Catalytic Dehydrogenation of Hydroaromatic Compounds in Benzene. II

BY HOMER ADKINS AND JAMES W. DAVIS[1]

The study of the aromatization of hydroaromatic compounds with benzene as a hydrogen acceptor[2] was continued with twelve variously substituted compounds as listed in Table I. The data on three of these compounds, *i. e.*, 2-methyl-1-ethyl-3,4-dihydronaphthalene, 2-methyl- and 2-ethyldecalin show that the corresponding naphthalene may be prepared from them in yields of more than 90% of the theoretical with a platinum catalyst. Attempts to aromatize alcohols, *i. e.*, 2-decalol and 2-methyl-1-ethyl-1,2,3,4-tetrahydro-1-naphthol, without loss of oxygen were not so successful. The highest yield of 2-naphthol over any catalyst was only 18–20% from 2-decalol or 2-decalone over a platinum catalyst, while the hydrocarbon 2-methyl-2-ethyl-naphthalene was obtained in 91% yield from the tetrol without any evidence of a phenol. However, a 65% yield of thymol from menthol was obtained[2] over a nickel catalyst.

The dehydrogenation of compounds with quaternary carbon atoms in the rings to be aromatized required more drastic conditions than for simple dehydrogenation. Data for the reaction of six such compounds are given in Table I. Three tetralins carrying two methyls, I, a methyl and an ethyl or a methyl and a phenyl group in the 1,1-position all gave 1-methylnaphthalene, II, but in rather low yields. The nickel on kieselguhr catalyst gave migration rather than elimination of the alkyl group so that 1,2-dimethylnaphthalene, III, was produced from the 1,1-dimethyltetralin. There was a similar migration of a carbon linkage in the aromatization of 1,1-spirocyclopentyl-1,2,-3,4-tetrahydronaphthalene, IV, to phenanthrene, V. A methyl or isopropyl group in an angular position of octahydrophenanthrene was eliminated

TABLE I

DEHYDROGENATION OF HYDROAROMATIC COMPOUNDS[a]

Compound	G. catalyst	Temp., °C.	
1,1-Dimethyl-1,2,3,4-tetrahydronaphthalene	0.5 Pt	350	25% 1-Methylnaphthalene 61% No reaction
	3 Ni (CrO)	370	38% 1-Methylnaphthalene 50% No reaction
	3 Ni (k)	350	35% 1,2-Dimethylnaphthalene 35% No reaction
1-Methyl-1-ethyl-1,2,3,4-tetrahydronaphthalene	3 Ni (CrO)	375	35–55% 1-Methylnaphthalene 27% No reaction
1-Methyl-1-phenyl-1,2,3,4-tetrahydronaphthalene	3 Ni (k)	350	12% 1-Methylnaphthalene
1,1-Spirocyclopentyl-1,2,3,4-tetrahydronaphthalene	3 Ni (k)	350	25–40% Phenanthrene
12-Methyl-1,2,3,4,5,6,7,8-octahydrophenanthrene	1 Pt	350	65% Phenanthrene
2-Methyl-12-isopropyl-1,2,3,4,5,6,7,8-octahydrophenanthrene	2 Ni (CrO)	350	50% 2-Methylphenanthrene
2-Methyldecalin	1 Pt	350	91% 2-Methylnaphthalene
2-Ethyldecalin	0.25 Pt	350	94% 2-Ethylnaphthalene
2-Methyl-1-ethyl-1,2,3,4-tetrahydro-1-naphthol	2 Ni (k)	300	66% 2-Methyl-1-ethylnaphthalene
1-Methyl-2-ethyl-3,4-dihydronaphthalene	0.25 Pt	300	91% 1-Methyl-2-ethylnaphthalene
2-Decalol	1 Pt	275	18% 2-Naphthol
2-Decalone	1 Pt	275	20% 2-Naphthol 33% Naphthalene

[a] The dehydrogenations were made on about 5 g. of compound, in 20–40 ml. of benzene for 10–12 hours, in chrome vanadium steel vessels having voids of 62 ml. (platinum catalysts) or 270 ml. (nickel catalysts).

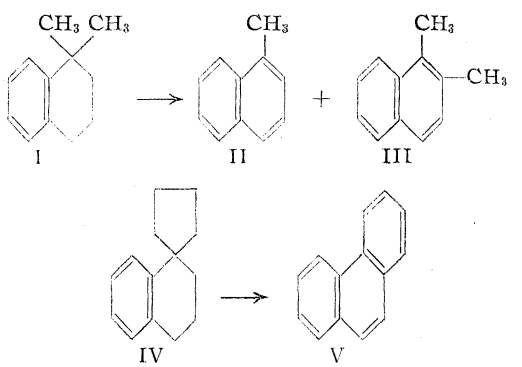
and a phenanthrene formed under the standard conditions for aromatization.



Experimental Part

The conditions and procedures used for the reactions referred to in the table were essentially the same as those described in the earlier paper. The physical properties and analyses for certain compounds are given in Table II. 2-Decalol, b. p. 140–143° (28 mm.), n^{25}D 1.4958–1.5000, was prepared by the hydrogenation of 2-naphthol over Raney nickel at 200°. The alcohol (40 g.) was oxidized to 2-decalone (24 g.) (b. p. 123.5–125 (27 mm.), n^{25}D 1.4885–1.4905) by the procedure described for the preparation of menthone.[10,11] 2-Methyldecalin[12] (b. p. 203–205°, n^{25}D 1.4712) and 2-ethyldecalin[13] (b. p. 85–87 (7 mm.), n^{25}D 1.4727) were prepared by hydrogenation at 200° over Raney nickel, from 2-methylnaphthalene and methyl 2-naphthyl ketone, respectively. 1,1-Dimethyl-1,2,3,4-tetrahydronaphthalene, (b. p. 94–95 (12 mm.), n^{25}D 1.5262); 12-methyl-1,2,3,4,5,6,7,8-octahydrophenanthrene (b. p. 150 (13 mm.), n^{25}D 1.5510); and 2-methyl-12-isopropyl-1,2,3,4,5,6,7,8-octahydrophenanthrene (n^{25}D 1.5435) were prepared as described.[14,15,16] Other procedures described below were in general patterned after those of Brunner and Grof[9] or of Bogert, Davidson, Apfelbaum and Perlman.[14,15]

1-Methyl-1-ethyltetralin.[14]—One hundred and sixty grams of 3-phenylpropyl bromide in 300 ml. of dry ether was added to 20 g. of magnesium over a period of fifty minutes. The mixture was refluxed for fifty minutes, and then 72 ml. of methyl ethyl ketone in 72 ml. of dry ether was added over a period of twenty minutes. After thirty minutes of refluxing, the addition product was hydrolyzed with saturated ammonium chloride solution. The ether solution was washed twice with water, dried over anhydrous sodium sulfate and the product (125 g.) distilled at 154–163° (23 mm.), n^{25}D 1.4970–1.5050.

Eighty-five grams of the alcohol so obtained was cooled to 15° and 85 ml. of cold, concentrated sulfuric acid was added dropwise while the mixture was stirred vigorously

and the temperature kept below 25°. Ten minutes after all the acid had been added, the mixture was diluted with water and ether. The ether solution was washed with a sodium carbonate solution, dried and distilled from sodium. The yield was 48.6 g., b. p. 125.5° (23 mm.), $n^{25}D$ 1.5250–1.5260. The product was redistilled from sodium through a modified Widmer column to give 34 g., b. p. 127–127.5° (23 mm.), $n^{25}D$ 1.5255.

Anal. Calcd. for $C_{13}H_{18}$: C, 89.59; H, 10.41. Found: C, 89.55; H, 10.35.

1-Methyl-1-phenyltetralin.[14]—A Grignard reagent was prepared as before from 125 g. of 3-phenylpropyl bromide in 225 ml. of ether and 72 ml. of acetophenone in 70 ml. of dry ether added over a period of twenty minutes. After one hour of refluxing, the addition compound was hydrolyzed with dilute sulfuric acid and the ether solution washed with water. The low boiling material was removed by distillation, and the crude alcohol cyclized as described above. There was obtained 73.2 g. or a 55% yield; b. p. 141–147° (2 mm.), $n^{25}D$ 1.5850–1.5855. The product was redistilled from sodium to give 67 g., b. p. 129–131° (1 mm.), $n^{25}D$ 1.5853, d^{25}_4 1.042. MD calcd.: 71.32. Found: 71.6. *Anal.* Calcd. for $C_{17}H_{18}$: C, 91.83; H, 8.17. Found: C, 91.60; H, 8.23.

1,1-Spirocyclopentyltetralin.[15]—A Grignard reagent was prepared as before from 160 g. of 3-phenylpropyl bromide and 71 ml. of cyclopentanone in 70 ml. of dry ether was added over a period of thirty minutes. After one hour of refluxing, the addition product was hydrolyzed with saturated ammonium chloride solution; the ether solution was washed with water, dried and distilled. The alcohol so obtained boiled at 150–170° (25 mm.), $n^{25}D$ 1.5200. The alcohol was cyclized by treatment with an equal volume of cold concentrated sulfuric acid as for methylethyltetralin. The tetralin was distilled from sodium through a modified Widmer column. The yield was 23.1 g., b. p. 158° (24 mm.), $n^{25}D$ 1.5535. *Anal.* Calcd. for $C_{14}H_{18}$: C, 90.25; H, 9.75. Found: C, 89.91; H, 9.74.

2-Methyl-1-tetralone.[9]—Nineteen and one-half grams of potassium was powdered in 500 ml. of xylene in a 1 l. three-necked flask fitted with a dropping funnel, a reflux condenser and a Hershberg stirrer. The mixture was cooled and 87 g. of diethyl methylmalonate was added over a period of ten minutes. After one hour, 93 g., of β-phenethyl bromide was added and the mixture was refluxed and stirred for twelve hours in an oil-bath at 150–160°. The xylene solution was washed with water, dried and distilled, and there was obtained 85 g. of diethyl methyl-β-phenethylmalonate, b. p. 188–192° (17 mm.), $n^{25}D$ 1.4818–1.4820.

Ninety-three grams of this ester was hydrolyzed by refluxing it ninety minutes with 56 g. of potassium hydroxide in 200 ml. of 50% aqueous alcohol. After water was added and the alcohol was distilled off, the solution was acidified to congo red with concentrated hydrochloric acid. The solid acid which precipitated was dissolved in ether and the aqueous solution was extracted with ether. The ether solutions were combined, washed with water, dried with anhydrous sodium sulfate and the ether distilled. The acid was heated to 180° and distilled after carbon dioxide ceased to be evolved. The yield of γ-phenyl-α-methylbutyric acid was 48.9 g. or 82%, b. p. 176–178° (17 mm.), $n^{25}D$ 1.5093–1.5100, plus 4.9 g., b. p. 178–183° (17 mm.). To 53.8 g. of this acid dissolved in 250 ml. of dry benzene was added 80 g. of phosphorus pentachloride, the solution refluxed thirty minutes, cooled, and 70 ml. of stannic chloride in 70 ml. of benzene added slowly. After twenty-five minutes the mixture was poured into 250 ml. of concentrated hydrochloric acid. The benzene solution was separated and washed with three 100 ml. portions of 10% hydrochloric acid, followed by three 100 ml. portions of a 5% sodium carbonate solution, dried and distilled. The yield (71%) was 34.2 g., b. p. 136–138° (16 mm.), $n^{25}D$ 1.5538.

2-Ethyl-1-tetralone[9] was prepared by the same method as 2-methyl-1-tetralone. From 20 g. of potassium, 94 g. of ethyl diethylmalonate and 93 g. of β-phenethyl bromide there was obtained 70 g. or 48% of diethyl ethyl-β-phenethylmalonate, b. p. 160–180° (4 mm.). A much lower yield was obtained when benzene instead of xylene was used as the solvent.

Hydrolysis and decarboxylation of 102.8 g. of this ester gave 62.5 g. of 93% of α-ethyl-γ-phenylbutyric acid, b. p. 146–161° (3 mm.), $n^{25}D$ 1.5010–1.5055. The ethylphenylbutyric acid (10.3 g.) was dissolved in 30 ml. of concentrated sulfuric acid, heated to 90° for 2.5 hours on the steam-bath, cooled, diluted with water and extracted with ether. The ether solution was washed with sodium carbonate solution, dried and the ether removed. The yield was 7.8 g. or 84%, which upon distillation gave a faintly yellow liquid, b. p. 147–148° (15 mm.), $n^{25}D$ 1.5460–1.5458. The combined yield of pure redistilled ketone from several cyclizations was 70%.

1-Ethyl-2-methyl-1-tetralol.—A Grignard reagent was prepared from 17.5 g. of ethyl bromide and 3.9 g. of magnesium in 70 ml. of ether. 2-Methyl-1-tetralone (20 g.) in 50 ml. of dry ether was added over a period of ten minutes and the solution refluxed six hours. The addition product was hydrolyzed with ice-cold dilute sulfuric acid, the ether solution washed with dilute sulfuric acid, a sodium carbonate solution and dried. The solid remaining after the distillation of the ether was recrystallized twice from acetone at about −70°. The yield of alcohol was 16.1 g. or 68%, m. p. 65–67°. *Anal.* Calcd. for $C_{13}H_{18}O$: C, 82.05; H, 9.54. Found: C, 82.27; H, 9.53.

1-Ethyl-2-methyl-3,4-dihydronaphthalene was prepared by dehydration of the filtrates from the crystallization of 1-ethyl-2-methyl-1-tetralol. The acetone was removed and the residue distilled from potassium bisulfate. The yield (26%) was 5.7 g., b. p. 125–130° (15 mm.). The crude product was redistilled from sodium to give 4.47 g., b. p. 121–127° (13 mm.), $n^{25}D$ 1.5660.

1-Methyl-2-ethyl-3,4-dihydronaphthalene.—Methylmagnesium iodide was prepared from 23 g. of methyl iodide and 3.9 g. of magnesium in 70 ml. of ether, to which was added 21.8 g. of 2-ethyl-1-tetralone in 50 ml. of dry ether and the mixture refluxed thirty minutes. The addition product was decomposed with a saturated ammonium chloride solution and the ether solution washed with water and dried. The thick oil left after the distillation of the ether did not crystallize. This oil was distilled from potassium bisulfate. The crude product below 135° (15 mm.) was redistilled from sodium. The yield was 16.6 g. or 79%, b. p. 132° (14 mm.), $n^{25}D$ 1.5658.

The m. p. of the trinitrobenzene derivative of 1,2-dimethylnaphthalene (148°) is the same as the m. p. of a mixture of 30% of the compound and 70% of the trinitrobenzene derivative of 1-methylnaphthalene. Mixtures of intermediate composition melt lower with a minimum of 147°. The mixtures containing a higher proportion of the derivative of 1-methylnaphthalene melt for 80% at 149.5°, 90% at 151° and the pure compound at 154°.

Summary

The method of aromatizing hydroaromatic compounds over nickel or platinum catalysts with benzene as a hydrogen acceptor has been applied to several substituted hydronaphthalenes and hydrophenanthrenes. Aromatization has in some cases involved the rupture of linkages to a quaternary carbon. The nickel on kieselguhr catalyst has been found to bring about aromatization through catalysis of migration as in the formation of phenanthrene from 1,1-spirocyclopentyltetralin. The platinum and nickel on nickel chromite catalysts brought about aromatization through elimination of an alkyl group on the quaternary carbon.

[A COMMUNICATION FROM THE LABORATORY OF ORGANIC CHEMISTRY OF THE UNIVERSITY OF WISCONSIN]

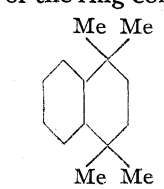
Catalytic Dehydrogenation of Hydroaromatic Compounds in Benzene. III. Compounds Containing Gem Dialkyl Groups

BY HOMER ADKINS AND DAVID C. ENGLAND

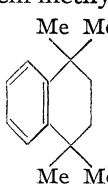
Hydroaromatic compounds may be aromatized in liquid phase in benzene with nickel, platinum or palladium catalysts, the benzene serving as hydrogen acceptor.[1,2] While gem or angular alkyls are rather stable under the conditions required for simple dehydrogenation, compounds carrying such substituents may be aromatized, with the elimination or migration of alkyl groups.[3]

The present paper is primarily concerned with the behavior of eleven hydroaromatic derivatives of naphthalene or phenanthrene which carry two alkyl groups on one of the carbon atoms of the nucleus. These compounds in benzene were heated at 350–375° in a closed chrome–vanadium steel vessel over platinum on activated carbon, nickel-on-kieselguhr and nickel-on-nickel chromite catalysts. With possibly one exception the aromatization reaction proceeded more cleanly over the platinum than over the nickel catalysts. The nickel catalysts gave aromatization with each of the eleven compounds but the isolation of the products was in general more difficult, and except for a few cases, the amounts isolated were lower.

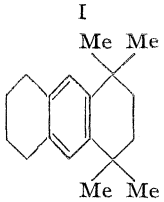
More drastic conditions are required to bring about an aromatization if a carbon-to-carbon bond must be ruptured than if only dehydrogenation is required. Thus 2,2-dimethyltetralin (V) is more difficult to dehydrogenate than tetralin itself, and 1,1,4,4-tetramethyltetralin (II) has not been dehydrogenated to any appreciable extent under the conditions employed in this work. 1,1,4,4-Tetramethyldecalin (I) was converted to the corresponding tetralin (II) in 90% yield without formation of significant amounts of methylnaphthalenes. Similarly a tetramethyloctahydroanthracene (III) was converted in 68% yield to the tetramethyltetrahydroanthracene (IV) without aromatization of the ring containing the gem methyl groups.



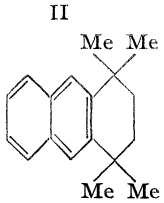
I



II



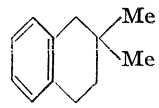
III



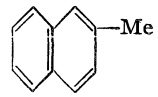
IV

(1) Adkins, Richards and Davis, THIS JOURNAL, **63**, 1320 (1941).
(2) Adkins, Rae, Davis, Hager and Hoyle, *ibid.*, **70**, 381 (1948).
(3) Adkins and Davis, *ibid.*, **71**, 2955 (1949).

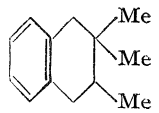
Both 2,2-dimethyltetralin (V) and 2-methyl-2-ethyltetralin were converted to 2-methylnaphthalene (VI) in yields of the order of 40%. The 2-methyl-2-ethyldecalin also gave 2-methylnaphthalene in a yield of the order of 80–85%. Similarly, one of the gem methyl groups was eliminated in 2,2,3-trimethyltetralin (VII) to give 2,3-dimethylnaphthalene (VIII) in a yield of perhaps 80%.



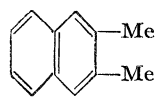
V



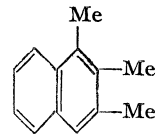
VI



VII



VIII



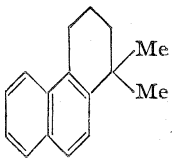
IX

There was evidence of migration as well as elimination of a methyl group and the formation of 1,2,3-trimethylnaphthalene (IX). With a nickel-on-kieselguhr catalyst migration was the chief reaction, the yield of IX being of the order of 40%. This nickel catalyst gave a mixture of two migration products 2,3-dimethylnaphthalene (VIII) and 1,2-dimethylnaphthalene in yields of 50 and 20%, respectively, from V. It also gave the migration product 2-methyl-3-ethylnaphthalene in 30% yield from 2-methyl-2-ethyltetralin and in 20% yield from the decalin.

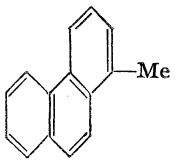
From 1,1-dimethyl-1,2,3,4-tetrahydrophenanthrene (X) over nickel (k) there was obtained 1,2-dimethylphenanthrene and from 1,1-diethyl-1,2,-3,4-tetrahydrophenanthrene there was evidence for the formation of 1,2-diethylphenanthrene. Thus it may be said that the platinum catalyst brings about aromatization through elimination of an alkyl group while the nickel (k) catalyst aromatizes through inducing migration of an alkyl group from a quaternary carbon atom. The nickel-on-nickel chromite catalyst is intermediate between the platinum (C) and the nickel (k) catalysts; it induces both elimination and migration of alkyl groups.

The tetrahydrophenanthrene (X) and the corresponding perhydrophenanthrene were both converted to 1-methylphenanthrene (XI) when aromatized over the platinum catalyst. Similarly the 1-methyl-1-ethyltetrahydrophenanthrene and perhydrophenanthrene lost an ethyl group and gave 1-methylphenanthrene (XI) among other products. The 1,1-diethyl-1,2,3,4-tetrahydrophenanthrene also lost one ethyl group in aromatization and so gave 1-ethylphenanthrene in fair yield and

purity. When the gem methyl groups were in the 2-position of tetrahydrophenanthrene, aromatization was accomplished, but no single product could be isolated or identified, except in the case of the nickel (k) catalyst where a migration product 1,2-dimethylphenanthrene was identified.

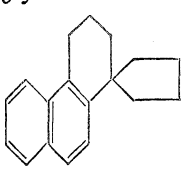


X

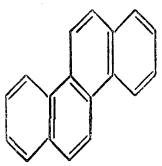


XI

1,1-Spirocyclopentano-1,2,3,4-tetrahydrophenanthrene (XII) was aromatized to chrysene (XIII) over all three catalysts to the extent of 15 to 50%. Since this conversion involves a migration of a carbon-to-carbon linkage it is not surprising that the nickel (k) catalyst gave a better yield (50%) than the platinum (C) catalyst (30%), both being superior as in other cases cited in this paper, to the nickel-on-nickel chromite catalyst which gave a 15% yield.



XII



XIII

The details as to identification, yields and purity of products are given in the experimental section. The percentage yields given above are approximations, based upon changes in refractive indices as well as weights of purified products isolated. The quantities of one to five grams used in each dehydrogenation did not permit a precise determination of the yield of each product.

The tetralins used in this work were prepared by modifications of a route described by others[4,5] through the condensation of substituted succinic anhydrides[6,7] with benzene in the presence of aluminum chloride, followed by a Clemmensen reduction,[8] ring closure with hydrogen fluoride, and another Clemmensen reduction[8] of the cyclic ketone so obtained. A similar procedure[9] using naphthalene instead of benzene was used to prepare 2,2-dimethyl-1,2,3,4-tetrahydrophenanthrene.

The 1,1-disubstituted-1,2,3,4-tetrahydrophenanthrenes were prepared in four steps from 1-chloromethylnaphthalene,[10] the first step being a Grignard reaction with ethylene oxide run in a manner analogous to the procedure described by Wilds[11] for the reaction of 1-bromonaphthalene with ethylene oxide. The resulting 3-(1-naphthyl)-1-propanol was converted to the bromide with phosphorus tribromide[12] from which the Grignard reagent was prepared for reaction with various ketones to give tertiary alcohols. These alcohols were cyclized in 85% sulfuric acid[13] to give the desired hydrocarbons.

Compounds containing more than one gem dimethyl grouping were prepared using procedures of Bruson and Kroeger.[14]

Analytical data and physical constants on compounds not previously reported are given in Tables I and II.

Experimental

Hydrogenations.—2-Methyl-2-ethyl-1,2,3,4-tetrahydronaphthalene (14.4 g., $n^{25}D$ 1.5208) was hydrogenated over Raney nickel at 225° under 3000 p. s. i. to give 2-methyl-2-ethyldecalin (14.2 g., $n^{25}D$ 1.4782, d^{25}_4 0.8880). The molecular refraction is 57.5 as compared with a calculated value of 57.8. 1,1-Dimethylperhydrophenanthrene and 1,1-diethylperhydrophenanthrene were prepared by the hydrogenation of the corresponding tetrahydrophenanthrenes over Raney nickel at 250° and 3000 p. s. i. The products of the first hydrogenations were rehydrogenated once or twice in methylcyclohexane in order to obtain the perhydrophenanthrene free of less completely hydrogenated products. 1,1,4,4-Tetramethyl-1,2,3,4-tetrahydronaphthalene (10.4 g., $n^{25}D$ 1.5192) was hydrogenated over Raney nickel at 250° under 3000 p. s. i. to give 1,1,4,4-tetramethyldecalin (10 g. b. p. 100–103° (11 mm.), $n^{25}D$ 1.4732, d^{25}_4 0.8816). The molecular refraction was thus 61.8 as compared with a calculated value of 62.4. A mixture of stereoisomers of 1,1,4,4,5,5,8,8-octamethylperhydroanthracene (m. p. 100–110° from alcohol) was prepared by the hydrogenation of the corresponding octahydroanthracene over Raney nickel at 340° for four hours at 3000 p. s. i. The hydrogenation of 1,1,4,4,7,7,10,10-octamethyl-1,2,3,4,7,8,9,10-octahydronaphthacene over Raney nickel in methylcyclohexane at 250° gave a mixture of stereoisomers of the corresponding perhydronaphthacene (m. p. 162–167° from chloroform–alcohol). 2,5-Dimethyl-3-hexyn-2,5-diol was hydrogenated at 27–75° over Raney nickel at 3000 p. s. i. to give a quantitative yield of 2,5-dimethyl-2,5-hexanediol.

Procedures of Dehydrogenation, Isolation and Characterization.—The dehydrogenations were carried out in a chrome–vanadium steel reaction vessel having a void of 270 ml. In general about 2 g. of the compound to be dehydrogenated in 5 ml. of benzene was heated for eight to twelve hours at 350–375° with 0.25 g. of a platinum-on-carbon catalyst carrying about 0.06 g. of reduced platinum. Where other conditions were used it is noted in the summary of experimental results given below. A nickel-on-nickel chromite (2 g.) and a nickel-on-kieselguhr catalyst (2 g.) were used also with all compounds, but the results are not given below in detail except in a few cases. The benzene was usually thiophene free. A little thiophene is advantageous with nickel catalysts.[2]

The products of reaction were removed from the steel vessel with ether, the catalyst separated by centrifuging, the solution decolorized with activated carbon and the solvents removed under reduced pressure. Usually a solid product was isolated by crystallization at about −80° from petroleum ether (b. p. 40–60°) using a "Dry Ice technique."[1] From the amount of solid isolated and/or the refractive index of the residue an estimate of the per cent. aromatization could be made. The formation of picrates, styphnates and trinitrobenzene derivatives served also to separate and characterize aromatic products. The hydrocarbon was conveniently recovered from these de-

rivatives by dissolving in the proper solvent (benzene for picrate and petroleum ether for trinitrobenzene derivatives) and passing through a tower packed with activated alumina. Thus, small amounts of low melting aromatic hydrocarbons were conveniently purified by preparing a higher melting derivative such as the picrate, recrystallizing to purity and recovering the hydrocarbon by passing the picrate in benzene solution through an alumina tower. The picric acid was adsorbed on the alumina and the purified hydrocarbon could be recovered by evaporation of the benzene. After determination of its refractive index and/or melting point other derivatives could be prepared.

Results of Dehydrogenations

2,2-Dimethyltetralin (1.54 g., $n^{25}D$ 1.5188) gave 1.27 g. of product $n^{25}D$ 1.5410, which after crystallization gave 0.44 g. crystals and 0.75 g. of oil $n^{25}D$ 1.5330. The crystalline product was characterized as 2-methylnaphthalene through the formation of the trinitrobenzene derivative which after three crystallizations from methanol showed a m. p. 123–125.5°. The m. p. of the derivative was not lowered when mixed with an authentic sample. Decomposition of the derivative over alumina gave a sample of 2-methylnaphthalene m. p. above 25° which gave a picrate m. p. 113–114° corresponding to that reported.[15]

2-Methyl-2-ethyltetralin (1.4 g., $n^{25}D$ 1.5170) gave a product (1.1 g., $n^{25}D$ 1.5595) which yielded 0.4 g. of crystals melting at room temperature and 0.67 g. of an oil $n^{25}D$ 1.5520. The crystals were characterized as 2-methylnaphthalene as described above.

2,2-Dimethyltetralin (2.9 g.) over the nickel (k) catalyst gave 1.03 g. m. p. 90–92° and 0.88 g. of an oil $n^{25}D$ 1.5950. The solid after four recrystallizations from methanol showed a m. p. 102–103.5° and gave a trinitrobenzene derivative m. p. 134.5–136.5°. These values correspond to those for 2,3-dimethylnaphthalene. 1,2-Dimethylnaphthalene was identified in the oil through the formation of the trinitrobenzene derivative m. p. 144–148° and comparison of it with an authentic compound. A few milligrams of the hydrocarbon was recovered from the derivative and converted to the picrate m. p. 124–128°.

2-Methyl-2-ethyltetralin and the corresponding decalin, over the nickel (k) catalyst, gave aromatic oils from which derivatives of 2-methyl-3-ethylnaphthalene ($n^{25}D$ 1.6003) were prepared. The yields of this compound were estimated to be 20–30%. The picrate m. p. 131.5–133.5°, styphnate m. p. 118–119°, and trinitrobenzene derivative m. p. 131–133.5° were unreported but a quinone mixture m. p. 64–68° prepared as by Karrer,[16] served to identify it as 2-methyl-3-ethylnaphthalene.

2-Methyl-2-ethyldecalin (2.3 g., $n^{25}D$ 1.4775) gave a product (2.1 g., $n^{25}D$ 1.5450) from which was obtained 1.53 g. of 2-methylnaphthalene (m. p. 23–25°) and 0.23 g. of oil. The 2-methylnaphthalene was characterized as described above.

2,2,3-Trimethyltetralin (1.08 g., $n^{25}D$ 1.5200) gave a product (1.0 g.) which yielded 0.77 g. of crystalline but impure 2,3-dimethylnaphthalene and a liquid (0.2 g., $n^{25}D$ 1.5720). Recrystallization of the crude 2,3-dimethylnaphthalene from petroleum ether (b. p. 40–60°) yielded 0.5 g., m. p. 95–99° and three crystallizations from methanol gave 0.2 g., m. p. 104–105°. The m. p. reported is 102°. The picrate, m. p. 123–124.5° and the trinitrobenzene derivative m. p. 137–138° were also prepared and found to agree with those reported.[17] From another run there was obtained 0.3 g. of crystalline 2,3-dimethylnaphthalene and 0.41 g. of oil $n^{25}D$ 1.5570. From the oil a picrate was prepared which after two recrystallizations from methanol melted at 138–142° and showed no lowering when mixed with the picrate of 1,2,3-trimethylnaphthalene m. p. 141–142° obtained from the nickel (k) run below. Therefore it was concluded that some of this hydrocarbon was present in the dehydrogenation product.

2,2,3-Trimethyltetralin (1 g.) over the nickel (k) catalyst gave 0.52 g. of an oil $n^{25}D$ 1.5725. A picrate m. p.

(15) Barbot, *Bull. soc. chim.*, **47**, 1317 (1930).

(16) Karrer and Epprecht, *Helv. chim. acta*, **23**, 277 (1940).

(17) Thiele and Troutman, *Ber.*, **68B**, 2247 (1935).

141–142° and the styphnate m. p. 136–139° corresponding to 1,2,3-trimethylnaphthalene were obtained.

1,1,4,4-Tetramethyldecalin (2.6 g., $n^{25}D$ 1.4732) gave 2.3 g. of a product $n^{25}D$ 1.5210. This value is similar to that of 1,1,4,4-tetramethyltetralin, $n^{25}D$ 1.5180, and identical with the product from an attempted dehydrogenation of the tetralin. There was also fair agreement in the densities, *i. e.*, d^{25}_4 0.9215 as compared with 0.9244 for the authentic tetralin.

1,1-Dimethyl-1,2,3,4-tetrahydrophenanthrene (2 g., $n^{25}D$ 1.6035) gave 1.1 g. of crystals and 0.58 g. of oil $n^{25}D$ 1.6092. After two crystallizations from petroleum ether (b. p. 60–68°) the 1-methylphenanthrene (0.47 g.) had a m. p. 115–117° and after three recrystallizations from methanol the m. p. was 118–119°. The picrate m. p. 135.5–137°, the styphnate m. p. 150.5–152°, and the trinitrobenzene derivative m. p. 160–161° were obtained. These values correspond with those of 1-methylphenanthrene and its derivatives.

1,1-Dimethyl-1,2,3,4-tetrahydrophenanthrene (2 g., $n^{25}D$ 1.6035) over the nickel (k) catalyst gave 0.6 g. of crystals which after three recrystallizations from methanol melted at 136–140°. The picrate melted at 151–153°. These values are in agreement with those reported for 1,2-dimethylphenanthrene.[18]

1,1-Dimethylperhydrophenanthrene (2.3 g., $n^{25}D$ 1.4940) gave 1.17 g. of crude 1-methylphenanthrene and 0.93 g. of oil $n^{25}D$ 1.5885. Crystallization and characterization as described above gave 0.68 g. of 1-methylphenanthrene m. p. 83–95° which was purified to 0.24 g., m. p. 116–117°.

1-Methyl-1-ethyl-1,2,3,4-tetrahydrophenanthrene (2 g., $n^{25}D$ 1.6002) gave 1 g. of a solid and 0.58 g. of an oil $n^{25}D$ 1.6138. Purification and characterization of the solid product, as described above for 1-methylphenanthrene, showed it to consist primarily of that compound. The quantities obtained were low, *i. e.*, 0.33 g., m. p. 99–107°, and 0.10 g., m. p. 117–120°.

1-Methyl-1-ethyl-perhydrophenanthrene (1.6 g., $n^{25}D$ 1.5010) gave 1.21 g. of a solid and an oil $n^{25}D$ 1.6145. Purification and characterization of the solid product as described above, indicated that 1-methylphenanthrene was produced along with other compounds in the dehydrogenation.

1,1-Diethyl-1,2,3,4-tetrahydrophenanthrene (2 g., $n^{25}D$ 1.5960) gave 0.72 g. of crystals and 0.77 g. of oil $n^{25}D$ 1.6210. 1-Ethylphenanthrene, 0.37 g., m. p. 60–61.5° was obtained by recrystallization of the product from methanol. Further recrystallization gave a sample m. p. 62.5–63° corresponding with that previously reported.[19] The above run repeated over a nickel (k) catalyst gave an oil $n^{25}D$ 1.6355. A trinitrobenzene derivative after six recrystallizations from methanol melted at 137–138° (0.1 g.). It gave the correct carbon and hydrogen analyses for the trinitrobenzene derivative of 1,2-diethylphenanthrene.

2,2-Dimethyl-1,2,3,4-tetrahydrophenanthrene (0.5 g., m. p. 45–46.5°) gave 0.4 g. of a product which formed a picrate that melted at 120–123° after being twice recrystallized from methanol. The m. p. of the picrate of 2-methylphenanthrene is 118–119°. The m. p. of a mixture of the two samples was 118–120°. Analysis of the picrate for carbon and hydrogen indicated that it was a mixture derived from a mono- and a dimethylphenanthrene. The hydrocarbon(s) recovered from the picrate over alumina showed a m. p. 65–75° which is higher than that of 2-methylphenanthrene, m. p. 53–54°.

2,2-Dimethyl-1,2,3,4-tetrahydrophenanthrene (1.06 g.) over nickel (k) catalyst gave 0.82 g. of solid. Four recrystallizations from methanol gave crystals melting at 142–143°, the reported melting point of 1,2-dimethylphenanthrene.[18]

1,1,4,4-Tetramethyl-1,2,3,4,5,6,7,8-octahydroanthracene (5 g., m. p. 88–91°) at 350° gave 4.8 g. of a solid product. Recrystallizations from ethanol gave 3.3 g. of 1,1,4,4-tetramethyl-1,2,3,4-tetrahydroanthracene m. p. 78–81° or 1.6 g., m. p. 82.5–84°. This compound reacted with 2,5-dichloro-2,5-dimethylhexane in the presence of aluminum chloride to give 1,1,4,4,7,7,10,10-octamethyl-1,2,3,4,7,8,9,10-octahydronaphthacene.

A sample of 1,1,4,4,7,7,10,10-octamethylperhydronaphthacene (2 g., m. p. 162–167°) gave upon dehydrogenation a product which after crystallization from toluene amounted to 1.2 g. of product m. p. 160–170°. After five recrystallizations there was obtained 0.05 g., m. p. 295–298° of a compound that is probably 1,1,4,4,7,7,10,10-octamethyl-1,2,3,4,7,8,9,10-octahydronaphthacene.

1,1,4,4,5,5,8,8-Octamethylperhydroanthracene resisted dehydrogenation even to the octamethyloctahydroanthracene under the conditions used in this work. This might be expected since the reverse hydrogenation was so difficult to accomplish, *i. e.*, 340° was required.

1,1-Spirocyclopentano-1,2,3,4-tetrahydrophenanthrene (0.8 g., m. p. 56–58°) gave after evaporative distillation of the dehydrogenation product 0.17 g., m. p. 200–244°. This solid could be crystallized from benzene to m. p. 250–251° and the melting point was not lowered on mixing with an authentic sample of chrysene m. p. 251–252°.

The above experiment was repeated using nickel (k) as catalyst and there was obtained after evaporative distillation 0.23 g., m. p. 240–250°.

Summary

Eleven tetralins, decalins, tetrahydrophenanthrenes and perhydrophenanthrenes carrying gem dialkyl groups have been prepared. These compounds have been aromatized in the liquid phase with benzene and platinum and nickel catalysts to substituted naphthalenes or phenanthrenes. The platinum catalyst brings about aromatization almost exclusively through elimination of an alkyl group and hydrogen, while the nickel-on-kieselguhr catalyst brings about aromatization through the catalysis of the migration of a carbon linkage. The latter catalyst, for example, brings about a rather clean transformation of 1,1-spirocyclopentano-1,2,3,4-tetrahydrophenanthrene to chrysene.

[A COMMUNICATION FROM THE LABORATORY OF ORGANIC CHEMISTRY OF THE UNIVERSITY OF WISCONSIN]

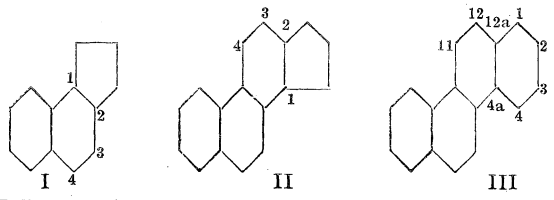
Catalytic Dehydrogenation of Hydroaromatic Compounds in Benzene. IV. Aromatization of Compounds Containing an Angular Alkyl Group

BY HOMER ADKINS AND GLENN F. HAGER[1]

The feasibility of the aromatization of a number of naphthalene, phenanthrene and chrysene derivatives containing angular alkyl groups, under conditions used for simple dehydrogenation, has been investigated, in conjunction with James W. Davis and David C. England.[2,3,4]

A summary of the experimental results obtained in the aromatization of a variety of compounds is given in Table I. The per cent. conversions, based upon the amount of compound undergoing reaction, were considerably higher than those given in the table. Except for one or two cases the amount of recovered starting material was such that 80–90% of the compound reacting went to the indicated product. 1-Methyl-1,2-cyclopentanodecalin and 2-methyl-1,2-cyclopentanoperhydrophenanthrene gave 10% yields of naphthalene and phenanthrene, respectively, in addition to 1,2-cyclopentenonaphthalene and 1,2-cyclopentenophenanthrene. No doubt small quantities of compounds not characterized were present in the various reaction mixtures.

The aromatizations were conducted under rather arbitrarily chosen conditions which were certainly not the optimum, especially from the standpoint of completeness of conversion. The aromatization of 1-methyl-1,2-cyclopentanodecalin was studied under a variety of conditions. The effect of the void in the steel vessel, of various amounts and qualities of benzene, of the addition of thiophene,[5] of ratio of catalyst to compound, of periods of reaction varying from two to twelve hours and of temperatures from 350 to 450°, were determined. The optimum conditions for yield of 1,2-cyclopentanonaphthalene over a Ni·NiCrO catalyst was found to be with equal weights (4 g.) of catalyst and organic compound, 20 ml. of pure benzene containing 40 mg. of thiophene, shaken in a 270-ml. steel vessel at 37° for eight hours. Under these conditions the yield of 1,2-cyclopentenonaphthalene was about 63% of the theoretical as compared with 45% as given in Table I. However, at the lower temperature referred to in the table, 50% of the starting material did not react so that the efficiency of conversion was better at the lower temperature.



A series of eight compounds, related to 1,2-cyclopentenonaphthalene (I), were aromatized to that compound in good yield. These compounds listed in Table I differed from each other in their degree of hydrogenation varying from di to tetra

to complete saturation. They also differed in that two of them did not carry a carbon substituent on the ring, while the others had substituents in the angular 1- or 2-positions. Two had methyl groups in the 1-position, one had a *n*-butyl group in the 1-position, two had carbethoxy groups in the 2-position, and one had a methyl group in the 2-position. There was not much difference in the yields of 1,2-cyclopentenonaphthalene from a tetralin as compared with a decalin, although the former was dehydrogenated more rapidly at 350° and could be dehydrogenated under milder conditions than the decalin. The methyl in the 2-position was more readily removed than when in the 1-position. An angular methyl group in the 1-position was more completely removed under the standard conditions than a *n*-butyl group. A carbethoxy group in the 2-position was quite readily eliminated from either the dihydronaphthalene or from the decalin.

The platinum catalyst gave somewhat better yields in most cases than did the nickel on nickel chromate catalyst. However, this is apparently due to a slower rate of aromatization over the nickel catalyst and not to the catalysis of other reactions. Palladium was also an effective catalyst. The nickel on kieselguhr catalyst was uniformly less useful for these compounds than the other catalysts mentioned so that no data for it are given.

A series of five compounds, related to 1,2-cyclopentenophenanthrene (II), were aromatized to that compound. The yields were rather good but somwhat inferior to those obtained for 1,2-cyclopentenonaphthalene discussed above. All of the compounds aromatized carried an angular methyl or ethyl or *n*-butyl group in the 1- or 2-position. There was little difference in the yield of 1,2-cyclopentenophenanthrene from tetra- as compared with perhydrophenanthrene. This is understandable since the conditions required for the elimination of an angular alkyl group are rather drastic, so that the relative ease of dehydrogenation of a tetrahydro as compared with a perhydro compound is not a significant factor in determining yields. The platinum catalyst gave on the average twice as high yields as did the nickel catalyst.

Chrysene (III) was obtained as a minor product (10%) in the aromatization of 2-methyl-1,2-cyclopentanoperhydrophenanthrene through ring expansion over the platinum catalyst. Chrysene was obtained in better yields by England[4] through ring expansion of another phenanthrene, *i. e.*, 1-spirocyclopentano - 1,2,3,4 - tetrahydrophenanthrene. An octahydro- and a perhydrochrysene, with a methyl group in the angular 4a position, gave good yields of chrysene over four different catalysts.

The methods of synthesis and properties of the compounds aromatized are given in another paper.[6] The catalysts were prepared and used as described in an earlier paper[2] except for palladium-on-carbon. This catalyst, carrying about 8% palladium, was prepared by a standard method,[7] and used in a glass liner.

Separation, Characterization and Estimation of Products

The products of reaction were removed from the reaction vessel and catalyst with ether or benzene. The products containing 1,2-cyclopentenonaphthalene were distilled in a 7-ml. modified Claisen flask at less than 1 mm. pressure. Yields were estimated from the refractive index of the distillate, assuming it to be a binary mixture of starting material and 1,2-cyclopentenonaphthalene. The validity of this assumption was justified by various experiments including the formation of various derivatives. Identification of 1,2-cyclopentenonaphthalene (b. p. 118 (0.5 mm.), n^{25}D 1.6300) was effected by conversion to its picrate (m. p. 109°) and trinitrobenzene (m. p. 121°) derivatives. The products containing 1,2-cyclopentenophenanthrene or chrysene were washed with two portions of about 7 ml. of petroleum ether, b. p. 40–60°, on a sintered glass funnel at −80° by the "Dry Ice technique"[2] to separate aromatic products from starting material. The solid was then distilled evaporatively in a sublimer tube at a pressure of about 0.1 mm. Yields and purity of product were estimated from the weight and m. p. of this distillate. When the distillate contained both 1,2-cyclopentenophenanthrene (m. p. 135°) and chrysene (m. p. 251°), yields were estimated from the melting point of the mixture. The melting points for mixtures containing various proportions of chrysene are: 12.5%, 158°; 25%, 175°; 37.5%, 191°; 50%, 202°; and 75%, 226°. These aromatics were separated by fractional crystallization and identified by conversion to trinitrobenzene derivatives: 1,2-cyclopentenophenanthrene-TNB, m. p. 165° and chrysene-TNB, m. p. 188°.

Summary

Fifteen compounds, in various stages of hydrogenation, related to 1,2-cyclopentenonaphthalene, 1,2-cyclopentenophenanthrene or chrysene and in thirteen cases containing angular substituents, have been aromatized to one of the three compounds just mentioned. Fairly good yields of the aromatic compound have been obtained in benzene under pressure at 350° over platinum, palladium or nickel catalysts.

Catalytic Dehydrogenation of Hydroaromatic Compounds in Benzene. V. Application to Pyrrolidines and Piperidines

BY HOMER ADKINS AND LESTER G. LUNDSTED

A catalytic method of dehydrogenating hydroaromatic compounds in benzene in the liquid phase[1] has been evaluated against representative pyrrolidines, indolines, hydrocarbazoles and piperidines. A summary of the results obtained in the dehydrogenation of nineteen compounds over the nickel-on-nickel chromite catalyst (Ni·NiCrO) is given in Table I. The temperatures and time intervals required for reaction are less for the heterocyclic compounds than for the carboxylic compounds studied earlier. Several dehydrogenations were accomplished at 250–300°.

There is more tendency for the heterocyclic compounds, especially the piperidines, to go to compounds of higher molecular weight during dehydrogenations. Nevertheless the yields with eight compounds containing the pyridine nucleus averaged about 50% of the theoretical. The yields of ten compounds containing the pyrrole nucleus averaged 73%. The yields for compounds having the carbazole nucleus were almost quantitative. The yields of 1-(*n*-amyl)-pyrrole (88%), 1-ethyl-2,3,4,5-tetramethylpyrrole (74%) and 2-ethyl-3,4,5-trimethylpyrrole (69%) appear particularly attractive from a preparational standpoint since these compounds have not been available. Successful dehydrogenations were not accomplished on 1-benzoylpyrrolidene, 1-carbethoxypyrolidine, nicotine or 4-phenylpiperidine. The yield of 2-phenylpyrrole from 2-phenylpyrrolidine was 46% and from 2-cyclohexylpyrrolidine was only 16%.

The nickel-on-nickel chromite catalyst was prepared as described.[2] The compounds submitted to hydrogenation were available through methods used by others in this Laboratory.[3,4,5,6,7,8] The pipecolines and 2,6-lupetidine were made by the hydrogenation of the corresponding pyridine derivatives from commerical sources, over W-4 Raney nickel at 150–175° during an hour or two. 1,2,3,4-Tetrahydrocarbazole m. p. 118–120° was made by the Fischer indole synthesis[9] from the phenylhydrazone of cyclohexanone in a yield of 86%.

The products of reaction indicated in Table I were isolated by conventional methods of distilla-

tion, steam distillation, crystallization and use of solid derivatives, as was appropriate to the compounds. The properties and analyses of four pyrroles apparently not reported earlier are given in Table II. Other products were identified through refractive indices, boiling points, melting points and solid derivatives.

Summary

Representative compounds, containing a pyrrolidine or piperidine nucleus, have been dehydrogenated in the liquid phase in benzene over a nickel catalyst, to compounds containing a pyrrole or pyridine nucleus.

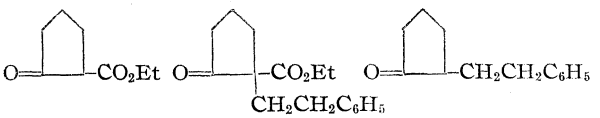
[A COMMUNICATION FROM THE LABORATORY OF ORGANIC CHEMISTRY OF THE UNIVERSITY OF WISCONSIN]

Synthesis of Cyclopentanohydronaphthalenes and Hydrophenanthrenes with Substituents in an Angular Position

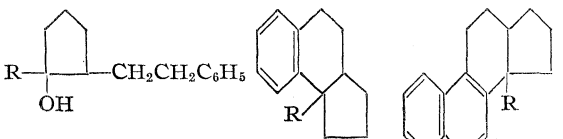
BY HOMER ADKINS AND GLENN F. HAGER[1]

In connection with another investigation,[2] a series of compounds has been made, which have a substituent in an angular position of partially or completely hydrogenated derivatives of 1,2-cyclopentenonaphthalene or 1,2-cyclopentenophenanthrene. The methods used were developments of those described earlier.[3,4,5,6,7,8,9]

The naphthalene derivatives were made through a series of reactions in which 2-carbethoxycyclopentanone (I) was alkylated with β-phenethyl bromide to give the substituted keto ester II. For one group of compounds the keto ester was decarboxylated to the ketone III, and converted to a tertiary alcohol IV, through the use of a Grignard reagent.



I II III

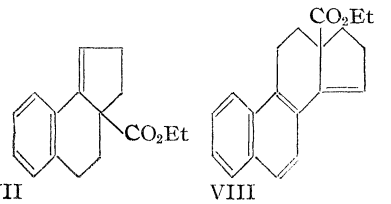


IV V VI

The latter was cyclized to a 1-alkyl-1,2-cyclopentano-1,2,3,4-tetrahydronaphthalene (V) where the alkyl group was methyl or *n*-butyl. The parent compound 1,2-cyclopentano-1,2,3,4-tetrahydronaphthalene, where R equals H in formula V, was prepared by reducing the ketone III to an alcohol over copper–chromium oxide, and closing the ring as in converting IV to V.

A group of angular substituted hydrophenanthrenes was prepared, by modifying the synthesis outlined above, through the use of α-$C_{10}H_7$-CH_2CH_2Br instead of $C_6H_5CH_2CH_2Br$ in alkylating the keto ester I. Thus, three 1-alkyl-1,2-cyclopentano - 1,2,3,4 - tetrahydrophenanthrenes (VI) were obtained, where the alkyl group was methyl, ethyl or *n*-butyl.

A modification of the synthesis was made in that the keto ester II was cyclized with liquid hydrogen fluoride to give a 2-carbethoxy-1,2-cyclopenteno - 3,4 - dihydronaphthalene (VII). The corresponding 2-carbethoxy-1,2-cyclopenteno-3,4-dihydrophenanthrene (VIII) was similarly prepared. In this latter case the cyclization went so rapidly that it was complete within five minutes at 0°. This method of closure gave excellent yields of compounds with a carbethoxy group in an angular position, and seems preferable to that used by Ruzicka and his associates and more recently by Ehmann and Miescher.[10]



VII VIII

The carbethoxy groups in compounds VII and VIII were hydrogenated to methylol groups and ultimately to the 2-methyl-1,2-cyclopentanodecalin and 2-methyl-1,2-cyclopentanoperhydrophenanthrene. Three catalysts were used in sequence, *i. e.*, copper–chromium oxide, Raney nickel and finally nickel-on-alumina. Several of the dihydro- and tetrahydronaphthalene and phenanthrene derivatives were converted to the corresponding substituted decalins or perhydrophenanthrenes over Raney nickel. The hydrogenated compounds are listed in Table I and the details of hydrogenation are given under the experimental section. Chrysene and 4a-methyl-1,2,3,4,4a,11,12,12a-octahydrochrysene, prepared

as by Perlman, Davidson and Bogert,[9] were hydrogenated to perhydrochrysenes.

1-Methyl-2-(*n*-propyl)-naphthalene was made through a series of reactions from 2-naphthol. The latter was converted to 2-hydroxy-1-naphthaldehyde by the Reimer–Tiemann reaction. The aldehyde was hydrogenated over Raney nickel to 1-methyl-2-decalol and the latter oxidized to 1-methyl-2-decalone. The decalone was converted to a tertiary alcohol with allylmagnesium bromide. Attempts to cyclodehydrate the resulting alcohol to 1-methyl-1,2-cyclopentanodecalin gave a mixture of dienes. Dehydrogenation of either the alcohol or the diene mixture in benzene gave 1-methyl-2-(*n*-propyl)-naphthalene.

Procedures

2-Carbethoxycyclopentanone.—Diethyl adipate (606 g., b. p. 135–137° (17 mm.), $n^{25}D$ 1.4256) was slowly added to a mixture of powdered sodium (100 g.), dry benzene (2.5 l.) and dry alcohol (5 ml.) held at 0–5°. After the addition of the ester the mixture was refluxed for twelve hours. The solid sodium salt was filtered off and decomposed with ice and dilute hydrochloric acid. The oil was separated and the water solution extracted twice with benzene. The oil and ether extractions were combined, washed with water and dried over anhydrous sodium sulfate. The ester (384 g. or 81%, $n^{25}D$ 1.4526) was distilled at 113–115° (20 mm.). The procedure is that suggested but not described in detail by Linstead and Meade.[11]

2-(β-Phenethyl)-2-carbethoxycyclopentanone (II).—2-Carbethoxycyclopentanone (78 g. in 50 ml. of toluene) was added to 19.5 g. of powdered potassium suspended in 750 ml. of dry toluene. The potassium was powdered in two portions in a liter flask and transferred in an atmosphere of nitrogen to the 2-liter reaction flask. No more than 15 g. of the ester was added to the flask until reaction was definitely underway. After the potassium salt of the keto ester had formed, 94.4 g. of β-phenethyl bromide was added rapidly and the mixture refluxed for twenty-eight hours. The mixture was cooled and the solid potassium bromide was separated, dissolved in water and extracted twice with benzene. The benzene and toluene solutions were combined, washed with water and dried over anhydrous sodium sulfate. The product II (96 g., 74%, $n^{25}D$ 1.5120) was distilled at 157–163° (2 mm.).

2-(β-1′-Naphthylethyl)-2-carbethoxycyclopentanone.—This compound was prepared as described above except that 221 g. of β-(1-naphthyl)-ethyl bromide[12,13] was used instead of β-phenethyl bromide. The quantities of other reagents were 37 g. of potassium, 147 g. of 2-carbethoxycyclopentanone in 1 liter of xylene. The yield was 205 g. (70%) boiling 210–215° (1 mm.).

2-(β-Phenethyl)-cyclopentanone.—The keto ester II (47 g.) in a mixture of 200 ml. of glacial acetic acid, 150 ml. of concentrated hydrochloric acid and 50 ml. of water was refluxed for six hours in an oil-bath maintained at 160–170° as by Bachmann and Struve.[13a] The cold mixture was diluted with 250 ml. of water and extracted with three 200-ml. portions of ether. The combined extracts were washed with water and dried. There was obtained by distilling at 163–166° (12 mm.) 28.4 g. of the desired product, $n^{25}D$ 1.5240.

2-(β-1′-Naphthylethyl)-cyclopentanone.—This compound, b. p. 160–165° (0.1 mm.) was obtained in 71% yield by the hydrolysis of the corresponding keto ester, by refluxing for ten hours under the conditions described just above.

1-Alkyl-1,2-cyclopentano-1,2,3,4-tetrahydro Derivatives of Naphthalene and Phenanthrene.—Several com-

pounds of this type were prepared by essentially the same procedure,[4] the difference being in the particular ketone and alkyl halide used and in the reagent for ring closure. A representative procedure was to add 37 g. of 2-(β-phenethyl)-cyclopentanone (III) to a 100-ml. ether solution of methylmagnesium iodide, which had been prepared from 6 g. of magnesium and 35.5 g. of methyl iodide. The mixture was allowed to stand overnight, refluxed for one hour and decomposed in an ice-cold saturated solution of ammonium chloride. The alcohol was extracted with ether and the crude alcohol left after the evaporation of the ether used for the next step.

The crude tertiary alcohol was heated with 80 g. of phosphoric acid for twenty-five minutes under a pressure of 6 mm. in a flask suspended in an oil-bath held at 135–140°.[3] The temperature of the bath was then raised to 170° and the crude product (29.3 g.) distilled over. The 1-methyl-1,2-cyclopentano-1,2,3,4-tetrahydronaphthalene (28.5 g., $n^{25}D$ 1.5449) was distilled from sodium at 128–129° (12 mm.). The yield for the *n*-butyl compound was 56%. The secondary alcohol 2-(β-phenethyl)-cyclopentanol (28 g.) was also dehydrated by the procedure just described to 1,2-cyclopentano-1,2,3,4-tetrahydronaphthalene (20.8 g., $n^{25}D$ 1.5490, b. p. 131–133° (15 mm.)).

The tertiary alcohols (50 g.) resulting from the reaction of 2-(β-1′-naphthylethyl)-cyclopentanone and a Grignard reagent were cyclized with 85% sulfuric acid (25 g.) in 50 ml. of petroleum ether at 0° as described.[9] The yields for the methyl, ethyl and *n*-butyl tetrahydrophenanthrenes were 72, 44 and 35%, respectively. The methyl compound had been previously prepared[4]; it distilled at 157–160° (0.6 mm.) and had $n^{25}D$ 1.6205.

2-Carbethoxy-1,2-cyclopenteno-3,4-dihydronaphthalene.—2-(β-Phenethyl)-2-carbethoxycyclopentanone (25 g.) was placed in a 500-ml. platinum vessel, which was cooled in an ice–salt-bath while approximately 150 ml. of liquid hydrogen fluoride was added. After standing one and one-half hours in an ice–salt-bath, the reaction mixture was poured over 400 g. of ice. The product was extracted with ether, the latter washed with a 5% sodium hydroxide solution until the washings were alkaline to litmus and the ether solution washed with water. After the solution was dried and the ether distilled there was obtained a crude product (15.5 g.) distilling at 160–170° (1 mm.). Upon fractionation through a modified Widmer column there was obtained at 125–128° (0.2 mm.) 14.5 g. of product which solidified. After crystallization from 95% alcohol the m. p. was 63–64°.

2-Carbethoxy-1,2-cyclopenteno-3,4-dihydrophenanthrene.—2-(β-1′-Naphthylethyl)-2-carbethoxycyclopentanone (50 g.) was cyclized in liquid hydrogen fluoride as described above. However, the cyclization was allowed to proceed for only five minutes instead of one and one-half hours. The product, after removal of the ether used in the extraction, was crystallized from 100 ml. of hot 95% alcohol giving 33 g., m. p. 96–98°. An additional 8 g. of product was obtained by distilling the mother liquors. After recrystallization the compound had a m. p. of 98–99°.

1-Methyl-2-decalol and 1-Methyl-5,6,7,8-tetrahydro-2-naphthol.—These compounds were obtained by the hydrogenation of 2-hydroxy-1-naphthaldehyde in ethanol over Raney nickel at 200° under 3600 p. s. i. of hydrogen during two and one-half hours. The aldehyde, m. p. 79–80°, was prepared in 40% yield as described.[14] The yield of the decalol in the hydrogenation was over 80%. Combination of the higher boiling fractions from several hydrogenations indicated the yield of the tetrahydronaphthol to be about 5%.

1-Methyl-2-decalone.—1-Methyl-2-decalol (99 g.) was slowly added to a solution of 120 g. of sodium dichromate in 100 g. of concentrated sulfuric acid and 500 ml. of water, the reaction mixture being kept below 45°. Stirring was continued for thirty minutes after all the alcohol had been added. The mixture was transferred to a separatory funnel and twice swirled, not shaken, with 200 ml. of ether. The ether was separated and the water layer again extracted by shaking with ether. The combined ether extracts were washed in a 5% sodium hydroxide solution until the ether was a light amber color. After drying and removal of the ether, the ketone (80 g.) was distilled at 105–107° (7 mm.).

1-Methyl-2-allyl-2-decalol.—The decalone (65 g. in 100 ml. of ether) was added at such a rate as to give gentle refluxing to allylmagnesium bromide in 400 ml. of ether, as obtained from allyl bromide (60.5 g.) and magnesium (72.9 g.). The addition product was decomposed by carefully mixing it with 500 ml. of a saturated solution of ammonium chloride. The desired alcohol (70 g.) was distilled 133–138° (7 mm.) and dehydrated to a mixture of dienes (30 g., $n^{25}D$ 1.4985–1.5250) distilling at 99–115° (7 mm.). The dehydration of 40 g. of the alcohol was made in a stream of nitrogen with a mixture of 40 g. of phosphoric anhydride and 200 ml. of phosphoric acid held in a bath at 180°. Dehydrogenation of the mixture of dienes in benzene over a nickel-on-alumina catalyst at 350° for twelve hours, gave 1-methyl-2-propylnaphthalene, b. p. 145–146° (10 mm.), $n^{25}D$ 1.5928. The same product was obtained in 53% yield by the dehydrogenation of the decalol.

Hydrogenations.—A number of compounds were hydrogenated in chrome–vanadium steel vessels having voids of 90 to 270 ml. at 1500 and 4500 p. s. i. of hydrogen with the standard copper–chromium oxide or W-2 Raney nickel catalyst. The hydrogenations listed immediately below were over W-2 Raney nickel. Both 1,2-cyclopentano-1,2,3,4-tetrahydronaphthalene (16 g.) and 1,2-cyclopentenonaphthalene (6.3 g.) were hydrogenated with 5 g. of catalyst in methylcyclohexane at 250° within less than an hour to 1,2-cyclopentanodecalin. 1-Methyl-1,2-cyclopentano-1,2,3,4-tetrahydronaphthalene (22 g.) at 200° for three hours gave 1-methyl-1,2-cyclopentanodecalin. 1-Methyl-1,2-cyclopentano-1,2,3,4-tetrahydrophenanthrene (20 g.) after a preliminary treatment at 250° in methylcyclohexane was again submitted to hydrogenation with fresh catalyst at 250° for three hours to give 1-methyl-1,2-cyclopentanoperhydrophenanthrene. 1,2-Cyclopentenophenanthrene (2 g.) in methylcyclohexane at 250° for five hours gave 1,2-cyclopentanoperhydrophenanthrene. 4a-Methyl-1,2,3,4,4a,11,12,12a-octahydrochrysene (11.5 g.) in 90 ml. of methylcyclohexane at 250° for two hours gave 4a-methylperhydrochrysene. Chrysene (3.5 g.) was similarly hydrogenated to perhydrochrysene. The yields in all of the hydrogenations described above were 80–95%, the discrepancy between the amount obtained and 100% being largely due to losses in handling small quantities with relatively large amounts (5 g.) of catalyst. 2-Carbethoxy-1,2-cyclopenteno-3,4-dihydronaphthalene and 2-carbethoxy-1,2-cyclopenteno-3,4-dihydrophenanthrene were hydrogenated to the tetrahydro compounds, at 50° over W-4 Raney nickel within an hour. Conversion of the dihydro or the tetrahydro to the perhydro compounds required in the case of decalin three hours at 175°, while two hydrogenations at 250° for several hours each were necessary in order to obtain perhydrophenanthrenes free of unsaturated compounds.

The keto groups in 2-(β-phenethyl)-cyclopentanone (27.5 g.) and 2-(β-phenethyl)-2-carbethoxycyclopentanone (100 g.) in ethanol were hydrogenated over 10% of their weight of copper–chromium oxide to the corresponding pentanols in yields of 90% at 160–175° in one to one and one-half hours.

The carbethoxy group in 2-carbethoxy-1,2-cyclopentanodecalin (10 g.) was converted in 80% yield to a methylol group after thirty-six hours at 250° over 2 g. of copper–chromium oxide. 2-Carbethoxy-1,2-cyclopenteno-3,4-dihydrophenanthrene in dioxane was hydrogenated as described just above to give a methylol derivative of a hydrophenanthrene containing two double bonds per molecule according to analysis. The hydrogenation to 2-methylol-1,2-cyclopentanoperhydrophenanthrene was completed with Raney nickel at 250° in six hours. 2-

(14) Russell and Lockhard, "Organic Syntheses," Vol. XXII, John Wiley and Sons, Inc., New York, N. Y., 1942, p. 63.

Methylol-1,2-cyclopentano-decalin (9 g.) was hydrogenated over 4 g. of nickel-on-alumina for eight hours at 325° to give a 79% yield of 2-methyl-1,2-cyclopentano-decalin. 2-Methyl-1,2-cyclopentanoperhydrophenanthrene was prepared from the methylol compound under the conditions just stated.

Summary

A number of derivatives of 1,2-cyclopentanohydronaphthalenes and of 1,2-cyclopentanohydrophenanthrenes, with a substituent in an angular position, have been prepared by development of the methods of Bardhan, Sengupta, Kon, Bougault, Bogert and Cook. The use of liquid hydrogen fluoride at 0° has made possible the cyclization in excellent yields of certain substituted β-keto esters with the formation of 1,2-cyclopentenodihydronaphthalenes and phenanthrenes, with a carbethoxy group in an angular position. The carbethoxy group in these compounds has been reduced to methylol and methyl groups. Derivatives of chrysene have been prepared by a modified Bogert–Cook synthesis. A practical synthesis of 1-methyl-2-alkylnaphthalenes from 2-naphthol has been illustrated.

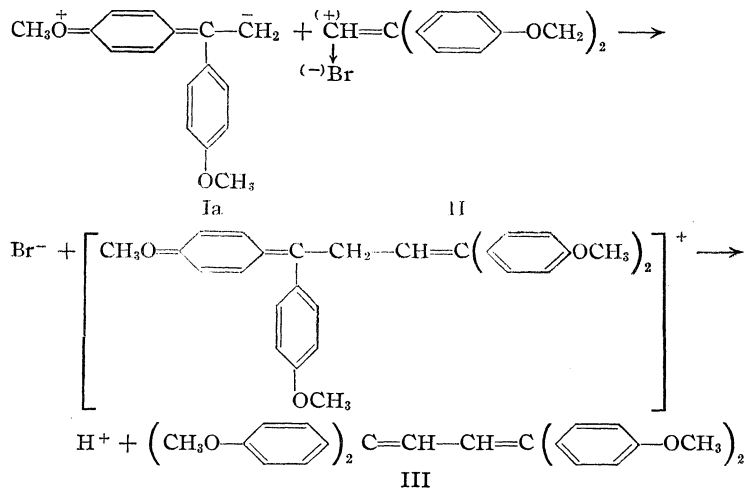
1,1,4,4-Tetraanisyl-1,3-butadiene

BY FELIX BERGMANN, JACOB SZMUSZKOWICZ AND ELCHANAN DIMANT[1]

Although 1,1-diphenylethylene can be dimerized by a variety of agents,[2] no success attended experiments to dimerize 1,1-di-(*p*-anisyl)-ethylene (I).[3] However, when we tried to convert (I) into the corresponding vinyl bromide (II) in acetic acid solution, we obtained a light-yellow substance of m. p. 207°, which we considered previously to be a "dimer."[4] Addition of sodium acetate to the bromination mixture prevented the formation of the yellow compound and stopped the reaction at the intermediate stage (II).

We have now found that the substance of m. p. 207° is not a dimer, but represents 1,1,4,4-tetraanisylbutadiene (III).[5] Proof of this structure can be given in the following way: (a) All unsaturated dimers of diarylethylenes represent butenes[2] and consequently absorb one mole of hydrogen. Compound (III) however takes up two moles of hydrogen. (b) Reaction of (II) with Grignard magnesium gives (III), in analogy to the synthesis of 1,1,4,4-tetraphenylbutadiene.[6] (c) The absorption spectrum of (III) is similar to that of 1,1,4,4-tetraphenylbutadiene (see Fig. 1).[7] Moreover, as in the latter compound, V, the spectrum remains unchanged after three hours of irradiation indicating a structure in which there is no possibility of a *cis–trans* transformation.

The direct formation of (III) during the bromination of dianisylethylene is probably to be interpreted in the following way



Ia II

III

If this explanation is correct, then (I) and (II) should react with each other to form (III). This reaction was found to proceed smoothly at 120° and to give a quantitative yield of (III). The above reaction scheme also explains why (I) cannot be dimerized by strong acids: The intermediate carbonium ion $R_2{}^+CCH_3$, because of resonance stabilization through the *p*-methoxy group, cannot attack the β-carbon of a second ethylene molecule. In the formation of the butadiene (III) the resonance form (Ia) acts as a nucleophilic agent, directly substituting the β-bromine atom. Experiments now under hand will show whether this reaction presents a general method for the synthesis of 1,1,4,4-tetraarylbutadienes.[8]

(8) *E. g.*, 1,1,4,4-tetraphenylbutadiene is obtained likewise by direct interaction of 1,1-diphenylethylene with 1,1-diphenylvinyl bromide. However, due to the absence of the activating *p*-methoxy groups the conditions of this reaction are much more drastic than in the synthesis of tetraanisylbutadiene. These and other experiments will be reported in a forthcoming paper.

Experimental

1. Dianisylvinyl Bromide and Magnesium.—Because of the difficulty to induce the grignardization of this bromide we used the entrainment method:

A Grignard solution was prepared from dianisylvinyl bromide (1.6 g.), methyl iodide (0.7 g.) and magnesium (0.27 g.) in ether (40 cc.). After one hour of reflux 3 g. of (II) was added and the mixture was again refluxed for thirty-six hours. A yellow precipitate formed in the mixture. After treatment with dilute sulfuric acid the yellow material was filtered off and washed with ether; m. p. 204°, yield 0.85 g. (25%). Recrystallization from butyl acetate gave yellow needles of m. p. 206–207°, which showed no m. p. depression upon admixture of (III). No attempt was made to isolate the ether-soluble reaction products.

2. Catalytic Reduction of 1,1,4,4-Tetraanisylbutadiene.—The diene (1.2 g.), suspended in ethyl acetate (40 cc.), absorbed 155 cc. of hydrogen in the presence of Adams platinum oxide (0.5 g.) within two hours (calcd. for 31°, 755 mm., 164 cc.). The oily reduction product crystallized after treatment with *n*-hexane and was obtained from a benzene–methanol mixture as white rods of m. p. 121°; yield, 1.1 g.

Anal. Calcd. for $C_{32}H_{34}O_4$: C, 79.67; H, 7.05. Found: C, 79.64; H, 7.12.

3. Condensation of Dianisylethylene and Dianisylvinyl Bromide.—The bromide (640 mg.) and the ethylene (480 mg.) were thoroughly mixed and heated in an oil-bath with the exclusion of moisture. The mixture melts at 100–110° and gives off fumes of hydrogen bromide. After a few minutes it resolidifies. It was kept at 120° for ten hours and then treated with butyl acetate; yield 0.95 g. (quantitative), m. p. 203–204°. Recrystallization from the same solvent gave yellow rods of m. p. 206–207°, identical with the two previous preparations of (III).

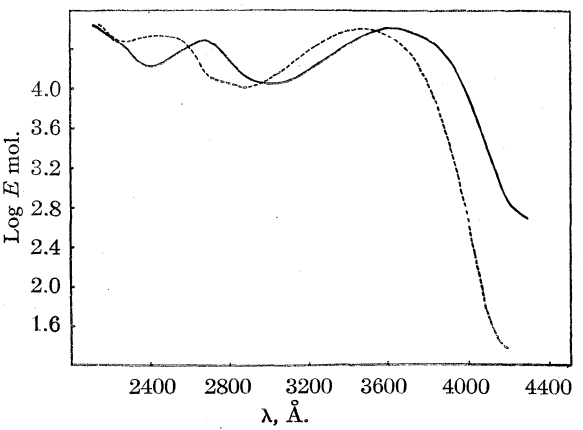

Fig. 1.—Ultraviolet absorption spectrum of — 1,1,4,4-tetraanisylbutadiene, ------ 1,1,4,4-tetraphenylbutadiene.

4. Absorption Spectra.—The spectra were measured in 95% ethanol by a Beckman quartz spectrophotometer.

Summary

The so-called "dimer," obtained in the bromination of dianisylethylene, is shown to be 1,1,4,4-tetraanisylbutadiene. The same substance can be prepared by interaction of dianisylethylene and dianisylvinyl bromide. The mechanism of this reaction is discussed.

3-Pyridols in the Mannich Reaction[1]

BY ARTHUR STEMPEL AND ELAINE C. BUZZI

The Mannich reaction with phenols has recently been extended to 3-pyridols in attempts to prepare pyridoxine,[2] its analogs,[3] and antagonists.[4] A Mannich type of reaction employing sodium hydroxide instead of organic amines for the direct introduction of hydroxymethyl groups in 3-pyridols has also been reported.[5] Since the directive influence of the phenolic group has been studied only in cases where the ortho position is unsubstituted,[5] the following investigation of the scope and direction of the Mannich reaction with 3-pyridols was undertaken.

The substituted 3-pyridol reacted rapidly with formaldehyde and dialkylamines, alkarylamines, and heterocyclic amines such as piperidine and morpholine to give 2-(substituted amino)-methyl-3-pyridols in good yield. In all cases, the products were most readily isolated by distillation *in vacuo*. Where the products were solid, purification by distillation was still preferable to crystallization. The basic pyridols appear to be stable to heat with the exception of 2-di-*n*-butylaminomethyl-3-pyridol which showed signs of decomposition during distillation. Although attempts to prepare an analytically pure crystalline dihydrochloride of this compound were unsuccessful, it has been included since, in work to be reported at a later date, an ester of the correct analysis has been isolated. In general, these compounds have been characterized as the dihydrochlorides. The side chain basic group reacts readily with one mole of methyl bromide in the cold to give nicely crystalline quaternary salts. Quaternization of the pyridine nitrogen requires higher temperatures. Compounds of this type are listed in Table I.

By the catalytic debenzylation of 2-(N-methylbenzylaminomethyl)-3-pyridol, 2-methylaminomethyl-3-pyridol was readily prepared. In this manner, by the selection of the proper N-sub-

stituted benzylamine, a series of the secondary amines may be prepared.

The extension of this reaction to the preparation of 2-(N-methylanilinomethyl)-3-pyridol by the reaction of 3-pyridol with formaldehyde and methylaniline was unsuccessful. This compound was, however, prepared with little difficulty by the reaction of 2-bromomethyl-3-pyridol hydrobromide[5a] with methylaniline. The extreme reactivity of the bromine in the side chain made it impossible to isolate free 2-bromomethyl-3-pyridol but the base was prepared in organic solvent by the use of an excess of amine to neutralize the hydrobromic acid. This approach allows the preparation of compounds similar to those obtained by the Mannich reaction in cases where the latter reaction does not occur.

In the preparation of 2-hydroxymethyl-3-pyridol, Urbanski[5a] proved that the hydroxymethyl group is in the 2-position. As proof that the Mannich reaction took the same course, 2-diethylaminomethyl-3-pyridol was synthesized by the reaction of 2-bromomethyl-3-pyridol hydrobromide with diethylamine and on reaction with methyl bromide, (3-hydroxy-2-pyridylmethyl)-diethylmethylammonium bromide was obtained, identical with the substance made by treating the product of a Mannich reaction between 3-pyridol, formaldehyde and diethylamine with methyl bromide.

Brown and Miller[3] have carried out the Mannich reaction with 6-methyl-3-pyridol,[6] formaldehyde and diethylamine, di-*n*-butylamine and piperidine, respectively. In this work we have also used dimethylamine[4a] and methylbenzylamine and prepared the secondary amine by the catalytic debenzylation of the tertiary amine. These compounds are listed in Table I.

It is evident from the work of Urbanski[5b] and Martin and Avakian[4] that the basic group enters the 2-position in 6-methyl-3-pyridol.[7]

A further proof that the basic groups entered the 2-position and not the 4-position was established as follows. In carrying out Urbanski's preparation of 2-hydroxymethyl-3-pyridol, a fraction, isolated as the hydrochloride, was found which analyzed for $C_7H_9O_3N \cdot HCl$ indicating that two hydroxymethyl groups had entered the pyridine ring. The yield was about 20%. Heating with 48% hydrobromic acid gave the corresponding bis-bromomethyl-3-pyridol and this was then reduced to the dimethylpyridol. The product is 2,6-dimethyl-3-pyridol[8] since the same compound was obtained by reduction of 6-methyl-2-bromomethyl-3-pyridol hydrobromide prepared from 6-methyl-3-pyridol.[5b]

The bis-hydroxymethyl compound is probably formed by a secondary reaction between 2-hydroxymethyl-3-pyridol and formaldehyde. This would indicate that the Mannich reaction would probably occur in the 6-position if the 2-position were blocked.

In order to obtain 2-methyl-3-pyridol for further study of the effect of a blocking group in the 2-position, a series of reactions were carried out with the indicated yields

$$\text{3-Pyridol} + CH_2O + (CH_3)_2NH \xrightarrow{70\%} \text{2-Dimethylaminomethyl-3-pyridol} \xrightarrow[87\%]{Ac_2O}$$

(6) McElvain and Goese, THIS JOURNAL, **65**, 2233 (1943), and Parker and Shive, *ibid.*, **69**, 63 (1947), have shown that the product isolated by sulfonation of α-picoline and subsequent alkali fusion is 6-methyl-3-pyridol and not the 2-methyl-3-pyridol claimed by Brown and Miller[3] and Wolff, U. S. Patent 1,880,645-6 (1932).

(7) The structure of 2-methyl-4-dimethylaminomethyl-3-pyridol proposed by Brown and Miller[3] for the Mannich product was accepted by Martin and Avakian[4] and their end-product was, therefore, erroneously assumed to be 2-methyl-4-hydroxymethyl-3-pyridol.

(8) Plazek, *Ber.*, **72**, 577 (1939), prepared 2,6-dimethyl-3-pyridol by nitration of 2,6-lutidine, reduction of the nitro compound to the amine, and diazotization. The product melted at 209°, and the material obtained above melted at 203–204° (uncor.).

$$\text{2-Acetoxymethyl-3-acetoxypyridine} \xrightarrow[82\%]{48\%\ HBr} \text{2-Bromomethyl-3-pyridol hydrobromide} \xrightarrow[90\%]{H_2 + Pd} \text{2-Methyl-3-pyridol hydrobromide}$$

The over-all yield in a typical run was 45%.

The process has the advantage that the product of the Mannich reaction is readily purified by distillation while the Urbanski method yields an impurity in the preparation of 2-hydroxymethyl-3-pyridol, as shown above, which must be removed by fractional crystallization.

The final proof that the basic group would enter in the 6-position if the 2-position were blocked was hoped to be obtained by the conversion of 2-methyl-3-pyridol to 2,6-dimethylpyridol by the series of reactions shown above for the preparation of 2-methyl-3-pyridol from 3-pyridol. The reactions of 2-methyl-3-pyridol have proved to be unlike those of the isomeric 6-methyl-3-pyridol. We have as yet been unable to isolate any pure product from the reaction of 2-methyl-3-pyridol with formaldehyde and dimethylamine or sodium hydroxide. When the first reaction of the series was carried out using diethylamine, the crude product was acetylated directly without further purification but instead of the expected replacement of the basic group by an acetoxy group, a readily distillable acetate was obtained which on hydrolysis by heating with 48% hydrobromic acid gave the hydrobromide of 2-methyl-6(?)-diethylaminomethyl-3-pyridol. The unusual resistance of the basic group to attack by acetic anhydride is in marked contrast with the behavior of the isomeric 6-methyl-2-diethylaminomethyl-3-pyridol.[4]

Investigation of the position of the basic group in the Mannich reaction with 2-methyl-3-pyridol is still in progress, since the possibility of reaction in the 4-position has not been ruled out. However, Perez-Medina, Mariella and McElvain[2] could not isolate any product after an attempted Mannich reaction with 2-methyl-5-hydroxymethyl-3-pyridol.

There is also the possibility of reaction on the methyl group in the α-position although α-picoline itself gives only small yields of a Mannich base. In the case of 6-methyl-3-pyridol there has been no evidence of reaction on the methyl groups.

Experimental

The preparation of 2-dimethylaminomethyl-3-pyridol is representative of the compounds listed in Table I.

2-Dimethylaminomethyl-3-pyridol.—To a solution of 41 g. of 3-pyridol in 65 cc. of water and 67 cc. of a dimethylamine solution (19.5 g. of dimethylamine), 36 cc. of a 35% formalin solution was added. After heating on a steam-bath for two hours, the solvent was removed by distillation *in vacuo* and the residue distilled. The fraction distilling at 86–96° (3.7 mm.) was collected as a light yellow oil that crystallized rapidly; yield, 46 g. (70%). It could be further purified by sublimation *in vacuo* at 60° and 0.3 mm.; m. p. 56–59°.

Anal. Calcd. for $C_8H_{12}ON_2$: N, 18 41. Found: N, 17.86.

Diacetate of 2-Hydroxymethyl-3-pyridol.—A solution of 10 g. of 2-dimethylaminomethyl-3-pyridol in 35 cc. of acetic anhydride was refluxed for one and one-half hours. The solution turned dark brown soon after heating began. Excess acetic anhydride and acetic acid were removed *in vacuo* and the residue distilled. The product was a light yellow oil distilling at 109–110° (0.8 mm.); literature,[5a] 118–122° (4 mm.); yield, 12 g. (87%).

2-Bromomethyl-3-pyridol Hydrobromide.—A solution of 11 g. of the diacetate of 2-hydroxymethyl-3-pyridol in 60 cc. of 48% hydrobromic acid was refluxed for one-half hour. After distillation of 45 cc. of hydrobromic acid, large crystals of 2-bromomethyl-3-pyridol hydrobromide formed on cooling. The crystals were filtered and washed with a small amount of cold water and acetone: yield, 11.6 g. (82%); m. p. 187–188° (dec.); literature,[5a] 182–184°. A portion of the product was recrystallized from a mixture of methanol and ether; m. p. 186–188° (dec.).

Anal. Calcd. for $C_6H_7ONBr_2$: C, 26.79; H, 2.62; N, 5.21. Found: C, 27.08; H, 2.59; N, 5.35, 5.23.

2-Methyl-3-pyridol.—A solution of 125 g. of 2-bromomethyl-3-pyridol hydrobromide in 1 liter of methanol containing 4–5 g. of 3% palladium on charcoal was shaken at room temperature with hydrogen. The theoretical quantity was taken up rapidly. After removal of the catalyst by filtration, most of the solvent was distilled off and anhydrous ether added to turbidity. Crystals of 2-methyl-3-pyridol hydrobromide formed: yield, 79 g. (90%); m. p. 195–197°. Recrystallization from a mixture of methanol and ether did not change the melting point.

Anal. Calcd. for C_6H_8ONBr: C, 37.92; H, 4.24; N, 7.37. Found: C, 37.72; H, 4.23; N, 7.47, 7.33.

The free base melted at 163–165°; literature, 160–161°,[5b] 167–168°.[9]

2-(N-Methylanilinomethyl)-3-pyridol.—A solution of 23 g. of methylaniline in 10 cc. of chloroform was added slowly to a stirred suspension of 27 g. of 2-bromomethyl-3-pyridol hydrobromide in 250 cc. of chloroform. The temperature rose from 26 to 42° and all the material went into solution. The solution was then heated slowly to reflux. When the temperature reached 50°, a crystalline solid began to separate. The mixture was refluxed for one hour, cooled and the crystalline product filtered off: yield, 26 g. (88%); m. p. 176–180° (dec.). Neutralization with sodium carbonate gave a white crystalline precipitate of 2-(N-methylanilinomethyl)-3-pyridol. After recrystallization from 80% ethanol, the product melted at 136–138°; yield, 16 g.

Anal. Calcd. for $C_{13}H_{14}ON_2$: C, 72.87; H, 6.55; N, 13.06. Found: C, 72.91; H, 6.59; N, 12.67.

(3-Hydroxy-2-pyridylmethyl)-diethylmethylammonium Bromide.—To a suspension of 5 g. of 2-bromomethyl-3-pyridol hydrobromide in 50 cc. of chloroform, 6 cc. of diethylamine was added slowly. The mixture became very warm and all the solid went into solution. After refluxing for one-half hour, the solvent was boiled off and the residue dissolved in water. After neutralization with sodium bicarbonate and evaporation to dryness, an acetone extract of the residue was treated with a 25% solution of methyl bromide in acetone. On standing in the refrigerator, crystals of (3-hydroxy-2-pyridylmethyl)-diethylmethylammonium bromide formed. After recrystallization from a mixture of methanol and ether, the product melted at 132–133° (dec.).

Anal. Calcd. for $C_{11}H_{19}ON_2Br$: C, 48.01; H, 6.96; N, 10.18. Found: C, 48.08; H, 7.13; N, 10.04.

2-Methylaminomethyl-6-methyl-3-pyridol Dihydrochloride.—To a prehydrogenated suspension of 1 g. of 3% palladium on charcoal in 50 cc. of methanol, 2.0 g. of (3-hydroxy-6-methyl-2-pyridylmethyl)-methylbenzylamine dihydrochloride was added. The theoretical amount of hydrogen was taken up after shaking for one-half hour at atmospheric pressure. The catalyst was removed by filtration and the solvent distilled off. The product was recrystallized from ethanol; m. p. 226–230° (dec.).

(9) Dornow, *Ber.*, **73B**, 78 (1940).

2,6-bis-Hydroxymethyl-3-pyridol Hydrochloride.—Nineteen grams of 3-pyridol was dissolved in 100 cc. of an aqueous solution containing 8 g. of sodium hydroxide. After addition of 42 cc. of a 35% formaldehyde solution, the reaction mixture was kept at room temperature for one hour and then heated on the steam-bath for two hours. The color was a light amber. It was then cooled, acidified with 15 cc. of glacial acetic acid, concentrated to dryness *in vacuo*, and the solid residue extracted with 2 liters of boiling acetone. After removal of the acetone by distillation, the residue was dissolved in about 200 cc. of 9 *N* alcoholic hydrochloric acid. Crystals formed within five minutes. They were kept in the refrigerator overnight, filtered, washed with acetone, and dried; yield, 28 g. About 16 g. of this material was dissolved in 50 cc. of water and acetone added to turbidity. Overnight in the refrigerator, 1.4 g. of 2-hydroxymethyl-3-pyridol hydrochloride crystallized. The melting point was not sharp but the compound darkened slowly above 170° and then decomposed above 200°. On addition of acetone to the filtrate, an additional 2.6 g. of the same material was isolated. At this point, 1175 cc. of acetone had been added. Addition of 900 cc. of acetone to the filtrate gave 10.5 g. of crystalline material, m. p. 135–139°. This fraction was recrystallized from 30 cc. of water and 300 cc. of acetone. This gave 5 g. of 2,6-bis-hydroxymethyl-3-pyridol hydrochloride, m. p. 143–146°. An additional 3.6 g. melting at 136–144° was isolated from the mother liquors. Recrystallization of the product melting at 143–146° from a mixture of methanol and ether raised the m. p. to 145–147°.

Anal. Calcd. for $C_7H_{10}O_3NCl$: C, 43.87; H, 5.26; N, 7.31; Cl, 18.50. Found: C, 44.37; H, 5.37; N, 7.61; Cl, 18.21, 18.52.

2,6-bis-Bromomethyl-3-pyridol Hydrobromide.—A solution of 4.5 g. of 2,6-bis-hydroxymethyl-3-pyridol hydrochloride in 100 cc. of 48% hydrobromic acid was refluxed for one hour. On concentration to a small volume *in vacuo*, crystals of 2,6-bis-bromomethyl-3-pyridol hydrobromide separated. They were filtered, washed with cold water, acetone, and ether, and dried, m. p. 186–188°. Two recrystallizations from a mixture of methanol and ether raised the m. p. to 188–190°.

Anal. Calcd. for $C_7H_8ONBr_3$: C, 23.23; H, 2.23; N, 3.87. Found: C, 23.16; H, 2.04; N, 3.88.

2,6-Dimethyl-3-pyridol.—To a prehydrogenated suspension of 1 g. of 3% palladium on charcoal in 50 cc. of methanol, 2.4 g. of 2,6-bis-bromomethyl-3-pyridol hydrobromide was added. The theoretical amount of hydrogen was taken up rapidly at room temperature and atmospheric pressure. After removal of the catalyst by filtration, most of the solvent was distilled off. Anhydrous ether was then added to turbidity and crystallization of 2,6-dimethyl-3-pyridol hydrobromide occurred rapidly on scratching; m. p. 183–185°. Recrystallization from a mixture of methanol and ether did not change the m. p.

Anal. Calcd. for $C_7H_{10}ONBr$: C, 41.20; H, 4.94; N, 6.86. Found: C, 40.83; H, 5.03; N, 6.90, 6.98.

The free base, m. p. 200–203°, was purified for analysis by sublimation at 0.4 mm. and a bath temperature of 100–110°. The sublimate melted at 202.5–204°.

Anal. Calcd. for C_7H_9ON: C, 68.27; H, 7.37; N, 11.37. Found: C, 68.12; H, 7.40; N, 11.38, 11.47.

Acetate of 2-Methyl-6(?)-diethylaminomethyl-3-pyridol.—To a solution of 10.9 g. of 2-methyl-3-pyridol and 7.3 g. of diethylamine in 25 cc. of water, 9 cc. of a 35% formaldehyde solution was added. The mixture was kept at room temperature for five days, and then warmed for one hour on a steam-bath. An oily layer, that seemed to be soluble in the cold and insoluble when hot, began to separate soon after heating began. On removal of the solvent by distillation *in vacuo*, the residue set to a solid. It was dissolved in 75 cc. of acetic anhydride and refluxed for one hour. The excess of acetic anhydride was distilled off *in vacuo* and the residue then distilled. A rough cut boiling at 78° (5 mm.)–120° (0.5 mm.) was taken and then redistilled. The acetate was collected in the fraction boiling at 111–115° (1.4 mm.); yield, 10.5 g.

2-Methyl-6(?)-diethylaminomethyl-3-pyridol.—A solution of 10.5 g. of acetate of 2-methyl-6(?)-diethylaminomethyl-3-pyridol in 50 cc. of 48% hydrobromic acid was refluxed for one-half hour. After removal of 35 cc. of hydrobromic acid by distillation, addition of acetone to the cooled residue gave crystals of 2-methyl-6(?)-diethylaminomethyl-3-pyridol hydrobromide. The product was filtered and washed with acetone. It melted at 219–220° (dec.); yield, 12 g. Recrystallization from a mixture of methanol and ether did not change the melting point.

Anal. Calcd. for $C_{11}H_{20}ON_2Br_2$: C, 37.10; H, 5.66; N, 7.87. Found: C, 37.29; H, 5.59; N, 7.91.

The free base was liberated with sodium carbonate, the solution evaporated to dryness *in vacuo*, and the base extracted with acetone. After removal of acetone, the free base was recrystallized from benzene; m. p. 139–141°.

Anal. Calcd. for $C_{11}H_{18}ON_2$: C, 68.00; H, 9.34; N, 14.42. Found: C, 68.20; H, 9.03; N, 14.26.

Acknowledgment.—The authors wish to express their appreciation to Dr. J. A. Aeschlimann for many helpful discussions during this investigation. We are also indebted to Mr. L. A. Dolan for the preparation of 3-pyridol and to Dr. A. Steyermark and his staff for the microanalyses reported in this paper.

Summary

Methods of preparation of 2-(substituted amino)-methyl-3-pyridols have been described.

The Mannich reaction with 6-methyl-3-pyridol has been extended.

An improved synthesis of 2-methyl-3-pyridol is described.

2,6-bis-Hydroxymethyl-3-pyridol has been isolated as a by-product in the preparation of 2-hydroxymethyl-3-pyridol.

The behavior of 2-methyl-3-pyridol in the Mannich reaction is discussed.

The Equilibria of Nickel Hydroxide, $Ni(OH)_2$, in Solutions of Hydrochloric Acid and Sodium Hydroxide at 25°

BY KARL H. GAYER AND A. B. GARRETT

The purpose of this investigation was to obtain data on the equilibria of nickel hydroxide in dilute solutions of sodium hydroxide and hydrochloric acid. Such data make possible (1) the determination of the character of the ions in dilute solutions, (2) the evaluation of the free energy of formation of these ions, (3) the evaluation of the solubility and the solubility product of nickel hydroxide, and (4) the amphoteric nature of the hydroxide.

Previous work on nickel hydroxide is at variance as to the magnitude of the water solubility and the solubility product. Almkvist[1] reported the solubility of nickel hydroxide to be 1×10^{-4} mole at 20°. Britton[2] calculated the solubility product to be 2.07×10^{-17} at 25°; while Wijs[3] reported a value of 1.6×10^{-14}.

No work is reported which can be used to show the complete record of the behavior of nickel hydroxide in acid and basic solutions; data for that record are presented in this paper.

Procedure

The general procedure is similar to that in a previous paper by Garrett and Heiks.[4]

Water.—Triply distilled water was used. It was boiled to free it from carbon dioxide and oxygen then it was stored under nitrogen.

Sodium Hydroxide Solutions.—Baker and Adamson Reagent sodium hydroxide pellets were dissolved in freshly boiled distilled water; barium hydroxide was added in slight excess to precipitate all the carbonate. The solutions were standardized against potassium acid phthalate using phenolphthalein indicator.

Nickel Nitrate Solutions.—Mallinckrodt C. P. reagent was used to prepare the hydroxide and to prepare the standards for the colorimetric determination of nickel.

Hydrochloric Acid Solutions.—Standard solutions for analysis and for the solubility measurements were prepared from C. P. reagent and standardized gravimetrically.

Other Reagents.—Nickel ammonium sulfate was used to prepare a second set of colorimetric and polarographic standards. A 1% alcoholic solution of dimethylglyoxime was prepared as specified by Sandell.[5]

Nickel Hydroxide.—The nickel hydroxide was prepared is an atmosphere of nitrogen. A hot solution containing 1 g. of nickel nitrate hexahydrate per liter of water was precipitated with an equal volume of 0.02 molar solution of sodium hydroxide. Ten two-liter washings of distilled water sufficed to give pure nickel hydroxide as evidenced by the total absence of sodium from a flame test.

Equilibration.—Two 180-ml. samples contained in 200-ml. round-bottom flasks were always prepared at each concentration of alkali or acid. One sample was agitated in a thermostat at 35° for a period of five to seven days, then transferred to the thermostat at 25 ± 0.02° for an additional period of seven days. The mates were placed directly in the 25° thermostat for five to seven days. By this means, equilibrium was approached from supersaturation and undersaturation. Both values were found to check within experimental limits.

Sedimentation.—After the completion of the agitation period, the flasks were clamped in an upright position in the 25° thermostat, and allowed to sediment for seven days.

Filtration.—The flasks were opened and the contents removed under an atmosphere of nitrogen to a covered sintered glass funnel and from this into a glass-stoppered bottle.

Measurement of Hydrogen Ion Concentration.—The *p*H values of the equilibrated samples were obtained by using a Beckman portable a. c., glass electrode. The meter was calibrated with potassium acid phthalate–sodium hydroxide buffer at *p*H 4, with disodium phosphate–monopotassium phosphate buffer at *p*H 7 and with boric acid–sodium hydroxide buffer at *p*H 10.

Analysis of Nickel.—The nickel analysis of the equilibrated samples was made with a Lumetron spectrophotometer using dimethylglyoxime to produce the colored complex; the method is described by Sandell.[5] The analyses were reproducible to ±2%.

The data are collected in Tables I and II and are shown graphically in Figs. 1, 2, and 3. Figure 1 shows the change of solubility of nickel hy-

droxide in hydrochloric acid solutions and Fig. 2 shows the change of solubility of nickel hydroxide in dilute hydrochloric acid solutions with the

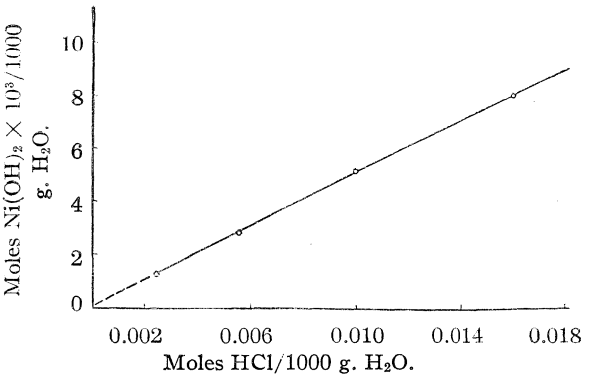

Fig. 2.—Solubility of nickel hydroxide in hydrochloric acid solution.

extrapolation to *p*H 7. Figure 3 shows the change of nickel hydroxide solubility near *p*H 7. Due to the extremely low solubility of nickel hydroxide in water and basic solutions, the inflection of the curve in Fig. 3 is drawn by interpolation and shows the most probable change.

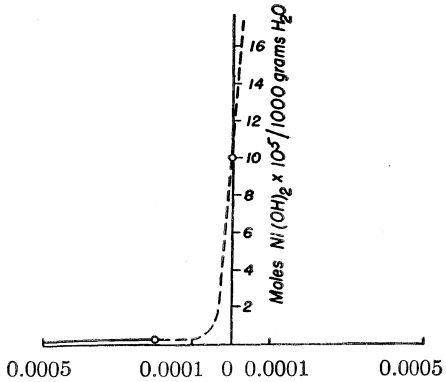

Fig. 3.—Change of nickel concentration near *p*H 7.

The high solubility of nickel hydroxide in acid solutions along with the *p*H values of these solutions (in the order of *p*H 7) and the low solubility of nickel hydroxide in basic solutions give qualitative evidence that nickel hydroxide is a strong base. Quantitative evidence for the basic character of nickel hydroxide is given by the values of the acidic and basic ionization constants.

The solubility of nickel hydroxide in sodium hydroxide solution was checked by means of several radioactive tracer experiments using the $^{58}_{27}$Ni isotope (half life of 36 hours). The nickel was prepared by alpha bombardment of iron in The Ohio State University Cyclotron.

The values for the activity coefficients for hydroxyl ions and divalent nickel ions were taken from Harned and Owen.[6]

General Equilibria.—In general the possible equilibria of nickel hydroxide in neutral, acidic and alkaline solutions may be represented by equations (1) to (8).

(1) $Ni(OH)_2(s) \rightleftarrows Ni^{++} + 2OH^-$

(2) $Ni(OH)_2(s) \rightleftarrows NiOH^+ + OH^-$

(3) $Ni(OH)_2(s) + OH^- \rightleftarrows HNiO_2^- + H_2O$

(4) $Ni(OH)_2(s) + 2OH^- \rightleftarrows NiO_2^= + 2H_2O$

(5) $Ni(OH)_2(s) + H^+ \rightleftarrows NiOH^+ + H_2O$

(6) $Ni(OH)_2(s) + 2H^+ \rightleftarrows Ni^{++} + 2H_2O$

(7) $Ni(OH)_2(s) \rightleftarrows HNiO_2^- + H^+$

(8) $Ni(OH)_2(s) \rightleftarrows Ni(OH)_2$

The value of K_8 is in the order of 10^{-7} and is too small to affect the values of K_3 and K_6 within the limits of their determinations from these data.

Equilibria in Basic Solutions.—Unfortunately the solubility of nickel hydroxide in alkaline solutions up to 15 molar sodium hydroxide was found to be so slight that only estimates of its solubility could be made by the analytical means available. We can make the very probable assumption that the solubility of nickel hydroxide in alkali is due to the reaction indicated by equation (3).

$$Ni(OH)_2(s) + OH^- \rightleftarrows HNiO_2^- + HOH \quad (3)$$

Values of K_3 calculated over the range of 0.0016 to 0.1 molar sodium hydroxide give an average value of $K_3 = 6 \times 10^{-5} \pm 5 \times 10^{-5}$ with a corresponding ΔF° of 6000 cal.

Using the value for K_3 and K_w, the ionization constant for water at 25°, the ionization constant K_7

$$Ni(OH)_2(s) \rightleftarrows HNiO_2^- + H^+ \quad (7)$$

for nickel hydroxide was computed

$$K_7 = K_3K_w/a_{H_2O} = 6 \times 10^{-19}$$
$$\Delta F^\circ = 25{,}000 \text{ cal.}$$

Equilibria in Acid Solutions.—The data of columns 1 and 3 of Table II indicate that equation 6 can account for the chemical change involved; if any $NiOH^+$ ions are present, they must

(6) Harned and Owen, "The Physical Chemistry of Electrolytic Solutions," Reinhold Publishing Corp., New York, N. Y., 1943, pp. 384, 423.

be so in small amounts. The value of K_6 was obtained by the use of the a_{H^+} measured by the glass electrode

$$Ni(OH)_2(s) + 2H^+ \rightleftharpoons Ni^{++} + 2H_2O \qquad (6)$$

$$K_6 = \frac{m_{Ni^{++}}\gamma_{Ni^{++}}}{m^2_{H^+}\gamma^2_{H^+}} = 6.5 \times 10^{10}$$

$$\Delta F^\circ = -15{,}000 \text{ cal.}$$

the values of $m_{Ni^{++}}$ are given in column 3 of Table II, and the values of $\gamma_{Ni^{++}}$ were obtained from a table of activity coefficients for divalent ions compiled by Harned and Owen.[6] Further evidence that the reaction indicated by equation 5 has little or no effect on the value of K_6 is the constancy of K_6 over the concentration range of $m_{HCl} = 0$ to 0.1. The error in K_6 is in the order of $\pm 0.5 \times 10^{10}$.

The high solubility of nickel hydroxide in acid solution and its low solubility in alkaline solution indicate qualitatively that nickel hydroxide is a relatively strong base. Finally, the calculated values of the acid and base constants of nickel hydroxide fully verify the strong basic character.

The Value of the Water Solubility at 25°.—The value of the water solubility of nickel hydroxide, 1.0×10^{-4}, was determined by extrapolating the solubility of nickel hydroxide in dilute acid solution of $m_{HCl} = 0$ (see Figs. 2 and 3). The extrapolation was made graphically (large scale) by the aid of the value of the slope of the line obtained in 0.006 to 0.05 molal acid solutions. This procedure was necessary because the solubility of nickel hydroxide in water is below that which can be determined accurately by any classical chemical method. Furthermore, this is probably a more accurate value than could be obtained by direct measurement, were a satisfactory method of analysis available, because of the error involved in a direct measurement due to (1) any adsorbed hydroxyl ions on the nickel hydroxide and (2) the colloidal nature of highly purified samples of nickel hydroxide. The value of the water solubility is probably good to $\pm 0.5 \times 10^{-4}$.

