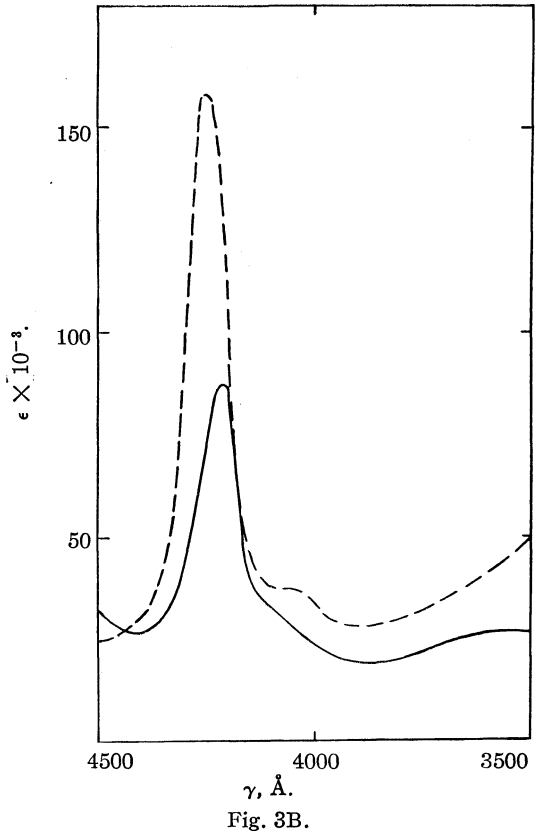

Fig. 3B.

quinones was attributed to the paramagnetism due to the one unpaired electron in the copper orbitals.[2] By similar reasoning, one might expect the paramagnetism of the oxygen molecule to shorten the lifetime of the triplet chlorin molecules causing any oxygenated run to have a slower rate than the corresponding quinone–chlorin reaction without oxygen. From the experimental evidence this is not the case for an ortho-quinone of lower potential than oxygen (*e. g.*, 9,10-phenanthraquinone). The presence of oxygen actually increases the over-all rate; furthermore, it has been demonstrated that oxygen does not inhibit, but competes with, a quinone–chlorin reaction. The oxygen is an external paramagnetic influence and apparently does not affect the chlorin transition probabilities to the same degree as the copper which is incorporated directly into the molecule.

67	Magnesium	0.551	7.28×10^{-3}	0.467	3.00	5.50	1.38	9.05	.00094

The spectra of the "bleached" products of zinc and magnesium chlorins, shown in Fig. 3, are markedly different. Even more surprising are the spectra of the metal-free products (Fig. 4) since, at this point, the compounds would have been identical provided that the hydrogen peroxide had attacked each of the original metallochlorins in the same manner. The obvious differences between the behavior of zinc and magnesium chlorins with oxygen suggests that the reaction may not be clean-cut but rather a compromise between several possibilities. Calvin and Dorough[2] have found that the "bleached" zinc chlorin product, when chromatographed on talc, yielded traces of metal-free chlorin and porphin as well as two unknown substances characterized by blue zones on the column.

Consistent with this is the observation that reaction rates and quantum yields toward a given oxidant change from one metallochlorin to another as illustrated in Table III of this paper and Table VI of the preceding paper.[1] Calvin and Dorough[2] showed that toward 1,2-naphthoquinone copper chlorin is only about one-hundredth as reactive as zinc chlorin. As would be expected, zinc chlorin solutions, in the presence of oxygen, are "bleached" within a few minutes by diffuse indoor light, whereas copper chlorin solutions under

(4) Solubility of oxygen in benzene at 19°: "International Critical Tables," 1st ed., 1928, Vol. III, pp. 261–283.

similar conditions are stable for many hours.

The absorption curves of the metallochlorin "bleached" products are qualitatively similar to the curves for irreversible "bleaching" of chlorophyll by oxygen in acetone, as reported by Aronoff and MacKinney.[5] Furthermore, in the same paper, these authors report a value of 5×10^{-4} for the quantum yield of irreversible "bleaching" of chlorophyll solutions in benzene. This is in order of magnitude agreement with our value of 9.4×10^{-4} for the quantum yield of the photo-oxidation of magnesium chlorin by oxygen.

(5) Aronoff and MacKinney, THIS JOURNAL, **65**, 956 (1943).

Summary

1. Zinc and magnesium tetraphenylchlorins may be photo-oxidized by molecular oxygen in a manner similar to ortho- and para-quinones.
2. Oxygen does not inhibit a chlorin–quinone reaction but merely reacts competitively with the quinone for the chlorin (at least for quinones of lower oxidation potential than oxygen).
3. A secondary reaction occurs between hydrogen peroxide and the porphin yielding a product similar to that obtained by "bleaching" chlorophyll in the presence of oxygen.

The Extraction of Gallium Chloride by Isopropyl Ether

BY NORMAN H. NACHTRIEB AND ROBERT E. FRYXELL

The distribution of gallium chloride between aqueous hydrochloric acid and diethyl ether has received the attention of several workers. Grahame and Seaborg[1] report that the distribution is independent of gallium concentration in the range 10^{-12} to 10^{-3} molar, but Swift[2] reports a relatively greater extraction for higher concentrations.

It is well known that the distribution of gold chloride[3,4] and ferric chloride[5,6,7,8] between aqueous hydrochloric acid and ethers is dependent on the concentration of the metal chloride. In a recent paper the present authors reported data for ferric chloride showing that this distribution (using isopropyl ether) follows the simple Nernst distribution law for sufficiently low ferric chloride concentrations.[7] It was suggested that the existence of polymers in the ether phase need not be postulated to explain the dependence of the distribution on iron at higher concentrations, but alternatively, the anomaly may be due to a self-promoted activity of ferric chloride in the aqueous phase.

This paper reports a similar study which has been made of the distribution of gallium chloride between aqueous hydrochloric acid and isopropyl ether.

Experimental

Preparation of Solutions.—For the majority of the experiments, radioactive Ga^{72} was used to facilitate analysis. The gallium was received as a mixture of oxide and nitrate.[9] A solution was prepared by dissolving 0.0559 g. of this material in 20.0 ml. of 7.30 molar hydrochloric acid, purified by extraction with two 20-ml. portions of isopropyl ether, and won back from the ether with water to provide a gallium tracer solution. This solution was diluted to 50.0 ml. It was assigned a concentration of 0.00594 *M*, based upon a gravimetric determination of the gallium in the oxide–nitrate mixture after its activity had decayed.

A stock solution of inactive gallium chloride was prepared as follows: 5.1457 g. of gallium metal (99.9%) was dissolved in hot aqua regia, evaporated to a sirupy consistency twice with 10-ml. portions of concentrated nitric acid, and finally taken to dryness. The residue was heated at *ca.* 260° until the nitrate was completely converted to oxide. An excess of concentrated hydrochloric acid (20.0 ml.) was added; warming effected complete solution. It was discovered that by warming and blowing air over the surface of this solution, a gel formed which would not redissolve on dilution. Apparently, this was a basic salt, since addition of a few ml. of hydrochloric acid caused solution. Aeration of the solution at room temperature was successful in removing the small excess of hydrochloric acid. Analysis of this solution after dilution to 75.0 ml. gave: $(Ga) = 0.8957\ M$, $(Cl^-) = 2.677\ M$.

The isopropyl ether was purified by shaking with alkaline potassium permanganate solution, drying over calcium chloride, and distilling. The fraction boiling in the range 66.5 to 67.5° at 747.1 mm. was collected.

Analytical Methods.—Measurement of the radioactivity of the samples served as a determination of relative concentrations of gallium. Aliquots of solutions were evaporated just to the point of dryness under an infrared lamp on 1″ copper disks having spun-up edges. Counting rates were determined with a thin-wall mica window Geiger–Müller tube in conjunction with a Higginbotham type scaler. Whenever possible, a total count of at least 5,000 was registered. The background of the counter was 28 counts/minute. The statistical error was probably lower than the errors due to self-absorption and to handling an isotope with a half life of only fourteen and one-tenth hours. The latter error was minimized by counting consecutively the copper disks corresponding to the ether and aqueous phases of a single extraction.

Gallium analyses listed in Table I and those noted in Table II were performed by the 8-hydroxyquinoline–potassium bromate titration method as described by Kolt-

hoff and Sandell.[10] This method was checked against the hydroxide precipitation method[11] and found to be good to 0.5% with 5–15 mg. of gallium. The method was also used to demonstrate that significant amounts of gallium were not lost in the evaporation of solutions on the copper counting disks.

Free acid was calculated from titrations with standard sodium hydroxide, allowing for the quantity of base consumed in the precipitation of gallium hydroxide. Brom cresol purple was the indicator used. The validity of this calculation is discussed later.

Determinations of chloride were made by the Fajans method on the solution remaining from the acidity determination. Dichlorofluorescein was the indicator used.

Extraction Procedure.—In an experiment similar to the one reported by Nachtrieb and Conway for ferric chloride,[12] extraction equilibrium was found to be established within six minutes. All extractions were carried out in 10-ml. glass-stoppered cylinders with 5.0 ml. of isopropyl ether and 5.0 ml. of aqueous solution of known gallium chloride and hydrochloric acid concentrations, except as noted. Cylinders were alternately thermostatted at 20.0 ± 0.1° and mixed by inversion for a total time of at least thirty minutes. The two phases were separated with pipets and transferred to stoppered test-tubes. Before the aliquots were taken for analysis, the tubes were centrifuged for several minutes to separate any small amount of the other phase.

The equilibrium concentrations of gallium in the aqueous and ether phases were calculated by solving sets of simultaneous equations of the type

$$a(\mathrm{Ga})_{aq} + b(\mathrm{Ga})_{eth} = c(\mathrm{Ga})_{initial} \quad (1)$$

$$\frac{(\mathrm{Ga})_{eth}}{(\mathrm{Ga})_{aq}} = \frac{\text{ether counting rate (counts/ml./min.)}}{\text{aqueous counting rate (counts/ml./min.)}} \quad (2)$$

where c is the initial aqueous volume and a and b are the final volumes of the aqueous and ether phases, respectively.

Discussion of Results

Empirical Formula of the Gallium Complex in the Ether Phase.—Analyses of a number of ether phases for gallium, chloride and ionizable hydrogen gave the results shown in Table I. The values given for hydrogen and chloride have been corrected for the solubility of hydrochloric acid in isopropyl ether as given by Nachtrieb and Conway.[12] The empirical formulas tabulated in the last column show that essentially equimolecular amounts of hydrochloric acid and gallium chloride are co-extracted from aqueous solutions initially less than 7 *M* hydrochloric acid. The fourth formula listed is far different from $HGaCl_4$. It may be that the solubility of hydrochloric acid in isopropyl ether is altered by the presence of the gallium complex and that the correction applied is too large. If so, the error is relatively larger for this particular sample, in which the total concentrations were quite low.

Extractions from 8 *M* hydrochloric acid gave $HCl:GaCl_3$ ratios significantly greater than unity. These formulas may correspond to conditions favoring the formation of complex molecules containing more than one HCl. Nevertheless, it seems clear that the empirical formula for the gallium complex is quite analogous to that determined for iron.[12]

All gallium analyses reported in Table I were made by the 8-hydroxyquinoline–potassium bromate method. It is interesting to note that the total cation concentration (hydrogen plus gallium) is usually 2–3% lower than the chloride concentration. This may represent an error in the calculation used in determining free acid, in which the assumption is made that gallium has consumed exactly three hydroxide ions at the brom cresol purple end-point. Potentiometric titrations were performed using a calomel–glass electrode system, but although the indicator end-point appeared slightly before the inflection in the potentiometric curve, the discrepancy was much less than the 2–3% error in the charge balance. The disagreement may be due to the occlusion of gallium salts within the gelatinous hydroxide or the precipitation of a basic gallium salt requiring less than three equivalents of hydroxide. A similar observation has been noted by Fricke and Meyring.[13]

Variation of the Distribution Coefficient with Gallium Chloride Concentration.—Similar to the case of ferric chloride,[7] it can be shown that on the assumption of a polymerized gallium complex in the ether phase, the distribution expression would be

$$(Ga)_{n\ eth}/(Ga)^n_{aq} = K_{(H^+),(Cl^-)}\ \text{constant} \qquad (3)$$

under conditions of constant aqueous hydrogen and chloride ion activities. The stoichiometric gallium concentration as analytically determined will be proportional to the concentration of the ion species which takes part in the distribution equilibrium under these conditions. Equation (3) may be expressed in the form

$$\log (Ga)_{n\ eth} = \log K + n \log (Ga)_{aq} \qquad (4)$$

from which it appears that the association number n would be the slope of a plot of the logarithm of the ethereal gallium activity against the logarithm of the aqueous gallium activity for extractions performed under conditions of constant aqueous hydrogen and chloride activity and of varying total gallium concentration.

Table II gives the initial gallium chloride and hydrochloric acid concentrations, the initial and final phase volumes, the final gallium concentrations and the distribution ratios at various initial hydrochloric acid concentrations. Figure 1 is a plot of the data in Table II. These curves are similar to those obtained for ferric chloride.[7] At sufficiently low gallium concentrations the slope is unity, corresponding to the "ideal" behavior predicted by the simple Nernst distribution equation. With increasing gallium concentration the slope increases sharply, and for higher acidities passes through a maximum, then decreases, becoming less than unity. The decrease in slope at these high gallium concentrations may be due to several causes, such as (1) decrease in the aqueous hydrochloric acid concentration due to its extraction, and (2) the approach to saturation of the gallium complex in the ether phase (see below).

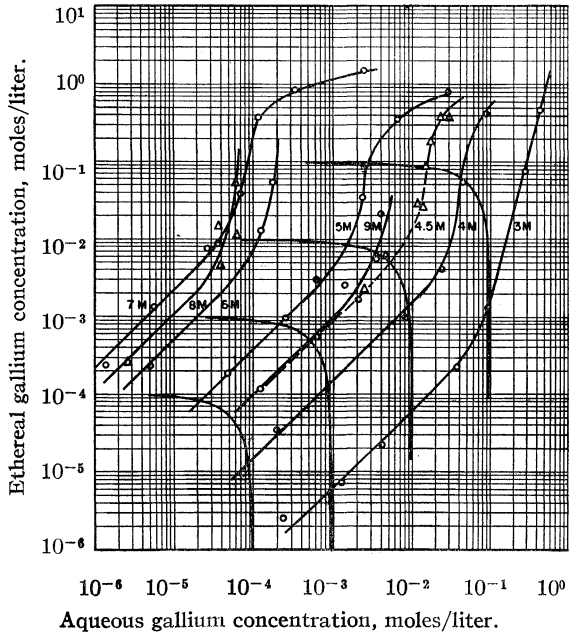

Fig. 1.—Variation of distribution with gallium concentration for several hydrochloric acid concentrations.

Variation of the Distribution Coefficient with Aqueous Hydrochloric Acid Concentration.—In Fig. 2 are plotted the distribution coefficients as a function of acidity for several initial gallium concentrations. These are taken from the intersections of the distribution curves with the rectangular hyperbolas (representing initial gallium concentrations) drawn in Fig. 1. The optimum acidity for efficient extraction is about 7.2 molar. It is evident that up to 0.01 molar, the distribution is essentially independent of gallium concentration, especially for the lower acidities. The salting-out effect, as postulated for the case of ferric chloride,[7] (if this be the cause of the changing slope in Fig. 1) becomes important above 0.01 molar gallium concentrations.

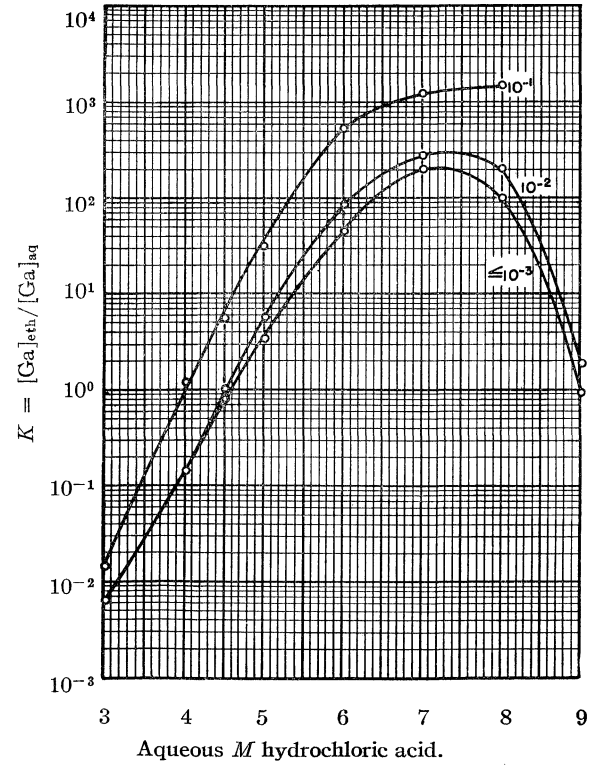

Fig. 2.—Variation of distribution coefficient with hydrochloric acid concentration for several initial gallium chloride concentrations.

Appearance of a Three Phase System.—For extractions made from 8.00 and 9.00 M hydrochloric acid, increase in the concentration of gallium chloride caused the separation of a

third liquid phase intermediate in density between the aqueous and ether phases, formed at the expense of the ether phase.[14] Near the lower gallium concentration limit of the three-phase region the volume of the intermediate ("heavy ether") phase is comparatively small, becomes larger at higher concentrations of gallium chloride, and at extremely high concentrations, the system again becomes two phase. Data obtained at 8.00 and 9.00 *M* hydrochloric acid are collected in Table III. The distribution coefficients at gallium concentrations below the three phase region are also plotted in Fig. 1. It is felt that the appearance of the third phase is related to the solubility of the gallium complex in isopropyl ether and, thus, the ether layer in the two phase system at very high gallium concentrations is considered "heavy." It is interesting to note that the ratio $(Ga)_{heavy\ ether}/(Ga)_{light\ ether}$ is relatively more constant than the other two possible distribution coefficients. This is reflected in the columns $(Ga)_{light\ ether}$ and $(Ga)_{heavy\ ether}$. However, with such a limited number of data, no conclusions can be drawn concerning the nature

(14) In the analogous system, ammonium chlorogallate in anhydrous diethyl ether, a second ether phase has been observed at high ammonium chlorogallate concentrations (H. Friedman, Dissertation, The University of Chicago, 1949).

[a] Gallium analysis by 8-hydroxyquinoline method.

and origin of the three phase system. For this purpose further investigation will be necessary. Measurement of densities, refractive indices and molecular weights would be highly desirable.

The dependence of the distribution coefficient on gallium concentration, the empirical formula of the gallium complex in the ether phase and the appearance of the third phase at high acid and gallium concentrations demonstrate a strong similarity of the gallium chloride and ferric chloride systems. (The third phase in the iron system has been reported by Dodson and coworkers[5].) It is unfortunate that the gallium solutions are not amenable to absorption spectrum measurements in the visual region. For $HFeCl_4$ in isopropyl ether, Beer's law conformity was observed for iron concentrations ranging from 0.01 to 0.4 molar.[12] By analogy, this lends support to the hypothesis that the anomalous distribution of gallium chloride between aqueous hydrochloric acid and isopropyl ether may be due to a salting-out effect and not necessarily to a polymerization of the gallium complex in the ether phase.

Acknowledgment.—It is a pleasure to acknowledge the assistance of Miss M. C. Bachelder who performed many of the gravimetric analyses, and of Mr. Lyle Raub, who helped in conducting the experiments with the radioactive isotope. The authors are also indebted to Dr. William L. Fink of the Aluminum Company of America for making available some of the gallium used in the investigation.

Summary

The distribution of gallium chloride between aqueous hydrochloric acid and isopropyl ether has been found to obey the simple Nernst partition law for low gallium concentrations. At concentrations of gallium exceeding 0.01 molar, the partition increases in favor of the ether phase. The empirical formula of the gallium complex in the ether phase is $HGaCl_4$, if extracted from an aqueous solution not exceeding 7 molar hydrochloric acid.

Under certain conditions, a third ether-rich phase has been observed.

Vapor Pressure of Titanium

BY JOHN M. BLOCHER, JR., AND I. E. CAMPBELL

In view of the current interest in the use of titanium metal at high temperatures, it is important that vapor-pressure data be made available. The vapor pressure of titanium has been determined over the range from 1500 to 1800°K., using the method of Langmuir.[1]

The vapor pressure (p) was calculated from the measured rate of evaporation *in vacuo* (m) of an electrically heated titanium wire by the well-known Knudsen equation

$$\alpha p = m(2\pi RT/M)^{1/2} \qquad (1)$$

where m is in grams per square centimeter per second, and M is the molecular weight in the vapor phase. The *accommodation coefficient* (α) was assumed to be unity as has been found generally to be the case for metals.[2]

Measurement of the weight per unit length of the wire before (w_0) and after (w) a run of t seconds duration leads to the rate of evaporation by the relationship[1]

$$m = \left(\frac{\rho}{\pi}\right)^{1/2} \frac{w_0^{1/2} - w^{1/2}}{t} \qquad (2)$$

where ρ is the density. These average m values may be checked by following the resistance of the wire during the run. If one plots the square root of the ratio of the resistance (R_0) of the wire at t = 0 (extrapolated) to the resistance at time t against t, one should obtain in the case of constant m, a straight line of slope x which leads to the rate of evaporation by the relationship[1]

$$m = (\rho w_0/\pi)^{1/2} x \qquad (3)$$

Experimental.—Titanium wire of 0.46-mm. diameter and of 99.7 to 99.9% purity was supplied by the U. S. Bureau of Mines. It was produced by the magnesium reduction of titanium tetrachloride.[3] Lengths of 8 to 9 cm. were mechanically cleaned and polished with fine emery paper. Contact with 1-mm. tungsten electrodes was made by placing the ends of the wire and of the electrodes into slotted copper blocks (0.95 × 0.95 × 1.6 cm.), and then crimping the assembly in a vise.

The filament assemblies were sealed in turn into a 1-liter Pyrex round-bottom flask, being oriented along the large diameter perpendicular to the axis of the neck. A plane Pyrex window was sealed into the neck of the flask through which the temperature measurements were made. In order to prevent clouding of the window between temperature readings by the condensed titanium, a magnetically operated shutter was provided between the window and the filament. The effectiveness of the shutter in preventing the progressive formation of appreciable optically absorbing film was evident from the constancy during each run of the product of the filament voltage and the cube-root of the current[1] together with the constancy of the observed optical temperature. The bulb was evacuated to 10^{-6} mm. of mercury by means of a vacuum system consisting of a Cenco-Hyvac mechanical pump followed by a single-stage mercury condensation pump and a liquid air-trap.

Prior to the run, the bulb was alternately outgassed by flaming, and flushed with pure dry helium. A glow discharge from a Tesla coil was played on the wire during the next to the last pump-down in an effort to clean off small particles of abrasive, etc.

A battery-stabilized direct-current supply was used to heat the filament wire, the resistance of which was derived from current and voltage. The heating current was determined by measuring with a potentiometer the voltage developed across a standard resistance in series with the filament. A voltage divider was provided to measure with the potentiometer, the voltage across the filament. Corrections were made for lead resistance determined at the end of the run by passing a current equal to the average of that used during the run through the lead assembly with the copper terminal blocks soldered together.

Filament temperatures were determined with a Leeds and Northrup optical pyrometer calibrated with window *in situ* against a N.B.S. standard tungsten-ribbon lamp. The observed temperatures were corrected for the emissivity of titanium.[4] It is fortunate that the heat conductivity of titanium is relatively low. This led to an observed constant temperature (±10°) over 95% of the length of the wire.

Approximately one-tenth of the filament was allowed to evaporate during each run. The rates of evaporation as determined by resistance change were quite constant throughout the runs, except for short periods at the start when the wire was becoming stabilized (evaporation of small magnesium content, transition from α- to β-titanium, etc.)

(1) I. Langmuir, *Phys. Rev.*, **2**, 329 (1913).

The titanium powder produced by the reduction was compacted and then sintered *in vacuo* at 1000° for sixteen hours, volatilizing the impurities, hydrogen and magnesium. The remaining principal impurities are Fe <0.1%, Si <0.1% and O + N, <0.1%.

(4) Van Arkel, "Reine Metalle," J. Springer, Berlin, 1939, p. 187. The emissivity was checked in the neighborhood of 1400°K., $\epsilon_{0.655\mu}$ = 0.49 by temperature observations on the surface of and on a hole in an induction-heated titanium block. The results checked to within ±10° (the uncertainty in the reading of the temperature of the filament wire).

Data.—The experimental results are given in Table I. A "high-temperature density" of 4.35 (as compared to the room-temperature value of 4.5) was determined from the observed sag in in the filaments upon heating.[5] This value was used for ρ in Equations (2) and (3).

TABLE I

RATE OF EVAPORATION OF TITANIUM

Temp., °K.	Time of run, sec.	Rate of evaporation,[a] g./sq. cm./sec.	
1510	144,000	1.62×10^{-8}	1.80×10^{-8}
1613	39,300	1.60×10^{-7}	1.86×10^{-7}
1636	21,120	2.9×10^{-7}	3.1×10^{-7}
1727	4,800	1.33×10^{-6}	1.37×10^{-6}
1822	1,050	9.2×10^{-6}	8.9×10^{-6}

[a] The first value was determined by resistance change, the second by weight loss.

One run was made at each of the recorded temperatures.

Thermodynamic Treatment.—The validity of the data can best be tested by determining the constancy of ΔH_0^0 in the relationship

$$R \ln p \text{ (atm.)} = \left(\frac{F^0 - H_0^0}{T}\right)_{\text{solid}} - \left(\frac{F^0 - H_0^0}{T}\right)_{\text{vapor}} - \frac{\Delta H_0^0}{T} \quad (4)$$

The free-energy function of the solid is related to the heat capacity as

$$\left(\frac{F^0 - H_0^0}{T}\right)_{\text{solid}} = \frac{1}{T}\int_0^T C_p dT - \int_0^T C_p d \ln T \quad (5)$$

The free-energy functions of the vapor can be determined accurately from spectroscopic data.[6]

The C_p data for solid titanium of Kelley[7] in the low-temperature range, and of Jaeger and others[8] from 200° to 1200° were used in evaluating Equation (5). Free-energy functions for titanium vapor were evaluated using spectroscopic data from Landolt–Börnstein.[9]

The values of ΔH_0^0 of sublimation as calculated from Equation (4) using the vapor-pressure data are given in the fifth column of Table II. The average value of ΔH_0^0, 111,064 cal., added to the difference between $(H^0 - H_0^0)$ of solid and vapor leads to the heat of sublimation at 298.2°K., $\Delta H_{298.2} = 111{,}720$ cal.

The fact that there is no apparent trend of ΔH_0^0 with temperature, and that the maximum deviation from the mean is only 578 cal. speaks well for the validity of the data.

Carpenter and Reavell[10] have recently determined the rate of evaporation of titanium using the present technique. In an advance announcement of their results, they give no data, but present the following equation for the rate of evaporation of titanium

$$\log mT^{1/2} = 7.70 - (2.07 \times 10^4/T) \quad (6)$$

TABLE II

ΔH_0^0 OF SUBLIMATION OF TITANIUM

T, °K.	$\left(\frac{F^0 - H_0^0}{T}\right)_{\text{vapor}}$	$\left(\frac{F^0 - H_0^0}{T}\right)_{\text{solid}}$	Vapor pressure,[a] atm.	ΔH_0^0,[a] cal.	ΔH_0^0 (C. and R.),[b] cal.
1510	46.282	12.26	2.05×10^{-9}	111,393	110,094
			2.28×10^{-9}	111,076	
1613	46.637	12.73	2.08×10^{-8}	111,394	110,926
			2.42×10^{-8}	110,894	
1636	46.713	12.84	3.8×10^{-8}	110,937	111,101
			4.1×10^{-8}	110,724	
1727	47.005	13.23	1.79×10^{-7}	111,633	111,892
			1.86×10^{-7}	111,512	
1822	47.294	13.61	1.28×10^{-6}	110,486	112,636
			1.24×10^{-6}	110,595	

Av. $\Delta H_0^0 = 111{,}064 \pm 578$ cal.

[a] The upper value was determined by resistance change, the lower by weight loss. [b] Calculated using Equation (6) of Carpenter and Reavell.

The authors have calculated ΔH_0^0 at their own experimental temperatures using this equation. The resulting values given in the sixth column of Table II show a trend with temperature of roughly twice the maximum spread of the present data. Thus, Equation (6) is inconsistent with the C_p data. However, there is fair agreement with the C_p data and with the present vapor-pressure data at 1613 and 1636°K. The reason for the deviation at higher and lower temperatures may become apparent when the experimental data of Carpenter and Reavell are published.

If the average value of ΔH_0^0 from the present work be substituted in Equation (4) together with a linear expansion of $(F^0 - H_0^0/T)_{\text{sublimation}}$ as a function of the absolute temperature, one arrives at the equation

$$\log p \text{ (atm.)} = 7.782 - (24{,}275/T) - 0.230 \times 10^{-3}T \quad (7)$$

which is believed to represent the vapor pressure of titanium to within 10% over the range 1200–2000°K. This equation together with the experimental data is plotted in Fig. 1. The points in the squares are those obtained from weight loss, and those in the small circles from resistance change. The large circles are centered midway between the weight-loss and resistance-change points, and have radii of 10°. The dashed curve is from Equation (6).

The data may be extrapolated to give an equation for the vapor pressure of liquid titanium. A reasonable entropy of fusion of 2.5 e. u. at the melting point, 2000°K.[11] is assumed together with a constant heat capacity for the liquid of 8.0 cal./mol./°. These values, when combined with ΔH_0^0

(5) Van Arkel, ref. 4, p. 185, gives 4.31 as the density of β-titanium at the transition temperature.

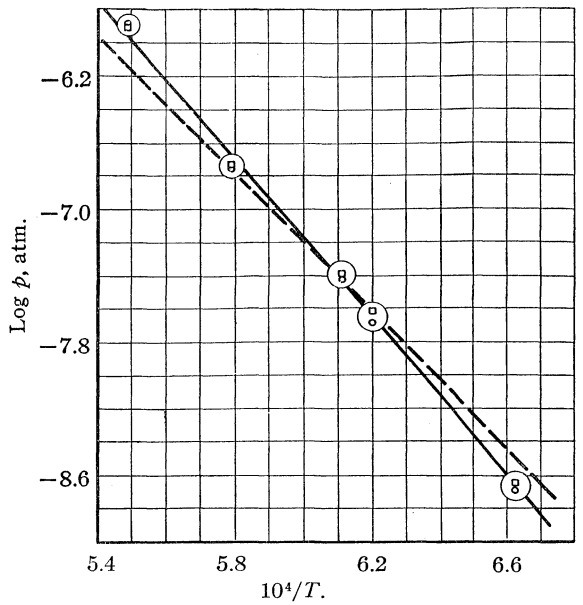

Fig. 1.—Vapor pressure of titanium: O, resistance change; □, weight loss; large circles, ±10° temperature. The full curve is that of Equation (7). The dashed curve is from Equation (6) of Carpenter and Reavell.

and the free-energy functions for titanium vapor as given by Latimer,[12] lead to vapor pressures which may be expressed to within 2.5% by the equation

$$\log p \text{ (atm.)} = 6.255 - (22{,}110/T)$$

The calculated boiling point is 3535°K.

It has been observed in this Laboratory that at the temperatures encountered in the present work, oxygen and nitrogen diffuse very rapidly into titanium, forming solid solutions. This fact greatly reduces the possibility of an error encountered with many metals using the Langmuir technique, *i. e.*, a lowering of the rate of evaporation by surface oxide or nitride films. The impurities in solid solution with the titanium used in the present work, a maximum of 0.005 mole-fraction, would reduce the vapor pressure of pure titanium, and might yield observed values roughly 99.5% of the true values. This difference is insignificant relative to experimental error.

Acknowledgment.—It is with gratitude that the authors acknowledge the financial aid of the Iodine Educational Bureau, Inc., in carrying out this work. The interest of Mr. A. C. Loonam[13] is gratefully acknowledged. His independent interpretation of the vapor-pressure data resulted in a ΔH_0^0 value but 160 cal. above that of the authors.

Summary

The vapor pressure of solid titanium has been determined in the range 1500–1800°K. by measuring the rates of evaporation of titanium wire using the Langmuir technique. The data fit the thermodynamic requirements quite well and yield heats of sublimation of 111,000 cal. at 0°K. and 111,700 at 298.2° K. The resulting equation for the vapor pressure of solid β-titanium, valid over the range 1200–2000°K., is $\log p$ (atm.) = $7.782 - (24{,}275/T) - 0.230 \times 10^{-3} T$.

The data may be extrapolated to yield an equation for the vapor pressure of the liquid: $\log p$ (atm.) = $6.255 - (22{,}110/T)$, leading to a normal boiling point of 3535°K.

The data agree over a limited range with the incomplete experimental results of Carpenter and Reavell. Their equation for the rate of evaporation of titanium has been shown to be inconsistent with other available thermodynamic data.

The State of Oxidation of S^{35} Formed by Neutron Irradiation of Potassium Chloride

BY W. S. KOSKI

When potassium chloride is irradiated with thermal neutrons the following is one of the reactions that takes place

$$Cl^{35} + n \longrightarrow S^{35} + H' + Q$$

The Q of this reaction as estimated from the masses is 0.63 mev. From simple considerations of conservation of energy and momentum, one can estimate the energy of the recoiling sulfur fragment as equal to 17.6 kev. Since it is believed[1,2] that ionization by a rapidly moving particle is probable only at velocities comparable to the effective velocities of free electrons, the recoiling sulfur fragment will produce no appreciable ionization by the process of electron ejection and capture. However, the irradiated chlorine is an ion in the crystal lattice, and the proton on leaving the compound nucleus will reduce the nuclear charge by +1 leaving the residual sulfur fragment with a double negative charge. This charge may be reduced by electron capture by the proton as it moves through the electronic field of the sulfur fragment. Such

considerations would lead one to believe that the sulfur activity should be present as sulfide ion or possible elementary sulfur. This seems to be contrary to observation,[3] since it has been reported that the sulfur activity appears in its highest state of oxidation rather than in its lowest. We thought it might be of interest to investigate this apparent contradiction, especially since this information was very pertinent to another problem that we have under investigation.

Experimental Details

Materials.—All of the chemicals used in this work were of a C. P. grade, and unless otherwise stated were used as commercially available with no further purification. The water that was used as a solvent was freshly distilled, having a specific conductance of $1\text{–}2 \times 10^{-6}$ mho. The alcohol was absolute and taken from a freshly opened container and no further attempts were made at purification.

Preparation of Carbonyl Sulfide.—The carbonyl sulfide that was used in this work was prepared[4] by the reaction of carbon monoxide with an excess of sulfur at 425° for sixteen hours. The carbon monoxide was prepared from oxalic and concentrated sulfuric acids. The water and carbon dioxide were removed with liquid nitrogen.

Separation of Carriers.—During the course of this work it was necessary to separate various combinations of carriers. Mixtures of sulfide and sulfate or sulfite and sulfate ions were separated by acidifying the solutions and distilling the resulting hydrogen sulfide or sulfur dioxide, and whenever necessary the gas samples were collected and oxidized with bromine and nitric[5] acid and precipitated as barium sulfate. Whenever mixtures of sulfide, sulfite and sulfate ions were used they were prepared just before use and always in alkaline solutions in order to avoid complications by reactions between sulfides and sulfites. In these cases the separations were performed by precipitating the sulfide by adding appropriately acidified copper chloride solution. The resulting copper sulfide was oxidized to the sulfate and the sulfate precipitated as barium sulfate. The sulfite ion was separated by distillation, collected, oxidized and precipitated as barium sulfate. In addition to using copper for the sulfide separation, lead acetate was used following the procedure of Bassett and Durrant,[6] thus enabling us to make the separation directly in the 2 *N* sodium hydroxide solution. The same results were obtained with both methods of separation.

Pre-irradiation Treatment of Potassium Chloride.[7]—In view of the nature of this experiment it was considered desirable to remove as much oxygen and water from the potassium chloride sample as possible. The potassium chloride was put into a quartz container and attached to a high vacuum system. The sample was then heated to a temperature of approximately 700° for sixty hours. The system was pumped on with an oil diffusion pump backed by a suitable mechanical pump, and at the conclusion of the heating treatment the pressure in the system with the heat on was better than 10^{-5} mm. The sample was permitted to cool, and then 15 cm. of purified carbon monoxide was admitted, the container was sealed and the sample was irradiated in the Oak Ridge pile.

Treatment of the Irradiated Samples.—The quartz vessel containing the irradiated potassium chloride sample was sealed on to a vacuum system. A portion of the carbon monoxide atmosphere in which the potassium chloride was bathed was put into a gas counter and tested for activity. The gas was radioactive but none of it was condensable in liquid nitrogen. A portion of this carbon monoxide was then mixed successively with sulfur dioxide, carbonyl sulfide and sulfur monochloride, and on separation of the condensable gases with liquid nitrogen only traces of activity were found in the condensed gases.

The potassium chloride container was then opened in a dry nitrogen atmosphere and some of the crystals were dissolved in water containing traces of carrier ions or, if necessary, in carrier-free alcohol. The various experiments discussed were performed with 5-cc. portions of these solutions.

Preparation of Radioactive Samples for Measurements.—All the sulfur samples that were measured for radioactivity were oxidized to the sulfate and precipitated as barium sulfate. The precipitates were then collected on one-inch filter papers in a Hirsch funnel, washed with water, acetone, dried, mounted and examined for activity with a Geiger–Müller counter. In all cases the amounts of sulfate present were adjusted so that all of the samples compared had the same amount of barium sulfate.

The activities of gaseous samples were measured by fitting a small gas cell over the mica window of the counter. This cell was pumped out, and then the gas to be tested was admitted and measured for activity.

Discussion of Results

Untreated Potassium Chloride Samples.—When a sample of potassium chloride which has had no outgassing treatment is irradiated with neutrons and then dissolved in a water solution containing sulfide, sulfite and sulfate ions as carriers, it is found that on separation of the carriers practically all of the activity is present as sulfate. This observation is in agreement with the results of Willard mentioned earlier.

One of the most obvious ways of oxidizing sulfur is by reaction with atmospheric oxygen. However, experience with reactions of macro amounts of sulfur and oxygen indicate that the tetravalent state of sulfur should be expected. This, however, is not a serious objection since the sulfur formed in the body of the crystal is in an unusual habitat, and it might well undergo oxidation to the hexavalent state through a heterogeneous catalytic process. Furthermore, the S^{35} at the moment of its creation is in a high state of electronic excitation and may well react with any oxygen present to form sulfur trioxide.

During the course of irradiation of the crystals elementary chlorine is formed and the sulfur fragments would be oxidized through the formation of such compounds as sulfur mono- and dichlorides. On hydrolysis, however, these compounds lead to sulfite rather than sulfate ions.

There is, of course, the possibility that some of the free chlorine formed during the irradiation may bring about oxidation of the sulfur when the sample is brought into solution. Experimental results that will be cited later indicate that very little of the oxidation is actually brought about by this mechanism.

If one tentatively takes air oxidation as the explanation for the presence of hexavalent sulfur it remains to be shown that potassium chloride

(7) This phase of the work was carried out at Brookhaven National Laboratory in collaboration with Dr. V. W. Cohen.

crystals can occlude reasonable amounts of foreign gaseous substances. Experimental studies[8] have shown that potassium, thallium and the halogens can be incorporated in alkali halide crystals. From such work it appears reasonable that the crystals in question can contain appreciable amounts of a gaseous substance such as air. The oxygen in a potassium chloride crystal may be present there as a result of two processes (1) diffusion and (2) incorporation in the crystal during the formation of the crystal from a solution. The latter is probably the most effective mechanism since diffusion of gases into solids is slow at ordinary temperatures; consequently only the surface layers would contain atmospheric oxygen which arrived through diffusion and absorption, whereas the body of the crystal would have oxygen which was probably introduced during crystal growth.

S^{35} from Outgassed Potassium Chloride.—In a number of experiments on a certain sample of outgassed and irradiated potassium chloride it was found that about 64% of the total sulfur activity present was in the hexavalent state and the remainder in a lower state. Essentially the same value was obtained even if the amounts of carriers were varied, indicating that there was no exchange between sulfide and sulfate or between sulfite and sulfate complicating the picture. This observation on the exchange is in agreement with the prior work of Voge and Libby.[9] It might be mentioned that different samples of potassium chloride varied widely as to per cent. activity present as sulfate. Some irradiated crystals have been obtained with as low as 15% of total activity present as sulfate. There are also indications that not even all of the individual crystals that have been irradiated simultaneously in the same container have the same per cent. total activity as sulfate. Only a few experiments have been done in this connection, but an indication has been obtained that the larger crystals have a much greater percentage of activity present as sulfate than the smaller crystals. This may not be too unexpected since a larger crystal would require more prolonged pumping and more severe outgassing conditions to remove its occluded oxygen.

Behavior of Trace Amounts of Sulfur Compounds in Solution.—It may be appropriate to comment at this point on the behavior of sulfur compounds in solution. If some potassium chloride crystals containing 63% of the activity as sulfate are put into ordinary distilled water from which no pains were taken to remove air and then carriers of sulfide and sulfate are added and separated, it is found that all of the activity appears as sulfate ion. If, on the other hand, the crystals are dissolved in a solution of sulfite and sulfate carriers and then some sulfide carrier is added, analysis shows that the activity is now 63% sulfate and 37% sulfite with the sulfide ions carrying no activity. Apparently the activity that was present as sulfide ions in trace amounts is rapidly oxidized to sulfite ion, and further rapid oxidation is prevented by the presence of macro amounts of sulfite carrier. As a result of a number of such experiments it was concluded that in general if the irradiated potassium chloride crystals were dissolved in distilled water from which air had not been removed the trace amount of radiosulfur is oxidized to the chemical form of the carrier having the lowest oxidation state. If no carrier or if only sulfate ion is present as a carrier the radiosulfur goes up to the hexavalent state. Water solutions of radiosulfur could be kept for hours without appreciable oxidation if care was taken to exclude atmospheric oxygen. This observation leads us to conclude that the free chlorine present in the crystal as a result of irradiation is not producing oxidation of the sulfur on solution of the crystal. It was found that if a potassium chloride crystal was dissolved in alcohol there was no oxidation even if the solution was kept for weeks. If a portion of the alcohol solution was put into distilled water containing dissolved air the sulfur compounds did oxidize with a half-time of about thirty minutes for 50% of the sulfide to be oxidized to sulfate. On the other hand, if the crystal was dissolved directly in a portion of the same water, the oxidation was complete in less than three minutes, indicating that in the presence of solid potassium chloride the oxidation is much faster and may be well a heterogeneous process on the surface of the crystal.

State of Oxidation of the Non-Sulfate Sulfur.—The results obtained for three samples of outgassed and neutron-irradiated potassium chloride crystals are summarized in Table I. These samples are not strictly comparable since sample number 2 was outgassed at a somewhat higher temperature than number 1 and sample number 3 was composed of very small crystals selected from sample number 2 after irradiation.

TABLE I

ACTIVITY IN CARRIERS

Carriers	Sample no.	Sulfide	Sulfite	Sulfate	Total activity	% activity as sulfate
Sulfide, sulfate	1	396	...	750	1160	64.6
Sulfite, sulfate	1	...	403	776	1194	64.9
Sulfide, sulfite, sulfate	1	430	36	755	1200	63
Sulfide, sulfate	2	780	...	465	1270	36.6
Sulfite, sulfate	2	...	630	430	1080	39.8
Sulfide, sulfate	3	602	...	121	758	16
Sulfite, sulfate	3	...	673	105	802	13

It is clear from these results which are representative of a number of such experiments that very little of the activity is present in the form of sulfite ion. It is felt that a safe upper limit is

(8) R. M. Barrer, "Diffusion in and through Solids," Cambridge University Press, 1941, p. 110.

(9) H. H. Voge and W. F. Libby, THIS JOURNAL, 59, 2474 (1937).

5% and very probably the figure is lower than this. The small amount of activity present in the sulfite may actually be due to a slight solution of the copper sulfide in the acid that was present or there may be a small amount of reaction between sulfide and sulfite ions. In the case of precipitation of the sulfide in strongly alkaline solution, no reaction between sulfide and sulfite is to be expected but here also a small residual activity seemed to be present in the sulfite carrier, although there was some indication that it might be less than that found in the former case. Normally one would expect the oxidation of sulfur to stop at sulfur dioxide, but as has been already pointed out, the conditions under which the sulfur finds itself in the crystal are far from normal and apparently when oxidation does occur it goes up to the hexavalent state.

The small amount of activity present as sulfite has an additional significance. It means that no appreciable portion of the recoiling sulfur fragments formed in the nuclear reaction Cl^{35} (*n.p.*) S^{35} react chemically with chlorine to form such compounds as SCl_2, S_2Cl_2, etc., for such compounds on hydrolysis give sulfur dioxide. Likewise the absence of sulfite activity indicates the absence of thionates and polythionates.

These various results indicate that the non-sulfate sulfur is either in the form of elementary sulfur or sulfide ions. Attempts to distinguish between sulfur and sulfide ions were unsuccessful because of the rapid exchange that exists between these two states of sulfur in solution.

Heating irradiated potassium chloride crystals above the melting point in an atmosphere of carbon monoxide failed to produce any carbonyl sulfide. This observation would indicate that little or no free sulfur was present, but admittedly this evidence is not too good since under such drastic treatment and in such an unusual habitat free sulfur if present may well undergo some chemical transformation.

Acknowledgment.—The author wishes to express his appreciation to Professor R. D. Fowler for many illuminating discussions which were extremely helpful during the course of this investigation. It is also desired to acknowledge the coöperation of various members of the staff of the Brookhaven National Laboratory where the initial phase of this work was carried out.

Summary

The state of oxidation of S^{35} formed by neutron irradiation of potassium chloride depends on the pre-irradiation treatment of the crystals. If the crystals were carefully outgassed by heating and pumping the radioactive sulfur appeared in part either as sulfur or more probably as sulfide ion. If no precaution was taken to remove air from the crystals all of the S^{35} appeared in the hexavalent state. In all cases tested there was always some activity present as hexavalent sulfur and in the most favorable situation as little as 15% of the total sulfur activity was present in the highest oxidation state. It is concluded that atmospheric oxygen which is occluded in the crystal is responsible for the hexavalent state of the radio sulfur.

Infrared Spectra of Ortho-, Meta-, Para- and Omega-Monodeuterotoluenes in the 2–16 Micron Region[1a]

BY JOHN TURKEVICH,[1] HUGH A. MCKENZIE,[2] LEWIS FRIEDMAN AND ROBERT SPURR[3]

In connection with studies being carried out on the mechanism of exchange reaction between deuterium and aromatic compounds, it was found necessary to investigate the infrared spectrum of the monodeuterotoluenes. The present paper contains information on the preparation of these compounds and the infrared spectrum in the 2–16 micron region.

Preparation of the Compounds

The various monodeuterotoluenes were prepared by deuterolysis of the appropriate Grignard reagent. The latter was made using the procedure and apparatus of Weldon and Wilson.[4] After the formation of the ether solution of the Grignard reagent, it was connected to a vacuum system and most of the ether was distilled off. It was found preferable not to remove the ether completely since complete removal would make it extremely difficult to effect the reaction between the Grignard compound and the heavy water. The reaction flask was cooled in a Dry Ice–acetone-bath and the heavy water was added dropwise. The system was then allowed to warm up slowly overnight. The reaction mixture was shaken vigorously and then allowed to stand for at least twenty-four hours. The hydrocarbon and remaining ether were removed from the flask

by vacuum distillation to a trap cooled with liquid air. The contents of the trap were then redistilled to obtain a deuterotoluene fraction. The latter was redistilled to obtain a fraction boiling at 110°. The compounds were prepared and purified at the Frick Chemical Laboratory of Princeton University. The mass spectra of all the deutero compounds were examined by Dr. F. Mohler of the National Bureau of Standards. The results indicate that there is less than 0.2% of the dideuterium compound present in each sample and at most 5% of non-deuterated toluene. Further data on the purity will be relegated to the end of the paper.

Materials

o-**Toluidine** was purified by crystallization of the oxalate[5] and the fraction boiling at 182° in a 70-cm. column was collected.

o-**Bromotoluene** was prepared from the *o*-toluidine by the method of Bigelow.[6]

m-**Bromotoluene** was the Eastman Kodak Co. product. Examination of its infrared spectrum showed that it was free from the ortho, para or omega compound.

p-**Toluidine** was purified by crystallization of the hydrochloride.

p-**Bromotoluene** was obtained by diazotization of *p*-toluidine at 5–10°.[7] The product obtained boiled at 183°.

Benzyl chloride was the 181° fraction of the Paragon benzyl chloride.

Toluene was a special sample obtained from the U. S. Bureau of Standards.

Heavy water of 99.8% purity was obtained from the Atomic Energy Commission.

Results

The infrared spectra in the 2- to 16-micron region were obtained in 0.1-mm. thick rock salt cells on the Baird Associates Double Beam Recording Spectrophotometer[8] of the Chemistry Department of the Brookhaven National Laboratory. The results obtained for toluene, ortho-, meta-, para- and omega-monodeuterotoluene are presented in Table I and Figs. 1–5. The figures contain the absorption both of the pure compound and of a 10% solution in carbon tetrachloride. The data in the carbon tetrachloride solution are of doubtful value in regions of strong absorption of carbon tetrachloride, namely, 705–840 cm.$^{-1}$.

Data are also given on the spectrum of toluene obtained by the Naval Research Laboratory and published by the American Petroleum Institute under the serial number 308.

Discussion

A complete discussion and interpretation of the results will be withheld until work is completed on spectra in the near infrared at high resolution using lithium fluoride optics, on the spectra in the 16- to 38-micron region using KBr and KRS 5 (thallium bromide–iodide) optics and on the Raman spectra. In the meantime, we wish to record the following observations.

The 4.6-micron region contains the bands due to the carbon–deuterium valence vibration. Non-deuterated toluene shows a very weak absorption in this region, undoubtedly due to an overtone or combination. When the deuterium atom is substituted in the ring the absorption band is at 2220–2252 cm.$^{-1}$, while when the deuterium atom is in the side chain the absorption is at 2150 cm.$^{-1}$. Thus it is easy to distinguish compounds containing deuterium in the ring from those containing deuterium in the side chain. Furthermore, the ortho-monodeutero compound absorbs at 2220 cm.$^{-1}$, the meta- at 2252 cm.$^{-1}$, and in the para compound the band is split in two at 2230 and 2252 cm.$^{-1}$. The per cent. of transmission of this carbon–deuterium stretching frequency is less in the meta compound than in the ortho compound and is least in the double peak of the para compound. All these bands are relatively sharp while that in the omega compound is rather broad and of the same intensity as that of the meta compound.

We would also like to discuss the purity of the compounds on the basis of the infrared data obtained. It is not possible to find a band that is characteristic of the non-deuterated toluene in this region of the infrared spectrum. The band at 730 cm.$^{-1}$ would satisfy this criterion were it not for the fact that the para compound has a broad band at 726 cm.$^{-1}$. The omega compound can be identified easily by the position of its carbon–deuterium stretching band at 2150 cm.$^{-1}$. The weakness of the absorption of other compounds in this region indicates the absence of the side-chain substituted deuterium in the ring-substituted deuterium compounds. The band at 1645 cm.$^{-1}$ can be used to establish the absence of the ortho compound in the meta, para and omega samples. The band at 879 cm.$^{-1}$ in the meta compound can be used to indicate the absence of this compound in the ortho, para and omega samples. The band at 1675 cm.$^{-1}$ is present in the para but not in the ortho, meta or omega samples. Thus the purity of the compounds is indicated within the accuracy of the infrared spectrometer.

Summary

The preparation of the ortho, meta, para and omega deuterotoluenes has been described and their infrared spectra from 2 to 16 microns presented.

Some Reactions of Triphenylsilane and Triphenyltin Hydride

BY HENRY GILMAN AND H. W. MELVIN, JR.

Previous reports[1a,b] have shown that triethylsilane reacts with organolithium compounds in ether to form tetrasubstituted silanes and lithium hydride. We are now reporting that the reaction of triphenylsilane with phenylithium, methyllithium and *n*-butyllithium resulted in the formation of tetraphenylsilane, methyltriphenylsilane and *n*-butyltriphenylsilane, respectively, in good yields. These reactions may be formulated as

$$(C_6H_5)_3SiH + RLi \longrightarrow (C_6H_5)_3SiR + LiH$$

It is interesting to note that some tetraphenylsilane was formed in the reaction with *n*-butyllithium, possibly as a consequence of disproportionation,[2] even under these mild conditions. However, lithium *p*-thiocresoxide was without effect on triphenylsilane when these reactants were heated in ether.

The extent of the reaction between triphenylsilane and phenylmagnesium bromide appeared to be insignificant, for 90% of the silane was recovered. Since it has been shown that the reactivity of Grignard reagents is increased when dioxane is added to their solutions,[3] triphenylsilane was treated with a phenylmagnesium bromide solution containing this compound. Apparently reaction was inappreciable because triphenylsilane was recovered to the extent of 90%.

In extending the examination of the reaction of organolithium compounds to other similar hydrides of Group IV elements, it was found that triphenyltin hydride reacts with phenyllithium to form tetraphenyltin (90%) and lithium hydride.

Pape[4] obtained tetrapropylsilane as well as the expected tripropylsilane when trichlorosilane and dipropylzinc were heated in a sealed tube at 150° for six hours. He wrote an equation to account for the transformations

$$2SiHCl_3 + 4Zn(C_3H_7)_2 \longrightarrow SiH(C_3H_7)_3 + Si(C_3H_7)_4 + 3ZnCl_2 + Zn + C_3H_8$$

The formation of tetrapropylsilane along with free zinc and propane might be explained by a reducing action of the Si–H bond in tripropylsilane. It appears not unlikely, however, that the tetrapropylsilane may have been formed by a reaction similar to that described with RLi compounds. Organometallic compounds differ largely in rate of reaction rather than in kind of reaction,[5] and the forced conditions used by Pape may have been the determining factor in the results obtained by him. Inasmuch as Grignard reagents lie between organolithium and organozinc compounds in reactivity, it is probable that they also would react like organolithium compounds under appropriate conditions.

In order to determine whether triphenylsilane is a reducing agent, a solution of it in xylene was heated with acridine.[6] No products that might be formed by such a reduction were isolated.

It is highly probable that R_3GeH and R_3PbH[7] compounds would react like the corresponding silicon and tin compounds. However, triphenylmethane is known to react as follows with RLi compounds

$$(C_6H_5)_3CH + RLi \longrightarrow (C_6H_5)_3CLi + RH$$[8]

Experimental

Triphenylsilane.—This compound was prepared in essential accordance with the directions of Reynolds, Bigelow and Kraus.[9] Our yield was 88% in a preparation starting with 0.62 mole of trichlorosilane. Hydrolysis was effected by pouring the reaction mixture on cracked ice containing sulfuric acid. Inasmuch as this compound melted at 44–45° instead of 36–37°[9] after two recrystallizations from 95% ethanol, it was analyzed.

Anal. Calcd. for $C_{18}H_{16}Si$: Si, 10.77. Found: Si, 10.67, 10.72.

Triphenyltin Chloride.—Triphenyltin chloride was prepared by a modification[10] of the procedure of Kocheshkow, Nadi and Aleksandrow[11] from 55 g. (0.1785 mole) of tetraphenyltin and 11.2 g. (0.0429 mole) of stannic chloride. The yield of triphenyltin chloride, melting at 103–104°, was 47.2 g. (72%). Repeated recrystallization from petroleum ether (b. p. 77–115°) did not raise the melting point.

Triphenyltin Hydride.—Triphenyltin chloride instead of the bromide was used in the preparation of this compound.[12] From 20 g. (0.0518 mole) of triphenyltin chloride was obtained 1.5 g. (8.3%) of triphenoltin hydride. In a second run, using 17.8 g. (0.046 mole) of triphenyltin chloride, the yield was 6.8 g. (42%) of triphenyltin hydride. The compound was purified by distillation *in vacuo* in an apparatus previously swept with nitrogen. No percentage yield was reported by the earlier workers.[12]

Triphenylsilane and Phenyllithium.—To 26 g. (0.1 mole) of triphenylsilane dissolved in 50 ml. of ether was added 0.1 mole of phenyllithium in 107 ml. of ether with the immediate formation of a white precipitate. At the end of the addition Color Test I[13] was negative. A portion of the precipitate was removed and analyzed as described under "Identification of Lithium Hydride." Subsequent to hydrolysis and recrystallization from benzene, there was obtained 30.3 g. (90%) of tetraphenylsilane, m. p. 230–232°.

Anal. Calcd. for $C_{24}H_{20}Si$: Si, 8.33. Found: Si, 8.3, 8.3.

Triphenylsilane and Methyllithium.—Triphenylsilane (0.044 mole) and 0.044 mole of methyllithium were interacted as described above. After working up the reaction mixture in the customary manner and recrystallizing the product from ethanol, 11.6 g. (93%) of methyltriphenylsilane, m. p. 66–67°,[14] was obtained. This product was identified by the method of mixed melting points.

Triphenylsilane and *n*-Butyllithium.—To 0.05 mole of triphenylsilane dissolved in 25 ml. of ether was added 0.045 mole of *n*-butyllithium in 70 ml. of ether. Color Test I[13] was negative after one-half hour. After hydrolysis, the hydrolysate was extracted with hot benzene. The benzene layer was separated, dried and the solvent removed by distillation. The residue, a gummy material, was extracted with 95% ethanol and the solid remaining was shown to be tetraphenylsilane (10.7% of the product). From the ethanol was obtained 10 g. (63.5%) of *n*-butyltriphenylsilane melting at 86°. Disproportionation[2] has been reported to occur among silicon compounds, and this phenomenon might account for the formation of tetraphenylsilane.

Anal. Calcd. for $C_{22}H_{19}Si$: Si, 8.86. Found: Si, 8.67, 8.72.

Triphenylsilane and Phenylmagnesium Bromide.—Three experiments in which triphenylsilane was treated with phenylmagnesium bromide were carried out. In the first, 0.023 mole of phenylmagnesium bromide and 0.031 mole of triphenylsilane were refluxed in ether for twenty-four hours. In the second, 0.0154 mole of triphenylsilane in 15 ml. of ether was treated with 0.012 mole of phenylmagnesium bromide in 10 ml. of ether. Most of the ether was removed by distillation and replaced with 20 ml. of dry xylene in which the reactants were refluxed for twenty-four hours. In the third, a mixture of 0.022 mole of phenylmagnesium bromide containing 3 ml. of dioxane and 0.019 mole of triphenylsilane was stirred at room temperature for twenty-four hours. In each case, Color Test I[13] was positive at the end of the reaction time. The quantities of triphenylsilane recovered were 7.4 g. (92.5%), 3.5 g. (88%) and 4.5 g. (90%), respectively.

Triphenyltin Hydride and Phenyllithium.—In the first of two runs of this reaction, 0.0043 mole of triphenyltin hydride was treated with 0.0044 mole of phenyllithium, a precipitate being formed at once. Then 0.0044 mole of benzyl chloride was added to react with any triphenyltinlithium that might have formed. On hydrolysis an ether-insoluble solid separated. This was collected on a filter, washed with five 5-ml. portions of ether and dried over sulfuric acid in a vacuum desiccator. The yield of tetraphenyltin melting at 228–230° (mixed m. p., 228–230°) was 1.7 g. (91%). In the second run, using 0.0117 mole of triphenyltin hydride, 0.0119 mole of phenyllithium and 0.0119 mole of benzyl chloride, a portion of the solid formed was analyzed as described under "Identification of Lithium Hydride." Subsequent to working up the mixture, the yield of tetraphenyltin was 4.5 g. (90%).

Identification of Lithium Hydride.—When triphenylsilane and triphenyltin hydride, respectively, were treated with phenyllithium, a white precipitate immediately formed. In each case the solid was allowed to settle and the ether decanted in a nitrogen atmosphere. The residue was then centrifuged for one and one-half hours and the supernatant ether was decanted. The solid was twice washed with anhydrous ether, centrifuged, and the ether decanted. The residual solvent was removed by heating the solid on a steam-bath *in vacuo*. The combined ether washings completely distilled at 36–38°, indicating the absence of benzene.

A sample of the dried precipitate was hydrolyzed, the solution was titrated for total alkalinity, and the solid residue was recovered. From 1.4300 g. of the solid formed in the reaction between triphenylsilane and phenyllithium was obtained 1.3968 g. of residue, identified as tetraphenylsilane. The total alkali, 0.00415 mole, was in agreement with the loss in weight of the sample (0.0332 g.) when this was calculated as lithium hydride (0.00418 mole). On hydrolysis of 0.2895 g. of the precipitate formed in the reaction between triphenyltin hydride and phenyllithium, 0.2842 g. of solid residue, identified as tetraphenyltin, was recovered. The total alkali (0.00067 mole) again checked with the loss in weight of the sample (0.0053 g.) when this was calculated as lithium hydride (0.00067 mole).

Triphenylsilane with Acridine, and with Lithium *p*-Thiocresoxide.—Twenty-six grams (0.11 mole) of triphenylsilane and 4.8 g. (0.027 mole) of acridine were dissolved in 80 ml. of dry xylene under nitrogen connected to a trap,[15] and the solution refluxed for thirty hours. On cooling, a solid was formed. This was dissolved in acetone and treated with ethanolic hydrogen chloride to precipitate acridine hydrochloride which, in turn, was treated with 10% sodium hydroxide to liberate the base. The base was recrystallized from ethanol, and 4.7 g. (98%) of acridine, melting at 106°, was recovered. No depression occurred when a mixed melting point determination with an authentic specimen was made. From the acetone solution 24.7 g. (95%) of triphenylsilane was obtained.

Lithium *p*-thiocresoxide was prepared from 5 g. (0.04 mole) of *p*-thiocresol in 20 ml. of ether and 0.036 mole of phenyllithium in ether. Color Test I[13] was negative at the end of the addition, and a solid separated. Then was added 7.8 g. (0.03 mole) of triphenylsilane dissolved in 25 ml. of ether. The mixture was refluxed, by external heating, for twenty-four hours with stirring. After working up the mixture, 7.5 g. (95%) of triphenylsilane was recovered. From the aqueous layer, 4.4 g. (88%) of *p*-thiocresol (mixed m. p.) was obtained.

Summary

The reaction between triphenylsilane and some organolithium compounds has been investigated, and it has been shown that the reaction which takes place is

$$(C_6H_5)_3SiH + RLi \longrightarrow (C_6H_5)_3SiR + LiH$$

A similar reaction occurs with triphenyltin hydride. Under corresponding conditions, phenylmagnesium bromide seems to be without effect in this type of reaction with triphenylsilane.

Disproportionation appears to occur in the reaction between triphenylsilane and *n*-butyllithium, inasmuch as some tetraphenylsilane was obtained in addition to the expected *n*-butyltriphenylsilane.

Triphenylsilane did not reduce acridine, nor did it react with lithium *p*-thiocresoxide.

Macromolecular Weights Determined by Direct Particle Counting. I. The Weight of the Bushy Stunt Virus Particle[1]

BY ROBLEY C. WILLIAMS AND ROBERT C. BACKUS

Introduction

The weights of macromolecules and particles of colloidal dimensions can be determined by a variety of methods: diffusion, osmotic pressure, sedimentation velocity, sedimentation equilibrium, X-ray patterns,[2] light scattering,[3] ultramicroscopy[4] and by direct electron microscopy. Each of these methods has advantages and limitations, and each is particularly applicable only over a certain range of sizes. In the application of any of the methods a determination must be made, either directly or indirectly, of one of two sets of quantities: (1) the volumes and densities of the macromolecular particles, or (2) the number of particles in a known volume of solution and the dry weight of the particles in an aliquot of that volume.

In a general way one would expect that the most reliable method would be the one which most directly determines the quantities involved in the definition of molecular weight: the mass in grams per mole of one molecular species. Any notably indirect method is subject to the assumptions involved in the derivation of the working formulas, and to the reliability of the chain of relations existing between the directly observable quantities and the weight of a gram-molecule. Thus, for example, in the sedimentation equilibrium method, what is directly measured is the space gradient of the index of refraction, or the opacity of the solution in the centrifuge cell. But in order to compute the molecular weight of the solute one must know the variation of the refractive index, or opacity, with concentration of solute, the partial specific volume of the solute while undergoing sedimentation, the density of the solution, the angular velocity of the centrifuge, and, additionally, one must sediment for a sufficient length of time to know that he has achieved equilibrium. Further, one must have reason to believe that the solute molecules do not interact, and that no electrical field gradients are set up by the concentration gradient, a condition best satisfied by the use of a dilute solution, but contrary to the *observational* requirement that a fairly concentrated solution be used.

On the other hand, the limitations on the two direct types of determinations are severe. Accurate measurement of particle size by electron microscopy is limited to particles larger than about $M = 10 \times 10^6$. The possible shrinkage effects of severe desiccation in the microscope make for uncertainty, and, of course, the density of the particle must be known. Determinations of M by ultramicroscopy are severely limited by the fact that, as seen in scattered light, all particles look approximately alike. Hence, one must have an external check on the homogeneity of the specimen. Further, the counting of particles in a suspension is difficult and uncertain, and is restricted to those particles whose size and index of refraction are great enough to allow them to be individually counted. The last restriction has effectively prevented the use of ultramicroscopy in accurately determining the weights of protein macromolecules.

The Method of Direct Particle Counting by Electron Microscopy

A direct method of determining weights of macromolecules has been developed which preserves the theoretical simplicity of ultramicroscopy and removes many of its limitations. The number of macromolecules or particles in a known volume of suspension is counted in the electron microscope and the dry weight of the particles in an aliquot of the known volume is measured. The lower limit of size of molecules is that which is barely countable (*ca.* $M = 70{,}000$), while the electron microscope itself furnishes a fairly reliable estimate of the homogeneity of the particles. The fundamental sources of error are four only: the evaluation of the volume of solution whose particles are being counted, the counts themselves, the degree of homogeneity of the material and the determination of the dry weights. These sources of error will be discussed in detail later. The use of the method of direct particle counts is illustrated in this contribution by a determination of the particle weight of the bushy stunt virus. This virus is chosen because it can be readily grown and highly purified; its particles are exquisitely uniform in size, are easily countable in electron micrographs, and the weight of the virus particles has been previously measured in several laboratories. This particle will hereafter be referred to as the BSV particle.

Experimental

The BSV Preparations.—The BSV particles[5] were obtained from *Datura metaloides* that had been infected with the bushy stunt virus, and were purified by differential centrifugation in a manner similar to that described by

(1) This research has been supported in large part by a grant from the American Cancer Society upon recommendation of the Committee on Growth of the National Research Council.

(2) These five methods are reviewed in Cohn and Edsall, "Proteins, Amino Acids and Peptides," Reinhold Publ. Corp., New York, N. Y., 1943.

(5) We are indebted to Mr. Russell Steere for furnishing us with ample quantities of plant juice containing the virus particles.

Stanley.[6] The leaves were frozen for several days, chopped while frozen and the cold juice pressed out through cheese cloth. The juice was then clarified at 4500 r.p.m. in an angle-head centrifuge and the clarified liquid filtered through a thin layer of Celite. The filtered juice was allowed to stand at 4° overnight and decanted into the ultracentrifuge tubes for an acceleration to 50,000 g., followed by immediate deceleration. The clarified juice was then spun at 50,000 g. for seventy-five minutes in a 10° Grebmeier rotor and the supernatant liquid discarded. The pellet was resuspended in fresh double distilled water and clarified at 4500 r.p.m. A sufficient aliquot of the resuspended, clarified pellet so obtained, designated P_1, was set aside for analysis.

The remainder of P_1 was carried through another high-speed sedimentation, resuspension and low-speed clarification cycle. The ultracentrifuge supernatant P_{2s}, as well as the second reworked pellet P_2, was now saved. The cycle was repeated until samples of P_1, P_2, P_3, P_4, as well as the corresponding supernatant suspensions, P_{2s}, P_{3s}, P_{4s} were obtained. Subsequent to the supernatant plant juice first discarded only undissolved material was discarded, and all resuspension volumes were precisely determined. The cycling was completed in seventy-two hours, with the temperature of the suspensions kept near 4° in order to minimize bacterial contamination.

Counting the BSV Particles.—The number of BSV particles per ml. of the seven suspensions obtained as above can be counted in the electron microscope if all of them in a known volume of diluted suspension can be surely observed. It has been found that an adaptation of a spraying technique is suitable for this purpose. (The details of the spraying method employed and an estimate of its reliability will be published elsewhere.[6a]) The BSV-particle suspension was diluted to an appropriate concentration and quantitatively mixed[7] with an aqueous suspension of Dow Latex polystyrene particles[8] *containing a known number of latex particles per ml.* The mixed suspension was then sprayed directly upon collodion-coated microscope screens to form small, approximately circular patterns containing both the latex and the BSV particles. The patterns varied in diameter from about 5 to 30μ and the dilutions were so adjusted that the average pattern contained about 50 latex particles and 100 BSV particles. The numbers of both the latex and BSV particles were counted, thus establishing the number of BSV particles per ml. The droplet patterns were shadow-cast and photographed at a magnification of about 4000×. Enough pictures were obtained to provide about 1000 latex particles for comparison with the number of BSV particles in each suspension.

Calibration of the Latex Particles.—There are several possible ways of determining the number of latex particles per ml., but only one way appeared to be immediately available to us. This consisted of the determination of (a) the volume average of the latex spheres, (b) the density of dry latex and (c) the dry weight of the latex particles in a known volume of a suspension to be used as the standard. The first two measurements yield the weight average of the particles, and this combined with the dry weight gives the number of latex spheres per ml. in the standard suspension.

The method of determining the average diameter of the latex particles has been reported.[8] From the value of the average diameter and an auxiliary curve of size dispersion (see below) the average volume of the particles was computed. The density was measured by immersing chips of thoroughly dried material in aqueous copper sulfate solutions of known densities.

The Dry Weight of the BSV Suspensions.—Small amounts (approx. 10 mg.) of the resuspended and clarified pellets of BSV were placed in weighing bottles and dried to constant weight over P_2O_5 *in vacuo*. The usual precautions were taken to avoid absorption of moisture while weighing. The dried material was further treated to six hours at 95° in P_2O_5-dried air in a vacuum-type desiccator. The desiccator was then evacuated to an air pressure of 100 μ while still hot, and allowed to cool while evacuated for thirty hours. The dry weights were then redetermined.

Tests for Homogeneity.—Inasmuch as the total weight of the dried material containing the BSV particles is measured, the effect of any non-volatile impurity, not counted as BSV particles, will be to increase the apparent particle weight. A search for impurities of this nature was made in a direct way (microscopically) and in an indirect way (spectrophotometrically): (1) It was found that the electron micrographs could be used as sensitive indicators of impurities. Spray droplets of fairly concentrated BSV particle suspensions, without the addition of latex, were photographed and carefully examined for what would appear to be material other than the BSV particles. The average micrograph of a droplet contained about 2000 BSV particles and all of any existing non-volatile impurity. Bacterial contamination was quantitatively assessed by examining several hundred droplet patterns. Areas of the microscope screens sufficiently large to contain an estimated 5 million BSV particles were scrutinized directly for bacteria as their images were moved across the fluorescent screen of the microscope. (2) The optical density of the BSV suspensions was measured through wave length 2600 Å., the peak of the absorption band of nucleic acid. Suspensions were diluted to contain approximately equal numbers of BSV particles per ml., and the ultraviolet absorption calculated in terms of BSV particles/ml. and also in mg. dry weight/ml. This measurement, like all others, does not give an absolute measure of purity, but rather an indication of relative purity.

Results

The Standard Polystyrene Latex Suspensions.—The average diameter of the polystyrene particles was taken[8] to be 2590 ± 25 Å. Recalculation with the aid of the distribution curve shown in Fig. 1, results in a diameter of 2600 Å. for the particle of average volume. The dry density of the latex was found to be 1.052 ± 0.001 g./cc., and the dry weight of 4.00 ml. of the standard sus-

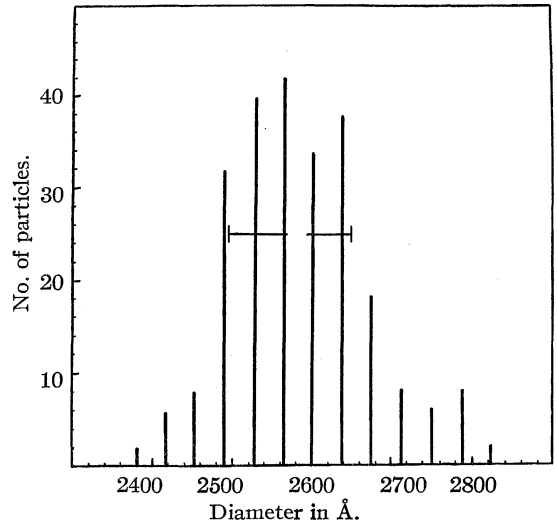

Fig. 1.—Dispersion curve of the diameters of 225 particles of Dow polystyrene latex. Horizontal line shows that 70% of the particles fall within a diameter range of ±3%.

TABLE I

DATA FOR THE DETERMINATION OF THE WEIGHT OF THE BSV PARTICLE BY COUNTS

Pellet	Total no. of PSL[a] counted	Ratio[b] of BSV/PSL	Dil. of BSV as sprayed[c]	No. of BSV/ml. in spray ($\times 10^{-10}$)	No. of BSV/ml. as weighed ($\times 10^{-14}$)	Dry wt. of BSV susp. (mg./ml.[d])	Wt. of one BSV particle (gm. $\times 10^{17}$)	(mol. wt. units $\times 10^{-6}$)
P_1	970	1.74	8000	7.76	6.21	10.8	1.74	10.4
P_2	1032	1.56	6000	6.96	4.18	7.30	1.74	10.4
P_3	1175	1.66	8000	7.41	5.93	9.00	1.52	9.2
P_4	1095	2.72	2000	12.1	2.42	3.90	1.61	9.6

[a] PSL = polystyrene latex particles. [b] Ratio of numbers of BSV particles to PSL particles as sprayed. [c] Dilution compared to the suspension as weighed. [d] Total weights were from 7.40 to 15.2 mg. No measurable difference between heated dried and unheated dried samples.

pension was found to be 69.2 ± 0.05 mg. The standard suspension was diluted 40-fold for spraying, and the dilution for each set of BSV particle counts was separately pipetted. Simple calculations show that the number of latex particles per ml. as sprayed was 4.46×10^{10}.