The Solubility Product Constant.—From the value of the ion product K_w of water and $K_6 = 6.5 \times 10^{+10}$ obtained from the solubility of nickel hydroxide in acid, the solubility product constant K_1 was calculated for the equation

$$Ni(OH)_2(s) \rightleftharpoons Ni^{++} + 2OH^- \qquad (1)$$

$$K_1 = \frac{K_6 K^2_w}{a^2_{H_2O}} = m_{Ni^{++}}\gamma_{Ni^{++}} m^2_{OH^-}\gamma^2_{OH^-}$$

$$K_1 = 6.5 \times 10^{-18}$$

$$\Delta F^0 = 23{,}000 \text{ cal.}$$

Summary

The solubility of nickel hydroxide has been determined in dilute acid and base at 25 ± 0.02°. The data show nickel hydroxide to be a relatively strong base. The reactions occurring in basic and acid solution are shown by equations

$$Ni(OH)_2(s) + OH^- \rightleftharpoons HNiO_2^- + H_2O \qquad (3)$$

$$Ni(OH)_2 + 2H^+ \rightleftharpoons Ni^{++} + 2H_2O \qquad (6)$$

The value for the solubility product of nickel hydroxide, is 6.5×10^{-18}. The value for the water solubility of nickel hydroxide is 1.0×10^{-4}. The acid dissociation constant of nickel hydroxide is 6×10^{-19}.

Measurement of the Capacity of the Electrical Double Layer at a Mercury Electrode

BY DAVID C. GRAHAME

It has long been known that the slope of the electrocapillary curve of a liquid metal in a salt solution gives the surface charge density of electricity at the interface.[1-5] In a like manner the second derivative of the electrocapillary curve gives the differential capacity,[3,4] a quantity which can also be measured directly with fair precision. It is less well known that from the interfacial tension or from the differential capacity one can obtain a considerable amount of further information about the electrical double layer. For example, it is possible to calculate the charge contributed by each ion separately,[4] the entropy and enthalpy changes associated with the electrochemical process which accompanies an infinitesimal transfer of charge through the cell,[6] and other less easily described properties.[6] In addition there are certain non-thermodynamic properties which are obtained by combining the thermodynamic properties with quantities calculated from the kinetic theory of the electrical double layer.[4] All this has been discussed elsewhere.

It is a matter of great difficulty to make interfacial tension measurements with sufficient precision to serve for these calculations, and we have accordingly attempted to develop apparatus for the precise measurement of the differential capacity of the double layer at a mercury surface. Two models of this apparatus have already been described.[3,7] Considerable changes have now

been made, and it is the principal function of the present paper to describe these changes, which are of importance to anyone planning a duplication or extension of the work. Some results obtained with the new form of the apparatus are also described.

Experimental Method

In principle the method remains unchanged. A droplet of mercury forms at the tip of a fine capillary (o. d. *ca.* 0.10 mm., i. d. *ca.* 0.04 mm.), Fig. 1, under the deaerated solution to be investigated. A second electrode, for which we use a platinized platinum gauze sphere Pt, with openings at the poles, surrounds the mercury droplet symmetrically. The system mercury–solution–platinum now forms a cell somewhat like a conductivity cell except that we are primarily interested in its capacity rather than its resistance. This cell is made the fourth arm of a bridge which differs from conventional conductance bridges primarily in that it measures the *series capacitance* of the cell. Stray capacitance and inductance must be severely limited, the effects being minimized by the use of a low frequency; 1000 cycles is convenient and sufficiently low, with good technique, for tenth-normal and possibly hundredth-normal salt solutions, but below this concentration the unavoidable bridge errors become large and a lower frequency must be used. The results obtained are believed to be independent of frequency within the experimental error.[7]

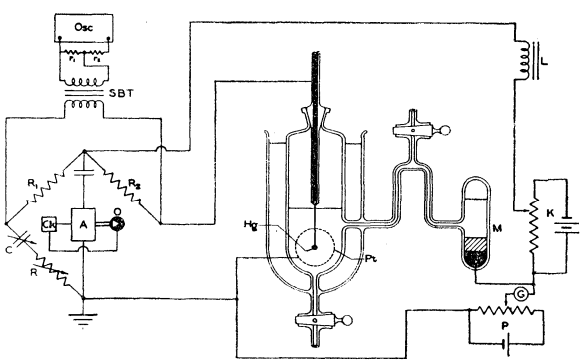

Fig. 1.—Schematic representation of the apparatus used for the determination of the capacity of the electrical double layer at a mercury–solution interface. The cell shown schematically here is depicted in more detail in Fig. 3 of the following paper.

The capacity of the double layer in contact with the platinum is enormous because of its relatively large surface area. Thus the observed capacity is sensibly the capacity of the double layer in contact with the mercury, the two capacitances being in series.

Because the capacity of the electrical double layer depends upon the d. c. potential, an additional electrode is required. Usually a calomel electrode is employed, especially when chlorides are to be investigated. A type K potentiometer, K, is used to impose a potential upon the double layer, as shown in Fig. 1. In order to keep the d. c. resistance from the mercury to the potential-fixing electrode as low as possible, the platinum gauze electrode in the solution is employed as the potential-fixing electrode. Since its potential wanders in an unpredictable manner relative to that of the calomel electrode M, the potential difference between the two is measured with a conventional potentiometer–galvanometer system P–G, and the difference applied as a correction to the potential imposed by the other potentiometer. In the circuit shown, the potentiometer P not only measures the correction but also applies it simultaneously, so that no actual reading of the magnitude of the correction is required.

An important new feature of the circuits was the inclusion of wholly different timing methods from those previously described. Since the mercury droplet is constantly growing in size until it falls, it is necessary to measure the time interval from the moment of its "birth" to the moment at which the bridge is balanced. Knowing the rate of flow of the mercury, which is also measured, it is then a simple calculation to find the area of the droplet at the moment of bridge balance. It may be mentioned in passing that the measured capacity is proportional to this area, other things being equal, as accurately as can be measured from 0.2 sec. after the "birth" of the droplet until just before the moment of fall, perhaps five seconds later.

The new method of timing is as follows: When a droplet falls, it produces a very abrupt change in the amplitude of the signal representing the degree of unbalance of the bridge. This signal is rectified or "detected" and applied to the grid of a thyratron which actuates a relay which starts a high-speed (2 r. p. s.) interval timer, Ck, Fig. 1. The interval timer is arranged so that with every revolution of the hand it produces a pulse which starts the sweep of the oscilloscope on which the bridge unbalance is presented. The sweep presents an expanded view of the manner in which the state of the bridge balance varies with time. A long-persistence screen is necessary, since successive sweeps do not present the same pattern. When R and C are adjusted to values such that a moment of perfect balance occurs during the lifetime of a droplet, one sees on the oscilloscope screen a pattern like that depicted in Fig. 2. The moment at which this state of perfect balance occurs is ascertained by means of auxiliary markers obtained from the clock and presented on the screen.

The instrumental accuracy is estimated at 0.1% or better in tenth-normal solutions under not-too-unfavorable conditions. Systematic errors not associated with the electrical circuits as such probably produce somewhat greater errors, perhaps up to 1% in unfavorable cases.

The rate of flow of the mercury is ascertained

by weighing the mercury delivered from the capillary over an interval of about 500–1000 seconds. The rate of flow was usually of the order of 0.8 mg./sec., although capillaries with rates ranging from 0.5 to 1.5 mg./sec. have been used satisfactorily.

The solutions were deaerated with nitrogen. It was not found necessary to remove the last traces of oxygen.

Experimental Results

In the development of the above technique, a tenth-normal solution of twice recrystallized potassium chloride in conductivity water was most often used for test purposes. Most of the measurements at this concentration were taken at 1000 cycles and at 25°. The results obtained are given in Table I, together with values of the first and second integrals with respect to potential. The integration was done by numerical summation, using segments 10 mv. wide in the potential interval 0.14–1.90 volt, and one mv. wide in the potential interval 0–0.14 volt. The adequacy of this procedure was checked by checking certain "critical" regions over still smaller intervals.

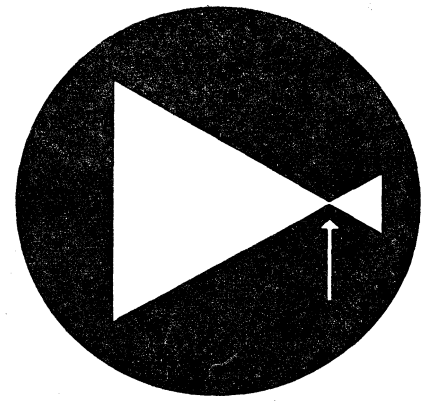

Fig. 2.—Appearance (except for the arrow) of the oscilloscope screen during a measurement. The pattern is a sine wave of variable amplitude, but because of the relatively slow sweep speed (~10 in./sec.) the sine waves are not resolved. At the point marked by the arrow the bridge is in a state of balance. A mark is made on the screen indicating the position of the sweep at a known time after the birth of the mercury droplet, and the bridge is adjusted to make its moment of balance coincident with this mark.

The results are mostly given to one more place (in small figures) than the absolute accuracy of the data warrants because the differences are known more accurately than the absolute values. The first column in Table I gives the potential relative to a normal calomel electrode. The liquid junction between normal and tenth-normal potassium chloride is not, of course, a source of any uncertainty. The second column gives the differential capacity C in microfarads per sq. cm. A plot of these data is not noticeably different from a plot already published[4] for tenth-normal sodium chloride. Minima occur at $E = 0.23$ and 1.15 volts. The intervening maximum occurs at $E = 0.35$ volt. The third column gives the value of $\int CdE$ starting from the potential of the electrocapillary maximum which we take at $E = 0.506$ volt as found in the following paper. The values of $\int CdE$ given in column 3 represent the surface charge density of electricity, as one can readily deduce from our two opening remarks.

Column 4 gives values of $\int\int Cd^2E$ where the second constant of integration has been arbitrarily set at zero at the potential of the e. c. max. At 18° its true value would be 426.7 ergs/cm.^{2} according to Gouy,[8] and it is usually considered that this changes very little with temperature, although there seem to be no published data on the matter. Fortunately, it is of minor consequence. Except for this slight uncertainty as to the magnitude of the additive constant, this

(8) Gouy, *Compt. rend.*, **146**, 1374 (1908); *Ann. phys.*, [9] **6**, 25 (1916).

column then gives the electrocapillary curve of tenth-normal potassium chloride. There are no published data of high precision with which to compare these results.

Discussion of Results

A rather full treatment of the significance of electrocapillary data has been published in another place.[4] The data here presented differ from those already published for *sodium* chloride[4] by only a small amount, the differential capacities of the two chlorides being within 2% of one another at comparable potentials over the range of potentials $E = 0.01$ to 1.2 volts. This great similarity indicates that sodium and potassium ions are hydrated in the double layer, since otherwise their different radii would necessarily be reflected in their capacities. Investigations with other cations now under way also point to this conclusion.

A further interpretation of the data (beyond that given in reference 4) has been attempted, but since it is not the purpose of this paper to present an extensive theoretical treatment of the electrical double layer, this interpretation will be postponed. For the present we shall be content to show, in the following paper, how the differential capacity may be used in conjunction with other data to give a fairly precise value of the potential of the e. c. max.

Summary

1. Recent modifications in the author's apparatus for measurement of the capacity of the electrical double layer at a mercury surface in contact with aqueous salt solutions are described.

2. The differential capacity of the electrical double layer, the surface charge density, and the electrocapillary curve of mercury in tenth-normal potassium chloride are presented in tabular form.

The Potential of the Electrocapillary Maximum of Mercury

BY DAVID C. GRAHAME, ROBERT P. LARSEN[1] AND MARILYN A. POTH

The potential of the electrocapillary maximum (e. c. max.) of mercury in contact with aqueous solutions is of the first importance in any theoretical or experimental study of the electrical double layer at such an interface. In addition to its direct thermodynamic significance, it has interest in connection with the kinetic theory of the electrical double layer, and a knowledge of its value is indispensable if one wishes to make full use of the very extensive information provided by studies of the differential capacity of the electrical double layer. In particular, integration of the last-named quantity with respect to potential gives the magnitude of the surface electronic charge except for a constant of integration, which is *zero* if the integration is begun at the potential of the electrocapillary maximum.

To the authors' knowledge there are only four papers on this subject, plus a few incidental measurements of the potential of the e. c. max. to be mentioned later. The first paper of importance in this connection, by Paschen,[2] uses a technique which has not been successful in the hands of later workers (who have found it necessary to remove dissolved oxygen), and it therefore comes as a surprise to find, as a result of the present work, that Paschen's values are very nearly correct. The second paper is by Gouy,[3] whose values of the e. c. max. potential are often quoted, but which the authors now believe to be somewhat in error for reasons explained below. A third paper by Winkel and Siebert,[4] gives value which sometimes agree and sometimes disagree with those of Gouy. The fourth paper, by Erdey-Gruz and Szarvas,[5] is difficult to compare with the others because these authors employed a saturated potassium chloride salt bridge, unlike the rest, and so measured a somewhat different quantity. We have attempted to make the conversion in a few simple cases and find satisfactory agreement with our own results when this is done.

The present authors have measured the potential of the electrocapillary maximum of mercury in tenth-normal potassium chloride and sodium chloride by five more or less independent methods. It is the principal function of this paper to describe these methods and their results.

Principle of Experimental Methods I, II and III

It is desirable to describe first the main principle upon which the first three methods depends. These three methods are really only variants of a single method, but since the least certain measurement is carried out differently in the three variants, we regard them as essentially independent.

Suppose that one knows the differential capacity of the electrical double layer in the solution in

question as a function of the potential relative to any convenient reference electrode. Suppose that one now assumes a value of the e. c. max. potential relative to the same electrode. By integrating the differential capacity from the assumed potential of the e. c. max. one obtains the corresponding values of the surface charge density of electrons, as has been done in the preceding paper.[6] A further integration starting from the same point gives the *shape* of the electrocapillary curve, but not the absolute magnitude of the interfacial tension at any point. This latter need not be known for the method we are describing. Results of this second integration are also given in the preceding paper.

A horizontal line drawn through the electrocapillary curve intersects it at two points of equal interfacial tension. The two potentials thus defined will be called isotension potentials. The average (or the sum) of these pairs of potentials will be a constant in the ideal case of an electrocapillary curve symmetrical about a vertical axis. In a typical real case (0.1 *N* potassium chloride) the sum or average changes by about 20% over the experimentally studied portion of the electrocapillary curve.

One can plot the sum of the isotension potentials against any convenient parameter, and as far as the methods we are discussing now are concerned, it would suffice to plot the sum against either one of the two components of the sum. In connection with another method (IV) to be described below, it is desirable to plot the sum against *both* components of the sum, and this has been done in Fig. 1. In Fig. 2 the same calculated points are shown, but in this case only the right-hand branch of the curve has been represented. In Figs. 1 and 2 the solid circles are taken from the electrocapillary curve calculated in the preceding paper.[6] It should be recalled that these points depend upon an assumed value of the potential of the e. c. max.

If one had assumed a value 1 mv. greater, the solid circles would have lain almost exactly 2 mv. above the ones shown and so on. Thus one can compute a *family* of curves, of which only one member is shown, corresponding to various assumed values of the e. c. max. These computations have been made. If the differential capacity measurements were in error by 1% over the range of potentials where such an error would have its greatest effect, an error of about 0.7 mv. would be introduced into the final result. A more likely estimate of the uncertainty arising on this account is ±0.3 mv.

It will be apparent that if one can observe a pair of isotension potentials on a capillary electrometer or otherwise, one can select from the family of curves that member corresponding to the correct value of the e. c. max. Three methods of observing isotension potentials will be described which, taken together with the above curves, constitute what we shall call methods I, II and III.

A fourth and fifth method of obtaining the e. c. max. potential are described below.

Experimental Methods

Method I.—We shall describe first the method developed last and considered by us to provide the most reliable results. In this method we determine isotension potentials with a capillary electrometer modeled after that used by Gouy[3] but improved and modified to take advantage of the increased accuracy made possible by the fact

that we do not need to measure the height of the mercury column but only to hold it constant. Our instrument is shown in Fig. 3. The solution to be investigated is deaerated either in the reservoir A or in the main body of the cell B. Two electrodes are used, a working electrode C and a primary standard D. In the work to be described in this paper, the latter was silver chloride in tenth-normal potassium chloride, prepared in the manner of Noyes and Ellis.[7] The working electrode was also of this type, except that the electrolyte was whatever chloride happened to be under investigation. By refilling the cell B with tenth-normal potassium chloride, the potential of the working electrode could be compared with that of the primary standard and checked for its proper operation.

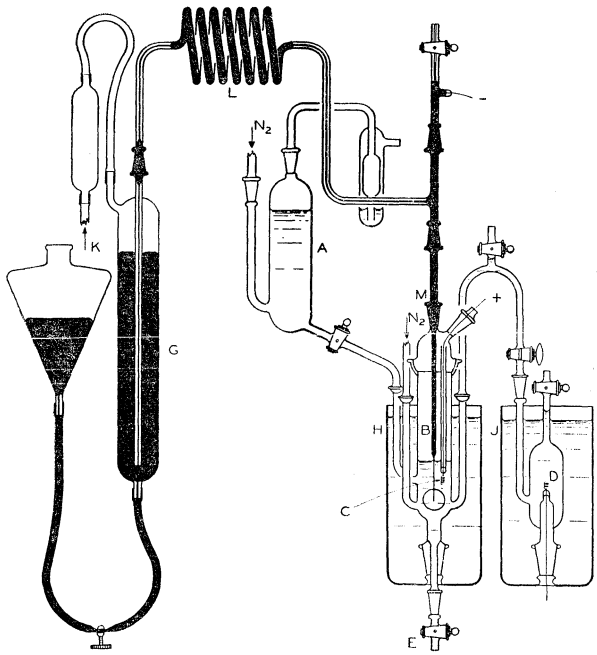

Fig. 3.—Differential capillary electrometer.

The capillary was drawn from Pyrex glass tubing and was approximately 1 mm. o. d. and 0.06 mm. i. d. The stopcock at the bottom of the cell was not greased for most of the measurements reported in this paper, but it was later found that Apiezon L grease could be used without deleterious effect, presumably because it was soon covered by mercury and was not in any case in intimate contact with the solution near the capillary. The ground-glass joints were not greased but were provided with mercury cups (not shown) except in the case of joint M, which was of the feed-through type, and therefore not susceptible to leakage. This construction made it easy to remove the capillary for cleaning whenever that became necessary.

The flexible tubing which connects the leveling bulb to the vertical reservoir was of Tygon tubing (a flexible semi-transparent plastic).[8] The rubber tubing K connects to a mouthpiece which can be used to oscillate the mercury in the capillary in the manner recommended by Gouy.[3] This is an indispensable feature of the apparatus. Two water jackets, H and J, were used to control the temperature of the cells, although temperature control is hardly necessary, since the temperature coefficient of the effect being measured is very small.

The main body of the cell and also the water jacket were provided with windows of optically flat glass. The former was fused into the cell, the latter was held on with picein wax. A cathetometer with a short travel, but with high magnification, made it possible to observe differences in level of the mercury in the capillary of the order of 0.002 mm.

The treatment of the capillary has been given much attention by those who have worked in this and similar fields. We have found it possible and desirable to clean the capillaries in very hot cleaning solution (sulfuric acid + sodium chromate). The subsequent rinsing is done in such a manner as to prevent dust-laden air from being drawn through the capillary. When this was not done, bits of lint lodged in the capillary could be seen under the microscope. It was not necessary to dry the capillary. Sometimes this treatment did not suffice to produce a clean capillary. In these cases a very brief (five seconds) treatment with 50% hydrofluoric acid always sufficed to overcome the difficulty. The enlargement of the capillary was not noticeable, nor was it rendered translucent. This cleaning of the capillary with hydrofluoric acid was sometimes done without removing it from the cell. For this purpose equal parts of 0.2 *N* potassium chloride and 50% hydrofluoric acid were mixed and introduced into the cell in order to avoid "shocking" the silver chloride working electrode. No damage to the cell, the optical flats, the stopcocks or the electrode was noted. Sometimes tenth-normal hydrochloric acid alone would suffice to clean the capillary *in situ* in case it had become contaminated with the hydroxides of the heavy metals when solutions of their chlorides were introduced.

Theoretical considerations indicate that the capillary should be very slightly tapered in order to achieve stability. The sensitivity depends upon the magnitude of the taper. Apparently some taper is always achieved when the capillary is drawn, but the behavior of seemingly identical capillaries might be found to be very different depending upon the amount of taper present.

The glass spiral L is intended to give flexibility to the top piece so that it can be removed and replaced.

(7) Noyes and Ellis, THIS JOURNAL, **39**, 2532 (1917).

(8) In a later model (not used in the measurements here reported and therefore not represented in the figure) we have eliminated the clamp, which causes incipient cracking of the tubing, by connecting the top of the leveling bulb to the top of the vertical reservoir by another piece of Tygon tubing.

It was found by experiment that the same results were obtained whether the solutions were deaerated or not.[9] Deaeration is desirable as a means of reducing the current flow (and thus protecting the working electrode) when mercury droplets are expelled from the tip. It would also seem to be desirable to prevent the products of the reduction of oxygen from accumulating at the mercury surface where measurements are being taken, but, very surprisingly, no effect traceable to this cause has been observed.

Two calibrated Leeds and Northrup student potentiometers were employed to fix the potential. These were wired in the usual manner and provided with a switch which made it possible to change over rapidly from one to the other. Thus the interfacial tension at two potentials could be the more readily compared. The technique employed in making measurements was as follows: The potential of the mercury in the capillary would be brought to such a value on the descending (cathodic) branch of the electrocapillary curve that the equilibrium position of the mercury would lie approximately one mm. from the tip of the capillary. In order to be sure that the mercury surface was clean, a droplet of mercury would be expelled by blowing gently upon the mouthpiece attached to the rubber tube K. There was usually no difficulty in obtaining reproducible values on this branch of the curve. Another droplet of mercury would then be expelled, and with the mercury flowing, the potential would be switched to a value on the ascending branch thought to have the same interfacial tension. The mercury flow would be arrested by sucking momentarily on the mouthpiece, whereupon the mercury came to its new equilibrium position. If this position was the same as that found at the other potential, the values so found corresponded to the same interfacial tension (isotension potentials). If not, it was found necessary to repeat the measurement at the higher (cathodic) potential before repeating the measurement (with a new potential) on the low side. The reason for this is not clear except that the mercury is apparently not completely freed from capillary-active impurities on the low potential side even after one or more droplets have been expelled. On the high potential side, this is not so. The equilibrium position on the low side usually does not persist for more than five or ten seconds, at best, after which a steady fall of the meniscus attests to the adsorption of impurities from the solution. It is remarkable that the most carefully purified solutions did not differ in this or in any other observable respect from solutions made up from ordinary C.P. salts. The measurements reported in this paper were all carried out with purified solutions, however.

(9) This is not to be confused with the statement made earlier that the method used by Paschen is generally considered to require deaeration for its successful execution. The method here described differs entirely from that used by Paschen.

The results obtained by this method for tenth-normal potassium chloride at 25° are shown by the open circles in Fig. 1. They are seen to agree with the calculated curve with an accuracy of ±1 mv., which represents an uncertainty in the e. c. max. potential of not over half a millivolt for any one reading, except near the e. c. max., where the rate of change of interfacial tension with potential is approaching zero, and the accuracy of the measurements is accordingly much diminished. Such points were not taken into account in selecting a "best" fit from the family of curves.

The "best" curve, which is the only one shown, corresponds to an e. c. max. potential of 0.506_0 volt relative to a normal calomel electrode or 0.559_0 volt relative to a tenth-normal calomel electrode or 0.513_5 volt relative to a tenth-normal silver chloride electrode. These values are considered correct within ±0.5 mv.

The method we are here discussing does not give satisfactory results in hundredth-normal solutions of chlorides (the only salts we have tried at this dilution). Not only are the results in disagreement with all curves in the family of curves calculated from the differential capacity, but they are in disagreement with other methods, and also with all reasonable expectation. The difficulty is undoubtedly associated with the fact that the equilibrium position in the capillary is achieved only slowly, by which time the mercury surface could have and generally would have become contaminated. Method V, to be discussed below, is believed to be the best of the five in more dilute solutions.

The only values of the e. c. max. potential to be found in the literature for tenth-normal potassium chloride are two very old values, one by Paschen,[2] who arrives at a result 6 mv. lower than ours, and another by Smith,[10] whose final result is 9 millivolts higher than ours.

Method II.—It was found that when the head of mercury which caused mercury to flow from the capillary tip in the apparatus shown in Fig. 3 was barely sufficient to maintain the flow, a gradual change of the potential toward that of the e. c. max. caused a fairly abrupt cessation of flow. More accurately stated, as the potential was changed, there would appear a point when there was a monentary pause, amounting to perhaps five-tenths of a second at first, between the fall of one droplet and the beginning of the formation of the next. This phenomenon could be observed directly or by watching a galvanometer in series with the capillary.[11] It was suspected that the arrest potential corresponded to a definite interfacial tension, depending upon the

(10) Smith, *Phil. Trans. A*, **193**, 47 (1899); quoted by Smith and Moss, *Phil. Mag.*, [6] **15**, 478 (1908).

(11) The galvanometer swings as the mercury droplet begins to flow, even in the absence of air, because of the charging current familiar in polarographic measurements. It swings abruptly back to zero when the mercury droplet falls unless a new droplet immediately begins to form.

head of mercury and the diameter of the capillary, and that two such arrest points on opposite sides of the e. c. max. potential would constitute a pair of isotension potentials. This expectation was tested and found to be valid in tenth-normal solutions. Figure 2 illustrates the kind of agreement obtained. The "best" value is not perceptibly different from that found by method I, although the uncertainty is about twice as great. In more dilute solutions there is some evidence that method II may constitute a more accurate method of estimating isotension potentials than method I.

Method III.—Measurements of drop weight have long been popular as a means of measuring surface tension or interfacial tension. In a modification of this method we have sought pairs of potentials having the same drop *time*. The apparatus is the same. An interval timer accurate to 0.01 sec. is used to measure the drop time. Usually five droplets are counted at each potential setting and a great many sets of values are taken alternately until a pair of potentials with the same drop time is found. One such pair is sufficient to fix the potential of the e. c. max. By this method, taking only one pair, we arrive at a value one millivolt higher than our "best" value quoted above. This method has not been explored to the fullest extent in our laboratory. It is very laborious, but may be advantageous under some circumstances.

Method IV.—All of the above methods demand a knowledge of the differential capacity, which may not be available in some cases. However, one knows that if the data were available, the family of curves would be qualitatively similar to those found for, say, potassium chloride. In particular, it is a necessary consequence of the method of calculation that the curves should have a minimum ordinate at the abscissa of the assumed value of the e. c. max. potential and that this minimum ordinate should be twice the e. c. max. potential. This fact can be understood by remembering that we are plotting twice the abscissa of the diameter of the electrocapillary curve against the abscissas of each of the two points of intersection of a horizontal transversal. Obviously all three abscissas coincide at the e. c. max.

Accordingly it is possible to obtain a fairly good estimate of the potential of the electrocapillary maximum by plotting the isotension potentials as before and interpolating the flat minimum portion without the aid of any theoretical curves, except insofar as one knows that the curve cannot bend sharply at any point. Half the ordinate of the minimum is then taken as the desired value of the e. c. max. potential.

Experience with this method indicates that an accuracy of ± 1 mv. is attainable by a very skillful operator in tenth-normal solutions of chlorides. This method may lead to very large errors, however, if it is not corroborated with independent evidence for at least some of the electrolytes under test. The values here given for tenth-normal potassium chloride can serve for such corroboration in future work. The method cannot be recommended, however, in view of the extreme skill required of the operator and the consequent danger of error in particular cases.

Method V.—This method is not new to this paper. It consists of allowing a stream of mercury to flow into a carefully purified and deaerated solution of the electrolyte under test and measuring its potential relative to some electrode. It has been used by Paschen, Palmaer, Smith and Moss, Erdey-Gruz and Szarvas, and perhaps by others. We have investigated the method thoroughly in this Laboratory and consider it to be the most reliable of the methods available for more dilute solutions than those mentioned in this paper. It can be carried out in the apparatus already described with the following changes: A short jagged fine-tipped capillary is used and arrangements are made for increasing the pressure on the mercury column. This may be done with a compressed gas and a commercial pressure regulator since only very rough control of the pressure is needed. Pressures of from 5 to 20 lb. per sq. in. are generally needed to reach a "plateau" in the readings, and only readings obtained on a good "plateau" may be regarded as valid. Because of the difficulty of removing reducible substances, and perhaps for other reasons of which we are not fully aware, it is not as highly reproducible as the sensitivity of the meter readings suggests. Moreover, in tenth-normal potassium chloride it gives values about 3 mv. lower than the other methods, which we consider the more reliable at this concentration. This amount of error would not be objectionable for many purposes, but it would be desirable to find its source before depending too heavily upon values obtained in this manner.

By the use of method V we find a temperature coefficient of -0.0705 mv./deg. for the potential of the e. c. max. of tenth-normal potassium chloride in the neighborhood of room temperature. This is for the case where the reference electrode (calomel or silver chloride) is in the same solution at the same (variable) temperature.

The results obtained by these five methods are summarized in Table I, along with other results discussed below.

Measurements with Tenth-Normal Sodium Chloride.—For a further check on our methods we have measured the potential of the e.c. max. in tenth-normal *sodium* chloride relative to an electrode in sodium chloride and again relative to an electrode in potassium chloride. This was done because more work has been reported on sodium chloride than on any other electrolyte and because the results have sometimes been reported relative to an electrode in potassium

TABLE I

POTENTIAL OF THE ELECTROCAPILLARY MAXIMUM IN TENTH-NORMAL SODIUM OR POTASSIUM CHLORIDE RELATIVE TO A TENTH-NORMAL CALOMEL ELECTRODE IN THE SAME ELECTROLYTE

chloride. No two authors have done exactly the same thing, and in order to make a comparison, we have made the best conversions we could to a single standard. Values given in Table I for tenth-normal sodium chloride are expressed relative to a calomel electrode in the *same* solution.

Except for the value by Gouy, these measurements are in reasonably good accord. Gouy obtained his result by extrapolation of the diameters of the electrocapillary curve, and close examination of his data reveals that the extrapolation was a long one, especially in this case. If one combines his interfacial tension measurements with our differential capacity data as in method I, thus eliminating the extrapolation, the disagreement with our "best" value disappears to within less than the accuracy to which Gouy's values are reported. This corrected value is entered along with the others in Table I.

Acknowledgment.—We are grateful to the Research Corporation for two grants from the Frederick Gardner Cottrell fund in support of this work.

Summary

1. Three techniques are described for the determination of "isotension potentials," pairs of potentials at which the interfacial tension is the same on the two branches of the electrocapillary curve.

2. A method is described for the determination of the potential of the electrocapillary maximum by combining isotension potential data with measurements of the capacity of the electrical double layer.

3. Values of the potential of the e. c. max. in tenth-normal potassium and sodium chlorides are obtained by these three methods and also by two other methods of which one is new. Good agreement is obtained.

4. A value of 0.559_0 volt is obtained for the e. c. max. potential of tenth-normal potassium chloride relative to a tenth-normal calomel electrode, both at 25°.

5. Essentially the same value is obtained for tenth-normal sodium chloride relative to a tenth-normal calomel electrode in sodium chloride. This value is compared with previously published values.

6. A temperature coefficient of −0.0705 mv./deg. is found for the e. c. max. potential in tenth-normal potassium chloride.

Properties of Electrolytic Solutions. XLIII. Effect of Ammonia and Water on the Conductance of Lithium, Sodium and Silver Ions in Pyridine at 25°[1]

BY CHARLES J. CARIGNAN[2] AND CHARLES A. KRAUS

I. Introduction

Burgess has shown that the conductance of tetrabutylammonium picrate in pyridine is changed but little on addition of ammonia. The observed effect may be accounted for by the viscosity change of the solvent; the dissociation constant of the salt remains unchanged. However, when ammonia is added to a solution of sodium picrate, the conductance of the salt is greatly increased. In view of the fact that the conductance of the quaternary ammonium picrate remains constant (except for viscosity effect), it may be concluded that the increased conductance of sodium picrate is due to an increase in the conductance of the sodium ion.

It seemed worth while to investigate this phenomenon in somewhat greater detail. Accordingly, we have measured the conductance of lithium picrate at five different concentrations of ammonia, sodium picrate at two concentrations, and sodium iodide and silver nitrate, each at one concentration of ammonia. In addition, we have measured the conductance of sodium picrate at three different concentrations of water.

II. Experimental

1. Materials.—Pyridine was purified according to the procedure of Luder[3] and Burgess[4]

(1) This paper is based on a portion of a thesis presented by Charles J. Carignan in partial fulfillment of the requirements for the Degree of Doctor of Philosophy in the Graduate School of Brown University, June, 1947.

(2) du Pont Fellow, Brown University, 1946-1947. Present address: E. I. du Pont de Nemours and Co., Wilmington, Delaware.

except that the treatment with zinc chloride was omitted. The fact that our conductance values for lithium picrate check those of Burgess and that the density and viscosity of our solvent agree with those in the literature indicates that the zinc chloride step is unnecessary.

Ammonia was dried over sodium amide in a special stock cylinder. In making up known solutions of ammonia in pyridine, the ammonia was condensed in a weighed cylindrical tube of 100-cc. capacity containing ammonium nitrate. The vapor pressure of the saturated solution is one atmosphere at 23.6°. The pyridine, about 800 cc., was weighed in a round-bottom flask; it was then attached to the system, cooled to −78° and exhausted to remove all air. The desired amount of ammonia was then condensed on the pyridine, the amount of ammonia being found by weight difference of the ammonium nitrate container. The pyridine was warmed up to 25° in a water-bath, being stirred by means of a magnetic stirrer. After noting the pressure of ammonia above the solvent, dry air was admitted to bring the pressure to one atmosphere. The solvent was transferred from the stock flask to the cell as needed, the stock flask being connected to a supply of an air–ammonia mixture having the same composition as the atmosphere in the flask.

The conductance of pure pyridine was of the order of 5×10^{-10}. On addition of ammonia or water, the conductance was increased approximately tenfold. The conductance of these solvent mixtures usually ranged from 1 to 1.5×10^{-8}; it was necessary to apply a solvent correction in the case of the more dilute solutions.

1. Salts.—Lithium picrate was recrystallized from nitromethane; sodium picrate was recrystallized from ethanol. Both salts were dried *in vacuo* at 80°. Care should be exercised not to overheat the picrates. Sodium iodide and silver nitrate were recrystallized from water; the former was dried at 100°, the latter *in vacuo* at room temperature in the dark.

2. Physical Constants.—Densities were determined with a pycnometer of 30-cc. capacity with a capillary 5 cm. long and 1.0 mm. diameter. This pycnometer was provided with a ground-glass cap. Values are given in the tables.

Viscosities were determined with a modified Ostwald viscometer. An atmosphere of ammonia and air was maintained above the liquid with which it was in equilibrium. Values are given in the tables.

Dielectric constants were determined with a special cell and the parallel arm bridge that was also used for measuring the conductance of the pure solvents. The cell was calibrated with pyridine, using the value 12.01 for the dielectric constant of pure pyridine. With a 0.4798 *N* solution of ammonia, the dielectric constant was found to be 12.06. The difference with respect to pure pyridine is negligible for present purposes. With water, a marked increase of the dielectric constant was found. Values are given in Table II.

3. Experimental Techniques and Procedure.—Conductance measurements were carried out at 25 ± 0.01° as described in earlier papers.[4] The conductance cell was provided with gray platinum electrodes and had a capacity of 60 cc. It was well filled so as to reduce the vapor space to a minimum. Dilution was made as already

described except that an atmosphere of air and ammonia was maintained above the liquid which was in equilibrium with it. When water was used, an atmosphere of dry carbon dioxide-free air was maintained over the solution.

III. Results

The results for the lithium and sodium picrates, for sodium iodide and silver nitrate in the presence of ammonia are presented in Table I. The concentration of ammonia and values of the density and relative viscosity, η/η_0, are given at the head of the several tables.

Results for sodium picrate in the presence of water are given in Table II. At the head of the several tables are given the concentration of water, the density, the relative viscosity and the dielectric constant.

IV. Discussion

The data presented in Tables I and II have been analyzed by the method of Fuoss and values of the limiting conductance, Λ_0, and the dissociation constant, K, have been determined. Fuoss plots are shown for lithium picrate in Fig. 1 and for sodium picrate, sodium iodide and silver nitrate in Fig. 2 (all in the presence of ammonia).

Plots for sodium picrate in the presence of water are shown in Fig. 4.

It will be noted that all the plots are linear, conforming to the Bjerrum–Fuoss relation. It is of particular interest to point out that our values for lithium picrate in pure pyridine are in good agreement with those of Burgess, although we used a simpler method in the purification of the solvent. Evidently, the treatment with zinc chloride is unnecessary.

1. Salts in Presence of Ammonia.—Values of Λ_0 and K as derived from the plots for ammonia–pyridine mixtures are listed in Table III (columns

[a] Corrected for change in solvent viscosity on addition of ammonia.

2 and 6). In the third column is given the anion conductance corrected for viscosity change, in the fourth column, the cation conductance, and in the fifth column, the percentage increase of cation conductance over that in the pure solvent.

As may be seen from Table III as well as from Fig. 3, the conductance of the lithium ion is greatly increased on addition of ammonia. The conductance evidently approaches a limiting value with increasing ammonia concentration; for an ammonia concentration of 0.37 molar, the conductance increase is 49%. In the limit, the increase must be considerably greater than this.

With sodium picrate, the cation conductance increases more rapidly than with the corresponding lithium salt. For an ammonia concentration of 0.22 molar, the (ion) conductance increase is 46%. It is of interest to note that the conductance increase of the sodium ion is the same for the iodide as for the picrate. It is also of interest to note that the conductance increase of the silver ion is much smaller than that of the lithium or the sodium ion.

TABLE IV

LIMITING EQUIVALENT CONDUCTANCE, ION CONDUCTANCES AND DISSOCIATION CONSTANT OF SODIUM PICRATE IN PYRIDINE–WATER MIXTURES

H_2O concn. moles/liter	Λ_0	Λ_0^- (cor.)	Λ_0^+	% Increase in Λ_0^+	Dissoc. const. $K \times 10^4$
0.0	60.5	33.7	26.8	...	0.43
0.1018	61.2	33.5	27.7	3.3	1.01
.2048	61.3	33.3	28.0	4.5	1.61
.3148	62.3	33.1	29.2	9.0	2.29

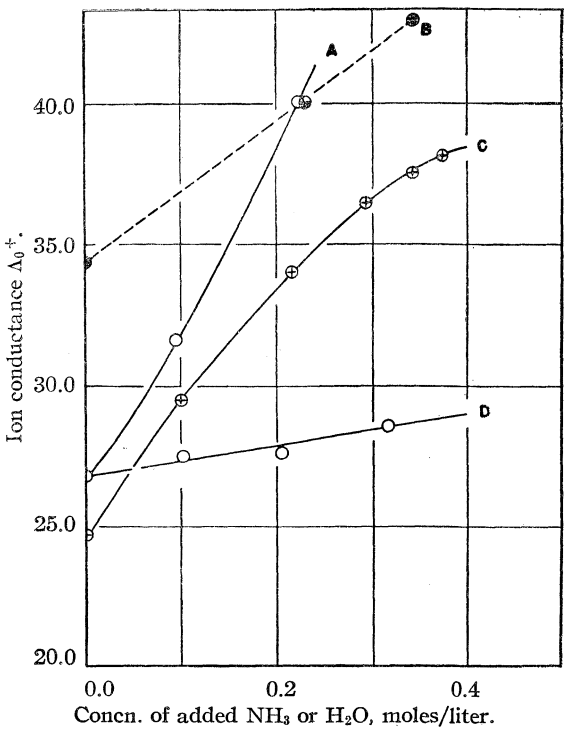

Fig. 3.—Conductance of lithium, sodium and silver ions in pyridine–ammonia mixtures and sodium ion in pyridine–water mixtures: (A) NaPi O, NaI ◒; (B) $AgNO_3$ ●; (C) LiPi ⊕; (D) NaPi with H_2O O.

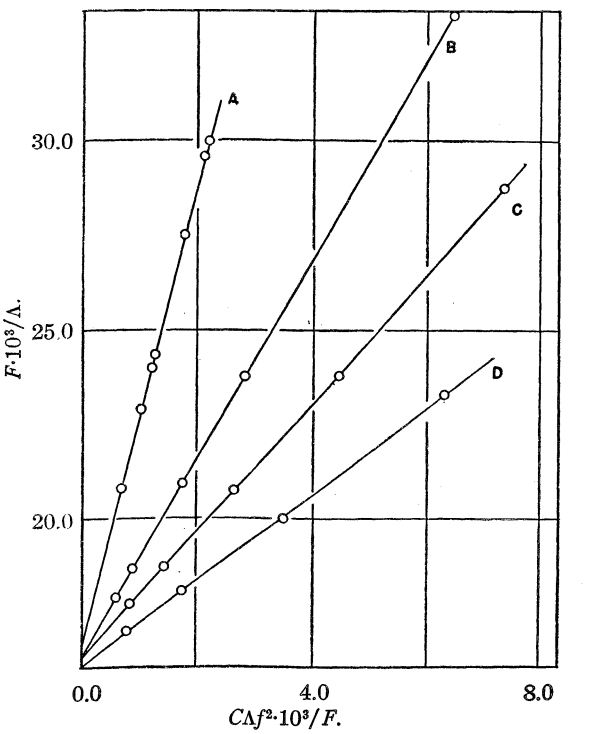

Fig. 4.—Fuoss plots for sodium picrate in pyridine–water mixtures: water concentration: (A) 0.00; (B) 0.1018 *m*; (C) 0.2048 *m*; (D) 0.3148 *m*.

The dissociation constant, on addition of ammonia, may increase, decrease or remain unchanged. Thus, for lithium picrate, there is an increase, for sodium iodide and silver nitrate, a decrease, while for sodium picrate there is no change. It appears that although free ions of lithium, sodium and silver become effectively smaller due to the presence of ammonia, in their ion pairs they may become either larger or smaller or undergo no change. Ion conductances are shown as a function of ammonia concentration in Fig. 3.

2. Sodium Picrate in Presence of Water.—In Table IV are given values for the constants of sodium picrate in the presence of water. Graphs are shown in Fig. 4.

As may be seen from Table IV, the conductance of the sodium ion in pyridine is increased on addition of water, but much less than on addition of ammonia. The increase is only 9% with 0.32 molar water. On the other hand, there is a marked increase of the dissociation constant, approximately six times for 0.32 molar water. This increase may be due, in part, to the higher dielectric constant of the water mixtures. At the concentration mentioned above, the dielectric constant is 7% greater than that of pyridine.

V. Summary

1. The conductance of lithium and sodium picrates and of sodium iodide and silver nitrate have been measured in pyridine solutions to which ammonia had been added.

2. The conductance of sodium picrate has been similarly measured in pyridine to which water had been added.

3. Values of the limiting conductance and the dissociation constant have been derived for the salts in these solutions by the Fuoss method and ion conductances have been determined.

4. The conductance of the three cations increases markedly on addition of ammonia. At an ammonia concentration of 0.2 molar, the conductance increase for the lithium, sodium and silver ions is, respectively, 33, 42 and 15%.

5. The conductance increase for the sodium ion on addition of 0.2 molar water is 4.5%.

6. On addition of ammonia, the dissociation constant of lithium picrate increases somewhat. Those of sodium iodide and silver nitrate decrease and that of sodium picrate remains unchanged. The dissociation constant of sodium picrate is increased markedly on addition of water.

The Effect of Centrifugal Force on Galvanic Potentials: (a) The Transference Numbers of Potassium Iodide, (b) The Iodide–Iodine Ion

BY D. A. MACINNES AND B. ROGER RAY[1a]

The effect of gradients of centrifugal force on the potentials of simple galvanic cells has been studied by Des Coudres[1] and more extensively by Tolman,[2] and some preliminary measurements have been reported by MacInnes.[3] Tolman and MacInnes used galvanic cells of the type

$$\underset{r_2}{(\mathrm{Pt});\ \mathrm{I_2},\ \mathrm{KI},\ \mathrm{I_2};}\ \underset{r_1}{(\mathrm{Pt})} \qquad (A)$$

in which two, otherwise identical, iodide–iodine electrodes with a uniform solution between them are placed at radii r_1 and r_2 in a centrifugal field. These researches have been interpreted by the equation

$$EF = 2\pi^2 n^2 (r_2^2 - r_1^2)[t_K(M_{KI} - \bar{V}_{KI}\rho) - (M_I - \bar{V}_I\rho)] \qquad (1)$$

in which F is the faraday, n is the number of revolutions per second, t_K is the transference number of the cation constituent, ρ is the density of the solution, M_{KI} and $\bar{V}_{KI}$ are the molecular weights and partial molal volumes of potassium iodide, and M_I and $\bar{V}_I$ are the atomic weight and partial atomic volume of iodine. It will be shown below that this is a limiting form of an equation which is based on more complete knowledge of the mechanism of cell A.

Studies of the closely related effect of differences of height on the potentials of galvanic cells have been made by Des Coudres[4] and more recently by Grinnell and Koenig.[5]

The results to be described below are the outcome of a long research undertaken to develop the centrifugal e. m. f. procedure into a precision method for obtaining transference numbers. It is of particular importance in that it can be used, as has been demonstrated by experiments already made, in the determination of transference numbers in non-aqueous solvents, where, due to Joule heat, the Hittorf and moving boundary methods encounter difficulties.

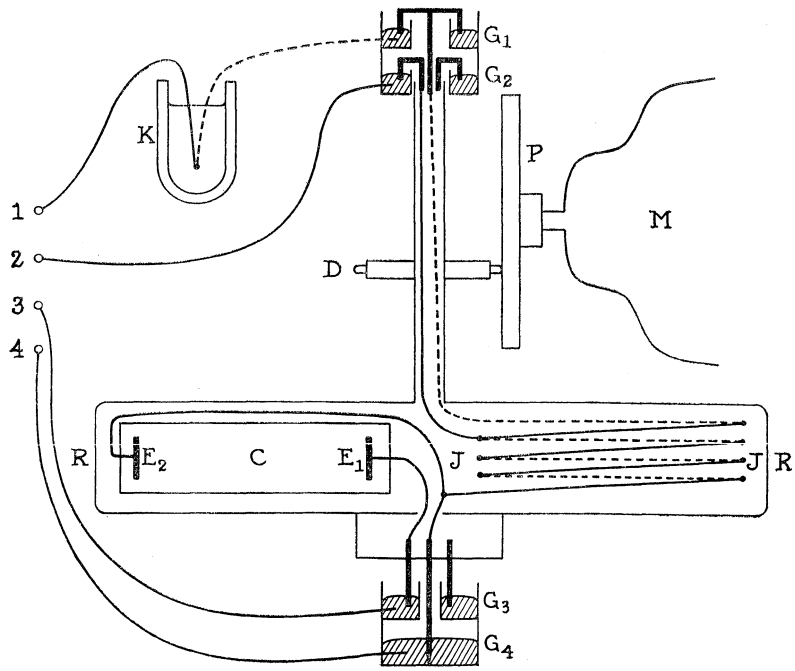

Fig. 1.—Diagram of apparatus.

The Apparatus

The apparatus,[6] and the electrical connections, are shown diagrammatically in Fig. 1. The rotor R-R, which is a disk of magnesium 23 cm. in diameter and 5 cm. thick, is turned in a horizontal plane by means of the pressure of the disk D on the plate P, which is rotated by the synchronous motor M. The rotor speed can be varied by changing the position of the disk D with the relation to the plate P. The potential between the electrodes E_1 and E_2 of the galvanic cell C can be measured, during the rotation, by electrical contacts through the mercury commutators G_3 and G_4. The difference of temperature at radii corresponding to the positions of E_1 and E_2 is obtained by means of the thermojunctions J-J. Twenty-two junctions are used, and are actually arranged around cell C. The resulting thermopotential is measured between the commutators G_2 and G_4. Finally, the temperature of the rotor is found using a single junction in the rotor, the commutators G_1 and G_2 and the reference junction in the external ice-bath K. Thus by shifting the leads of the potentiometer to the appropriate pairs of the contacts 1, 2, 3 and 4 the e. m. f. of the cell, the differential temperature, and the temperature of the rotor may be measured. The temperature measurements are essential since the measured potentials have been found to be considerably affected by radial temperature gradients. Such gradients are minimized by surrounding the rotor with a chamber in which a vacuum of 1 μ or better can be maintained. This prevents the production of appreciable heat through gas friction. The heat generated at the vacuum bearing is controlled by the circulation of cooling water. Radial temperature differences are reduced to less than 0.01° by empirically choosing the temperature of the water. This arrangement also greatly reduces the rise, during a determination, of the temperature of the rotor.

The cell used in obtaining the data to be described below is shown in Fig. 2. The electrodes E_1 and E_2, which are platinum disks 1 cm. in diameter and 6.4 cm. apart, are sealed into the Jena 16 III glass ends of the cell. The platinum leads, L_1 and L_2, are enclosed in flexible plastic tubing. Filling and removal of the solution are carried out through the tube T which is closed with a ground-glass cap G. The cell is enclosed in the brass shell S, the space between the shell and the cell being filled with vaseline. This semi-fluid material helps to equalize the pressure on the two sides and bottom of the cell when in a centrifugal field. The Bakelite spacers, V_1 and V_2, hold the glass cell in a fixed position in the shell S.

To determine the radii r_1 and r_2 of eq. 1 the procedure was as follows. The glass portion of the cell shown in Fig. 2 was filled with, and immersed in, a microscope immersion oil with the same coefficient as glass, and the distances of the electrodes E_1 and E_2 from the top edge of the cell, P, which was ground flat, were read with an accurate comparator, equipped with a travelling microscope. The cell was then assembled, as shown in the figure, inserted in the centrifuge, and run at top speed to ensure definite settling into place. The cell assembly was then placed on a surface plate and the distance between the top edge P and the bottom of the brass shell S was measured with a depth gage. When placed in the rotor R-R of Fig. 1, the cell and its counterpoise rest against disks closing the ends of the channel. The effective diameter of the rotor, *i. e.*, the distance between these disks, was measured with the aid of a precision vernier caliper. With these data

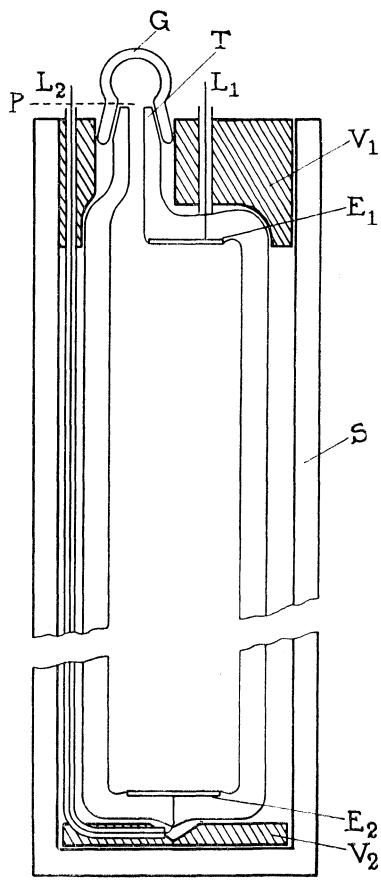

Fig. 2.—The galvanic cell.

(6) The apparatus is more fully described in an article by Ray and MacInnes in the *Rev. Sci. Inst.*, **20**, 52 (1949).

the radii r_1 and r_2 may be computed. Since the electrodes E_1 and E_2 are not exactly parallel the factor $(r_2^2 - r_1^2)$, which for the cell used in these experiments was 86.04 cm.,[2] may be in error by about ±0.2%. Another design of cell which allows for greater precision in this factor has also been used in our work.[6]

It is quite important that the counterpoise have the same moment of inertia as the cell, *i. e.*, imitate it closely in distribution of weight, since otherwise the rotor may precess, and may not rotate about its geometrical center.

The mercury commutators G_1, G_2, G_3 and G_4 are described in detail elsewhere.[6] With them it was possible to make measurements to one microvolt, or better, of potentials developed in the rotor, this precision being necessary because the highest potentials determined are of the order of one millivolt.

The measurements of the speeds of rotation, which ranged between 400 and 7200 r. p. m., were made with the aid of stroboscopic patterns, as described in a paper from this Laboratory.[7] The rotating top surface of the commutator G_1 of Fig. 1 is painted black, with a white radial streak. This surface is illuminated by a stroboscopic lamp, which is operated from the local a. c. current, and yields flashes at the rate of 60 per second. At definite speeds stationary stroboscopic patterns are observed which are related by the formula r. p. m. $= (3600 \times m)/n$ in which n is the number of bands in the pattern, and m is the "multiplicity." Patterns are observed for integral values of m and n except when they have a common factor. As the same pattern occurs at a series of related speeds it is necessary to have a rough preliminary estimate of its value. This is furnished by a scale attached to the adjustment mechanism of the disk D of Fig. 1. Since stationary patterns could be obtained for indefinite periods, with occasional slight manual adjustments, the accuracy of the speed measurement was nearly that of the a. c. source, and was more than necessary for our purpose.

The Preparation of the Solutions

The measurements described in this paper were made with 0.1941 *N* potassium iodide, to which varying amounts of iodine were added. In preparing this solution the best commercial salt was recrystallized several times, dried in an electric oven, followed by heating to 500° in a platinum boat in a current of purified nitrogen. The material was then weighed with the aid of the Richards bottling apparatus[8] procedure, after which the salt was dissolved in a weighed amount of conductivity water. A solution 0.1941 *N* in potassium iodide and 0.1585 *N* in iodine was made by adding a weighed amount of iodine (several times resublimed) to the stock potassium iodide solution. The solutions with smaller proportions of iodine were made by diluting, by volume, with carefully calibrated pipets, with the stock potassium iodide solution.

After many experiments designed to discover the source of persistent irregularities in the measurements, a source of difficulty was located in the minute suspended particles in the solutions. These were present although every effort had been made to ensure cleanliness in preparing the solutions. Such particles are far more important in this centrifugal work than in other e. m. f. measurements, since particles that are denser than the solution in which they are suspended will drift toward the outer, and less dense ones to the inner electrode, in both cases producing contamination of the platinum surface, and thus affecting the measured potential. To overcome this difficulty many of the solutions were ultrafiltered, with suction, through collodion membranes supported on sintered glass. This procedure yielded solutions which appeared optically clear in a Tyndall beam. Another procedure gave somewhat less complete, but apparently sufficient, removal of suspended material. This was the repeated filtration between each crystallization of the hot saturated solutions of potassium iodide, using the most dense hardened filter paper obtainable. The paper was pre-washed and supported on a steam-heated funnel. Solutions made up from this salt were very nearly optically clear and were used for part of the work. In earlier work the results appeared to be influenced by the presence of oxygen in the solutions, and elaborate precautions were made to exclude it from the solutions and the surroundings of the cell. With the use of ultrafiltration, the need of these precautions apparently disappeared. It seems possible that a really clean surface of platinum can overcome the disturbing effect of a small concentration of oxygen, whereas a contaminated surface is unable to do so. However, we do not consider the matter to be fully settled.

The Experimental Results

The Effects of Temperature Control.—As mentioned above, correct, constant values of the e. m. f. of the galvanic cell were obtained only when there was no difference of temperature between the radii of the rotor corresponding to the positions of the electrodes E_1 and E_2. This is clearly indicated by some typical measurements illustrated in Fig. 3. In this figure the top curve shows the potentials of the galvanic cell, the next lower one the temperature of the rotor, and the bottom curve the difference of temperature at the points occupied by the electrodes, all plotted as

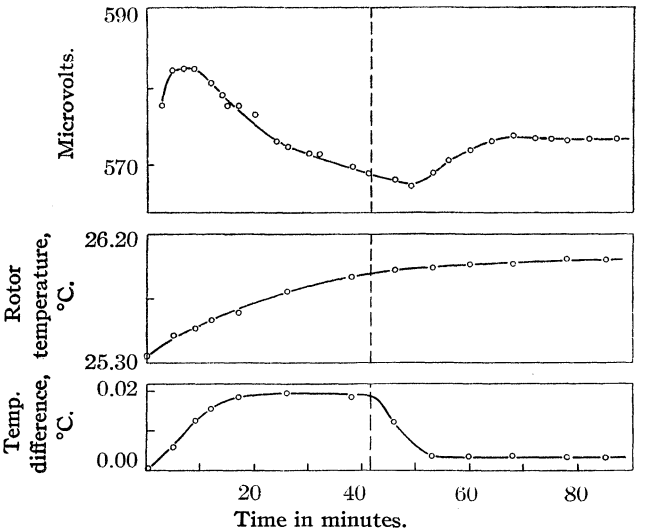

Fig. 3.—Effect of temperature difference on e. m. f. of cell and on rotor temperature.

functions of the time, the zero being the moment at which the rotor attained a speed of 5400 r. p. m. It will be seen that there is a quick rise of the e. m. f. of the cell, followed by a slower decrease. During the same period there is a slow increase of the temperature of the rotor, and a corresponding rise to a low maximum of the differential temperature. At a time indicated by the vertical dotted line running water was used to fix, at an appropriate point, the temperature of the rotor bearing. It will be observed in the figure that the differential temperature dropped rapidly to nearly zero, and shortly after the e. m. f. of the

cell, and the temperature of the rotor, assumed constant values.

With experience, it was possible to adjust the temperature of the bearing at the start so as to avoid appreciable temperature gradients in the cell during the measurements. The measured potentials of the cell at each speed were, in general, established immediately, and remained constant, within one or two microvolts, for the period of the measurement, generally about ten minutes.

A Typical Experiment.—The results of a typical experiment are shown in line A of Fig. 4, in which the values of the potentials E, in microvolts, are plotted as functions of the square, n^2 of the speed of rotation in seconds. According

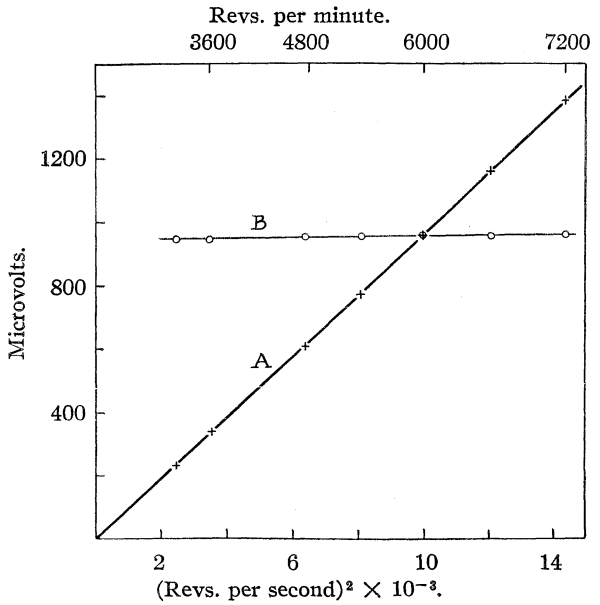

Fig. 4.—Results of a typical experiment.

to eq. 1 and the following eq. 8 this relation should be linear and pass through the origin. That A is a straight line is shown by plotting the slopes, E/n^2, against n^2 as shown in line B. The slope is thus seen to be constant within a very small limit of error. These data were obtained using solution 8, of Table I, in the galvanic cell.

TABLE I

RESULTS OF MEASUREMENTS OF POTASSIUM IODIDE–IODINE SOLUTIONS

	Iodine normality	Density 25°	Molar cond. Λm 25°	E/n^2 × 10^8 obs.	No. runs	Av. dev., %	E/n^2 × 10^8 comp.
1	0	1.02037	126.70	(6.71)			6.684
2	0.00165	1.02053	126.57	6.738	2	0.1	6.712

4	.01981	1.02230	125.09	6.967	2	.05	7.005
5	.03961	1.02418	123.49	7.380	5	.4	7.341
6	.07922	1.02798	120.31	8.049	1		8.047
7	.1188	1.03178	117.15	8.851	4	.6	8.790
8	.1585	1.03558	114.05	9.586	1		9.604

If, at the higher speeds, the experiment is prolonged the measured potentials drop slowly. This is to be expected, since, under the influence of the centrifugal force, there is a tendency of the salt and of the iodine to drift in the direction of the outer electrode. In an ultracentrifuge at much higher speeds than those used in our experiments Pedersen[9] attained sedimentation equilibrium for a number of salts, such as cesium chloride and lithium iodate.

The e. m. f. data plotted in Fig. 4 and recorded in Table I were obtained using a series of increasing speeds. The same accuracy has not yet been obtained with decreasing speeds, a phenomenon for which we can give no explanation.

A Summary of the Measurements.—Table I contains the results of a series of measurements on solutions of potassium iodide containing 0.1941 mole per liter at 25° and in addition varying amounts of iodine. The normalities of the iodine, *i. e.*, gram atomic weights per liter, are shown in column 2 of the table. The densities of the solutions, given in column 3, were determined by a magnetic float method which will be described in a future publication from this Laboratory. In the fourth column are given the observed molar conductances, $\Lambda_m = 1000\kappa/0.1941$, in which κ is the measured specific conductance. We are indebted to Dr. Theodore Shedlovsky for aid in making these measurements, which were made with the conductance bridge developed in this Laboratory, and in an oil thermostat regulating to 0.003°. The E/n^2 values given in column 5 were obtained by the method of least squares from the original data. Each "run" consisted of an experiment such as is shown in the results plotted in Fig. 4, with the potentials, E, measured at seven different speeds. For the cases in which more than one run was made, as indicated in column 6, the average deviation in per cent. is given in the following column.

Discussion of the Results

It will be seen from the data in Table I that the value of the quantity E/n^2 increases quite rapidly as the proportion of iodine in solution ascends. In the following discussion it is shown, quantitatively, that the effect is due to the effect of an iodide–iodine complex on the mechanism of the cell.

During the passage of current through the cell

$$(Pt);\ I_2,\ KI,\ I_2;\ (Pt) \qquad (A)$$

the electrochemical reaction

$$I^- = I^0 + \epsilon^- \qquad (2)$$

occurs at the anode and at the cathode. Here

$$\epsilon^- + I^0 = I^-$$

I^0 represents iodine in an uncharged condition. It may be in the form of I_2 or as a complex I^-_{j+1} with the iodine ion, in which j is the number of equivalents of uncharged iodine in the complex. During the passage of one faraday F through the cell, t_K equivalent of potassium ion constituent

(9) K. O. Pedersen, *Z. physik. Chem.*, **A170**, 41 (1934).

will migrate from the region of the anode and appear at the cathode, t representing a Hittorf transference number. The remainder of the current is transported in the reverse direction by t_I equivalent of I^- and t_C equivalent of the complex ion. The net loss around the anode is t_K equivalent of potassium ion and $(1 - t_I - t_C) = t_K$ equivalent of negatively charged ion. Thus there is a net loss of t_K equivalent of potassium iodide from the region of the anode. Since reverse phenomena occur at the cathode, a transport of t_K equivalent of the salt from one electrode to the other takes place. This is accompanied by the appearance of one equivalent of I^0 at the anode by the electrochemical reaction, eq. 2, and jt_C equivalent of that material by transference.

The transport process per faraday for the galvanic cell A is therefore t_K equivalent of potassium iodide from the anode to cathode and $(1 + jt_C)$ equivalents of I^0 in the reverse direction. If gradients of chemical potential $\Delta\mu$ exist in the cell the Gibbs free energy ΔZ of its reversible operation will be

$$-\Delta Z = EF = t_K \Delta\mu_K - (1 + jt_C)\Delta\mu_{I^0} \quad (3)$$

Since the operation of the cell takes place in a centrifugal field the chemical potentials μ will be functions of the radius r in addition to the usual variables which are temperature, pressure, P, and the mole fractions of the components of the solution.

Assuming constant temperature and uniform concentration of the solution in the cell we have

$$\frac{d\mu_i}{dr} = \left(\frac{\partial\mu_i}{\partial r}\right)_P + \left(\frac{\partial\mu_i}{\partial P}\right)_r \frac{dP}{dr} \quad (4)$$

Now the change of μ_i with r is given by

$$(\partial\mu_i/\partial r) = -M_i\phi \quad (5)$$

in which ϕ is the centrifugal force per unit mass and M_i is the molecular or atomic weight. The negative sign is due to the fact that the energy of a component is increased by movement toward the center of rotation. The differential Gibbs free energy dZ of a solution is given by

$$dZ = -sdT + VdP + \mu_1\, dN_1 + \mu_2\, dN_2 \ldots \mu_i\, dN_i \quad (6)$$

in which N_1, N_2, . . . , N_i represent the numbers of moles. Since dZ is an exact differential the partial molal volume $\bar{V}_i$ can be obtained by the cross differentiation[10]

$$\partial\mu_i/\partial P = \partial V/\partial N_i = \bar{V}_i \quad (7)$$

Substituting $dP/dr = \rho\phi$ and eqs. 5 and 7 into eq. 4 we obtain

$$-d\mu_i/dr = \phi(M_i - \bar{V}_i\rho) = 4\pi^2 n^2 r(M_i - \bar{V}_i\rho) \quad (8)$$

since $\phi = 4\pi^2n^2r$, in which n is the number of rotations per second. Using this expression in eq. 3 after integrating between radii r_2 and r_1 yields[11]

$$-EF = 2\pi^2n^2(r_2^2 - r_1^2) \times [t_K(M_{KI} - \bar{V}_{KI}\rho) - (1 + jt_C)(M_I - \bar{V}_I\rho)] \quad (9)$$

It will be observed that this equation reduces to eq. 1, as the proportion of iodine, and thus the transference number t_C, decreases. Thus using eq. 1 and a limiting value of E/n^2 obtained by a short linear extrapolation from the data in Table I the transference number of the potassium ion in 0.1941 normal potassium iodide is found to be $t_K = 0.487_3$. This agrees closely with the value 0.4887 obtained by Longsworth[12] by the quite independent method of moving boundaries. In our computation values of the partial molecular and atomic volumes $\bar{V}_{KI}$, and $\bar{V}_I$ are necessary. Longsworth gives a formula, based on existing density data, from which $\bar{V}_{KI} = 46.34$ is obtained, and the value $\bar{V}_I = 30.31$ was computed from the density data in Table I. These quantities will be the subject of another contribution from this Laboratory.

With the aid of the conductance measurements, given in Table I, for potassium iodide solutions, with varying proportions of added iodine, a test of the validity of eq. 9 may be made. Assuming Kohlrausch's law of independent ion mobilities[13] the measured equivalent conductance Λ_m is given by

$$\Lambda_m = \lambda_K + (1 - R/j)\lambda_I + (R/j)\lambda_C \quad (10)$$

in which the λ values are equivalent conductances of ion constituents; R is the ratio C_{I^0}/C_{KI}, and j is, once more, the number of equivalents of uncharged iodine carried by the complex. From this equation

$$\lambda_C = \lambda_I - (j/R)(\Lambda_{KI} - \Lambda_m) \quad (11)$$

and also

$$t_K = \lambda_K/\Lambda_m \text{ and } t_C = R\lambda_C/j\Lambda_m \quad (12)$$

since transference numbers are the proportion of the total current carried by a given ion constituent. Substituting these values in eq. 9 we have

$$-FE = 4\pi^2n^2(r_2^2 - r_1^2) \times \left[\frac{\lambda_K}{\Lambda_m}(M_{KI} - \bar{V}_{KI}\rho) - \left(1 + \frac{R\lambda_I - j(\Lambda_{KI} - \Lambda_m)}{\Lambda_m}\right)(M_I - V_I\rho)\right] \quad (13)$$

To test the validity of this equation in terms of our experimental results we must have, in addition to the data given in Table I, values of the ion conductances λ_K and λ_I. With the aid of Longsworth's[12] value 0.4887 of t_K for 0.2 N potassium iodide and the value of Λ_m for solution 1 of Table I, $\lambda_K = 61.92$ and $\lambda_I = 64.78$ are obtained.

On the assumption that for the complex I^-_{j+1},

(10) The thermodynamic function, Z, applicable to processes at constant temperature and pressure, is of service here since, although there is a gradient of pressure along the galvanic cell, the cell mechanism does not involve any alteration of this pressure distribution. Equations 6 and 7 are eqs. Nos. 92 and 272 of Gibbs' "Equilibrium of Heterogeneous Substances."

(11) This equation is equivalent to equation 83, for the effect of height, in the paper by Koenig and Grinnell, *J. Phys. Chem.*, **44**, 463 (1940).

(12) Longsworth, THIS JOURNAL, **57**, 1185 (1935).

(13) This law is only approximate at 0.2 N, but it is a sufficiently good assumption for computing the relatively small term jt_C of eq. 9.

j should be an integer, values of E/n^2 were computed for $j = 1$, 2 and 3, corresponding to ratios R from the data in Table I. Those for $j = 2$ are given in that table in the eighth column, and are seen to agree closely with the quantities E/n^2 obtained experimentally. That the experimental results indicate the presence of the complex I_3^-, and are not in accord with I_2^- or I_4^- is shown graphically in Fig. 5 in which values E/n^2 for $j = 1$, 2 and 3 computed from eq. 13 are given as functions of the ratio $R(= C_{I_0}/C_{KI})$ as abscissas and the corresponding experimental values of E/n^2 from Table I are plotted as small circles. Here again the indication is clearly in close quantitative agreement with $j = 2$, or the complex ion I_3^-.

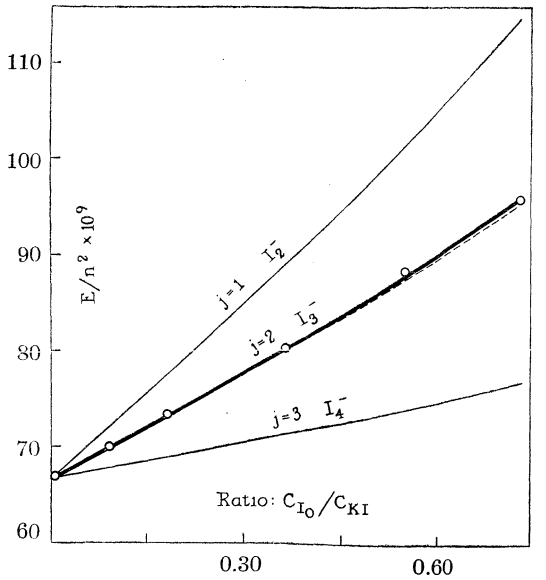

Fig. 5.—The variation of E/n^2 values with the ratio C_{I^0}/C_{KI}.

The existence of a complex of that composition has, from transference and distribution measurements, been known for a long time.[14] The results of this paper may, therefore, be regarded as a confirmation, by a quite new method, of the earlier conclusions.

A number of workers have determined the mass law constant for the equilibrium

$$I^- + I_2 = I_3^-$$

the most recent value being 1.40×10^{-3} at 25° for a total iodide concentration of 0.2 N as found by Jones and Kaplan.[14] A small proportion of the iodine in solution, therefore, exists in the form I_2 and the ratio R should, strictly, be corrected for this effect. The effect of the correction is shown in Fig. 5 by the dotted line diverging from the curve for $j = 2$, and is within the experimental error of the present series of measurements.

Summary

The potential, E, of a galvanic cell consisting of two iodide–iodine electrodes at two different radii in a rotor has been measured at different speeds of rotation, n. Reproducible potentials were obtained only when radial temperature gradients were eliminated and the solutions in the cell were free from suspended particles. A series of measurements were made on solutions which had a constant concentration of potassium iodide, but varying concentrations of iodine. For each solution values of E/n^2 were found to be accurately constant, through a range of values of of n from 1800 to 7200 r. p. m. The ratio E/n^2 increases with the proportion of free iodine, a fact that is quantitatively accounted for by the presence in solution of the ionic complex I_3^-. The measurements also yielded a value of the transference numbers of potassium iodide in agreement with those obtained by the moving boundary method.

Effect of Ethanol in the Electro-reduction of *p*-Nitroaniline at the Dropping Mercury Electrode

BY O. D. SHREVE[1] AND E. C. MARKHAM

For solubility reasons, many of the organic polarographic reductions reported in the literature have been studied in mixtures of water with ethanol or other water miscible organic solvent. As pointed out by Kolthoff and Lingane,[2] the effect of such solvents on the measured half-wave potentials and diffusion currents is often overlooked, with resulting confusion in the interpretation of organic polarographic data. When reductions at the dropping mercury electrode are carried out in the approved manner, *i. e.*, in well buffered solutions, the over-all effect of added organic solvent on the potential will include: (a) the change resulting from any alteration in the hydrogen ion activity of the aqueous buffers; (b) any change in potential of the quiet mercury anode (or change due to the introduction of a liquid junction if an outside reference anode is used); and (c) any effect on the inherent reduction potential of the reducible compound. The effect on the diffusion currents will reflect the influence of the solvent on one or more of the terms in the Ilkovic equation (diffusion coefficient or capillary characteristics).

Investigations of the effect of organic solvents on metal ion reductions[3] indicate that diffusion currents are depressed but potentials only slightly affected. In the organic field a few experiments on the effect of varying solvent composition[4] have been reported, but these are limited in scope and incidental to the investigator's chief purpose.

The present report describes a complete quantitative study of the effect of ethanol, the most commonly used polarographic solvent, on (a) the *p*H values as calculated from hydrogen electrode potentials, for a series of commonly used buffers covering a wide *p*H range and (b) the usual polarographic values measured in the reduction of *p*-nitroaniline in these buffers. The appreciable solubility of this compound in water makes possible a direct comparison of its polarographic behavior in the presence of varying amounts of ethanol with that in water.

Experimental

Using the polarographic cell-aqueous calomel electrode combination described below, polarographic and glass electrode potential measurements were made on 5.4×10^{-4} *M* *p*-nitroaniline solutions in nine buffer series, each series comprising a commonly used buffer system made up in water and in six ethanol–water mixtures. All solutions contained 0.02% gelatin as maximum suppressor and the total concentrations of buffer constituents in each series were held constant at those calculated to yield an ionic strength of 0.1 in water.[5]

Using the same cell combination, hydrogen and glass electrode potential measurements were made on 5 of the above series (compositions being identical except for the absence of the small amount of *p*-nitroaniline). The glass electrode potentials in these solutions were identical with those in the corresponding solutions containing *p*-nitroaniline and a plot of glass electrode *versus* hydrogen electrode potentials (Fig. 1) yielded a 45° straight line. Hydrogen electrode potentials for the remaining four series were not measured directly, but were derived from glass electrode measurements with the aid of this calibration curve. "Apparent" *p*H values for all solutions polarographed were then calculated from the measured or derived hydrogen electrode potentials.

Cell Assembly.—All measurements were made in a polarographic cell–aqueous saturated calomel electrode combination similar to that described by Lingane and Kolthoff[6] except that the cell was all Pyrex glass and was designed to accommodate both hydrogen and glass electrodes as well as a dropping electrode and salt bridge[7] through ground joints. The whole assembly was thermostated at 25°.

Polarographic Measurements.—A manually operated polarographic apparatus capable of accurate potential and current measurements was used. The circuit was similar to one which has been described by Lingane and Kolthoff.[6] Potentials were simultaneously applied and measured with a Leeds and Northrup potentiometer. Currents were measured in microamperes with a sensitive, long period Leeds and Northrup D'Arsonval galvanometer in conjunction with a lamp and curved scale. The galvanometer was calibrated in a manner similar to that recommended by Kolthoff and Lingane[8] and was adjusted to a "round number" sensitivity before each run (0.05 μa./mm. for most of the work) to facilitate conversion of scale readings to microamperes.

The observed diffusion current in each solution was corrected for residual current by the direct method[6] to obtain the true diffusion current, (i_d), and the potential corresponding to $i_d/2$ was taken as the half-wave applied potential. The half-wave applied potential was then corrected for *i*R drop after measurement of the cell circuit resistance[9] to give the true half-wave potential ($E_{1/2}$).

The same dropping capillary sealed directly to a Pyrex glass mercury reservoir was used throughout the study; the pressure on the dropping mercury was maintained constant

(5) The small contribution of the weakly ionized buffer acids to the ionic strength was ignored in these calculations.

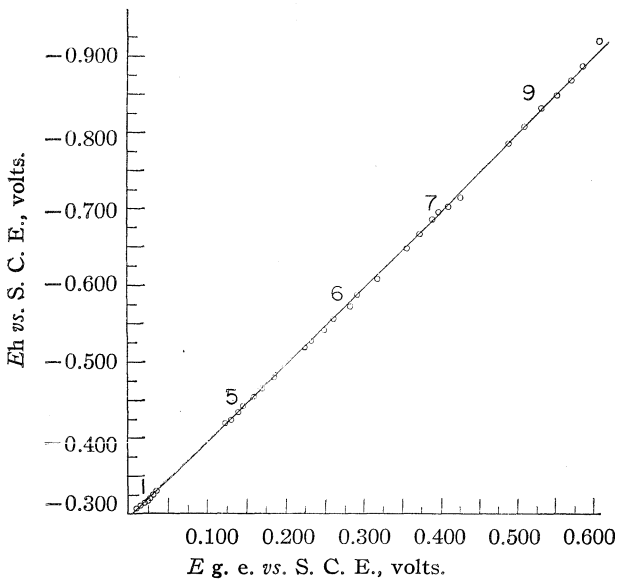

Fig. 1.—Glass electrode *versus* hydrogen electrode potential. Numbers refer to buffers identified in Table II. Points from left to right in each group correspond to increasing ethanol concentrations given in Table II.

at 30.8 cm. of mercury by a pressure regulating device.[6] All solutions were deaerated with purified nitrogen which passed through a portion of the solution under study in a side arm of the cell before entering the cell proper.

Hydrogen and Glass Electrode Measurements.—The hydrogen electrode measurements were made with a Leeds and Northrup Type K potentiometer, in the usual way, with a sensitive D'Arsonval galvanometer as null point indicator. The purified hydrogen bubbled through a portion of the solution in the cell side arm before entering the cell proper and measurements were taken until constant within ±1 mv. for buffers containing 0–35% ethanol and ±2 mv. for those richer in ethanol.

The glass electrode potentials were measured with a Coleman Model 3D *p*H electrometer, using a Coleman 3001 F electrode.

The cell set-up used in these measurements was exactly the same as that used for the polarographic measurements except, of course, for the replacement of the dropping electrode by a glass or hydrogen electrode.

Materials.—The *p*-nitroaniline used was an Eastman product purified by recrystallization from water and alcohol, m. p. 146–147°.

Absolute ethanol (U. S. Industrial Chemicals, Inc.) was distilled from alkaline silver oxide and the middle fraction of the distillate redistilled from aluminum amalgam to give the pure dry product used in the experiments.

"Hydrion Buffer Salts" (Micro Essential Laboratory, Brooklyn, N. Y.) were used for preparing buffers without further purification. The salts used included potassium chloride, glycine, sodium acetate, monopotassium phosphate and boric acid. The hydrochloric acid, acetic acid and potassium hydroxide stock solutions used in preparing buffers were made from J. T. Baker Analyzed C. P. grade chemicals and were standardized by the usual methods.

The tank nitrogen, used for deaerating, was purified by passing through a train consisting of (a) a Drierite tube; (b) copper gauze, maintained at 500° by an electric furnace; (c) solid potassium hydroxide; (d) phosphorus pentoxide; and (e) a second Drierite tube, before entering the polarographic cell.

The electrolytic hydrogen used for the hydrogen electrode measurements was purified by passing through a train consisting of (a) a soda-lime tube; (b) a bubble counter containing concentrated sulfuric acid; (c) a Pyrex furnace containing platinized asbestos at 500°; and (d) a Drierite tube before entering the cell.

Baker U. S. P. gelatin was used for suppressing maxima. Fresh solutions were frequently prepared and a trace of thymol added as preservative.

Results

Reduction in Aqueous Medium.—Shikata and Taguchi[10] studied the reduction of the nitroanilines in aqueous buffers at 25°. Since their work was done before the introduction of the half-wave potential concept, however, they reported "tangent" potentials and these were derived from polarograms showing maxima in varying degree. In agreement with the results reported by these investigators, we have observed only one wave in the reduction of *p*-nitroaniline throughout the *p*H range studied in buffer solutions but two waves in an unbuffered solution consisting of 10^{-4} *N* hydrochloric acid in 0.1 *N* potassium chloride.

The effect of varying concentration of the reducible compound on half-wave potential and diffusion current in aqueous acetate buffer (no. 6) is given in Table I. These data indicate that the Ilkovic equation holds reasonably well for the reduction. The half-wave potentials are fairly constant over the range 10^{-4} to 10^{-3} *M* but decrease below and increase above this concentration range.

TABLE I

Effect of Ethanol on *p*H of Buffers and Half-Wave Potentials.—The *p*H values for the alcoholic as well as the aqueous buffers were calculated from the hydrogen electrode potentials using the usual equation for the *aqueous* saturated calomel–hydrogen electrode combination, $pH = (E_h - 0.2438)/0.0591$ as recommended for such cases.[11] It should be emphasized that the observed effect of ethanol on the *p*H values thus calculated includes the unknown effect on the E_0 value of the hydrogen electrode and the liquid junction potential as well as the effect on the actual hydrogen ion activity of the solutions.

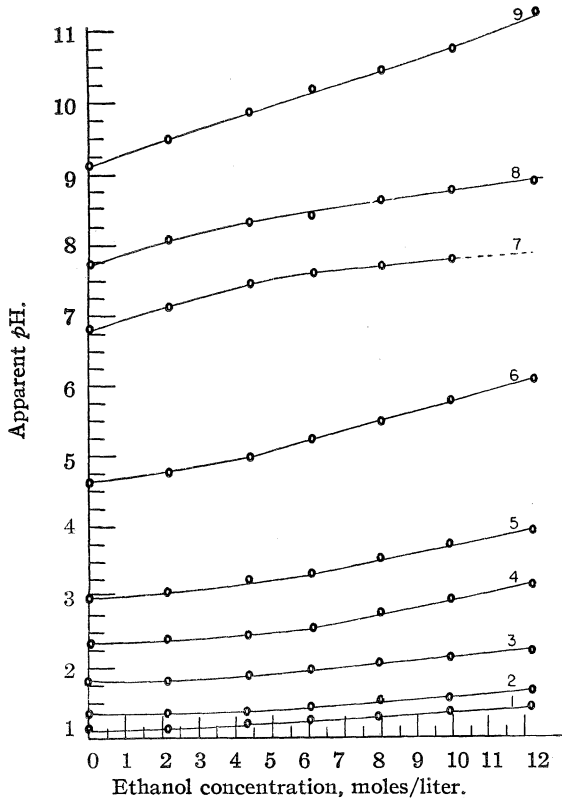

Fig. 2.—Apparent *p*H as a function of solvent composition. Curve numbers refer to buffer numbers in Table II.

The *p*H values are therefore designated as "apparent" *p*H numbers.

The curves of Fig. 2 show the effect of ethanol on the *p*H values of the nine buffers studied. It is seen that each of the curves for the acidic buffers undergoes an increase in slope after the addition of a certain amount of ethanol while those for the buffers near the neutral region tend to decrease in slope after the initial additions. The curve for the basic buffer is approximately linear over the entire range. The slopes of the curves beyond their inflection regions increase with increasing original *p*H of the buffers through the acid region, decrease in the neutral region and increase again in the case of the basic buffer. It will be noted that the more acidic buffers will tolerate considerable ethanol without serious effect on *p*H while the buffers of higher original *p*H are affected by relatively low concentrations.

The effect of ethanol on the half-wave potentials in the reduction of *p*-nitroaniline in these buffers is given in Fig. 3. It is seen that the potentials are shifted strongly to more negative values. In the acidic buffers the presence of about 2 to 3 *M* ethanol has little effect but beyond this concentration the curves increase sharply in slope and proceed linearly, the slopes increasing with increasing original *p*H of the buffers. In the neutral and basic buffers 2 *M* ethanol has a considerable effect but the slopes of the main portions of the curves tend to decrease with increasing original buffer *p*H.

Effect of Ethanol on Diffusion Currents.—The diffusion currents obtained in each buffer in the various solvent media are given in Table II. In all cases the values decrease with increasing ethanol, pass through a flat minimum at 8 to 10 *M* ethanol, and then tend to increase. This behavior is graphically illustrated in Fig. 4 where the diffusion currents in 0.1 *N* hydrochloric acid and in the acetate buffer (no. 6), are plotted as a function of solvent composition. In the case of these two media, it was possible to extend the experiments to higher ethanol content (14.66 *M*) and thus better illustrate the increase in i_d beyond the minimum.

Effect of Varying *p*H on Half-Wave Potentials, Diffusion Currents and Capillary Characteristics in Each Solvent Medium.—Plots of half-wave potential *versus* apparent *p*H (Table II) in each of the seven solvent media are linear over the entire *p*H range studied in water and in 2.17, 4.34 and 6.08 *M* ethanol. In the solvents richer in ethanol the relation is linear up to an apparent *p*H of about 8 beyond which point the curves undergo a decrease in slope. Empirical equations for the variation of half-wave potential with *p*H in the various solvent media are given in Table III.

In water and 2.17 *M* ethanol the diffusion currents show a slight initial increase with increasing *p*H (Table II). In each solvent medium richer in ethanol the diffusion currents are nearly constant over the entire *p*H range, no appreciable initial rise occurring.

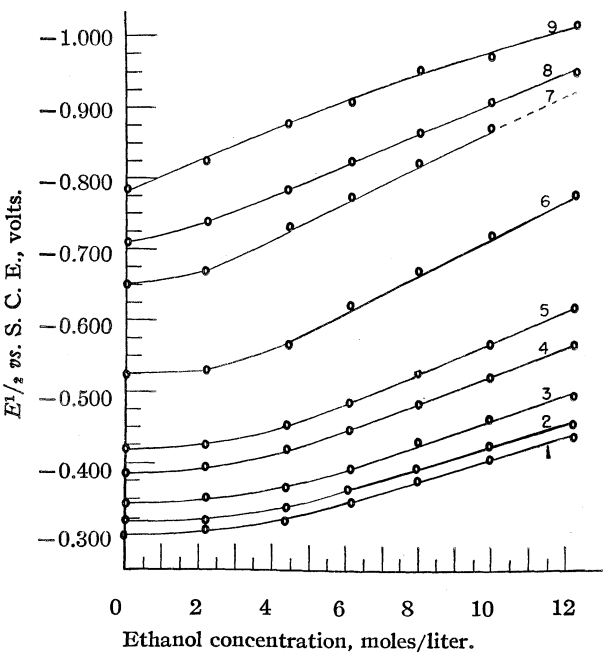

Fig. 3.—Half wave potential as a function of solvent composition: 5.4×10^{-4} *m* *p*-nitroaniline in nine buffers. Curve numbers refer to buffer numbers in Table II.

TABLE III

EQUATIONS FOR THE POLAROGRAPHIC WAVE AND α VALUES (5.4×10^{-4} *M* *p*-NITROANILINE IN VARIOUS SOLVENT MEDIA)

Medium	Equation	Valid *p*H range	α[a]
Water	$E_{1/2} = -0.244 - 0.061\ p\mathrm{H}$	1 to 9	0.83
2.17 *M* Ethanol	$E_{1/2} = -0.244 - 0.062\ p\mathrm{H}$	1 to 9.5	.81
4.34 *M* Ethanol	$E_{1/2} = -0.250 - 0.064\ p\mathrm{H}$	1 to 9.8	.78
6.08 *M* Ethanol	$E_{1/2} = -0.270 - 0.066\ p\mathrm{H}$	1 to 9	.75
7.95 *M* Ethanol	$E_{1/2} = -0.293 - 0.068\ p\mathrm{H}$	1 to 9	.70
9.92 *M* Ethanol	$E_{1/2} = -0.308 - 0.072\ p\mathrm{H}$	1 to 8	.68
12.21 *M* Ethanol	$E_{1/2} = -0.332 - 0.074\ p\mathrm{H}$	1 to 8	.63

[a] Average for nine buffers.

The $m^{2/3}t^{1/6}$ value of the capillary is practically independent of solvent composition and *p*H. In all solutions, except those comprising the most basic buffer (no. 9), this value is 1.95 ± 0.01 $mg.^{2/3}sec.^{-1/2}$. In buffer 9 a somewhat lower average value of 1.90 ± 0.01 is observed.

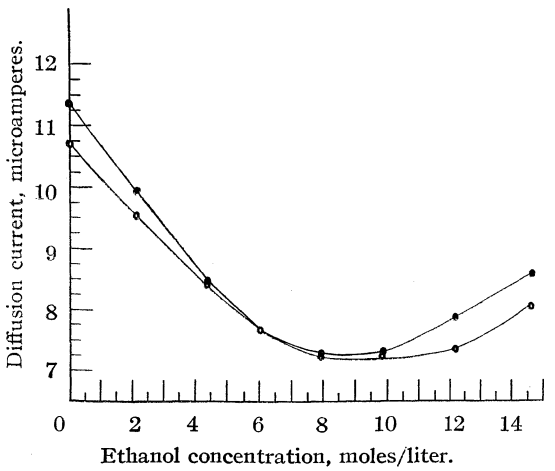

Fig. 4.—Diffusion current as a function of solvent composition: 5.4×10^{-4} *m* *p*-nitroaniline: ●, buffer no. 6 (HAc–NaAc); O, buffer no. 1 (0.1 *N* HCl).

Effect of Ethanol on the Potential–Current Relationship at Points on the Polarographic Wave.—Plots of log $i/(i_d - i)$ *versus* cathode potential at points on the waves yield straight lines for all polarograms in all solvent media and the potential at which log $i/(i_d - i) = 0$ coincides with the measured half-wave potential. The values of *n* in the usual expression

$$E = E_{1/2} \frac{-0.059}{n} \log \frac{i}{i_d - i}$$

however, as determined from the slopes of the log plots[12] are not integral but are always less than 1. The equation for the waves therefore, takes the form

$$E = E_{1/2} \frac{-0.059}{\alpha} \log \frac{i}{i_d - i}$$

where α is *fractional*. The α values as determined from the slopes of the log plots are practically independent of buffer composition in a given solvent medium but decrease with increasing ethanol concentration as indicated in Table III.

Discussion

The general equation for the polarographic waves experimentally established in this reduction is of the form which has been found to hold in several irreversible organic reductions.[13] Although numerous theories have been advanced, the mechanism of the electrode reaction in such reductions has not been established. For this reason, and because of the many variables involved, no theoretical interpretation of the effect of ethanol on the half-wave potentials and the slopes of the waves will be attempted.

The variation in the magnitude of the *p*H increment produced by the addition of a given quantity of ethanol to each of the nine buffers is attributed mainly to the variable effect of this solvent on the dissociation of the various buffer acids. A similar variation was observed by Smith,[14] who determined *p*H values for several buffers in water and in 50% ethanol solutions. Investigations of the effect of ethanol on the dissociation of various acids are reviewed (through 1937) by Kolthoff and Rosenbloom in their monograph "Acid-Base Indicators."[15] There are also

(12) Ref. 2, p. 145.
(13) Ref. 2, p. 195.
(14) R. B. Smith, *J. Am. Pharm. Assoc.*, **17**, 241 (1928).
(15) Kolthoff and Rosenbloom, "Acid-Base Indicators," The Macmillan Co., New York, N. Y.

more recent investigations too numerous to list here. As might be expected the effect is slight in the case of strong acids but the dissociation constants of weak acids may be 10^4 to 10^6 times smaller in absolute ethanol than in water.[16]

Diffusion Current Data and Calculation of Diffusion Coefficient.—The diffusion current behavior illustrated in Fig. 4 may be attributed mainly to the effect of the viscosity of the medium on the diffusion coefficient. No viscosity data for the electrolyte solutions studied are available but if the viscosities of water–ethanol mixtures[17] are plotted against ethanol content, the curve shows a flat maximum over a region coinciding roughly with that of the minimum in the curves of Fig. 4. A similar effect was observed by Pasternack and Halban in the reduction of two ketones[4] and by Zlotowski and Kolthoff in the reduction of barium and strontium.[3]

The electroreduction of *p*-nitroaniline at a mercury electrode has been found to involve 6 electrons.[18] Assuming $n = 6$ in the Ilkovic equation, it is possible to calculate the diffusion coefficient (D) for the *p*-nitroaniline molecule from the polarographic data. In the aqueous phosphate buffer of *p*H 6.8 (no. 7, Table II), such a calculation yields a value of $D = 8.79 \times 10^{-6}$cm.^{2}sec.$^{-1}$. No data permitting a direct calculation of a diffusion coefficient value for this molecule could be found in the literature; an approximate value can be obtained, however, by assuming, as suggested by Kolthoff and Lingane,[19] that the required diffusion coefficient is equal to that of an organic ion of similar size and shape for which conductivity data are available and applying the equation

$$D^\circ = 2.67 \times 10^{-7} (\lambda^\circ/\text{valence})$$

Thus, the diffusion coefficient for the *p*-aminobenzoate ion, for which $\lambda^\circ = 32$ mhos.,[20] is 8.54×10^{-6} cm.^{2}sec.$^{-1}$, a value in good agreement with that calculated from the polarographic data above and tending to confirm the assumption that six electrons are indeed involved in the reduction. Using the value $n = 6$, together with the $m^{2/3}t^{1/6}$ values given above, and applying the Ilkovic equation, values for the diffusion coefficient, D, in all buffer solutions studied can be obtained from the data of Table II.[21]

Summary

1. "Apparent" *p*H values have been determined for a series of commonly used buffer systems in water and 6 ethanol–water mixtures and the polarographic reduction of *p*-nitroaniline in these buffers has been investigated.

2. The Ilkovic equation has been shown to hold for the reduction and evidence that 6 electrons are involved has been given.

3. Equations relating half-wave potentials to apparent *p*H in each solvent medium have been given.

4. Data showing the effect of ethanol on (a) the equation for the polarographic waves, (b) the magnitude of the half wave potential and (c) the various terms in the Ilkovic equation have been presented and discussed.

5. The polarographic data given affords a means of obtaining diffusion coefficient values for *p*-nitroaniline in the solutions studied.

The Ultraviolet Absorption Spectra of Alkoxy- and Hydroxybenzils

BY NELSON J. LEONARD, RICHARD T. RAPALA,[1] HERSHEL L. HERZOG[2] AND ELKAN R. BLOUT

The yellow color of glyoxal and benzil was contrasted by Robinson[3] with the absence of color in ethyl oxalate and crystalline 4,4′-diethoxybenzil. The difference was explained on the basis that ethyl oxalate possesses a neutralized system (an electron-donating group attached to an electron-accepting group) and that the ethoxyl groups in 4,4′-diethoxybenzil have an influence on the diketone system of benzil through the benzene nuclei similar to that which obtains by direct union in ethyl oxalate. A quantitative comparison of the color of these compounds can be found in the determination of their absorption spectra.

The ultraviolet absorption maximum for ethyl oxalate[4] has been shown to lie at much shorter wave length than the maxima of glyoxal,[5] methyl-

glyoxal,[6] and biacetyl,[7] which is consistent with Robinson's theory. However, our investigation shows that the absorption spectra of 4,4′-diethoxybenzil and of a series of alkoxy- and hydroxybenzils do not have an analogous relationship when compared with that of benzil. We have found that the introduction of alkoxyl and hydroxyl groups into the benzil molecule produces a bathochromic shift in ultraviolet absorption, and we have observed that, whereas crystalline 4,4′-diethoxybenzil is colorless, solutions of the compound are yellow.

Experimental

Preparation of Substituted Benzils: Method A

Preparation of Symmetrical Benzoins.—One-tenth mole of the aldehyde was dissolved in 30 ml. of ethanol and 15 ml. of water. Two grams of potassium cyanide was added and the solution was heated under reflux for one and one-half hours. After the material had been allowed to cool and to stand for three hours, it was poured into two volumes of water. The oil which separated was extracted with ether. The ether was removed and the residual oil was used directly in the oxidation.

Preparation of Unsymmetrical Benzoins.—Five hundredths mole of the substituted benzaldehyde and 0.05 mole of benzaldehyde were dissolved in 30 ml. of ethanol and 15 ml. of water. The condensation and isolation methods were identical with those employed for the symmetrical benzoins.

Oxidation of Benzoins to Benzils.[8]—To 0.05 mole of impure benzoin was added a solution of 20 g. of copper sulfate in 30 ml. of pyridine and 10 ml. of water. The mixture was heated under reflux for two hours, after which it was poured into three volumes of water. The product was extracted with ether and the ether was removed. The residue was recrystallized at least five times from aqueous ethanol.

Method B

Preparation of *m*-Alkoxyphenyl Benzyl Ketones.—The reaction between the *m*-alkoxybenzamide and benzyl magnesium chloride was conducted according to the method of Jenkins[9] to obtain the corresponding *m*-alkoxyphenyl benzyl ketone.

Oxidation of *m*-Alkoxyphenyl Benzyl Ketones to Benzils.—The oxidation was carried out according to the method of Hatt, Pilgrim and Hurran.[10] The benzil was recrystallized five times from aqueous ethanol.

Method C

Friedel–Crafts Reaction. Preparation of 4,4′-Diethoxybenzil.—To a well-stirred, ice-cooled solution of 0.2 mole of phenetole and 0.1 mole of oxalyl chloride in 100 ml. of carbon disulfide, 30 g. of aluminum chloride was added in small portions over a period of two hours. The reaction mixture was then warmed gently on the steam-bath for thirty minutes. The complex was decomposed by means of hydrochloric acid and ice. The carbon disulfide was removed by distillation and the residue was filtered. The 4,4′-diethoxybenzil thus collected was recrystallized first from glacial acetic acid and then several times from aqueous ethanol.

Method D

Hydrolysis, Preparation of 4,4′-Dihydroxybenzil.[11]—A solution of 20.2 g. (0.074 mole) of 4,4′-dimethoxybenzil in

(6) Woo and Chang, *Trans. Faraday Soc.*, **41**, 157 (1945), reported $\lambda_{max.}$ = 440 mμ and log ε = 1.14 in ether.

150 ml. of acetic acid was heated to boiling, and 48% hydrobromic acid was added in portions until the solution became turbid. Boiling was continued for two hours, after which the mixture was cooled and poured into water. The crude product (15.6 g.) was recrystallized five times from nitroethane.

The absorption spectra measurements were made with a Beckman quartz spectrophotometer model DU using a 1-cm. quartz cell and a hydrogen discharge tube as the ultraviolet source. Ninety-five per cent. ethanol was used as the solvent throughout. In Table I are reported the physical, analytical and spectrographic data for the compounds studied, and in Figs. 1 through 5, the ultraviolet absorption curves for these compounds.

Discussion

Macroscopic examination of the colors of the 4,4′-disubstituted benzils in the crystalline state shows that the diethoxy compound is colorless whereas the dihydroxy and dimethoxy compounds are definitely yellow. Microscopic examination of the crystals of these compounds, as obtained from aqueous ethanol, indicates that 4,4′-dimethoxy- and 4,4′-diethoxybenzil crystals are orthorhombic, although probably not isomorphous because of the different orientation of the index ellipsoid axes with respect to the prism axis. 4,4′-Dihydroxybenzil crystals are monoclinic.[19]

In all three compounds, the resonance configurations should be similar, which would lead us to expect that the absorption spectra should be similar. This is, in fact, the case, as the ultraviolet absorption determination shows. All three compounds are characterized essentially by one high-intensity absorption peak at 300 mμ (Fig. 4). This is a similar bathochromic shift of 30–40 mμ (compared to benzil) to that observed with the *p,p′*-disubstituted benzalazines.[20] In the wave length region above 410 mμ, the curves for the 4,4′-disubstituted benzils are also similar and resemble closely that of benzil. The prediction from these absorption curves that all of the ethanolic solutions should be yellow is verified simply by visual examination. Since the diethoxy compound is similar to the dimethoxy and dihydroxy compounds in ultraviolet absorption and visible absorption in solution, the lack of color in the 4,4′-diethoxybenzil solid is related to the crystalline habit of the material and is not an effect directly attributable to the electron-donating property of the ethoxyl group, as has been proposed. This seems to be another example of the relatively well-known fact that the color of crystals does not indicate necessarily the color of the molecules in solution.

The inconsistency between color of solid and color of solutions is not exhibited by the corresponding 2,2′-disubstituted benzils. 2,2′-Diethoxybenzil and 2,2′-dimethoxybenzil are colorless as solids and colorless in solution; 2,2′-dihydroxybenzil is pale yellow as a solid and yellow in ethanol solution. As would be expected

(19) The authors are indebted to Miss E. J. Weichel for the crystallographic and optical analyses.

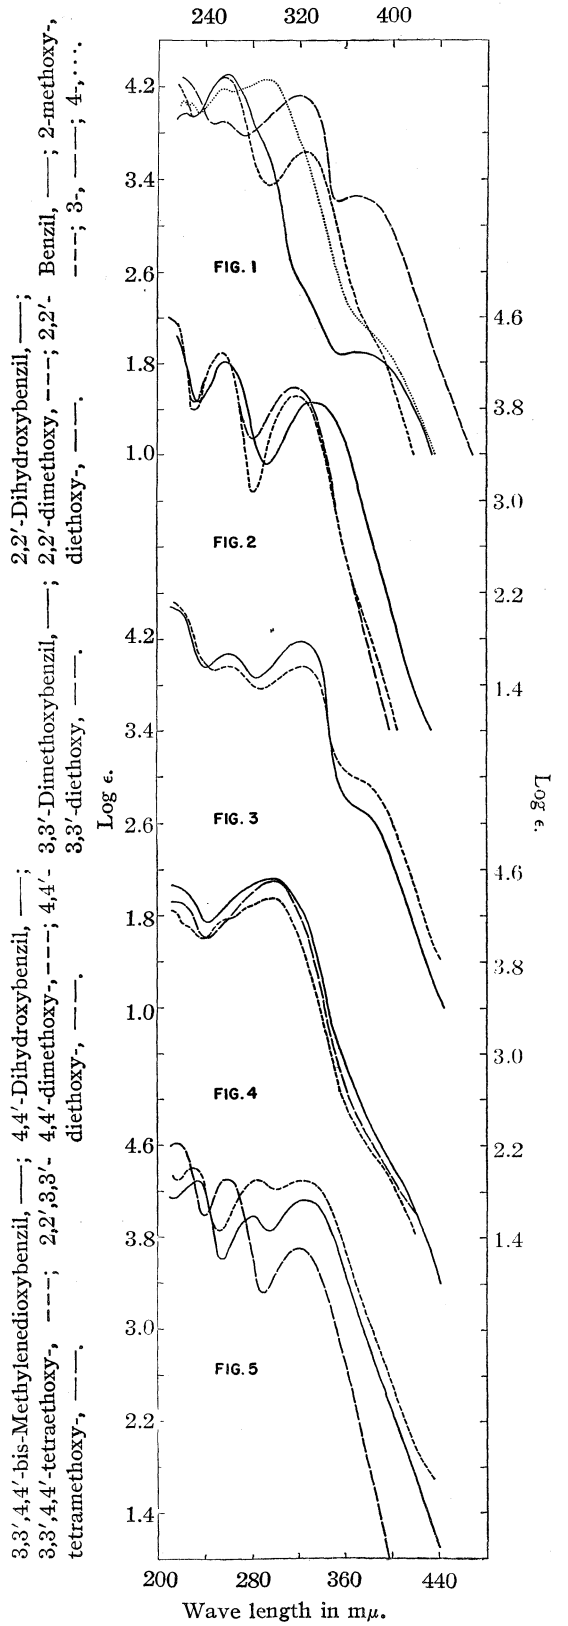
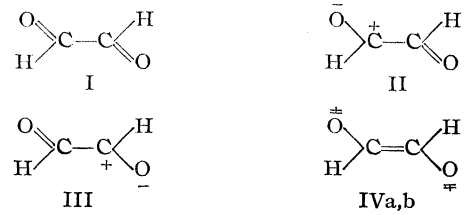


Figs. 1–5.—Absorption spectra of benzils.

because of their similar electronic configurations, the first two compounds exhibit similar absorption maxima at 254 and 318 mμ; the dihydroxy compound likewise has a maximum at 257 mμ, but the second maximum has shifted to 332 mμ (Fig. 2). The end absorption, above 380 mμ, is less for 2,2′-diethoxybenzil and 2,2′-dimethoxybenzil (colorless in solution) than it is for benzil, while the end absorption of 2,2′-dihydroxybenzil (yellow in solution) is similar to that of benzil. The spectral determination is thus, in this case, consistent with visual examination of the solids and solutions.

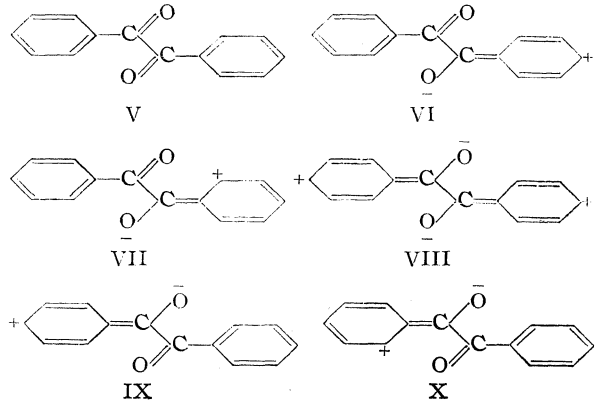
While comparison of light absorption of different benzils is warranted, similar comparison of absorption of aromatic 1,2-diketones with that of aliphatic 1,2-diketones has less meaning. Since the time when Robinson proposed the common basis for the yellow color of benzil and glyoxal and for the lack of color of 4,4′-diethoxybenzil and ethyl oxalate,[3] the spacial configuration of the dicarbonyl groups in these molecules has been elucidated. The accumulated evidence indicates that the dicarbonyl system in benzil has a skew configuration, whereas the carbonyl groups in glyoxal and biacetyl have a coplanar, *trans* configuration. The conclusion that the benzil molecule has a skew structure, in which the two benzoyl units lie in planes approximately at right angles to each other, has been reached from X-ray examination of crystals by Knaggs and Lonsdale,[21] from dipole moment measurement of benzil in solution by Caldwell and LeFèvre,[22] and from parachor determination by Gibling.[23] For glyoxal and biacetyl, LuValle and Schomaker[24] have found that the electron diffraction, dipole moment, and chemical data indicate uniformly that both molecules are planar with the *trans* configuration and that rotation about the C—C bond (1.47 ± 0.02 Å.) connecting the adjacent carbonyls is restricted. Observations by Gaydon[25] on the spectrum resulting from a Tesla discharge through glyoxal vapor are best explained on the assumption that the glyoxal molecule has the planar, *trans* form. The bond orders in glyoxal, as calculated by the method of molecular orbitals,[26] are also consistent with the molecular structure of glyoxal as advanced by LuValle and Schomaker.

The exact chemical state of glyoxal can be considered most adequately as a resonance hybrid of a number of contributing structures (I, II, III, IVa, IVb). The fact that structures IVa and IVb contribute to the ground state of the molecule is evidenced by the shortened distance, 1.47 Å., between the carbonyl carbon atoms.



It has been suggested[27,28] that the absorption (and therefore the visible yellow color) of such an aliphatic 1,2-dicarbonyl compound is due to excitation of the electronic oscillations represented mainly by the formulas IVa and IVb.

In the benzil molecule, structures of type IV should make much less contribution to the resonance hybrid because the molecule is skew and will resist the coplanarity demanded by such contributing structures. The more likely resonance structures for benzil are indicated by formulas V-X. The absorption spectra observations are consistent with the known differences



in the structure of glyoxal and benzil. The wave length (450 mμ) and magnitude (log ϵ = 0.50)[29] of absorption by glyoxal[5] are not commensurate with the wave length (259, 370 mμ) and magnitude (log ϵ = 4.31, 1.89) of absorption by benzil (Fig. 1). The "dicarbonyl" absorption has been greatly modified in the benzil molecule.

Since we must consider the 1,2-dicarbonyl systems in the aliphatic and aromatic compounds as essentially different, we cannot expect hydroxyl or alkoxyl groups on the benzil molecule to have an effect on the absorption spectra analogous to that found in going from glyoxal to oxalic acid and its esters. Because of the skew structure of benzil, the absorbing units must act more or less like individual benzoyl groups (V-X), and the spectral effect of substitution of alkoxyl or hydroxyl groups on benzil should be similar to that of analogous substitution on benzaldehyde or acetophenone. The spectra of such compounds in ethanol have been previously deter-

mined, but in order to facilitate comparison of the ultraviolet absorption maxima of benzaldehydes and benzils, the pertinent data are collected and reproduced in Table II.

TABLE II

SUBSTITUTED BENZALDEHYDES

Compound	$\lambda_{max.}$ mμ	log ε	mμ	log ε	mμ	log ε
Benzaldehyde[30]	240	4.12	278	3.02	320	1.7
Acetophenone[30]	240	4.12	278	3.02		
Propiophenone[31]	245	4.1	~280	3.05		
o-Hydroxybenzaldehyde[30]	255	4.00	325	3.48		
p-Hydroxybenzaldehyde[30]	221	4.14	284	4.24	~332	2.25
o-Methoxybenzaldehyde[30,32]	253	4.07	319	3.62		
m-Methoxybenzaldehyde[30,32]	252	3.92	314	3.45		
p-Methoxybenzaldehyde[30]			277	4.17		
Piperonal[33]			275	3.8	315	4.0

It can be seen from Tables I and II that the effect of *o*-, *m*- and *p*-hydroxy- and alkoxy-substitution in benzaldehyde are indeed parallel to the effects of analogous substitution in both rings of benzil. In general, such substitution shifts the absorption maxima to longer wave lengths. In both series, *ortho*- and *meta*-substituted compounds exhibit two main peaks and *para*-substituted compounds have essentially one absorption band in the ultraviolet.[34] The wave lengths of the maxima are proximate for the benzaldehyde and benzil analogs. The closest agreement is found for the maxima exhibited by *o*-methoxybenzaldehyde and 2,2′-dimethoxybenzil. The wave lengths of the maxima are practically identical and the extinction coefficients of the 2,2′-dimethoxybenzil maxima are about double those of *o*-methoxybenzaldehyde. Thus, the transitions to the excited states responsible for absorption must be similar for the two compounds. There is also close agreement between the maxima of *o*-methoxybenzaldehyde and 2,2′-diethoxybenzil (Fig. 2) and good agreement between the maxima of *o*-hydroxybenzaldehyde and 2,2′-dihydroxybenzil. The maxima for *m*-methoxybenzaldehyde and 3,3′-dimethoxy- and 3,3′-diethoxybenzil (Fig. 3) differ only by 8–10 mμ in wave length, but the long wave length absorption of benzil (370 mμ) appears as an inflection point (380 mμ) in the 3,3′-dialkoxybenzils, indicating that additional electronic transitions are possible in this molecule. The greatest difference of wave length for comparative maxima is found between *p*-hydroxybenzaldehyde and 4,4′-dihydroxybenzil (15 mμ), between *p*-methoxybenzaldehyde and 4,4′-dimethoxybenzil (21 mμ). The shift of the maxima toward longer wave lengths with these *para*-substituted benzils can be due either to an increase in the number of configurations for the excited state or to an increase in the electron density of such states. Because two adjacent carbonyl groups are not very effective in transmitting conjugation through a molecule, it is difficult to see how the length of the absorbing system can be increased over that which exists in *p*-hydroxy- or *p*-alkoxybenzaldehydes.

When the absorption curves of different benzils are compared, we observe that there is close correspondence between those of 4,4′-dihydroxybenzil and 4,4′-dimethoxybenzil, whereas the longer wave length maximum of 2,2′-dihydroxybenzil undergoes a 14 mμ bathochromic shift compared to that of 2,2′-dimethoxybenzil (*cf.* Figs. 2 and 4). Morton and Stubbs[30] observed a similar displacement of 18 mμ between the absorption maxima of *o*-hydroxybenzaldehyde and *o*-methoxybenzaldehyde in hexane solution. They attributed this to chelation in the *o*-hydroxybenzaldehyde, an explanation which is also admissible for 2,2′-dihydroxybenzil.

As mentioned previously, the long wave length maximum of benzil appears as an inflection point in the absorption curves of 3,3′-dialkoxybenzils (Fig. 3), but is not present in the curves of the 2,2′- or 4,4′-dialkoxybenzils (Figs. 2 and 4).[35] This maximum, present in benzil, either has disappeared or has shifted toward shorter wave length and lost its identity in the 2,2′- and 4,4′-disubstituted compounds.

The absorption curves of the 2-, 3- and 4-alkoxybenzils are intermediate between those of benzil and the corresponding disubstituted benzils (*cf.* Figs. 1, 2, 3, 4), as expected. The curves of 3,3′,4,4′-bis-methylenedioxybenzil and 3,3′,4,4′-tetraethoxybenzil (Fig. 5) are a composite of those of 3,3′- and 4,4′-dialkoxybenzil and that of 2,2′,-3,3′-tetramethoxybenzil (Table I) is a composite of those of 2,2′- and 3,3′-dimethoxybenzil.

Summary

The ultraviolet absorption spectra of benzil and seventeen alkoxy- and hydroxybenzils have been determined.

The absorption maxima and the color of series of *o*-, *m*- and *p*-substituted benzils in ethanol solution show regularities which are not exhibited by these compounds in the crystalline state.

The absorption maxima of the substituted benzils and the correspondingly substituted benzaldehydes have been shown to lie at closely comparable wave lengths. This is consistent with the skew structure of benzil, likewise to be expected for the substituted benzils, and is an in-

(34) The gross structure of the main ultraviolet absorption bands in the benzil series seems to parallel closely that observed with the similarly substituted benzalazines.[20] In particular, it should be pointed out that in both series the symmetrically *para*-substituted compounds exhibit but a single maximum in the region examined, whereas two main absorption peaks become increasingly evident as one proceeds from the symmetrically substituted *meta* to the symmetrically substituted *ortho* compounds.

(35) The presence of a true inflection point at 380–400 mμ in the 4,4′-dihydroxy- and 4,4′-dimethoxybenzil is certainly open to question.

dication that the excited structures which give the major contribution to absorption are closely related to those which contribute to the absorption of the substituted benzaldehydes.

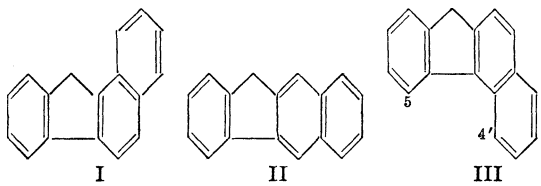
Structure of the Benzfluorenes and Benzfluorenones

BY MILTON ORCHIN[1] AND ROBERT A. FRIEDEL[2]

Introduction

Of the three possible benzfluorenes, I–III, 1,2-benzfluorene, I, and 2,3-benzfluorene, II, have strikingly similar chemical and physical properties and ultraviolet spectra. 3,4-Benzfluorene, III, is however considerably different from its isomers. The benzfluorenes, I and II, are high melting, difficult to separate and relatively insoluble. They both form unstable pic-



I II III

rates and trinitrobenzene complexes in the ratio of 2 moles of polynitro compound to 1 mole of hydrocarbon. The benzfluorene, III, is much lower melting, relatively soluble, easily separated from its isomers and forms stable molecular complexes in a molar ratio of 1:1.

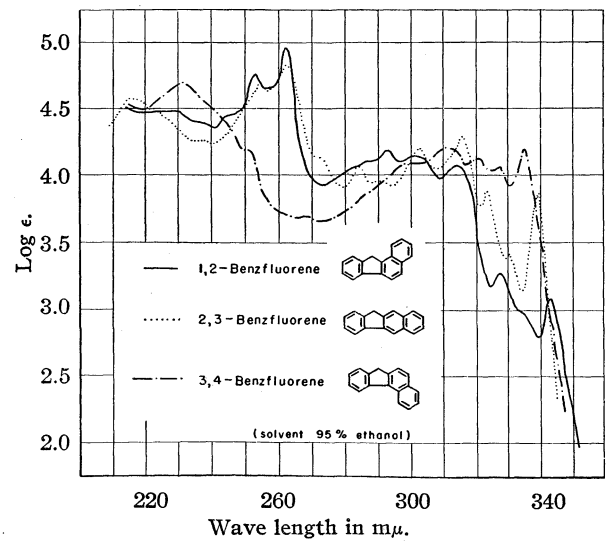


Fig. 1.—Ultraviolet spectra of the benzfluorenes.

Discussion

A possible explanation of the contrasting properties of the benzfluorenes is revealed in a comparison of them with the phenylnaphthalenes. Both I and II may be considered as 2-phenylnaphthalene derivatives while III may be considered as a derivative of 1-phenylnaphthalene. The ultraviolet absorption spectra of the three isomers (Fig. 1) show that although some dissimilarity exists between the spectra of I and II in the 270–300 mμ region, on the whole the spectra of I and II are quite similar and differ from that of III in a manner analogous to the difference in spectra between 1- and 2-phenylnaphthalene.[3] Thus it will be noted that I and II have strong absorption bands in the 260 mμ region, a feature also characteristic of the spectrum of 2-phenylnaphthalene, while the spectrum of the 3,4-benzfluorene, III, exhibits a minimum in this region similar to that shown by 1-phenylnaphthalene.

In 1-phenylnaphthalene there is unquestionably

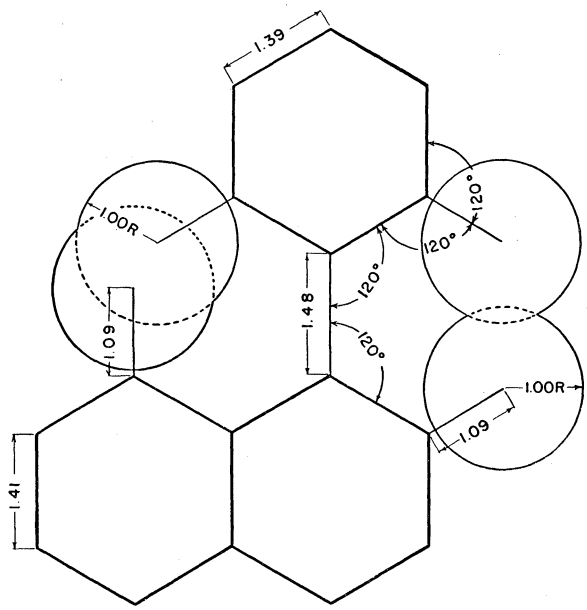

Fig. 2.—Planar representation of 1-phenylnaphthalene.

(3) Friedel, Orchin and Reggel, THIS JOURNAL, **70**, 199 (1948). The relationship of the spectra of the benzfluorenes and the phenylnaphthalenes has been commented on previously by Jacobs, Craig and Lavin, *J. Biol. Chem.*, **141**, 51 (1941).

steric interference between the hydrogen atoms at the 2′- and 8-positions which inhibits coplanarity. Figure 2 shows the probable extent of the hydrogen overlap at these positions in the planar model. The non-planar structure which is favored because of this interference probably explains the low melting point of 1-phenylnaphthalene as compared to 2-phenylnaphthalene. In view of the spectral resemblance of 3,4-benzfluorene III, to 1-phenylnaphthalene and the relatively low melting point of III, it is of interest to consider the hydrogen overlap in the structure of the latter and to consider also the structure of fluorene.

Cook and Iball concluded from an X-ray crystal study of fluorene, that the fluorene molecule is not planar but that the planes of each six-membered ring are inclined at an angle of 20° to that of the five-membered ring and at about 40° to each other (*cis*-form).[4]

Hughes, LeFèvre and LeFèvre, on the basis of dipole measurements in solution at first proposed a planar model of fluorene.[5a] They pointed out that if it is assumed that the five-membered ring is regular with internal angles of 108°, then the aromatic rings must be distorted 12° from a diphenyl structure and this requires the external angles around the diphenyl linkage to be 132°. These authors later stated[5b] that their measurements did not exclude the possibility of a non-planar structure in which the diphenyl linkage is distorted 8° (irregular pentagon) and the planes of the benzene ring are bent at about 20° either *cis* or *trans*. Figure 3 shows a planar model of 3,4-benzfluorene using angles and carbon to carbon distances which we regard as most probable if fluorene were planar.[6] In such a planar model there is only a minor amount of overlap between hydrogens at 4′ and 5 compared to the overlap in 1-phenylnaphthalene (Fig. 2). This is an additional incentive to favor a non-planar form for fluorene since in either the non-planar model suggested by Cook or inferred by Hughes, LeFèvre and LeFèvre, the interference of the hydrogens in III would be larger and of the magnitude involved in the overlap in 1-phenylnaphthalene. This overlap would cause strain which is additional to that present in the other benzfluorenes, I and II, and may tend to rotate the phenyl ring about the diphenyl linkage (as in the case with 1-phenylnaphthalene) so that the five-membered ring itself may become slightly non-planar. In any case, the postulated hydrogen overlap and the strain which it effects are now proposed to explain the relation between the spectra of 3,4-benzfluorene, III, and 1-phenylnaphthalene on the one hand and the other two benzfluorenes and 2-phenylnaphthalene on the other.

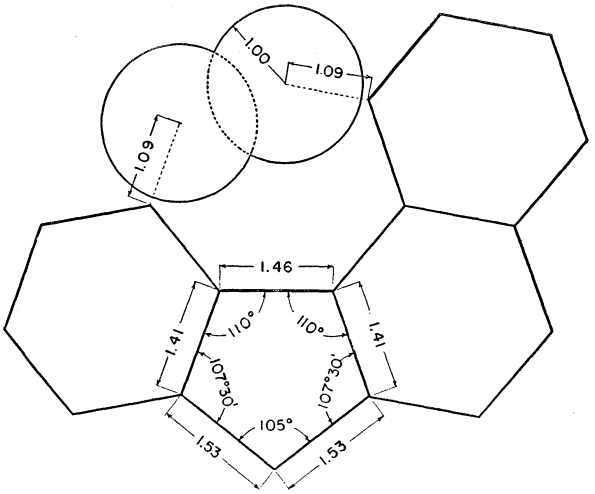

Fig. 3.—Planar representation of 3,4-benzfluorene.

The interesting differences observed with complex compound formation in this series, the data for which are found in Table I, are deserving of comment. The benzfluorenes, I and II, related to 2-phenylnaphthalene, form with 1,3,5-trinitrobenzene (T. N. B.) and with picric acid, complexes containing two moles of the polynitro compound. These complexes dissociate very readily. 2-Phenylnaphthalene also forms a 2:1 T. N. B. and its picrate is so unstable as to elude isolation. On the other hand, 3,4-benzfluorene, III, forms stable, sharp melting complexes with these nitro compounds in a molar ratio of 1:1.[7] These differences may be due to the smaller overall volume of 3,4-benzfluorene as compared to its isomers or they may be related to the strain differences discussed above which tend to make 3,4-benzfluorene less planar than its isomers. It will be noted that all the hydrocarbons in Table I form stable, high melting complexes with 2,4,7-trinitrofluorenone[8] (T. N. F.), in a 1:1 ratio. This fact may be due to some geometrical features of T. N. F. which permits its closer approach to relatively similar hydrocarbons or to the fact that T. N. F. is a relatively large molecule with widely separated positive centers. Observations

(4) Cook and Iball, *Chem. and Ind.*, 467 (1936). These authors point out that the non-planar configuration of fluorene does not necessarily demand the existence of stereoisomeric fluorenes because sufficient elasticity to oscillate may be possessed. Fieser and Joshel, THIS JOURNAL, **62**, 957 (1940), prepared 9-hydroxy-9-methyl-3,4-benzfluorene, which if 3,4-benzfluorene were non-planar, should exist as two racemic mixtures, each of which is resolvable. However, they isolated only one product in 85% yield.

(5) (a) Hughes, LeFèvre and LeFèvre, *J. Chem. Ind.*, **545**, 581 (1936); (b) *J. Chem. Soc.*, 202 (1937).

(6) The planar models of fluorene given by Hughes, LeFèvre and LeFèvre, ref. 5b, and by Pinck and Hilbert, THIS JOURNAL, **59**, 8 (1937), are not drawn accurately to scale. In the latter case, if the model is drawn with the bond lengths indicated and the angles about the diphenyl linkage as 107.5°, the angle at the methylene group is about 104° and not 110°.

(7) Attempts to prepare complexes with 1-phenylnaphthalene were unsuccessful in all cases but melting point–composition diagrams are needed before it can definitely be decided whether compound formation occurs.

(8) (a) Orchin and Woolfolk, THIS JOURNAL, **68**, 1727 (1946); (b) Orchin, Reggel and Woolfolk, *ibid.*, **69**, 1225 (1947).

made in this and other laboratories[9] indicate that in general, T. N. F. is to be preferred over other polynitro compounds for complex compound formation in the polycyclic series.

TABLE I

TABLE OF PROPERTIES

Name	Hydrocarbons M. p., °C.	Picric acid[a] complex	T. N. B. complex	T. N. F. complex	Ketones M. p., °C.	T. N. B. complex
			115	170		
2-Phenylnaphthalene	103	...	2:1	1:1	...	...
		127	145	215		126
1,2-Benzfluorene	186	2:1	2:1	1:1	135	1:1
		122	139	222		124
2,3-Benzfluorene	214	2:1	2:1	1:1	155	1:1
		131	155	192		128
3,4-Benzfluorene	127	1:1	1:1	1:1	160	1:1

[a] The top number under the various complexes is the melting point; below it is the ratio of moles polynitro component to moles of compound.

The ultraviolet absorption spectra of the benzfluorenones (Fig. 4) show an interesting reversal as compared to the parent benzfluorenes. Whereas

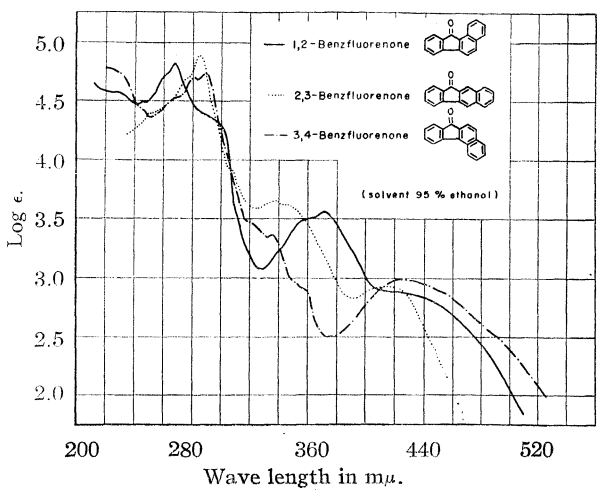

Fig. 4.—Ultraviolet spectra of the benzfluorenones.

in the hydrocarbon series, 3,4-benzfluorene exhibits a spectrum different from that of the other two isomers, in the ketone series 1,2-benzfluorenone has the spectrum which is easily distinguished from that of its isomers. This may be due to interaction between the carbonyl group at position 9 and the hydrogen on carbon 1′ giving rise to weak internal hydrogen bonding and incipient six-membered ring formation. The two main absorption maxima in the spectrum of 1,2-benzfluorenone are located at shorter wave lengths as compared to these maxima in the spectra of its isomers. This indicates less carbonyl contribution in the case of the 1,2-benzfluorenone as indeed would be expected if the oxygen were partially involved in hydrogen bonding. It will be noted from Table I that this ketone is the lowest melting of the isomers.

Acknowledgment.—The authors wish to thank Mr. Martin Michael for expert drafting aid and Mrs. Lois Harnack for assistance with the spectral measurements.

Experimental[10]

1,2-Benzfluorenone.—This compound was prepared on a large scale by a new method which will be reported later.[11] It had a melting point of 134.5–135.0°.

The complex with 1,3,5-trinitrobenzene was prepared in the usual way in ethanol solution and the complex separated as yellow-orange needles, m. p. 125.0–126.0°. Recrystallization from ethanol resulted in a less pure material. The material isolated in the first crop was used for analysis. *Anal.* Calcd. for $C_{25}H_{13}N_3O_7$: C, 62.3; H, 3.0. Found: C, 62.3; H, 3.0.

2,3-Benzfluorenone.—A small sample of this compound was secured from Professor L. F. Fieser.[12] The preparation of a complex with 4 mg. of this material and double the molar proportions of 1,3,5-trinitrobenzene was attempted. The first crops isolated were unchanged trinitrobenzene but later crops consisted of the complex. One recrystallization of the complex gave yellow prisms, softening at 117° and m. p. 124°. Ultraviolet absorption spectra analysis showed this complex to consist of 49 molar per cent. trinitrobenzene and 51 molar per cent. ketone.

3,4-Benzfluorenone.—This compound was also the generous gift of Professor L. F. Fieser.[13]

The complex with 1,3,5-trinitrobenzene was prepared in ethanol; the complex separated in yellow gold needles, which after recrystallization from ethanol had a melting point of 128.0–128.4°. *Anal.* Calcd. for $C_{25}H_{13}N_3O_7$: C, 62.3; H, 3.0. Found: C, 62.3; H, 2.6. The complex was much lighter in color than the ketone itself.

1,2-Benzfluorene, I.—This compound was prepared by reduction of the corresponding benzfluorenone with phosphorus and hydriodic acid, essentially according to the directions of Graebe.[14] Crystallization from ethanol gave small colorless crystals, m.p. 185.4–186.0°.

The picrate has been prepared previously[15] and has been shown to consist of 2 moles of picric acid to 1 mole of hydrocarbon.

The trinitrobenzene complex was obtained from ethanol as small yellow crystals, m.p. 144.0–145.0°. *Anal.* Calcd. for $C_{29}H_{18}N_6O_{12}$: N, 13.1. Found: N, 13.9.

The complex with 2,4,7-trinitrofluorenone separated as red crystals which after crystallization from benzene–ethanol had a melting point of 213.5–215.5°. *Anal.* Calcd. for $C_{30}H_{17}N_3O_7$: C, 67.8; H, 3.2. Found: C, 68.0; H, 3.3.

2,3-Benzfluorene, II.—The properties of this compound have been reported by us previously.[8b]

The picrate was made from the hydrocarbon and picric acid in petroleum ether and recrystallized from petroleum–ether (90–100°) whereupon it separated as yellow-orange crystals, softening at 118° and melting at 121.8–122.5°. *Anal.* Calcd. for $C_{29}H_{18}N_6O_{14}$: C, 51.6; H, 2.7. Found: C, 51.8; H, 3.1.

The complex with 1,3,5-trinitrobenzene was obtained from petroleum ether (90–100°) as bright yellow plates, m.p. 138.0–139.0°. *Anal.* Calcd. for $C_{29}H_{18}N_6O_{12}$: N, 13.1 Found: N, 13.6.

(9) For example, Newman and Hart, THIS JOURNAL, **69**, 298 (1947); Cheronis and Entrikin, "Semimicro Qualitative Analysis," Thomas Y. Crowell, New York, N. Y., 1947, pp. 311, 314.

(10) All melting points corrected. All analyses are microanalyses by Mr. G. L. Stragand, University of Pittsburgh.

(11) We wish to thank Mr. Leslie Reggel for this preparation and for other valuable assistance with a portion of the experimental work.

(12) Fieser and Gates, THIS JOURNAL, **62**, 2335 (1940).

(13) Fieser and Joshel, *ibid.*, **62**, 957 (1940).

(14) Graebe, *Ber.*, **29**, 828 (1896).

(15) Graebe, *Ann.*, **335**, 135 (1904), gives a melting point of 127.5° and Cook and Hewett, *J. Chem. Soc.*, 365 (1934), give a melting point of 124–126°.

In this series of 2:1 complexes it is desirable to avoid the use of ethanol as a solvent. Chloroform or petroleum ether is more satisfactory for the isolation of the unstable complexes.

The 2,4,7-trinitrofluorenone complex has been reported previously[8b] but its analysis did not correspond to any simple molar ratio. This conclusion was reached on the basis of several nitrogen analyses at different laboratories, all of which checked but all of which we have found subsequently to be in error. The carbon and hydrogen analyses showed the complex to be a 1:1 combination. *Anal.* Calcd. for $C_{30}H_{17}N_3O_7$: C, 67.8; H, 3.2. Found: C, 68.1; H, 3.5.

3,4-Benzfluorene, III.—An attempted reduction of 3,4-benzfluorenone with phosphorus and iodine in acetic acid resulted in the almost complete recovery of the ketone. It was then successfully reduced by the Huang-Minlon[16] modification of the Wolff–Kishner reaction. A solution of 0.317 g. of the ketone, 0.5 cc. of 85% hydrazine hydrate, 0.4 g. of sodium hydroxide and 25 cc. of ethylene glycol was refluxed for two hours. During this time the yellow solid became red and gradually went into solution; then all the red color disappeared leaving a clear yellow solution. At the end of the two hours, the condenser was removed and the contents boiled in the open until the temperature in the flask was 200°. The condenser was replaced and the solution refluxed two hours, cooled and poured into ice and hydrochloric acid. The precipitate was dried and crystallized from ethanol. The first crop (0.19 g.) separated as nearly colorless plates tinged with a pink color, m.p. 122.6–124.0°. The second crop (0.05 g.) had about the same melting point. On recrystallization of the first crop from benzene–alcohol a small amount of insoluble material was noted and separated. This melted at 241.5–244.0° and was probably the hydrazone of the benzfluorenone.

(16) Huang-Minlon, THIS JOURNAL, **68**, 2487 (1946).

The soluble fraction gave pure 3,4-benzfluorene, m.p. 126.8–127.4°.[17]

The known mono-picrate[17] was obtained from ethanol as fine red needles, m.p. 131.4–132.2°.

The trinitrobenzene complex was obtained from benzene–alcohol as orange-yellow crystals, m.p. 154.2–155.2°. *Anal.* Calcd. for $C_{23}H_{15}N_3O_6$: C, 64.3; H, 3.5. Found: C, 64.5; H, 3.5.

The trinitrofluorenone complex separated from benzene-alcohol as fine, light red needles, m.p. 191.8–192.8°. *Anal.* Calcd. for $C_{30}H_{17}N_3O_7$: C, 68.8; H, 3.2. Found: C, 67.6; H, 2.9.

2-Phenylnaphthalene and its complex with 2 moles of trinitrobenzene has been described previously[3] as has the complex with trinitrofluorenone.[8b]

Summary

The physical properties and ultraviolet absorption spectra of the three benzfluorenes and the three benzfluorenones were determined and significant features discussed. The molecular complexes formed between these compounds and various polynitro compounds were prepared and studied. In nearly all respects the behavior of 1,2- and 2,3-benzfluorene was similar but 3,4-benzfluorene differed from its isomers. It is proposed that the differences stem from the possibility of hydrogen overlap in the 3,4-benzfluorene molecule which may cause it to assume a less planar structure than its isomers.

(17) Cook, Dansi, Hewett, Iball, Mayneord and Roe, *J. Chem. Soc.*, 1319 (1935), give the melting point of the hydrocarbon as 124–125° and the melting point of its picrate as 130–131°.

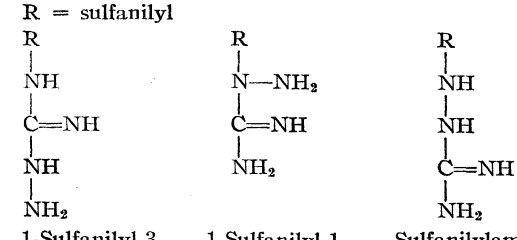
Isomerism of Sulfanilylaminoguanidines[1]

BY ALBERT H. GREER,[1a] DENNIS L. KERTESZ[2] AND G. B. L. SMITH[3]

A sulfanilylaminoguanidine melting at 208–210° was prepared by Winnek, *et al.*,[4] by condensation of N^4-acetylsulfanilyl chloride with S-methylthiourea or with cyanamide, followed by hydrazinolysis or hydrazination and deacetylation. More recently, Owades[5] has obtained the same sulfanilylaminoguanidine by the catalytic hydrogenation of N^4-acetylsulfanilylnitroguanidine and subsequent deacetylation. Prior to this, Kertesz[6] had prepared another sulfanilylaminoguanidine melting at 298–300° by condensing *p*-nitrobenzenesulfonyl chloride with aminoguanidine, and reducing the product by catalytic hydrogenation. We have now prepared a third sulfanilylaminoguanidine melting at 188–190°.

It is evident that three structural isomers of sulfanilylaminoguanidine are possible, as follows

R = sulfanilyl



1-Sulfanilyl-3-aminoguanidine I

1-Sulfanilyl-1-aminoguanidine II

Sulfanilylamidoguanidine III

The above does not include the tautomeric isomers for which formulas can be written. Isomer I has three tautomers, isomer III has two, and isomer II only one.[4]

The present paper describes the preparation

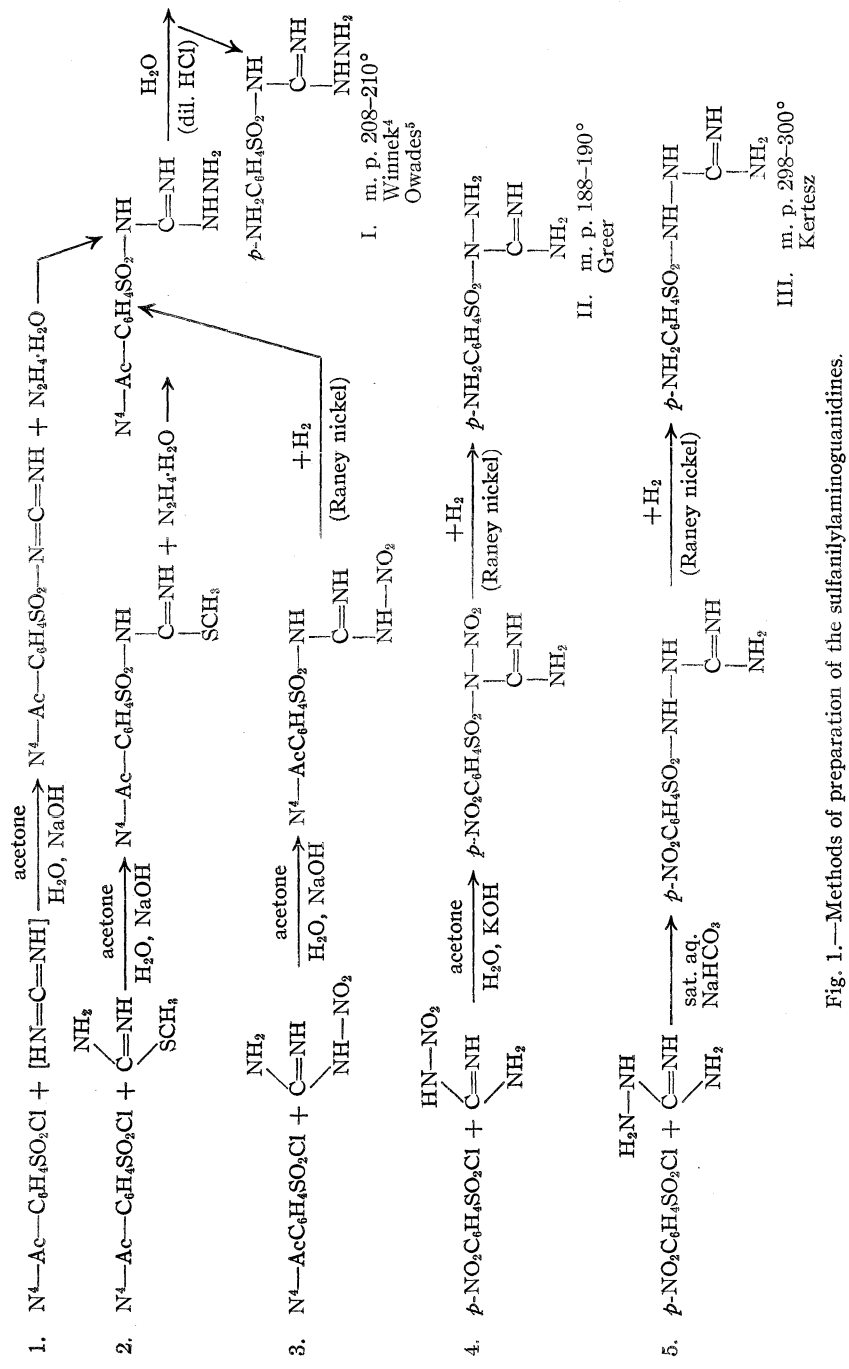

Fig. 1.—Methods of preparation of the sulfanilylaminoguanidines.

and properties of the three isomeric sulfanilylaminoguanidines and deduces therefrom the structural formula applicable to each.

Experimental Part

1-Sulfanilyl-3-aminoguanidine (I) from Nitroguanidine.—Nitroguanidine, 5.2 g. (0.05 mole) was suspended in 60 ml. of acetone, and to this mixture 0.5 g. of potassium hydroxide in 10 ml. of water was added slowly with vigorous stirring. The initial *p*H was approximately 10–11. After the nitroguanidine was dissolved completely, the solution was cooled to 18° and 11 g. (0.05 mole) of N⁴-acetylsulfanilyl chloride was added during a period of thirty minutes. The mixture was stirred for three hours at room temperature by which time a voluminous precipitate had formed. Thirty milliliters of water was added, the precipitate was filtered off, washed with cold water and recrystallized from 80% ethanol, to give 2 g. (13%), of colorless crystals, m. p. 195–198°. This 1-N⁴-acetylsulfanilyl-3-nitroguanidine (6.0 g., 0.02 mole) in ethanol solution was reduced with hydrogen in the presence of Raney nickel catalyst, the catalyst was removed by filtration, and the 1-N⁴-acetyl-sulfanilyl-3-aminoguanidine, obtained by carefully evaporating the solvent, was recrystallized from 70% ethanol; yield, 3.2 g. (57%), m. p. 256–257°. Five grams (0.018 mole) of the acetyl compound was heated for two hours under reflux in a mixture of 30 ml. of ethanol and 5 ml. of 6 *N* hydrochloric acid. On cooling, dilute sodium hydroxide solution was added, I precipitated, was filtered off and recrystallized from ethanol; yield 2.2 g. (53%), m. p. 208–210°.

Isomer I from Aminoguanidine.—Aminoguanidine hydrobromide, 6.2 g. (0.04 mole), was heated in 50 ml. of dry pyridine on a steam-bath. When nearly complete solution had taken place, 9.3 g. (0.04 mole) of N⁴-acetylsulfanilyl chloride was added slowly with stirring. After ten additional minutes on the steam-bath, the mixture was cooled for twenty-four hours. A small residue consisting of unreacted aminoguanidine salt was removed by filtration, the filtrate was evaporated to dryness and the residue was recrystallized from a small quantity of 70% ethanol; yield, 1.5 g. (14%), m. p. 256–257°. The material was identical with the intermediate obtained above, and therefore it was not deacetylated.

1-Sulfanilyl-1-aminoguanidine (II).—Nitroguanidine, 13.8 g. (0.12 mole), was suspended in 180 ml. of acetone and to this was added 18.6 g. of potassium hydroxide dissolved in 30 ml. of water. After the nitroguanidine had dissolved completely, 30 g. (0.13 mole) of *p*-nitrobenzenesulfonyl chloride[7] was added during a period of thirty minutes, while the temperature was maintained at 18°. In a few minutes after the last addition of *p*-nitrobenzenesulfonyl chloride a voluminous mass of yellowish-white crystals appeared. After the addition of 50 ml. of water,

(7) The workers in this Laboratory for many years have prepared *p*-nitrobenzenesulfonylchloride and this substance had a melting point of 67°. Recently, this substance was obtained from Eastman Kodak Company and the melting point was 76°, as most frequently given in the literature. Mixed melting point determination of the two materials gave 76°. Therefore we had been dealing formerly with a thermodynamically less stable polymorph.

the mixture was stirred for three hours at room temperature. The mixture was neutralized with glacial acetic acid; the solid material was removed by filtration and washed with small quantities of water, crystallized four times from 70% ethanol and decolorized with charcoal; yield 18 g. (52%), m. p. 202–203° dec. This 1-*p*-nitrobenzenesulfonyl-1-nitroguanidine in ethanol solution was reduced with hydrogen in the presence of Raney nickel catalyst, using chloroplatinic acid as promotor.[8] After removal of the catalyst, the solvent was evaporated under reduced pressure at 40° to give a light orange oil which crystallized on cooling. The product was dissolved in ethanol, decolorized with carbon, and upon the addition of a small quantity of water, white crystals were formed. Recrystallization from 60% ethanol afforded 8.6 g. (60%) of II, m. p. 188–190°.

Sulfanilylamidoguanidine (III).—Aminoguanidine sulfate ($CN_4H_6 \cdot {}^1/_2H_2SO_4$), 4.92 g. (0.04 mole), dissolved in 20 ml. of water, was added to 100 ml. of a saturated solution of sodium bicarbonate (saturated at 45°), to give a solution of *p*H 8.5. *p*-Nitrobenzenesulfonyl chloride, 5 g. (0.023 mole), was added during a period of thirty minutes to the above solution which had been heated to 55°. The *p*-nitrobenzenesulfonyl chloride dissolved in about two hours and the solution was evaporated to dryness under reduced pressure. The residue was extracted with small portions of hot absolute ethanol first by decantation and finally by repeated washings of the solid material on a Büchner funnel. The alcoholic solution was evaporated under reduced pressure to incipient crystallization and then cooled. The nitro compound was filtered, recrystallized from ethanol, washed with ether and dried over phosphoric anhydride; yield 3 g. (50%), m. p. 298–299° dec. Reduction of this compound by hydrogen in the presence of Raney nickel catalyst yielded 1.7 g. (64%) of III, m. p. 298–300° dec., which was recrystallized from ethanol.

X-Ray Diffraction Measurements.—X-Ray diffraction photographs were taken of the three isomers according to methods outlined by Fankuchen[9] and Buerger.[10] These transmission powder diffraction patterns showed that three distinct crystalline compounds have been formed. Single crystal oscillation patterns about all three axes of the three sets of crystals gave different axial lengths and different cell volumes. The molecular weights were calculated from the cell volumes using the equation.

$$\text{Mol. wt.} = \frac{\text{Volume (Å.}^3) \times \text{density}}{n \times 1.65}$$

where n = number of molecules per unit cell. The density of each set of crystals was determined by the flotation method of solid suspended in a liquid of the same density, Table I.

Isomer I.—The symmetries of the single crystal photographs proved that the crystals must have one of the triclinic symmetries. The space group is therefore P1 or P$\bar{1}$ (C_1^1 or C_i^1). The cell dimensions are d(100) = 9.32 Å., b = 9.75 Å., c = 22.20 Å., volume = 1990 (Å.^{3}). The number of molecules per unit cell is 8.

Isomer II.—The symmetries of the single crystal photographs proved that the crystals must have one of the monoclinic symmetries. The space group is therefore Pm or P2 (C_s^1 or C_2^1). The crystals are elongated with blunt edges and the intermediate refractive index is along the length of the needle axis. The acute bisectrix makes an angle of 14° with the main face of the crystal. The cell dimensions are a = 7.43 Å., b (needle axis) = 5.54 Å., c sine beta = 12.30 Å., volume = 506 (Å.^{3}). The number of molecules per unit cell is 2.

Isomer III.—The symmetries of the single crystal photographs proved that the crystal must have one of the orthorhombic symmetries. The needle crystals had straight extinction and its cross-section contains an angle of 77°. Reflections of the type $0kl$ occur only when l is even and reflections of the type $hk0$ occur only when h is even. The space group is therefore Pcma or Pc-a (D_{2h}^9 or C_{2v}^8). The cell dimensions are a = 7.85 Å., b = 10.00 Å., c = 24.65 Å., volume = 1934 (Å.)^3. The number of molecules per unit cell is 8.

Discussion

Three sulfanilylaminoguanidines, with the empirical and molecular formula, $C_7H_{11}O_2N_5S$, as shown, respectively, by analyses and X-ray molecular weight determination, have been prepared. That these are indeed three different compounds is demonstrated uniquely by mixed melting points and properties (Table I).

TABLE I

PROPERTIES OF THE THREE ISOMERS

Isomer			I	II	III

[d] 1-*p*-Nitrobenzenesulfonyl-1-nitroguanidine, $C_7H_7O_6N_5S$; Calcd.: C, 29.06; H, 2.43. Found: C, 28.85; H, 2.59. [e] *p*-Nitrobenzenesulfonylamidoguanidine, $C_7H_9O_4N_5S$: Calcd.: C, 32.42; H, 3.49; S, 12.36; N (total nitrogen) (Dumas), 27.01. Found: C, 32.30; H, 3.40; S, 11.00; N, 26.44.

The structural formula (*vide supra*) applicable to each substance can be deduced from the methods of synthesis. The method of Winnek, *et al.*,[4] can give a compound to which only formula I is applicable. The condensation of N^4-acetylsulfanilyl chloride with either amino- or nitroguanidine gives Winnek's compound and therefore formula I is applicable to the product of these con-

(8) Lieber and Smith, THIS JOURNAL, **58**, 2170 (1936).

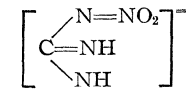
(9) Fankuchen, "Physical Methods of Organic Chemistry," 1st ed., Chapter 14, Interscience Publ., New York, N. Y., 1945, p. 585.

(10) Buerger, "X-Ray Crystallography," 1st ed., John Wiley & Sons, Inc., New York, N. Y., 1942.

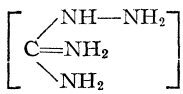
densations. Reduction of the condensation product of *p*-nitrobenzenesulfonyl chloride with nitroguanidine gives a different compound and therefore cannot have formula I. The mode of synthesis of this second compound precludes formula III and therefore formula II is applicable. Reduction of the condensation product of *p*-nitrobenzenesulfonyl chloride with aminoguanidine gives still a third compound and hence it is represented by formula III.

Further evidence for the correctness of the assignment of structural formulas to the three compounds is furnished by two chemical reactions. (1) Determination of hydrazine nitrogen according to the Jamieson method as developed by Smith and Wheat[11] gave a quantitative result in the case of I. For II a slight qualitative reaction was observed which may be attributed to contamination with I. With III no reaction was observed, even when subjected to drastic hydrolytic conditions. (2) When the N^4-acetyl or *p*-nitro intermediates of the three isomers were treated with acidic solution of benzaldehyde only I and II formed benzylidene derivatives. Pellizzari and Cuneo[12] separated two alkylaminoguanidines analogous in structures to II and III by the formation of a benzylidene derivative which formed only with the alkylaminoguanidine corresponding to structure II. It is seen that I and II have a free amino group attached to a nitrogen atom and part of a hydrazine group. In III, however, only an =NH group is present.

The formation of a particular isomer depends upon the *p*H of the medium in which the condensation is effected and also upon the properties of (1) the benzenesulfonyl chloride employed and (2) the compound with which this substance is condensed. When *p*-nitrobenzenesulfonyl chloride is condensed with nitroguanidine, 1-*p*-nitrobenzenesulfonyl-1-nitroguanidine is formed while N^4-acetylsulfanilyl chloride gives 1-N^4-acetylsulfanilyl-3-aminoguanidine. Here the inductive effect of the para-substituent group on the benzene ring may be the determining factor. On the other hand, hydrogen bonding of the nitro group and the (=NH) group may protect the 1- and 2-nitrogen atoms. Further study should prove of interest. The condensation in each case is effected in a very strong alkaline medium (*p*H above 10) and under such conditions the predominating ionic species of nitroguanidine is probably the secondary anion[13]



Aminoguanidine is a moderately strong to strong base. In weakly acidic or weakly alkaline solution the primary aminoguanidonium ion is the predominating species present



The nitrogen atoms connected to the carbon atom are blocked by the stability of the aminoguanidonium ion but in this medium the fourth nitrogen is available for condensation. This condensation has been effected only in a saturated solution of sodium bicarbonate. It has also been found that when N^4-acetylsulfanilyl chloride and aminoguanidine are allowed to react in pyridine, condensation is on the 1- or 2-nitrogen atoms resulting in the formation of 1-N^4-acetylsulfanilyl-3-aminoguanidine.

Acknowledgment.—The authors are indebted to Dr. I. Fankuchen of the Polytechnic Institute of Brooklyn for his assistance in the X-ray analysis of this study.

Summary

The three possible structural isomers of sulfanilylaminoguanidine have been prepared. Mixed melting point determinations, characteristic chemical and physical properties, and X-ray diffraction studies have demonstrated conclusively that these are three distinct compounds. On the basis of their modes of formation formulas have been assigned to each compound. The reasons for the formation of each isomer have been discussed.

The Reaction of Aryl Carbinols with Aluminum Chloride and Aromatic Hydrocarbons[1]

BY HERBERT E. UNGNADE AND ELBERT W. CRANDALL[2]

Benzyl alcohol and benzhydrol can react with benzene and aluminum chloride to give phenyl substituted methanes.[3,4] This reaction may be interpreted as an alkylation reaction in which these carbinols act as alkylating agents. In the presence of excess aluminum chloride this reaction is entirely suppressed and the same reactants furnish anthracene.

When toluene and diphenylmethane are used in the place of benzene, the two carbinols yield identical mixtures of dimethyl and dibenzylanthracenes, respectively, as the only products. Identical mixtures of such disubstituted anthracenes are also produced from benzaldehyde by reaction with aluminum chloride and the above hydrocarbons.

As an explanation for these reactions it is suggested that benzyl alcohol and benzhydrol can act as carbon monoxide donors when larger amounts of aluminum chloride are used. The hydrocarbon solvent provides the outside rings of the substituted anthracenes while the carbon monoxide from the carbinol furnishes the meso carbons.[5]

A similar explanation has been advanced for the formation of anthracene from aromatic aldehydes.[6]

The proposed mechanism is strengthened by the observation that benzyl alcohol and benzhydrol yield carbon monoxide when stirred with aluminum chloride at 60°, as is the case for benzaldehyde.

Triphenylcarbinol is a by-product in the reaction with benzhydrol only when benzene is used as a solvent. Its formation is favored by lower temperatures (Table I). It is also formed from various substituted aromatic aldehydes, aluminum chloride and benzene[7] and is possibly derived from a reaction between benzene and carbon monoxide. The yields of both anthracene and triphenylcarbinol are increased by adding carbon monoxide to the reaction mixture. Triphenylcarbinol remains unchanged when treated with benzene and aluminum chloride at 60°.

TABLE I

THE REACTION OF BENZHYDROL WITH BENZENE AND ALUMINUM CHLORIDE

Temp., °C.	Moles $AlCl_3$[a]	Triphenylmethane, g.	Triphenylcarbinol, g.	Anthracene, g.	Tar, g.
0	1.0	15.1	0	0	0
0	2.0	1.90	17.1	0	0
0	3.1	0	12.03	8.26	0
60	3.1	0	3.68	4.89	8.64
60[b]	3.1	0	5.94	7.95	9.05

[a] Per mole of benzhydrol. [b] With addition of carbon monoxide gas during the reaction.

Experimental[8]

The Reaction of Benzyl Alcohol with Aromatic Hydrocarbons and Aluminum Chloride.—Benzyl alcohol (19.5 g.), dissolved in 50 cc. of benzene, was added during fifteen minutes to a mixture of 100 cc. of benzene and 56 g. of aluminum chloride. The mixture was stirred for three and one half hours at 60°, then it was decomposed in the usual manner and steam-distilled. The dry non-volatile residue weighed 14.4 g. and gave 57% of crystalline material on vacuum sublimation. Chromatographic adsorption of the sublimate on aluminum oxide from Skellysolve C solution yielded 90.3% of pure anthracene, m. p. 212–214°.

When this reaction was carried out under identical conditions with toluene, the non-volatile product (25.5 g.) yielded 64.7% of sublimate which melted at 213–215° after crystallization from Skellysolve C. It depressed the melting point of anthracene, gave correct analytical values and identical absorption spectra as the mixture of dimethylanthracenes obtained from benzaldehyde, aluminum chloride and toluene.[7]

The non-volatile material from the reaction of benzyl alcohol (25 g.) with diphenylmethane (60 cc.) and aluminum chloride (67 g.) weighed 32.12 g. Vacuum distillation of the crude product at 180–210° (1×10^{-3} mm.) gave 35.5% of distillate which was chromatographically uniform and melted at 191–192° (from Skellysolve C). By analogy with the dimethylanthracenes, this substance may be a mixture of 2,6- and 2,7-dibenzylanthracenes.[9]

Anal. Calcd. for $C_{28}H_{22}$: C, 93.85; H, 6.15. Found: C, 93.99; H, 6.37

The Reaction of Benzhydrol with Aromatic Hydrocarbons and Aluminum Chloride.—The vigorous reaction between benzhydrol, benzene and aluminum chloride was moderated by adding benzhydrol (27.6 g.) slowly during two hours to a mixture of 150 cc. of benzene and aluminum chloride maintained at the specified temperature (Table I). Stirring was continued for one and one-half hours and the mixture was decomposed and steam-distilled. The residue from the steam-distillation was dried by distillation with benzene and weighed. The light colored residues from the reaction at 0° were used directly for the chromatographic separation. The other products were first sublimed at 2 mm.

Adsorption of the mixtures on alumina from Skellysolve C solution permitted a nearly quantitative separation of the constituents. The experimental results are given in Table I.

The reaction of benzhydrol (0.09 mole) with aluminum chloride (0.28 mole) and 150 cc. of toluene yielded 14.96 g. of non-volatile residue which contained 39.7% tar.

(2) In part from the Ph.D. thesis of E. W. Crandall.

(3) Huston and Friedemann, THIS JOURNAL, **38**, 2528 (1916).

(4) Huston and Friedemann, *ibid.*, **40**, 791 (1918).

(5) An alternative explanation is possible for the formation of dimethylanthracenes from benzyl alcohol and toluene, as was pointed out by the referee. Direct condensation of two moles of benzyl alcohol could produce anthracene which could then be methylated by methyl groups from the toluene. An attempt to methylate anthracene with toluene in this manner under the conditions of the reaction, however, yielded only unchanged anthracene and tar.

(6) Hey, *J. Chem. Soc.*, 72 (1935).

(7) Ungnade and Crandall, THIS JOURNAL, **71**, 2209 (1949).

(8) All temperatures uncorrected.

(9) NOTE ADDED IN PROOF.—Oxidation of the mixture of dibenzylanthracenes (1 g.) with chromic oxide (4 g.) in acetic acid (30 cc.) and water (4 cc.) yielded 1.14 g. (98%) of dibenzoylanthraquinone, m. p. 241–242° (from 95% alcohol). *Anal.* Calcd. for $C_{28}H_{16}O_4$: C, 80.70; H, 3.85. Found: C, 80.50; H, 4.04.

The sublimate melted at 215–217° (from Skellysolve C) and was identical with the mixture of dimethylanthracenes obtained previously.

A mixture of benzhydrol (25 g.), diphenylmethane (60 cc.) and aluminum chloride (56 g.) maintained for three hours at 60° yielded 40.43 g. of non-volatile product. Vacuum distillation at 180–210° (1×10^{-3} mm.) yielded 16.0% of dibenzylanthracene, m. p. 191–192°, which was spectroscopically identical with the substance isolated from the benzyl alcohol reaction (Table II).

The Reaction of Benzaldehyde with Diphenylmethane.—Benzaldehyde (25 g.), aluminum chloride (67 g.) and diphenylmethane (70 cc.) gave 55.7 g. of non-volatile product under the same conditions. Dibenzylanthracene, m. p. 190–191°, was obtained from this residue as the only distillable substance. It proved to be identical in all respects with the dibenzylanthracenes described above.

Absorption Spectra.—The ultraviolet absorption spectra of the dimethyl and dibenzylanthracenes were determined in cyclohexane in 0.00128 and 0.00073 molar solutions with a Beckmann spectrophotometer.[10]

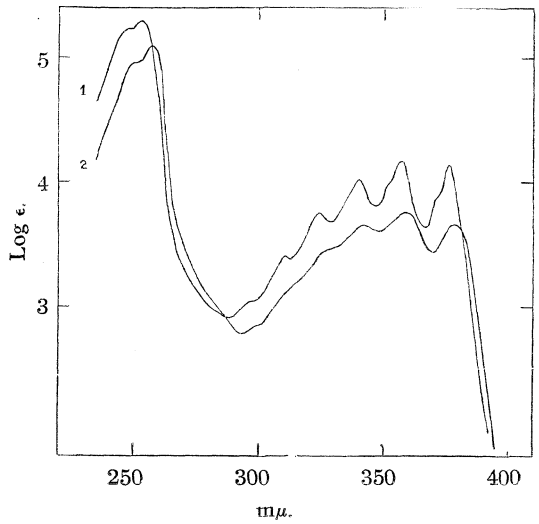

Fig. 1.—Ultraviolet absorption spectra: curve 1, dibenzylanthracenes; curve 2, dimethylanthracenes.

TABLE II

ULTRAVIOLET ABSORPTION SPECTRA

376	4.161	4.130	4.136	380	...	3.756	3.774
381	...[b]	3.895	3.906				

[a] I, product from benzaldehyde, II from benzhydrol, III from benzyl alcohol. [b] This small maximum, which is not present in anthracene, was probably overlooked in the first curve.

One curve each is shown in Fig. 1. Extinction values for maxima and minima of all six substances are listed in Table II. The spectral characteristics of the compounds are in good agreement with the proposed structures. The methylanthracenes exhibit a small hypsochromic effect, slight bathochromic effect and loss of fine structure as compared to anthracene[11] while the benzyl substituents cause general hyperchromic effect, no bathochromic effect and no loss in fine structure.

Summary

Evidence has been presented to show that benzyl alcohol and benzhydrol can act as carbon monoxide donors in the presence of excess aluminum chloride.

Preparation of Azo Compounds for the Study of Inhibition of Tumor Growth*

BY ORRIE M. FRIEDMAN, RALPH M. GOFSTEIN AND ARNOLD M. SELIGMAN

Following the demonstration by Haddow[1] that certain carcinogenic hydrocarbons are able to inhibit the growth of certain tumors in animals, many compounds with a structural resemblance to carcinogenic substances were subjected to this type of bioassay.[2] Isolated instances of inhibition of tumor growth with non-carcinogenic substances were observed, for example, with the unsymmetrical azonaphthalene (I).[2] Haddow suggested that this compound bears a superficial resemblance to the carcinogen, 1,2,5,6-dibenzanthracene (II). However, the only forms in which the unsymmetrical azonaphthalene (I) has features in common with the polynuclear carcinogenic hydrocarbons are the *cis* structures (III) and (IV) which resemble benz- derivatives of both 1,2-benzanthracene and chrysene. The hydrocarbon 1,2,5,6-dibenzphenanthrene, suggested by formula (IV), was found to be an inhibitor of tumor growth.[2] In order to explore further possible relationships between structure of azo compounds and their activity as inhibitors

(*) This investigation was aided by a research grant from the National Cancer Institute, National Institutes of Health, Public Health Service.

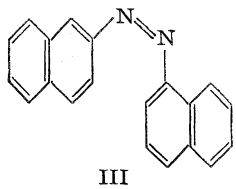
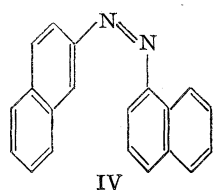
II

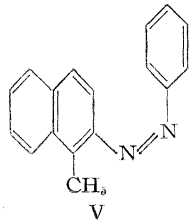


III

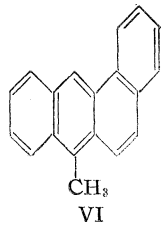


IV

of tumor growth,[3] about twenty-five azo compounds were prepared. When written in the hypothetical *cis* configuration, most of them bear a spatial resemblance to a carcinogenic polynuclear hydrocarbon. As an example the *cis* structure is written for 2-benzeneazo-1-methylnaphthalene (V) and may be compared with the potent carcinogen 10-methyl-1,2-benzanthracene (VI). This azo compound was prepared by the method previously described.[4] No presumption is made as to the actual existence of these substances in the *cis* form, although there is evidence



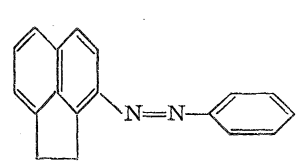
V



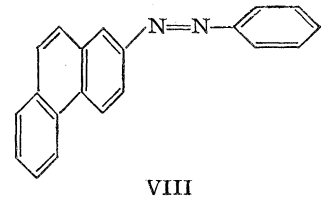
VI

that conversion of the *trans* to the *cis* form can be effected to a significant degree by exposure to ultraviolet light.[5]

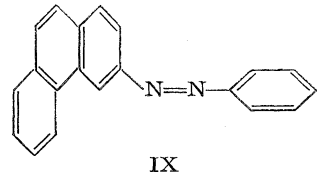
The novel method of Michaelis and Petou[6] for the preparation of 1-benzeneazonaphthalene by the action of phenylhydroxylamine on 1-thionylaminonaphthalene proved useful for the preparation of 3-benzeneazoacenaphthene (VII), 2-benzeneazophenanthrene (VIII), and 3-benzeneazophenanthrene (IX). The required 3-aminoacenaphthene was prepared by catalytic reduction of 3-nitroacenaphthene, described by Morgan,[7] and its structure was confirmed by comparison with the amine obtained from 3-acetoacenaphthene[8] by a Hoffmann rearrangement. The thionylamino compounds were prepared by the reaction of thionyl chloride with the respective



VII



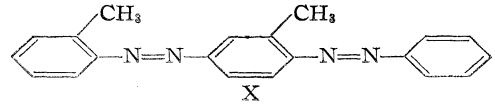
VIII



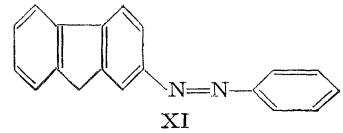
IX

amines. The products thus obtained were treated with phenylhydroxylamine in benzene. Heat was evolved and a black tarry by-product deposited as a sludge.[6] The products were obtained pure although in rather small yield after chromatographic treatment on alumina.

Use was made of the condensation of phenylamines with nitrosobenzene in acetic acid for the preparation of 2-benzeneazo-5-(*o*-tolueneazo)-toluene (X). This method worked well for the preparation of 2-benzeneazofluorene (XI). The reaction followed a different course with amines of naphthalene, acenaphthene, anthracene and phenanthrene. Products deep purple in color were produced, and although some were obtained in crystalline form after chromatographic separation they were not characterized further.



X



XI

Azo-3,4,5-trimethoxybenzene (XII) was prepared by reaction of 3,4,5-trimethoxybenzene diazonium chloride with an excess of cuprous chloride in aqueous solution under conditions described by Borgoslovski.[9]

The diazo coupling reaction was used for the preparation of 3,4,5,4′-tetramethoxyazobenzene (XIII) and 1-(3,4,5-trimethoxybenzeneazo)-

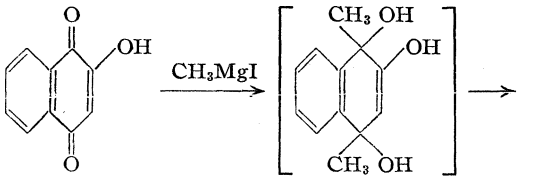
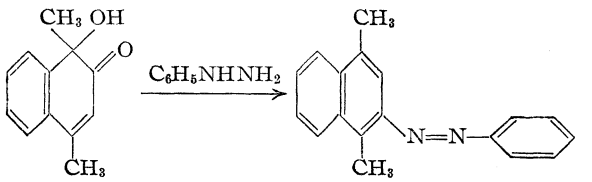
XIV

4-methoxynaphthalene (XIV). 3,4,5-Trimethoxybenzenediazonium chloride was coupled with phenol and α-naphthol, respectively. The products were converted to the corresponding methyl ethers with dimethyl sulfate.

2-Benzeneazo-1,4-dimethylnaphthalene (XVII) was prepared according to Bargellini[10] from



XV



XVI XVII

1,4-dimethyl-1-hydroxy-2-ketodihydronaphthalene (XVI) by condensation with phenylhydrazine. The dihydronaphthalene derivative (XVI) which had been prepared previously[11] by oxidation of 1,4-dimethylnaphthol-2 obtained by degradation of santonous acid, was prepared from the 2-hydroxy-1,4-naphthoquinone (XV) by reaction with excess methylmagnesium iodide.

The authors are grateful to Professor Louis F. Fieser for his helpful interest.

Experimental[12]

3-Aminoacenaphthene (a) **From 3-Nitroacenaphthene.**—The required 3-nitroacenaphthene was prepared according to Morgan[4] by nitration of acenaphthene in acetic anhydride. The nitro compound (10 g.) suspended in 100 cc. of pure alcohol with 0.5 g. of Adams catalyst was shaken under 30 pounds pressure of hydrogen for four hours. The yellow nitro compound dissolved leaving a nearly colorless solution with a strong blue fluorescence. When the solution was filtered and concentrated to small volume the amine separated in nearly pure form, 8.1 g. (95%), m.p. 82–83°.

(b) **From 3-Acetoacenaphthene.**[12a]—This preparation was carried out to obtain a reference sample of 3-aminoacenaphthene. The oxime of 3-acetoacenaphthene was rearranged in ether with phosphorus pentachloride to give a 50% yield of the acetylamino derivative, m. p. 192–193°. On acid hydrolysis the acetyl amine gave a product m. p. 82–83° which did not depress the melting point of the material obtained in (a).

3-Benzeneazoacenaphthene (VII).—3-Aminoacenaphthene (8.5 g.) in 100 cc. of benzene was treated with 3.6 g. of thionyl chloride. After five hours under reflux the solution was filtered and the benzene removed at reduced pressure. The residue, washed with petroleum ether, was treated with 11 g. of phenylhydroxylamine in 100 cc. of dry benzene, heat being evolved as a tarry sludge deposited. After being allowed to stand for twelve hours the mixture was filtered. The filtrate was chromatographed on alumina. The orange band eluted with benzene gave 1.7 g. (13%) of red crystals obtained as red needles after several recrystallizations from 70% alcohol, m. p. 99–100°.

Anal. Calcd. for $C_{18}H_{14}N_2$: C, 83.70; H, 5.46. Found: C, 83.55; H, 5.42.

2-Benzeneazophenanthrene (VIII).—The required 2-aminophenanthrene was prepared according to Bachmann and Boatner[13] from 2-acetylphenanthrene. A mixture of 12 g. of the amine and 10 cc. of thionyl chloride in 120 cc. of dry benzene was refluxed at slightly reduced pressure for twelve hours. At this time the heavy precipitate initially formed appeared to have gone into solution. The excess thionyl chloride and solvent were removed by distillation at reduced pressure and the dark residue thoroughly extracted with a mixture of equal volumes of chloroform and petroleum ether. When distilled to dryness the extract left 8.5 g. of the thionylamino compound as an orange-colored crystalline material. This product in 100 cc. of dry benzene was treated with 12 g. of phenylhydroxylamine in 150 cc. of dry benzene. The mixture became warm immediately and deposited a gray amorphous powder. After twelve hours the reaction mixture was filtered. When concentrated and cooled the filtrate deposited 3 g. of crude crystalline product. This material after three recrystallizations from benzene was obtained as lustrous golden orange platelets, 2.5 g. (15%), m. p. 143–144°.

Anal. Calcd. for $C_{20}H_{14}N_2$: C, 85.07; H, 5.00. Found: C, 84.98; H, 5.11.

3-Benzeneazophenanthrene (IX).—The required 3-aminophenanthrene was prepared according to the method of Bachmann and Boatner[13] from 3-acetylphenanthrene. The amine (6 g.) was dissolved in 100 cc. of dry benzene and 2.2 g. of thionyl chloride added. After heating for twelve hours under slightly reduced pressure, the dark solution was filtered and the benzene removed under reduced pressure. The residue was dissolved in petroleum ether and filtered. The petroleum ether was removed at reduced pressure leaving an orange crust of material. This was then treated with a solution of 6.4 g. of phenylhydroxylamine in 100 cc. of benzene. The solution became very warm and turned a bright red depositing a black tarry sludge. After filtration the benzene solution was chromatographed on an alumina column 20 × 2 cm. The orange band was eluted with benzene and the eluate rechromatographed. After removal of the benzene a red crystalline residue remained. This was taken up in alcohol and water added at the boiling point. On cooling and scratching a crystalline material deposited, m. p. 139–140°. Recrystallization is best from ethanol–acetone to give long orange needles.

Anal. Calcd. for $C_{20}H_{14}N_2$: C, 85.07; H, 5.00. Found: C, 84.96; H, 5.04.

2-Benzeneazo-5-(*o*-toluneazo)-toluene (X).—Nitrosobenzene[14] (1.4 g.) in 30 cc. of glacial acetic acid was added to a cooled solution of 3.0 g. of 2-(3-tolylazo)-5-aminotoluene in 60 cc. of glacial acetic acid. On standing at room temperature for three days the mixture deposited 2.4 g. (60%) of crystalline product, m. p. 104–106°. The material was crystallized from chloroform–alcohol as fine orange-brown needles, m. p. 105–106°. It is soluble in hot chloroform; insoluble in methanol, ethanol or acetone.

Anal. Calcd. for $C_{20}H_{18}N_4$: N, 17.81. Found: N, 17.99.

(14) "Organic Syntheses," Coll. Vol. I, p. 455.

2-Benzeneazofluorene (XI).—The required 2-aminofluorene was prepared by reduction of 2-nitrofluorene with calcium chloride and zinc dust according to Diels.[15] The amine (5 g.) in 25 cc. of acetic acid was treated with 3 g. of nitrosobenzene[13] in 25 cc. of glacial acetic acid. The mixture was kept at 0° for twelve hours during which a crystalline material deposited. After recrystallization from 95% alcohol the product formed yellow leaflets, 4 g. (54%), m. p. 173–174°.

Anal. Calcd. for $C_{19}H_{14}N_2$: C, 84.41; H, 5.18. Found: C, 84.39; H, 5.22.

3,4,5-Trimethoxy-4′-hydroxyazobenzene.—The required 3,4,5-trimethoxyaniline was prepared in 65% yield from 3,4,5-trimethoxybenzoic acid amide[16] according to "Organic Syntheses"[17] by treatment with sodium hypochlorite. The amine (7.0 g.) in 47 cc. of 13% hydrochloric acid was diazotized at 0° by the addition of 2.3 g. of sodium nitrite in a small amount of water. The clear diazonium salt solution diluted to 50 cc. with ice-water was used as a stock solution. An aliquot (43 cc.) of the stock solution was mixed with an ice-cooled solution of 2.0 g. of phenol and 3.0 g. of sodium hydroxide. After fifteen minutes the mixture was acidified. The product was separated on a filter and after recrystallization from methanol–water was obtained as golden-orange needles, 2.5 g. (79%), m. p. 165–166°.

Anal. Calcd. for $C_{15}H_{16}N_2O_4$: C, 62.47; H, 5.59. Found: C, 62.70; H, 5.78.

3,4,5,4′-Tetramethoxyazobenzene (XIII).—An aqueous solution of 2.5 g. of the above azo-phenol and 0.4 g. of sodium hydroxide heated on the steam-bath and vigorously shaken, was treated with small portions alternately of dimethyl sulfate and aqueous alkali so that the solution was kept as nearly as possible slightly alkaline. The treatment was carried on for about one hour when methylation appeared complete. The product, which separated during the course of the reaction, was collected on a filter and washed with alkali and water. After a few recrystallizations from methanol–water the substance was obtained as glistening orange platelets, 1.5 g., m. p. 106–107°.

Anal. Calcd. for $C_{16}H_{18}N_2O_4$: C, 63.57; H, 6.00. Found: C, 63.80; H, 6.06.

1-(3,4,5-Trimethoxybenzeneazo)-4-methoxynaphthalene (XIV).—An aliquot (65 cc.) of stock solution of trimethoxybenzenediazonium chloride, corresponding to 3.0 g. of 3,4,5-trimethoxyaniline, was mixed in the cold with an aqueous solution of 4.5 g. of α-naphthol and 3.0 g. of sodium hydroxide. The dark red mixture that resulted was acidified with hydrochloric acid. The gummy precipitate, separated on a filter, was dissolved without purification in a minimum of aqueous alkali and treated with methyl sulfate as described in the preparation of (XIII). The methylated product dissolved in benzene was purified by passage over activated alumina in a tower 12 cm. × 1 cm. The orange band eluted with benzene gave a product obtained as orange platelets after two recrystallizations from chloroform–methanol, 2.5 g. (45%), m. p. 152–153°. The substance is soluble in chloroform, acetone and benzene; almost insoluble in methanol.

Anal. Calcd. for $C_{20}H_{20}N_2O_4$: C, 68.17; H, 5.72. Found: C, 68.23; H, 5.94.

Azo-3,4,5-trimethoxybenzene (XII).—An aliquot (65 cc.) of the stock solution of 3,4,5-trimethoxybenzenediazonium chloride was added over a period of five minutes to a vigorously stirred ice-cooled solution of cuprous chloride prepared according to Borgoslovski[9] from 12 g. of copper sulfate in 100 cc. of hot water by addition of a mixture of 5 g. of hydroxylamine hydrochloride and 4 g. of potassium hydroxide in aqueous solution. Finally just sufficient ammonium hydroxide was added so that a clear cuprous chloride solution resulted. A precipitate formed with the addition of the diazonium salt. Stirring was continued for one hour after which the product was separated on a filter and washed with methanol. The yellow powder remaining crystallized nicely as orange needles from chloroform–methanol, 1.5 g. (50%), m. p. 217–218°.

Anal. Calcd. for $C_{18}H_{22}O_6N_2$: C, 59.65; H, 6.12. Found: C, 59.56; H, 6.30.

1,4-Dimethyl-1-hydroxy-2-ketodihydronaphthalene (XVI).[11]—A solution of 10 g. of 2-hydroxy-1,4-naphthoquinone[18] in 450 cc. of warm dry benzene was slowly added over a period of one hour to a refluxing solution of methyl Grignard prepared from 12 cc. of methyl iodide in 500 cc. of dry ether and 250 cc. of dry benzene. The addition precipitated an orange solid which rapidly turned gray. After heating under reflux for an additional twenty-four hours the mixture was decomposed with excess saturated ammonium chloride solution. The benzene–ether layer, extracted three times with 10% sodium carbonate and washed with water, was distilled to remove the solvent. From the red oily residue, by distillation at reduced pressure, there was obtained 2.2 g. of crude product as gummy crystals, b. p. 130–160°, 2 mm. A small sample crystallized from ethyl acetate–benzene as almost colorless granules, m. p. 103–105° (m. p. 104–105° reported by Cannizzaro).[11]

2-Benzeneazo-1,4-dimethylnaphthalene (XVII).[10]—The azo compound was prepared according to Bargellini[10] from the crude hydroxy ketone (XVI) in solution in 80 cc. of methanol by addition of 1.8 g. of phenylhydrazine hydrochloride in 40 cc. of water to which a few drops of hydrochloric acid was added. The mixture turned orange in color and soon began to deposit clusters of orange crystals. After forty-eight hours the reaction mixture was filtered. The product crystallized as beautiful large orange-red needles from methanol, 1.8 g. (48%), m. p. 82.5–83° (reported by Bargellini,[10] 83–84°).

Anal. Calcd. for $C_{18}H_{16}N_2$: C, 83.05; H, 6.16. Found: C, 82.99; H, 6.33.

Summary

The synthesis of eight new azo compounds is described: 3-benzeneazoacenaphthene, 2-benzeneazophenanthrene, and 3-benzeneazophenanthrene by reaction of the appropriate thionylamino compounds with hydroxylamine; 2-benzeneazo-5-(*o*-tolueneazo)-toluene and 2-benzeneazofluorene by the use of nitrosobenzene; azo-3,4,5-trimethoxybenzene by the action of cuprous chloride on the diazonium salt; and 3,4,5,4′-tetramethoxyazobenzene and 1-(3,4,5-trimethoxybenzene)-azo-4-methoxynaphthalene by the diazo coupling reaction. There is also described a new method of preparation of 1,4-dimethyl-1-hydroxy-2-ketodihydronaphthalene, an intermediate in the preparation of 2-benzeneazo-1,4-dimethylnaphthalene.

Analogs of Pteroylglutamic Acid. IV. Replacement of Glutamic Acid by Other Amino Acids

BY WILLIAM B. WRIGHT, JR., DONNA B. COSULICH, MARVIN J. FAHRENBACH, COY W. WALLER,[1] JAMES M. SMITH, JR., AND MARTIN E. HULTQUIST

Variations in the structure of pteroylglutamic acid (I)[2] have given substances of widespread interest. Hutchings, *et al.*,[3] synthesized pteroylaspartic acid, the first analog of pteroylglutamic acid to be isolated in pure form and adequately characterized. It showed pteroylglutamic acid antagonist activity in a number of species. Previous communications from this Laboratory described the synthesis of the N^{10}-alkyl,[4] 4-amino[5] and 9-methyl[6] derivatives of pteroylglutamic acid. The present paper describes a number of analogs prepared for preliminary screening experiments in which the glutamic acid moiety is replaced by other amino acids. Also described are some of the corresponding 4-aminopteroyl derivatives which contain an amino group in the 4-position of the pteridine ring.

Synthesis was accomplished by the method of Waller, *et al.*,[7] in which 2,4,5-triamino-6-hydroxypyrimidine, 2,3-dibromopropionaldehyde, and the N-(*p*-aminobenzoyl)-amino acid are brought together in water at an acid *p*H. For the 4-amino derivatives,[5] 2,4,5,6-tetraminopyrimidine[8] was substituted for the triaminohydroxypyrimidine. Usually one-half equivalent of iodine or sodium dichromate was added during the condensation.

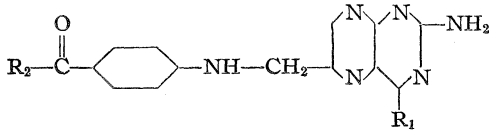
In certain cases 1,1,3-tribromoacetone,[9a] the tetraminopyrimidine, and N-(*p*-aminobenzoyl)-amino acid were used, in a modification of the method of Hultquist and Dreisbach.[9b] The following were purified by methods similar to those described for pteroylglutamic acid and its analogs[6,9,10]: pteroylalanine (II), pteroyl-β-alanine (III), pteramidomalonic acid (IV), 4-aminopteramidomalonic acid (V), and 4-aminopteroylserine (VI). The remainder of the analogs described herein were examined as the crude reaction products (see Table III).



R_1 = OH: I, R_2 = —NHCH(COOH)CH_2CH_2COOH; II, R_2 = —NHCH(CH_3)COOH; III, R_2 = —$NHCH_2CH_2$COOH; IV, R_2 = —NHCH(COOH)$_2$

R_1 = —NH_2: V, R_2 = —NHCH(COOH)$_2$; VI, R_2 = —NHCH(CH_2OH)COOH

In the course of this work a number of N-(*p*-nitrobenzoyl)-amino acids and N-(*p*-aminobenzoyl)-amino acids were prepared which have not been reported in the literature. Data on these compounds are given in Tables I and II.

The biological properties of these pteroylglutamic acid derivatives have been examined by Dr. E. L. R. Stokstad and Dr. B. L. Hutchings of the Lederle Laboratories Division, American Cyanamid Company, Pearl River, New York. The details of this work will be published elsewhere.

Experimental

N-(*p*-Nitrobenzoyl)-amino Acids.—The serine and threonine derivatives were prepared by the method of Fischer and Jacobs.[11]

The other compounds were prepared as described below. One-tenth mole of the amino acid and 0.2 mole of 1*N* sodium hydroxide solution were mixed and cooled to 0–10°. One-tenth mole of *p*-nitrobenzoyl chloride was added and the mixture was stirred at 0–10° for one-half hour and then allowed to warm slowly to room temperature. The total reaction time was one and one-half to three hours. The unreacted *p*-nitrobenzoyl chloride was filtered off. The filtrate was cooled in an ice-bath as dilute acid was added until the mixture was at *p*H 2–3. After additional cooling, the product was filtered, washed with water, and dried overnight at 50–60°. The crude products were purified by recrystallization from the solvents indicated. An initial extraction with boiling ether removed much of the impurity from the alanine, phenylalanine and ε-aminocaproic acid derivatives.

In the case of cystine, 0.4 mole of 1*N* sodium hydroxide and 0.2 mole of *p*-nitrobenzoyl chloride were used and the bis derivative was obtained. The product was insoluble in alcohol and was purified by dissolving with cold dilute alkali, treating with Darco, and precipitating by addition of dilute acid (see Table I).

N-(*p*-Aminobenzoyl)-amino Acids.—The N-(*p*-nitrobenzoyl)-amino acids in alcohol solution were reduced catalytically using palladium on activated charcoal as a catalyst (see Table II).

The N-(*p*-aminobenzoyl) derivatives of cystine, methionine and sarcosine were not isolated and characterized. The reduction solution was used directly in the reaction with dibromopropionaldehyde and 2,4,5-triamino-6-hydroxypyrimidine (see Table III).

Diethyl *p*-Nitrobenzamidomalonate.—Diethyl isonitrosomalonate was prepared in 82% yield, and reduced to diethyl aminomalonate by the method of Cerchez.[12] The product was treated directly without isolation with *p*-nitrobenzoyl chloride in a modification of the method of Redemann and Dunn[13] for the preparation of diethyl benzamidomalonate. An example of our procedure is described in detail below.

To 200 g. (1.06 moles) of diethyl isonitrosomalonate dissolved in 1600 ml. of ether was added the aluminum amalgam prepared from 48 g. of aluminum foil. Efficient cooling with an ice-bath was required to control the initial reaction. When the reaction had subsided, 300 ml. of water was added dropwise over a five-hour period to the refluxing mixture. The mixture was filtered and the precipitate washed with ether. To the combined filtrates were added 100 g. of pyridine and 500 ml. of water. A solution of 110 g. (0.6 mole) of *p*-nitrobenzoyl chloride in 400 ml. of ether was then added over a one-half hour period at reflux temperature. After heating under reflux for one hour longer, 1000 ml. of water was added, and the precipitate was filtered. It was recrystallized once from 1400 ml. of 2B alcohol to yield 83 g. (24%) of diethyl *p*-nitrobenzamidomalonate which melted at 135.5–136.5°. The ether layer was washed with water and then combined

[a] ϵ is the molecular extinction coefficient as defined by $I = I_0 10^{-\epsilon cl}$ where c is the concentration in moles/liter and l is the cell length in centimeters. Transmittancy (I/I_0) measurements of 10 mg./l. solutions were made in 1 cm. cell at mμ intervals on a Model DU Beckman spectrophotometer using a solvent filled cell in the reference position. Additional data were obtained at 2 mμ intervals at maxima, minima and points of inflection.

with the above alcohol filtrate. Evaporation until precipitation began yielded an additional 60 g. (18%) which melted at 132.0–135.0°.

Anal. Calcd. for $C_{14}H_{16}N_2O_7$: C, 51.85; H, 4.97; N, 8.64. Found: C, 52.1; H, 4.80; N, 8.71.

Diethyl *p*-Aminobenzamidomalonate.—Catalytic hydrogenation of 9.72 g. (0.03 mole) of diethyl *p*-nitrobenzamidomalonate suspended in 200 ml. of 2B alcohol, using a palladium on activated charcoal catalyst, yielded 8.2 g. (93%) of diethyl *p*-aminobenzamidomalonate in the form of long white needles which melted at 122–123°.

Anal. Calcd. for $C_{14}H_{18}N_2O_5$: C, 57.15; H, 6.16; N, 9.52. Found: C, 57.2; H, 6.23; N, 9.53.

***p*-Aminobenzamidomalonic Acid.**—A mixture of 5.88 g. (0.02 mole) of diethyl *p*-aminobenzamidomalonate and 50 ml. (0.10 mole) of 2 *N* sodium hydroxide solution was stirred for two hours. The reaction was acidified with 50 ml. (0.10 mole) of 2 *N* hydrochloric acid, cooled in an ice-bath for three hours, filtered, and the precipitate dried overnight at 40°. The product, 4.7 g. (99%), was almost insoluble in water, alcohol, acetone and ether. A portion which was redissolved in *N* sodium hydroxide solution, filtered, acidified with *N* hydrochloric acid and allowed to stand at room temperature precipitated as clusters of white needles. These were dried for analysis at room temperature in vacuum over phosphorus pentoxide. The dried sample contained one mole of water of crystallization, lost water or decarboxylated at about 150°, and did not melt completely at 250°.

Anal. Calcd. for $C_{10}H_{10}N_2O_5 \cdot H_2O$: C, 46.86; H, 4.72; N, 10.94; H_2O, 7.04. Found: C, 46.6; H, 5.00; N, 11.0; H_2O, 8.08.

Pteroylalanine (II).—Pteroylalanine was prepared by a modification of the method of Waller[7] from 2,4,5-triamino-6-hydroxypyrimidine, 2,3-dibromopropionaldehyde, and N-(*p*-aminobenzoyl)-alanine; 0.5 equivalent of iodine or sodium dichromate was added as oxidant during the condensation. Pteroylalanine was purified and isolated as the magnesium salt by known methods[6,9b,10] (see Table III).

Anal. Calcd. for $C_{17}H_{15}N_7O_4Mg \cdot H_2O$: C, 48.19; H, 4.04; N, 23.15; Mg, 5.74. Found: C, 48.6; H, 3.69; N, 23.5; Mg, 5.89.

Pteroyl-β-alanine (III).—This compound was prepared from N-(*p*-aminobenzoyl)-β-alanine by the method of Waller,[7] modified as for II above, and purified by known methods.[6,9b,10] The purity was 77.9% by chemical assay.[14] Final purification was accomplished as follows: The sample (400 mg.) was dissolved in 10 ml. of dilute sodium hydroxide; the sodium salt was precipitated by the addition of 10 ml. of 10 *N* sodium hydroxide. The crystalline sodium salt was filtered off and recrystallized from 40 ml. of 5 *N* sodium hydroxide. It was converted to the free acid by solution in 20 ml. of water, acidification with 5 ml. of concentrated hydrochloric acid, and dilution to 40 ml. volume. The product which was filtered off was recrystallized by dissolving in 10 ml. of 6 *N* hydrochloric acid and diluting to 35 ml. The final product was collected, washed with water, alcohol and ether and dried fifteen hours at 100° (1 mm.). The purity by chemical assay was 98% (see Table III).

Anal. Calcd. for $C_{17}H_{17}O_4N_7$: C, 53.3; H, 4.44; N, 25.6. Found: C, 52.94; H, 4.74; N, 25.30.

Pteramidomalonic Acid (IV).—This compound was prepared from *p*-aminobenzamidomalonic acid by the method of Waller,[7] modified as for II above and purified and characterized as the magnesium salt by known methods.[6,9b,10]

Anal. Calcd. for $C_{17}H_{12}N_7O_6Mg_{1.5} \cdot 2H_2O$: C, 42.29; H, 3.34; N, 20.32; Mg, 7.56. Found: C, 42.0; H, 3.56; N, 20.4; Mg, 7.78.

4-Aminopteramidomalonic Acid (V).—This compound was prepared by the method of Waller, *et al.*,[7] from 2,4,5,6-tetraaminopyrimidine, 2,3-dibromopropionaldehyde, and

(14) Hutchings, *et al.*, *J. Biol. Chem.*, **168**, 705 (1947).

p-aminobenzamidomalonic acid, modified as for II above (see Table III). Also, V was synthesized by a variation of the procedure employed by Hultquist and Dreisbach using 1,1,3-tribromoacetone.[9] The crude product prepared by the latter method contained about 30% of the desired compound, as estimated by the chemical assay of Hutchings, *et al.*[14] The crude was dissolved in 5% sodium carbonate solution at a concentration of 6 g. of V per liter, filtered, and the filtrate was acidified to *p*H 4 and cooled several hours at 2°. The precipitate was collected on the filter and washed with ice water, and then crystallized (at 5 g./l.) three times from hot 0.1 *N* hydrochloric acid. The material thus obtained had a chemical assay[14] of 66.4%.

4-Aminopteroylserine (VI).—This compound was synthesized from N-(*p*-aminobenzoyl)-serine by the method of Waller, *et al.*,[7] as modified for II above (see Table III) and also by a variation of the procedure of Hultquist and Dreisbach,[9] as indicated above for V. The crude material was heated at 60° with lime in water at a concentration of VI of 1 g./l. The solution was filtered and the filtrate was adjusted to *p*H 10.5–11.0 with aqueous zinc chloride. Insolubles were removed by filtration and the solution was acidified to *p*H 4, and the precipitated material was collected on the filter. It was extracted with 0.1 *N* hydrochloric acid at 80°. The residue was dissolved in dilute sodium hydroxide and reprecipitated with acid at 80°; after cooling to 10° the yellow, partially crystalline product obtained was filtered and dried. It showed a chemical assay[14] of about 70%. It was purified further by repeating the process above and then extracting with 0.1 *N* hychloric acid and reprecipitating three times more.

Anal. Calcd. for $C_{17}H_{18}O_4N_8 \cdot 3H_2O$: C, 45.1; H, 5.35; N, 24.7; H_2O, 11.9. Found: C, 45.3; H, 5.15; N, 24.7; H_2O, 9.9.

The hot 0.1 *N* hydrochloric acid extracts contain additional 4-aminopteroylserine which can be recovered by cooling and reworking as above.

Other Pteroyl- and 4-Aminopteroylamino Acids.—These were prepared by the method of Waller[7] from the N-(*p*-aminobenzoyl)-amino acids. One-half an equivalent of iodine or sodium dichromate was added during the condensation.

Acknowledgment.—We are indebted to Mr. Kenneth H. Collins for technical assistance in this investigation, to Miss Ruth Abbott for the ultraviolet absorption spectra studies, and to Mr. O. Sundberg and co-workers for the microanalyses.

Summary

1. The N-(*p*-nitrobenzoyl) derivatives of β-alanine, ε-aminocaproic acid, diethyl aminomalonate, isoleucine, sarcosine and tryptophan, have been prepared.

2. The N-(*p*-aminobenzoyl) derivatives of the following amino acids have been prepared: alanine, β-alanine, ε-aminocaproic acid, aminomalonic acid, isoleucine, phenylalanine, serine, threonine, tryptophan, and valine.

3. Pteroyl derivatives of alanine, ε-aminocaproic acid, aminomalonic acid, isoleucine, phenylalanine, sarcosine, serine, threonine, tryptophan, valine, β-alanine, cystine and methionine have been prepared as crude reaction products. With the exception of the last three, the corresponding 4-aminopteroylamino acids also have been prepared.

4. Pteroylalanine, pteroyl-β-alanine, pteramidomalonic acid, and 4-aminopteroylserine have been purified.

Fatty Acid Amides. II.[2] Amides as Derivatives for the Identification of Some Long-Chain Unsaturated Fatty Acids

BY DANIEL SWERN, JEANNE M. STUTZMAN AND EDWARD T. ROE

Four techniques are usually employed for the identification of long-chain unsaturated fatty acids. They are (a) rigorous purification of the acid, followed by comparison of its properties with those of the acid with which it is presumed to be identical, (b) cleavage of the acid by any one of several well-known procedures, followed by identification of the fragments, (c) preparation of relatively high melting derivatives involving the ethylenic system, and (d) preparation of derivatives involving the carboxyl group.[3] The relatively high solubility of unsaturated fatty acids in organic solvents, their tendency to form crystalline mixtures of invariant composition, and the need for extremely low temperatures in their isolation and purification render the first technique time-consuming and impractical, and often it does not produce a product of sufficiently high purity, particularly when complex mixtures of fatty acids are employed as the starting material. The second technique is time-consuming, and in addition the severe conditions sometimes required to cleave the chain may cause isomerization. Furthermore, this technique may not give definitive results because of poor yields of cleavage products and the fact that the stereochemical nature of the parent acid cannot be deduced after the molecule is degraded. The third technique, which is the one most widely used, generally involves the formation of brominated or hydroxylated products. Although quantitative

hydroxylation of mono-unsaturated acids is conveniently carried out,[4] and this technique has some promise for identification purposes, the impossibility of regenerating the parent acid from the derivative by any simple procedure is a disadvantage. Furthermore, poly-unsaturated acids cannot be hydroxylated in good yields by any of the methods known at present, and the products obtained consist of mixtures of isomers difficult or impossible to separate. Poly-unsaturated acids are usually identified as polybromo acids, and the disadvantages of this technique have already been pointed out.[5] The fourth technique, however, appears to have none of the drawbacks of the others. This technique has been explored somewhat,[5,6,7] but the emphasis has been primarily on the preparation of esters, which not only have relatively low melting points, but in esters of poly-unsaturated acids do not give the calculated analytical values.

Amides are among the highest melting fatty acid derivatives, and although considerable reliable data are available on the long-chain saturated acids, the literature on amides of unsaturated fatty acids is generally incomplete and often unreliable. This paper describes the preparation and some of the properties of the unsubstituted, the N-(2-hydroxyethyl)-, and the N-(*n*-dodecyl)-amides of linoleic, ricinoleic, 10-hendecenoic (undecylenic) and elaidic acids. The results are summarized in Tables I and II (the characteristics of the corresponding amides of oleic acid, taken from a previous paper,[2] are included for comparison).

The unsubstituted amides of oleic,[2] 10-hendecenoic and elaidic acids, and the N-(2-hydroxyethyl)- and N-(*n*-dodecyl) amides of oleic, linoleic, ricinoleic, 10-hendecenoic and elaidic acids were readily prepared in good yield. They were white, crystalline solids which had the calculated analytical characteristics. N-(2-Hydroxyethyl)-hendecenamide had a strong pepper-like taste. We were unable to purify linoleamide, and this amide, as well as N-(2-hydroxyethyl)-linoleamide, rapidly became rancid and dark at room temperature. They were soon converted to viscous, brown oils, although all operations on these and the other amides described were conducted in an atmosphere of nitrogen, and the samples were stored under nitrogen. These two amides undoubtedly undergo rapid oxidation and polymerization in the presence of small quantities of oxygen. N-(*n*-Dodecyl)-linoleamide, however, was much more stable than the other linoleamides, and after storage for several months it was only pale yellow and slightly rancid. The amides of the monounsaturated acids were stable, provided that they were not heated in air. It was essential to dry the amides in an atmosphere of nitrogen, otherwise incorrect analytical values were obtained. Some difficulty was experienced in obtaining theoretical iodine values on purified 10-

hendecenamide and N-(*n*-dodecyl)-hendecenamide, even though the elemental analyses were correct. The iodine values obtained on these two compounds were usually about two to three units lower than the calculated values, but microhydrogenation numbers were satisfactory.[8] It has been reported that elaidamide melts at 93–94°,[9] but the highest melting point we were able to obtain was 90°, even though we worked with carefully purified materials. The melting points of oleamide (76°) and elaidamide (90°) differ significantly and are readily duplicated, even though widely different preparative reactions are employed. This is good evidence that the conventional reactions for preparing amides[2] do not cause *cis–trans* isomerization.

In the hydrolysis of N-(*n*-dodecyl)-amides to the acid and amine hydrochloride by refluxing with constant boiling hydrochloric acid, approximately twelve hours reflux time was required, and acid fractions with iodine numbers only about one-third or one-fourth those calculated were obtained. The hydrolysis of the unsubstituted or 2-hydroxyethyl amides, however, was complete in about one hour when a large excess (about 500%) of constant boiling hydrochloric acid was employed, and the iodine numbers of the acid fractions were over 90% of those calculated.

In view of the low melting points and relative instability of the linoleamides, no attempt was made to prepare the corresponding amides of linolenic and eleostearic acids, since these would be expected to have even lower melting points and to be less stable.

Experimental[9a]

Materials Used.—Linoleic acid, iodine number 180.3, was prepared by the debromination of 9,10,12,13-tetrabromostearic acid, m. p. 115.0–115.3°, with zinc dust in diethyl ether solution.[10] Methyl ricinoleate, b. p. 196–199° (2.3–2.5 mm.), $n^{30}D$ 1.4598, iodine number 81.3, was prepared from castor oil by methanolysis, followed by fractional distillation through a Vigreux column 3 feet long and 1 inch in diameter.[11] 10-Hendecenoic acid, m. p. 24.3–24.5°, b. p. 180° (26.5 mm.), iodine number 137.2, was prepared[12] from the purest commercial grade by fractional distillation, and crystallization from petroleum naphtha, hexane fraction, at −20°. Elaidic acid, m. p. 44°, was prepared from oleic acid by isomerization with powdered selenium.[13] Monoethanolamine and dodecylamine were the purest commercial grades, and they were distilled before use through efficient fractionating columns.

Preparation of Derivatives. Unsubstituted Amides.—Linoleic, 10-hendecenoic and elaidic acids were converted to the corresponding acid chlorides by reaction with oxalyl chloride in benzene solution, as described by Bauer.[14] After removal of benzene and excess oxalyl chloride, the acid chlorides were added dropwise to a large excess (500–900%) of ice-cold concentrated aqueous ammonium hydroxide, with stirring. The crude amides were separated from the aqueous layer and dissolved in a suitable solvent (petroleum naphtha was employed for linoleamide, and 95% ethanol was employed for 10-hendecenamide and elaidamide; 4 to 5 ml. of solvent per gram of solute), treated with activated carbon and filtered. The filtrates were cooled to 0 to 5° (room temperature in the case of elaidamide), and the amides which precipitated were filtered off and washed with cold solvent. Linoleamide was obtained as a white solid which could not be completely purified. Additional manipulation caused both the melting point and iodine number to decrease. On standing, the product, which contained 0.44% of chlorine, rapidly darkened and became rancid, and it was soon converted to a brown viscous oil. 10-Hendecenamide and elaidamide were white crystalline solids, which were purified by recrystallization from 95% ethanol at 15 to 25°. They were stable at room temperature. Since ricinoleic acid is difficult to purify and is reported to be unstable, no attempt was made to prepare ricinoleamide from it.

N-(2-Hydroxyethyl)-amides.—Linoleic, 10-hendecenoic and elaidic acids, and methyl ricinoleate were refluxed with a 50% molar excess of monoethanolamine (methyl ricinoleate, one hour reflux; the others, two hours). The cooled reaction mixtures were dissolved in petroleum naphtha, 95% ethanol, petroleum naphtha and acetone, respectively (3 to 8 ml. of solvent per gram of solute). The solutions were treated with activated carbon and filtered. The filtrates were cooled (N-(2-hydroxyethyl)-elaidamide, 25°; N-(2-hydroxyethyl)-linoleamide, 0°; the others, −20°) to precipitate the amides, which were filtered off and washed with cold solvent. The products were then recrystallized to constant melting point (N-(2-hydroxyethyl)-elaidamide from 95% ethanol at 10°). N-(2-Hydroxyethyl)-linoleamide was unstable.

N-(*n*-Dodecyl)-amides.—Linoleic, 10-hendecenoic and elaidic acids, and methyl ricinoleate were heated at 230° with a 1% molar excess of *n*-dodecylamine (methyl ricinoleate, three-hour reaction period; the others, thirty-five minutes). The cooled reaction mixtures were dissolved in 95% ethanol (4 to 5 ml. of solvent per gram of solute), the solutions were treated with activated carbon and filtered. The filtrates were cooled to 0° (N-(*n*-dodecyl)-elaidamide was crystallized at 25°), and the precipitated amides were filtered off and washed with cold solvent. The products were then recrystallized to constant melting points.

Acknowledgment.—The authors are indebted to Jane Dixon and Mary Jane Welsh of the Analytical and Physical Chemistry Division of this Laboratory for the carbon, hydrogen and nitrogen analyses.

Summary

N-(2-Hydroxyethyl)- and N-(*n*-dodecyl)-linoleamides, ricinoleamides, elaidamides and 10-hendecenamides, as well as the unsubstituted amides, elaidamide and 10-hendecenamide, have been prepared and characterized. These amides are suitable derivatives for the identification of the parent unsaturated acids. Linoleamide could not be completely purified. This compound, as well as N-(2-hydroxyethyl)-linoleamide, was unstable at room temperature, both being rapidly converted to dark-brown viscous oils.

The Preparation of Quinolinic and Cinchomeronic Acids by Ozone Oxidation

BY ALBERT F. LINDENSTRUTH AND CALVIN A. VANDERWERF

In an attempt to develop a convenient synthesis for quinolinic and cinchomeronic acids, a study was made of the ozone oxidation of quinoline, 8-hydroxyquinoline and isoquinoline. Mainly out of theoretical interest, the investigation was later extended to include 6-aminoquinoline, 6-nitroquinoline, 6-fluoroquinoline, and 6-fluoro-8-aminoquinoline.