The Counts, Weights, and Particle Weights of BSV Particles.—In Table I are shown the results of the counts, dry weights, and particle weights obtained from the preparations P_1, P_2, P_3 and P_4.

Ultraviolet Absorption.—The data and results of the measurement of optical density at 2600 Å. are shown in Table II.

TABLE II

ULTRAVIOLET ABSORPTION OF BSV PREPARATIONS

Pellet or supn.	No. of BSV/ml.[a] ($\times 10^{-13}$)	Opt. dens.[b] (D) at 2600 Å.	(D) per BSV/ml. ($\times 10^{-13}$)	Dry wt.,[c] (mg./ml.)	(D) for a 0.1% susp.
P_1	1.03	0.87	0.85	0.018	4.8

TABLE III

INTERNAL CHECK ON BSV PARTICLE COUNTS AND DILUTIONS

Pell. or supn. fluid	Vol. in ml. which resus.[a]	Vol. in ml. in subseq. pelleting	No. of BSV/ml. ($\times 10^{-14}$)	No. of BSV in volumes indic. in: Col. 2 ($\times 10^{-15}$)	No. of BSV in volumes indic. in: Col. 3 ($\times 10^{-15}$)	Appar. loss of BSV[b] in: (%)	Appar. loss of BSV[b] in: (mg.)
P_1		8.8	6.21		5.47	9	7.8
P_{2s}	14.4		0.55	0.79			
P_2	10.0	8.0	4.18	4.18	3.34	5	1.7
P_{3s}	14.4		0.52	0.75			
P_3	4.10	2.5	5.87	2.41	1.47	5	1.4
P_{4s}	14.4		0.29	0.42			
P_4	4.00		2.42	0.97			

[a] Volume to which pellet was resuspended; supernatant volume left unchanged. [b] Difference in % between numbers of BSV particles in P_n(col. 6) and [P_{n+1} + $P_{(n+1)s}$] (col. 5).

Internal Check on BSV Particle Counts and Dilution Factors.—The data provide a convenient internal check on the precision of the counts and of the dilutions. Inasmuch as the solid material in each resuspended and clarified pellet, plus its supernatant, derives from the solid material in the preceding resuspended and clarified pellet (less the known amount removed for analysis), the accuracy of the counting and dilution can be checked by simple subtraction. Thus, for example, P_1 was resuspended in 10 ml. of distilled water and 1.2 ml. removed for assay. The remaining 8.8 ml. were used in the formation of P_2 and P_{2s}. The total number of BSV particles found in the resuspended and clarified P_2 plus P_{2s} should equal that found in the 8.8 ml. of P_1. Table III gives the data and the results of the internal checks.

Discussion

Precision of the Particle Weight Determination.—The evaluation of the number of latex particles per unit volume depends upon two kinds of measurements: the average volume of the latex spheres, and the density of the dried latex. Calculation of average volume is based upon a determination of average diameter and shape discussed elsewhere.[8] Other determinations of average diameter have been privately communicated to us from six different laboratories, and the extremes of average diameter have been 2560 ± 30 and 2610 ± 30 Å. Since the spread in seven independent measurements, by wholly independent methods, is about 2%, it is felt that our adopted value of 2590 Å. is probably reliable to 1%. The average volume can be calculated only after a dispersion curve of relative diameters is obtained. Figure 1 shows a distribution of diameters obtained for 225 particles. When the latex material is handled properly in the microscope, so as to avoid undue heating by the electron beam, its uniformity in size is quite satisfactory. Some small error of finite sampling is introduced, however, by the failure of the latices to be of perfectly uniform diameter. Since small errors in diameter are multiplied by a factor of three when translated to error in volume, a generous estimate of the limit of uncertainty of the volume-average of the latex spheres might accordingly be estimated at 5%.

The density of the dried latex can easily be

measured to an accuracy far greater than 1%. The uncertainty here is whether or not the density of an individual particle is the same as that obtained for the dried chips. The latex dilutions were made with a precision far exceeding 1% and the weight of the dried sample was enough (69.2 mg.) to assure a high precision in weighing. It is concluded that the uncertainty in the figure for the number of latex particles per ml. is about the same as the major uncertainty indicated above (5%) in the volume of a single particle. This estimated 5% uncertainty in the average mass of the latex particles is troublesome in that it enters systematically into all of our determinations of particle weights. However, other methods of measuring either the mass of the particles or the number per ml. are available (by sedimentation velocities in media of different densities, and by light-scattering) and any subsequent refinement in these determinations can be applied directly as a correction to the calculated values of weights determined by this method.

Drying and Weighing the Virus-Containing Material.—Although the BSV suspensions have been dried and weighed in an accepted manner there is still the likelihood that some water has been weighed along with the protein. The error in the weight determination alone has been estimated by repeated weighings, and the standard deviation is about 0.5%. But the unanswerable question as to whether the results represent the anhydrous macromolecular weight of the virus is precisely the same question that plagues any determination of molecular weight of proteins, since *all* methods involve at some stage either a determination of density or of dry weight. It can only be said that our results represent the weight of the BSV particle under conditions of drying involving heating to 95° and prolonged exposure *in vacuo* to phosphorus pentoxide.

The Tests for Purity and Homogeneity of the BSV-Containing Material.—As Pirie[9] and others have adequately discussed, there is no single criterion of purity of a protein preparation, nor does the sum of all criteria offer any proof of purity. Indeed, the concept of purity has meaning only as related to the experimental methods used for detecting impurities.

Electron microscopy coupled with our technique of specimen preparation has been relied upon heavily for indications of impurity in our BSV preparations. The electron microscope has formerly been little used with any confidence for this purpose, owing to the difficulty of defining fields representative of the original suspension, but by spraying droplets containing the purified BSV particles, one obtains a representative field in each drop pattern. Droplets of suspensions of all seven pellets and supernatants have been sprayed in sufficiently concentrated form to result in about 2000 BSV particles per drop pattern, and micrographs of these have been carefully examined. In the case of P_1 and to a less extent in P_2, P_{2s} and P_{4s}, there was some very small-sized material present. Pellets P_3 and P_4 had no detectable inhomogeneous material, although an amount as great as 1% of the total would have been readily observable. (A high-quality, uranium-shadowed micrograph will show the presence of objects as small as 30 Å. in mean diameter, or 1/1000 the volume of a BSV particle.) There are, however, three kinds of impurities essentially undetectable by electron microscopy alone: particles too small to be detectable and which do not form observable aggregates upon drying, material of about the same size and shape as the BSV particles, and material of great size but rarely present. Although there is no way to detect the presence of the first impurity by electron microscopy, it is believed that the great dilutions involved in four cycles of centrifugation would have reduced the concentration of the first impurity to a negligible amount. The second type of impurity will cause little error in our determination of particle weight since it will be counted and weighed along with the BSV particles. The third type, typically to be found as bacteria, could cause serious error, since a medium-sized bacterium is equal in weight to about 20,000 BSV particles. No bacterial material, nor any material of comparable size, was found in a search embracing fields containing about 5 million BSV particles, and the conclusion is that the error in weight due to contamination by particles of relatively great size is less than 1%.

The evidence from the light absorption at 2600 Å., combined with the molecular weight determinations, is indicative of relative purity if we assume that non-BSV proteins contain little, if any, nucleic acid. As Tables I and II show, the nucleic acid absorption per BSV particle is approximately constant in all pelleted material, and even in all supernatant liquids except the first one, P_{2s}. The absorption per unit weight concentration is found to increase significantly for the most completely washed pellets, P_3 and P_4, while the calculated particle weights are smallest for these pellets. This relation is best explained by assuming that in the first two pellets there was some non-BSV material present which added to the dry weights but not to the ultraviolet absorption.

It is to be noted that analytical centrifugation and electrophoresis have not been used as criteria of purity of our preparations. The reason for this deliberate omission is that both of these methods are sensitive only to rather special kinds of impurities: those which are present in sufficient concentration and are sufficiently homogeneous (either with respect to sedimentation velocity or in net ampholytic charge-density) to create detectable skewness in a concentration gradient. Gross amounts of impurities of miscellaneous sedimentation and/or electrophoretic velocities can be in the solutions and remain undetectable by these methods.

(9) Pirie, *Biol. Rev., Cambridge Phil. Soc.*, **15**, 377 (1940).

Precision of the Counts.—The error of counting can be statistically analyzed for the size of the most probable error. Computations of standard deviation have been made for all counts and have fallen between 2 and 4%. From statistical theory it is known that the standard deviation in ascertaining the number ratio of 1000 pairs of particles, if mixing is perfect, should be about $1/\sqrt{1000}$, or 3% (*i. e.*, if the counts show this standard deviation, the mixing would be defined as perfect). There is the possibility of a systematic error in the distribution of particles in the drop patterns; some, for example, may become dislodged from the substrate film before shadowing. This possibility has been checked by running a dilution curve of BSV particles *vs.* latex particles over a 5 × 2-fold series of dilutions. These results will be published in detail later, but they can be summarized briefly by saying that the dilution factors calculated from pipetting are checked to within 4% by the counts.

The internal consistency of dilutions and counts, Table III, is a further check against a systematic error. Some loss is to be expected in going from one pellet to the next pellet and supernatant. Some of the loss will be in the clarification sediment, roughly estimated to be 1 mg. in $P_1 \rightarrow P_2 + P_{2s}$, and to be negligible for the later pellets. In resuspending each pellet, however, care was taken not to include any material clearly outside the pellet and clinging to the side of the ultracentrifuge tube. In the $P_1 \rightarrow P_2 + P_{2s}$ cycle an observable quantity was found here and might amount to 2 or 3 mg. Allowance for these obvious losses reduces the per cent. loss in the $P_1 \rightarrow P_2 + P_{2s}$ operation to about 6%. It is felt that since this over-all check on counts and dilutions does not indicate a discrepancy greater than 6% in any of the three cycles, only the statistically predictable small random errors are present. This conclusion is particularly evident when it is noted from the last two paragraphs that both ratios and sums are internally consistent.

Summary of Estimated Errors and Results.—The errors detailed above, if added unfavorably, would result in an upper limit of error of an individual determination of particle weight of about 10%. The question now arises of how best to average the values of the particle weights obtained from the four pellets. An arithmetic mean would decrease the probability of an accidental error strongly affecting the result, but would neglect the evidences for increased purity in the last two pellets. In view of the strength of this evidence, *the most probable value of the dry weight of the bushy stunt virus particle obtained by the method of direct particle counts is* $9.4 \pm 0.7 \times 10^6$ *in molecular weight units.*

Conclusions Regarding the Method.—The method of measuring macromolecular weights by direct counting has the primary advantage of simplicity and directness. It serves as a proper check on molecular weights obtained by centrifugation owing to its freedom from the complications and assumptions involved in sedimentation studies. Its largest uncertainty at present, at least in the case of the highly-purifiable BSV particles, is the calibration of the concentration of the latex particles. The counts of the particles can be made to within any predetermined accuracy with sufficient patience and, indeed, if all the counts discussed here had been made on a suspension of only one pellet, the standard deviation of counting would have been reduced to about 1%. The drying, weighing, and assessing of impurities are measurements that are common to all determinations of large molecular weights, although the methods of measurement vary. In particular, sedimentation velocity provides a sensitive and convenient way of detecting and measuring one component of a paucidisperse system. Even here, however, polydispersity or undetected impurities will cause trouble, since they affect the precision of the auxiliary diffusion constant.

A particularly inviting aspect of the method of direct particle counts is that the suspensions can be sprayed and counted at astonishingly low concentrations. All other methods of measuring macromolecular weights become observationally more precise as the concentration of solute is increased, but since side effects, such as aggregation, always enter at high concentrations, it is common practice to extrapolate experimental results to infinite dilution. With the particle count method the solute is best sprayed at concentrations less than 1 mg. per liter or 0.0001%, compared with the usual sedimentation concentration of 0.4%. At a dilution of 1 mg. per liter, each BSV particle is allotted an average solvent volume of 10 μ^3, or 100,000 times the volume of the particle. The droplets lose water by evaporation in their flight from the spray gun to the microscope screen, but their particle content is determined by the concentration in the droplet at the moment it becomes a discrete entity in the spray.

There are three limitations on the method: (1) the ubiquitous problem of purity, already discussed; (2) the lower limit of size of particles which are countable in the electron microscope, estimated at present to be at about $M = 70{,}000$ and (3) the necessity of suspending the particles in a medium which is wholly volatile.

Comparison with Other Determinations of the Weight of the Bushy Stunt Virus Particle.—A review of the determinations of the weight of the BSV particle, up to 1943, has been given by Lauffer,[10] and values obtained by sedimentation equilibrium, sedimentation velocity and diffusion and by X-ray patterns are critically examined. More recently Oster[11] has given a preliminary value of the molecular weight from light-scattering measurements. The four different kinds of deter-

(10) In "Colloid Chemistry," Vol. V, Reinhold Publ. Corp., New York, N. Y., 1944, pp. 801–805.

(11) Oster, *Science*, **103**, 306 (1946).

minations have yielded four rather divergent results for the anhydrous particle weight.

Sedimentation equilibrium	7.6×10^6
Sedimentation velocity and diffusion	10.6×10^6
X-Ray analysis	13.0×10^6
Light scattering	9.0×10^6

It is seen that the method of direct particle counts provides a mean value (9.4×10^6) not outside the limits of previous determinations.

Summary

1. A method of determining the particle weights of macromolecules suspended in a volatile medium is described. The method is called that of "direct particle counts," and consists essentially of counting, on electron micrographs, the numbers of macromolecules per unit volume of solution, and of obtaining the dry weight of an aliquot of the unit volume. Representative specimen fields are obtained by a spray method.

2. Dow latex particles of polystyrene are used as reference particles to determine the volumes of the spray droplets, which also contain the macromolecules.

3. The dry weight of centrifugally purified particles of the bushy stunt virus has been determined, and is found to be $9.4 \pm 0.7 \times 10^6$ in molecular weight units.

4. Discussions of sources of error are given, and it is concluded that the primary source of error is in the determination of the weight concentration of the latex particles in the spray droplets.

5. Evidence bearing on the purity of the bushy stunt virus preparations is discussed, and it is concluded that the particle weights of the material in the two most highly purified pellets are the most reliable.

Configurational Correlation of (*levo*)-Glyceraldehyde with (*dextro*)-Lactic Acid by a New Chemical Method[1]

BY M. L. WOLFROM, R. U. LEMIEUX,[2] S. M. OLIN[2] AND D. I. WEISBLAT

Freudenberg[3] converted (*dextro*)-glyceric acid to (*dextro*)-lactic acid by methods which did not sever any of the bonds directly attached to the rotational center. (*levo*)-Glyceric acid was obtained by the oxidation of D-(*dextro*)-glyceraldehyde by Wohl and Schellenberg.[4] These data effect a configurational correlation between D-(*dextro*)-glyceraldehyde and (*levo*)-lactic acid and establish the designation D-(*levo*)-lactic acid. We report herein a confirmation of this correlation by a chemical method similar in principle to that employed in correlating L-(*levo*)-glyceraldehyde with L-(*dextro*)-alanine.[5]

Tetraacetyl-2-methyl-D-glucose diethyl thioacetal (I) was reductively desulfurized to yield tetraacetyl-2-methyl-1-desoxy-D-glucitol (II). Deacetylation of II produced 2-methyl-1-desoxy-D-glucitol (III) which on periodate cleavage with subsequent oxidation yielded an O-methyllactic acid (IV) that was isolated as its chromatographically purified *p*-phenylphenacyl ester[6] of m. p. 74–75° and $[\alpha]^{23}D$ −16.5° (*c* 2, benzene). This derivative was found to be identical with that obtained on the methylation of the *p*-phenylphenacyl ester of L-(*dextro*)-lactic acid (V), thus effecting a configurational correlation between L-glyceraldehyde and L-(*dextro*)-lactic acid. Carbon two in I is originally D_g, wherein the subscript[7] denotes the reference standard glyceraldehyde, but this carbon becomes L_g in the product of periodate cleavage in which the aldehyde group of D-glucose has been reduced to the hydrocarbon stage. These operations effectively produce an interchange of groups on this rotatory center with a consequent reversal of configuration.

Incidental to the above transformations, we describe herein the crystalline tetraacetyl-2-methyl *aldehydo*-D-glucose obtained by demercaptalation of I according to general technics previously described.[8,9]

Experimental[10]

Tetraacetyl-2-methyl-D-glucose Diethyl Thioacetal (I).[11]—2-Methyl-D-glucose diethyl thioacetal[12] (20 g.) was acetylated by overnight treatment at room temperature with acetic anydride (150 ml.) and pyridine (75 ml.). Crystalline material of fair purity was obtained on pouring the reaction mixture into 3 liters of ice and water; yield 27 g. Pure material was obtained on further crystalliza-

tion from methanol–water; yield 25 g., m. p. 45–46°, $[\alpha]^{24}D$ +40° (*c* 3, abs. $CHCl_3$), diamond-shaped plates. The substance was readily soluble in alcohol, ether and chloroform and was insoluble in water and petroleum ether.

Anal. Calcd. for $C_{11}H_{20}O_5S_2(CH_3CO)_4$: C, 48.70; H, 6.88; CH_3CO, 8.54 ml. 0.1 *N* NaOH per 100 mg. Found: C, 48.58; H, 6.70; CH_3CO, 8.93 ml.

Tetraacetyl-2-methyl-*aldehydo*-D-glucose.[11]—To 12.6 g. of tetraacetyl-2-methyl-D-glucose diethyl thioacetal dissolved in 45 ml. of acetone was added 25 g. of finely powdered cadmium carbonate and 5 ml. of water. To this was added with vigorous mechanical stirring, 25 g. of mercuric chloride dissolved in 40 ml. of acetone. Stirring was maintained for twenty hours at room temperature and then the reaction mixture was heated rapidly to boiling and gently refluxed for thirty minutes. The mixture was filtered into a flask containing cadmium carbonate (10 g.) and the residue was washed with acetone. The filtrate and washings were concentrated to dryness at 35° under reduced pressure in the presence of cadmium carbonate. The residue was extracted with three 100-ml. portions of warm chloroform (U. S. P.) and the extract was washed successively with water, 10% aqueous potassium iodide, and water until halide-free. The sirup obtained on solvent removal from the dried (decolorizing carbon) extract was crystallized from 25 ml. of ether; yield 6.3 g. (70%), m. p. 87–89°. Pure material was obtained on further crystallization from acetone–ether–petroleum ether (2:1:3); m. p. 89–90°, $[\alpha]^{24}D$ +24° (*c* 3, abs. $CHCl_3$), $[\alpha]^{25}D$ +7.5° (extrapolated) → +31° (1.5 hr., *c* 3, methanol). The substance crystallized as elongated prisms that reduced Fehling solution. It was readily soluble in ether, alcohol, chloroform, acetone and hot water; it was insoluble in petroleum ether and cold water.

Anal. Calcd. for $C_7H_{10}O_6(CH_3CO)_4$: C, 49.72; H, 6.12; CH_3CO, 11.04 ml. 0.1 *N* NaOH per 100 mg. Found: C, 49.78; H, 6.03; CH_3CO, 11.08 ml.

Tetraacetyl-2-methyl-1-desoxy-D-glucitol (II).—Raney nickel (25 g.) and tetraacetyl-2-methyl-D-glucose diethyl thioacetal (5 g.) was refluxed in 70% aqueous ethanol (110 ml.). After five hours no ethanethiol odor could be detected on acidification of the warm alcoholic solution and the reaction was assumed to be complete. The catalyst was removed by centrifugation and washed with 95% ethanol. The centrifugate and washings were combined, treated with activated carbon and filtered through a bed of Celite.[13] The sirup obtained on solvent removal under reduced pressure was crystallized from ethanol–water at 15°; yield 3.7 g. (92%), m. p. 62–65°, $[\alpha]^{23}D$ +39° (*c* 2, $CHCl_3$). Further crystallization enhanced the melting point to 67–68°.

Anal. Calcd. for $C_{15}H_{24}O_9$: C, 51.72; H, 6.93. Found: C, 51.92; H, 6.99.

2-Methyl-1-desoxy-D-glucitol (III).—Tetraacetyl-2-methyl-1-desoxy-D-glucitol (2.85 g.) was dissolved in anhydrous methanol (125 ml.) and a rapid stream of anhydrous ammonia was passed into the solution for fifteen minutes at 0°. The mixture was maintained at 25° for two hours and evaporated to dryness at reduced pressure. The crystalline residue was dissolved in warm methanol and crystallization was effected at 15°; yield 1.33 g. (2 crops, 92%), m. p. 133–134°, $[\alpha]^{23}D$ +21.5° (*c* 3, water). Further crystallization from methanol did not alter these constants.

Anal. Calcd. for $C_7H_{16}O_5$: C, 46.65; H, 8.95. Found: C, 46.70; H, 9.23.

***p*-Phenylphenacyl Ester of O-Methyl-L-lactic Acid (IV) from 2-Methyl-1-desoxy-D-glucitol (III).**—A solution of 1.18 g. of 2-methyl-1-desoxy-D-glucitol in 20 ml. of water was treated at 25° for sixty minutes with 25 ml. of *N* periodic acid. The solution was then made just alkaline to phenolphthalein with aqueous barium hydroxide. The filtered solution was kept overnight with strontium carbonate (10 g.) and bromine (5 g., shaken until dissolved). The filtered solution was then acidified with 2.5 *N* hydrochloric acid (2.5 ml.) and extracted with ether for seventy-two hours in a continuous extractor containing barium carbonate and 25 ml. of water in its distillation flask. The ether was then distilled from the suspension, which was then heated on a boiling water-bath for two hours. Barium carbonate was removed by filtration and the aqueous filtrate was concentrated to dryness under reduced pressure. The residual barium salt was dissolved in 4 ml. of water, acidified with 0.5 ml. of 6 *N* hydrochloric acid and refluxed for sixty minutes with 12 ml. of a solution of 0.6 g. of *p*-phenylphenacyl bromide in 12 ml. of 95% ethanol. Crystalline material separated on pouring the cooled solution into 20 ml. of water; yield 0.8 g.

An amount of 0.5 g. of the above material was dissolved in 25 ml. of benzene and added at the top of a 200 × 55 mm. (diam.) column of precipitated silicic acid[14] (160 g.) and developed with 1 liter of 2:2 benzene:petroleum ether (b. p. 85–100°, volume ratio). Two zones, at 16–17 mm. and 20–21 mm. from the top, were detected on the extruded column by ultraviolet light. Crystalline material was obtained from the acetone eluate of the sectioned top zone; yield 0.4 g., m. p. 72–74°, $[\alpha]^{22}D$ −16.0° (*c* 2, benzene). Pure material was obtained on recrystallization from ethanol–water; m. p. 74–75° unchanged on admixture with the product obtained from O-methyl-L-lactic acid as described below; $[\alpha]^{23}D$ −16.5° (*c* 2, benzene).

p-Phenylphenacyl O-Methyl-L-lactate from L-(*dextro*)-Lactic Acid (V).—An authentic sample of L-(*dextro*)-lactic acid[15] was converted to the *p*-phenylphenacyl ester (m. p. 139–140°[16]) and 0.76 g. of this ester, 7.5 g. of silver oxide and 20 ml. of methyl iodide were shaken mechanically at room temperature for four hours. The silver salts were removed by filtration and washed with warm methanol. The filtrate and washings were concentrated to a crystalline residue under reduced pressure; yield 0.70 g., m. p. 70–73°, $[\alpha]^{22}D$ −15.5° (*c* 3, benzene). Recrystallization from ethanol–water yielded pure material with constants unaltered by further crystallization or by chromatographic purification effected as described above; yield 0.54 g., m. p. 74–75°, $[\alpha]^{22}D$ −16.2° (*c* 3, benzene).

(15) A product of high purity made by the fermentation of carbohydrate material and for which we are indebted to the Clinton Industries, Inc., Clinton, Iowa.

(16) N. L. Drake and J. Bronitsky, THIS JOURNAL, **52**, 3715 (1930), record 145° as the melting point of the *p*-phenylphenacyl ester of lactic acid (presumably D,L).

Anal. Calcd. for $C_{18}H_{18}O_4$: C, 72.47; H, 6.08. Found: C, 72.49; H, 6.06.

Summary

1. Reductive desulfurization of tetraacetyl-2-methyl-D-glucose diethyl thioacetal (I) yielded tetraacetyl-2-methyl-1-desoxy-D-glucitol (II) which on deacetylation (III) and periodate cleavage with subsequent oxidation produced an O-methyllactic acid (IV) whose *p*-phenylphenacyl ester was identical with that obtained by esterification and methylation of L-(*dextro*)-lactic acid (V). This effects a direct chemical correlation of L-(*levo*)-glyceraldehyde with L-(*dextro*)-lactic acid.

2. Tetraacetyl-2-methyl-*aldehydo*-D-glucose is described.

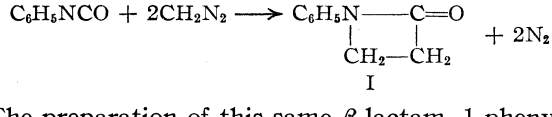
The Reaction of Diazomethane with Isocyanates and Isothiocyanates

BY JOHN C. SHEEHAN AND PATRICK T. IZZO[1]

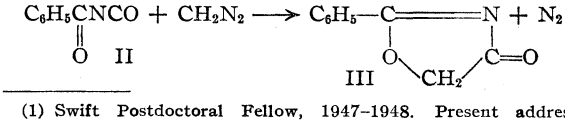
In a recent communication from this Laboratory the action of diazomethane on phenyl isocyanate was reported.[2] In a reaction analogous to the formation of cyclobutanone from ketene and diazomethane, the β-lactam of N-phenyl-β-alanine is formed.



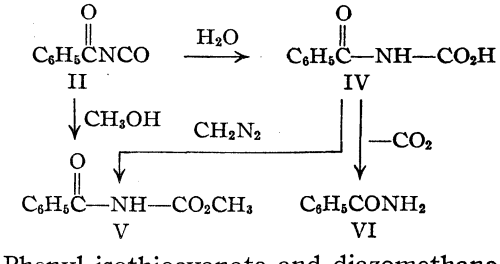
The preparation of this same β-lactam, 1-phenyl-2-azetidinone (I), by cyclization of an ester of N-phenyl-β-alanine with a Grignard reagent has since been described.[3] Phenyl isocyanate and diazomethane were reported by v. Pechmann[4] to yield an oily product which was not further characterized.

With *p*-bromophenyl isocyanate a β-lactam also is obtained. Under similar conditions no β-lactam was isolated from the treatment with diazomethane of α-naphthyl, *p*-nitrophenyl, benzyl and benzoyl isocyanates, or methyl and phenyl isothiocyanates.

Benzoyl isocyanate (II) reacted very rapidly at ice-bath temperature to give, in 68–70% yield, 2-phenyl-4-oxazolone (III). Unlike the formation of the β-lactam in the case of phenyl isocyanate, benzoyl isocyanate added only one methylene group, bridging its two reactive carbonyl groups.



The structure of 2-phenyl-4-oxazolone was proved by cleavage with boiling water. Hydrolysis took place at the carbon–nitrogen double bond, forming benzoylglycolic acid amide, which was identified by comparison with an authentic sample.[5] About 10–15% of the total reaction products was found to be N-benzoyl methyl carbamate (V), which was also obtained by interaction of methanol and benzoyl isocyanate. Absorption of a small amount of moisture during the addition of diazomethane to benzoyl isocyanate would explain the formation of this compound. A portion of the unstable N-benzoylcarbamic acid (IV) formed by the addition of water to the isocyanate presumably was methylated by diazomethane, and thus its decarboxylation to benzamide (VI) was prevented. However, some decomposition to VI apparently took place as benzamide was found in small amounts among the reaction products.



Phenyl isothiocyanate and diazomethane have been reported by v. Pechmann[4] to form an equimolar adduct, m. p. 172.5°, in unspecified yield. We obtained the addition product in 60% yield,

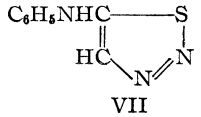
m. p. 179–180°, with decomposition. The addition was first assumed by v. Pechmann to have taken place in either of two ways to the nitrogen–carbon double bond of phenyl isothiocyanate. Failure to convert the supposed thiocarbonyl group to a carbonyl by treatment with mercuric oxide (confirmed by us) later led v. Pechmann[6] to formulate the reaction as proceeding by addition of diazomethane across the thiocarbonyl group of phenyl isothiocyanate to produce a sulfur-containing ring.

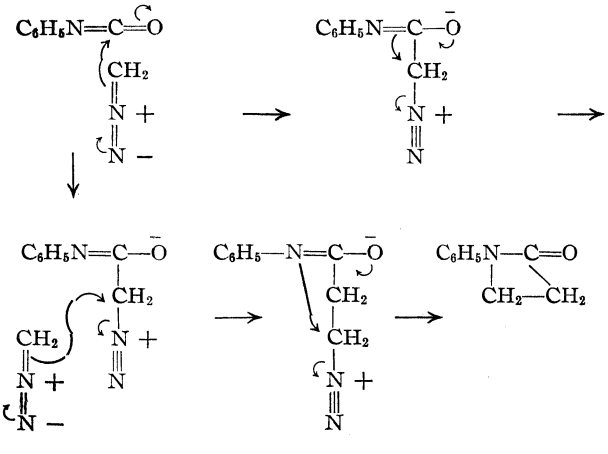
Of the two possible formulas v. Pechmann favored 5-anilino-1,2,3-thiadiazole (VII) or the tautomeric 5-phenylimino-1,2,3-thiadiazoline.



VII

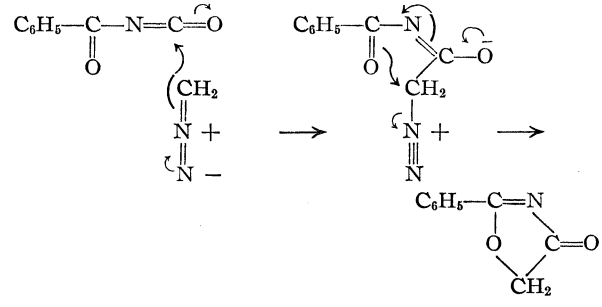
Our degradation studies confirm this structure. Hydrolysis with 10% sodium hydroxide produced a soluble sodium salt, but no sulfide ion was liberated. Reflux with 20% sulfuric acid yielded hydrogen sulfide and aniline (identified by the benzenesulfonamide and the phenylthiourea), but the adduct was essentially resistant to prolonged heating in boiling water. No methylaniline was found and no formaldehyde could be detected by the sensitive dimedon method. These results tend to rule out any structures having a thiocarbonyl group or a methylene unattached to carbon.

Although diazomethane reacts with phenyl isocyanate, benzoyl isocyanate and phenyl isothiocyanate to give three distinctly different types of products, related electronic interpretations can be made. The formation of a β-lactam may be explained by the successive addition of two methylene groups to the polarized carbonyl double bond of phenyl isocyanate.

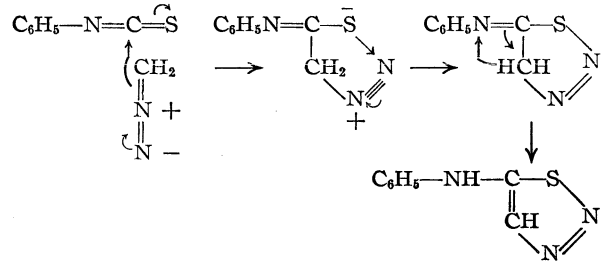


Apparently the addition of one methylene group leads to an electronic structure which is either unable to form a stable three-membered ring (an α-lactam), or such a substance may actually be formed but combines immediately with another molecule of diazomethane to enlarge the ring to the more stable four-membered ring (a β-lactam).

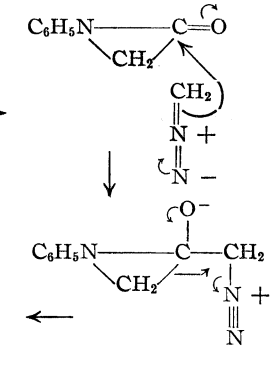
An electronic representation of the reaction with benzoyl isocyanate is similar. However, the presence of a neighboring carbonyl group changes the course of the reaction after the addition of one methylene group. The intermediate is so constituted that a stable five-membered oxazoline ring is preferentially formed, and the addition of a second methylene group does not take place.



The formulation of the phenyl isothiocyanate–diazomethane addition product as 5-anilino-1,2,3-thiadiazole receives further support from the following electronic interpretation of the addition mechanism.



In this case also structural differences in the isocyanate alter the course of the reaction. A molecule of diazomethane adds to the thiocarbonyl group, but the nucleophilicity of the neighboring sulfur atom makes possible ring closure to a stable five-membered ring at a faster rate than nitrogen is eliminated.



In each of the three cases the methylene portion of diazomethane first adds to the polarized carbonyl bond of the isocyanate (or isothiocyanate); the subsequent sequence of reactions is determined by structural characteristics of the particular isocyanate or isothiocyanate.

Diazomethane reacted vigorously with α-naphthyl, *p*-nitrophenyl and benzyl isocyanates,

(6) H. v. Pechmann and A. Nold, *Ber.*, **29**, 2588–2593 (1896).

but no well-defined monomeric products were isolated. Methyl isothiocyanate and diazomethane did not react appreciably at room temperature in ether; both starting materials were recovered in good yield.

Experimental[7]

β-Lactam of N-(*p*-Bromophenyl)-β-alanine.—Two grams (0.01 mole) of *p*-bromophenyl isocyanate was dissolved in 25 ml. of anhydrous ether and 35 ml. of a 0.49 *M* sodium-dried ether solution of diazomethane was added in small portions with shaking. A reaction set in immediately with brisk evolution of nitrogen and simultaneous precipitation of an amorphous, orange powder. After allowing the mixture to stand overnight, the clear ethereal solution was separated from the solid by decantation. The solid weighed 0.5 g. and gave positive tests for halogen.

The ether solution was evaporated to dryness, leaving 1.5 g. of a soft, brown semi-solid. This material was triturated with anhydrous acetone, which dissolved the larger part but left undissolved a white, pulverulent substance insoluble in the common organic solvents. This material was not further investigated.

The acetone solution was evaporated to dryness at reduced pressure and the brown, viscous residue was subjected to a slow evaporative distillation. A colorless, crystalline product (0.25 g., m. p. 110–118°) sublimed at 120–130° and 0.05 mm. After one recrystallization from benzene–ligroin, glistening platelets were obtained which melted at 126–127°.

Anal. Calcd. for C_9H_8ONBr: C, 47.82; H, 3.56; N, 6.19. Found: C, 47.86; H, 3.68; N, 6.28.

The compound hydrolyzed with dilute sodium hydroxide, but the hydrolysis did not proceed as readily as in the case of the simpler unhalogenated β-lactam, already reported.

2-Phenyl-4-oxazolone.—To a solution of 3.12 g. (0.021 mole) of benzoyl isocyanate[8] in 10 ml. of absolute ether, was added slowly from a buret a 0.23 *N* sodium-dried ethereal solution of diazomethane. Since the reaction was extremely vigorous, care was necessary to prevent violent bubbling and ejection of the reaction mixture from the flask. The diazomethane reacted instantaneously with the isocyanate without any discoloration of the solution and with simultaneous deposition of the colorless, crystalline oxazolone. The isocyanate solution could be "titrated" with the diazomethane to the appearance of the yellow color. The color did not appear until 88 ml. of the diazomethane solution had been added. The theoretical amount required on the basis of mole-for-mole reaction is 90 ml. Ten milliliters of diazomethane solution was added in excess and the reaction mixture was allowed to stand for one hour at room temperature and then overnight at 0–5°.

The colorless, crystalline mass was separated from the solution by filtration. This material weighed 2.30 g. (68%) and melted at 154–156°. Recrystallization from benzene lowered the m. p. to 150–152° dec.

Anal. Calcd. for $C_9H_7O_2N$: C, 67.07; H, 4.37; N, 8.68; mol. wt., 161.2. Found: C, 67.14; H, 4.35; N, 8.36; mol. wt., 185 (Rast, using camphor as a solvent).

Hydrolysis of 2-Phenyl-4-oxazolone.—To 0.5 g. of the oxazolone was added 40 ml. of water and the mixture was refluxed for two and one-half hours. Solution took place immediately upon warming; no ammonia was evolved. The cooled, clear solution was evaporated to dryness at reduced pressure, leaving a colorless oil which soon crystallized (m. p. 60–80°). After two recrystaliizations from hot water, the compound melted constantly at 121–122° (0.23 g.). This product was insoluble in sodium bicarbonate solution and dissolved very slowly in hot 10% sodium hydroxide with evolution of ammonia. The melting points of mixtures with benzoic acid and benzamide showed a depression, but the melting point of a mixture with an authentic sample[5] of benzoyl glycolic acid amide (m. p. 120–121°) showed no depression.

Anal. Calcd. for $C_9H_9O_3N$: C, 60.33; H, 5.06; N, 7.82; mol. wt., 179.2. Found: C, 60.12; H, 5.29; N, 8.09; mol. wt., 190 (Rast, using camphor as a solvent).

N-Benzoyl Methyl Carbamate.—On standing in the cold, a second crop of crystals (0.6 g., m. p. 110–118°) separated from the concentrated ethereal mother liquor from the 2-phenyl-4-oxazolone preparation. After two recrystallizations from benzene, this compound melted constantly at 118–119°. The analytical data indicated an hydrolysis product of 2-phenyl-4-oxazolone. The melting point of a mixture with benzoyl glycolic acid amide was depressed.

Anal. Calcd. for $C_9H_9O_3N$: C, 60.33; H, 5.06; N, 7.82. Found: C, 60.47; H, 5.27; N, 7.90.

N-Benzoyl methyl carbamate was prepared from benzoyl isocyanate and absolute methanol in anhydrous ether. After two recrystallizations from ethanol, the compound melted constantly at 118.6–120°. The melting point of a mixture with the above compound showed no depression.

The ethereal mother liquor was evaporated to dryness, leaving a brown, oily residue (0.35 g.) which crystallized on standing. Evaporative distillation of this material gave a good recovery of colorless crystals, m. p. 80–90°. Two recrystallizations from benzene gave a compound melting constantly at 127–128°. The melting point of a mixture with benzamide showed no depression.

5-Anilino-1,2,3-thiadiazole.—To 2.70 g. (0.02 mole) of phenyl isothiocyanate in 10 ml. of absolute ether was added 35 ml. of cold 0.65 *M* sodium-dried ethereal solution of diazomethane. Evolution of nitrogen did not immediately set in, but soon the solution turned deep amber and a crystalline product began to precipitate. After allowing the mixture to stand at room temperature for one hour, during which time a substantial amount of nitrogen was evolved, the reaction was stored overnight at 0–5°. The tan crystals were separated by filtration (1.7 g.) and the mother liquor was concentrated to about one-half its volume and allowed to stand in the cold for a few hours, giving a second crop of crystals (0.4 g.). The total yield of crystalline compound amounted to 2.1 g. (60%). This crude material turned to a black mass at 120° and decomposed at 168°. For purification, the crystals were first quickly triturated with cold acetone, which dissolved most of the dark-colored impurities. The solid residue was dissolved in hot absolute alcohol and decolorized (Norit). The compound crystallized in long, nearly colorless needles. A further recrystallization yielded a product with a faintly yellow cast, which darkened slightly at 170° and melted with decomposition at 179–180° (reported,[4] m. p. 172.5°).

Anal. Calcd. for $C_8H_7N_3S$: C, 54.22; H, 3.98; N, 23.71; mol. wt., 177.2. Found: C, 54.55; H, 4.12; N, 24.10; mol. wt., 205.3 (Rast, using camphor as a solvent).

The adduct was hydrolyzed by boiling with 20% sulfuric acid. After basification, a small amount of an amine was isolated by ether extraction. This was identified as aniline by the preparation of two derivatives and comparison with authentic samples: the benzenesulfonamide, m. p. 109–111°, and the phenyl thiourea, m. p. 152–153°. No formaldehyde could be detected (dimedon).

A portion (0.25 g.) of 5-anilino-1,2,3-thiadiazole was refluxed for three and one-half hours with 20 ml. of 10% sodium hydroxide solution. The compound dissolved completely as the solution warmed. The resulting water-clear solution was tested frequently with lead acetate paper; all tests were negative.

Summary

Diazomethane has been found to undergo three entirely different types of reaction with various

(7) All melting points are corrected.

(8) O. Billeter, *Ber.*, **36**, 3218 (1903).

isocyanates and isothiocyanates. Phenyl isocyanate and *p*-bromophenyl isocyanate interact with diazomethane in cold ethereal solution to form the β-lactams of N-phenyl-β-alanine and N-(*p*-bromophenyl)-β-alanine.

Benzoyl isocyanate reacts vigorously with diazomethane to give in 68–70% yield 2-phenyl-4-oxazolone. With phenyl isothiocyanate, diazomethane forms a crystalline equimolar addition product, 5-anilino-1,2,3-thiadiazole. An electronic interpretation of the reactions is presented.

The Metalation of Some Sulfur-Containing Organic Compounds[1a]

BY HENRY GILMAN AND F. J. WEBB[1b]

Methyl phenyl sulfide was shown to undergo exclusive lateral metalation[2] with *n*-butyllithium in diethyl ether.

$$C_6H_5SCH_3 + n\text{-BuLi} \xrightarrow[HOH]{CO_2} C_6H_5SCH_2COOH$$

Under corresponding conditions nuclear metalation[3] is effected with both diethylbarium and diethylstrontium to give metalation products which yield on carbonation, *o*-methylmercaptobenzoic acid. Metalations of methyl phenyl sulfide with other reagents are now reported. To determine the generality of the lateral metalation with *n*-butyllithium, a number of aryl methyl sulfides and higher-alkyl aryl sulfides were studied.

lithium in ether, *n*-butyllithium in petroleum ether (b. p. 28–38°) and phenylsodium in benzene gave lateral metalation (Table I). The rate of reaction was especially slow in petroleum ether. Lateral metalation also occurred with *n*-butyllithium at 150° in the absence of solvent. Under corresponding conditions at 150–155°, *n*-butylmagnesium bromide gave a nuclear metalation since *o*-methylmercaptobenzoic acid was isolated subsequent to carbonation. Thus, ortho-nuclear substitution was effected by metalating agents of the Group II metals, magnesium, barium[3] and strontium[3] but lateral metalation by the metalating agents of the Group I metals, lithium and sodium. Anisole also gives ortho-

TABLE I

METALATION OF METHYL PHENYL SULFIDE

Metalating agent[a]	Time, hr.	Temp., °C.	Solvent	Acid[b] yield, %	Thiophenol yield, %	Recovered sulfide, %
Sodium	18	25–28	Ether	3.9	20.9	52.4
Sodium	18	25–28	Benzene	Trace[c]	Trace[c]	87.5
Mercuric acetate	9.5	95–100		36.6[d]		
n-Butylmagnesium	2	135–140	None[e]	42.0[f]	Trace[c]	63.0
bromide	5	150–155	None	0.2[g]		67.0
Methyllithium	20	34	Ether	0.12		84.0
n-Butyllithium	20	28–38	Pet. ether	Trace[c]		91.5
n-Butyllithium	168	28–38	Pet. ether	3.6	2.27	31.7
n-Butyllithium	3	130–150	None	Trace[c]	22.7	29.0

Phenylsodium	5	Room	Benzene	8.9		44.4
Phenylcalcium	46	34	Ether	[i]		78.5
iodide	3.5	150–160	None	[i]	13.0	58.8

[a] The mole ratio of metalating agent to sulfide was 1:1. [b] Phenylmercaptoacetic acid was isolated unless otherwise specified. The yield was calculated on sulfide introduced. [c] Traces were not identified. [d] The product was *p*-acetoxymercuriphenyl methyl sulfide. [e] The ether was distilled, prior to addition of the sulfide, until the desired temperature was reached, as measured by a thermometer in the liquid. [f] Valeric acid only was isolated. [g] The product was *o*-methylmercaptobenzoic acid. [h] The sulfide was added to the cooled residue, after distillation of the ether. The mixture was heated to 150° during thirty minutes and cooled during the next thirty minutes. [i] Benzoic acid only was isolated.

Metalation of Methyl Phenyl Sulfide.—The position substituted was conditioned by the metalating agent employed rather than by solvent or temperature. Methyl- and phenyl-nuclear metalation with Grignard reagents.[4] Phenylcalcium iodide failed to metalate methyl phenyl sulfide in ether or at 150–160° in the absence of solvent. This reagent did not metalate phenyl sulfide[5] but did metalate dibenzothiophene in the 3-position.[6] Mercuric acetate gave

the *p*-acetoxymercuri- compound with methyl phenyl sulfide. The para substitution was proved by comparison of the bromomercuri- compound prepared from the acetoxymercuri- derivative and sodium bromide with that obtained from *p*-methylmercaptophenylmagnesium bromide and mercuric bromide. This orientation appears to be general for alkyl aryl and aryl ether types as both anisole[7] and phenyl sulfide[8] undergo *p*-mercuration.

Metalation of Other Aryl Methyl Sulfides.—*n*-Butyllithium in diethyl ether gave exclusive lateral metalation with each of the aryl methyl sulfides investigated as evidenced by the isolation of the corresponding arylmercaptoacetic acid on carbonation and hydrolysis (Table II). Identifications were completed by mixed melting point determinations with authentic specimens. Arrangement of the aryl radicals in order of decreasing yield of metalation product gives the series: phenyl-, *p*-tolyl-, α-naphthyl- > *p*-dimethylaminophenyl- > β-naphthyl- > *p*-chlorophenyl-.

TABLE II

METALATION OF ARYL METHYL SULFIDES BY *n*-BUTYLLITHIUM

Aryl group[a]	Time, hr.	Acid,[b] yield, %	Recovered sulfide, %
p-Tolyl	16	38.2	51.0
p-Chlorophenyl	5	5.8[c]	[d]
p-Dimethylaminophenyl	19	22.4[e]	52.1
p-Dimethylaminophenyl	19	15.1	43.1
α-Naphthyl	5	35.4	[d]
β-Naphthyl	20	11.7	85.0

[a] The mole ratio of metalating agent to sulfide was 1:1. The reactions were performed in refluxing ether solution. [b] The corresponding arylmercaptoacetic acid was isolated in each case and identified by a mixed melting point determination with an authentic specimen. The yields, based on sulfide introduced, are for pure acid or acid melting within 1–2° of the pure compound, unless otherwise noted. In check runs the yields differ by less than 10%. The reaction time beyond about five hours is not critical since the yields of phenylmercaptoacetic acid from methyl phenyl sulfide were 43.5 and 35.2% in fifteen hours and 37.6 and 39.7% in five and four and one-half hours, respectively. [c] The crude acid melted at 99–100° or at 105° after two recrystallizations from petroleum ether (b. p. 60–68°). [d] The neutral fraction was not investigated. [e] The crude acid melted at 75–80° and at 85–86° after two recrystallizations from benzene.

Higher-Alkyl Aryl Sulfides.—In marked contrast to the *methyl* aryl sulfides, the sulfides having higher-alkyl groups gave only *ortho* nuclear metalation, the corresponding *o*-alkylmercaptobenzoic acid being isolated (Table III). This orientation corresponds to that given by the oxygen ether types previously examined.[9] In general, the lateral metalations proceeded to a greater extent than the nuclear metalations. Ethyl phenyl sulfide was not metalated by phenylcalcium iodide on refluxing in ether solution for sixty hours. Traces of sulfur-containing acids other than the metalation acid were obtained from isopropyl and *n*-butyl phenyl sulfides with *n*-butyllithium. These melted at 154–156° and 79–80°, respectively, but were not identified.

TABLE III

METALATION OF HIGHER-ALKYL ARYL SULFIDES BY *n*-BUTYLLITHIUM

Sulfide[a]	Time, hr.	Metalation[b] acid, %	Benzoic[c] acid, %	Recovered sulfide, %
Ethyl phenyl	15	7.7	[d]	51.5
	15	5.4	3.3	59.4
n-Propyl phenyl	20	6.9	3.4	54.5
Isopropyl phenyl[e]	20	9.0	0	65.0
	20	11.0	0	67.8[f]
n-Butyl phenyl	19[g]	6.2	4.1	57.0
	19[g]	4.9	4.5	63.0
	18	6.4	1.2	64.0
Cyclohexyl phenyl	48	11.4[h]	(10 mg.)	58.4
	24	8.5[h]	0	60.5
Ethyl β-naphthyl	20	20.4[i]		37.3

[a] The mole ratio of sulfide to metalating agent was 1:1. The reactions were performed in refluxing ether solution. [b] The corresponding *o*-alkylmercaptobenzoic acid was isolated and identified by comparison with an authentic specimen, except in the last reaction. The yields are for pure acid based on sulfide introduced, unless otherwise noted. [c] The crude benzoic acid melted in the range 117–119°. [d] A small quantity (0.6 g.) of a crude acid isolated in this experiment probably contained benzoic acid. [e] The acid melted at 116–117° from petroleum ether (b. p. 60–68°) and was identified by comparison with a specimen from methyl thiosalicylate and isopropyl bromide in alcoholic potassium hydroxide. *Anal.* Calcd. for $C_{10}H_{12}O_2S$: S, 16.33. Found: S, 16.53. [f] The neutral fraction gave, from a one-tenth mole run, 1.25 g. of an unidentified oil, b. p. 174–176° (5–6 mm.), in addition to the recovered sulfide, b. p. 97–98° (20 mm.). [g] The *n*-butyllithium solutions used in these two experiments were filtered free of coarse particles but contained some finely-divided solid. All other *n*-butyllithium solutions were filtered entirely free of solid. [h] The acid melted at 85–86° from petroleum ether (b. p. 60–68°) and was identified by a mixed melting point determination with a specimen from thiosalicylic acid and bromocyclohexane in alcoholic potassium hydroxide. *Anal.* Calcd. for $C_{13}H_{16}O_2S$: S, 13.56. Found: S, 13.71. The yield was based on material melting in the range 75–80°. [i] The yield was based on crude acid melting at 130–135°. Two recrystallizations from benzene raised the melting point to 157–158° where it remained unaltered after recrystallization from aqueous acetic acid. The acid was not identified. It contained sulfur but the neutral equivalent did not agree with the theoretical value for a monocarboxyethyl naphthyl sulfide.

Diphenyl Disulfide.—With *n*-butyllithium in ether there was obtained 4.3% of crude *o,o'*-dicarboxydiphenyl disulfide, 31.4% of *n*-butyl phenyl sulfide and 17.9% of recovered diphenyl disulfide. The same acid was isolated in a previously reported reaction with thiophenol.[10]

***p*-Bromophenyl Methyl Sulfide.**—In contrast to *p*-bromoanisole which is metalated by *n*-butyl-[11] and methyllithium[12] to give 5-bromo-2-methoxy-

benzoic acid, *p*-bromophenyl methyl sulfide gave interconversion with *n*-butyllithium and chiefly coupling with methyllithium, the reaction products being, respectively, *p*-methylmercaptobenzoic acid and methyl *p*-tolyl sulfide. *p*-Bromophenyl methyl sulfide failed to form an organolithium compound in ether and was quantitatively recovered.

Methyl Phenyl Selenide.—Like phenyl selenide,[5] methyl phenyl selenide was cleaved by *n*-butyllithium in refluxing ether. On carbonation, 28.4% of benzoic acid and 25.6% of *n*-butyl methyl selenide were obtained. Amylsodium in petroleum ether (b. p. 28–38°) gave a 25% yield of benzoic acid after four hours at room temperature. Only a trace of acidic material was isolated on carbonating a mixture of methyl phenyl selenide and sodium sand in petroleum ether (b. p. 28–38°) after four hours of stirring at room temperature.

Cleavage Reactions.—No appreciable cleavage occurred when the aryl methyl sulfides were refluxed with *n*-butyllithium in diethyl ether for periods of time up to twenty hours. Noticeable cleavage resulted from more strenuous conditions of time and temperature. In each case the *methyl* group was eliminated with the formation of thiophenol. Refluxing of methyl phenyl sulfide with *n*-butyllithium in petroleum ether (b. p. 28–38°) for one hundred and sixty-eight hours gave 2.27% of thiophenol. Increased yields of thiophenol (10–22.7%) were obtained from methyl phenyl sulfide and *n*-butyllithium and phenylcalcium iodide at temperatures up to 160° in the absence of solvent. On carbonating a mixture of sodium sand and methyl phenyl sulfide which had been stirred eighteen hours at room temperature, there was isolated 20.9% of thiophenol and 3.5% of phenylmercaptoacetic acid. It is possible that the metalating agent was methylsodium.

$$C_6H_5SCH_3 + 2Na \longrightarrow C_6H_5SNa + CH_3Na$$

Ethyl, *n*-propyl, *n*-butyl and cyclohexyl phenyl sulfides, unlike the aryl methyl sulfides, were cleaved by *n*-butyllithium in refluxing ether with elimination of the *alkylmercapto* group and formation of benzoic acid in addition to the metalation acid. No thiophenol was found. The alkylmercapto residue was isolated only from the reaction of *n*-butyllithium with *n*-butyl phenyl sulfide which gave 6.5% of *o*-(*n*-butylmercapto)-benzoic acid, 1.2% of benzoic acid and 1.0% of butyl mercaptan (as the lead salt).[13] An exception was the reaction of isopropyl phenyl sulfide with *n*-butyllithium from which no benzoic acid was isolated in spite of a careful search. *n*-Butyl phenyl sulfide was cleaved in two ways by lithium metal in refluxing ether to yield on carbonation 11.9% of benzoic acid, 20.5% of thiophenol, 0.24% of *o*-(*n*-butylmercapto)-benzoic acid and 18.1% of recovered *n*-butyl phenyl sulfide. A trace of an acid melting at 270°, after recrystallization from ethanol, was also found but was not identified. The formation of *o*-(*n*-butylmercapto)-benzoic acid was probably due to a metalation by phenyllithium formed in the cleavage reaction. The formation of a trace of benzoic acid has been observed in the reaction of phenyl *n*-tetradecyl sulfide with *n*-butyllithium.[14]

Experimental

Sulfides.—The methyl and ethyl sulfides were generally prepared from the corresponding sulfate and aryl mercaptan in aqueous alkali. *n*-Propyl, isopropyl, *n*-butyl and cyclohexyl phenyl sulfides were prepared from the corresponding halide and thiophenol in alcoholic potassium hydroxide solution.[15] The boiling points and refractive indices agreed with the reported values.

General Procedure.—The metalations were performed according to procedures reported earlier.[16] The organolithium, -calcium and -magnesium reagents were filtered free of solid before use. The metalation reactions were worked up, following carbonation on Dry Ice, by acidification of the mixture and extraction with ether. The ether layer was successively extracted with 8% sodium bicarbonate solution and 10–20% potassium hydroxide solution. The neutral fraction was recovered from the ether layer after drying over anhydrous sodium sulfate. The two aqueous extracts were acidified and the precipitates recovered by filtration or extraction. Benzoic acid was separated from the metalation acid by fractional crystallization from petroleum ether (b. p. 60–68°) or was isolated by ether extraction of the filtrate from the acidified bicarbonate extract.

Diphenyl Disulfide.—A solution of *n*-butyllithium prepared from 0.2 mole of *n*-butyl bromide and 0.4 g. atom of lithium in 200 ml. of ether, was treated with 10.9 g. (0.05 mole) of diphenyl disulfide, refluxed for twenty hours and carbonated on Dry Ice. In the usual manner there was isolated 0.65 g. of crude *o,o'*-dicarboxydiphenyl disulfide. The pure white compound was obtained after several recrystallizations from ethanol and acetic acid–water mixtures; m. p. 302–305° (microscope stage).

Anal. Calcd. for $C_{14}H_{10}O_4S_2$: neut. equiv., 153. Found: neut. equiv., 156.

The methyl ester, prepared from the acid and diazomethane, melted at 131–132° after one recrystallization from ethanol.[17]

Distillation of the neutral fraction gave 5.2 g. (31.4%) of *n*-butyl phenyl sulfide; b. p. 96–98° (4 mm.), $n^{20}D$ 1.5458.[16] The distillation residue was recrystallized from ethanol to yield 1.95 g. (17.9%) of diphenyl disulfide identified by a mixed melting point determination.

***p*-Acetoxymercuriphenyl Methyl Sulfide.**—A mixture of 12.4 g. (0.1 mole) of methyl phenyl sulfide and 15.0 g. (0.05 mole) of mercuric acetate was stirred and heated on a steam-bath for nine and one-half hours and allowed to stand overnight. The white solid which formed was recrystallized from ethanol to give 6.7 g. of *p*-acetoxymercuriphenyl methyl sulfide; m. p. 183–184°, yield 36.6%. The constant melting point from ethanol was 184°.

Anal. Calcd. for $C_9H_{10}O_2SHg$: Hg, 52.40. Found: Hg, 52.84, 52.78.

***p*-Bromomercuriphenyl Methyl Sulfide.**—To an ethanol solution of 1.0 g. (0.0027 mole) of *p*-acetoxymercuriphenyl methyl sulfide was added 0.32 g. (0.0027 mole) of potassium bromide in 100 ml. of aqueous ethanol. The resulting precipitate weighed 0.93 g. (85.5%) and was purified by Soxhlet extraction with chloroform; m. p. 268–269°.

(17) List and Stein, *Ber.*, **31**, 1670 (1898), report a melting point of 130.5° and Gattermann, *ibid.*, **32**, 1151 (1899), gives a melting point of 134°.

A mixed melting point determination with a specimen prepared from *p*-methylmercaptophenylmagnesium bromide and mercuric bromide showed no depression.

Anal. Calcd. for C_7H_7SHgBr: Hg, 49.68. Found: Hg, 49.64.

p-Dimethylaminophenyl Methyl Sulfide.[18]—To a solution of 5.1 g. (0.22 g. atom) of sodium in 100 ml. of liquid ammonia was added slowly, with stirring, 33.4 g. (0.1 mole) of bis-(*p*-dimethylaminophenyl) disulfide (prepared from the Grignard reagent and sulfur). A further small quantity of the disulfide was added to discharge the blue color, the solution being pink at the end. Dropwise addition of 28.4 g. (0.2 mole) of methyl iodide in 30 ml. of ether resulted in the formation of a white precipitate. After the ammonia had evaporated the residue was partitioned between water and ether. Evaporation of the dried ether layer followed by distillation gave 26.4 g. (79%) of *p*-dimethylaminophenyl methyl sulfide, b. p. 159–160° (20 mm.).

p-Dimethylaminophenylmercaptoacetic Acid.—To 1.67 g. (0.005 mole) of bis-(*p*-dimethylaminophenyl) disulfide in 75 ml. of liquid ammonia was added 0.23 g. (0.01 g. atom) of sodium followed by 0.95 g. (0.005 mole) of chloroacetic acid in 50 ml. of liquid ammonia. The ammonia was allowed to evaporate and the pink solid residue neutralized and extracted with ether. Evaporation of the dried ether solution gave the required acid, m. p. 85°, after recrystallization from benzene. The mixed melting point determination with the acid obtained by metalating *p*-dimethylaminophenyl methyl sulfide showed no lowering.

Anal. Calcd. for $C_{10}H_{13}O_2NS$: N, 6.63. Found: N, 6.66.

Methyl Phenyl Sulfide and Sodium.—A mixture of 12.4 g. (0.1 mole) of methyl phenyl sulfide and 2.5 g. (0.11 g. atom) of sodium sand in 75 ml. of diethyl ether was stirred for eighteen hours at room temperature (25–28°) prior to carbonation on Dry Ice. The reaction was worked up in the usual way to give 0.40 g. of phenylmercaptoacetic acid by precipitation and 0.25 g. of the same acid by extraction of the filtrate; m. p. 61–63°, yield 3.9%. By extraction with potassium hydroxide solution there was isolated 2.3 g. (20.9%) of thiophenol; b. p. 84–85° (50 mm.), $n^{23.5}D$ 1.5850. The recovered methyl phenyl sulfide amounted to 6.5 g. or 52.4%.

***n*-Butyl Phenyl Sulfide and Lithium.**—To a suspension of 1.38 g. (0.2 g. atom) of lithium cut in small pieces (1–2-mm. square) in 50 ml. of ether was added 16.6 g. (0.1 mole) of *n*-butyl phenyl sulfide in 25 ml. of ether. The mixture was stirred at room temperature for seven hours and then refluxed for thirty-six hours before carbonation on Dry Ice. Acidification of the bicarbonate extract gave 2.7 g. of acidic material, melting at 90–100°. Extraction with petroleum ether (b. p. 60–68°) separated an insoluble substance (unidentified) weighing 0.03 g. and melting at 270° after recrystallization from ethanol-water. The petroleum ether-soluble portion was fractionally crystallized to give 1.3 g. (10.6%) of benzoic acid and 0.05 g. (0.24%) of *o*-(*n*-butylmercapto)-benzoic acid both of which were identified by mixed melting point determinations. An additional 0.15 g. (1.3%) of benzoic acid was isolated by ether extraction of the original aqueous filtrate. The potassium hydroxide extract on acidification and distillation yielded 2.25 g. (20.5%) of thiophenol. Three grams (18.1%) of the starting material was recovered.

***p*-Bromophenyl Methyl Sulfide and Methyllithium.**—A solution of methyllithium, prepared from 14.2 g. (0.1 mole) of methyl iodide and 1.38 g. (0.2 g. atom) of lithium in 100 ml. of ether, was filtered, concentrated and treated with 10.2 g. (0.05 mole) of *p*-bromophenyl methyl sulfide in 20 ml. of ether. The total volume was 85 ml. After fifteen minutes, a 5-ml. aliquot was removed and carbonated. The remainder was refluxed for twenty-two hours before carbonation. Both portions were worked up in the same manner. The aliquot yielded only a trace of acidic material which was insufficient for investigation and 83.3% of recovered *p*-bromophenyl methyl sulfide. The main portion gave 5–10 mg. of *p*-methylmercaptobenzoic acid identified by a mixed melting point determination. Three fractions were obtained on distillation of the neutral fraction: (1) methyl phenyl sulfide (10.3%) boiling range, 80–87° (18 mm.); (2) methyl *p*-tolyl sulfide (14.1%) boiling range 96–100° (18 mm.); and (3) *p*-bromophenyl methyl sulfide, (5.9%) boiling range 115–120° (10 mm.). Each of the three fractions was identified by hydrogen peroxide oxidation to the corresponding sulfone and determination of the mixed melting point with an authentic specimen.

***p*-Bromophenyl Methyl Sulfide and *n*-Butyllithium.**—To the filtered solution of *n*-butyllithium prepared from 6.85 g. (0.05 mole) of *n*-butyl bromide and 0.70 g. (0.1 g. atom) of lithium in 100 ml. of ether, was added rapidly with stirring 5.08 g. (0.025 mole) of *p*-bromophenyl methyl sulfide in 50 ml. of ether. After fifteen minutes at room temperature, a 50-ml. aliquot was removed and carbonated on Dry Ice. By means of the usual procedures, there was isolated 1.23 g. (88%) of *p*-methylmercaptobenzoic acid[19]; m. p. 189.5–190°. The remainder of the reaction mixture was refluxed for seventeen hours before carbonation. There was isolated 6.1% of *p*-methylmercaptobenzoic acid and 18.3% of recovered sulfide.

Methyl Phenyl Selenide and *n*-Butyllithium.—Methyl phenyl selenide[20] was prepared from selenophenol and dimethyl sulfate in 80% yield; b. p. 89–90° (15 mm.), $n^{25}D$ 1.6060.

To the filtered solution of *n*-butyllithium prepared from 13.7 g. (0.1 mole) of *n*-butyl bromide and 1.40 g. (0.2 g. atom) of lithium in 100 ml. of ether was added 8.35 g. (0.05 mole) of methyl phenyl selenide in 25 ml. of ether. The solution was stirred for one-half hour at room temperature, refluxed for nineteen hours, carbonated on Dry Ice and worked up in the usual way. There was isolated 28.4% of benzoic acid, 25.6% of *n*-butyl phenyl selenide and 13.8% of recovered methyl phenyl selenide. The liquids were identified by boiling point and refractive index. When the reflux period was shortened to four hours, 21% of benzoic acid was obtained.

Methyl Phenyl Selenide and *n*-Amylsodium.—The metalating agent was prepared[21] at ice-bath temperature from 10.6 g. (0.1 mole) of *n*-amyl chloride and 5.7 g. (0.25 g. atom) of sodium in 100 ml. of petroleum ether (b. p. 28–38°). Without removing the ice-bath, 8.35 g. (0.05 mole) of methyl phenyl selenide was added rapidly. No change was observed for about fifteen minutes, when the mixture changed from a black to a gray color and refluxed for a few minutes. When the refluxing ceased, the ice-bath was removed and the stirring continued for four hours at room temperature. The thick brown mixture was carbonated as usual. The mixture was worked up by means of the customary procedures to yield 1.92 g. (31.8%) of crude benzoic acid, m. p. 117–119°. In an attempt to crystallize the acid from water, 0.15 g. remained undissolved and was removed by filtration. The filtrate deposited 1.5 g. of benzoic acid; m. p. 120–121°, yield 25%. The insoluble material was organic in nature but did not melt at 280°. It was not identified.

Since the amylsodium in the foregoing experiment contained excess sodium metal, it seemed advisable to test the action of sodium on methyl phenyl selenide. Accordingly, a mixture of 3.4 g. (0.02 mole) of methyl phenyl selenide and 1.05 g. (0.045 g. atom) of sodium sand in petroleum ether (b. p. 28–38°) was stirred for four hours and carbonated by Dry Ice. Only a trace of a red oil was isolated by acidification of the bicarbonate extract.

Sulfones.—Attempts were made to metalate methyl and ethyl phenyl sulfones, phenyl sulfone and dibenzothio-

(18) Zincke and Jörg, *Ber.*, **42**, 3374 (1909), prepared this compound by another method.

phene-5-dioxide. As expected from the known reactions of sulfones with Grignard reagents,[22] bicarbonate-soluble products were isolated in each case but only from methyl phenyl sulfone was the product identified. Here, *n*-butyllithium gave 47% of benzenesulfonylacetic acid and 45.5% of the sulfone was recovered. Ethyl phenyl sulfone reacted vigorously with ethylmagnesium bromide to yield on carbonation an acidic gum which was not identified. There was also separated a trace of an unidentified bicarbonate-insoluble but potassium hydroxide-soluble crystalline solid, m. p. 156°. The starting material was recovered to the extent of 61%. An unidentified acidic oil was also obtained from ethyl phenyl sulfone and *n*-butyllithium. This substance turned black on standing. Diphenyl sulfone reacted vigorously with *n*-butyllithium to give in low yield an acid melting at 200° after darkening from 120°. Attempts to purify this substance by recrystallization from a variety of solvents were unsuccessful.

An acidic gum was obtained from dibenzothiophene-5-dioxide and *n*-butyllithium following carbonation. All efforts to crystallize the product were unsuccessful.

Summary

1. Methyl aryl sulfides, in general, undergo lateral metalation with metalating agents of the Group I metals.

2. Methyl phenyl sulfide is metalated in the nucleus by *n*-butylmagnesium bromide.

3. Ethyl phenyl, *n*-propyl phenyl, isopropyl phenyl and *n*-butyl phenyl sulfides give *ortho*-nuclear metalation with *n*-butyllithium in diethyl ether.

4. Some cleavage reactions of alkyl phenyl sulfides with lithium and sodium metals and with *n*-butylmagnesium bromide and *n*-butyllithium have been examined.

Properties of the Fractions and Linear Subfractions from Various Starches

BY SYLVIA LANSKY, MARY KOOI AND THOMAS JOHN SCHOCH

There have been no critical standards by which to evaluate the purity and extent of degradation of the fractions from various starches. As a consequence, doubts frequently arise regarding the quality of the parent starch, the possibility of hydrolytic degradation during fractionation, and the purity of the final fractions. The present investigations were initiated primarily to isolate the linear and branched components of various common starches by optimum fractionation techniques, and to establish precise standards of purity and degree of degradation on the basis of iodine affinity and intrinsic viscosity. As this work progressed, the substantial differences between the linear fractions from the various starches required further elucidation from a molecular standpoint. This led to the development of a technique for separating the total linear material into a graded series of subfractions by partial precipitation methods. Various reducing value determinations for aldehydic end-groups have been investigated as a means for comparing the relative molecular size of the linear fractions and subfractions. These physical and chemical criteria have likewise had application in estimating the degree of hydrolysis of various modified starches and in elucidating the mechanism of β-amylase action on the starch fractions. Through the kindness of A. L. Potter and W. Z. Hassid, osmotic molecular weights and non-aldehydic end-group assays (by periodate oxidation) have been reported on many of the identical fractions here described.[1]

In the present paper, the linear and branched starch components are designated as the A-fraction and the B-fraction, respectively, in conformance with previously established definitions.[2]

Source of Starches.—Various samples of commercial corn starch were selected over a period of four years, choosing those lots which possessed the highest "hot paste viscosity." The wheat starch was an experimental batch produced at the Northern Regional Research Laboratory by sulfur dioxide steeping. Tapioca starches included samples from Brazil (kindly supplied by Mr. George Caesar of Stein, Hall and Company) and from the Dominican Republic, in each case selected by reason of high paste viscosity. Limited data are likewise available on the A-fraction from pre-war Javanese tapioca. Potato starches were of Maine and Idaho origin, from the New England Starch Company and Idaho Potato Starch Company, respectively. Data are also included on the B-fraction from pre-war German potato starch. Since commercial sago starch is frequently bleached with oxidizing agents, a sample of virgin unmodified sago flour was secured through the courtesy of Dr. C. G. Caldwell of the National Starch Company. This was suspended in methanol and screened through silk bolting cloth, then repeatedly sedimented in methanol and finally in distilled water. This treatment served to remove all foreign material and most of the pigment. Easter lily starch was furnished by Dr. R. M. Hixon of Iowa State College. The corn, wheat, sago and lily starches were defatted by five two-hour digestions under reflux with boiling 85% methanol, filtering and washing with 85% methanol after each digestion. In later studies, raw corn starch (non-defatted) was fractionated directly.

Fractionation Methods.—In all cases, primary separation was effected by selective precipitation with Pentasol (commercial mixture of amyl alcohols marketed by Sharples Solvents). Where the starch was dissolved by autoclaving, defatted starch was employed and the system was buffered at *p*H 6.2–6.3 prior to autoclaving by the addition of 40 ml. of 20% phosphate solution (16.4% with respect

(1) Potter and Hassid, THIS JOURNAL, **70**, 3488, 3774 (1948).

(2) Schoch in "Advances in Carbohydrate Chemistry," edited by Pigman and Wolfrom, Vol. I, Academic Press, New York, N. Y., 1945, pp. 247–277.

to anhydrous KH_2PO_4 and 3.6% to anhydrous K_2HPO_4) per 450-g. batch of starch in 15 l. of water. A number of starches were fractionated without autoclaving; in these cases, raw starch may be employed directly without preliminary defatting. In a 5-gal. Pyrex bottle equipped with mechanical stirrer and reflux condenser and heated in a suitable boiling water-bath, 300 g. of the starch was gelatinized in a boiling mixture of one liter of Pentasol and 15 l. of distilled water containing 50 ml. of the above phosphate buffer. The mixture was gently refluxed for three to four hours at 92° with continuous agitation, then cooled overnight with stirring and finally refrigerated for twenty-four hours. The A-fraction complex crystallized as rounded spherules; centrifugation at 50,000 r. p. m. in the Sharples continuous supercentrifuge gave a dense well-packed deposit, with no evidence of slimy material. This mode of fractionation is preferred over previous methods, since it avoids both the defatting operation and the possible hydrolytic degradation during autoclaving.

To isolate the B-fraction, the supernatant solution from the centrifuge was treated with one-third its volume of methanol, the mixture vigorously stirred for several minutes, then refrigerated overnight.[3] The B-fraction precipitated quantitatively as a soft curd which was removed and dehydrated by grinding for two or three minutes in a Waring Blendor with fresh methanol.

Two methods were employed for recrystallization of the A-fraction. By the earlier method,[2] the crude moist A-fraction was dissolved in boiling water in the presence of excess *n*-butyl alcohol to give a 1% solution (on dry substance basis). This was supercentrifuged to remove extraneous impurities, cooled and refrigerated to crystallize the A-fraction. Two such recrystallizations sufficed to raise the iodine affinity of the product to a maximum value. Since it became evident that this technique caused some subfractionation, a later method employed Pentasol as the recrystallizing agent. The crude moist A-fraction was dissolved in hot water (95–100°) with vigorous agitation, to give a solution of 0.2% concentration (dry substance basis). The hot solution was passed through the Sharples supercentrifuge, giving only a small amount of dark brown sediment in the lower part of the rotor. An excessive amount of white or light colored material indicates incomplete solution of the A-fraction, due to too low a temperature or to inadequate stirring during solution of the crude material. Any such undissolved residue can usually be recovered by dissolving in boiling water and recentrifuging. The total centrifugate was reheated to 90–95°, 5–6% by volume of Pentasol added, the mixture cooled overnight with continuous agitation, then refrigerated twenty-four hours and centrifuged. When crystallized at 0.2% concentration, the A-fraction separated as well-defined rosettes which gave a dense deposit in the centrifuge rotor. Attempts to recrystallize 1% solutions with Pentasol gave soft, bulky and even "sloppy" deposits. As many as seven recrystallizations with Pentasol were employed in an effort to attain maximum iodine affinity. While no attempt was made in these studies to control *p*H during recrystallization, it might be advisable to add a small amount of phosphate buffer.

The A-fraction was dehydrated by suspending in 10 volumes of *n*-butyl alcohol, stirring for several hours and filtering. This treatment was repeated several times and the product finally dried *in vacuo* at 70°. This method of drying avoids retrogradation, and the dried A-fraction is completely soluble in boiling water. Yields of A-fraction were not determined except in the case of certain modified starches.

Subfractionation of A-Fraction.—A number of methods have been investigated for the separation of A-fraction into a graded series of subfractions of different chain lengths. Selective retrogradation and partial precipitation with methanol were ineffectual. By far the best procedure involved partial precipitation with minimal amounts of the higher alcohols. While cyclohexanol has been used in some of these studies, *n*-octyl alcohol is preferred by reason of its lower solubility in water and more precise control of subfractionation. It should be noted that these agents precipitate the A-fraction at temperatures substantially above the levels of *n*-butyl alcohol or Pentasol precipitation.

The following procedure is cited as an example of optimum subfractionation technique (Run 17). One hundred g. of potato A-fraction (Batch P-7/9-A, twice recrystallized with Pentasol) was dissolved in 10 l. of boiling water and passed through the supercentrifuge or filtered through Pyrex glass wool to remove any slight trace of insoluble material. The clarified solution was reheated to 80–85°, 1.5 ml. of *n*-octyl alcohol added dropwise with agitation, and the mixture allowed to cool spontaneously with continuous stirring. Turbidity developed when the temperature dropped to 72°, and crystalline precipitation occurred in the range from 70 to 62°, as indicated by a "watered-silk" appearance on stirring. The mixture was allowed to cool overnight with stirring, then passed through the Sharples supercentrifuge at a rate of 200 ml. per minute, using the smallest injector nozzle. The first subfraction (designated as 17-a, to indicate Run 17, first subfraction) was removed from the rotor, dehydrated by successive digestions in *n*-butyl alcohol, filtered and dried to constant weight in the vacuum oven at 70°. The centrifugate was reheated to 80–85°, 1.0 ml. of octyl alcohol added and the mixture similarly cooled with stirring. After removal of the second subfraction (17-b), the third, fourth and fifth subfractions were similarly precipitated by the addition of 1.0-ml. portions of octyl alcohol. The sixth and last portion was precipitated with excess octyl alcohol. Mechanical losses of linear material during these successive centrifugings may total 10–15%. Consequently, weight distribution of the subfractions was calculated on the basis of total recovered material.

Hydrolysis Studies.—It was also of interest to determine the characteristics of linear and branched molecules smaller than those in the native starch. For this purpose, granular corn starch was hydrolyzed to various levels by treatment with dilute acid at a temperature below the gelatinization point, in much the same fashion as for the commercial production of "thin-boiling" starches. Suspensions of raw corn starch (40% on weight basis) in 0.075 *N* hydrochloric acid were digested in a constant temperature bath at 50° for five, sixteen, twenty-six and forty hours. The converted starches were neutralized to *p*H 6.0 with sodium carbonate, filtered, washed and air-dried. Similar conversions were run in 0.3 *N* hydrochloric acid for two, seven and sixteen hours at 50°. The acid-modified starches were subsequently fractionated by Pentasol precipitation and the linear fractions recrystallized twice with Pentasol.

Iodine Affinity.—The potentiometric titration method of Bates, French and Rundle[4] has been modified for routine evaluation of iodine affinity. A bright platinum electrode was employed in conjunction with a low resistance calomel electrode (Leeds and Northrop No. 1199–11 electrode, or Coleman No. 3-070 electrode with saturated potassium chloride junction). Potentials may be determined with an ordinary *p*H meter adaptable to millivolt readings, though use of a Leeds and Northrop Type K bridge and No. 2420-C galvanometer provides much simpler and more precise operation. To calibrate the electrode system, 373 mg. of potassium chloride and 830 mg. of potassium iodide were dissolved in 100 ml. of water and titrated with standard iodine solution between e. m. f. limits of 230–280 millivolts, the solution being stirred mechanically during the titration. The standard iodine solution was 0.05 *N* with respect to potassium iodide, 0.05 *N* to potassium chloride, and contained exactly 0.200 mg. of iodine per ml.; this was most conveniently prepared just prior to use by tenfold dilution of a stock iodine solution, the latter being standardized against arsenious oxide. Since the solution and iodine reagent were both 0.05 *N* with respect to potassium chloride and potassium iodide, there was no change in salt concentration during

(3) Schoch and French, *Cereal Chem.*, **24**, 231 (1947).

(4) Bates, French and Rundle, THIS JOURNAL, **65**, 142 (1943).

the titration. From the plotted curve of this titration, a calibration chart was prepared giving the total milligrams of free iodine in solution for each half-millivolt reading from 230–280 mv.

Before evaluation of iodine affinity, all starchy materials were Soxhlet-extracted for twenty-four hours with ethyl alcohol, to remove residual fractionating agents or natural lipids which repress the iodine affinity. The sample was then dried and pulverized to pass a 40-mesh screen. To prepare unmodified granular starches for analysis, the starch was gelatinized in boiling water to give a 1% paste, this was disintegrated by five minutes agitation in the Waring Blendor and the starch substance flocculated by the addition of excess methanol. Modified or so-called "thin-boiling" starches do not require pregelatinization. An appropriate sample (*i.e.*, approximately 40 mg. of A-fraction, 100 mg. of whole starch, or 200 mg. of B-fraction) was transferred to a dry 250-ml. beaker. Five ml. of 1 *N* potassium hydroxide solution was added by pipet and the sample dispersed in the alkali by trituration with a stirring rod, with care to avoid the formation of difficultly soluble lumps. The mixture was allowed to stand with occasional stirring for one hour, or until a perfectly clear solution was obtained. It was then neutralized to methyl orange with 0.5 *N* hydrochloric acid, 10 ml. of 0.5 *N* potassium iodide added and the solution diluted to 100 ml. (*i.e.*, by addition of 75 ml. of water). With some B-fractions, the sample did not dissolve to give the requisite crystal-clear solution in the alkali. In such cases, the mixture was neutralized and gently heated to assist solution.

Except for the presence of starchy substance, this solution was identical with that employed for the calibration. It was titrated potentiometrically in the same manner. After each addition of iodine, the solution was allowed to equilibrate for two minutes before determining the e. m. f.

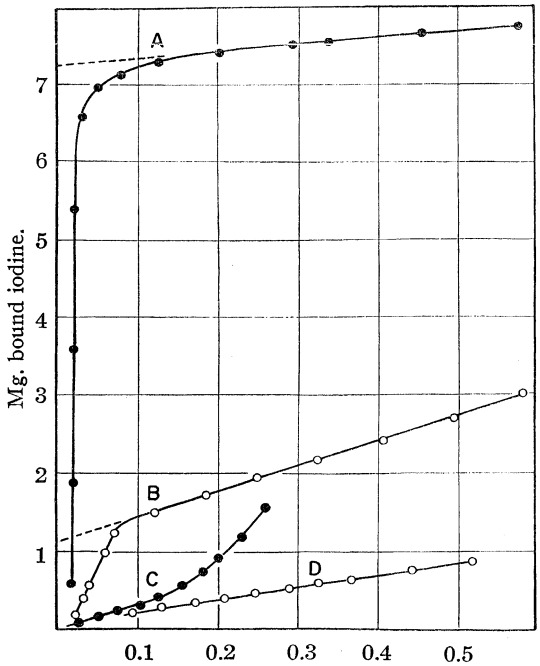

Fig. 1.—Method of plotting potentiometric evaluation of iodine affinity, showing titrations of (A) 38.4 mg. of corn A-fraction, (B) 182 mg. of corn B-fraction, (C) 193 mg. of tapioca B-fraction, and (D) 190 mg. of soluble "phytoglycogen" from Golden Bantam sweet corn. High quality waxy maize starch yields a curve identical with (C); the shape of the latter cannot be explained.

For each point of the titration, the free iodine in solution was calculated for the corresponding e. m. f. of the calibration chart, and this amount was deducted from the total iodine added at that point (*i.e.*, ml. of iodine added × 0.200 mg.) to give the bound iodine. Free iodine was then plotted against bound iodine as shown in Fig. 1. The upper linear portion of this curve was extrapolated to the zero axis (a mode of plotting suggested by Dr. Dexter French) and this amount of bound iodine taken as the iodine affinity of the sample. Results were converted to dry basis by separate moisture determination on the sample (*viz.*, four hours *in vacuo* at 70°). In the titration of A-fractions and normal starches, it is only necessary to obtain some 5 or 6 readings between 250–280 mv., omitting the lower ascending portion of the curve. With B-fractions or waxy starches, readings should be taken between 230–270 mv. Two or more determinations have been run on all samples here reported; average deviation from the mean is ±0.08% iodine affinity.

Intrinsic Viscosity.—The primary difficulty in evaluation of starch viscosity is the choice of solvent. The viscosity of solutions in such basic media as anhydrous ethylenediamine or aqueous potassium hydroxide shows a progressive decrease over a period of days, probably due to slow oxidative degradation of the polysaccharide. This is particularly objectionable when ethylenediamine is employed as solvent for the B-fraction, since one to three days are required to effect a homogeneous solution. Use of chloral hydrate or 30% ammonium thiocyanate solution avoids this drift in viscosity, but these agents do not dissolve the A-fraction, particularly when retrograded. One normal potassium hydroxide solution was finally selected because of its ease of preparation and standardization. Also, since its solubilizing action is much more rapid than ethylenediamine, degradation may be kept to a minimum. The intrinsic viscosity can be determined within two hours; hence no precautions are exercised to exclude oxygen or carbon dioxide.

The A-fraction (either retrograded or non-retrograded) dissolves readily and completely in 1 *N* potassium hydroxide solution. The B-fraction does not dissolve completely in either 1 or 5 *N* alkali, seemingly due to persistent aggregation effects.[3] However, the following procedure overcomes aggregation and is recommended for either fraction. An amount of the fraction equivalent to 2.00 g. on dry basis was quantitatively sifted into 200–300 ml. of cold water in a 600-ml. beaker, stirring vigorously with a glass propeller-type agitator to avoid formation of lumps. The suspension was heated in a boiling water-bath for thirty minutes, then allowed to cool to room temperature, stirring being continued throughout the heating and cooling periods. To prevent formation of insoluble skins by evaporation, the beaker was covered with a perforated watchglass during the heating and cooling operations. When cold, 100 ml. of 5 *N* potassium hydroxide solution was added by pipet and stirring continued for ten to fifteen minutes, usually producing a perfectly clear solution, entirely devoid of gel particles. The alkaline solution was rinsed into a 500-ml. volumetric flask and diluted to volume with distilled water, to give an 0.4% solution of the starch fraction in 1 *N* potassium hydroxide. This was filtered through a loose plug of Pyrex glass wool in a funnel stem, to remove any trace of fiber or insoluble material which might impede capillary flow. Accurate dilutions were made to some five or six concentrations between 0.1–0.4%, using 1 *N* potassium hydroxide solution for dilution. Viscosity was determined at each concentration with an Ostwald–Cannon–Fenske No. 100 pipet, maintained in a thermostated water-bath at 35.0°. Flow time at each concentration was determined to a precision of ±0.1 second or better (average deviation from mean), filling the viscometer at least twice and running at least three flow times for each filling. Specific viscosity was determined with reference to 1 *N* potassium hydroxide, and intrinsic viscosity was evaluated by plotting the function (η_{sp}/concn.) against concentration and extrapolating to zero concentration. Both the 1 and 5 *N* potassium hydroxide solutions must be adjusted within 1% of the

stipulated values (*i.e.*, 0.99–1.01, 4.95–5.05 *N*), since the flow time of the solvent varies markedly with concentration. Duplicate determinations on a large number of samples indicated a precision of ±0.02 in the intrinsic viscosity (average deviation from the mean).

This method overcomes any aggregation or retrogradation of the starch substance. For example, non-retrograded wheat A-fraction had an intrinsic viscosity of 1.54 ± 0.03. When this material was dissolved in boiling water at 0.2% concentration and retrograded by prolonged refrigeration, the intrinsic viscosity of the product was 1.50. In another test, corn B-fraction was precipitated from aqueous solution by three different methods: (a) by gross addition of methanol, (b) by slow addition to excess methanol, and (c) by addition of 10% methanol followed by freezing, thawing, filtering and spontaneous air-drying.[3] These three products had radically different solubility behavior, both in water and in 1 *N* potassium hydroxide, yet their intrinsic viscosities were 1.32, 1.28 and 1.30, respectively. However, the method has not been reliable for evaluating the viscosity of unmodified granular starches, apparently due to persistent granule structure which is not completely disaggregated either by pregelatinization in boiling water or by treatment with 1 or 5 *N* alkali.

The slope of the viscosity curve (η_{sp}/concn., against concentration) was determined for each sample, but this value appeared to have no significance. In general, the higher the viscosity, the greater was the slope.

The use of intrinsic viscosity does not entirely eliminate the energy characteristics of the viscometer. For example, the intrinsic viscosity of a commercial 75-fluidity corn starch was 0.53 with a No. 50 Cannon–Fenske pipet, 0.48 with a No. 100 pipet, and 0.33 with a No. 200 pipet. The No. 100 pipets employed in these studies gave flow times of approximately forty-five seconds for distilled water. Identical intrinsic viscosities were obtained with a regular Ostwald pipet of similar flow time.

Retrogradation Time.—It was of interest to compare the relative retrogradation tendencies of various linear starch substances, particularly to explain the low retrogradation of tapioca A-fraction. Retrogradation has been entirely a qualitative characteristic which is difficult to translate into quantitative terms. As an approximation, the retrogradation tendency is here expressed as the time required for development of initial turbidity in a 1% solution of the linear substance. Admittedly, the criterion and mode of testing are not good. It is often difficult to estimate the point at which turbidity first appears, particularly with linear substances which require more than fifteen to twenty hours for retrogradation. While flocculation normally occurs soon after the initial appearance of turbidity, a number of samples showed initial turbidity followed by a long period during which there was no further change. As a further criticism of the data, it was not feasible to run these tests at constant temperature, despite the known influence of temperature on retrogradation.

One hundred mg. (on dry basis) of the linear substance was dissolved in 2.0 ml. of 1 *N* potassium hydroxide solution. The mixture was stirred occasionally for one to two hours to effect a perfectly clear solution, 5.5 ml. of water added and the solution neutralized to phenolphthalein with 1 *N* hydrochloric acid. Since *p*H has a marked influence on retrogradation, 0.5 ml. of *p*H 6.3 phosphate buffer solution was added (16.4% with respect to anhydrous KH_2PO_4 and 3.6% to anhydrous K_2HPO_4). The solution was transferred to a stoppered 5-inch test-tube which was placed in a device designed to rotate some fifteen tubes end-over-end at a rate of about 20 r. p. m. Incidence of the characteristic blue-white haze as viewed against a black background was taken as the time of retrogradation. In some cases, shreds of insoluble material were formed during the neutralization; however, this did not significantly influence the time of retrogradation. Two to six tests were run on each sample here reported; precision was of the order of ±15%.

Reducing Value.—A variety of oxidizing agents and different conditions of oxidation have been investigated for aldehydic end-group assay of the A-fraction. Hypoiodite methods (variations of the Harris[5], Kline–Acree,[6] and Willstätter–Schudel techniques) were completely useless, since a large and indeterminable amount of iodine was consumed in oxidation of hydroxyl groups along the starch chain. This over-oxidation increased progressively (a) with increasing *p*H levels from 8.7 to 11.9, (b) with increasing time and temperature of reaction, and (c) with increasing concentration of iodine. No method could be devised to limit the oxidation to terminal aldehyde (*e.g.*, by use of borate buffer) or to correct for over-oxidation (by plotting iodine consumption against reaction time and extrapolating to zero time). The same criticisms applied to oxidation with bromine–potassium bromide mixtures at buffered *p*H levels between 4.5–7.0. While ferricyanide,[7] alkaline copper[8] and alkaline 3,5-dinitrosalicylate reagents appeared somewhat more selective toward terminal aldehyde, the reducing values by these methods were influenced to a major degree by concentration of oxidizing agent, the *p*H of the medium, and the time and temperature of the reaction. As a further complication, these last three oxidizing agents do not yield a stoichiometric relationship between glucose and maltose; hence, any extension to the higher polysaccharides is entirely arbitrary. It is therefore concluded that absolute evaluation of terminal aldehyde is not possible with any of the above reagents.

However, some relative index of reducing value was required for comparison of various linear subfractions. While alkali numbers have been determined on most of the samples here reported, this value is primarily a test for hydrolytic degradation, not a relative index of molecular weight. The colorimetric 3,5-dinitrosalicylate method of K. H. Meyer and his associates[9,10] was finally employed because of its simplicity and because it gave more reproducible results than the copper, ferricyanide or hypoiodite method. Furthermore, the intensity of color produced with either maltose or A-fraction followed Beer's law; the reducing value was therefore independent of the size of sample. Meyer's technique was modified in several respects. When the dinitrosalicylate reducing value was plotted against time of digestion at 65°, it was found that the initial primary oxidation was not always complete in thirty minutes; oxidations were therefore conducted for one hour to bring the reducing value into the more uniform over-oxidation range. An amount of the linear starch substance equivalent to 2–4 mg. of maltose was transferred to a clean dry 6 × 0.75 inch test-tube. Fifteen ml. of alkaline dinitrosalicylate reagent (666 mg. of twice-recrystallized 3,5-dinitrosalicylic acid dissolved in 200 ml. of 1 *N* potassium hydroxide) was added by pipet, and the sample dispersed by thorough mixing with a stirring rod. The mixture was allowed to stand with occasional stirring for an hour, or until the sample completely dissolved. The solution was then heated for one hour in a thermostated bath at 65°, cooled, quantitatively rinsed into a 50-ml. volumetric flask and diluted to mark. Blanks were simultaneously run on 15-ml. portions of the dinitrosalicylate reagent. Light transmission at 5000 Å. (predetermined as the point of maximum color development) was compared against the blanks, using 1-cm. cuvettes in a Beckman quartz spectrophotometer. In order to standardize the method, 1–5-mg. samples of maltose (analyzed by the Kline–Acree technique) were digested in similar fashion and transmission at 5000 Å. determined against comparable blanks. Percentage transmission was plotted against mg. of maltose hydrate to give a calibration curve.

[a] Batch designations are given to facilitate cross reference and to identify samples investigated by other laboratories. Thus C-71/73-A indicates a composite sample of the corn A-fractions from Runs 71 to 73, inclusive. [b] Degree of polymerization, as determined from osmotic pressure by Potter and Hassid.[1] [c] This represents an average value for commercial dent corn starch. [d] Corn starch was solubilized by pregelatinization in liquid ammonia according to the method of Hodge, Montgomery and Hilbert.[13] Product was then dissolved in hot water, fractionated with Pentasol and the A-fraction thrice recrystallized with *n*-butyl alcohol. [e] High iodine affinity is not necessarily a characteristic of Easter lily bulb starch. Defatted starches from Croft, Ace, Estate and Creole varieties of Easter lily bulbs (from Vaughn Seed Co.) analyzed 5.16, 5.88, 5.43 and 5.36% iodine affinity, respectively.

By use of the latter, color development in the starch sample was calculated in terms of mg. of maltose hydrate per gram of starch substance. Two or more determinations were run on each sample; average deviation from the mean was ±0.04 mg. of maltose hydrate. It should be stressed that these values cannot be translated into molecular weight. Much higher reducing values are obtained by digesting for five minutes at 100°. The use of Rochelle salt[10] in the digestion mixture merely depresses the reducing value without decreasing the rate of over-oxidation.

Discussion

There has been a tendency to consider that hypothetically "pure" linear material has an iodine-binding capacity of 20.0%. This value is frequently employed for calculation of the percentage of linear material in various starch preparations. The present work shows that no such criterion is possible, since the iodine affinity depends on the source of the A-fraction and on the methods of fractionation and recrystallization. The A-fractions listed in Table I were all recrystallized to constant maximum iodine affinity by identical methods of precipitation with *n*-butyl alcohol. They may surely be considered as "pure" substances in the sense that the B-fraction has been completely removed, yet their iodine affinities range from 18.5 to 20.0%. In several unrecorded instances, corn A-fraction was recrystallized by cooling only to 35–40° and centrifuged without refrigeration. The resulting products had iodine affinities in the range of 20.5–20.8%, apparently due to subfractionation and loss of linear material of somewhat lower iodine affinity. When Pentasol was employed as recrystallizing agent (Table II), the iodine affinities were consistently and substantially lower. While one or two recrystallizations with *n*-butyl alcohol sufficed to give a constant maximum iodine affinity, successive recrystallizations with Pentasol gave a very slow but progressive increase in iodine affinity, with no evidence of a constant maximum even after seven recrystallizations of corn A-fraction. Similarly, the A-fractions from thin-boiling corn starches have iodine affinities lower than that of unmodified corn A-fraction (Table III). As will be shown more definitely by subfractionation studies, the total A-fraction represents a graded spectrum of molecular types, certainly differing with respect to chain length and perhaps even containing irregularities of linkage. Since these factors must necessarily influence the iodine affinity, no standard linear material can possibly be established which will apply equally to all A-fractions, regardless of source, hydrolytic level or manner of purification. Hence, it is strongly recommended that the linear characteristic of starches be expressed merely in terms of iodine affinity, with no reference to percentage of linear substance.

[a] Yields of A-fraction are based on once-recrystallized product. [b] Reducing value toward dinitrosalicylate, expressed as mg. of maltose hydrate per gram of starch substance (dry basis).

The iodine affinities of the B-fractions likewise show a variation, from 0.0% for Dominican tapioca to 0.6–0.7% for corn starch. It has not been positively established whether this represents a residual trace of unremoved linear material, or whether certain B-fractions possess a small but definite iodine-binding capacity. The latter explanation seems more plausible. Otherwise, it would be difficult to explain why Pentasol consistently gives B-fractions of very low or negligible iodine affinity from potato and tapioca starches, while the B-fractions from the cereal starches are substantially higher in iodine-binding capacity. It has been claimed that the iodine affinity of the B-fraction can be reduced to zero by treatment with cotton. However, this is apparently due to the introduction of fatty substances from the cotton, thereby concealing the presence of residual iodine-binding material. If alcohol-defatted cotton is employed, there is no reduction of residual iodine affinity. In accord with theories suggested by Kerr[11] and more recently elaborated by K. H. Meyer,[12] a portion of the total B-fraction may have a few outer branches of sufficient unobstructed length to bind a small amount of iodine, though too short or too infrequent to precipitate with Pentasol.

Intrinsic viscosities also reveal substantial differences between the various A-fractions and likewise between the various B-fractions. In general, the fractions isolated from boiled starch pastes have somewhat higher intrinsic viscosities than those from autoclaved pastes. Despite careful buffering, autoclaving probably causes a slight degradation of the starch substance. For this reason, prolonged boiling in the presence of excess Pentasol is now preferred as a means of solubilizing starch prior to fractionation. To avoid autoclaving, use of the Waring Blendor has been suggested to disintegrate swollen starch pastes for fractionation. However, the B-fraction undergoes degradation under the violent shearing action of the Blendor, seemingly by a "mechanical hydrolysis" of the molecule. For example, a hot 3% corn starch paste (buffered at *p*H 6.3) was disintegrated in the Blendor for fifteen minutes, then fractionated with Pentasol and the A-fraction thrice recrystallized with *n*-butyl alcohol. Intrinsic viscosities of the A and B fractions were 1.39 and 1.07, respectively. The A-fraction was not degraded, perhaps because of its smaller molecular size together with the possibility that it can align itself along the flow lines and thus escape mechanical rupture.

(11) Kerr, "Chemistry and Industry of Starch," Academic Press, New York, N. Y., 1944, p. 154.

(12) Meyer, Bernfeld, Rathgeb and Gurtler, *Helv. Chim. Acta*, **31**, 1536 (1948).

In another instance, a buffered 3% solution of corn B-fraction was agitated for one hour in the Blendor, then precipitated with methanol and dried. The intrinsic viscosity was lowered from 1.17 to 0.95 by this treatment. Pregelatinization in liquid ammonia (as recommended by Hodge, Montgomery and Hilbert[13]) provides an excellent but somewhat inconvenient method for dissolving granule structure without degradation (*cf.* Batch C-141 in Table I).

During acid-modification of granular corn starch (Table III), both fractions appear to be hydrolyzed at approximately the same rate, as indicated by increase in alkali number. In comparison with these laboratory-modified starches, the intrinsic viscosities of commercial thin-boiling corn starches (sulfuric acid modification) were as follows: 15-fluidity, 1.09; 40-fluidity, 0.90; 50-fluidity, 0.73; 60-fluidity, 0.62; 75-fluidity, 0.46; 90-fluidity, 0.38.[14] These values have had practical application in determining the hydrolytic level of various starch derivatives and of pregelatinized starches. Thus, when a 75-fluidity corn starch was gelatinized and dried on heated rolls, the product had an intrinsic viscosity of 0.45. Similarly, a granular starch ether of low degree of substitution prepared from 40-fluidity starch had an intrinsic viscosity of 0.92.

The intrinsic viscosity may have theoretical application in indicating the mechanism of enzyme action on the starch fractions. For example, the β-amylase limit dextrin from waxy maize starch had an intrinsic viscosity of 1.25 and an alkali number of 5.5 (values for the parent starch substance were 1.21 and 3.6, respectively). Since intrinsic viscosity is essentially a measure of molecular shape (*i. e.*, the "axial ratio" of length of molecule to diameter), the similar values for

[a] Reducing value toward dinitrosalicylate, expressed as mg. of maltose hydrate per gram of starch substance (dry basis). [b] Runs 1–5 inclusive employed cyclohexanol as fractional precipitant. Due to its higher solubility in water, considerably larger quantities of this agent were employed than with octyl alcohol. Runs 6–17 inclusive were conducted with octyl alcohol. [c] Run 16 may have been slightly degraded during subfractionation.

(13) Hodge, Montgomery and Hilbert, *Cereal Chem.*, **25**, 19 (1948).

(14) Industrial fluidity values represent the ml. of 5% starch paste in 1% sodium hydroxide solution passed by a standard fluidity funnel in seventy seconds (Buel, 8th Intern. Congr. Pure Applied Chem., *Orig. Com.*, **13**, 63 (1912)). It will be noted that these values show good correlation with intrinsic viscosity.

waxy maize and its limit dextrin are in accord with the concept of a highly branched globular molecule; the limit dextrin would be smaller in size but similar in shape. In another case, corn A-fraction was treated with β-amylase[15] and samples withdrawn at several stages during the conversion. From intrinsic viscosities and alkali numbers of the residues, it appears that the enzyme attacks and destroys the shorter molecules first, leaving a residue of longer average chain length than the parent A-fraction:

Conversion, hr.	Degradation, %	Alkali no. of residue	[η] of residue
0	0	20.4	1.23
1.75	41	17.4	1.39
6.0	61	16.3	1.38

The subfractions obtained by partial precipitation with cyclohexanol or octyl alcohol show a progressive gradation in intrinsic viscosity, alkali number, dinitrosalicylate reducing value and retrogradation time (Table IV). The subfraction first precipitated has the highest intrinsic viscosity and the lowest terminal aldehyde content, apparently consisting of those molecules of longest chain length. When the cumulative percentage yield of the successive subfractions is plotted against intrinsic viscosity as shown in Fig. 2, a frequency distribution curve is obtained indicative of a continuous series of homologous linear chains. There is no evidence of two or more separate and sharply defined component substances. Intrinsic viscosities of the various

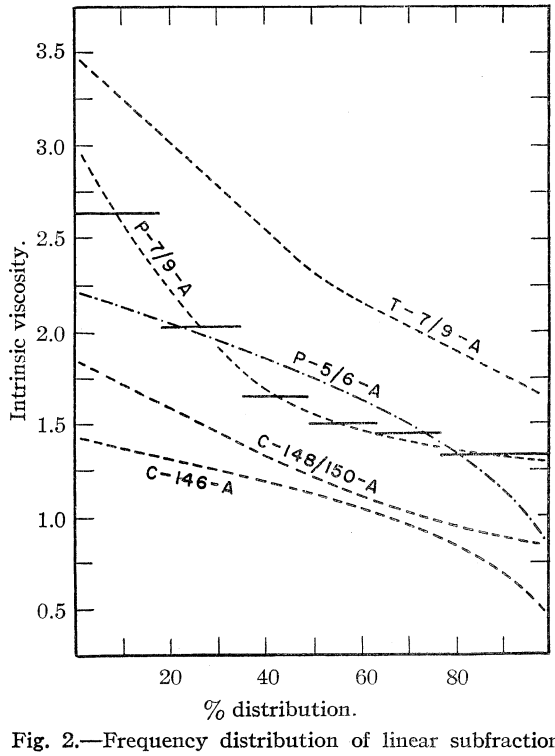

Fig. 2.—Frequency distribution of linear subfractions from various A-fractions plotted against their respective intrinsic viscosities. Method of plotting is shown for subfractionation No. 17 (twice-recrystallized potato A-fraction P-7/9-A); curves for other A-fractions are similarly derived.

(15) The enzyme used in these studies was furnished through the kindness of Miss Edna M. Montgomery, Northern Regional Research Laboratory, Peoria, Illinois.

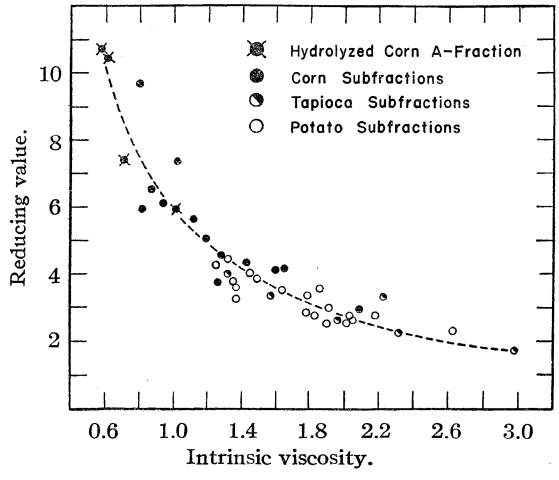

Fig. 3.—Relationship between intrinsic viscosity and dinitrosalicylate reducing value of various linear starch substances.

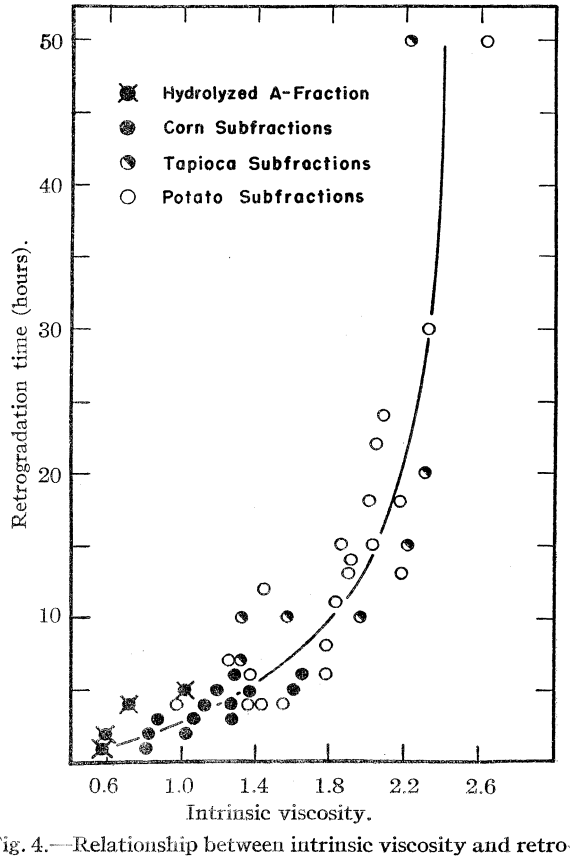

Fig. 4.—Relationship between intrinsic viscosity and retrogradation time of various linear starch substances.

subfractions show excellent correlation with dinitrosalicylate reducing value (Fig. 3) and with retrogradation time (Fig. 4), independent of the source of the subfraction. In addition, the intrinsic viscosities of the various A-fractions are arranged in the same order as their osmotic molecular weights, as determined by Potter and Hassid (Table I). Hence, the primary difference between tapioca, potato and corn A-fractions appears to be merely a matter of relative chain length. It does not seem probable that the A-fraction of one starch is strictly linear while that of another starch is slightly branched; such a situation would radically alter the relationship between intrinsic viscosity and reducing value. Since the shorter subfractions of potato A-fraction and the longer subfractions of corn A-fraction have the same intrinsic viscosity, dinitrosalicylate reducing value and retrogradation time, it must be assumed that they are molecularly identical. It has been claimed that tapioca A-fraction does not retrograde because its chain molecule is too long to permit ready orientation to an aggregated state.[16] Present evidence supports this theory, since the retrogradation tendency of the subfractions is inversely related to intrinsic viscosity. The theory is no longer tenable that the low-retrogradation tendency of tapioca starch is due to a slight branching peculiar to its A-fraction molecule.[16] Maximum retrogradation is observed with the hydrolyzed corn A-fractions down to an intrinsic viscosity of 0.57 (Table III). Somewhere below this level, a reversal must occur as the linear fragments become too short to retrograde.

Iodine affinities of the various fractions and subfractions are somewhat at variance with the foregoing concept of homologous series of linear chains. The following irregularities may be noted:

1. The B-fractions originally isolated from corn and potato starches by primary separation with *n*-butyl alcohol had iodine affinities of 1.5–1.7%,[2] as compared with present values of 0.0–0.6% by Pentasol precipitation. Since *n*-butyl alcohol gave only 22–23% yield of A-fraction from corn starch, while Pentasol gave 28–29%, it was previously assumed that Pentasol was a "more effective" fractionating agent.

2. In the present studies, maximum iodine affinity is rapidly attained by one or two recrystallizations with *n*-butyl alcohol, while repeated recrystallizations with Pentasol give a very slow increase in iodine affinity, without reaching the maximum value of the product recrystallized with *n*-butyl alcohol. Yet the lower iodine affinity of the Pentasol-recrystallized product cannot possibly be attributed to contamination by B-fraction.

3. There is no correlation between iodine affinity and intrinsic viscosity or reducing value of the various linear subfractions. Likewise, there are substantial differences between the iodine affinities of the acid-modified corn A-fractions and of the linear subfractions of comparable intrinsic viscosity.

4. In the subfractionation of Pentasol-recrystallized A-fractions, the composite iodine affinity of the subfractions is substantially higher than that of the parent A-fraction. There is less discrepancy with the A-fractions recrystallized by *n*-butyl alcohol. In all cases, the final subfractions have the lowest iodine affinity.

To explain these anomalies, it is suggested that corn, potato and tapioca starches contain a minor proportion of material intermediate between strictly linear and highly branched molecules.[17] These transition types may conceivably range from branched molecules with long exterior branches to predominantly linear molecules containing a relatively small number of branches. This intermediate material is apparently precipitated by Pentasol but not by *n*-butyl alcohol; on this basis, its presence in corn starch is estimated at 5–7% of the total starch substance. In collaborative studies, W. Z. Hassid is endeavoring to isolate and identify this material. From present concepts of the dual enzymatic synthesis of starch, it seems entirely reasonable that such an intermediate range of molecular types might be formed. Except for the somewhat questionable criterion of β-amylase conversion, it is not possible at this time to distinguish between strictly linear and slightly branched starch substances. To prepare fractions with minimum inclusion of such intermediate types, it would seem advisable to conduct the primary separation with Pentasol and to recrystallize the A-fraction with *n*-butyl alcohol.

Summary

As a preferred mode of fractionation, starch is gelatinized in a buffered Pentasol–water mixture, gently boiled under reflux for several hours, then cooled and refrigerated to precipitate the linear A-fraction. This technique avoids the slight hydrolytic degradation occasioned by autoclaving and likewise permits direct fractionation of nondefatted cereal starches.

Improved methods have been developed for characterizing the starch fractions in terms of (a) intrinsic viscosity in 1 *N* potassium hydroxide solution, (b) iodine affinity by potentiometric titration, (c) reducing value toward alkaline 3,5-dinitrosalicylate reagent, and (d) retrogradation tendency of the linear component. These methods have been employed to describe and differentiate the linear A-fractions and branched B-fractions from corn, wheat, sago, Easter lily, potato and tapioca starches. In addition, these criteria have had useful application in detecting minor hydrolytic changes in the starch substance,

(16) Kerr, *Paper Trade J.*, **115**, no. 22, 30 (1942).

(17) The existence of an intermediate fraction has been suggested by Kerr and Trubell, *Paper Trade J.*, **117**, no. 15, 25 (1943).

in evaluating various modified starches, and in elucidating the action of β-amylase on the starch fractions. A study of the reducing values of the A-fraction toward hypoiodite, bromine, alkaline copper, ferricyanide and alkaline dinitrosalicylate indicates that none of these reagents is specific for terminal aldehyde groups.

A technique has been devised for subfractionating the A-fraction by successive partial precipitations with *n*-octyl alcohol. The A-fraction appears to consist of a continuous series of homologous linear polymers, rather than a limited number of discrete components. The linear material of longest chain length (as indicated by intrinsic viscosity and reducing value) is precipitated first by octyl alcohol, followed successively by subfractions of progressively shorter chain length. The ease of retrogradation of a linear starch substance is inversely related to its chain length. Linear subfractions of equal intrinsic viscosity and reducing value have the same retrogradation tendency, irrespective of their source. Thus the lower retrogradation of tapioca and potato starches must be attributed to the longer chain length of their A-fractions and not to anomalous branching.

However, indirect evidence from iodine affinities suggests the presence of a material intermediate between the strictly linear and the highly branched fractions, possibly amounting to 5–7% of the total starch substance in the case of corn starch. This material is precipitated by Pentasol but not by *n*-butyl alcohol. To minimize contamination of the fractions by this intermediate material, it is recommended that Pentasol be used for the primary separation and *n*-butyl alcohol for recrystallization.

Starch. III. Structure of Apple Starch

BY A. L. POTTER, W. Z. HASSID AND M. A. JOSLYN

While all starches possess certain fundamental common structural features, it is now recognized that starches from different sources vary in the following respects: (1) proportion of the two constituents, amylose and amylopectin, (2) average length of the amylose chains, (3) average chain length of the amylopectin branches in the molecule, (4) molecular size of amylose and of amylopectin.

Practically all the available information regarding starch structure has been derived from work on cereal and tuber starches, chiefly corn and potato. It was therefore of interest to examine a fruit starch in order to ascertain whether or not its structure differs from that of the cereal and tuber starches previously studied.

The starch was isolated from apples and separated by Schoch's "Pentasol" precipitation method[1] into amylose and amylopectin. The yield of amylose was 24.8% of the total starch. Analysis of the whole starch by Schoch's[2] modification of Bates and collaborators'[3] potentiometric iodine titration method showed an amylose content of 26.5%. The intrinsic viscosity of the amylose was 0.99 and that of the amylopectin was 0.96.

Treatment with crystalline β-amylase hydrolyzed the amylose to the extent of 90% maltose. With amylopectin the hydrolysis ceased when 63.5% was degraded to maltose.

Upon acetylation of the two fractions with acetic anhydride at room temperature and the determination of their osmotic pressures, a number-average molecular weight of 160,000 (560 glucose residues) was obtained for the acetylated amylose and 1,200,000 (4200 glucose residues) for the acetylated amylopectin.

In a previous study[4] the number-average molecular weights of six acetylated amylose components from starches of six different plant sources ranged from 180,000 to 370,000. The acetylated amylopectins from the same sources ranged from 2,000,000 to 10,000,000.

The same osmotic pressure–concentration relationship was used as previously reported for the other acetylated amyloses and amylopectins.[4] Using the values $n = 1.39$ and 2.25 for acetylated apple amylose and acetylated amylopectin, respectively, and plotting π/C against C^n, straight lines were obtained. Employing this method, the intercept of the coördinate could be determined with greater accuracy, thus resulting in more reliable molecular weight determinations.

End-group determination by the periodate oxidation method showed an average of 24 glucose residues per end-group for the amylopectin. For the amylose an average chain-length of 530 glucose residues was obtained. The latter value is in fair agreement with 560 obtained by osmotic pressure measurements, indicating that, like po-

tato and Easter lily amylose,[4] a single chain represents one amylose molecule. The apple amylopectin data are in accord with the data obtained for other amylopectins, showing that the molecule consists of a great number of branched chains averaging approximately 24 glucose residues per end-group.

The study of the apple starch did not reveal any anomalous features concerning its structure. It appears to be similar to that of the cereal and tuber starches previously examined, except that the molecular weights of the apple starch are lower.

Experimental

Preparation of Apple Starch.—The starch was prepared from Newtown Pippin apples grown in Willow Glen district of San Jose, California. Approximately 25 lb. of apples were harvested early in August, stored for a week at 0°, then crushed in an apple grater and pressed in a hydraulic press, using wooden racks and canvas cloths. The press juice was collected and treated with 5 g. of potassium metabisulfite ($K_2S_2O_5$) to inhibit browning. The press cake was mixed with an equal weight of water and pressed again. The juice was stored at room temperature until the starch settled, the supernatant liquid was decanted and the sediment washed with water to remove pulp particles by flotation. The starch was then resuspended in water and the washing was repeated several times until all the pulp particles and soluble material was removed. The starch was filtered on a Buchner funnel, washed with ethanol and dried *in vacuo* at 60°. The fatty acids were removed from the dry material according to Schoch's[5] method by means of five successive twenty-four-hour extractions with hot 85% methanol. The yield was 23 g. When viewed under the microscope the granules appear spherical or sometimes slightly irregular. Their size varies from 2.5 to 10 μ.

Separation of the Starch into Amylose and Amylopectin.—The two fractions were separated according to Schoch's method.[1] A 2% suspension was made, using 20 g. of defatted apple starch, gelatinized on a steam-bath and autoclaved for three hours at 18 lb. pressure. After the addition to the hot solution of 10% (by volume) "Pentasol" and cooling, the amylose precipitated in the form of spherocrystals. The crude material was purified by reprecipitating four times with butanol.

The amylopectin was isolated from the first mother liquor by the addition of methanol. The precipitate was dissolved in water and the amylose impurities removed by the addition of butanol. A yield of 4.96 g. of amylose and 12.4 g. of amylopectin was obtained. The amylose yield constitutes 24.8%.

The proportion of amylose and amylopectin was determined in the apple starch by using the potentiometric iodine titration method of Bates, French and Rundle as modified by Schoch.[2] The iodine bound by the amylose was found to be 19.0% whereas that of the amylopectin was 0.1%. The unfractionated starch absorbed 5.1% iodine, showing a 26.5% amylose content.

Intrinsic Viscosity.—In evaluating the intrinsic viscosities of the fractions, the relative viscosity was determined in an Oswald type viscosimeter, using 1 *N* potassium hydroxide solution as a solvent. Determination of four concentrations between 0.1 and 0.4% were made in a constant temperature bath at 35 ± 0.01°. The log of the relative viscosity was plotted against concentration and the intrinsic viscosity was evaluated by multiplying the value of the slope of the line by 2.3.[6] The intrinsic viscosity $[\eta]$ of the amylose was found to be 0.98 and that of amylopectin 0.95.

Acetylation.—Two-gram samples of the starch fractions were dispersed in formamide and acetylated at room temperature with acetic anhydride in the presence of pyridine as previously described.[4] The yield of acetylated amylopectin was 88% and that of the acetylated amylose 90%. An acetyl value of 43.6% was obtained for the acetylated amylose and 44% of the acetylated amylopectin. The calculated $COCH_3$ content for the triacetate $(C_6H_7O_5(CH_3CO)_3)_n$ is 44.8%. The specific rotation of both the acetylated amylopectin and amylose in chloroform (c, 2) was $[\alpha]_D$ +170°.

TABLE I

OSMOTIC PRESSURE DATA FOR ACETYLATED APPLE STARCH FRACTIONS

Concn., C, g. per l.	$C^{1.39}$	Osmotic pressure, π (g. per sq. cm.)	π/C
	Amylose		
2.83	4.2	0.350	0.182
5.74	11.4	0.920	.235
7.17	15.4	1.30	.266
10.05	24.7	2.18	.319
	Amylopectin		
	$C^{2.25}$		
12.3	280	0.325	0.0389
15.1	450	0.540	.0525
17.6	630	0.760	.0634
20.0	840	1.06	.0778

Determination of Molecular Weights.—The molecular weights of the acetylated apple amylopectin and amylose were determined by osmotic pressure measurements, using chloroform as a solvent. The method employed was the same as that previously used for the determination of a number of acetylated starch fractions from various plant sources.[4] The osmotic pressure was measured for each acetylated starch fraction at several different concentrations (Table I).

The intercept of the coördinate was determined by plotting π/C against C^n and the molecular weight was calculated using the van't Hoff equation. From the intercepts of the ordinates values of π/C were obtained equal to 0.157 and 0.0210 for acetylated amylose and amylopectin, respectively. These values corresponded to a number-average molecular weight of 160,000 for acetylated amylose of 1,200,000 for acetylated amylopectin.

End-Group Determination of Amylopectin and Amylose by Periodate Oxidation.—A series of five 0.2-g. samples of amylopectin were oxidized with 0.37 *M* sodium periodate at 2° according to the method previously described.[7] After ten hours the samples were taken at five-hour intervals and analyzed for formic acid by titrating with 0.01 *N* barium hydroxide. The number of ml. of base (5.2) at twenty-five hours was taken as the end-point for the amylopectin. The average number of glucose residues per end-group for amylopectin, calculated on the basis of one mole of formic acid produced per chain, was found to be 24.

Duplicate 0.5-g. amylose samples were similarly oxidized with sodium periodate for twenty-five hours. The acid produced required 1.75 ml. of 0.01 *N* barium hydroxide for neutralization. The average chain-length of amylose, calculated on the basis of 3 moles of formic acid produced per chain, was 530 glucose residues.

Hydrolysis with β-Amylase.—A 0.02-g. sample of polysaccharide was dissolved in 1 ml. of 1 *N* potassium hydroxide, diluted to 35 ml. and mixed with 5 ml. of 2 *M* acetate buffer at *p*H 4.7. One drop of crystalline β-amylase[8] solution, containing approximately 500 Schwimmer units, and a drop of toluene were added to the mixture

(7) A. L. Potter and W. Z. Hassid, THIS JOURNAL, **70**, 3488 (1948).

(8) A. K. Balls, M. K. Walden and R. R. Thompson, *J. Biol. Chem.*, **173**, 9 (1948).

and the hydrolysis was allowed to proceed for twenty-four hours. Another drop of β-amylase was then added and the mixture was allowed to remain at room temperature for another twenty-four hours. The reducing value was then determined by oxidation with ferricyanide[9,10] and calculated as maltose.

The amount of polysaccharide originally present in the sample was found by determining the glucose obtained when a 2-ml. aliquot portion was treated with 1 *N* sulfuric acid for two and one-half hours at 100°. On this basis, the extent of the amylopectin hydrolyzed with β-amylase to maltose was estimated to be 63.5%. The limit of amylose hydrolysis with this enzyme was 90%.

Acknowledgment.—The authors are grateful to the Corn Industries Research Foundation for their support of this work, and to Dr. A. K. Balls for the crystalline β-amylase.

Summary

Apple starch was separated into amylose and amylopectin, the amylose content being 24.8% of the total. Osmotic pressure measurements of the acetylated fractions gave a number-average molecular weight of 160,000 (560 glucose residues) for the acetylated amylose and 1,200,000 (4200 glucose residues) for the acetylated amylopectin.

End-group determination by periodate oxidation showed an average of 24 glucose residues per end-group for the amylopectin and a chain-length of 530 glucose residues for the amylose. Since the end-group value for amylose is in fair agreement with the value of 560 obtained from osmotic pressure measurements, it is assumed that a single chain represents one amylose molecule.

The data indicate that apple starch is similar in structure to the cereal and tuber starches, with the difference that the molecular weights of its components are smaller.

Chain Initiation in Styrene Emulsion Polymerization[1]

BY WENDELL V. SMITH

Introduction

The chain length and rate of polymerization in emulsion are controlled principally by the relationship between two quantities, the rate of chain initiation and the rate of chain propagation. In contrast with bulk polymerization, the rate constant for the termination step does not play a significant role in the mechanism of emulsion polymerization.[1a] The rate of chain propagation in styrene polymerization has already been considered[1a] and this paper discusses the rate of the initiation step in styrene polymerization.

Three methods are used for investigating the rate of initiation. The first is based on the observation that fragments of the chain initiator, persulfate, are chemically combined with the polymer.[2] It consists in determining how rapidly these fragments become combined by measuring the rate of polymerization and the radioactivity of polystyrene prepared using radioactive persulfate as initiator. The second consists in determining the initial rate of polymer particle formation from measurements of the size of the particles and the rates of growth of the particles, making use of a previously developed theory relating these.[1a] The third consists in determining the rate of molecule formation from the molecular weight of polymer and the rate of polymerization.

Experimental Procedures

Radioactive Potassium Persulfate.—The radioactive S^{35} was received as a trace constituent of potassium chloride from Clinton Laboratories (now Oak Ridge National Laboratory) on allocation by the U. S. Atomic Energy Commission.

The active sulfur in the irradiated unit was isolated as barium sulfate by boiling with bromine in water solution then precipitating with barium ion. The barium sulfate (1.3 mg.) was converted to sulfate free potassium persulfate by dissolving in concentrated sulfuric acid, adding potassium sulfate and electrolyzing cold. The precipitated potassium persulfate after washing and drying (0.35 g.) contained 12% of the total sulfur; it was made up to a 1.81% solution. After the preliminary measurements the persulfate was regenerated by a new electrolysis at which time it was further diluted with inactive sulfur.

Determination of Sulfur Content of Polystyrene from its Radioactivity.—All radioactivities were determined using a Radiation Counter Laboratories thin mica window Geiger–Müller counter tube and scaling circuit.

The resolving time[3] of 2.5×10^{-4} sec. requires a correction of only 0.25% for a counting rate of 10 per sec.

The range of the β-radiation from S^{35} is quite

short; Libby[4] gives the aluminum range as 13.5 mg./sq. cm. Thus for active samples which are appreciably thicker than this, the radiation escaping from unit surface is independent of the thickness of the sample and, for a given concentration, depends only on the absorption characteristics of the material comprising the sample.

For this investigation the absorption characteristics of the materials comprising the samples are characterized sufficiently when a relationship is determined between the radiation from an infinitely thick sample (*i. e.*, thickness greater than the range) and that from a sample thin enough that absorption of radiation within the sample can be neglected. Thus, if I_0 is the radiation from a mass, m, of sample thin enough that self-absorption can be neglected, and if I_∞ is the radiation from an area, A, of the sample which has a thickness greater than the range of the radiation in the sample, then there exists a relation

$$I_0/m = \alpha I_\infty/A$$

where α is a characteristic of the absorption of the material.

The value of α for water as defined by the above equation was determined as follows: A water solution of the active persulfate (0.02 mg./ml.) was placed in an aluminum dish 1 inch in diameter giving a sample thickness of 300 mg./sq. cm. The radiation intensity from the surface of the sample escaping through a circular window 1 cm. in radius was

$$I_\infty/A = (3.176 - 0.394)/\pi = 0.886 \text{ cm.}^{-2} \text{ sec.}^{-1}$$

where 3.176 sec.$^{-1}$ was the rate of reception of impulses by the counter when the sample was in place and 0.394 sec.$^{-1}$ was the background rate. Next a sample of the solution was evaporated to dryness in an aluminum dish, giving a film of thickness 0.02 mg./sq. cm., which was thin enough to neglect self-absorption. The intensity of radiation obtained from this gave

$$I_0/m = (15.5 - 0.4)/100 = 0.151 \text{ mg.}^{-1} \text{ sec.}^{-1}$$

Thus for water

$$\alpha_\omega = 0.151/0.886 = 0.170 \text{ cm.}^2/\text{mg.}$$

To compare the absorption of polystyrene with that of water a sample of polystyrene was prepared in emulsion using radioactive potassium persulfate. This active sample, polymer *A* was mixed with 32 parts of a low molecular weight inactive polystyrene. A portion of the mixed benzene solution was evaporated to dryness in an aluminum dish to give a polystyrene film of thickness 56 mg./sq. cm. The intensity of radiation from this film measured through a 1-cm. radius window gave for the undiluted polymer *A*

$$I_\infty/A = 33(1.337 - 0.338)/\pi = 10.5 \text{ cm.}^{-2} \text{ sec.}^{-1}$$

For measuring the radiation from a thin film of the polymer a film containing 0.853 mg. of the undiluted polymer *A* was used. Since the thickness of this film was 0.17 mg./sq. cm. it was necessary to apply a small correction for self-absorption. This was done assuming exponential absorption so that the intensity I from area A of a film of thickness l is given by

$$I/A = (I_0/m) \int_0^l e^{-\alpha l}\, dl$$

For sufficiently small values of αl this gives

$$I_0/m = (I/m)(1 + \alpha l/2)$$

For

$$\alpha = 0.17 \text{ cm.}^2/\text{mg.}$$

and

$$l = 0.17 \text{ mg./cm.}^2$$

the correction factor is 1.015 so

$$I_0/m = 1.015\,(1.826 - 0.338)/0.853 = 1.77 \text{ mg.}^{-1} \text{ sec.}^{-1}$$

Thus

$$\alpha_p = 1.77/10.5 = 0.169 \text{ cm.}^2/\text{mg.}$$

which is practically the same as that found for water.

The value of the "absorption coefficient," α, found for water and polystyrene in this investigation is considerably smaller than the value of 0.32 sq. cm./mg. reported by Henriques[5] and coworkers for absorption in benzidine sulfate. It is believed that this difference reflects largely the different techniques used in determining the "absorption coefficient" rather than different absorption characteristics of the polystyrene or water and benzidine sulfate.

The comparison between water and polystyrene in this investigation was made using a continuous film of the polymer in the radiation measurements. However, for the subsequent measurements of the activities of different polymer samples it was more convenient to determine the activity of the polymer when it was in the form of a fine powder, as that is the condition in which it was isolated from the latex. Consequently a series of comparisons was made of the intensity of radiation from the same polystyrene in a continuous film and in powder form. These comparisons consistently showed that the radiation from the film was less than that from the powder, giving the relation: activity of film = 0.965 × activity of powder. This correction factor was used in all calculations.

The sulfur contents of the active polymers were determined by making a direct comparison between the activity of the purified polymer and that of the over-all latex. Since the total sulfur content of the latex was known from the ingredients comprising the charge, the sulfur content of the polymer was calculated from the ratio of the activities. Errors due to fluctuations in the sensitivity of the counting mechanism were minimized by counting the polymer and latex with a minimum time interval between measure-

ments. With the very low activity polymer produced at 30.5° the counting rate with the sample in the counter was only slightly greater than the background, so a long series of alternate counting with and without the sample in place was made.

Polymerization.—The polymers used for the radioactivity determinations were made separately from those used for polymer yield and molecular weight determinations to avoid unnecessary manipulations with active polymer. A typical charge was made up by adding to a test-tube: 3.00 ml. of a 0.55% (by weight) S. F. Flakes soap solution, 0.300 ml. of a 1.81% radioactive potassium persulfate solution and 2.00 ml. of distilled styrene. The test-tube and charge were cooled with ice and the vapor space swept out with nitrogen, after which the test-tube was sealed. The charge was then placed on a rotating carriage in a water-bath thermostated at the desired temperatures until substantially complete polymerization had taken place. The test-tube was opened and a 1-ml. portion of latex was diluted with 100 ml. of water, then flocculated by addition of hydrochloric acid. After warming, filtering and washing with water and methanol, the polymer was dried on the filter by radiation with an infrared lamp while air was simultaneously sucked through it. It was then ready for comparing its radioactivity with that of a sample of the original latex as described above.

The method of purification proved to be quite important for obtaining significant results. Thus the first procedure investigated consisted in coagulating by adding the latex to a large amount of methanol, then dissolving the precipitated polymer in benzene and reprecipitating with methanol. However, when this method was tested on latex prepared from inactive potassium persulfate, but to which active persulfate was added after polymerization, the polymer was found to be active and no amount of subsequent purification would render it appreciably less active. In contrast, when this same experiment was done using the method of purification finally adopted as described above the dried polymer was inactive.

The charges used for rate of polymerization and molecular weight determination were made up practically the same as those described above. However, they were coagulated by transferring the entire charge to 100 ml. of methanol containing 2 ml. of a 5% aqueous solution of hydroquinone as a short-stop. The precipitated polystyrene was filtered, washed twice with boiling methanol, then dried overnight on a vacuum line. Representative data on polymerization time and polymer yield for the series used in comparing with the radioactivity measurements are given in Table I. The last time in each sequence corresponds with the time used for polymerizing the samples with radioactive persulfate.

TABLE I

RATES OF STYRENE EMULSION POLYMERIZATIONS

30.5°; 0.5% soap; 0.172% persulfate

Time, min.	60	120	180	240	300	330

G. polymer per ml. water	0.095	0.244	0.364	0.458	0.497	0.505
Intrinsic viscosity	1.25	1.36	1.43	1.42	1.39	1.42

From the last charge of each sequence a small quantity of latex was saved for particle size determination, which was done by means of electron microscope photographs of the particles. For each latex examined the diameters of 100 particles were measured. From these diameters the average volume of the particles was calculated and used with the polymer yield to calculate the number of particles per ml. of water solution.

Molecular Weight.—The molecular weights were estimated from intrinsic viscosities which were determined in benzene, using a Fenske viscometer. A single concentration of polystyrene was used and the intrinsic viscosity was calculated from the relation

$$\eta_{sp}/c_v = [\eta] + 0.375[\eta]^2 c_v$$

where c_v is the concentration of the polymer in grams per 100 ml. of solution.

The relationship between intrinsic viscosity and molecular weight for polystyrene prepared in oil phase[6] has been established over a molecular weight range from 10^4 to 6×10^5. Since most of the polymers in the present investigation had molecular weights above this range, extrapolation of the relationship was carried out using Debye's theory of solution viscosities.[7] In Debye's theory the relationship between intrinsic viscosity and molecular weight can be represented by the conventional equation

$$[\eta] = KM^a$$

where the exponent, a, is substantially constant over a limited molecular weight range but decreases slowly to a value of $1/2$ as the molecular weight increases. Debye has established the nature of the relation between a and molecular weight. Thus, the procedure used was to fit the above equation to the experimental data,[6] then to extrapolate using Debye's calculated relationship between a and molecular weight. While leaving much to be desired, this method of estimating the molecular weight appeared to be the best available. The low molecular weight polystyrene prepared in emulsion at 90° had the same relationship between intrinsic viscosity and osmotic molecular weight as the polymers referred to above[6]; thus, the emulsion process of polymerization does not produce any particularly unusual molecular weight distribution.

Results

The first step in the investigation consisted in determining how many atoms of sulfur are com-

	2.0% soap; 0.165% persulfate			
70	11.7	1.05×10^6	2.1×10^6	2.0

The sulfur content in column 3 is obtained from the radioactivity of the polymer as discussed above. The molecular weight is obtained from the intrinsic viscosity of the last sample in each sequence of Table I. This intrinsic viscosity was converted to number average molecular weight as described above. The last column giving the atoms of sulfur per polymer molecule is, of course, the quotient of the two preceding columns. This quotient approximates two for the higher temperature polymers but is much less than that for the polymer prepared at 30°.

The number of particles produced in the emulsion polymerization of styrene depends primarily on the rate of particle formation, the rate of particle growth and the amount of soap available. A previous approximate discussion of this problem[1a] indicates that the number N, of polymer particles produced per ml. of water solution up to the time that all the soap becomes adsorbed on polymer particles should be given by a law of the type

$$N = k(\rho/\mu)^{2/5}(a_s S)^{3/5}$$

where k is a numerical constant with a value between 0.37 and 0.53, ρ is the initial rate of formation of polymer particles per ml. of water solution, μ is the rate of increase in volume of a polymerizing polymer particle, and $(a_s S)$ is the interfacial area of the initial soap micelles per ml. of water solution. Thus measurements of the number of particles and rate of polymerization should yield information on the initial rate of formation of polymer particles. The second column of Table III gives the average volumes of the polymer particles produced in the last sample of each sequence of runs listed in Table I.

From this volume and the polymer content of Table I the number of particles per ml. is calculated and given in column 3. From the polymer content as a function of time given in Table I, the rate of polymerization is calculated by

TABLE III

TOTAL NUMBER AND INITIAL RATE OF FORMATION OF PARTICLES

Temp., °C.	Average volume of particles, cc.	Number of particles,[a] N	Rate of pol. per particle, g./sec.	Initial rate of particle formation,[a] ρ, sec.$^{-1}$

fitting the data (except for the high conversions) with a least-squares straight line. This rate divided by the number of particles gives the rate of polymerization per particle given in column 4. The value of the initial rate of particle formation given in the last column is calculated from the equation given above. In making the calculation the lower value of k, namely, 0.37, was used. The interfacial area for soap micelles was taken to be 6×10^6 cm.^{2}/g. The rate of polymerization per particle given in column four was multiplied by 2.6 to obtain the rate of volume increase, μ. The factor of 2.6 comes from the measured ratio between volume of swollen particle and weight of polymer found for polystyrene latex particles swollen to equilibrium with liquid styrene at 50°.[1a] These values for the initial rate of particle formation cannot be considered to be at all accurate since small errors in the particle size measurements become greatly magnified in calculating ρ due to raising to the power 15/2.

Under conditions of constant molecular weight and rate of polymerization the rate of polymer molecule formation is given by dividing the rate of polymerization by the molecular weight. The effect of concentration of polymer particles on rate of molecule formation is shown in Table IV.

TABLE IV

RATE OF POLYMER MOLECULE FORMATION—EFFECT OF NUMBER OF POLYMER PARTICLES

(Seed)[b]	2.9×10^{13}	4.68×10^{-6}	2.8	0.85×10^6	3.3×10^{12}

[a] Per ml. of water solution (excluding polymer). [b] These charges were prepared using a small amount of previously polymerized polystyrene latex as seed but with no added soap.

The number of polymer particles and hence rates of polymerization were varied by varying

the soap concentration and in two cases by using seed polystyrene particles with no added soap. The rates of polymerization given are from least-squares treatment of the yield data in the range in which the yield appears linear with time. The intrinsic viscosity given in column four is the average for the three or four last runs in each sequence which appear to have substantially constant intrinsic viscosities. The molecular weight was estimated from the intrinsic viscosity as discussed above. The rate of molecule formation is the rate of polymerization multiplied by Avogadro's number and divided by the molecular weight. This table indicates that the rate of molecule formation approaches a constant for the lower particle concentrations but becomes greater for the higher concentrations; in fact, the data suggest that the molecular weight may be approaching a maximum limiting value at the highest particle concentrations. The simplest interpretation is that the molecular weight is limited in the high region by chain transfer with styrene monomer and that the rate of initiation is constant. When the number of particles is small enough, free radicals enter the particles sufficiently rapidly that almost all the polymer molecules are formed by mutual termination of radicals and only a negligible fraction by self-transfer. The 50° data are consistent with the assumptions of a constant rate of initiation and a self-transfer constant of 10^{-5}. This order of magnitude is the same as that to be reported by Mayo, Gregg and Matheson[6] for transfer with the monomer in oil phase.

The effect of persulfate concentration on the rate of molecule formation is shown in Table V.

The various quantities in this table are obtained in the same manner as the corresponding quantities in Table IV. These data show the expected increase in rate of molecule formation with increase in concentration of persulfate. At the higher temperature, 70°, the rate of molecule formation is very nearly proportional to the persulfate concentration. At 50° this does not appear to be the case but the lack of proportionality may be due to the fact that an appreciable fraction of the molecules are formed by transfer with styrene when the persulfate concentration is low.

To obtain the temperature coefficient, studies were made at the four temperatures given in Table VI. Again the various quantities are obtained in the same manner as those in Table IV. Analysis of these data by the Arrhenius rate equation using the method of least squares gives 28 kcal. for the activation energy of molecule formation.

The rate of sulfur combination, initial rate of particle formation and rate of polymer molecule formation must all be related to the rate of chain initiation process and hence they must themselves be interrelated. They are compared in Table VII.

The rate of sulfur combination is obtained by dividing the rate of polymerization (Tables IV, V and VI) by the grams of polymer per mole of sulfur (Table II), then multiplying by Avogadro's number. The initial rate of polymer particle formation is the same value as that given in Table III. For comparison the rates of molecule formation from Tables IV, V and VI are multiplied by 2 and inserted in Table VII. The factor of 2 is used because the formation of each molecule requires two free radicals. These three quantities agree within an order of magnitude indicating that, indeed, all three are determined principally by the rate of initiation reaction. The comparison of the rate of sulfur combination with the

[a] Rates are given in number, atoms or molecules per second per ml. of water solution.

rate of molecule formation is really the same comparison which was made in Table II. While the initial rates of polymer particle formation are consistently lower than the rates of molecule formation, not much significance can be attached to this because of the larger error and uncertainty involved in calculating the initial rate of particle formation. Of the three methods for determining the rate of free radical formation by the initiation reaction, the rate of molecule formation is the most reliable.

Summary

The rate of persulfate combination from radioactivity measurements, the initial rate of polymer particle formation from polymer particle size measurements, and the rate of molecule formation from molecular weight measurements have been obtained for styrene emulsion polymerization, and all three quantities agree within an order of magnitude. This indicates that all three are determined principally by the rate of formation of free radicals.

The rate of free radical formation does not appear to depend on the interfacial area between organic and aqueous phases.

The Structure of Neoprene. IV. Infrared Spectra and Spectral Changes with Crystallization[1]

BY W. E. MOCHEL AND M. B. HALL

Infrared spectroscopy has been valuable in elucidation of some structural features of high polymers and was therefore applied to the current examination of neoprene (polychloroprene). The infrared spectrum of neoprene has been reported previously[2] and the statement has been made that there are differences between polychloroprenes made under different conditions of polymerization.[3] However, no description of the differences has appeared. In the present study, examination of Neoprenes Type GN and Type CG and analysis of the dichroic effects in their spectra together with comparison with the infrared absorption of polybromoprene have yielded a more complete and reliable interpretation of the spectrum of neoprene than was previously available. These particular neoprenes were selected for study because they are illustrative of the effect of polymerization temperature on the rate of crystallization,[4] *i. e.*, Neoprene Type CG, made at 10°, crystallizes in a few hours at room temperature while Neoprene Type GN, made at 40° in essentially the same emulsion system, requires many days for crystallization to a comparable extent. The crystallization of neoprenes in general has been well established[5] by X-ray diffraction, dilatometry and other methods but the structural differences responsible for observed differences in crystallization rates have not been clearly demonstrated.

Experimental

Materials.—For many of the experiments commercial samples of Neoprene Type CG and Neoprene Type GN were used. To remove undesirable polymerization adjuvants from such samples, they were extracted with acetone in A.S.T.M. extractors or were dissolved in benzene and completely precipitated with methanol. Laboratory samples were also prepared using the emulsion system previously described.[4] The polymers were isolated from the alkaline latices by coagulation with large volumes of alcohol, since it was found that this procedure gave products practically free from sodium rosinate, rosin and other polymerization residues. The polymers were dried *in vacuo* at room temperature and kept under nitrogen.

To prepare films the dry polymers were dissolved in benzene to form solutions of known concentration which were used to cast films inside glass rings on a mercury surface. After the film was dry the ring could be lifted and the attached film examined directly or transferred to another specimen holder. Films were also prepared directly from the latices by filtration on porous battery cups.[6] Films 20–35 microns in thickness were generally used for infrared studies.

Instruments.—Two different instruments were used to obtain the data presented here. For most of the work in the wave length range 2–14 microns there was used a prism instrument after

the design of Wright,[7] employing a 60° rock salt prism with a six-inch base. The 2–4-micron range was examined in the same instrument at a resolution sufficient to show clearly the chlorine isotope split in hydrogen chloride, by replacing the prism with a 7200-lines-per-inch grating. The recording system employed a split beam and the ratio recorder described by Wild.[8]

In most of the work a Nernst filament was used as source for the 15–23-micron region to avoid the sharp minimum at 16.2 microns in the globar emission. The radiation was polarized when desired by reflecting it at the Brewsterian angle from a selenium mirror according to the method of Pfund.[9] Since the beam striking the selenium mirror is converging, all the rays cannot be incident at exactly the Brewsterian angle, and hence complete polarization cannot be achieved.[10] However, this was not an important limitation since complete orientation could not be produced in the polymer samples under study. In general, the absorption bands reported are accurate to 5 wave numbers except in the cases of overlapping bands, where somewhat greater error may be involved.

For some of the work in the range 2-15 microns and for all of the work at longer wave lengths, a Perkin–Elmer spectrometer was used with a rock salt prism for some purposes and a potassium bromide prism for others. The light entering the Perkin–Elmer instrument was polarized when desired by use of the selenium mirror. The reflection from the selenium mirror was arranged to cause reinforcement of the polarization produced by the prism in the spectrometer.

Results and Discussion

Crystallization Effects.—The most striking feature in the spectra of the neoprenes is the existence in crystallized polymer of strong bands which do not appear in the completely amorphous material. Thus Neoprene Type CG, normally crystalline at room temperature, exhibits absorption bands at 578, 781 and 955 wave numbers (cm.$^{-1}$) which do not appear in the spectrum of the non-crystalline Neoprene Type GN (Fig. 1). These bands do not appear in the spectrum of Neoprene Type CG until the polymer crystallizes and they are present in the spectrum of Neoprene Type GN when the polymer is crystallized by stretching to 800–1000% elongation. (A very weak band at 781 cm.$^{-1}$ appeared in the spectra of some aged, unstretched Neoprene Type GN samples.) They can also be intensified in crystalline Neoprene Type CG by stretching the sample and examining it in that condition. Although these bands appear in the spectrum for

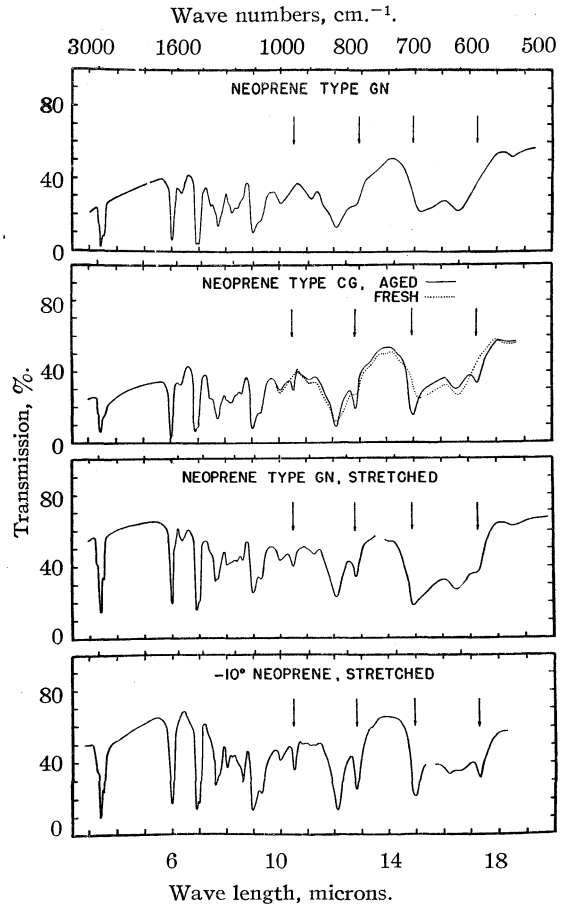

Fig. 1.—Comparison of the infrared spectra of unstretched Neoprene Type GN one day old, unstretched Neoprene Type CG fresh and one day old, stretched Neoprene Type GN and stretched neoprene made at −10°. The arrows indicate absorption bands which are associated with crystallization.

Neoprene Type GN examined while it is stretched, a stretched and then relaxed sample fails to show the bands. Furthermore, these absorption bands disappear from the spectrum of a sample of Neoprene Type CG heated to 50° to melt the crystallites. These absorption bands therefore definitely appear to be associated with crystallization in neoprene.[11]

It was also found that a band maximum at 658 cm.$^{-1}$ exhibited by both polymers is greatly enhanced by crystallization and shifted some 10 cm.$^{-1}$ to 667 cm.$^{-1}$. Crystallization causes less pronounced spectral changes in a group of maxima between 1150 and 1250 cm.$^{-1}$ amounting essentially to an increase in intensity of the bands at

(8) Wild, *Rev. Sci. Instruments*, **18**, 436 (1947).

(9) Pfund, *Astrophys. J.*, **24**, 19 (1906).

(10) Since the work described here was done, Pfund has designed an improved polarizer which overcomes this difficulty; see Pfund, *J. Optical Soc. Am.*, **37**, 558 (1947).

(11) Differences in the spectra of low molecular weight materials as a result of state of aggregation have been reported: *e. g.*, see Thompson, *Nature*, **158**, 234 (1946), and Richards and Thompson, *Proc. Roy. Soc., (London)*, **A195**, 1 (1948). Williams and Taschek, *J. Appl. Phys.*, **8**, 497 (1937), observed in the spectrum of natural rubber stretched radially, the appearance of a relatively intense band at 2084 cm.$^{-1}$ where there is no intense absorption in the unstretched material.

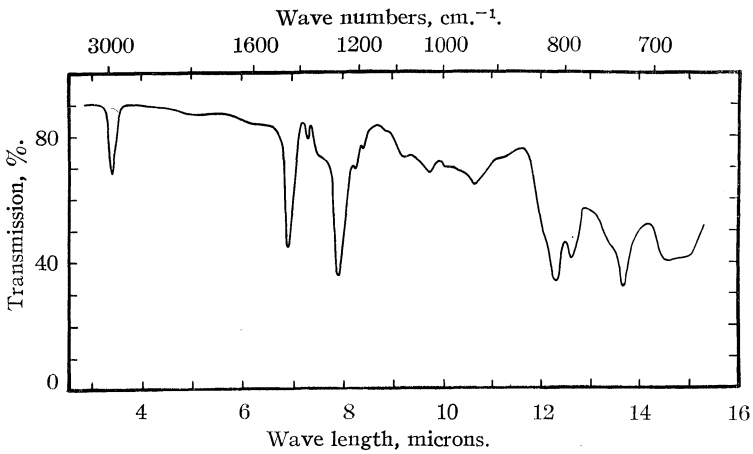

Fig. 2.—Infrared absorption spectra of chlorinated neoprene.