The manufacture of pyridine carboxylic acids by the action of ozone on pyridine derivatives has been claimed previously,[1] but details concerning the ozonolysis, isolation, and characterization procedures are lacking. Quinolinic acid has been prepared by the oxidation of quinoline with hydrogen peroxide in the presence of copper sulfate and sulfuric acid,[2] of quinoline and quinoline derivatives carrying substituents in the benzene ring with alkaline permanganate[3] and of 8-hydroxyquinoline with fuming nitric acid,[4] as well as by the electrolytic oxidation of quinoline.[5] Cinchomeronic acid is commonly obtained by oxidation of isoquinoline with alkaline permanganate[6] and of quinine hydrochloride with nitric acid.[7]

Our studies have shown that with quinoline, one mole of ozone was readily fixed, whereupon further addition of ozone to form a diozonide was considerably slower.[8] In all cases, the addition compound formed was usually stable, resisting decomposition, even under drastic conditions, by the reagents commonly employed for decomposing ozonides. Only when 30% hydrogen peroxide[9] or concentrated nitric acid was used, could traces of the desired product, quinolinic acid, be obtained. Upon strong heating, samples of the addition compound liberated ozone and quinoline.

Quinoline derivatives bearing one or more substituents in the benzene ring added ozone less rapidly than quinoline itself, particularly if the substituents were electron-withdrawing in nature. All gave quinolinic acid as the only identifiable product, in poor yield if the substituents were electron-withdrawing, in good yield if they were electron-releasing. Ozone oxidation of 8-hydroxyquinoline, for example, consistently gave 90–95% yields of quinolinic acid, whereas the yields with 6-nitroquinoline for corresponding ozonization times were less than 6%. In the cases of those compounds which gave only low yields of acid, almost half of the starting material could be recovered by steam distillation of the ozonized reaction mixture. These results substantiate the observation that the pyridine ring in quinoline is much more resistant to oxidation than the benzene ring. Because it gave a clean, facile reaction, hydrogen peroxide in acid solution was utilized in the decomposition of the substituted quinoline ozonides.[10] Decomposition, in every case, could be accomplished merely by treatment with hot water, but the reaction was slower and the yields of acid somewhat lower.

Ozone added relatively slowly to isoquinoline forming diozonides. The diozonide formed by the attack of ozone on the benzene nucleus was reactive in comparison with the unsubstituted quinoline diozonide, decomposing directly in solution to yield cinchomeronic acid, if small amounts of water were present. Treatment of the remaining ozonated solution with 30% hydrogen peroxide[11] yielded phthalic acid and small amounts of cinchomeronic acid, indicating that, in marked contrast to its action on quinoline, ozone attacked both the benzene and pyridine rings. Cinchomeronic and phthalic acids prepared in this manner were obtained together in yields of 45 and 50%, respectively.

Experimental Details

Ozonizer.—The source of ozone was a Type T-12 ozonator purchased from Ozone Processes, Inc., Philadelphia, Pa., designed for operation on a 115-volt, 60 cycle a. c. current. At an oxygen rate of 20 liters per hour, the weight concentration of ozone produced was 9–10%.

Ozonization of 8-Hydroxyquinoline.—A solution of 72.5 g. (0.5 mole) of 8-hydroxyquinoline in 400 ml. of glacial acetic acid was subjected to a stream of 9–10% ozonized oxygen at 20 l. per hour, for forty-eight hours at room temperature. During the early stages of the ozonization the solution turned dark brown and the temperature rose to 35°. After twenty-four hours, the solution turned a light yellow color and the temperature dropped to that of the room. Then 110 g. of 30% hydrogen peroxide[12] was added cautiously to the ozonated solution. The resulting solution was refluxed for two hours and then concentrated almost to dryness. The yellow

(7) Kirpal, *Monatsh.*, **23**, 239 (1902).

(8) Ozonized oxygen of known ozone concentration was employed, and ozone absorption was followed by systematic titration of the effluent gases. The curve obtained by plotting time *vs.* ozone concentration flattened when ozone was no longer absorbed by the reacting solution. The fact that no quinoline could be obtained upon distillation of the reaction product in basic solution indicated that all of the quinoline had been converted to the ozonide.

(9) Henne and Hill, THIS JOURNAL, **65**, 752 (1943).

(10) Only starting material and tarry oxidation products could be isolated after similar treatment of any of the substituted quinolines themselves.

(11) Similar treatment of isoquinoline yielded, in addition to starting material, only tarry oxidation products from which no pure compound could be isolated.

(12) When decomposition of the ozonide was effected by use of water, rather than of hydrogen peroxide, the yields were slightly over 70%. The ozonized solution was concentrated under vacuum to one-fifth its original volume, an equal volume of water added, and the mixture refluxed for four hours.

solid obtained was recrystallized from hot water yielding 76 g. (92%) of quinolinic acid, which decomposed at 190.0–191.2° into a black solid (nicotinic acid), which remelted at 229.2–230.4°. The melting point was not depressed when the product was mixed with an authentic sample of quinolinic acid. If small amounts of water were present some quinolinic acid precipitated during the ozonization.

Ozonization of Quinoline.—The ozonization was conducted as described above. The solvent was removed under vacuum and the resulting product refluxed in turn with water, concentrated sodium hydroxide solution, concentrated hydrochloric acid, glacial acetic acid and zinc, stannous chloride and hydrochloric acid, 30% hydrogen peroxide and concentrated nitric acid. Traces of quinolinic acid were isolated only in the last two cases as well as upon low pressure catalytic hydrogenation with 5% palladium on charcoal and subsequent treatment with 30% hydrogen peroxide. The addition compound, upon steam distillation in a basic solution, did not produce any unreacted quinoline. Attempts to distill the compound under low pressures failed, the majority of the material forming a tar, while, to a lesser extent, quinoline and ozone were regenerated. The ozone was detected by the formation of a sodium hydroxide ozonate,[13] which results from the action of ozone on solid sodium hydroxide and which liberates oxygen when placed in an acid solution.

Ozonization of Isoquinoline.—A solution of 20.0 g. (0.155 mole) of isoquinoline in 200 ml. of glacial acetic acid was ozonized as previously described. Best results were obtained if a small amount of water was added to the solvent; cinchomeronic acid (11.4 g., 44.5%), m. p. 259–260°, then precipitated from solution during the ozonization. The solid material was separated by filtration and the filtrate refluxed with 35 g. of 30% hydrogen peroxide for two hours. Evaporation to dryness (or continuous ether extraction) of the resulting solution yielded 12.8 g. (49.5%) of phthalic acid, melting at 204–205°, and small amounts of cinchomeronic acid. The yield of cinchomeronic acid was lowered to 10% when the ozonization time was reduced to twelve hours.

Ozonization of Other Quinolines.—6-Amino-, 6-fluoro-8-amino-, 6-fluoro- and 6-nitroquinoline yielded 65, 44, 15 and 6%, respectively, of quinolinic acid when ozonized as previously described. Tarry oxidation products were also formed and, in the last two cases, almost half of the quinolines were recovered unchanged.

(13) A study of sodium hydroxide ozonates is being conducted in this Laboratory by Mr. Thomas Whaley.

Summary

1. Preparation of quinolinic acid in 90–95% yield and of cinchomeronic acid in 45% yield by ozone oxidation of 8-hydroxyquinoline and isoquinoline, respectively, is described.

2. Studies on the oxidation by ozone of quinoline, 6-aminoquinoline, 6-fluoroquinoline, 6-nitroquinoline, and 6-fluoro-8-aminoquinoline are also reported.

The Chemical Effects Accompanying Hydrogen Bonding. II. Alkylation of the Oximes of 2-Hydroxy-5-methylbenzophenone

BY A. H. BLATT AND S. ARCHER[1]

The chemical effects of hydrogen bonding were examined in a study of the acyl derivatives of the oximes of 2-hydroxy-5-methylbenzophenone where it was shown that the isomeric bonded (I) and non-bonded (II) oximes behaved similarly on acylation, but that their acyl derivatives showed striking differences in behavior.[2] We have examined the alkylation of these same oximes and find that the differences in behavior show up in the alkylation reaction rather than in the chemistry of the alkylation products.

The generalization in the chemical literature which describes the alkylation of ketoximes in alkaline solution with alkyl halides or dimethyl sulfate is that mixtures of O- and N-alkyl derivatives are formed.[3] The generalization is not applicable to the alkylation of the oximes I and II. The bonded oxime I in normal sodium methoxide solution with methyl iodide (ratios of oxime, alkyl halide, base = 1, 1.5, 1) furnishes the O-methyl ether III in 77–83% yield.[4] None of the N-methyl ether V is obtained. The non-bonded oxime II under the same conditions furnishes the N-methyl ether VI in 83–90% yield. None of the isomeric O-methyl ether IV is obtained. The course of the alkylation is completely controlled by the presence or absence of bonding and it seems reasonable to suggest that the bonding operates by freezing the configuration shown in I and thus preventing the rear-ward approach to the nitrogen atom which would lead to the N-ether V. A scale model of the oxime I shows this clearly. A similar model of the isomeric oxime shows that the oximino group cannot be accommodated to the atomic dimensions involved in IIa and that some rotation about the bond between the substituted phenyl group and the carbon atom of the C=N group is necessary to accommodate the oximino group. In arrangements such as II in which this rotation has taken place the nitrogen atom is relatively accessible to rear-ward approach.

In the alkylation of the non-bonded oxime II, variations in the ratio of oxime to base and to alkylating agent as well as variations in the concentration of the base were without effect. The only product obtained was the N-ether VI. In the alkylation of the bonded oxime I, by con-

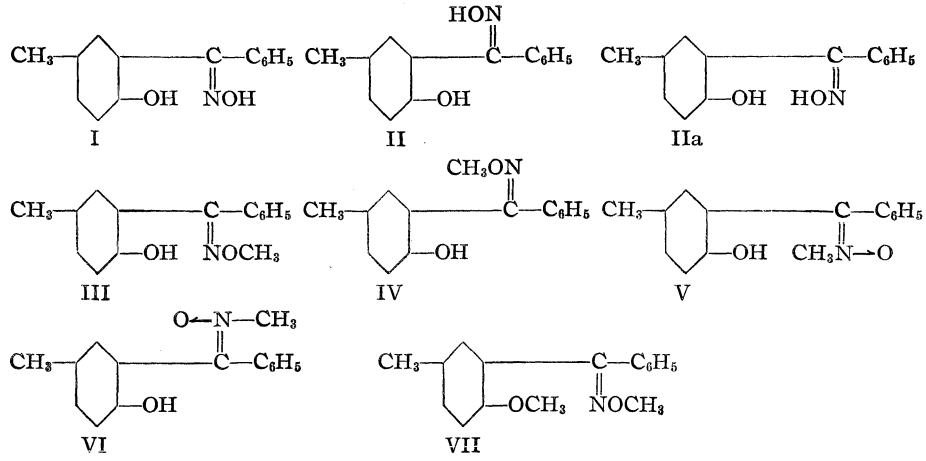
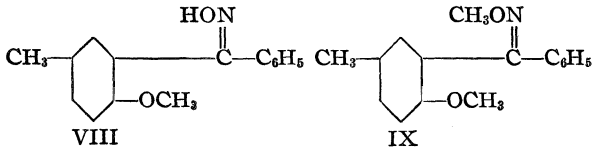
(4) The evidence for the configuration and structure of the alkylation products is to be found in the experimental section.



trast comparable variations in the concentration and molar ratios of the reactants did determine the nature of the alkylation product. The principal product was usually the O-ether III. If, however, a large excess of base and alkylating agent was used, the O-ether III was accompanied by the dimethyl ether VII. The dimethyl ether presumably results from further alkylation of the monomethyl ether III; in fact, the most convenient method of preparing VII is by alkylation of the monomethyl ether III with methyl iodide and sodium methoxide. When the concentration of the sodium methoxide was increased from 1 to 2 *N*, the monomethyl ether III and the dimethyl ether VII were again formed, but the principal product was the N-methyl ether V. This seems to be the result of the formation of the phenoxide ion which would destroy the bonding in I; then the oxime behaves in normal fashion to yield a mixture of N-methyl and O-methyl derivatives.

Experimental

In addition to the alkylations, a number of experiments were run in order to establish the structure and configuration of the alkylation products; and to prepare the reference compounds VIII and IX which were not obtained by alkylation. These experiments are described first and are followed by a description of the alkylation reactions.



syn-**Phenyl 2-Hydroxy-5-methylphenyl Ketoxime O-Methyl Ether (III).**—This ether is most conveniently prepared from the ketone and methoxyamine. When 6.7 ml. of concd. hydrochloric acid diluted to 15 ml. with water was added to a solution of 10.6 g. of 2-hydroxy-5-methylbenzophenone and 3.7 g. of methoxyamine in 50 ml. of alcohol and the reaction mixture was boiled for four hours, an oil separated. The oil was redissolved by the addition of hot alcohol. On cooling, 7.5 g. of the ether crystallized; yield, 62%. The ether crystallizes from methyl alcohol in stout plates which melt at 94–95°.

Anal. Calcd. for $C_{15}H_{15}NO_2$: OCH_3, 12.9. Found: OCH_3, 13.1.

The ether is sparingly soluble in methyl and ethyl alcohols, moderately soluble in ligroin and very soluble in acetone, benzene, chloroform and ether. The structure of the compound is established by its method of preparation; the configuration follows from the fact that the material shows no hydroxyl group absorption in the infrared. We are indebted to Dr. Oliver Wulf for examining the infrared absorption spectrum.

The ether does not form an acetyl derivative when its solution in acetic anhydride is warmed for ten minutes. It undergoes no shift of configuration and is recovered unchanged after treatment at room temperature or at the boiling point with aqueous potassium hydroxide solutions ranging in concentration from 10 to 40% of potassium hydroxide. Similarly, the ether was recovered unchanged after 1.3 g. in 13 ml. of 3 *N* sodium methoxide was kept at room temperature for fourteen days.

syn-**Phenyl 2-Methoxy-5-methylphenyl Ketoxime O-Methyl Ether (VII).**—To a solution of 0.23 g. of sodium in 10 ml. of methanol, was added 1.2 g. of *syn*-phenyl 2-hydroxy-5-methyl ketoxime O-methyl ether (III) and 1 ml. of methyl iodide. After twenty-four hours at room temperature, the precipitate of dimethyl ether (VII) was filtered; 1.05 g., 80%. The filtrate on dilution with water furnished a mixture of starting material and dimethyl derivative—see below.

The dimethyl ether (VII) crystallizes from methanol or ligroin in hemispherical clusters of fine needles which melt at 91–92°.

Anal. Calcd. for $C_{16}H_{17}NO_2$: C, 75.3; H, 6.7; OCH_3, 24.3. Found: C, 74.8; H, 6.4; OCH_3, 23.7.

An equimolar mixture of the dimethyl ether (VII) and monomethyl ether III melts fairly sharply at 67–68°. (*Anal.* Calcd. for a mixture of $C_{15}H_{15}NO_2$ (III) and $C_{16}H_{17}NO_2$ (VII): OCH_3, 18.6. Found: OCH_3, 18.5.) This mixture often crystallizes from solutions containing both ethers. The mixture can be separated into its components by careful crystallization from methyl alcohol. The first crop consists of the characteristic plates of the monomethyl ether III. After they have been separated, the filtrate is evaporated to dryness and the residue taken up in ligroin. From this solvent the dimethyl ether VII crystallizes first.

The structure of the dimethyl ether follows from its method of preparation. It has been assigned the same configuration as the monomethyl ether III because that ether undergoes no change in configuration in sodium methoxide solution.

anti-**Phenyl 2-Methoxy-5-methylphenyl Ketoxime (VIII).**—To prepare this oxime 4.5 g. of 2-methoxy-5-methylbenzophenone was dissolved in 20 ml. of alcohol and 2.0 g. of hydroxylamine hydrochloride in 5 ml. of water was added. The solution was boiled for two hours and diluted with 10 ml. of water. The crude oxime, which crystallized as the solution cooled, weighed 4 g., 83%. In a parallel experiment using hydroxylamine hydrochloride and excess sodium hydroxide the yield of crude oxime was 93%. For analysis the oxime was crystallized from ethanol. The pure product melts at 162–163°.

Anal. Calcd. for $C_{15}H_{15}NO_2$: OCH_3, 12.9. Found: OCH_3, 13.2.

The structure and configuration of the oxime were established by a Beckmann rearrangement. When 1.7 g. of

the oxime suspended in 30 ml. of absolute ether was treated with an equal weight of phosphorus pentachloride, the oxime dissolved to furnish a yellow solution. After an hour and a half the reaction mixture was poured onto ice and water and left until the ether had evaporated. The yield of crude product was quantitative. For analysis the material was crystallized from ethanol. It was obtained as stout matted needles which melted at 90.5–91.5°.

Anal. Calcd. for $C_{15}H_{15}NO_2$: OCH_3, 12.9. Found: OCH_3, 13.1.

The rearrangement product to be expected from the oxime VIII is 2-methoxy-5-methylbenzanilide, described as melting at 96°.[5] We prepared a sample of this anilide by methylating 2-hydroxy-5-methylbenzanilide with sodium methoxide and methyl iodide. The synthetic product melted at 93–94° and a mixture of the synthetic product and rearrangement product melted at 92.5–93.5°.

The oxime VIII does not furnish a copper derivative when its ethereal solution is shaken with aqueous copper acetate. When it is warmed with acetic anhydride, the oxime furnishes an acetate which melts at 104–105° after recrystallization from ethanol.

Anal. Calcd. for $C_{17}H_{17}NO_3$: OCH_3, 10.95. Found: OCH_3, 10.75.

***anti*-Phenyl 2-Methoxy-5-methylphenyl Ketoxime O-Methyl Ether (IX).**—A solution of 2.5 g. of methoxyamine hydrochloride in 5 ml. of water was added to 4.5 g. of 2-methoxy-5-methylbenzophenone in 20 ml. of ethanol. The reaction mixture was boiled for two and one-half hours during which time an oil separated. Water was added and the reaction mixture was left in the ice-chest overnight. The solid thus obtained was crystallized from methanol and furnished 3.3 g. of the dimethyl ether IX which melted at 67–68°; yield, 66%.

Anal. Calcd. for $C_{16}H_{17}NO_2$: OCH_3, 24.3. Found: OCH_3, 24.6.

The dimethyl ether is related configurationally to the oxime VIII by its preparation from that oxime. When 1.2 g. of the oxime VIII in 10 ml. of methanol containing 0.23 g. of sodium was treated with 1 ml. of methyl iodide, the reaction mixture furnished, after twenty-four hours, 0.8 g. of the dimethyl ether IX; yield, 63%.

Alkylation of the Oximes I and II.—The alkylations were run unless otherwise specified on 4.5 g. (0.02 mole) quantities of oxime. The oxime was dissolved in sodium methoxide solution, the alkylating agent added and the reaction mixture left stoppered for eighteen to twenty-four hours at room temperature. Any solid was removed by filtration, then water was added to the filtrate and the organic material extracted with ether. In experiments where an excess of base was used the reaction mixtures were acidified.

When 1 mole of the bonded oxime I was treated with 1 mole of 1 or 1.3 *N* sodium methoxide and 1.5 to 2 moles of methyl iodide, the product obtained in 77–83% yield was the oxime O-methyl ether III. From 1 mole of oxime, 2 moles of 1 *N* sodium methoxide and 1 mole of methyl iodide, the principal product was the non-bonded oxime II; 70% of the oxime I which was not converted into its stereoisomer II appeared as the monomethyl ether III. From 1 mole of oxime, 3 moles of 1 *N* sodium methoxide and 4 moles of methyl iodide, the yield of crude alkylation product was very satisfactory; but the product was a mixture of the ether III and the dimethyl ether VII and more than half of the material was lost in the fractional crystallization, so that the yields of III and VII were 30 and 5%, respectively. When the concentration of the base was increased to 2 *N*, the N-methyl ether V appeared as a product. From 1 mole of oxime, 4 moles of sodium methoxide and 3 moles of methyl iodide, the yield of N-methyl ether was 50%; the filtrates furnished a mixture of the monomethyl ether III and the dimethyl ether VII.

***syn*-Phenyl 2-hydroxy-5-methylphenyl ketoxime N-methyl ether (V)** is obtained as small cubes by recrystallization from methyl or ethyl alcohol. It is almost insoluble in ether. The melting point of the material, 180–181°, varies with the rate of heating.

Anal. Calcd. for $C_{15}H_{15}NO_2$: C, 74.65; H, 6.3. Found: C, 74.6; H, 6.1; methoxyl, negative.

The structure of the N-ether was established by its ready hydrolysis. Boiling with methyl alcohol and hydrochloric acid for twenty minutes brought about complete hydrolysis to 2-hydroxy-5-methylbenzophenone.

The experiments with methyl *p*-toluenesulfonate paralleled those with methyl iodide and need not be described in detail. The ester is so readily hydrolyzed, however, that in the runs using 1 mole of ester and 2 to 4 moles of sodium methoxide only unreacted oxime was obtained. In a single run using diazomethane the only product obtained was unchanged oxime.

The non-bonded oxime on alkylation furnished only the N-methyl derivative VI. This material, ***anti*-phenyl 2-hydroxy-5-methylphenyl ketoxime N-methyl ether**, crystallizes from methyl or ethyl alcohol in splendid yellow cubes which melt at 142–143°.

Anal. Calcd. for $C_{15}H_{15}NO_2$: C, 74.65; H, 6.3. Found: C, 74.9; H, 6.2; methoxyl, negative.

The N-methyl derivative turns purple on exposure to light. It is hydrolyzed by twenty minutes of boiling in a solution of 7 parts of methanol and 1 part of concd. hydrochloric acid to 2-hydroxy-5-methylbenzophenone (85% yield) and N-methylhydroxylamine hydrochloride.

From 1 mole of the non-bonded oxime II, 1 mole of sodium methoxide and 1.5 or 2 moles of methyl iodide the yield of N-ether VI was 83–90%. The same ether, VI, was the only product isolated from 1 mole of oxime, 2 moles of 1 *N* sodium methoxide and 1 mole of methyl iodide, and from 1 mole of oxime, 4 moles of 1 *N* sodium methoxide and 2.5 moles of methyl iodide. In these experiments the yields were not so good and oily products were also formed.

Alkylation of the non-bonded oxime with methyl *p*-toluenesulfonate and sodium methoxide and with diazomethane also furnished only the N-methyl ether VI.

Summary

The behavior on alkylation of the bonded and non-bonded oximes of 2-hydroxy-5-methylbenzophenone was studied. The non-bonded oxime furnished only the N-ether, *anti*-phenyl 2-hydroxy-5-methylbenzophenone ketoxime N-methyl ether, regardless of the ratios of oxime to alkylating agent and base. On the other hand, the nature of the products formed when the bonded oxime was alkylated did depend on the concentrations of the reactants. When one mole of base and two moles of iodide were used only *syn*-phenyl 2-hydroxy-5-methylphenyl ketoxime O-methyl ether was obtained. Increasing the quantities of base and methyl iodide resulted in the appearance of the dimethyl ether, *syn*-phenyl 2-methoxy-5-methylphenyl ketoxime O-methyl ether. With a very large excess of base and alkylating agent another product, namely, *syn*-phenyl 2-hydroxy-5-methylphenyl ketoxime N-methyl ether was encountered also.

The Apparent Ionization Constants and Ultraviolet Spectra of *o*-, *m*- and *p*-Chloro- and *p*-Sulfamyl-DL-phenylalanine

BY JUDD C. NEVENZEL,[1] WESLEY E. SHELBERG[2] AND CARL NIEMANN

At least four problems under investigation in these Laboratories, *i.e.*, the enzymatic synthesis of acylated α-amino acid amides,[3] the specificity and kinetics of chymotrypsin action,[4] the development of metabolic antagonists of the natural α-amino acids,[5] and the relation between chemical structure and thyroxine-like activity[6] have required the use of nuclear substituted phenylalanines or their analogs[7] and it thus has become imperative to have at hand more information regarding the physical and chemical properties of these compounds than is presently available. In this communication we wish to report observations relative to the apparent ionization constants and ultraviolet absorption spectra of the three isomeric nuclear substituted monochloro-DL-phenylalanines and of *p*-sulfamyl-DL-phenylalanine.

The apparent ionization constants of phenylalanine and the above four nuclear substituted phenylalanines, in 0.1 formal aqueous sodium chloride at approximately 25°, are given in Table I. It appears that the earlier values[8,9] for the pK'_{CO_2H} of phenylalanine are either too high (2.58) or too low (1.83) since the former is inconsistent with values reported for alanine and its derivatives[10] and the latter with values now available for additional derivatives of phenylalanine. A nuclear chlorine atom, irrespective of its position, was found to increase the acid strength of the ammonium group in phenylalanine by approximately 0.2 of a pK unit whereas a *p*-sulfamyl group caused an increase of approximately 0.5 of a pK unit. In contrast the above nuclear substituents had relatively little effect upon the acid strength of the carboxyl group.

An attempted independent determination of the acid ionization constant of the sulfamyl group in *p*-sulfamyl-DL-phenylalanine by a spectroscopic technique[11] was not successful and the assignment of the first, second, and third ionization constants found by titration, to the carboxyl, ammonium, and sulfamyl groups, respectively, was necessarily based upon comparison with representative values for other compounds containing these functional groups.[10]

The principal features of the ultraviolet absorption spectra of phenylalanine, the three isomeric nuclear substituted monochlorophenylalanines, and *p*-sulfamylphenylalanine are given in Table II. The spectrum of phenylalanine is in agreement with that reported by Smith[12] with the exception that the band in the 250-260 mμ region was found to have a fine structure not seen in Smith's curves. The replacement of any one of the nuclear hydrogen atoms by a chlorine atom, or of the *p*-hydrogen atom by a sulfamyl group, produced the expected[13] batho- and hyperchromic effects.

Experimental

***o*-Chloro-DL-phenylalanine (I).**[14]—Simultaneous reduction and hydrolysis[15] of 77 g. of 2-phenyl-4-(*o*-chlorobenzal)-5-oxazolone,[16,17] m. p. 159–161° (cor.) gave after successive recrystallizations from aqueous-ammonia and aqueous-methanol (90% methanol) 16 g. of I, long silky needles, m. p. 241–242°, dec. In contrast to phenylalanine and the other substituted phenylalanines described in this communication, I did not form well-defined crystals when recrystallized from water.

Anal. Calcd. for $C_9H_{10}O_2NCl$ (199): C, 54.3; H, 5.0; N, 7.0. Found: C, 54.6; H, 5.3; N, 6.8.

T.[21-23] From 2 kg. of chloramine-T sufficient anilide was obtained to permit the isolation of 150 g. of twice recrystallized V. V gave a phenylhydrazone, yellow leaflets, m. p. 237–238° (cor.) after recrystallization from ethanol.

Anal. Calcd. for $C_{13}H_{13}O_2N_3S$ (275): C, 56.8; H, 4.8; N, 15.3; S, 11.6. Found: C, 56.9; H, 4.8; N, 15.2; S, 11.6.

A mixture of 18.5 g. of V, 17.9 g. of hippuric acid, 16.5 g. of sodium acetate, and 100 ml. of acetic anhydride was heated on a steam-bath for three hours, the reaction mixture cooled, the precipitate collected and washed with acetic acid and ethanol to give 40 g. of crude 2-phenyl-4-(*p*-sulfamylbenzal)-5-oxazolone (VI). Thirty grams of crude VI was dissolved in 50 ml. of 5 *N* methanolic sodium hydroxide and 100 ml. of water, the solution heated to boiling, chilled and acidified with 5 *N* hydrochloric acid. The crystalline precipitate was collected, recrystallized from aqueous ethanol and dried to give 19.5 g. of crude α-benzamido-*p*-sulfamyl-cinnamic acid (VII), m. p. 194–195° (cor.) with preliminary sintering at 150°. The crude VII was recrystallized twice from hot water to give VII, sheaves of colorless needles, m. p. 197.5–198.5° (cor.) with preliminary sintering at 150°. VII was dried at 100° prior to analysis.

Anal. Calcd. for $C_{16}H_{14}O_5N_2S$ (346). C, 55.5; H, 4.1; N, 8.1. Found: C, 55.0; H, 4.0; N, 8.1.

A suspension of 150 g. of VII, m. p. 197.5–198.5°, in 600 ml. of ethanol was reduced at 30–40 lb. of hydrogen pressure over 20 g. of 5% palladized charcoal, VII dissolving as the hydrogenation proceeded. After removal of the catalyst the ethanol solution was evaporated to dryness, the residue dissolved in 10 liters of hot water, the solution decolorized and allowed to stand for several days at 5°. The gummy precipitate was collected and dried *in vacuo* to give 103 g. of crude N-benzoyl-*p*-sulfamyl-DL-phenylalanine (VIII). One hundred grams of crude VIII was refluxed for two hours with 2 liters of 2.5 *N* hydrochloric acid, the hydrolysate allowed to stand at 5° for several days, the precipitate collected, the filtrate extracted with ether, and the aqueous phase adjusted to *p*H 2.6 with silver carbonate. The precipitate obtained from the chilled hydrolyzate (above) was washed with ether and dried to give 43 g. of crude VIII which was again refluxed with 800 ml. of 2.5 *N* hydrochloric acid for two hours. The hydrolysate was treated as described above and the aqueous phase, adjusted to *p*H 2.6, was combined with the aqueous phase obtained from the first hydrolysate. This solution was concentrated *in vacuo* to 100–150 ml., the concentrate adjusted to *p*H 6 with acetic acid and ammonium hydroxide, and placed in a desiccator over sulfuric acid. After standing for several months the crystalline residue was dissolved in the minimum quantity of hot water, the solution decolorized, an equal volume of ethanol added to the colorless filtrate and the solution allowed to stand several days at 5°. The crystalline precipitate was collected, washed with ethanol and dried to give 16.5 g. of IV, glistening colorless platelets, m. p. 246–251°, dec.

Anal. Calcd. for $C_9H_{12}O_4N_2S$ (244): C, 44.3; H, 4.9; N, 11.5; S, 13.1. Found: C, 44.4; H, 5.2; N, 11.3; S, 13.3.

The α-amino acid nitrogen content[24] of IV was found to be 5.67% which is in good agreement with the calculated value of 5.74%.

The residue remaining after the second hydrolysis described above was alternately recrystallized from aqueous ethanol and water to give VIII, blunt prisms, m. p. 204–205° (cor.).

Anal. Calcd. for $C_{16}H_{16}O_5N_2S$ (348): C, 55.2; H, 4.6; N, 8.0. Found: C, 55.1; H, 4.6; N, 7.8.

Miscellaneous Preparations.—Synthetic DL-phenylalanine (Winthrop) was recrystallized three times from water. Toluenesulfonamide (IX), m. p. 135.7–137.0° (cor.) was obtained by dissolving crude IX in 5% sodium hydroxide followed by precipitation with dilute hydrochloric acid and recrystallization from aqueous ethanol. Eastman Kodak Co. White Label benzenesulfonamide was used without further purification.

Potentiometric Determination of Apparent Ionization Constants.—Twenty-ml. aliquots of 0.01–0.02 formal amino acid in 0.05, 0.10 and 0.20 formal aqueous sodium chloride were titrated at 24.4 ± 2.1° with standard 0.2 normal hydrochloric acid or sodium hydroxide using a Beckman Model G *p*H meter equipped with No. 1170 and No. 1190E electrodes. The constants were evaluated analytically[25,26] recognizing over-lapping ionizations in the case of *p*-sulfamyl-DL-phenylalanine and correcting in every instance for the amount of acid or base added which did not react with the amino acid. As a check, several of the constants were also evaluated by the method of Speakman.[27] The reduced data summarized in Table I were obtained from thirty-three independent titrations which revealed no significant dependence of the ionization constants upon ionic strength over the range studied. The values given are believed to be accurate to within 0.05 of a *pK* unit.

Absorption Spectra.—All spectra were determined with a Beckman Model DU Quartz Spectrophotometer at a temperature of 25 ± 3° and at intervals of 2 mμ or less from the lower limit of the instrument to 280 mμ and then at 10 mμ intervals to 320 mμ.

(27) J. C. Speakman, *J. Chem. Soc.*, 855 (1940).

Spectrophotometric Titrations.—The procedure of Stenstrom and Goldsmith[11] was employed using solutions approximately 0.001 formal in sulfonamide and adjusted to the desired *p*H maintaining the total ionic strength at approximately 0.12. The values found for $pK'_{SO_2NH_2}$ for benzenesulfonamide were 9.96 ± 0.05 and for *p*-toluenesulfonamide 10.21 ± 0.05.

Summary

The apparent ionization constants and ultraviolet absorption spectra of DL-phenylalanine, *o*-, *m*- and *p*-chloro- and *p*-sulfamyl-DL-phenylalanine have been determined. These nuclear substituents have been found to increase the acid strength of the ammonium group by approximately 0.2 of a *pK* unit for the chloro-compounds and by 0.5 of a *pK* unit for the *p*-sulfamido-derivative. Since these substituents effect the acid strength of the carboxyl group to a lesser degree all of the above substituted DL-phenylalanines have apparent isoelectric points which are more acidic than that of the parent amino acid.

The Viscosities of Binary Liquid Mixtures: Monofluorodichloromethane and Acetone

BY J. R. LACHER, C. H. WALDEN AND J. D. PARK

Viscosity determinations on a binary liquid mixture of a haloform and a solvent containing donor atoms have been carried out by various investigators[1] and it was recognized at once that it presented a case of marked non-ideality of liquid mixtures. However, all of the early investigators in this field failed to arrive at any satisfactory treatment of the experimental results. The activated complex theory proposed by Eyring[2] does present a method of drawing certain conclusions about the viscosity process which may be expressed as follows

$$\eta = \frac{Nh}{V} \exp. \left[\frac{N_1 \Delta F_1^{\pm} + N_2 \Delta F_2^{\pm} - \frac{\Delta F_m}{2.45}}{RT} \right] \quad (1)$$

This formula has been applied to the benzene–phenol binary mixtures.[3] Here V is the average molar volume and $\Delta F_1^{\pm}$ and $\Delta F_2^{\pm}$ are the free energy of activation for the pure components and ΔF_m is the excess free energy of mixing. There is not sufficient information available at this time to calculate ΔF_m for the mixture treated in this paper and hence the validity of this equation cannot be checked. However, the viscosity results on the monofluorodichloromethane–acetone mixture will be discussed qualitatively on the basis of this theory. The mixture chosen for investigation was of special interest, for the heat of mixing has been determined in this Laboratory[4] and the extreme electronegativity of the fluorine atom in monofluorodichloromethane should give results differing from the less electronegative bromoform and chloroform used by others.

Experimental Details.—A Fischer–Irany type viscometer was used in these determinations. It is a modification of the Ostwald type which allows the flow to take place in a closed system. It was housed in an insulated bath equipped with windows to allow one to view the flow of the liquid. The bath was ice water for the 0° determinations and dry ice–acetone for the −40 and −80° runs. It was stirred with an electric stirrer and the temperature was determined within 0.1° with a single junction copper–constantan thermocouple. The binary mixtures were weighed out and their densities determined all in one operation by employing a special pycnometer designed in this Laboratory. It is constructed of metal and capillary tubing and designed to withstand the high vapor pressures encountered in working with certain fluorine-containing compounds at room temperature. The results at −80° are given in Table I for rounded mole fractions. The acetone used was purified by the method of Shipsey and Werner[5] using sodium iodide. Monofluorodichloromethane

was furnished us through the courtesy of Mr. R. J. Thompson of Kinetic Chemicals, Inc. It was distilled in a twenty-plate column and dried by passing repeatedly over phosphorus pentoxide.

TABLE I

DENSITY OF MONOFLUORODICHLOROMETHANE–ACETONE MIXTURE AT −80°

Mole fraction $CHCl_2F$	Density, g./ml.
0.0000	0.8996
.2500	1.0721
.5000	1.2450
.7500	1.4175
1.0000	1.5862

Discussion.—Three sets of determinations were carried out over a temperature range of 80°. They were 0, −40 and −80°. This constitutes almost the entire temperature range over which it is possible to make these measurements as the boiling point of monofluorodichloromethane is 9° (760 mm.) and the freezing point of acetone is −95°. The values of the viscosity in centipoises as a function of the mole fraction of monofluorodichloromethane at −80° are shown in Fig. 1. From

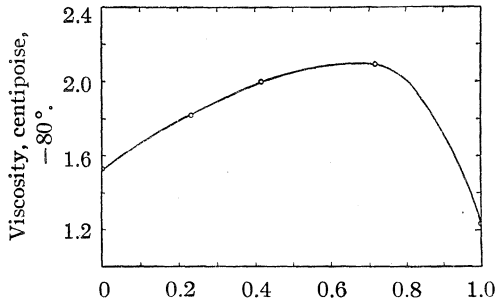

Fig. 1.

curves of this kind, the viscosities at rounded mole fractions were obtained for the three temperatures. The data are given in Table II, column two, three and four. A graph of the logarithm of the viscosity at constant composition against $1/T$ gave excellent straight lines for both the pure components and the various mixtures. This would seem to preclude any strong type of association such as that in water and other hydrogen bonded liquids as these do not give a linear relationship.[2] From the equation first suggested empirically by Arrhenius and derived by both Eyring and Andrade,[2] $\eta = A \exp[-E_{vis}/RT]$ the energy of activation for viscous flow, E_{vis}, may be calculated. The values so obtained are given in Table II, column five. Using the experimental values of the constant A, the entropy of activation for viscous flow, $\Delta S^{\pm}$, was calculated from the following equation also due to Eyring

$$A = \frac{hN}{V} \exp.\left[\frac{-\Delta S^{\pm}}{R}\right]$$

Here N is Avogadro's number, h is Planck's constant and V is the molar volume which is obtainable from the experimental density measurements. The equation assumes $p\,\Delta v$ is negligible in comparison with $\Delta H^{\pm}$. The entropies so calculated are also given in Table II. They are positive with monofluorodichloromethane having the smallest value. The free energy of activated flow, $\Delta F^{\pm}$, at 233°K. may be readily calculated and the results are given in Table II, column seven.

Figure 2 gives E_{vis}, $\Delta S^{\pm}$ and $\Delta F^{\pm}$ as a function of the mole fraction of monofluorodichloromethane. It is apparent that E_{vis} and $\Delta S^{\pm}$ vary with

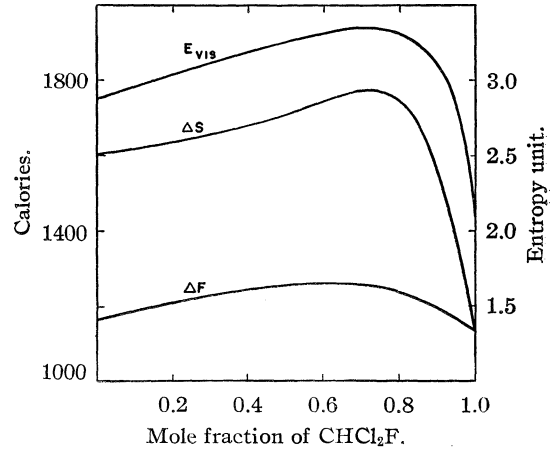

Fig. 2.

the composition in a similar way and have a maximum at about 0.75 mole fraction. The more positive $\Delta S^{\pm}$ is, the greater amount of randomness produced in going to the activated state. It takes less energy for a molecule of monofluorodichloromethane to reach the activated state necessary for viscous flow than it does for pure acetone and the various mixtures, but to reach this state the monofluorodichloromethane molecules undergo a smaller positive entropy change. The variations in E_{vis} and $\Delta S^{\pm}$ tend to counteract each other in $\Delta F^{\pm}$ with the result that the latter function is more nearly independent of the mole fraction.

TABLE II

Mole fraction $CHCl_2F$	Viscosity, centipoise −80°	−40°	0°	E_{vis}, cal.	$\Delta S^{\pm}$, e. u.	$\Delta F^{\pm}$, cal.	$\Delta E_{vap.}$, cal.	$\Delta E_{vap.}/E_{vis}$	ΔF_m, cal.
0.0000	1.526	0.713	0.398	1747	2.499	1165	6577	3.75	...
.2500	1.848	.791	.453	1834	2.659	1214	6568	3.58	−113
.5000	2.042	.869	.487	1889	2.701	1259	6357	3.36	−231
.7500	2.064	.854	.473	1938	2.945	1252	5921	3.05	−242
1.0000	1.232	.664	.412	1441	1.323	1133	5260	3.65	...

Eyring has found that the ratio of the energy of vaporization to the energy of activation for flow, $\Delta E_{vap}/E_{vis}$, gives interesting information.[2] Spherical molecules require a hole one-third the size of the molecule for flow and consequently $\Delta E_{vap}/E_{vis}$ has a value of about three. Polar and elongated molecules have values of this ratio nearer four. In these cases several orientations for viscous flow are possible and the molecules tend to acquire those requiring the least E_{vis}. In making the calculations of the energy of vaporization that of acetone was taken to be 6557 cal./mole[6] and that of monofluorodichloromethane as 5260 cal./mole.[7] The energy of vaporization of the mixtures was calculated from the following equation using heat of mixing data[4]

$$\Delta E_{vap} = N_1\Delta E_1 + N_2\Delta E_2 + \Delta H_{mix}$$

The results of these calculations are given in Table II, column eight, together with the ratio, $\Delta E_{vap}/E_{vis}$ in column nine. The ratio is 3.75 for acetone which compares with 3.86 given by Ewell and Eyring[8] for apparently a higher temperature range.

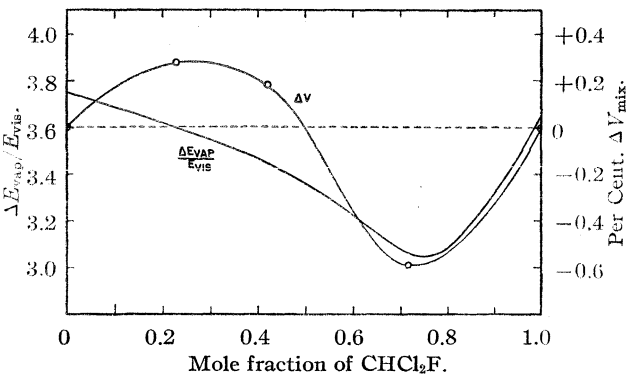

Fig. 3.

The value of 3.65 for monofluorodichloromethane is slightly lower than the value of 3.76 given for chloroform.[8] As is shown in Fig. 3, $\Delta E_{vap}/E_{vis}$ has a minimum value at a mole fraction of about 0.75. The per cent. change in volume which results when one mole of solution is produced from the pure components is also given in Fig. 3. The curve was calculated from density measurements made at −80°. A similar type of curve was noted by Hubbard[9] for chloroform–acetone mixtures. Except for a small initial rise, the volume changes are of the same general form as that given by $\Delta E_{vap}/E_{vis}$. In order to account for the curves in Figs. 2 and 3 we will assume, with Trew,[10] that acetone is a partially associated liquid and that a weak complex forms between acetone and monofluorodichloromethane. Whether this complex forms in a 1:1 ratio is not known. However, Wyatt[11] found from freezing point curves that such was the case with the analogous mixture of chloroform–acetone. When monofluorodichloromethane is added to pure acetone, the association between the acetone molecules decreases and that between the acetone and monofluorodichloromethane increases. The two effects do not balance exactly and E_{vis} and S increase slightly even though there is a slight volume increase on mixing the two pure components. At a mole fraction of 0.75 the volume change has its maximum negative value and for solutions richer in monofluorodichloromethane, E_{vis} and S fall off rapidly. Apparently the monofluorodichloromethane molecules pack in tightly with the acetone–monofluorodichloromethane complexes at this mole fraction. A maximum of activation energy is required to produce viscous flow which, when it takes place, ruptures the closely packed liquid structure and the entropy of activation is also a maximum. The fact that the viscosity is strongly dependent upon the free volume has been previously pointed out by Eyring,[2] Kottler[12] and Batschinski.[13]

Although it is not possible to test the validity of Equation I directly for this mixture, it is possible to determine what value of F_m is required to satisfy the equation when the experimental values of viscosity and free energy of activation for viscous flow are used. The values so obtained are included in Table II, column ten.

Summary

The viscosities of binary liquid mixtures of monofluorodichloromethane and acetone have been measured for several mole fractions and over a temperature range of −80 to 0°. The results are discussed in terms of the activated complex theory of Eyring for viscous flow.

The Dissociation Constants of Some Unsymmetrically Substituted Diphenylselenium Dibromides[1]

BY JAMES D. MCCULLOUGH AND MAX K. BARSH

In earlier communications measurements of the dissociation constants of diphenylselenium dibromide[2a] and some symmetrically disubstituted diphenylselenium dibromides[2b] have been reported. The equilibria involved are of the type

$$R_2SeBr_2 = R_2Se + Br_2$$

Spectrophotometric measurements on carbon tetrachloride solutions of the dibromides at measured temperatures near 25° enabled determination of the concentrations of the species involved. The dissociation constants, $K = (R_2Se)(Br_2)/(R_2SeBr_2)$ were then readily computed and ranged in value from 2.7×10^{-5} for the di-*p*-methoxydiphenylselenium dibromide to 1.1×10^{-2} for the di-*m*-chloro compound. When the values of log K for the symmetrically disubstituted dibromides were plotted against Hammett's[3] substituent constants, σ, a reasonably close approximation to a straight line resulted.

The study of unsymmetrically substituted diphenylselenium dibromides reported in the present communication was undertaken primarily to test a postulate of additivity of the σ value for a substituent on one ring to the σ value for a substituent on the other ring. Additivity of these values is to be expected if pronounced resonance effects are not produced by the combination of substituents. It is conceivable that in the symmetrically disubstituted compounds, the very symmetry of the molecules might either enhance or suppress the effect of the substituents. The additivity postulate was tested by making a single plot of the log K values for all types of dibromides against the sums of the σ values involved.

A second objective of the investigation was a more accurate treatment of the effects of temperature on the equilibria through better control of the temperatures of the solutions at the time of measurement. This has permitted a better evaluation of ΔH and ΔS for the dissociations.

Experimental

Materials.—The selenides used in this investigation were synthesized by the methods of Campbell and McCullough.[4] The identity of these compounds is supported by the methods of synthesis (taken into consideration with the starting materials) and by the equivalent weights of the dihalides as determined by the method of McCullough, Campbell and Krilanovich.[5] Physical constants for the compounds prepared are given in Table I.

[a] Crystalline solid could not be obtained. [b] New compounds.

Carbon tetrachloride and bromine were of reagent grade and were carefully dried and distilled before use.

Procedure.—The dissociation constants were determined spectrophotometrically using a Beckman Model DU Quartz Spectrophotometer. For those selenides which form stable crystalline dibromides, the method was essentially that described earlier.[1a] Where crystalline dibromides were not obtainable, the selenides (which in these cases were liquid) were purified through several recrystallizations of the dichlorides from carbon tetrachloride. The dichlorides were then reduced by refluxing their carbon tetrachloride solutions for several hours with C. P. zinc dust in excess. The solid phases were then removed by filtration through sintered glass and the carbon tetrachloride distilled off, finally using a pressure of 100 mm. at 40° for two days in order to remove the solvent as completely as possible with minimum decomposition of the selenides. The selenides thus purified are colorless oils. By ordinary reduced pressure distillation they are at best light orange in color, due to decomposition. Solutions of the selenides having known concentrations were made up by weighing the pure liquids. Dibromide solutions were prepared by addition of the required amount of a carbon tetrachloride solution of bromine from a microburet. From this point the procedure was the same as that used when the solid dibromide is obtainable.

Temperature Control.—The temperature of the solutions was held constant within 0.2° by means of a specially built chamber inserted between the main part of the spectrophotometer and the photo-tube compartment. The central segment of the chamber consisted of the absorption-cell compartment furnished with the instrument and was flanked on both sides by brass plates $^7/_{16}$" thick.

These plates were drilled to fit the instrument and to provide paths for the light beam and for circulation of the thermostating fluid. The thermoregulator was carried in a well in one plate and a thermometer in the other. The thermostating fluid (water in the present case) was circulated from a thermostated bath placed nearby.

Results and Discussion

The temperatures at which the spectrophotometer measurements were made for each dibromide and the corresponding values for log K are given in columns two and three of Table II. For purposes of comparing the dissociation constants of the various compounds it was necessary to compute values for the constants at some fixed temperature, in this case 25°. In the work of McCullough and Eckerson[1b] this correction was made by use of an average value (8.6 kcal./mole) for ΔH for three different dibromides. An average value was used because the observed values showed no correlation with Hammett's sigma values. Actually there should be a linear relationship between ΔH and σ. This follows from the reasonable assumption that ΔS is constant for a given reaction series. With ΔS constant at some fixed temperature, the equation

$$\Delta H = \Delta F + T\Delta S \qquad (1)$$

becomes

$$\Delta H = \Delta F + b \qquad (2)$$

where b is a constant. Substituting for ΔF, we have

$$\Delta H = -RT \log K + b \qquad (3)$$

But log K is a linear function of σ, thus

$$\log_{10} K = \rho\sigma + \log_{10} K^\circ \qquad (4)$$

where $\log_{10} K^\circ$ is a constant.

Substituting in equation (3), changing to ordinary logarithms and combining constants leads to the equation

$$\Delta H = -2.30\, RT\rho\sigma + A \qquad (5)$$

where A and ρ are constant for a given reaction series.

Attempts to correlate equation (5) with the experimentally determined ΔH values were disappointing. Although the seven experimental values (four from the present work and three from the work of McCullough and Eckerson) show a trend in the right direction, the points are so badly scattered that a significant line cannot be drawn through them. This scattering is considerably greater than can be attributed to experimental errors alone and indicates that ΔS is not constant for the reaction series.

Log K values for 25° were obtained from the values at higher and lower temperatures in those cases where determinations were made at two temperatures. In the three remaining cases, log K (25°) was obtained through use of an average ΔH value of 10.6 kcal. per mole obtained from the seven experimental ΔH values. Errors in log K

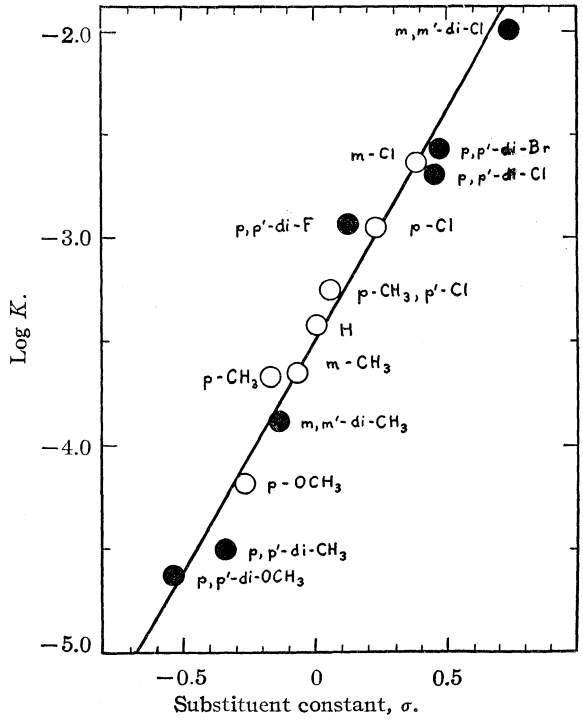

Fig. 1.—Graph of log K *vs.* Hammett's substituent constant for substituted diphenylselenium dibromides: O, present work; ●, McCullough and Eckerson.

caused by this approximate treatment are not large because of the shortness of the temperature intervals involved.

Log K, ΔF, ΔH and ΔS values for the dissociations are given in Table II. In Fig. 1, the log $K(25°)$ values are plotted against the substituent constant, σ. The data from the present work are indicated by open circles while the data of McCullough and Eckerson are indicated by full circles. The sigma values employed for the disubstituted diphenylselenium dibromides are the sums of the two individual sigma values concerned (twice Hammett's sigma values in the cases of the symmetrically disubstituted compounds). The straight line shown is the result of a least squares treatment of all of the data and has a slope, ρ, of 2.2. This indicates a rather high susceptibility of the selenium–bromine bond to changes in electron density on the selenium atom.

The fact that all of the log K values lie reasonably close to a single straight line is convincing evidence of the additivity of the effects of a substituent on the first ring to those of a substituent on the second ring in this type of system.

Summary

1. Dissociation constants for a number of unsymmetrically substituted diphenylselenium dibromides in carbon tetrachloride solution have been determined and the values (as log K) are given in Table II.

2. The values of log K (25°) from the present study have been plotted together with those from an earlier study of symmetrically disubstituted dibromides against Hammett's substituent constant, σ. The fact that all log K values lie reasonably close to a single straight line with slope, ρ, of 2.2 shows that the σ value for a substituent on one ring is additive to that for a second substituent on the other phenyl group.

3. The quantities ΔF, ΔH and ΔS at 25° have been evaluated for the dissociations and are listed in Table II.

Spectrophotometric Studies of Dilute Aqueous Periodate Solutions[1]

BY CARL E. CROUTHAMEL, HOMER V. MEEK, D. S. MARTIN AND CHARLES V. BANKS

The solubility behavior of various sparingly soluble periodates was found to be anomalous as interpreted through the equilibrium constants for the dilute aqueous periodate system as reported in the literature. Thus it was necessary to investigate these equilibria as a possible reason for the anomaly. Reinterpretation of this solubility behavior in light of the results of this investigation will be reported at a later date.

The ionization of periodic acid in aqueous solutions has been studied previously by various authors.[2,3] Giolitti[2a] and Partington and Bahl[3] found evidence of the dibasicity of periodic acid. Dubrisay[2b] found somewhat doubtful evidence of a third replaceable hydrogen. Rothmund and Drucker[4] reported the dissociation constant $K_1 = 2.3 \times 10^{-2}$ for paraperiodic acid, H_5IO_6. Rae[5] ran a conductometric titration of paraperiodic acid with sodium hydroxide and obtained two breaks. The first is in accord with the K_1 value reported by Rothmund and Drucker and from the second break he estimated that K_2 may be of the order of 10^{-6}. The literature generally concurs with the fact that paraperiodic acid, H_5IO_6, is the only solid periodic acid which is capable of existence in equilibrium with aqueous solutions of the acid. Hill[6] estimated a K_3 value of 4.6×10^{-11} using the previously reported values of K_1 and K_2 as a basis for his estimate.

In this study we have confirmed the previously reported value of $K_1 = 2.3 \times 10^{-2}$ and have assigned new values of $K_2 = 4.35 \times 10^{-9}$ and $K_3 = 1.05 \times 10^{-15}$. K_1 was confirmed from spectrophotometric studies, K_2 was estimated from spectrophotometric and potentiometric studies and K_3 was estimated using the method of Hill[6] and was confirmed by spectrophotometric data.

Aqueous solutions of periodate in the absence of interfering ions show an absorption maximum at 222.5 mμ in the ultraviolet region of the spectrum over a limited pH range. Since the start of this investigation MacDonald, Thompsett and Mead[7] reported an absorption maximum at 222 mμ and indicated that Beer's law was obeyed but neglected to mention the critical nature of pH. The full importance of pH is adequately described below.

Experimental

In the spectrophotometric studies a Beckman Quartz Spectrophotometer (Model DU) and a Cary Recording Spectrophotometer (Model 12) were employed. A Beckman Glass Electrode pH Meter (Model H-2) was used in carrying out the potentiometric titrations. Sources of periodate were paraperiodic acid manufactured by the

G. Frederick Smith Chemical Company, Columbus, Ohio, and Baker and Adamson reagent grade potassium metaperiodate. The spectra obtained were found to be independent of the starting material in the absence of interfering substances. Ions which exhibited no interference were perchlorate, sodium and potassium. Ammonium ion exhibited no interference in concentrations attained by adjusting 10^{-4} M potassium metaperiodate up to pH of *ca.* 10.5 with filtered reagent grade ammonia solutions. Nitrate, sulfate and carbonate ions and carboxylate groups definitely interfere.

After originally establishing the nature of the absorption, solutions of both potassium metaperiodate and paraperiodic acid were scanned on the Cary instrument using 1.000 cm. silica cells at various pH values as adjusted with perchloric acid. Figure 1 shows the nature of the variation of the absorption spectra of solutions 1.01×10^{-4} M potassium metaperiodate at various pH values as adjusted by perchloric acid and using the Cary instrument. Figure 2 similarly shows the variation in the alkaline region of 1.05×10^{-4} M potassium metaperiodate at various pH values as adjusted by potassium hydroxide and unlike Fig. 1 these solutions are 10^{-2} M in sodium perchlorate.

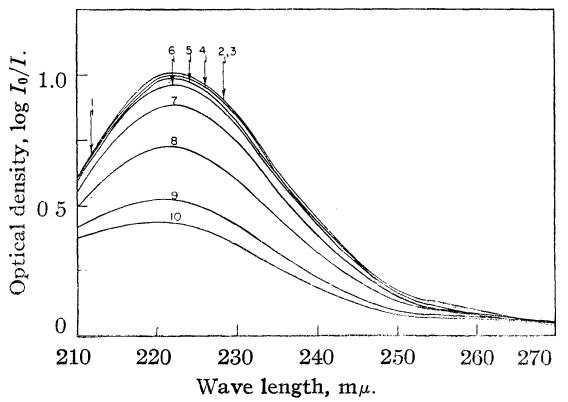

Fig. 1.—Absorption spectra of 1.01×10^{-4} M potassium periodate solutions at pH values: 1, 6.92; 2, 4.78; 3, 3.43; 4, 3.04; 5, 2.80; 6, 2.35; 7, 1.80; 8, 1.35; 9, 1.10.

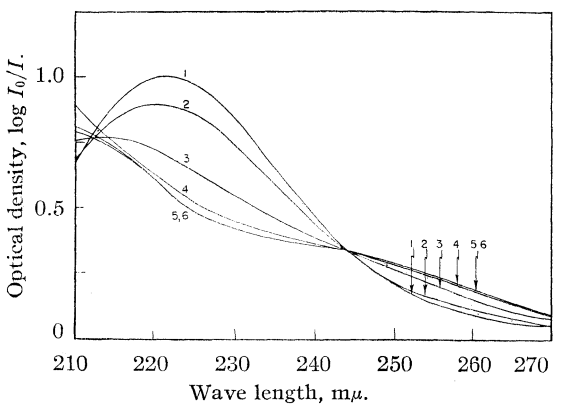

Fig. 2.—Absorption spectra of 1.05×10^{-4} M potassium periodate solutions at pH values: 1, 6.50; 2, 7.50; 3, 8.50; 4, 9.30; 5, 10.15; 6, 10.75.

Isobestic points are apparent at approximately 213 mμ and 244 mμ. Solutions of paraperiodic acid gave absorption curves identical within experimental error when similarly adjusted in pH. Figure 3 is a plot of the optical densities at 222.5 mμ for solutions 1.009×10^{-4} M in potassium metaperiodate at various pH values as adjusted with perchloric acid or sodium hydroxide. The Beckman instrument (0.998 cm. silica cells) was used up to pH 12 but at higher pH the Cary instrument was used because it appears to be better suited to the measurement of very high optical densities. High optical densities at pH values above 12.0 were due to the fact that sodium hydroxide solutions of very high pH even though they contain only relatively small amounts of carbonate nevertheless absorb considerably at 222.5 mμ. The experimental values plotted in Curve 1, Fig. 3, above pH 12.0 represent the difference between optical densities of the periodate solutions at the pH values indicated and distilled water of the same pH values as adjusted by the same sodium hydroxide solution. As indicated on Fig. 3 the series of experimental optical density values above pH 12.0 represent Cary instrument readings converted to equivalent Beckman instrument readings. This was necessitated by the fact that different molecular extinction coefficients, ϵ, were found for the $H_3IO_6^=$ ion on the two instruments. This is explainable by the fact that th molecular extinction coefficient for this ion was determined not at an absorption maximum but at a wave length where the optical density is changing rapidly with wave length. Therefore minor discrepancies in the wave length scales of the two instruments would be reflected quite sensitively in the molecular extinction coefficients obtained for this ion. In the case of the $H_4IO_6^-$ ion no such discrepancy would be expected because the molecular extinction coefficient for this ion was determined at an absorption maximum where optical density is rather insensitive to wave length. Experimental values are in agreement with this explanation. In curve 1, Fig. 3, the ionic strength, μ, varies only as a consequence of the addition of perchloric acid or sodium hydroxide required in adjusting pH. The solutions for Curve 2, Fig. 3, differ from those of curve 1 only in that the former are all 0.0625 M in sodium perchlorate. Differences between curves 1 and 2 are due only to differences in ionic strength and experimental error. Table I lists observed and calculated data corresponding to Fig. 3.

Discussion and Calculations

Aqueous solutions of periodate were found to follow Beer's law at given pH values from 1.0 to 10.5 at all wave lengths in the range where appreciable absorption occurs. The equilibria

$$H_5IO_6 \longleftrightarrow H_4IO_6^- + H^+, K_1 = \frac{a_{H^+}a_{H_4IO_6^-}}{a_{H_5IO_6}} \quad \text{Eq. 1}$$

$$H_4IO_6^- \longleftrightarrow H_3IO_6^{=} + H^+, K_2 = \frac{a_{H^+}a_{H_3IO_6^{=}}}{a_{H_4IO_6^-}} \quad \text{Eq. 2}$$

$$H_3IO_6^{=} \longleftrightarrow H_2IO_6^{\equiv} + H^+, K_3 = \frac{a_{H^+}a_{H_2IO_6^{\equiv}}}{a_{H_3IO_6^{=}}} \quad \text{Eq. 3}$$

predict that the ratios of the activities of the various species remain constant at constant pH. Yet deviation from Beer's law might be caused by the variation of the activity coefficients in the solutions studied. In these solutions, however, either the ionic strength was so low that all activity coefficients were nearly 1.0 or the ionic strength was maintained constant by the addition of an electrolyte. In this work the pH value indicated by the glass electrode instrument, calibrated by means of three standard buffers of pH 4, 7 and 10, is taken as $-\log a_{H^+}$. For values less than 1.0 or greater than 12.0 the pH was calculated from the molar concentration of H^+ or OH^- and estimated values of activity coefficients.

However, an equilibrium such as

$$2H_3IO_6^{=} \longleftrightarrow I_2O_9^{==} + 3H_2O, K_4 = \frac{a_{I_2O_9^{==}}a^3_{H_2O}}{a^2_{H_3IO_6^{=}}} \quad \text{Eq. 4}$$

does predict a departure from Beer's law at any pH value at which this equilibrium is of importance, because the activities of the $I_2O_9^{==}$ and $H_3IO_6^{=}$ ions are raised to different powers in the expression for K_4. Therefore this equilibrium is of no importance up to a pH of 10.5 and is probably never appreciably involved in dilute aqueous solutions of periodates. The formulation $K_4I_2O_9 \cdot 9H_2O$ frequently encountered in the literature[8] is probably better represented as $K_2H_3IO_6 \cdot 3H_2O$. Reactions of simple hydration or dehydration of the various periodate species involved in Equations 1, 2 and 3 predict no departure from Beer's law and are not considered in this work. Treatment of the data obtained using only K_1, K_2 and K_3 accounts completely for the variation of the optical densities of the solutions with pH.

A molecular extinction coefficient was estimated for H_5IO_6 using a solution of known periodate concentration and 1.14 M in perchloric acid. Molecular extinction coefficients for $H_4IO_6^-$ and

(8) Latimer, "Oxidation Potentials," Prentice-Hall, Inc., New York, N. Y., 1938, p. 59.

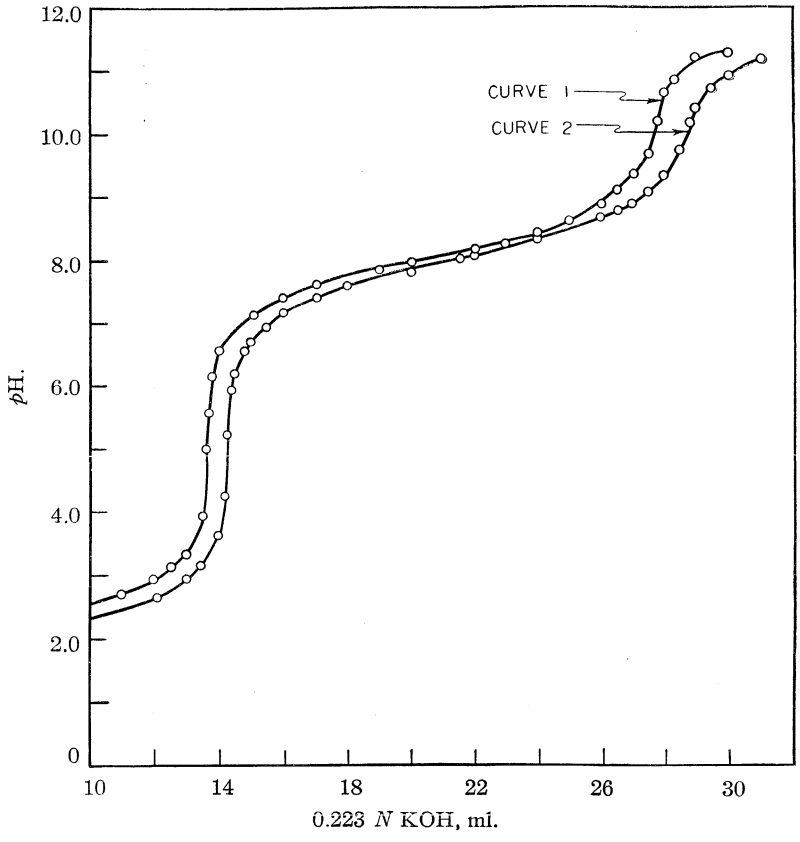

Fig. 4.—Potentiometric titration curves of paraperiodic acid.

$H_3IO_6^=$ were estimated from the wide plateaus obtained in dilute acid and dilute alkaline solution respectively in the plot of optical densities *vs.* *p*H for known concentrations of periodate. Table II lists the molecular extinction coefficients estimated for the various species of periodate using both the Cary and Beckman instruments.

TABLE II

MOLECULAR EXTINCTION COEFFICIENTS AT 222.5 mμ OF THE VARIOUS PERIODATE SPECIES IN DILUTE AQUEOUS SOLUTION

Instrument	$\epsilon_0 \times 10^{-3}$	$\epsilon_1 \times 10^{-3}$	$\epsilon_2 \times 10^{-3}$	$\epsilon_3 \times 10^{-3}$
Beckman	2.18	10.08	5.24	0.00
Cary	2.18	9.97	5.86	0.00

Good agreement was obtained except in the case of $H_3IO_6^=$ and the probable reason for this has already been cited (see Experimental). This is not unexpected since Ewing and Parsons[9] have shown relative discrepancies of half this magnitude among ten Beckman instruments themselves at constant band width.

By substituting $\gamma_0M_0, \gamma_1M_1, \gamma_2M_2$ and γ_3M_3 for the activities of H_5IO_6, $H_4IO_6^-$, $H_3IO_6^=$ and $H_2IO_6^{\equiv}$, respectively, in equations 1, 2 and 3 and solving these equations for the molar concentrations of the various periodate species the following equation may be written for the total periodate concentration, assuming that $\gamma_0 = 1$

$$M_{\text{total}} = M_0 + \frac{K_1M_0}{\gamma_1 a_{H^+}} + \frac{K_1K_2M_0}{\gamma_2 a^2_{H^+}} + \frac{K_1K_2K_3M_0}{\gamma_3 a^3_{H^+}} \quad \text{Eq. 5}$$

The activity coefficients as functions of the ionic strength were estimated in the following manner for all points except for *p*H 14. For γ_1, values of $\gamma_\pm$ for aqueous potassium chloride solutions[10] were used. Values for γ_2 were calculated from values of $\gamma_{C_2O_4^=}/\gamma_{Cl^-} \times \gamma_{HC_2O_4^-}$ indicated in the potentiometric evaluation of the second ionization constant of oxalic acid[11] together with the values of γ_1. The activity coefficient, γ_3, was calculated in the conventional manner from values of $\gamma_\pm$ reported for various rare earth chlorides.[12] For *p*H of 14, γ_1 was taken from values of $\gamma_\pm$ for sodium hydroxide and γ_2 was calculated from values of $\gamma_\pm$ for alkaline earth halides tabulated by Harned and Owen.[13] The values of K_1, K_2 and K_3 are quite easily estimated from equation 5 and the following relation for the optical density

$$D = l\left[\epsilon_0M_0 + \frac{\epsilon_1K_1M_0}{\gamma_1 a_{H^+}} + \frac{\epsilon_2K_1K_2M_0}{\gamma_2 a^2_{H^+}} + \frac{\epsilon_3K_1K_2K_3M_0}{\gamma_3 a^3_{H^+}}\right] \quad \text{Eq. 6}$$

since a_{H^+} is known from *p*H measurements, M_{total} is known from chemical analysis, l is the cell thickness in cm. and ϵ_3 is very nearly zero. In this way the values for K_1, K_2 and K_3 which gave the best agreement between experimental and calculated optical density values at low ionic strength were found to be

$$K_1 = 2.30 \times 10^{-2}$$
$$K_2 = 4.35 \times 10^{-9}$$
$$K_3 = 1.05 \times 10^{-15}$$

The value of K_1 thus determined agrees exactly with previously reported values.[4,5] The value of K_2, a new constant, was substantiated from the potentiometric titration data shown in Fig. 4 in the following manner.

From equation 2 it follows that

$$K_2 = a_{H^+} \text{ when } \frac{a_{H_3IO_6^=}}{a_{H_4IO_6^-}} = \frac{\gamma_2M_2}{\gamma_1M_1} = 1 \quad \text{Eq. 7}$$

(13) Harned and Owen, "The Physical Chemistry of Electrolytic Solutions," Reinhold Publishing Corp., New York, N. Y., 1943, p. 567.

Knowing the total quantity of periodate, the volume of solution, how the assumed values for γ_1 and γ_2 vary with ionic strength, and how the ratio of $M_2:M_1$ varies with ml. of base added, the condition where Eq. 7 is satisfied was evaluated by a series of successive approximations. This condition was found to occur where $\sqrt{\mu}$ was *ca.* 0.25 and

$$\frac{M_2}{M_1} = \frac{\gamma_1}{\gamma_2} = \frac{0.805}{0.428} = 1.88$$

This molar ratio corresponds to *p*H values of 8.24 and 8.26 on curves 1 and 2, respectively, in Fig. 4. This gives a value of $K_2 = 5.6 \times 10^{-9}$ which, in view of the uncertainties involved in γ_1 and γ_2, is in good agreement with the value of $K_2 = 4.35 \times 10^{-9}$ obtained from the spectrophotometric studies.

The value of K_3, also a new constant, agrees, within experimental error, with the value of K_3 obtained from K_1 and K_2 using the method of Hill.[6]

Activity Coefficients.—The magnitudes of the differences between Curves 1 and 2 in Fig. 3 are much greater than predicted differences due to such changes in ionic strength, using normal γ_1 and γ_2 values. This suggests an abnormal decrease of the actual activity coefficients of the $H_4IO_6^-$ and $H_3IO_6^=$ ions, particularly the latter, with increasing ionic strength. For this reason values of K_1 and K_2 were calculated from the data for low ionic strength where errors due to such abnormalities would be very small. Estimates of the actual γ_1 and γ_2 values at the ionic strengths indicated may be made from the magnitudes of the differences between the two curves.

Analytical Significance.—From these studies it is quite obvious that for the analytical determination of periodate (in the absence of interfering substances) spectrophotometrically, *p*H is a very important factor. Inspection of the plot of optical density at 222.5 mμ *versus* *p*H shows clearly that a *p*H of *ca.* 5.0 is the optimum *p*H to use in acid solutions for this determination. For solutions of low ionic strength *p*H values of 5.0 ± 1.5 are quite satisfactory, the optical density not varying appreciably in this region. Concentrations as low as 10^{-7} molar in periodate should be detectable using 5.00-cm. silica cells. In the event that it is desirable to determine periodate spectrophotometrically in alkaline solutions, *p*H values between *ca.* 10.5 and 12.5 are desirable. Such analysis leads to a sacrifice in sensitivity of the method at 222.5 mμ because of the lower molecular extinction coefficient of the $H_3IO_6^=$ ion as compared to that of the $H_4IO_6^-$ ion used in the lower *p*H range. This disadvantage may be eliminated by simply carrying out the analysis at a somewhat lower wave length, *i. e.*, at a wave length nearer to or at which the $H_3IO_6^=$ ion shows an absorption maximum.

Summary

It was shown that most probably any equilibria involving the formation of the dimesoperiodate ion, $I_2O_9^{=}$, is of no importance in dilute aqueous solutions. Three simple equilibria involving stepwise dissociation of paraperiodic acid, H_5IO_6, account completely for the variation of the ultraviolet absorption spectra of dilute aqueous solutions of periodate with *p*H. K_1[4,5] was substantiated and new estimates of K_2 and K_3 were made from spectrophotometric studies. K_2 was substantially confirmed by potentiometric studies and K_3 was confirmed by the method of Hill.[6] Evidence was shown for abnormal activity coefficients of $H_4IO_6^-$ and $H_3IO_6^=$ ions with increasing ionic strength. Recommendations were made for the spectrophotometric determination of periodate in slightly acid and alkaline solutions.

The Acid Properties of Iron Tetracarbonyl Hydride

BY P. KRUMHOLZ AND H. M. A. STETTINER

It has been shown previously[1] that the reaction between iron pentacarbonyl and alkalies does not produce, as assumed by Hieber,[2] the free iron tetracarbonyl hydride but its monobasic salts. The acid behavior of iron carbonyl hydride could be confirmed later by preparing salts with complex amine cations.[3] Some of them, as shown by Hieber,[4] behave in solution as strong electrolytes. Meanwhile Hieber[4] stated that structures as $[Fe(CO)_4H]^-$ are not stable and only can be stabilized by the formation of salts with complex cations, that the alkaline solutions of the hydride contain aquo salts rather than normal salts not yet prepared,[5] and that the formation of metal derivatives of $Fe(CO)_4H_2$ is by far not as general as it is supposed to be in an ordinary formation of salts.

In order to destroy any doubts regarding the behavior of iron carbonyl hydride as an ordinary acid we tried to determine its dissociation constant[6] by potentiometric titration of its salts with

(1) F. Feigl and P. Krumholz, *Monatsh.*, **59**, 314 (1932).
(2) W. Hieber and F. Leutert, *Z. anorg. Chem.*, **204**, 145 (1932).
(3) F. Feigl and P. Krumholz, *ibid.*, **215**, 242 (1933).
(4) W. Hieber and E. Fack, *ibid.*, **236**, 83 (1938).

(5) The monosodium salts prepared by F. Feigl and P. Krumholz, ref. 1, as alcoholates could not be freed completely from alcohol.

(6) A. A. Blanchard, *Chem. Rev.*, **21**, 3 (1937), assumed that the dissociation constant of cobalt tetracarbonyl hydride should be about 10^{-5}.

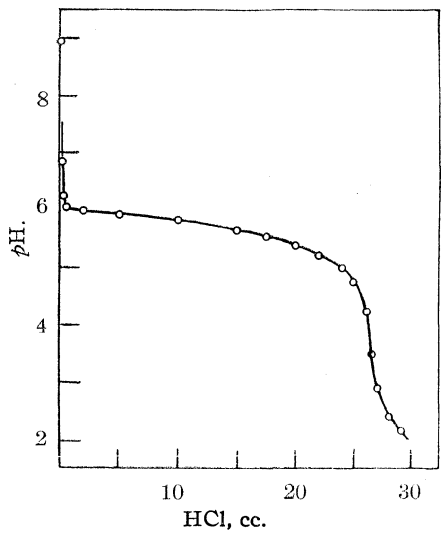

Fig. 1.—Titration of 0.055 m. $[Fe(CO)_4H]_2Ba$ with 0.57 *N* HCl; initial volume 135 cc., $T = 17.5°$.

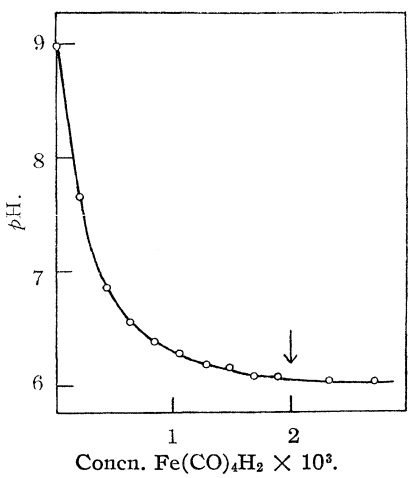

Fig. 2.—Titration of 0.055 m. $[Fe(CO)_4H]_2Ba$ with 0.57 *N* HCl.

HCl. Figs. 1 and 2 show the change of *p*H during the titration of a solution of the barium salt $[Fe(CO)_4H]_2Ba$ obtained by allowing barium hydroxide to react upon an excess of iron pentacarbonyl[1] according to

$$2Fe(CO)_5 + 3Ba(OH)_2 = [Fe(CO)_4H]_2Ba + 2BaCO_3 + 2H_2O \quad (1)$$

Those diagrams represent typical titration curves of salts of a weak acid of low solubility, since, immediately after starting the titration, the initially steep slope of the titration curve turns suddenly flat. At this point the initially clear solution becomes turbid due to the separation of free iron carbonyl hydride (the point where the first visible turbidity appears is indicated by an arrow in Fig. 2). From this part of the titration curve the molar solubility of $Fe(CO)_4H_2$ (at 17.5°) may be calculated as about 1.8×10^{-3}. The *p*H at the endpoint of the titration is 3.60; it corresponds to a thermodynamic dissociation constant[7] of $\approx 3.4 \times 10^{-5}$ (at 17.5°). Computing the dissociation constant from *p*H values at different concentrations of $[Fe(CO)_4H]^-$, and assuming that the concentration of undissociated $Fe(CO)_4H_2$ remains constant, we obtained as mean value $K_1 = 4.15 \times 10^{-5}$ (Table I).

TABLE I

$C_{Fe(CO)_4KH}$	*p*H	$K_1 \times 10^5$
1×10^{-1}	6.00	4.17
7.5×10^{-2}	5.88	4.13
5.3×10^{-2}	5.71	4.31
4.3×10^{-2}	5.63	4.20
2.3×10^{-2}	5.36	4.14
8.4×10^{-3}	4.95	3.92

The titration curve shows furthermore that the reaction between barium hydroxide and excess $Fe(CO)_5$ proceeds to an extent of at least 99.8% according to (1).

Solutions of the mono potassium salt of iron carbonyl hydride prepared by allowing $Fe(CO)_5$ to react with potassium and barium hydroxide in quantities corresponding to the equation

$$Fe(CO)_5 + KOH + Ba(OH)_2 = Fe(CO)_4KH + BaCO_3 + H_2O \quad (2)$$

behave in a similar way.

As iron carbonyl hydride also forms bibasic salts with some heavy metals,[3,8] and as Blanchard[9] recently assumed the formation of a bibasic potassium salt $Fe(CO)_4K_2$, we submitted solutions prepared according to

$$Fe(CO)_5 + 2KOH + Ba(OH)_2 = Fe(CO)_4K_2 + BaCO_3 + 2H_2O \quad (3)$$

to potentiometric titrations. As shown in Fig. 3 the *p*H values in the first moiety of the diagram are lower than the corresponding values of potassium hydroxide of equal concentration (represented by the dotted line in Fig. 3). This proves the formation of the dibasic salt, hydrolyzed to an extent of about 45% in 0.18 molar solution. We computed the second dissociation constant of iron carbonyl hydride from the hydrolytic equilibrium of the bibasic salt according to[10]

$$K_2 = K_{H_2O} \times \frac{C_{K_2X} - (OH^-)}{[C_{KHX} + (OH^-)](OH^-)} \times \frac{\gamma_{bi}}{(\gamma_{mono}^2)}$$

where C_{K_2X} and C_{KHX} represent the analytical concentrations of the bibasic and monobasic salt, $K_{H_2O} = 5.6 \times 10^{-15}$ (at 17.5°) and γ the activity coefficients of the ions.[11] We obtained

(7) Assuming the activity coefficient of $[Fe(CO)_4H]^-$ to 0.75 and γ_H to 0.80 at the ionic strength of 0.15.

(8) H. Hock and H. Stuhlmann, *Ber.*, **61**, 2097 (1928).

(9) A. A. Blanchard and G. W. Coleman, "Inorganic Syntheses," vol. 2, p. 243 (1946).

(10) *Cf.* I. M. Kolthoff and H. A. Laitinen, "*p*H and Electro Titrations," John Wiley and Sons, New York, N. Y., 1941.

(11) The initial ionic strength of the solution is 0.46, diminishing during the titration, mainly due to the disappearance of the bivalent ion $[Fe(CO)_4]^=$, reaching the value of 0.33 at the first equivalence point. We assumed (from known activities of salts of bibasic acids) at the beginning of the titration $\gamma_{mono} = 0.66$ and $\gamma_{bi} = 0.20$ and at the equivalence point $\gamma_{mono} = 0.70$ and $\gamma_{bi} = 0.24$.

the OH^- concentrations by comparing the measured potentials with those of potassium hydroxide solutions containing the same amount of K^+ (as KCl) as the solution of the iron carbonyl salt.[12]

The mean value (Table II) of the second dissociation constant of iron tetracarbonyl hydride at 17.5° thus obtained is $K_2 = 3.7 \times 10^{-14}$.

TABLE II

$C_{Fe(CO)_4K_2}$	$C_{Fe(CO)_4KH}$	(OH^-)	$K_2 \times 10^{14}$
1.8×10^{-1}	0	7.8×10^{-2}	4.25
1.13×10^{-1}	6.15×10^{-2}	4.5×10^{-2}	3.7
8.2×10^{-2}	9.05×10^{-2}	3.0×10^{-2}	3.8
4.1×10^{-2}	1.27×10^{-1}	1.45×10^{-2}	3.45
1.6×10^{-2}	1.50×10^{-1}	5.5×10^{-3}	3.40

The *p*H of the second equivalence point is 3.56 corresponding to a value of $K_1 = 3.7 \times 10^{-5}$. The mean value of this constant computed from *p*H values between the first and the second equivalence point[13] (Table III) is $K_1 = 4.3 \times 10^{-5}$.

TABLE III

$C_{Fe(CO)_4KH}$	*p*H	$K_1 \times 10^{-5}$
1.47×10^{-1}	6.11	4.45
1.25×10^{-1}	6.04	4.42
9.8×10^{-2}	5.94	4.37
6.3×10^{-2}	5.78	4.06
1.7×10^{-2}	5.20	4.16

The experimental error of the indicated values amounts to ±10%. The assumed values of the activity coefficients, specially of the bivalent ion, may be wrong to an extent of about 10–20%. A further error may be due to differences in the liquid junction potentials, so that the obtained values of the dissociation constants may be uncertain within ± one unit.

For the dissociation constants of iron tetracarbonyl hydride at 17.5° we can assume the approximate values

$$K_1 = 4 \times 10^{-5} \text{ and } K_2 = 4 \times 10^{-14}$$

exact within about ± one unit.

Thus, iron carbonyl hydride as monobasic acid is stronger than acetic acid, while the relation between the two dissociation constants reaches the extremely high value of $1:10^9$.

Furthermore, we tried to prepare the solid alkali salts from solutions obtained according to equations (2) and (3). These solutions, if prepared and kept under complete exclusion of oxygen, are only slightly brownish or pink and perfectly stable.

(12) The ionic strength of the potassium hydroxide solution is smaller (initially 0.36) than the ionic strength of the carbonyl solution. As the activity coefficients of OH^- vary less within those limits than the experimental error of the *p*H measurements, we assumed that equal potentials do not only correspond to equal values of the activities, but also to equal values of the concentrations of OH^-.

(13) Assuming $\gamma[Fe(CO)_4H]^- = 0.70$ at the ionic strength of about 0.30.

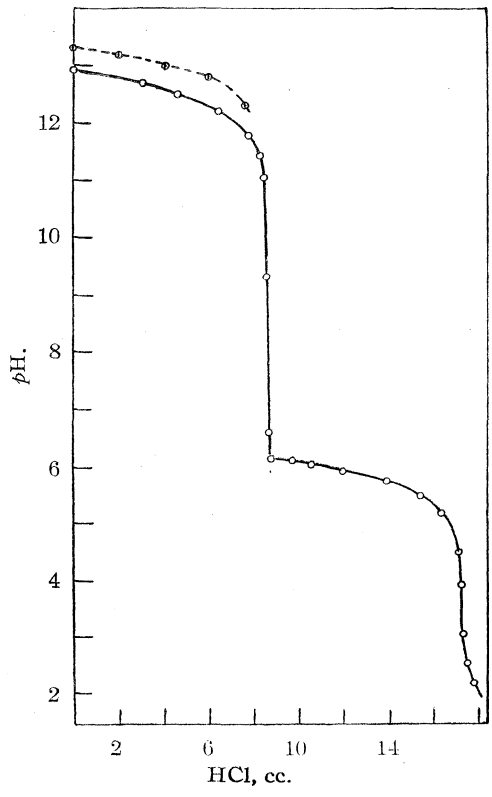

Fig. 3.—Titration of 0.18 m. $Fe(CO)_4K_2$ with 2 *N* HCl; initial volume 96 cc., $T = 17.5°$. Dotted line: titration of 0.18 *N* KOH + 0.18 *N* KCl with 2 *N* HCl.

On concentrating the solution of the bibasic salt at a low temperature, colorless crystals appear when the volume is reduced to a few cc. A slightly brownish mass remains when dried over phosphorus pentoxide at 0.5 mm; its analysis corresponds closely to the bibasic anhydrous salt $Fe(CO)_4K_2$. The salt is very soluble in water, producing a brownish solution due to an unavoidable small decomposition. Such a solution reacts with mercuric chloride according to

$$Fe(CO)_4K_2 + 2HgCl_2 = Fe(CO)_4Hg_2Cl_2 + 2KCl \quad (4)$$

yielding 98% of the theoretical amount of the mercuric salt.

These results allow no further doubts as to the existence of the anhydrous salt $Fe(CO)_4K_2$. They also exclude the possibility that the product obtained represents a mixture of $Fe(CO)_4KH$ and potassium hydroxide, specially as a potassium hydroxide solution retains about 2 molecules of water when dried under similar conditions over phosphorus pentoxide.

Treating solutions of the monobasic salt in an analogous way one obtains no separation of crystals, but the residue of the evaporation solidifies over phosphorus pentoxide to a brownish amorphous substance, with analytical data corresponding to the anhydrous salt $Fe(CO)_4KH$. This salt is extremely hygroscopic and, like the

bibasic salt, very sensitive to oxygen. Its brownish solution reacts with mercuric chloride according to

$$Fe(CO)_4KH + 2HgCl_2 = Fe(CO)_4Hg_2Cl_2 + HCl + KCl \quad (5)$$

yielding 97% of the theoretical amount of the mercuric salt, but only 92% of the theoretical amount of hydrogen chloride due to a loss of the very volatile $Fe(CO)_4H_2$ through hydrolysis of the monobasic salt and to a simultaneous formation of $Fe(CO)_4K_2$.

Since at least 97% of the substance consists of $Fe(CO)_4KH$ and $Fe(CO)_4K_2$, as shown by the reaction with mercuric chloride, it seems certain that $Fe(CO)_4KH$, too, exists as an anhydrous salt. It is possible, of course, that the ions $[Fe(CO)_4]^=$ and $[Fe(CO)_4H]^-$ are hydrated in aqueous solution. No further doubt may exist as to the rather peculiar fact that iron tetracarbonyl hydride behaves as an acid forming "normal" salts not only with amine cations but also with alkali metals.

The acidic behavior of iron carbonyl hydride—formation of hydrogen ions (or hydroxonium ions) in aqueous solution—is in contradiction to the easy decomposition of the hydride to molecular hydrogen explained by Hieber[2] with the formulation of $Fe(CO)_4H_2$ as a true hydride with direct iron-hydrogen bond. But this formulation explains hardly the acidic functions of $Fe(CO)_4H_2$. Furthermore, electron diffraction studies by Evans and Lister[14] seems to indicate that the hydrogen atoms are fixed on the oxygen atoms according to the formula $Fe(CO)_2(COH)_2$.

This formulation, especially in the electronic expression like $Fe^{=}:C:::^{++}O:H$ or $Fe^{-}::C::^{+}O:-H$, might explain the acid behavior of the hydride as the positively charged oxygen atoms must repel protons.[15]

But neither of both formulations is able to explain by itself the experimental facts, that iron carbonyl hydride may lose neutral hydrogen atoms as well as protons.

The structural problems in question will be discussed further in a later paper.

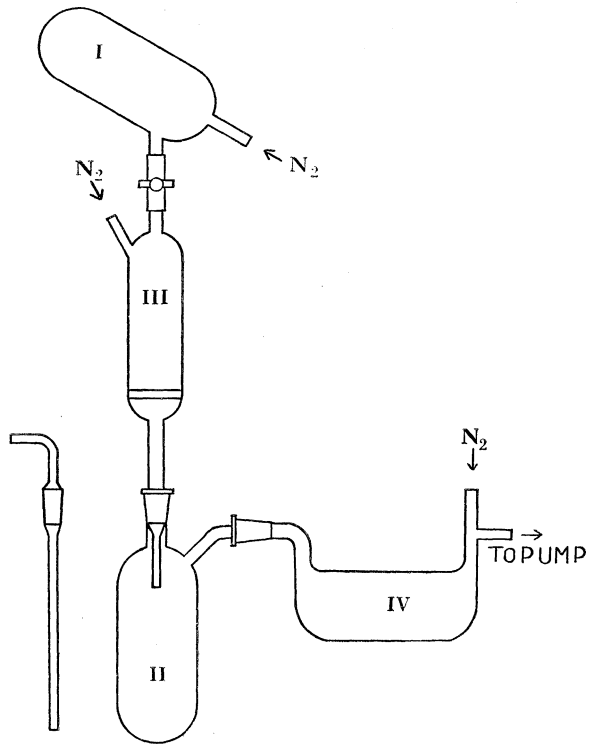

Fig. 4.—I, Reaction vessel; II, filter vessel; III, filter tube; IV, trap.

Experimental Part

Due to the enormous sensitivity of iron carbonyl-hydride and its salts to oxygen, all operations have to be performed under nitrogen absolutely free from oxygen, taking extreme care to exclude air during the manipulations.

We prepared the solutions for the potentiometric titrations in a modified Schlenck apparatus,[1] by shaking for three hours excess $Fe(CO)_5$ with a 0.33 *N* solution of barium hydroxide, or, according to equations (2) and (3) exact quantities of $Fe(CO)_5$ with solutions containing 0.18 mole of barium hydroxide and 0.18 or 0.36 mole of potassium hydroxide, respectively, in 1000 ml. and filtering the solution from the precipitated barium carbonate. The filtered solution was transferred to a titration vessel consisting of a 500-cc. erlenmeyer flask containing the glass and reference electrodes, buret, thermometer and inlet and outlet tubes for nitrogen. The titrations were performed with hydrochloric acid to 17.5 ± 0.2° after calibrating the glass electrodes with buffer solutions. It is known that glass electrodes show large alkali errors at *p*H above 10, even in potassium salt solutions. To eliminate these errors we calibrated the electrode in the strongly alkaline range with potassium hydroxide solutions containing the same amount of K^+ (as KCl) as the titrated solution. The reproducibility of the potentials during calibration and over the whole range of the titration —excepting perhaps the immediate proximity of the first equivalence point—was better than 1 mv. In order to obtain this accuracy in the strong alkaline range one has to wash the electrodes before every use for at least six hours in pure water, particularly after being used in acid solutions, and to wait about five minutes before taking the first reading. If oxygen is not entirely excluded, it is impossible to obtain constant readings near the first equivalent point, the liberated $Fe(CO)_4H_2$ being immediately destroyed by oxidation.

As already stated, soon after the first equivalence point, there appears free $Fe(CO)_4H_2$ at first in the form of a milky turbidity, separating later as a yellow oily layer that soon turns deeply red by decomposition. This decomposition however does not influence the titration. Apparently enough hydride always remains to give a saturated solution as shown by the constancy of the potentials, and the fact that calculated values of K_1 are constant within the limits of accuracy over the whole range of titration. Only at a temperature of over 25° does the decomposition become great enough in more acid solutions so that one is no longer able to determine the second equivalence point exactly.

Preparation of the Potassium Salts.—We prepared the solutions of the potassium salts by a procedure similar to that used for the potentiometric titration, using the apparatus shown in Fig. 4. The solution prepared in the

(14) R. V. G. Evans and M. W. Lister, *Trans. Faraday Soc.*, **35**, 681 (1939).

(15) See the similar formulation of carboxyl groups by L. Pauling, "The Nature of the Chemical Bond," 2nd ed., p. 202.

reaction vessel I was filtered through the filter tube into the previously weighed vessel 2 connected with an ice cooled trap. After having exchanged the filter tube for a gas inlet tube, the vessel was immersed in a water-bath at 20° and evaporated at about 5 mm. in a slow stream of nitrogen. After the evaporation the trap was exchanged for one filled with phosphorus pentoxide, and evacuated at less than 0.5 mm. to constant weight.

For analysis the content of the weighed vessel was dissolved in water and decomposed by slow addition of neutral 10% hydrogen peroxide, boiling finally until the iron tetracarbonyl formed had disappeared completely. To prevent loss by volatilization of iron carbonyl the vessel was connected with a wash bottle containing 0.2 *N* alcoholic potassium hydroxide and a small quantity of hydrogen peroxide. The solution filtered from the iron oxide contains the potassium as carbonate. The carbonate was determined by acidimetric titration. The iron was determined in the residue on the filter and in the contents of the washing bottle.

$Fe(CO)_4K_2$.—The solution was prepared from 1 ml. = 0.0074 mole $Fe(CO)_5$ and 40 ml. of a solution containing exactly 0.0074 mole of $Ba(OH)_2$ and 0.0148 mole of KOH. *Anal.* Calcd. for $Fe(CO)_4K_2$: Fe, 22.70; K, 31.78. Found: Fe, 22.89, 23.30, 22.73; K, 31.3, 31.45. 1.316 g. of the dry salt was dissolved in 50 ml. of water freed from air and poured under nitrogen into a saturated solution containing 5 g. of mercuric chloride. The mixture was shaken for thirty minutes to complete the reaction, then filtered, washed with water, dilute hydrochloric acid, alcohol and ether (to remove small quantities of iron tetracarbonyl) and dried *in vacuo*, giving 3.4484 g. of the yellow $Fe(CO)_4Hg_2Cl_2$. *Anal.* Calcd.: Fe, 8.72; CO, 17.51. Found: Fe, 8.65, 8.63; CO, 17.08, 16.98. Calculating the amount of pure mercuric salt from the found CO value the relation $Fe(CO)_4K_2$:$Fe(CO)_4Hg_2Cl_2$ is 1:0.98.

$Fe(CO)_4KH$.—Prepared from 1.5 cc. of $Fe(CO)_5$ (excess) and 40 cc. of a solution containing exactly 0.0074 mole of $Ba(OH)_2$ and 0.0074 mole of KOH. *Anal.* Calcd. for $Fe(CO)_4KH$: Fe, 26.85; K, 18.80. Found: Fe, 27.35, 26.87; K, 18.89.

The reaction of 0.845 g. of this salt with $HgCl_2$ yields 2.5716 g. of the mercuric salt. *Anal.* Found: Fe, 8.54; CO, 17.05. In the filtrate from the mercuric salt we determined the HCl by acidimetric titration. The relation $Fe(CO)_4KH$:$Fe(CO)_4Hg_2Cl_2$:HCl is 1:0.97:0.92 if the salt is calculated as pure $Fe(CO)_4KH$. As the salt contains about 5% $Fe(CO)_4K_2$ this relation is still about 1% nearer to the theoretical amount.

Summary

The dissociation constants of iron tetracarbonyl hydride at 17.5° have been determined to $K_1 = 4 \times 10^{-5}$ and $K_2 = 4 \times 10^{-14}$.

The molar solubility of iron carbonyl hydride at 17.5° is about 1.8×10^{-3}.

The anhydrous salts $Fe(CO)_4K_2$ and $Fe(CO)_4KH$ (the latter containing about 5% of $Fe(CO)_4K_2$) have been prepared.

Disperse Structure of Manganese Oxides and a Magnetic Method for Studying Depolarizer Action in the Leclanché Cell[1]

BY P. W. SELWOOD, R. P. EISCHENS,[2] MARYLINN ELLIS AND KATHRYN WETHINGTON

The object of this work was to explore the possibility of using magnetic methods for the study of chemical changes occurring *in situ* in the dry cell. Manganese is the only paramagnetic constituent in the cell, and the number of unpaired electrons increases as tetravalent manganese is reduced. Consequently it was considered possible to follow the valence changes of the manganese during cell discharge and recovery by observing changes of magnetic susceptibility.

Magnetically dilute tetravalent manganese has three unpaired electrons and a well established, spin-only, magnetic moment of about 3.9 Bohr magnetons. Similarly, manganese in the oxidation states of three and two has magnetic moments of 4.9 and 5.9, respectively. With adequate magnetic dilution the susceptibility at any one temperature is virtually linear with oxidation state.

Unfortunately, the crystalline transition group oxides are so magnetically concentrated that large interactions occur between adjacent paramagnetic ions. Thus, the susceptibility at 25° for crystalline *pyrolusite* is 27×10^{-6}, that for the crystalline sesquioxide (*bixbyite*) is 89×10^{-6}, but for the monoxide (*manganosite*) it is only 67×10^{-6}. Furthermore, all these substances show large and uncertain values for the Weiss constant, and, at lower temperatures, wide deviations from the Curie–Weiss law.

These effects eliminate the possibility of using crystalline *pyrolusite* as depolarizer in quantitative magnetic studies. Attention was, therefore, turned to supported oxides, which have been shown to approach high magnetic dilution at moderately low concentration.[3]

A series of studies on manganese oxides on various supports showed that the oxidation state of supported manganese was determined in part by the crystal structure of the support, and this observation led to the general principle of valence inductivity, as previously described.[4] It was established that the experiment on the dry cell could be carried out if the manganese depolarizer were supported on high-area titania, in the *rutile* modification.

At this point in the work it was discovered that many laboratory prepared samples of manganese

(1) This paper describes, in part, work performed under contract with the Squier Signal Laboratory, Signal Corps Engineering Laboratories, as part of their program for the improvement of dry cells.

(2) Present address: The Texas Company, Beacon Laboratories, Beacon, N. Y.

(4) Selwood, *ibid.*, **70**, 883 (1948).

dioxide and practically all natural and commercial samples of manganese dioxide had an astonishing magnetic difference from pure highly crystalline *pyrolusite*. These samples all have high magnetic susceptibilities and are properly considered as magnetically dilute substances. The effect must be related to the attenuated structure possessed by these oxides. The effect has been observed in various other inorganic solids, and appears to offer promise for the structural study of many so-called gels of transition group oxides.

This observation eliminated the necessity for work with supported oxides, fruitful though that study had been. Cells were made with the gel-like manganese dioxides as depolarizers and the magnetic study of such cells was rapidly completed. There are described below, first the magnetic observations on gel-like oxides as compared with highly crystalline samples; and second, the magnetic changes occurring during dry cell discharge. Those oxides of a highly crystalline, magnetically concentrated form we shall continue to designate as "massive" solids in accordance with the terminology used in our earlier papers on supported oxides. Those oxides of an attenuated gel-like structure, as shown by magnetic dilution effects, we shall designate as "disperse" solids.

Preparative Methods[5]

Analytical Methods.—Analyses were performed for total manganese and for active oxygen. Manganese was determined by reaction with standard ferrous sulfate after all of the manganese had been oxidized to permanganate. Solution of the sample was effected by treatment with dilute sulfuric acid containing ferrous sulfate. Oxidation of the manganese from a valence of two to seven was accomplished by sodium bismuthate in nitric acid.

Active oxygen was found by using a known excess of standard ferrous ammonium sulfate in dissolution of the sample. The excess was then titrated with standard permanganate. Active oxygen is then eight times the number of equivalents of ferrous ion oxidized in the dissolution process.

Pyrolusite.—Massive *pyrolusite* was prepared by thermal decomposition of manganous nitrate in accordance with well known procedures.[6] "Reagent grade" manganous nitrate was recrystallized from water and the crystals were heated to 120–125° until the whole mass appeared on the verge of solidifying. A stream of air was directed over the open evaporating dish to facilitate the removal of oxides of nitrogen and of water vapor. Water was added to the mass, and it was stirred and filtered. The solid was dried at 110° for twenty-four hours in air. It was ground to pass through a 150-mesh sieve and reheated at 150° in air for twenty-four hours. The crystals were next washed with 1:1 nitric acid and finally with water to remove the nitric acid. The acid and wash water should both be boiling for best results. Final drying was done at 160° in air for fifty-two hours. The product was dark gray in color.

Analysis gave the following: Calcd. for MnO_2: Mn, 63.19; active oxygen, 18.4. Found: Mn, 63.1; active oxygen, 18.3. The X-ray diffraction pattern agreed in detail with the ASTM index cards. The sample appeared to be as pure as any heretofore obtained.

γ(I) Manganese Dioxide.—The preparation so designated was based on the first of three methods given by Glemser.[7] To a solution of manganous sulfate (50 g. hydrate in a liter of water) there was added 100 ml. of 2 *N* sulfuric acid. The resulting mixture was heated to boiling and 113 g. of ammonium persulfate was added slowly. A black precipitate formed and the supernatant liquid was decanted. Washing was by decantation with temperature of wash liquid 70–80°. This was continued until tests showed that the precipitate was free of sulfate. The precipitate was now filtered and washed with hot water and dried for two days at 60°. Analysis gave Mn, 60.7; "active" oxygen, 16.8. Apparent formula $MnO_{1.95}\cdot 0.25H_2O$. The X-ray diffraction pattern for this preparation was in reasonably satisfactory agreement with that reported by Glemser, as shown.

d (Å.) Reported	Found	*I*/*I*max. Found
3.88	4.03	0.5
2.42	2.42	1.0
2.11	2.12	0.6
..	2.06	.3
1.80	1.83	.1
1.62	1.62	.9
1.42	1.40	.5
1.30	..	..

γ-II Manganese Dioxide.—The second of the three methods given by Glemser was used for a preparation designated by us as γ-(II)MnO_2. A solution of 36 g. of manganous sulfate hydrate and 24 g. of potassium nitrate in 2.5 l. of water was heated to boiling. Approximately 1 l. of 2% potassium permanganate solution was now added (until the solution acquired a pink color). The supernatant liquid was decanted and the solid was washed four times with 3-l. portions of water. The product was filtered through asbestos, and washed free of sulfate. The brown product was dried for two days at 60°. Analysis yielded a formula $MnO_{1.96}\cdot 0.81H_2O$. The X-ray diffraction pattern was very similar to that for the γ-(I) preparation, although quite diffuse.

(5) Magnetic and X-ray methods have been described in earlier papers from this Laboratory.

(6) A comparison of preparations and properties for the solid oxides and hydroxides of manganese will appear in a forthcoming paper by Moore, Selwood and Ellis.

(7) Glemser, *Ber.*, **72B**, 1879 (1939).

Gel(I) Manganese Dioxide.[8]—Preparation of a gel form of manganese dioxide was attempted by the hydrolysis of manganese(IV) sulfate. The sulfate was prepared by oxidizing a 55% sulfuric acid solution of manganous sulfate with potassium permanganate. The temperature was kept below 80° because the sulfate decomposes above that temperature in a 55% acid solution. The product was filtered and washed, and hydrolysis was carried out with sodium acetate. The resulting hydrous oxide was filtered, washed and dried at 70° for three days in air. It was very hard, black and shiny, and gave no X-ray pattern. Analysis showed the product to be $MnO_{1.88}\cdot 0.83H_2O$.

Gel II Manganese Dioxide.[7]—Dilute sulfuric acid (1:4) and a 50% solution of sodium permanganate were added slowly to a concentrated solution of manganous sulfate until no more oxide precipitated. The temperature of the solution was kept at about 60° during the reaction. The precipitate was washed by decantation, then filtered and washed free from permanganate and sulfate ion. The product was dried for three days at 60° under vacuum. The sample was brown and soft, and gave only a diffuse X-ray pattern. Analysis showed $MnO_{1.97}\cdot 0.33H_2O$.

Results on Oxides

Magnetic susceptibility data on the several gel-like hydrous oxides and on massive pyrolusite are shown in Table I. Results are shown also on two natural ores. The results on the natural materials are, however, less reliable because these materials always contain a trace of ferromagnetic impurity for which correction must be attempted.

TABLE I

MAGNETIC SUSCEPTIBILITIES OF MASSIVE AND DISPERSE OXIDES

(The data are given in the following order: sample, %Mn, susceptibility $\times 10^6$ at indicated temperature, and susceptibility per gram-atom of Mn at 25°)

Massive *pyrolusite*, 63.1% Mn; χ = 27 (25°), 31 (−80°), 44 (−185°); χ_M = 2360 (25°).

γ-(I), 60.7% Mn; χ = 34.8 (86°), 35.8 (61°), 37.7 (37°), 38.0 (25°), 42.6 (−26°), 46.2 (−56°), 49.0 (−87°); χ_M = 3440 (25°).

γ-(II), 55.0% Mn; χ = 45.0 (25°), 74.3 (−87°), 109 (−171°); χ_M = 4490 (25°).

Gel(I), 55.3% Mn; χ = 37.2 (25°), 46.3 (−87°), 58.2 (−171°); χ_M = 3690 (25°).

Gel II, 59.1% Mn; χ = 41.4 (25°), 62.7 (−87°), 79.1 (−171°); χ_M = 3840 (25°).

African Ore, 56.6% Mn; χ = 43 (25°); χ_M = 4160 (25°).

Brazilian Ore, 47.3% Mn; χ = 34 (25°); χ_M = 3960 (25°).

These results all show the surprising and gratifying result that natural and synthetic manganese dioxides are often magnetically dilute, and that in this respect they have the character of attenuated inorganic gels. In some cases the molal susceptibility of the manganese is almost twice what it is in the massive pyrolusite.

The sample γ-(I) is seen to follow the Curie–Weiss law, hence it is possible to calculate the magnetic moment. The moment for the manganese in this substance is 3.9, compared with a theoretical moment of 3.87. The Weiss constant has the value of 210°.

Similar calculations of Gel(II) show that the manganese has a moment of 3.7. The other hydrous oxides show small deviations from the Curie–Weiss law, hence calculations of the moment for these cases were not attempted.

All these results are in sharp contrast to data on the massive *pyrolusite* which show the typical behavior of a magnetically concentrated substance. The results on the disperse oxides show that some of these are well suited for the experiment on the dry cell. It is anticipated that this property of gel-like oxides in showing magnetic dilution will be no less useful than the corresponding property has been in structural studies of supported transition group oxides.[9]

The Dry Cell Experiment

Magnetic Measurements.—The horizontal displacement Gouy method was used. The cell was placed on a brass holder suspended by two fine copper wires. The wires were about 2 meters long and served the double purpose of suspension and electrical conduction. The cell was placed so that one end was in a region of maximum magnetic field intensity and the other end in a negligible field. The field was supplied by a large Alnico permanent magnet.[10] The field was about 9000 gauss over a 1-inch gap, with 4-inch diameter poles cut to truncated cones having 2-inch faces. This magnet gave complete satisfaction. All measurements were made at room temperature.

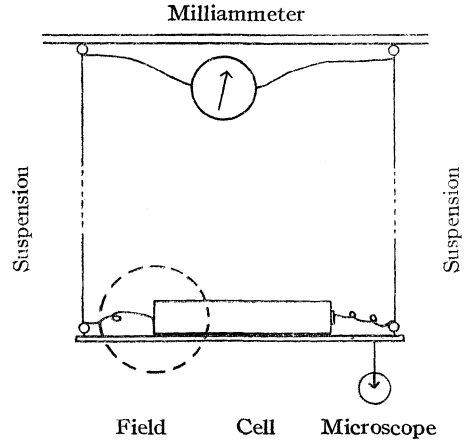

Fig. 1.—Diagram of the apparatus used in finding relative magnetic susceptibility as a function of cell discharge.

The object of the experiment was to obtain relative magnetic susceptibility measurements as a function of

(10) Obtained from the Indiana Steel Products Corporation, Valparaiso, Indiana.

time. Displacements of the cell from its initial position were observed with a micrometer microscope. These displacements may be shown to be linear with average susceptibility. The cell was connected through the copper suspension wires directly to a milliammeter. The cell, suspensions, and ammeter provided adequate resistance. For obvious reasons no measurements could be made while the current was flowing, but equilibrium was attained within a few seconds after the circuit was opened. The apparatus had excellent sensitivity.

Preparation of Cells.—Cells used in this experiment were constructed in general according to a modified standard procedure.[11] In order to have the cells of sufficient length to extend from high to negligible magnetic fields the following procedure was adopted. The zinc containers from two small commercial cells were combined to make a cell about 9 cm. long. Commercial carbon rods were used for the positive electrode, and acetylene black was used for internal conduction. It was desired to analyze the constituents of the cells before and after each run. Small muslin sacks were therefore used to hold the carbon and the depolarizer. This procedure made accurate weighing possible. The full sacks were then dipped in 10% ammonium chloride solution, and fitted into the zinc containers. Preliminary magnetic measurements on container and contents showed them to be free from ferromagnetism.

Results of Cell Experiment

A total of ten cells was prepared for this study. All gave results in general agreement. One typical set of results will be given in detail, and the remaining results will be described in more general terms.

A cell was prepared using 4.08 g. of $MnO_{1.97} \cdot 0.33H_2O$ (gel II as previously described), and 1.03 g. of acetylene black.

A plot of deflection against coulombs is shown in Fig. 2.

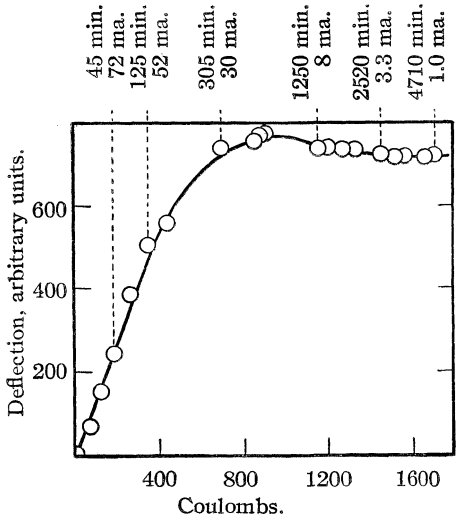

Fig. 2.—Deflection in the magnetic balance as a function of coulombs withdrawn from the cell. Time and discharge rate are given at the top.

During discharge the cell became more paramagnetic as would be expected for a decreasing oxidation state of the manganese. It is reasonable to suppose that the deflection is roughly linear with oxidation state for a cell containing gel-like manganese dioxide.

It will be noted that the deflection finally became virtually constant, although current continued to flow from the cell. The amperage fell steadily with increasing paramagnetism, but when the deflection became constant the amperage also became nearly constant. When this "steady" condition was reached the cell had already lost all its useful voltage, but nevertheless it could still yield a large number of coulombs.

Our conclusions from these observations are that the magnetic method is a very useful tool for following chemical changes in the depolarizer without in any way opening or disturbing the cell. The method gives the expected result of a linear relation between oxidation state and coulombs withdrawn over the useful life of the cell. Then, however, it is clearly indicated that there is a second depolarization mechanism. This second mechanism only comes into observation when the cell has lost its useful life, but presumably it is going on from the start of discharge. It is possible that the second depolarization mechanism may be produced by air. It is, of course, of no significance in sealed conventional cells.

A series of five cells was now made for the purpose of comparing the chemically determined oxidation state of the manganese with the magnetic data. All cells were made with 3.10 g. of a mixture prepared by adding 4.35 g. of acetylene black to 13.11 g. of Gel(II), as used in the first cell. Despite all precautions these cells differed considerably in starting amperage, total deflection, and rate of discharge. Nevertheless the deflection *vs.* coulombs curves for all cells had the same general shape.

The initial oxidation state of the manganese was, of course, 3.94, found as described above by chemical analysis. Two cells were completely discharged, and the final oxidation state was found to be 3.54 in each case. (This relatively high final oxidation state simply means that a considerable fraction of the depolarizer was not reached by continuous carbon filaments.) Three cells were run to the point where deflection stops. The final oxidation states were 3.32, 3.44 and 3.42. One cell was run to roughly two-thirds of the discharge at which deflection would have stopped. The oxidation state was then found to be 3.58.

These results support the magnetic data and serve as a rough calibration from which the oxidation state at any discharge point may be found. There is some evidence that the oxidation state of the manganese may actually increase very slightly during the period of air-depolarization, and this observation seems to be supported by the magnetic data.

One cell was discharged intermittently to answer an old question. This question is: does the oxidation state of the manganese change during discharge or during recovery? The cell had an

(11) Circular 79, U. S. Bureau of Standards, Washington, D. C.

initial discharge rate of 0.210 ampere. It was discharged for two minutes during which time the rate fell to 0.0180 ampere, and a deflection of 40 units was produced. The cell now stood for twenty minutes after which the discharge rate was 0.200 ampere, but the deflection was still exactly 40 units.

Discharge of this cell intermittently was continued with relatively long recovery periods, until discharge was virtually complete. The results were the same throughout the whole experiment, namely, that the manganese oxidation state changes during discharge and not during recovery. This view is contrary to that often expressed. The final oxidation state in this particular cell was 3.42, and the deflection *vs.* coulombs curve was similar to that already presented.

During the course of this work some cells were studied containing as depolarizers supported manganese (+4) on γ-alumina, and supported-iron (+3 and +4) on alumina and titania, respectively. The results on these cells will be described in forthcoming papers dealing with the preparation and properties of supported oxides.

Our thanks are due to Dr. T. E. Moore for invaluable assistance in some of the early phases of this work.

Summary

Preparations of manganese dioxide show widely varying magnetic dilution. This effect will be useful in studying the degree of attenuation in solid inorganic gels formed by oxides of the transition elements.

Disperse manganese dioxide showing high magnetic dilution has been used as depolarizer Leclanché cells. In this way it has been possible to make magnetic susceptibility measurements on discharging cells *in situ*.

The Chromatographic Separation of Perrhenic and Molybdic Acids

BY GUY B. ALEXANDER[1]

The problem of separating rhenium from samples containing large amounts of molybdenum has been investigated in connection with the analytical determination of rhenium and in connection with the extraction of rhenium from molybdenite concentrates. Hiskey and Meloche[2] devised an analytical method, refined by Snyder[3] and Alexander,[4] for the determination of rhenium in molybdenite minerals; the procedure was based on the separation of rhenium from the other components of the mineral by distilling from sulfuric acid solution. Feit[5] utilized the slight solubility of potassium perrhenate in a process for the recovery of rhenium from molybdenite concentrates. Melaven and Bacon[6] have reported a method for extracting rhenium from molybdenite roaster flue dust by (a) a water leaching, (b) precipitation of crude potassium perrhenate, and (c) the purification of this crude product.

In the course of an experiment in which it was attempted to recover rhenium by roasting a molybdenite concentrate at a controlled temperature, Snyder[3] discovered that perrhenic acid was adsorbed by Norit. Following this discovery, Snyder studied several of the variables of the adsorption of rhenium and molybdenum compounds on Norit, including the effect of the concentration of hydrochloric and sulfuric acids on adsorption, and the effect of temperature and *p*H on desorption. Although Snyder's work was limited to the equilibrium or batch technique, his results suggest that a chromatographic process might be useful in separating compounds of rhenium and molybdenum.

The purpose of this paper is to show that a quantitative separation of rhenium and molybdenum can be made by the chromatographic method with Norit as the adsorbent. The basis of the separation is the fact that, from a sulfuric acid solution of perrhenic and molybdic acids, perrhenic acid is more strongly and more rapidly adsorbed on Norit.

Experimental

In order to provide a basis for predicting the behavior of perrhenic and molybdic acids in a chromatographic process, the adsorption of each adsorbate was studied before attempting a chromatographic separation. All adsorption studies were carried out in 1.95 *N* sulfuric acid, since it has been shown[3] that there is a difference in the adsorption of perrhenic and molybdic acids from this solvent.

Reagents.—Stock solutions of molybdic acid were prepared by dissolving reagent grade ammonium molybdate in 1.95 *N* sulfuric acid. The molybdenum content of these solutions was determined by titrating with standardized potassium permanganate after passage through a Jones reductor.

A perrhenic acid solution was prepared by dissolving a weighed amount of recrystallized potassium perrhenate in 1.95 *N* sulfuric acid. The rhenium content of this solution was checked by precipitating the perrhenate with Nitron and weighing the dried product.

Norit A, technical decolorizing carbon, from the Fisher Scientific Co. was used as the adsorbent.

Molybdic Acid Adsorption.—The rate of adsorption of molybdic acid (see Table I) was determined by stirring 2.50 g. of Norit with 100 ml. of 1.95 *N* sulfuric acid containing 1.33 millimoles (based on H_2MoO_4) of molybdic acid for timed intervals, filtering, and analyzing the filtrate for molybdenum by the volumetric permanganate method.

TABLE I

RATE OF MOLYBDIC ACID ADSORPTION

72	50.0

of Norit for desorption studies were prepared by stirring 2.50 g. of Norit with 100 ml. of 1.95 *N* sulfuric acid containing 5.33 millimoles of molybdic acid for three days, then filtering. The filtrates contained 0.0314 ± 0.0003 millimole of molybdic acid per ml. The Norit "held up" approximately 6 ml. of solution containing 0.19 millimole of molybdic acid, hence the total amount of molybdic acid present in the desorption experiments was 2.39 millimoles of which 2.20 millimoles was adsorbed.

The observed slow rates of adsorption and desorption (Tables I and II) indicate that reaction rates will play a predominant role in molybdic acid chromatography. Thus in the formation of a chromatographic band, the front boundary will tend to be broad and diffuse, resulting in premature break-through. During development of the chromatogram, the band will migrate at a slower rate than might otherwise be expected, and the rear boundary will tend to become very diffuse. This condition will necessitate the use of large volumes of developing agent in order to remove the last traces of adsorbed molybdic acid from a column.

The adsorption isotherm ($\log f = 0.87 \log c - 0.45$) shown in Fig. 1 is based on data obtained by stirring 2.50 g. of Norit with various amounts of molybdic acid in 100 ml. of 1.95 *N* sulfuric acid for three days. Evidence that equilibrium is nearly complete in this time is the fact that a point almost on the isotherm is obtained by approaching equilibrium for seventy-two hours by desorption. (Note that the location of this point is unaffected when either the eighteen- or seventy-two hour reading is taken; see Table II.)

Figure 2 shows the behavior of molybdic acid in a chromatographic process. Two hundred ml. of 1.95 *N* sulfuric acid containing 1.06 millimoles of molybdic acid was passed through a column (19 mm. dia. and 100 mm. high) of 12.0 g. of Norit at a rate of 0.8 ml. per minute. The molybdate band was developed with 1.95 *N* sulfuric acid. Theory predicted[7] break-through after a total of about 450 ml. of solution had passed through the column. In actual experiment, however, 82% of the in-

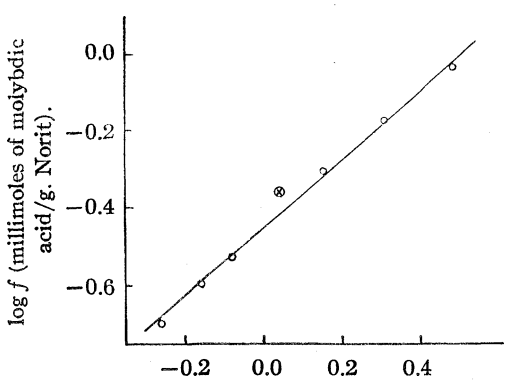

Fig. 1.—The molybdic acid isotherm: ⊗, distribution of molybdic acid after seventy-two hours of desorption (Table II).

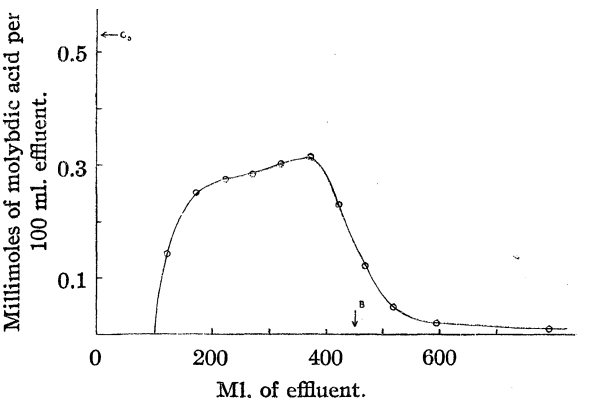

Fig. 2.—The behavior of molybdic acid in a chromatographic process: C_0, concentration of molybdic acid in the influent; B, theoretically predicted break-through.

(7) DeVault, THIS JOURNAL, **65**, 532 (1943).

fluent molybdic acid was present in the effluent at the 450-ml. stage; break-through occurred at the 100-ml. stage. Moreover, the front boundary was not sharp. This behavior is probably due to the slowness with which equilibrium is established.

Perrhenic Acid Adsorption.—The rate of adsorption of perrhenic acid is shown in Table III. After stirring the adsorbent and solution for a given time, the slurry was filtered; rhenium in the filtrate was precipitated as the sulfide and determined by the Nitron method. It is impossible to compare rigorously the reaction rates of perrhenic and molybdic acids, since the structure of the polymolybdic acid which is adsorbed is not known. However, from Tables I and III it would appear that the reaction rates are such that adsorption of perrhenic acid will be favored in the formation of a chromatogram.

TABLE III

RATE OF PERRHENIC ACID ADSORPTION

Adsorbent, 1.00 g. Norit; adsorbate, 0.349 millimole of $HReO_4$; solvent, 100 ml. 1.95 N H_2SO_4

Time of contact, hours	Adsorption, %
0.07	84.0
.25	85.4
1.0	87.1
2.0	89.8
5.0	90.9
30	91.7

Figure 3 shows the chromatographic adsorption of perrhenic acid. In this experiment a 4.0-g. Norit column (19 mm. dia. and 30 mm. high) was treated with 2.44 millimoles of perrhenic acid in 350 ml. of 1.95 N sulfuric acid at a rate of 1.6 ml. per minute. Thereafter the band was developed with 1.95 N sulfuric acid. The capacity of the column before break-through was 1.74 millimoles of perrhenic acid (*i. e.*, 109 mg. of $HReO_4$ per g. of Norit), break-through occurring after 250 ml. of solution had passed through the column. Theory[7] predicts break-through at the 425-ml. stage. (The prediction is based on the isotherm, $\log f = 0.33 \log c - 0.08$. This isotherm was determined in the usual manner; however, only three concentrations of perrhenic acid were studied.)

A comparison of the molybdic and perrhenic acid chromatographic experiments shows that despite the fact that a slower rate (0.8 compared with 1.6 ml./min.) and a longer column (100 mm. compared with 30 mm.) were used in the former case, the latter more closely approaches the theoretical behavior. Thus the ratio of experimental to theoretical capacity of the columns at break-through was 0.58 in the perrhenic acid case and was only 0.22 in the case of molybdic acid. Moreover, the maximum concentration of perrhenic acid in the effluent was 90% of that of the influent, while for molybdic acid the maximum was 60% of the original. The better agreement of theory and experiment with perrhenic acid substantiates the conclusion reached from the comparison of Tables I and III, *i. e.*, that reaction rates will favor the chromatographic separation of the two acids.

Rhenium–Molybdenum Equilibrium Adsorption.—The exchange adsorption equilibrium between perrhenic and molybdic acids was determined by stirring different amounts of these compounds in 100 ml. of 1.95 N sulfuric acid with 1.00 g. of Norit for three days. The filtrate from this slurry was analyzed; after precipitation as sulfides, molybdenum was determined by 8-hydroxyquinoline and rhenium by Nitron.[8] The results of this experiment which are found in Table IV, and Fig. 4, indicate that the adsorption of

perrhenic and molybdic acids approaches the exchange isotherm[9]

$$\log (f_{HReO_4}/f_{H_2MoO_4}) = 0.72 \log (c_{HReO_4}/c_{H_2MoO_4}) + 0.73$$

over the range studied. The rhenium–molybdenum equilibrium adsorption experiments show that perrhenic acid is preferentially adsorbed.

Chromatographic Separation Run 1.—In the first experiment a solution containing 0.349 millimole of perrhenic acid (65.0 mg. of rhenium) and 0.43 millimole of molybdic acid (41 mg. of molybdenum) in 100 ml. of 1.95 *N* sulfuric acid was passed through a 19 mm. dia. and 50 mm. high column of 6.0 g. of Norit at a rate of 1.2 ml. per minute. The chromatogram was developed with 1.95 *N* sulfuric acid until the concentration of molybdenum in the effluent had dropped below 0.1 mg. per 100 ml.; this required a total of 700 ml. of developing agent. Tests for rhenium in the effluent fractions were negative. (The limit of detection of rhenium was 50 micrograms per 100 ml. of effluent.) The adsorbent was removed from the column and the remaining adsorbate was eluted by two treatments of 600 ml. of boiling 0.1 *N* sodium hydroxide solution.[3] On analysis, the combined hydroxide solutions were found to contain 63 mg. of rhenium and less than 0.2 mg. of molybdenum. The summary of Run 1, found in Table V, shows that a quantitative separation of rhenium and molybdenum was obtained in this experiment.

TABLE V

THE CHROMATOGRAPHIC SEPARATION OF RHENIUM AND MOLYBDENUM, RUN 1

Adsorbent, 6.0 g. Norit; flow rate, 1.2 ml. per minute; developing agent, 700 ml. 1.95 *N* H_2SO_4; molybdenum used, 41 mg.; rhenium used, 65 mg.

Fraction effluent, ml.	Molybdenum recovered	Rhenium recovered
100	13.5	0
100	22.7	0
100	2.0	0
100	1.4	0
100	0.8	0
100	.5	0
100	.2	0
100	.0	0
Alkaline eluate	.0	63
Total	41.1	63[a]

[a] Incomplete recovery of rhenium may have been due to incomplete elution of rhenium. In Run 2, a third treatment with sodium hydroxide eluted 1 mg. of rhenium.

(9) Rothmund and Kornfeld, *Z. anorg. allgem. Chem.*, **103**, 129 (1918).

Run 2.—In the second experiment 100 ml. of 1.95 *N* sulfuric acid solution containing 0.232 millimole of perrhenic acid and 2.90 millimoles of molybdic acid was passed through an 8.0-g. Norit column (19 mm. dia. and 65 mm. high) at a flow rate of 1.2 ml. per minute; this was followed by 2100 ml. of developing agent Analysis revealed 2.90 millimoles of molybdic acid and no perrhenic in the effluent, 0.23 ± 0.01 millimole of perrhenic acid and 0.04 millimole of molybdic in the column after development. Thus a sample which originally contained 0.080 millimole of perrhenic acid for each millimole of molybdic acid was fractionated into: one fraction containing 98.4% of the total molybdic acid recovered and no perrhenic acid; a second fraction containing 6 millimoles of perrhenic acid for each millimole of molybdic.

Conclusion.—There is sufficient difference in the adsorption characteristics of perrhenic and molybdic acids to permit a quantitative chromatographic separation of these compounds—using 1.95 *N* sulfuric acid as the solvent and developing agent and Norit as the adsorbent. It is possible that a chromatographic process similar to those described above might be applied in the separation of rhenium from samples containing molybdenum prior to analysis or for the extraction of rhenium from molybdate concentrates.

Summary

1. Equilibrium for the adsorption of molybdic or perrhenic acid from 1.95 *N* sulfuric acid on Norit requires several days. The Freundlich isotherms for the adsorption of these acids are $\log f = 0.87 \log c - 0.45$, and $\log f = 0.33 \log c - 0.08$, respectively.

2. As expected from the slow reaction rates, the chromatographic behavior of molybdic acid does not agree with the equilibrium theory. The agreement is a little better in the case of perrhenic acid.

3. The equilibrium adsorption of perrhenic and molybdic acids on Norit approaches the exchange isotherm behavior in the range studied.

4. Rhenium and molybdenum may be effectively separated chromatographically.

Rates of Water Oxidation in Ceric Perchlorate Solutions[1]

BY DON KOLP[2] AND HENRY C. THOMAS[3]

The oxidation of water by cerium(IV) in perchloric acid solutions has been observed and investigated by several workers.[4-7] In their communication Heidt and Smith[7] propose a mechanism which accounts for their results on the photochemical reduction of cerium(IV) by water. Weiss and Porret[5] as well as Heidt and Smith observed that the reaction is retarded by the presence of cerium(III). The present work was undertaken only incidental to a study of the oxidation of formic acid in perchloric acid solutions of cerium(IV) and does not constitute an exhaustive investigation of the water reaction. However, the effect of the concentration of cerium(III) has been the object of particular study. We are concerned here with the thermal reaction; excitation by ultraviolet radiation was not present.

Experimental

Eighteen solutions of mixed ceric and cerous perchlorate were used. The perchlorate solutions were near 3.6, 5.4 and 7.4 molar. Cerium(IV) concentrations varied from 0.1 to 0.4 molar in two steps; cerium(III) concentrations, from 0.1 to 0.3 molar in two steps. (All concentrations mentioned in this section and in the section on results are to be understood as analytical concentrations, in volume formal units, and will be designated by *M*.)

The solutions were prepared as follows. "Reference" grade ammonium hexanitratocerate, stated by the manufacturer (the G. Frederick Smith Chemical Co.) to be 100.0% pure, in amount 1.2 moles, was dissolved in a minimum quantity of distilled water. This solution was added slowly with vigorous stirring to twice the equivalent amount of 3% ammonia solution. After the heavy precipitate of ceric hydroxide had settled, the liquid was decanted and the precipitate transferred to a Buchner funnel fitted with a circle of hardened paper. The precipitate was washed about twenty times on the filter, the final washings giving a negative test for ammonia. The precipitate was divided into three nearly equal parts. One portion was dissolved in 670 ml. of "Baker's Analyzed" perchloric acid, another, in 500 ml., and the third, in 330 ml. of the acid. These solutions were filtered through sintered glass, and each was diluted to a volume of one liter. The three solutions were approximately 0.4 *M* in cerium(IV). Solutions approximately 0.1 and 0.2 *M* in ceric cerium were prepared by dilution with appropriate acid. Six additional solutions were thus prepared.

Solutions containing cerium(III) were prepared from the 0.2 and 0.4 *M* cerium(IV) solutions by reduction of a portion with a few drops of 30% hydrogen peroxide and subsequent addition of a similar volume of the parent solution: Of the solutions thus produced those with cerium(IV) concentrations of 0.2 *M* were further partially reduced. These operations produced nine additional solutions.

The eighteen solutions were analyzed for total cerium by the method of Willard and Young.[8] The perchloric acid was removed by evaporation with sulfuric acid to fumes of sulfur trioxide before oxidation with ammonium persulfate. Titrations were made with recently standardized ferrous ammonium sulfate solution. This solution was standardized against a ceric sulfate solution which had been standardized by weight against Bureau of Standards sodium oxalate. Duplicate determinations of total cerium agreed to 0.1%.

The perchlorate content of each of the eighteen solutions was determined by the method of V. Rothmund.[9] The excess titanous sulfate was destroyed with an equivalent amount of potassium permanganate. Chloride was determined in the resulting solutions by the Volhard titration. A blank determination was carried out on the reagents, the results of which were applied to the data. Duplicate determinations agreed to 0.2%.

If the cerium hydroxide precipitate contained no bases other than $Ce(OH)_4$ and $Ce(OH)_3$, the available hydrogen ion content of the solution resulting when the precipitate was dissolved in perchloric acid is given by $(H^+) = (ClO_4) - 3(CeIII) - 4(Ce(IV))$. This formula will continue to hold when a part of the Ce(IV) is reduced to Ce(III) because one hydrogen ion is liberated in the reduction of each Ce(IV), whether the reduction be accomplished by water or by hydrogen peroxide. Thus the hydrogen ion concentrations of the solutions may be calculated from the analytical data on perchlorate and cerium.

The rate measurements were carried out as follows. For a single series twelve 13 × 100 mm. test-tubes were cleaned by heating in dichromate–sulfuric acid solution, rinsing ten times with tap water and five times with distilled water. The tubes were dried and a 5-ml. portion of the solution to be studied was sealed into each. The tubes were placed in a thermostat and allowed two to five hours to reach temperature equilibrium. To determine the initial cerium(IV) concentration, a tube was opened and emptied into a flask, previously weighed with its contents, containing 25 ml. of cool 2 *M* sulfuric acid. The reaction was stopped by this dilution in sulfuric acid. The flask was again weighed and the cerium(IV) determined by titration with ferrous solution, using ferroin as the indicator. Because of some fading of the end-point these titrations are subject to an error of ±0.3%. The initial concentration of cerium(III) follows from the known total cerium content of the solution. The remaining samples were titrated by the same procedure at intervals of one or two days. The time at which each sample was stopped was observed with an uncertainty of no more than a minute.

The densities of the reaction mixtures were determined pycnometrically at the temperatures of the rate measurements. They were found to change less than 0.1% as the reaction proceeded.

Results

Eighteen runs were made at 60.0°. Three runs each were made at 45.0 and 30.0°. The results were much more consistent at the highest temperature. In Table I the complete data are given for a single run at 60.0°. The entries are self-explanatory with the exception of those in the fifth and sixth columns, which were arrived at as follows.

(9) V. Rothmund, *Z. anorg. Chem.*, **62**, 108 (1909).

An empirical differential equation has been found which correlates all of the results in a satisfactory manner. Writing C_4 and C_3 for the analytical concentrations of cerium(IV) and cerium(III), this equation is

$$\frac{dC_3}{dt} = k_e \frac{C_4^{5/3}}{C_3} \quad (1)$$

at fixed perchlorate concentration and at fixed temperature. On integration this equation gives the relation

$$f \equiv \frac{3(C_4 + C_3)}{2C_4^{2/3}} + 3C_4^{1/3} = k_e t + f_0 \quad (2)$$

where f_0 is the value of the left side of the equation at the time ($t = 0$) of the first analysis of a series. The computed values of $f - f_0$ according to (2) are given in the fifth column of Table I and the corresponding values of k_e in the sixth. The linearity with time of $f - f_0$ is evident. The results at 60° are all reasonably well represented by such straight lines. The data at the lower temperatures are much less precise. Table II gives the initial conditions for the various series and the values of k_e as graphically determined. At 30° these slopes can be considered only rough approximations.

The experimental results are summarized in the following empirical equations for the constants k_e of equation (1). Variation with total perchlorate content at fixed temperature

$$60° \quad \log k_e = 0.116[ClO_4] - 4.29$$
$$45° \quad \log k_e = 0.238[ClO_4] - 6.19$$
$$30° \quad \log k_e = 0.218[ClO_4] - 7.08$$

Variation with temperature at fixed total perchlorate content

$$7.50M\ ClO_4 \quad \log k_e = 16.7 - 6700/T$$
$$5.25M\ ClO_4 \quad \log k_e = 20.5 - 8100/T$$
$$3.75M\ ClO_4 \quad \log k_e = 25.8 - 9900/T$$

Since the total perchlorate content of the solutions does not vary during the course of the reaction, it, rather than the perchloric acid content, has been selected as the basis for the correlation of the data.[10] These equations are not to be taken as implying the independence of the reaction rate and hydrogen ion concentration. They are only summaries of the experimental results under the conditions given in Table II.

Discussion

A possible interpretation of the empirical differential equation (1) is afforded by the mechanism proposed by Heidt and Smith[7] for the photochemically excited oxidation of water by cerium (IV). For our case, in which only thermal excitation is present, their mechanism is represented by the equations

(10) In the abstract of this paper published for the 115th National Meeting of the American Chemical Society these equations were erroneously given in terms of perchloric acid content. Here also the constant for the temperature variation at 7.50 M ClO_4 was given as 17.7 instead of 16 7.

$$2C_m \rightleftharpoons C_p \qquad K$$
$$C_p \longrightarrow C_p^* \qquad k_1$$
$$C_p^* + H_2O \longrightarrow 2C_3 + 2H^+ + {}^1/_2O_2 \qquad k_2 = k_2'[H_2O]$$
$$C_p^* + C_3 \longrightarrow C_p + C_3 \qquad k_3$$
$$C_p^* + S \longrightarrow C_p + S \qquad k_4 = k_4'[S]$$

The oxidation is considered to be caused by an energetic dimer, C_p^*, of ceric cerium. The dimerization is supposed to be fast with respect to the remaining reactions. The inhibition of the water oxidation is due to the deactivation of the excited dimer by cerous cerium, C_3; further inhibition by the remainder of the environment, S, is repre-

sented by the last equation. If we write $T = 2C_p + \sqrt{C_p/K}$ for the total Ce(IV) content of the solution, neglecting C_p* as compared to the bulk of the Ce(IV), the usual steady state approximation immediately produces the rate equation

$$-\frac{dT}{dt} = \frac{kC_p}{m + C_3} \quad (4)$$

where $k = 2k_1k_2/k_3$ and $m = (k_2 + k_4)/k_3$. For convenience we select $z = \sqrt{C_p/K}$ as the dependent variable and integrate (4) with the result

$$F \equiv \frac{M}{Kz} + \left(\frac{1}{K} - 4M\right) \ln z + 6z + 4Kz^2 = kt + F_0 \quad (5)$$

In this equation $M = m + a + b$, a and b being the initial total Ce(IV) and Ce(III) concentrations, respectively. In equation (5) we have a means of representing the rate data in terms of the equilibrium constant of the dimerization and the group of constants m. Unfortunately there are not available independent determinations of these constants, hence the application of (5) to the data of this paper can be considered only tentative. Comparison of the empirical equation (1) and equation (4) indicates that m is probably small with respect to C_3 and hence with respect to $a + b$. As a preliminary test of (5) we thus put $M \simeq a + b$. We now have an equation with one adjustable constant, K. The data on the water oxidation at 60° can be well represented by this equation with reasonable values of K. If one chooses $K = 1.0$ and applies (5) to a run with $[ClO_4] = 7.16$, $a = 0.0830$, $b = 0.2853$, the values of $F - F_0$ fall close to a straight line with slope $k = 1.15 \times 10^{-3}$. Using the same value of K in a run with nearly the same perchlorate concentration, $[ClO_4] = 7.43$, and a widely different ratio of initial concentrations, $a = 0.1572$ and $b = 0.0315$, the straight line through the points has the slope $k = 1.17 \times 10^{-3}$. Since the only criterion for the correct choice of K is the fit of the data to a straight line, considerable latitude in the choice of K is permissible. About the most that can be said is that higher values of K must be chosen for lower perchloric acid concentrations. Thus at $[ClO_4] = 3.72$, K must be chosen in the range 2.0 to 2.5. It will be necessary to test the mechanism using independent determinations of the dimerization constants. A further interesting study will be the comparison of the rate of the deactivation reaction, given by k_3, with the rate of the electron exchange reaction between ceric and cerous cerium.

Summary

1. Rate data are presented on the thermal reaction in perchloric acid solution between ceric cerium and water. Empirical equations summarizing these data are reported.

2. The results are examined in the light of the mechanism of Heidt and Smith for this reaction. The data are shown to be consistent with this mechanism.

The Chlorination of Bicyclo[2,2,1]heptane (Norbornylane)

BY JOHN D. ROBERTS,[1] L. URBANEK[2] AND ROSE ARMSTRONG

The nitration of bicyclo[2,2,1]heptane (norbornylane[3]) has been reported to give 1-nitrobicyclo[2,2,1]heptane.[4] In the present investigation a study was made of the peroxide-catalyzed chlorination of bicyclo[2,2,1]heptane with sulfuryl chloride[5] in an attempt to find a convenient synthesis for the 1- and 7-chlorobicyclo[2,2,1]-heptanes. Both mono- and dichloro products were isolated from the chlorination of bicyclo-[2,2,1]heptane in methylene chloride solution. The monochloride fraction had practically the same physical properties (Table I) and infrared absorption spectrum (Fig. 1) as a sample of norbornyl chloride (2-chlorobicyclo[2,2,1]heptane) made by the addition of hydrogen chloride to norbornylene (bicyclo[2,2,1]2-heptene).[6]

TABLE I

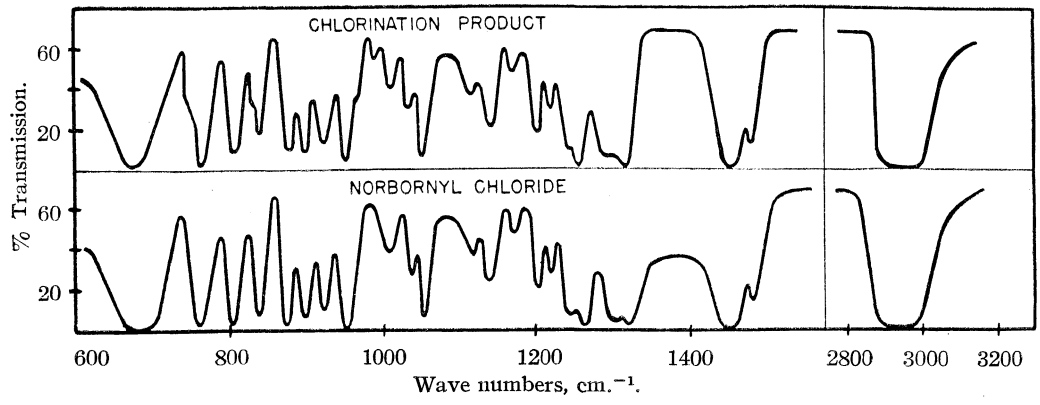

Fig. 1.—Infrared spectra.

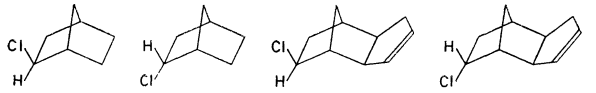
In order to confirm the identity of the monochlorination product, the rate constant of its solvolytic reaction at 85° in aqueous alcohol (80% ethanol and 20% water by volume) was compared with that of the material prepared from norbornylene. The results are given in Table I along with the rate constant obtained for cyclopentyl chloride under the same conditions. Although the rate constant of the chlorination product was very close to that of norbornyl chloride, the presence of a small amount (5%) of less reactive chloride was indicated by the deviation from first-order kinetics in the later stages of the reaction. To concentrate any less reactive chloride, the monochlorination product was boiled for five hours with a water–acetone mixture. The physical properties of the recovered unreacted chloride were not appreciably different from those of the starting material. However, the solvolytic rate measurements (Fig. 2) showed clearly the presence of 15–25% of substances less reactive than norbornyl chloride. Since the unreacted chloride amounted to about 25% of the material taken, it is evident that only about 5% of the monochlorination product was not norbornyl chloride.[7]

The solvolytic reactivity of norbornyl chloride is nine times greater than that of cyclopentyl chloride in 80% ethanol at 85°. The very considerable reactivity of norbornyl chloride as compared to cyclopentyl chloride is particularly interesting since cyclopentyl chloride is more reactive in solvolytic reactions than most typical secondary alkyl chlorides.[8] Furthermore, the similarly constituted chlorodihydro-*exo*-dicyclopentadiene (II) has been reported to be very unreactive.[9]



Ia Ib IIa IIb

The configurations (Ia and Ib or IIa and IIb) of the chlorine atoms in I and II with respect to the methylene bridges are not certain[10] and may

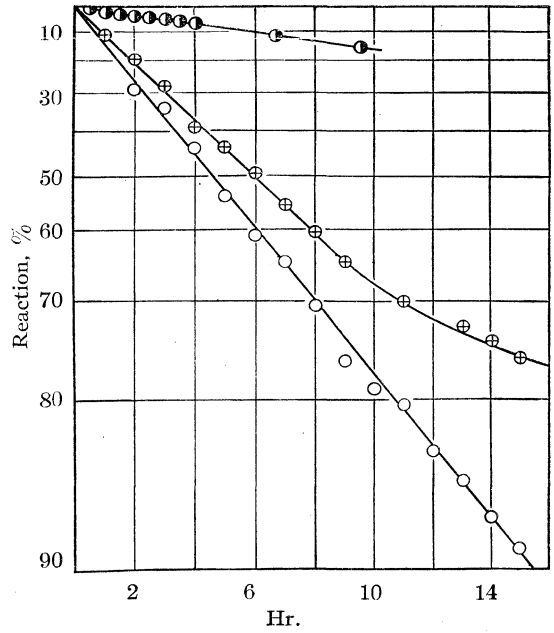


Fig. 2.—Solvolysis of chlorides at 85°: O, norbornyl chloride; ⊕, chlorination product after partial hydrolysis; ◑, cyclopentyl chloride.

(7) The high degree of specificity in this chlorination is unusual, particularly since with the possibility of *exo–endo* isomerism (*vide infra*) substitution at only four (at the most) of the ten secondary positions of norbornylane can give equivalent chlorination products.

(8) In 50% alcohol–50% water (by volume) solutions at 90°, cyclopentyl chloride solvolyses approximately five times more rapidly than diethylcarbinyl chloride. For solvolytic reaction rate constants of other secondary alkyl chlorides, see Roberts [THIS JOURNAL, **71**, 1880 (1949)].

(9) Bruson and Riener, THIS JOURNAL, **67**, 726, 1178 (1945). The compound was referred to in these papers as chloro-dihydro-*nor*-dicyclopentadiene. See Bartlett and Schneider, *ibid.*, **68**, 6 (1946) and Bruson and Riener, *ibid.*, **68**, 8 (1946). The position of the double bond is uncertain in this substance.

(10) The *exo*(*cis*)-configuration (Ia) of chlorine and bridge has been assigned by Komppa and Beckman (cited in ref. 3) to the chloride resulting from the treatment of *exo*-norborneol with phosphorus

possibly account for the difference in reactivity between I and II. However, it is noteworthy that if I is a mixture of *exo*- and *endo*-forms, these must have very similar solvolytic rate constants since the solvolysis of I follows the first-order rate law to well over 90% reaction as shown by Fig. 1.

Further experiments are in progress on the determination of the mechanisms of displacement reactions of norbornyl derivatives.

Acknowledgment.—We are indebted to Dr. R. C. Lord, Jr., and Mr. R. S. McDonald for the infrared determinations.

Experimental

Chlorination of Bicyclo[2,2,1]heptane.—A mixture of 48 g. of bicyclo[2,2,1]heptane,[11] 34 g. of sulfuryl chloride, 0.25 g. of benzoyl peroxide and 40 ml. of methylene chloride was refluxed (about five hours) until no further loss of weight was observed. The mixture was filtered and fractionally distilled through a 30-cm. Vigreux column. The yield of monochloride, b. p. 88–89° (74 mm.), was 23 g. (70% based on sulfuryl chloride). The weight of dichloride, b. p. 122–123° (75 mm.), was 4 g.

Anal. Calcd. for $C_7H_{10}Cl_2$ (dichloride): C, 50.93; H, 6.10. Found: C, 51.47; H, 6.27.

The monochloride (20 g.) was refluxed for five hours with a mixture of 50 ml. of water, 50 ml. of acetone and 50 g. of sodium carbonate. The recovered chloride amounted to 5 g., b. p. 79° (46 mm.).

Rate Determinations.—Weighed samples (0.5–1 g.) of the chlorides were made up to 50.0 ml. with aqueous alcohol (80% alcohol and 20% water by volume) at room temperature. Five-milliliter samples were sealed in soft glass test-tubes and heated in a thermostat at 85.0 ± 0.1°. The reaction rate was followed by titration of the liberated acid with standard alkali.

pentachloride. The properties b. p. 66–67° (25 mm.), m. p. −5° of the chloride prepared by Komppa and Beckman are very similar to those obtained in the present work.

(11) The bicyclo[2,2,1]heptane was prepared by low-pressure hydrogenation in acetic acid over platinum oxide of bicyclo[2,2,1]2-heptene made by the method of Joshel and Butz, THIS JOURNAL, **63**, 3350 (1941), as modified by Thomas, *Ind. Eng. Chem.*, **36**, 310 (1944). The low pressure hydrogenation process is somewhat more convenient than that described by Thomas and gives no methylcyclohexane.

Summary

The peroxide-catalyzed chlorination of bicyclo-[2,2,1]heptane with sulfuryl chloride was found to give norbornyl chloride as the principal monochlorination product.

Norbornyl chloride solvolyzes in 80% ethanol at 85° nine times faster than cyclopentyl chloride.

[A COMMUNICATION FROM THE LABORATORY OF ORGANIC CHEMISTRY OF THE UNIVERSITY OF WISCONSIN]

Hydroformylation of Unsaturated Compounds with a Cobalt Carbonyl Catalyst

BY HOMER ADKINS AND GEORGE KRSEK[1]

Dicobalt octacarbonyl, $Co_2(CO)_8$, proved to be quite effective and useful[2] in catalyzing the formation of aldehydes through the addition of carbon monoxide and hydrogen (H_2CO) to alkene linkages. The present paper is concerned with improvements in the method and a survey of the usefulness and of the limitations of the hydroformylation reaction. The use of a soluble cobalt catalyst was developed from the earlier work[3–6] with a Fischer–Tropsch type of insoluble catalyst. Two publications on the use of the insoluble catalyst have appeared recently.[7,8]

The hydroformylation reaction has given good results with unsaturated compounds of quite diverse structures. Hydrocarbons of the types RCH=CH_2 and RCH=CHR, allyl ethers, α,β-unsaturated esters such as acrylates, crotonates and fumarates, and allyl and vinyl acetates and allylidene diacetate added the elements of formaldehyde in good to fair yields. A summary of the numerical results is given in Table I.

The yields of aldehydes reported in the tables are based upon distillation of the reaction mixtures, titration with hydroxylamine hydrochloride, determination of refractive indices, and the chromatographic separation of 2,4-dinitrophenylhydrazones, as described in the experimental part of this paper. Since it is difficult to isolate an aldehyde without considerable loss, the yields in Table I should be interpreted in consideration of the more detailed results given in the experimental part for representative syntheses.

The reactions were run at 120–125° in benzene, under a pressure of 100–150 atm. of hydrogen and 100–150 atm. of carbon monoxide, as measured at 23°. These conditions differ from those used earlier with dicobalt octacarbonyl, in that benzene rather than ether was the reaction medium, the total pressure was lower, and the ratio of carbon monoxide to hydrogen was 1:1 instead of 2:1. Benzene was chosen as the reaction medium after a comparison of several liquids. The hydroformylation of methyl undecylenate went twice as rapidly in benzene or methylcyclohexane as in diethyl ether and three times as rapidly as in methyl formate. The reaction went as rapidly

in acetone as in benzene, but the yield of aldehyde isolated was lower, presumably due to condensation. The hydroformylation reaction proceeds well in a mixture of benzene and ethanol but the acetal of the aldehyde may be the chief product, as described later in the hydroformylation of ethyl acrylate.

The catalyst for hydroformylation is apparently not poisoned by sulfur compounds, as would be true of a catalytic metal such as cobalt. The reaction of carbon monoxide and hydrogen went almost as rapidly and gave approximately the same yield of aldehyde when diphenyl sulfide was present as when it was not.

The rate of reaction and temperatures required for hydroformylation, as shown by the data in Table I, are quite dependent upon the amount and ratio of catalyst to unsaturated compound. However, the yield of aldehyde isolated was usually about the same in a rapid reaction as in a slow one.

In several cases the compounds are unsymmetrically substituted derivatives of ethylene so that, depending on the direction of addition, there was a possibility of two isomeric aldehydes being produced. In four compounds of the type $RCH=CH_2$ where R was $-CO_2C_2H_5$, $-CH_2O_2CCH_3$ and $-CH(O_2CCH_3)_2$, addition of —CHO went exclusively to the terminal carbon, with the production of aldehydes of the type RCH_2CH_2CHO. In the case of two alkenes $(C_2H_5)_2C=CH_2$ and $C_2H_5C(CH_3)=CH_2$ addition of —CHO was also exclusively to the terminal carbon. In ethyl crotonate the addition of —CHO was apparently exclusively to the carbon carrying the methyl group rather than to the one adjacent to a carbethoxy group.

In contrast with these results four alkenes of the type $RCH=CH_2$, where R was phenyl, or α-naphthyl, or ethoxymethyl, or *n*-butoxy, showed addition of —CHO on the substituted carbon atom. The aldehydes isolated in good yields were of the structure $RCH(CH_3)CHO$. It is probable that the isomeric aldehydes, RCH_2CH_2CHO, were also produced, but with one exception they were not isolated. The absorption of hydrogen and carbon monoxide in the hydroformylation indicated a much higher yield of aldehyde than the 29–31% actually isolated in the four cases just mentioned.

Derivatives of ethylene of the type $RCH=CH_2$, where R was $n\text{-}C_4H_9$-, $n\text{-}C_{16}H_{33}$-, $-(CH_2)_8CO_2CH_3$, $-CH_2OC_6H_5$, $-CH_2OC_2H_5$ and $-O_2CCH_3$, all gave mixtures of aldehydes of the types RCH_2CH_2CHO and $RCH(CH_3)CHO$. The alkene $C_2H_5CH=CHCH_3$ also gave a mixture of $C_2H_5CH_2CH(CH_3)CHO$ and $(C_2H_5)_2CHCHO$. It is possible that the starting materials in the case of the hydrocarbons and methyl undecylenate were not homogeneous with respect to the position of the double bond, or that migration of the double bond took place during reaction.[7] However, there can be no doubt that vinyl acetate and the allyl ethers underwent simultaneous addition of —CHO at both the terminal and the secondary carbon atom.

Certain α,β-unsaturated carbonyl compounds were reduced without hydroformylation, through the action of hydrogen in the presence of cobalt carbonyls. Crotonaldehyde and acrolein were reduced to butyraldehyde and propionaldehyde, respectively, while methyl vinyl ketone and mesityl oxide gave methyl ethyl ketone and methyl isobutyl ketone. Similarly ethyl cinnamate and ethyl β-(2-furan)-acrylate gave ethyl β-phenylpropionate and ethyl β-(2-furan)-propionate. The yields with the aldehydes were 40–50% while with the ketones and esters they were in the range 70–90%. Higher yields could no doubt be obtained if the optimum conditions for the hydrogenation and isolation of the products were sought. The hydrogenation of the α,β-unsaturated carboxy compounds was apparently catalyzed by a compound soluble in benzene whose activity was not adversely affected by the addition of diphenyl sulfide (1.2 g.) to the cobalt carbonyl (1.6 g.).

Acrolein diethyl acetal, α-vinylfuran and acrylonitrile absorbed 50–75% of the amount of hydrogen and carbon monoxide required for complete hydroformylation. Apparently the desired reaction took place, but no aldehyde could be isolated from the reaction mixtures, although qualitative tests showed them to be present. It appeared that the aldehyde first formed underwent further reaction. 1,2-Dihydronaphthalene, 2-(4-methylphenyl)-propene-1,11-bromododecene-1, 5-bromo-pentene-1 and allyl chloride absorbed about 50% as much gas as required for complete hydroformylation but aldehydes were not found in the reaction mixture. In the case of the compounds containing a halogen, all of the cobalt present in the reaction mixture was converted to a cobalt halide. 1-Phenyl-butadiene-1,3, phenylacetylene, Δ^9-octalin, phenanthrene, furan and acetonylacetone did not react at an appreciable rate when exposed to carbon monoxide and hydrogen at 125° with dicobalt octacarbonyl in benzene.

Experimental Part

Attention is again called to the precautions necessary in handling carbon monoxide and metal carbonyls. The methods described in the preceding paper[2] were in general followed except that dicobalt carbonyl was prepared in benzene rather than in ether. Some of the unsaturated compounds were obtained from commercial sources, *i. e.*, butyl vinyl ether, $n^{25}D$ 1.3991, and allylidene diacetate, $n^{25}D$ 1.4172, from Carbide and Carbon Chemicals Corporation; allyl alcohol and acrolein from Shell Chemical Company; vinyl acetate, $n^{25}D$ 1.3934, from the Niacet Company; and ethyl acrylate, $n^{25}D$ 1.4037, from the Rohm and Haas Company. Several compounds were made by dehydration of alcohols over various catalysts: cyclopentanol over sulfuric acid to cyclopentene $n^{25}D$ 1.4183; 2-(1-naphthyl)-ethanol over potassium hydroxide at 165° (16 mm.) to α-vinylnaphthalene,[9] $n^{25}D$ 1.6420; and β-decalol over zinc chloride at 180° to a mixture of

[a] Semicarbazone. [b] *p*-Nitrophenylhydrazone. [c] 2,4-Dinitrophenylhydrazone. [d] Reaction at 70° with hydrogen only. [e] 1.2 g. of diphenyl sulfide in reaction mixture.

octalins,[10] $n^{25}D$ 1.4926–1.4955. Hexene-1, $n^{25}D$ 1.3863, 2-methylbutene-1, $n^{25}D$ 1.3760, octadecane-1, $n^{25}D$ 1.4435, and 2-ethylbutene-1, $n^{25}D$ 1.3952, were made by the pyrolysis of the acetates of the corresponding primary alcohols as described by Marvel and his associates.[11] Hexene-1 was also made by the reaction of allyl chloride and *n*-propylmagnesium bromide[12] and by the dehydration of *n*-hexanol through the Tschugaev reaction. The products from all three preparations had the same refractive index. Methyl undecylenate, $n^{25}D$ 1.4381, ethyl crotonate, $n^{25}D$ 1.4230, diethyl fumarate, $n^{25}D$ 1.4395, and allyl acetate, $n^{25}D$ 1.4026, were prepared by esterification of the alcohols with the acids or acetic anhydride. Allyl phenyl ether, $n^{25}D$ 1.5181, was prepared from allyl bromide and phenol in the presence of potassium bicarbonate and allyl ethyl ether, $n^{25}D$ 1.3856, from ethyl bromide and the sodium alkoxide of allyl alcohol.[13]

The distillation of aldehydes was usually carried out in an atmosphere of hydrogen, even when distillations were made at low pressures. In most cases about 0.1 g. of hydroquinone was added to a mixture before distillation. All distillations were made at as low a pressure and as rapidly as was feasible. Some of the physical properties of the products obtained and of their derivatives are given in Tables I and II.

The estimation of aldehydes by titration[14] was made as follows. A freshly prepared 4% solution (4 ml.) of hydroxylamine hydrochloride and 3 drops of a methyl orange solution were placed in a 50-ml. Erlenmeyer and the solution made neutral with dilute sodium hydroxide. About 0.002 mole of aldehyde was added and the solution allowed to stand about fifteen minutes in a stoppered flask. The free acid was then titrated with 0.1 *N* sodium hydroxide solution. The per cent. of aldehyde in the sample is given by the expression ml. of base × *N* of base × mol. wt. of aldehyde × 100 divided by the weight of the sample. In order to secure accurate results with the hydroxylamine method it is necessary that hydroxylamine hydrochloride be in about a 20% molecular excess over the aldehyde, so that in the directions given above the size of the sample titrated is specified in terms of the amount of aldehyde added and *not* in terms of the weight of sample. Thus in order to secure good results several titrations may be necessary before the proper weight of sample is ascertained. The method has given accurate results with pure samples of propionaldehyde, butyraldehyde and acetone.

Chromatographic Separation of 2,4-Dinitrophenylhydrazones.—Sixty grams of acid-washed alumina (Merck No. 8R1605) was placed in an absorbent column containing 50 ml. of dry petroleum ether. A column 1.4 × 25 cm. with a 19/22 ground glass joint and fritted glass plate, as designed by Zechmeister and sold by Scientific Glass Apparatus Co., was used. The alumina was added slowly through a funnel and the column was tapped gently during

[a] 2,4-Dinitrophenylhydrazone. [b] Semicarbazone. [c] The aldehyde was converted by hydrogenation to 2-butoxypropanol-1, $n^{25}D$ 1.4184, b. p. 81° (24 mm.). [d] The aldehyde was converted by oxidation with air to monoethyl α-methylsuccinate. [e] The aldehyde and its derivatives were also prepared by a Grignard synthesis from 2-ethylbutanol-1 and orthoformic ester. [f] The aldehyde was converted by air oxidation to γ-acetoxybutyric acid, b. p. 113° (1 mm.), $n^{25}D$ 1.4343, and its lactone.

this addition. The hydrazone(s) (240 mg.) in petroleum ether (400 ml.) was passed into the column under a positive pressure of about 0.1 atm. The band of the absorbed hydrazone was 30–60 mm. in length depending upon the compound(s). Usually the band was developed with a solution of dry benzene in petroleum ether passed into the column under a pressure of 0.1 atm. The volume of solvent was 4–7 l. in most cases containing about 10% of benzene. However, there was considerable variation in the ratio of the solvents depending upon the solubility of the hydrazones. Petroleum ether (6 l.) without benzene was used with the hydrazone of γ-acetoxybutyraldehyde, while a solution (5 l.) containing 20% benzene was used with the hydrazone of α-butoxypropionaldehyde. The petroleum ether had a boiling range of 60–68°. The band was in most cases spread over almost all the length of the column. The column of alumina was removed from the tube and in most instances cut into five or six sections. Each section was extracted with diethyl ether and the 2,4-dinitrophenylhydrazone recovered for determination of m. p. and analysis where necessary. The weight of hydrazone recovered was usually of the order of 85–90% of that placed on the column.

Air Oxidation of Aldehydes.—Aldehydes were in several cases oxidized with air to the corresponding acids. A typical procedure was as follows: γ-acetoxybutyraldehyde (29.2 g., 94% pure) and 0.2 g. of manganese dioxide or cobalt acetate was placed above a fritted glass plate sealed in a U-tube so that air could be blown up through the plate and the sample of aldehyde. The U-tube was held in an oil-bath at 65 ± 5° and was provided with a reflux condenser. Air was passed in rapidly for a period of twenty-four hours. The crude acid (31 g.) after the removal of the manganese dioxide showed a neutral equivalent of 142. After fractionation γ-acetoxybutyric acid (25.5 g., b. p. 111–113° (1 mm.), $n^{25}D$ 1.4343) was obtained having a neutral equivalent of 144 and a saponification equivalent of 145. The calculated values for the pure acetoxy acid are 146.

Ethyl β-Formylbutyrate.—In a representative experiment 50 g. of ethyl crotonate and 0.6 g. of dicobalt octacarbonyl in 70 ml. of benzene were placed in a chrome vanadium steel reaction vessel having a void of 270 ml. Carbon monoxide was added to a pressure of 1800 p. s. i. and hydrogen to a total pressure of 3600 p. s. i. After shaking for one minute the total pressure was 3500 p. s. i. at 23°. The vessel with rocking was heated within twenty minutes to 125° and 4600 p. s. i. During eighty minutes with rocking, the pressure decreased to 2200 p. s. i. at 125°. The vessel was then allowed to cool to 23° when the pressure was 1600 p. s. i. The gases were then burned by releasing them through a Bunsen burner. The contents and washings of the reaction vessel were transferred to a 250-ml. bottle, stoppered and centrifuged. The solvent was distilled under reduced pressure and the product through a Vigreux column (1 cm. i. d., 15 cm. long). The product (50.1 g.) distilled at 96–100° (30 mm.), and was 95% pure according to titration. Upon refractionation the product had the properties given in Table I.

The 2,4-dinitrophenylhydrazone (120 mg.) was chromatographed as described above. After the alumina column was cut into six portions there was obtained six yellow crystalline portions of the derivative: 6.1 mg., no m. p.; 22.1 mg., m. p. 66–67°; 46.2 mg., m. p. 67–68°; 21.1 mg., m. p. 67–68°; 9.4 mg., m. p. 66–67°; and 5.2 mg., no m. p. These results indicate that the derivative of only one aldehyde was present.

Succindialdehyde-1,1-diacetate.—Allylidene diacetate (51 g.) and 0.5 g. of dicobalt octacarbonyl in 70 ml. of benzene, were subjected to conditions similar to those described above for ethyl crotonate. The original pressure at room temperature was 2650 p. s. i., the maximum observed pressure at 125° was 3400 p. s. i., and after reaction it was 1800 p. s. i. or 1200 p. s. i. at room temperature. The gas absorption was thus approximately 0.57 mole while 0.67 mole would be required if one mole each of hydrogen and carbon monoxide had been absorbed per mole of allylidene diacetate.

The distillation of the product was carried out in an apparatus consisting of two 250-ml. bulbs connected with a short piece of glass tubing 2.5 cm. in diameter. An opening for the insertion of a thermometer was provided in this tube. One bulb of the flask was placed in an oil-bath and the other was cooled with solid carbon dioxide. The second bulb was provided with a side-arm of glass tubing 2 mm. in diameter for connection to the oil pump and for pouring out the product after distillation. The product was distilled as rapidly as possible at 50–110° (0.8 mm.). The distillate (53.6 g.) showed 90% aldehyde by titration. Pure succinaldehyde-1,1-diacetate $n^{25}D$ 1.4030 was distilled at 102–103° (0.04) through a Vigreux column, as described above for ethyl β-formylbutyrate. If quantities as large as 50 g. are subjected to fractionation there is likely to be condensation before fractionation is complete. It was therefore necessary to carry out fractionations, intended to give pure aldehyde, upon quantities of the order of 10 g.

For purposes of characterization succindialdehyde-1,1-diacetate (0.5 g.) was hydrolyzed by shaking for five minutes in 9 ml. of a water solution containing 0.6 g. of sodium hydroxide and 3 ml. of alcohol. A solution of 1.5 g. of hydroxylamine hydrochloride in 8 ml. of water was added and the mixture warmed in a steam-bath for ten minutes. The crude dioxime of succindialdehyde was obtained by cooling the mixture in an ice-bath. After recrystallization from a mixture of water and ethanol the dioxime showed a m. p. 122–123°.[24] The 2,4-dinitrophenylhydrazone of succindialdehyde, m. p. 278–279°, was also prepared.[25]

(24) Willstätter and Heubner, *Ber.*, **40**, 3872 (1907).

(25) Keagle and Hartung, THIS JOURNAL, **68**, 1609 (1948).

β-Carbethoxypropionaldehyde.—Ethyl acrylate (65 g.) and 1.2 g. of dicobalt octacarbonyl in 50 ml. of benzene was hydroformylated as described above in sixteen minutes. The pressures at room temperature were 3500 and 1100 p. s. i. at the beginning and end of the reaction with a maximum of 4550 p. s. i. at 125°. The gas absorption was 75–80% of the theoretical amount. A product of 61.7 g., b. p. 70–80° (10 mm.), and 98% pure was obtained. Refractionation gave a product which according to titration was 99% pure. In a similar experiment with 50 g. of ethyl acrylate and 1.3 g. of dicobalt octacarbonyl 1.5 g. of diphenyl sulfide was added to the reaction mixture. The absorption of hydrogen and carbon monoxide required thirty minutes and the yield of aldehyde was 71% of the theoretical as compared with 74% for the reaction mixture not containing diphenyl sulfide.

α-(1-Naphthyl)-propionaldehyde.—The hydroformylation of α-vinylnaphthalene (31 g.) was carried out in the usual way and the drop in pressure (1050 p. s. i. at 23°) corresponded to the absorption of approximately a mole each of hydrogen and carbon monoxide per mole of unsaturated compound. Fractionation of the product gave 26 g., b. p. 110–150° (3 mm.), which by titration was 45% aldehyde. Refractionation gave a product 142–143° (3 mm.) which was by titration 96% pure.

Ethoxybutyraldehydes.—Allyl ethyl ether (15 g.) was hydroformylated in the usual way. Distillation of the products gave 21 g., b. p. 30–70° (20 mm.), which by titration was 41% aldehydes. This corresponds to a 41% yield of ethoxybutyraldehydes. Another hydroformylation on 36 g. of allyl ethyl ether gave a 40% yield of aldehydes. Refractionation of the crude product gave a mixture which titrated 97% aldehyde, b. p. 51–54° (20 mm.), $n^{25}D$ 1.4118. The mixture of 2,4-dinitrophenylhydrazones obtained from the mixture melted over the range 48–53°. Through chromatographing there was obtained, from 248 mg. of the mixture of hydrazones, 21.4 mg. (yellow) m. p. 88–89°, 28.3 mg. (red) m. p. 172–175°, 17.2 mg. (orange) m. p. 55–62°, 70 mg. (yellow) m. p. 75–76°, 87.7 mg. (yellow) m. p. 77–78° and 9.4 mg. of an oil. The derivative m. p. 88–89° corresponds to γ-ethoxybutyraldehyde,[26] while that of m. p. 77–78° is apparently that of β-ethoxyisobutyraldehyde. The α-ethoxybutyraldehyde has a much higher m. p. of 135°.[27]

α- and β-Acetoxy-propionaldehydes.—Vinyl acetate (45 g.) and 3.6 g. of dicobalt octacarbonyl in 70 ml. of benzene was hydroformylated in the usual way, the drop in pressure being from 3500 to 1700 p. s. i. as measured at 23°, corresponding to the absorption of about 0.7 mole of hydrogen and carbon monoxide for 0.5 mole of vinyl acetate. Distillation of the reaction mixture gave 31.1 g., b. p. 45–70° (8 mm.), which contained according to titration 91% of the aldehydes. Fractionation gave 15.4 g. b. p. 46–52° (8 mm.) and 9.0 g., b. p. 62–66° (8 mm.). These fractions each contain 90–94% aldehyde. Refractionation of the lower boiling sample gave α-acetoxypropionaldehyde 98% pure, b. p. 41–42° (8 mm.), $n^{25}D$ 1.4160. The aldehyde was characterized by its semicarbazone, m. p. 162–163°. The higher boiling β-acetoxypropionaldehyde could not be purified beyond 90%. The compound was characterized by hydrogenation to propanediol-1,3 and the formation of the bis-phenylurethan, m. p. 136–137°, of the glycol.

Diethylacetal of β-Carbethoxypropionaldehyde.—Ethyl acrylate (50 g.) and 1.3 g. of dicobalt octacarbonyl in 20 ml. of benzene and 50 ml. of dry ethanol was hydroformylated in the usual way and the products separated by fractionation. There was obtained 28.6 g. (98% pure) of β-carbethoxypropionaldehyde b. p. 86–92° (15 mm.), and 23.3 g. of the diethylacetal of β-carbethoxypropionaldehyde, b. p. 100–103° (10 mm.), $n^{25}D$ 1.4180.[28] Another experiment showed that β-carbethoxypropionaldehyde (46 g.) could be converted to its diethyl acetal (43.8 g.) under the conditions used for the hydroformylation. The formation of the acetal was avoided by carrying out the hydroformylation of ethyl acrylate in benzene free of alcohol.

Reduction of Ethyl 2-Furanacrylate with a Cobalt Carbonyl Catalyst.—Ethyl β-(2-furan)-acrylate (37 g.) and 0.6 g. of dicobalt octacarbonyl in 85 ml. of benzene, under a pressure of 4700 p. s. i. of equal parts hydrogen and carbon monoxide at 125° was rocked for six and one-half hours. The pressure dropped to 3700 p. s. i. during the period. After the usual procedures there was obtained 34.3 g. of ethyl β-(2-furan)-propionate b. p. 94–98° (4 mm.) $n^{25}D$ 1.4812.[29] The saponification equivalent of the product was 167 as compared with a calculated value of 168.

Summary

The hydroformylation of several unsaturated hydrocarbons, ethers and esters, through the use of dicobalt octacarbonyl in benzene at 100–300 atmospheres of carbon monoxide and hydrogen, has given good yields of aldehydes free of isomers. The reaction of substituted ethylenes of the types $RCH{=}CH_2$ and $R_2C{=}CH_2$ have given in six cases aldehydes of the type RCH_2CH_2CHO and R_2CHCH_2CHO. However, where R was phenyl, 1-naphthyl, *n*-butoxy, acetoxy and ethoxymethyl, aldehydes of the type $RCH(CH_3)CHO$ were produced. Three alkenes of the type $RCH{=}CHR'$ have given good yields of a single aldehyde.

Some of the limitations of the reaction, due to the formation of mixtures of aldehydes or the failure of the hydroformylation reaction to take place, have been illustrated. The presence of a sulfur containing compound in the reaction mixture did not significantly poison the catalytic activity of the benzene soluble cobalt carbonyl catalyst. This catalyst has proven to be effective for the hydrogenation of the carbon to carbon double bond in certain α,β-unsaturated carbonyl compounds.

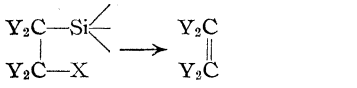
γ-Eliminations Involving Silicon. A New Synthesis of the Cyclopropane Ring[1]

BY LEO H. SOMMER, RICHARD E. VAN STRIEN[2] AND FRANK C. WHITMORE[3]

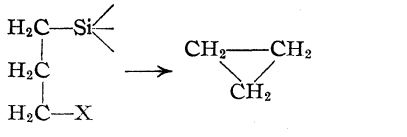
In previous work[4] we found that the remarkable reactivity of halogen bound to carbon in the beta relation to silicon (X—C—C—Si≡) is associated with cleavage of the carbon–silicon bond. Many examples of this type of reaction have been found. All take place according to the general equation



(1)

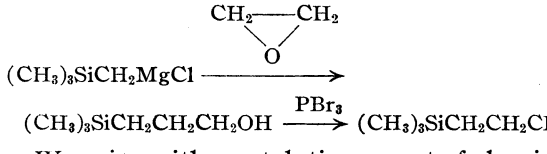
Equation (1) shows that these reactions are β-eliminations involving silicon, formally similar to the dehydrohalogenation of ordinary organic halides.

In extension of this work we have investigated the reactions of γ-haloalkyl silicon compounds and now report two γ-eliminations involving silicon which give cyclopropane.

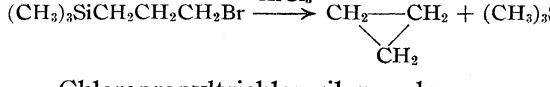


(2)

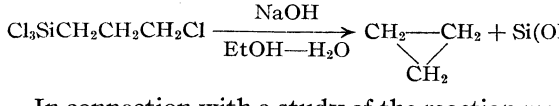
γ-Bromopropyltrimethylsilane was synthesized by the following sequence of reactions.



Warming with a catalytic amount of aluminum chloride gave a 92% yield of pure cyclopropane.



γ-Chloropropyltrichlorosilane also gave pure cyclopropane (31% yield) when heated with a solution of sodium hydroxide in aqueous ethanol.



In connection with a study of the reaction mechanisms of these γ-eliminations, it was found that when the reagents are interchanged, *i. e.*, γ-bromopropyltrimethylsilane is treated with base and γ-chloropropyltrichlorosilane is treated with aluminum chloride, no cyclopropane is formed. Furthermore, 5-bromopentyltrimethylsilane failed to give cyclopentane when treated with aluminum chloride in catalytic amounts.[5] Instead, somewhat impure 1-pentene was obtained in low yield. The other products were polymers, presumably polyamylenes, and trimethylbromosilane.

5-Bromopentyltrimethylsilane was synthesized from γ-bromopropyltrimethylsilane by the reaction sequence

Experimental

Synthesis of γ-Bromopropyltrimethylsilane.—Ethylene oxide, 10 moles, dissolved in 750 cc. of dry ether was added to the Grignard reagent prepared from 5 moles of chloromethyltrimethylsilane. The reaction mixture was stirred for three days and then 1 liter of ether was distilled and replaced by 1 liter of dry benzene. After refluxing for twenty hours, the product was treated with 500 cc. of water followed by 3 liters of 10% hydrochloric acid. The organic layer was separated and the water layer extracted once with ether. After washing the ether–benzene solution of the product with saturated salt solution and drying with sodium sulfate, the ether and most of the benzene were removed by fractionation in a column of about 15 theoretical plates and the remaining material was rapidly distilled from a 1-liter distillation flask. This distillate was then fractionated in a glass-helix packed column of about 15 theoretical plates. There was obtained 468 g., 3.57 moles, of γ-hydroxypropyltrimethylsilane, b. p. 83° at 27 mm., $n^{20}D$ 1.4290, d^{20} 0.8316, a yield of 71%.

Anal. Calcd. for $C_6H_{16}SiO$: Si, 21.2. Found: Si, 21.3.

In a 1-liter flask equipped with a stirrer, reflux condenser and dropping funnel there was placed 326 g. (2.47 moles) of γ-hydroxypropyltrimethylsilane. The flask was cooled in an ice-bath and 350 g., 1.29 moles, of phosphorus tribromide was slowly added to the alcohol. After completion of the addition, the reaction mixture was allowed to warm to room temperature. This was followed by heating (85–90°) for a period of four hours. After cooling to room temperature, the reaction product was poured on ice and the resulting layers were separated. The organic layer was washed with water and then with dilute potassium carbonate solution. Drying was effected with sodium sulfate. Fractionation gave 404 g., 2.07 moles, of γ-bromopropyltrimethylsilane, b. p. 70° (25 mm.), $n^{20}D$ 1.4541, d^{20} 1.1173, a yield of 84%.

(5) When cyclopentane (10 g.) is refluxed with aluminum chloride (3 g.) for eight hours no change takes place; see Cox, *Bull. soc. chim.*, **37**, 1549 (1925).

Cyclopropane Formation from γ-Bromopropyltrimethylsilane.—The procedure used was as follows: The γ-bromopropyltrimethylsilane was placed in a 100-cc. flask equipped with a reflux condenser and a dropping bottle for introduction of aluminum chloride. The exit end of the condenser led to a 5-liter flask filled with saturated salt solution which was used to measure the volume of gas evolved.

γ-Bromopropyltrimethylsilane, 19.1 g., 0.098 mole was placed in the reaction flask and treated with a few crystals of sublimed aluminum chloride (*ca.* 0.2 g.). Reaction was spontaneous and the reaction mixture became somewhat cooler than room temperature. After most of the reaction had taken place, gentle heating was applied by means of a water-bath held at 70°. Air was then passed into the reaction flask in order to sweep all of the gaseous product into the receiving flask. The gas mixture collected comprised 2960 cc. of which 670 cc. was shown to be air by gas analysis.

A sample of the gas mixture was condensed in a trap cooled in Dry Ice acetone mixture, and was then charged to the isothermal distillation apparatus of Zook, Oakwood and Whitmore.[6] After removal of air, a series of vapor pressure–temperature measurements were made and the data were plotted for comparison with cyclopropane and propylene.[7] Figure 1 shows that the gaseous product of the reaction is pure cyclopropane. The yield was 92%.

The material remaining in the reaction flask consisted of 12.5 g., 82% yield, of trimethylbromosilane, b. p. 79° (732 mm.)[8]; Br, 52.4 (calcd., 52.3).

Formation of Cyclopropane from γ-Chloropropyltrichlorosilane.—In a 500-cc. flask equipped with a reflux condenser connected to a gas collector, and a dropping funnel, was placed a solution of 28 g., 0.50 mole, of potassium hydroxide dissolved in 100 cc. of absolute ethanol. Then 24.6 g., 0.116 mole of γ-chloropropyltrichlorosilane[9] was slowly added to this solution. An immediate reaction took place as each portion of γ-chloropropyltrichlorosilane was added, a precipitate of potassium chloride being formed. At the end of the addition, the reaction mixture was brought to reflux. However, the volume of gas collected amounted to only 70 cc. when the reaction mixture was cooled to room temperature. To the reaction flask were then added 150 cc. of water and an additional 28 g. of potassium hydroxide. The material was once more brought to reflux and the total volume of gas collected was 1320 cc. of which 410 cc. was shown to be air.

Following a procedure similar to that used above, the gaseous product of the reaction was shown to be pure cyclopropane (see Fig. 1). The yield was 31%.

Reaction of γ-Bromopropyltrimethylsilane with Potassium Hydroxide in 50% Aqueous Ethanol.—γ-Bromopropyltrimethylsilane (0.067 mole) was treated with a solution of potassium hydroxide (56 g., 1 mole) in 50% aqueous ethanol (260 cc.) at reflux temperature for five hours. No gas was evolved. Reaction was shown to be complete by treatment of the product with silver nitrate and weighing the silver bromide formed. Apparently, normal dehydrohalogenation and/or metathesis occurred. Since the major point under investigation was formation or non-formation of cyclopropane, and because of lack of material, a larger run was not made, and the organosilicon products were not identified.

Reaction of γ-Chloropropyltrichlorosilane with Aluminum Chloride.—In a 50-cc. flask was placed 9.7 g. of γ-chloropropyltrichlorosilane. Through the top of the reflux condenser was added a few crystals of aluminum chloride. No reaction was observed at room temperature. Upon heating by means of a water-bath held at 60°, the liquid turned brown. Heating was gradually increased and the reaction mixture was finally heated for two hours at 95–97°. Throughout the heating period there was no appreciable formation of a gaseous product. After cooling, the product was distilled at reduced pressure until the temperature reached 135° at 35 mm. Distillation of this material at atmospheric pressure gave only 2.7 g. of material boiling between 60° and 180°. A residue of about 3 g. of viscous material was also not identified. The complex mixture of products obtained in this reaction are characteristic of the reaction of many organic compounds with aluminum chloride at about 100° for a number of hours.

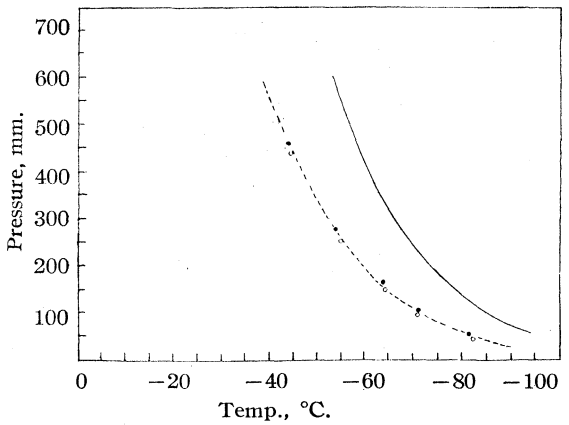

Fig. 1.—Vapor pressure curves: O, cyclopropane from γ-bromopropyltrimethylsilane; ●, cyclopropane from γ-chloropropyltrichlorosilane; ----, cyclopropane curve from the literature; —, propylene curve from the literature.

Synthesis of 5-Bromopentyltrimethylsilane.—The Grignard reagent was prepared in the usual manner from 390 g., 2 moles, of γ-bromopropyltrimethylsilane and 48 g. of magnesium turnings in 1 liter of ether. To the Grignard reagent was added 200 cc. of ethylene oxide dissolved in 150 cc. of dry ether. On standing for a period of eighteen hours at room temperature the reaction mixture solidified. This was treated with 2 liters of water followed by addition of sufficient hydrochloric acid to render the mixture acid to litmus. The water layer was extracted with pentane and the combined organic layers were washed with potassium carbonate solution and then with water. After drying with anhydrous sodium sulfate, fractionation gave 206 g., 1.3 moles, of 5-hydroxypentyltrimethylsilane, b. p. 85° at 8 mm., $n^{20}D$ 1.4371, 64% yield.

Anal. Calcd. for $C_8H_{20}SiO$: Si, 17.50. Found: Si, 17.45.

In a 100-cc. reaction flask equipped with a condenser and dropping funnel was placed 42.9 g., 0.27 mole, of 5-hydroxypentyltrimethylsilane. Phosphorus tribromide, 36 g., 0.13 mole, was then slowly added with frequent shaking of the flask. After standing at room temperature for eighteen hours, followed by heating at 95–99° for one hour, the layers were separated. Ether was added to the organic layer which was then washed twice with water and once with ammonium hydroxide. The product was dried over calcium chloride and fractionated under reduced pressure. There was obtained 47.1 g., 0.21 mole, of 5-bromopentyltrimethylsilane, b. p. 113° at 23 mm., $n^{20}D$ 1.4570, 78% yield.

Anal. Calcd. for $C_8H_{19}SiBr$: Si, 12.57; Br, 35.81. Found: Si, 12.72; Br, 35.66.

Reaction of 5-Bromopentyltrimethylsilane with Aluminum Chloride.—A 200-cc. flask was equipped with a condenser arranged for distillation. 5-Bromopentyltrimethylsilane was placed in the flask and a few small crystals of aluminum chloride were added. Reaction was spontaneous, but heat was applied to distill any volatile

(6) Design of the apparatus will be submitted for publication.

material which formed. Two runs, utilizing a total of 108 g., 0.485 mole, of the bromide were made.

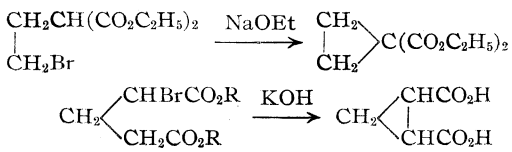
The combined distillate, 54 g., which contained trimethylbromosilane, was carefully washed with ice-water and then with potassium carbonate solution. All washings were made in capped bottles to prevent loss by volatilization. Drying was effected with sodium sulfate to give 34 g. of product. Fractionation in a column of 40 theoretical plates gave 6.0 g. of somewhat impure pentene-1, b. p. 28.6-29.5° at 732 mm., $n^{20}D$ 1.3702-1.3722, d^{20} 0.644,[10] which was identified by characterization of its ozonolysis products as formaldehyde (dimedone deriv., m. p., 189-190°) and butyraldehyde (2,4-dinitrophenylhydrazone deriv. m. p. 120-121°). The yield of impure pentene-1 was 17%. No evidence was found for formation of cyclopentane, b. p. 49.3° at 760 mm., $n^{20}D$ 1.40645, or ethylcyclopropane, b. p. 32.5°, $n^{20}D$ 1.379.[11]

In addition to pentene-1, there was also obtained from the fractionation 15.0 g., 0.098 mole, of hexamethyldisiloxane, b. p. 98°, $n^{20}D$ 1.3770, and a higher-boiling residue of 3.8 g.

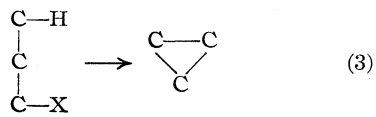
Fractionation of the material originally remaining in the reaction flask gave 20.1 g., 0.131 mole, of trimethylbromosilane, b. p. 77° at 725 mm., Br 52.6 (calcd. 52.3), and a residue of black tarry material, likely consisting of polymerized pentene. The yield of recovered material containing the trimethylsilyl group was 67%.

Discussion

Some Common Aspects of γ-Eliminations Involving Silicon and Other Syntheses of Cyclopropyl Compounds.—One of the methods for closing the cyclopropane ring involves γ-elimination of hydrogen halides from organic compounds. The following equations provide two examples of this type of synthesis.[12]

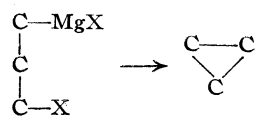


A large number of cyclopropane derivatives (but not cyclopropane itself) have been prepared by these reactions which take the general form



(3)

For the preparation of cyclopropane, reaction of an active metal such as magnesium or sodium with a 1,3-dihalopropane in an organic solvent may be used. In these reactions it seems probable that cyclopropane is formed from an organometallic intermediate.[13]



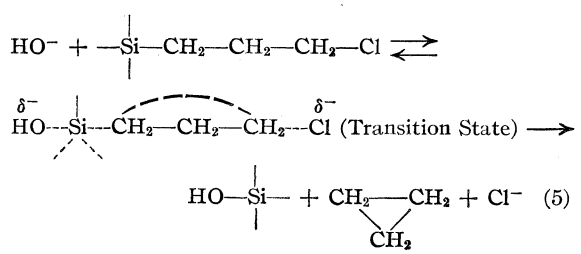
(4)

Comparison of equations (2), (3) and (4) indicates that the formation of cyclopropyl compounds from γ-haloalkyl silicon compounds and from purely organic halides are similar in three general ways: (1) Both give cyclopropyl compounds by 1:3 elimination reactions. (2) Both involve removal of an element more electropositive than carbon (silicon, hydrogen, or an active metal)[14] together with an element more electronegative than carbon (halogen). (3) Both types involve electron-release to carbon from an element more electropositive than carbon.

Similar considerations apply to a comparison of β-eliminations involving silicon with the dehydrohalogenation of purely organic halides to give olefins.[4b]

Mechanism.—β-Eliminations involving silicon are greatly accelerated by bases and take place by a one-stage mechanism involving initial nucleophilic attack on silicon. A study of the effect of structural variations in the β-haloalkylsilane on reaction velocity has shown that substitution of a single halogen on silicon by alkyl results in a tenfold decrease in rate. This relationship of structure to reactivity is the expected one for a mechanism involving nucleophilic attack on silicon since the presence of electronegative substituents should make the silicon a more effective center for nucleophilic attack.[4b]

If the mechanism of cyclopropane formation from compound II and alkali involves nucleophilic attack on silicon as the major driving force, it should follow that a decrease in the electrophilic activity of the silicon, *i. e.*, by replacement of halogen on silicon by alkyl, would result in a decrease of reaction velocity or in complete prevention of the reaction. The effect on γ-elimination should far exceed that on β-elimination because of the lesser ease of formation of cyclopropane as compared to olefin formation. The observed facts and the nucleophilic character of aqueous base are therefore in complete harmony with the following mechanism



(5)

The above mechanism is closely similar to the mechanism of γ-eliminations of purely organic compounds with bases which consist of 1:3 elimination of HX.[14a]

(10) Physical constants for pentene-1 are b. p. 30.1° at 760 mm., $n^{20}D$ 1.3714, d^{20} 0.630. See Egloff, "Physical Constants of Hydrocarbons," Vol. I, Reinhold Publishing Corporation, New York, N. Y., 1940.

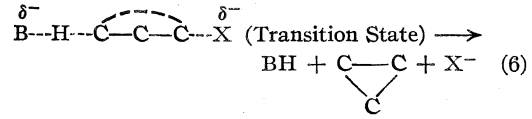
(14) Pauling, "Nature of the Chemical Bond," Cornell University Press, Ithaca, N. Y., 1940, p. 60.

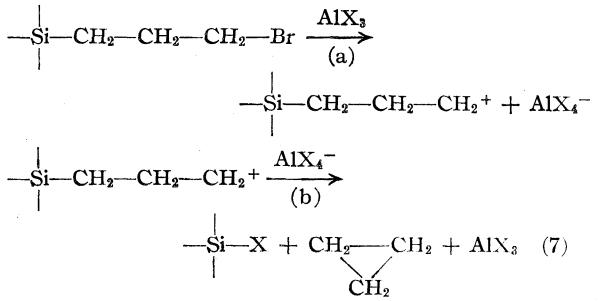
(14a) Hauser, THIS JOURNAL, **62**, 933 (1940).



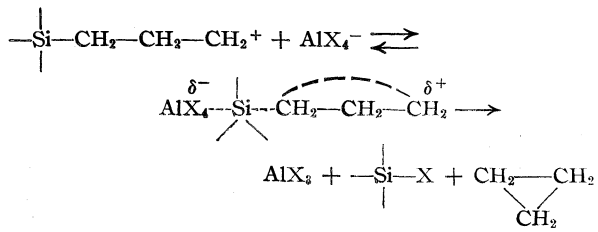
In these latter syntheses of cyclopropyl compounds nucleophilic attack on γ-hydrogen is facilitated by the activating effect of a carbonyl group adjacent to the hydrogen atom.

The only difference between the mechanisms is that in (5) the base attacks electropositive silicon instead of the protonic part of an activated hydrogen atom.

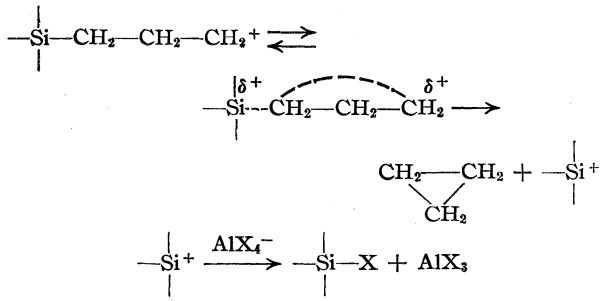
Previous work has shown that electron-release from silicon to electronically deficient carbon in the beta relation to silicon constitutes a general mechanism whereby cleavage of the carbon–silicon bond can occur in a variety of organosilicon structures.[4b] β-Eliminations involving silicon which take place with electrophilic reagents such as aluminum chloride are examples of reactions proceeding by this mechanism. The electropositive nature of silicon and the ability of aluminum chloride to cause ionization of the carbon–halogen bond make a similar mechanism seem probable for the reaction of γ-bromopropyltrimethylsilane with aluminum chloride.[15]



There are two reaction paths for the silicon in (7b) which comprise possible extremes of mechanism: (1) A transition state in which the siliconium ion is transferred to the new linkage with halogen without being set free. (2) A reaction process



in which a siliconium ion is actually set free prior to combination with halogen from AlX_4^-.



The question as to whether a siliconium ion is set free for a period of time sufficient for the designation of such an ion as an actual reaction intermediate, or is transferred to the new linkage without acquiring the full status of an ion, is an interesting one. However, we wish to make it clear that the important general aspects of the mechanism given in equation (7) in no way depend upon the degree of freedom of the siliconium ion involved. These aspects are adequately summarized by the concept that the major driving force for these reactions derives from the ability of electropositive silicon to release an electron-pair to electronically deficient carbon within the molecule, regardless of whether the silicon has started to combine with an anion at substantially the same time. Similar considerations apply to β-eliminations involving silicon which result from reaction with electrophilic reagents.[16]

The failure of 5-bromopentyltrimethylsilane to give cyclopentane when treated with aluminum chloride is in accord with the mechanism for cyclopropane formation given in (7). In 5-bromopentyltrimethylsilane the deficiency on carbon is created at a distance from silicon which is great enough to prevent an intramolecular transmission of charge sufficient for cyclization, despite the lesser strain involved in a 5-membered ring.

Summary

1. A synthesis of pure cyclopropane has been found which results from γ-elimination of silicon and halogen from two organosilicon compounds.

2. Proposed mechanisms for these γ-eliminations involve as major driving forces (1) nucleophilic attack on silicon, and (2) electrophilic attack on halogen in the group being cleaved from silicon.

3. The latter type of γ-elimination extends the applicability of the concept of electron-release from silicon to electronicallydeficient carbon as constituting *one* major factor in eliminations involving silicon. Formation of free siliconium ions

(15) The failure of γ-chloropropyltrichlorosilane to give cyclopropane with aluminum chloride is very likely due to the inhibiting effect of chlorine substituents on silicon (relative to alkyl) toward electron-release from silicon to electronically deficient carbon. For example, work on intramolecular rearrangements has shown that the replacement of only one alkyl group on silicon by a chlorine substituent completely prevents intramolecular rearrangement with aluminum chloride of $(CH_2)(CH_3)_2SiCl$ as compared to $(CH_2Cl)(CH_3)_3Si$: paper presented before the Organic Division in Chicago, April 22, 1948. These effects are readily explained on an inductive effect basis.

(16) Swain, Esteve and Jones, THIS JOURNAL, **71**, 965 (1949), have recently shown that a siliconium ion intermediate is unlikely in the reaction of triphenylfluorosilane with the relative weak electrophilic reagent, 50% water–50% acetone solution. These authors further point out, however, that their work does not preclude the possibility of siliconium ion intermediates with more powerful electrophilic reagents such as aluminum chloride.

as reaction intermediates is not a necessary condition for reactions proceeding by this mechanism. The greater or lesser degree of freedom of such ions must depend upon the organosilicon compound undergoing reaction, the attacking reagent, and the reaction medium, whereas the only essential requirement for reactions proceeding by the above mechanism is the creation of electron-deficiency at a carbon atom which is sufficiently close to the silicon so as to cause release of an electron-pair from silicon to carbon.

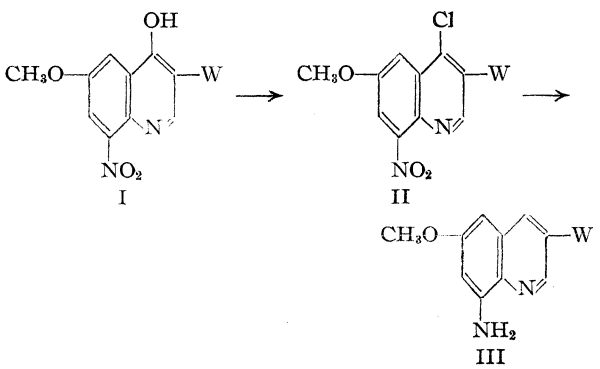
6-Methoxy-8-nitroquinolines with Substituents in the 3- and 4-Positions[1]

BY ROBERT H. BAKER, J. G. VAN OOT, SAMUEL W. TINSLEY, JR., DOROTHY BUTLER AND BYRON RIEGEL

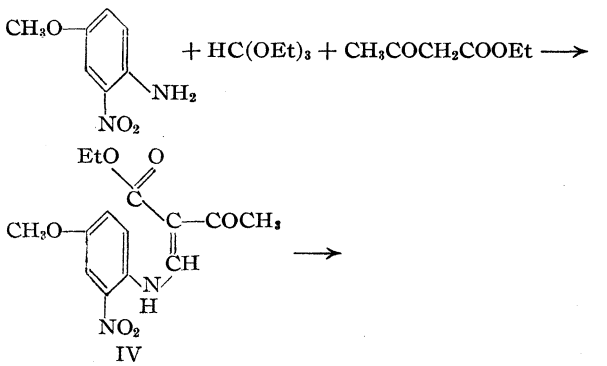
A common procedure for the replacement of hydroxyl by hydrogen in 4-quinolinols is conversion to the halide followed by reduction. Although this sequence of reactions had not been studied when other groups were in the 3-position, it appeared to be an attractive route to the 3-substituted-6-methoxy-8-aminoquinolines, III.

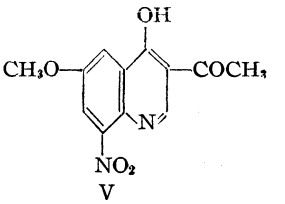


(W = CN, COOEt, C_6H_5 or CH_3CO)

The conversion to the halide, II, was difficult but could be accomplished with a mixture of phosphorus oxychloride and pentachloride.[2] However, none of a variety of conditions of hydrogenation over palladium, platinum or Raney nickel catalysts would effect reductive dehalogenation of II to III.

The preparation of 3-acetyl-6-methoxy-8-nitro-4-quinolinol (V) was accomplished by cyclization of the "anil" (IV) which in turn could be made by three methods. Direct combination of the nitroanisidine, ortho ester and keto ester is simpler but gives poorer yields than the reaction of the anisidine with ethoxymethyleneacetoacetic ester (formed by prior reaction of the latter two reagents). The third method involves reaction of the ortho ester and anisidine to give the substituted diphenylformamidine which in turn reacts with the keto ester.[3] Attempts were also made to produce ethoxymethylene-*m*-nitroanisidine which would be expected to be a useful intermediate but generally the diarylformamidine was the product.





Considerable difficulty has been encountered during "anil" formation in the use of α-formyl esters for quinolinol syntheses.[4] With formylphenylacetic ester and *m*-nitroanisidine, this difficulty is overcome by the use of zinc chloride to catalyze the reaction.

Successful attempts to prepare plasmochin-type drugs with blocking groups in the 3-position will be described in forthcoming publications.

Experimental[5]

3-Acetyl-6-methoxy-8-nitro-4-quinolinol.—Equimolar quantities of *m*-nitroanisidine and ethyl ethoxymethyleneacetoacetate were heated at 150° for fifteen minutes, cooled and the "anil" crystallized from ethanol in quantitative yield, m. p. 153–154°. This material was added to fifteen times its weight of boiling Dowtherm (a mixture of biphenyl and diphenyl ether). Eighteen minutes of

(1) This work was supported by a grant from the National Institute of Health, U. S. Public Health Service.

(2) C. C. Price, N. J. Leonard and H. F. Herbrandson, THIS JOURNAL, **68**, 1251 (1946), used thionyl chloride for this conversion on simpler compounds but we were unable to use it in this work.

(3) These combinations of reactants were previously studied by H. R. Snyder and R. E. Jones, *ibid.*, **68**, 1253 (1946).

(4) Because of this, we have previously used the α-oxalyl esters and subsequent decarboxylation, R. H. Baker and R. M. Dodson, *ibid.*, **68**, 1283 (1946); B. Riegel, C. J. Albisetti, Jr., G. R. Lappin and R. H. Baker, *ibid.*, **68**, 2685 (1946).

(5) Microanalyses by Jane Gibbs, Rosalind Guy and Virginia Hobbs.

heating was found to be the optimum time for 5 g. of "anil." The quinolinol was precipitated from the cooled reaction mixture by addition of Skellysolve "C" (petroleum ether, b. p. 85–100°). Crystallized from methanol the maximum yield was 40% of yellow plates. These change to needles at 180°, m. p. 232.5–235°.

Anal. Calcd. for $C_{12}H_{10}N_2O_5$: N, 10.68. Found: N, 10.72.

3-Acetyl-4-chloro-6-methoxy-8-nitroquinoline.—The corresponding 4-quinolinol was covered with a large excess of freshly distilled phosphorus oxychloride and heated on the steam-bath for an hour. Fresh oxychloride was added and the solution refluxed for another hour. The excess phosphorus oxychloride was distilled at reduced pressure and the residue cooled in an ice-bath. This was slowly poured with vigorous stirring into a slurry of shaved ice. The acid was partially neutralized at 0° with sodium hydroxide. The precipitate was removed by filtration and crystallized from isopropyl alcohol (decolorized by Norit) to give fibrous white crystals, m. p. 118–119°. The yield varies greatly from run to run and has never exceeded 15%.

Anal. Calcd. for $C_{12}H_9ClN_2O_4$: N, 10.0. Found: N, 9.94.

2,2′-Dinitro-4,4′-dimethoxydiphenylformamidine.—A solution of 4.2 g. (0.025 mole) of *m*-nitroanisidine and 3.7 g. (0.025 mole) of ethyl orthoformate in 50 ml. of xylene was distilled slowly through a short distilling column until 3 ml. of alcohol and xylene had been collected. On cooling, 3 g. (69%) of red needles was obtained, m. p. 165–166°. Occasionally the product was long yellow needles, m. p. 41–42°, which appeared to be **ethoxymethylene-*m*-nitroanisidine,** but the preparation of this compound was unreliable.[6]

The formamidine was also prepared by the method of Lander.[7] 2-Nitro-4-methoxyformanilide, m. p. 142–143°, was prepared in 88% yield by refluxing 16.8 g. (0.10 mole) of the amine in 50 ml. of 50% formic acid for twelve hours and cooling to produce crystals. To a solution of 3.3 g. (0.027 mole) of the formanilide in 12.5 g. (0.08 mole) of ethyl iodide was added portionwise 10 g. of freshly prepared dry silver oxide. During the addition the mixture was diluted with 50 ml. of dry ether, and when it had all been added, the mixture was refluxed for two hours. After filtration, the solvent was evaporated and the residue crystallized from acetone, 1 g. (22%), m. p. 163–164°. Mixed with the material from the ortho ester preparation there was no depression in m. p.

Anal. Calcd. for $C_{15}H_{14}N_4O_6$: N, 16.2. Found: N, 16.1.

3-Carbethoxy-4-chloro-6-methoxy-8-nitroquinoline.—The corresponding 4-quinolinol[8] was covered with phosphorus oxychloride and heated at 100° for six hours. After cooling and pouring into a slurry of ice, the product was crystallized from Skellysolve "C" to give yellow needles, m. p. 108–109°, in 20% yield.

Anal. Calcd. for $C_{13}H_{11}ClN_2O_5$: N, 9.34. Found: N, 9.11.

Ethyl α-Phenyl-β-(2-nitro-4-methoxyanilino)-acrylate.—An equimolar mixture of *m*-nitroanisidine and ethyl formylphenylacetate[9] was heated in an oil-bath to 165–170° and then freshly fused and powdered zinc chloride (one part per ten parts of mixture) was carefully added.[10] After maintaining the temperature for twenty-five minutes, the solution was cooled, diluted with chloroform and filtered. The filtrate was evaporated and the residue crystallized from ethanol to give two crystalline modifications of red needles. The higher melting, 138–139°, was the one most readily purified.

Anal. Calcd. for $C_{18}H_{18}N_2O_5$: N, 8.19. Found: N, 8.15.

The lower melting isomer, 114–115°, was obtained by repeated crystallization from ethanol. A mixture of the two forms melted at 100°, but both forms gave the same cyclization products described below.