1162 and 1250 cm.$^{-1}$. A weak, perpendicular band which is enhanced by crystallization occurs at about 475 cm.$^{-1}$ in the spectra of crystalline samples. Its presence in other records is doubtful because of the overlapping water vapor rotation lines.

An experimental polychloroprene[12] made at −10° crystallizes in a few seconds, compared to hours for Neoprene Type CG and days for Type GN, but with the exception of somewhat greater intensity in the crystalline-phase bands, it shows no marked spectral differences from Neoprene Type CG.

Except for these crystalline-phase bands there appear to be no significant differences qualitatively among the infrared absorption patterns of the various neoprenes under discussion.[13] Careful examination at high resolution in the 3-micron region, using a grating, revealed no differences in C–H vibrations. There was no evidence for the presence of side vinyl groups from 1,2- or 3,4-addition polymer.[14] Furthermore, chlorinated neoprenes[15] made from both Type GN and Type CG appeared identical in infrared absorption, indicating no difference in structure (Fig. 2). Of course, any geometrical differences in arrangement about the double bonds of the respective neoprenes would be lost on chlorination.

Dichroism.—Examination of stretched Neoprenes Type CG and Type GN with polarized infrared radiation revealed a strong dichroism.[16] The crystalline-phase bands are very prominent for stretched films examined with direction of stretch perpendicular to the vibration plane[17] but are absent or relatively insignificant when the direction of stretch is parallel to the vibration plane (Fig. 3). In addition, several other absorption bands of stretched neoprene are dichroic. For example, it has been shown that the band at 1667 cm.$^{-1}$ in neoprene is similar in dichroism to that of balata, the natural *trans*-polyisoprene. In both polymers this band has maximum intensity when the direction of stretch is perpendicular to the vibration plane. On the other hand, the 1667 cm.$^{-1}$ band of Hevea

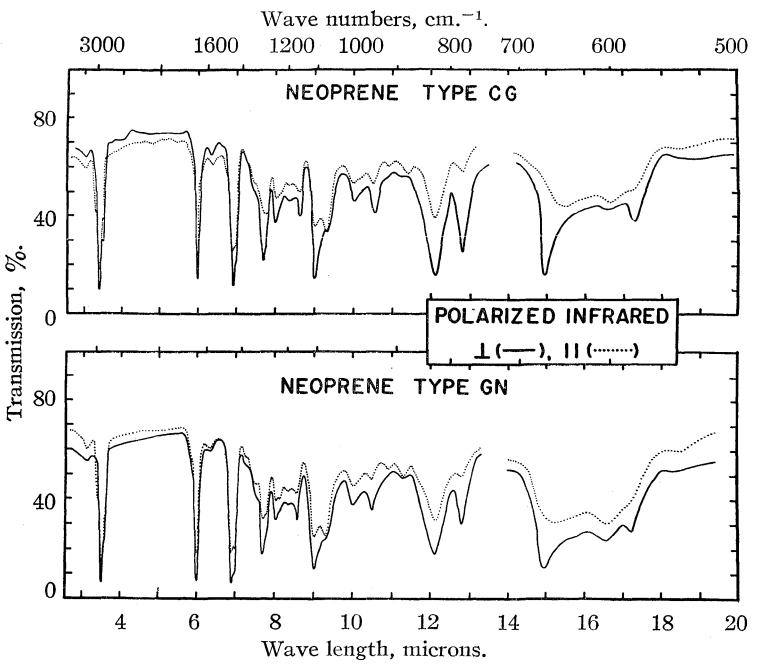

Fig. 3.—Comparison of infrared absorption of stretched Neoprene Type CG and Neoprene Type GN when examined with polarized infrared radiation. Perpendicular (⊥) refers to results obtained when the direction of stretch was perpendicular to the vibration plane.

(12) The authors are indebted to Dr. R. S. Barrows of the Organic Chemicals Department, Jackson Laboratory, E. I. du Pont de Nemours and Company, for supplying this polymer.

(13) The spectra exhibit slight quantitative differences which have not been completely established as yet.

(14) Unpublished ozonolysis studies confirm the absence of appreciable amounts of side vinyl groups. *Cf.* also Rabjohn, *et al.*, THIS JOURNAL, **69**, 314 (1947).

(16) There have appeared in the literature several reports of other studies of polymers by means of polarized infrared. See Thompson and Torkington, *Trans. Faraday Soc.*, **41**, 260 (1945); Mann and Thompson, *Nature*, **160**, 17 (1947); Thompson, *J. Chem. Soc.*, 289 (1947); Sutherland and Jones, *Nature*, **160**, 567 (1947); Elliott and Ambrose, *ibid.*, **159**, 641 (1947); Glatt and Ellis, *J. Chem. Phys.*, **15**, 880, 884 (1947); *ibid.*, **16**, 551 (1948); Elliott, Ambrose and Temple, *ibid.*, **16**, 877 (1948).

(17) A band that is stronger when the direction of stretch and the vibration plane are perpendicular than when they are parallel will be referred to as a "perpendicular" band as distinct from a "parallel" band, the intensity of which is a maximum when the vibration plane and direction of stretch are parallel.

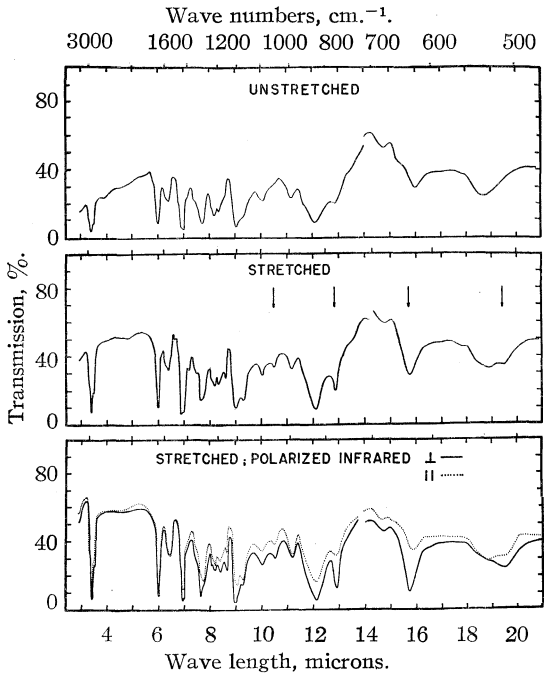

Fig. 4.—Infrared absorption spectra of polybromoprene unstretched, stretched approximately 500% and examined with polarized infrared radiation.

rubber, the *cis*-isomer,[18] has its maximum intensity when the direction of stretch is parallel to the vibration plane of the polarized radiation.[19]

Polybromoprene.—To ascertain which of the bands in the neoprene spectrum result from vibrations involving the C–Cl bonds, samples of polybromoprene[20] were prepared at 40° and their infrared spectra studied using both polarized and non-polarized radiation (Fig. 4). The spectra obtained were very similar, even with respect to dichroism and effects of crystallization, and they demonstrated that the vibrations appreciably involving the C–Cl bonds all lie at longer wave lengths than 15 microns (667 cm.$^{-1}$). The band at 826 cm.$^{-1}$ (12.1 microns) in all polychloroprene spectra and the band that appears at 781 cm.$^{-1}$ when the sample is stretched or when crystallization occurs on aging, occur at 824 and 776 cm.$^{-1}$, respectively, in the polybromoprene spectrum.

Poly-2,3-dichloro-1,3-butadiene.—Another reference compound examined was poly-2,3-dichloro-1,3-butadiene,[21] which was informative in indicating that the band at 1078 cm.$^{-1}$ in the neoprene spectrum involves a bending of the olefinic C–H bond in the plane parallel to the chains. Such a vibration is expected to give rise to a band in the neighborhood of 1100 cm.$^{-1}$. The band at 1078 cm.$^{-1}$ in the neoprene spectrum, rather than the one at 1112 cm.$^{-1}$, is probably the expected one since the only band near this position in the spectrum of polydichlorobutadiene, which has no olefinic C–H, is a perpendicular band at 1095 cm.$^{-1}$ resembling the 1112 cm.$^{-1}$ band of neoprene (Fig. 5). The 1078 cm.$^{-1}$ band, on the other hand, shows little or no dichroism. The various other C–H bending and stretching and double bond stretching bands occur at the expected positions.

A hysteresis in the relation between polarized infrared absorption and stretching was indicated in the case of Neoprene Type GN, suggesting a slow change in ordering or orientation following stretching. The dichroism of the bands at 578, 667, 781 and 955 cm.$^{-1}$ increased slowly over a period of several days following stretching.

Molecular weight was eliminated as an important factor in the changes of infrared absorption observed since no significant differences were found in the spectra of fractions of Neoprene Type CG ranging from 23,000 to 210,000 and fractions of Neoprene Type GN ranging from 44,000 to 250,000 in molecular weight. Furthermore, there were no apparent differences between sol and gel samples of the same polymer.

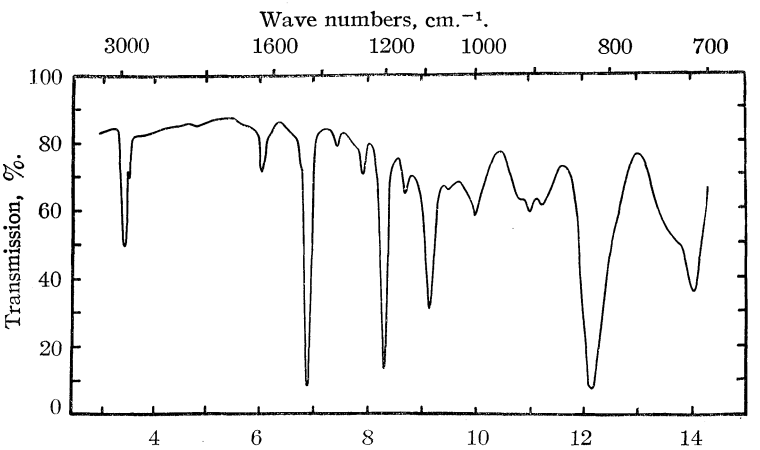

Fig. 5.—Infrared absorption of poly-2,3-dichlorobutadiene examined unstretched.

Interpretation of Results

Table I gives a description of representative neoprene spectra and lists assignments, some of them tentative, of the stronger bands to vibrating groups.

Neglecting small frequency (less than about 5 cm.$^{-1}$) and intensity differences, the only prominent bands present in neoprene, but absent in

[a] Potassium bromide prism used for region 450 to 700 cm.$^{-1}$; rock salt prism used for region 700 to 4000 cm.$^{-1}$. [b] Very weak bands which are sometimes imperceptible. A very weak absorption in some neoprene spectra near 475 cm.$^{-1}$ has been neglected. [c] A perpendicular band (⊥) has maximum absorption when the direction of stretch is perpendicular to the vibration plane. A parallel band (∥) has maximum absorption in parallel position.

polybromoprene, are those at 578 and 667 cm.$^{-1}$ and the broad absorption around 602 cm.$^{-1}$. These bands in neoprene have certain characteristics that serve to identify the corresponding bands in the polybromoprene spectrum. The band that appears at 578 cm.$^{-1}$ at the edge of the broad 602 cm.$^{-1}$ absorption in the spectrum of crystalline neoprene, but not in amorphous neoprene, is a perpendicular-type band. A much weaker band at 505 cm.$^{-1}$, a shoulder only, at the edge of the 530 cm.$^{-1}$ absorption is probably the corresponding band in the polybromoprene spectrum, since it also is a perpendicular band with intensity in the unstretched polymer diminished relative to that in the stretched polymer.

The 658 cm.$^{-1}$ band of non-crystalline neoprene appears with greatly enhanced intensity and with its peak shifted some 10 cm.$^{-1}$ to 667 cm.$^{-1}$ in the crystalline neoprene. It is likewise a perpendicular-type band. The band in the stretched polybromoprene spectrum at 635 cm.$^{-1}$ behaves similarly in each respect and otherwise resembles the 667 cm.$^{-1}$ band of neoprene. It is therefore believed to arise from a vibration of the same form.

The absorption in neoprene with its center at 602 cm.$^{-1}$ and that in polybromoprene with its center at 530 cm.$^{-1}$ probably arise from the same vibrations, since they are both broad absorptions insensitive to crystallization and only very slightly dichroic in stretched samples.

Evidently, then, the vibrations giving rise to bands at 578, 602 and 667 cm.$^{-1}$ in the neoprene spectrum strongly involve the C–Cl bond. Of these, the 578 and 602 cm.$^{-1}$ bands apparently result from vibrations in which the chlorine component is about the same as it would be in a hypothetical diatomic radical C–Cl, since replacement of chlorine by bromine shifts the bands about the amount estimated for a similar sub-

TABLE I (*Continued*)

Remarks	Assignments
Shifted about 70 cm.$^{-1}$ by Cl $->$ Br substitution. Appears with crystallization. Strongly perpendicular[c]	Vibrations involving CCl bond strongly. Cl motion about same as in simple CCl structure
Broad (about 50 cm.$^{-1}$). Shifted about 70 cm.$^{-1}$ by Cl $->$ Br substitution. Very little dichroism	
Peak frequency decreased about 30 cm.$^{-1}$ by Cl $->$ Br substitution. Strongly enhanced by crystallization. Strongly perpendicular	Vibration involving CCl bond. Cl motion less than in simple CCl
Appears with crystallization. Very strongly perpendicular. Frequency lowered about 5 cm.$^{-1}$ by Cl $->$ Br substitution	
Shoulder at about 855 cm.$^{-1}$ fades and band narrows with crystallization. Strongly perpendicular	Probably CH_2 deformation vibration
Very weak, parallel band. Stronger, but less parallel in polybromoprene	
Very weak, parallel band	
Appears with crystallization. Strongly perpendicular	Suggest sum frequency: 955 = 781 + 174
	Suggest sum frequency: 1002 = 826 + 176
Apparently little or no dichroism	Olefinic CH parallel bending vibration
Strongly dichroic	
Envelope of four overlapping bands; 1162 and 1250 cm.$^{-1}$ bands strongly perpendicular and enhanced by crystallization, especially stretching	
Other overlapping shoulders at about 1290, 1350 and 1390 cm.$^{-1}$; 1315 cm.$^{-1}$ band strongly perpendicular	
Apparently perpendicular	CH_2 bending vibrations
Perpendicular	
Broad absorption sometimes present	
Perpendicular	Double bond stretching vibration
At least five bands on grating records: at about 2835, 2850, 2920, 2950, and 3020 cm.$^{-1}$ for neoprenes; at about 2825, 2840, 2915, 2945 and 3000 cm.$^{-1}$ for polybromoprene	Saturated CH stretching
	Olefinic CH stretching

stitution in the C–Cl radical. In the case of the 667 cm.$^{-1}$ band the shift is less than that predicted for the C–Cl radical. The band at 826 cm.$^{-1}$, which appears in the spectra of all neoprenes, cannot involve the C–Cl bond appreciably because it occurs within two wave numbers of the same place in the polybromoprene spectrum. The high intensity of this 826 cm.$^{-1}$ band in neoprene and the fact that it is strongly perpendicular suggest that it arises from a vibration consisting essentially of a hydrogen deformation, since it does not arise from a vibration involving the chlorine atom.[22]

The similarities between the bands at 781 cm.$^{-1}$ and 955 cm.$^{-1}$ and between those at 826 cm.$^{-1}$ and 1002 cm.$^{-1}$ suggest that the 955 and 1002 cm.$^{-1}$ bands are sum frequencies involving a vibration of about 175 cm.$^{-1}$ plus the 781 and 826 cm.$^{-1}$ bands, respectively.

(22) A perpendicular band at 735 cm.$^{-1}$ in polythene has been assigned to a hydrogen deformation vibration on the basis of deuterium substitution data; Sheppard and Sutherland, *Nature*, **159**, 739 (1947).

The appearance of strong absorption bands as a result of crystallization of the polymer is a phenomenon that apparently has not been recognized previously in high polymers. Evidently it is a factor that must not be neglected in the interpretation of the spectra of polymers. In the spectrum of neoprene the crystalline-phase bands appear to be associated with several different vibrations. The band at 578 cm.$^{-1}$ involves strong motion of the chlorine atom while those at 781 and 955 cm.$^{-1}$ involve very little. All of these bands are of maximum intensity in the oriented polymer when the vibration plane and direction of stretch are perpendicular and are absent or nearly so when the vibration plane and direction of stretch are parallel.

That such bands should appear as a result of crystallization is curious. One might have expected a large decrease—rather than an increase—in the intensity of a strongly dichroic band as a result of simply orienting the sample, as in stretching. For, neglecting background, a perfectly oriented sample would be transparent to one

component of radiation of the wave length of a completely perpendicular or parallel band. Hence, when non-polarized radiation is used, Beer's law should not apply for dichroic bands of oriented samples. This effect would, therefore, tend to counteract and thus partially obscure the observed increase in absorption.

While we have been unable to confirm any of several explanations for these bands apparently caused by crystallization, at present we are inclined to consider them the result of very large intensity increases in imperceptible absorptions of the amorphous polymer. Considered from the point of view of the simple classical theory, the rate of absorption of energy from the infrared field by the absorbing structures will increase with the amplitude of vibrations in those structures. Accordingly, we might expect bands to be greatly enhanced if increasing order in the sample suppresses the processes responsible for removal of absorbed energy from the vibrating groups.

That more extensive modes of vibration should develop upon crystallization or that a recoupling of vibrating components should render infrared-active in the crystalline polymer a vibration which was inactive in the amorphous material, would imply an extension of the regions of rigidity requiring stronger forces than appear to be involved in crystallization or would imply the existence of very unlikely, unstable equilibria. A simple explanation of the appearance of the bands in terms of combination frequencies, resonance splitting, or in terms of the changes in the mutual electrostatic interaction of proximate, similar (and also similarly oriented) vibrating groups is unsatisfactory because of such factors as the sharpness of the bands and the absence of other expected components.

The differences in chemical structure between Neoprene Type CG and Type GN must be relatively small since they are not revealed by infrared. Furthermore, it is probable that the differences are only in degree, which would be revealed only by precise quantitative measurements. The spectra have not been completely elucidated but there is no evidence to indicate the presence of any 1,2- or 3,4-polychloroprene.[23] This has also been the result of an independent observation.[24] *cis*- and *trans*-2-chloro-2-butenes were examined by infrared as possible reference compounds to distinguish *cis* and *trans* structures in neoprene, but apparently were too low in chain length to serve as reference compounds, since the absorption bands were considerably shifted in many cases from their positions in the neoprene spectrum.

(23) Patat in an I. G. Report dated February 17, 1943, reported by the U. S. Technical Oil Mission, (Reel No. 53, Bag 3413, Frames 00385–00392) stated that in polycholoroprene made in emulsion at 0°, 1,2-polymers predominate but at 60°, 1,4-polymerization is most prevalent. The present authors, on the basis of results obtained in this Laboratory, cannot agree with such a hypothesis.

Acknowledgments.—The authors are indebted to their colleagues, Drs. J. R. Downing, S. L. Scott and C. J. Mighton for the initial discovery that the infrared spectra of Neoprenes Type GN and Type CG are different and to Miss Doris Huck for her assistance with the infrared measurements. Acknowledgments likewise are made to Drs. A. W. Kenney, D. M. McQueen, G. D. Patterson and B. C. Pratt for aid and encouragement and to many staff members of the Organic Chemicals Department of this Company for valuable criticisms and advice. The authors are particularly thankful to Professors R. C. Lord, F. T. Wall, J. A. Wheeler and the late A. H. Pfund for many helpful discussions.

Summary

Infrared absorption spectra of amorphous and crystalline Neoprenes Type CG and Type GN have been studied in the wave length range 2–23 microns. Spectra of polybromoprene and poly-2,3-dichloro-1,3-butadiene, the dichroism of stretched samples and spectral changes accompanying crystallization have been used to assign most of the strong bands to vibrations of more or less limited regions of the molecule. The spectra appear to be unchanged by variations in molecular weight or sol–gel relationships.

Spectral changes, some very pronounced, accompany crystallization of neoprene, either in the unstretched state or following stretching. Perceptible spectral changes were found to occur for several days following stretching of Neoprene Type GN, which crystallizes slowly. These spectral changes, particularly the surprising appearance of strong absorption bands when the polymer crystallizes, are of interest because of their relation to order in the polymer. The appearance of bands because of crystallization has been tentatively ascribed to very large intensity increases in normally imperceptible absorptions of the amorphous polymer caused by suppression in the ordered molecules of some processes responsible for dissipation of absorbed energy from the vibrations.

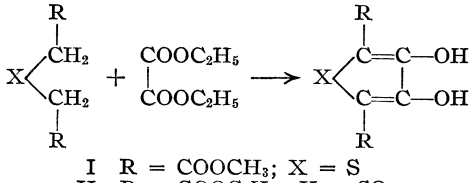
Ultraviolet Absorption Spectra and Acidic Strengths of Certain Dihydroxythiophene-1-oxides and 1-Dioxides[1,2]

BY RICHARD H. EASTMAN AND ROBERT M. WAGNER[3]

Introduction

As part of a program devised to evaluate the electrical effect of the sulfur atom in various states of oxidation on contiguous groups in organic molecules we have prepared 2,5-dicarbomethoxy-3,4-dihydroxythiophene (I),[4] 2,5-dicarbethoxy-3,4-dihydroxythiophene-1-oxide (II), 2,5-dicarbethoxy - 3,4 - dihydroxyethiophene - 1 - dioxide (III), 3,4-dihydroxy-2,5-diphenylthiophene-1-dioxide (IV), 2,5-dicarbethoxy-3,4-dihydroxyfuran (V),[5] 2,5-dicarbethoxy-3,4-dihydroxycyclopentadiene-2,4 (VI)[6], and N-ethyl-2,5-dicarbethoxy-3,4-dihydroxypyrrole (VII)[7] by the oxalic ester condensations as indicated schematically:



I R = $COOCH_3$; X = S
II R = $COOC_2H_5$; X = SO
III R = $COOC_2H_5$; X = SO_2
IV R = C_6H_5; X = SO_2
V R = $COOC_2H_5$; X = O
VI R = $COOC_2H_5$; X = CH_2
VII R = $COOC_2H_5$; X = C_2H_5N

The electrical effect of the sulfur atom in various states of oxidation (Compounds I, II, III, IV) and that of other hetero-atoms (Compounds V, VII) on the properties of the ester condensation products has been assessed by measurement of acidic strengths and ultraviolet absorption spectra.

Experimental[8]

A. Preparation of Compounds. 2,5-Dicarbomethoxy-3,4-dihydroxythiophene (I).—The compound was prepared according to the directions given by Hinsberg.[4] Our material had m. p. 177° (reported 177°) and gave a green color with ferric chloride in alcohol.

2,5-Dicarbethoxy-3,4-dihydroxythiophene-1-oxide (II).—To fifteen grams of ethyl thiodiacetate dissolved in 20 ml. of acetone was added 7.5 ml. of 30% hydrogen peroxide solution. After four days acetone was removed at reduced pressure, benzene was added and the mixture was distilled until the distillate was clear. The residue on distillation yielded 9.0 g. of **ethyl sulfinyldiacetate**, an oil of b. p. 140–146° (4 mm.).

Eight grams of ethyl sulfinyldiacetate and 5.3 g. of ethyl oxalate were added to a solution of 1.7 g. of sodium dissolved in 30 ml. of absolute methanol. The reaction mixture was heated under reflux for one hour, allowed to stand twelve hours, and then decomposed by addition to three times its volume of water which contained 2.2 ml. of concentrated hydrochloric acid. The precipitate which appeared was separated by filtration, washed with methanol and crystallized from methanol four times to yield 1.2 g. of white needles, of m. p. 121–122°. The compound gave a green color with ferric chloride in alcohol and analyzed for 2,5-dicarbethoxy-3,4-dihydroxythiophene-1-oxide (II). The equivalent weight was determined as described below under C.

Anal. Calcd. for $C_{10}H_{12}O_7S$: C, 43.5; H, 4.38; neut. equiv. (two acidic groups), 138. Found: C, 43.8; H, 4.55; neut. equiv., 137.

2,5-Dicarbethoxy-3,4-dihydroxythiophene-1-dioxide (III).—Sulfonyldiacetic acid[9] was prepared in 85% yield by hydrogen peroxide oxidation of thiodiacetic acid in glacial acetic acid. Our material had m. p. 184–185° (reported[7] 182°) after crystallization from concentrated hydrochloric acid.

A mixture of 98.0 g. of sulfonyldiacetic acid, 135 ml. of 95% ethanol, 2.0 g. of toluenesulfonic acid, and 500 ml. of benzene was refluxed with an attached water separator until no water appeared in the condensate. The reaction mixture was washed thoroughly with water, the benzene was removed by distillation, and the residue was distilled at reduced pressure to yield 118 g. of **ethyl sulfonyldiacetate,**[10] a colorless oil of b. p. 178–181° (5 mm.), d^{27} 1.258, $n^{25}D$ 1.4652.

To a warm solution of 20 g. of sodium in 200 cc. of absolute ethanol was added, in portions with stirring, a mixture of 44 g. of ethyl oxalate and 69 g. of ethyl sulfonyldiacetate. When the mildly exothermic reaction had subsided, the reaction mixture was heated for one hour on the steam-bath. The mixture was centrifuged and the gummy solid obtained was spread on glass plates where it dried in twelve hours to a bright-yellow powder. Forty-three grams of the yellow powder was dissolved in 150 ml. of water and acidified to *p*H 1 with concentrated nitric acid, and to the solution was added, with stirring, a solution of 150 g. of mercurous nitrate in 150 ml. of dilute nitric acid. The precipitated mercurous salt was separated by filtration, washed with water, and suspended in 100 ml. of water. To the suspension was added an excess of concentrated hydrochloric acid. The calomel which precipitated was separated by filtration and the filtrate was concentrated to one-third its original volume by distillation at reduced pressure. The crystalline material which separated was collected, washed with concentrated hydrochloric acid, crystallized twice from small volumes of 20% hydrochloric acid, and twice from benzene after drying to yield 17 g. of 2,5-dicarboxy-3,4-dihydroxythiophene-1-dioxide (III) in the form of white cubes of m. p. 116–117.5°.

Anal. Calcd. for $C_{10}H_{12}O_8S$: C, 41.1; H, 4.14; neut. equiv., 146 (two acidic groups); C-methyl, 2 (two ethyl ester groups); active H, 2 per mol. wt., 292. Found: C, 41.4; H, 3.98; neut. equiv., 146; C-methyl, 1.88; active H, 1.97, 2.00.

The compound is very soluble in water to give a yellow

solution, crystallizable from strongly acidic, aqueous solutions and benzene, is strongly acidic in reaction (*cf.* Discussion) and gives a wine-red coloration with ferric chloride in water or alcohol.

The solubility in water and the high acidity of 2,5-dicarbethoxy-3,4-dihydroxythiophene-1-dioxide caused difficulty in the isolation of the compound. Thus, although the compound is soluble in ether, a strongly acidified solution of the above-described reaction mixture could be extracted continuously with ether without any of the free acid appearing in the ether phase. Isolation was achieved by formation of the barium salt which was insoluble in 1:1 ethyl alcohol–water, followed by reaction of it with the calculated amount of sulfuric acid, and by the use of a cation exchange resin in the hydrogen cycle; but both of these methods proved inferior to the above-described separation through the mercurous salt.

3,4-Dihydroxy-2,5-diphenylthiophene-1-dioxide (IV).—Five grams of dibenzyl sulfone, 3.0 g. of ethyl oxalate, and 3.0 g. of dry sodium methoxide were heated together for one hour during which time 2.9 ml. of low-boiling liquid distilled from the reaction mixture. The dark residue was dissolved in 100 ml. of water and the solution was acidified to *p*H 2 with concentrated hydrochloric acid. The solid which separated was collected and crystallized from 1:3 ethanol–benzene to give 3.5 g. of 3,4-dihydroxy-2,5-diphenylthiophene-1-dioxide, white crystals of m. p. 232–233°.

Anal. Calcd. for $C_{16}H_{12}O_4S$: C, 64.1; H, 4.06; S, 10.7; neut. equiv., 150 (two acidic groups). Found: C, 64.2; H, 4.12; S, 10.7; neut. equiv., 148.

The substance gave an orange color with ferric chloride in alcohol and dissolved in dilute sodium bicarbonate to give a deep yellow solution. Its neutral equivalent was determined by titration in an anhydrous medium as described below under C.

2,5-Dicarbethoxy-3,4-dihydroxyfuran (V).—The compound was prepared according to the directions given by Johnson and Johns.[5] Our material had m. p. 190° (reported[5] 189–190°) and gave a purple color with ferric chloride solution in alcohol.

2,5-Dicarbethoxy-3,4-dihydroxycyclopentadiene-2,4 (VI).—The compound was prepared according to the method of Dieckmann.[6] Our sample had m. p. 118° (reported[6] 118°) and gave a wine-red color with ferric chloride in alcohol.

N-Ethyl-2,5-dicarbethoxy-3,4-dihydroxypyrrole (VII).—**Ethylimino-bis-acetonitrile** was prepared by the method of Knoevenagel and Mercklin,[11] characterized as its hydrochloride of m. p. 112–113° (reported[11] 112–113°) and converted to **diethyl N-ethyliminodiacetate** by alcoholysis according to Curtius.[12] Our sample of the latter compound had b. p. 210–225° (11 mm.).

Five grams of diethyl N-ethyliminodiacetate and 3.5 g. of ethyl oxalate were added to a solution of 1.5 g. of sodium in 60 ml. of absolute ethanol. The reaction mixture was heated gently for one hour, distilled nearly to dryness in a stream of nitrogen, and the residue was dissolved in 50 ml. of water. Acidification of the solution with 5.3 ml. of concentrated hydrochloric acid threw down a white precipitate which was collected, washed with water, and crystallized from 50% alcohol to yield 0.7 g. of N-ethyl-2,5-dicarbethoxy-3,4-dihydroxypyrrole, white crystals of m. p. 83–83.5°.

Anal. Calcd. for $C_{12}H_{17}O_6N$: C, 53.1; H, 6.33; N, 5.17. Found: C, 53.4; H, 6.38; N, 5.13.

The compound was insoluble in water, gave a green ferric reaction in alcohol, and was decomposed by alkali as evidenced by the appearance of a transient yellow coloration when the substance was dissolved in dilute sodium hydroxide.

B. Determination of Ultraviolet Absorption Spectra.—The absorption characteristics of the compounds were studied in a variety of media using a Beckman Quartz Spectrophotometer, Model DU. The instrument was balanced by varying the slit width with the sensitivity knob kept three and one-half turns from the extreme clockwise position giving a maximum nominal band width of 2 mμ, and measurements were made at 5 mμ intervals.

The absorption characteristics of the compounds in the various media did not change during the time required for the observations, and, with the single exception of the study of N-ethyl-2,5-dicarbethoxy-3,4-dihydroxypyrrole which decomposed in alkaline media, there was no evidence, spectrophotometric or other, for decomposition of the compounds under the conditions employed. Thus, compounds I, VI and VII were recovered unchanged by dilution after one hour of solution in concentrated sulfuric acid. The spectra are reported in Figs.1–4.

C. Determination of Acidic Strengths.—Titration curves for the compounds were obtained in water and in an anhydrous medium composed of isopropyl alcohol and propylene glycol according to the method of Palit[13] using a Beckman *p*H meter. When the *p*H meter was used in the anhydrous medium, it was found necessary to equilibrate the glass electrode for several hours with the medium before use.

The pK values are taken as equal to the *p*H value at the half-neutralization points for the corresponding acidic hydrogens where the shape of the titration curve shows typical weak acid behavior.

The pK' values are similarly derived from titrations carried out in the anhydrous medium and are considered to be of value in establishing relative acidic strengths only. The similar calculation of the pK_2' values for the second enolic hydrogens of compounds I, II, III and IV is of little significance since in the titrations of these compounds the precipitation of a sodium or potassium salt commenced shortly after the equivalence point for the first hydrogen was reached. On the basis of the equilibria involved, this precipitation of the anion as a salt causes the acid to appear stronger than it actually is. Such values for pK_2' are bracketed in Table I.

The titration curves are plotted in Figs. 5 and 6, and the corresponding pK and pK' values are summarized in Table I. Some reference compounds are included to establish the validity of the method.

TABLE I

ACID STRENGTHS

Compound	In water pK_1	In water pK_2	In anhydrous medium[a] pK_1'	In anhydrous medium[a] pK_2'
Picric acid	Strong		Strong	
III	Strong	Strong[b]	Strong	(4.1)
Malonic acid	2.9	6.1	4.5	7.8
IV	*ca.* 4.3	...	5.0	(10.0)
Benzoic acid	4.2		6.2	
II	...	...	6.8	(9.5)
Acetic acid	4.8		7.2	
I	...	...	7.7	(9.9)
VI	...	...	7.9	10.4

[a] The pK' values are considered to be of value in determining relative acidic strengths only (*cf.* discussion under part C in Experimental Section). [b] While this article was in process of publication, Professor F. O. Koenig and Lorraine Mildred Winslow of the Department of Chemistry at Stanford University made an accurate determination of pK_2 for 2,5-dicarbethoxy-3,4-dihydroxythiophene-1-dioxide (III) by the methods of Hamer [THIS JOURNAL, **56**, 860 (1934)] and Harned and Ehlers [*ibid.*, **54**, 1350 (1932)]. The value for pK_2 so obtained was 2.59 which may be compared with the value 1.92 obtained by Hamer for the bisulfate ion.

Although the titration data are plotted in terms of per cent. neutralized in Figs. 5 and 6, the determinations were

(11) Knoevenagel and Mercklin, *Ber.*, **37**, 4093 (1904).

(13) Palit, *Ind. Eng. Chem., Anal. Ed.*, **18**, 246 (1946).

carried out on weighed samples and, thus, served to determine the equivalent weights of the substances studied.

The insolubility of 3,4-dihydroxy-2,5-diphenylthiophene-1-dioxide in water precluded determinations of its acidity by titration in water. However, a saturated solution of the substance in water had a concentration by weight analysis of 4.7×10^{-4} mole per liter and showed *p*H 3.9. These data indicate an approximate pK_1, neglecting the second hydrogen, of 4.3.

Discussion

Comparison of the pK_1' values for the first enolic hydrogens of 2,5-dicarbomethoxy-3,4-dihydroxythiophene (I) (pK_1' = 7.7) and 2,5-dicarbethoxy-3,4-dihydroxythiophene-1-oxide (II) (pK_1' = 6.8) indicates that the sulfoxide group exerts only a slightly stronger proton-releasing effect on the enolic hydrogen than does a sulfide function in the same position. This observation is in accord with the reported[14] failure of bis-(phenylsulfinyl)-methane to show acidic properties. The near identity of the ultraviolet absorption spectra of the two compounds (I and

II) in alcoholic hydrogen chloride (Fig. 1), in which medium the substances may be assumed to be present as undissociated molecules, further emphasizes the similarity of the electrical effect of the groups –S– and –SO– on attached groups. Both the sulfide and sulfoxide functions appear, however, to exert an electron-attracting influence relative to a methylene group in the same position as evidenced by comparison of the pK_1' values for the thiophene derivatives (I and II) with that for 2,5-dicarbethoxy-3,4-dihydroxycyclopentadiene-2,4 (VI) (pK_1' = 7.9). The similarity in the absorption spectra of the three thiophene derivatives (I, II, III), the cyclopentadiene derivative (VI), and 2,5-dicarbethoxy-3,4-dihydroxypyrrole (VII) (Fig. 1) finds explanation in the observation that the systems –CO–C(CH_3)=CH– and –CO–C(Br)=CH– have the same ultraviolet absorption spectra and that in general the concept of cross conjugation is without physical basis.[15]

The appearance of a single absorption maximum for 2,5-dicarbethoxy-3,4-dihydroxyfuran (V) (Fig. 1) in acidic solution taken with the appearance of the two characteristic bands in alkaline medium (Fig. 2) suggests that the furan derivative is present in the acidic solution in a different molecular form than that of the thiophene, pyrrole and cyclopentadiene derivatives (I, II, III, VI, VII) under the same conditions.

The ultraviolet absorption spectra of the 2,5 - dicarbethoxy - 3,4 - dihydroxythiophene - 1-dioxide (III) (Figs. 1, 2, 3, 4) in various media are similar to those of the other compounds studied insofar as the two characteristic bands are present. In the case of the sulfone (III), however, the intensity of absorption is lower for both bands, the short wave length band is considerably shifted to shorter wave lengths, and the position of maximum absorption for the long wave length band is little altered by changes in the medium (*cf.* Figs. 1, 2, 3). The latter situation is not the case with the thiophene (I) and thiophene-1-oxide (II) derivatives in which the low intensity bands, as well as the high intensity bands, undergo marked bathochromic shifts in going from moderately acidic to alkaline media, *i. e.*, from neutral molecule to conjugate base. This observation that the presence of the enolic hydrogens in III has little to do with the ultraviolet absorption characteristics of the compound suggests that the electron distribution is not much dependent upon the presence of the enolic hydrogens, a situation tantamount to ascribing to the sulfone (III) a very high level of acidity.

Such is indeed the case. From the titration curve for the compound in the anhydrous medium (Fig. 6), in which acetic acid shows approximately a four hundred-fold decrease (pK' = 7.2) relative to its strength in water (pK = 4.8), it is evident that the first enolic group of the sulfone (III) still shows strong acid behavior. The basicity of the anhydrous medium, is, however, enough lower than that of water to bring out the weak acid nature of the second enolic hydrogen of III, which was not observed in the titration of the compound in water (*cf.* Fig. 5). Although the titration procedure was not extended to even less basic solvents in order to evaluate a relative acid-

(15) Woodward, THIS JOURNAL, **63**, 1123 (1941).

ity for the first hydrogen of the sulfone (III), it is apparent from the curve (Fig. 6) that the compound is at least as strong an acid as picric acid ($pK = 1$). It is probably stronger with regard to the first enolic hydrogen since even in 0.25 molar solution the second hydrogen of III showed strong acid behavior (Fig. 5) and the first and second dissociation constants of dibasic acids having proximate acidic groups usually differ by a factor of at least three powers of ten.

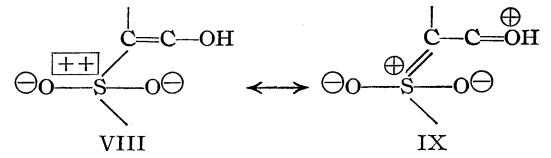
The ultraviolet absorption spectra for the compound (III) in 1 *M* alcoholic hydrogen chloride, 9 *M* sulfuric acid, and concentrated sulfuric acid (Figs. 1, 3, and 4) show little difference which suggests that, in contrast to the behavior of the much less strongly acidic I, VI, and VII under similar conditions (*cf.* Fig. 4 and the discussion below) the thiophene dioxide (III) is present, not as its conjugate acid, but rather in molecular form in concentrated sulfuric acid. Such behavior would be expected of only the most weakly basic substances, and hence of only the strongest acids when the molecule in question has ampholytic character.

In the anhydrous medium the first enolic hydrogen of 3,4-dihydroxy-2,5-diphenylthiophene-1-dioxide (IV) shows an acidic strength (pK_1' 5.0) only 3-fold less than that of the first hydrogen of malonic acid (pK_1' 4.5, pK_1 2.9) in the same medium. Because of its low solubility in water the diphenylthiophene derivative (IV) could not be titrated in aqueous solution. However, it is apparent that the compound is as strong an acid as a typical carboxylic acid in water (pK 5). An approximate determination of the acidic strength in water, as described under C in the Experimental Section, gave pK_1 4.3.

It is apparent from these considerations that the strong electron-attracting influence of the sulfonyl group is transmitted through the carbon–carbon double bond to the enolic hydroxyl groups in the compounds studied. Indeed, the effect is greater than that exerted by a carbethoxyl group in the same position as indicated by a comparison of the acidic strengths of 2,5-dicarbomethoxy-3,4-dihydroxythiophene (I) (pK_1' 7.7) and 2,5-dicarbethoxy-3,4-dihydroxycyclopentadiene-2,4 (VI) (pK_1' 7.9) with those of the thiophene derivatives III and IV. This conclusion is in accord with the observation that bis-(phenylsulfonyl)-methane dissolves in aqueous sodium hydroxide and may be alkylated by treatment of the alkaline solution with alkyl halides[14] while malonic ester is unreactive in the same sense under the same conditions.

Since, in the compounds studied, the powerful electron-attracting influence of the sulfonyl group is transmitted through a double bond it is concluded that the effect is not one of simple induction but is better symbolized by the resonance hybridization VIII ⟷ IX.

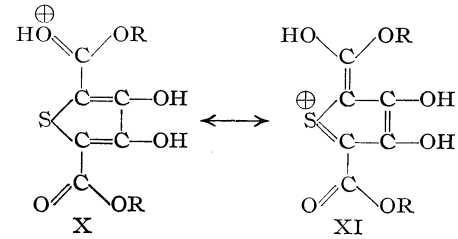
Structures VIII and IX involve a sulfur atom with a decet of electrons. Such an expansion of the octet, involving the unused *d* orbitals of the



VIII IX

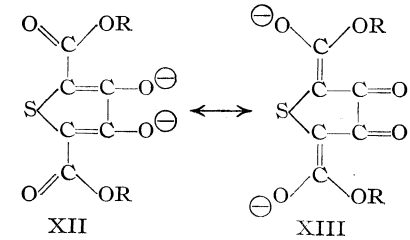
sulfur atom has been suggested by various investigators to explain the physical and chemical properties of organic and inorganic compounds of sulfur.[16] The work reported here thus provides additional experimental evidence in support of this hypothesis.

We turn now to a consideration of the marked bathochromic shifts observed in the spectra of 2,5-dicarbomethoxy-3,4-dihydroxythiophene (I) and N-ethyl-2,5-dicarbethoxy-3,4-dihydroxypyrrole (VII) in going from a 1 *M* alcoholic hydrogen chloride medium to a concentrated sulfuric acid medium (*cf.* Figs. 1 and 4). Both I and VII are weakly acidic, and unlike 2,5-dicarbethoxy-3,4-dihydroxythiophene-1-dioxide (III), might be expected to be converted to their conjugate acids in concentrated sulfuric acid. In view of the failure of thiophene and pyrrole to show basic properties attributable to their hetero atoms, and the reported[17] conversion of carboxylic esters to their conjugate acids by concentrated sulfuric acid we propose structures of the type X ⟷ XI for the conjugate acids of the thiophene derivative I and the pyrrole VII, present in solutions of the compounds in concentrated sulfuric acid.



X XI

In these structures, no charge separation is required by the resonance hybridization. The same situation obtains in the conjugate bases of the type XII ⟷ XIII, and it is not surprising that both the conjugate acids and the conjugate bases have spectra shifted bathochromically relative to the neutral molecules.[18,19]



XII XIII

(16) For discussions of earlier work on the expanded sulfur valence shell problem, *cf.* Fehnel and Carmack, THIS JOURNAL, **71**, 84, 231 (1949); Heymann, *ibid.*, 260 (1949); Fehnel, *ibid.*, 1063 (1949).

(17) Hammett, "Physical Organic Chemistry," McGraw-Hill Book Company, New York, N. Y., 1940, p. 45–47.

(18) Lewis and Calvin, *Chem. Rev.*, **25**, 273 (1939).

(19) Hammett, "Physical Organic Chemistry," McGraw-Hill Book Company, New York, N. Y., 1940, p. 61.

The bathochromic shift observed in the case of 2,5-dicarbethoxy-3,4-dihydroxycyclopentadiene-2,4 (VI) in going from alcoholic hydrogen chloride as solvent to concentrated sulfuric acid contrasts with the hypsochromic shift in the case of the sulfone (III) under the same conditions (Figs. 1, 3, 4), and is interpreted as involving conjugate acid formation at a carbethoxyl group in VI with consequent elimination of charge separation in the resonating chromophoric system.

Summary

A study of the acidic strengths and ultraviolet absorption spectra of certain dihydroxythiophene-1-oxides and 1-dioxides has provided further evidence for an expanded valence shell for the sulfur atom in the sulfone configuration.

Inorganic Complex Compounds Containing Polydentate Groups. II. The Complexes Formed between Triethylenetetramine and the Nickel(II) Ion

BY HANS B. JONASSEN AND B. E. DOUGLAS[1,2,3]

The stereochemical configuration of the quadricovalent complexes of the nickel(II) ion has been extensively investigated. This ion has been shown to be able to direct its valence bonds toward the corners of a tetrahedron[4,5,6,7] and of a plane.[6,7,8,9]

Various criteria have been used to obtain information about the configuration of these complex compounds. Lifschitz and co-workers[10] attempted to relate color and magnetic properties to bond direction. Yellow compounds were classed as planar because of diamagnetism; blue paramagnetic compounds indicated tetrahedral bond direction. This distinguishing characteristic, however, breaks down in many cases.

Mellor and co-workers[7] found that the electronegativity of the coördinating group influences the stereochemical configuration. The very electronegative donor atom, oxygen, imposes tetrahedral sp^3 bonds upon the nickel(II) ion. As the electronegativity decreases through nitrogen to sulfur, the bonds are directed toward the corners of a coplanar square. In the compounds containing four nitrogen donor atoms the statistical distribution is about half planar, half tetrahedral. Many complexes of this type can show both configurations.[10] Other factors such as steric hindrance due to coördinating groups and functional groups attached to donor atom also affect the configuration of these complexes.

In most of these complexes the coördinating group is a mono- or bidentate group. Very few quadridentate complexes containing the same donor atom have been investigated. In all of these cases[8,9,11] the configuration of the coördinating group imposes a planar configuration upon the complex.

This study was undertaken to determine the type of configuration of the complex or complexes formed between the nickel(II) ion and triethylenetetramine ($NH_2C_2H_4NHC_2H_4NHC_2H_4NH_2$) (abbreviated trien). This quadridentate base can orient itself with little difference in strain around a metal ion exhibiting tetrahedral or planar valence bond direction.

Since the configuration of the trien molecule does not impose a definite bond direction upon the central ion, this investigation may throw more light upon the factors which influence the direction of valence forces in the complexes containing the nickel(II) ion.

Since the nickel(II) ion also has a tendency to form octahedral complexes, the data obtained in this study may also indicate the ease of conversion of nickel(II) complex ions from tetra- to hexacoördination. This may lead to some information about the configuration of the tetracoordinated complexes since Dwyer and Mellor[12] found that planar diamagnetic nickel(II) complex ions show little tendency to assume sixfold coordination. Paramagnetic tetrahedral complex compounds, however, can easily be converted to an octahedral configuration by the uptake of two more donor groups.

Experimental

A. Spectrophotometric Studies. 1. Absorption Data.—Standard solutions of 0.05 *M* nickel chloride and 0.05 *M* trien were used in the absorption studies. Fixed amounts of nickel chloride were mixed with varying amounts of trien to give solutions with the following ratios

of nickel chloride to trien: 1:2, 2:1, 3:2, 1:1, 2:3, 1:2, 1:4. A drop of hydrochloric acid was added to each of the first three solutions to prevent hydrolysis of the non-complexed nickel(II) ion. The optical density values of the solutions were determined between the wave lengths of 500 and 1000 mμ using a Beckman spectrophotometer and matched Corex cells with a depth of 1 cm. The optical density curves are shown in Fig. 1. No change in absorption characteristics was obtained after the ratio of nickel(II) to trien becomes smaller than 2:3. The optical density values for the 1:2 and 1:4 nickel(II) ion to trien solutions are therefore not shown.

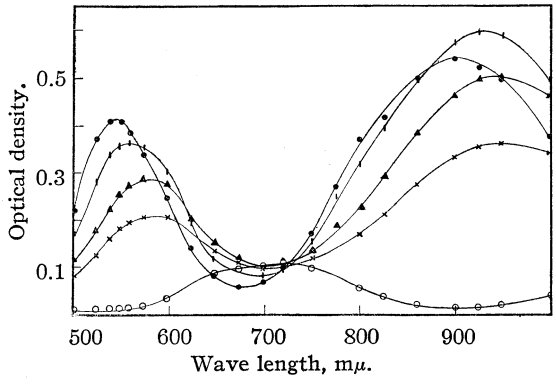

Fig. 1.—Absorption curves for solutions containing 0.05 *M* of nickel chloride and 0.0 to 0.075 *M* of trien: —O—, 0.05 *M* nickel chloride; —×—, ratio of 2:1 (Ni^{+2}:trien); —▲—, ratio of 3:2 (Ni^{+2}:trien); —|—, ratio of 1:1 (Ni^{+2}:trien); —●—, ratio of 2:3 (Ni^{+2}:trien).

Discussion.—As Fig. 1 shows the absorption characteristics of solutions containing a mole ratio of nickel(II) ion to trien of 2:1, 3:2 and 1:1 are very similar indicating the existence of a 1:1 complex [Ni trien]$^{+2}$ ion in the solution. However, after the 1:1 ratio has been exceeded a shift of the absorption maximum towards shorter wave lengths occurs indicating the existence of another colored complex in solution. Since no further change occurs after the ratio becomes smaller than 2:3, the composition of the other complex should correspond to $[Ni_2\ trien_3]^{+4}$ and no other colored complex with a mole ratio smaller than 2:3 should be present in the solution.

2. Continuous Variation Studies.—Solutions 0.1 *M* in nickel chloride and 0.1 *M* in trien were prepared for the continuous variation studies.[13] The optical density of solutions whose total solute concentration was 0.1 *M* with varying amounts of nickel(II) ions and trien was measured at the wave lengths 550, 565, 580, 600 and 860 mμ. In Fig. 2 *x* (the fraction of trien) is plotted against *y* (the difference between the observed optical density of the complex and the optical density calculated for no reaction) for the wave lengths 580 and 860 mμ. Figure 3 shows a similar plot for the nickel chloride–trien system at 550 mμ. In this graph, however, *y'* (*y'* is the difference between the observed optical density and that calculated for the 1:1 complex) is plotted against *x* (fraction of trien).

Discussion.—The continuous variation studies indicate that, in solutions containing nickel(II) ions and trien, the [Ni trien]$^{+2}$ ion is present as is shown by the maxima at $x = 0.5$ in Fig. 2.

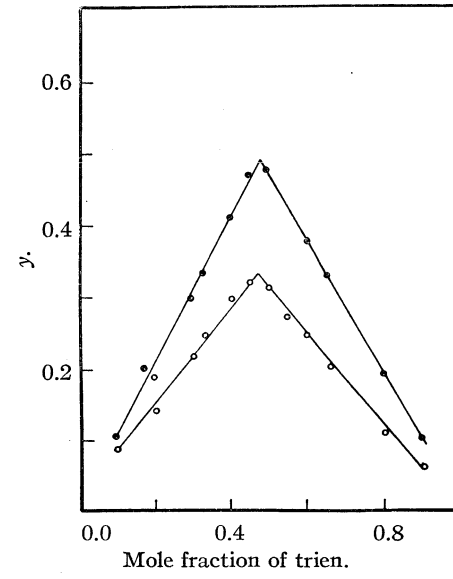

Fig. 2.—Continuous variation studies Ni^{+2}–trien system: ●, 860 mμ; O, 580 mμ.

Figure 3 shows a maximum at $x = 0.6$ indicating the existence of the $[Ni_2\ trien_3]^{+4}$ ion. No other maxima are obtained in these studies substantiating the conclusions drawn from the absorption

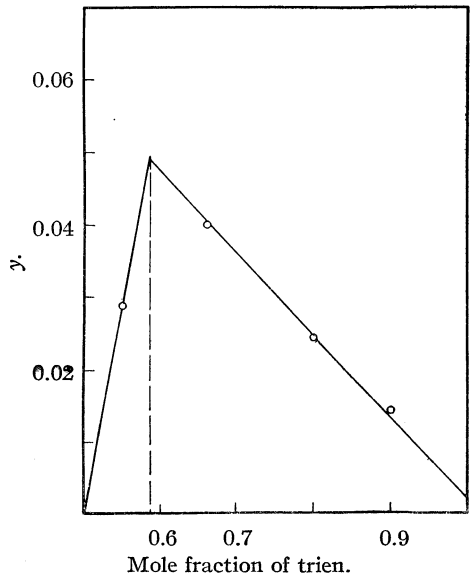

Fig. 3.—Continuous variation studies Ni^{+2}–trien system: O, 550 mμ.

data about the absence of colored complex ions of lower mole ratio in these solutions.

B. Preparation of Complex Compounds

1. Special Reagents.—The trien was a Technical Grade of 79% purity purchased from Eastman Kodak Company, Rochester, New York. The trien used in the absorption studies was distilled over sodium at reduced pressure (the fraction collected boiled at 139–141° at 10 mm. pressure) and was standardized potentiometrically.[14] All other chemicals used were standard reagents of C. P. quality.

2. Preparation of the Nickel(II) Chloride Complex $[Ni_2\ trien_3]Cl_4 \cdot 2H_2O$.—Twenty ml. of a 2 molar solution of trien was added to 10 ml. of 2 molar nickelous chloride with stirring. The color of the solution changed from green to a deep purple. This solution was evaporated almost to dryness, whereupon a mixture of 20 ml. of methyl alcohol and 10 ml. of ether was added. A light pink precipitate settled out immediately. It was washed with 20 ml. of methyl alcohol and 20 ml. of ether and dried in the oven at 65°.

Anal. Calcd. for $[Ni_2\ trien_3]Cl_4 \cdot 2H_2O$: Cl, 19.14; Ni, 15.5; C, 29.2; H, 7.9; N, 22.9. Found: Cl, 19.2; Ni, 15.7; C, 29.3; H, 7.7; N, 23.0.

3. Preparation of the Nickel(II) Nitrate Complex.—The complex nitrate was prepared in the same manner as the chloride. The precipitate obtained is slightly more violet in color.

Anal. Calcd. for $[Ni_2\ trien_3](NO_3)_4 \cdot H_2O$: Ni, 13.8; C, 26.3; H, 6.6; N, 20.4. Found: Ni, 13.9; C, 26.2; H, 6.7; N, 20.3.

4. Preparation of the Nickel(II) Tetrachloroplatinite Complex $[Ni_2\ trien_3][PtCl_4]_2$.—One hundred ml. of 0.01 *M* nickel chloride and 200 ml. of 0.005 *M* trien in aqueous solution were mixed in a beaker. A color change from green to blue to purple occurred. To this purple solution was added slowly and with stirring 100 ml. of 0.01 *M* potassium chloroplatinite. A light pink precipitate settled out of the solution immediately. The precipitate was washed successively with 200-ml. portions of cold water, 95% alcohol and ether. Drying to constant weight led to the formation of a light green precipitate which decomposed at 250–260°.

Anal. Calcd. for $[Ni_2\ trien_3](PtCl_4)_2$: Pt, 30.8; Ni, 9.30; C, 17.1; H, 4.3. Found: Pt, 30.8; Ni, 9.40; C, 16.8; H, 4.2. The loss of weight was found to be 2.66% which corresponds to two molecules of water of hydration in the pink complex compound.

Discussion.—The compounds obtained from the solutions containing nickel(II) ion, chloride or nitrate ions, and trien show a coördination number of 6 with octahedral valence bond distribution.

Since the spectrophotometric investigation of solutions containing nickel(II) ions and trien also indicates the existence of the $[Ni\ trien]^{+2}$ ion, potassium chloroplatinite was added. It was hoped that the large chloroplatinite ion would form a precipitate with the 1:1 complex ion similar to the insoluble [Pt trien] [Pt Cl_4].[15] However, the $[Ni_2\ trien_3]$ [Pt $Cl_4]_2$ precipitated under these conditions indicating that even though the tetracoördinated $[Ni\ trien]^{+2}$ ion is present in solution its chloroplatinite is more soluble than that of the $[Ni_2\ trien_3]^{+4}$ ion.

(14) H. B. Jonassen, R. B. LeBlanc and R. Rogan, THIS JOURNAL, in press.

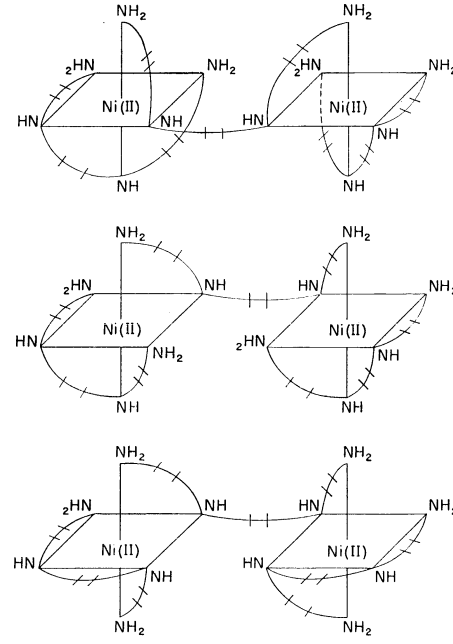
(15) N. L. Cull and H. B. Jonassen, *ibid.*, **71**, 4097 (1949).

C. Attempted Resolution of $[Ni_2\ trien_3]Cl_4$.—To 4 g. of $[Ni_2\ trien_3]Cl_4$ dissolved in 45 g. of water was added 15 g. of ammonium *d*-α-bromocamphor-π-sulfonate. Upon cooling in ice-water and allowing air to blow over the solution, some of the excess resolving agent crystallized out. Further evaporation of the solution of the complex *d*-α-bromocamphor-π-sulfonate produced several fractions. These fractions showed the same rotation and no measurable difference in physical properties. Similar results were obtained with ammonium *d*-tartrate.

Discussion.—Since it was not possible to resolve the complex ion, three possible explanations can be presented.

The diastereoisomers do not differ greatly in solubility. This possibility seems unlikely, however, since two resolving agents were used without effecting resolution.

It may be possible that only the meso forms were present in solution, the structures of which are given below.



$-N{+}{+}N- = -NC_2H_4N-$

Thirdly, it may be that the bonds are predominately ionic and that racemization occurs rapidly. This would produce a mixture with statistical distribution of optically active complexes and the meso forms.

Formation constant determinations in progress at the present time indicate that the formation of the $(Ni_2\ trien_3)^{+4}$ complex is a two-step reaction. The 1:1 complex forms first which is then changed to the $[Ni_2\ trien_3]^{+4}$ complex ion. The most stable binding of two 1:1 complexes to give the $(Ni_2\ trien_3)^{+4}$ ion is through the *cis*-positions of the two complexes. This would indicate $sp.^3$ ionic linkage for the 1:1 complex. This is in line with the observations reported by Dwyer and Mellor.[12]

D. Magnetic Investigations. The mass susceptibilities of $[Ni_2\ trien_3]Cl_4$, $[Ni_2\ trien_3](NO_3)_4$,

and $[Ni_2trien_3](PtCl_4)_2$ were determined on a modified Curie–Cheneveau balance.[16]

The measurements were made at 25° using ferrous ammonium sulfate (μeff = 5.25)[17] as a calibrating agent. From the mass susceptibilities measured at 25° the molecular susceptibility (χ_M) was determined. The effective Bohr magneton numbers were calculated from the formula

$$\mu\text{eff} = 2.83\sqrt{\chi_M T}$$[18]

The average effective moments per Ni(II) ion were:

$[Ni_2\ trien_3]Cl_4$ = 2.93	eff. Bohr magneton numbers
$[Ni_2\ trien_3](NO_3)_4$ = 2.91	eff. Bohr magneton numbers
$[Ni_2\ trien_3][PtCl_4]_2$ = 2.87	eff. Bohr magneton numbers

This is in good agreement with the values expected for two unpaired electrons in the nickel(II) ion with octahedral valence bond direction.

(18) Ref. 17, p. 79.

Acknowledgments.—Mr. N. L. Cull prepared the $[Ni_2\ trien_3][PtCl_4]_2$ complex compound. The C, H and N analysis were performed by the Clark Micro Analytical Laboratories, Urbana, Illinois.

Summary

1. Spectrophotometric investigation of the nickel(II) ion–triethylenetetramine system indicates the existence of the colored $[Ni\ trien]^{+2}$ and $[Ni_2\ trien_3]^{+4}$ ions in solution.

2. The following compounds of the $[Ni_2\ trien_3]^{+4}$ ion were prepared: $[Ni_2\ trien_3]Cl_4 \cdot 2H_2O$, $[Ni_2\ trien_3](NO_3)_4 \cdot H_2O$ and $[Ni_2\ trien_3][PtCl_4]_2$.

3. It was not possible to isolate any compounds containing the $[Ni\ trien]^{+2}$ ion.

4. No optically active isomers could be isolated, possibly because of the ionic-metal-to-donor-atom link.

5. Magnetic studies of the compounds of the $[Ni_2\ trien_3]^{+4}$ ion indicate the existence of two unpaired electrons in the octahedral complex compounds.

Inorganic Complex Compounds Containing Polydentate Groups. III. Platinum(II) and Palladium(II) Complexes with Triethylenetetramine[1,2]

BY HANS B. JONASSEN AND N. L. CULL

Elements showing a coördination number of four may form complex compounds with linkages of either the tetrahedral sp^3 or the planar dsp^2 type. The most abundant and satisfactory evidence for the planar structure may be found among the compounds of bivalent platinum and palladium.[3] The alleged resolution of optically active complex compounds of these ions by Reihlen[4] is the only evidence for a possible tetrahedral structure. However, the optical isomer was never obtained free from the resolving agent. Other workers[5,6] were unable to effect any resolution of platinum(II) and palladium(II) complex compounds. Mills and Quibell[7] and Lidstone and Mills[8] successfully resolved bis-chelate complexes of platinum(II) and palladium(II) which would be optically active if the central ion directed its valence forces toward the corners of a planar square or square pyramid. Dipole moment studies, however, completely eliminate the latter possibility.[9]

Magnetic susceptibility measurements of the complexes of bivalent platinum and palladium have shown them to be diamagnetic,[10,11] which constitutes further evidence for planar dsp^2 linkage.[12]

In this investigation triethylenetetramine ($H_2NC_2H_4NHC_2H_4NHC_2H_4NH_2$) (abbrev. trien) was used as a coördinating agent for platinum(II) and palladium(II) complex compounds. Since trien acts as a quadridentate group,[13,14] its use offers interesting possibilities because the amine with little difference in strain may assume either a planar or a tetrahedral configuration around the central ion.

In the tetrahedral complex the presence of two unpaired electrons in the sp^3 linkage should produce paramagnetism.[12] Furthermore, if the linkage in the tetrahedral complex were mainly covalent[12] the complex should be capable of resolution since its structure is unsymmetrical.

A planar complex on the other hand would show diamagnetism due to dsp^2 type linkage,[12] and would be non-resolvable.

Absorption Studies

1. Special Reagents.—Some special reagents were used in the preparation and study of the complexes formed between bivalent platinum and palladium and trien: the trien was Technical Grade 70% pure (70% trien, 30% water) purchased from Eastman Kodak Company, Rochester, New York. The trien for the absorption studies was distilled over sodium at reduced pressures, the fraction collected boiled at 139–141° at 10 mm. pressure. The trien was standardized potentiometrically. The C. P. chloroplatinic acid was obtained from the American Platinum Company of Newark, New Jersey, and the C. P. palladous chloride from Eimer and Amend, New York, N. Y. All other chemicals and reagents used were of standard C. P. quality.

Preparation of Potassium Chloroplatinite.—Five grams of chloroplatinic acid was treated with 1.6 g. of potassium chloride and the resulting potassium chloroplatinate was reduced with sulfur dioxide solution in the manner described by Keller.[15]

2. Experimental.—Standard solutions of 0.001 *M* potassium chloroplatinite, 0.001 *M* potassium chloropalladite and 0.001 *M* trien were used in the absorption studies. Fixed amounts of the potassium chloroplatinite and potassium chloropalladite were mixed with varying amounts of trien in the molar ratios of 1:0, 1:0.5, 1:1, 1:2, 1:5 and 1:10, respectively. The optical densities of these solutions were determined between the wave lengths of 280 and 800 mμ, using a Beckman spectrophotometer and matched Corex cells one centimeter in depth. The optical density values obtained for the potassium chloroplatinite–trien system are shown graphically in Fig. 1, and for the potassium chloropalladite–trien system in Fig. 2. The 1:10 and the 1:5 solutions in both instances showed practically the same absorption spectrum as the 1:2 solution and are not shown on the graphs. Absorption studies using 0.01 *M* potassium chloroplatinite and 0.01 *M* trien were made but the results were not reproducible because of the formation of a precipitate upon standing.

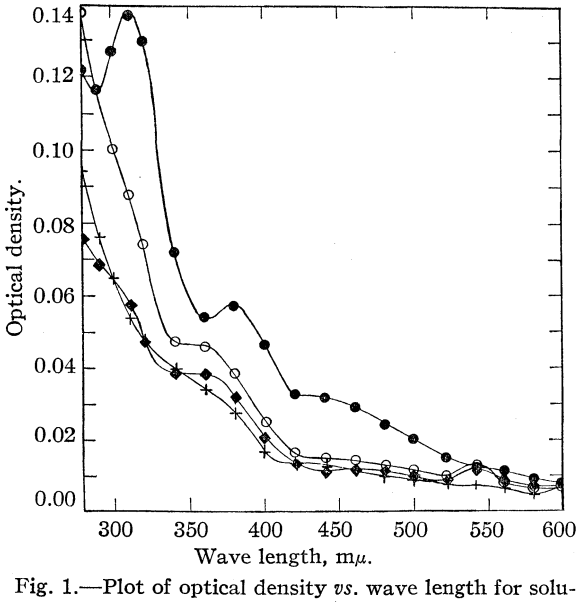

Fig. 1.—Plot of optical density *vs.* wave length for solutions 0.001 *M* in platinum(II) ion with varying concentrations of triethylenetetramine: ●, K_2PtCl_4; O, 1:0.5; ◆, 1:1; +, 1:2.

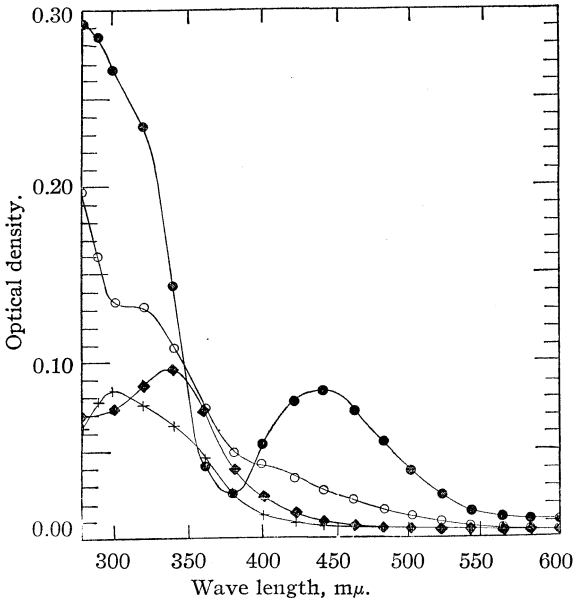

Fig. 2.—Plot of optical density *vs.* wave length for solutions 0.001 *M* in palladium(II) ion with varying concentrations of triethylenetetramine: ●, K_2PdCl_4; O, 1:0.5; ◆, 1:1; +, 1:2.

3. Discussion.—The study of the absorption spectra for the potassium chloroplatinite–trien and the potassium chloropalladite–trien systems clearly indicates the formation of one or more colored complexes in each instance. In the potassium chloroplatinite–trien system a disappearance of the absorption characteristics of the chloroplatinite ion is noted as the mole ratio of trien is increased. A shift of the maxima toward shorter wave lengths is noted for the 1:0.5 and the 1:1 solutions. In the 1:2 solution a disappearance of the characteristic maxima of the chloroplatinite ion occurs. This shifting of the maxima of the absorption curves toward shorter wave lengths is even more marked in the potassium chloropalladite–trien system. It indicates a disappearance of the tetrachloro complexes of bivalent platinum and palladium in solutions of high trien concentration and the formation of one or more trien complexes.

Continuous Variation Studies

Continuous variation studies were also at-

(15) G. Keller, "Inorganic Syntheses," Vol. II, McGraw-Hill Book Company, Inc., New York, N. Y., 1946, p. 247.

tempted but very little information could be obtained from these. This is not unexpected from theoretical considerations since the difference in the absorption characteristics between the $[PtCl_4]^=$, $[PdCl_4]^=$ ion and the complexes of the system Pt(II) (Pd(II))–trien is very small. Furthermore, replacement of the chloro groups in the tetrachloro compounds by amines is very complex,[16] which makes it very difficult to interpret the results of the continuous variation studies.

Preparations

A. [Pt trien][PtCl$_4$], a Magnus-type Salt.[17]—Potassium chloroplatinite was allowed to react with an aqueous solution of trien in the ratio of 2 moles of trien to 1 mole of potassium chloroplatinite. The reddish purple precipitate which settled out after thirty minutes was filtered, washed successively with 200-ml. portions of cold water, 95% ethyl alcohol and finally with ether. It was dried in an oven at 110–120° overnight. The resultant product was a purple-red powder, non-hygroscopic, and only very slightly soluble in water; yield was approximately 20% of theoretical. The salt was found to decompose at temperatures exceeding 260°.

Anal. Calcd. for [Pt trien][PtCl$_4$]: Pt, 57.5; Cl, 20.9; N, 8.26. Found: Pt, 57.4; Cl, 21.2; N, 8.17.

B. Triethylenetetramineplatinum(II) Ion.—The $[Pt\ trien]^{++}$ ion was prepared by the addition of a large excess of trien to an aqueous solution of potassium chloroplatinite. The color of the solution changes from a cherry red to a light yellow as excess amine is added.

C. The Aminium Salt of Platinum.—Five grams of chloroplatinic acid was reduced to the chloroplatinous acid using sulfur dioxide solution as described by Keller.[18] The color of the solution changes from an orange to a cherry red during the course of the reduction. Approximately 0.01 mole of chloroplatinous acid was diluted to 100 ml. and 2 ml. of 70% trien was added, and the solution allowed to stand overnight. It was filtered and the precipitate was washed successively with 600 ml. of cold water, 300 ml. of 95% ethyl alcohol, and finally with 300 ml. of diethyl ether, and dried at 110° overnight. The resultant powder was light orange, non-hygroscopic, and decomposed at 260–265°; yield was about 10%. The complex was slightly soluble in water, insoluble in all common organic solvents. The effect of *p*H on the formation of the aminium salt was investigated. In general it was found that the aminium salt was formed in solutions of low *p*H (2–3), while the Magnus-type salt of platinum and trien was formed in neutral or basic media.

Anal. Calcd. for $(PtCl_4)_2H_4(trien)\cdot 2H_2O$: Pt, 45.6; Cl, 32.8; N, 6.52. Found: Pt, 45.8; Cl, 33.1; N, 6.74.

D. Triethylenetetraminepalladium(II) Chloropalladite.—A saturated solution of potassium chloropalladite was prepared by treating palladous chloride with a slight excess of potassium chloride. To 100 ml. of the potassium chloropalladite was added dropwise 0.5 ml. of 70% trien. A light brownish-orange precipitate settled out of solution and was filtered off immediately. It was washed with 200 ml. of cold water, 200 ml. of 95% ethyl alcohol and 100 ml. of diethyl ether and dried in an oven at 110–120° overnight. The resultant product was a light tan, non-hygroscopic powder which decomposed at 230–235°. It was found that on standing the filtrate yielded another crop of crystals which were light yellow in color. The metal analyses for the light tan and yellow precipitates were almost identical. The variation in color may be attributed to differences in precipitation conditions and particle size. The precipitates formed were practically insoluble in all common solvents. Total yield was about 40%.

Anal. Calcd. for [Pd trien][PdCl$_4$]: Pd, 42.6; Cl, 28.3. Found: Pd, 42.7; Cl, 27.9.

E. Triethylenetraminepalladium(II) Ion.—The $[Pd\ trien]^{++}$ ion was prepared by adding a large excess of trien to an aqueous solution of potassium chloropalladite. The color of the solution changes from brown to light yellow as excess amine is added.

F. The Aminium Salt of Palladium.—Several attempts were made to prepare the aminium type complex of palladium by treating palladous chloride with excess hydrochloric acid and then adding trien. In all cases, a yellow precipitate was obtained which metal analyses proved to be [Pd trien][PdCl$_4$]. All attempts to form the aminium salt were unsuccessful.

Structural Investigation of Complexes

1. The Complex Compounds Pt$_2$trien Cl$_4$ and Pd$_2$trienCl$_4$: Conductometric Titrations

Experimental.—One hundred ml. of 5.95×10^{-4} [Pt trien][PtCl$_4$] was titrated with 0.09468 *N* silver nitrate using the conductometric method. The distilled water in all solutions was boiled for one half hour prior to use to remove any dissolved gases. A plot of bridge readings against ml. of silver nitrate added is shown in Fig. 3.

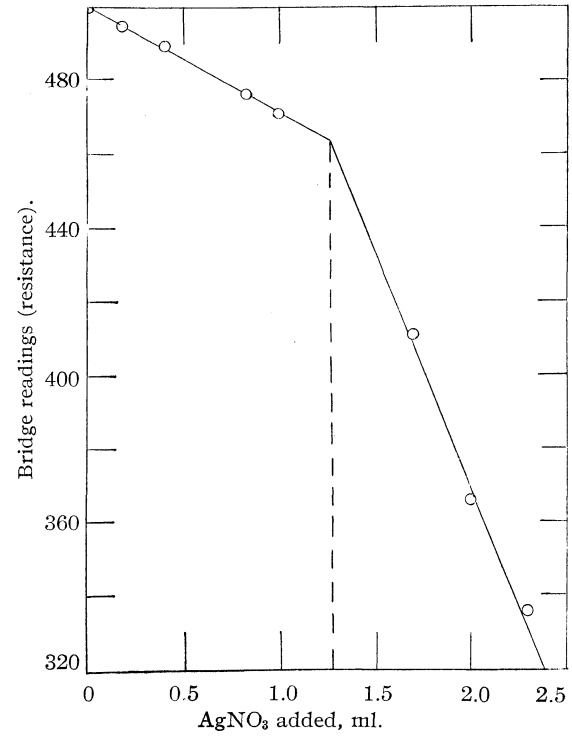

Fig. 3.—Conductometric titration of [Pt(trien)][PtCl$_4$] with $AgNO_3$.