3-Phenyl-6-methoxy-8-nitro-4-quinolinol.—The "anil," 3.5 g., was added to 50 ml. of refluxing Dowtherm and heated for twenty-five minutes. Addition of Skellysolve "C" to the cooled solution precipitated an amorphous product which was very difficult to crystallize due to gel formation. Brown prisms, m. p. 178–180°, were produced by slow evaporation of a dilute methanol solution.

Anal. Calcd. for $C_{16}H_{12}N_2O_4$: N, 9.46. Found: N, 9.58.

3-Phenyl-4-chloro-6-methoxy-8-nitroquinoline.—The procedure described for the 3-acetyl derivative was used on the amorphous 4-quinolinol. The product was crystallized from isopropyl alcohol in white fibrous needles, m. p. 166–167°. The yield based on "anil" was 56%.

Anal. Calcd. for $C_{16}H_{11}ClN_2O_3$: N, 8.91. Found: N, 8.33.

3-Cyano-4-chloro-6-methoxy-8-nitroquinoline.—According to the method of Snyder and Jones[8] 0.25 mole each of *m*-nitroanisidine, 42 g., ethyl orthoformate, 37 g., and ethyl cyanoacetate, 28 g., were mixed and heated at 160–165° until no more ethanol distilled. The "anil," m. p. 160–164°, was cyclized by refluxing for four hours in ten times its weight of Dowtherm. The product obtained by dilution with Skellysolve "C" was crystallized from acetic acid to give 8 g., 13%, of yellow needles, m. p. about 320°. This crude quinolinol was covered with an excess of a 3:1 mixture of phosphorus oxychloride and pentachloride and refluxed for five hours. The product worked up as previously described and crystallized from ethanol gave yellow needles, m. p. 194–195°, in 80% yield.

Anal. Calcd. for $C_{11}H_6ClN_3O_3$: N, 15.9. Found: N, 15.6.

Summary

6-Methoxy-8-nitro-4-quinolinols with cyano, carbethoxy, acetyl and phenyl groups in the 3-position have been described. These have been converted into the corresponding 4-chloro derivatives. Reductive dehalogenation of the chloro derivatives was unsuccessful.

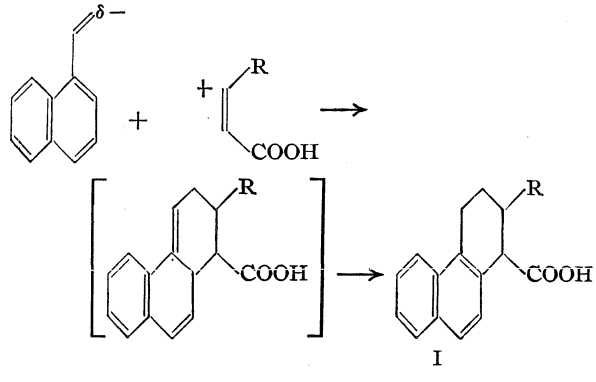
The Diels–Alder Reaction of 1-Vinylnaphthalene with α,β- and $\alpha,\beta,\gamma,\delta$-Unsaturated Acids and Derivatives

BY W. E. BACHMANN AND N. C. DENO[1]

The reaction of 1-vinylnaphthalene as a diene in the Diels–Alder reaction[2] was extended recently to the addition of fumaric acid, citraconic anhydride, and mesaconic acid.[3] We have now studied the addition of a number of α,β- and $\alpha,\beta,\gamma,\delta$-unsaturated acids and derivatives. In general, the yields of adducts were low on account of two competing reactions: homopolymerization of the 1-vinylnaphthalene and copolymerization with the dienophile. In most of the reactions two structural isomers were possible of formation, since the diene and the dienophile were unsymmetrically substituted. The structural isomer which was formed in each reaction was that expected from an application of the general principle of the English school that the most nucleophilic carbon atom will bond to the most electrophilic carbon atom.[4] In applying this principle to 1-vinylnaphthalene, the terminal carbon atom of the vinyl group was assumed to be the most potentially nucleophilic carbon atom by analogy with styrene.[5]

In the usual type of Diels–Alder reaction which involves a hydrocarbon diene and an α,β-unsaturated carbonyl compound as the dienophile, we prefer to consider that the attack is initiated by the strongly electrophilic β-carbon atom of the dienophile upon the easily polarizable diene. A second type of reaction suggests itself in which the polarities are reversed. A strongly electrophilic diene (such as sorbic acid) could attack an easily polarizable nucleophilic olefin. Apparently no unequivocal examples of this type involving unsymmetrical reactants have been mentioned; the closest approach appears to be the reaction of cyclones with unsaturated hydrocarbons. Three examples are reported in this paper. The cyclic dimerization of dienes does not fall cleanly into either category, but represents an intermediate type where both the diene and the dienophile are easily polarizable.

1-Vinylnaphthalene as the Diene. Formation of Hydrophenanthrene Derivatives.—1-Vinylnaphthalene reacted with α,β-unsaturated acids in acetic acid or propionic acid to yield 1,2,3,4-tetrahydrophenanthrene-1-carboxylic acids (I).



I

The initial adducts (shown in brackets) were isomerized to the compounds with a naphthalene nucleus by the action of the acidic medium in accordance with previous experience.[3]

Acrylic acid yielded 1,2,3,4-tetrahydrophenanthrene-1-carboxylic acid (I, R = H) whose structure was proved by the ultraviolet absorption spectrum (Fig. 1), which showed the presence of a naphthalene ring, by the failure of the compound to decolorize neutral permanganate, and by sulfur dehydrogenation to the known phenanthrene-1-carboxylic acid. Acrylic acid was the only dienophile of those studied which polymerized extensively with itself.

Crotonic acid (*trans*-β-methylacrylic acid) and β-ethylacrylic acid gave 2-methyl and 2-ethyl-1,2,3,4-tetrahydrophenanthrene-1-carboxylic acids (I, R = CH_3; I, R = CH_3CH_2), respectively. Both stereoisomers (*cis* and *trans*) of I (R = CH_3) were isolated in a 1:4 ratio, but the configurations were not established. This result is not considered to be an exception to the rule of *cis* addition, but is attributed to partial isomerization of the crotonic acid to isocrotonic acid under the conditions of the reaction. The structures were proved by decarboxylation and dehydrogenation of I (R = CH_3) to 2-methylphenanthrene and of I (R = CH_3CH_2) to 2-ethylphenanthrene. Neither dienophile showed much tendency to copolymerize with 1-vinylnaphthalene.

A study of the factors affecting the yields of adduct was made with crotonic acid. When the reaction was carried out in air, total polymerization of the 1-vinylnaphthalene resulted. For this reason all of the reactions were conducted in an inert atmosphere of nitrogen or carbon dioxide. Strong acids such as *p*-toluenesulfonic acid promoted complete polymerization of the 1-vinylnaphthalene. The addition of small amounts of picric acid or *sym*-trinitrobenzene, which have been found to act as inhibitors of

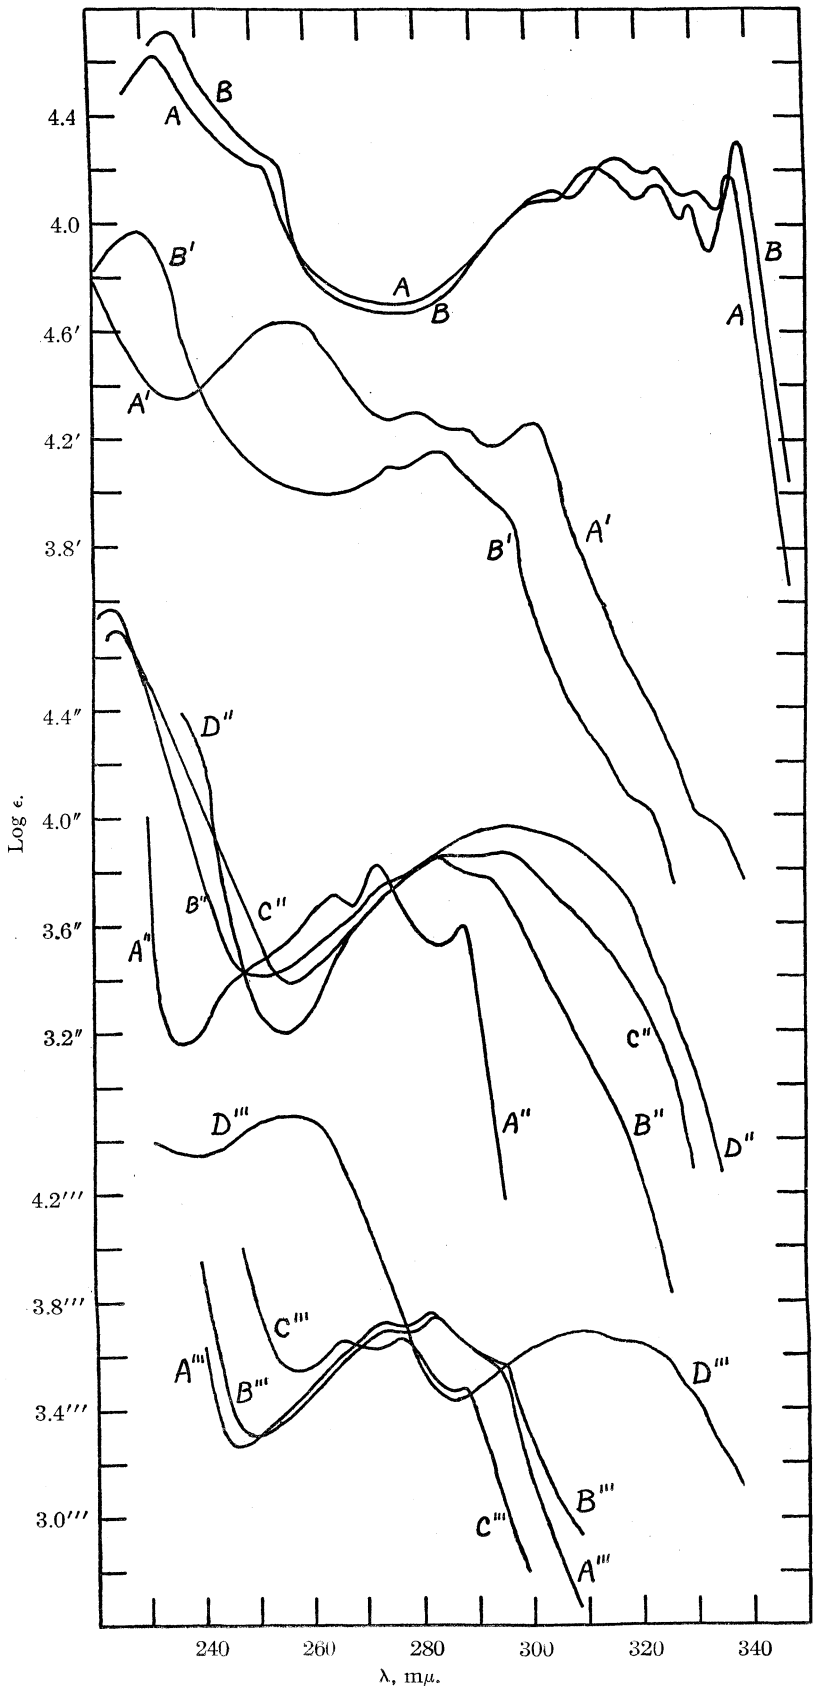

Fig. 1.—A, 3,4-Benzfluorene (XIII, R = H); B, 6-methyl-3,4-benzfluorene (XIII, R = CH_3); A′, 1-(1′-naphthyl)-phenanthrene; B′, 1-(1′-naphthyl)-1,2,3,4-tetrahydrophenanthrene (XVI); A″, naphthalene (Askew, *J. Chem. Soc.*, 512 (1935); B″, 1-(1′-cyclohexenyl)-naphthalene; C″, 1-(1′-cyclopentenyl)-naphthalene; D″, 1-propenylnaphthalene [Pestemer and Manchen, *Monatsh.*, **68**, 97 (1936)]. A‴, 1,2,3,4-Tetrahydrophenanthrene-1-carboxylic acid (I, R = H); B‴, 1-carboxymethyl-1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic anhydride (IV); C‴, *trans*-1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic acid; [3] D‴, 3,4-dihydrophenanthrene-1-carboxylic acid (III).

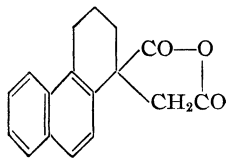
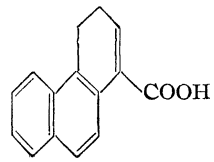
certain polymerizations,[6] resulted in very low yields of adduct. Hydroquinone was employed in many runs as a precautionary measure, although it had no effect on the yield of the adduct from crotonic acid.

Itaconic acid yielded the anhydride of 1-carboxy-1,2,3,4-tetrahydrophenanthrene-1-acetic acid (II) in addition to copolymer. The structure of the adduct was proved by decarboxylation and dehydrogenation to 1-methylphenanthrene.



II



III

The adduct from α-bromoacrylic acid split out hydrogen bromide during the reaction and formed 3,4-dihydrophenanthrene-1-carboxylic acid (III). The acid rapidly decolorized permanganate in aqueous acetone, and the ultraviolet absorption spectrum (Fig. 1) clearly showed the double bond conjugated with the naphthalene ring. Addition of a mole of hydrogen to the unsaturated acid yielded 1,2,3,4-tetrahydrophenanthrene-1-carboxylic acid (I, R = H), which confirmed the structures of both acids.

Aconitic acid yielded the anhydride of 1-carboxymethyl-1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic acid to which the structure IV has been assigned. The degradation of the compound with various reagents is of interest. Sulfur dehydrogenation eliminated the acetic acid group with the formation of phenanthrene-1,2-dicarboxylic anhydride (V), while treatment with palladium at 310° yielded 1-methylphenanthrene. Unexpectedly, the acetic acid moiety was removed also by dry distillation of a mixture of the sodium salt of the acid and calcium hydroxide, and phenanthrene was the sole volatile product. The monomethyl ester anhydride, the free triacid, and the trimethyl ester were prepared from the adduct.

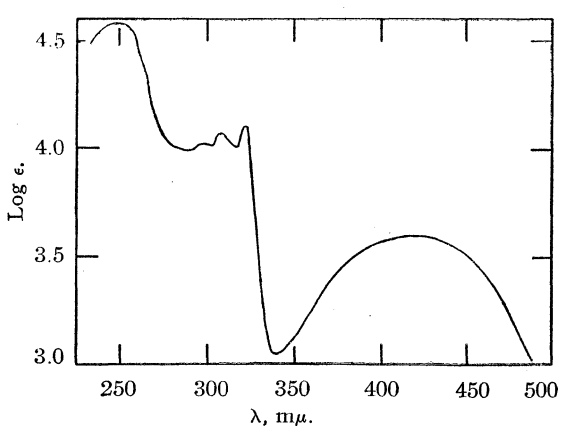


Fig. 2 —1,4-Chrysoquinone (VIII).

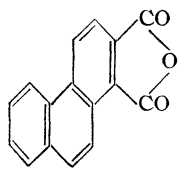
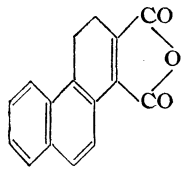
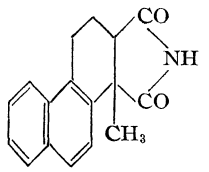
IV



V



VI

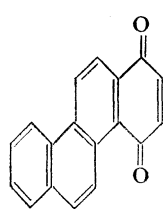


VII

Chloromaleic anhydride reacted with 1-vinylnaphthalene with elimination of hydrogen chloride, for the product was 3,4-dihydrophenanthrene-1,2-dicarboxylic anhydride (VI). Mesacon-β-amidic acid, $CH_3(COOH)C{=}CHCONH_2$, gave 1-methyl-1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic imide (VII), whose structure was established by independent synthesis of the imide from the corresponding acid of Bachmann and Scott.[3] The same imide was obtained from 1-vinylnaphthalene and *cis*- and *trans*-ethyl β-cyanocrotonate after the reaction mixture had been submitted to hydrolytic conditions. The major product from 1-vinylnaphthalene and fumaronitrile was copolymer.

Under the usual conditions acetylenedicarboxylic acid gave only copolymer. In dibutyl ether, however, phenanthrene-1,2-dicarboxylic anhydride was produced in low yield, the intermediate adduct having been dehydrogenated apparently by the excess dienophile.

1,2-Chrysoquinone (VIII, absorption spectrum in Fig. 2) was formed in high yield from *p*-benzoquinone. The intermediate adduct was dehydrogenated by the excess quinone. Methyl



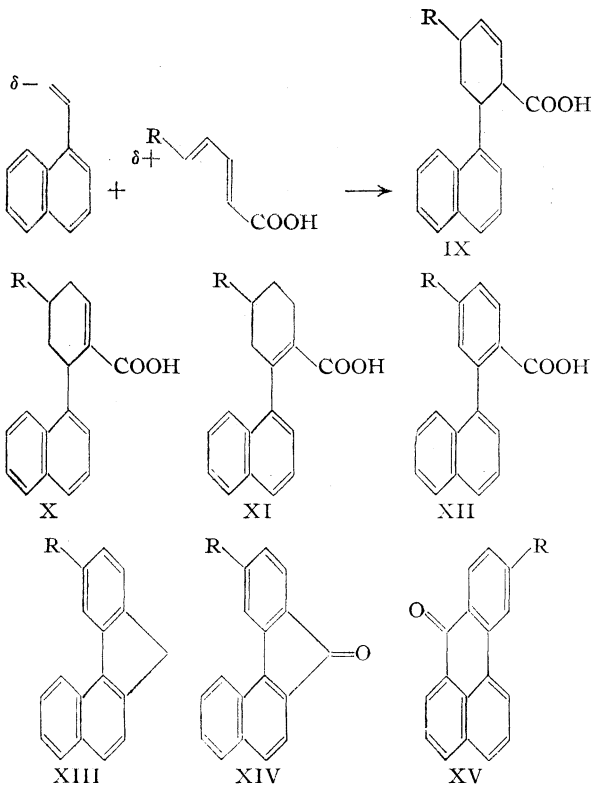
VIII

vinyl ketone gave an adduct which from theoretical considerations is probably 1-acetyl-1,2,3,4-tetrahydrophenanthrene, although its structure has not been established.

Under the conditions that were successful with crotonic acid, aconic acid, β-angelica lactone, and β-acetylacrylic acid gave low yields of products that were not investigated further; 1,2-diacetylethylene and mucobromic acid gave chiefly copolymer; and β,β-dimethylacrylic acid, β-furylacrylic acid, 5-methylcyclohexene-1,5-dicarboxylic acid, and butadiene monoxide failed to react.

1-Vinylnaphthalene as the Dienophile. Formation of 1-Cyclohexenylnaphthalene Deriva-

tives.—1-Vinylnaphthalene reacted as the dienophile with butadiene-1-carboxylic acid, sorbic acid, and muconic acid and formed 1-cyclohexenylnaphthalene derivatives. This represents a new synthesis of hydrobiaryl acids. We found no evidence for the formation of tetrahydrophenanthrene derivatives.



Each of the three diene acids yielded a mixture of adducts from which crystalline isomeric (called α and β) 1-cyclohexenylnaphthalene-2′-carboxylic acids were isolated, in which the location of the double bond has not been established with certainty. The six adducts behaved toward bromine in carbon tetrachloride more like α,β-(slow decolorization) than β,γ-unsaturated acids (IX); this implied that the double bond had shifted toward the carboxyl group (as in X and XI) during the reaction. The β adducts were isomerized to the α adducts by alkali; with R = H or CH_3, the conversion was quantitative. In agreement with the interpretation that this might represent a further shift of the double bond from its position in the β adduct (X) to a position in conjugation with the aromatic ring in the α adduct (XI)[7] was the greater reactivity of the α adducts to 3% sodium amalgam and water. On the basis of the available information, these structures seem more likely than IX for the β adducts and X or an epimer of IX for the α adducts. The ultraviolet absorption spectra (Fig. 3) do not distinguish between the various possibilities, because the absorption due to the conjugation of the double bond with the carboxyl group is masked by the strong absorption of the naphthalene ring, and the conjugation with the naphthalene ring is not manifested apparently on account of steric inhibition of resonance.[8]

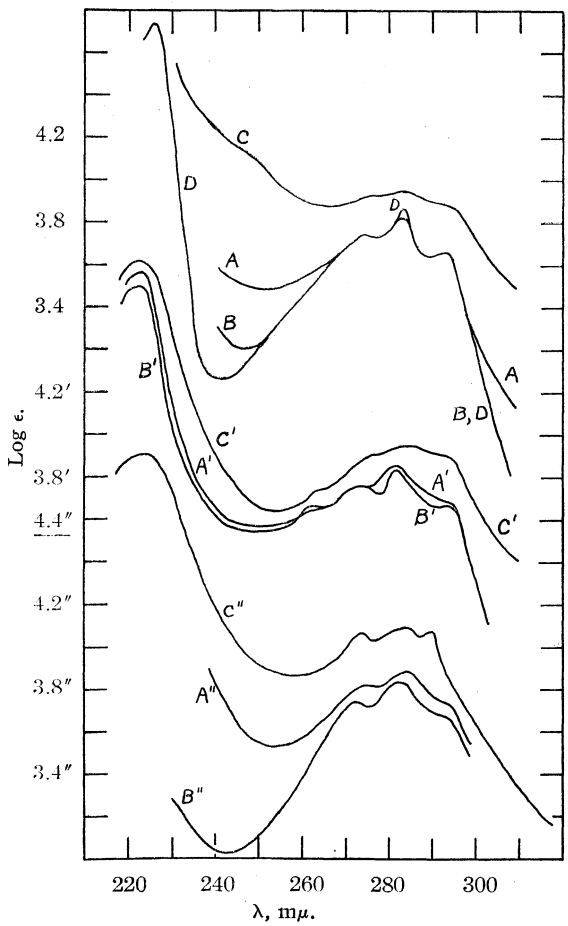


Fig. 3.—A, α-1-Cyclohexenylnaphthalene-2′,5′-di-carboxylic acid (probably XI, R = COOH); B, β-1-cyclohexenylnaphthalene-2′,5′-dicarboxylic acid (probably X, R = COOH); C, 1-phenylnaphthalene-2′,5′-dicarboxylic acid (XII, R = COOH); D, presumably 1-cyclohexylnaphthalene-2′,5′-dicarboxylic acid. A′, α-1,1-Cyclohexenylnaphthalene-2′-carboxylic acid (probably XI, R = H); B′, β-1-cyclohexenylnaphthalene-2′-carboxylic acid (probably X, R = H); C′, 1-phenylnaphthalene-2′-carboxylic acid (XII, R = H). A″, α-5′-Methyl-1-cyclohexenylnaphthalene-2′-carboxylic acid (probably XI, R = CH_3); B″, β-5′-methyl-1-cyclohexenylnaphthalene-2′-carboxylic acid (probably X, R = CH_3); C″, 5′-methyl-1-phenylnaphthalene-2′-carboxylic acid (XII, R = CH_3).

The cyclohexenylnaphthalene structure of the adducts from butadiene-1-carboxylic acid was proved by sulfur dehydrogenation to the known 1-phenylnaphthalene-2′-carboxylic acid (XII, R

(7) Linstead, *J. Chem. Soc.*, 2498 (1929).

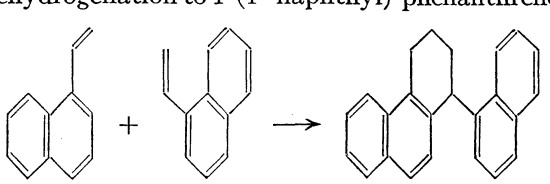
(8) Compare the spectrum of 1-(1′-cyclohexyl)-naphthalene in Fig. 8 with that of 1-phenylnaphthalene [Jones, *Chem. Rev.*, **32**, 34 (1942)].

= H; absorption spectrum in Fig. 3). Dry distillation of a mixture of the sodium salt of the adduct and calcium hydroxide followed by palladium treatment of the distillate at 300° gave the known 3,4-benzfluorene (XIII, R = H). This unexpected result apparently involved cyclization in the alkaline medium to tetrahydrobenzfluorenone followed by internal dehydrogenation–reduction to the hydrocarbon. After the structure of the product had been elucidated, it was learned that *o*-phenylbenzoic acid yields fluorenone when heated with soda–lime.[9]

In a similar manner sulfur dehydrogenation of the adducts from sorbic acid yielded 5′-methyl-1-phenylnaphthalene-2′-carboxylic acid (XII, R = CH_3), which was cyclized to the known 10-methyl-7-oxo-7-benz(de)anthracene (XV, R = CH_3). Likewise, 6-methyl-3,4-benzfluorene (XIII, R = CH_3) was obtained by the procedure which gave 3,4-benzfluorene; the similarity in absorption spectra of these two hydrocarbons (Fig. 1) was evidence for the structure of the methyl derivative.[10]

The adducts from muconic acid were dehydrogenated to 1-phenylnaphthalene-2′,5′-dicarboxylic acid (XII, R = COOH) with palladium. Apparently some disproportionation took place, for a compound was isolated whose analysis and absorption spectra (Fig. 3) corresponded to those of 1-cyclohexylnaphthalene-2′,5′-dicarboxylic acid.[11] The best method of preparation of 1-phenylnaphthalene-2′,5′-dicarboxylic acid (36% yield from 1-vinylnaphthalene) was dehydrogenation of the dimethyl ester of the crude adduct with sulfur followed by hydrolysis. The ring system was established by decarboxylation of the diacid to 1-phenylnaphthalene and by cyclization to the known 7-oxo-7-benz(de) anthracene-10-carboxylic acid (XV, R = COOH).

1-Vinylnaphthalene as the Diene and Dienophile. Dimerization.—When 1-vinylnaphthalene alone was refluxed in propionic acid, polymerization occurred; from the product 1-(1′-naphthyl)-1,2,3,4-tetrahydrophenanthrene (XVI) was isolated. The absorption curve (Fig. 1) showed the presence of two naphthalene rings and the complete structure was proved by sulfur dehydrogenation to 1-(1′-naphthyl)-phenanthrene.



XVI

(9) Fittig and Schmitz, *Ann.*, **193**, 115 (1878); Fittig and Ostermayer, *ibid.*, **166**, 372 (1873).

(10) These spectra differed from the spectrum of 7-benz(de)-anthracene [Clar and Furnari, *Ber.*, **65**, 1420 (1932)], which had been a ring system under consideration.

(11) Cook and Lawrence, *J. Chem. Soc.*, 1431 (1936), observed disproportionation of 1-cyclohexenylnaphthalene under similar conditions.

The resemblance of the spectrum of the latter hydrocarbon with that calculated for a mole of naphthalene and one of phenanthrene may be interpreted in terms of steric inhibition of conjugation between the two ring systems in the molecule.

Observations on the Reactions.—Our results are in agreement with the view that a strongly electrophilic carbon atom of an olefin or diene attacks the potentially nucleophilic terminal carbon atom of 1-vinylnaphthalene. They also demonstrate a close correlation between the reaction of an electrophilic olefin or diene in the Diels–Alder reaction and the reaction of the olefin or diene with strongly nucleophilic anions. For example, the anion of malonic ester attacks diethyl citraconate at the β-position[12] and the ester of sorbic acid and of butadiene-1-carboxylic acid at the δ-carbon atom.[13] Analogously, it is the β-carbon atom of citraconic anhydride[3] and the δ-carbon atom of the two diene acids that bond to the terminal carbon atom of 1-vinylnaphthalene.

In connection with the study of the derivatives of phenylnaphthalenes, the absorption curves of 1-(1′-cyclohexenyl)-naphthalene and of 1-(1′-cyclopentyl)-naphthalene were recorded (Fig. 1). Calvin[14] had noticed a correlation between nonplanarity (as evidenced by steric inhibition of resonance in the ultraviolet spectra) and decreased reactivity of certain dienes in the Diels–Alder reaction. This effect may explain the low reactivity of 1-(1′-cyclohexenyl)-naphthalene[15] compared to the reactivity of 1-(1′-cyclopentenyl)-naphthalene,[16] for the absorption curves seem to indicate a lesser tendency for the cyclohexenyl derivative to be planar.

Experimental

1-Vinylnaphthalene and Acrylic Acid.—A mixture of 20 cc. of an 85% aqueous solution of acrylic acid,[17] 0.4 g. of hydroquinone and 3 cc. of 1-vinylnaphthalene (prepared by dehydration of β-1-naphthylethyl alcohol[2]) was refluxed for one hundred hours in an atmosphere of carbon dioxide. The clear brown gum was dissolved in aqueous potassium hydroxide, the solution was extracted with benzene, and the aqueous layer was acidified. The precipitated gum was evaporatively distilled up to 250° at 0.1 mm., and the distillate (2.68 g.) was again evaporatively distilled at 200° and 0.1 mm. Crystallization of the distillate from ethyl acetate gave 0.53 g. (12%) of **1,2,3,4-tetrahydrophenanthrene-1-carboxylic acid (I, R = H)**; m. p. 155–159°, which was raised to 159–161° by several recrystallizations.

Anal. Calcd. for $C_{15}H_{14}O_2$: C, 79.62; H, 6.24. Found: C, 79.48; H, 6.34.

Only 1.5% of the 1-vinylnaphthalene was accounted for as neutral homopolymer. A 6% yield of the acid (I, R =

H) was obtained from a solution of methyl acrylate in acetic acid that had been refluxed for six hours with 0.5 g. of *p*-toluenesulfonic acid. After the addition of 0.5 g. of sodium acetate, 1-vinylnaphthalene was added and the mixture was refluxed for two hundred hours.

Dehydrogenation of the Adduct.—A mixture of 55 mg. of I (R = H) and 30 mg. of sulfur was heated at 235–245° under nitrogen for fifteen minutes, and the product was separated into neutral and acidic fractions with alkali and benzene. The resulting phenanthrene-1-carboxylic acid (40 mg., m. p. 217–225°), after two recrystallizations from ethanol, had the m. p. 229–230° (reported, 232–233°,[18] 228°[19]); the m. p. of its methyl ester was not depressed when mixed with an authentic sample.

1-Vinylnaphthalene and Crotonic Acid.—A mixture of 1.5 cc. (0.01 mole) of 1-vinylnaphthalene, 4.3 g. (0.05 mole) of crotonic acid, and 0.2 g. of hydroquinone in 10 cc. of propionic acid was refluxed for two hundred hours under carbon dioxide. By means of alkali the product was separated into 1-vinylnaphthalene homopolymer (1.14 g. or 74%) and acidic material; the latter on evaporative distillation at 200° and 0.1 mm. yielded a colorless solid (0.63 g. or 26%; m. p. 151–158°), which was separated into the *cis* and *trans* forms of **2-methyl-1,2,3,4-tetrahydrophenanthrene-1-carboxylic acid (I, R = CH_3)** by numerous fractional recrystallizations from benzene. Both isomers formed colorless prisms; one (21% yield) with m. p. 156–157°, the other (5%) with m. p. 211–212°.

Anal. Calcd. for $C_{16}H_{16}O_2$: C, 79.97; H, 6.97; neut. equiv., 240. Found: (lower melting isomer) C, 79.91; H, 6.97; neut. equiv., 241; (higher melting isomer) C, 79.91; H, 6.78; neut. equiv., 241.

When the reaction was carried out in the presence of air, 5% of *p*-toluenesulfonic acid, 5% of *sym*-trinitrobenzene, or in pyridine as the solvent, only the homopolymer of 1-vinylnaphthalene was formed. The presence of 5% of picric acid or of water lowered the yield; the addition of hydroquinone had no effect.

The **methyl ester** of the 156–157° acid, formed in quantitative yield with diazomethane, crystallized from methanol in colorless prisms; m. p. 57–57.5°.

Anal. Calcd. for $C_{17}H_{18}O_2$: C, 80.29; H, 7.14. Found: C, 80.50; H, 7.38.

The ester yielded the original acid when refluxed with 20% aqueous-methanolic sodium hydroxide for twenty-four hours.

Degradation of the Adducts to 2-Methylphenanthrene.—To a solution of 240 mg. of the 156–157° acid in 5 cc. of 0.5 *N* sodium hydroxide was added 0.5 g. of calcium oxide. After thorough mixing, the mixture was evaporated and the residue was ground with 0.5 g. of calcium oxide. Dry distillation in a nitrogen atmosphere gave a liquid distillate, which was heated with 50 mg. of 5% palladium on charcoal catalyst under nitrogen. Evaporative distillation of the product at 150° and 0.01 mm. yielded 170 mg. of a colorless liquid which gave the picrate of 2-methylphenanthrene (56% yield based on the original acid); m. p. 115.5–116.5° (reported,[20] 118–119°). The hydrocarbon generated from the picrate had the m. p. 54.5–55.5° (reported,[20] 55–56°). In a similar manner, 42 mg. of the 211–212° acid yielded 22 mg. (66%) of 2-methylphenanthrene. When the methyl ester of the lower melting acid was heated with 5% palladium on charcoal under nitrogen at 310–320° for fifteen minutes, 2-methylphenanthrene was formed in 70% yield.

1-Vinylnaphthalene and β-Ethylacrylic Acid.—The unsaturated acid was prepared by the method of Auwers.[21] When the malonic acid was completely dissolved in the pyridine before the addition of the propionaldehyde, the yield of β-ethylacrylic acid was 59%; the yield was much lower when a small amount of piperidine[22] was added.

The reaction with 1-vinylnaphthalene, carried out in the manner described for crotonic acid, gave 28% of adduct and 68% of neutral homopolymer. After several recrystallizations from ethyl acetate, the **2-ethyl-1,2,3,4-tetrahydrophenanthrene-1-carboxylic acid (I, R = CH_3-CH_2)** had the m. p. 129.5–131°; yield, 18%.

Anal. Calcd. for $C_{17}H_{18}O_2$: C, 80.28; H, 7.13. Found: C, 80.22; H, 7.11.

By the procedure described for the methyl homolog, 2-ethylphenanthrene (52%; m. p. 52–55°) was obtained; after several recrystallizations from ethanol the hydrocarbon melted at 65–65.5° (reported,[23] 64–65°); m. p. of the picrate, 92–93.5° (reported,[23] 92–93°).

1-Vinylnaphthalene and Itaconic Acid.—The procedure was similar to that with crotonic acid except that 2.6 g. (0.02 mole) of itaconic acid[24] was used. After being poured into excess dilute potassium hydroxide, the mixture was heated for thirty minutes at 100° in order to hydrolyze anhydrides. Evaporative distillation of the acidic portion up to 200° at 0.1 mm. gave 1.41 g. of distillate, a solution of which in acetone–petroleum ether deposited 1.26 g. (47%) of **the anhydride of 1-carboxy-1,2,3,4-tetrahydrophenanthrene-1-acetic acid (II)**; m. p. 145.5–148°, raised by further recrystallization to 147.5–148°.

Anal. Calcd. for $C_{17}H_{14}O_3$: C, 76.68; H, 5.30. Found: C, 76.94; H, 5.40.

The diacid obtained by alkaline hydrolysis did not have a sharp melting point; at about 190° it changed to the anhydride. The **dimethyl ester of 1-carboxy-1,2,3,4-tetrahydrophenanthrene-1-acetic acid,** formed in nearly quantitative yield with diazomethane, crystallized from methanol–petroleum ether in large, glistening prisms; m. p. 60–62°.

Anal. Calcd. for $C_{19}H_{20}O_4$: C, 73.06; H, 6.45. Found: C, 72.84; H, 6.33.

The picrate of the dimethyl ester crystallized from methanol in yellow needles; m. p. 90.5–91.5°.

Degradation of the Adduct to 1-Methylphenanthrene.—A mixture of 100 mg. of II and 400 mg. of 5% palladium–charcoal catalyst was heated at 310–320° under nitrogen for fifteen minutes. The 1-methylphenanthrene obtained on distillation at 15 mm. crystallized from ethanol in glistening flakes (16 mg.); m. p. 119–119.5° alone and when mixed with an authentic sample. Of interest is the observation that the melting point (135–136°) of the picrate of 1-methylphenanthrene is not depressed by the picrate (m. p. 142–143°) of phenanthrene.

When less catalyst was used or when II was dry-distilled with soda-lime, the m. p. of the 1-methylphenanthrene could not be raised above 110°, although its picrate melted sharply at 135–136°.

1-Vinylnaphthalene and α-Bromoacrylic Acid.—The acidic adduct (from 2 g. of α-bromoacrylic acid, 1.5 cc. of 1-vinylnaphthalene, 10 cc. of acetic acid, fifty hours refluxing under nitrogen), after separation from the neutral homopolymer (1.14 g.), was evaporatively distilled up to 210° at 0.1 mm., and the solid distillate (0.4 g. or 18%, m. p. 194–204°) after several recrystallizations from ethanol gave colorless, glistening prisms of 3,4-dihydro-1-phenanthrenecarboxylic acid (III); m. p. 211–212° (reported,[25] 213–214°). The product immediately decolorized a solution of potassium permanganate in aqueous acetone.

Hydrogenation of the Unsaturated Acid.—A mixture of 95 mg. of 3,4-dihydrophenanthrene-1-carboxylic acid and 20 mg. of Adams catalyst in 15 cc. of ethanol was shaken for two hours under two atmospheres of hydrogen. The colorless needles of 1,2,3,4-tetrahydrophenanthrene-1-carboxylic acid (80 mg.) after recrystallization from aqueous ethanol melted at 157–159.5°, alone and when mixed with the adduct from acrylic acid.

1-Vinylnaphthalene and Aconitic Acid.—The reaction mixture (3 cc. 1-vinylnaphthalene, 7 g. aconitic acid, 20

cc. acetic acid, one hundred hours refluxing under nitrogen) was concentrated at 100° in a current of air and the acidic adduct was separated from the neutral homopolymer (2 g.) with alkali. The adduct was evaporatively distilled up to 270° at 0.1 mm.; addition of benzene to a solution of the distillate (1.07 g.) in hot ethyl acetate gave 0.86 g. (14%) of colorless prisms of the **anhydride of 1-carboxymethyl-1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic acid (IV)**; m. p. 215–219°, which was raised to 218–219° by recrystallization.

Anal. Calcd. for $C_{17}H_{12}O_5$: C, 68.91; H, 4.08. Found: C, 68.92; H, 4.48.

The **monomethyl ester** of the anhydride acid, formed with diazomethane in ether, crystallized from benzene–petroleum ether in colorless prisms; m. p. 178.5–179.5°.

Anal. Calcd. for $C_{19}H_{16}O_5$: C, 70.36; H, 5.00. Found: C, 70.61; H, 5.11.

The **trimethyl ester of 1-carboxymethyl-1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic acid,** formed from the triacid (obtained by alkaline hydrolysis of IV) and diazomethane in ether–methanol, crystallized from methanol in colorless prisms; m. p. 95–97°.

Anal. Calcd. for $C_{20}H_{20}O_6$: C, 68.09; H, 5.98. Found: C, 67.73; H, 5.97.

When a mixture of acetic acid (15 cc.) and acetic anhydride (5 cc.) was used as the solvent, the distilled product contained phenanthrene-1,2-dicarboxylic anhydride (V), isolated as yellow needles (1%, m. p. 304–306°) on recrystallization from acetone. This surprising result was checked repeatedly. When propionic acid was employed, the higher temperature caused decarboxylation of some of the aconitic acid to itaconic acid with the resultant formation of the itaconic acid adduct (II) in 14% yield in addition to the aconitic acid adduct (IV) in 8% yield.

Degradation of the Adduct from Aconitic Acid.—Palladium–charcoal treatment of the adduct in the manner described for II gave 1-methylphenanthrene (m. p. 115–116°) in 18% yield. After recrystallization from ethanol the hydrocarbon melted at 118–119°, alone and when mixed with an authentic specimen.

A mixture of 74 mg. of IV and 17.6 mg. of sulfur was heated at 310–320° under nitrogen for fifteen minutes and then sublimed under reduced pressure. Two recrystallizations from acetic anhydride gave 10 mg. (16%) of phenanthrene-1,2-dicarboxylic anhydride (V); m. p. 305–308°, alone and when mixed with an authentic specimen.

A solution of 0.1 g. of the anhydride acid (IV) and 0.3 g. of sodium hydroxide in 5 cc. of water was treated with calcium oxide and worked up as described for the itaconic acid adduct; yield of phenanthrene, 20 mg. (32%). The product obtained from the soda-lime pyrolysis before the treatment with palladium was chiefly phenanthrene.

1-Vinylnaphthalene and Chloromaleic Anhydride.—The cooled mixture (1.5 cc. of 1-vinylnaphthalene, 2.64 g. of chloromaleic anhydride, 10 cc. acetic acid, twenty-five hours refluxing under nitrogen) deposited 3,4-dihydrophenanthrene-1,2-dicarboxylic anhydride (VI, 1.12, g., m. p. 270–272°), which was separated mechanically from adhering brown powder and recrystallized from 40 cc. of acetic anhydride; yield, 1.01 g. (40%); m. p. 270–271°, alone and when mixed with an authentic sample.[26]

1-Vinylnaphthalene and Mesacon-β-amidic Acid.—From 1.55 g. of mesacon-β-amidic acid[27] 37% of evaporatively distilled adduct was obtained by the procedure used with crotonic acid. Recrystallization of the adduct from ethyl acetate gave 0.49 g. (19%) of colorless prisms of **1-methyl-1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic imide (VI)**; m. p. 209–212° which was raised to 211.5–212.5° by recrystallization.

Anal. Calcd. for $C_{17}H_{15}O_2N$: C, 76.96; H, 5.70; N, 5.28. Found: C, 77.06; H, 5.63; N, 5.26.

The same imide was formed by shaking 50 mg. of *cis*-1-methyl-1,2,3,4-tetrahydrophenanthrene-1,2-dicarboxylic anhydride[3] with 20 cc. of concentrated aqueous ammonia for five hours, acidifying the concentrated solution, and subliming the precipitate at 170° and 0.1 mm. Recrystallization of the sublimate from ethyl acetate gave the imide; m. p. 210–212°, alone and when mixed with the adduct described previously.

1-Vinylnaphthalene and *cis* and *trans* Ethyl β-Cyanocrotonate.—To the propionic acid solution of the adduct from 1.8 cc. of *cis*-ethyl β-cyanocrotonate[28] obtained by the procedure used with crotonic acid was added 5 cc. of concentrated hydrochloric acid and 5 cc. of acetic acid, and the mixture was refluxed for forty-eight hours. Evaporative distillation of the acidic fraction at 0.1 mm. and fractional crystallization of the distillate from ethyl acetate–petroleum ether and from benzene yielded 1-methyl-1,2,3,4-tetrahydrophenanthrene dicarboxylic anhydride (4.5%) and its imide (VI, 9.5%). Under similar conditions *trans*-ethyl β-cyanocrotonate[28] gave 10% of the anhydride and 7.5% of the corresponding imide (VI).

1-Vinylnaphthalene and Fumaronitrile.—By the procedure used in the preceding experiment, 0.41 g. of crystalline sublimate (m. p. 187–226°) was obtained from 1.56 g. of fumaronitrile; the chief product was copolymer (1.74 g.). Two recrystallizations of the sublimate from ethyl acetate gave 40 mg. (1.5%) of phenanthrene-1,2-dicarboxylic anhydride (V); m. p. 305–307°.

1-Vinylnaphthalene and Acetylenedicarboxylic Acid.—A solution of 1.55 cc. of 1-vinylnaphthalene, 2.28 g. of acetylenedicarboxylic acid, and 0.2 g. of hydroquinone in 20 cc. of dibutyl ether was kept at 100° under carbon dioxide for one hundred and fifty hours. The yellow precipitate was isolated and sublimed at 220° and 0.1 mm. and the sublimate (0.31 g.) was recrystallized from acetic anhydride; yield of phenanthrene-1,2-dicarboxylic anhydride (V), 0.2 g. (8%); m. p. 307.5–310°.

When the reaction was run in boiling acetic acid only copolymer was formed. The product obtained at room temperature in acetic acid was the phenanthrene derivative in low yield.

1-Vinylnaphthalene and Methyl Vinyl Ketone.—The ketone which separated on addition of excess potassium carbonate to 15 cc. of the 85% azeotrope[29] at 0° was decanted into a solution of 3 cc. of 1-vinylnaphthalene in 50 cc. of acetic acid, and the solution was refluxed under nitrogen for seventy hours. The viscous liquid (2 g., b. p. 112–185° at 0.1 mm.) obtained by fractional distillation formed yellow needles, presumably the **picrate of 1-acetyl-1,2,3,4-tetrahydrophenanthrene,** when treated with 1 g. of picric acid in 10 cc. of methanol; yield, 0.48 g. (5%); m. p. 90–91°.

Anal. Calcd. for $C_{16}H_{16}O \cdot C_6H_3N_3O_7$: C, 58.22; H, 4.22. Found: C, 58.12; H, 4.10.

1-Vinylnaphthalene and *p*-Benzoquinone.—The precipitate in the cooled mixture (6 cc. of 1-vinylnaphthalene, 24 g. of *p*-benzoquinone, 100 cc. of acetic acid, five hours at 100°) was collected and washed with three 10-cc. portions of acetic acid and two of ether; yield, 8.23 g. (78%); m. p. 200–207°. After several recrystallizations from acetic acid the glistening golden-bronze flakes of **1,4-chrysoquinone (VIII)** melted at 206.5–207.5°.

Anal. Calcd. for $C_{18}H_{10}O_2$: C, 83.71; H, 3.90. Found: C, 83.47; H, 4.15.

In an attempt to isolate the intermediate in the formation of 1,4-chrysoquinone, several solvents were tried; only in diethyl ether did the solution remain bright yellow. When the isolated yellow solid was heated in acetic acid, the solution became red and the golden flakes of 1,4-chrysoquinone crystallized.

1-Vinylnaphthalene and Butadiene-1-carboxylic Acid.—A solution of 3 g. of butadiene-1-carboxylic acid (prepared from acrolein and malonic acid[30]), 3 cc. of 1-vinylnaphthalene and 0.5 g. of hydroquinone in 20 cc. of acetic acid was

heated at 100° under nitrogen for two hundred hours, and then added with good stirring to 100 cc. of benzene. The clear solution which was decanted from the precipitated gum was washed well with dilute sodium sulfate solution and then extracted with 50 cc. of 5% aqueous potassium hydroxide. The acid obtained on acidification of the alkaline extract with acetic acid was evaporatively distilled up to 230° at 0.1 mm., and the distillate (1.6 g.) was crystallized from aqueous methanol. Repeated recrystallization of the prisms (1 g., m. p. 143–182°) from aqueous methanol gave 0.23 g. (5%) of the α adduct, probably **1-(1′-cyclohexenyl)-naphthalene-2′-carboxylic acid (XI, R = H)**; m. p. 180–185°. The highest m. p. obtained was 184–185°. This acid and most of the others were dried at 100° and 0.1 mm. for analysis.

Anal. Calcd. for $C_{17}H_{16}O_2 \cdot CH_3OH$: C, 75.53; H, 6.67. Found: C, 75.97; H, 6.24.

The β adduct was obtained by refluxing a solution of 9.5 g. of butadiene-1-carboxylic acid, 15 cc. of 1-vinylnaphthalene and 0.1 g. of hydroquinone in 100 cc. of propionic acid for two hundred hours under nitrogen. After removal of the solvent at 100° and 15 mm. the residue was stirred with 50 cc. of benzene, 150 cc. of water and 20 g. of sodium bicarbonate. The benzene layer was separated and extracted twice with 50 cc. of saturated sodium bicarbonate solution. Extraction with dilute aqueous potassium hydroxide followed by acidification of the extract gave an acid which was evaporatively distilled up to 210° at 0.1 mm.; crystallization of the distillate (3.58 g.) from ethanol gave massive prisms of the β adduct, probably **1-(3′-cyclohexenyl)-naphthalene-2′-carboxylic acid (X, R = H)**; yield, 1.35 g. with m. p. 135.5–136° and 0.11 g. with m. p. 133–134°.

Anal. Calcd. for $C_{17}H_{16}O_2$: C, 80.92; H, 6.39. Found: C, 80.62; H, 6.44.

Isomerization of the β-Adduct to the α-Adduct.—A solution of the β-adduct in 10% aqueous potassium hydroxide was kept at 100° for four days. Acidification and ether extraction gave the α adduct (m. p. 178–184°) in quantitative yield.

Dehydrogenation of the Adducts.—A mixture of 111 mg. of the α-adduct from butadiene-1-carboxylic acid and 30 mg. of sulfur was heated at 250–260° under nitrogen for twenty minutes, and then evaporatively distilled up to 220° at 0.1 mm. The acidic fraction, after purification through its salt, was dissolved in benzene–petroleum ether; slow evaporation of the solution gave 20 mg. (18%, m. p. 147–150°) of 1-phenylnaphthalene-2′-carboxylic acid. After two recrystallizations from methanol the acid melted at 154–155°, alone and when mixed with an authentic specimen prepared from diazotized methyl anthranilate and naphthalene.[31]

Formation of 3,4-Benzofluorene.—A solution of 370 mg. of the β-adduct from butadiene-1-carboxylic acid and 60 mg. of sodium hydroxide in 10 cc. of water was stirred at 100° with 1.8 g. of calcium oxide for five minutes and evaporated. The residue was ground with 1.8 g. of calcium oxide and heated under nitrogen with a free flame. The yellow distillate was heated with 30 mg. of 5% palladium–charcoal catalyst at 310–320° under nitrogen for ten minutes and evaporatively distilled up to 145° at 0.1 mm. The nearly colorless distillate (170 mg.) when treated with an equal weight of picric acid in ethanol gave 80 mg. of the picrate of 3,4-benzfluorene as red needles; m. p. 113–116°. Further recrystallization raised the m. p. to 120–123°, not depressed when mixed with an authentic specimen.[32] The hydrocarbon, generated from the picrate, after two recrystallizations from aqueous ethanol formed glistening flakes; m. p. 120–122° alone and when mixed with 3,4-benzfluorene.[32] There was excellent agreement in the ultraviolet absorption spectra of the two samples.

Anal. Calcd. for $C_{17}H_{12}$: C, 94.40; H, 5.60. Found: C, 94.42; H, 5.50.

1-Vinylnaphthalene and Sorbic Acid.—A solution of 10.5 g. of sorbic acid (prepared from crotonaldehyde and malonic acid[30]) and 11.3 cc. of 1-vinylnaphthalene in 50 cc. of propionic acid was refluxed under carbon dioxide for two hundred hours, and then worked up as described for X (R = H). The crystalline distillate (6.41 g.) obtained by evaporative distillation up to 240° at 0.1 mm. of the potassium hydroxide extracted material was triturated with benzene and with 30–60° alkanes, and the fine, colorless needles of the α adduct, probably **5′-methyl-1-(1′-cyclohexenyl)-naphthalene-2′-carboxylic acid (XI, R = CH_3)**, were collected; m. p. 175–178°. The acid was recrystallized from ethyl acetate or aqueous ethanol; m. p. 180–181°. Usually another crystalline modification crystallized in colorless prisms with m. p. 168–168.5°; when this was mixed with the 180–181° form, the mixture sintered at 168°, resolidified and melted at 181°. A similar result was obtained with a third modification which was obtained as long colorless needles with m. p. 160–161°.

Anal. Calcd. for $C_{18}H_{18}O_2$: C, 81.17; H, 6.8; neut. equiv., 266. Found: C, 80.82, 80.94; H, 6.83, 6.91; neut. equiv., 265.

The colorless crystals (0.73 g., m. p. 145–151°) recovered from the benzene and alkanes digestion appeared to be a mixture of the α- and β-adducts.

The β-adduct was obtained by refluxing a solution of 22.4 g. of sorbic acid and 15 cc. of 1-vinylnaphthalene in 100 cc. of acetic acid under nitrogen for one hundred and twenty hours. The solution was diluted with 200 cc. of benzene and 100 cc. of ether and extracted with three 200-cc. portions of dilute aqueous sodium sulfate, then with 130 cc. of saturated sodium bicarbonate solution (to remove sorbic acid), and finally with 200 cc. of 5% aqueous potassium hydroxide. Acidification of the last extract gave a gum which was rinsed well with water and heated with 200 cc. of ethanol. The cooled solution, after being filtered to remove some copolymer, yielded 5.81 g. of crystals (m. p. above 140°) which crystallized from ethanol–water in colorless prisms; yield 3.83 g.; m. p. 149.5–152° (which was depressed to 134–148° by the α adduct). The β adduct, probably **5′-methyl-1-(3′-cyclohexenyl)-naphthalene-2′-carboxylic acid (X, R = CH_3)**, crystallized from benzene–alkanes in colorless needle-like blades; m. p. 152.5–153.5°.

Anal. Calcd. for $C_{18}H_{18}O_2$: C, 81.17; H, 6.81. Found: C, 81.27; H, 6.86.

Additional β-adduct was isolated from the aqueous alcoholic filtrate; it was purified by evaporative distillation up to 210° at 0.1 mm. followed by recrystallization. The total yield of β-adduct was 14%. Both the α- and β-adducts showed typical naphthalenic absorption in the ultraviolet (Fig. 3). They decolorized permanganate rapidly at *p*H 10; neither showed any evidence of decomposition when heated to 250°.

Isomerization of the β-Adduct to the α-Adduct.—After a solution of the β-sorbic acid adduct in 10% aqueous potassium hydroxide had been kept at 100° for six days, acidification and ether extraction gave the α adduct in quantitative yield; m. p. 179–181°. After a single day's treatment a mixture of acids (m. p. 78–92°) was obtained.

Dehydrogenation of the Adducts to 5′-Methyl-1-phenylnaphthalene-2′-carboxylic Acid (XII, R = CH_3).—A mixture of 250 mg. of the adduct (α or β) and 70 mg. of sulfur was kept at 260–270° under nitrogen for forty-five minutes, and then evaporatively distilled up to 190° at 0.1 mm. After a separation from neutral material with alkali, the acidic portion was dissolved in ethanol–water; slow spontaneous evaporation to dryness gave yellowish granules (110 mg. or 44%, m. p. 164–169°), which were separated mechanically from a brittle gum. By recrystallization from benzene–alkanes and then from methanol the dehydrogenated acid was obtained as colorless needles; m. p. 174–174.5°.

Anal. Calcd. for $C_{18}H_{14}O_2$: C, 82.84; H, 5.38. Found: C, 82.80; H, 5.85.

Cyclization to 10-Methyl-7-oxo-7-benz(de)anthracene (XIV, R = CH_3).—A mixture of 60 mg. of 5′-methyl-1-

phenylnaphthalene-2'-carboxylic acid and 60 mg. of phosphorus pentachloride in 4 cc. of benzene was kept at 60° for thirty minutes; 300 mg. of aluminum chloride was added and the mixture kept at 60° for eight hours. The product was extracted from the hydrolyzed mixture with ether, the ether solution was washed with water and dilute alkali, the solvent was removed and a solution of the residue in 10 cc. of benzene was passed through a $^3/_8'' \times 12''$ alumina column. Development into a dark brown upper band, an orange-red middle band, and a yellow lower band was accomplished with benzene (100 cc.). Elution of the yellow band with hot ethanol yielded 10 mg. (18%) of yellow needles of 10-methyl-7-oxo-7-benz(de)anthracene; m. p. 155–157°. After one recrystallization the cyclic ketone melted at 157–158°, alone and when mixed with a sample prepared by the Scholl reaction from 1-naphthyl *p*-tolyl ketone,[33] but purified more efficiently by chromatographic adsorption than by recrystallization from ethanol alone.

Elution of the orange-red band with hot ethanol gave 3 mg. (5%) of orange-red blades (m. p. 155–156°), which may be the isomeric 6-methyl-3,4-benzfluorenone.

6-Methyl-3,4-benzfluorene (XIII, R = CH_3).—The reaction with 230 mg. of the adduct (α or β) from sorbic acid was carried out as described for 3,4-benzfluorene. The liquid (90 mg.) obtained by evaporative distillation gave 30 mg. of deep red needles of the **picrate of 6-methyl-3,4-benzfluorene** in alcohol; m. p. 116–116.5°, raised to 119–120.5° by recrystallization.

Anal. Calcd. for $C_{18}H_{14}\cdot C_6H_3N_3O_7$: N, 9.17. Found: N, 9.14.

The hydrocarbon, generated from the picrate, crystallized from ethanol in glistening colorless flakes; m. p. 72–72.5°. Its absorption curve (Fig. 1) agrees with that of 3,4-benzfluorene. The *sym*-**trinitrobenzene complex** crystallized from ethanol in fine, yellow needles; m. p. 147.5–148.5°.

Anal. Calcd. for $C_{18}H_{14}\cdot C_6H_3N_3O_6$: C, 65.16; H, 3.87; N, 9.50. Found: C, 65.52; H, 3.50; N, 9.48.

Hydrogenation, Oxidation, and Bromination of the α-Adduct.—A solution of 110 mg. of the adduct in 15 cc. of ethanol and 1 cc. of acetic acid (necessary for reaction) with 30 mg. of platinum oxide catalyst absorbed a mole of hydrogen in one hour. Crystallization of the product from ethyl acetate gave 20 mg. of colorless needles; m. p. 201–202.5°, raised to 202–202.5° by recrystallization from ethanol–water. The analysis corresponds to a **tetrahydro derivative** of the adduct.

Anal. Calcd. for $C_{18}H_{22}O_2$: C, 79.96; H, 8.15. Found: C, 79.58; H, 8.02.

The ultraviolet absorption curve corresponded to a benzenoid system without conjugation with a double bond. The acid slowly decolorized permanganate in aqueous acetone.

A solution of 130 mg. of the α adduct and 1.3 g. of potassium permanganate in 50 cc. of water was kept at 100° for six hours. The manganese dioxide was removed by filtration and washed with water, and the filtrate was acidified and evaporated to dryness. Sublimation at 200° in a slow current of air gave 30 mg. of sublimate which after trituration with water yielded 15 mg. (20%) of phthalic anhydride (m. p. 127.5–128.5°), identified by mixed m. p. and through its imide and anilide. Oxidation with potassium dichromate in acetic acid likewise gave phthalic acid.

A crystalline bromo derivative was obtained in one experiment. A solution of 266 mg. of α adduct, 1 cc. of thionyl chloride and a drop of pyridine was allowed to stand for six hours. After removal of the excess thionyl chloride at 15 mm., bromine (0.2 g.) was added. After six hours the mixture was heated with aqueous alkali and the acidic product was sublimed at 0.1 mm., and recrystallized several times from aqueous ethanol; yield of colorless needles, 190 mg. (55%); m. p. 201°, raised to 208–209° by further recrystallization. The compound is considered to be **4-bromo-5'-methyl-1-(1'-cyclohexenyl)-naphthalene-2'-carboxylic acid,** for the absorption curve indicated the presence of the bromine on the naphthalene ring.

Anal. Calcd. for $C_{18}H_{17}O_2Br$: C, 62.62; H, 4.96. Found: C, 62.20; H, 4.90.

1-Vinylnaphthalene and Muconic Acid.—A mixture of 8.5 g. of muconic acid (prepared from α,α'-dibromoadipic acid and alkali[34]), 7.5 cc. of 1-vinylnaphthalene and 0.2 g. of hydroquinone in 300 cc. of propionic acid was refluxed under carbon dioxide for two hundred hours. The chilled solution was filtered from unchanged muconic acid and evaporated at 100° and 25 mm. The residue was warmed with 100 cc. each of benzene and water and an excess of sodium bicarbonate, the layers were separated and the benzene solution extracted again with 50 cc. of saturated sodium bicarbonate solution. The gum obtained on acidification of the aqueous extracts was heated with 150 cc. of methanol containing 1 g. of benzenesulfonic acid hydrate for eighteen hours. After the addition of sodium acetate and the removal of the methanol, acidic material was removed with alkali, and the dimethyl ester of the adduct was evaporatively distilled up to 205° at 0.1 mm.; yield, 9.73 g. Treatment of the acidic fraction with diazomethane, followed by evaporative distillation yielded an additional 0.42 g. of the ester; total yield, 10.15 g.

A solution of the ester in 50 cc. of benzene was added to an alumina column, $^1/_2'' \times 24''$; the first 10 cc. of eluate contained practically no product; the next 30 cc. contained 6.38 g. of colorless oil, which was hydrolyzed by heating with 30 cc. of acetic acid and 15 cc. of concentrated hydrochloric acid at 100° for twenty-four hours. After several recrystallizations of the product from acetic acid, 3.13 g. (19%) of the β-adduct, probably **1-(3'-cyclohexenyl)-naphthalene-2',5'-dicarboxylic acid** (X, R = COOH), containing one-half mole of acetic acid of crystallization was obtained as colorless, granular crystals; m. p. 271–274°, raised to 274–275° by further recrystallization. The acetic acid is not removed at 65° and 0.1 mm.

Anal. Calcd. for $2(C_{18}H_{16}O_4)\cdot CH_3COOH$: C, 69.92; H, 5.56; neut. equiv., 130. Found: C, 70.06; H, 5.68; neut. equiv., 126.

When the compound is heated to 150° the acetic acid is eliminated.

Anal. Calcd. for $C_{18}H_{16}O_4$: C, 72.96; H, 5.44; neut. equiv., 148. Found: C, 72.75; H, 5.56; neut. equiv., 147, 149.

When the residues from the β-adduct were recrystallized from acetone–ethyl acetate, 0.27 g. of the α adduct, probably **1-(1'-cyclohexenyl)-naphthalene-2',5'-dicarboxylic acid** (XI, R = COOH) was obtained; m. p. 275–275.5° (depressed to 248–256° by the β adduct). The α adduct crystallized from acetic acid with one mole of acetic acid that was not lost at 65° and 0.1 mm.

Anal. Calcd. for $C_{18}H_{16}O_4\cdot CH_3COOH$: C, 67.40; H, 5.65. Found: C, 67.77; H, 5.65.

Both adducts are little soluble in most solvents except hot ethanol and acetic acid. They sublime unchanged at 180–210° and 0.1 mm. and show no evidence of decomposition even at 300°. Decolorization of permanganate is slow in aqueous acetone but is rapid in aqueous solution at *p*H 10. The absorption curves (Fig. 3) are nearly identical with the curve for naphthalene.

In addition to the adducts described above 0.01 g. of 1-phenylnaphthalene-2',5'-dicarboxylic acid (XII, R = COOH; m. p. 299–301°) was isolated. This result showed that some dehydrogenation took place.

Isomerization of the β-Adduct to the α-Adduct.—The dimethyl ester, prepared from 1 g. of the β adduct and diazomethane in methanol–ether followed by removal of the solvents, was added to a suspension of sodium methoxide (prepared from 0.3 g. of sodium) in 15 cc. of dry benzene, and the mixture was refluxed for five hours. After the addition of acetic acid to the cooled mixture, the benzene solution was washed with bicarbonate solution

(33) Fieser and Martin, THIS JOURNAL, **58**, 1443 (1936).

(34) Ingold, *J. Chem. Soc.*, 952 (1921).

and evaporated. Hydrolysis of the ester by refluxing with 10 cc. of acetic acid and 5 cc. of concentrated hydrochloric acid for twelve hours gave the acid from which 0.29 g. of the α adduct (m. p. 274–275°) was obtained by recrystallization from acetic acid.

Dehydrogenation of the Adducts to 1-Phenylnaphthalene-2',5'-dicarboxylic Acid (XII, R = COOH).—The dimethyl ester (from 0.45 g. of the β-adduct) and 50 mg. of 5% palladium–charcoal catalyst was heated under nitrogen at 310–320° for thirty minutes. The product obtained by evaporative distillation up to 190° at 0.1 mm. was heated with 8 cc. of acetic acid and 4 cc. of concentrated hydrochloric acid at 100° for twenty-four hours. Crystallization of the isolated diacid from 3 cc. of acetic acid gave 0.1 g. (22%) of cream-colored granules of XII (R = COOH); m. p. 304–304.5°, raised to 304.5–305° by further recrystallization.

Anal. Calcd. for $C_{18}H_{12}O_4$: C, 73.97; H, 4.13. Found: C, 73.43; H, 4.04.

The diacid failed to decolorize permanganate even at a *p*H of 10.

A mixture of 0.45 g. of sulfur and 2.07 g. of the dimethyl ester of the crude adducts (part of the 10.15 g.) was heated at 250–260° under nitrogen for fifty minutes and evaporatively distilled up to 220° at 0.1 mm. A solution of the distillate in 40 cc. of acetic acid and 20 cc. of concentrated hydrochloric acid was refluxed for fifty hours, concentrated to 20 cc. and cooled, whereupon 1.1 g. (58%, or 36% based on 1-vinylnaphthalene) of 1-phenylnaphthalene-2',5'-dicarboxylic acid (m. p. 299–301°) precipitated.

When the crude dimethyl ester was heated with palladium, a 16% yield of XII (R = COOH) was obtained; in addition, 9% of a new diacid (colorless needles from ethyl acetate–benzene) was isolated; m. p. 242–244.5°, raised to 247.5–248° by further recrystallization. The diacid does not decolorize permanganate even at *p*H 10; its analysis corresponds to that of **1-cyclohexylnaphthalene-2,5'-dicarboxylic acid.**

Anal. Calcd. for $C_{18}H_{18}O_4$: C, 72.47; H, 6.08. Found: C, 72.42; H, 6.34.

Decarboxylation of 1-Phenylnaphthalene-2',5'-dicarboxylic Acid.—A mixture of 0.2 g. of the acid, 0.2 g. of copper bronze, and 0.6 g. of barium hydroxide octahydrate was thoroughly mixed and dry-distilled. After the removal of water in the distillate by reduced pressure, the nearly colorless liquid (100 mg.) was dissolved in 0.5 cc. of acetic acid and treated with 0.2 cc. of 100% nitric acid in 0.5 cc. of acetic acid. After two hours, seeding induced immediate crystallization of 4-nitro-1-phenylnaphthalene (23 mg., m. p. 121–124°); after one recrystallization from ethanol it melted at 124–125°, alone and when mixed with a sample (m. p. 124–126°) prepared by the method of Weiss and Woidlich,[35] who report a m. p. of 132°.

10-Carbomethoxy-7-oxo-7-benz(de)anthracene (XV, R = $COOCH_3$).—A solution of 100 mg. of 1-phenylnaphthalene-2',5'-dicarboxylic acid in 3 cc. of acetic anhydride was refluxed for one hour. The acetic anhydride was removed slowly by distillation, the temperature was raised to 300°, and the pressure was lowered to 0.1 mm. After two hours at 320°, sublimation was complete. The yellow-orange crystals (60 mg. or 64%, m. p. 285–298°) were converted to the methyl ester by diazomethane and a solution of the ester in benzene was passed through an alumina column, where it was developed with benzene (400 cc.). Elution of the yellow band with hot methanol gave 7 mg. of bright yellow needles of XV (R = $COOCH_3$); m. p. 168–169° (reported,[36] 167–168°). Cyclization of 100 mg. of the acid with 10 cc. of anhydrous hydrogen fluoride at 25° gave similar results.

Dimerization of 1-Vinylnaphthalene.—A solution of 10 cc. of 1-vinylnaphthalene in 67 cc. of propionic acid was refluxed under nitrogen for two hundred hours. The chilled solution was filtered from precipitated gum, the propionic acid was removed under reduced pressure, and a solution of the residue in 50 cc. of benzene was passed through a 30" × 1/2" column of alumina and followed with more benzene. The first 50 cc. was collected and evaporated, and the residue was evaporatively distilled at 160–240° and 0.1 mm. The colorless crystalline distillate (2.16 g. or 21%; m. p. 140–145°) of **1-(1'-naphthyl)-1,2,3,4-tetrahydrophenanthrene** (XVI) was recrystallized from benzene–ethanol; m. p. 147–148°.

Anal. Calcd. for $C_{24}H_{20}$: C, 93.46; H, 6.54; mol. wt., 308. Found: C, 93.34; H, 6.44; mol. wt. (Rast method), 325.

1-(1'-Naphthyl)-phenanthrene.—A mixture of 100 mg. of the tetrahydro compound and 25 mg. of sulfur was heated in a narrow tube at 240–250° for fifteen minutes; the sides of the tube were washed down with a few drops of acetone and the process repeated. The product obtained by evaporative distillation up to 250° at 15 mm. was dissolved in acetone and heated with 0.5 g. of zinc dust. After removal of the zinc, a little ethanol was added and the solution was concentrated by boiling on a steam-bath. On cooling 25 mg. of 1-(1'-naphthyl)-phenanthrene crystallized in glistening, colorless blades; m. p. 113–115°, raised to 115–116.5° by further recrystallization. The second crop (60 mg., m. p. 112–115°) was converted to the picrate, which was recrystallized from ethanol; m. p. 135–136°.

The hydrocarbon and its picrate were identical with those prepared from 2 g. of 1-keto-1,2,3,4-tetrahydrophenanthrene and 1-naphthylmagnesium bromide.[37] The carbinol, which was not obtained crystalline, was dehydrated when heated at 200° and above under reduced pressure and evaporatively distilled. The resulting **1-(1'-naphthyl)-3,4-dihydrophenanthrene** crystallized from alcohol–acetone in colorless plates or hexagonal prisms, yield, 0.6 g.; m. p. 134–134.5°. The hydrocarbon gives a blue color with concentrated sulfuric acid.

Anal. Calcd. for $C_{24}H_{18}$: C, 94.1; H, 5.9. Found: C, 94.4; H, 5.9.

The 1-(1'-naphthyl)-phenanthrene, obtained in 80% yield by treatment of the dihydro derivative with palladium-charcoal at 320° for one-half hour, crystallized from alcohol–acetone in colorless plates; m. p. 117.5–118°.

Anal. Calcd. for $C_{24}H_{16}$: C, 94.7; H, 5.3. Found: C, 94.5; H, 5.2.

The picrate crystallized from absolute ethanol in light orange plates; m. p. 135.5–136°.

Anal. Calcd. for $C_{24}H_{16}\cdot C_6H_3N_3O_7$: N, 7.9. Found: N, 7.9.

Summary

1-Vinylnaphthalene reacted as the diene component in the Diels–Alder reaction with twelve olefinic dienophiles. The adducts were derivatives of 1,2,3,4-tetrahydrophenanthrene except in two examples in which the adduct was dehydrogenated to the phenanthrene derivative during the reaction.

With two olefinic dienophiles containing an α-halogen atom, the halogen acid was eliminated during the reaction with the formation of a dihydrophenanthrene derivative. The single acetylenic dienophile that was tried gave a phenanthrene derivative.

1-Vinylnaphthalene acted as the dienophile component with three diene acids and gave 1-cyclohexenylnaphthalene compounds, representing a new synthesis of partially hydrogenated biaryl acids as well as the first unequivocal examples of the combination of an electrophilic diene and a nucleophilic dienophile.

1-Vinylnaphthalene acted both as diene and dienophile in undergoing a Diels–Alder type of dimerization to 1-(1′-naphthyl)-1,2,3,4-tetrahydrophenanthrene.

The results of the reactions have added support to current electronic interpretations of the Diels–Alder reaction.

The Preparation and Proof of Structure of 1,2:5,6-Dicyclohexylidene-D-glucofuranose[1]

BY ROBERT C. HOCKETT,[2] ROBERT ELLSWORTH MILLER[3] AND ALLEN SCATTERGOOD

Acetone is the only ketone whose reaction products with D-glucose have been fully characterized and determined structurally.[4] The products of the reaction, the water-soluble and non-reducing "monoacetoneglucose" and "diacetoneglucose" have been unequivocally shown to be 1,2-isopropylidene-D-glucofuranose and 1,2:5,6-diisopropylidene-D-glucofuranose, respectively.[5]

We have now found that the acid-catalyzed condensation of D-glucose with cyclohexanone forms a crystalline non-reducing dicyclohexylidene-glucose (I) which, in contrast to "diacetoneglucose," is water-insoluble. A 14-experiment yield study in which the variables were mole ratio of cyclohexanone to glucose, sulfuric acid concentration, and time, indicated that the best crude yield that could be secured under anhydrous conditions at room temperature was about 40%.

Structure

One hydroxyl group was shown to be present in I by the preparation in crystalline form of a monobenzoate (IIa), a benzenesulfonate (IIb) and a *p*-toluenesulfonate (tosylate, IIc). We were unable to secure the acetylation product or the methylation product of I in the crystalline condition. The preparation of these monoesters of non-reducing I showed that four of the five hydroxyl groups of a hemiacetal form of the D-glucose were blocked, probably by the formation of two heterocyclic rings. When compound IIb was heated under reflux with sodium iodide in acetic anhydride, practically no insoluble sodium benzenesulfonate was formed. This indicated that the benzenesulfonate group of IIb would undergo a displacement reaction only with considerable difficulty. In the absence of a neighboring hydroxyl group, an arylsulfonate group reluctant to undergo a displacement reaction is usually considered to be attached to a secondary carbon atom[6] or to have the back side approach of the replacing group blocked.[7] Thus it seemed probable that the hydroxyl group of I was on a ring which was blocked by other attached groups so that the approach of a replacing group was made difficult.

The location of the hydroxyl group of I was ascertained by an acid-catalyzed methanolysis of tosylate IIc followed by an acetylation of the sirupy product (III). Crystalline methyl 3-tosyl-2,4,6-triacetyl-β-D-glucopyranoside (IV) resulted, and demonstrated that carbon atom number three of I was the site of the hydroxyl group. Compound IV had previously been obtained by Peat and Wiggins[8] through a similar series of reactions starting with 1,2:5,6-diisopropylidene-D-glucofuranose (diacetoneglucose).

The location and size of the acetal rings of I was determined by the discovery that one of the two cyclohexylidene groups of I could be removed selectively. Controlled acid-catalyzed methanolysis of I gave a non-reducing crystalline monocyclohexylidene-D-glucose (V). Product V, obtained in good yield, could readily be recrystallized from water in contrast to 1,2-isopropylidene-D-glucofuranose ("monoacetone-glucose") which is very soluble in water.

The benzoylation of V gave a crystalline tribenzoate (VI) demonstrating the presence of three hydroxyl groups in V. The acid-catalyzed hydrolysis of VI gave 3,5,6-tribenzoyl-D-glucofuranose (VII) previously obtained by Fischer and Rund[9] from 1,2-isopropylidene-D-glucofuranose ("monoacetoneglucose"). Compound VII was isolated as its carbon tetrachloride addition product first observed by Fischer.

(9) Fischer and Rund, *Ber.*, **49**, 88 (1916).

The isolation of VII from VI indicated that the three benzoyl groups in VI and thus the three hydroxyl groups in V are in the 3, 5 and 6 positions. Since V was obtained by the removal of one cyclohexylidene residue from I (which had previously been shown to contain one hydroxyl group in position 3) the two hydroxyl groups thus liberated (positions 5 and 6) must be the site of one of the cyclohexylidene residues.

Since V is non-reducing the aldehyde group originally present at carbon atom number one in the glucose molecule must be blocked in some manner. Positions 2 and 4 must also be blocked since it has been demonstrated above that V has only three hydroxyl groups which are located on carbon atoms 3, 5 and 6. The most probable explanation for the blocking of positions 1, 2 and 4 in V is the presence of two heterocyclic rings involving these three positions. Of the structures that can be written for such a monocyclohexylideneglucose the one most probable is 1,2-cyclohexylidene-D-glucofuranose, V. Thus I becomes 1,2:5,6-dicyclohexylidene-D-glucofuranose.

Two other possibilities remain to be considered. They are (1) the inversion of the configuration of one or more of the asymmetric carbon atoms of the glucose molecule and (2) the wandering of a tosyl group or acetal ring during one or more of the reactions carried out. Results of parallel experiments under similar conditions conducted by many other workers on reactions of 1,2:5,6-diisopropylidene-D-glucofuranose make both of these possibilities unlikely.

Determination of the position of the hydroxyl group in 1,2:5,6-dicyclohexylidene-D-glucofuranose is shown in I, IIc, III, IV; preparation and structure determination of 1,2-cyclohexylidene-D-glucofuranose in I, V, VI, VII.

Experimental

1,2:5,6-Dicyclohexylidene-D-glucofuranose, I.—Anhydrous D-glucose (45 g., 0.25 mole, Merck reagent grade) was added to a mixture of cyclohexanone (100 ml., 1 mole, du Pont commercial grade) and concentrated sulfuric acid (6.5 ml., d. 1.84) and the reaction mixture was shaken at room temperature for twelve hours. Commercial *n*-heptane (250 ml.) was then added and the mixture was heated until the solids had dissolved and two liquid layers had formed. The *n*-heptane layer was decanted from the dark oily layer, allowed to cool and then refrigerated. The product (36.8 g., 43.2%) crystallized overnight. It softened at 105° (uncor.) and melted at 109–113° (uncor.). The compound was recrystallized from methylcyclohexane (6 ml./g.) and then from *n*-heptane (20 ml./g.) to give a product which melted at 131.4–132.4° (cor.) and showed a rotation in alcohol $[\alpha]^{31}D$ −2.20° (*c*, 2.27) (0.5683 g. in 25 ml. solution gave α −0.10° in a 2-dcm. tube). The rotation in chloroform was $[\alpha]^{31}D$ + 1.65° (*c*, 2.10) (1.0509 g. in 50 ml. of solution gave α + 0.14° in a 4-dm. tube). The compound is soluble in acetone, alcohol, chloroform, benzene and methyl "cellosolve." It is soluble in warm isobutanol, hot *n*-heptane and hot methylcyclohexane but is insoluble in water. It does not reduce hot Fehling solution.

Anal. Calcd. for $C_{18}H_{28}O_6$: C, 63.51; H, 8.29. Found: C, 63.36; H, 8.13.

3-Benzoyl-1,2:5,6-dicyclohexylidene-D-glucofuranose, IIa.—1,2:5,6-Dicyclohexylidene-D-glucofuranose (6.8 g., 0.02 mole) was added to a mixture of benzoyl chloride (3.7 g., 0.026 mole, Hooker Chemical Company) in anhydrous pyridine (10 ml., 0.124 mole). The reaction mixture was chilled until the initial heat evolution had dissipated. After standing at room temperature for three days the mixture was chilled, cold water (10 ml.) was added with chilling and shaking and the turbid solution was refrigerated. An oil separated which did not crystallize. The oil was extracted with chloroform (100 ml.) and water was bubbled through the chloroform solution overnight. The chloroform layer was removed, dried over granular calcium chloride and then concentrated under reduced pressure at 45–50° to a thick, yellow sirup. This sirup was dissolved in hot methanol (50 ml.) and the solution was allowed to cool to room temperature. An oil formed which upon standing and scratching with a glass rod crystallized. This product (5.20 g., 58.5%) melted at 109–110.3° (uncor.). The compound was recrystallized from *n*-heptane (5 ml./g.) and then from methanol (8 ml./g.) to a product which melted at 111.2–112.2° (cor.) and showed a rotation in chloroform $[\alpha]^{26}D$ −37.0° (*c*, 1.2) (0.6210 g. in 50 ml. of solution gave α −0.92° in a 2-dm. tube). The substance is soluble in acetone and chloroform, slightly soluble in methanol, methyl "cellosolve" and alcohol. It is soluble in warm *n*-heptane and warm isobutanol but is insoluble in water.

Anal. Calcd. for $C_{25}H_{32}O_7$: C, 67.54; H, 7.26. Found: C, 67.14; H, 7.59.

3-Benzenesulfonyl-1,2:5,6-dicyclohexylidene-D-glucofuranose, IIb.—Benzenesulfonyl chloride (14 ml., 0.109 mole, Eastman Kodak Company, "Eastman" grade) was added in one portion to a solution of 1,2:5,6-dicyclohexylidene-D-glucofuranose (34.0 g., 0.1 mole) in anhydrous pyridine (50 ml., 0.62 mole). A heat evolution was not observed. After being shaken at room temperature overnight the reaction mixture was chilled; cold water (50 ml.) was added slowly with shaking and the turbid solution was refrigerated. A sirup formed which did not crystallize. The liquid layer was decanted and discarded. The sirup was triturated with six portions (25 ml. each) of cold water and these water washings were discarded. The residue was dissolved in warm absolute alcohol (100 ml.), decolorized with charcoal and filtered. The clear filtrate upon refrigeration gave a product (24 g., 50%) melting at 90–92° (uncor.). Concentration of the mother liquor gave a second crop of 7.14 g. (total yield 65%). The product after recrystallization from *n*-heptane (2.5 ml./g.) and then from absolute alcohol (5 ml./g.) melted at 94.6–95.4° (cor.) and showed a rotation in chloroform $[\alpha]^{28}D$ −61.4° (*c*, 1.71) (0.8585 g. in 50 ml. of solution gave α −2.11° in a 2-dm. tube). The compound is soluble in acetone and chloroform. It is soluble in warm alcohol, warm isobutanol, warm methyl "cellosolve" and hot *n*-heptane but is insoluble in water.

Anal. Calcd. for $C_{24}H_{32}O_8S$: C, 59.98; H, 6.71; S, 6.67. Found: C, 59.80; H, 6.79; S, 6.63.

Attempted Replacement of the Benzenesulfonate Group in 3-Benzenesulfonyl-1,2:5,6-dicyclohexylidene-D-glucofuranose, IIb.—A solution of 3-benzenesulfonyl-1,2:5,6-dicyclohexylidene-D-glucofuranose (1.20 g., 0.0025 mole) and sodium iodide (0.5 g., 0.0034 mole, Merck reagent grade) in acetone (25 ml.) was boiled under reflux for three days. No precipitate was formed.

A solution of 3-benzenesulfonyl-1,2:5,6-dicyclohexylidene-D-glucofuranose (1.20 g.) and sodium iodide (0.5 g.) in acetic anhydride (25 ml.) was heated under reflux for twenty-four hours. The reaction mixture became very black but only a negligible amount of a precipitate formed.

3-*p*-Toluenesulfonyl-1,2:5,6-dicyclohexylidene-D-glucofuranose, IIC.—1,2:5,6-Dicyclohexylidene-D-glucofuranose (6.80 g., 0.02 mole) was added to a solution of *p*-toluenesulfonyl chloride (4.8 g., 0.025 mole, Eastman Kodak Company, "Eastman" grade) in anhydrous pyridine (10 ml., 0.124 mole). The solid immediately dissolved without any heat evolution. After being shaken at room temperature for ten days the reaction mixture was chilled; cold water (10 ml.) was added slowly with chilling and shaking and the resultant turbid solution was refrigerated. A white sirup formed which did not crystallize. The liquid layer was decanted and discarded. The sirup was triturated with three portions (20 ml. each) of cold water and these washings were discarded. The residue was dissolved in chloroform (150 ml.) and water was bubbled through the chloroform solution overnight. The chloroform layer was dried over granular calcium chloride and then concentrated under reduced pressure to a sirup. This residue was dissolved in warm methanol (50 ml.) and the methanol solution was allowed to stand in an open beaker overnight. A crystalline product (7.5 g., 75.8%) of m. p. 88.5–90° (uncor.) was thus obtained. The compound was alternately recrystallized from isobutanol (4 ml./g.) and from *n*-heptane (7 ml./g.) to a constant m. p. of 89.7–91.1° (cor.) and then showed a rotation in chloroform $[\alpha]^{26}D$ −67.6° (*c*, 0.18) (0.0924 g. in 50 ml. of solution gave α −0.50° in a 4-dm. tube). The compound is soluble in acetone and chloroform; slightly soluble in ethyl acetate and methyl "cellosolve." It is soluble in hot alcohol, hot *n*-heptane and hot 80% alcohol but is insoluble in water.

Anal. Calcd. for $C_{25}H_{34}O_8S$: C, 60.71; H, 6.93; S, 6.48. Found: C, 60.41; H, 7.20; S, 6.48.

Conversion of 3-*p*-Toluenesulfonyl-1,2:5,6-dicyclohexylidene-D-glucofuranose, IIc, to Methyl 3-*p*-Toluenesulfonyl-2,4,6-triacetyl-D-glucopyranoside, IV.—3-*p*-Toluenesulfonyl-1,2:5,6-dicyclohexylidene-D-glucofuranose (19 g., 0.038 mole) was dissolved in warm, anhydrous methanol containing hydrogen chloride (500 ml., 1.97 g. hydrogen chloride/100 ml. solution). The reaction mixture was refluxed under a water-cooled condenser, protected from the atmosphere by a calcium chloride drying tube, until a constant angular rotation was observed (approximately twenty-seven hours). The light yellow solution was then neutralized with excess silver carbonate and filtered. The residue was washed with four portions of methanol (50 ml. each) and discarded. The filtrate and washings were combined and concentrated under reduced pressure to a sirup. The sirup was dissolved in chloroform and some residual silver *p*-toluenesulfonate was removed by filtration. The chloroform filtrate was then concentrated under reduced pressure at 45° to a thick sirup. The sirup was dissolved in a hot mixture of acetic anhydride (200 ml.) and anhydrous sodium acetate (15 g.) The reaction mixture was heated at 85–90° on a steam-bath for three hours and was then poured into a vigorously stirred mixture of ice and water (1 liter). An oil separated which did not crystallize. The mixture was extracted with four portions of chloroform (50 ml. each) and the combined chloroform extracts were concentrated to a thin sirup under reduced pressure at 50°. The sirup was dissolved in anhydrous benzene (50 ml.) and the resulting solution was concentrated under reduced pressure to a thick sirup. Ether was added (50 ml.); the sirup slowly dissolved and a crystalline material soon began to appear. Refrigeration gave 4.7 g. (26.2%) of product melting at 131–132° (uncor.). After several recrystallizations from methanol the product melted at 135.5–137° (cor.) and showed a rotation in chloroform $[\alpha]^{25}D$ −18.6° (*c*, 0.6), (0.1513 g. in 25 ml. of solution gave α −0.45° in a 4-dm. tube).

Anal. Calcd. for $C_{20}H_{26}O_{11}S$: C, 50.62; H, 5.52; S, 6.76. Found: C, 50.49; H, 5.57; S, 6.77.

An authentic sample of methyl 3-*p*-toluenesulfonyl-2,4,6-triacetyl-D-glycopyranoside, IV, was obtained from Dr. L. F. Wiggins. His sample melted at 135–135.5° (cor.). A mixture of his sample and our product melted at 135–136° (cor.).

Acid-catalyzed Methanolysis of 1,2:5,6-Dicyclohexylidene-D-glucofuranose, I.—1,2:5,6-Dicyclohexylidene-D-glucofuranose (3.4034 g., 0.01 mole) was dissolved in commercial methanol (45 ml.) in a 50-ml. volumetric flask.

Methanolic hydrogen chloride (1.12 *N*, 0.45 ml.) was added and the reaction mixture was immediately diluted to the mark with commercial methanol. (The reaction mixture was 0.20 molar in 1,2:5,6-dicyclohexylidene-D-glucofuranose and 0.01 *N* in hydrogen chloride.) The reaction mixture was thoroughly mixed; transferred to a 2-dm. polarimeter tube and the reaction was followed polarimetrically. The curve (angular rotation *versus* time) is plotted on Fig. 1.

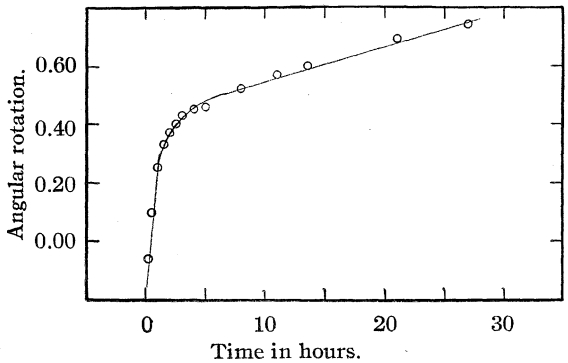

Fig. 1.—Acid-catalyzed methanolysis of 1,2:5,6-dicyclohexylidene-D-glucofuranose: 0.2 molar in dicyclohexylidene-D-glucose, 0.01 molar in hydrogen chloride.

1,2-Cyclohexylidene-D-glucofuranose, V.—1,2:5,6-Dicyclohexylidene-D-glucofuranose (68 g., 0.2 mole) was dissolved in commercial methanol (980 ml.) in a one-liter volumetric flask and methanolic hydrogen chloride (1.12 *N*, 9.0 ml.) was then added. The reaction mixture was diluted to the mark with methanol and allowed to stand at room temperature for four hours. (The reaction mixture was 0.2 molar in 1,2:5,6-dicyclohexylidene-D-glucofuranose and 0.01 *N* in hydrogen chloride. These are the same concentrations as those used in following the reaction polarimetrically.) Excess solid sodium bicarbonate was added and then 10% aqueous sodium hydroxide until the mixture became alkaline to litmus. The solution was filtered and the filtrate was concentrated under reduced pressure at 45–50° to a thick, sirupy-solid mass. Water (100 ml.) and *n*-heptane (200 ml.) were added and the mixture was heated until two clear liquid layers were obtained. The two layers were separated, allowed to cool to room temperature and then refrigerated. From the *n*-heptane layer, starting material (16.2 g.) was recovered, while the aqueous solution yielded crystalline 1,2-cyclohexylidene-D-glucofuranose (29.5 g., 74.5% based on 1,2:5,6-dicyclohexylidene-D-glucofuranose consumed) of m. p. 145–148° (uncor.). Concentration of the aqueous filtrate gave a second crop of product, 4.85 g. (total yield 87%). The compound after recrystallization from isobutanol (7 ml./g.) and from water (3 ml./g.) melted at 151.7–153.1° (cor.) and showed a rotation in acetone $[\alpha]^{29}D$ +4.00° (*c*, 1.4), (0.1376 g. in 10 ml. of solution gave α +0.11° in a 2-dm. tube). The compound is soluble in acetone and only slightly soluble in water. It is soluble in hot alcohol, hot isobutanol and hot methyl "cellosolve." The compound does not reduce hot Fehling solution.

Anal. Calcd. for $C_{12}H_{20}O_6$: C, 55.37; H, 7.75. Found: C, 55.01; H, 7.71.

3,5,6-Tribenzoyl-1,2-cyclohexylidene-D-glucofuranose, VI.—Benzoyl chloride (4 ml., 0.034 mole, Hooker Chemical Company) was added in one portion with vigorous stirring to a chilled mixture of 1,2-cyclohexylidene-D-glucofuranose (2.60 g., 0.01 mole) in anhydrous pyridine (10 ml., 0.12 mole). The reaction mixture was kept overnight in a 50° bath and the mixture was then poured into a vigorously stirred mixture of ice and water (400 ml.). An oil formed which slowly solidified. The solid was removed by filtration, washed several times with water and dried. The product (5.34 g., 93%) melted at 123.5–125° (uncor.). The compound after recrystallization from isobutanol (10 ml./g.) and then from *n*-heptane (20 ml./g.) melted at 124.6–125.6° (cor.) and showed a rotation in chloroform $[\alpha]^{26}D$ −90.4° (*c*, 0.62), (0.3139 g. in 50 ml. of solution gave α −2.27° in a 4-dm. tube). The compound is soluble in acetone, benzene, chloroform and ethyl acetate. It is soluble in hot isobutanol, hot *n*-heptane and hot methyl "cellosolve" but is insoluble in water.

Anal. Calcd. for $C_{33}H_{22}O_9$: C, 69.21; H, 5.63. Found: C, 68.80; H, 5.64.

3,5,6-Tribenzoyl-D-glucofuranose–Carbon Tetrachloride, VII.—3,5,6-Tribenzoyl-1,2-cyclohexylidene-D-glucofuranose (26.3 g., 0.046 mole) was dissolved in hot 80% acetic acid (600 ml.) and the reaction mixture was refluxed for five and one-third hours. The solution was allowed to cool to room temperature and was then seeded with starting material but nothing crystallized from the reaction mixture while standing overnight. (Previous experimentation had shown that the starting material while soluble in hot 80% acetic acid crystallized readily from the cool solution.) The reaction mixture was concentrated under reduced pressure at 45–50° to a light yellow, thick sirup. The sirup was taken up in room temperature carbon tetrachloride (200 ml.); the solution was seeded with 3,5,6-tribenzoyl-D-glucofuranose–carbon tetrachloride[10] and refrigerated. The product (20.8 g., 70%) crystallized overnight. The compound after several recrystallizations from carbon tetrachloride (15 ml./g.) softened at 65° (cor.) and melted at 69–78° (cor.).

Anal. Calcd. for $C_{28}H_{24}O_9Cl_4$: C, 52.03; H, 3.74; Cl, 21.94. Found: C, 51.88; H, 3.85; Cl, 20.81.

Mutarotation of 3,5,6-Tribenzoyl-D-glucofuranose–Carbon Tetrachloride.—A solution of 0.5030 g. of 3,5,6-tribenzoyl-D-glucofuranose–carbon tetrachloride which had been prepared from 1,2-cyclohexylidene-D-glucofuranose and recrystallized five times from carbon tetrachloride was made in absolute alcohol in a 25-ml. volumetric flask. The alcohol was added at zero time and the solution was made up to 25 ml. and transferred to a jacketed 2-dm. polarimeter tube. In Fig. 2 the specific rotation observed during the mutarotation is plotted against the time for two different temperatures.

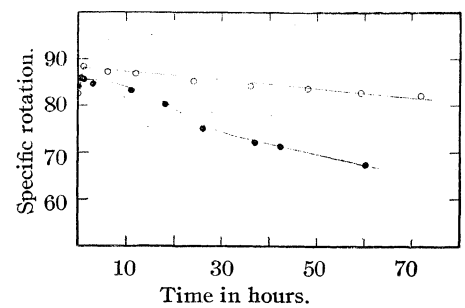

Fig. 2.—Mutarotation of 3,5,6-tribenzoyl-D-glucose in alcohol: ● at 30°; ○ at 20°.

Not all the mutarotation values which have been reported for this compound by Fischer and Rund[9] could be checked. The temperature at which these workers made their observations was not stated, but if it was 20° or lower the final part of the curve may have been so slow that the change was not detected.

Summary

1. Condensation of D-glucose with cyclohexanone has been found to form crystalline 1,2:5,6-dicyclohexylidene-D-glucofuranose (I). Three crystalline esters of this substance have also been prepared.

(10) Prepared by Dr. Franklin E. Morris, M. I. T. Chemistry Department Thesis, 1945, from 1,2-isopropylidene-D-glucofuranose.

2. Preferential hydrolysis of I has been found to yield crystalline 1,2-cyclohexylidene-D-glucofuranose. A crystalline tribenzoate of this substance has also been secured.

3. Proof of structure of all these substances is offered.

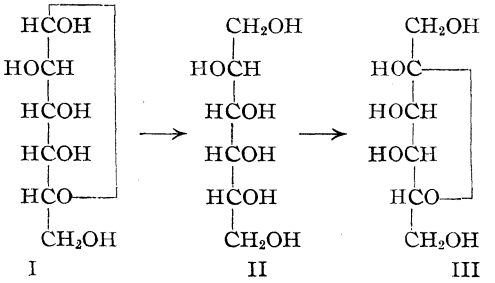
The Synthesis of D-Tagatose by Biochemical Oxidation and by an Improved Chemical Method[1]

BY EZRA L. TOTTON AND HENRY A. LARDY

In connection with work being carried out in this Laboratory on the intermediary metabolism of galactose, it became necessary to prepare D-tagatose (III). Since a wide variety of polyalcohols containing *cis*-hydroxyl groups at one end of the carbon chain had been oxidized to ketoses by *Acetobacter* species,[2] it was decided to test the action of *Acetobacter suboxydans* on D-talitol (II) as a means of preparing D-tagatose (III).



D-Talitol (II) was prepared for this purpose by the catalytic reduction of D-altrose (I). The latter was synthesized by methods developed by Robertson and Griffith[3] and Richtmyer and Hudson.[4]

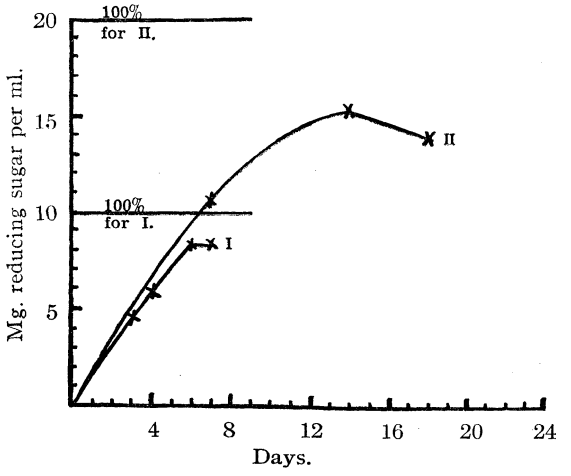


Fig. 1.—Oxidation of 1 and 2% solutions of D-talitol by *A. suboxydans*.

The D-talitol was rapidly oxidized by growing cultures of *A. suboxydans*. At concentrations of talitol below 5%, D-tagatose (III) was produced in yields of 75 to 84%. The rate of oxidation at 30° is shown in Fig. 1. When more concentrated solutions (5 to 16%) of talitol were employed, about 50% of the talitol was converted to tagatose. The yields quoted were based on a copper reduction method[5] standardized against pure D-tagatose. The bacterial oxidation product from D-talitol was demonstrated to be D-tagatose, since it gave a strongly positive test with Selivanov's reagent, was only very slightly oxidized by alkaline iodine, and gave a *p*-bromophenylosazone and a phenylosazone which were identical with those prepared from galactose.

The oxidation of D-talitol (II) to D-tagatose (III) by *A. suboxydans* offers a synthesis of D-tagatose which might be of preparative value should D-talitol become more readily available.

Since the synthesis of sufficient D-talitol to meet our needs for preparing tagatose would have been too laborious, we used the chemical procedure of Reichstein and Bosshard[6] for the preparation of larger quantities of tagatose. However, when using their procedure considerable difficulty was experienced in isolating, consistently, the tagatose from the mixture of isomerized galactose. The method was therefore modified by the use of lead acetate rather than absolute ethanol[6] to precipitate proteins and gums following the fermentation of the remaining galactose. The excess lead ions were then removed with an IR-100 ion exchange resin.[7] This modification eliminated many of the difficulties involved in the isolation of the product, and insured reproducible results.

It was also found that the rate of removal of galactose from the isomerized mixture may be increased by the use of a strain of yeast which rapidly adapts to galactose fermentation. The baker's yeast used by Reichstein and Bosshard required four days to ferment the excess galactose.

(7) From Resinous Products Co., Philadelphia, Pennsylvania.

In this work a culture of *S. cerevisiae* (Y-30)[8] fermented the galactose in fourteen to twenty-four hours.

The D-tagatose obtained by this modification of Reichstein and Bosshard's procedure agreed in m. p. with that reported by them for a product recrystallized several times. It gave the same characteristic tests and derivatives as the D-tagatose produced by the action of *A. suboxydans* on D-talitol. Since the bacterial oxidation product has a higher negative rotation, $[\alpha]^{25}D$ − 5°, than any previously described specimen of D-tagatose, it probably represents a purer compound.

Experimental[9]

D-Talitol (II) was prepared by the catalytic reduction of 18 g. of D-altrose in a 14% aqueous solution with 18 g. Raney nickel[10] under 1500 lb. hydrogen pressure at 100° for five hours.

D-Tagatose (III).—In a typical experiment, a solution of 1 g. of talitol, 0.5 g. of Difco yeast extract and 0.1 g. of glycerol in 100 ml. of water were placed in a cotton-stoppered 2-liter erlenmeyer flask. After autoclaving for fifteen minutes at 15 lb. pressure the cooled solution was inoculated with 1 ml. of a growing culture of *A. suboxydans*.[8] A test for reducing sugar was negative. After incubation at 30° for four days the medium was well covered with pellicle and an aliquot showed a reducing sugar value of 5.8 mg. per ml. calculated as tagatose. Two days later the substrate was 84% oxidized. The value was unchanged on the following day. The bacterial culture was then filtered to remove the cells, decolorized with norite and the proteins were removed from the solution by adding 6 ml. of saturated lead acetate solution. The clear filtrate was passed through a bed (30 cm. × 2.5 cm. diameter) of IR-100 ion exchange resin in the acid phase to remove the lead ions. The solution was concentrated under reduced pressure to a dry sirup. This was then taken up in 6 ml. of hot absolute methanol and 25 ml. of hot absolute ethanol was added with shaking. After 75 ml. of cold absolute ethanol was added, the mixture was allowed to stand one hour before filtering. The filtrate was again evaporated to a dry sirup under reduced pressure. The product was taken up in the smallest possible amount of absolute methanol and hot absolute ethanol was added until the first signs of turbidity appeared. Scratching the flask initiated crystallization. The product was collected after crystallization had proceeded at 5° for twenty-four hours. The dry crystals weighed 0.76 g. and melted at 120°. Recrystallization from 0.5 part water and 3 parts absolute alcohol gave a product which melted at 131–132°; $[\alpha]^{25}D$ − 5° (*c* 1 in water).[10a] Repeated recrystallizations raised the m. p. to 133–134° but did not alter the rotation. Reichstein and Bosshard[6] reported m. p. 134–135° and $[\alpha]^{20}D$ −2.3° (*c* 2.19 in water) for recrystallized tagatose prepared by treating galactose with pyridine.

Reaction with Hypoiodite (Willstätter–Schudel titration).—This reaction was run under conditions described by Hinton and Macara.[11] In a standardizing run 0.080 g. of glucose was quantitatively oxidized by iodine, giving a value of 1.40 g. iodine per g. of glucose. Under these conditions, galactose gave an iodine value of 1.17 g. per g. of galactose; the bacterial oxidation product of D-talitol gave an iodine value of 0.018 g. of iodine per gram of product.

D-Tagatose, reacting for twenty-five minutes with the reagent of Shaffer and Somogyi,[5] gave a copper reduction value 79% as great as an equivalent amount of glucose reacting for fifteen minutes.

The Selivanov Test.—The procedure of Roe[12] was followed in carrying out this test. A quantitative comparison (Evelyn colorimeter, filter 490) of the color formed by Selivanov's reagent and the bacterial oxidation product with the color formed by the reagent and D-fructose showed that the intensity of the colors were practically identical.

D-*lyxo*-Hexose *p*-Bromophenylosazone.—The method of Neuberg[13] was used to prepare this compound from a sample of the bacterial oxidation product. Two recrystallizations from 70% ethanol gave crystals which melted at 180–182° (slow heating). A mixed m. p. with an authentic sample prepared from galactose showed no depression. Neuberg reported a m. p. of 182–183° for D-*lyxo*-hexose *p*-bromophenylosazone prepared from galactose.