Discussion.—The conductometric titration shows that two equivalents of silver ion is necessary to react with one equivalent of [Pt trien][PtCl$_4$] resulting in a precipitate of silver chloroplatinite. The precipitate formed during this titration has the typical brown color of silver chloroplatinite and analysis showed it to be this compound. These data prove that the 2:1 complex in the basic solution is a Magnus-type salt with a

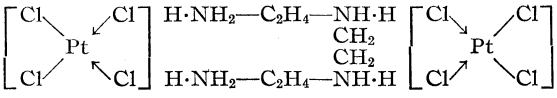
(16) Emeleus and Anderson, "Modern Aspects of Inorganic Chemistry," D. Van Nostrand Company, Inc., New York, N. Y., 1944, p. 105.

(17) G. Magnus, *Poggendorfs Ann.*, **14**, 239 (1828).

(18) G. Keller, "Inorganic Syntheses," Vol. II, McGraw-Hill Book Company, Inc., New York, N. Y., 1946, p. 250.

structural formula of [Pt trien][$PtCl_4$]. Attempts were also made to repeat the above procedure for the 2:1 complex of palladium, but it was so insoluble that no reproducible results could be obtained. By analogy to the platinum complex, however, it would seem that the palladium complex also possesses a Magnus-type structure, *viz.*, [Pd trien][$PdCl_4$].

2. The Complex Compound $Pt_2trienH_4Cl_8$.—The absorption spectrum of a solution of this salt showed the absorption characteristics of the tetrachloroplatinite ion (see Fig. 1) indicating that its structure is



3. The [Pt(trien)]$^{++}$ and [Pd(trien)]$^{++}$ Ions:

A. Attempted Optical Resolution

Experimental.—Several attempts were made to precipitate the [Pt(trien)]$^{++}$ and [Pd(trien)]$^{++}$ ions using a large optically active anion. Saturated solutions of *d*-tartaric acid and *d*-α-bromocamphor-π-sulfonate were added to solutions of the ions. Dry air was blown over the solutions for several hours and the resulting precipitate was tested for platinum. In all instances the tests revealed only the presence of organic material.

Discussion.—Although the 1:1 complex had been isolated for either the Pt(II) or Pd(II) systems, its existence in solution has been shown. By treatment with [$PtCl_4$]$^{=}$ or [$PdCl_4$]$^{=}$ ions the corresponding Magnus-type salts precipitate.

If a covalent tetrahedral [Pt trien]$^{++}$ or [Pd trien]$^{++}$ ion were present in solution a large optically active anion should bring about resolution. Since the fractions obtained contained no platinum the resolving agents must be more insoluble than the platinum salts. No structural information can therefore be obtained from these data.

B. Magnetic Behavior

Experimental.—The magnetic behavior of the solid complexes prepared, *viz.*, [Pt trien][$PtCl_4$], [$PtCl_4$]$_2H_4$(trien)·$2H_2O$, and [Pd trien][$PdCl_4$] was investigated on a Curie–Cheneveau type balance.[19,20] The investigation was made at room temperature (25°). Previously boiled distilled water was used to calibrate the balance. In all instances the salts under investigation were found to be diamagnetic. Average mass susceptibilities found for [Pt trien][$PtCl_4$], H_4(trien)($PtCl_4$)$_2$·$2H_2O$ and [Pd trien][$PdCl_4$] were found to be -0.22×10^{-6}, $-0.31 \times 10-^{6}$ and -0.42×10^{-6} units, respectively.

Discussion.—The diamagnetism exhibited by all of the complexes investigated is in accord with the predictions of theory and constitutes further evidence for the planar structure of bivalent platinum and palladium complexes.[12]

Summary

1. The absorption spectra of the system triethylenetetramine and platinum(II) or palladium(II) ions indicate that one or more complexes are present in these systems.

2. The complex compounds [Pt trien][$PtCl_4$], [Pd trien][$PdCl_4$] and [trienH_4 ($PtCl_4$)$_2$]·$2H_2O$ were prepared and their structures determined.

3. Attempts to resolve the [Pt trien]$^{++}$ and [Pd trien]$^{++}$ ions were unsuccessful.

4. Magnetic investigations of the complex compounds show them to be diamagnetic, indicating planar dsp^2 linkage.

NEW ORLEANS, LOUISIANA RECEIVED APRIL 22, 1949

CONTRIBUTION FROM THE DEPARTMENT OF CHEMISTRY, CORNELL UNIVERSITY, AND THE DEPARTMENT OF CHEMISTRY, UNIVERSITY OF CHICAGO]

The Kinetics of the Reaction of Ozone and Chloride Ion in Acid Aqueous Solution

BY LE ROY BROUGH YEATTS, JR.,[1,2] AND HENRY TAUBE

Kinetic investigations of reactions of ozone with reducing agents are in most instances difficult. The reactions are often so rapid that it is difficult to follow the rate, as for example in the reactions with stannous ion, iodide ion or ferrous ion. Often, too, the reaction with the reducing agent induces decomposition of ozone. This is observed in the reactions of ozone with hydrogen peroxide,[3] formic acid,[4] oxalic acid and phosphorous acid.[5] By contrast, in the system under present study, the main net reaction

$$2H^+ + 2Cl^- + O_3 = O_2 + H_2O + Cl_2 \qquad (A)$$

proceeds slowly enough so that the rate may be followed by ordinary methods, and it accounts almost completely for the change in the system. A very slight decomposition of ozone is observed, but since it varies in an erratic way from experiment to experiment it appears to be unrelated to reaction A. Elsewhere[3] it has been shown, and this observation is confirmed by the present work, that the spontaneous decomposition of ozone in acid solution is inhibited by chloride ion.

(1) From a thesis submitted by Le Roy B. Yeatts, Jr., to the Department of Chemistry, Cornell University, in partial fulfillment of the requirements for the Ph.D. degree.

(3) Taube and Bray, THIS JOURNAL, **62**, 3357 (1940).

(4) Taube, *ibid.*, **63**, 2453 (1941).

(5) Taube, unpublished observations.

The rate of reaction A has been measured at various concentrations of ozone, chloride ion and hydrogen ion at different temperatures and in the presence of various metal ions that might be expected to act as catalysts.[6] The data on the variation of rate with temperature yield the value of the "*a*" factor which is of particular interest in the present system. The over-all reaction involves a spin change. It seemed of interest to discover whether an abnormally low "*a*" factor, as has been predicted[7] for a reaction of this type if the spin change takes place in the rate determining step, would be observed for reaction A.

Experimental Procedure

For each experiment a large supply of a solution of ozone was prepared by bubbling ozonized oxygen through conductivity water acidified with perchloric acid. This solution was maintained at the particular temperature chosen for the experiment. A series of calibrated reaction cells (designed to minimize gas volume, see Fig. 1) previously cooled to the temperature of the bath, and each containing the required amount of chloride ion, was rapidly filled from the reservoir through a tube issuing from its bottom. The cells were then stoppered and placed in the constant-temperature bath shielded from light, withdrawn at intervals and the ozone and chlorine content determined. The initial concentration of ozone was determined by analysing at once the contents of a cell from which chloride ion had been omitted.

In carrying out an analysis, the cell was attached to the analysis train diagrammed in Fig. 1, air was drawn rapidly through the system and the ozone and chlorine removed from the gas stream by neutral potassium iodide contained in tubes C. It was found that the ozone concentration in the reaction cell fell to 40% of its initial value after an aspiration period of one minute. In making analyses, the aspiration was continued for ten minutes. This is sufficiently long to insure complete removal of ozone and of chlorine.

The method for determining chlorine and ozone depends on the fact that both react with iodide ion, and that the reaction of ozone with iodide ion consumes hydrogen ion quantitatively. An excess of acid in known amount was added to the contents of tubes C, and the total oxidizing agent (T. Ox.) determined by titration with standard thiosulfate. Then iodate in excess was added and the liberated iodine again titrated. The second titration measures the amount of acid left after the ozone has reacted with the iodide ion, and on comparing it with amount of acid added, gives the amount of ozone. The precision of the analytical method may be gaged by comparing the figures for T. Ox at zero time with the concentration of ozone at zero time. The latter figure is based on the acidimetric analysis.

The thiosulfate solution was standardized against potassium iodate and against potassium dichromate. The acid was standardized by means of the iodate method used in the analysis.

All solutions were made up using conductivity water. The perchloric acid was 60% C. P. acid. For most of the experiments, hydrochloric acid of special grade, low in heavy metals, was used as the source of chloride ion. For experiments in which the chloride ion concentration exceeded that of the hydrogen ion, C. P. sodium chloride was added to supply chloride ion. The ionic strength was maintained constant in a series by means of sodium perchlorate. A solution of this salt was prepared by neutralizing perchloric acid with sodium carbonate.

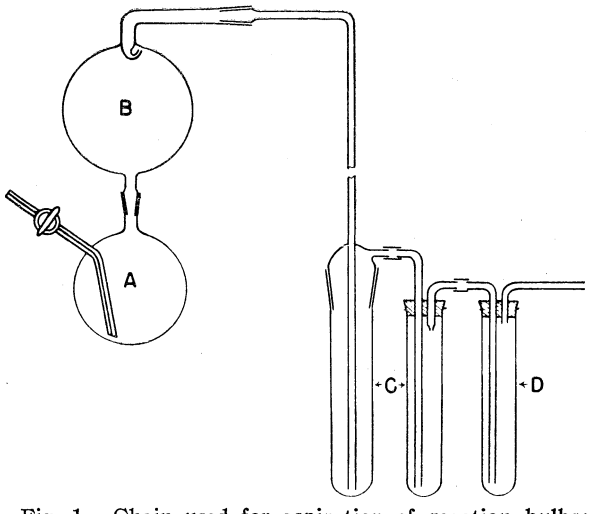

Fig. 1.—Chain used for aspiration of reaction bulbs: A, reaction bulb; B, bulb to prevent entrainment of liquid; C, tubes containing neutral potassium iodide solution; D, trap connected to water aspirator.

An ice–water mixture was used to maintain a temperature of 0°, and a solid dioxane–liquid dioxane mixture for 9.5°.

Throughout the paper, time is expressed in minutes and concentration in moles per liter.

The data are treated with reference to the rate law

$$-\mathrm{d}(O_3)/\mathrm{d}t = k(O_3)(Cl^-) + k^*(O_3) \qquad (I)$$

The second term on the right-hand side allows for the slight decomposition of ozone which accompanies the oxidation of chloride ion. The spontaneous decomposition is first order[8] in the absence of chloride ion, and it was assumed to be first order in the present system also. When this rate law is integrated under the condition that (O_3) is the only concentration variable (other reagents in great excess) it leads to the following form, which is the form applied to the data.

$$k = \frac{2.303}{(Cl^-)_{av}t} \frac{\Delta(Cl_2)}{\Delta(O_3)} \log \frac{(O_3)_0}{(O_3)_t} \qquad (II)$$

It is evident that as long as the decomposition of ozone is slight (*i.e.*, T. Ox. remains almost constant in an experiment), $\Delta(Cl_2) = \Delta(O_3)$ very nearly and the correction factor $\Delta(Cl_2)/\Delta(O_3)$ is nearly unity. Values of T. Ox. have been reproduced in Tables I, IV, V and VI to indicate how nearly this condition is approached in the experiments.

Results

Variation of Rate with Ozone Concentration.—Table I presents some of the data which show how the rate of reaction varies with the concentration of ozone, the other variables being kept almost constant. The concentration of ozone has been varied by using different initial concentration, and by following the natural decrease with time during an experiment.

	1062	14.68	6.534	.03942		.0201
4	0	15.21	9.205	.04028	.05175	
	450	15.23	6.275	.03999		.0213
	1490	15.26	2.740	.03901		.0205

The data show that over a range three-fold in initial ozone concentration and about eight-fold for the extreme concentrations, the rate of reaction is first order with respect to ozone concentration. In other experiments also (see below) the ozone concentration changed three or four-fold in an experiment. With the exception of a few early experiments, in none was there evidence for deviation from the first order law beyond what might be attributed to experimental error. In a few of the earlier runs, a decrease of specific rate with time was observed. The precise cause of this drift was not discovered, but it disappeared after some details of the analytical procedure were improved, and did not reoccur in any of the later experiments.

Experiment 4 was conducted by permitting the reaction to proceed for ten hours before the first sample was analyzed. In this period of time the concentration of chlorine built up to about two-thirds that of the ozone for the first sample of the series. The rather good agreement of the specific rates in this run with the others shows that there are no important effects caused by accumulation of products, or by the destruction of a catalyst.

Surface Effect.—To investigate the possibility that the cell surfaces might influence the rate of reaction A, the series of experiments presented in Table II was performed. Comparisons of rate were made varying the surface to volume ratio about four-fold, using in one experiment soft glass beads and in the others pyrex tubing. It may be concluded from the data that the observed rate is independent of surface area in the range studied. The slight increase observed for the packed vessels can be entirely attributed to the higher concentration of acid in these experiments (see below)—in performing the experiments the fact that the packing material occupied some of the volume was overlooked when the hydrochloric acid was measured into the cells.

Variation of Rate with Concentration of Chloride Ion.—Data bearing on the variation of rate with the concentration of chloride ion are presented in Table III. These data show that the rate of reaction A is accurately first order with respect to chloride ion concentration over the four-fold range investigated.

Variation of Rate with the Concentration of Hydrogen Ion.—Table IV presents the results of a series of experiments at constant ionic strength by varying values of hydrogen ion concentrations. The averages of the specific rates for each experiment are plotted against the averages of the hydrogen ion concentrations in Fig. 2. The result shows that the rate law has two terms, one independent of hydrogen ion concentration, and the other, first order in hydrogen ion concentration.

$$d(Cl_2)/dt = k_1(O_3)(Cl^-) + k_2(O_3)(Cl^-)(H^+) \quad (III)$$

At μ = 0.30 and 0°, k_1 = 0.0128 1. mole.$^{-1}$ min.$^{-1}$ and k_2 = 0.124 1.^{2} mole.$^{-2}$ min.$^{-1}$

Variation of the Rate of Reaction with Temperature.—A series of experiments was carried out at 9.5°, keeping μ at 0.3 and varying the concentration of hydrogen ion. The results are presented in Table V, and are shown in graphical form in Fig. 2 (lower curve). The values of k_1 and k_2 at 9.5° are found to be 0.0379 and 0.366, respectively. Two experiments were carried out also at a higher temperature, 25°. Under these conditions the decomposition of ozone becomes marked, and the initial concentration of ozone is low. These factors make the experimental error so great that further work at this temperature was abandoned. The data indicate that the temperature coefficient in the range 9.5 to 25° does not differ seriously from that in the range 0 to 9.5°.

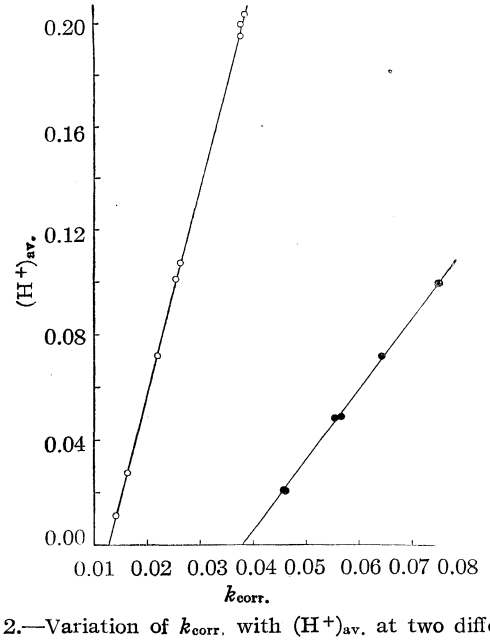

Fig. 2.—Variation of $k_{corr.}$ with $(H^+)_{av.}$ at two different temperatures: O, 0°; ●, 9.5°; μ = *ca.* 0.30.

	261	13.36	5.005	.04936	.1000	.0749

Applying the Arrhenius equation to the data for the temperatures 0 and 9.5°, the values of the activation energy for the hydrogen ion dependent path and the hydrogen ion independent path are calculated to be 17,500 ± 300 and 17,600 ± 300 cal., respectively; the "a" factors are 1.2 × 10^{13} l.^{2} mole.$^{-2}$ min.$^{-1}$ and 1.4 × 10^{12} l. mole.$^{-1}$ min.$^{-1}$, respectively.

Catalysis by Metal Ions.—The influence of metal ions on the rate of reaction was investigated to some extent. The data obtained in this phase of the study are presented in Tables VI and VII.

In Table VII the observed values of k are compared with those expected if metal ion were omitted but the ionic strength kept the same. This comparison necessitates a slight correction for the difference in ionic strength between the solutions used here and those used for the earlier experiments. The correction was made using the Brönsted relation for the variation of specific rate with ionic strength. A correction presumably is required only for the second term of the rate law. In the most extreme case the correction changed the value of k at (H^+) = 0.100 M from 0.0252 at μ = 0.30 to 0.0306 at μ = 0.152.

The comparison of columns 7 and 8 of Table VII shows that Cu^{++} and Fe^{+++} at concentrations near 0.01 M do not exert a marked effect on the rate of reaction A. The correction applied for the ionic strength is undoubtedly too great;

even assuming that the corrected values are as much as 5% too high, the effect of these metal ions is seen to be very slight. By contrast, cobaltous ion at much lower concentration accelerates the reaction markedly. The data for cobaltous ion have been treated under the assumption that to the two terms of equation III must be added the term $k_3(O_3)(Co^{++})$. Not enough experiments have been done to test the rate law rigorously, but it does describe accurately the present data which cover a two-fold change in (Cl^-), a four-fold change in (Co^{++}) and approximately a five-fold change in (O_3). The value of k_3 at 0° is 39.3 l. mol.$^{-1}$ min.$^{-1}$ It is of interest to note that Co^{++} in the presence of Cl^- does not catalyze the decomposition of ozone, as is the case if chloride ion is absent.[3,6]

Discussion of the Results

Rate law III shows that in acid solution there are two paths for reaction A. A reasonable mechanism for the hydrogen ion independent path is

$$O_3 + Cl^- \xrightarrow{k_1} O_2 + ClO^- \text{ (rate determining)}$$
$$2H^+ + Cl^- + ClO^- = Cl_2 + H_2O \text{ (rapid)}$$

The hydrogen ion dependent path may be supposed to differ only in that each activated complex contains one hydrogen ion in addition to the ozone molecule and chloride ion.

Alternative possibilities for the products formed in the rate determining step have been considered. The most reasonable of these are discussed below, and the arguments which have led to their rejection are presented.

$$\text{(a)}\quad Cl^- + O_3 + H_2O \longrightarrow Cl + HO + HO^- + O_2 \qquad (1')$$

This reaction postulates a one-electron oxidation–reduction process for $O_3 + Cl^-$. Calculation shows this step to be endothermic to the extent of about 45 kcal. This value exceeds the observed activation energy by much more than the error in the calculations, hence reaction 1′ may be ruled out as a possibility. The fact that the catalytic decomposition is very slight also argues against reaction 1′ as the slow step. Atomic chlorine initiates a rather pronounced catalytic decomposition of ozone also in water solution[3]; the decomposition observed in the present system is slight and is unrelated to the main reaction.

$$\text{(b)}\quad Cl^- + O_3 \longrightarrow Cl{-}O{-}O^- + O$$

Using bond energy values and thermal data,[9] ΔH for this reaction is estimated as 62 kcal., which is again much in excess of the observed activation energy.

$$\text{(c)}\quad Cl^- + O_3 \longrightarrow ClO_2^- + O$$

(9) Pauling, "Nature of the Chemical Bond," Cornell University Press, 1939; thermal data from Bichowsky and Rossini, "Thermal Chemistry of Chemical Substances," Reinhold Publishing Corp., New York, N. Y.

This reaction can be rejected because it is not in agreement with the observed chemistry. If ClO_2^- were formed it would certainly lead to the formation in the system of ClO_2 or ClO_3^-. Furthermore, for this reaction also ΔH (= 41 kcal.) much exceeds the observed activation energy.

It appears that only if a strong oxygen to oxygen bond is maintained in the products (as is the case when O_2 is a product) will the value of ΔH be compatible with the activation energy. ΔH for reaction 1 is -18.9 kcal.

The observed activation energy does not preclude the possibility that the oxygen found in the rate determining step is left in an excited state. Thus for the reaction

$$Cl^- + O_3 \longrightarrow ClO^- + O_2{}^1\Delta$$

ΔH is 3.5 kcal. A formulation of this type ($^1\Sigma$ oxygen is another possibility) may in fact explain why the "a" has about the normal value, 1.4×10^{12}, although there is a spin change in the over-all reaction. The spin change may take place after the rate determining step by deactivation of the singlet oxygen. In a study recently published[10] the "a" factor in another reaction in which a spin change takes place

$$ClO^- + H_2O_2 \longrightarrow H_2O + O_2 + Cl^-$$

was also found to be normal. In this reaction also the activation energy is high enough so that the oxygen formed as product in the rate determining step may be in an excited singlet state, and the spin change may therefore take place after the rate determining step.

It may be of interest to note that the oxidation of bromine ion by ozone[11] at low hydrogen ion proceeds by a path similar to that of term 1 of equation III. As might be expected, the specific rate of the $Br^- + O_3$ reaction is much greater than that of the $Cl^- + O_3$ reaction, 1600 as compared to 0.28 at 0°.

It seems remarkable that hydrogen ion exerts a catalytic effect by enhancing the "a" factor rather than by lowering activation energy. The oxidation of halide ions by hydrogen peroxide is also governed by a rate law similar in form[12] to rate law III. Participation by hydrogen ion in these reactions leads to a decrease in activation energy amounting to 2,860 cal. in the reaction of hydrogen peroxide with chloride ion.

Catalysis of reaction A by cobaltous ion may be explained by the reaction of cobaltous ion with ozone to form cobaltic ion as the slow step. Cobaltic ion is known to react rapidly with chloride ion, thus the catalyst at the steady state will be present mainly in the lower oxidation state. This interpretation gives for the specific rate of the reaction $Co^{++} + O_3$ ($+H_2O$) the value of 39.3 l. mole^{-1} min.$^{-1}$. This reaction is important also in the decomposition of ozone catalyzed by cobaltous ion, and Hill[13] has measured the specific rate in the latter system as 37. Hill has suggested $CoOH^{++} + OH + O_2$ as the products formed in step 3. This formulation is consistent with the present work. HO at high Cl^- in acid is expected to react rapidly to produce Cl, Cl in turn is expected to react rapidly to form Co^{+++}. Thus, the net result of the interaction of one mole of ozone and one mole of cobaltous ion is the production of two moles of cobaltic ion, equivalent to one mole of chlorine. In the absence of chloride ion, each $Co^{++} + O_3 \longrightarrow$ act accounts for the net destruction of two molecules of ozone.[6]

The data show that acceleration or inhibition of the reaction by cupric or ferric ions even at 0.01 M is inappreciable. It may therefore be concluded that the oxidation of these substances by ozone is very slow. Any catalytic effects to the magnetic moments of these substances are also very slight.

Acknowledgment.—The authors wish to express to Prof. E. R. VanArtsdalen their appreciation for the help he has given and interest he has taken in this work.

Summary

The rate law for the reaction of ozone with chloride ion in acid solution is

$$d(Cl_2)/dt = k_1(O_3)(Cl^-) + k_2(H)(Cl^-)(O_3)$$

At 0° and $\mu = 0.3$, k_1 is 0.0128 l. mole^{-1} min.$^{-1}$ and k_2 is 0.124 l.^{2} mole^{-2} min.$^{-1}$. The activation energies and "a" factors corresponding to the first and second terms are 17.6 and 17.5 kcal., 1.4×10^{12} and 1.2×10^{13}.

Cupric and ferric ions affect the rate of reaction only slightly, if at all. Cobaltous ion exerts a strong catalytic effect, expressible by adding the term k_3 (Co^{++}) (O_3) to the rate law. The value of k_3 is found to be 39.3 l. mole^{-1} min.$^{-1}$ in agreement with the value obtained by Hill in an independent system.

Mechanisms for the three reaction paths have been proposed.

The Rates of Reaction of Isocyanates with Alcohols. I. Phenyl Isocyanate with 1- and 2-Butanol[1]

BY ELIZABETH DYER, HUGH A. TAYLOR,[2] SHIRLEY J. MASON[3] AND JAN SAMSON[4]

In this Laboratory a program of investigating the factors influencing the reactivity of polymers both in solution and in solid form has been undertaken. In order to interpret the results it is desirable to secure information on lower molecular weight analogs of the polymers to be studied. Therefore, as a basis for understanding the reactivity of hydroxy-containing polymers with isocyanates, kinetic data have been secured on the interaction of normal and secondary butyl alcohols with phenyl isocyanate.

The first work on the kinetics of the action of alcohols with isocyanates was that of Davis and Farnum[5] who studied the relative reactivities of phenyl isocyanate with the lower aliphatic alcohols by allowing two alcohols to compete for a limited quantity of phenyl isocyanate and then determining the ratio of the two products from freezing points of the mixtures obtained. Tarbell, Mallatt and Wilson[6] showed the effect of certain acid and basic catalysts on the yields of urethans obtained from α-naphthyl isocyanate and phenols. A detailed investigation of the kinetics of the base-catalyzed reaction of various isocyanates with methanol was made by Baker and Holdsworth.[7] By the use of the Stagg[8] method of analysis for isocyanate groups, Baker and Holdsworth showed that the addition of the alcohol to the isocyanate follows second order kinetics in the presence of a constant concentration of a tertiary base. In subsequent papers Baker and Gaunt[9,10,11,12] have studied thoroughly both the base-catalyzed and "spontaneous" reactions of phenyl isocyanate with methyl, ethyl and isopropyl alcohols in di-*n*-butyl ether and in benzene solutions, and have secured kinetic evidence for the mechanism of these reactions.

In the present investigation a dilatometric method was developed for the determination of the reaction rates of *n*- and *s*-butyl alcohols with phenyl isocyanate. The correctness of the method was verified by chemical analyses.

Experimental

Equipment.—The dilatometer was of the coil type in order to provide adequate surface for heat transfer. The coil, made from forty inches of Pyrex tubing, 10 mm. o. d., was sealed to two lengths of capillary tubing, 1.5 mm. i. d. The open ends of the capillaries were attached to stopcocks carrying calcium chloride tubes. The dilatometer was calibrated by the thermal expansion of water in order to make certain that there were no irregularities in the capillaries.

For the kinetic studies at 15, 25 and 35° the dilatometer was immersed in a stirred seven-gallon water-bath, the temperature of which was controlled by an "H-B Red Top Thermoregulator." Readings taken once a minute for twenty minutes showed a regular cycle of sharp rise and slow decline with an outside variation of 0.03 to 0.04°. This variation could be taken care of when necessary by applying a slight experimental correction of 0.009 scale unit per 0.01°. The reactions at 0° were carried out in a one-gallon thermos jug in which a mixture of ice and water was kept stirred. The temperature variation was found to be negligible by checking with a Beckmann thermometer.

Materials.—Xylene was a satisfactory solvent for the dilatometric work. Solvents such as benzene and dioxane could not be used because of their volatility.

Care was taken to remove water from all solvents and reagents. Xylene was distilled over sodium and fractionated. Acetone was dried over calcium chloride and distilled. Piperidine was fractionated after standing over solid potassium hydroxide. Phenyl isocyanate was distilled under reduced pressure, b. p. 58.2–59.5° at 18–20 mm. Normal and secondary butyl alcohols were purified by treatment with sodium followed by fractionation. A convenient test for the absence of moisture was to let a mixture of the alcohol, isocyanate and solvent stand for two days; if water was present crystals of the very insoluble diphenyl urea separated. Tertiary butyl alcohol was purified by refluxing over barium oxide, followed by several distillations from sodium. Alpha terpineol[13] was a redistilled sample, m. p. 34.5–35.5°.

Dilatometer Method.—Equal volumes of xylene solutions of alcohol and the isocyanate, of known concentration and previously brought to the bath temperature, were mixed quickly and introduced into the dilatometer by suction. Readings were made of time, accurate to ±1 second, and of the scale, accurate to ±0.01 unit, at periodic intervals until no further contraction occurred. In the initial work at least fifty readings were taken for each determination. For calculation of the velocity constants the customary second order expressions (1) and (3) were used in the form of equations (2) and (4) for equal and unequal reactant concentrations, respectively.[14]

$$(1)\quad k = \frac{1}{t}\,\frac{x}{a(a-x)}$$

(13) This material was furnished in pure condition through the courtesy of the Hercules Powder Company.

(14) A derivation of equations (1) and (4) and a discussion of errors in their use is given in the thesis of J. Samson, University of Delaware, June, 1949.

$$(2)\quad k = \frac{1}{t}\frac{R_0 - R_t}{a(R_t - R_\infty)}$$

$$(3)\quad k = \frac{1}{t}\frac{2.303}{a - b}\log\frac{b(a - x)}{a(b - x)}$$

$$(4)\quad k = \frac{1}{t}\frac{2.303}{a - b}\log\frac{a(R_0 - R_\infty) - b(R_0 - R_t)}{a(R_t - R_\infty)}$$

Where R_0, R_t and R_∞ are dilatometer readings at the times indicated.

The R_0 was found for equation (2) by extrapolating the plot of $1/(R_t - R_\infty)$ against time and for equation (4) by extrapolating the plot of log $(R_t - R_\infty)$ against time. The k values were determined graphically from data such as those shown in Figs. 1 and 2. At least fourteen points were plotted to obtain the slopes of the lines.

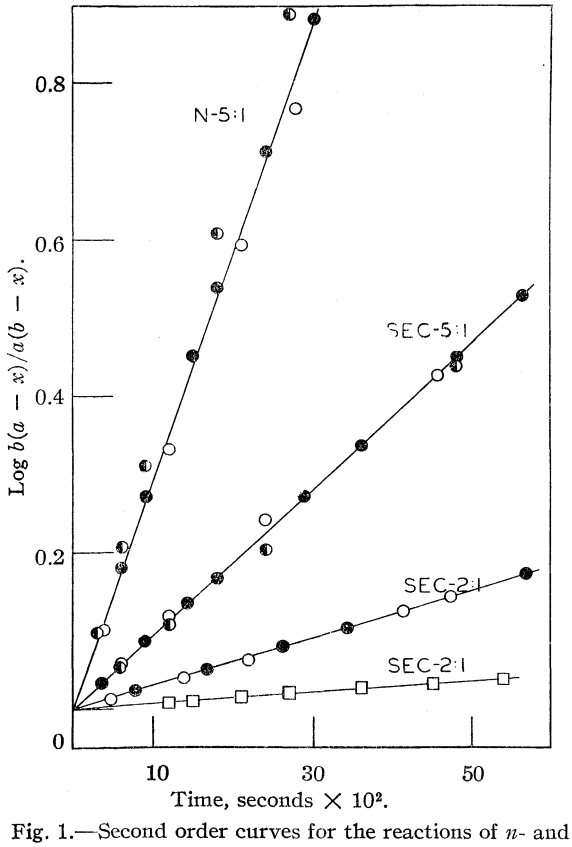

Fig. 1.—Second order curves for the reactions of *n*- and *s*-butyl alcohols with phenyl isocyanate in varying ratios of alcohol to isocyanate: O and ●, duplicate dilatometric analyses at 25°; ◐, chemical analysis at 25°; □, dilatometric analysis at 0°; a and b, initial concentrations of –OH and –NCO; x, –NCO reacted, moles/l.

Chemical Method.—Solutions of the alcohol and isocyanate of known concentrations were made up by weighing into volumetric flasks and diluting at constant temperature with xylene. Ten-milliliter samples of the alcohol solutions were transferred by pipet to each of several test-tubes to which were added at appropriate intervals ten-milliliter portions of the isocyanate solutions, and the mixtures were

allowed to stand in the constant temperature bath. At exactly the desired time each of the reactions was stopped by the addition of a known volume of a standard piperidine solution in xylene. After one-half hour the excess of piperidine was titrated with standard 0.1 N hydrochloric acid, using methyl red–methylene blue indicator. Blank determinations were always run on the piperidine and on the isocyanate. Thus the quantity of isocyanate which had reacted was determined by this modification of the Stagg method.[8] Analyses on known samples showed that the method had a precision of 3 parts per 1000 and an accuracy of 5 parts per 1000 or better. In work subsequent to that reported here the titration has been improved by the use of brom phenol blue as indicator and the addition of sufficient methanol-free acetone to give a one-phase system.

Determination of Volume Contraction.—The dilatometer was calibrated in terms of ml. per scale division by weighing water at constant temperature. From the calibration graph and the R_0 value for a given rate experiment the initial volume and hence the initial weight of isocyanate in the dilatometer was obtained. The total contraction, obtained from the value of $R_0 - R_\infty$, was used to find the contraction in ml. per mole of isocyanate reacted, shown in Table II.

Results and Discussion

A summary of the results obtained is given in Table I. All of the reactions studied were shown to follow the second order rate law to a high percentage of completion of reaction (see Figs. 1 and 2 and column 4 of Table I). The reactions at the lower reactant ratios are slow, but it was desirable to avoid the use of a catalyst so that in later work mixtures of polymers and reactants in films could be dried before appreciable reaction occurred.

The *k* values obtained by the chemical analysis were in the same general range as those from the dilatometric data, although in the 5:1 *n*-butyl alcohol–isocyanate reaction the points from the chemical plot are consistently slightly higher than those from the dilatometric one. In the other chemical run and in several not yet reported there is good agreement between dilatometric and titration data.

The second order *k* values for both the *n*- and *s*-butyl alcohols decreased with decreasing concentration of the alcohols. This is in accord with the behavior of methyl, ethyl and isopropyl alcohols with phenyl isocyanate as observed by Baker and Gaunt.[10] The explanation given by these investigators was that the alcohol acted as a catalyst through the formation of an intermediate complex with the isocyanate

$$C_6H_5NCO + ROH \rightleftarrows C_6H_5N\bar{C}O\text{(complex)} \quad \begin{array}{c}|\\ ROH\\ +\end{array}$$

$$\text{complex} + ROH \longrightarrow C_6H_5NHCOOR + ROH$$

The validity of this mechanism was established by the derivation of the following kinetic equation which could be tested graphically.

$$(ROH)/k_0 = k_2/k_1k_3 + (ROH)k_1$$

A similar test of the data from this investigation

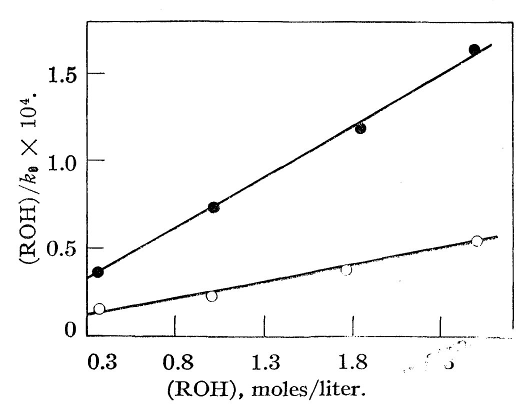

Fig. 4.—Effect of alcohol concentration on velocity constants: ○, *n*-butyl alcohol; ●, *s*-butyl alcohol, both with PhNCO in xylene solution at 25°. Each k_0 value is the average of those of approximately the same concentration from Table I.

is given in Fig. 4. The linearity of the plot of (ROH)/k_0 against (ROH) shows that the action of *n*- and *s*-butyl alcohols may be explained by the Baker and Gaunt mechanism.

It is of interest to compare the constants obtained in this work for the *n*- and *s*-butyl alcohols with the relative values reported by Davis and Farnum.[5] Their value for k_n/k_s is 3.03. In this investigation the value of k_n/k_s is 2.95 for the 5:1 ratio of reactants, and 3.24 for the 2:1 ratio of reactants, using in both cases the average of the dilatometric figures at 25°.

The rate of reaction of *t*-butyl alcohol with phenyl isocyanate to give a carbamate could not be determined because of the rapid formation of diphenyl urea. The reaction of α-terpineol with phenyl isocyanate in a 1:1 ratio at a concentration of 0.36 *M* for each reactant was followed by chemical analysis for a period of eight weeks. The data obtained were in accord with a second order reaction rate for the first five weeks; the velocity constant was 9×10^{-7} mole^{-1} l. sec.$^{-1}$. This may not be a correct value, however, because in this case also diphenyl urea was formed, although more slowly. It is not known whether the dehydration preceded or followed the interaction of the hydroxyl and isocyanate groups. Even with the *s*-butyl alcohol there was evidence of the same dehydration in the presence of phenyl isocyanate; at 35° an appreciable quantity of diphenyl urea was formed, although all reactants were anhydrous. At 25° or lower the *s*-butyl alcohol and phenyl isocyanate yielded traces of diphenyl urea, formed when 80% or more of the reaction had been completed. In the calculation of the velocity constants on the *s*-butyl alcohol experiments a possible source of error is the assumption that the R_∞ reading was not appreciably affected by the presence of traces of diphenyl urea crystals.

The effect of temperature on the rate constants for the action of *n*- and *s*-butyl alcohols with phenyl isocyanate at 2:1 reactant ratios is shown in Fig. 3. The slopes of the straight line graphs of log *k* against $1/T$ were determined by the method of least squares. The energy of activation, calculated by the Arrhenius equation, was 8100 cal./mole for the *n*- and 9900 cal./mole for the *s*-butyl alcohol.

The volume changes during the reactions, calculated as described in the experimental section, are given in Table II. It is apparent that the shrinkage per mole of isocyanate used is practically the same for various concentrations of the two different alcohols.

TABLE II

1:1	19.9	20.2
Average	19.9	20.2

Work is in progress on the reactivity of difunctional isocyanates with simple alcohols, and also with polymeric alcohols in the film state.

Acknowledgment.—The authors are indebted to Dr. H. M. Spurlin of the Hercules Powder Company for suggesting this problem and giving valuable advice during the course of the work, to Dr. C. C. Lynch of the University of Delaware for helpful discussions, and to Mr. G. W. Creighton for making some of the measurements.

Summary

A dilatometric method has been developed for the measurement of the reaction rates of isocyanates with alcohols in solution. The velocity constants for the action of phenyl isocyanate with *n*- and *s*-butyl alcohols, respectively, in xylene at various temperatures are reported. It has been shown that these reactions follow closely second order kinetics, regardless of whether the ratio of alcohol to isocyanate is 5:1, 2:1 or 1:1. The value of the constant is somewhat higher, however, in the presence of an excess of the alcohol. The values for energy of activation are 8100 and 9900 cal./mole for the *n*- and *s*-butyl alcohols, respectively. The volume contraction during the reactions at 25° is approximately 20 ml. of solution per mole of isocyanate used.

Infrared Studies of Hindered Phenols

BY WILLIAM C. SEARS AND LELAND J. KITCHEN

Infrared absorption measurements have proved[1] a useful method for studying the formation of hydrogen bonds between hydroxyl groups. Fox and Martin[2] observed the primary O–H bands for mono-, di- and triphenylcarbinols in the associated state at 2.97 μ, 2.89 μ and 2.87 μ, respectively. Each of these bands approached the value of 2.77 μ on extreme dilution in a non-polar solvent.

Coggeshall[3] used the wave length shift between the associated and unassociated states of the hydroxyl group as a measure of the strength of the hydrogen bond formed. He classed phenols containing ortho alkyl substituents as unhindered, partially hindered or hindered on the basis of wave length shifts $\Delta\lambda > 0.15$ μ, $0.04\mu < \Delta\lambda < 0.15$ μ or $\Delta\lambda < 0.04$ μ, respectively. On this basis phenols having no or small ortho substituents were classed as unhindered phenols.

In the present investigation the primary O–H bands of twenty-nine alkyl and alkoxy phenols were studied by the dilution method. Several of the phenols were unhindered; but the others contained one or two methyl, isobornyl, *t*-butyl or *tt*-octyl groups or a combination of one of these groups with methyl, as hindering ortho substituents. Relative hindrances imparted by these groups to the hydrogen bonding of the phenol hydroxyl were determined. A hydrogen bonding index was devised in order to compare the various groups in hindering power.

Several of the compounds reported by Coggeshall[3] were remeasured because he did not differentiate between the liquid and solid states. It is now found that there are large infrared shifts between the melt and solid states for several of these phenols, particularly for those without ortho substituents. Therefore a valid comparison of strengths of hydrogen bonds as determined by infrared shifts should be based on measurements on the liquid phase.

Experimental

Procedure.—Infrared bands were measured with an evacuable automatic recording spectrometer with a large sodium chloride prism, designed and constructed in the laboratories of The Firestone Tire & Rubber Co.

Wave length shifts were determined by comparing absorption bands of dilute solutions (0.07 molar solutions in carbon tetrachloride) with bands for concentrated solutions, for melts, and for crystalline solids. The concentrated solutions were prepared by wetting the phenols with just sufficient carbon tetrachloride to effect solution. Three phenols liquid at room temperature were measured without solvent. Several phenols were examined in the melted state at temperatures slightly above their melting points; then they were allowed to crystallize and the spectra were remeasured.

The melted and crystalline samples were 0.001 in. thick compared with 0.066 in. for the dilute solutions. Thickness of the concentrated solutions varied from 0.001 to 0.002 in.

Results are summarized in Table I. Conveniently the shift of the hydroxyl band from its wave length in dilute solution to the wave length in concentrated solution is defined as $\Delta\lambda_c$; the shift from dilute solution to melt as $\Delta\lambda_m$; and the shift to the solid state, $\Delta\lambda_s$.

Values for $\Delta\lambda$ are accurate within ± 0.004 μ, while the probable error in the determination of λ is ± 0.02 μ.

In comparison with values for $\Delta\lambda_s$ which are available in the literature, the present values are intermediate between those of Coggeshall[3] and those obtained by examination of the published curves of Richards and Thompson.[4] In making these comparisons it is assumed that Coggeshall measured 4-*t*-butylphenol, 4-*t*-amylphenol and 2-*t*-butyl-4-methylphenol in the solid state. Elsewhere agreement is good except for phenol.

Materials.—The solvent was C. P. carbon tetrachloride, which was found to have no absorption in the hydroxyl region.

Most of the phenols were of analytical purity (99.0–99.9%), having been purified by recrystallization and having melting points listed in Table I. The 2,4-dimethylphenol (Eastman Kodak Co. grade) and several other liquids—2,4-dimethyl-6-*t*-butylphenol, 2,4-dimethyl-6-*tt*-octylphenol and 2,6-di-*t*-butyl-4-*s*-butylphenol—which were not purified beyond fractional distillation were about 95% pure. The 2,6-diisobornyl-4-methylphenol, which was obtained as a solid resin of b. p. 254–276° (10 mm.) and could not be purified through recrystallization, was estimated to have a purity of 70–80%.

The 2,6-dimethylphenol, 3,4,5-trimethylphenol, 2,4,6-trimethylphenol, 2,3,6-trimethylphenol and 2,3,5,6-tetramethylphenol samples were supplied through the courtesy of Shell Development Company.

Alkyl phenols containing *t*-butyl groups in the ortho position were prepared by isobutylene alkylation.[5] The *tt*-octyl- or 1,1,3,3-tetramethylbutylphenols were prepared by alkylations with diisobutylene.[6] The isobornylphenols were the samples which have been described.[7] Phenol, 4-cresol, 4-*t*-amylphenol and 4-*tt*-octylphenol were obtained by recrystallization of commercial materials.

Discussion

Association in Crystalline State Compared with Liquid.—It is apparent from comparison of $\Delta\lambda_m$ and $\Delta\lambda_s$ values of Table I that the change in phase from liquid to solid cannot be neglected in

[a] Literature value for $\Delta\lambda_c$, 0.181.[2] [b–l] Literature values for $\Delta\lambda_s$: [b] 0.264; [c] 0.45[3] and 0.354; [d] 0.40[3] and 0.334; [e] 0.334; [f] 0.324; [g] 0.123; [h] 0.184; [i] 0.224; [j] 0.063; [k] 0.023; [l] 0.01.[3]

comparing the hydrogen bonding of different phenols. Since $\Delta\lambda_s$ is greater than $\Delta\lambda_m$ for all phenols for which data were obtained, except 4-methoxyphenol, hydrogen bonding in the crystalline state appears to be stronger than in the liquid phase. On solidifying, the phenols crystallize into lattice structures in which force fields in addition to those from simple hydrogen bonding may affect the primary O–H force constant and the infrared shift. There could, for example, be a weak bond formed in crystals between the hydroxyl hydrogen atom and an aromatic carbon atom as suggested by Richards and Thompson[4] in the case of *o*-hydroxydiphenyl. Moreover, the packing coefficient of crystalline phenols would vary with substituents in the meta and para positions. The data appear to support these conclusions as evidenced by several anomalous effects. For example, among phenols with different para substituents the difference between $\Delta\lambda_s$ and $\Delta\lambda_m$ ranged from -0.053 μ to 0.188 μ. Unexpectedly the $\Delta\lambda_s$ value for 2,4-dimethyl-6-isobornylphenol was greater than the corresponding value for 2-isobornylphenol, although the former has methyl instead of hydrogen in the 2-position. However, the shifts within the liquid phase are in the expected order.

It is concluded that comparisons between different phenols of hydrogen bonding should be made on infrared shifts within the liquid phase. A study of corresponding $\Delta\lambda_c$ and $\Delta\lambda_m$ values in Table I reveals that they are essentially the same, the maximum deviation being 0.02 μ. This is of interest because the $\Delta\lambda_c$ values frequently are measured more readily than the $\Delta\lambda_m$ values on unknowns to determine the positions of substituent groups.

Hydrogen Bonding Index.—The phenols without ortho substituents, being unhindered, exhibited the greatest shifts. Among the seven para substituted phenols without ortho substituents included in Table I the maximum wave length shift is about 0.267 μ. The "hydrogen bonding index" is defined as the shift from dilute solution to the liquid state divided by 0.267 μ. This index can assume values only between 0 for complete hindrance to hydrogen bonding and 1 for unhindered phenol. The hydrogen bonding index calculations which follow were based on the average shift $(\Delta\lambda_c + \Delta\lambda_m)/2$.

Comparison of Homologous Series.—The six para substituted phenols of Table I containing the *t*-butyl group in both ortho positions were almost completely hindered with respect to hydrogen bonding. The various para substituents had only a slight effect on hydrogen bonding, since the bonding indices for the six phenols were within the range 0.01 to 0.03.

Hydrogen bonding indices for hindered 4-methylphenols are compared in Table II. One methyl group in the ortho position decreased hydrogen bonding slightly, bringing the index down to 0.73. When both ortho positions were occupied by methyl groups, the index was 0.29, about equivalent to one *t*-butyl group (0.30) or to a *tt*-octyl group (0.29).

TABLE II

HYDROGEN BONDING INDICES[a] OF HINDERED 4-METHYLPHENOLS

Ortho substituent in 2-position	Ortho substituent in 6-position				
	Hydrogen	Methyl	Isobornyl	*t*-Butyl	*tt*-Octyl
Hydrogen	1.00				
Methyl	0.73	0.29[b]			
Isobornyl	.59[c]	.10	0.05		
t-Butyl	.30	.15[d]		0.03	
tt-Octyl	.29	.11			0.00

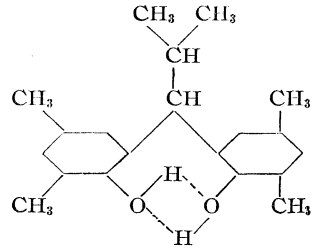
[a] Index is wave length shift of O–H band from dilute soln. to liquid state divided by 0.267 μ. [b] 2,6-Dimethylphenol had an index of 0.33. [c] 2-Isobornylphenol had an index of 0.57. [d] 2-Methyl-4,6-di-*t*-butylphenol had an index of 0.13.

An ortho isobornyl group, with an index of 0.59, was between methyl and *t*-alkyl in hindrance to hydrogen bonding. However, when the isobornyl group was combined with methyl in the other ortho position, the index was 0.10, which indicated less hydrogen bonding than with a combination of methyl and *t*-alkyl in the ortho positions. The apparently anomalous increase in hindrance may be due to the bicyclic structure of the isobornyl group.

With isobornyl or *t*-alkyl groups in both ortho positions, hydrogen bonding in liquid phase approached zero, the index being 0.00–0.05, contrasted with a value of about 1.00 for the para substituted phenols without ortho substituents.

Effect of meta Substitution.—It is well known that a meta methyl group, in itself, does not hinder the phenolic hydroxyl group. However, when both ortho and meta substituents are present on adjacent carbon atoms, the meta substituent can exert a hindering effect. For example, 2,3,5,6-tetramethylphenol had an index of only 0.14 compared with indices of 0.20, 0.29 and 0.33, respectively, for 2,3,6-trimethylphenol, 2,4,6-trimethylphenol and 2,6-dimethylphenol. Apparently a meta methyl group forces an adjacent ortho methyl group closer to the hydroxyl, increasing the hindrance.

Intramolecular Hydrogen Bonding.—Evidently intramolecular association occurs between the two O–H groups of bis-(2-hydroxy-3,5-dimethylphenyl)-isopropylmethane, indicated by the fact that its O–H absorption band did not shift all the way back to the non-associated state as a result of dilution. Therefore it is concluded to be associated



Structure of Isobornylphenol.—The preparation of a monoisobornylphenol of m. p. 77.8–78.6° was described previously.[7] Its hydrogen bonding index is 0.57, compared with 0.58 for 2-isobornyl-4-methylphenol; thus it is the ortho isomer, 2-isobornylphenol, rather than the para isomer, 4-isobornylphenol.

Acknowledgment.—The authors wish to express their appreciation to Dr. E. E. Hanson and Dr. G. E. P. Smith, Jr., for their advice and encouragement and to The Firestone Tire & Rubber Company for permission to publish this work. They wish to thank Mr. Harold C. Ransaw, to whom they are indebted for assistance in obtaining the data in this paper.

Summary

Twenty-nine phenols, twenty-two of which contained methyl, *t*-butyl, *tt*-octyl and isobornyl groups as ortho substituents, were examined for degrees of hydrogen bonding by means of infrared spectroscopy. Hydrogen bonding indices were assigned to the various phenols to indicate their tendencies to associate in liquid phase. It was found that the isobornyl group, a secondary alkyl group, hindered more than methyl but less than the tertiary alkyl groups, of which *tt*-octyl hindered to a slightly greater extent than *t*-butyl.

The effect of change of phase was investigated; O–H bands for the crystalline state included anomalies such that comparisons among phenols required measurements on the liquid phase.

Methyl groups in the meta position were found to increase the hindering action of adjacent ortho methyl substituents.

An example of intramolecular hydrogen bonding with formation of an eight-membered chelation ring is pointed out.

On the basis of its observed hydrogen bonding index, a monoisobornylphenol of m. p. 77.8–78.6° was found to be 2-isobornylphenol.

X-Ray Diffraction Analysis of Vaccenic Acid[1]

BY JAMES H. BENEDICT AND B. F. DAUBERT

In a previous communication[2] from this Laboratory the *trans* configuration of natural vaccenic acid was confirmed by comparison of its infrared absorption data with those of oleic and elaidic acids. Subsequent to this work a comparison of the infrared data was made of a synthetic vaccenic acid submitted to us by Dr. F. M. Strong,[3] with the natural acid. On the basis of the comparative infrared results and mixed melting points it was concluded by Strong[3] that the synthetic vaccenic acid was of *trans* configuration and accordingly identical with the natural acid.

In order to provide further identification data, the natural and synthetic vaccenic acids were submitted to X-ray diffraction analysis, and the data compared with those for elaidic acid. Also, since the earlier X-ray diffraction data for elaidic acid[4] were very meager a more detailed analysis was made and is herewith reported.

The comparative X-ray data in Table I indicate that synthetic vaccenic and elaidic acids possess similar crystal structures since the two patterns have nearly identical long and short spacings. The dissimilarities in the diffraction pattern of natural vaccenic acid as compared to the patterns for synthetic vaccenic and elaidic acids may be attributed to differences in the angles of tilt in the crystals, and possibly to differences in the structure of the acids.

The exceedingly shorter long spacing for natural vaccenic acid as compared to elaidic acid could readily be explained by a greater angle of tilt in the natural vaccenic crystal structure since both acids are of *trans* configuration and differ only in the position of the double bond. It should also be noted that a vaccenic acid obtained as a product of the hydrogenation[5] of β-elaeostearic acid gave a pattern essentially identical to that obtained on the natural vaccenic acid.

Experimental

The elaidic acid was prepared by isomerization of highly purified oleic acid with nitrous acid according to the method of Lyutenberg.[6] It was recrystallized several times from ethyl ether and methyl alcohol; m. p. 44.5°, I. V. 89.9 (calcd. 89.9).

The vaccenic acid used in this study was a portion of the same acid, isolated from beef tallow, which was used in the infrared studies previously described.[2] The synthetic vaccenic acid was kindly furnished us by Dr. F. M. Strong of the University of Wisconsin and was prepared by methods described by Strong and co-workers.[3]

X-Ray Diffraction Analysis.—The X-ray diffraction patterns were obtained in a manner analogous to that previously described.[7] The solvent-crystallized acids were analyzed and the data are given in Table I.

	1.74 VW		

To determine the presence or absence of other polymorphic forms, the acids packed in nylon tubes were fused, cooled rapidly, and then stabilized by holding at −20° for four days. After X-ray exposure, melting points were determined. The fused samples under the experimental conditions indicated gave diffraction patterns similar to those obtained for the solvent-crystallized acids.

On the Existence of the Higher Oxides of Neodymium[1]

BY ALEXANDER I. POPOV AND GEO. GLOCKLER

A literature survey showed that the question of the existence of the higher oxides of neodymium still remains unsettled. Earlier workers with the rare earth elements often claimed to have obtained NdO_2 and Nd_2O_5 either by heating the sesquioxide in air[2] or by heating the oxalate in oxygen.[3,4] Mark[5] claimed to have obtained excess of combined oxygen in a didymium–cerium mixture, which he attributed to the formation of neodymium "superoxide." Waegner[3] and Popovici[6] both claimed to have obtained Nd_2O_5 by fusion of the oxalate or the trifluoride with ammonium nitrate.

On the other hand Marsh[7] in 1946 repeated the work of Mark and failed to obtain any evidence for the formation of the higher oxides of neodymium. He also postulated that Waegner's and Brauner's results were due to the unusual stability of the basic neodymium oxide NdO(OH). This compound was first prepared by Joye and Garnier[8] in 1912 and seems to have the same reflection spectrum as Waegner's "superoxide." Pagel and Brinton[9] in 1929 attempted to oxidize the sesquioxide of neodymium by heating it to 350° with oxygen under 215-lb. pressure but found no evidence of oxidation.

Experimental Results

In an attempt to clarify this question the work of the earlier investigators was repeated. It was found that heating the sesquioxide in a current of oxygen at temperatures varying between 500 and 1000° did not result in any oxidation of the compound.

It was next decided to try the combustion of neodymium oxalate in a current of oxygen. The oxalate was obtained by precipitation of an acidified neodymium nitrate solution with oxalic acid and drying the precipitate at 120°. Weighed portions of the oxalate, in a porcelain boat, were introduced into an electrical combustion furnace. Dried commercial oxygen was passed while the furnace was progressively brought to the desired temperature. The period of heating was varied from one to two and a half hours. The resulting oxide was cooled in a current of dry nitrogen, weighed and dissolved in an acid potassium iodide solution. Liberated iodine was titrated with a standard sodium thiosulfate solution and the percentage of "active" oxygen calculated.

Seven experiments were made at 550, 700 and 950°. The average amount of "active" oxygen found in the product was 0.1%. No significant variation of this figure with temperature was observed. The active oxygen percentage in NdO_2 should be 4.54. The small amount of "active" oxygen found is probably due to traces of praseodymium, because the present sample of neodymium oxide was faintly grayish in color in comparison with a small sample of very pure neodymium oxide which originated in Professor Rolla's laboratory in Florence and which was at our disposal.

Neodymium oxalate which was heated to 550° was reintroduced into the combustion tube after being weighed and was heated again to 1000°. A tared drying tube was attached to the system and again a current of dry oxygen was passed. After heating the sample for one hour the boat was withdrawn and the weight of the drying tube redetermined. A blank was also run and gave negative results within the limits of experimental error (Table I).

TABLE I

DEHYDRATION OF BASIC NEODYMIUM OXIDE

	Sample, g.	Water obtained, mg.	Water calcd., mg.
Expt. 1	0.2412	13.0	12.2
Expt. 2	.2099	10.7	10.6
Expt. 3	.3714	19.0	18.9

It thus seems that the supposition of Marsh is correct and that by heating hydrated neodymium oxalate to 550° the basic oxide of the element is formed, which subsequently decomposes in the neighborhood of 1000° to the sesquioxide and water.

The fusion of neodymium oxalate, sesquioxide or the trifluoride with ammonium nitrate also failed to give any higher oxides.

As the fusion of praseodymium oxide with sodium chlorate yields praseodymium dioxide,[10]

(10) W. Prandtl and K. Huttner, *Z. anorg. allgem. Chem.*, **149**, 235 (1925).

this method was tried for the oxidation of neodymium. Weighed portions of the sesquioxide were mixed intimately with about 20 times their weight of C. P. sodium chlorate and the mixture was fused for various lengths of time (thirty minutes to six hours and thirty minutes) at 250–300°. The melt was extracted with hot water, washed, dried and dissolved in acid potassium iodide solution. In all cases only traces of iodine were liberated.

Conclusions

The results obtained seem to indicate that the earlier reports of the existence of the higher oxides of neodymium were due to the use of impure compounds or to the mistaken identity of the basic oxide. It seems reasonable to conclude that the trivalent state of neodymium is the highest oxidation state of the element observed up to the present time.

Summary

1. A product claimed to be neodymium dioxide was identified as basic neodymium oxide NdO(OH).

2. The trivalent state of neodymium is the highest oxidation state observed so far.

Heat Capacities at Low Temperatures and Entropies of Magnesium and Calcium Fluorides

BY S. S. TODD[1]

In an earlier paper[2] from this Laboratory, heat content and entropy-increment data were reported for magnesium and calcium fluorides, in the temperature range 298.16 to 1800°K. The present paper is a low-temperature calorimetric study of these compounds from 52 to 298°K. Throughout this temperature range, heat capacities of magnesium fluoride and calcium fluoride were obtained at regular intervals, and from the data their entropies were calculated. No previous similar data exist for magnesium fluoride. Eucken and Schwers[3] have investigated the heat capacity of calcium fluoride from 17 to 86°K. and Koref[4] has made two mean specific heat measurements at 136.4 and 236.5°K. However, from these data an entropy value[5] for calcium fluoride at 298.16°K. was derived which had an uncertainty of about 2.5%.

Materials

The magnesium fluoride used in these measurements was part of the material prepared for the heat content study of this substance by Naylor.[2] His method of preparation and analysis are repeated here. Baker C. P. Analyzed magnesium oxide, containing less than 0.3% Ca and 0.5% SO_4, was treated with hot 48% HF for sixteen hours and then dried at 400°. Analysis for magnesium by conversion to sulfate and weighing as magnesium sulfate gave 38.97% Mg (theoretical 39.02%).

The calcium fluoride sample was some large natural fluorite crystals, having a very faint purple color, which were coarsely ground in a diamond mortar and the iron removed with a magnet. Since Naylor[2] employed some of the same batch of fluorite, his analysis is given here. The ground fluorite when successively treated with hydrochloric and sulfuric acids and weighed as $CaSO_4$, gave 51.27% Ca (theoretical 51.33%).

Heat Capacities

The method and apparatus used in the heat capacity measurements have been described in

detail by Kelley, Naylor and Shomate.[6] The conventional thermochemical calorie[7] (1 cal. = 4.1833 int. joules) is used throughout, and the ice-point is taken as 273.16°K. The calorimeter contained 102.01 g. and 252.02 g. *in vacuo* of magnesium and calcium fluorides, respectively.

All the experimental results are listed in Table I and shown graphically in Fig. 1.

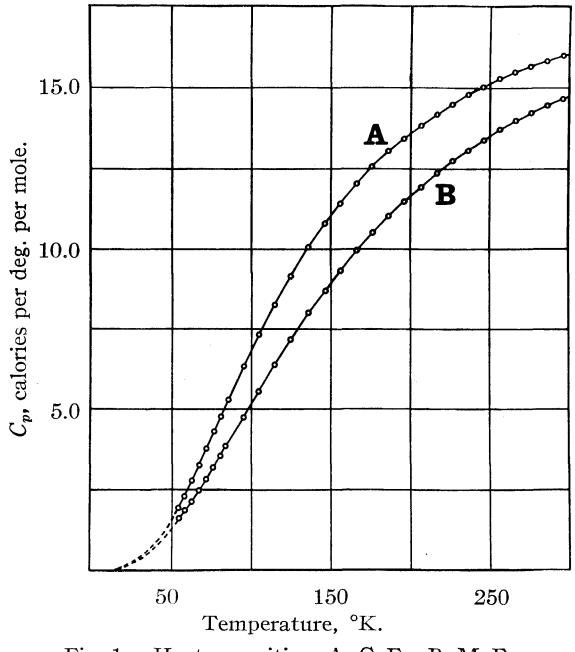

Fig. 1.—Heat capacities: A, CaF_2; B, MgF_2.

Also in Table I are extrapolated values of the heat capacity of each fluoride at 298.16°K. The molecular weights in Table I are taken from the 1947 table of international atomic weights.[8]

The heat capacity results are believed accurate on the average to within ±0.3% in the absolute sense and have a precision error under 0.1%. The early heat capacity measurements of Eucken and Schwers[3] on calcium fluoride from 17 to 86°K. have considerably less precision than the present work. In the overlapping temperature range, 53 to 86°K., their results run progressively higher than present values by amounts ranging from zero to 3%. At lower temperatures their values are below any reasonable extrapolation of the present results.

	MgF_2	CaF_2
0–51.00°K. (extrap.)	0.54	0.64
51.00–298.16°K. (meas.)	13.14	15.82
$S^\circ_{298.16}$	13.68 ± 0.07	16.46 ± 0.08

The extrapolated entropy values, 0.54 for magnesium fluoride and 0.64 for calcium fluoride, constitute less than 4% of their entropies at 298.16°K. as given in Table II. The previously accepted entropy value,[5] 16.4 ± 0.4 at 298.1°K., for calcium fluoride has not been changed materially by the present work but its uncertainty has been reduced sharply in magnitude.

Summary

The heat capacities of magnesium fluoride and calcium fluoride have been measured throughout the temperature range 52 to 298°K.

Their entropies at 298.16°K. have been calculated to be 13.68 ± 0.07 and 16.46 ± 0.08 cal./deg./mole, respectively.

The Effects of Radioactivity on Oleic Acid[1,2]

BY VIRGINIA L. BURTON

In initial research[3,4] pertaining to the role of radioactivity in petroleum genesis, it was shown that paraffinic components of petroleum could be produced by the irradiation with alpha particles or deuterons of certain fatty acids known to occur in source sediments. Likewise, a cycloparaffin has been produced from a naphthenic acid.

In all these early bombardments hydrogen was usually the major component of the gaseous products. However, since hydrogen is found only in minute quantities in the natural gases associated with petroleum, the theory that radioactivity plays a part in petroleum genesis has been subject to some criticism. Although it had been proposed that hydrogen could disappear to the atmosphere by diffusion through the cap rock, it seemed likely that the unsaturated compounds in source sediments might be hydrogenated under the influence of radioactivity and thus absorb at least part of the hydrogen produced.

Benzoic acid was the first unsaturated compound to be bombarded with deuterons in an effort to determine if the hydrogen usually produced during a bombardment would saturate the double bonds of the ring. That is, an effort was made to determine if hydrogen produced by the decomposition of one molecule would, under the influence of radiation, enter the ring of another molecule. The volume of gas produced was very small; it consisted of 85% of carbon dioxide and only 1.8% of hydrogen. No evidence has been found for the formation of the saturated compounds, hexahydrobenzoic acid or cyclohexane, and attempts to identify the infusible reaction product have been unsuccessful.

Because considerable data were available concerning the effects of radioactivity on the fatty acids, a carefully purified sample of oleic acid was bombarded in the M. I. T. cyclotron. Bombardment techniques and equipment have been described elsewhere.[5]

Results

Gaseous products were analyzed and found to consist mainly of carbon dioxide and hydrogen. Table I shows the complete analysis. The data from a preliminary alpha bombardment are given for comparison. The columns under "deuteron" represent analyses of the gas sample collected during each thirty-minute period of the two-hour bombardment. There appears to be a consistent increase in hydrogen production and decrease in carbon dioxide formation during the irradiation.

TABLE I

GASEOUS BOMBARDMENT PRODUCTS FROM OLEIC ACID

[a] Mass spectrometric analyses. [b] Low temperature omit combustion analysis.

The acid changed during the bombardment from a light colorless liquid to an amber, fluorescent, highly viscous material resembling heavy motor oil. Thirty-one per cent. of the original oleic acid remained after bombardment. Of the material converted, 10% was recovered as non-saponifiable material, 52.5% as polymerized acid and an estimated 1.7% as stearic acid.

Thirty per cent. of the non-saponifiable material was separated as a light colorless hydrocarbon (3% of the original oleic acid).[6]

A second product from the bombardment was a viscous material remaining in the flask following the saponification. This material, which was insoluble in the alcoholic solution and in ether, went into soapy solution in water. After hydrolysis, these polymerized acids, which were now ether-soluble, weighed 10.5 g. (52.5% of the total oleic acid bombarded). Although an infrared analysis has been run, no further data have been obtained. It appears that polymerization occurs as a result of unsaturation since no polymerized acidic material had been recovered in earlier bombardments of saturated fatty acids.

After the stearic acid was isolated, it was purified and mixed with an authentic sample of the compound. The stearic acid recovered from the bombarded oleic acid had a melting point of 69.5° and the mixed melting point was 70°. No stearic

(6) Burton and Breger, submitted for publication.

acid could be detected in the original unbombarded oleic acid proving that hydrogenation had taken place under the influence of the deuteron beam.

The following material balance was drawn up for the bombardment:

Reactant	Mole
Oleic acid	0.201
Products	
(Total moles liberated during bombardment)	
Oleic acid (recovered after bombardment)	0.063
Carbon dioxide	0.043
Hydrogen	0.066
Other gaseous products	0.019
Heptadecene	0.007
Stearic acid	0.003
Polymeric acids (52.5%) and uninvestigated non-saponifiables (7%)	...
Total	0.201

The moles of polymeric acids formed could not be calculated because of the difficulty in determining the molecular weight of the material. These acids were insoluble in the solvents commonly used for this purpose and a high molecular weight is therefore inferred.

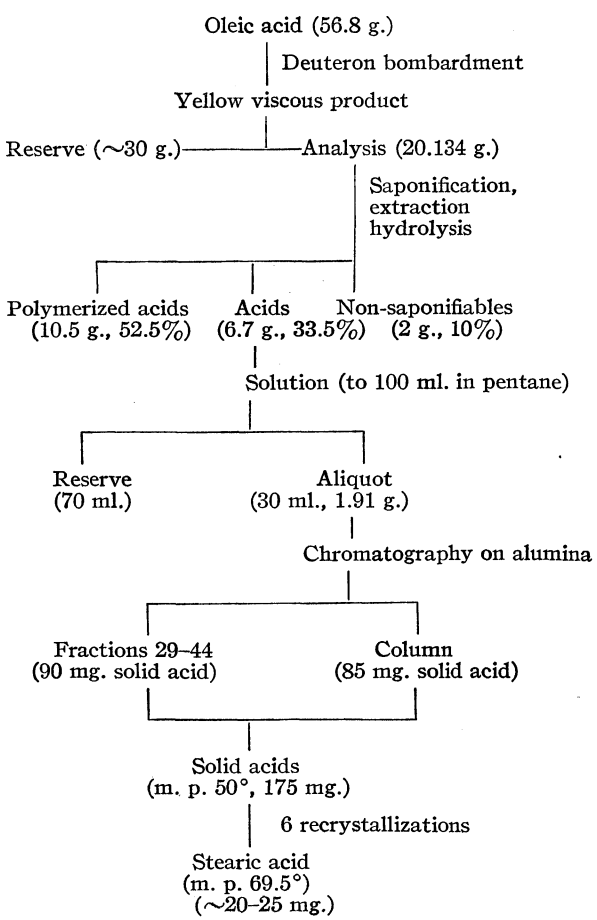

Fig. 1.—Analytical scheme used in separating stearic acid.

The number of molecules of oleic acid converted per one hundred electron volts of energy input was 2.16. Likewise, the number of molecules of stearic acid formed was 0.047. This indicates that approximately 2.5 molecules of stearic acid were formed for every one hundred molecules of oleic acid that were converted.

Experimental

Several methods for the purification of oleic acid were attempted, but a modification of the procedure of Wheeler and Riemenschneider[7] was used. This method consisted of the fractional distillation and crystallization of the methyl esters followed by hydrolysis and distillation of the acid.

Technical oleic acid (2 l.) obtained from the Eastman Kodak Company, Rochester, New York, was converted to the methyl ester by refluxing with 2 l. of methanol and 75 ml. of sulfuric acid for three hours. The methyl ester was then fractionated under 1–2 mm. of mercury in a two-foot jacketed Vigreux column to give 1765 ml. of product.

To simplify handling, all crystallizations were carried out batchwise. The ester (1320 ml.) was dissolved in 16.8 l. of acetone and cooled to −60° with stirring to remove the linoleic and linolenic acids. The heavy white precipitate of methyl oleate was rapidly filtered on a Büchner funnel maintained at the crystallization temperature by a Dry Ice–acetone jacket.

The crystals were allowed to melt, and the material was then dissolved in acetone (10 ml. per g.) and crystallized at −37° to remove palmitic and stearic acids. The precipitate was filtered on a Büchner funnel as before. This procedure was repeated twice and was then followed by another −60° crystallization; yield, 480 ml. Unlike the method of Wheeler and Riemenschneider, which included a second distillation of the methyl esters followed by two crystallizations at −65°, the methyl oleate was next hydrolyzed with alcoholic potassium hydroxide. The soap formed was carefully neutralized with hydrochloric acid to remove the pure acid and this was then fractionated under 1 mm. of mercury to yield 75 ml. of oleic acid, b. p. 220–221° (1.5 mm.), $n^{20}D$ 1.4592, freezing point (from curve) 5.74°–8.92°. Small percentages of linoleic and linolenic acids were probably still present in the final product. These compounds were of little importance to the object of this work.

The purified oleic acid (56.8 g.) was bombarded for two hours with an average beam intensity of 9 microamperes using the gold plated chamber described by Honig.[5] After the bombardment, 20 g. of the thick viscous product was saponified by refluxing for three hours with 50 ml. of 10% sodium hydroxide and 100 ml. of alcohol. The amber-colored solution was decanted from the insoluble polymerized acids and was then extracted with ether, enough water being added to yield two phases. A small amount of hexane was added to cut down the solubility of the water in ether.

The sodium hydroxide solution was acidified with excess hydrochloric acid and was extracted with ether which was then dried over sodium sulfate and evaporated on a steam-bath. The residue was made up to 100 ml. with pentane in a volumetric flask (6.7 g., 33.5% of the oleic acid bombarded). To a 30-ml. aliquot was added 70 ml. of pentane, 15 ml. of ether, and 2 ml. of benzene to obtain a clear solution which was then passed through a 12 × 800 mm. column packed with a mixture of five parts of J. T. Baker alumina to one part of Celite 545. The filtrate was collected in 10-ml. portions in a running chromatogram and the column was washed with 175 ml. of the pentane–ether–benzene solution, 50 ml. of pentane containing 10% methanol, and 120 ml. of pentane containing 20% methanol. A total of 44 cuts was collected.

(7) Wheeler and Riemenschneider, *Oil and Soap*, **16**, 207 (1939).

Fractions 29–44 contained an infusible solid in each flask after the solvent was evaporated. When ether was added the precipitate swelled and became very gelatinous. Following hydrolysis of several of the above cuts with hydrochloric acid, extraction with ether, and evaporation of the solvent, an oily residue remained indicating that the acids had come through the column as aluminum salts. Since a solid residue was recovered from cut 44 after hydrolysis, cuts 29–44 inclusive were combined, hydrolyzed, extracted with ether and dried over sodium sulfate. After the ether was evaporated on a steam-bath, 90 mg. of solid material was separated from the above cuts by crystallization from acetone at −20°.

The chromatographic column was next cut into four sections each of which was eluted with methanol. The three lower sections contained gelatinous precipitates which, after hydrolysis, yielded solid residues. One hundred and seventy-five milligrams of solid material (m. p. 50°) was separated from the column and the filtrates. By means of six crystallizations from acetone at −20° in a centrifuge tube, the melting point of this solid was raised from 50 to 69.5°. A mixed melting point with authentic stearic acid was 70° (stearic acid, m. p. 70°). All melting points were taken on a microscope hot stage. The analytical scheme to this point is shown in Fig. 1.

Because the loss of stearic acid during recrystallization was so great, it was necessary to use an indirect method to estimate the amount present. A blank chromatogram containing 3% of stearic acid (42 mg.) in the purified oleic acid was next run. Seventy-four milligrams of solid acid (m. p. 50°) was separated as above. From melting point curves for mixtures of oleic and stearic acids,[8,9] it was established that the isolated material contained 25% of stearic acid, a recovery of 18.5 mg. or 44%.

The solid separated from the bombarded oleic acid (175 mg.) also contained 25% stearic acid (43.8 mg.) as indicated by its melting point of 50°. After correcting for the 44% recovery by chromatography, as indicated above, it was found that the stearic acid isolated (100 mg.) amounted to 5.3% of the non-polymerized saponifiable material. On the basis of the original acid bombarded this figure becomes 1.7%.

Since the stearic acid isolated had been concentrated by a factor of nearly three upon the removal of the polymeric acids and the non-saponifiable material (62.5%), it was necessary to determine if the acid (1.7%) represented original impurity which was below the limit of chromatographic detection using the unbombarded acid. A sample of the purified oleic acid to which was added 1% of stearic acid was, therefore, chromatographed by the above procedure and the stearic acid was easily detectable. No stearic acid could be isolated when the oleic acid itself was chromatographed.