Anal. Calcd. for $C_{18}H_{20}O_4N_4Br_2$ (516.2): N, 10.85. Found: N, 10.73.

D-*lyxo*-Hexose Phenylosazone.—The procedure of Fischer[14] was followed for the synthesis of the phenylosazone from a sample of the bacterial oxidation product. Three recrystallizations from ethanol and water gave crystals which melted at 186° (slow heating). A mixed m. p. with a sample prepared from galactose showed no depression.

Anal. Calcd. for $C_{18}H_{22}O_4N_4$ (358.39): N, 15.64. Found: N, 15.55.

The Synthesis of D-Tagatose by an Improved Chemical Method.—One hundred grams of dry galactose in 1 liter of dry pyridine[15] was refluxed for five hours; the reaction mixture was protected from moisture with a calcium chloride tube. The pyridine was removed under reduced pressure. Remaining traces of pyridine were removed by evaporating, successively, two 0.5-liter portions of water under reduced pressure. The solution was concentrated to 125 ml. and 200 ml. of warm absolute ethanol was added in small portions. After twenty-four hours at 5°, the galactose was collected on a filter and washed with methanol. About 75% of the original galactose was recovered. The mother liquor was concentrated under reduced pressure to a thick sirup (30 ml.). A small amount of galactose was removed by filtration. The combined sirup and rinsings (50 ml.) were divided into two equal parts and each portion was added to a 2-liter erlenmeyer flask containing 500 ml. of a 0.5% Difco yeast extract solution. After sterilizing, each solution was inoculated with 25 ml. of a growing culture of *S. cerevisiae* (Y-30) and incubated with shaking at 30° for twenty-four hours. The combined medium was filtered, decolorized with norite, and concentrated under reduced pressure to 70 ml. Five ml. of saturated lead acetate solution was added. After filtering, the solution was passed through an IR-100 exchange resin in the acid phase. Three hundred ml. of warm absolute alcohol was added to the solution. After three hours the mixture was filtered and the mother liquor concentrated to a thin, free flowing sirup. Scratching the flask initiated crystallization, and the flask was allowed to remain at 5° for twenty-four hours. The product weighed 6 g. (6% of theoretical), and melted at 124–125°, $[\alpha]^{25}D$ −0.8° (*c* 5 in water). When recrystallized from 1/2 part water and 3 parts absolute alcohol, m. p. 131–132°, $[\alpha]^{25}D$ −0.8° (*c* 5 in water). This m. p. agrees with that reported for D-tagatose by Reichstein and Bosshard.[6] The product gave the same characteristic tests and derivatives as the compound produced by the bacterial oxidation of D-talitol.

Summary

Acetobacter suboxydans oxidized D-talitol to D-tagatose, m. p. 133–134°, $[\alpha]^{25}D - 5°$, in yields of 75 to 84%.

The isomerization method by which Reichstein and Bosshard prepared tagatose from galactose has been modified to obtain more consistent yields by the use of an ion exchange resin in the purification procedure.

An Improved Synthesis of Esters of Nitroacetic Acid[1]

BY H. FEUER, H. B. HASS[2] AND K. S. WARREN[3]

Esters of nitroacetic acid have recently come into prominence as intermediates in the preparation of amino acids.[4] These esters have been prepared by W. Steinkopf[5] who employed two methods. The one which gave a 37% yield of the ethyl ester consisted of suspending dipotassium nitroacetate in absolute ethanol and introducing dry hydrogen chloride.

The second method, which gave a 71% yield based on nitroacetic acid, involved the following three steps

$$2CH_3NO_2 + 2KOH \longrightarrow KO_2N{=}CHCOOK + NH_3 + 2H_2O \quad (1)$$

$$KO_2N{=}CHCOOK + 2HCl \longrightarrow O_2NCH_2COOH + 2KCl \quad (2)$$

$$O_2NCH_2COOH + ROH \xrightarrow{H^+} O_2NCH_2COOR + H_2O \quad (3)$$

The disadvantage of this procedure lies in the second step because it requires the preparation and isolation of nitroacetic acid from the dipotassium salt and this can only be accomplished with a 60–70% yield. Furthermore, nitroacetic acid is very unstable. It decomposes into nitromethane and carbon dioxide, and this further decreases the yield in the esterification step. Steinkopf[5] stated that he was unable to prepare esters directly from the dipotassium salt with concd. sulfuric acid and the desired alcohol. He claimed that the rate of decomposition of the nitroacetic acid liberated from its dipotassium salt was faster than the rate of esterification. This statement seemed, however, contradictory to the fact that he was able to prepare esters by working with the free nitroacetic acid and using an equimolar amount of concd. sulfuric acid at −15 to +3° as indicated in step 3 above.

It seemed therefore advisable to attempt the synthesis of esters of nitroacetic acid directly from the dipotassium salt by acidification with concd. sulfuric acid and by working at low temperatures. As a result, the methyl and ethyl esters have been prepared in a 60% yield.

The results of several experiments are given in the following three tables to illustrate the influence of reaction temperature, reaction time, and amount of sulfuric acid upon the ester formation.

TABLE I

EFFECT OF REACTION TEMPERATURE ON THE YIELD OF METHYL NITROACETATE

In run No. 6 anhydrous sodium sulfate was omitted.

Run	Temp. during first 24 hours, °C.	Temp. during the next 144 hours, °C.	Yield, %
1	0 to +5	23 to 25	12
2	− 2 to 0	23 to 25	28
3	−15 to −10	23 to 25	38
4	−60 to −50	23 to 25	60
5	−60 to −50	1 to 5	60
6	−60 to −50	1 to 5	45

TABLE II

EFFECT OF REACTION TIME ON THE YIELD OF METHYL NITROACETATE

In run No. 9 anhydrous sodium sulfate was omitted. In all ten experiments 90.5 g. (0.5 mole) of dipotassium nitroacetate, 500 ml. (12.38 moles) of methanol, 100 g. (1 mole) of concd. sulfuric acid, and 15 g. (0.1 mole) of anhydrous sodium sulfate (except in 6 and 9), were used.

Run	Time in hr. at −60 to −50°	Yield, %
7	1	25
8	24	40
9	24	29
10	48	45

TABLE III

EFFECT OF THE AMOUNT OF CONCD. SULFURIC ACID ON THE YIELD OF METHYL NITROACETATE

In all these experiments the same conditions and amounts were used as in run No. 4.

Moles concd. H_2SO_4	Yield, %
1	18
1.5	45
2	60
3	60

The data in Table I show that a lower reaction temperature during the first twenty-four hours of

(1) Presented before the Division of Organic Chemistry at the St. Louis Meeting of the American Chemical Society, September 8, 1948.

(2) Present address: General Aniline and Film Corp., New York City, N. Y.

(3) Present address: Picatinny Arsenal, Dover, N. J.

(4) Lyttle and Weisblat, THIS JOURNAL, **69**, 2118 (1947).

(5) Steinkopf, *Ann.*, **434**, 21 (1923).

the reaction increases the yields. While a low reaction temperature is important during the first twenty-four hours, a further extension of the reaction at a low temperature does not increase the yields appreciably as indicated in Table II.

Omission of anhydrous sodium sulfate resulted in lower yields. A 2:1 ratio of concd. sulfuric acid to dipotassium nitroacetate is needed to get optimum yields as indicated by the data in Table III.

Experimental

Preparation of the Dipotassium Salt of Nitroacetic Acid.—In a three-liter flask provided with stirrer, condenser and dropping funnel was placed 1500 ml. (20.2 moles) of freshly prepared 50% potassium hydroxide. When the temperature had risen to 60° on dissolving of the potassium hydroxide, 300 g. (4.91 moles) of nitromethane was added dropwise with vigorous stirring. During the one and one-half hours required for the addition of the nitromethane, the temperature rose to 102°. Ammonia was liberated during the latter half of the addition and the reflux condenser was removed after the entire amount of nitromethane had been added. The reddish brown mixture was then heated until the first crystals appeared. After cooling, the potassium salt which had separated out was filtered and washed with methanol. This first crop weighed 210 g. representing a yield of 44.5%.

Anal. Calcd. for $C_2HNO_4K_2$: K, 43.03. Found: K, 42.61.

The mother liquor was evaporated further and after cooling a second crop of crystals was obtained which weighed 60 g., representing a yield of 12.7%.

Anal. Found: K, 42.43.

Still further evaporation of the mother liquor gave a third crop of crystals (70 g.) which was found by analysis to be 43% contaminated with potassium carbonate which formed in the reaction.

Anal. Found: K, 48.90.

Preparation of Methyl Nitroacetate.—In a one-liter flask fitted with stirrer, thermometer and dropping funnel were placed 90.5 g. (0.5 mole) of dipotassium nitroacetate, 500 ml. (12.38 moles) of methanol and 15 g. (0.1 mole) of anhydrous sodium sulfate. The flask was placed in a Dewar and cooled down to −50 to −60° by a trichloroethylene–dry ice mixture. One hundred grams (1 mole) of concentrated sulfuric acid (d. 1.84) was added dropwise to the mixture during a period of one and one-half hours. The reaction mixture was kept in the Dewar for twenty-four hours with stirring (temp. −50 to −60°) and then for one hundred and forty-four hours at 23–25° with occasional shaking. The precipitated potassium sulfate was then filtered off and the excess methanol was evaporated under vacuum. The oily residue was diluted with ether and neutralized with a 5% solution of sodium carbonate. The ether layer, which contained the ester, was dried and the ether was evaporated. Vacuum distillation of the residue at 15 mm. yielded 36 g. (60%) of the ester, boiling at 93–94°; $n^{20}D$ 1.4245; neut. equiv. calcd. for $C_3H_5O_4N$, 119, found 121.

Preparation of Ethyl Nitroacetate. The procedure was the same as for the synthesis of methyl nitroacetate. Forty grams (60%) of ethyl nitroacetate was obtained, boiling at 105–107° at 25 mm., d^{20}_4 1.11950, $n^{20}D$ 1.4252.

Acknowledgments.—The authors wish to express their appreciation to Mr. L. Friedman for his technical assistance and express their thanks to the General Tire and Rubber Company, Akron, Ohio, for financial assistance in this work.

Summary

An improved synthesis of esters of nitroacetic acid has been presented. The methyl and ethyl esters of nitroacetic acid have been prepared in two steps from nitromethane in 60% yield.

The Chemistry of Nitroacetic Acid and its Esters. II. The Synthesis of Ethyl α-Nitro-β-(3-indole)-propionate from Gramine and Ethyl Nitromalonate[1]

BY D. I. WEISBLAT AND D. A. LYTTLE

We have recently reported a synthesis of *dl*-tryptophan (V) in which the key intermediate, ethyl α-nitro-β-(3-indole)-propionate (IV), was prepared from gramine and ethyl nitroacetate.[2] A new synthesis of this intermediate, starting with ethyl nitromalonate (I), is described in this communication.

The alkylation of ethyl nitromalonate (I) by gramine (II) under reaction conditions similar to those reported for the alkylation of ethyl nitroacetate[2] gives ethyl α-nitro-α-carbethoxy-β-(3-indole)-propionate (III) in excellent yield. The structure of ethyl nitromalonate, in contrast to that of ethyl nitroacetate, excludes dialkylation[2,3] as a possible side reaction and this, together with the activating effect of the second carbethoxy group, probably accounts for the higher yields and purer product obtained in the present alkylation.

Since powdered sodium hydroxide is an effective catalyst for the dialkylation of ethyl nitroacetate by gramine,[2] it was expected that it would greatly accelerate the present alkylation. Contrary to our expectations, however, it was found that not only sodium hydroxide but basic substances in general cause extensive decomposition. For this reason the rapid removal of dimethylamine, which is formed in the reaction, is essential for optimum yield and purity of product.

The conversion of III to IV in a yield of 91.6% was readily accomplished by treating a solution of III in ether with one equivalent of sodium in alcohol.[4]

Improvements in the reduction of IV and the hydrolysis of ethyl *dl*-tryptophan to *dl*-tryptophan (V) have increased the over-all yield on these steps to 87 from 50% as reported previously.[2]

Attempts to obtain ethyl α-amino-α-carbethoxy-β-(3-indole)-propionate by catalytic reduction of III with Raney nickel and hydrogen at 2500 p. s. i. and 100° were unsuccessful. The hydrogen uptake was almost 4 moles per mole of III, indicating that hydrogenolysis had occurred. The only product isolated was the known ethyl α-carbethoxy-β-(3-indole)-propionate (VI).[5]

Chemical reduction of III with zinc dust and acetic acid gave a product representing only partial reduction of the nitro group, ethyl α-hydroxylamino-β-(3-indole)-propionate (VII), in a yield of 56%.

When the nitration of Arndt and Rose,[6] which consists of treating methyl malonate with fuming nitric acid, was applied to the preparation of ethyl nitromalonate, yields varying from 45 to 76% were obtained. An investigation of this reaction showed that a higher temperature is necessary for optimum yields. When the nitration is allowed to proceed for several hours at 15–20°, consistent yields of around 92% can be obtained.

We have found, however, that ethyl nitromalonate prepared by these nitration procedures invariably is contaminated with oxides of nitrogen which initiate autocatalytic decomposition of the nitro ester. These oxides, which cannot be removed by repeated washing and/or distillation, are completely removed by treatment of the nitro ester with an amide such as urea or acetamide. Ethyl nitromalonate so treated is stable over long periods of time.

Experimental

Ethyl Nitromalonate (I).—Ethyl malonate (80.0 g., 0.5 mole) was placed in a 500-cc. three-necked flask fitted with a dropping funnel, a stirrer, a thermometer and an outlet protected by a drying tube. The flask was cooled by tap water at 12°, and 184 cc. of fuming nitric acid (d. 1.5) was added at a rate sufficient to maintain the temperature between 15 and 20°. The addition required one hour, after which the mixture was allowed to stir for three and one-half hours at 15°. The solution was poured onto 1 l. of ice and water and the ester extracted with 200- and 100-cc. portions of toluene. The combined toluene extracts were washed twice with water, and then with 200-cc. portions of 5% aqueous urea solution until a starch–potassium iodide test for oxides of nitrogen in the wash was negative. The toluene solution was extracted with 10% sodium carbonate solution in portions until acidification of a test portion of extract showed that it contained no nitro ester. The sodium carbonate extracts were combined and washed once with 200 cc. of toluene. The aqueous solution was then carefully acidified to congo red paper with concentrated hydrochloric acid, with cooling by the occasional addition of ice. The ester was collected by extracting with 500-, 200- and 100-cc. portions of toluene. The toluene solution was washed twice with 200-cc. portions of water and then with 5% aqueous urea solution, checking again with starch–potassium iodide test paper for the complete absence of oxides of nitrogen. Drying of the toluene solution was done over magnesium sulfate. The yield of ester was determined by weighing the toluene solution, taking an aliquot, adding an equal volume of alcohol, and titrating the nitro ester with 1 *N* sodium hydroxide to a phenolphthalein end-point. The assay showed that the yield was 94.1 g. or 91.7%. If the analytically pure ester is desired, it may be obtained by concentrating and distilling; b. p. 81–83° at 0.3 mm.; $n^{21}D$ 1.4274.

Ethyl α-Nitro-α-carbethoxy-β-(3-indole)-propionate (III).—Distilled ethyl nitromalonate,[7] 43.3 g. (0.25 mole), 250 cc. of toluene dried by distillation, and gramine,[8] 51.3 g. (0.25 mole) were placed in a 500-cc., three-necked flask fitted with stirrer, nitrogen inlet, thermometer in the mixture, and an efficient reflux condenser. With a vigorous stream of nitrogen[9] passing through the well-stirred mixture, it was heated rapidly to vigorous reflux. Dimethylamine evolution began at about 90 to 95° and was very rapid at the boiling point. Refluxing, nitrogen flow and stirring were continued until evolution of dimethylamine ceased, usually after three hours. The solution was cooled and extracted twice with 50-cc. portions of 10% hydrochloric acid, washed with 50 cc. of water, then extracted with two 50-cc. portions of 5% sodium hydroxide and washed twice with water. The toluene solution was dried over magnesium sulfate and concentrated at reduced pressure. The last traces of solvent were removed by heating at 80° and 0.5 mm. with stirring. There remained 80.5 g. (96.5%) of III as a light red, thick sirup.

Anal. Calcd. for $C_{16}H_{18}N_2O_6$: C, 57.48; H, 5.43; N, 8.38. Found: C, 57.29, 57.19; H, 5.14, 5.14; N, 8.45, 8.23.

Ethyl α-Nitro-β-(3-indole)-propionate (IV).—Ethyl α-nitro-α-carbethoxy-β-(3-indole)-propionate, 80.5 g. (0.24 mole), in 500 cc. of anhydrous ether was cooled in an ice-

(5) Snyder, Smith and Stewart, THIS JOURNAL, **66**, 203 (1944).

(6) Arndt and Rose, *J. Chem. Soc.*, 1 (1935).

(7) Equally good results are obtained, however, when a stoichiometric amount of undistilled ester in toluene solution is used.

(8) Kuhn and Stein, *Ber.*, **70**, 567 (1937).

(9) This is necessary to insure rapid and complete removal of dimethylamine. If this is not done, both yield and quality of product are poor.

bath. A solution of 5.55 g. (0.24 mole) of sodium in 260 cc. of absolute alcohol was added slowly, with vigorous stirring, over a period of two hours. Precipitation of the sodium salt of IV and probably some sodium ethylate occurred to form a very thick slurry. This was stirred overnight, then filtered. The salt was washed twice with 125-cc. portions of ether, transferred to a separatory funnel, covered with 200 cc. of ether and acidified with 100 cc. of 10% hydrochloric acid. Vigorous shaking was continued until all the solid had disappeared. The ether layer was separated and the aqueous phase extracted with 100 cc. of ether. The ether solutions were combined and washed with two 200-cc. portions of water. Drying and concentration left 57.9 g. (91.6%) of crystalline IV. The identity of this material and that obtained by alkylation of ethyl nitroacetate was established by a mixed melting point.

DL-**Tryptophan.**—The reduction of 57.9 g. (0.221 mole) of IV was carried out in an Aminco rocking hydrogenator using 150 cc. of absolute alcohol and 6 g. of Raney nickel catalyst at 100° for one hour. The bomb was heated as rapidly as possible since we have found that a rapid reduction is necessary to avoid undesirable by-products and low yields. The catalyst was removed by filtration and to the filtrate was added 60 g. of 20% sodium hydroxide. The solution was allowed to stand overnight at room temperature. The *p*H was then adjusted to 5.9 with glacial acetic acid and crystalline material separated. After the mixture had stood in the ice-box overnight, the tryptophan was filtered and washed with water, alcohol and ether. The product was dried *in vacuo*. There was thus obtained 39.3 g. (87.1%) of white, crystalline *dl*-tryptophan; m. p. 265° (uncor., dec.).

Ethyl α-Carbethoxy-β-(3-indole)-propionate (VI).—Ethyl α-nitro-α-carbethoxy-β-(3-indole)-propionate (III), 16.72 g. (0.05 mole), in 50 cc. of absolute alcohol was reduced catalytically at 180 atm. and 100° in the presence of approximately 3 g. of Raney nickel. The observed hydrogen absorption was approximately 3.8 moles per mole of III. The oil which remained after filtration and concentration crystallized readily, representing a nearly quantitative yield of VI. An analytical sample was prepared by recrystallizing several times from 75% alcohol, m. p. 62.0–62.5° (uncor.).[5]

Anal. Calcd. for $C_{16}H_{19}NO_4$: C, 66.42; H, 6.62; N, 4.84. Found: C, 66.74; H, 6.52; N, 5.06.

Ethyl α-Hydroxyamino-α-carbethoxy-β-(3-indole)-propionate (VII).—To 3.34 g. (0.01 mole) of III in 25 cc. of glacial acetic acid was added 0.5 cc. of water and then 5 g. of zinc dust in small portions. The temperature was held below 45° during the addition. After forty minutes, the zinc and zinc acetate were removed by centrifugation and washed with glacial acetic acid. Concentration at reduced pressure was followed by partitioning of the crude between water and ether. The ether was washed with 5% sodium hydroxide, then with water. Drying and concentration left 1.80 g. (56%) of crystalline material. After several recrystallizations from alcohol the hydroxylamino ester melted at 131–132° (uncor.).

Anal. Calcd. for $C_{16}H_{20}N_2O_5$: C, 59.99; H, 6.29; N, 8.75. Found: C, 60.16, 59.75; H, 6.41, 6.09; N, 9.00, 9.08.

Acknowledgments.—The authors wish to thank Mr. Jack Richmond for assistance with a portion of the laboratory work, and Mr. Harold Emerson and his associates for some of the microanalyses.

Summary

1. A new synthesis of *dl*-tryptophan employing ethyl nitromalonate and gramine is reported.

2. An improved method for preparing and stabilizing esters of nitromalonic acid is described.

KALAMAZOO, MICHIGAN RECEIVED APRIL 27, 1949

[CONTRIBUTION FROM THE LABORATORY FOR THE STUDY OF HEREDITARY AND METABOLIC DISORDERS AND THE DEPARTMENTS OF BIOLOGICAL CHEMISTRY AND MEDICINE, UNIVERSITY OF UTAH SCHOOL OF MEDICINE]

Some Peptides and Peptide Derivatives Containing Leucine and Alanine

BY W. J. POLGLASE AND EMIL L. SMITH

In order to investigate further the specificity of the enzyme, leucine aminopeptidase,[1] a number of new leucine compounds were required. For a study of the stereochemical specificity[2] of this enzyme, dipeptides containing L-leucine in combination with L- and D-alanine and β-alanine were prepared. We wish to report the synthesis of D-alanyl-L-leucinamide acetate, L-alanyl-L-leucinamide acetate, L-leucyl-L-alaninamide acetate, L-leucyl-D-alaninamide acetate and β-alanyl-L-leucinamide hydrochloride. The preparation of L-alanyl-L-leucine is given in detail since this compound has not been previously synthesized by the carbobenzoxy method. The preparation of L-leucyl-L-alanine and L-leucyl-D-alanine by the carbobenzoxy method has already been described by Bergmann and co-workers.[3] Some additional data on intermediate products in the synthesis of these two peptides have now been obtained and a synthesis from racemic alanine was accomplished.

It has been the practice of most workers when preparing a dipeptide containing a D-amino acid first to resolve a racemic mixture of the amino acid by the use of an optically active base. In the preparation of a dipeptide by the carbobenzoxy method it is often possible to obtain one or two crystalline intermediate compounds as well as the final crystalline dipeptide. Thus, if a carbobenzoxy-L-amino acid is coupled to a DL-amino acid ester there may be as many as three synthetic steps at which to effect separation of the resulting diastereoisomers. We have found this method particularly useful in the preparation of L-leucyl-D-alanine and L-leucyl-L-alanine. Thus, carbobenzoxy-L-leucine was coupled through the azide with the methyl ester of DL-alanine. Carbobenzoxy-L-leucyl-D-alanine methyl ester was readily crystallized from the mixture. The diastereoisomeric compound could not be crystallized from

the mother liquor but after saponification with alkali, the resulting carbobenzoxy-L-leucyl-L-alanine was crystallized. Reduction by hydrogenation of the carbobenzoxy dipeptides gave the pure dipeptides in both instances. This procedure for the preparation of dipeptides containing a D-amino acid residue is being investigated further with other amino acids.

There appear to be few instances of the preparation of peptides by such methods. However, Behrens, Doherty and Bergmann[4] separated the products resulting from the reduction of acetyldehydrophenylalanyl-L-leucine; they obtained by differential crystallization acetyl-L-phenylalanyl-L-leucine and acetyl-D-phenylalanyl-L-leucine. Recently, Cook, Cox and Farmer[5] coupled *l*-α-bromisovaleryl chloride and DL-N-methylvaline; these products were converted to the hydroxy compounds and then to the lactones. The diastereoisomeric lactones were then separated chromatographically.

The D-alanine used in this work was prepared as described by Fischer.[6] The carbobenzoxy-D-alanine was obtained by an enzymatic resolution of carbobenzoxy-DL-alanine.[7] In the presence of aniline and cysteine-papain, the carbobenzoxy-L-alaninanilide is synthesized and crystallizes from solution; the carbobenzoxy-D-alanine is readily recovered from the mother liquor.[8] The procedure has successfully been used for the resolution of the DL mixtures of derivatives of several amino acids.[9]

Experimental

Preparation of Amino Acid Esters.—The amino acid was dissolved in ten times its weight of anhydrous methanol saturated with anhydrous hydrogen chloride at 0° and allowed to stand at 0° overnight. The reaction mixture was then concentrated to a sirup under reduced pressure and the concentration repeated several times after the addition of anhydrous methanol. The amino acid ester hydrochloride generally crystallized and was suspended in ether and collected by filtration. A solution of the free ester in the desired organic solvent was then prepared as described by Fischer.[10]

Coupling of Amino Acids.—Following the well-known method of Bergmann and Zervas,[7] the amino acid (or amino acid ester) required as the first moiety of the desired peptide was acylated with a 10% excess of carbobenzoxy chloride in the presence of two equivalents of alkali. The resulting compound was converted to the chloride (or azide) and allowed to react with the ester of the amino acid required as the second moiety. The carbobenzoxy dipeptide ester thus obtained was then saponified to the carbobenzoxy dipeptide or ammonolyzed to the carbobenzoxy dipeptide amide. Hydrogenation in the usual manner[7] of a methanolic solution of the carbobenzoxy compound in the presence of acetic acid and water and with palladium as catalyst gave the desired dipeptide or dipeptide amide acetate.

Carbobenzoxy-L-leucyl-D-alanine Methyl Ester.—This was prepared from D-alanine methyl ester hydrochloride and carbobenzoxy-L-leucine azide as described by Bergmann and co-workers,[3] m. p. 129–130°, which is the same as that previously given.[3] The optical rotation has not been reported; $[\alpha]^{27}D$ −1° (*c* 4, ethanol). The same product was obtained from carbobenzoxy-L-leucine azide and racemic alanine methyl ester hydrochloride. An ether solution of carbobenzoxy-L-leucine azide prepared from 15.6 g. of carbobenzoxy-L-leucine hydrazide[3] was added to an ether solution of DL-alanine methyl ester obtained from 5.0 g. of the hydrochloride. The mixture was allowed to stand at room temperature overnight in the hood. The ether solution was then washed with water, *N* hydrochloric acid, saturated bicarbonate and dried over sodium sulfate. The filtered solution was concentrated under reduced pressure to about 70 cc. whereupon the carbobenzoxy-L-leucyl-D-alanine methyl ester crystallized; yield 2.95 g.; m. p. 126–129°. This compound was recrystallized from ethyl acetate-petroleum ether; m. p. 129–130°, unchanged upon admixture with a specimen prepared with pure D-alanine; $[\alpha]^{21}D$ −1° (*c* 4, ethanol).

L-Leucyl-D-alanine.—This was prepared as previously described[3] by saponification of 2.02 g. of carbobenzoxy-L-leucyl-D-alanine methyl ester and reduction of the sirupy carbobenzoxy dipeptide; yield 0.9 g. The peptide was recrystallized from methanol–ethyl acetate; yield 0.7 g.; $[\alpha]^{27}D$ +80° (*c* 1, water). Bergmann, *et al.*,[3] give $[\alpha]^{22}D$ + 76.0 (*c* 2.5, water).

Anal. Calcd. for $C_9H_{18}O_3N_2$: N, 13.86. Found: N, 13.72.

Carbobenzoxy-L-leucyl-D-alaninamide.—Carbobenzoxy-L-leucyl-D-alanine methyl ester, 2.20 g., was dissolved in 30 cc. of methanol previously saturated at 0° with ammonia. After forty hours in a pressure bottle at room temperature, the solution was concentrated under reduced pressure and the amide crystallized. The product was recrystallized from ethanol-ether; needles, yield 1.65 g.; m. p. 181–182°; $[\alpha]^{22}D$ − 6° (*c* 1, ethanol).

Anal. Calcd. for $C_{17}H_{25}O_4N_3$: N, 12.5. Found: N, 12.2.

L-Leucyl-D-alaninamide Acetate.—This was obtained by hydrogenation over palladium of 1 g. of the carbobenzoxy derivative in 20 cc. of methanol containing 1 cc. of acetic acid and 1 cc. of water. The reduction was complete in two hours, the catalyst was removed by filtration and the filtrate concentrated under reduced pressure. The product crystallized after repeated concentration with anhydrous methanol and was recrystallized from methanol-ethyl acetate: needles, yield 0.72 g.; m. p. 250–255° (dec.); $[\alpha]^{22}D$ + 61° (*c* 1, water).

Anal. Calcd. for $C_{11}H_{23}O_4N_3$: N, 16.1. Found: N, 16.0.

Carbobenzoxy-L-leucyl-L-alanine Methyl Ester.—The synthesis of this compound has been described[3] (m. p. 92–93°) but the optical rotation was not reported. We observed m. p. 95–96°; $[\alpha]^{22}D$ −38° (*c* 1, ethanol).

Carbobenzoxy-L-leucyl-L-alanine.—This compound was previously described as a sirup. It was prepared as described[3] by saponification of the methyl ester. The compound crystallized at room temperature in large dodecahedra from a mixture of ethyl acetate, ethyl ether and petroleum ether (boiling range 65–110°): yield quantitative; m. p. 152–153°, $[\alpha]^{27}D$ −25° (*c* 1, ethanol).

Anal. Calcd. for $C_{17}H_{24}O_5N_2$: C, 60.7; H, 7.2; N, 8.33. Found: C, 60.4; H, 7.2; N, 8.44.

This compound was also obtained from the mother liquor of the carbobenzoxy-L-leucyl-D-alanine methyl ester resulting from coupling carbobenzoxy-L-leucine azide with racemic alanine ester. The mother liquor was concentrated to a sirup, dissolved in 20 cc. of acetone and saponi-

(10) E. Fischer, *Ber.*, **34**, 433 (1907).

fied with 11 cc. of *N* sodium hydroxide. After forty-five minutes at room temperature the solution was acidified and the acetone removed under reduced pressure. The resulting sirup was extracted into ethyl acetate and this solution extracted with 25 cc. of a saturated solution of sodium bicarbonate. The sodium bicarbonate solution was acidified and extracted with ethyl acetate and this extract dried with sodium sulfate. The ethyl acetate solution was concentrated to a sirup and the product crystallized from ethyl acetate, ethyl ether and petroleum ether (boiling range 65–110°); dodecahedra, yield 0.7 g., m. p. 152–153°, unchanged on admixture with a specimen prepared with L-alanine; $[\alpha]^{25}D$ −25° (*c* 1, ethanol).

L-Leucyl-L-alanine.—This was prepared as described by Bergmann and co-workers,[3] except that the above crystalline compound was the starting material. Three grams of carbobenzoxy-L-leucyl-L-alanine yielded 1.75 g. of the dipeptide. The compound was recrystallized from methanol–ethyl acetate. Fischer (see[3]) recrystallized this dipeptide by dissolving it in a large volume of hot absolute ethanol and collecting successive crops of crystals. We found that the methanol–ethyl acetate mixture gave higher yields of material having the required optical rotation. The dipeptide was dried *in vacuo* at 50°; $[\alpha]^{25}D$ + 22.9° (*c* 5, methanol) identical with that previously found.

Carbobenzoxy-L-leucyl-L-alaninamide.—This was prepared from 2.04 g. of the ester and methanol previously saturated with ammonia at 0°. After forty hours at room temperature in a pressure bottle, the solution was concentrated under reduced pressure to a crystalline mass. This was suspended in ether and filtered; needles, yield 1.76 g. The compound was recrystallized from ethanol–water; m. p. 189°, $[\alpha]^{27}D$ − 26° (*c* 0.6, ethanol).

Anal. Calcd. for $C_{17}H_{25}O_4N_3$: C, 60.9; H, 7.5; N, 12.5. Found: C, 60.9; H, 7.3; N, 12.6.

L-Leucyl-L-alaninamide Acetate.—This was prepared by hydrogenation of 1.03 g. of carbobenzoxy-L-leucyl-L-alaninamide. The reduction was complete in ninety minutes; needles, yield 0.65 g.; m. p. 250–255° (dec.); $[\alpha]^{21}D$ + 4° (*c* 1, water). The compound was dried *in vacuo* at 50°.

Anal. Calcd. for $C_{11}H_{23}O_4N_3$: C, 50.6; H, 8.9; N, 16.1. Found: C, 51.2; H, 9.0; N, 15.9.

Enzymatic Preparation of Carbobenzoxy-D-alanine.[8]—Commercial papain, 10.2 g., was stirred for thirty minutes with 255 cc. of water and filtered. Two hundred cc. of the filtrate was added to a mixture of 112 g. of carbobenzoxy-DL-alanine,[7] 135 cc. of 2 *N* sodium hydroxide, 46 cc. of aniline, 3.0 g. of cysteine and 200 cc. of citrate buffer, *p*H 5.0. The volume of the mixture was adjusted to 1,000 cc. by the addition of water and then incubated for seven days at 40°. The mixture was cooled to 0°, filtered and the precipitate washed twice with 250-cc. quantities of water. The filtrate was boiled and filtered and this filtrate was acidified with 100 cc. of 20% hydrochloric acid. The acidic solution was extracted with ether and the ether solution was extracted with saturated sodium bicarbonate solution. This solution was acidified and extracted with ether, the ether solution was washed with water and dried over sodium sulfate. The solution was then concentrated under reduced pressure to a sirup which crystallized on standing *in vacuo*. The crystalline residue was tritrated at 0° with 200 cc. of 2 *N* hydrochloric acid, filtered and the product dried in air; yield 49.5 g. For recrystallization, the product was dissolved in 200 cc. of ethyl ether and 600 cc. of light petroleum ether was added slowly, in portions. The carbobenzoxy-D-alanine was collected by filtration; m. p. 84–86°, $[\alpha]^{28}D$ + 14.0° (*c* 9, acetic acid). The constants reported by Bergmann and Zervas for carbobenzoxy-L-alanine[7] are: m. p. 84°; $[\alpha]^{17}D$ −14.3° (*c* 9, acetic acid). Hunt and du Vigneaud[11] give $[\alpha]^{27}D$ −13.9° and + 14.0 for the L and D derivatives.

Carbobenzoxy-D-alanyl-L-leucine Methyl Ester.—Carbobenzoxy-D-alanine, 5.0 g., was dissolved in 20 cc. of anhydrous ethyl ether and shaken at 0° with 5.0 g. of phosphorus pentachloride until all but a trace of the latter had dissolved. Light petroleum ether, previously cooled to −50° (*cf.* 11) was added and the oil which precipitated was washed three times with petroleum ether. The oil was then dissolved in 30 cc. of chloroform, previously cooled to −50°. This solution was added to a solution of L-leucine methyl ester (from 8.2 g. of the hydrochloride) in 30 cc. of chloroform. After thirty minutes at 0° and one hour at room temperature, the chloroform solution was washed with water, saturated sodium bicarbonate and *N* hydrochloric acid. The chloroform layer was dried over sodium sulfate and concentrated to a sirup which crystallized upon addition of petroleum ether; yield 5.7 g. The product was recrystallized from ethyl ether–petroleum ether (boiling range 30–60°); m. p. 72–73°; $[\alpha]^{27}D$ −9° (*c* 1, ethanol).

Anal. Calcd. for $C_{18}H_{26}O_5N_2$: N, 8.0. Found: N, 7.9.

Carbobenzoxy-D-alanyl-L-leucinamide.—This was prepared at room temperature by ammonolysis for forty hours with saturated methanol–ammonia of 3.75 g. of the corresponding ester. The amide crystallized upon concentration of the reaction mixture under reduced pressure; needles, yield 2.84 g. The product was recrystallized from ethanol–water; m. p. 187–188°; $[\alpha]^{30}D$ − 6° (*c* 1, ethanol).

Anal. Calcd. for $C_{17}H_{25}O_4N_3$: N, 12.5. Found: N, 12.5.

D-Alanyl-L-leucinamide Acetate.—This was obtained by hydrogenation of 2.25 g. of carbobenzoxy-D-alanyl-L-leucinamide. It crystallized in needles after repeated concentration of the filtered reaction mixture with ethanol; yield 1.61 g. The compound melted at 147°, immediately re-solidified and melted with decomposition at 249–250°; $[\alpha]^{26}D$ − 35° (*c* 1.5, water). The compound was dried *in vacuo* at 25°.

Anal. Calcd. for $C_{11}H_{23}O_4N_3$: C, 50.6; H, 8.9; N, 16.1. Found: C, 50.6; H, 8.9; N, 16.1.

Carbobenzoxy-L-alanyl-L-leucinamide.—Carbobenzoxy-L-alanine, 11.1 g., was converted to the acid chloride and dissolved in chloroform (75 cc.) as described above in the preparation of carbobenzoxy-D-alanyl-L-leucine methyl ester. The chloroform solution was added to a chloroform solution of leucine methyl ester obtained from 9.1 g. of the hydrochloride. After about five minutes, potassium bicarbonate, 5 g. in water, was added and the mixture shaken at frequent intervals. After one hour, the chloroform layer was washed with dilute hydrochloric acid and with water, dried over sodium sulfate and concentrated under reduced pressure to a sirup. The entire product was converted to the amide with saturated methanol–ammonia. After forty hours the solution was concentrated under reduced pressure and the amide crystallized: needles, yield 4.3 g.; m. p. 185–187°. The product was recrystallized from ethanol–water, m. p. 188–189°; $[\alpha]^{30}D$ − 41° (*c* 1, ethanol).

Anal. Calcd. for $C_{17}H_{25}O_4N_3$: N, 12.5. Found: N, 12.6.

L-Alanyl-L-leucinamide Acetate.—This was prepared by hydrogenation of 3.00 g. of carbobenzoxy-L-alanyl-L-leucinamide; needles, yield 2.32 g. The compound was dried at 25° *in vacuo*. It softened at 158° and gradually darkened on further heating, melting at 250°; $[\alpha]^{28}D$ −9° (*c* 2, water).

Anal. Calcd. for $C_{11}H_{23}O_4N_3$: C, 50.6; H, 8.9; N, 16.1. Found: C, 50.9; H, 9.2; N, 16.0.

L-Alanyl-L-leucine.—This compound has been prepared by Fischer[12] but its synthesis by the carbobenzoxy method has not been reported. Carbobenzoxy-L-alanine, 22.3 g., was coupled with leucine methyl ester (from 20 g. of the hydrochloride) as described above in the preparation of carbobenzoxy-L-alanyl-L-leucinamide. The resulting sirupy carbobenzoxy-L-alanyl-L-leucine methyl ester was saponified in 150 cc. of acetone and 45 cc. of *N* sodium

(11) M. Hunt and V. du Vigneaud, *J. Biol. Chem.*, **124**, 699 (1938).

(12) E. Fischer, *Ber.*, **40**, 1754 (1907).

hydroxide. After forty-five minutes at room temperature, the solution was neutralized with *N* hydrochloric acid and the acetone removed by distillation under reduced pressure. The water insoluble sirup was taken into ethyl acetate, and the solution dried and concentrated. The resulting sirup was hydrogenated in 60 cc. of methanol containing 4 cc. of acetic acid and 4 cc. of water with palladium catalyst. The reduction was complete after forty-eight hours. The catalyst was removed by filtration, the filtrate concentrated under reduced pressure to a sirup from which the acetic acid and water were removed by repeated concentration with anhydrous methanol. The product was crystallized from methanol–ether and dried at 75° *in vacuo:* yield 2.60 g.; $[\alpha]^{21}D$ − 17.0° (*c* 5, water). Fischer[12] found $[\alpha]^{20}D$ − 17.2 and − 16.8°.

Carbobenzoxy-β-alanyl-L-leucinamide.—Carbobenzoxy-β-alanine,[13] 6.65 g., in anhydrous ethyl ether, 25 cc., was converted to the acid chloride as previously described[13] and was added to an ether solution of L-leucine methyl ester prepared from 5.9 g. of the hydrochloride. After a few minutes at 0°, 3.5 g. of potassium bicarbonate in water was added and the mixture shaken frequently for an hour during which time the mixture was allowed to come to room temperature. The ether layer was separated and washed with dilute hydrochloric acid and with water. The solution was dried over sodium sulfate and then concentrated under reduced pressure to a sirup. The sirupy product was converted to the amide as described above; needles, yield 5.70 g., m. p. 172–173°. The amide was recrystallized from ethanol–water, m. p. 174–175°.

Anal. Calcd. for $C_{17}H_{25}O_4N_3$: C, 60.9; H, 7.5; N, 12.5. Found: C, 61.0; H, 7.2; N, 12.5.

(13) R. H. Sifferd and V. du Vigneaud, *J. Biol. Chem.*, **108**, 753 (1935).

β-Alanyl-L-leucinamide Hydrochloride.—This was prepared by hydrogenation of 2.50 g. of carbobenzoxy-β-alanyl-L-leucinamide. The reduction was complete in three hours and the catalyst was removed by filtration. The filtrate was concentrated under reduced pressure to a sirup and this procedure repeated several times after the addition of successive small portions of ethanol. Since the product failed to crystallize as the acetate, the sirup was dissolved in 30 cc. of ethanol and 1 cc. of concentrated hydrochloric acid was added. The compound crystallized as the hydrochloride upon the addition of ether as plates; yield after drying *in vacuo* over sulfuric acid at 25°, 1.55 g.; m. p. 120° with evolution of gas; hygroscopic, $[\alpha]^{26}D$ − 17° (*c* 2, water).

Anal. Calcd. for $C_9H_{20}O_2N_3Cl$: C, 45.5; H, 8.5; N, 17.7. Found: C, 45.3; H, 8.6; N, 17.6.

Acknowledgment.—This investigation was aided by grants from the United States Public Health Service.

Summary

1. The preparation and properties of some dipeptides and dipeptide derivatives containing L-leucine, D- and L-α-alanine and β-alanine are described.

2. L-Leucyl-D-alanine and L-leucyl-L-alanine have been synthesized from L-leucine and racemic alanine.

3. The enzymatic preparation of carbobenzoxy-D-alanine from carbobenzoxy-DL-alanine is described.

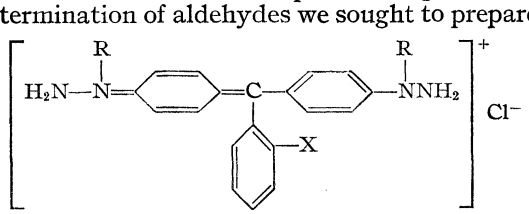
Triphenylmethane Dyes Containing the Hydrazine Group and Their Condensation Products with Aldehydes

BY LESTER P. KUHN AND LOUIS DEANGELIS

In order to obtain an improved reagent for the determination of aldehydes we sought to prepare a



I. X = H, R = H
II. X = H, R = CH_3
III. X = SO_3^-, R = CH_3

dye which contains a functional group capable of reacting readily with aldehydes and which as a result of its reaction would change color. Schwarzenbach[1] prepared N,N′ substituted phenylhydrazine sulfonphthalein dyes and showed that they are deeply colored stable compounds quite similar in properties to the aniline sulfonphthaleins. More recently *p,p′*-dihydrazinotriphenylmethyl chloride, I, and its N-methyl derivative, II, have been prepared.[2] It was shown that these dyes react readily with aldehydes, but not with ketones, and that the color of the dye solution changes from red to blue or to green. In the present work the preparation of I and II has been repeated, and the new dye III has been prepared. An attempt has been made to further evaluate these compounds as reagents for the determination of aldehydes and also to explain the color changes which are observed.

The dyes I, II and III can exist in several different states depending upon the *p*H of the solution in the manner shown here.

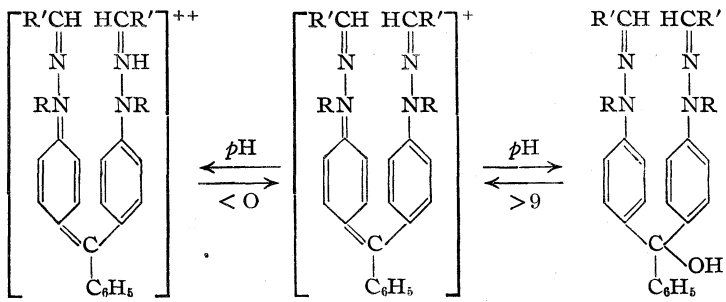
(2) Ciusa and Ottolino, *Gazz. chim. ital.*, **75**, 171 (1945); *C. A.*, **41**, 4137 (1947).

The hydrazones show a similar behavior



Red Blue to green Colorless

In the hydrazone series the conversion of the singly charged cation to the doubly charged cation requires a relatively concentrated solution of sulfuric or hydrochloric acids whereas in the hydrazine series the change occurs at a *p*H of 2–3. This difference which is due to the stronger basicity of the hydrazine group as compared with the hydrazone makes possible the use of these dyes as extremely good reagents for aldehydes. Ciusa and Ottolino[2] described the hydrazine dye as red and the hydrazone dye as blue or green and did not mention the fact that the color of these compounds depends upon the solution *p*H. Apparently they happened to be working in the *p*H range in which the hydrazine dye is stable in its red form and the hydrazone in its blue form.

A solution of any of the hydrazine dyes may be prepared in either water, methanol, or mixtures of the two and acidified to the point where the red color is obtained. Upon the addition of a drop of solution containing an aldehyde a color change is obtained within a minute. With aliphatic aldehydes the color becomes blue and with aromatic aldehydes it becomes green due to the formation of the hydrazone dye. The results obtained with a number of different aldehydes are given in Table I. Interestingly enough, ketones do not react under the conditions employed except the very readily enolizable ketone, ethyl acetoacetate. Sugars and chloral hydrate were the only aldehydes which did not give a positive test. With this reagent we have been able to detect 2 parts of benzaldehyde in a million parts of methanol.

Figures 1, 2 and 3 show the absorption curves for dyes I, II and III, respectively, in the red and blue forms and also the curves for the hydrazones formed from formaldehyde, acetaldehyde and benzaldehyde.

For the quantitative determination of aldehydes dye III should be used because its hydrazones are more soluble than the hydrazones of dyes I and II. A calibration curve is first prepared by making up solutions of known concentrations of the aldehyde to be determined and excess dye and then obtaining the optical density as a function of concentration. Figure 4 shows the calibration curves for acetaldehyde and benzaldehyde. The latter is a straight line but the former is slightly concave downward because the unreacted hydrazine dye has an appreciable absorption at the wave length where the absorption maximum of the acetaldehyde hydrazone occurs. The concentration of aldehyde in the solution to be analyzed can be obtained by comparing the intensity of color which it yields upon reaction with the reagent with the calibration curve, if the experimental conditions are kept constant. It is beyond the scope of this paper to make a complete evaluation of this reagent

TABLE I

EFFECT OF VARIOUS SUBSTANCES UPON DYES

Compound	Color produced
Formaldehyde	Blue
Acetaldehyde	Blue
Benzaldehyde	Green
Glyoxal	Blue
Furfural	Green
Crotonaldehyde	Green
Chloral hydrate	No change
Anisaldehyde	Green
p-Nitrobenzaldehyde	Green
Glucose	No change
Fenchone	No change[a]
Acetone	Deeper red[b]
Acetophenone	Deeper red[b]
Paraldehyde	Blue
Acetonyl acetone	No change[b]
Methyl glyoxal	Purple
Piperonal	Green
Ethyl acetoacetate	Blue
Cinnamaldehyde	Green
p-Dimethylaminobenzaldehyde	Green

[a] Turns blue after standing for ten minutes. [b] Turns purple after standing for ten minutes.

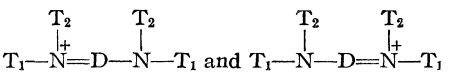
Fig. 1.—Absorption spectrum of I in methanol–water: 1, *p*H < 2; 2, *p*H 5; 3, formaldehyde added *p*H < 2; 4, acetaldehyde added *p*H < 2; 5, benzaldehyde added *p*H < 2.

for quantitative determinations but it is rather our intention to indicate the possibility of its use.

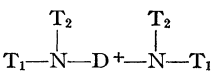
The absorption maxima of the various dyes are given in Table II. The following changes in the dye molecule result in a deepening of the color (bathochromic effect): replacement of the amino group of the diaminotriphenylmethane dye with the hydrazine group, replacement of the hydrogen atom on the nitrogen with methyl, conversion of the hydrazine dye to a hydrazone. The position of the absorption maximum of the hydrazone dyes derived from aldehydes of the general formula, RCHO, is displaced toward the longer wave lengths as R goes through the series H, CH_3, *p*-nitrophenyl, phenyl, *p*-methoxyphenyl, C_6H_5-CHCH.

A number of interesting relationships between the constitution of cyanine dyes and their color have been deduced by Brooker.[3] These relationships have been extended to the dyes of the triphenylmethane series by Branch and co-workers.[4]

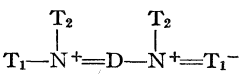
It is of interest to apply these relationships to these new dyes. The dyes in their deeply colored state have a high degree of resonance and it is possible to picture the various structures which contribute to the actual state of the molecule using the symbolism devised by Branch.[4] Let us represent the dye by the symbol $T_1T_2N—D—N—T_1T_2$, where D is $C_6H_4C(C_6H_5)$-C_6H_4, the N's are the auxochromic nitrogen atoms and T_1 and T_2 are the terminal groups bound to these nitrogen atoms. Thus for dye I, T_1 is H and T_2 is NH_2. The various structures contributing to the actual structure of the molecule are



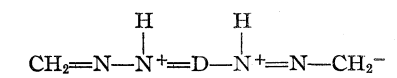
which are the A structures



which is the P structure and



which is the T structure. Contributions from the T structures are possible only if T_1 or T_2 contains a double bond. It may be illustrated by the formaldehyde hydrazone of dye I



Constitutive features which increase the stability of structures A and T have a bathochromic effect upon the dye. The stability of the A structure depends upon the ability of the nitrogen to contribute its unshared electrons to the resonating system and thereby becoming positively charged. This ability depends upon the nature of the substituents on the nitrogen atom, the more electronegative the substituent the less will be the tendency of the nitrogen to donate its unpaired electrons. Since hydrogen is more electronegative than NH_2 which is more electronegative than CH_3, it is in agreement with theory that the hydrazinotriphenylmethane dye absorbs at longer wave length than the amino dye but at slightly shorter wave length than the methylamino dye.

Conversion of the hydrazine dyes to the hydrazone dyes with an aldehyde, RCHO, reduces the basicity of the auxochromic nitrogen and hence reduces the stability of the A structure which should result in a hypsochromic effect. However, it makes possible the existence of the T structures and the net result is a deepening of the color. When R is aromatic the colors are deeper than when R is aliphatic because the polarizability of the benzene ring makes the T structures more stable. The introduction of the electron attracting nitro group into the benzene ring of R would be expected to produce a bathochromic effect since it stabilizes the T structure

Similarly the methoxy group should produce a hypsochromic effect since it tends to yield electrons and become positively charged, and hence reduces the stability of the T structure. Since the expected effects are opposite to those which are actually observed it seems likely that other resonance forms must be considered which make significant contributions to the actual state of the molecule and which influence the color. For the

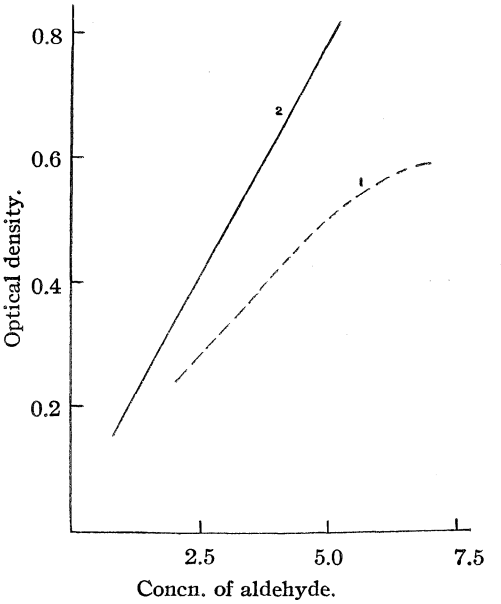


Fig. 4.—Calibration curve for the determination of aldehydes with III pH < 2: 1, acetaldehyde; 2, benzaldehyde.

nitro compound the structure

which is similar to the P structure may account for the observed hypsochromic effect. The methoxy group would stabilize the form

which like the A structure would produce a bathochromic effect. With molecules of this type a number of different resonance structures can be pictured which make significant contributions to the actual state of the molecule. Some of these structures can be associated with a bathochromic effect and other structures with a hypsochromic effect. The introduction of a substituent may stabilize several different structures which have opposing effects upon the color, and hence it is not easy to predict what the net result will be.

Lengthening the conjugated carbon chain in the terminal group, T_1, has a bathochromic effect as can be seen by comparing the benzaldehyde dyes with the cinnamaldehyde dyes; also the crotonaldehyde compounds are deeper than the acetaldehyde dyes.

Experimental

Dyes I and II were prepared by the reactions

$$C_6H_5CCl_3 + 2C_6H_5CH{=}NNRC_6H_5 \xrightarrow{ZnCl_2} [(C_6H_5CH{=}NNRC_6H_4)_2CC_6H_5]^+Cl^- + 2HCl$$

$$[(C_6H_5CH{=}NNRC_6H_4)_2CC_6H_5]^+Cl^- + 2H_2O \xrightarrow{H_2SO_4} 2C_6H_5CHO + [(H_2NNRC_6H_4)_2CC_6H_5]^+Cl^-$$

I, R = H
II, R = CH_3

The benzalhydrazone dyes were isolated as green lustrous crystals. The structure of these was not proven; however, evidence for the validity of the assigned structure is based upon the elementary analyses, the method of synthesis and the similarity of properties with the properties of other triphenylmethane dyes whose structures are well known. The dyes I, II and III were prepared by the hydrolysis of the corresponding benzalhydrazones. They were not isolated but were used in the solutions in which they were prepared.

Benzalhydrazone of I.—Benzotrichloride, benzalphenylhydrazone and anhydrous zinc chloride in molar ratio of 1:2:1 were intimately mixed and heated slowly to 80° with constant mixing by hand. The mixture turned green and was maintained at 80° for thirty minutes. After cooling to room temperature the product was broken up and washed with ligroin. It was then dissolved in methanol, precipitated with dilute hydrochloric acid, filtered and washed with dilute hydrochloric acid and air dried. The product was dissolved in chloroform, the chloroform solution washed with dilute hydrochloric acid and then water and dried with calcium chloride. The product was precipitated by the addition of ethyl ether, filtered and washed with ethyl ether. It was finally recrystallized from acetic acid and benzene. The pure product crystallized out after standing for several days. The analytical data suggest that the dye contains 1 mole of water.

Anal. Calcd. for $C_{33}H_{27}N_4ClH_2$: C, 74.5; H, 5.50; N, 10.5. Found: C, 74.0; H, 5.80; N, 10.3.

The benzalhydrazone of II was prepared in the same manner except that benzalphenylmethylhydrazone was used instead of benzalphenylhydrazone. For analysis this dye was converted to its methyl ether by dissolving the dye in methanol and adding sodium methylate solution until the green color disappeared. The methyl ether was precipitated with water, filtered and washed with water and dried over phosphoric anhydride. The methyl ether can be converted back to the original colored dye by the addition of acid.

Anal. Calcd. for $C_{36}H_{34}N_4O$: C, 80.5; H, 6.0; N, 10.4. Found: C, 79.6; H, 6.4; N, 10.4.

The benzalhydrazone of III was prepared in the same manner except that the benzotrichloride was replaced by the pseudo dichloride of *o*-sulfobenzoic acid.

Anal. Calcd. for $C_{36}H_{31}N_4SClO_3$: C, 67.5; H, 5.04; N, 9.00; S, 5.15. Found: C, 67.1; H, 5.44; N, 8.43; S, 5.12.

To hydrolyze, 50 mg. of the dye was dissolved in 25 ml. of methanol, and 25 ml. of 20% by volume aqueous sulfuric acid was added. The solution was heated on a steam bath for 0.5 to one hour or until the color of the solution has turned from green to red, the volume being kept approximately constant by the addition of 50% methanol. The benzaldehyde resulting from the hydrolysis evaporated off. After filtration the solution may be used as an aldehyde reagent. Its reactivity seems to decrease slowly and after two weeks it reacts sluggishly with aldehydes. We have found that the reagent performs satisfactorily for a period of a week after it has been prepared. For this reason it is advisable to store the dye as the hydrazone and to hydrolyze it as it is needed.

The qualitative tests with the various aldehydes were run by adding a drop of aldehyde to about 5 ml. of the reagent. The calibration curves for the quantitative determination of acetaldehyde and benzaldehyde, respectively, were obtained by measuring into 10-ml. volumetric flasks 3 ml. of the reagent Dye III and varying amounts from 0 to 0.8 ml. of aldehyde solution which contained 1 drop of aldehyde in 400 ml. of aldehyde-free methanol. The flasks were brought up to volume with methanol and were allowed to stand overnight. The readings were taken with a Beckman Spectrophotometer at the wave length where absorption of the dye formed with the particular aldehyde is at a maximum. This of course must be determined in advance using an excess of aldehyde. It was found that the concentration of dye in the reagent should be such that the contents of the flask which contains no aldehyde should have an optical density of 0.03 to 0.04 at the wave length at which the measurements will be taken.

Summary

Three hydrazinotriphenylmethane dyes have been prepared and have been tested with various aldehydes to yield the corresponding hydrazones. An explanation has been provided for the color change accompanying this reaction which corrects misconceptions of previous workers. The absorption of these compounds in the visible spectral region has been measured. The usefulness of these dyes as reagents for the qualitative determination of aldehydes has been demonstrated and the possibility of using them for quantitative measurements has been indicated. The relationship between the color and constitution of these compounds has been discussed and principles set forth by previous workers on other dyes have been extended.

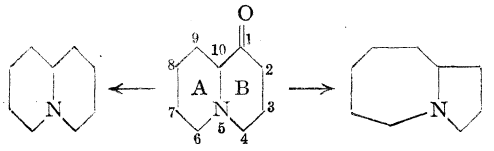
Rearrangement of α-Aminoketones During Clemmensen Reduction. I. Bicyclic Compounds Containing a Bridge-head Nitrogen[1]

BY NELSON J. LEONARD AND WILLIAM C. WILDMAN

The Clemmensen reduction of 1-ketoquinolizidine (I) leads not to the normal product, quinolizidine (II),[2] but to the rearrangement product, 1-azabicyclo[5.3.0]decane (III).[3] We have now established that this reductive rearrangement proceeds with ketone-ring (B) contraction.



II I III

Quinolizidine (II),[4] the parent nucleus of the *Lupin* alkaloids, was first synthesized by Clemo, Ramage and Raper in 1932.[5] The compound was also synthesized satisfactorily in the same laboratory[2] by the Clemmensen reduction of 2-ketoquinolizidine and by the Wolff–Kishner reduction of 1-ketoquinolizidine (I). However, when the Clemmensen method was applied to I, an isomer of II was obtained, the structure of which was unknown until proved through an unequivocal synthesis by Prelog and Seiwerth[3] to be 1-azabicyclo[5.3.0]decane (III). No clearly outlined mechanism for this unusual rearrangement has been proposed, but Prelog and Seiwerth suggested that the first step might be a cleavage of the α–C–N bond in the acid medium, followed by an intramolecular condensation of the secondary amino group with the carbonyl group and reduction to give the new ring system. The work of Cromwell[6] indicates that α-aminoketones are not as readily cleaved as β-aminoketones in acid medium. Nevertheless, if cleavage is involved as the initial step in the rearrangement, it is conceivable that α,β-unsaturation might develop. The secondary amine could then add intramolecularly in a 1,4-manner to the unsaturated ketone. In other words, the conversion of I to III does not indicate whether it is ring A or ring B which contracts from a six to a five-membered ring. A logical way to begin the study of the mechanism of the rearrangement is to learn which ring contracts and which expands.

The "labelling" of either ring with a methyl group provides an attractive means of following contraction or expansion. Clemo and his coworkers have provided the model compounds, for they carried out Clemmensen reductions of 1-keto-2-methylquinolizidine (IV)[7] and 1-keto-8-methylquinolizidine (V).[8] The products of Clemmensen reduction were not identical with each other and were not identical with the normal (Wolff–Kishner) reduction product of each: 2-methylquinolizidine (VI).[9]

The Clemmensen reduction products are therefore represented as VII and VIII, but the question as to which rearranged amine resulted from which aminoketone could not be decided until the amines were synthesized by an unequivocal method. We have now completed unequivocal syntheses of VII and VIII, and it is the comparison of these amines with the Clemmensen reduction products of IV and V which enables us to state that the ketonic ring (B) contracts. In brief, identical physical properties were exhibited by the derivatives of 8-methyl-1-azabicyclo[5.3.0]decane (VII) (picrate, m. p. 181–182°; picrolonate, m. p. 189–190°) and the Clemmensen reduction product of IV (picrate, m. p. 182°; picrolonate, m. p. 189°)[7]; by the derivatives of 4-methyl-1-azabicyclo[5.3.0]decane (VIII) (picrate, m. p. 189°; picrolonate, m. p. 138–139°) and the Clemmensen reduction product of V (picrate, m. p. 189°; picrolonate, m. p. 138°).[8] The established course of

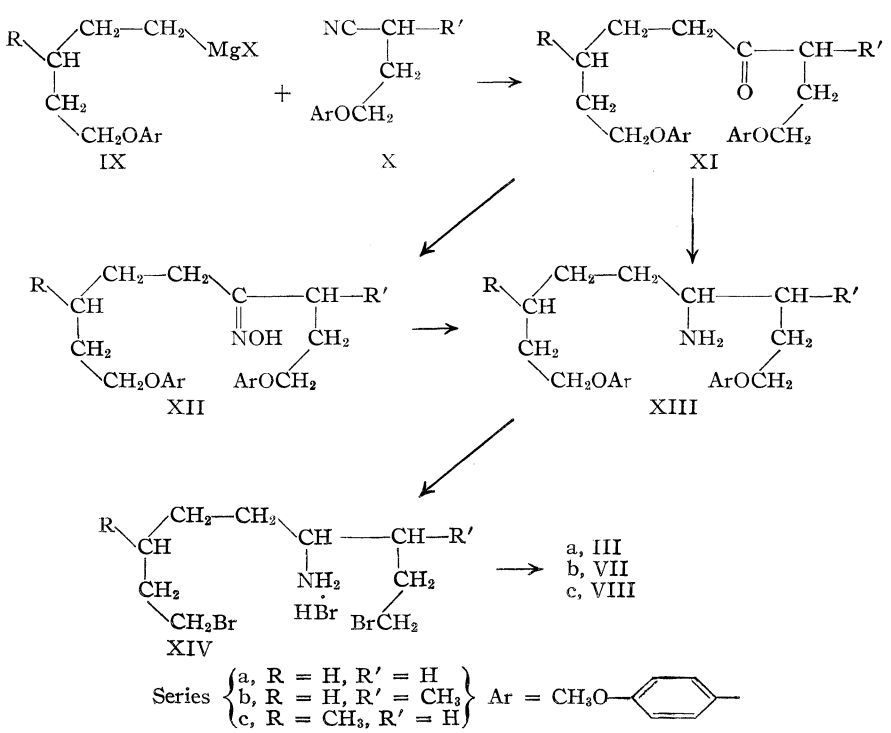
(8) Clemo, Cook and Raper, *ibid.*, 1183 (1938).

(9) The product of Wolff–Kishner reduction of IV was described as 2-methyloctahydropyridocoline (picrate, m. p. 158°; picrolonate, m. p. 219°)[7]; that from V, as 8-methyloctahydropyridocoline (picrate, m. p. 150°; picrolonate, m. p. 197°).[8] Both products should be named 2-methyloctahydropyridocoline (or 2-methylquinolizidine). Even if they were not actually identical, they could only be different racemates represented by the same structure (VI).

the Clemmensen reduction is thus indicated by the unbroken arrows in the accompanying diagram (IV → VII and V → VIII).

Unequivocal methods of synthesis of VII and VIII were realized by applying certain modifications to the general method which Prelog and his co-workers devised for the preparation of bicyclic compounds containing a bridge-head nitrogen.[3,10,11] Our modified method was checked by a "control" run: the synthesis of the known compound, 1-azabicyclo[5.3.0]decane (III), through the intermediates IXa, Xa, XIa, XIIa, XIIIa, and XIVa. The methyl-substituted products VII and VIII were then prepared by the similar reaction series b and c. The use of the terminal aryloxy group in the intermediates (IX, X, XI, and XIII) was suggested by our desire to work with crystalline and easily separable compounds. The utilization of the *p*-methoxyphenoxy group specifically was guided by the finding of Ziegler and his coworkers[12] that certain *p*-methoxyphenyl ethers were cleaved by acid more readily than the analogous phenyl ethers. The use of the *p*-methoxyphenoxy group insured facile acid cleavage of XIII to XIV.



The first step in the general procedure employed for the synthesis of III, VII and VIII was the Grignard reaction. The halide precursors of the Grignard reagents IXa and IXc were made by condensation of hydroquinone monomethyl ether with 1,5-dichloropentane and 1,5-dibromo-3-methylpentane,[13] respectively. The nitriles Xa and Xb were made by methods previously described for the phenoxy analogs. The reaction between the Grignard reagents (IX) and the nitriles (X) proceeded normally, but special precautions were necessary in the hydrolysis and isolation to insure the maximum yield of each ketone, 1,9-bis-(*p*-methoxyphenoxy)-4-nonanone (XIa), 1,9-bis-(*p*-methoxyphenoxy)-3-methyl-4-nonanone (XIb), and 1,9-bis-(*p*-methoxyphenoxy)-3-methyl-6-nonanone (XIc). Oximes (XII) were formed from each ketone, and the oximes could be reduced with sodium and ethanol to the corresponding amines (XIII). However, the conversion of the ketones (XI) to the amines (XIII) was accomplished more efficiently by hydrogenation in liquid ammonia over Raney nickel catalyst at high temperature and pressure. 4-Amino-1,9-bis-(*p*-methoxyphenoxy)-nonane (XIIIa) was obtained in crystalline form without difficulty. Although the other two amines (XIIIb and XIIIc) were not readily crystallizable, suitable crystalline derivatives were found in the hydrochloride monohydrate of 4-amino-1,9-bis-(*p*-methoxyphenoxy)-3-methylnonane (XIIIb) and in the half ammonium oxalate salt of 6-amino-1,9-bis-(*p*-methoxyphenoxy)-3-methylnonane (XIIIc). No attempt was made to isolate the α,ω-dibromoamine hydrobromides (XIV) which were obtained by hydrobromic acid cleavage of XIII, although the quantitative recovery of hydroquinone in a trial run indicated that cleavage was proceeding satisfactorily. The crude α,ω-dibromoamine hydrobromides (XIV) were converted to the 1-azabicyclo[5.3.0]decanes (III, VII, VIII) by intramolecular dialkylation of the primary amine group in dilute aqueous sodium hydroxide. The final products (III, VII, VIII) were characterized by the formation of suitable derivatives. Although diastereoisomeric racemates might have been expected from both 8-methyl-1-azabicyclo[5.3.0]-decane (VII) and 4-methyl-1-azabicyclo[5.3.0]-decane (VIII), single derivatives were isolated in every case.

With the establishment of the fact that the ketone ring contracts during the Clemmensen reduction of the 1-ketoquinolizidines (I, IV, V), it be-

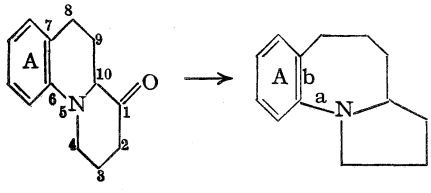
(13) Leonard and Wicks, THIS JOURNAL, **68**, 2402 (1946).

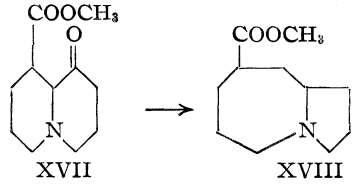
comes possible to assign correct structures to the Clemmensen reduction products of several analogous compounds investigated by Clemo and his co-workers. The product of Clemmensen reduction (which differed from the normal or Wolff–Kishner product)[14] of 1-keto-6,7-benzoquinolizidine (XV)[15] therefore has the structure: benzo[b]-1-azabicyclo[5.3.0]decane (XVI). The product of Clemmensen reduction (which differed from the Wolff–Kishner product)[14] of 1-keto-6,7-hexa-



XV XVI

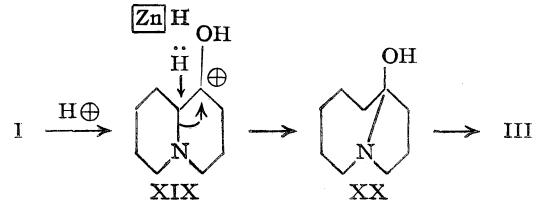
(a, ring A fully saturated)

hydrobenzoquinolizidine (XVa)[16] is therefore hexahydrobenzo[b]-1-azabicyclo[5.3.0]decane(XVIa). The product of Clemmensen reduction of methyl 9-ketoquinolizidine-1-carboxylate (XVII) (which was degraded by Clemo, Ramage and Raper[17] to 1-azabicyclo[5.3.0]decane (III)) must possess the structure: methyl 1-azabicyclo[5.3.0]-decane-5-carboxylate (XVIII).



XVII XVIII

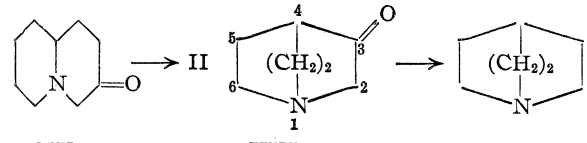
These examples serve as illustrations of a rearrangement which appears to be general in scope. The products of the rearrangement can be accounted for by an elaboration of the suggestion of Prelog and Seiwerth[3]



XIX XX

The first step would involve the migration of the R_2N- group to the geometrically-fixed, adjacent carbonium carbon (formed from the carbonyl group in acid solution),[18a] with the subsequent or simultaneous attack of hydrogen at the newly-formed carbonium ion of the α-carbon (XIX → XX). Reductions of the type represented by the second step, conversion of XX to III, appear to occur readily.[18b,c]

The limitations, the confining structural features of the α-substituted ketones, and a study of the proposed mechanism of the rearrangement constitute the subject matter of succeeding articles. At present, it is important to mention the fact that rearrangement was found not to occur in the Clemmensen reduction of at least two related α-aminoketones of the bicyclic, bridge-head-nitrogen type. Clemmensen reduction of 3-ketoquinolizidine (XXI) gave a low yield of the normal product, quinolizidine (II),[19a] and similar reduction of 3-ketoquinuclidine (XXII) gave quinuclidine (XXIII).[19b]



XXI XXII XXIII

Clemmensen reduction of β-aminoketones of the bicyclic, bridge-head-nitrogen type invariably produced unrearranged products.[2,20]

Experimental[21,22]

Halides

1-Bromo-3-(*p*-methoxyphenoxy)-propane.—The procedure used for the condensation of hydroquinone monomethyl ether with α,ω-dihaloalkanes was based on the method of Ziegler and Weber[12a] for phenoxyalkyl halides. The yields were similar for all compounds synthesized in this manner. The following synthesis is representative of the series. A solution of 28 g. (0.5 mole) of potassium hydroxide in 350 ml. of methanol was added over a period of one hour to a stirred solution of 62 g. (0.5 mole) of hydroquinone monomethyl ether (Tennessee Eastman Corporation) and 400 g. (1.98 moles) of 1,3-dibromopropane at reflux temperature. The reaction mixture was boiled under reflux until the solution was neutral to litmus (about six hours). The solution was cooled, and sufficient water was added to dissolve the potassium bromide. The non-aqueous layer was washed twice with water, dried over magnesium sulfate, and distilled. Three hundred grams of 1,3-dibromopropane was recovered. The 1-bromo-3-(*p*-methoxyphenoxy)-propane was obtained as a light yellow oil, b. p. 120–130° (1 mm.); yield, 75 g. (61.5%). The crude product was redistilled for analysis, b. p. 126–127° (1 mm.); $n^{20}D$ 1.5463; d^{20}_4 1.3788.

Anal. Calcd. for $C_{10}H_{13}O_2Br$: C, 49.00; H, 5.34; MR_D 55.85. Found: C, 49.25; H, 5.47; MR_D 56.31.

1-Bromo-3-methyl-5-(*p*-methoxyphenoxy)-pentane.—B. p. 133–134° (0.5 mm.); $n^{20}D$ 1.5311; d^{20}_4 1.2829.

Anal. Calcd. for $C_{13}H_{19}O_2Br$: C, 54.37; H, 6.66; MR_D 68.69. Found: C, 54.46; H, 6.93; MR_D 69.27.

Nitriles

Ethyl α-Cyano-γ-(*p*-methoxyphenoxy)-butyrate.—The ester was prepared by the procedure of Robinson and Watt[23] for the condensation of phenoxyethyl bromide with ethyl cyanoacetate, with the exception that twice the recommended pressure was employed. A mixture of 92.4 g. (0.40 mole) of 1-bromo-2-(*p*-methoxyphenoxy)-ethane, 56.0 g. (0.40 mole) of anhydrous potassium carbonate, and 226 g. (2.0 moles) of ethyl cyanoacetate was heated under reflux at 130° and 120 mm. for twenty-two hours. The reaction mixture was cooled, and sufficient water was added to dissolve the inorganic salts. The ester layer was washed with water until neutral and was fractionally distilled. The first fraction contained 116 g. of unreacted ethyl cyanoacetate, b. p. 95–98° (14 mm.). The second fraction consisted mainly of unreacted 1-bromo-2-(*p*-methoxyphenoxy)-ethane, 37 g., b. p. 80–135° (1 mm.). The condensation product boiled at 166–170° (1 mm.); yield 51.0 g. (81% based on unrecovered halide). The crude product was redistilled for analysis, b. p. 169–170° (1 mm.); $n^{20}D$ 1.5083; d^{20}_4 1.1431.

Anal. Calcd. for $C_{14}H_{17}NO_4$: C, 63.86; H, 6.51; N, 5.32; *MR*D 67.95. Found: C, 64.14; H, 6.57; N, 5.48; *MR*D 68.66.

Ethyl α-Cyano-α-methyl-γ-(*p*-methoxyphenoxy)-butyrate.—The sodium derivative of ethyl-α-cyano-γ-(*p*-methoxyphenoxy)-butyrate was prepared by the addition of 52.6 g. (0.20 mole) of ethyl α-cyano-γ-(*p*-methoxyphenoxy)-butyrate to an ethanolic solution of 0.2 mole of sodium ethoxide from the reaction of 4.6 g. (0.20 mole) of sodium with 200 ml. of absolute ethanol. Eighty-five grams (0.60 mole) of methyl iodide was added over a period of one-half hour at reflux temperature to the stirred solution of the sodio-derivative. The mixture was refluxed for five hours. The ethanol and methyl iodide were removed by distillation. The oily residue was washed with water, and the water layer was extracted twice with ether. The combined ester and ether layers were dried over magnesium sulfate and distilled. The ethyl α-cyano-α-methyl-γ-(*p*-methoxyphenoxy)-butyrate was obtained as a colorless liquid, b. p. 162–163° (0.5 mm.); $n^{20}D$ 1.5024; d^{20}_4 1.1413; yield 50.5 g. (91%).

Anal. Calcd. for $C_{15}H_{19}NO_4$: C, 64.96; H, 6.91; N, 5.05; *MR*D 72.77. Found: C, 65.06; H, 6.79; N, 4.91; *MR*D 72.13.

α-Cyano-α-methyl-γ-(*p*-methoxyphenoxy)-butyric Acid.—A solution of 45 g. (0.162 mole) of ethyl α-cyano-α-methyl-γ-(*p*-methoxyphenoxy)-butyrate in 100 ml. of ethanol was treated with one equivalent of 30% aqueous potassium hydroxide and allowed to stand at room temperature for six hours. The mixture was neutralized with one equivalent of 6 *N* hydrochloric acid. The cyano acid was separated, and the aqueous solution was extracted twice with ether. The cyano acid and ether extracts were combined and dried over magnesium sulfate. The ether was removed under reduced pressure. The residual yellow oil was caused to crystallize by standing twelve hours at 0°. The α-cyano-α-methyl-γ-(*p*-methoxyphenoxy)-butyric acid was isolated by filtration. The filtrate (15.1 g.) was composed largely of unreacted ester which was resaponified and worked up in the same manner. The total yield of the crude cyano acid was 36 g. (89.3%). For analysis a small portion was recrystallized twice from hot water to yield white needles, m. p. 80–81°.

Anal. Calcd. for $C_{13}H_{15}NO_4$: C, 62.64; H, 6.07; N, 5.62. Found: C, 62.86; H, 6.14; N, 5.64.

1-(*p*-Methoxyphenoxy)-3-cyanobutane (Xb).—Sixty grams (0.24 mole) of crude α-cyano-α-methyl-γ-(*p*-methoxyphenoxy)-butyric acid was heated at 200° for two hours. The liquid was cooled, washed once with 5% sodium carbonate solution and once with water, dried over magnesium sulfate, and distilled. The 1-(*p*-methoxyphenoxy)-3-cyanobutane was obtained as a colorless liquid, b. p. 146–149° (1.3 mm.); yield 37 g. (75%). The nitrile solidified upon standing. For analysis a small portion was recrystallized from ether as colorless platelets, m. p. 46–47°.

Anal. Calcd. for $C_{12}H_{15}NO_2$: C, 70.22; H, 7.37; N, 6.82. Found: C, 70.38; H, 7.53; N, 6.64.

1-Cyano-3-(*p*-methoxyphenoxy)-propane (Xa).—The following procedure was that employed by von Braun[24] for the preparation of the phenoxy homolog. A solution of 77.0 g. (0.314 mole) of 1-bromo-3-(*p*-methoxyphenoxy)-propane and 65 g. (1.0 mole) of potassium cyanide in 520 ml. of 70% ethanol was boiled under reflux for six hours. The ethanol was removed by distillation. The nitrile was dissolved in 100 ml. of ether, washed twice with water, and dried over anhydrous magnesium sulfate. The nitrile boiled at 150–153° (1 mm.); yield 45 g. (75%). The nitrile solidified upon standing. Recrystallization of a small portion from ethanol yielded colorless platelets, m. p. 37–38°.

Anal. Calcd. for $C_{10}H_{13}NO_2$: C, 69.10; H, 6.85; N, 7.33. Found: C, 69.24; H, 6.70; N, 7.45.

Ketones

1,9-bis-(*p*-Methoxyphenoxy)-4-nonanone (XIa).—A solution of 8 g. (0.042 mole) of 1-cyano-3-(*p*-methoxyphenoxy)-propane in 35 ml. of anhydrous ether was added with stirring to a Grignard reagent prepared from 1.25 g. (0.052 mole) of magnesium, 11.4 g. (0.05 mole) of 1-chloro-5-(*p*-methoxyphenoxy)-pentane, and 35 ml. of anhydrous ether. The mixture was boiled under reflux for five hours and then was decomposed at 0° by the slow addition of 80 ml. of 1.2 *N* hydrochloric acid. The crude ketone was isolated by filtration. The ether layer of the filtrate was separated, washed twice with water, and dried over anhydrous magnesium sulfate. The ether was evaporated, and the oily residue was crystallized from ethanol. The combined crude ketone was obtained as colorless platelets from ethanol, m. p. 72–75°; yield 10.0 g. (61.8%). For analysis a small portion was recrystallized twice from ethanol, m. p. 80–81°.

Anal. Calcd. for $C_{23}H_{30}O_5$: C, 71.48; H, 7.82. Found: C, 71.56; H, 8.06.

1,9-bis-(*p*-Methoxyphenoxy)-3-methyl-4-nonanone (XIb).—A solution of 10.2 g. (0.05 mole) of 1-(*p*-methoxyphenoxy)-3-cyanobutane in 40 ml. of anhydrous ether was added to a Grignard reagent prepared from 1.44 g. (0.06 mole) of magnesium, 14.8 g. (0.065 mole) of 1-(*p*-methoxyphenoxy)-5-chloropentane, and 30 ml. of anhydrous ether. The mixture was boiled under reflux for five hours and then decomposed at 0° by the slow addition of 100 ml. of 1.2 *N* hydrochloric acid. The crude ketone was isolated by filtration. The ether layer of the filtrate was separated, washed twice with water, and dried over anhydrous magnesium sulfate. The ether was evaporated, and the oil residue was crystallized from an ethyl acetate–petroleum ether mixture. The combined crude ketone was dissolved in boiling ethyl acetate and allowed to cool to 50°. One gram of non-ketonic material, m. p. 127–

(23) Robinson and Watt, *J. Chem. Soc.*, 1536 (1934).

(24) von Braun, *Ber.*, **42**, 2047 (1909).

128°, was isolated by filtration, but it was not investigated further. The 1,9-bis-(*p*-methoxyphenoxy)-3-methyl-4-nonanone was obtained as white rosettes upon the addition of petroleum ether to the cold ethyl acetate solution, m. p. 42–43°; yield 10.2 g. (51%).

Anal. Calcd. for $C_{24}H_{32}O_5$: C, 71.97; H, 8.05. Found: C, 72.15; H, 8.02.

1,9-bis-(*p*-Methoxyphenoxy)-3-methyl-6-nonanone (XIc).—A solution of 4.76 g. (0.025 mole) of 1-cyano-3-(*p*-methoxyphenoxy)-propane in 20 ml. of anhydrous ether was added with stirring to a Grignard reagent prepared from 0.72 g. (0.03 mole) of magnesium, 9.2 g. (0.032 mole) of 1-bromo-3-methyl-5-(*p*-methoxyphenoxy)-pentane, and 20 ml. of anhydrous ether. The mixture was boiled under reflux for five hours and then decomposed at 0° by the slow addition of 50 ml. of 1.2 *N* hydrochloric acid. The ether layer was separated, washed twice with water, and dried over anhydrous magnesium sulfate. After removal of the solvent by distillation, the ketone was obtained as an oil which could not be induced to crystallize, yield 8.4 g. (84%).

Oximes

One gram (0.0025 mole) of the ketone in 15 ml. of 50% methanol was heated under reflux for eighteen hours with 0.6 g. (0.0086 mole) of hydroxylamine hydrochloride and 1.2 g. (0.0147 mole) of anhydrous sodium acetate. The oxime crystallized upon cooling and was washed with water. Recrystallization from 95% ethanol yielded 0.6 g. (60%).

1,9-bis-(*p*-Methoxyphenoxy)-4-nonanone Oxime (XIIa).—Needles, m. p. 76–77°.

Anal. Calcd. for $C_{23}H_{31}NO_6$: C, 68.80; H, 7.78; N, 3.49. Found: C, 68.93; H, 7.84; N, 3.57.

1,9-bis-(*p*-Methoxyphenoxy)-3-methyl-4-nonanone Oxime (XIIb).—Platelets, m. p. 76.5–77°.

Anal. Calcd. for $C_{24}H_{33}NO_6$: C, 69.37; H, 8.00; N, 3.37. Found: C, 69.36; H, 8.20; N, 3.46.

1,9-bis-(*p*-Methoxyphenoxy)-3-methyl-6-nonanone Oxime (XIIc).—Platelets, m. p. 78–79°.

Anal. Calcd. for $C_{24}H_{33}NO_6$: C, 69.37; H, 8.00; N, 3.37. Found: C, 69.65; H, 8.29; N, 3.63.

Amines

A mixture of 12.5 g. of the ketone and 50 ml. of liquid ammonia was hydrogenated over Raney nickel catalyst at 150° and 150–200 atmospheres for five hours. The amine was dissolved in ethanol, and the catalyst was separated by filtration.

4-Amino-1,9-bis-(*p*-methoxyphenoxy)-nonane (XIIIa).—The ethanol was evaporated, and the residual light yellow oil was caused to crystallize by the addition of cold ether. The pure amine was obtained in approximately 60% yield as needles upon recrystallization from anhydrous ether, m. p. 71–72°.

Anal. Calcd. for $C_{23}H_{33}NO_4$: C, 71.29; H, 8.58; N, 3.62. Found: C, 71.13; H, 8.48; N, 3.72.

4-Amino-1,9-bis-(*p*-methoxyphenoxy)-3-methylnonane (XIIIb).—After removal of the ethanol by distillation, the amine was obtained as a red oil which could not be crystallized. The hydrochloride was prepared by the addition of five drops of the amine to a solution of 2 ml. of 50% ethanol and three drops of concentrated hydrochloric acid. The crude product was recrystallized from hot water as colorless platelets, m. p. 104–105°. Chemical behavior, infrared spectrum and analysis proved the compound to be **4-amino-1,9-bis-(*p*-methoxyphenoxy)-3-methylnonane hydrochloride monohydrate** (yield, *ca.* 60%).

Anal. Calcd. for $C_{24}H_{36}ClNO_4 \cdot H_2O$: C, 63.24; H, 8.40; N, 3.07. Found: C, 63.35; H, 8.63; N, 3.08.

6-Amino-1,9-bis-(*p*-methoxyphenoxy)-3-methylnonane (XIIIc).—After removal of the ethanol by distillation, the amine was obtained as a red oil which could not be induced to crystallize. The oxalate was chosen as a derivative. A 30% ethanolic solution of anhydrous oxalic acid was added dropwise to a solution of five drops of the amine in 5 ml. of ethanol. The monoammonium monoamine oxalate was obtained as white needles, m. p. 194–196° (yield, *ca.* 40%).

Anal. Calcd. for $C_{26}H_{39}N_2O_8$: C, 61.52; H, 7.75; N, 5.52. Found: C, 61.80; H, 7.81; N, 5.87.

α,ω-Dibromoamine Hydrobromides

A solution of 9 g. of the amine (XIII) in 190 ml. of glacial acetic acid was saturated with hydrogen bromide. The solution was treated with 190 ml. of 48% hydrobromic acid and boiled under reflux for seventy-two hours. The solvents were removed by distillation under reduced pressure. The residue was dissolved in 50% ethanol and evaporated to dryness under reduced pressure. The α,ω-dibromoamine hydrobromide was not purified but was used directly in the next step.

1-Azabicyclo[5.3.0]decanes

The method of preparation of the tertiary amines (III, VII, VIII) was essentially that of Prelog, Cerkovnikov and Ustricev[25] for the synthesis of bicyclic amines possessing a bridge-head-nitrogen atom. The steam volatile tertiary base was acidified with 10% hydrochloric acid. The water was removed by distillation under reduced pressure. The residue was treated with 20 ml. of 2 *N* sodium hydroxide, extracted twice with ether, and the ethereal solution was dried over anhydrous magnesium sulfate. The ethereal solution was used for the preparation of derivatives.

1-Azabicyclo[5.3.0]decane (III) Picrate.—Prepared in ether and recrystallized twice from methanol, the picrate formed yellow needles which melted with decomposition at 213–214° (reported, 213–214°,[3] 213°[2]).

8-Methyl-1-azabicyclo[5.3.0]decane (VII) Picrate.—Prepared in ether and recrystallized twice from methanol, the picrate formed yellow needles which melted with decomposition at 181–182°.

Anal. Calcd. for $C_{16}H_{22}N_4O_7$: C, 50.25; H, 5.80; N, 14.65. Found: C, 50.46; H, 5.93; N, 14.46.

4-Methyl-1-azabicyclo[5.3.0]decane (VIII) Picrate.—Prepared in ether and recrystallized twice from methanol, the picrate formed yellow needles which melted with decomposition at 189°.

Anal. Calcd. for $C_{16}H_{22}N_4O_7$: C, 50.25; H, 5.80; N, 14.65. Found: C, 50.21; H, 5.99; N, 14.93.

8-Methyl-1-azabicyclo[5.3.0]decane (VII) Picrolonate.—Prepared in ether and recrystallized twice from ethanol, the picrolonate formed yellow needles which melted at 189–190°.

4-Methyl-1-azabicyclo[5.3.0]decane (VIII) Picrolonate.—Prepared in ether and recrystallized twice from ethanol, the picrolonate formed deep yellow clusters of small prisms, m. p. 138–139°.

Summary

8-Methyl-1-azabicyclo[5.3.0]decane (VII) has been synthesized by an unequivocal method and has been shown to be identical with the Clemmensen reduction product of 1-keto-2-methylquinolizidine (IV).

4-Methyl-1-azabicyclo[5.3.0]decane (VIII) has been synthesized by a similar method and has been shown to be identical with the Clemmensen reduction product of 1-keto-8-methylquinolizidine (V).

By these comparisons, it has been established that it is the ketonic ring which undergoes contraction during the Clemmensen reduction-rearrangement of 1-ketoquinolizidines.

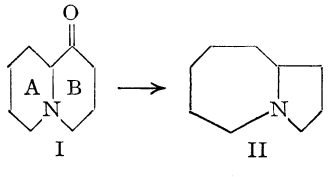
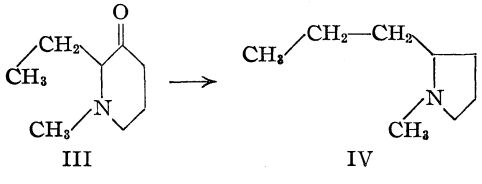
Rearrangement of α-Aminoketones During Clemmensen Reduction. II. Contraction of a Six-membered Ring in the Monocyclic Series

BY NELSON J. LEONARD AND WILLIAM V. RUYLE[1]

In the first article in this series[2] proof was provided that the Clemmensen reduction–rearrangement of 1-ketoquinolizidine (I) to 1-azabicyclo-[5.3.0]decane (II) proceeds through contraction of the six-membered *ketone ring* (B) to a five-membered ring. Since it was also established that contraction is the general fate of the ketonic ring in 1-ketoquinolizidines subjected to Clemmensen reduction, it was of interest to determine if a closely analogous *monocyclic* tertiary α-aminoketone (III) behaved similarly under Clemmensen conditions. Accordingly, the model compound 1-methyl-2-ethyl-3-piperidone (III) has been synthesized and has been subjected to Clemmensen reduction. The fact that the product obtained was 1-methyl-2-*n*-propylpyrrolidine (IV) indicates that the reductive rearrangement is not limited to the bicyclic series, and that ring contraction occurs in the monocyclic series when the amino and carbonyl groups are homocyclic.

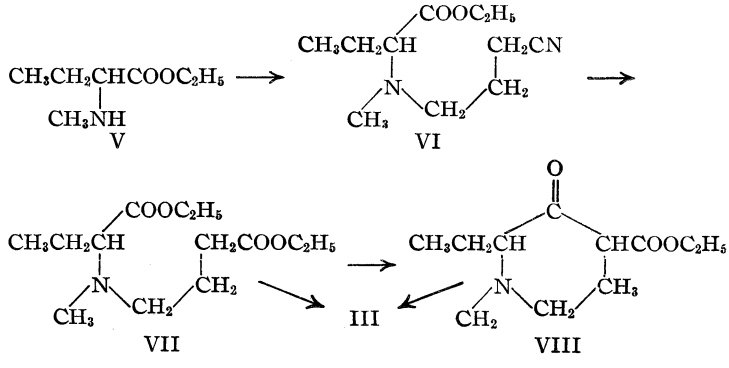


I II



III IV

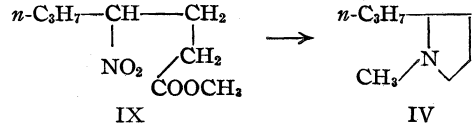
The synthesis of the cyclic aminoketone (III) used in this study was carried out by a series of reactions similar to those employed by Clemo and Ramage[3] in the synthesis of bicyclic aminoketones and by Prill and McElvain[4] in the synthesis of monocyclic aminoketones. Ethyl α-methylaminobutyrate (V) was obtained by condensation of methylamine with α-bromobutyric acid, followed by esterification. Treatment of V with γ-bromobutyronitrile in the presence of anhydrous potassium carbonate furnished α-carbethoxypropyl-γ'-cyanopropylmethylamine (VI), and ethanolysis of VI gave the diester VII.



V VI VII III VIII

Ring closure of the diester (VII) was accomplished by the Dieckmann reaction under two different sets of conditions. When sodium ethoxide was used,[4a] the keto ester (VIII) was isolated as the hydrochloride, which was then hydrolyzed and decarboxylated to give the hydrochloride of III in 60% yield (based on the diester). When potassium was used,[3] the intermediate keto ester (VIII) was not isolated but was immediately hydrolyzed and decarboxylated to give 1-methyl-2-ethyl-3-piperidone (III) in 50% yield. The Clemmensen reduction of 1-methyl-2-ethyl-3-piperidone resulted in a 71% yield of an amine which possessed properties different from those of 1-methyl-2-ethylpiperidine but identical with those of 1-methyl-2-propylpyrrolidine (IV).[5-7]

For direct comparison with the Clemmensen reduction product of III, a sample of 1-methyl-2-propylpyrrolidine (IV) was prepared by the reductive cyclization of methyl γ-nitroheptanoate (IX).[8] The hydrogenation was carried out in dioxane solution over copper oxide–chromium oxide catalyst at 260° and 250 atmospheres. The result was somewhat surprising in that the desired product (IV) was obtained directly, indicating that the process had included N-methylation (by the methanol available from cleavage of the ester).



IX IV

The products of Clemmensen reduction of III and reductive cyclization of IX were identical (see Table I).

As the monocyclic aminoketone III corresponds

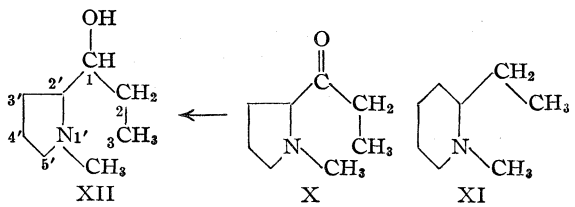
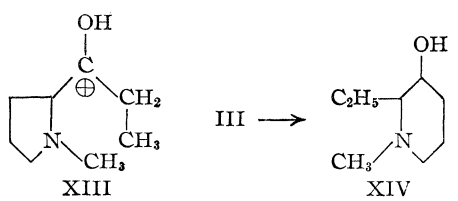
to 1-ketoquinolizidine (I) with the non-ketonic ring (A) opened, so the monocyclic aminoketone, 1-methyl-2-propionylpyrrolidine (X), is a model of 1-ketoquinolizidine (or, more accurately, of 1-ketoöctahydropyrrocoline) with the ketonic ring (B) opened. If X were to undergo analogous rearrangement during Clemmensen reduction, the product would be 1-methyl-2-ethylpiperidine (XI), and the process of *non-ketonic ring* expansion from five to six members would effect essentially the reverse of the process (III → IV) of *ketonic ring* contraction from six to five members. 1-Methyl-2-propionylpyrrolidine (X) was prepared



XII X XI

and subjected to Clemmensen reduction. In several runs representing variations in conditions, the only product isolated was 1-(1′-methyl-2′-pyrrolidyl)-1-propanol (XII). Complete reduction did not occur, nor did rearrangement occur. The difference in the behavior of X in the Clemmensen reaction as compared with III (and I)[9] might be rationalized on the basis of the absence in X of the apparently important geometrical directing effect,[2] and thus the carbonium carbon-1 (XIII) may capture a hydride ion (to give XII) before the nitrogen can attack. On a statistical basis, the nitrogen has less opportunity to approach carbonium carbon-1 in X than it does in III where their positions are both fixed by the ring structure. Among the structural features which determine whether rearrangement accompanies reduction, evidently the coexistence of the amino and carbonyl groups in the same ring is important.



XIII XIV

The possibility of the rearrangement (III → IV) proceeding through an ethyleneimonium ion intermediate,[10] formed after Clemmensen conversion of 1-methyl-2-ethyl-3-piperidone (III) to the carbinol (XIV) or corresponding chloro compound, has not been neglected. However, such a sequence seems unlikely since compound XIV was recovered unchanged when subjected to Clemmensen reduction conditions—a behavior similar to that of most secondary alcohols.[11] 1-Methyl-2-ethyl-3-hydroxypiperidine (XIV) as obtained both by catalytic and by sodium and ethanol reduction of III was used in the attempted, unsuccessful conversion (XIV → IV). Our findings are similar to those of von Braun and Weissbach[12] in the α-thiaketone series. These workers found that 4-ketoisothiochroman underwent reduction-rearrangement under Clemmensen conditions to give 1-methyl-1,2-dihydroisothionaphthene, but that 4-hydroxyisothiochroman and 4-chloroisothiochroman did not undergo rearrangement under the same conditions, giving instead isothiochroman. The parallel behavior of the α-amino- and α-thiaketones merits further investigation.

Experimental[13,14]

Ethyl α-Methylaminobutyrate (V).—A mixture of 56 g. (0.34 mole) of α-bromobutyric acid and 1.5 l. of a 35% solution of methylamine in water was stirred at room temperature for four days. The excess methylamine and water were removed by distillation at water pump pressure, with the receiver immersed in a dry ice–ethanol mixture. In this way, 1.34 l. of aqueous methylamine solution (29% methylamine) was recovered. The recovered material was used in a subsequent run without serious diminution of yield. To the residue remaining after removal of the methylamine was added 39 g. of potassium hydroxide in 50% aqueous solution and 200 ml. of 95% ethanol, and the mixture was evaporated to dryness *in vacuo*. In order to effect complete removal of methylamine and water, the residue was treated with 150 ml. of ethanol and was evaporated to dryness *in vacuo*. This process was repeated twice, and the residue at this stage consisted of small colorless crystals suspended in a viscous sirup. The mixture was stirred with 500 ml. of absolute ethanol until the sirupy material was in solution; the crystalline material remained undissolved. The mixture was saturated with dry hydrogen chloride and was allowed to stand overnight. After refluxing for one and one-half hours, the mixture was distilled *in vacuo* almost to dryness. The residue was cooled in an ice–salt-bath and overlayered with 300 ml. of ether. To the well-stirred mixture was added slowly a cold solution of 50 g. of potassium hydroxide in 50 ml. of water, while the temperature was maintained below 10°. The flask was stoppered and shaken vigorously. The yellow ether layer was decanted from the alkaline slurry, which was in turn shaken successively with one 200-ml. portion and three 100-ml. portions of ether. The combined ether extracts were dried over anhydrous magnesium sulfate. After removal of ether by distillation, the product was fractionally distilled, b. p. 64–65.5° (20 mm.); $n^{20}D$ 1.4174; yield, 30.4 g. (63%).

The **picrate** formed slowly in ether solution, and was recrystallized from ether containing a very small amount of methanol, m. p. 103–104.5°.

(11) It was recognized that existing evidence shows that the Clemmensen reduction of >CO to >CH₂ does not proceed by way of the carbinol (Martin, in "Organic Reactions," Vol. I, John Wiley and Sons, Inc., New York, N. Y., 1947, p. 156), but the possibility was not precluded that the α-aminoketones might exhibit unique behavior. The mechanism which was proposed in Paper I for change in ring size in the bicyclic compounds does not require the interim formation of the carbinol and hence continues valid for both bicyclic and monocyclic types.

(13) All melting points are corrected. Microanalyses were performed by Miss Emily Davis, Mrs. Jane Wood and Mr. Maurice Dare.

(14) The assistance of Dr. Gerhard Leubner is gratefully acknowledged.

Anal. Calcd. for $C_{13}H_{18}N_4O_9$: C, 41.71; H, 4.85; N, 14.97. Found: C, 41.77; H, 4.96; N, 15.04.

α-Carbethoxypropyl-γ′-cyanopropylmethylamine (VI).—A stirred mixture of 59.0 g. (0.407 mole) of ethyl α-methylaminobutyrate, 60.2 g. (0.406 mole) of γ-bromobutyronitrile, and 58.0 g. (0.42 mole) of finely ground anhydrous potassium carbonate was heated in an oil-bath at 100° for one and one-half hours. After cooling, 150 ml. of water was added to the mixture to dissolve the inorganic salts, and the organic layer was separated. The aqueous layer was extracted three times with 30-ml. portions of ether, which were combined with the organic layer. The ethereal solution was dried and the ether was removed. The residue was distilled *in vacuo*. After a considerable forerun, b. p. 28–120° (2 mm.), the product was collected, b. p. 120–122° (2 mm.); yield, 54.6 g. (63.5%); $n^{20}D$ 1.4450. Fractional distillation of the forerun resulted in recovery of approximately 17% of each of the unchanged reactants.

The **picrate**, prepared in ether and recrystallized from ether–ethanol, melted at 78–82°. Repeated recrystallization failed to improve the melting point.

Anal. Calcd. for $C_{17}H_{23}N_5O_9$: C, 46.26; H, 5.25. Found: C, 46.38; H, 5.24.

α-Carbethoxypropyl-γ′-carbethoxypropylmethylamine (VII).—A solution of 54.6 g. (0.257 mole) of α-carbethoxypropyl-γ′-cyanopropylmethylamine in 225 ml. of absolute ethanol, cooled in an ice-bath and protected from moisture, was saturated with dry hydrogen chloride. The solution was warmed to approximately 35° for one and one-half hours and was then heated under reflux for two and one-half hours. After cooling, the ammonium chloride was collected and washed with absolute alcohol. The combined filtrate and washings were concentrated to a small volume *in vacuo*, and the residue taken up in 60 ml. of water. The solution was overlayered with 50 ml. of ether. The mixture was cooled in an ice-bath, and 50% aqueous potassium hydroxide was added until a distinctly alkaline reaction was given. The aqueous layer was extracted three times with 50-ml. portions of ether. The ethereal solution was dried and the ether was removed. The product distilled at 119–120° (2 mm.); yield, 55.9 g. (84%); $n^{20}D$ 1.4391.

Anal. Calcd. for $C_{13}H_{25}NO_4$: C, 60.20; H, 9.72; N, 5.40. Found: C, 60.38; H, 9.85; N, 5.39.

Attempts to prepare the picrate and picrolonate in ether or ethanol failed.