This work indicated that the original oleic acid contained less than 1% of stearic acid and the bombarded oleic acid contained approximately 1.7%, both values being determined by the same analytical technique. It was thus shown that oleic acid was hydrogenated to stearic acid.

Acknowledgments.—The author wishes to thank Prof. Clark Goodman and Prof. W. L. Whitehead for their encouragement and counsel. Considerable advice and assistance was given by I. A. Breger. Mass spectrometric analyses were obtained by Earle C. Farmer and through the courtesy of R. E. Honig of the Socony–Vacuum Company. The bombardment was made possible through the coöperation of Mr. Farmer, Dr. Eric Clarke and the M. I. T. cyclotron crew.

Summary

Purified oleic acid has been bombarded with deuterons in the M. I. T. cyclotron. Analysis of the irradiated material has revealed the formation of stearic acid, heptadecene, and polymerized acids.

It has been shown that the hydrogen produced by decomposition of an organic molecule under the influence of radioactivity can enter the double bond of a neighboring molecule. It has thus been demonstrated that hydrogen which may be produced by the effects of radioactivity on the organic constituents of a petroleum source sediment could, in part, be removed from the gas phase by reaction with unsaturated components of the sediments.

Metal–Salt Interactions at High Temperatures: the Cerium–Cerium Chloride System[1]

BY DANIEL CUBICCIOTTI[2]

The properties of alkali halide crystals containing excess metal have been the subject of extensive investigation by Pohl and co-workers.[3] Their study has led to an explanation of the ability of an alkali halide to dissolve excess metal and to the development of the theory of lattice defect points in crystals.[4] For divalent halides, studies of the miscibility of metal and salt have been made[5]; however, few other data have been accumulated on such systems. Only one report of metal–salt equilibria for trihalide salts is known to this author. The bismuth–bismuth trichloride and bismuth–bismuth tribromide phase diagrams are reported by Eggink.[6] These systems appear to be similar to those recently reported for divalent halides.[5]

To extend the data in the field of metal–salt equilibria the present study on a trivalent halide was made. The system cerium–cerium chloride was chosen because the melting point of cerium

is very near that of cerium chloride and thus no elaborate containers were necessary for the materials.

Experimental

Method.—The methods used in this work were the same as those reported in a previous paper.[5] Since cerium metal dissolves iron, however, it was impossible to use iron containers or thermocouple wells. The containers used were molybdenum crucibles formed from sheet metal and welded under a helium atmosphere. The end of the thermocouple well was a molybdenum test-tube of 0.01-inch wall thickness and 4 inches long. This end was machined from a solid rod of metal. It was threaded and screwed into an iron tube to give the thermocouple well sufficient length.

Materials.—Cerium metal and anhydrous cerium trichloride were supplied by Dr. F. H. Spedding of Iowa State College. The trichloride was found to contain 3 weight % other rare earths and less than 0.1 weight % insoluble matter (oxide or oxychloride). The metal had been prepared by the chemical reduction of its chloride and contained 0.4 mole % of chloride. The metal was found to freeze at 770° as compared to a m. p. of 775° given by Kelley.[7] The trichloride froze at 802° as compared to a melting range of 790 to 810° given by Jantsch and Wien.[8]

Results

Some of the cooling curves obtained are shown in Fig. 1 as illustrations of the magnitude of the thermal effects observed. Figure 1, a, b, c, gives curves obtained on the pure salt and salt-rich mixtures. The humped character of the first break indicates some supercooling of the mixture before the solid salt phase separated. The temperatures of the break in such cases was taken as the temperature at the top of the hump.

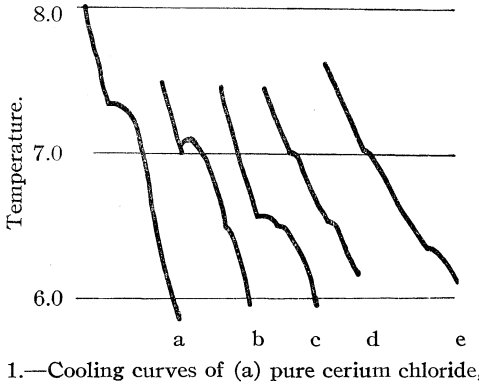

Fig. 1.—Cooling curves of (a) pure cerium chloride, (b) cerium chloride with 10 mole % cerium, (c) cerium chloride with 29 mole % cerium, (d) cerium metal, and (e) cerium metal with 14 mole % cerium chloride (temperature scale in millivolts from a Pt–Pt 10% Rh thermocouple).

In Figure 1, d, e the cooling curves obtained on the metal and a metal-rich mixture are given. In both of these curves there are two breaks detectable. The higher temperature breaks occurred at the same temperature, while the temperatures of the lower breaks are only approximately the same. The higher-temperature breaks for both the metal and the mixture must have been the invariant temperature corresponding to two liquid plus one solid equilibrium. Apparently, the 0.4 mole per cent. of cerium chloride impurity in the metal was sufficient to lower the freezing point of the metal to the temperature of the three-phase invariant. The lower temperature breaks of these metal-rich mixtures are assumed to correspond to the eutectic break. The temperatures of the lower breaks are below the eutectic break, as observed in the salt-rich region, presumably because the mixture super-cooled.

At one temperature (810°) the compositions of the two liquids in equilibrium were measured. A mixture of salt and metal was equilibrated at that temperature and then quenched by immersing the bottom of the crucible in water.[9] When cold, the metal phase was found on the bottom of the crucible. It had all the appearances of the original metal. The salt-rich phase was an intensely black, friable solid that reacted vigorously with dilute acid.

The temperature–composition diagram for the solid–liquid equilibria of the cerium–cerium chloride system is shown in Fig. 2. Since the cerium metal used was not pure, a literature value for the f. p. of pure cerium is included in the diagram. The point at 775° and 100% cerium is the m. p. of pure cerium as given by Kelley.[7] The shapes of the curves outlining the miscibility gap were assumed to be similar to those observed in other metal–salt systems,[5] and were drawn in through the observed points.

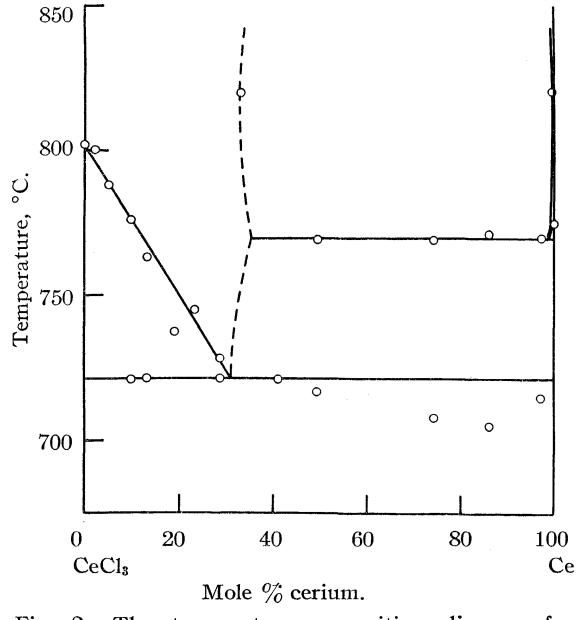

Fig. 2.—The temperature–composition diagram for solid–liquid equilibria in the cerium chloride–cerium system.

Discussion

A comparison of the solubility of cerium in its chloride with the solubilities of other metals in

(7) Kelley, "Contributions to the Data on Theoretical Metallurgy," Bur. Mines Bull. No. 393.

(9) See ref. (5) for experimental details.

their salts is made in Table I which gives the concentration of metal in the salt phase of the two-phase equilibrium between liquid metal and liquid salt. The metals chosen for the comparison are those whose cationic radii are approximately equal because it has been shown that for divalent systems the solubility depends on the cationic radius.[5]

TABLE I

Metal	Solubility in mole %	Cationic radius[a] in Å.
K	1[b]	1.33
Sr	20[c]	1.13
Ce	33	1.15[d]

[a] Radii from Pauling "The Nature of the Chemical Bond." [b] Estimated from the data of Mollwo, *Z. Physik*, **85**, 56 (1933), on the solubility of potassium in its solid halides and Rogener, *Ann. Phys. Leipzig*, [5] **29**, 386 (1937), on the solubility of potassium in liquid potassium bromide. [c] Estimated from data on other alkaline earth systems, see ref. (5). [d] The radius of trivalent cerium is assumed to be the same as that for trivalent lanthanum.

From Table I it appears that the solubility of a molten metal in its chloride depends upon the charge of the cation of the pure salt. However, this dependence may be a dependence of the solubility upon some property related to the cationic charge. Thus, the significant property may be the ratio of number of cations to number of anions in the salt, which, for a given anion, is proportional to the cationic charge. Additional data would be required to select the property upon which the solubility truly depends.

Summary

The temperature–composition diagram has been determined for the liquid–solid equilibria in the cerium–cerium chloride system. The diagram is similar to those previously reported for some alkaline earth metal–halide systems.

Quantitative Determination of Amino Acids on Filter Paper Chromatograms by Direct Photometry[1]

BY LOUIS B. ROCKLAND AND MAX S. DUNN

The following types of procedures have been suggested for the determination of amino acids on filter paper chromatograms: (A) elution of the spots before or after staining with a chromogenic agent (such as ninhydrin) and analysis of the elutes,[2–8] (B) modified isotope dilution analysis of the spots with the aid of radioactive tracer amino acids,[9] (C) visual comparison of the color intensities of standard and test sample chromatograms stained with ninhydrin,[2] and (D) direct comparison of spot sizes or color intensities of ninhydrin-stained standard and test-sample chromatograms.[10–14] Amino acid test mixtures have been analyzed by Bull, *et al.*,[11] and Woiwod[3] and protein hydrolyzates by Polson, *et al.*,[2] Martin and Mittlemann,[4] Keston, *et al.*,[9] and Block.[13]

Alanine and glycine have been determined in silk fibroin in the present study by a rapid, direct photometric analysis of color intensities of filter paper chromatograms stained with ninhydrin.

Experimental

Filter paper chromatograms were prepared by the capillary ascent test-tube method of Rockland and Dunn.[15] Ten dilutions, 2×10^{-4} ml. each, of standard containing from 0.625 to 6.250 mg. per ml. of DL-alanine and of glycine were placed on eight replicate strips ($10 \times 18 \times 140$ mm.) of Whatman No. 1 filter paper with the aid of a 0.01 ml. total displacement Gilmont ultramicroburet.[16] Similarly, seven dilutions of an acid hydrolysate[17] containing from 3.010 to 12.040 mg. per ml. of silk fibroin (moisture- and ash-free basis) were placed on three replicate strips of the filter paper. The chromatograms were developed simultaneously for three hours at room temperature in 8-inch test tubes containing water saturated phenol, dried for 5 minutes at 100°, sprayed lightly eight times on each side with 0.25% ninhydrin solution in water saturated butanol and heated for five minutes at 100°. The alanine was resolved completely at the seven levels but glycine only at the two lowest levels.

In order to determine the concentrations of the amino acids, the filter paper strips were placed in a special sample holder containing an opening of a size just sufficient to enclose the entire area of the colored spot and the color intensities were read directly with the aid of a photoelectric colorimeter.[19] The alanine and glycine content of silk fibroin were estimated by interpolation from the standard curves drawn from plots of per cent. transmission against concentration of amino acid on coördinate paper.

TABLE I

PERCENTAGES OF ALANINE AND GLYCINE IN SILK FIBROIN[a]

Amino acid		Alanine	Glycine
Analysis of filter paper chromatograms	Indirect photometric, Polson *et al.*[2]	37.6	39.9
	Direct: Visual Polson, *et al.*[2]	34.0	42.4
	Direct: Photometric, authors	34.9	43.4
Selective pptn., Bergmann and Niemann,[21]		26.4	43.8
Microbiological, Shankman, *et al.*[20]		..	43.6

[a] Corrected for moisture and ash.

The data obtained for glycine and alanine in silk fibroin are given in Table I. It may be noted that the value (43.4%) found for glycine in silk fibroin is in good agreement with the values (39.9 to 43.8%) reported by earlier workers who used microbiological,[20] selective precipitation[21] and analogous photometric-chromatographic[2] procedures. Although the value 34.9% found for alanine is in good agreement with the values, 34.0 and 37.6%, reported by Polson, *et al.*,[2] it is much higher than the value of 26.4%, obtained by Bergmann and Niemann.[21]

Summary

A method has been described for the quantitative determination of amino acids on filter paper chromatograms by direct photometry. It has been found by this method that silk fibroin contained 43.4 per cent. of glycine and 34.9 per cent. of alanine. These values are in good agreement with others given in the literature.

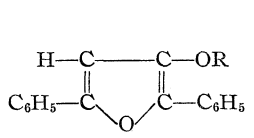
The Transetherification of 3-Alkoxy-2,5-diphenylfurans[1]

BY PHILIP S. BAILEY AND JOHN D. CHRISTIAN

The conversions of 3-methoxy- and 3-ethoxy-2,5-diphenylfurans (I), one into the other, in solutions of the opposite alcohol, triethylamine hydrochloride and a trace of hydrogen chloride was reported in an earlier paper.[2] In the present paper is described a further study of this reaction which might be termed a transetherification[1b] by comparison to the corresponding transesterification reaction which esters undergo. Both employ an acid catalyst and both involve the displacement of an alkoxy group directly attached to an unsaturated grouping.



I (a) R = CH_3
(b) R = C_2H_5
(c) R = C_3H_7-*n*
(d) R = C_4H_9-*n*
(e) R = C_4H_9-*i*
(f) R = $-C(=O)-CH_3$

Concerning the minimal conditions necessary for the reaction, it was found in the study that the hydrogen chloride was essential, whereas the amine hydrochloride was not. No conversion was observed in the absence of the hydrogen chloride even though the amine hydrochloride was present. Under the opposite conditions, conversion did occur, but in poorer yield than when both reagents were present. In all subsequent runs, therefore, both reagents were used.

The reaction using 3-methoxy-2,5-diphenylfuran was found to occur with ethanol, *n*-propyl alcohol, *n*-butyl alcohol and isobutyl alcohol. The yields varied from 68 to 55%. Isopropyl alcohol and *t*-butyl alcohol gave no reaction, and *s*-butyl alcohol, *n*-amyl alcohol and isoamyl alcohol gave principally non-crystalline products which are assumed to be of a different nature, since the corresponding alkoxyfurans should be crystalline by comparison to the others known.[3] Transetherifications of alkoxyfurans of higher molecular weight to alkoxyfurans of lower molecular weight were also carried out.

The alcoholysis reaction was extended also to 3-acetoxy-2,5-diphenylfuran, using methanol and *n*-propanol. Isopropyl alcohol, *n*-butyl alcohol and isobutyl alcohol reacted differently to yield oils plus a dimolecular oxidation product, 2,2′-bis-(2,5-diphenylfuranone-3).[4] The reaction failed with 3-(4-morpholinyl)-2,5-diphenylfuran (II) and, as reported earlier,[2] with 3-chloro-2,5-diphenylfuran. All of the above described transformations are listed in Table I.

From the viewpoint of synthesis of alkoxyfurans, the alcoholysis of 3-methoxy-(or 3-ethoxy-) and 3-acetoxy-2,5-diphenylfurans is of limited value. However, since only 3-methoxy- and 3-ethoxy-2,5-diphenylfurans can be made from 1,2-dibenzoyl-1,2-dibromoethane,[2,5,6] these transfor-

mations constitute the best known method for the cases applicable. Very poor yields are obtained from the addition of alcohols to 1,2-dibenzoylethylene.[2,5]

It is interesting to note that under the conditions of the transetherification reaction the purely aliphatic, unsaturated alkyl vinyl ethers undergo addition[7] and the purely aromatic anisole (III) gives no reaction. Other alkoxyunsaturates, in between these two extremes as far as stability of the unsaturated nucleus is concerned, should, like the alkoxydiphenylfurans (I), react by displacement. This displacement perhaps occurs by an addition mechanism similar to that of the transesterification reaction. Such a mechanism has previously been suggested for the etherification of β-naphthol by alcoholic hydrogen chloride.[8]

The similarity between the alkoxyfurans (I) and esters does not extend too well to other reactions. No reaction was observed between 3-methoxy-2,5-diphenylfuran and ammonia (in methanolic solution) or hot morpholine. Hydrolysis occurred, however, when the methoxyfuran was refluxed with 6 *N* hydrochloric acid. The product was 2,2′-bis-(2,5-diphenylfuranone-3)[4] (IV), presumably formed by the oxidation of 3-hydroxy-2,5-diphenylfuran.

The characteristic nitric acid oxidation of Lutz and Wilder[9] has been carried over to several 3-alkoxy-2,5-diphenylfurans in order to facilitate identification.

Experimental[10]

Typical Experiment. Reaction of 3-Methoxy-2,5-diphenylfuran with Ethanol.—A solution of 1 g. of 3-methoxy-2,5-diphenylfuran, 1 g. of triethylamine hydrochloride, 30 ml. of ethanol (distilled from sodium ethoxide) and enough ethanolic hydrogen chloride to give an indicated *p*H of 2 (*p*-Hydrion paper) was refluxed for thirty hours, during which time the *p*H was maintained at 2–3. The solution was evaporated to dryness, the residue was extracted with ether and the ether extract was washed and evaporated. Crystallization of the residue from ethanol gave 0.7 g. (66% yield) of 3-ethoxy-2,5-diphenylfuran (m. p. 90.5–92.5°; identified by a mixture melting point with an authentic sample).[5] A red viscous oil remained.

When the triethylamine hydrochloride was omitted, everything else remaining the same, only a 33% yield of the ethoxyfuran was obtained. No reaction was obtained when the hydrogen chloride was omitted and the triethylamine hydrochloride was present (80% recovery of methoxyfuran plus an intractable oil) nor when both the hydrogen chloride and triethylamine hydrochloride were omitted (96% recovery of methoxyfuran).

Attempted reaction of 3-methoxy-2,5-diphenylfuran with morpholine (1 g. of furan and 40 ml. of morpholine for thirty hours at 70°) gave a 87% recovery of the methoxyfuran (m. p. 112–114°, identified by a mixture melting point) and a red oil. A similar reaction with a saturated methanolic solution of ammonia (1 g. furan, 80 ml. solution) was attempted for eight days at room temperature. The recovery of methoxyfuran was 99%.

Acid Hydrolysis of 3-Methoxy-2,5-diphenylfuran.—A mixture of 1 g. of the 3-methoxyfuran and 50 ml. of 6 *N* hydrochloric acid was refluxed with stirring for thirty hours. The mixture was evaporated to dryness by a stream of air, the residue was treated with ether, and the resulting mixture was filtered. On the filter paper was obtained 0.33 g. (34% yield) of 2,2′-bis-(2,5-diphenylfuranone-3) which melted at 243–246° and was identified by a mixture melting point with an authentic sample.[4] Evaporation of the ether extract gave an oil which resisted crystallization.

The nitric acid oxidation of 3-methoxy-2,5-diphenylfuran was carried out by the general method of Lutz and Wilder[9] in acetic acid medium at room temperature. The yield of known 1,2-dibenzoyl-1-methoxyethylene, which, incidentally, must be the *cis* isomer,[9] was 14% (m. p. 103–106°, identified by a mixture melting point with a known sample[6]). A red oil also was obtained.

The nitric acid oxidation[9] of 3-ethoxy-2,5-diphenylfuran was carried out in propionic acid at 0° for ten minutes. The yield of *cis*-1,2-dibenzoyl-1-ethoxyethylene (m. p. 97–100°, identified by a mixture melting point with an authentic sample[6]) was 78%. The lower temperature apparently accounts for the improved yield over that of the preceding experiment.

TABLE I

Reactants[a]	Products	Yield, %

cis-**1,2-Dibenzoyl-1-*n*-propoxyethylene** was prepared from 2,5-diphenyl-3-*n*-propoxyfuran by the general method[9] described in the experiment just preceding. After several recrystallizations from ethanol and isopropyl alcohol the material melted at 72–73°; the yield was 77%.

Anal. Calcd. for $C_{19}H_{18}O_3$: C, 77.53; H, 6.17. Found: C, 77.18; H, 6.16.

The propoxyethylene was converted back to the furan by reduction with zinc and acetic acid.[6]

cis-**1,2-Dibenzoyl-1-isopropoxyethylene** was prepared from 2,5-diphenyl-3-isopropoxyfuran[5] in propionic acid at 0° by the general method[9] described above. The yield of material melting at 108–109° after recrystallization from isopropyl alcohol was 78%.

Anal. Calcd. for $C_{19}H_{18}O_3$: C, 77.53; H, 6.17. Found: C, 77.74; H, 6.44.

Zinc and acetic acid reduction[6] converted the material back to the furan from which it was made.

The difference in melting points between 1,2-dibenzoyl-1-*n*-propoxyethylene and 1,2-dibenzoyl-1-isopropoxyethylene makes them easily distinguished. Thus the corresponding furans can easily be distinguished through these derivatives. They are otherwise difficult to differentiate between, since the isopropoxyfuran melts at 87–88°, the *n*-propoxyfuran at 86–87° and the mixture melting point between the two is 82–85°.

Acknowledgments.—The authors wish to thank the Research Corporation, New York, N. Y., for a grant-in-aid which helped make this work possible. They also wish to thank Mr. Elias E. Kawas for carrying out three of the alcoholysis experiments.

Summary

1. 3-Alkoxy-2,5-diphenylfurans have been found to undergo alcoholysis, termed transetherification, under acidic conditions.

2. A comparison is made of transetherification, transesterification and the addition of alcohols to alkyl vinyl ethers.

3. The nitric acid oxidation of 2,5-diarylfurans to *cis*-1,2-diaroylethylenes has been extended to 3-alkoxy-2,5-diphenylfurans.

A Glyco-lipide Produced by *Pseudomonas Aeruginosa*[1]

BY F. G. JARVIS[2] AND M. J. JOHNSON

Several crystalline compounds[3,4,5,6,7] and at least two partially purified oils[8,9] have been isolated from *Pseudomonas aeruginosa* cultures. These materials have been primarily investigated with respect to their antibacterial activity. With the exception of pyocyanin,[3,4] none of these metabolic products have been fully characterized. The isolation and investigation of the structure of an acidic, crystalline glyco-lipide produced by *P. aeruginosa* is described in this paper. The compound contains the same structural units (L-rhamnose and *l*-β-hydroxydecanoic acid) as the oil isolated by Bergström, *et al.*,[9] but has a higher molecular weight and a higher rhamnose–hydroxy-acid ratio. It is quite possible that the compound is identical to the crystalline material isolated by Birch-Hirschfeld[6] but insufficient data are available for suitable comparison. Our compound was found to be bacteriostatic to *Mycobacterium tuberculosis* H37 Rv in a concentration of about 0.5 mg. per ml. of culture medium. Five mg. given introperitoneally to mice killed in about sixteen hours.[10]

Isolation.—The organism was grown on a 4% Difco peptone–3% glycerol broth at 30° on a reciprocating shaker. Cultures were harvested after from four to five days growth. The acid was produced by each of three strains of *P. aeruginosa* tested (University of Washington strains no. 141, 142, 261). The one strain of *P. florescens* tested failed to produce the compound. Yields as high as 2.5 g. per liter were obtained. The crystalline acid was not produced (or could not be isolated by our procedure) when the peptone was replaced by tryptone or the glycerol replaced by glucose in the growth medium.

The compound was obtained in crystalline form by acidifying the whole culture to *p*H 2 with sulfuric acid and refrigerating for two or three days. The crystals were collected on very coarse filter paper, taken up in a small volume of ethyl ether (insoluble residues discarded) and precipitated by addition of petroleum ether. After the removal of solvent by decantation and evaporation, the precipitate was dissolved in dioxane and crystallized by adding water and chilling. The material could be recrystallized in the cold by acidifying water solutions of its sodium salt or by adding water to dioxane or acetone solutions of the free acid.

Properties.—The compound crystallizes in the form of thin, colorless rectangular platelets. It is very soluble in ether, ethyl alcohol, acetone, dioxane and dilute sodium bicarbonate solution. It is nearly insoluble in water and petroleum ether. The compound (m. p. 86°, α_D = −84°, 3% in chloroform) has a neutral equivalent of about 665. Molecular weight determinations by the Rast method gave a value of about 650.

Anal.[11] Calcd. for $C_{32}H_{58}O_{14}$: C, 57.64; H, 8.77. Found: C, 57.62; H, 8.74.

Other data (see below) indicate that the true formula is $C_{32}H_{60}O_{14}$. Quantitative acetylation of the material showed 4.3 hydroxyl groups per mole; however, chromatographic analysis of the acetylated material gave three acidic bands indicating either incomplete acetylation or decomposition during the reaction. The chromatographic

(11) The carbon–hydrogen analyses were performed by the Clarke Microanalytical Laboratory, Urbana, Illinois.

procedure of Ramsey and Patterson[12] was employed, modified to the extent that Celite 545 was used as the supporting phase in place of silica gel. Tests for other active groups were negative. The compound undergoes acid hydrolysis. Periodate oxidation resulted in the uptake of 2 atoms of oxygen per mole of compound. The compound gives a positive Molisch test but does not reduce Fehling solution. A loss of weight equivalent to 1 water molecule per mole of acid occurs upon heating under reduced pressure to 60° for twenty-four hours. The weight loss is more rapid at higher temperatures. The resultant product (m. p. 60–64°) could not be crystallized from dry solvents. When crystallized from aqueous solutions, the original acid (m. p. 86°) was obtained.

Degradation.—The water-soluble fraction obtained by acid hydrolysis (1 *N* hydrochloric acid in 50% redistilled dioxane for two hours at reflux temperature) was obtained in pure crystalline form by neutralization to *p*H 7, removal of solvent by distillation under reduced pressure, extraction of the residue with absolute ethyl alcohol, and crystallization from acetone–ethanol or acetone–water mixtures. The crystalline material gave the usual qualitative tests for an aldose-type monosaccharide.

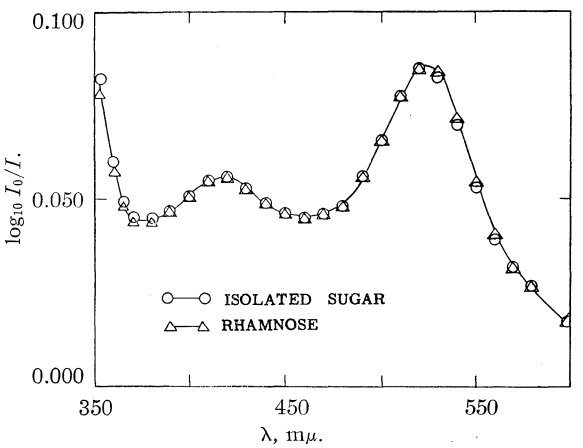

Fig. 1.—Absorption spectra of carbazole–sugar reaction mixtures. Sugar concentrations were 15γ/ml. of reaction mixture: O—O, isolated sugar; △—△, rhamnose.

The absorption spectrum of its carbazole reaction product in sulfuric acid[13,14,15] was determined (Beckman photometer model A, 1-cm. Corex cell and tungsten filament lamp), and found to be identical with that for L-rhamnose (Fig. 1). Although the efficacy of this method has been questioned,[15] we have found that the differences in the absorption spectra (340–600 mμ) of the sugars tested (glucose, galactose, mannose, arabinose, xylose and rhamnose) are more than sufficient for the qualitative indentification of pure sugars if suitably controlled conditions are employed. The sugar (α_D = +8.4°, 5% solution in water) crystallized in two forms, the usual hydrated form (m. p. 92–93°) and the anhydrous form (m. p. 121–123°). A phenylosazone was also prepared (m. p. 179–180°).

Anal. (hydrated form). Calcd. for $C_6H_{14}O_6$: C, 39.56; H, 7.75. Found: C, 39.75; H, 7.69.

All of these data indicate that the sugar is L-rhamnose.

Two moles of reducing sugar were shown to be present in each mole of original acid by quantitative measurement of of hydrolysis (Fig. 2). Quantitative sugar analyses were made by the Shaffer and Somogyi method[16] with their reagent 50 with 5 g. of potassium iodide. Titrations were referred to a standard rhamnose curve. The rates of release of the two reducing groups were quite different, the first being released much more readily than the second. When hydrolysis was halted after the release of the first mole of sugar and the reaction mixture extracted with petroleum ether, the second mole of sugar (unhydrolyzed) was found in the petroleum ether fraction. The sugar present in each fraction was found to be L-rhamnose after isolation.

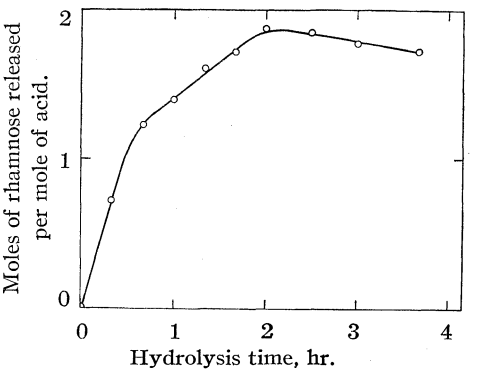

Fig. 2.—Acid hydrolysis of isolated crystalline acid: the reaction mixture contained 200 mg. of isolated acid in 50 ml. of 1 *N* hydrochloric acid in 50% redistilled dioxane at zero hours. Hydrolysis was conducted at reflux temperature and 1 atm.

No other water-soluble compound could be found in appreciable quantity after complete hydrolysis.

The ether-soluble fraction from a two-hour acid hydrolysis was examined by chromatography.[12] Two major acidic fractions were isolated, one of which passed through the column very rapidly and the other much more slowly. The slow component, after separation from small amounts of two closely related impurities by chromatography, was recrystallized from petroleum ether.

Anal. Calcd. for $C_{10}H_{20}O_3$: C, 63.80; H, 10.71. Found: C, 63.93; H, 10.52.

The acid was shown to contain one hydroxyl group per mole by quantitative acetylation followed by chromatography. Two acids were recovered from the column, one with a neutral equivalent of 232 (acetylated acid) and one with a neutral equivalent of 170 (probably dehydrated acid). Titration of the acetylated material produced corresponded closely to theory for the amount of acetic anhydride used. The isolated acid (α_D = −21°, 2.5% solution in chloroform) melted at 47–48°. The S-benzylthiouronium salt melted at 129–130°. Upon oxidation by chromic acid by the method used by Bergström, *et al.*,[9] a volatile, optically inactive liquid acid (neut. equiv. 145) was obtained which was chromatographically identical to *n*-caprylic acid. The chromatographic method employed[12] was found to be sufficiently efficient to positively differentiate between *n*-pelargonic, *n*-caprylic and *n*-enanthic acids. The amide of the oxidized acid was prepared (m. p. 105–106°). A mixed melting point with *n*-caprylamide showed no depression.

Anal. Calcd. for $C_8H_{17}ON$: N, 9.78. Found (Kjeldahl): N, 9.85.

These data indicate that the isolated acid is normal *l*-β-hydroxydecanoic acid although the possibility of its being a branched chain isomer has not been rigorously excluded.

The other major component of the ether-sol-

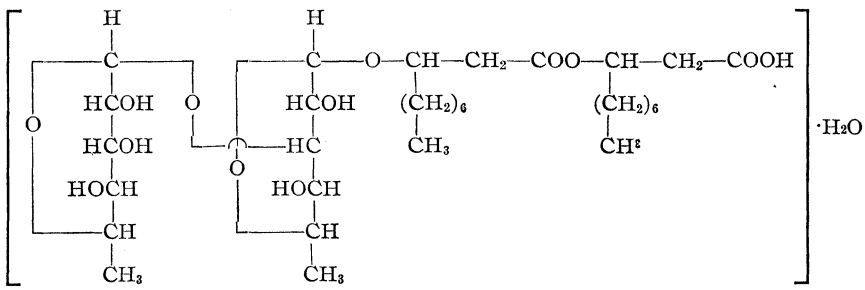
uble hydrolytic fraction could not be obtained in crystalline form. It proved to have a neutral equivalent of about 360 and yielded two moles of β-hydroxydecanoic acid upon saponification. As no such ester is formed by the conditions employed during hydrolysis, and as the proportion of this compound decreases with hydrolysis time, it was concluded that two moles of *l*-β-hydroxydecanoic acid exist in esterified form in the original acidic compound.

The following formula is presented as being most compatible with the accumulated data. The 1,3-linkage shown is, of course, largely speculative as the only pertinent data obtained were the uptake of only two atoms of oxygen per mole of compound by periodate oxidation. Assuming a pyranoside-type ring, either the 1,2- or 1,4-linkages would result in a structure which would normally take up three oxygen atoms. No direct evidence for the type of sugar linkages involved (α or β) was obtained.



Summary

A crystalline, acidic glyco-lipide was produced by three strains of *Pseudomonas aeruginosa* on peptone–glycerol broth.

This compound was found to contain two units each of L-rhamnose and normal *l*-β-hydroxydecanoic acid.

The most likely formula on the basis of the available data is proposed.

The Preparation of 3,4,5-d_3-Lithocholic Acid[1]

BY W. H. PEARLMAN, M. R. J. PEARLMAN AND S. ELSEY

Schoenheimer and Berliner[2] described a procedure whereby deuteriolithocholic acid might be obtained by reduction of methyl $\Delta^{4,5}$-3-ketocholenate in ethanol–ether solution in the presence of platinum oxide; the isotopically labelled bile acid should prove useful for metabolic study. However, their work was carried out with hydrogen and not with deuterium. On repeating their procedure but using deuterium, we obtained lithocholic acid containing only 0.35 atom % excess deuterium whereas the theoretical value for 3,4,5-d_3-lithocholic acid is 7.50. This result is not altogether surprising in view of the observation by Anderson and MacNaughton[3] that deuterium is exchanged for the hydroxyl hydrogen of alcohols such as isopropyl alcohol in the presence of catalysts; evidence was obtained, however, that exchange did not occur with isopropyl alcohol as long as any acetone was present. When absolute ether was substituted for ethanol–ether in the catalytic reduction, lithocholic acid was obtained containing 1.92 atom % excess deuterium. Further investigation of optimal conditions for catalytic deuteration of methyl $\Delta^{4,5}$-3-ketocholenate appeared to be desirable; the results of such an investigation are summarized in Table I. The most satisfactory procedure found was the following. Reduction of methyl $\Delta^{4,5}$-3-ketocholenate in ether using a 5% palladium on charcoal catalyst gave a mixture consisting principally of methyl 3-ketocholanate and some methyl 3-ketoallocholanate; the mixture contained 3.59 atom % excess deuterium. Deuteration of this mixture in ether in the presence of platinum oxide yielded lithocholic acid with a slightly higher value, 3.72 atom % excess deuterium. Another run was made under identical conditions starting with methyl $\Delta^{4,5}$-3-ketocholenate; lithocholic acid was obtained containing 3.89 atom % excess deuterium. Thus, it appears that two step deuteration of methyl $\Delta^{4,5}$-3-ketocholenate furnishes lithocholic acid with twice as much deuterium as that obtained in the single step procedure; yet, theoretically three deuterium atoms should enter the steroid molecule in either procedure.[4] By way of comparison, it is interesting that Schoenheimer,

(1) This investigation was supported by a grant-in-aid from the United States Public Health Service, under the National Cancer Institute Act.

(2) R. Schoenheimer and F. Berliner, *J. Biol. Chem.*, **115**, 19 (1936).

(3) L. C. Anderson and N. W. MacNaughton, THIS JOURNAL, **64**, 1456 (1942).

(4) Since there are 40 hydrogen atoms per molecule, the value corresponding to a content of three deuterium atoms is 7.5 atom% excess deuterium. A fourth deuterium atom is introduced but, being an hydroxyl deuterium, it is readily exchanged in subsequent manipulation.

et al.,[5] obtained 4,5-d_2-coprostanone-3, which is identical in structure with methyl 3-ketocholanate with respect to rings A and B, by deuteration of $\Delta^{4,5}$-cholestenone-3 in dry ether in the presence of palladium and that this product contained 3.44 atom % deuterium (theoretical value 4.35). However, the 3,4,5-d_3-coprosterol described by Anchel and Schoenheimer[6] contained only 2.32 atom % deuterium (theoretical value 6.25); unfortunately, the mode of preparation of this compound was not described.

Further study of the mechanism of catalytic reduction of α,β-unsaturated ketones might afford an explanation of the results described here; Anderson and MacNaughton[3] studied the mechanism of catalytic reduction of some carbonyl compounds with the aid of deuterium.

Of incidental interest is the observation that the proportion of non-digitonin precipitable products (chiefly if not entirely lithocholic acid) formed on complete reduction of methyl $\Delta^{4,5}$-3-ketocholenate is dependent on the nature of the solvent used (see Table I). In addition to lithocholic acid and 3(β)-hydroxyallocholanic acid previously[2] described, a small amount of 3(β)-hydroxycholanic acid was isolated.

TABLE I

CATALYTIC DEUTERATION OF METHYL $\Delta^{4,5}$-3-KETOCHOLENATE

Reduction procedure (in D_2 at atm. pressure)	Non-digitonin pptble. fraction (as % of total reduction products)	Reduction product analyzed	Analysis[a] (atom % excess deuterium)

[a] The "falling-drop method" was employed as described by A. S. Keston, D. Rittenberg and R. Schoenheimer, *J. Biol. Chem.*, **122**, 227 (1937–1938), and modified by M. Cohn in "Preparation and Measurement of Isotopic Tracers," J. W. Edwards, Ann Arbor, Michigan, 1947. [b] Similarly, deuteration of methyl $\Delta^{4,5}$-3-keto,12(α)-hydroxycholenate gave a reduction mixture containing 1.80 atom % excess deuterium; 74% of this mixture was non-digitonin precipitable. [c] Similarly, deuteration of $\Delta^{4,5}$-cholestenone-3 gave a reduction mixture containing 0.98 atom % excess deuterium.

(6) M. Anchel and R. Schoenheimer, *ibid.*, **125**, 23 (1935).

Experimental[7]

3,4,5-d_3-Lithocholic Acid.—8.56 g. of methyl $\Delta^{4,5}$-3-ketocholenate, m. p. 124–125°, obtained by Oppenauer oxidation[2] of methyl $\Delta^{5,6}$-3(β)-hydroxycholenate,[8] was dissolved in 400 ml. of absolute ether and shaken in deuterium at atmospheric pressure at 5° in the presence of 3.5 g. of 5% palladium on charcoal catalyst (previously treated with deuterium) until there was no further uptake of gas. The reduction product appeared to consist chiefly of methyl 3-ketocholanate and some methyl-3-ketoallocholanate. This mixture was dissolved in 400 ml. of absolute ether and deuterated under the same conditions as above but in the presence of 4.0 g. of platinum oxide. The final reduction mixture was separated into digitonin and non-digitonin fractions in a manner essentially that described by Schoenheimer and Berliner.[2] The latter fraction weighed 5.51 g. It was dissolved in 3 ml. of benzene plus 21 ml. of petroleum ether, b. p. 35–45°, adsorbed on a column containing 40 g. of aluminum oxide (Harshaw), and eluted with mixtures of benzene (5–100%)–petroleum ether. The eluates were worked up individually, yielding from aqueous methanol, a total of 3.51 g. of crystals with melting points ranging from 120 to 125°. This material was refluxed for two hours with 5% potassium hydroxide in 90% methanol; the solution was poured into water, acidified and extracted with ether. The product after two recrystallizations from ethyl acetate yielded 2.71 g. of lithocholic acid, m. p. 186–187°, containing 3.89 atom % excess deuterium; an additional 0.34 g. of crystals, m. p. 185–185.5° were obtained from the mother liquors.

The digitonin-precipitable material weighed 2.96 g. It yielded on treatment with ether–petroleum ether 740 mg. of crystals, m. p. 139–144°. The material in the mother liquor gave crystalline mixtures and hence was dissolved in 1.6 ml. of benzene plus 8 ml. of petroleum ether, adsorbed on a column containing 25 g. of aluminum oxide (Harshaw) and eluted with benzene (10–100%)–petroleum ether and finally with methanol. The benzene (10–20%)–petroleum ether eluates gave on repeated crystallization from aqueous methanol 380 mg., m. p. 108.5–110.5°. This material was hydrolyzed as above and crystallized from ethanol to furnish 359 mg. of 3(β)-hydroxycholanic acid,[9] m. p. 176–177.5°. The benzene (50–100%)–petroleum ether eluates were worked up individually furnishing, from aqueous methanol, a total of 224 mg. of crystals with melting points ranging from 141 to 148°. This material was combined with 740 mg. of the aforementioned product, m. p. 139–144°, and hydrolyzed as before; on repeated crystallization from ethanol, 604 mg. of 3(β)-hydroxyallocholanic acid, m. p. 219–220°, was obtained.

Summary

3,4,5-d_3-Lithocholic acid, containing 3.89 atom % excess deuterium, has been prepared by catalytic deuteration of methyl $\Delta^{4,5}$-3-ketocholenate in two steps. In addition, 3(β)-hydroxyallocholanic acid and 3(β)-hydroxycholanic acid were obtained.

A New Reaction of Nitriles. III. Amides from Dinitriles[1]

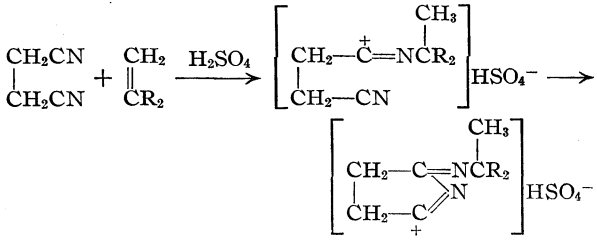
BY FREDERIC R. BENSON[2] WITH JOHN J. RITTER

The previous publications in this series have described the interaction of mononitriles and olefins to form N-substituted amides,[3] and the application of this reaction to the synthesis of *t*-carbinamines.[4] The use of dinitriles in this substituted amide synthesis, as well as a description of a variation of the reaction in which alcohols are used in place of olefins, form the subject matter of the present report.

Reaction of one mole of malononitrile, succinonitrile or glutaronitrile with two moles of an olefin such as isobutene, 2-methylbutene-2, camphene or diisobutene was carried out according to the previously described procedure.[3] In most instances the anticipated N,N′-disubstituted diamides were obtained (Table I). The reaction of succinonitrile with isobutene, diisobutene or camphene, however, under the same conditions resulted in the formation of N-monosubstituted succinamides, the second cyanide group of the dinitrile hydrolyzing in the usual manner. This anomalous behavior of succinonitrile

$$CH_2{=}C(CH_3)CH_3 + NCCH_2CH_2CN \xrightarrow[(2)\ H_2O]{(1)\ H_2SO_4} (CH_3)_3CNHCOCH_2CH_2CONH_2$$

possibly involves a cyclic mechanism according to the scheme



Subsequent hydrolytic reactions of the above intermediate would give rise to the monosubstituted amide. There is no immediately obvious explanation for the fact that 2-methylbutene-2-reacts with succinonitrile to yield the N,N′-diamide.

In view of the requirement of a strongly acid medium for the conduct of the reaction, it seems probable that a carbonium ion is an essential intermediate. Consideration of other possible sources of carbonium ions, besides the alkene–acid combination, led to the idea that alcohols might also function in this synthesis.[5] Accordingly, succinonitrile and *t*-butanol were subjected to reaction in the acetic acid–sulfuric acid solvent found suitable for use with olefins. The product isolated was found to be N-mono-*t*-butyl succinamide, identical with that obtained using isobutene. By means of this modification, it was found possible to utilize cyanogen in the synthesis of a diamide. Although preliminary work had failed to develop a means of effecting reaction between cyanogen and diisobutene, when *t*-butanol was employed, N,N′-di-*t*-butyloxamide was obtained, having the same properties described by Brander.[6]

The use of a secondary alcohol was investigated next. While reaction of secondary alcohols and nitriles in the acetic acid–sulfuric acid solvent could not be effected, concentrated sulfuric acid alone proved to be satisfactory for this purpose. Isopropyl alcohol and malononitrile produced N,N′-diisopropylmalonamide which has previously been prepared by conventional means.[7] Efforts to utilize a primary alcohol in the reaction proved fruitless; expedients such as the use of elevated temperatures, prolonged heating or the employment of fuming sulfuric acid were unsuccessful in the production of N-primary alkyl amides.

Comparison of the yields (Table I) of the products from dinitriles and olefins or alcohols, reveals that fumaronitrile is appreciably more active than any of the saturated dinitriles in the formation of substituted amides. It is evident that the reactivity of the cyanide groups is enhanced by the presence of the double bond.

Experimental

The following specific directions will serve to illustrate the methods followed in the preparation of the N-alkyl diamides. Recrystallizations of most of the succinamides and glutaramides were performed using benzene to which a small quantity of alcohol had been added. N,N′-Diisopropyl and *t*-butyl malonamides were recrystallized from hexane, while for N,N′-di-*t*-octylmalonamide, di-*t*-butyloxamide, and di-*t*-butylfumaramide an alcohol–water mixture was used. Glacial acetic acid was required for N,N′-dicyclohexylfumaramide.

The carbon, hydrogen and Kjeldahl nitrogen determinations were performed in the Laboratory of Microchemistry at New York University.

N,N′-Di-*t*-amylglutaramide.—A mixture of 50 ml. of glacial acetic acid, 10.2 g. (0.1 mole) of concentrated sulfuric acid and 4.7 g. (0.05 mole) of glutaronitrile was prepared at room temperature. To this solution was added 7.0 g. of 2-methylbutene-2 which dissolved immediately. The temperature of the reaction rose to 50° and was kept below this point by periodic cooling with water. After remaining overnight, the reaction mixture was poured into 250 ml. of water; white crystals separated quickly from

[a] R = R′ except where otherwise noted. [b] Calcd.: C, 60.6; H, 9.1. Found: C, 60.9; H, 8.9. [c] Calcd.: C, 63.7; H, 9.8. Found: C, 63.6; H, 9.3. [d] Calcd.: C, 69.0; H, 9.4. Found: C, 68.9; H, 9.2. [e] Or isobutene.

the solution. These were filtered, slurried with 50 ml. of dilute sodium carbonate solution, washed with 50 ml. of water and recrystallized from water. A further crop of crystals was obtained by neutralizing the acid filtrate with sodium carbonate. This batch of crystals was also recrystallized from water. On twice recrystallizing the combined yield from a mixture of benzene and hexane, 5.0 g. of the compound with a constant melting point of 147° was obtained.

N-Mono-*t*-butylsuccinamide: (1) From Isobutene.—Isobutene was passed for two and one-half hours into a solution of 16 g. (0.2 mole) of succinonitrile in 100 ml. of glacial acetic acid and 40.8 g. of concentrated sulfuric acid until 25 g. (0.45 mole) was absorbed. The mixture was allowed to stand overnight and was worked up as described above.

(2) **From *t*-Butanol.**—To a mixture of 10.2 g. of concentrated sulfuric acid, 50 ml. of glacial acetic acid and 4.0 g. of succinonitrile was added 7.4 g. (0.1 mole) of *t*-butanol. The temperature of the reaction mixture rose spontaneously to 50°, and was maintained below this point by occasional cooling. After standing overnight, the product was separated and worked up as described above. Its melting point, alone and mixed with the product from isobutene, was 149°.

N,N′-Di-*t*-butyloxamide.—Cyanogen, generated from 40 g. of sodium cyanide, was passed into a mixture of 40 ml. of glacial acetic acid, 10.2 g. of concentrated sulfuric acid and 7.5 g. of *t*-butanol. The temperature rose from 20 to 26°. Isolation and purification of the product was accomplished as indicated above immediately after stopping the flow of cyanogen.

N,N′-Diisopropylfumaramide.—To 3.9 g. of fumaronitrile dissolved at room temperature in 20 ml. of concentrated sulfuric acid, was added, over a period of twenty minutes, 6.0 g. (0.1 mole) of isopropyl alcohol, the temperature being kept below 45° by means of an ice-bath. After two hours the reaction mixture was treated as described to separate and purify the product. Both the recrystallized and unrecrystallized material melted with decomposition at 320°, after beginning to darken at 225°. The substance decolorizes aqueous potassium permanganate in the cold. The following qualitative solubilities were noted: insoluble in water, benzene, acetone, ethyl acetate; soluble in ethanol and hot methanol.

Summary

A series of dinitriles have been converted to N-substituted diamides by means of the reaction with olefins. Use of tertiary and secondary alcohols instead of alkenes in this reaction also leads to N-substituted amides.

A New Reaction of Nitriles. IV. Synthesis of N-Benzoylamino Acids[1]

BY LAWRENCE W. HARTZEL[2] WITH JOHN J. RITTER

Previous work in this Laboratory[3] has shown that nitriles interact with certain alkenes and alcohols in the presence of sulfuric acid to form substituted amides. In order to extend the scope of this reaction, the reaction of benzonitrile with a number of unsaturated acids and esters, and hydroxy esters, has now been investigated. This paper describes the preparation of N-benzoylamino acids by this novel procedure. Table I lists the reactants used and the products obtained, together with yields, melting points and analyses.

It was found that only certain of the acids and esters examined would undergo reaction with benzonitrile under the conditions of these experiments; compounds of the general types

$$R_1CCR_2R_2COOR_1 \text{ (OH)} \quad \text{and} \quad R_1C{=}CR_2COOR_2$$

where R_1 = alkyl and R_2 = H or alkyl

were found to be very reactive, while certain other types showed less reactivity. Among the compounds which failed to react with benzonitrile under a variety of conditions were methyl acrylate, methyl methacrylate, methyl crotonate, ethyl lactate, vinyl acetic acid, allyl acetic acid, maleic acid, diethyl fumarate and citraconic acid.

Two of the products obtained, β-benzoylamino-β-methylbutyric acid and β-benzoylamino-β-phenylpropionic acid, have been prepared previously by conventional methods.[4] A comparison of the physical properties found with those recorded in the literature established their identity. Hydrolysis of β-benzoylamino-α-ethyl-β-methylbutyric acid and β-benzoylamino-β-methylbutyric acid yielded β-amino-α-ethyl-β-methylbutyric acid and β-valine, respectively. The latter compound has been described by Slimmer.[4a] No attempt has been made to determine the position of the benzoylamino group on benzoylaminohendecanoic acid.

Experimental

Certain of the unsaturated and hydroxy esters were prepared by means of the Reformatsky reaction; two of the hydroxy esters, ethyl β-hydroxy-β-methylcaprylate and ethyl β-hydroxy-β-methyl-γ-phenylbutyrate have not been previously described.

All reactions were carried out in concentrated sulfuric acid with no other solvent. The same general procedure was followed in most cases; detailed directions are given for only a few typical preparations. Most of the products were recrystallized from benzene; in a few cases mixed solvents were used.

Analyses were performed in the Laboratory of Microchemistry at New York University. Nitrogen determinations were carried out by the Kjeldahl method.

Ethyl β-Hydroxy-β-methylcaprylate.—Reaction of methyl *n*-amyl ketone and ethyl bromoacetate in the presence of zinc using the Natelson and Gottfried[5] modification of the Reformatsky reaction gave a colorless oil in 71% yield; b. p. 93–95° (3 mm.), $n^{22}D$ 1.4350, d^{22}_{22} 0.941.

Anal. Calcd. for $C_{11}H_{20}O_3$: C, 65.3; H, 11.0. Found: C, 65.4; H, 11.1.

Ethyl β-Hydroxy-β-methyl-γ-phenylbutyrate.—Reaction of methyl benzyl ketone and ethyl bromoacetate as described above gave a viscous oil in 61% yield; b. p. 118–119° (2 mm.), $n^{22}D$ 1.5041, d^{22}_{22} 1.051.

Anal. Calcd.for $C_{13}H_{18}O_3$: C, 70.3; H, 8.2. Found: C, 70.9; H, 8.2.

Reaction of Benzonitrile with Unsaturated and Hydroxy Esters.—The following procedure is typical of that used throughout the work. A mixture of 14.6 g. (0.1 mole) of ethyl β-hydroxy-β-methylbutyrate and 10.3 g. (0.1 mole) of benzonitrile was cooled in an ice-bath and 20 ml. of concentrated sulfuric acid was added with stirring so that the temperature remained below 20°. When all the acid had been added, the temperature was allowed to rise to 40–45° until the exothermic reaction subsided. The mixture was allowed to stand at room temperature overnight and was then poured into 200 ml. of ice-water. The crude ester so precipitated was hydrolyzed to the benzoylamino acid by refluxing for two hours with 50 ml. of ethanol and 10 ml. of 50% aqueous potassium hydroxide solution. The hydrolysis mixture was poured into 400 ml. of water, non-acidic impurities were removed by extraction with ether; the free acid was precipitated by acidification with hydrochloric acid and recrystallized from benzene. The data on this compound and on the others prepared in this work are given on Table I.

β-Valine.—A mixture of 3.0 g. (0.0135 mole) of β-benzoylamino-β-methylbutyric acid, 20 g. (approximately 0.1 mole) of dried C. P. barium hydroxide and 180 ml. of distilled water was refluxed for one hundred and twenty hours, the condenser being fitted with a soda lime tube to exclude carbon dioxide. The hot solution was filtered, acidified with dilute sulfuric acid, and allowed to stand overnight. The heavy barium sulfate precipitate was filtered and washed thoroughly with distilled water. The filtrate and washings, approximately 400 ml. in all, were combined and made slightly alkaline with aqueous barium hydroxide. After standing overnight the mixture was filtered and washed. The filtrate and washings were combined and evaporated on a water-bath to a 50-ml. volume. This solution was again acidified with dilute sulfuric acid and allowed to stand overnight. The precipitate was filtered and washed. The filtrate and washings were combined and extracted with four 30-ml. portions of hexane. The aqueous solution was then shaken for ten minutes with 10 g. of Amberlite IR-4B[6] resin, which had previously been purified by shaking for ten minutes with six successive portions of distilled water. The mixture was filtered and washed. The filtrate was treated with further portions of resin until the *p*H of the solution no longer changed (approximately 5.9–6.1 as measured by indicator paper). The clear filtrate was heated with charcoal on a water-bath, filtered, and evap-

Nitric Acid Oxidation of 2,4:3,5-Dimethylene-D-gluconic Acid; Some Derivatives of 2,4-Methylene-D-glucarolactone-3,6

BY I. A. COLÓN, R. FERNÁNDEZ-GARCÍA, LUIS AMORÓS AND HILDA BLAY

In a previous communication[1] from this Laboratory a modification of Zief and Scattergood's preparation of 2,4:3,5-dimethylene-D-gluconic acid was recorded. This paper deals with the nitric acid oxidation of dimethylene-D-gluconic acid as well as with the preparation and properties of derivatives of monomethylene glucarolactone, the oxidation product.

The oxidation of 2,4:3,5-dimethylene-D-gluconic acid was carried out with concentrated nitric acid. No spontaneous reaction could be noticed when dilute nitric acid was used at room temperature. Using the minimum amount of concentrated nitric acid required to dissolve all the dimethylene gluconic acid, a yield of 56% of the theoretical amount was obtained. A higher proportion of concentrated nitric acid led to slightly higher yields (67%).

The oxidation product crystallized directly from the reaction solution on cooling. The physical properties of this substance and of its monoethyl ester, dimethyl ester, monomethyl ester and diamide agreed with the values reported[2,3] for 2,4-methylene-D-glucarolactone-3,6 and its corresponding derivatives.

The stability of the 2,4-methylene acetal ring

[a] A sample of 80.42 mg. lost on heating *in vacuo* at 100°, 4.96 mg.; calculated for such sample of $C_{11}H_{20}N_2O_6 \cdot H_2O$, 4.87 mg. [b] A sample of 87.93 mg. lost on heating *in vacuo* at 100°, 4.52 mg.; calculated for such sample of $C_{15}H_{28}N_2O_6 \cdot H_2O$, 4.52 mg.

in boiling concentrated nitric acid was surprising even though the limited acetolysis of methyl 2,4:3,5-dimethylene-D-gluconate has been shown[4] to result in the cleavage of only the 3,5-methylene acetal ring. The acetolysis reaction was tried on methyl 2,4-methylene-D-glucarolactone-3,6 and on dimethyl 2,4-methylene-D-glucarate at 0° for forty-five minutes. The monomethyl ester was subjected to a similar treatment with propionic acid–propionic anhydride mixture. The 2,4-methylene acetal ring was not cleaved in any of the three cases as shown by the formation of N,N'-dimethyl-2,4-methylene-D-glucarodiamide.

Some N,N'-disubstituted 2,4-methylene-D-glucarodiamides have been prepared which appear to be new; their properties are listed in Table I.

Experimental

Oxidation of 2,4:3,5-Dimethylene-D-gluconic Acid.—The reaction was carried out in a fume hood. In a 1.5-l. beaker 408 g. (1.86 moles) of dimethylenegluconic acid[1] was placed and 650 ml. of concentrated nitric acid added. After ten–fifteen minutes the mixture started to react and the temperature increased steadily to about 100°; a violent evolution of oxides of nitrogen was produced. The solid did not dissolve completely and the temperature started to decrease; 70 ml. of concentrated nitric acid was added and after a few minutes the solid dissolved so that a clear solution was obtained at the end of the reaction (one hour). On cooling a white crystalline precipitate was formed. The crude product was filtered, washed with 100 ml. of cold water, and dried under reduced pressure; m. p. 170–172°. The yield of the partially hydrated substance was (232 g.) 56% of the theoretical amount. The acid was recrystallized from methanol and dried *in vacuo* at 100°; m. p. 177.6–178.2; neutral equivalent found 201, calculated for $C_7H_8O_7$: 204; $[\alpha]^{28.6}D$ + 121 (c, 2.22; water), in close agreement with the values reported by Henneberg and Tollens[2] and by Haworth and Jones[3] for 2,4-methylene-D-glucarolactone-3,6. The monoethyl, monomethyl and dimethyl esters were prepared and their physical properties found to be in close agreement with the values reported.[3] The diamide was obtained from the ethyl ester.

Anal. Calcd. for $C_7H_{12}O_6N_2$: N, 12.7. Found: N, 12.4.

Using essentially the same procedure, 440 g. of dimethylenegluconic acid treated with 1260 ml. of concentrated nitric acid produced 297 g. (67%) of monomethylene glucarolactone.

N,N'-Disubstituted 2,4-Methylene-D-glucarodiamides.—Through a suspension of 0.02 mole of ethyl ester of monomethylene glucarolactone in methanol at 0° was passed enough of the freshly distilled amine to dissolve the ester. Any undissolved residue was filtered out and the solution allowed to stand at 5–10° for twenty-four hours. The first crop of crystalline amide was filtered out and washed with ether; on adding ether to the mother liquor further crops were obtained. The crude amides were recrystallized from methanol–ether except the N,N'-di-β-hydroxyethyl amide which was recrystallized from methanol. Specific rotations were determined in methanol as solvent for all the diamides except the unsubstituted diamide and N,N'-di-β-hydroxyethyl amide in which cases water was used as solvent. The specific rotations as well as concentrations and temperatures are indicated in Table I. All the diamides were found to be insoluble in benzene and ether but soluble in methanol except the unsubstituted diamide and N,N'-di-β-hydroxyethyl amide. All were found to be insoluble in water except N,N'-di-β-hydroxyethyl amide. The N,N'-diethyl and N,N'-dibutyl amides were obtained as hydrates.

Dimethyl 3,5-Diacetyl-2,4-methylene-D-glucarate.—To an ice-cold mixture of 35 ml. of acetic anhydride, 15 ml. of glacial acetic acid and 1 ml. of concentrated sulfuric acid, 4.7 g. (0.019 mole) of dimethyl 2,4-methylene-D-glucarate[3] was added. The mixture was shaken for forty-five minutes at 0°. It dissolved completely when shaken at room temperature for fifteen minutes. The solution was poured into a beaker containing 400 g. of ice. Seventy grams of sodium bicarbonate was added to nearly neutralize the solution; the precipitate was filtered and upon recrystallizing from benzene–petroleum ether it melted at 87.8–89.2°. The solid was soluble in benzene in which it showed a specific rotation $[\alpha]^{25.6}D$ −15.5° (c, 2.67; benzene). The yield was (2.8 g.) 44% of the theoretical amount.

Anal. Calcd. for $C_{13}H_{18}O_{10}$: C, 46.7; H, 5.4. Found: C, 47.1; H, 5.4.

N,N'-Dimethyl-2,4-methylene-D-glucarodiamide from Dimethyl 3,5-Diacetyl-2,4-methylene-D-glucarate.—Methylamine was bubbled through a solution of 0.5 g. of dimethyl 3,5-diacetyl-2,4-methylene-D-glucarate in 25 ml. of methanol at 0° until the theoretical amount had dissolved. The solution was left overnight at 5–10°. A white precipitate was formed when ether was added; m. p. 219–220° (dec.) and a specific rotation $[\alpha]^{28.2}D$ + 62.3 in methanol (c, 1.13), these data being in agreement with those previously found for the N,N'-dimethyl-2,4-methylene-D-glucarodiamide obtained by the action of methylamine on ethyl ester of monomethyleneglucarolactone. A mixed melting point determination with N,N'-dimethyl-2,4-methylene-D-glucarodiamide from this source showed no depression.

(4) Mehltretter, Mellies and Rist, THIS JOURNAL, 70, 1064 (1948).

Methyl-5-acetyl-2,4-methylene-D-glucarolactone-3,6.—To an ice-cold mixture of 20 ml. of acetic anhydride, 8 ml. of glacial acetic acid and 0.5 ml. of concentrated sulfuric acid, 2.6 g. (0.012 mole) of methyl 2,4-methylene-D-glucarolactone-3,6[3] was added. The mixture was shaken for forty-five minutes at 0°. The solid dissolved and almost immediately a white precipitate was formed. It was filtered, washed with water and recrystallized from hot water. The yield was (2.1 g.) 68% of the theoretical amount; m. p. 190.6°–192°; $[\alpha]^{27.2}D$ + 133 (*c*, 1.99; acetone).

Anal. Calcd. for $C_{10}H_{12}O_8$: C, 46.1; H, 4.6. Found: C, 46.1; H, 4.7.

N,N'-Dimethyl-2,4-methylene-D-glucarodiamide from Methyl-5-acetyl-2,4-methylene-D-glucarolactone-3,6.—In 30 ml. of ice-cold methanol 2.1 g. (0.008 mole) of methyl-5-acetyl-2,4-methylene-D-glucarolactone-3,6 was suspended. Methylamine was passed through the mixture until the solid dissolved. The solution was allowed to stand at 5–10° overnight. A white precipitate (0.5 g.) was formed; m. p. 217–218° (dec.). The filtrate was evaporated to dryness and crude product was recrystallized from methanol–ether. The yield was (2.1 g.) 95% of the theoretical amount; m. p. 223–224° (dec.) and a specific rotation $[\alpha]^{26.6}D$ + 60.0° in methanol (*c*, 0.69), these data being in agreement with those previously found for the N,N'-dimethyl-2,4-methylene-D-glucarodiamide obtained by the action of methylamine on ethyl ester of monomethyleneglucarolactone. A mixed melting point determination with N,N'-dimethyl-2,4-methylene-D-glucarodiamide from this source showed no depression.

Methyl-5-propionyl-2,4-methylene-D-glucarolactone-3,6.—To an ice-cold mixture of 35 ml. of propionic anhydride, 15 ml. of propionic acid and 1 ml. of concentrated sulfuric acid, 5.0 g. (0.023 mole) of methyl 2,4-methylene-D-glucarolactone-3,6 was added. The mixture was shaken for forty-five minutes at 0°. The solid dissolved and almost immediately a white precipitate was formed. It was filtered, washed with water and ether and recrystallized from hot water. The yield was (5.0 g.) 79% of the theoretical amount; m. p. 164.6–165.8°; $[\alpha]^{28.6}D$ + 153° (*c*, 2.06; chloroform).

Anal. Calcd. for $C_{11}H_{14}O_8$: C, 48.2; H, 5.1. Found: C, 48.2; H, 5.3.

N,N'-Dimethyl-2,4-methylene-D-glucarodiamide from Methyl-5-propionyl-2,4-methylene-D-glucarolactone-3,6.—In 15 ml. of ice-cold methanol 0.6 g. of methyl 5-propionyl-2,4-methylene-D-glucarolactone-3,6 was suspended. Methylamine was passed through the mixture until the solid dissolved and the solution allowed to stand at 5–10° overnight. A white precipitate was formed; m. p. 223° (dec.). The crude product was recrystallized from methanol–ether and the specific rotation determined in methanol $[\alpha]^{27.2}D$ + 61.7° (*c*, 1.03); these data are in agreement with those previously found for the N,N'-dimethyl-2,4-methylene-D-glucarodiamide obtained by the action of methylamine on ethyl ester of monomethyleneglucarolactone. A mixed melting point determination with N,N'-dimethyl-2,4-methylene-D-glucarodiamide from this source showed no depression.

Summary

1. The nitric acid oxidation of 2,4:3,5-dimethylene-D-gluconic acid has been shown to yield 2,4-methylene-D-glucarolactone-3,6 in 67% yield.

2. An attempted controlled acetolysis of dimethyl-2,4-methylene-D-glucarate and of methyl 2,4-methylene-D-glucarolactone-3,6 did not remove the 2,4-methylene acetal ring.

3. Some N,N'-disubstituted-2,4-methylene-D-glucarodiamides have been prepared which appear to be new.

Some N-Aminophenylarsanilic Acids

BY ROBERT L. MCGEACHIN

Since it was found recently that Melarsen,[1,2] a diamino triazino derivative of *p*-arsanilic acid, is an effective trypanocidal agent, it was decided to study the preparation of some N-aminophenylarsanilic acids.

Barber[3] condensed 3-nitro-4-chlorophenylarsonic acid with certain aromatic amines to give N-phenylarsanilic acids but no studies on the condensation of dinitrochlorobenzene with *p*-arsanilic acid have been made. However, Linke[4] condensed dinitrochlorobenzene with *p*-aminobenzoic acid and Kogan, Voronov and Lyubiteleva[5] condensed dinitrochlorobenzene with *p*-aminophenol-3,5-disulfonic acid.

Heating *p*-arsanilic acid and 2,4-dinitrochlorobenzene in 5% aqueous sodium hydroxide for seven hours proved to be an unsatisfactory method since excessive hydrolysis of the 2,4-dinitrochlorobenzene to 2,4-dinitrophenol occurred under these conditions. Sodium acetate and calcium carbonate (in aqueous alcohol medium) were found to be satisfactory condensing agents, however, with the latter the better of the two since it produced less by-products than the sodium acetate and gave better yields of N-2,4-dinitrophenylarsanilic acid. N-2,4-Diaminophenylarsanilic acid was prepared from this dinitro compound.

It was found that 3-nitro-4-chlorophenylarsonic acid would react with *p*-aminodimethylaniline and *p*-aminodiethylaniline under conditions outlined by Barber[3] to give N-4-dimethylaminophenyl-3-nitroarsanilic acid and N-4-diethylaminophenyl-3-nitroarsanilic acid. Attempts to reduce the nitro groups in these compounds to amino groups were unsuccessful, however, presumably due to the instability of the products formed.

Experimental

N-2,4-Dinitrophenylarsanilic Acid (I). A.—Six grams of *p*-arsanilic acid, 5 g. of 2,4-dinitrochlorobenzene and

0.5 g. of calcium carbonate were added to 100 ml. of 50% aqueous ethyl alcohol and the mixture heated under reflux on a steam-bath for eight hours. The reaction mixture was cooled, diluted with 50 ml. of water and filtered. The residue was dissolved in 10% sodium hydroxide (the solution was deep blood-red in color), treated with 0.5 g. of activated charcoal and the solution filtered. On acidification of the solution to congo red with concd. hydrochloric acid, a canary-yellow solid precipitated. After allowing the acidified mixture to stand overnight in the ice-box, the product was filtered off and dried at 130° for twelve hours giving a yield of 3.8 g. (41%). This compound did not melt below 250°.

Anal.[6] Calcd. for $C_{12}H_{10}O_7N_3As$: As, 19.58. Found: As, 19.44.

B.—I was also prepared from *p*-arsanilic acid and 2,4-dinitrochlorobenzene using sodium acetate as the condensing agent. In this reaction a considerable quantity of a red-orange solid was formed as a by-product. The product was isolated and purified, the same procedure used in method A giving a yield of 30%.

Anal. Calcd. for $C_{12}H_{10}O_7N_3As$: As, 19.58. Found: As, 19.16.

N-2,4-Diaminophenylarsanilic Acid.—One gram of I was reduced using 10.1 g. of ferrous sulfate in the method of Jacobs, Heidelberger and Rolf.[7] The product was a dark-red solid which rapidly turned black in the presence of air. The yield was 0.3 g. (36%).

Anal. Calcd. for $C_{12}H_{14}O_3N_3As$: As, 23.22. Found: As, 23.10.

(6) Cislak and Hamilton, THIS JOURNAL, **52**, 638 (1930).

(7) Jacobs, Heidelberger and Rolf, *ibid.*, **40**, 1581 (1918).

N-4-Dimethylaminophenyl-3-nitroarsanilic Acid.—Four grams of 3-nitro-4-chlorophenylarsonic acid was dissolved in 10 ml. of 10% sodium hydroxide and 8 ml. of water, 3 ml. of *p*-aminodimethylaniline added and the mixture heated under reflux in an oil-bath at 140° for eight hours. On addition of concd. hydrochloric acid to the neutral point, a sticky dark-brown solid precipitated. This product was purified by twice redissolving in 5% sodium hydroxide, charcoaling the solution, filtering and reacidifying. The red-brown solid was filtered off, washed well with water and alcohol and dried at 100° for twenty-four hours to yield 3 g. of product (56%).

Anal. Calcd. for $C_{14}H_{16}O_5N_3As$: As, 19.40. Found: As, 19.29.

N-4-Diethylaminophenyl-3-nitroarsanilic Acid.—This product was prepared by the same method used for the dimethylamino compound. It was a red-brown solid. The yield was 3.5 g. (60%).

Anal. Calcd. for $C_{16}H_{20}O_5N_3As$: As, 18.32. Found: As, 18.36.

Summary

The reaction of *p*-arsanilic acid with 2,4-dinitrochlorobenzene to form N-2,4-dinitrophenylarsanilic acid has been studied. N-2,4-Diaminophenylarsanilic acid has been prepared.

N-4-Dimethylaminophenyl-3-nitroarsanilic acid and N-4-diethylaminophenyl-3-nitroarsanilic acid have been prepared.

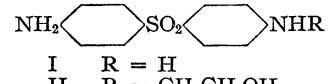
Monosubstituted Diaminodiphenyl Sulfones

BY JOHN WEIJLARD AND EDWARD SWANEZY

The antistreptococcal and antitubercular efficacy of substituted 4,4′-diaminodiphenyl sulfones appears to be increased if one amino group is free; consequently a number of monosubstituted diaminodiphenyl sulfones have been reported upon recently.[1,2] These compounds have generally been prepared either by reducing 4-nitro-4′-halodiphenyl sulfone followed by reaction of the resultant 4-amino-4′-halodiphenyl sulfone with the requisite amine,[1] or by alkylation of 4-nitro-4′-aminodiphenyl sulfone followed by reduction of the nitro group.[2] In either case the methods are laborious, the replacement reactions are often sluggish and the yields poor. This is particularly noticeable when 4-nitro-4′-aminodiphenyl sulfone is subjected to hydroxyethylation with compounds such as ethylene bromohydrin.[2]

A simple and rapid method has now been found for these compounds consisting of treating the readily available 4-acetylaminobenzene sulfonyl chloride with monochlorobenzene in presence of aluminum chloride to give 4-acetylamino-4′-chlorodiphenyl sulfone in 88% yield and of reacting the latter with, for instance, ethanolamine or isopropanolamine in presence of copper to yield the corresponding 4-amino-4′-(β-hydroxyethylamino)- or (β-hydroxypropylamino)-diphenyl sulfone, respectively, in 70 to 85% yields. Other amines, such as N-aminoethylmorpholine, reacted readily to give 4-amino-4′-(β-morpholineëthylamino)-diphenyl sulfone in high yield. With ammonia water, 4,4′-diaminodiphenyl sulfone was obtained in good yield. It is noteworthy that deacetylation takes place simultaneously with the alkylations.

A simplified method for the preparation of the parent substance, 4,4′-diaminodiphenyl sulfone, is thus available, and in addition a general method for preparing a large number of monosubstituted diaminodiphenyl sulfones, by selecting the proper amine and catalyst. The preparation of four compounds in this class is described.



I R = H
II R = CH_2CH_2OH
III R = CH_2CHCH_3 (OH)
IV R = CH_2CH_2N (morpholino)

(1) Amstutz, Fehnel and Woods, THIS JOURNAL, **69**, 1922 (1947).

(2) Jackson, *ibid.*, **70**, 680 (1948).

The new compounds, III and IV, show activity *in vitro* against *M. Tuberculosis;* compound III has also been found to be active against *D. pneumoniae* and *Staph. aureus.*[3] Compound II is being investigated elsewhere.

Experimental

4-Acetylamino-4′-chlorodiphenyl Sulfone.[4]—Four hundred sixty-seven grams of 4-acetylaminobenzene sulfonyl chloride (2 moles) was mixed with 1500 cc. of monochlorobenzene and warmed to 50°; 533 g. of anhydrous aluminum chloride (4 moles) was added in portions over a period of one hour at 55–65° with rapid stirring. The mixture was stirred at 70–80° for an additional three hours, then the excess monochlorobenzene was distilled *in vacuo.* The hot residual sirup was poured into a mixture of 2 kg. of crushed ice and 400 cc. of concentrated hydrochloric acid and stirred till completely disintegrated. The product was collected, washed with liberal quantities of water, then alcohol, and dried at 50°; yield 544 g. (88%), m. p. 194°.

Anal. Calcd. for $C_{14}H_{12}O_3NSCl$: N, 4.57. Found: N, 4.87.

4,4′-Diaminodiphenyl Sulfone.—Thirty-one grams of 4-acetylamino-4′-chlorodiphenyl sulfone (0.1 mole) was mixed with 100 cc. of concentrated ammonia water containing 0.5 g. of cuprous chloride, and the mixture was held in a mechanically agitated steel bomb at 180–190° for twelve hours. The cooled reaction mixture was filtered, washed with water and dried; yield 22 g. of crude sulfone (89%). The crude product was dissolved in 400 cc. of hot 50% methanol, the copper was precipitated with hydrogen sulfide, 2 g. of decolorizing black was added, and the solution was filtered through a heated filter. The clear filtrate was poured into 1400 cc. of water containing a trace of hydrosulfite, and the precipitated sulfone was filtered and washed with water; yield 18.6 g. (84.5%) of white sulfone, m. p. 172°.

Anal. Calcd. for $C_{12}H_{12}O_2N_2S$: C, 58.06; H, 4.87; N, 11.30. Found: C, 57.78; H, 4.84; N, 10.99.

4-Amino-4′-(β-hydroxyethylamino)-diphenyl Sulfone.—Thirty-one grams of 4-acetylamino-4′-chlorodiphenyl sulfone (0.1 mole) was mixed with 37 g. of ethanolamine (0.6 mole) and 0.5 g. of cuprous chloride, and the mixture was stirred and refluxed at 160–168° for twenty-two hours. The cooled reaction mixture was diluted with 400 cc. of water and cooled in ice overnight. The mother liquor was decanted and the gummy residue was dissolved in 180 cc. of hot 50% ethanol. The solution was treated with hydrogen sulfide and 2 g. of decolorizing black, filtered, scratched until crystallization was well under way, then chilled at 0° for forty-eight hours. The crystals were collected, washed with iced 50% ethanol and dried *in vacuo;* yield 21.0 g. (73%), m. p. 128–131°. After recrystallization in absolute alcohol the product melted at 131–132°.[5]

Anal. Calcd. for $C_{14}H_{16}O_3N_2S$: C, 57.52; H, 5.52; N, 9.58. Found: C, 57.55; H, 5.31; N, 9.73.

The X-ray diffraction pattern was identical with that from the sulfone made by the Jackson method,[2] and the solubility analysis indicated a purity of over 95%.[6]

4-Amino-4′-(β-hydroxypropylamino)-diphenyl Sulfone.—One-tenth of a mole of 4-amino-4′-chlorodiphenyl sulfone was mixed with 45 g. of isopropanolamine (0.6 mole) and 0.5 g. of cuprous chloride, and the mixture was stirred and refluxed at 165–175° for fifteen hours. The reaction mixture was worked up essentially as above, except that the crude product was dissolved in a hot mixture of 200 cc. of alcohol and 100 cc. of acetone. After removal of the copper and treatment with Darco, the solution was diluted with two volumes of water and cooled overnight in ice; yield 26.0 g. (85%), m. p. 183–186°. After recrystallization in absolute alcohol, the m. p. rose to 190–192°.

Anal. Calcd. for $C_{15}H_{18}O_3N_2S$: C, 58.80; H, 5.92; N, 9.14. Found: C, 58.87; H, 5.88; N, 9.22.

4-Amino-4′-(β-morpholineethylamino)-diphenyl Sulfone.—One-tenth of a mole of 4-amino-4′-chlorodiphenyl sulfone, 65 g. of N-aminoethylmorpholine (0.5 mole), and 0.5 g. of cuprous chloride were mixed and held at 200° for fifteen hours with stirring. The reaction mixture was diluted with 600 cc. of water and the precipitated product was separated by decantation and dissolved in 250 cc. of hot alcohol. The copper was removed with hydrogen sulfide, the clear filtrate was concentrated *in vacuo,* and during the concentration the sulfone crystallized suddenly. The crystals were filtered, washed with cold alcohol and dried at 50°; yield 30.1 g. (83%), m. p. 204–205°.

Anal. Calcd. for $C_{18}H_{23}O_3N_3S$: N, 11.63. Found: N, 11.54.

Acknowledgment.—We are indebted to Dr. Max Tishler for his interest and valuable suggestions.

Summary

A new and rapid method for the preparation of monosubstituted diaminodiphenyl sulfones is described. Two new sulfones have been prepared.

RAHWAY, N. J. RECEIVED JULY 2, 1949

(3) The study of the chemotherapeutic activity of these compounds is being carried out by Dr. Morris Solotorovsky and Miss Bettina M. Frost of the Merck Institute for Therapeutic Research.

(4) Heymann and Fieser, *ibid.*, **67**, 1979 (1945), isolated the 4-amino-4′-chlorodiphenyl sulfone from a mixture of incompletely ammonolyzed 4,4′-dichlorodiphenyl sulfone.

(5) Two forms of this compound have been observed, one of m. p. 145–146°, the other of m. p. 131–132°. The form of lower m. p. appears to be the more stable.

(6) We are indebted to Mr. F. A. Bacher of the Research Laboratories of Merck and Co., Inc., for carrying out these measurements.

Synthesis of 1′-Dehydro-β-ionone

BY HARRY SOBOTKA AND J. D. CHANLEY

In a recent publication[1] we have indicated the role of 2,2,6-trimethyl-1-ethynylcyclohexanol[2] as a useful intermediate in the synthesis of vitamin A. We have accomplished the dehydration of this carbinol (III) by the use of thionyl chloride and pyridine to 2,2,6-trimethyl-1-ethynylcyclohexene-1 (IV), a compound which takes a central position in a projected total synthesis of vitamin A.[1] The physical properties of this hydrocarbon and the successful synthesis of tetrahydroionone therefrom in high yield confirms its structure. The physical properties of hydrocarbon fractions, previously described[3] as 2,2,6-trimethyl-1-ethynylcyclohexene-1, differ considerably. One of us[4] had previously referred to the dehydration of the carbinol over an alumina catalyst in analogy to the dehydration of the simple 1-ethynylcyclohexanol. Subsequent studies, however, had thrown doubt on the nature of the dehydration product. As will be reported in a subsequent paper,[5] dehydration over alumina is accompanied by methyl migration and by migration of hydrogen from the ring into the side chain, leading to aromatization. Besides the resulting benzenoid hydrocarbon, there is found in small amounts an acetylenic fraction of which an insignificant portion, in turn, may be the desired 2,2,6-trimethyl-1-ethynylcyclohexene-1. The major part of the acetylenic fraction, however, lacks the conjugation of the double bond with the triple bond.

Condensation of acetic anhydride with the Grignard derivative of the true acetylenic hydrocarbon yielded 1′-dehydro-β-ionone (V). This compound shows the typical spectral qualities expected from a conjugated system so closely related to β-ionone; its λ_{max} is 288 mμ with an extinction of ϵ_{max} 11,800, and its refractive index is $n^{20}D$ 1.5205. It was subsequently hydrogenated and yielded a tetrahydroionone (VI) whose semicarbazone was found to be identical with that of an authentic sample of tetrahydroionone to which Prelog[6] assigns the *cis*-configuration.

The Grignard derivative of 2,2,6-trimethyl-1-ethynylcyclohexene-1 was condensed with acetaldehyde; the resulting DL-dehydro-β-ionol (VII) was catalytically hydrogenated to DL-tetrahydroionol (VIII); this, in its turn, was oxidized to a saturated ketone (VI) characterized by three derivatives, which were again identical with those obtained from tetrahydroionone prepared from β-ionone.

The dehydration of 1-ethynylcyclohexanol to ethynylcyclohexene over alumina proceeds with relative ease. The difficulty encountered in the instance of the trimethyl compound is due, not merely to the fact that only one, instead of four hydrogen atoms, is available, but also to steric considerations[7] and to the further complication that a neopentyl alcohol type system is present.[8] It is generally believed that elimination of the elements of water is predicated upon the *trans*-position of hydrogen and hydroxyl with respect to each other. Two diastereomeric racemates are possible for 2,2,6-trimethyl-1-ethynylcyclohexanol-1, only one of which may be expected to dehydrate without rearrangement, namely, that carbinol which carries the ortho hydrogen atom *trans* to the hydroxyl group. The reaction of sodium acetylide with trimethylcyclohexanone (I) may be anticipated to yield a mixture of both forms.[9] From the negative outcome of dehydration experiments, one is led to assume that the *cis*-diastereomer prevails in the reaction mixture. Thus, we set out to replace the hydroxyl group by a group X in a reaction which probably proceeds with racemization at carbon atom 1. This should lead to a product containing a higher percentage of the *trans*-compound. Removal of HX from the resulting mixture should then lead to the proper hydrocarbon. As the carbinol did not react with dry hydrogen chloride, thionyl chloride in excess pyridine was employed. This did not lead to a simple replacement of hydroxyl by chlorine, but the proper hydrocarbon was isolated in 15% yield. The major reaction product (60%) was a chloro compound of the elementary composition $C_{11}H_{17}Cl$. This substance still contained the —C≡CH grouping as it formed a silver salt, which speaks against the formation of an allene.[10] The chlorine atom is easily removable, rendering unlikely the formulation of this compound as a vinyl chloride derivative.[11] Replacement of chlorine by hy-

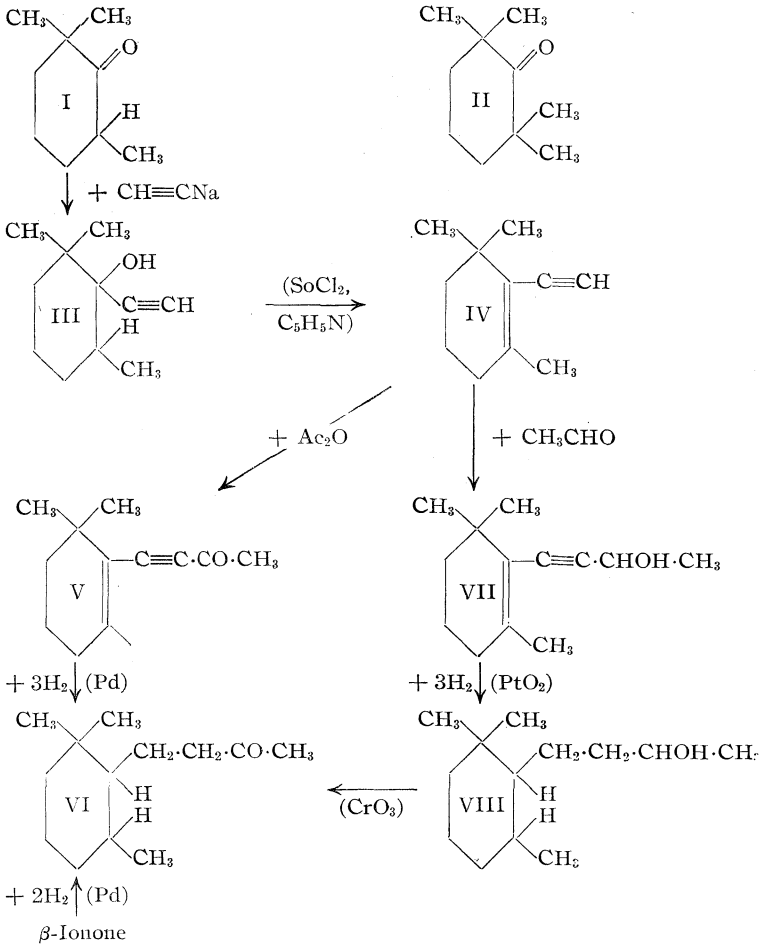
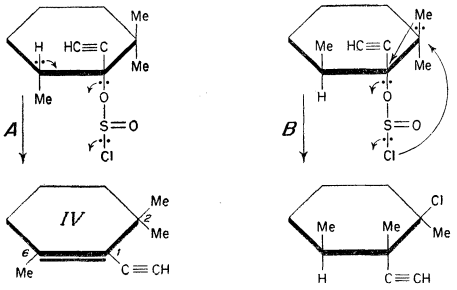
(11) Hurd and Jones, THIS JOURNAL, **56**, 1924 (1934), have shown that the action of thionyl chloride–pyridine on 1-ethynylcyclohex-

droxyl did not regenerate the original carbinol, but gave rise to a new carbinol, presumably with an altered carbon skeleton. The chloro compound, when treated with reagents used for dehydrohalogenation, did not yield the desired hydrocarbon.

The chloro compound can be derived from the *cis*-carbinol under the following assumption: Since no simple elimination reaction is possible in this stereomer of the hypothetical –OSOCl intermediate (B), the latter may react in two other ways, namely, by formation of the corresponding chloro compound, with loss of sulfur dioxide, or by rearrangement and subsequent addition of the chloride ion to another part of the molecule. The latter presumably occurs according to a reaction exemplified by scheme B. Contraction of the ring is not excluded nor migration of the methyl group on carbon atom 6, rather than that on carbon atom 2. The *trans*-form reacts according to scheme A which involves the loss of a proton from carbon atom 6 and the simultaneous loss of sulfur dioxide and chloride ion, leading to the formation of the "ene–yne" system. An alternative explanation, equally compatible with the results, is that scission of the C–O bond in the intermediate addition product results in the generation of a carbonium ion, which assumes a planar configuration, implying racemization at carbon atom 1. From this carbonium ion both reactions may proceed in proportion to their respective rates, and lead to the products isolated. This mechanism appears to be less likely.[12] We consider it most probable that the modest yield of the correct hydrocarbon in the thionyl chloride–pyridine reaction originated from the *trans*-form present in the carbinol. Work is in progress to establish the structure of the chloro compound.





Experimental

The ultraviolet absorption spectra were obtained with a Beckman spectrophotometer Model DU using 95% ethanol as solvent except as otherwise noted. We are indebted for the microanalyses to the late Dr. Gertrude Oppenheimer and her associates, Microchemical Laboratory, California Institute of Technology, Pasadena, California.

***o*-Methylcyclohexanone** was prepared for us by Givaudan–Delawanna, Inc., Delawanna, N. J., through the courtesy of Drs. Luthy and Fiori by the catalytic hydrogenation of purest *o*-cresol and subsequent oxidation of the resulting 2-methylcyclohexanol with dichromate.

Preparation of 2,2,6-Trimethyl-1-cyclohexanone (I) and 2,2,6,6-Tetramethyl-1-cyclohexanone (II).[12a]—The introduction of one methyl group into *o*-methylcyclohexanone has been described by one of us.[13] The crude dimethylcyclohexanone fraction of b. p. 169–173° was further methylated in two to three mole batches by the use of sodamide and methyl iodide under the same conditions as in the preparation of the dimethyl compound. The reaction was brought to conclusion by refluxing the mixture for seven hours. After decomposition of the reaction mixture with 10% sulfuric acid, the organic layer was

anol produced some 1-ethynylcyclohexene, but for the most part 1-(α-chlorovinyl)-cyclohexene-1. Such a conjugated diene system, carrying a chlorine atom, would show λ_{max} around 230–235 mμ; *cf.* Bowden, Brauder and Jones, *J. Chem. Soc.*, 948 (1946). Our product showed no absorption in the ultraviolet.

(12a) We are greatly indebted to Givaudan-Delawanna, Inc., whose Mr. Kaiser prepared for us considerable quantities of trimethylcyclohexanone and the corresponding ethynylcarbinol by the methods here described.

(13) J. D. Chanley, THIS JOURNAL, **70**, 244 (1948).

dried and carefully fractionated in a packed column of 15 theoretical plates. Two main fractions boiling from 171–176° and from 176–183°, respectively, were collected. In order to achieve further purification, we resorted to fractional crystallization of the semicarbazones.

Semicarbazones of Fraction b. p. 171–176°.—To 100 g. of this fraction dissolved in 1000 ml. of 95% ethyl alcohol, 84 g. of semicarbazide hydrochloride and 126 g. of sodium acetate trihydrate, dissolved in 1000 ml. of water, were added with stirring over a period of twenty minutes. After standing an additional ten minutes, the crude semicarbazone of 2,2-dimethylcyclohexanone separated; yield, 37 g.; m. p. 190–193°. The filtrate was then allowed to stand for three hours in the ice-box, where a mixture of di- and trimethylcyclohexanone crystallized. The filtrate from the second crop was then refluxed for a few hours and eventually 850 ml. of ethanol was distilled off. The resulting mixture was left in the ice-box overnight. The next day the crude semicarbazone of trimethylcyclohexanone was collected.

Semicarbazone of Fraction b. p. 176–183°.—This fraction contained an inconsequential amount of the dimethyl compound, but was contaminated with the tetramethyl compound, which does not form a semicarbazone. It was, therefore, worked up differently. One hundred grams of the crude ketones was dissolved in 1000 ml. of 95% ethanol and the same quantities of semicarbazide hydrochloride and sodium acetate in water were added as above. After refluxing for ninety minutes, the mixture was allowed to stand in the ice-box overnight. The crude semicarbazone was collected the next day. Its yield was 50% of the theoretical for this fraction. The combined impure semicarbazones (from fractions of b. p. 171–176° and 176–183°) were twice recrystallized from absolute ethanol; m. p. 207–209°; reported 220°.[14] The yield of the semicarbazone, calculated on the methylcyclohexanone, from which we had started, was 25–30%.

Anal. Calcd. for $C_{10}H_{19}N_3O$: C, 60.88; H, 9.70; N, 21.31. Found: C, 60.93; H, 9.95; N, 21.72.

Two hundred and fifty-six grams of the combined purified semicarbazone were mixed with 220 g. of phthalic anhydride and steam distilled until one liter of distillate was collected. The oily layer was separated, dried over sodium sulfate and distilled through a packed column of 15 theoretical plates; yield, 165 g. (91%) of pure trimethylcyclohexanone; b. p. 178.7–179° at 767 mm.; $n^{20}D$ 1.4480, $n^{25}D$ 1.4460, d^{25}_4 0.8983, *MR*, calcd. 41.59. Found: *M R* 41.62; reported,[3] 177–178.5° (758 mm.), $n^{25}D$ 1.4465.

Anal. Calcd. for $C_9H_{16}O$: C, 77.08; H, 11.50. Found: C, 76.97; H, 11.79.

The oxime prepared from this ketone melted at 103°; reported,[15] 104–105°.

The 2,4-dinitrophenylhydrazone melted at 141°.

Anal. Calcd. for $C_{15}H_{20}N_4O_4$: N, 17.5. Found: N, 17.8.

Tetramethylcyclohexanone (II), which does not form a semicarbazone had remained behind in the mother liquor and because of its high volatility was also found in the ethanol distillates. The ketone was purified by distillation. It boiled at 183.5–184° (772 mm.), m. p. 15°; $n^{20}D$ 1.4473; reported,[15] b. p. 182–184° (753 mm.), $n^{15.6}D$ 1.4484.

Anal. Calcd. for $C_{10}H_{18}O$: C, 77.86; H, 11.76. Found: C, 77.44; H, 11.74.

2,2,6-Trimethyl-1-ethynylcyclohexanol-1 (III) was prepared in half-mole batches from the pure ketone with sodium acetylide in liquid ammonia following the procedure of Campbell.[16] The compound was obtained in 71% yield; b. p. 121–121.5° (49–50 mm.), 93° (13–14 mm.), $n^{20}D$ 1.4791, $n^{25}D$ 1.4770; reported,[3] b. p. 88–90° (20 mm.) $n^{25}D$ 1.4740. The compound formed an insoluble silver salt with alcoholic silver nitrate.

Anal. Calcd. for $C_{11}H_{18}O$: C, 79.47; H, 10.91. Found: C, 79.58; H, 10.84.

The 3,5-dinitrobenzoate prepared in pyridine and recrystallized from 95% ethanol melted at 141°. The yield of this derivative was very small.

Anal. Calcd. for $C_{18}H_{20}N_2O_6$: C, 59.99; H, 5.59; N, 7.78. Found: C, 60.01; H, 5.98; N, 8.31.

2,2,6,6-Tetramethyl-1-ethynylcyclohexanol was prepared by the same method as above, b. p. 129.5° (50 mm.), m. p. 36–37°, $n^{30}D$ 1.4775.

Anal. Calcd. for $C_{12}H_{20}O$: C, 79.94; H, 11.18. Found: C, 80.03; H, 11.41.

Preparation of 2,2,6-Trimethyl-1-ethynylcyclohexene-1 (IV) and the Chloro Compound $C_{11}H_{17}Cl$.—To 100 g. of the pure trimethylcarbinol, dissolved in 150 ml. of dry pyridine, was added 71.2 g. of thionyl chloride, purified according to Fieser,[17] dissolved in 150 ml. of dry pyridine, with stirring in the cold (ice-bath) over a period of two hours. The mixture was allowed to react for one further hour and then poured into 2000 ml. of ice water and thoroughly extracted ten times with 200-ml. portions of petroleum ether (b. p. 40–60°). The combined extracts, after washing with sodium carbonate solution, water, saturated sodium chloride solution and drying over anhydrous potassium carbonate, in the presence of traces of hydroquinone, were distilled *in vacuo* through a packed column of ten to twelve theoretical plates. Two main fractions were collected; the hydrocarbon fraction boiled at 69–70° (13 mm.), $n^{20}D$ 1.4915, $n^{25}D$ 1.4892, $\epsilon_{max.}$ 13,000, at $\lambda_{max.}$ 227 mμ. The yield was 13.5 g. or 15%. On standing, the compound polymerized even at ice-box temperature, unless stabilized by hydroquinone. The compound gave a precipitate (silver salt) with alcoholic silver nitrate.

Anal. Calcd. for $C_{11}H_{16}$: C, 89.12; H, 10.88. Found: C, 88.73; H, 11.22.

The second fraction, the chloro compound, boiled at 96° (14 mm.), $n^{20}D$ 1.5030 and amounted to 60 g. (54%).

Anal. Calcd. for $C_{11}H_{17}Cl$: C, 71.53; H, 9.28; Cl, 19.20. Found: C, 72.44; H, 9.73; Cl, 19.00.

By boiling with the stoichiometric amount of silver nitrate in 75% ethanol, four-fifths of the chlorine was removed from this compound and an additional amount of silver nitrate produced the formation of a silver acetylide which was then decomposed by ammonium thiocyanate. In this manner we obtained in one experiment a carbinol of the same elementary composition as the original carbinol, but differing in its physical properties: b. p. 83° (13 mm.), $n^{20}D$ 1.4754.

Anal. Calcd. for $C_{11}H_{18}O$: C, 79.47; H, 10.91. Found: C, 80.03; H, 10.94.

1′-Dehydro-β-ionone (V).—To a solution of 0.067 mole of ethylmagnesium bromide in 25 ml. of dry ether was added 10 g. (0.067 mole) of 2,2,6-trimethyl-1-ethynylcyclohexene-1 in 25 ml. of ether over a period of one hour. The mixture was stirred and refluxed for an additional two hours and allowed to stand overnight under nitrogen. The Grignard compound, thus formed, was added with stirring during two hours to a solution of 13.8 g. of acetic anhydride in 40 ml. of dry ether at −70°. The mixture, after reacting another two hours, was decomposed with saturated ammonium chloride solution. The organic layer was then distilled *in vacuo*. The product 6.5 g. (50% yield) was collected boiling at 119–120° (10 mm.), $n^{20}D$ 1.5205, $\lambda_{max.}$ 288 mμ, $\epsilon_{max.}$ 11,800.

Anal. Calcd. for $C_{13}H_{18}O$: C, 82.06; H, 9.53. Found: C, 82.32; H, 9.55.

The semicarbazone prepared in the usual manner and recrystallized from ethanol (platelets) melted at 129.2°; $\lambda_{max.}$ 292 mμ, $\epsilon_{max.}$ 20,800.

Anal. Calcd. for $C_{14}H_{21}N_3O$: N, 16.99. Found: N, 16.70, 17.01.

From the mother liquors a small amount of a second semicarbazone, fine needles, presumably another form of the former was obtained; m. p. 129–130° (recrystallized from ethanol–water mixture). It showed a marked melting point depression in admixture with the aforementioned semicarbazone. Its ultraviolet absorption spectrum showed $\lambda_{max.}$ 292 mμ, $\epsilon_{max.}$ 16,700.

Anal. Calcd. for $C_{14}H_{21}N_3O$: N, 16.99. Found: N, 17.47.

The 2,4-dinitrophenylhydrazone melted after recrystallization from ethanol at 145–145.2°. It showed in alcohol $\lambda_{max.}$ 372 mμ, $\epsilon_{max.}$ 28,600; in chloroform $\lambda_{max.}$ 380 mμ $\epsilon_{max.}$ 28,800.

Anal. Calcd. for $C_{19}H_{22}N_4O_4$: N, 15.13. Found: N, 15.77.

The ultraviolet absorption spectrum, not previously reported, of the 2,4-dinitrophenylhydrazone of 1-(1′-cyclohexenyl)-butyn-1-one-3[1] showed $\lambda_{max.}$ 372 mμ, $\epsilon_{max.}$ 27,800 in alcohol and $\lambda_{max.}$ 376 mμ, $\epsilon_{max.}$ 28,100 in chloroform.

Tetrahydroionone Semicarbazone.—1′-Dehydro-β-ionone (0.77 g.) was hydrogenated in 50 ml. of ethanol at atmospheric pressure employing 100 mg. of palladium-on-calcium carbonate (5%) as catalyst. Ninety per cent. of the volume of hydrogen required by one double and one triple bond was consumed. The residual oil, after filtration and evaporation of the solvent, was converted into the semicarbazone derivative. Three recrystallizations from 95% ethanol afforded the pure semicarbazone of tetrahydroionone of melting point 179–180°. This derivative showed no depression on admixture with an authentic specimen, m. p. 182°, which had been prepared by the hydrogenation of β-ionone employing the same catalyst as mentioned above; reported m. p. 183–184°,[6] reported m. p. 179–180°.[18]

It had been mentioned that the dehydration of 2,2,6-trimethyl-1-ethynylcyclohexanol over alumina yielded among other products an acetylenic hydrocarbon fraction. The Grignard compound of this acetylene was condensed with acetic anhydride in the same manner as described above. In a run starting with 7.0 g. of hydrocarbon, b. p. 64–66° (14–15 mm.), $n^{20}D$ 1.4771, $\lambda_{max.}$ 227 mμ, $\epsilon_{max.}$ 4000, we obtained 0.8 g. of an impure ketonic fraction, b. p. 123–127° (20 mm.), which after further purification by evaporative distillation showed $n^{22}D$ 1.5055. Its spectrum exhibited two absorption maxima at $\lambda_{max.}$ 224 mμ and $\lambda_{max.}$ 287 mμ with the respective $\epsilon_{max.}$ of 9000 and 5000. The semicarbazone prepared from this fraction and recrystallized from ethanol melted at 112–114°; $\lambda_{max.}$ 265 mμ, $\epsilon_{max.}$ 14,000. We ascribe this semicarbazone to that compound of the ketonic mixture which is responsible for $\lambda_{max.}$ 224 mμ.

Anal. Calcd. for $C_{13}H_{18}O$: C, 82.05; H, 9.53. Found: C, 79.12; H, 9.57. Calcd. for $C_{14}H_{21}N_3O$: N, 16.99. Found: N, 16.00.

DL-1′-Dehydro-β-ionol (VI).—The Grignard derivative from 14.8 g. (0.10 mole) of 2,2,6-trimethyl-1-ethynylcyclohexene-1 was prepared as above and 4.4 g. of freshly distilled acetaldehyde in 40 ml. of dry ether was added thereto during one hour at −15°. The mixture was allowed to react for another three hours with stirring at 0° and for a further hour at room temperature. After decomposition with saturated ammonium chloride solution, the organic layer was distilled and 12 g. of product (58% yield) was isolated; b. p. 103–104° (2.4 mm.), 108° (3 mm.); $n^{25}D$ 1.5070, d^{25}_4 0.9355; *MR* calcd. 59.11, found 61.27, exaltation 2.16; $\lambda_{max.}$ 232 mμ, $\epsilon_{max.}$ 13,000.

Anal. Calcd. for $C_{13}H_{20}O$: C, 81.20; H, 10.49. Found: C, 81.53; H, 10.59.

(18) Ruzicka, Seidel and Pfeiffer, *Helv. Chim. Acta*, **31**, 827 (1948).

DL-Tetrahydroionol (*cis*) (VIII).—One and four-tenths of a gram of dehydro-β-ionol was hydrogenated in the presence of platinum oxide at atmospheric pressure in 50 ml. of purified glacial acetic acid as solvent. The theoretical amount of hydrogen was absorbed. The reaction product, after evaporative distillation at 50° (2–3 mm.), amounted to 1.2 g., $n^{20}D$ 1.4700; reported $n^{20}D$ 1.4717,[19a] $n^{20}D$ 1.4770.[19b]

One gram of the above tetrahydroionol was oxidized in 10 ml. of glacial acetic acid by 0.55 g. of chromium trioxide at 80° during one hour. The reaction mixture, diluted with water, was extracted with petroleum ether (b. p. 30–60°). After washing with sodium carbonate solution and drying over sodium sulfate, the product was evaporatively distilled at 38° (3 mm.); yield, 0.74 g., $n^{22}D$ 1.4655. Reported $n^{22}D$ 1.4660 (*cis*)[6]; $n^{22}D$ 1.4634 (*trans*). The semicarbazone prepared from the above ketone and recrystallized from ethanol melted at 179–180° and again showed no melting point depression on admixture with authentic tetrahydroionone semicarbazone.

The 2,4-dinitrophenylhydrazone was prepared and recrystallized from methanol, m. p. 118.5–120°, and showed no depression of melting point on admixture with an authentic sample, m. p. 119–120.5°, which had been prepared from the hydrogenation product of β-ionone; reported m. p. 120–120.5°.[19b]

The 4-phenylsemicarbazone was prepared. The melting point rose gradually from 104° for the crude reaction product to 114–115° (clear melt at 118°) on recrystallizations from methanol. Prelog[6] reports m. p. 109–110° for the 4-phenylsemicarbazone of the hydrogenation product of ionone, while he finds 133° for the analogous derivative derived from dihydrocyclocitral to which he ascribes *trans*-substitution on the ring. To our surprise, both the tetrahydroionone obtained by our synthesis and that obtained by the hydrogenation of β-ionone, gives rise to two 4-phenylsemicarbazones melting at 109–110° and 114–115° (clear melt at 118°). These two forms may be obtained alternatively from methanol solution, depending on conditions, not completely understood, as their recrystallization may not always be influenced by seeding with one form. We consider the two forms allomorphs of Prelog's *cis*-form, since we were able to derive each from the other one. No melting point depressions were observed in mixture of the lower or the higher-melting derivatives, prepared from the synthetic and authentic tetrahydroionone. Moreover, mixtures of the lower-melting form and higher-melting form from either source (synthetic and authentic) melted over the intermediate range, showing no depression.

Acknowledgment.—We wish to thank Miss Bernice Hamerman and Mrs. Edith Rosen Kaplan for their able and painstaking assistance.

Summary

1. The preparation of 2,2,6-trimethylcyclohexanone and 2,2,6,6-tetramethylcyclohexanone and of the ethynyl carbinols, derived from them, is described.

2. The dehydration of 2,2,6-trimethyl-1-ethynylcyclohexanol by means of thionyl chloride and pyridine leads to 2,2,6-trimethyl-1-ethynylcyclohexene-1.

3. The acetylenic analogs of β-ionone (1′-dehydro-β-ionone) and of β-ionol were prepared and their structure was confirmed by conversion into the perhydro compounds.

The Partial Reduction of an Enyne System by Lithium Aluminum Hydride

BY J. D. CHANLEY AND HARRY SOBOTKA

We have found that lithium aluminum hydride[1] is effective as a selective reducing agent for the triple bond in the enyne system of 1-(1′-cyclohexenyl)-1-butyn-3-ol (I); the dienol, trisnor-β-ionol (II) was obtained in 70% yield. In contrast, catalytic hydrogenation of this triple bond failed to yield more than spectroscopically detectable traces of the dienol. When the catalytic hydrogenation was interrupted upon absorption of 1 mole of hydrogen, a mixture of saturated or monounsaturated reaction products together with unchanged starting material was found.

Rearrangement, during reduction, of the carbon skeleton or allylic shift of the hydroxyl group was excluded, since complete hydrogenation yielded 1-cyclohexyl-3-butanol (III) and the oxidation of the latter led to the known 1-cyclohexyl-3-butanone (IV). By oxidation according to Oppenauer the alcohol II was, furthermore, converted to the corresponding ketone, 1-(1′-cyclohexenyl)-1-buten-2-one (V), the trisnor analog of β-ionone. After the preparation of this paper, two publications by Heilbron and co-workers[2a,b] have appeared, which describe the preparation of the enynol (I)[2a] by the same method as employed by us, but of the dienone (V)[2b] by two other methods; the physical constants of our compounds and their derivatives agree with those given by Heilbron, *et al.*

The synthesis of trisnor-β-ionone permits the comparative examination of the ultraviolet absorption spectra of this group. Table I gives the absorption maxima and the molecular extinction coefficients for the dienone, its derivatives and precursors, and the same data for the corresponding enynes.[3]

TABLE I

ABSORPTION SPECTRA OF CYCLOHEXENYL ETHYLENES AND ACETYLENES

	$C_6H_9CH{=}CHR$		$C_6H_9C{\equiv}CR$	
R	λ_{max}, mμ	ϵ_{max}	λ_{max}, mμ	ϵ_{max}
-H	230[7]	8,500	223[8]	10,400
-CHOH·CH_3	233.5	24,300	227.5	12,500
-CO·CH_3	280	26,700	274[8]	9,500
-C[:NNHCONH_2]CH_3	290	45,000	285[3]	14,500
-C[:NNH$C_6H_3(NO_2)_2$]CH_3	390	30,000	372[5]	27,800

The λ_{max} of these dienes is regularly 5–7 mμ higher than that of the analogous enynes. As was to be foreseen on the basis of numerous examples adduced by Heilbron and co-workers[4] the extinction was about twice as strong. A comparable difference in λ_{max} of 8 mμ has also been observed for the pair β-ionone and dehydro-β-ionone.[5] This difference in λ_{max} between the spectra of dienes and enynes is not found in open chain compounds[4] such as 2,4-pentadien-1-ol and 2-penten-4-yn-1-ol or 3,5-hexadien-2-ol and 3-hexen-5-yn-2-ol; however, the extinction coefficients in these cases are twice as high in the dienes, compared to the enynes.

Experimental

All reactions were carried out under nitrogen. The ultraviolet absorption spectra were obtained with a Beckman spectrophotometer Model DU in 95% ethanol solutions. All melting points were corrected. The microanalyses were performed by Elek Microanalytical Laboratories, Los Angeles 16, Calif.

DL-1-(1′-Cyclohexenyl)-1-butyn-3-ol (I).—To an ice-cold suspension of 0.65 mole of the Grignard compound of 1-ethynylcyclohexene[3] in one liter of dry ether, 28.6 g. (0.65 mole) acetaldehyde was added during a period of two and one-half hours. The reaction mixture was stirred for additional three hours at room temperature, decomposed with saturated ammonium chloride solution and worked up in the usual manner; yield of carbinol (I): 62 g. (59%), b. p. 99–100° at 3 mm. (distilled and stored in the presence of hydroquinone).

Anal. Calcd. for $C_{10}H_{14}O$: C, 79.95; H, 9.39. Found: C, 79.84; H, 9.42.

DL-1-(1′-Cyclohexenyl)-1-buten-3-ol (II).—Twelve grams of the preceding compound (I) (0.08 mole) in 100 ml. of absolute ether was added over a period of one-half hour to a solution of 1.87 g. (0.05 mole) of lithium aluminum hydride in 250 ml. of absolute ether. A voluminous precipitation occurred; the mixture was then refluxed and stirred for three hours, the precipitate having dissolved at the end of the first hour. After decomposition with water and dilute sulfuric acid, the product was isolated in the customary manner; yield, 8.5 g. (70%); b. p. 98–100° at 3–4 mm. The presence of traces of hydroquinone during distillation is vital for the prevention of polymerization.

Anal. Calcd. for $C_{10}H_{16}O$: C, 78.80; H, 10.58. Found: C, 78.92; H, 10.53.

On careful redistillation the physical constants obtained for the two carbinols are:

	Enynol (I)	Dienol (II)
B. p. at 2 mm., °C.	93.5–94	.....
B. p. at 1.5 mm., °C.	.....	90
$n^{25}D$	1.5197	1.5220
d^{25}_4	0.9740	0.9572
MR found	46.84	48.52
MR calcd.	45.25	46.78
Exaltation	1.59	1.74
λ_{max}, mμ	227.5	233.5
ϵ_{max}	12,500	24,300
$\lambda_{infl.}$, mμ	.....	229

The slight increase rather than diminution of the refractive index and of the exaltation of the molecular refraction upon partial reduction is peculiar.[4,6]

The shift of λ_{max} by 6 mμ toward higher wave lengths in the diene is analogous to the difference between λ_{max} of cyclohexenylacetylene[3] (223 mμ) and that of cyclohexenylethylene[7] (230 mμ), a pair which shows, however, no appreciable difference in extinction.

DL-1-**Cyclohexyl-3-butanol** (III).—Two grams (0.013 mole) of the dienol (II) was hydrogenated completely over 100 mg. of platinum oxide in 100 ml. of ethanol. Hydrogen uptake at 26° and 750 mm.: calculated for two double bonds, 662 ml.; found (corrected for uptake by the catalyst), 622 ml. The saturated product was obtained in the theoretical yield and boiled at 84° at 4 mm.; $n^{25}D$ 1.4670. Oxidation by sodium hypoiodite according to Shriner and Fuson[8] yielded iodoform.

Anal. Calcd. for $C_{10}H_{20}O$: C, 76.91; H, 12.91. Found: C, 77.26; H, 12.57.

1-Cyclohexyl-3-butanone (IV).—A solution of 1.1 g. of cyclohexylbutanol (III) in 10 ml. of glacial acetic acid and 0.82 g. of chromic anhydride was heated gently on the steam-bath for thirty minutes and permitted to stand overnight. The mixture, poured into 50 ml. of water, was extracted with petroleum ether, which was then washed and dried. The residue was evaporatively distilled at 16 mm. and 50° bath temperature; yield, 0.85 g. (76%); $n^{20}D$ 1.4590; reported[9] $n^{20}D$ 1.4586.

The semicarbazone of IV, recrystallized from aqueous methanol, melted at 166–168°; reported[9] m. p. 163°.

The 2,4-dinitrophenylhydrazone of IV, recrystallized from methanol, melted at 106°; reported[9] m. p. 106°.

Trisnor-β-ionone (V).—A mixture of 1.8 g. (0.118 mole) of trisnor-β-ionol (II) and 4.55 g. of aluminum *t*-butoxide in 90 ml. of dry acetone plus 135 ml. of dry benzene were refluxed under nitrogen for forty-eight hours. After decomposition with 150 ml. of 2 *N* sulfuric acid, the reaction product was worked up in the customary manner. According to the spectral data, the crude distillate (1.5 g.) of b. p. 92–95° at 4 mm. consisted of five-sixth ketone and the rest starting material. The ketone was converted into the semicarbazone. After one recrystallization from ethanol, decomposition according to Heilbron[9] and subsequent evaporative distillation at 47° bath temperature and 12 mm. pressure yielded 0.77 g. (43% yield) of the pure ketone; $n^{20}D$ 1.5500, λ_{max} 280 mμ, ϵ_{max} 26,700. The secondary maximum at 234 mμ, due to the presence of the dienol in the crude product was not completely eliminated.

Anal. Calcd. for $C_{10}H_{14}O$: 79.95; H, 9.39. Found: C, 79.57; H, 9.55.

The **semicarbazone,** melting after two recrystallizations at 201–203° (dec.), had a λ_{max} of 290 mμ, ϵ_{max} 45,000; it turns yellow on exposure to light.

Anal. Calcd. for $C_{11}H_{17}N_3O$: C, 63.74; H, 8.27; N, 20.27. Found: C, 63.58; H, 8.13; N, 19.78.

The **2,4-dinitrophenylhydrazone,** recrystallized three times from absolute ethanol, consisted of garnet-red crystals melting at 199–200° (dec.); λ_{max} 390 mμ, ϵ_{max} 30,000.

The **4-phenylsemicarbazone,** buff-colored platelets recrystallized from ethanol, m. p. 199–200° (dec.).

Catalytic Reduction of the Enynol I.—Various attempts to reduce selectively the triple bond of I with hydrogen over a 0.3% palladium–calcium carbonate catalyst in ethyl acetate yielded mixtures which were subjected to fractional distillation. The lowest boiling fractions, comprising less than 20% of the reduction product, showed, in typical runs, λ_{max} between 231 and 233.5 mμ with ϵ_{max} from 4000 to 6600 and $n^{20}D$ of 1.4960, supposedly a mixture of one-fourth or less (5% of the total yield) of dienol with three-fourths non-conjugated carbinol of low refractive index (either compound III or trisnordihydroionol). The higher fractions, comprising the bulk of the mixture, converged toward λ_{max} 229 mμ with ϵ_{max} up to 11,600 and $n^{20}D$ 1.5086, with starting material predominating. Similar results were obtained with Raney nickel in ethyl acetate, whereas no reduction at all was achieved with copper-zinc in alcohol.

Acknowledgment.—We thank Miss Bernice Hamerman for her able assistance in these experiments.

Summary

Lithium aluminum hydride serves for the partial hydrogenation of the triple bond to a double bond in cyclohexenylbutynol. The resulting trisnor-β-ionol was oxidized to trisnor-β-ionone. The ultraviolet absorption spectra of cyclohexenyl ethylenes and acetylenes are discussed.

Grignard Reactions. XX.[1] Effect of Cuprous Chloride on the Reaction of *t*-Butylmagnesium Chloride and Trimethylacetyl Chloride

BY NEWELL C. COOK AND WILLIAM C. PERCIVAL

In a continuation of the study of the reaction between acid halides and Grignard reagents we have now found conditions which make it possible to obtain consistently high yields of a highly branched ketone from a reaction which heretofore has given mainly reduction products. In earlier attempts to prepare hexamethylacetone from *t*-butyl Grignard reagent and trimethylacetyl chloride[2] no ketone was formed using a one-to-one ratio of the Grignard reagent and the acid chloride. With a five-to-one ratio of reagents and using reverse addition at −10°, there was obtained a 32% yield. We have now shown that through the use of cuprous chloride with a one to one ratio of reactants, yields of 70 to 80% hexamethylacetone are readily obtained.

The role of cuprous chloride in such reactions was suggested when an 87% yield of 2,4,4-trimethyl-3-hexanone was obtained by treating *t*-amylmagnesium chloride and isobutyryl chloride in a copper reactor.[3] Previously, only 10 to

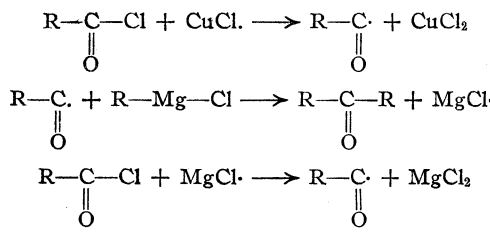
(1) For Paper XIX see Stehman, Cook and Whitmore, THIS JOURNAL, **71**, 1509 (1949).

(2) Whitmore, *Rec. trav. chim.*, **57**, 562 (1938).

(3) In the original note[1] this compound was erroneously reported as 2,4,4-trimethyl-3-pentanone.

15% yields had been realized from these reactions.[4] The reaction of *t*-butylmagnesium chloride and trimethylacetyl chloride, one of the most difficult tests of the beneficial effect of cuprous salts, was found to give hexamethylacetone in yields as high as 80% under cuprous chloride catalysis. We have confirmed our findings in several other syntheses of highly branched ketones to be reported later.

Kharasch[5] has shown that metallic ions such as the cuprous ion give rise to free radicals in Grignard reactions. If such were the case here the following could represent the mechanism by which the cuprous chloride causes the formation of the hexamethylacetone.



The reactions tried to date using straight chain acid chlorides and Grignard reagents show that yields of ketones are improved but not as markedly as with highly branched reactants. It is believed that conditions such as temperature and more effective catalysts can be found which will give more satisfactory results. This work is being continued.

Experimental

The fractionation columns were of the total condensation variable take-off type packed with $^3/_{32}$ in. single turn glass helices. The dimensions (cm.) are for the packed section: column I, 70 × 1.5; column II, 90 × 2.2.

The Grignard reactors were of seven-liter capacity, water jacketed copper vessels (11″ × 8″) stirred with an off-center propeller (4″) driven by a $^1/_4$ hp. motor.

The *t*-butyl Grignard reagent (3.1 moles/l.) used in these reactions was synthesized in a large preparation and stored in a glass carboy under a nitrogen atmosphere. Only clear reagent was used in all runs.

The trimethylacetyl chloride, made by carbonation of *t*-butyl Grignard reagent and subsequent treatment of the trimethylacetic acid with thionyl chloride, had the following properties: b. p. 104°, n^{20}D 1.4123. The ethyl ether used was Mallinckrodt reagent grade.

The runs were either five or three mole reactions. Products from the five mole runs were fractionated in column I while those from the three mole runs were fractionated in column II. From several reactions using a variety of conditions it was established that with cuprous chloride yields of 70–80% hexamethylacetone could be obtained, and that reactions in glass without cuprous chloride gave only 1–2% hexamethylacetone. Even normal addition with cuprous chloride gave a 53% yield of ketone.

Reaction of *t*-Butylmagnesium Chloride and Trimethylacetyl Chloride.—Filtered *t*-butylmagnesium chloride (5 moles, 3 *M* solution) was added at reflux temperature over a one-hour period to 5 moles of trimethylacetyl chloride and 5 g. of cuprous chloride dissolved in 2 l. of anhydrous ethyl ether in a 7-l. Grignard reactor. A take-off condenser was then attached and warm water passed through the jackets of the reactor until the majority of the solvent had been stripped from the reactants. Steam was then passed through the reactor for a period of three days. The reaction mixture was drowned with ice, neutralized and ether extracted. The products were fractionated through a twenty-plate column, giving 1.3% *t*-butyl pivalate (b. p. 135°, n^{20}D 1.3920), 1.0% neopentyl alcohol (b. p. 112°, m. p. 50°), 71.6% hexamethylacetone (b. p. 153°, n^{20}D 1.4392) and 9.8% residue, calculated as trimethylacetyl radical.

Identification of Products.—Hexamethylacetone: by reduction with lithium aluminum hydride to the alcohol which was converted to the phenylurethan, m. p. 120–121°. *t*-Butyl pivalate: by neutral equivalent (4 *N* sodium ethylate), obs. 156, calcd. 158; molecular weight, obs. 146, calcd. 158; trimethylacetic acid from hydrolysis ester, anilide, m. p. 133–134°. Neopentyl pivalate: by hydrolysis and derivative of trimethylacetic acid (anilide m. p. 133–134°) and neopentyl alcohol (m. p. 50°)(phenylurethan m. p. 112–113°). Trimethylacetic acid: as the anilide, m. p. 133–134°. Neopentyl alcohol: as the phenylurethan, m. p. 112–113°.

All derivatives were established by mixed melting points with authentic samples.

Summary

The reaction of *t*-butylmagnesium chloride and trimethylacetyl chloride to form hexamethylacetone has been investigated. With the use of cuprous chloride as a catalyst yields of from 70 to 80% are obtained, using one to one ratios of reactants. The temperature of addition has little effect upon the reaction. Although good yields are obtained using normal addition, reverse addition gives better results. A free radical mechanism is postulated.

NOTES

Cyclopentanes and Petroleum Origin

By Benjamin T. Brooks

Cyclopentanes and cyclopentenes are not found in nature in plants or essential oils and five carbon ring structures are only very rarely found in complex substances such as pyrethrin, jasmone as a minor component in oil of peppermint and in the perfume oil of jasmine, chaulmoogric acid and combined with other ring structures as in a few of the triterpenes and isoprenic steroids. Cyclopentanes are found in the gasoline fractions of all types of petroleums, and in many cases, in substantial proportions. The careful analyses of seven petroleums made by Rossini[1] and his coworkers show the following percentages of cyclopentanes in the gasoline fraction distilling in the range 40–180°.

Crude source	Total cyclopentanes, per cent. by volume
Ponca, Okla.	8.86
East Texas	11.03
Bradford, Pa.	5.49
Greendale, Mich.	3.32
Winkler, Texas	5.46
Midway, Calif.	13.61
Conroe, Texas	5.66

In view of the extreme rarity of the five carbon ring structure in nature, the presence of cyclopentanes in petroleums is certainly not due to degradation of any natural products containing such structures. It is suggested that the cyclopentanes in petroleums have been formed by rearrangement of cyclohexanes. Such rearrangements have been observed experimentally at temperatures as low as 25° by the action of moist aluminum chloride.[2] It is believed that the occurrence of cyclopentanes in petroleums gives support to the theory that active surface minerals act catalytically in forming the wide diversity of hydrocarbons found in petroleums. Other evidence for this has been more fully presented in other papers.[3]

There is no constant relation between the per cent. of cyclohexane and methylcyclopentane and no relation between the ratios of these hydrocarbons and present bottom hole temperatures. The ratios of these two hydrocarbons do not correspond in the case of the gasolines noted, to the calculated thermal equilibrium compositions for any particular small temperature range and the high ratio of methylcyclopentane to cyclohexane found in some cases, 4.03% methylcyclopentane to 2.04% cyclohexane in East Texas gasoline, is far out of line with the equilibrium compositions found experimentally (in the presence of aluminum chloride). At 77.4° the experimental equilibrium mixture contained 25.6% methylcyclopentane and lower percentages at lower temperatures. The lowest ratio of methylcyclopentane to cyclohexane in any of these gasolines was 2.97 to 4.34 in the Conroe, Texas, gasoline, or 39% of the sum of these two hydrocarbons. The composition of gasolines is full of similar inconsistencies when reference is made to calculated thermal equilibrium compositions. One such calculation led to a temperature of petroleum formation within the range of commercial cracking processes, a condition which is clearly precluded by the time element as well as many of the facts as to chemical composition of crude petroleum.

Enzymatic Hydrolysis of Steroid Hormone Esters by Blood Serum[1]

By Fritz Bischoff, Robert E. Katherman, John J. Moran and Yee Sing Yee

The solubilities of testosterone, progesterone and estradiol in mammalian blood serum are accounted for by the solubilities of these substances in solutions of the serum constituents.[2,3] Testosterone propionate and estradiol benzoate,[4] are much less soluble in solutions of serum constituents than the corresponding free steroids, but the solubilities of these esters in serum on equilibration approach the solubilities of the free parent steroids. These results can be explained only by postulating the existence of a serum steroid hormone esterase.

Proof for this enzymatic hydrolysis by rabbit, bovine and human serum has been established using the Folin–Ciocalteu phenol reaction with estradiol benzoate as substrate. The benzoate ester gives no color with the phenol reagent, while estradiol develops the characteristic blue color, following Beer's law over a wide range. Serum or serum diluted with 6% bovine albumin is incubated with estradiol benzoate (0.2 mg. per cc.), which is added in ethanol so that final ethanol concentration is below 10%. Serum heated for one hour at 63° serves as a control for enzyme activity. Heated and unheated sera without substrate serve as controls for sera constituents reacting with the phenol reagent. The reaction is ended by precipitation at 80 to 90% ethanol concentration, removing the proteins which would react with the phenol reagent.

(4) F. Bischoff, R. E. Katherman and J. J. Moran, Abst. 115th Meeting Am. Chem. Soc., 1949, p. 6C.

Any liberated estradiol is recovered (90 ± 5%) in the filtrate. Aliquots of the filtrates are evaporated to dryness *in vacuo* at room temperature, and extracted with chloroform or acetone, which further removes chromogenic substances. After evaporation the residue is ready for the Folin–Ciocalteu reaction. The reaction mixture is taken to *p*H 7.0 before ethanol precipitation in order to prevent appreciable hydrolysis of unchanged estradiol benzoate during processing.

The following are typical results of estradiol liberated for 1 cc. of serum at 37.5°. Rabbit serum, *p*H 7.0 in albumin buffer for thirty minutes: 0.50 mg. estradiol. Control heated rabbit serum: 0.015 mg. estradiol. Human serum, *p*H 7.2 in albumin buffer for six hours: 0.18 mg. estradiol. Control heated human serum: 0.03 mg. estradiol. Bull serum, *p*H 8.3 for thirty minutes: 0.070 mg. estradiol. Control heated bull serum: 0.008 mg. estradiol.

The degree of hydrolysis of solutions of estradiol benzoate in aqueous albumin or sodium lauryl sulfate in the *p*H range and concentration used in the enzymatic reaction is of the low order found for serum heated one hour at 63° or ten minutes at 70°. The marked hydrolytic effect of unheated serum therefore proves the existence of a steroid hormone esterase.

The enzymatic action has also been demonstrated in rat, chicken and pigeon blood, and on the substrates estradiol diproprionate and estrone acetate.

A Hydrogen Transfer Reaction of the Butylenes and Butyl Alcohols in Sulfuric Acid

BY WILLIAM H. CALKINS AND T. D. STEWART

Isobutylene, 2-butene and the four butyl alcohols each react in 96% sulfuric acid at 0° to yield up to 20% isobutane. This reaction was observed by us during a study of the alkylation of isobutane by 2-butene.[1]

We had occasion to introduce 2-butene alone, as a gas, into a flask containing stirred sulfuric acid and nitrogen gas at atmospheric pressure; the reactor was fitted with a mercury manometer. With a rate of introduction of 10 ml./min. the pressure rose immediately to 7–8 mm., remained nearly constant for ten to fifteen minutes, and then started to rise again. When the 2-butene flow was shut off within five minutes the pressure immediately fell to practically its original value; but if it was shut off during the later rise, the pressure fell only 2–3 mm. and then continued to rise for an hour or more without further 2-butene input. The same behavior, and to the same degree, was observed with the rate of input 27 ml./min. The volume of the reactor system was 600 ml.; the sulfuric acid varied from 25–100 ml. The eventual pressure rise for a charge of about 150 ml. of 2-butene was 20–30 mm., which, when corrected to room temperature, corresponded to a 17% yield of gas.

A preliminary examination of the gas formed, by Orsat combustion, indicated butane. This was confirmed by an analysis performed for us by the Shell Development Company, using their Consolidated Mass Spectrometer, which indicated 4% by volume of isobutane, 1% isopentane and traces of possible hexanes, in the nitrogen. Routine analyses were later made by an infrared spectrophotometer (National Technical Laboratories), calibrated at the wave lengths 8.48, 9.78 and 10.2 μ against pure samples of normal butane, isobutane and isopentane, and following the procedure of Brattain, Rasmussen and Cravath.[2]

This isobutane evolution is related to the conversion of the four-carbon alkenes and alcohols to liquid saturated hydrocarbons under similar, but not identical, circumstances.[3] Its uniqueness lies in the high percentage of isobutane, which may be a precursor to the hydrocarbons of higher molecular weight. The reaction is characterized by the presence of an induction period of a few minutes, in the case of 2-butene, and by the fact that rate of gas evolution from any given solution is approximately first order. However, both the rate and amount of gas formation vary somewhat with different amounts of sulfuric acid used. Table I details typical results.

TABLE I

In the case of the alcohols, solution was effected slowly at 0° in a small amount of the acid outside the stirred reactor; this solution was then added rapidly to the excess of acid. Gas evolution was followed manometrically and analysis showed it to be almost entirely isobutane.

The induction periods in the case of the alcohols were striking. For *n*-butyl it was seventy-five minutes, for isobutyl thirty minutes, for *s*-butyl five minutes, and for *t*-butyl no induction period was observable. This corresponds to induction periods for 2-butene and isobutylene of a few minutes and none, respectively.

The relative rates of isobutane formation, based upon that from 2-butene as unity and using 25 ml. of sulfuric acid, were approximately as follows: 2-butene, 1; isobutylene, *t*-butyl alcohol and isobutyl alcohol, 0.5; *s*-butyl alcohol, 1.7; *n*-butyl alcohol, 0.2. The half-life of the 2-butene reaction was twenty-five to thirty minutes. It may be noted also that whereas in general the gas evolution from a given solution seemed to be a first-order reaction, that from the tertiary alcohol or isobutylene was distinctly not, the end reaction being very slow.

It is tentatively suggested that this apparent dismutation and rearrangement is based, not upon simple reactions of the original materials, but involves some polymeric material, perhaps through dealkylation; until polymer is formed no isobutane is evolved. The problem then con-

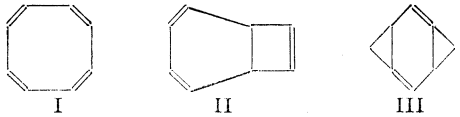
Some Observations on Certain Cycloöctatetraene Derivatives

BY S. L. FRIESS AND V. BOEKELHEIDE

In a recent publication, Reppe and his co-workers[1] have described the preparation of cycloöctatetraene (C.O.T.) and its conversion to many different derivatives. In attempting to explain the formation of the various reaction products of C.O.T., Reppe, *et al.*, have considered that C.O.T. may react as though it were present as any one of three different forms, I, II and III.

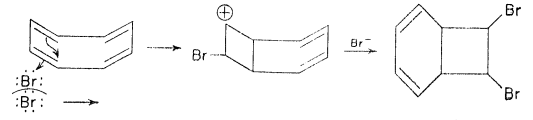


I II III

However, since I, II and III cannot very well be considered to be contributing forms to a resonance hybrid, it would appear desirable that the formation of unusual products from C.O.T. should be explicable on some other basis.

One possible explanation for the formation of certain of these products would be to consider that under attack by a reagent C.O.T. may undergo molecular rearrangement. The reaction of C.O.T. with bromine and with perbenzoic acid has been considered from this viewpoint and the results obtained in the present study are in support of such a postulation.

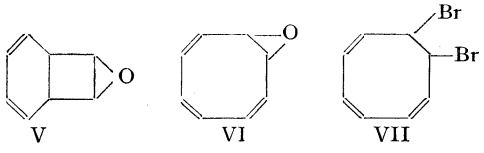
If the assumption is made that the strongest case yet presented for the structure of C.O.T. is the X-ray study[2] pointing to the "tub" or all-*cis* form, then it seems possible to explain certain of the reactions of the compound, and in particular those involving transitions from an initial eight-membered ring to a six–four bicyclic system, by a direct participation of a suitably situated neighboring double bond[3] in these reactions. The bromination process, for example, could be represented by the following scheme, involving the participation of a neighboring double bond in the reaction form presented by the molecule to the attack of a reagent;



IV

This formulation of the bromination of C.O.T. is in accord with the chemical evidence which Reppe, *et al.*,[1] have presented in support of structure IV.

A similar formulation could be postulated for epoxidation, using the electrophilic entity $:\ddot{O}:H^+$ from the perbenzoic acid. The result of participation of the neighboring double bond during epoxidation would be that C.O.T. oxide should be represented by formula V.



V VI VII

In this case, however, Reppe, *et al.*,[1] have assigned structure VI to C.O.T. oxide. A reinvestigation of the oxide has been made and evidence supporting structure V has been found.

The ultraviolet absorption spectrum of C.O.T. oxide in ethanol is shown in Fig. 1. It is seen that the position of the absorption peak for the oxide (λ_{max} = 241 mμ, log ϵ = 3.60) is compatible with a cyclic diene structure, V, as inferred by comparison with the peak of cyclopentadiene[4] in isoöctane (λ_{max} = 241, log ϵ = 3.50). The maximum of the dibromide (λ_{max} = 260, log ϵ = 3.70) is somewhat displaced to longer wave lengths, but is not quite as high as would be expected for the conjugated triene form VII.

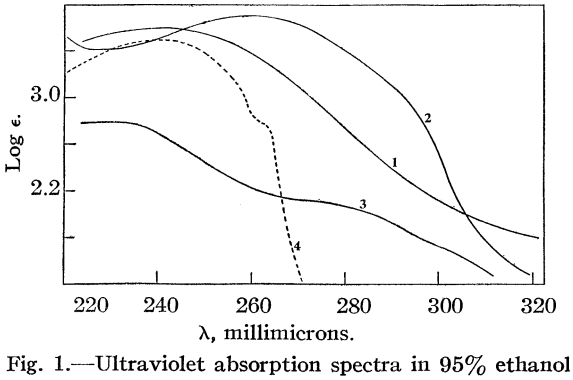


Fig. 1.—Ultraviolet absorption spectra in 95% ethanol of: 1, C. O. T. oxide; 2, C. O. T. dibromide; and 3, C. O. T. oxide hydrogenation product. Curve 4 is for cyclopentadiene in isoöctane.[5]

Further evidence for the diene character of the oxide was obtained from its maleic anhydride adduct. It would be expected that V would yield VIII, whereas structure VI should give IX. When the Diels–Alder reaction was carried out in benzene under anhydrous conditions, an exothermic

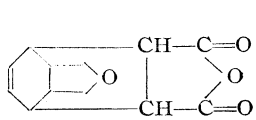
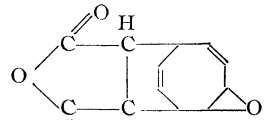
(3) For participation of a neighboring double bond in replacement reactions, see Winstein and Adams, THIS JOURNAL, **70**, 838 (1948).

(4) The ultraviolet absorption spectrum for cyclopentadiene in isoöctane solution is given for illustration since it is recorded in the literature,[9] whereas the complete solution spectrum of 1,3-cyclohexadiene was not available to us. A study of the variation of λ_{max} and log ϵ with increasing ring size in the conjugated cyclic dienes is contemplated.

(5) Data for cyclopentadiene were obtained from Ultraviolet Spectrograms, National Bureau of Standards, A.P.I. Research Project 44, serial no. 53.



VIII



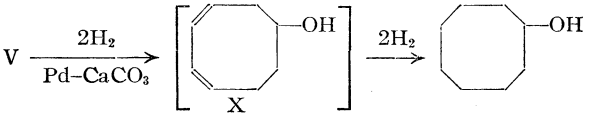
IX

reaction occurred giving an adduct, m. p. 206–207°, which corresponds to that reported by Reppe. Upon catalytic hydrogenation in ethanol with Adams catalyst at one atmosphere pressure, the adduct consumed exactly one mole of hydrogen, would take up no more, and yielded the dihydro compound of m. p. 240–245°, as reported. Upon treatment with perbenzoic acid in chloroform, the adduct consumed exactly one mole of the reagent, indicative again of just one double bond and form VIII as the molecular structure. This affords rather conclusive evidence for V as the structure of the oxide.

Interestingly, when the Diels–Alder reaction on the oxide was carried out under non-anhydrous conditions, a fair proportion of an isomeric adduct of m. p. 147–148° was also obtained. This too consumed exactly one mole of hydrogen, in methanol with platinum catalyst, and also consumed just one mole of perbenzoic acid. In the latter reaction, the product $C_{12}H_{10}O_5$ was isolated as a crystalline material sintering above 300°.

The only important evidence not favoring V as the structure of C.O.T. oxide is the fact that the oxide yields cycloöctanol on hydrogenation. In view of the strain which would be present in a molecule having a fused tricyclic ring system of this type, it seemed possible that cleavage of the fused rings would occur during hydrogenation so that V also would yield cycloöctanol. Evidence for this was obtained as follows.

When C.O.T. oxide in methanol solution was hydrogenated over a palladium-on-calcium carbonate catalyst, and the vigorous hydrogenation process stopped after absorption of just two moles of hydrogen, a colorless liquid fraction was obtained whose ultraviolet absorption spectrum in ethanol (λ_{max} = 230 mμ, log ϵ = 2.79) is also shown in Fig. 1. The position of the peak strongly suggests that a diene structure exists within the molecule. Further, the infrared spectrum of the substance shows a high intensity band at 2.85μ (3509 cm.$^{-1}$), a region characteristic[6] of the OH group vibration. This combination of features makes the formula X for the product most probable, although its homogeneity is not proven, and raises the possibility that in the complete hydrogenation of C.O.T. oxide, an over-all process requiring four moles of hydrogen to cycloöctanol,[1] the ring-fusion and the oxide ring are ruptured first, before the diene system is touched.



Portions of the infrared curves of C.O.T., the oxide and the dibromide are shown in Fig. 2. The oxide and dibromide curves are both quite different from that of C.O.T.

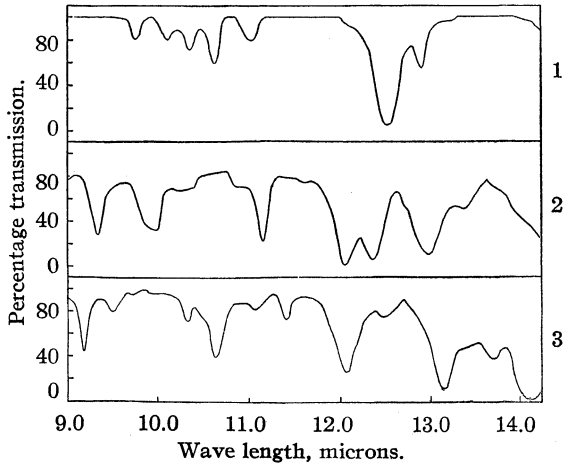


Fig. 2.—Infrared absorption spectra of: cycloöctatetraene (1); C. O. T. oxide (2); and C. O. T. dibromide (3). Data were obtained using 0.025-mm. cell.

Experimental[7]

C.O.T. Oxide.—This compound was prepared essentially according to Reppe's procedure,[1] but in considerably higher yields. In the best run, 5.5 g. of C.O.T. yielded 3.3 g. of oxide; b. p. 68–69° (12 mm.), $n^{21}D$ 1.5397.

C.O.T. Dibromide.—This too was prepared according to Reppe,[1] in comparable yield. The light yellow liquid had the following constants: b. p. 102–103° (5.5 mm.), $n^{21}D$ >1.7.

C.O.T. Oxide Hydrogenation Product (X).—To 25 ml. of methanol containing 1.1 g. of prereduced palladium–calcium carbonate catalyst was added 2.36 g. of C.O.T. oxide. The solution was allowed to absorb two molar equivalents (994 ml.) of hydrogen at atmospheric pressure, the catalyst was filtered off, the methanol removed under reduced pressure, and the residue fractionally distilled. There was collected a 0.76-g. fraction of colorless oil; b. p. 82–83° (16 mm.), $n^{21}D$ 1.4967.

Anal. Calcd. for $C_8H_{12}O$: C, 77.37; H, 9.74. Found: C, 77.27; H, 10.06.

Maleic Anhydride Adducts of the Oxide.—Reppe's procedure was again followed, with strict precautions against moisture. The adduct A crystallized from the benzene solution as white needles, which were filtered, washed with petroleum ether, and air-dried. From 3.3 g. of the oxide there was obtained 4.3 g. of adduct, m. p. 206–207°. In one run, where the drying tube on the reaction flask was eliminated, a benzene-soluble fraction of the adduct was an isomeric product B. This was obtained in 24% yield as white clusters, m. p. 147–148°.

Anal. Calcd. for $C_{12}H_{10}O_4$: C, 66.05; H, 4.62. Found: C, 66.18; H, 4.76.

Per Acid Titration of the Adducts.—A 0.24-g. sample of adduct A was added to a dried standardized chloroform solution of perbenzoic acid, prepared in the customary manner.[8] The per acid was present in excess. Consump-

(7) Analyses by Mrs. G. L. Sauvage; melting points are uncorrected.

(8) Braun, "Organic Syntheses," Coll. Vol. I, John Wiley and Sons, Inc., New York, N. Y., 1947, p. 431.

tion of per acid was checked by titration[9] of aliquots at timed intervals. At the end of 111.7 hours at room temperature the adduct had consumed exactly one molar equivalent of per acid, and would take up no more.

Per acid titration of a 0.246-g. sample of B was carried out in the same manner. During the course of the reaction, the product crystallized from solution. Exactly one molar equivalent of per acid had been consumed when the reaction stopped, 125.9 hours after mixing. The crystalline product was filtered, washed, and purified by sublimation under high vacuum. The product sintered above 300°.

Anal. Calcd. for $C_{12}H_{10}O_5$: C, 61.54; H, 4.30. Found: C, 61.68; H, 4.28.

Hydrogenation of the Adducts.—To 0.10 g. of Adams catalyst prereduced in 10 ml. of ethanol was added 0.400 g. of adduct A dissolved in 40 ml. of alcohol. Hydrogenation at atmospheric pressure and room temperature progressed to the absorption of one molar equivalent of hydrogen (45 ml.) in the course of five and one-half hours, and stopped. After removal of catalyst and solvent, the crude dihydro product melted at 240–245° as reported by Reppe.

A similar hydrogenation of 0.30 g. of B in methanol likewise progressed to the extent of exactly one mole up take (37 ml.) of hydrogen in one hour and stopped.

Acknowledgment.—We gratefully acknowledge receipt of several samples of purified cycloöctatetraene from General Aniline and Film Corp., Easton, Pa.

The Anion-exchange Separation of Zirconium and Hafnium[1]

BY E. H. HUFFMAN AND R. C. LILLY

An effective separation of zirconium and hafnium as negative fluo-ions has been obtained by using one of the strongly basic anion exchange resins recently developed, although earlier attempts using the weakly basic resins first available were unsuccessful.

Twenty milligrams of zirconium and 10 mg. of hafnium, as oxides, were added to zirconium and hafnium tracers in a small amount of hydrofluoric and nitric acids, warmed until dissolved, and fumed with 0.5 ml. of sulfuric acid. The residue was dissolved in water and the hydroxides precipitated with ammonium hydroxide. The precipitate was centrifuged, washed with water, dissolved in 5 ml. of 0.64 *M* hydrofluoric acid and diluted to 10 ml. with water. Six hundred milligrams of 200–325 mesh Amberlite IRA-400 resin, in its original chloride form, was added to the sample and the mixture shaken for three hours. The resin was separated from the solution and washed well with 10 ml. of water. Tracer count of the solution and washings indicated that 96% adsorption had taken place. This portion of resin was slurried onto the top of a column of the same resin 30 cm. in length and 0.78 sq. cm. in cross section. Elution with a solution of 0.2 *M* hydrochloric acid and 0.01 *M* hydrofluoric acid at the rate of 6 ml. per hour gave the results shown in Fig. 1. The solid parts of the curve were obtained by counting Zr^{95} and Hf^{181} tracers and the dotted parts by spectrographic analysis. The order of elution of the two elements is the reverse of that obtained by cation-exchange.[2]

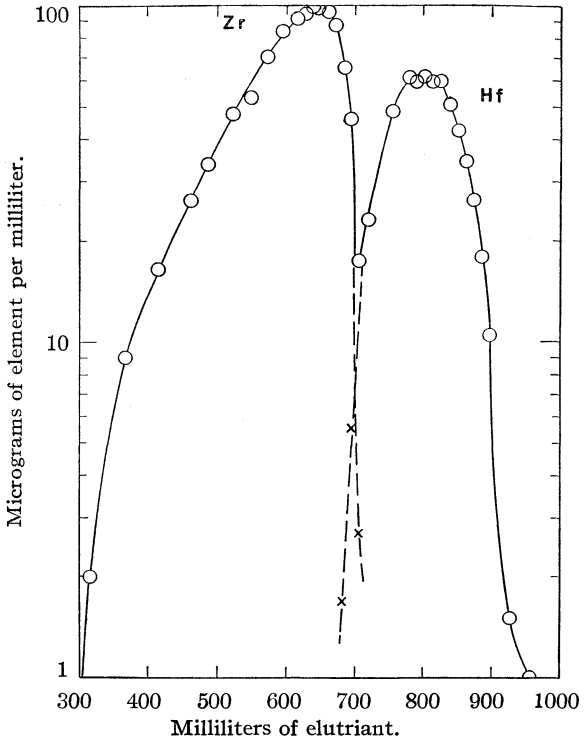

Fig. 1.—Elution of fluozirconate and fluohafniate with 0.2 *M* hydrochloric acid and 0.01 *M* hydrofluoric acid.

Combined fractions of elutriant from 300 ml. to 653 ml., containing 13.8 mg. of zirconium or 69% of the starting material, were found to contain no hafnium detectable by spectrographic analysis. The portion from 300 ml. to 686 ml., containing 17.0 mg. of zirconium or 85% of the starting material, was found to contain 0.04% hafnium. Spectrographic analysis of the 752–1020-ml. portion showed 0.02% zirconium in the 6.9 mg. of hafnium (69% of the starting material). Similarly, 0.03% zirconium was found in the 704–1020-ml. portion containing 8.3 mg. of hafnium (83% of the starting material). The amounts of the major constituents in these portions were determined from the curves.

This work was done under the auspices of the Atomic Energy Commission.

[a] This compound has been reported by VIAUD, without any chemical data, *Prod. Pharmac.*, **2**, 53 (1947), to have no antihistaminic activity *in vitro* or *in vivo*. [b] Calcd.: Cl, 19.42. Found: Cl, 19.41. [c] Calcd.: Cl, 19.87. Found: Cl, 19.81.

replaced by a dialkylaminoalkyl group (see Table I).

5,6-Dihydrophenanthridine, the starting material, was prepared according to Ritchie[3] by reduction of phenanthridine with tin and concentrated hydrochloric acid and also (for the first time) by catalytic reduction using Raney nickel in dry ethanol. The latter method gave quantitative yields. 5,6-Dihydrophenanthridine as well as a number of substituted 5,6-dihydrophenanthridines were condensed with different substituted aminoethyl halides in the presence of sodamide using toluene as the solvent to give the desired compounds. The reaction mixtures were worked up according to the method previously described.[4]

The following four compounds (Table I) are reported at the present time. Compounds, 1, 3 and 4 have been tested in our Pharmacology Department (Dr. N. Ercoli, director) for their inhibitory action on contractions of the isolated guinea pig intestine induced by histamine. Compounds 1 and 4 were found to be completely inactive while compound 3 had very slight activity. (The doses required for inhibition were higher than 20 gamma/cc.)

Inspection of the generic structure of these compounds (Table I) reveals that they differ from the Antergan type only in the existence of the linkage represented by the dotted line. Whereas ring closures of this type can result in compounds of increased activity in the field of antispasmodics (*e. g.*, β-diethylaminoethyl diphenylacetate, Trasentine → β-diethylaminoethyl fluorene-9-carboxylate, Pavatrine[5]), it would seem that the same does *not* hold true in the case of antihistaminics. The loss of activity which occurs if the diphenylmethyl group of Benadryl is replaced by 9-fluorenyl[6] could be mentioned as an additional example.

The compounds, 1, 3 and 4 were also found to have no trypanocidal activity when tested in maximum tolerated dosage against *Trypanosoma equiperdum* in mice.

The author wishes to thank Dr. H. M. Wuest for his interest and encouragement.

Some Reactions of the Trifluoromethyl Group in the Benzotrifluoride Series. I. Hydrolysis

BY GENE M. LE FAVE[1]

The inertness of the trifluoromethyl (CF_3–) group in benzotrifluoride and many of its derivatives is well-known.[2] However, it has also been observed that concentrated hydrobromic acid,[3] sodium hydroxide,[4] and 60–80% sulfuric acid[5,6] can bring about the hydrolysis of this group in benzotrifluoride or certain of its derivatives.

While attempting to sulfonate benzotrifluoride with concentrated sulfuric acid, hydrolysis occurred resulting in excellent yields of benzoic acid rather than the expected *m*-sulfonic acid of benzotrifluoride. In order to ascertain the applicability of this reaction, the substituted benzoic acids listed in Table I were prepared from the corresponding benzotrifluorides by treatment with approximately 100% sulfuric acid followed by hydrolysis of the reaction product.

[a] All melting points are uncorrected.

Trifluoromethylaryls.—With the exception of *m*-hydroxybenzotrifluoride, all trifluoromethylaryls were obtained through the courtesy of the Hooker Electrochemical Company and were used without further purification. The *m*-hydroxybenzotrifluoride was easily prepared by conversion of *m*-aminobenzotrifluoride through the diazonium transformation.

Hydrolysis of Benzotrifluoride.—A mixture of 36.5 g. (0.25 mole) of benzotrifluoride and 28 g. of 100% sulfuric acid was heated cautiously until the evolution of hydrogen fluoride began as could be detected by its etching of the glass walls of the reaction vessel. The heat source then was withdrawn and reapplied intermittently until the benzotrifluoride layer disappeared. After the evolution of hydrogen fluoride had ceased, the reaction mixture was poured, with stirring, into 1 l. of ice-water, the resultant precipitate sucked dry, and finally washed thoroughly with cold water. The crude product was purified through its sodium salt using Norit, and the free acid was recrystallized from hot water.[7] This procedure is typical for the series investigated.

Using 80% sulfuric acid the starting material is recovered unchanged after refluxing for several hours, while with 20–30% fuming sulfuric acid small amounts of sulfones and sulfonic acids are formed. Prolonged or excessive heating gives rise to tars. Occasionally it is difficult to initiate the reaction. In these cases, the addition of small amounts of 20–30% oleum portionwise is effective. *m*-Nitrobenzotrifluoride in particular is subject to this difficulty and with it 15% oleum must be used for the reaction to take place.

Since 65% fuming sulfuric acid is required to effect satisfactory sulfonation of trifluoromethylaryls,[8] probably because of the strong inductive effect of the meta-directing CF_3– group, it is apparent that the rate of sulfonation is far slower than attack of the CF_3– group. This competitive situation accounts for the appearance of sulfur-containing by-products only at the higher concentrations of sulfur trioxide.

Acknowledgments.—The author expresses appreciation to Dr. K. M. Seymour and Mr. P. G. Scheurer for their helpful suggestions.

(7) Only traces of fluorine and no sulfur or chlorine could be detected by the usual qualitative tests.

Steroidal Sapogenins. 174. 17-Hydroxy-20-ketopregnanes from Steroidal Sapogenins

BY RUSSELL E. MARKER[1]

In the synthesis of cortisone and its analogs the introduction of a hydroxyl group on the C-17 carbon of the pregnanes is quite complicated and involved leading to low yields. A new and very simple reaction has now been found in which this can be accomplished in high yield from naturally occurring steroidal sapogenins containing ketonic groups on C-12. As sapogenins occur widely distributed in nature, they now present a large potential source of material for this synthesis.

Treatment of the oxidation product of the diacetate of pseudobotogenin with a dilute methanolic solution of potassium carbonate gives an immediate precipitation of the acetate of 16-dehydropregnen-5-ol-3-dione-12,20 removing it from further action with the alkaline solution.[2] A small amount of a secondary product resulting from this reaction was further studied. It has now been found that this new material is the major product of the hydrolysis if alcoholic potassium hydroxide is employed instead of dilute methanolic potassium carbonate. In this case the product does not precipitate during the reaction. The same product was obtained when 16-dehydropregnen-5-ol-3-dione-12,20 acetate was treated with alcoholic potassium hydroxide. The new product analyzes for a pregnendioldione, containing two hydroxyl groups, only one of which acetylates with boiling acetic anhydride. It is recovered unchanged when shaken with hydrogen and palladium catalyst, showing that it does not contain the conjugated double bond system. These reactions indicate that the new hydroxyl group was introduced in the 17-position as a tertiary carbinol. A secondary hydroxyl group on C-16 would readily form an acetate under the conditions employed. Whether the formation of a 17-hydroxyl group in the conjugated ketone system by alkali is characteristic only of pregnenes containing a ketone group in the beta-position at C-12 has not been determined but present indications are that the addition of water to the 16-double bond is influenced by the presence of a C-12 ketone in the molecule. In the strong alkaline hydrolysis of the oxidation product, the first product formed is probably the expected 16-dehydropregnene which then hydrates under the influence of alkali to give the 17-hydroxy compound.

Because of the significance of this reaction in the preparation of cortisone or its analogs from steroidal sapogenins, it has been applied to kammogenin, another possible starting material for the antiarthritic hormone. This sapogenin is now known to occur in many plants and new sources for it and the other steroidal sapogenins will be reported at a later date.

Pseudokammogenin triacetate[3] was oxidized as described for pseudobotogenin diacetate.[2] Treatment of the oxidation product with alcoholic potassium hydroxide gave a diketopregnene containing three hydroxyl groups, only two of which are acetylatable. The product cannot be

(1) Present address: Hotel Geneve, Mexico City, Mexico.

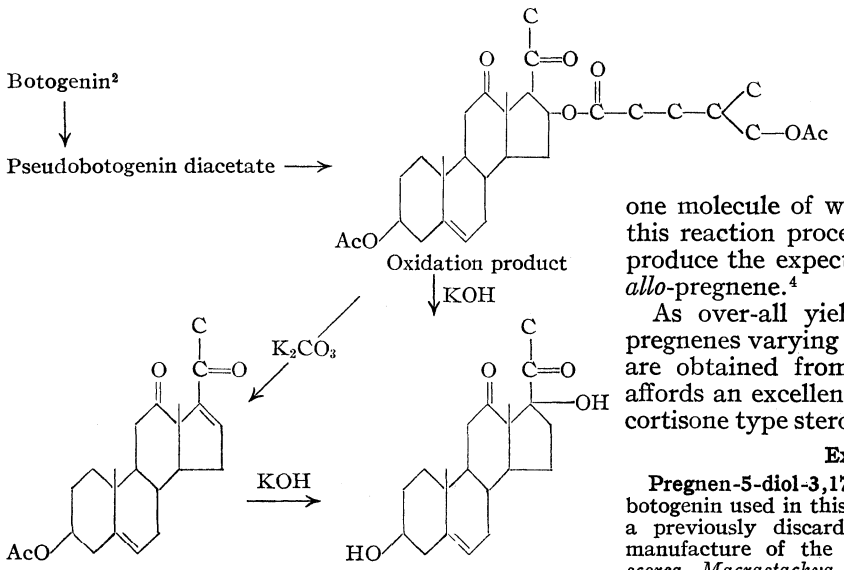
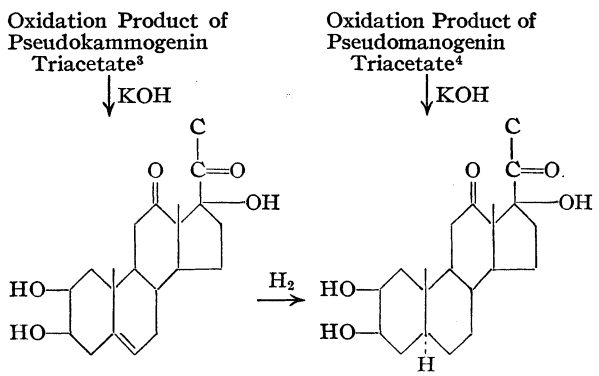
(3) Marker and Lopez, *ibid.*, **69**, 2373, 2375 (1947).



reduced by hydrogen using palladium catalyst, indicating absence of the C-16 double bond and that a new hydroxyl group was introduced as described above to form pregnen-5-triol-2,3,17-dione-12,20. Mild catalytic reduction using hydrogen and platinum oxide catalyst saturated the double bond in the 5-position. This product was identical with the product obtained by the alkali treatment of the oxidation product of the triacetate of pseudomanogenin followed by acetylation, which also contains a hydroxyl group that does not form an acetate.



It was previously reported[2] that *allo*-pregnantrione-3,12,20 was formed by the reduction of pregnen-5-ol-3-dione-12,20 (erroneously this should have read *16-dehydro*-pregnen-5-ol-3-dione-12,20) followed by mild oxidation.[2] The material actually used was the alcoholic potassium hydroxide hydrolysis product of the acetate of 16-dehydropregnen-5-ol-3-dione-12,20, which has now been shown to give the 17-hydroxypregnene instead of the expected 16-dehydropregnene. Analysis of the triketone produced in this reaction shows it to be 17-hydroxy-*allo*-pregnantrione-3,12,20 containing a tertiary hydroxyl group which does not acetylate. This product is identical with the triketone produced from the oxidation product of pseudohecogenin followed by strong alkaline hydrolysis. Previously it was assumed from the analysis that this was a triketone containing one molecule of water of crystallization and that this reaction proceeded in its normal manner to produce the expected 16-dehydro-3,12,20-triketo-*allo*-pregnene.[4]

As over-all yields of the 17-hydroxy-20-keto-pregnenes varying from 40–55% on a weight basis are obtained from the 12-keto-sapogenins, this affords an excellent method for the production of cortisone type steroids.

Experimental Part

Pregnen-5-diol-3,17-dione-12,20 from Botogenin.—The botogenin used in this work was prepared from ricogenin,[5] a previously discarded by-product in the commercial manufacture of the steroidal sex hormones from *Dioscorea Macrastachya* in Mexico. The crude oxidation product of pseudobotogenin diacetate, prepared from 5 g. of botogenin acetate[2] was refluxed for thirty minutes with 500 cc. of 3% alcoholic potassium hydroxide. Water was added and the product was extracted with a large volume of ether. Upon concentration to a small volume the material crystallized. It was recrystallized from ether, m. p. 258–260°; yield 2.7 g.

Acetylation with boiling acetic anhydride followed by crystallization from ether gave a mono-acetate, m. p. 232–234°. Mixed with the acetate of 16-dehydro-pregnen-5-ol-3-dione-12,20 it gave a depression of 15–22°.

Anal. Calcd. for $C_{23}H_{32}O_5$: C, 71.1; H, 8.3. Found: C, 71.4; H, 8.7.

Hydrolysis of the acetate with alcoholic potassium hydroxide followed by crystallization from ether gave the above unacetylated product, m. p. and mixed m. p. 258–260°.

Anal. Calcd. for $C_{21}H_{30}O_4$: C, 72.8; H, 8.8. Found: C, 72.6; H, 8.7.

A solution of 1 g. of the acetate of 16-dehydro-pregnen-5-ol-3-dione-12,20 in 100 cc. of 3% alcoholic potassium hydroxide was refluxed for one hour. The product was crystallized from ether to give pregnen-5-diol-3,17-dione-12,20, m. p. and mixed m. p. with the above product, 258–260°. Acetylation of this product followed by crystallization from ether gave the 3-acetate of pregnen-5-diol-3,17-dione-12,20, m. p. and mixed m. p. with the above mono-acetate, 232–234°.

Anal. Calcd. for $C_{23}H_{32}O_5$: C, 71.1; H, 8.3. Found: C, 71.4; H, 8.5.

***allo*-Pregnanol-17-trione-3,12,20.**—The preparation of this product was previously reported[2] but erroneously the starting material used in the experiment should have read *16-dehydro*-pregnen-5-ol-3-dione-12,20. This was prepared by alcoholic potassium hydroxide hydrolysis of the acetate of 16-dehydro-pregnen-5-ol-3-dione-12,20 which has now been shown to add water to its 16-double bond to form a new C-17 tertiary hydroxyl group. It melted at 262–264° and gave no depression in melting point when mixed with the same product prepared by alcoholic potassium hydroxide hydrolysis of the oxidation product of pseudohecogenin as previously described.[4] It is unaffected by boiling acetic anhydride.

Anal. Calcd. for $C_{21}H_{30}O_4$: C, 72.8; H, 8.8. Found: C, 72.8; H, 8.6.

Pregnen-5-triol-2,3,17-dione-12,20 from Kammogenin.—To a solution of 2 g. of pseudokammogenin triacetate[3]

(4) Marker and co-workers, THIS JOURNAL, 69, 2167 (1947).
(5) Marker, *ibid.*, 71, 3856 (1949).

in 100 cc. of glacial acetic acid was added a solution of 800 mg. of chromic anhydride in 10 cc. of 90% acetic acid keeping the temperature at 20°. After standing thirty minutes water was added and the product was extracted with ether. The solvent was removed and the residue was refluxed for thirty minutes with 100 cc. of 3% alcoholic potassium hydroxide. Water was added, the solution was neutralized and the product was filtered and washed with water. It was recrystallized from ether, m. p. 275–278°, yield 0.9 g.

Anal. Calcd. for $C_{21}H_{30}O_5$: C, 69.6; H, 8.4. Found: C, 70.0; H, 8.6.

Acetylation with boiling acetic anhydride followed by crystallization from ether gave a diacetate, m. p. 264–265°. Upon shaking with hydrogen and palladium catalyst in ethyl acetate the product was recovered unchanged.

Anal. Calcd. for $C_{25}H_{34}O_7$: C, 67.1; H, 7.7. Found: C, 67.4; H, 7.8.

A solution of 200 mg. of the above diacetate in 25 cc. of acetic acid containing 100 mg. of platinum oxide catalyst was shaken with hydrogen at 40 pounds pressure for fifteen minutes. After filtration, water was added and the product was extracted and crystallized from ether, m. p. 265–267°. It gave no depression in melting point when mixed with the 2,3-diacetate of *allo*-pregnantriol-2,3,17-dione-12,20 prepared from the potassium hydroxide hydrolysis of the oxidation product of pseudomanogenin triacetate followed by acetylation. Mixtures of both products with the unreduced diacetate from kammogenin gave depressions in melting point of 12–18°.

Anal. Calcd. for $C_{25}H_{36}O_7$: C, 66.8; H, 8.1. Found: C, 67.0; H, 8.4.

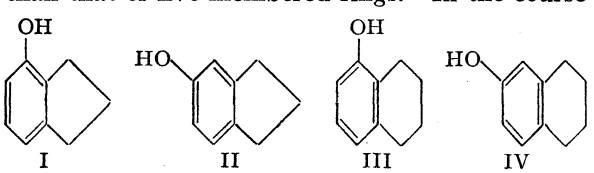
Partition Studies on Phenols. III. Steric Effects

BY MILTON ORCHIN[1] AND CALVIN GOLUMBIC[1]

It has been previously suggested that the partition coefficient of a phenol between water and an organic phase provides a sensitive index of the degree of steric hindrance around the phenolic group.[2] This arises from the fact that an important factor affecting the solubility of a phenol in the aqueous phase often is the degree of hydrogen bonding between the phenol and the water molecules; if the approach to the phenolic group is sterically inhibited, hydrogen bonding and, hence, solubility in water is reduced.

Arnold and co-workers have shown in a series of papers[3] that the relative steric influence of methylene groups in six-membered rings is greater than that of five-membered rings. In the course of our investigations on partition coefficients, we have obtained information on the same subject.



I II III IV

The partition coefficients of the indanols, I and II, and the tetrahydronaphthols, III and IV, were determined in the system cyclohexane–water (Table I). The partition coefficient (k) of 5-hydroxy-1,2,3,4-tetrahydronaphthalene, III, is 5.6 times that of 4-indanol, I. It would be expected, of course, that III would have less solubility in water than I solely on the basis of its greater molecular weight, but that III's high partition coefficient is due mainly to steric inhibition of hydrogen bonding is shown by comparison with its isomer IV, the hydroxyl group of which is unhindered. The ratio of partition coefficients of IV/I is only 1.9 as compared to III/I of 5.6. These results agree with Arnold's contention that methylene groups in five-membered rings offer less steric hindrance than those in six-membered rings. Further evidence of the correctness of this view is provided by the infrared specta of I and III in the hydroxyl group region. The spectrum of I shows a rather broad band at 2.93μ, while that of III shows only a weak shoulder at 2.91μ. This significant difference between the two spectra indicates the greater association through hydrogen bonding in the case of 4-indanol.[4] The slightly higher k value of I as compared to II indicates some steric interference of hydrogen bonding by the five-membered ring. This is consistent with the fact that I is the lower boiling of the two isomers.

TABLE I

PARTITION COEFFICIENTS AND IONIZATION CONSTANTS OF PHENOLS[a]

Compound	k(H_2O)	m	pK
4-Indanol (I)	4.5	0.98	10.2
5-Indanol (II)	3.7	1.03	10.2
5-Hydroxy-1,2,3,4-tetrahydronaphthalene (III)	25.3	1.04	10.1
6-Hydroxy-1,2,3,4-tetrahydronaphthalene (IV)	8.6	1.08	9.9

[a] Measurements at 25°.

Table I also lists the pK values of the four phenolic compounds calculated from observed partition coefficients at various pH values in the manner previously described.[2] The slopes (m) of the straight lines obtained by plotting the logarithms of the observed partition coefficients against pH are also listed in Table I. These values are in good agreement with the theoretical slope of one for monobasic phenols.

Experimental[5]

4-Indanol (I) was isolated by Dr. E. O. Woolfolk from the products of the hydrogenation of coal at the Bureau of Mines. It had a melting point of 47–48°.

(3) For the most recent paper in this series see Arnold and Richter, *ibid.*, **70**, 3505 (1948).

(4) We wish to thank Dr. R. A. Friedel, Lois Harnack and Marion Springer for the spectral data. Both spectra were determined in a 7% carbon disulfide solution and will be published in greater detail with other material in another article. We are indebted to George Goldbach for assistance with the experimental work.

(5) All melting points corrected.

5-Indanol (II) was also isolated by Dr. Woolfolk from coal-hydrogenation oils. It had a melting point of 52.4–53.8°.

5-Hydroxy-1,2,3,4-tetrahydronaphthalene (III) was prepared from pure 1-naphthol by hydrogenation.[6] Repeated crystallization gave a spectroscopically pure sample, m. p. 67.8–69.0°.

6-Hydroxy-1,2,3,4-tetrahydronaphthalene (IV) was prepared by the hydrogenation of 2-naphthol according to the directions of Stork.[7] We experienced considerable difficulty in freeing the tetrahydro compound from its aromatic precursor. Purification was achieved by distributing the mixture between cyclohexane and an aqueous alkaline buffered (pH 12.5) solution. In such a system all the 2-naphthol and a portion of the tetrahydronaphthol is retained in the aqueous phase and the organic phase contains pure tetrahydronaphthol. The tetrahydro compound was recovered from the organic phase by distillation and recrystallization. The pure material had a melting point of 57.2–58.4° and its ultraviolet absorption spectrum indicated the absence of naphthol.

Partition Experiments.—The phenols were dissolved in 20 ml. of spectrographic grade cyclohexane (0.5 mg. per ml.) and shaken with an equal volume of water for two minutes. After phase separation, the concentration of the phenol in the organic phase was determined by ultraviolet spectrophotometry in the usual way.[4]

The Reaction of Sodium Hypobromite with Arylcyanopyruvic Esters

BY SIGVARD WIDEQVIST

The appearance of a paper on the bromination of esters of arylcyanopyruvic acid[1] has prompted us to report some experiments, carried out some years ago, on the reaction between sodium hypobromite and certain organic compounds having labile hydrogen atoms. One of these was ethyl phenylcyanopyruvate. It was found that a cleavage of the ester took place with the production of phenylbromoacetonitrile, probably according to the equation

$$C_6H_5—CH(CN)—COCOOC_2H_5 + NaOBr \longrightarrow C_6H_5—CH(CN)Br + NaOCOCOOC_2H_5$$

This reaction was later used for synthetic purposes.

Treatment of an alkaline solution of ethyl phenylcyanopyruvate with an iodine–potassium iodide solution yielded a crystalline iodo compound, presumably phenyliodoacetonitrile, which, however, was very unstable and decomposed with the liberation of iodine. Ethyl α-naphthylcyanopyruvate was also cleaved in the same manner.

Phenylbromoacetonitrile.—Twenty-one and seven-tenths grams (0.1 mole) of ethyl phenylcyanopyruvate was dissolved in 200 cc. of water containing 5 g. of sodium hydroxide. The solution was cooled to 0°, and an ice-cold mixture of 16 g. of bromine, 9 g. of sodium hydroxide and 100 cc. of water was added. Phenylbromoacetonitrile immediately separated as a heavy, lemon-yellow oil; yield 16 g. (82%). It was converted into diphenylacetonitrile by the Friedel–Crafts reaction.

α-Naphthylbromoacetonitrile.—Ethyl α-naphthylcyanopyruvate (m. p. 114–115°, prepared from α-naphthylacetonitrile and diethyl oxalate; yield 73%) 5.0 g. (0.019 mole) was dissolved in 35 cc. of 2 N sodium hydroxide solution and cooled to 0°. A cold mixture of 5 g. of bromine and 40 cc. of 2 N sodium hydroxide was added. α-Naphthylbromoacetonitrile immediately separated as an orange-yellow oil which solidified in a few minutes; yield 4 g. (87%). It was recrystallized from hot alcohol (m. p. 101–102°).

Anal. Calcd for $C_{12}H_8NBr$: C, 58.54; H, 3.28; N, 5.69; Br, 32.49. Found: C, 58.80; H, 3.42; N, 5.59; Br, 32.92.

The Synthesis of 2-Fluoro-4- and 2-Fluoro-6-pyridinecarboxylic Acid and Derivatives

BY ARTHUR ROE, P. H. CHEEK AND G. F. HAWKINS[1]

The synthesis of 2-fluoronicotinamide,[2] 5-fluoronicotinamide[3] and 6-fluoronicotinamide[2] has been reported; preliminary reports indicate that at least one of them acts as a growth inhibitor for some microörganisms. It was therefore of interest to prepare some fluorinated isomers of nicotinic acid; this note reports the preparation of 2-fluoro-4-pyridinecarboxylic acid and 2-fluoro-6-pyridinecarboxylic acid together with their methyl esters and amides. The synthesis involved preparation of 2-fluoro-4-methylpyridine and 2-fluoro-6-methylpyridine followed by oxidation to the fluoro acids.

The authors are indebted to Eli Lilly and Company for generous support of this and related projects.

Experimental

The preparation of the fluoromethylpyridines and fluoro acids was carried out as described[2,3] for the fluoronicotinic acids, except that the water solubility of the 2-fluoro-6-pyridinecarboxylic acid made it necessary to remove the water from the acidified oxidation concentrate; this was accomplished by addition of ethanol and benzene, with subsequent distillation, in a manner somewhat similar to that reported by Black, Depp and Corson.[4] The acid was extracted from the inorganic material with benzene–alcohol. The methyl esters were obtained by allowing the acids to react with diazomethane[3]; the amides were prepared by the reaction of the methyl esters with 1:1 methanol–liquid ammonia mixture. The properties and analyses of the compounds prepared are given in Table I.

Some Cyclic Acetals of Tris-(hydroxymethyl)-nitromethane and their Derivatives

BY ALLEN SCATTERGOOD AND ALAN L. MACLEAN[1]

The cyclic acetals derived from tris-(hydroxymethyl)-nitromethane and five different aldehydes have been reported by Senkus[2] who prepared them by the azeotropic removal of water from equimolar quantities of the nitro triol and the aldehyde in the presence of a catalytic amount of *p*-toluenesulfonic acid. These cyclic acetals are the 5-nitro-5-(hydroxymethyl)-2-alkyl-1,3-dioxanes and should theoretically be capable of existing in both *cis* and *trans* forms. Although *cis–trans* isomers of cyclic acetals of tris-(hydroxymethyl)-nitromethane have never been obtained, Senkus[3] has prepared two sets of *cis–trans* isomers of cyclic acetals of a nitro glycol.

It seemed possible that tris-(hydroxymethyl)-nitromethane might serve as a model polyol useful in exploring conditions that could be employed in the acid catalyzed formation of cyclic acetals of carbohydrates or their derivatives in aqueous solution. Accordingly this triol was allowed to react with several aldehydes in an aqueous medium that was two molar in both reactants and also in hydrochloric acid. Three of the aldehydes formed crystalline acetals under these conditions. Two of these crystalline acetals were derived from aldehydes previously employed by Senkus. However, these acetals melted at higher temperatures than the acetals obtained by Senkus. It is probable that the compounds isolated by Senkus are *cis–trans* isomers of the ones prepared by us. We have demonstrated the presence of a free hydroxyl group in all of our acetals by the formation of their crystalline benzoates. We have also secured one *p*-toluenesulfonate and a cyanoethylation product. The properties of the new compounds are given in Table I.

Experimental

Cyclic Acetals of Tris-(hydroxymethyl)-nitromethane.—One-tenth mole (15.1 g.) of tris-(hydroxymethyl)-nitromethane (supplied by the Commercial Solvents Corporation, Terre Haute, Indiana), 10 cc. of water, 8 cc. (0.1 mole) of concentrated hydrochloric acid and 10 cc. of methyl cellosolve (to act as a mutual solvent, omitted in the case of *n*-butyraldehyde) and 0.1 mole of the aldehyde were mixed, and the volume of the mixture (which may be two phase) was made up to 50 ml. with water. Thus the mixture was two molar in each of the reactants and also in hydrochloric acid. Homogeneous mixtures were allowed

to stand at room temperature until the bulk of the product had crystallized, while two phase mixtures were shaken by machine at room temperature until formation of product was complete. After several days at room temperature, the solid product was filtered off, washed with water until neutral, and air-dried. The solid products were recrystallized to constant melting point. The solvent, melting point and analytical data for each acetal are given in Table I. No solid acetals were obtained from the reaction of tris-(hydroxymethyl)-nitromethane and the following aldehydes under our conditions: propionaldehyde, isobutyraldehyde, α-ethyl-*n*-hexaldehyde, *n*-heptaldehyde and α-ethyl-β-*n*-propyl-acrolein.

Benzoates and Tosylates of Cyclic Acetals of Tris-(hydroxymethyl)-nitromethane.—One-tenth mole of each acetal was dissolved or suspended in 0.2 mole of purified pyridine and 0.1 mole of benzoyl chloride or *p*-toluenesulfonyl chloride was added all at once. If the temperature went above 50° the reaction mixture was cooled until the temperature had gone below this figure. After twenty-four hours at room temperature, the reaction mixtures were poured into water, and the solid products were removed by filtration and washed with additional water. The solvents used in recrystallization together with the melting points and analytical data are listed in Table I.

2-Phenyl-5-nitro-5-(β-cyanoethoxymethyl)-1,3-dioxane.—One-tenth mole of the benzaldehyde acetal of tris-(hydroxymethyl)-nitromethane was dissolved in 65 cc. of dioxane containing 5.3 g. (0.1 mole) of acrylonitrile, and 0.4 g. of sodium hydroxide dissolved in a little water was added. After standing overnight, the solution was concentrated and the viscous residue was extracted with hot *n*-hexane. After recrystallization from *n*-hexane the substance melted at 77.7°. The analytical data are recorded in Table I.

Side Reaction in the Hydrogenation of 4-Nitro-2-chlorobenzoic Acid and Its Esters

BY ANNA WEIZMANN

In attempts to prepare diethylaminoethyl 4-amino-2-chlorobenzoate,[1] the catalytic hydrogenation of the corresponding 4-nitro-acid, its ethyl and its β-diethylaminoethyl ester was studied. A number of side reactions were observed which made the method impractical from a preparative point of view.

In some cases, incomplete reduction resulted, leading to hydroxylamino- and azoxybenzene derivatives, in others the chlorine atom was lost—this occurred in hydroxylic solvents, not in ethyl acetate. Sometimes, β-diethylaminoethyl 4-nitro-2-chlorobenzoate suffered hydrogenolysis to give *ethyl* esters; in one case even a *methyl* ester was formed, before the nitro group was attacked. These hydrogenolytic reactions are somewhat unusual; they recall similar, very recent observations of Metayer.[2]

Experimental

4-Nitro-2-chlorobenzoic acid is best prepared by the method of Cohen and McCandlish[3] with some modifications: a mixture of 2 kg. of 4-nitro-2-chlorotoluene and 6 liters of 33.5% nitric acid (1.32) is heated (autoclave) at 120° for eight hours. While 1010 g. of the starting material remains unattacked, 1090 g. of the desired acid is obtained; m. p. 138–139°; conversion, 49.5%; yield, 93.6%. *Ethyl ester*, b. p. 188° (24 mm.); 145–147° (3 mm.); 122–123° (0.2 mm.).

Diethylaminoethyl 4-Nitro-2-chlorobenzoate.—A mixture of 23 g. of ethyl 4-nitro-2-chlorobenzoate and 26.4 g. of diethylaminoethanol was heated for six hours at 140–150° and the reaction product treated with water and ether and fractionated; b. p. 162–163° (0.18 mm.); 140° (0.02 mm.); yield, 16 g. (52%).

Anal. Calcd. for $C_{13}H_{17}O_4N_2Cl$: C, 52.0; H, 5.7; N, 9.3. Found: C, 51.8; H, 5.5; N, 9.0.

Hydrochloride from ethyl acetate, white needles, m. p. 144°.

Anal. Calcd. for $C_{13}H_{18}O_4N_2Cl_2$: C, 46.3; H, 5.3; N, 8.3; Cl, 21.1. Found: C, 46.6; H, 5.2; N, 8.2; Cl, 21.5.

Approximately the same yield (50%) was obtained when the reaction was carried out under reflux in dioxane as solvent (six hours, bath temperature 120°); *trans*-esterification in presence of toluene and aluminum isopropoxide as catalyst (150°, five hours, with continuous removal of the ethyl alcohol formed) gave a yield of 37.5%.[4]

Diethylaminoethyl Acetate.—Azeotropic esterification of 160 g. of ethylene chlorohydrin and 120 g. of acetic acid in 100 cc. of benzene took five hours, when 10 cc. of concentrated sulfuric acid was employed as catalyst. The resulting solution was washed with sodium carbonate and dried and the β-chloroethyl acetate purified by fractionation; b. p. 145–147° (760 mm.); 50° (18 mm.); yield, almost quantitative.[5] The ester obtained (200 g.) was refluxed with an excess of diethylamine (250 g.) for eight hours, and after addition of another 125 g. of diethylamine for the same period again. The filtered solution was fractionated; b. p. 147°; yield, 130 g.

Hydrogenation of Diethylaminoethyl 4-Nitro-2-chlorobenzoate.—Three representative experiments are reported: (a) A solution of 9 g. (0.03 mole) of the nitro-ester in 50 cc. of anhydrous ethyl alcohol absorbed, at room temperature and in presence of 1 g. of palladium–barium sulfate catalyst, 2010 cc. of hydrogen (0.09 mole) within five and one-half hours. The oily residue of the filtered solution crystallized partly; trituration with cold chloroform gave a white solid which was recrystallized from butyl acetate and melted at 135°. Analysis and reducing properties pointed to the formation of **diethylaminoethyl 4-hydroxylamino-2-chlorobenzoate**, $HONH{\cdot}C_6H_3(Cl){\cdot}COO{-}CH_2CH_2N(C_2H_5)_2$.

Anal. Calcd. for $C_{13}H_{19}O_3N_2Cl$: C, 54.5; H, 6.6; N, 9.8; Cl, 12.2. Found: C, 54.3, 54.7; H, 6.9, 7.1; N, 9.8; Cl, 12.4.

Evaporation of the chloroform solution left a strongly basic oil of anesthetic properties which boiled at 130–135° (0.05 mm.) and gave, with alcoholic hydrogen chloride, crystals of ethyl 4-aminobenzoate hydrochloride, m. p. 210°, which were identified by analysis and mixed m. p.

Anal. Calcd. for $C_9H_{12}O_2NCl$: C, 53.7; H, 6.0. Found: C, 53.8; H, 5.9.

(b) When a solution of 6 g. (0.02 mole) of the nitro-ester in 30 cc. of diethylaminoethyl acetate was hydrogenated at room temperature in presence of 0.5 g. of the palladium catalyst, a thick precipitate appeared after the absorption of 500 cc. of hydrogen (0.02 mole), and no further absorption took place. Extraction of the solid phase with butyl acetate gave 2 g. of the above hydroxylamino-compound, m. p. 135°, while the liquid phase contained 3 g. of an oil which crystallized partly on standing. Recrystallization from methanol gave **ethyl 4-amino-2-chlorobenzoate** of m. p. 110°.[1]

(5) For the usual acetylation of ethylene chlorohydrin, see "Beilstein," Vol. II, p. 128; 2nd suppl. Vol. II, p. 136.

In another experiment, the liquid phase gave, upon trituration with petroleum ether, a solid which crystallized from methyl alcohol and melted at 77–78°. Analysis and comparison with an authentic specimen prepared from 4-nitro-2-chlorobenzoic acid (3 g.) and methyl alcohol (20 cc.) in presence of concentrated sulfuric acid (6 drops) indicated that methyl 4-nitro-2-chlorobenzoate had formed.

Anal. Calcd. for $C_8H_6O_4NCl$: C, 44.7; H, 2.8; N, 6.5; Cl, 16.3. Found: C, 45.0; H, 2.8; N, 6.4; Cl, 16.1.

In addition, a small amount of an unidentified substance was formed which crystallized from butyl alcohol or isobutyl acetate in slightly yellowish leaflets of m. p. 152°.

(c) A solution of 15 g. of diethylaminoethyl 4-nitro-2-chlorobenzoate (0.05 mole) in 105 cc. of ethyl acetate absorbed in presence of palladium–barium sulfate catalyst, 3850 cc. of hydrogen (3.44 moles) at room temperature in three hours. The residue of the filtered solution crystallized upon standing. After trituration with methanol and recrystallization from methanol or petroleum ether, the substance melted at 92°. It is characterized by the formation of dimorphous crystals: yellow needles and orange-red prisms. Analysis proved the formula of diethyl 3,3′-dichloro-azoxybenzene-4,4′-dicarboxylate.

Anal. Calcd. for $C_{18}H_{16}O_5N_2Cl_2$: C, 52.6; H, 3.9; N, 6.8; Cl, 17.3; mol. wt., 411. Found: C, 52.6; H, 3.9; N, 7.2; Cl, 17.0; 17.1; mol. wt. (in camphor), 396.

3,3′-Dichloroazoxybenzene-4,4′-dicarboxylic acid was isolated in one experiment, in which 5 g. of 4-nitro-2-chlorobenzoic acid was hydrogenated in 30 cc. of isopropyl alcohol at room temperature and the reaction came to a standstill after the absorption of 1.9 moles of hydrogen. Recrystallization from butyl alcohol gave short needles, m. p. 320°.

Anal. Calcd. for $C_{14}H_8O_5N_2Cl_2$: C, 47.3; H, 2.3. Found: C, 47.5; H, 2.6.

The hydrogenation experiments with 4-nitro-2-chlorobenzoic acid and its ethyl ester were carried out at room temperature and atmospheric pressure, in approximately 10% solutions, using palladium-on-barium sulfate (5%) as catalyst. In ethyl acetate, the acid and the ethyl ester absorbed 3 moles of hydrogen in twenty-four and three hours, respectively, and gave 4-amino-2-chlorobenzoic acid (from toluene, m. p. 213°)[6] and ethyl 4-amino-2-chlorobenzoate (from methanol, m. p. 110°) in quantitative yield. In isopropyl alcohol as solvent, 4 moles of hydrogen were absorbed in sixteen and five hours, respectively, without any break in the rate of absorption. The products isolated were 4-aminobenzoic acid (m. p. 187°; yield, 90%) and the hydrochloride of ethyl 4-aminobenzoate (m. p. 211°, from ethyl acetate; yield, quantitative). Also an aqueous solution of sodium 4-nitro-2-chlorobenzoate absorbed 4 moles of hydrogen (in eight hours) and gave 4-aminobenzoic acid (in 90% yield).

Irreversible Decolorization of Pinacyanol Chloride in the Presence of Paraffin-Chain Salts[1]

BY ANNA MAE TIMBERS AND E. C. LINGAFELTER

In using pinacyanol chloride as a means of determining the critical concentration of paraffin-chain salts,[2] we have observed that the color fades upon standing. Since we do not plan to pursue this investigation, we wish at this time to report some preliminary observations on the factors which affect the rate of disappearance of the color.

1. The disappearance of color is not due to the familiar effect of hydrogen ion, since it is not reversed by the addition of hydroxide ion.

2. The disappearance of color is due to an oxidation, since the rate is decreased by removing oxygen (either by passing nitrogen through the solution or by adding hydroquinone) and is increased by the addition of hydrogen peroxide. The oxidation of pinacyanol chloride to colorless products by nitric acid and by alkaline potassium ferricyanide has been reported previously.[3]

3. The reaction is photosensitive, the rate being markedly increased by exposure to intense illumination. For example, a solution containing 10^{-5} *M* pinacyanol chloride, 0.27 *M* hydrogen peroxide, and 0.01 *M* sodium decanesulfonate showed no loss of color after several days in the dark, but was completely decolorized after ninety-five minutes in daylight or after eight minutes of exposure to a Cenco mercury arc.

4. The rate of decolorization is independent of the concentration of added sodium chloride but is markedly affected by the presence of paraffin-chain salts. The results of three sets of experiments using sodium decanesulfonate (critical concentration, 0.04 *M*) are shown in Fig. 1. Similar results were obtained with other concentrations of hydrogen peroxide and also with sodium octane-

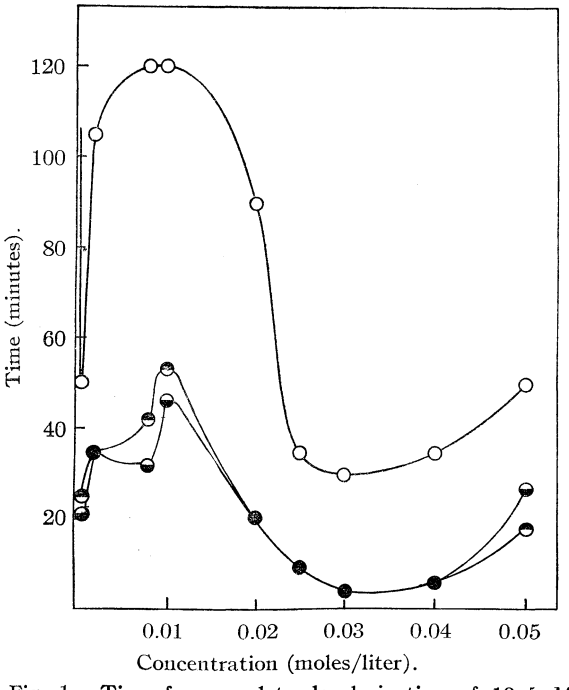

Fig. 1.—Time for complete decolorization of 10^{-5} *M* pinacyanol chloride as a function of concentration of sodium 1-decanesulfonate: ○, 0.03 *M* H_2O_2; ◓, 0.35 *M* H_2O_2; ◒, 0.53 *M* H_2O_2.

sulfonate and sodium dodecyl sulfate as the paraffin-chain salts.

We have no explanation to offer at the present time for the effect of concentration of paraffin-chain salt, although the phenomenon is not surprising in view of the profound effect of paraffin-chain salts upon the absorption spectrum of the dye.

NEW COMPOUNDS

p,p'-Dichlorobenzhydryl-β-cyanoethyl Ether

Ten grams (0.04 mole) of *p,p'*-dichlorobenzhydrol[1] (m. p. 88–89°) and 1.0 ml. of phenyltrimethylammonium hydroxide (Monsanto, 20% aqueous solution) were dissolved in 40 ml. of purified dioxane. A solution of 2.3 g. (0.04 mole) of redistilled acrylonitrile in 10 ml. of dioxane was added dropwise with stirring. After pouring into 200 ml. of water, the oil layer was separated. On standing overnight 11 g. (91%) of solid melting 52–66° formed. Crystallization from 50 ml. of 95% ethanol gave 7.6 g. (67%) melting 74–76°.[2] For analysis a sample was recrystallized; m. p. 75–76.5°.

Anal. Calcd. for $C_{16}H_{13}OCl_2N$: Cl, 23.2; N, 4.58. Found: Cl, 22.45; N, 4.43.

Attempts to hydrolyze this cyanide in alkaline solution to β-(*p,p'*-dichlorobenzhydroxy)-propionic acid unexpectedly cleaved the ether linkage with the formation of *p,p'*-dichlorobenzhydrol. Five grams (0.016 mole) of the ether and 50 ml. of 15% aqueous sodium hydroxide were refluxed for twenty-four hours. At the end of this time the evolution of ammonia had practically ceased. After cooling and filtering 2.5 g. of solid, m. p. 83–85°, was collected. A mixed melting point with authentic *p,p'*-dichlorobenzhydrol was 84–88°. Acidification of the filtrate gave no precipitate. With 50 ml. of 25% sodium hydroxide solution and four hours of refluxing, the yield of alcohol was 97% of the theoretical.

Derivatives of Di-(*p*-chlorophenyl)-acetic Acid

Di-(*p*-chlorophenyl)-acetic acid, m. p. 164–166°, was made by the alkaline hydrolysis of DDT.[1]

Methyl Di-(*p*-chlorophenyl)-acetate.—From 16.9 g. (0.06 mole) of di-(*p*-chlorophenyl)-acetic acid, 20 ml. (14.2 g., 0.44 mole) of methanol and 1 ml. of concentrated sulfuric acid reacted at reflux for four hours there was obtained 9 g. (54%) of ester boiling at 208–212° (5–6 mm.). On standing overnight the product crystallized; m. p. 37–39° (see Table I for analysis).

Phenacyl Di-(*p*-chlorophenyl)-acetate.—From 8 g. (0.03 mole) of acid as the salt and 6.23 g. (0.032 mole) of phenacyl bromide reacted in the usual way at reflux for two hours 8.0 g. (71%), m. p. 129–130°, of ester formed.[2] A sample purified by crystallization from benzene melted 132–133°.

(1) Grummitt, Buck and Egan, *Org. Syn.*, **26**, 21 (1946).

Di-(*p*-chlorophenyl)-acetic Anhydride.—A mixture of 20 g. (0.07 mole) of acid and 15.7 g. (0.15 mole) of reagent grade acetic anhydride was refluxed gently for two hours. Distillation at 0.5 mm. gave 2.1 g. at 135–165°, 14.7 g. at 165–195°, 0.2 g. at 195–260° and 2 g. of black residue. Redistillation of the 165–195° fraction gave 11.6 g. at 180–190° (0.5 mm.). Addition of ether precipitated 8.9 g. of yellow solid melting 82–123°. Crystallization from 12 ml. of dry chloroform gave 2.6 g., m. p. 158–163°; a mixed melting point with di-(*p*-chlorophenyl)-acetic acid gave 159–164°. Repeated crystallizations of the chloroform-soluble portion from benzene–petroleum ether (b. p. 60–70°) (1/2 by volume) finally gave 2.6 g. of faintly yellow needles melting 104–105.5°.

Hydrolysis of 0.5 g. of the anhydride by refluxing with 10 ml. of 10% sodium hydroxide solution gave 0.4 g. of di-(*p*-chlorophenyl)-acetic acid, m. p. 163–165°; mixed m. p. 163–165°.

2-(*p,p'*-Dichlorobenzhydryl)-benzimidazole.—From 8 g. (0.028 mole) of acid and 3.2 g. (0.03 mole) of freshly crystallized *o*-phenylenediamine reacted in the usual way there was obtained 5.0 g., 50%, melting 246–248°, after crystallization from 1/1 alcohol–benzene.[3]

Di-(*p*-chlorophenyl)-acetyl Chloride.—A mixture of 8 g. (0.029 mole) of acid and 11 g. (0.09 mole) of purified thionyl chloride was refluxed for four hours. Removal of the excess chloride gave 8.5 g. (95%) of a brown oil which decomposed on vacuum distillation at 3–4 mm. Attempted crystallization from petroleum ether (b. p. 60–70°) gave an oil which did not crystallize at 0°. Hydrolysis of 2.0 g. of the acid chloride with ice yielded 1.7 g. of di-(*p*-chlorophenyl)-acetic acid, m. p. 158–162°, mixed melting point, 159–163°.

Di-(*p*-chlorophenyl)-acetamide.—Seven grams (0.023 mole) of the acid chloride and 12 ml. (0.092 mole) of ice cold concentrated ammonium hydroxide gave 5.5 g., (85%) of crude amide melting 136–138° dec. Several crystallizations from 95% ethanol gave a product melting 152–154°.

Di-(*p*-chlorophenyl)-acetanilide.—A mixture of 8 g. (0.03 mole) of the acid chloride, 5.5 g. (0.06 mole) of redistilled aniline and 100 ml. of benzene was refluxed for one-half hour. The benzene layer was decanted from the aniline hydrochloride, washed with water, 5% sodium carbonate solution, 10% hydrochloric acid, and water, and evaporated to give 1.2 g. melting 205–206°. Extraction of the aniline hydrochloride with benzene in a Soxhlet extractor gave 5.8 g., m. p. 203–206°, for a total yield of 7.0 g., 75%. Crystallization from 1/1 benzene–pyridine gave a product melting 205–206°.

Di-(*p*-chlorophenyl)-aceto-4-chloranilide.—Prepared as the acetanilide from 9.5 g. (0.034 mole) of acid chloride, 8.9 g. (0.07 mole) of *p*-chloroaniline and 50 ml. of benzene with two and one-half hours' reflux. The crude product, 9.5 g., 72% melting 220–240° dec. was crystallized from benzene: m. p. 258–260°.

***p,p'*-Dichlorobenzhydryl Phenyl Ketone.**—A Friedel–Crafts reaction of 9.4 g. (0.088 mole) of aluminum chloride in 50 ml. of reagent grade benzene with 18.2 g. (0.06 mole) of di-(*p*-chlorophenyl)-acetyl chloride in 100 ml. of benzene at 0–10° for one hour gave 19.5 g. (94%) of crude ketone melting 81–86°. Crystallization from 80 ml. of 95% ethanol gave 14.0 g. (67%), m. p. 90–91°.

Di-(*p*-chlorophenyl)-acetonitrile.—A mixture of 5.0 g. (0.018 mole) of di-(*p*-chlorophenyl)-acetamide and 9.5 g. (0.08 mole) of freshly purified thionyl chloride was refluxed for four hours, cooled, and poured onto 200 g. of ice. After extraction with ether the crude nitrile was vacuum distilled at 2 mm. but decomposition was apparent. Another portion of the ether extract on standing

6	Di-(*p*-chlorophenyl)-acetamide	152–154	$C_{14}H_{11}Cl_2NO$	25.3	25.0	5.00	4.60		
7	Di-(*p*-chlorophenyl)-acetanilide[a]	205–206	$C_{20}H_{15}Cl_2NO$	19.9	19.9	3.93	4.03		
8	Di-(*p*-chlorophenyl)-aceto-4-chloroanilide	258–260	$C_{20}H_{14}Cl_3NO$	27.2	27.3	3.59	3.65		
9	*p,p'*-Dichlorobenzhydryl phenyl ketone	90–91	$C_{20}H_{14}Cl_2O$	20.9	20.9			341	353[h]
10	Di-(*p*-chlorophenyl)-acetonitrile[b]	85–86	$C_{14}H_9Cl_2N$	27.1	25.8	5.34	5.62		

[a] Described by Gatzi and Stammbach, *Helv. Chim. Acta*, **29**, 563 (1946), as melting 202–204° in a paper published after our synthesis had been done. [b] Despite the sharp m. p., analysis shows that this compound is not pure. [c] These m. p.'s are uncorrected. [d] The m. p.'s of the corresponding diphenylacetic acid (m. p. 148–149°) derivatives were taken from the literature for comparison; they are 1, 60°; 3, 98°; 5, 56–57°; 6, 167–168°; 7, 180–181°; 9, 136–137°. In these examples the diphenylacetic acid derivatives frequently are higher melting. [e] Saponification values of this ester ran 75–100% over the calculated, probably as the result of a secondary reaction of phenacyl alcohol with alkali. Boiling point rise molecular weights in benzene gave high values, indicative of association. This value was found by the Rast camphor method. [f] By saponification equivalent. [g] By neutral equivalent. [h] By b. p. rise in benzene.

partially crystallized to give 1.5 g. of solid melting 83–85°. Crystallization from 10 ml. of 95% ethanol gave 1.0 g. (18%) melting 85–86°. Despite the sharp melting point, analysis indicated an impure compound.

COMMUNICATIONS TO THE EDITOR

GEOMETRIC ISOMERS OF 1-PHENYL-1,3-BUTADIENE

Sir:

1-Phenyl-1,3-butadiene made by the hydrolysis of the cinnamaldehyde–methylmagnesium bromide addition compound in 30% sulfuric acid[1] has been shown to be the pure *trans* isomer by its quantitative Diels–Alder reaction with maleic anhydride.[2] Varying the conditions of hydrolysis does not, as previously reported,[3] give the *cis* and *trans* forms but only the *trans* is obtained.

cis-1-Phenyl-1,3-butadiene has been made by ultraviolet irradiation of the *trans* isomer. The *cis* compound does not react with maleic anhydride at room temperature. Irradiation of the *cis* compound isomerizes it partially to the *trans*. The two isomers differ markedly in physical properties:

	Dist. temp., °C.	Mm.	F. p., °C.	d^{25}_4	$n^{25}D$	Molar ref.[a]
cis	71	11	−56.99 ± 0.04	0.9197	1.5822	47.25
trans	83	11	4.52 ± .04	.9232	1.6089	48.82

[a] The molar refraction calculated from the Lorentz–Lorenz equation is 43.85.

The boiling point, density and refractive index are usually greater for the *cis* form of olefinic hydrocarbons. This is also true of piperylene.[2] The exceptional behavior of the phenylbutadienes is noteworthy.

In ultraviolet absorption spectra the *cis* form shows a maximum at 265–269 mμ, molar extinction 184 × 10^2, and the *trans* at 280 mμ, molar extinction 298 × 10^2. An outstanding difference in infrared absorption spectra is the 14.20-μ band for the *cis* and the 10.56-μ band for the *trans* which are unique for each isomer.

Neither geometric isomer adds sulfur dioxide to give a cyclic sulfone.

THE PREPARATION OF HAFNIUM-FREE ZIRCONIUM

Sir:

We have recently performed a series of experiments which indicate that silica gel strongly and preferentially adsorbs hafnium compounds from a zirconium–hafnium compound mixture in certain organic solvents, and that this fact provides a new, simple, and effective means of preparing hafnium-free zirconium.

A solution of 455 g. of zirconium tetrachloride dissolved in 2275 ml. of anhydrous methanol was allowed to stand for three hours and filtered. The filtered solution contained 106 mg. total oxide per ml. A column 30″ in length × 27 mm. in diameter was packed with 290 g. of 28 to 120 mesh silica gel which had been purified by elution with 1:1 nitric acid and activated four hours at 300°. The column was prepared by sludging silica gel and methanol, and hence initially contained approximately 200 ml. of methanol; 1800 ml. of the above solution was then fed into the column, the flow being from bottom to top at a rate of 200 ml./hr. The effluent was collected in approximately 200-ml. batches and the total oxides in 5-ml. aliquots of each batch precipitated and analyzed spectrographically. The results were as shown (weights refer to ignited oxide, analyses to per cent. hafnium in sample).

TABLE I

COMPOSITION OF SUCCESSIVE BATCHES

No.	1	2	3	4	5	6	7	8	9
Wt. g.	7	18.2	21.5	22.5	22.9	25.0	24.7	18.5	22.1
% Hf	[a]	0.00	0.03	0.15	0.38	0.66	0.80	0.93	1.10

[a] Analysis uncertain due to large Fe and Ti content. The $ZrCl_4$ used contained approximately 0.13% $FeCl_3$ and 0.53% $TiCl_4$.

The column was then stripped with one liter of methanol made 1.2 *M* in anhydrous hydrochloric acid, the eluant being collected in four fractions. Analyses over 15% Hf are rough spectrographic estimates since the method has not yet been extended to this region.

TABLE II

COMPOSITION OF FRACTIONS OF ELUANT

No.	1	2	3	4
Wt. g.	9.0	2.5	0.68	0.48
% Hf	1.8	15	60	40

Similar, but not quite so striking results have been obtained using acetone instead of methanol as solvent; the degradation of acetone by zirconium tetrachloride tends to cause tars and clogging in the column which causes some inconvenience.

To summarize: Hafnium in zirconium may be reduced to less than 0.1% by passing a 1:5 solution of the chlorides in methanol through a silica gel column; 290 g. silica gel will furnish 60 g. purified oxide; the column can be stripped with 1 *M* anhydrous hydrochloric acid in methanol and re-used. By feeding in an oxide equivalent of approximately 65 g., in this case, the purified oxide yield would be about 90%.

Work on the mechanism of this and similar processes is being continued and will be reported at a later date.

We are indebted to V. A. Fassel and C. H. Anderson for spectrographic analyses.

THE METAL ION CATALYZED DECARBOXYLATION OF DIMETHYLOXALOACETIC ACID

Sir:

Recent investigations[1] of the metal ion catalysis of the enzymatic and non-enzymatic decarboxylation of oxaloacetic acid have prompted us to make a detailed study of the mechanism of the decarboxylation of α,α-dimethyloxaloacetic acid and of its monoethyl ester. The synthesis of these compounds is outlined below.

$$C_2H_5O_2CCO_2C_2H_5 + (CH_3)_2CHCO_2C(CH_3)_3 \xrightarrow{(C_6H_5)_3CNa} C_2H_5O_2CCOC(CH_3)_2CO_2C(CH_3)_3 \xrightarrow[HOAc]{HBr}$$

(A)

$$C_2H_5O_2CCOC(CH_3)_2CO_2H \xrightarrow[H_2O]{HCl} HO_2CCOC(CH_3)_2CO_2H$$

(B) (C)

The condensation was carried out by Hauser's method,[2] the cleavage of the *t*-butyl ester, A, by a method based on the work of Tronow,[3] and the hydrolysis of the ethyl ester, B, by a method based on the work of Michael.[4]

Anal. Calcd. for diester, A, (b. p. 107–111° (7 mm.)): C, 59.0; H, 8.20. Found: C, 58.7; H, 8.21. Calcd. for monoester, B, (m. p. 38–39°): C, 51.0; H, 6.43. Found: C, 50.8; H, 6.44. Calcd. for diacid, C, (m. p. 105.5–106.5°): C, 45.0; H, 5.03. Found: C, 45.1; H, 5.18.

Both the monoester and the diacid decarboxylated smoothly at 25° in aqueous solutions of *p*H between 2 and 7 to form the expected products. (The 2,4-dinitrophenylhydrazone of α-keto-β-methylbutyric acid melted[5] at 194–194.5°; the

(5) G. Ramage and J. Simonsen, *J. Chem. Soc.*, 532 (1935).

2,4-dinitrophenylhydrazone of the ethyl ester (from B) melted at 171.5–172°. *Anal.* Calcd. for $C_{13}H_{16}O_6N_4$: C, 48.2; H, 4.97; N, 17.3. Found: C, 48.0; H, 4.80; N, 17.0). Some first order rates of decarboxylation, determined manometrically near *p*H 5 in the presence and absence of metal ions, are shown in the table below.

Metal ion	Monoester B Concn. of metal ion, m./l.	Monoester B k, min.$^{-1}$	Diacid C Concn. of metal ion, m./l.	Diacid C k, min.$^{-1}$
None		0.075		0.0032
Cu^{++}			0.001	.14
	0.01	.069	.01	*ca.* 1.6
Al^{+++}	.01	.070	.001	0.13
Ni^{++}	.01	.075	.01	.022
Mn^{++}	.01	.066	.01	.0046

Thus metal salts strongly catalyze the decarboxylation of the diacid, C, but do not affect the rate of decarboxylation of the monoester, B. Since no enol form of α,α-dimethyloxaloacetic acid is possible, it is clear that the *keto* acid (like dimethylacetoacetic acid[6]) undergoes decarboxylation. Further, these experiments show that the metal ion catalysis of the decarboxylation of dimethyloxaloacetic acid requires the formation of a complex between the metal ion and the carboxyl group gamma to the one lost; presumably the metal ion is also coördinated with the carbonyl oxygen atom. By analogy, these conclusions also apply to the decarboxylation of oxaloacetic acid itself.

The investigation of these reactions is continuing.

DEGRADATION PRODUCTS OF PSEUDOHECOGENIN

Sir:

It has been shown that "*allo*-pregnan-3,12,20-trione" from pseudohecogenin does not agree in properties with *allo*-pregnan-3,12,20-trione prepared from 12(α)-acetoxyprogesterone.[1] We have now reinvestigated "16-*allo*-pregnen-3,12,20-trione" from pseudohecogenin. From its method of synthesis and analysis, it was assumed to be an α,β-unsaturated triketone containing a molecule of water of crystallization.[2] However, we find that this material does not show an absorption maximum in the ultraviolet typical for α,β-unsaturated ketones, that it is unchanged by conditions of hydrogenation with palladium catalyst and that *it is actually identical with the compound designated as "allo-pregnan-3,12,20-trione,"* also assumed to contain a molecule of water of crystallization. It is not changed by hot acetic anhydride and pyridine, which suggests that the "molecule of water" might be a tertiary hydroxyl group at C-17. Mild chromic acid oxidation gives impure starting material in agreement with the results of Reichstein and Gatzi[3] for this ketol system. It is noteworthy that mild oxidation of the isomeric D-homo derivative is reported to give an acidic product.[4]

Hydroxyl groups in steroids have been associated with infrared absorption maxima at 3570 to 3620 cm.$^{-1}$ along with a carbonyl harmonic band at 3300 to 3475 cm.$^{-1}$ if a ketone group is also present.[5] It was hoped that such data (Fig. 1) would support the assignment of a hydroxyl group to this substance; however, the results are inconclusive. A scarcity of material has curtailed further work.

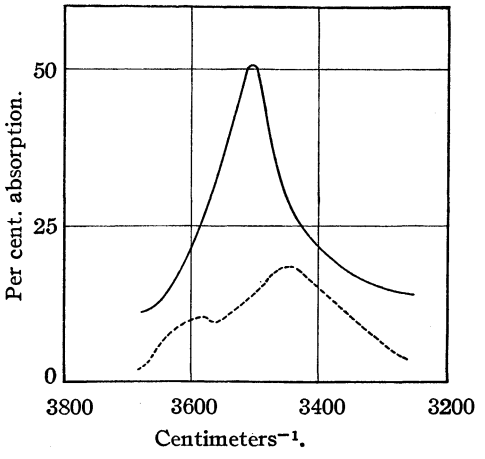

Fig. 1.—Infrared absorption spectra in carbon disulfide solution: ...., 17(α)-hydroxyprogesterone; ——, degradation product from pseudohecogenin.

Although it is not possible to state definitely the structure for this product, it becomes clear that the non-identity of it with *allo*-pregnan-3,12,20-trione is not necessarily due to an incorrect assignment of the C-12 oxygen in hecogenin and botogenin.[6]

We thank Parke, Davis and Company for their help.

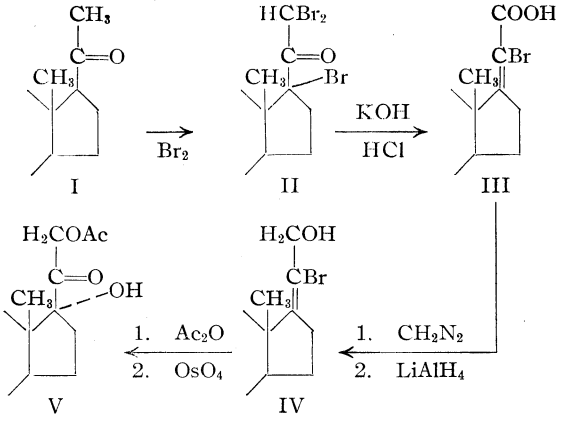
A NEW ROUTE TO THE CORTICAL SIDE CHAIN

Sir:

The conversion of the readily available bromopregnanolones to compounds of the cortical series having a dihydroxyacetone side chain has been achieved. The key steps involve a rearrangement of a tribromoketone and subsequent reduction of the product.



Bromination of pregnan-3(β)-ol-20-one acetate (I) with three moles of bromine yields the 17,21, 21-tribromo derivative (II), m. p. 196° (dec.), $[\alpha]^{25}D$ −3.4° (chloroform). Calcd. for $C_{23}H_{33}O_3Br_3$: Br, 40.1. Found: Br, 40.3. Rearrangement with alcoholic potash yields 17-pregnen-3(β)-ol-20-bromo-21-oic acid (III), m. p. 273° (dec.), $[\alpha]^{25}D$ + 41° (dioxane). Calcd. for $C_{21}H_{31}O_3Br$: C, 61.4; H, 7.6; Br, 19.4. Found: C, 62.0; H, 7.7; Br, 19.1. Reduction of the bromo acid with hydrogen and platinum catalyst gives pregnan-3(β)-ol-21-oic acid, m. p. and mixed m. p., 220°.[1] Lithium aluminum hydride reduction of the methyl ester of III yields the unsaturated 20-bromo-21-ol (IV), m. p. 253° (dec), $[\alpha]^{25}D$ +53° (dioxane). Calcd. for $C_{21}H_{33}O_2Br$: C, 63.5; H, 8.4. Found: C, 63.4; H, 8.5. Treatment of the diacetate of IV with osmium tetroxide in ether yields pregnan-3(β),17(α),21-triol-20-one diacetate (V), m. p. 153°, $[\alpha]^{28}D$ +49° (dioxane). Calcd. for $C_{25}H_{38}O_6$: C, 69.1; H, 8.8. Found: C, 68.8; H, 8.8. Hydrogenation of V gives the same tetrol obtained by the lithium aluminum hydride reduction of methyl 17-pregnen-3(β)-ol-21-oate with subsequent hydroxylation (OsO_4), isolated as the triacetate, m. p. and mixed m. p. 184°, $[\alpha]^{28}D$ +55° (chloroform). Calcd. for $C_{27}H_{42}O_7$: C, 67.8; H, 8.9. Found: C, 67.4; H, 8.9.

We thank Parke, Davis and Company for their help.

HOMOLOGATION OF ALCOHOLS

Sir:

The conversion of an alcohol to the primary alcohol containing one carbon atom more than the original is usually a tedious procedure. We wish to report a simple one-step homologation reaction. The process consists in treating the alcohol with synthesis gas (carbon monoxide and hydrogen) in the presence of a cobalt catalyst under conditions resembling those employed in the oxo reaction.

The oxo or hydroformylation reaction consists of the conversion, by means of synthesis gas, of an olefin to a mixture of aldehydes containing one carbon atom more than the starting material.

$$R{-}CH{=}CH_2 + CO + H_2 \xrightarrow{Co} R{-}CH_2{-}CH_2{-}CHO + R{-}CH(CH_3)CHO$$

As developed in Germany, a mixture of olefins secured from the Fischer–Tropsch reaction was usually used as the starting material. The aldehydes resulting from the oxo reaction were then converted in a separate step, to a mixture of alcohols which were of value for detergent manufacture. It has been reported recently[1] that olefins may be converted in one step directly to the alcohol if the usual oxo reaction is operated at slightly higher temperatures. That our homologation reaction need not proceed *via* an olefin intermediate followed by a one-step hydroformylation–hydrogenation is shown by the fact that benzyl alcohol is converted to β-phenylethyl alcohol under our conditions: $PhCH_2OH + 2H_2 + CO \rightarrow PhCH_2CH_2OH$. Other conversions we wish to report consist of the formation of *n*-butyl alcohol and of isobutyl alcohol from isopropyl alcohol and of isoamyl alcohol from *t*-butyl alcohol. *n*-Propyl alcohol gave a mixture of *n*-butyl and isobutyl alcohols but the reaction proceeded so slowly at 180° that part of the initial products was transformed by further homologation to higher alcohols.

We are inclined to believe that the homologation reaction is an acid ($HCoCO_4$) catalyzed reaction that proceeds *via* a carbonium ion according to a mechanism that will be discussed in detail later.

In a typical experiment, *t*-butyl alcohol (86 g., 1.3 moles) and cobaltous acetate (7.0 g., 0.03 mole) were placed in an 0.5-liter stainless steel autoclave and heated with synthesis gas (3200 p. s. i., $1H_2$:1CO) at 160–180° for one and one-half hours Gas absorption was 89% of the theoretical according to the equation

$$(CH_3)_3C{-}OH + 2H_2 + CO \longrightarrow (CH_3)_2CH{-}CH_2{-}CH_2OH + H_2O$$

There was obtained a 63% yield of isoamyl alco-

hol; α-naphthylurethan, m. p. 65.6–66.3°; mono ester with 3-nitrophthalic anhydride, m. p. 165.3–166.4°. Somewhat better results were obtained with cobaltous oxide as catalyst.

Benzyl alcohol gave toluene (49%) and β-phenylethyl alcohol (26%); α-naphthylurethan, m. p. 117.5–118.5°. Distillation of the alcohol from molten potassium hydroxide gave an 86% yield of styrene, identified through its dibromide.

Isopropyl alcohol gave 11% of a mixture of *n*-butyl and isobutyl alcohol; the former was identified by its infrared spectrum and the latter by its phenylurethan, m. p. 84.6–85.5°. *n*-Propyl alcohol reacted slowly at 180° to give a mixture of butyl, isobutyl, isoamyl and *n*-amyl alcohols, identified by their infrared absorption spectra.

NEW BOOKS

Radioactive Indicators. Their Application in Biochemistry, Animal Physiology, and Pathology. By GEORGE HEVESY, Institute for Research in Organic Chemistry, University of Stockholm, Sweden; Institute for Theoretical Physics, University of Copenhagen, Denmark. Interscience Publishers, Inc., 215 Fourth Avenue, New York 3, N. Y., 1948. xvi + 556 pp. Illustrated. 16 × 24 cm. Price, $10.00.

Thirty-six years ago the first paper on the use of radioactive indicators was published by Paneth and Hevesy. They first determined the solubility of some lead compounds and for several years were the only research workers applying this new tool. Ten years later, in 1923, Hevesy reported the first biological application of radioactive indicators: a study of the absorption and translocation of lead in plants. The present book is the most recent of a long series of publications by this pioneer in applied radiochemistry.

Chemists not primarily concerned with life science research will find little of direct interest in this book since it is a reference book written as a very extensive review article of the applications of radioactive indicators in biochemistry, animal physiology and pathology.

The first three chapters cover the production, availability and measurement of radioactive tracers. These chapters and the next two on atomic interchange and applications in chemical analysis do not fall within the province of the author's major interests and suffer as a consequence thereof. They represent an uncritical compilation of some of the literature and include such items as a copy of the 1947 catalog and price list of radioisotopes available from the U. S. A. E. C. Three long tables showing the decay of Na^{24}, K^{42} and P^{32} also seem unnecessary in a book of this type. The remaining eighty per cent. of the book is a substantial contribution to the literature of radioactive indicators, representing as it does a review of thirteen years of intensive work by many investigators in a very active field of research.

This section follows a logical pattern, starting with the general considerations of absorption, distribution and excretion of more than twenty-five elements, as simple inorganic species, in the whole animal organism. This is followed by a discussion of the problems associated with the transport of ions and compounds across the many types of membranes in living systems. Metabolic studies, including intermediary metabolism, are treated next. This section closes with a survey of the new information obtained from radioactive indicator studies of the special organs; the skeleton and red cells. The shortcomings of radioactive indicators in biology treated in the final chapter provide a timely warning for overenthusiastic readers.

Throughout the book many of the data from the original articles are reproduced in tables and graphs and detailed references are given. A Segre chart is included in an attached envelope in the back of the book. The author index and subject index are both excellent as they should be for this type of reference book.

Since the use of radioactive indicators in the fields of biochemistry, animal physiology and pathology is increasing so rapidly, Hevesy's "Radioactive Indicators" may be the last complete review of these fields. It will serve well as a point of departure for subsequent reviews of the accumulating knowledge, during the next few years.

JOHN W. IRVINE, JR.

Chemistry of Specific, Selective and Sensitive Reactions. By FRITZ FEIGL, Eng., Dr. Sc., Laboratory of Mineral Products, Ministry of Agriculture, Rio de Janeiro, Brazil; formerly Professor of Analytical and Inorganic Chemistry at the University of Vienna. Translated by Ralph E. Oesper, Professor of Chemistry, University of Cincinnati, Ohio. Academic Press, Inc., New York, N. Y., 1949. xiv + 740 pp. 15 × 23 cm. Price $13.50.

Perhaps few books have been written under greater hardships and handicaps than this one. The author began the laborious task of collecting and preparing material long before World War II but this was all lost during his flight from Europe and he had to make a new start after getting relocated in Brazil. The manuscript was written in German and translated into English by Professor R. E. Oesper, to whom the author pays especial thanks for his technical advice, patience ("even with last minute changes"), and deep understanding of the aims of the work. The "earmarks" of a translation, so often evident in English translations of technical books, are pleasingly missing and the reviewer found no serious typographical errors while reading the book from cover to cover.

The contents of the book and the method of presentation were chosen with three groups of readers in mind: (1) "those who wish to know the chemical basis of many modern analytical procedures," (2) "those who are actively engaged in research in analytical chemistry or in related fields," and (3) "those interested in experimental chemistry as a part of science which is still a fertile field for the trained and alert investigator." This was indeed an ambitious undertaking and no one is better qualified for such a task than Fritz Feigl who for more than a quarter of a century has made outstanding contributions to the

chemistry of specific, selective and sensitive reactions. He is the originator of modern spot test analysis to which he and his students have added many new and novel techniques in the field of qualitative and quantitative analysis.

The book contains twelve chapters which deal with the following topics: General comments on the analytical usefulness of chemical reactions (Chapter I, 5 pages); characterization of chemical tests and the role of reaction conditions (Chapter II, 16 pages); complex and coördinating compounds (Chapter III, 44 pages); masking and demasking of reactions (Chapter IV, 42 pages); enhancement of reactivity of compounds and reaction systems (Chapter V, 57 pages); effect of certain atomic groupings on the specific and selective activity of compounds in inorganic analysis (Chapter VI, 202 pages) and in organic analysis (Chapter VII, 13 pages); regularities and anomalies in the solution of materials in indifferent solvents (Chapter VIII, 28 pages); influence of size and weighting effects on solubility and salt-forming ability (Chapter IX, 21 pages); surface effects in analytical chemistry (Chapter X, 180 pages); genetic formation of materials and topochemical reactions (Chapter XI, 58 pages); and analytical uses of fluorescence effects and photochemical reactions (Chapter XII, 23 pages).

Hundreds of references to the original literature are given throughout the book as well as many previously unpublished observations by the author and his co-workers. A valuable feature of the book is the many suggestions for future research problems. There is hardly a page from which one does not glean valued suggestions for future work. Another feature of the book is the large number of critical remarks (frequently given as footnotes in smaller type) pertinent to the subject. The reviewer regrets that most of the footnotes were not incorporated in the main text; reading would have been much easier because of less frequent interruption. A hasty count revealed that 190 pages have a footnote, some fairly long, and that about 40 pages have two or more footnotes. This is not intended as a serious criticism but only a suggestion for a future edition; indeed, some readers may prefer the frequent use of footnotes in a work of this type.

The book has both an author and a subject index, many useful tables (29), and makes liberal use of structural formulas. Printing, paper and binding are good.

Dr. Feigl deserves congratulations and much praise for making such a noteworthy contribution to the "chemistry of specific, selective and sensitive reactions."

Page 1937. In col. 2, lines 16 and 15 from the end should read "nin has one carbonyl group, two lactone groups and two (and probably." In line 3 from the end, for "carboxyl" read "carbonyl."—FRANCIS T. JONES.

Charles C. Templeton. The Distribution of Rare Earth Nitrates between Water and *n*-Hexyl Alcohol at 25°.

Page 2188. In Table I, the oxides referred to in the first two columns are, respectively, La_2O_3, CeO_2, Pr_6O_{11}, Nd_2O_3 and Sm_2O_3. Equations (1) and (2) are thus not applicable to the cases of cerous and praseodymium nitrates, and the mole-fractions given for these two salts are in error. The correct mole-fractions, as calculated from suitable modifications of equations (1) and (2), are:

Weight % oxide			
Aqueous phase	Alcohol phase	$X'_{R^{3+}}$	$X''_{[R(NO_3)_3]}$
	Cerous Nitrate, C. P.		
30.3[a]	2.87	0.0574	0.0176
29.57	2.34	.0548	.0143
28.5	1.70	.0515	.0103
27.57	1.28	.0485	.0077
26.2	0.85	.0446	.0051
24.47	.57	.0400	.0034
22.83	.34	.0361	.0020
21.5	.26	.0330	.0015
	Praseodymium Nitrate, C. P.		
28.75[a]	2.71	0.0533	0.0168
28.7[a]	2.68	.0533	.0166
28.4[a]	2.36	.0517	.0146
26.05	1.43	.0452	.0087
25.4	1.09	.0432	.0066
25.35[a]	0.99	.0431	.0060
23.9	.74	.0393	.0044
22.6	.51	.0361	.0031
21.3	.35	.0329	.0021
20.25	.25	.0308	.0015

Page 2189. In Fig. 1, the corrected data raise the cerium line slightly above the lanthanum line, and the praseodymium line up nearer to the neodymium line. This makes the order of increasing extractability into the alcohol the same as that of the atomic numbers, and *invalidates the contention that cerium is in an anomalous position*. The only part of the Discussion affected is the material in the first two paragraphs, ending with line 16, first column, page 2189.

Page 2190. Summary, paragraph 2, should read: For all the rare earth nitrates investigated there is an increased extractability into *n*-hexyl alcohol from aqueous solution with increasing atomic number.—CHARLES C. TEMPLETON.

Ralph G. Pearson. The Alkylation of Malonic Ester.

Page 2212. In col. 1, line 4 of Experimental, for "0.9982" read "1.0012."