Dieckmann Ring Closure of α-Carbethoxypropyl-γ′-carbethoxypropylmethylamine

A. With Potassium: 1-Methyl-2-ethyl-3-piperidone (III).—Potassium metal (10.0 g., 0.256 gram atom) was powdered under 50 ml. of dry xylene in a 200-ml. round-bottomed, three-necked flask fitted with stirrer, dropping funnel, and reflux condenser protected by a calcium chloride tube. With the temperature of the heating bath maintained at 105–115°, 14.5 g. (0.056 mole) of α-carbethoxypropyl - γ′ - carbethoxypropylmethylamine dissolved in 20 ml. of dry xylene was added over a period of fifty minutes while the mixture was stirred rapidly. The mixture was stirred for an additional three hours at the same temperature. After cooling, 15 ml. of absolute ethanol was added cautiously to destroy excess potassium, then 40 ml. of water was added. The layers were separated, and the xylene layer was extracted with three 10-ml. portions of water. To the aqueous extracts was added 70 ml. of concentrated hydrochloric acid, and the mixture was heated under reflux on a steam-bath for two and one-half hours. The mixture was concentrated *in vacuo* to a small volume. The dark red, semi-crystalline residue was taken up in 40 ml. of water and was overlayered with 50 ml. of ether. To the cooled mixture was added with stirring an excess of a saturated aqueous solution of sodium hydroxide. The layers were separated and the aqueous layer was extracted several times with small portions of ether. After drying the ether solution, the ether was removed and the colorless product was distilled at 80–85° (14 mm.); yield, 4.04 g. (51%). A small sample was redistilled for analysis, b. p. 64° (5 mm.); $n^{20}D$ 1.4620.

Anal. Calcd. for $C_8H_{15}NO$: C, 68.04; H, 10.71. Found: C, 67.94; H, 10.94.

The **picrate** was made in ether solution and was recrystallized from absolute ethanol, m. p. 131.5–132.5°.

Anal. Calcd. for $C_{18}H_{23}N_5O_6$: C, 53.33; H, 5.72. Found: C, 53.55; H, 5.69.

B. With Sodium Ethoxide: 1-Methyl-2-ethyl-4-carbethoxy-3-piperidone (VIII) Hydrochloride.—Sodium ethoxide[15] was prepared from 2.23 g. (0.097 gram atom) of sodium in a 100-ml. Claisen flask fitted with stirrer, dropping funnel, and receiver, and protected from atmospheric moisture. To the sodium ethoxide was added 25.16 g. (0.097 mole) of the diester. The stirred mixture was heated gradually in an oil-bath. At 120° (bath temp.) ethanol began to distil, and in a period of thirty minutes the temperature was raised to 145° and maintained there for fifteen minutes, after which no more ethanol distilled. The cooled reaction mixture was dissolved in 75 ml. of water, and the solution was made acid to congo red with hydrochloric acid, while the temperature was kept below 10°. The solution was then neutralized to litmus with potassium carbonate, and was extracted with ether until the extracts no longer gave a red color with ferric chloride solution. The combined ether extracts were dried and then concentrated to a volume of about 50 ml. Dry hydrogen chloride was passed into the solution until precipitation of the hydrochloride was complete; yield, 18.71 g. (77%); m. p. 158–160°. After one recrystallization from absolute ethanol–ether mixture, the product melted, with decomposition, at 162–163° and weighed 16.02 g. (66%).

Anal. Calcd. for $C_{11}H_{20}ClNO_3$: C, 52.90; H, 8.07; N, 5.61. Found: C, 53.03; H, 8.32; N, 5.66.

1-Methyl-2-ethyl-3-piperidone Hydrochloride.—1-Methyl-2-ethyl-4-carbethoxy-3-piperidone hydrochloride was hydrolyzed and decarboxylated by heating with 6 *N* hydrochloric acid on a steam-bath for three hours. Removal of excess hydrochloric acid by distillation *in vacuo* and recrystallization of the residue from dry acetone gave a 91% yield of 1-methyl-2-ethyl-3-piperidone hydrochloride, m. p. 133–134°.

Anal. Calcd. for $C_8H_{16}ClNO$: C, 54.08; H, 9.08; N, 7.88. Found: C, 54.35; H, 9.30; N, 7.59.

The **picrate** prepared from this hydrochloride had the same melting point as the picrate prepared from the free base in procedure A, and there was no depression of melting point when the two were mixed.

Reductive Cyclization of Methyl γ-Nitroheptanoate (IX).—Twenty and three-tenths grams of methyl γ-nitroheptanoate (0.1 mole) dissolved in 65 ml. of purified dioxane was hydrogenated in the presence of copper chromite catalyst at 260° and 250 atmospheres.[8] About 65% of the theoretical amount of hydrogen was taken up in four hours. After removal of the catalyst by filtration, the bulk of the dioxane was removed by distillation through a six-inch Fenske column. The product distilled at 138–146°; yield, 4.5 g. (36%). A considerable amount of higher boiling material remained in the distilling flask. A final distillation of the product from metallic sodium yielded 2.8 g. of amine, b. p. 145–146° (742 mm.); $n^{20}D$ 1.4378; d^{15}_4 0.823. The picrate, picrolonate and chloroaurate are described in Table I.

Clemmensen Reduction of 1-Methyl-2-ethyl-3-piperidone Hydrochloride.—Mossy zinc (36 g.) was washed with 5% hydrochloric acid and was then shaken for five minutes with a mixture of water (65 ml.), concentrated hydrochloric acid (4 ml.) and mercuric chloride (4 g.).

(15) Hauser and Hudson, in "Organic Reactions," Vol. I, John Wiley and Sons, Inc., New York, N. Y., 1947, p. 279.

TABLE I

	[a]Product of Clemmensen reduction of 1-methyl-2-ethyl-3-piperidone	[a]Product of Reductive cyclization of methyl γ-nitro-heptanoate	Reported for 1-methyl-2-propylpyrrolidine

Picrolonate, m. p. °C.	169.5–171	168–169.5	.....
Chloroaurate, m. p., °C.	76–77	75–77	76[5]
Chloroplatinate, m. p., °C.	145–146.5	.....	145–146[5]

[a] Admixture of the corresponding derivatives caused no depression in melting point.

The solution was decanted from the amalgam, which was then washed once with distilled water by decantation. To the amalgam was added cautiously a solution of 1-methyl-2-ethyl-3-piperidone hydrochloride (4.0 g.) in 40 ml. of concentrated hydrochloric acid. After the vigorous initial reaction had subsided, the mixture was heated under reflux for twelve hours. (This period of time was found to be sufficient and was used in subsequent comparative experiments.) At intervals of three hours, 10-ml. portions of concentrated hydrochloric acid were added. After cooling, the solution was decanted, and the residual amalgam was washed with small portions of water. The excess hydrochloric acid was removed from the solution and aqueous washings *in vacuo*. The residual viscous sirup was made strongly alkaline with a solution of 50 g. of potassium hydroxide in 200 ml. of water. The resulting slurry of zinc salts was subjected to steam distillation. The first 40-ml. fraction of distillate appeared to contain most of the organic product, and was collected separately from the subsequent 200 ml. of distillate. The first fraction was saturated with potassium hydroxide with cooling, and was then extracted five times with 10-ml. portions of ether. The ethereal solution was dried and the ether was removed. The product distilled at 143–146° (743 mm.); yield, 1.87 g. (65.3%). Mineral oil was added to the distilling flask, and the last traces of product were forced over by heating strongly. The picrate (4.9% of theory) prepared from this fraction melted at 121–123° without recrystallization, and the melting point was not depressed on admixture with the picrate prepared from the main fraction. A small amount (1.1% of theory) of the same picrate was isolated from the second fraction of steam distillate. The total yield of the product and its picrate was thus 71.3%. A final distillation of the product from metallic sodium furnished material having the physical constants shown in Table I.

Anal. Calcd. for $C_8H_{17}N$: C, 75.52; H, 13.47; N, 11.01. Found: C, 75.58; H, 13.41; N, 10.74.

Picrolonate, small yellow prisms from absolute ethanol.

Anal. Calcd. for $C_{18}H_{25}N_5O_5$: C, 55.23; H, 6.44; N, 17.89. Found: C, 55.06; H, 6.47; N, 17.66.

Catalytic Hydrogenation of 1-Methyl-2-ethyl-3-piperidone Hydrochloride. 1-Methyl-2-ethyl-3-hydroxypiperidine (XIII) Hydrochloride.—The hydrochloride (1.5 g.) of 1-methyl-2-ethyl-3-piperidone was dissolved in 50 ml. of absolute ethanol and was subjected to hydrogenation at 2.5 atmospheres at 25° in the presence of 0.2 g. of platinum oxide catalyst. Slightly more than the theoretical amount of hydrogen was taken up in one hour. After removal of the catalyst by filtration and the solvent by distillation *in vacuo*, the residue was dissolved in hot, dry acetone. Colorless prisms formed slowly on cooling. After a second recrystallization from acetone, the colorless, hygroscopic prisms melted at 109–111°, and weighed 0.62 g. (41%). The compound gave negative Benedict and Tollens tests.

Anal. Calcd. for $C_8H_{18}ClNO$: C, 53.47; H, 10.10; N, 7.80. Found: C, 53.47; H, 10.33; N, 7.68.

The **picrate**, prepared from the hydrochloride by liberating the free base, extracting into ether, and treating the ether solution with ethereal picric acid, crystallized from ethanol–ether as short needles, m. p. 105–108°.

Anal. Calcd. for $C_{14}H_{20}N_4O_8$: C, 45.16; H, 5.41; N, 15.05. Found: C, 45.25; H, 5.67; N, 15.27.

The mother liquors obtained from the recrystallization of the hydrochloride could not be made to yield more crystalline material. The sirupy residue remaining after removal of solvent gave negative Benedict and Tollens tests. The sirup was converted to the free base, and thence to the **picrate**, which weighed 1.04 g. (33%) and melted at 104–106°. Recrystallization from ethanol–ether mixture raised the melting point to 107–109.5°.

Anal. Calcd. for $C_{14}H_{20}N_4O_8$: C, 45.16; H, 5.41; N, 15.05. Found: C, 45.19; H, 5.73; N, 15.33.

Admixture of the two picrates (m. p.'s 105–108° and 107–109.5°) gave no depression in melting point. From appearance and solubility characteristics, the two picrates were identical. On occasions, when ethanol–ether solution of the picrate were cooled in the refrigerator for several days, the compound crystallized in the form of small prisms which melted at 113–116°. Admixture with the lower melting form produced a melting range of 105–116°. Although the rather wide melting ranges of these picrates might indicate mixtures of the two possible diastereoisomers, the formation of the two diastereoisomeric entities has not been shown definitely.

Catalytic hydrogenation of the free base, 1-methyl-2-ethyl-3-piperidone, was attempted, but the absorption of hydrogen was much slower and less complete than in the case of the hydrochloride, and the product appeared to contain considerable unchanged ketone.

Reduction of 1-Methyl-2-ethyl-3-piperidone with Sodium and Ethanol.—Three grams of the hydrochloride of 1-methyl-2-ethyl-3-piperidone was converted to the base, and the aminoketone was dissolved in 40 ml. of absolute ethanol contained in a 200-ml. round-bottomed flask bearing a reflux condenser. Sodium (8.0 g.) in small pieces was dropped through the condenser at a rate sufficient to maintain rapid reflux. Toward the end of the addition it was necessary to heat the mixture to cause the sodium to dissolve. Twenty-five milliliters of water was added, and the mixture was subjected to steam distillation. The distillate was collected as long as it showed an alkaline reaction to litmus (approx. 160 ml.), and was then acidified with hydrochloric acid and evaporated to dryness *in vacuo*. The residue was basified with a saturated aqueous solution of potassium hydroxide, extracted into ether, and the extracts were dried. After removal of the ether, the product distilled at 73–77° (4 mm.); $n^{20}D$ 1.4800; yield, 1.4 g. (58%).

Anal. Calcd. for $C_8H_{17}NO$: C, 67.08; H, 11.97. Found: C, 67.37; H, 12.21.

The **picrate**, recrystallized from ethanol–ether mixture, melted at 104.5–108°, and the melting point was not depressed by admixture with the picrate of the catalytic hydrogenation product. The hydrochloride crystallized from acetone as colorless prisms, whose melting point and mixed melting point (109–111°) were the same as the hydrochloride of the catalytic hydrogenation product.

Treatment of 1-Methyl-2-ethyl-3-hydroxypiperidine under Clemmensen Conditions.—The hydrochloride was subjected to the Clemmensen reduction in the same manner as was 1-methyl-2-ethyl-3-piperidone hydrochloride. Sixty per cent. of the starting material was recovered from the reaction mixture as the picrate. No other product was isolated.

The free base obtained from the sodium reduction of the amino-ketone likewise was unchanged when subjected to Clemmensen conditions.

2-Propionylpyrrole.—This compound was prepared by the method of Oddo[16] in a yield of 35%, b. p. 227–230°, m. p. 50–52°.

1-(2′-Pyrrolidyl)-1-propanol.—By sodium and ethanol reduction of 2-propionylpyrrole,[17] a 22% yield of 1-(2′-pyrrolidyl)-1-propanol was obtained, b. p. 97–100° (17 mm.). Recrystallization from petroleum ether gave colorless hygroscopic needles, m. p. 48–50°.

1-Methyl-2-propionylpyrrolidine (X).—By the method of Hess,[18] a 78% yield of the compound was obtained, b. p. 70–72° (12 mm.), $n^{20}D$ 1.4611. The **picrate**, recrystallized from ethanol as orange leaflets, melted at 103–104°. The free base gave a positive Tollens test in the cold, but a negative Benedict test, even when heated.

Clemmensen Reduction of 1-Methyl-2-propionylpyrrolidine.—The free base (1.27 g.), when subjected to the Clemmensen reduction in the usual manner, yielded 0.79 g. (62%) of a liquid which boiled at 79–80° (13 mm.). The boiling point reported for 1-(1′-methyl-2′-pyrrolidyl)-1-propanol (XII) is 83° (14–15 mm.),[19] and the analytical figures were consistent with the assignment of this structure to the product.

Summary

It has been established that Clemmensen reduction of 1-methyl-2-ethyl-3-piperidone results in the formation of the rearrangement product, 1-methyl-2-*n*-propylpyrrolidine.

The Clemmensen reduction–rearrangement of α-aminoketones, which was previously recognized only in the bicyclic series (1-ketoquinolizidines), has thus been shown to occur in the monocyclic series (six-membered ring). It can be said that ring contraction occurs in the monocyclic series when the α-amino and carbonyl groups are homocyclic.

URBANA, ILLINOIS RECEIVED FEBRUARY 21, 1949

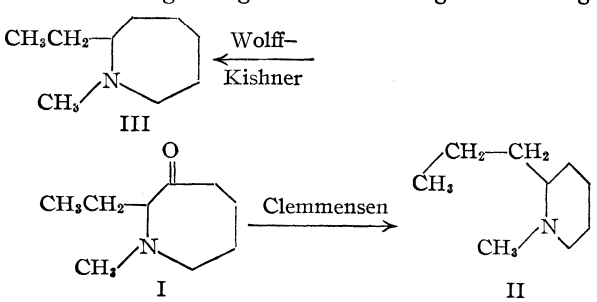
Rearrangement of α-Aminoketones During Clemmensen Reduction. III. Contraction of a Seven-membered Ring in the Monocyclic Series

BY NELSON J. LEONARD AND ERIC BARTHEL, JR.

Since the fact has been established that under Clemmensen reduction conditions the six-membered ring in 1-methyl-2-ethyl-3-piperidone undergoes contraction to a five-membered ring with the formation of 1-methyl-2-*n*-propylpyrrolidine,[1] we wished to determine whether the seven-membered homolog (I) would undergo contraction to a six-membered ring. This information would constitute the beginning of our knowledge concerning



the possible effect of ring size in limiting the rearrangement process. Accordingly, 1-methyl-2-ethyl-1-azacycloheptan-3-one (I) has been prepared and has been subjected to Clemmensen reduction. The product obtained was identified as the rearranged product, 1-methyl-2-*n*-propylpiperidine (II).

The synthesis of I was accomplished by a method similar to that used by Prill and McElvain[2] for the compound lacking the 2-ethyl group. Ethyl α-methylaminobutyrate[1] was condensed with δ-chlorovaleronitrile to give α-carbethoxypropyl-δ′-cyanobutylmethylamine. Ethanolysis of the cyanoester produced the diester, α-carbethoxypropyl-δ′-carbethoxybutylmethylamine. Dieckmann ring closure of the diester furnished 1-methyl-2-ethyl-1-azacycloheptan-3-one (I), isolated as the hydrochloride in 52% yield. The normal carbonyl reduction product of I, 1-methyl-2-ethylazacycloheptane (III), was obtained by the Wolff–Kishner method; the Clemmensen reduction product of I was isomeric with III. The Clemmensen product and its derivatives had the properties requisite for 1-methyl-2-*n*-propylpiperidine (*dl*-N-methylconiine) (II),[3,4] and identity was fully established by direct comparison with an authentic sample of II.

The results indicate that the Clemmensen reduction-rearrangement of monocyclic α-aminoketones is not limited to contraction of six-membered rings.

Experimental[5]

δ-Chlorovaleronitrile.—Sixty-eight and five-tenths grams of 95% potassium cyanide (1.0 mole) was dissolved

(5) All melting points are corrected. Microanalyses were performed by Miss Emily Davis, Mrs. Jane Wood and Mr. Maurice Dare.

in 1.2 l. of commercial absolute methanol and to this solution was added 660 g. (5.2 moles) of 1,4-dichlorobutane.

The mixture was refluxed on the steam-bath with stirring for seventeen hours. The flask was cooled in an ice-bath and the precipitated salts were collected and washed with absolute methanol. The solvent was removed by distillation and the dark purple residue was subjected to fractional distillation under reduced pressure. 1,4-Dichlorobutane (501 g.), b. p. 61–65° (27–28 mm.), was recovered and the product was collected at 115–118° (28 mm.); $n^{20}D$ 1.4447; yield, 71.7 g. (61% based on potassium cyanide).

α-Carbethoxypropyl-δ′-cyanobutylmethylamine.—A vigorously stirred mixture of 28.4 g. (0.242 mole) of δ-chlorovaleronitrile, 35.1 g. (0.242 mole) of ethyl α-methylaminobutyrate,[1] and 34.5 g. (0.25 mole) of finely ground anhydrous potassium carbonate was heated at 120–130° for twenty-four hours. The mixture was cooled and 100 ml. of water was added to dissolve the inorganic material. The organic layer was separated and the aqueous layer was extracted with three 50-ml. portions of ether, which were combined with the organic layer. The ethereal solution was dried and the ether was removed. The residue was distilled *in vacuo;* b. p. 110–112° (0.4 mm.); $n^{20}D$ 1.4482; yield, 44.7 g. (82%).

Anal. Calcd. for $C_{12}H_{22}N_2O_2$: C, 63.68; H, 9.80; N, 12.38. Found: C, 63.97; H, 9.97; N, 12.52.

Attempts to prepare the picrate and picrolonate in ether or ethanol failed.

α-Carbethoxypropyl-δ′-carbethoxybutylmethylamine.—A solution of 44.7 g. (0.197 mole) of α-carbethoxypropyl-δ′-cyanobutylmethylamine in 250 ml. of absolute ethanol, cooled in an ice-bath and protected from moisture, was saturated with dry hydrogen chloride. The solution was allowed to stand at room temperature (*ca.* 25°) for two hours and was heated under reflux for two hours. After cooling, the precipitated ammonium chloride was collected and washed with absolute ethanol. The combined filtrate and washings were concentrated to a small volume under reduced pressure. The residue was taken up in 80 ml. of water, the solution was cooled in an ice-bath, and 15% aqueous potassium hydroxide solution was added until the solution was definitely alkaline to litmus paper. The organic layer was separated and the aqueous layer was extracted with two 50-ml. and two 25-ml. portions of ether. The organic layer and ether extracts were combined and dried, and the ether was removed. The product was collected at 125–128° (1.1 mm.); $n^{20}D$ 1.4427; yield, 38.5 g. (71.5%).

Anal. Calcd. for $C_{14}H_{27}NO_4$: C, 61.51; H, 9.96; N, 5.12. Found: C, 61.77; H, 9.77; N, 5.32.

The picrate and picrolonate could not be prepared in ether or ethanol.

Dieckmann Ring Closure of α-Carbethoxypropyl-δ′-carbethoxybutylmethylamine. 1-Methyl-2-ethyl-1-azacycloheptan-3-one (I) Hydrochloride.—Sodium ethoxide[6] was prepared from 3.24 g. of sodium in a 1-l. round-bottomed, three-necked flask fitted with a mercury seal stirrer and a Vigreux fractionating column. A thermometer was inserted in the head of the column and the side arm was attached to a condenser set for downward distillation. The system was protected from moisture. A solution of 38.5 g. (0.141 mole) of the aminodiester in 600 ml. of dry xylene was added. The stirred mixture was heated sufficiently to cause gentle refluxing in the column. Periodically the temperature was raised and the mixture of ethanol and xylene was distilled until the thermometer registered the boiling point of pure xylene. At the end of thirty hours, no more ethanol distilled over. The cooled residue was extracted with four 30-ml. portions of water and was made slightly acid with dilute hydrochloric acid. The xylene layer was extracted with 40-ml. portions of dilute hydrochloric acid until the aqueous extract gave a negative enol test with ferric chloride solution. Concentrated hydrochloric acid (100 ml.) was added to the combined aqueous extracts and the solution was refluxed for two and a quarter hours. A test with ferric chloride solution for the enol function was negative at this time. The reaction mixture was concentrated by evaporation *in vacuo*, cooled in an ice-bath, and made distinctly alkaline to litmus by the slow addition of a saturated aqueous solution of potassium hydroxide. The basic solution was extracted with eight 25-ml. portions of ether. The extracts were combined and dried. Dry hydrogen chloride was passed through the ethereal solution with the formation of a thick, viscous, yellowish gum. The ether was decanted and the residue was recrystallized from ethanol–ether; yield, 14.1 g. (52%) of colorless elongated prisms, m. p. 162.5–163°.

Anal. Calcd. for $C_9H_{18}ClNO$: C, 56.39; H, 9.46; N, 7.31. Found: C, 56.57; H, 9.55; N, 7.07.

The **picrate**, made from the ethereal solution, crystallized from dilute ethanol as bright yellow needles, m. p. 169–169.5°.

Anal. Calcd. for $C_{15}H_{20}N_4O_8$: C, 46.87; H, 5.25; N, 14.58. Found: C, 47.11; H, 5.24; N, 14.87.

The **picrolonate**, prepared similarly, crystallized as golden-yellow needles, m. p. 164.5–165.5°, from absolute ethanol.

Anal. Calcd. for $C_{19}H_{25}N_5O_6$: C, 54.41; H, 6.01; N, 16.70. Found: C, 54.39; H, 6.22; N, 16.72.

1-Methyl-2-ethyl-1-azacycloheptan-3-one (I).—Four grams (0.029 mole) of anhydrous potassium carbonate dissolved in 10 ml. of water was added to 5 g. (0.026 mole) of the aminoketone hydrochloride in 10 ml. of water. The organic layer which separated was collected in 10 ml. of ether and the aqueous layer was extracted with two additional 10-ml. portions of ether. The extracts were combined and dried and the ether was removed. Distillation of the residue yielded 3.37 g. (84%) of the free base, b. p. 91–92° (13 mm.); $n^{20}D$ 1.4696.

Wolff-Kishner Reduction of 1-Methyl-2-ethyl-1-azacycloheptane-3-one. 1-Methyl-2-ethylazacycloheptane (III).—A mixture of 3.4 g. (0.022 mole) of the aminoketone, 4.2 g. (0.074 mole) of potassium hydroxide, 3 ml. of 85% hydrazine hydrate, and 30 ml. of triethylene glycol was heated at 140–145° under reflux for one hour. The condenser was then set for downward distillation and the temperature of the bath was increased slowly to 250° and was maintained at that point until distillation ceased. The organic matter was removed from the aqueous portion of the distillate by extraction with two 10-ml. portions of ether. After drying, the ether was removed and the residue was distilled, yielding 1.30 g. (42%) of basic material, b. p. 174–175° (755 mm.); $n^{20}D$ 1.4472.

Anal. Calcd. for $C_9H_{19}N$: C, 76.53; H, 13.56; N, 9.92. Found: C, 76.96; H, 13.67; N, 10.48.

The **picrate**, formed in ether, crystallized from absolute ethanol as yellow needles, m. p. 166.5–167.5°.

Anal. Calcd. for $C_{15}H_{22}N_4O_7$: C, 48.64; H, 5.99; N, 15.13. Found: C, 48.63; H, 6.07; N, 15.23.

Clemmensen Reduction of 1-Methyl-2-ethyl-1-azacycloheptan-3-one.—Mossy zinc (27 g.) was amalgamated by shaking for five minutes with 3 g. of mercuric chloride, 3 ml. of concentrated hydrochloric acid, and 35 ml. of water. The solution was decanted from the amalgam, which was then washed once with distilled water. Four grams (0.021 mole) of the aminoketone in 40 ml. of concentrated hydrochloric acid was added cautiously to the amalgam. The mixture was heated under gentle reflux for twelve hours. At intervals of two hours, 15-ml. portions of concentrated hydrochloric acid were added and, after seven hours, there was added 20 g. of mossy zinc, amalgamated as before with 2 g. of mercuric chloride, 2 ml. of concentrated hydrochloric acid, and 30 ml. of water. At the end of twelve hours, the aqueous layer was decanted and the residual metal was washed once with distilled water. The solution and washings were concentrated by evaporation *in vacuo*. The resulting viscous sirup was made strongly alkaline to litmus by the addi-

tion of a saturated aqueous solution of potassium hydroxide. The white slurry thus obtained was subjected to steam distillation until the distillate was no longer basic to litmus paper. The organic layer was separated and the aqueous layer was extracted with four 40-ml. portions of ether. The organic layer and extracts were combined and dried and the ether was removed. Distillation of the residue yielded 1.49 g. (50%) of basic material, b. p. 61–63° (13 mm.); 163–165° (759 mm.); $n^{20}D$ 1.4491.

Anal. Calcd. for $C_9H_{19}N$: C, 76.53; H, 13.56; N, 9.92. Found: C, 76.13; H, 13.68; N, 9.99.

The **picrate** was prepared in ether and recrystallized from dilute ethanol as long light-yellow needles, m. p. 108.5–109°.

Anal. Calcd. for $C_{15}H_{22}N_4O_7$: C, 48.64; H, 5.99; N, 15.13. Found: C, 48.75; H, 6.19; N, 15.29.

The **chloroplatinate** was prepared by adding an aqueous solution of the amine hydrochloride to an aqueous solution of platinum chloride and was recrystallized from dilute ethanol as bright orange prisms, m. p. 194.5–196°.

The **chloroaurate** was prepared similarly, yielding greenish yellow needles, m. p. 88.5–90.5°.

The **hydrochloride** was formed in ether and deposited white needles when recrystallized from acetone, m. p. 168–168.5°.

1-Methyl-2-pyridone.—This compound was prepared by the method of Prill and McElvain[7] in a yield of 83%, b. p. 134–136° (18 mm.); $n^{20}D$ 1.5679.

(7) "Organic Syntheses," Coll. Vol. II, John Wiley and Sons, Inc., New York, N. Y., 1947, p. 419.

1-Methyl-2-piperidone.—Fifty-five and four-tenths grams of 1-methyl-2-pyridone was dissolved in 200 ml. of glacial acetic acid and the solution was hydrogenated at 2–3.5 atmospheres and 26° in the presence of 0.5 g. of platinum oxide catalyst. Slightly more than the theoretical amount of hydrogen was taken up in seventeen hours. The catalyst was removed by filtration and the solvent was removed by evaporation under reduced pressure. Distillation of the residue yielded 50.36 g. (87.5%) of product, b. p. 102–106° (15 mm.); $n^{20}D$ 1.4711.

1-Methyl-2-*n*-propylpiperidine.—The method of Lukes and Smetackova[3] was used in the preparation of this material from 1-methyl-2-piperidone in a yield of 9.7%; b. p. 167–168° (757 mm.); $n^{20}D$ 1.4500. The derivatives of 1-methyl-2-*n*-propylpiperidine were made in the same manner as were the derivatives of the product of the Clemmensen reduction of 1-methyl-2-ethyl-1-azacycloheptan-3-one. They are listed in Table I.

Summary

It has been established that Clemmensen reduction converts 1-methyl-2-ethyl-1-azacycloheptan-3-one to the rearrangement product, 1-methyl-2-*n*-propylpiperidine (*dl*-N-methylconiine). The process involves ring contraction from seven to six members.

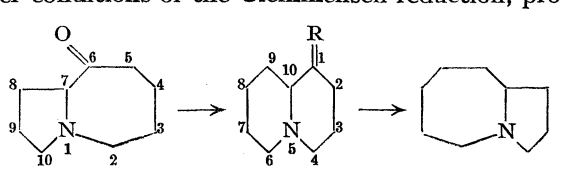
Rearrangement of α-Aminoketones During Clemmensen Reduction. IV. Contraction of a Seven-membered Ring in the Bicyclic Series

BY NELSON J. LEONARD AND WILLIAM C. WILDMAN[1]

In a previous communication[2] the authors showed that the rearrangement of 1-ketoquinolizidine (IIb) to 1-azabicyclo[5.3.0]decane (III), under conditions of the Clemmensen reduction, proceeds with contraction of the ketonic ring and expansion of the non-ketonic ring, and a mechanism was suggested for this transformation. Now we have shown that the 1-azabicyclo[5.3.0]decane ring system can be transformed to the quinolizidine ring system by the same process. The Clemmensen reduction of 6-keto-1-azabicyclo[5.3.0]-decane (I) produced the rearrangement product, quinolizidine (1-azabicyclo[4.4.0]decane) (IIa).

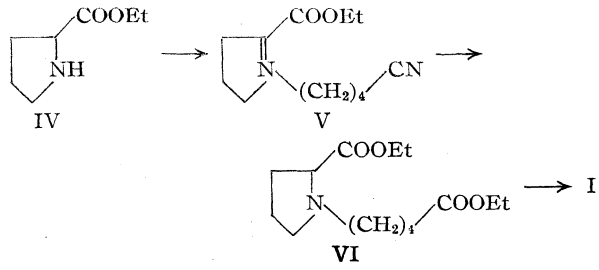


(a, R = H_2; b, R = O)

The synthesis of I was accomplished by the Dieckmann ring closure of ethyl δ-N-(2-carbethoxypyrrolidyl)-valerate (VI) without isolation of the intermediate ketoester. The diester VI was obtained by ethanolysis of δ-N-(2-carbethoxypyrrolidyl)-valeronitrile (V), product of the condensa-

(1) Present address: Department of Chemistry, University of Wisconsin, Madison, Wisconsin.

(2) Leonard and Wildman, THIS JOURNAL, 71, 3098 (1949).



tion of ethylproline (IV) with δ-bromovaleronitrile.

The normal carbonyl reduction product of 6-keto-1-azabicyclo[5.3.0]decane (I) was obtained by the Wolff–Kishner method and was identified as 1-azabicyclo[5.3.0]decane (III). The Clemmensen reduction product of I was the result of rearrangement and was identified as quinolizidine (IIa). Authentic samples of IIa and III were available for direct comparison with these reduction products. The conversion of I to IIa under Clemmensen conditions thus proceeds with the contraction of the seven-membered ketonic ring and expansion of the five-membered non-ketonic ring. The contraction of a seven-membered ring has also been observed in the Clemmensen reduction of a monocyclic α-aminoketone.[3]

Experimental[4]

δ-Bromovaleronitrile.—A solution of 783 g. (3.62 moles) of tetramethylene bromide, 47.0 g. (0.724 mole) of potassium cyanide, and 600 ml. of methanol was heated under reflux for twenty-four hours. The methanol was removed by distillation. The residue was washed twice with water, dried over anhydrous magnesium sulfate, and fractionally distilled. After removal of the excess tetramethylene bromide, the δ-bromovaleronitrile was obtained as a colorless liquid, b. p. 114–115° (12 mm.); $n^{21.5}D$ 1.4795; yield, 50.0 g. (42.7%).

Ethyl Proline.—The ester was prepared by the procedure of Kapfhammer and Matthes[5] except that the ethanolic solution of proline ethyl ester hydrochloride was concentrated, redissolved in 100 ml. of absolute ethanol, and resaturated with hydrogen chloride. The solution then was concentrated under reduced pressure and treated with ether and anhydrous ammonia as described.[5] This modification resulted in yields as high as 80%.

δ-N-(2-Carbethoxypyrrolidyl)-valeronitrile.—A mixture of 20.0 g. (0.14 mole) of proline ethyl ester, 22.7 g. (0.14 mole) of δ-bromovaleronitrile, and 22.1 g. (0.16 mole) of anhydrous potassium carbonate was heated at 100° for six hours. The reaction mixture was cooled, and water was added to dissolve the inorganic salts. The cyano ester was separated, and the aqueous layer was extracted with ether. The cyano ester and ether extract were combined, washed with water, dried over anhydrous magnesium sulfate, and distilled. The nitrile was obtained as a colorless liquid, b. p. 102–103° (0.5 mm.); $n^{20}D$ 1.4630; d^{20}_4 1.0333; yield, 23.1 g. (74%).

Anal. Calcd. for $C_{12}H_{20}N_2O_2$: C, 64.28; H, 8.99; N, 12.50; MR_D 60.75. Found: C, 64.38; H, 9.00; N, 12.65; MR_D 59.76.

Ethyl δ-N-(2-Carbethoxypyrrolidyl)-valerate.—A solution of 22.6 g. (0.105 mole) of δ-N-(2-carbethoxypyrrolidyl)-valeronitrile in 125 ml. of absolute ethanol, cooled in ice and protected from moisture, was saturated with dry hydrogen chloride. The solution was allowed to stand at room temperature for two hours and then was boiled under reflux for two hours. The ammonium chloride was removed by filtration, and the ethanolic solution of the diester was concentrated under reduced pressure. The residue was dissolved in 50 ml. of water, cooled to 0°, and made alkaline with 15% potassium hydroxide solution. The organic layer was separated, and the aqueous solution was extracted with ether. The diester and the ether extract were combined, dried over anhydrous magnesium sulfate, and distilled. The product was obtained as a colorless liquid, b. p. 110–113° (0.3 mm.); $n^{20}D$ 1.4563; d^{20}_4 1.0413; yield, 16.2 g. (60%).

Anal. Calcd. for $C_{14}H_{25}NO_4$: C, 61.97; H, 9.29; N, 5.16; MR_D 71.90. Found: C, 62.01; H, 9.31; N, 5.37; MR_D 70.88.

Dieckmann Ring Closure of Ethyl δ-N-(2-Carbethoxypyrrolidyl)-valerate. 6-Keto-1-azabicyclo[5.3.0]decane.—Sodium ethoxide[6] was prepared from 1.36 g. (0.058 mole) of sodium in a 500-ml. three-necked flask fitted with a mercury-sealed stirrer, a dropping funnel, and a Vigreux fractionating column. A thermometer was inserted in the head of the column, and the side-arm was set for downward distillation. A solution of 15.9 g. (0.058 mole) of the diester in 200 ml. of dry xylene was added to the sodium ethoxide at 25°. The solution was caused to reflux gently in the Vigreux column. The bath temperature was raised periodically, and the ethanol–xylene mixture was distilled until the boiling point of pure xylene was attained. At the end of eighteen hours no ethanol was found in the distillate. The solution was cooled and extracted three times with water. The xylene layer then was extracted with dilute hydrochloric acid until ferric chloride reagent gave a negative test for the enol function. The aqueous extracts were combined and refluxed three hours with 50 ml. of concentrated hydrochloric acid. The solution was concentrated *in vacuo*, cooled to 0°, and made basic with 30% potassium hydroxide solution. The amino ketone was extracted with ether and dried over anhydrous magnesium sulfate. The ether was removed under reduced pressure through a ten-inch column packed with glass helices. The 6-keto-1-azabicyclo[5.3.0]decane was obtained as a colorless liquid, b. p. 105–106° (12 mm.); yield, 2.43 g. (27.4%). The amino ketone darkened rapidly on standing. To prevent further decomposition, it was dissolved in absolute ether, and the solution was saturated with dry hydrogen chloride.

6-Keto-1-azabicyclo[5.3.0]decane Picrate.—Prepared in ether and recrystallized three times from ethanol, the picrate formed golden needles, m. p. 170–171°.

Anal. Calcd. for $C_{15}H_{18}N_4O_8$: C, 47.12; H, 4.75; N, 14.66. Found: C, 47.11; H, 4.87; N, 14.54.

6-Keto-1-azabicyclo[5.3.0]decane Picrolonate.—Prepared in ether and recrystallized from ethanol, the picrolonate formed orange platelets, m. p. 165–166°.

Anal. Calcd. for $C_{19}H_{23}N_5O_6$: C, 54.67; H, 5.55; N, 16.78. Found: C, 54.70; H, 5.65; N, 16.97.

Clemmensen Reduction of 6-Keto-1-azabicyclo[5.3.0]-decane. Quinolizidine.—Seven grams of mossy zinc was amalgamated with 1 g. of mercuric chloride, 1 ml. of concentrated hydrochloric acid, and 15 ml. of water. The mixture was swirled for five minutes. The aqueous layer was decanted, and the zinc was washed once with water. A mixture of 1 g. (0.0053 mole) of 6-keto-1-azabicyclo-[5.3.0]decane hydrochloride, 7 g. (0.107 mole) of amalgamated zinc, and 20 ml. of concentrated hydrochloric acid was refluxed for ten hours. An additional 10 ml. of acid was added every two hours during this time. The solution was cooled and made basic with 50% sodium hydroxide solution. The zinc hydroxide was removed by filtration using Super-Cel as a filtering aid. The filtrate was distilled until no basic material was found in the distillate. The distillate was saturated with potassium carbonate and extracted four times with ether. The ethereal

(4) All melting points are corrected.

(5) Kapfhammer and Matthes, *Z. physiol. Chem.*, **223**, 43 (1934).

(6) Hauser and Hudson, "Organic Reactions," Vol. I, John Wiley and Sons, Inc., New York, N. Y., 1942, p. 279.

solution of the amine was dried over anhydrous magnesium sulfate and used for the preparation of derivatives.

Quinolizidine Picrate.—Prepared in ether and recrystallized from methanol, the picrate formed yellow elongated plates, m. p. 197.5–198.5°.

Quinolizidine Picrolonate.—Prepared in ether and recrystallized from ethanol, the picrolonate formed orange plates, m. p. 244–245° (dec.).

Quinolizidine Methiodide.—Prepared in ether and recrystallized from ethanol–ether, the methiodide formed colorless cubes, m. p. 329–330° (dec.).

Wolff–Kishner Reduction of 6-Keto-1-azabicyclo[5.3.0]decane. 1-Azabicyclo[5.3.0]decane.—A solution of 0.5 g. (0.0026 mole) of 6-keto-1-azabicyclo[5.3.0]decane hydrochloride, 1 g. (0.017 mole) of hydrazine hydrate (85%) and 1.5 g. (0.027 mole) of potassium hydroxide in 10 ml. of triethylene glycol was refluxed for one hour. The solution was then distilled until no basic material was found in the distillate. The distillate was saturated with potassium carbonate, extracted twice with ether, and dried over anhydrous magnesium sulfate. The derivatives were prepared from the ethereal solution.

1-Azabicyclo[5.3.0]decane Picrate.—Prepared in ether and recrystallized three times from methanol, the picrate formed yellow elongated plates, m. p. 213–214°. The melting point of a mixture with authentic 1-azabicyclo-[5.3.0]decane picrate[2] was not depressed.

1-Azabicyclo[5.3.0]decane Methiodide.—Prepared in ether and recrystallized from ethanol–ether, the methiodide formed colorless needles, m. p. 282–283°.

Quinolizidine.—Quinolizidine was prepared by the method of Boekelheide and Rothchild[7] from diethyl β-(2-pyridyl)-ethyl malonate in 70% yield, b. p. 72° (12 mm.); $n^{20}D$ 1.4765. The picrate, picrolonate and methiodide were prepared and were recrystallized from the same solvents as were the derivatives of the Clemmensen reduction product of 6-keto-1-azabicyclo[5.3.0]decane: **picrate**, m. p. 197–198°; **picrolonate**, m. p. 244–245° (dec.); **methiodide**, m. p. 329–330° (dec.). No depressions in melting points were observed when corresponding derivatives of the amines from the two syntheses were mixed.

Summary

It has been established that Clemmensen reduction converts 6-keto-1-azabicyclo[5.3.0]decane to the rearrangement product, quinolizidine.

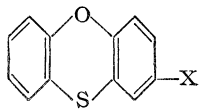
Vinyl Compounds: Phenoxathiin and Dibenzothiophene Derivatives

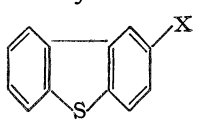
BY RALPH G. FLOWERS AND LEOLA WILLS FLOWERS

During an investigation of the properties of different polymeric materials, several phenoxathiin and dibenzothiophene derivatives were prepared. Interest in these compounds was centered upon the role played by the sulfur atom in determining their electrical properties. The vinylphenoxathiin was synthesized by the hydrogenation of the ketone to the carbinol with subsequent dehydration.



I, X = —$COCH_3$
II, X = —$CHOHCH_3$
III, X = —$CH{=}CH_2$

A similar scheme was carried out in the synthesis of the vinyldibenzothiophene.



IV, X = —$COCH_3$
V, X = —$CHOHCH_3$
VI, X = —$CH{=}CH_2$

The 2-acetylphenoxathiin (I) was prepared by a Friedel–Crafts reaction, using a modification of the work reported by Suter, McKenzie and Maxwell.[1] 2-(α-Hydroxyethyl)-phenoxathiin (II), prepared by the hydrogenation of I, was dehydrated in the vapor phase to 2-vinylphenoxathiin (III), m. p. 39.5–41°. The low melting point of this monomer allows it to be used for impregnation applications as well as in the form of its polymer and copolymers.

A number of investigators[2] have prepared the 2-acetyldibenzothiophene (IV) which we have hydrogenated to the 2-(α-hydroxyethyl)-dibenzothiophene (V). No evidence of catalyst poisoning was observed during the hydrogenation of these sulfur compounds or in subsequent runs using the same bombs with other materials. Two methods for the dehydration of V to 2-vinyldibenzothiophene (VI) were carried out in the present work. VI is also a low melting monomer, m. p. 45.0–45.5°, which may be utilized under the same conditions as those for III.

Experimental[3]

2-Acetylphenoxathiin (I).—One hundred thirty-five grams of anhydrous aluminum chloride and 300 cc. of carbon disulfide were placed in a 2-liter, 3-necked flask, equipped with an efficient stirrer, separatory funnel, condenser and a thermometer. A mixture of 200 g. of phenoxathiin in 700 cc. of carbon disulfide and 85 g. of acetyl chloride was added dropwise through the separatory funnel. The addition of the reactants took about six hours after which the mixture was allowed to stand one-half hour.

A yellow precipitate, which was obtained by hydrolyzing the mixture with ice and hydrochloric acid, was collected in a Büchner funnel and washed several times before drying. The fraction which distilled over at 165–185° at 1 mm. was recrystallized two times from ethyl alcohol: 74 g., 31% yield, of I was obtained which had a melting point of 111–112°.

2-(α-Hydroxyethyl)-phenoxathiin (II).—Seventy and one-half grams of I, dissolved in 1 liter of absolute methyl alcohol, and 5 g. of copper-chromium oxide catalyst[4] were placed in a glass lined, high pressure bomb. The reaction was carried out in the presence of hydrogen at 160° at

(4) Adkins, "Reactions of Hydrogen," Univ. of Wisconsin Press, Madison, Wisconsin.

pressures ranging from 2000 to 2400 p.s.i. with shaking for five hours. The reaction mixture was filtered to remove the catalyst. After the solvent had been distilled off, 64 g. (90% yield) was crystallized out of ligroin as small white needles, m. p. 65–67°.

Anal. Calcd. for $C_{14}H_{12}O_2S$: C, 68.84; H, 4.95. Found: C, 68.59; H, 4.99.

2-Vinylphenoxathiin (III).—Forty-seven grams of II was dissolved in 100 cc. of benzene, and introduced into the top of a vertical stainless steel column 1″ in diameter and 18 in. long. This reaction column was packed with alumina pellets[5] and maintained at a temperature of 340–360° and a pressure of 10–20 mm. The reaction products were collected in an ice-cooled receiver and then recrystallized from alcohol: 35 g., 79% yield, of III was obtained which had a melting point of 39.5–41°. The infrared absorption spectrum of this compound was marked by the absence of absorption bands due to the contributions of the carbonyl and hydroxyl groups.

Anal. Calcd. for $C_{14}H_{10}OS$: C, 74.33; H, 4.47. Found: C, 74.30; H, 4.69.

Polymers of III.—This monomer was found to polymerize very readily with heat or with any of several catalysts.[6] Such catalysts as boron trifluoride, benzoyl peroxide, *t*-butyl hydroperoxide and potassium persulfate were employed. These polymers were precipitated from benzene solution with methyl alcohol as white powders having softening points of about 200°.

A disk of polyvinylphenoxathiin prepared by heating the monomer in an open beaker at 130° for one hour, was hard, transparent and brittle at room temperature but it was very pliable at temperatures above 200°. The electrical properties of the disk were determined at 25°. At 60 cycles, the polymer had a power factor of 0.108% and a dielectric constant of 3.42. At one megacycle, the power factor was 0.15% and the dielectric constant was 3.34.

Copolymers of III.—One part of III was copolymerized with 0.8 part vinyl acetate, 1.0 part acenaphthylene, 1.0 part styrene, 0.6 part acrylonitrile, 1.0 part maleic anhydride and 0.35 part butadiene.[7] The butadiene–III copolymer was made by polymerizing in an emulsion. This product formed a tough, pliable film with good electrical properties.

2-(α-Hydroxyethyl)-dibenzothiophene (V).—Ninety-eight grams of IV, dissolved in 1400 cc. of absolute methyl alcohol, was heated with shaking in the presence of a copper–chromium oxide catalyst and 2000 p. s. i. of hydrogen. After reacting for five hours at 130°, the product was filtered to remove the catalyst and then recrystallized from dilute alcohol: 90 g., 91% yield, of white needles, m. p. 61.0–62.0° was obtained.

Anal. Calcd. for $C_{14}H_{12}OS$: C, 73.65; H, 5.26; S, 14.03. Found: C, 73.87; H, 5.13; S, 13.85.

2-Vinyldibenzothiophene (VI).—Thirty-eight grams of V was dissolved in 200 cc. of benzene and this solution was then added dropwise into the top of the vertical reaction column. The column was packed with alumina pellets[5] and maintained at a temperature of 325–350° and a pressure of 10 mm. during the reaction. The product was recrystallized from ethyl alcohol as small white needles, m. p. 45.0–45.5°; 17.5 g., 50% yield, was obtained from the conversion.

In an alternative procedure V and *p-t*-butylcatechol, as a polymerization inhibitor, were gently heated in a porcelain crucible until molten. Anhydrous copper sulfate was added to the mixture and heated a few minutes longer. The product was then recrystallized from alcohol.

Anal. Calcd. for $C_{14}H_{10}S$: C, 79.96; H, 4.76; S, 15.23. Found: C, 79.98; H, 4.77; S, 15.09.

Polymers of VI.—Products with high softening points and good electrical properties were prepared by polymerizing the monomer, both with catalysts and with heat alone. In one example VI was placed in a 125° oven for forty hours to give a hard brittle mass. This polymer when molded into a disk at 150° and 20,000 p.s.i. had a power factor of 0.1% and a dielectric constant of 2.8 at one megacycle.

Copolymers of VI.—Copolymers which are white powders with softening points ranging from 174° to above 220° were obtained by polymerizing one part of VI with one part of the following monomers: styrene, vinyl acetate, N-vinylcarbazole, N-vinylphthalimide, acrylonitrile and acenaphthylene.

Acknowledgment.—The authors wish to thank Mr. E. D. Elliott, Jr., of this Laboratory for his work on the emulsion polymerization of 2-vinylphenoxathiin.

Summary

The synthesis and properties are given for 2-(α-hydroxyethyl)-phenoxathiin, 2-vinylphenoxathiin, 2-(α-hydroxyethyl)-dibenzothiophene and 2-vinyldibenzothiophene. Polymers and copolymers have been prepared from the 2-vinylphenoxathiin and from the 2-vinyldibenzothiophene.

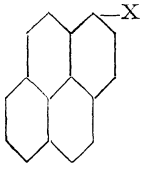
The Preparation and Properties of 1-Vinylpyrene

BY RALPH G. FLOWERS AND FRANK S. NICHOLS

The synthesis and investigation of the properties of 1-vinylpyrene (I) was undertaken as part of a program in which various polymerizable aromatic compounds were being studied. Interest in the physical and particularly the electrical properties of polymers having large aromatic nuclei stimulated the present work on the vinylpyrene.

Two different methods for the preparation of I were successfully carried out. In the first method, 1-acetylpyrene (II) was hydrogenated to the 1-(α-hydroxyethyl)-pyrene (III) with subsequent dehydration to I.



I X = —CH=CH$_2$
II X = —COCH$_3$
III X = —CHOHCH$_3$
IV X = —CHO
V X = —CH=CHCOOH

Bachmann and Carmack[1] prepared II as yellow crystals, m. p. 80–90°, and III as pale yellow crystals, m. p. 112–112.5°, from the hydrogenation of II with aluminum isopropoxide. The method used in the present work was to hydrogenate II in the presence of a copper–chromium oxide catalyst.[2] Some ethylpyrene is formed, even under the mildest conditions, when II is treated with more than equimolecular amounts of hydrogen. An excellent yield of 1-ethylpyrene was prepared by using a large amount of hydrogen. This is in agreement with results reported by Homer Adkins for aryl- and poly-aryl carbinols bearing an aryl group in the 2 position with respect to the hydroxy group.[3]

The second procedure for the preparation of I involved the treatment of 1-pyrenylaldehyde (IV) with malonic acid to give the 1-pyrenylacrylic acid (V) which was decarboxylated to I.

IV was prepared from phosphorus oxychloride, formylmethylaniline and pyrene as described by Vollman, *et al.*[4] Bergmann and Bograchov[4] prepared V from IV using piperidine as the condensation catalyst. The decarboxylation of V to I was attempted by the method of Walling and Wolfstirn[5] by which they decarboxylated cinnamic acids. The method, however, was not satisfactory in this case as the product obtained was almost entirely polymerized. A vapor phase modification of this method gave good results and has the added advantage that continuous rather than batch reactions may be carried out.

Experimental

1-(α-Hydroxyethyl)-pyrene (III).—Twenty-four grams of II, 0.119 mole, dissolved in 120 cc. of absolute methyl alcohol was agitated with 1.4 g. of copper–chromium oxide catalyst[2] and 0.12 mole of hydrogen for seven hours at 80° in a 270-cc. bomb. The initial pressure of 260 pounds per square inch fell to zero during this time; 17 g., 70% yield, of III, m. p. 113°, was obtained on recrystallization from benzene.

1-Ethylpyrene.—Twelve grams of II, 0.059 mole, dissolved in 120 cc. of absolute methyl alcohol was placed in a 270-cc. bomb with 0.7 g. of copper–chromium oxide catalyst. 0.55 mole of hydrogen was introduced into the bomb which was then agitated for one-half hour at 83–88°; 10 g., 83% yield, of the ethyl compound was obtained which had a melting point of 95° as previously reported.[6]

1-Vinylpyrene (I) from III.—Sixty-two grams of III dissolved in 200 cc. of dioxane was added dropwise into the top of a vertical stainless steel column 1/2 in. in diameter and 18 in. long. The column was packed with alumina pellets[7] and was maintained at a temperature of 340–360° and a pressure of 6 mm. during the reaction. Much charring of the product was observed under these conditions; 10 g., 18% yield, of light yellow 1-vinylpyrene, m. p. 87–89°, along with a considerable quantity of polymer was obtained.

Anal.[8] Calcd. for $C_{18}H_{12}$: C, 94.69; H, 5.30. Found: C, 94.35; H, 5.69.

1-Vinylpyrene (I) from V.—Nine grams of V in 150 cc. of benzene and 25 cc. of quinoline were allowed to pass down through a stainless steel column packed with copper borate–alumina pellets.[5] The temperature of the tube was kept at 520–580° and a pressure of 10–20 mm. was maintained on the system during the reaction. The product was washed with cold 2.4 *N* hydrochloric acid and then several times with water. The benzene was removed and the residue taken up with alcohol. This alcohol solution was boiled with activated charcoal and filtered; 5 g., 66% yield, of I, m. p. 87–89°, crystallized out of the light yellow solution.

Polymers of 1-Vinylpyrene.—Six grams of I dissolved in benzene was treated with boron trifluoride etherate to give a quantitative yield of a white powder, softening point about 220°, when precipitated out with methyl alcohol. This powder was molded into a disk at 160° using 40,000 p. s. i. pressure. This polymer had a dielectric constant of 3.2 and a power factor of 0.07% at one megacycle.

Polyvinylpyrene was also prepared by heat alone and with catalysts such as benzoyl peroxide and *t*-butyl perbenzoate.

Copolymers of 1-Vinylpyrene.—Copolymers have been obtained by polymerizing one part of I with one part of each of the following monomers: vinyl acetate, styrene, acenaphthylene, N-vinylphthalimide, N-vinylcarbazole, acrylonitrile and maleic anhydride. The softening points of these copolymers ranged from 155° for styrene and 180° for vinyl acetate to above 220° for the acenaphthylene and maleic anhydride products.

Summary

The properties of 1-vinylpyrene and its preparation by two methods have been described. Polymers and copolymers of 1-vinylpyrene have been made.

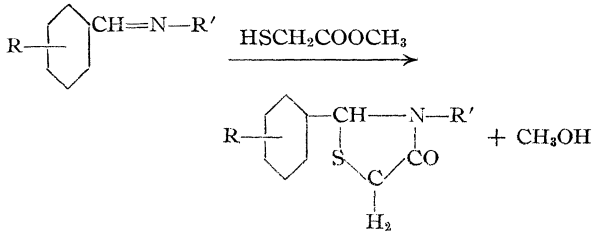
The Preparation of 4-Thiazolidones. III. The Reaction of Methyl Thioglycolate with Benzylidene Dialkylaminoalkylamines

BY ALEXANDER R. SURREY

Recently it has been shown that 2,3-diaryl- and/or 3-alkyl-2-aryl-4-thiazolidones may be easily prepared by the reaction of thioglycolic acid[1] or of thioglycolic esters[1d] with Schiff bases. In continuation of a general investigation on the synthesis of 4-thiazolidones, a series of 2-aryl-3-dialkylaminoalkyl derivatives was prepared to make them available for pharmacological studies.

A convenient method of synthesis,[1b] involving the reaction of methyl thioglycolate with the appropriate benzylidene dialkylaminoalkylamine (Table I), was employed for this purpose. However, in some instances the intermediate anils were not isolated and the crude material was used directly in the next step.



In contrast to the benzylidene anilines,[1b] the anils in the present series react with a thioglycolic ester to give good yields of the 2,3-disubstituted 4-thiazolidones. When the reaction was carried out in refluxing Skellysolve E (b. p. 120°) with a separator connected to the apparatus, the methanol which formed during the reaction was collected as a distinct layer in the separator. Heating was discontinued when no further separation of methanol was noted, which in most instances approached the theory. With lower-boiling petroleum fractions as a solvent, the reaction proceeded in the expected manner. However, the separation of methanol could not be observed.

In most cases, after removal of the solvent by distillation, the crude residue was dissolved in ether, and the 2-aryl-3-dialkylaminoalkyl-4-thiazolidone was extracted with dilute hydrochloric acid. The base obtained from the acid extract was then converted to the crystalline hydrochloride (Table II).

In the preparation of 3-(3-diethylamino-2-hydroxypropyl)-2-phenyl-4-thiazolidone two isomeric crystalline bases and hydrochlorides were obtained. Although two possible racemic mixtures can also be formed in the preparation of the corresponding 2-(4-methoxyphenyl) derivative, only one compound was isolated.

Preliminary pharmacological studies[2] indicate that several of the 2-aryl-3-dialkylaminoalkyl-4-thiazolidones reported in this paper show marked local anesthetic activity. 3-(2-Dibutylaminoethyl)-2-(4-chlorophenyl)-4-thiazolidone, (Win 2126) 3-(2-dibutylaminoethyl-2-(3,4-methylenedioxyphenyl)-4-thiazolidone (Win 2777) and 3-(2-diethylaminoethyl-2-(3,4-methylenedioxyphenyl)-4-thiazolidone (Win 2125) are the most active compounds studied in this series. Win 2777 is much more active than procaine while Win 2125 is as active as procaine and also shows activity as a topical anesthetic (cornea). The compounds reported are very stable to heat, acid or base and in most instances are non-irritating.

Experimental[3]

Preparation of Benzylidene-dialkylaminoalkylamines. (Table I).—Equimolecular quantities of the appropriate aromatic aldehyde and dialkylaminoalkylamine in benzene were refluxed with a water separator connected to the apparatus. When the reaction was completed the benzene was removed and the product was distilled under reduced pressure.

Preparation of 2-Aryl-3-dialkylaminoalkyl-4-thiazolidone Hydrochlorides.—The general procedure for the preparation of the compounds described in Table II is described below.

Equimolecular quantities (0.1 mole) of the benzylidene dialkylaminoalkylamine (Table I) and methyl thioglycolate[4] in 150 ml. of Skellysolve E were refluxed until approximately the theoretical amount of methanol was collected in a separator connected to the apparatus. After distilling the solvent *in vacuo*, the residue was dissolved in ether, and the desired product was extracted with dilute hydrochloric acid solution. The base, obtained from the acid extracts, was dissolved in acetone and alcoholic hydrogen chloride was added. Where necessary, dry ether was added and the solution was allowed to stand at room temperature. The solid hydrochloride which precipitated was purified by recrystallization.

3-(3-Diethylamino-2-hydroxypropyl)-2-phenyl-4-thiazolidone.—A solution of 23.4 g. of benzylidene 3-diethylamino-2-hydroxypropylamine and 11 g. of methyl thioglycolate in 150 ml. of Skellysolve E was treated as described above. The crude crystalline hydrochloride (16 g.) melted at 120–125°. After several recrystallizations from isopropanol, the product melted at 155.6–160.9° cor.

Anal. Calcd. for $C_{16}H_{25}ClN_2O_2S$: S, 9.29; Cl^-, 10.30. Found: S, 9.23; Cl^-, 10.12.

A sample of the hydrochloride was converted to base which solidified on standing. After recrystallization from Skellysolve A it melted at 58.8–60° cor.

Anal. Calcd. for $C_{16}H_{24}N_2O_2S$: S, 10.37. Found: S, 10.55.

(2) The author is indebted to Dr. F. P. Luduena and Miss J. Sherndal for the local anesthetic testing, the details of which will be published elsewhere.

(3) All melting points and boiling points are uncorrected unless otherwise specified. The corrected melting point determinations and analyses recorded were performed by the analytical staff of these laboratories under the direction of M. E. Auerbach.

[a] Ionic chlorine. [b] The base of this compound was reported by Troutman and Long, Ref. 1d. [c] Yield based on substituted benzaldehyde. [d] Yield of crude base was 74%.

The hydrochloride prepared from the crystalline base melted at 160–161°.

In another experiment the crude base solidified on standing. It was recrystallized from Skellysolve A, m. p. 74.2–75.6° cor.

Anal. Found: S, 10.42.

The hydrochloride prepared from this base melted at 143.2–144° cor. A mixed melting point with the higher melting hydrochloride was depressed.

3-(2-Diethylaminoethyl)-2-(4-nitrophenyl)-4-thiazolidone Hydrochloride (Win 2502).—A mixture of 30.2 g. of 4-nitrobenzaldehyde and 23.6 g. of 2-diethylaminoethylamine in 150 ml. of Skellysolve E was refluxed for three hours (2.4 ml. of water collected). After allowing to cool, 21.8 g. of methyl thioglycolate was added to the reaction mixture and refluxing continued for seventeen hours. At the end of this time approximately 9 ml. of methanol had separated. The solvent was decanted from the oily layer which separated and the latter was dissolved in 250 ml. of acetone and filtered with Norite. Alcoholic hydrogen chloride was added to the filtrate to give 45 g. of a yellow solid. Recrystallization from ethanol yielded 38 g. (53%) of product melting at 194.1–194.9° cor.

2-(4-Aminophenyl)-3-(2-diethylaminoethyl)-4-thiazolidone Hydrochloride (Win 2531).—A mixture of 36 g. of the above nitro base, 150 ml. of water, 250 ml. of ethanol, 140 g. of iron filings and 3.6 ml. of acetic acid was refluxed with stirring for one hour. An additional 7 ml. of acetic acid was added and refluxing continued for two hours longer. The mixture was basified with sodium carbonate and filtered hot. The ethanol was removed by distillation and the aqueous mixture was extracted with ether. After drying and removing the ether by distillation 25 g. of the crude base was obtained which yielded 18 g. of hydrochloride.

A sample of this hydrochloride was converted to the base which solidified on standing. After recrystallization from Skellysolve B it melted at 62.8–64.4° cor.

Summary

The preparation of a series of 2-aryl-3-dialkylaminoalkyl-4-thiazolidones by the reaction of methyl thioglycolate with several benzylidene dialkylaminoalkylamines is reported.

Several of the compounds reported showed marked local anesthetic activity.

A New Method for the Preparation of α-Bromoesters[1]

BY J. R. DICE AND J. N. BOWDEN[2]

The reaction of the metal salts of carboxylic acids with chlorine or bromine to yield an alkyl or aryl halide and carbon dioxide[3] is well known. Recently, Hunsdiecker[4] employed this reaction in the preparation of α-bromo aliphatic acids from the half-esters of ω,ω′-dicarboxylic acids. There are no reports in the literature of the use of the metal salts of the half acid esters of alkylmalonic acids in this synthesis.

It was reasoned that if one mole of halogen would react with the metal salts of the monoesters of alkylmalonic acids in the same manner as with simple carboxylic acid salts, the product would be an α-haloester.

$$R{-}CH(COOC_2H_5)(COO\text{-}Metal) + X_2 \longrightarrow R{-}CHX{-}COOC_2H_5 + Metal{-}X + CO_2$$

To test this hypothesis the dry potassium salts of the monoesters of several alkylmalonic acids were treated with bromine. Although the expected α-bromoesters were obtained, the yields in most experiments were relatively low. In general, bromination of acid chlorides[5] would be a preferred route to these compounds. Compounds prepared by the new method were ethyl α-bromobutyrate, ethyl α-bromoisovalerate, ethyl α-bromocyclohexylacetate, ethyl α-bromocaproate and ethyl α-bromo-β-phenylpropionate.

Although silver salts have been used most frequently in the reaction, other metal salts such as mercury, copper or potassium also have been used successfully.[6] In this study the potassium salts were utilized throughout and carbon tetrachloride was used as solvent.

With the potassium salt of monoethyl malonate we obtained the same result in carbon tetrachloride as that reported by Freund[7] for aqueous solution; *i. e.*, a mixture of ethyl bromoacetate and ethyl dibromoacetate was formed. In this reaction hydrogen bromide was evolved during the addition of bromine. The liberation of hydrogen bromide is apparently caused by a substitution reaction which occurs prior to or simultaneously with decarboxylation. Substitution does not follow decarboxylation, since ethyl bromoacetate does not react visibly with bromine under the conditions of our experiment.

Experimental

Potassium Salts of Monoesters of Alkyl Malonic Acids.—The ethyl alkylmalonates used were prepared from ethyl malonate (b. p. 198° at 746 mm.) and the respective alkyl halides essentially as described by Adams and Johnson,[8] and they were redistilled before use. Potassium salts of the mono acid esters of these compounds were synthesized following the procedure of Freund.[7] To a solution of 0.15 mole of diethyl alkylmalonate in 100 ml. of absolute alcohol was added, with stirring, a solution of 8.7 g. (0.15 mole) of potassium hydroxide in 100 ml. of absolute alcohol. The solution was allowed to stand at room temperature for four to twelve hours; the *p*H of the final mixture had a value between 7 and 8 as measured with *p*-Hydrion paper. Any solids which formed were assumed to be the dipotassium salt of the alkylmalonic acid and were removed by filtration.

TABLE I

ETHYL α-BROMOESTERS

α-Bromoesters	Yield,[a] %	B. p., °C.	Mm.	$n^{25}D$	d^{25}_4
Acetate[b]	23	165–168	749		
Butyrate	36	177–180	745		
Caproate	67	208–209	748[c]	1.4468	1.2210
iso-Valerate	30	185–187	754[d]	1.4392	1.2325[e]
Cyclohexyl-acetate[f]	45	133–136	13	1.4708	1.1466
β-Phenyl-propionate	80	155–159	15	1.5180[g]	

[a] All yields are based on the weight of diethyl alkylmalonate employed. [b] Hydrogen bromide was evolved during the bromine addition and a 20% yield of ethyl dibromoacetate (b. p. 185–192° (749 mm.)) also was obtained. [c] 111–113° at 25 mm. [d] 105–115° at 25 mm. [e] Schleicher, *Ann.*, 267, 116 (1892), reported d^{12}_{12} to be 1.2276. [f] J. v. Braun, *Ber.*, 2184 (1923). [g] This compound decomposed on standing for twenty-four hours, so a density determination was not obtained.

The alcohol was distilled until only a thick sirup remained in the flask. The last traces of solvent were removed *in vacuo* and the resulting crystals were placed in a vacuum desiccator for twelve hours. The salts were used without further purification.

Preparation of α-Bromoesters.—The dried, finely pulverized, potassium salt was mixed with 100 ml. of carbon tetrachloride. The ice-cold mixture was stirred vigorously while a solution of 25 g. (0.15 mole) of bromine in 50 ml. of carbon tetrachloride was added dropwise over a period of two to four hours. The bromine was decolorized rapidly at the start of the reaction, but persisted after all of the bromine solution had been added. The mixture was filtered and the solvent was removed in a current of air. The residue was distilled at reduced pressure to give in every case a colorless, strongly lachrymatory liquid. The yields and physical constants of the compounds prepared are given in Table I.

Summary

The reaction of the potassium salts of monoethyl alkylmalonates with bromine provides a new method of preparing α-bromoesters.

The Apparent Sulfur in Cucumber Virus 4

BY C. A. KNIGHT

Rather extensive chemical analyses have been made of tobacco mosaic virus (TMV) and several of its strains; and cucumber viruses 3 and 4 (CV3 and CV4) have been included in these studies.[2] The consideration of CV3 and CV4 as strains of TMV has been based on their mutual possession of an uncommon size and shape, on weak but definite serological cross reactions, on a common unusual resistance to heat and desiccation, and on possession of apparently identical quantities of protein and pentosenucleic acid.[3-5] On the other hand, it has not been possible to perform one of the tests of strain relationship, the cross-protection test, for as yet no common host has been reported for TMV and the cucumber viruses. Furthermore, it appears that the particles of CV3 and CV4 differ slightly but significantly in size from those of TMV and some of its other strains.[6,7] However, whether they are actually distantly related strains of TMV as supposed, or whether they are distinct viruses, it seems evident that the facts revealed from their study could ultimately be brought to bear on problems of the relationship of biological, serological, and physical properties to the chemical composition and structure of the virus, or of biologically active proteins in general. As a consequence of this viewpoint, it seemed imperative to determine the nature of the sulfur in CV3 or in CV4, for, while the sulfur of TMV and of most extensively studied proteins has been shown to occur mainly in well-known sulfur-containing amino acids, the sulfur apparently present in CV3 and CV4 has eluded identification.[3,8]

It will be shown in the present report that CV4 differs decidedly from TMV and some of its strains in that CV4 probably contains no sulfur at all.

Materials and Methods

Preparation of Virus.—Highly purified preparations of CV4 were obtained from the expressed juice of appropriately diseased cucumber plants by differential centrifugation as previously described.[3] The salt content of the preparations was reduced to a very low level by handling the virus in distilled water during two or more cycles of centrifugation, by dialysis against flowing distilled water, or by electrodialysis. These preparations were then frozen and dried *in vacuo*, and then further dried to constant weight at 110° in a drying oven.

Sulfur Analyses.—The first sulfur values for highly purified, dried preparations of CV3 and CV4 were those of Bawden and Pirie in which a range of 0.0 to 0.6% sulfur was reported.[9] No explanation of the possible significance of this range of results was advanced, and the value recorded later by Bawden appears to be a mean of the earlier determinations, namely, 0.3%.[4] A figure of 0.85% sulfur was given by Knight and Stanley as the mean of 8 analyses made on 3 different preparations of CV4.[3] Since that time and including the individual analyses leading to the figure just given, a total of forty-one analyses have been made by three different analysts on thirteen of our preparations. The analyses were made by the customary Carius pressure-tube method and yielded an average of 0.6% sulfur, but the individual values obtained ranged from 0.07 to 1.26%. Furthermore, a given analyst obtained with the same preparations of virus, but on different occasions, sulfur values which differed by as much as 50%. Also, different analytical laboratories, analyzing portions of the same sample of virus, reported results equivalent to three- to ten-fold differences in sulfur content. No analyst was consistently high or low in his results.

Despite this confusing situation, the results seemed to indicate that there is some sulfur in CV4, but that it is for some unknown reason, inherently difficult to obtain a reliable estimate of its quantity.

Attempts to Identify Sulfur in CV4.—A series of tests made on numerous preparations of CV4 over a period of several years has established the absence from this virus of amounts greater than traces of the amino acids, cys-

teine, methionine and thiolhistidine.[10] Cysteine and cystine were ruled out by the failure of CV4 to give a positive nitroprusside test either in the presence or absence of cyanide, the failure of CV4 to reduce uric acid reagent, and by the fact that these amino acids were not detected in the Baernstein determination of sulfur amino acids.[3,8,11-13] Methionine was eliminated from consideration by its failure to appear in the Baernstein separation, the Kolb and Toennies color reaction,[14] or in microbiological assays.[2] It should be noted also that the Baernstein method yielded no sulfate sulfur at all when applied to several of the samples. At one time, it was thought that positive color tests for thiolhistidine were obtained[8] but in more carefully controlled experiments these were not secured, which, coupled with the failure of thiolhistidine to appear in the Baernstein separation, make its presence in CV4 very dubious. Some microbiological tests for biotin, kindly made on a hydrolysate of CV4 by Dr. William Trager, indicated that this sulfur-containing vitamin was absent.

While the tests mentioned above did not preclude the possible presence in CV4 of some rarely occurring or previously unknown sulfur component, it nevertheless seemed advisable to test next for the possible presence of some element other than sulfur, but related to it, such as selenium.

Tests for Selenium in CV4.—When CV4 was digested and treated with codeine sulfate according to the procedure of Gortner and Lewis[15] or some modification of it, a blue color indicative of the presence of selenium was obtained. This color was not secured under comparable conditions with tobacco mosaic virus. However, application of the more specific distillation method of Klein[16] showed no detectable selenium in a 100-mg. sample of CV4. In a control experiment, using this method, the addition to a sample of the virus of 25 micrograms of selenium in the form of sodium selenite resulted in a recovery of 22 micrograms. The absence of selenium from CV4 was further confirmed by examination of the emission spectrum of the virus by Dr. G. I. Lavin. This test showed the absence of even traces of selenium from CV4. Therefore, it can be concluded that selenium is not present in CV4, although no explanation has yet been found for the positive codeine color reaction given by this virus.

The absence of tellurium, as well as selenium, was also indicated by failure to detect either of these elements when the test of Drew and Porter[17] was applied to 500 mg. of virus.

In view of the foregoing, it seemed pertinent to return to the potential sulfur in CV4 and to seek a decisive test which would indicate whether or not this element was present. The use of radiosulfur was selected for this purpose.

Experiments with Sulfur 35.—It had been found that radioactive phosphorus was incorporated into tobacco mosaic virus when mosaic-diseased tobacco plants cultured in sand were fed a nutrient solution to which had been added disodium phosphate containing radioactive phosphorus.[18] It seemed likely, therefore, that if CV4 contained sulfur, a radioactive isotope of that element could be introduced into the virus by a similar procedure. For this purpose, about 100 young cucumber plants growing in sand culture were inoculated with CV4, and starting the following day and continuing for about thirty days, the plants were watered with 17 parts of Spencer's medium nitrogen nutrient solution[19] to which had been added 1 part of potassium chloride solution containing S^{35}.[20] Each plant received about 100 ml. of solution every other day. A day after the last feeding, the plants were harvested, frozen and subsequently processed for CV4 by the usual methods.[3] The virus was handled in diminishing concentrations of phosphate buffer through successive cycles of centrifugation, starting with 0.1 *M* and working down through 0.05, 0.01 *M* and going finally to water, from which the preparation was frozen and dried. A portion of partially purified virus, containing a small but visible amount of green impurity, was reserved for radioactivity measurements. The highly purified, dried virus was white in color.

In order to compare the results obtained with CV4 to those procurable in the case of a strain of tobacco mosaic virus known to contain sulfur, an experiment similar to that just described was performed with tobacco mosaic virus grown in three Turkish tobacco plants.[21]

The sulfur in the various fractions was converted to sulfate by Carius oxidation and precipitated from the digests as benzidine sulfate.[22] Measurements of S^{35} activity were made in a Lauritzen electroscope[23] using the methods of Henriques and co-workers.[22] Carrier sulfur was used when necessary and all samples of benzidine sulfate measured for radioactivity came within the weight range of 6.7 to 7.1 mg.

The data, which are summarized in Table I, indicate that a negligible quantity of the S^{35} supplied to the cucumber plants appeared in the highly purified CV4. On the other hand, the partially purified virus, which contained a visible trace of green impurity, was found to possess 45 times the radioactivity of the highly purified virus. This, and the considerable amount of radioactivity found in the sap and in the plant residue after ex-

traction of the virus, show that a significant portion of the S^{35} supplied to the plants was taken up and utilized. One can, therefore, conclude that if CV4 had contained S, even in the smallest amount shown by the analytical data, this would have been manifested by appreciable radioactivity in the isolated and highly purified CV4. Confirmation of this conclusion appears to be provided by the outcome of the TMV experiment where, as shown in Table I, 55% of the expected S^{35} activity was found in the highly purified TMV. The author was assisted in these experiments by Miss Jessie Mason McNeil.

Discussion and Summary

The fact that a highly purified preparation of cucumber virus 4 obtained from cucumber plants which had received a nutrient solution containing S^{35}, possessed much less than 1% of the potential, calculated radioactivity of a compound containing 0.6% sulfur, indicates that no sulfur is present in CV4. This conclusion is supported by the finding that 55% of the calculated radioactivity was present in a similar preparation of tobacco mosaic virus, which is known to contain 0.2% of sulfur.[24]

The sulfur values obtained by two different laboratories on portions of the CV4 of the S^{35} experiment illustrate the confusing results which made the isotope experiment imperative, for the analyst who had previously obtained high values for most preparations, reported essentially no sulfur present (0.07%), whereas a second analyst found an amount comparable to that present in TMV, *i. e.*, about 0.2%. The nature of this pseudo-sulfur, found in 90% of the analyses of CV4 thus far, remains to be solved. It seems clear, however, that it is an artifact.

As an incidental point, the S^{35} experiment demonstrated in a graphic manner how a virus can be separated from normal plant materials in a stepwise fashion by the technique of differential centrifugation. The clarified plant sap, from which the virus was separated by an initial high-speed centrifugation, possessed over 2 million units of S^{35} activity. After 3 cycles of centrifugation, the total S^{35} activity of the viral preparation was about 1500 units, and after 5 cycles, 31 units. It seems reasonable in view of these facts, to assign the relatively minute amount of radioactivity in the highly purified CV4 to a residual trace of impurity.

The demonstration that CV4 contains no sulfur constitutes a striking difference between this virus and the other strains of TMV which have been studied chemically thus far, for the latter all contain sulfur, mainly in the form of cysteine.

The Effects of Substituents on the Dissociation Constants of Substituted Phenols. I. Experimental Measurements in Aqueous Solutions[1]

BY CHARLES M. JUDSON[2,3] AND MARTIN KILPATRICK[4]

The Sarmousakis modification[5] of the Kirkwood–Westheimer[6] electrostatic theory of the effects of substituents on the dissociation constants of benzenoid acids was originally tested by a comparison with the experimentally observed constants for the benzoic acids in several different pure solvents. To assist in providing a further test of the Sarmousakis treatment, the dissociation constants of a number of substituted phenols have been measured using a stepwise colorimetric method similar to that used previously in this Laboratory.[7] Complete data for the substituted phenols measured by a consistent method have been reported in the literature only for certain alcohol–water mixtures.[8] Values in a pure solvent are preferred for comparison with the electrostatic theory. The data obtained in the present investigation along with the previously available data have provided a satisfactory set of values for the substituted phenols in aqueous solution. These values have been compared with values calculated by the electrostatic theory and have been used to provide additional support for the theory.[9]

The ratio of the dissociation constant of an indicator A_i to that of an uncolored acid A may be defined by the equation

$$K_{A_iB} = c_{B_i}c_A/c_{A_i}c_B \qquad (1)$$

where B_i and B refer to the corresponding conjugate bases. By placing a small measured amount of the indicator in a buffer solution of known concentration of the uncolored acid with its sodium salt, the ratio of the dissociation constants can be determined from a colorimetric measurement of the concentration of one form of

the indicator. By making a series of such measurements of relative dissociation constants and including in this series one compound, acetic acid, for which the dissociation constant in water had been previously established, the dissociation constants were measured for a series of nitrophenol indicators and uncolored substituted phenols. This procedure was particularly suitable for measurement of phenols with nitrophenol indicators because the extrapolation to zero concentration is simplified when the buffer acid and the indicator have the same charge type, the ratio of the dissociation constants being to a first approximation independent of concentration.

Experimental

Apparatus.—Preliminary measurements were made with a Rubicon photoelectric colorimeter (number 4600) using a galvanometer and a 4400 Å. filter supplied by the manufacturer.

With the object of increasing the precision of the measurements, another colorimeter was constructed by modifying the instrument used by Minnick and Mears.[7] The modified instrument consisted of a projection bulb source, a regulated power supply for the source, a Hilger spectroscope used as a monochromator, a light-tight box within which four absorption cells could be brought successively into the light path, and a 931 multiplier phototube circuit to measure the intensity of the transmitted light.[10]

The optical system was essentially that used by Minnick and Mears. The absorption cells were plane-window, cylindrical glass cells with a path of 25 mm., obtained from the Phoenix Precision Instrument Co. The cells were found to have identical effective solution depths as determined by extinction measurements. The monochromator was calibrated by reference to a mercury arc. All measurements were made at 4450 Å. with a half-width of 24 Å.

The electrical circuits were modified because of the difficulties reported by previous workers. The voltage regulators used for the light source supply was similar to one described by Terman.[11] A three-phase full-wave rectifier circuit with 1120 volt center-tapped transformers supplied the power to the regulator. Using twenty-one 6L6 tubes in parallel in the regulator, an output of one ampere was obtained. The 200 volt output was dropped through a resistance to obtain a 100 volt potential for the source. The resulting potential was constant to 0.002 v. which was shown to be sufficient to ensure regulation of light intensity to 0.01%. The 110 v. projection bulb was operated at 100 v. increasing its life at some expense of intensity.

Two separate filtered half-wave power supply circuits were provided for the dynode and anode potentials of the multiplier phototube. A Sola constant-voltage transformer was used to regulate the input to both supply circuits. The output of the dynode supply was further controlled by an electronic voltage regulator similar to one designed for a Geiger counter supply.[12] This regulator was found more convenient than regulation based on the control characteristics[13] of the tube in which the voltage step at one dynode is made unequal to that at the other dynodes. The potential supplied to the anode was 280 v. The potential supplied to the dynodes was 560 v., constant to 0.1 v. This potential was divided into nine equal portions by a 180,000 ohm divider. The limit of accuracy of the transmittance measurements was apparently set by the regulation of the dynode potentials. Because this regulator was drawing more current than it was designed for, the precision of the transmittance measurements was limited to 0.2%.

The output of the phototube was measured by passing the photocurrent through a high resistance decade (R1 in Fig. 1) and measuring the potential developed across the decade with a type K potentiometer (R2). A second potentiometer (R3) was used to compensate for the dark current of the phototube which generally amounted to about 0.3% of the photocurrent. The balance of the potentiometer was measured with a Rubicon galvanometer (0.0012 μa/mm.) used in conjunction with an Ayrton shunt (not shown in Fig. 1).

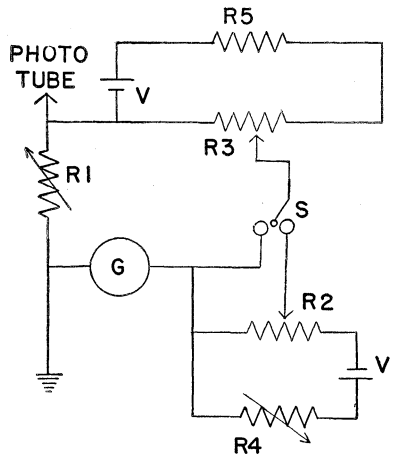

Fig. 1.—Circuit for measuring photocurrent: R1, 100,000ω decade; R2, type K potentiometer; R3, 30ω slide wire; R4, 1000ω decade, R5, 7000ω; V, 1.5 volt batteries; G, galvanometer.

Instead of using a standard cell, the photocurrent for the measured transmittances was always compared with the photocurrent obtained with a cell containing pure water. As the type K potentiometer used was not designed for direct reading of potentials compared to a standard of unity, it was necessary to use the standard cell position, 1.018 v., for the measurement of the reference solution, the ratio of the two photocurrents then being 1.018 times the reading of the potentiometer.

The optical system was placed in a transite air-bath lagged with rock wool. Water cooled to 5° by a mechanical refrigerating unit was circulated through a radiator inside the air-bath. A thyratron relay controlled by a bimetallic regulator operated a nichrome wire heater and simultaneously a mercury switch relay which in turn controlled an impeller pump in the cooling system. Three fans were used to circulate the air. The temperature inside the absorption cell box was 25.0 ± 0.1°. The temperature was measured with a Beckmann thermometer calibrated by comparison with a Bureau of Standards platinum resistance thermometer.

Solutions measured with the Rubicon colorimeter were brought to 25° in a water-bath and were then quickly transferred to the test-tube absorption cells and the transmittance measured immediately. The temperature could be controlled in this way to ±0.5°.

Procedure.—At the beginning of each series of measurements with the photomultiplier instrument, the four absorption cells were cleaned and filled with water and the windows were polished. Using one cell as a reference, the relative transmittances of the other three cells were measured to obtain a calibration of the cells. Three of the cells were then removed, rinsed with the solutions to be measured, filled and replaced without touching the cell

(10) We are indebted to J. P. Hervey of the Johnson Foundation for Research in Medical Physics of the University of Pennsylvania and to J. Presper Eckert of the Moore School of Electrical Engineering of the University of Pennsylvania for suggestions in the design of the electrical circuits used.

window. The transmittances of the three solutions were then measured by comparison with the reference cell containing pure water. The cells were then filled with another set of solutions in the same way. At the end of the group of measurements the cells were again filled with water and the cell calibration checked. In filling the cells an air bubble was left just below the stopper to prevent the formation of small bubbles on the window. The light source and the thermostat were allowed two hours to come to equilibrium for each measurement. The fans and cooling system were turned off momentarily during the measurements to avoid vibration.

The dark current compensation was adjusted with the light beam interrupted just before each measurement and was checked after the measurement. The comparison of the cell transmittances was repeated several times in quick succession, balancing the potentiometer in the standard cell position for the reference absorption cell by varying R4, and then balancing the potentiometer slide wire for the photocurrent from the unknown solution. The repeated comparison was carried out in a systematic way so that the effects of photocell fatigue would be reproducible.

In using the Rubicon colorimeter, the light intensity was first adjusted with no absorption cell in place to an arbitrary value so that a reading of 0.99 would be obtained with a cell containing pure solvent. Two cells were selected which showed identical transmittances with water and with absorbing solutions and duplicate measurements of the solvent and of each solution were made in these cells. Dark current readings were made before and after each series of measurements by turning off the light source. A correction was made using the average of the two dark current readings.

A blank correction was made for the absorption of the buffer solution whenever applicable. This blank was determined either by adding a small amount of hydrochloric acid to the buffer solution immediately after measuring the transmittance or by measuring a buffer solution made up without any indicator. In the former case a small correction was made in the blank for the transmittance of the acid form of the indicator present in the acidified solution.

Preliminary measurements were made of the transmittances of solutions of the complete acid form and the complete basic form of each indicator used. It was found that a single wave length could be used which was suitable for all of the nitrophenols used.

Solutions on the basic and acid forms of each indicator were then measured as a function of concentration. In each case a quantity of sodium hydroxide or hydrochloric acid was added sufficient to ensure a negligible contribution to the absorption from the opposite form of the indicator. Blanks were subtracted for the apparent absorption of the added acid or base where required. In some cases a slight variation of the transmittance with the amount of added base or acid was observed and the value required was obtained by extrapolation to dilute solution, the concentration always being kept high enough to keep the indicator completely in the acid or basic form.

The extinction constant k defined by Beer's law

$$-\log T = kc \qquad (2)$$

was calculated from the measured transmittance T and the concentration c for each indicator in the basic and in the acid form. The extinction constant generally showed small variations with indicator concentration. The measured values of k were plotted against c or against $-\log T$.

The transmittances of buffer solutions of the acids with suitable indicators were then measured for two different buffer ratios differing by a factor of about two and for several different concentrations for each pair of compounds being compared. Each solution contained an amount of indicator sufficient to make the transmittance around 40% which is near to the transmittance at which maximum precision is obtained. The buffer solutions were prepared by adding measured volumes of stock solutions of the indicator and buffer acids and of standard 0.08 N carbonate-free sodium hydroxide.

The calculation of the concentration of the basic and acid forms of the indicator was made by a series of approximations. The absorption of the acid form was first neglected and the approximate concentration of the basic form calculated from the measured transmittance and the previously determined extinction constant for the basic form. The concentration of the acid form was then estimated from the known total concentration and the approximate concentration of the basic form. A correction was then made for the absorption by the acid form and a second approximation for the basic form calculated, etc. The amounts of the basic and acid forms of the buffer acid were calculated from the amount of acid and base added, the amount of indicator converted to the basic form and the amount of hydroxyl or hydrogen ion formed. The hydrogen ion concentration was calculated from the value of the dissociation constant of either the buffer or the indicator acid since one of these constants was known in each case. In calculating the hydrogen ion concentration the activity coefficient was estimated from the Debye-Hückel approximation.

Materials.—The 2,5-dinitrophenol and the 3,4-dinitrophenol were separated from the mixture obtained by the nitration of Eastman Kodak *m*-nitrophenol.[14] The 2,5-dinitrophenol was recrystallized several times from alcohol (m. p. 105.8–106.2°). The 3,4-dinitrophenol was purified by dissolving in aqueous sodium hydroxide solution and precipitating with dilute acid. After two purifications in this manner the product could be recrystallized from dry benzene without forming an oil and was then recrystallized from an alcohol–water mixture (m. p. 134.6–135.1°). No 2,3-dinitrophenol could be isolated from this nitration mixture.

m-Nitromesitol was prepared from mesitylene.[15] Dinitromesitylene prepared from Eastman Kodak Co. mesitylene[16] was reduced with ammonium acid sulfide in a bomb,[17] and the resulting nitromesidine was diazotized and nitromesitol obtained by boiling the diazonium sulfate solution with sulfuric acid solution.[17,18] The product was precipitated from sodium carbonate solution with acid, recrystallized from alcohol and finally purified by vacuum sublimation (m. p. 63.4–63.9°). Attempts to prepare *m*-nitromesitol by nitration of mesitol were unsuccessful.

The *o*-nitrophenol (m. p. 44.9–45.3°) and *m*-nitrophenol (m. p. 96.6–96.8°) were Eastman Kodak Co. products recrystallized several times from alcohol–water mixtures. The *o*-nitrophenol was first steam distilled. The *p*-nitrophenol was a Kahlbaum product recrystallized from water (m. p. 113.1–113.8°).

The phenol was a J. T. Baker product purified by fractional distillation (b. p. 182.0–182.5°; m. p. 39.8–39.9°). The *p*-chlorophenol was a Paragon Testing Laboratory product, purified by fractional distillation (b. p. 219–220°; m. p. 43.2–43.7°). The *m*-chlorophenol (b. p. 216.7°, m. p. 33.2–33.5°), *o*-chlorophenol (b. p. 176°) and *o*-bromophenol (b. p. 194–195°) were Eastman Kodak Co. products fractionally distilled. The 2,4-dichlorophenol was an Eastman Kodak Co. product purified by fractional sublimation (m. p. 42.0–42.8°).

The *p*-fluorophenol was prepared from Eastman Kodak Co. *p*-fluoroanisole by treatment with aluminum chloride following the procedure described for the preparation of *o*-fluorophenol.[19] The product was purified by fractional distillation (b. p. 185.0–185.5°).

The acetic and benzoic acids were Kahlbaum products used without further purification.

Fractional distillations were carried out in an eleven-ball, lagged, electrically-heated Snyder column at a 10:1 reflux ratio except for the distillations of *m*-chlorophenol

and *p*-fluorophenol which were carried out in a smaller six-ball column. Melting points and boiling points were measured with calibrated thermometers and stem corrections were made throughout. All products were dried over phosphorus pentoxide before use.

The melting points found for *m*-chlorophenol and *p*-chlorophenol are about 5° higher than those listed in Landolt–Börnstein but are in agreement with those recently reported by the Dow Co.[20]

Standard carbonate-free sodium hydroxide was used to make up the buffer solutions. The sodium hydroxide was standardized by comparison with Bureau of Standards benzoic acid and was kept in a bottle coated with Vulcalock cement.[21] All solutions were made up in water which had been redistilled from alkaline permanganate, fractionally condensed and freed of carbon dioxide by long bubbling with nitrogen gas.

The volumetric glassware and the balance weights used had been calibrated according to standard procedures.

Results

A preliminary measurement of each dissociation constant ratio was made with the Rubicon colorimeter in order that optimum values of the buffer ratio could be selected for the final measurements. Because of the length of time required for a set of measurements with the photomultiplier colorimeter, measurements were made with this instrument only for the first six comparisons in Table I which constituted the main series of comparisons relating phenol to acetic acid. The other comparisons, which involved a ratio with one of the compounds in the main series, were made with the Rubicon colorimeter because the accuracy required was not so high in these measurements. The error in the determination of the dissociation constant of an acid, which was ultimately compared to benzoic acid or to phenol, involved the error in each of several of the main series of comparisons but involved not more than one of the comparisons which were made with the Rubicon colorimeter.

The measured value of K_{AiB} was plotted against the ionic strength and the thermodynamic constant $K_{AiB}°$ was determined by extrapolation to zero concentration using the method of least squares. Where the plot showed no distinct trend the data were averaged without extrapolation. $K_{AiB}°$ was calculated separately for the two different buffer ratios used and the two values were averaged.

The accepted values of log $K_{AiB}°$ are shown in Table I with the calculated probable error. The dissociation constants of the various acids were calculated from these data using the value 1.751×10^{-5} for the dissociation constant of acetic acid, calculated on a molarity basis from the average of the electromotive force[22] and conductance[23] values. In Table II the logarithm of the dissociation constant $K_c°$ and the logarithm of the ratio of the dissociation constant to that of phenol, K_{AxB_0}, are shown for each acid measured. The constant K_{AxB_0} is the quantity to be used in the study of the effects of substituents. Values which have been reported in the literature for these compounds are shown in Table III for comparison purposes. These values have been corrected to

25° using temperature coefficients from the literature.[24]

Discussion

Extrapolation.—Reasonably good extrapolation lines were obtained by plotting log K_{A_iB} against the ionic strength u. Actually it was found that, over the small range of concentrations involved, the extrapolation could just as well be made by plotting K_{A_iB} instead of log K_{A_iB}. The extrapolation against the ionic strength is based on the equation[25] for the variation in the activity coefficient with ionic strength.

In two different experiments it was found, unexpectedly, that the data for the different buffer ratios formed distinctly separate lines extrapolating to the same value of $K_{A_iB}°$. That is, the extrapolation depended on c_A as well as on c_B which is nearly equal to μ.

Kortüm[26] has studied the variation in the extinction coefficient of nitrophenols with varying concentration of electrolyte and non-electrolyte. He found particularly marked changes in the extinction of 2,4-dinitrophenolate caused by the addition of phenol. With these experiments by Kortüm in mind an equation was developed for the extrapolation of the measured K_{A_iB} assuming that the major effect was a change in extinction constant which was linear with c_A. The equation obtained was

$$K_{A_iB}° = K_{A_iB} + \frac{K_{A_iB}c_A(c_{B_i} + c_{A_i})\delta}{kc_{A_i}} \qquad (3)$$

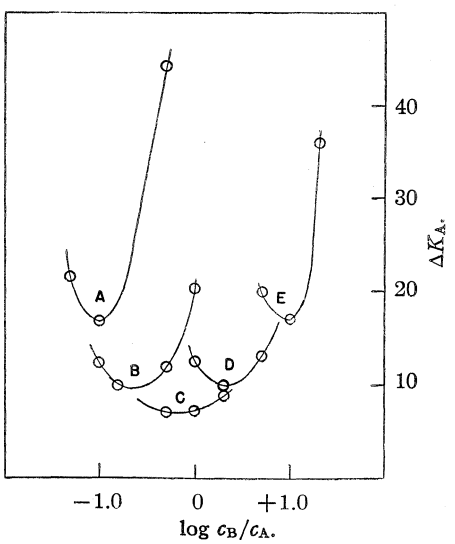

Fig. 2.—Relative error in K_{A_iB}: A, K_{A_iB} = 50; B, K_{A_iB} = 10; C, K_{A_iB} = 1; D, K_{A_iB} = 0.1; E, K_{A_iB} = 0.01: horizontal axis, log c_B/c_A; vertical axis, $(\Delta K_{A_iB}/K_{A_iB})/(\Delta c/c)$.

where δ is a proportionality constant for the change of k with c_A. It can be shown that the last term on the right is approximately proportional to c_B for relatively large values of c_{B_i}/c_{A_i} so that an extrapolation according to equation (3) will differ appreciably from an extrapolation against μ or c_B only for experiments using relatively low values of c_{B_i}/c_{A_i}. In all of the experiments involving low values of the indicator ratio it happened that K_{A_iB} was nearly independent of concentration so that the fit of the data to equation (3) was no better and no worse than an extrapolation against μ. Further consideration of the problem suggested that if the extinction coefficient varied markedly with c_A the activity coefficient might also vary with c_A as well as with μ. In any case if the activity or extinction coefficient depends on c_A the extrapolation against concentration will give separate lines for different values of the buffer ratio.

Precision.—The relative error in measuring indicator concentrations colorimetrically can be calculated by differentiating equation (2). With the Rubicon colorimeter, having a constant absolute error in the transmittance, the error in measuring concentration is lowest at about 37% transmittance. With the photomultiplier colorimeter the relative error in transmittance can be kept constant over a considerable concentration range and the error of the measurement continues to decrease slightly at transmittances below 37%. As it was not convenient to use high indicator concentrations, all measurements were made with concentrations selected to give a transmittance of about 40%.

The selection of the buffer ratio to be used was more complicated. Using rather arbitrary assumptions about the sources of error the curves shown in Fig. 2 were obtained for the relative error in the measured K_{A_iB} as a function of K_{A_iB} and c_B/c_A. In any case it can be shown that the error in measuring a given value of K_{A_iB} will have a minimum value at some intermediate buffer ratio and will increase at very high and very low values of c_B/c_A and that the optimum point will be at lower buffer ratios for high values of K_{A_iB}. The buffer ratios used were selected from the curves of Fig. 2 to give approximately the minimum errors.

Measurements were made at two different buffer ratios for each experiment in order to reduce the possibility of errors. Although it is not immediately obvious, a detailed examination shows that it is possible for a mixture of two indicators with different dissociation constants but with comparable extinction constants to give rise to an intermediate K_{A_iB} value which appears to be nearly constant over a range of buffer ratios. The evidence for the purity of the indicators must then rest on other grounds than the constancy of K_{A_iB} with changing buffer ratio.

If significant quantities of carbon dioxide were present in the solutions, an error would be caused

in the buffer ratio. If the amount of carbon dioxide can be assumed constant in solutions with decreasing buffer concentration, a distinct curvature would be introduced into the extrapolation line. The absence of such curvature in the data obtained was taken as evidence that the precautions taken to keep out carbon dioxide were sufficient.

Some measurements were made at temperatures other than 25° to estimate the temperature coefficients of the dissociation constants and of the extinction constants. It was concluded that 0.1° regulation was satisfactory for an accuracy of 0.2% in the measured K_{AiB}.

Comparison with Literature.—The dissociation constant of *m*-nitromesitol has not been measured previously. The values measured for the other nitrophenols are in reasonably good agreement with the values given in Table III except for the value given by Holleman and Wilhelmy for *m*-nitrophenol which is apparently in error. The visual colorimetric values of Kolthoff and of Michaelis seem also to be consistently lower than the values obtained in other ways. The values reported by Bader[27] for the mononitrophenols are not shown in Table III as they are entirely out of line with all later measurements.

The agreement for the chlorophenols is only fair. Abichandani and Jatkar[28] measured the complete set of chloro-, bromo- and iodophenols and reported that the dissociation constants of the bromo- and iodophenols were somewhat lower than those for the chlorophenols, particularly for the ortho compounds. The measurement of *o*-bromophenol in the present investigation was made to check this point, failing to show a difference comparable with the 0.28 log unit difference reported by Abichandani and Jatkar. Bennett, Brooks and Glasstone[29] also reported from measurements in ethanol–water mixtures that the fluorophenols were distinctly weaker than the chlorophenols, the largest difference being observed for the para isomer. The present measurement of *p*-fluorophenol verifies the marked difference between this compound and *p*-chlorophenol.

Summary

A photoelectric colorimeter has been constructed and used for precise measurements of the ratio K_{AiB} between the dissociation constant in aqueous solution at 25° for a nitrophenol indicator and the constant for another substituted phenol. A detailed study has been given to the sources of error in measurements by this method. The thermodynamic dissociation constant and the ratio K_{AxB_0} between the dissociation constant of the substituted phenol and the constant for phenol have been calculated from these data for twelve substituted phenols. The values obtained have been compared with the results of previous measurements.

The Effects of Substituents on the Dissociation Constants of Substituted Phenols. II. Calculations from the Electrostatic Theory[1]

BY CHARLES M. JUDSON[2,3] AND MARTIN KILPATRICK[4]

Measurement of the dissociation constants of some substituted phenols have been described in the preceding paper.[5] The equation developed by Sarmousakis[6] using electrostatic theory to calculate the ratio K_{AxB_0} between the dissociation constant for a substituted acid and the constant for the unsubstituted acid has been applied in this paper to the substituted phenols. The conventions used to determine the variable parameters in the equation were changed slightly from those used by Sarmousakis. The calculated values have been compared with the observed values from the previous paper and from the literature. The test of the agreement between the calculated and observed values was made more rigorous by making the comparison for both the phenols and the benzoic acids using a consistent method of calculation.

The equation developed by Sarmousakis is a modification of the equation used by Kirkwood and Westheimer[7] for the electrostatic interaction between a substituent dipole and a dissociating proton. It can be readily shown from a simple treatment that this equation should have the general form

$$-2.3 \log K_{AxB_0} = \frac{e\mu \cos \theta}{r^2 D_E k T} \qquad (1)$$

(6) Sarmousakis, *J. Chem. Phys.*, **12**, 277 (1944).

(7) Kirkwood and Westheimer, *ibid.*, **6**, 506 (1938); Westheimer and Kirkwood, *ibid.*, **6**, 513 (1938); Westheimer and Shookhoff, THIS JOURNAL, **61**, 555 (1939); Westheimer, *ibid.*, **61**, 1977 (1939).

where μ is the dipole moment of the substituent, r is the distance from the center of the dipole to the dissociating proton, θ is the angle between the vector representing the dipole and the vector corresponding to r, e is the charge on the electron, k is the Boltzmann constant, T is the absolute temperature and D_E is an effective dielectric constant. Kirkwood and Westheimer first showed how the term D_E could be estimated for certain cases. They calculated D_E for the para-substituted benzenoid acids by considering the molecule to be a prolate spheroidal cavity of low internal dielectric constant D_i embedded in a medium of higher dielectric constant D which is the dielectric constant of the solvent.

Sarmousakis set up as a model for the para-substituted acid an oblate rather than prolate spheroid with the proton and the center of the dipole located on the focal circle of the speroid, obtaining the equation

$$-\log K_{A_xB_0} = \frac{1}{2.3kT}\left[\frac{e\mu_\xi \cos(/\mu_\xi/i_1,r)}{r^2 D_\xi} + \frac{e\mu_\phi \cos(/\mu_\phi/i_2,r)}{r^2 D_\phi}\right] \quad (2)$$

The terms of this equation have been defined by Sarmousakis. It is sufficient to note that the equation is similar in form to equation (1) but is expressed in vector form with two quantities D_ξ and D_ϕ representing the effective dielectric constant. Sarmousakis showed how to calculate the quantities D_ξ and D_ϕ in terms of D and D_i and a parameter ξ_0 defining the shape of the molecule. The solution was expressed in terms of certain Legendre polynominals which were tabulated in Sarmousakis' paper. The quantity ξ_0 can be calculated in a simple manner from the molecular volume τ and the focal radius c which define the spheroidal cavity. It was possible using equation (2) to make calculations for the metasubstituted acids as well as the parasubstituted acids.

Sarmousakis recognized that there was a certain arbitrariness in the selection of numerical values for some of the parameters in equation (2). Instead of calculating the focal radius c from the distance between the dipole and the proton in the parasubstituted acid, he adjusted the focal radius c arbitrarily for each metasubstituted benzoic acid so as to give agreement between the calculated and observed values for the dissociation constant in aqueous solution. Using the same value for c in the parasubstituted acid, the difference between the calculated and observed values for the parasubstituted acid was then attributed to a resonance effect.

There are two possible positions which may be assumed for the proton in a substituted benzoic acid, a free rotation position permitting rotation about both the C–C bond and the C–O bond, and an extended position in which the C–O–H bond is frozen with the proton away from the dipole. The arbitrary values of c selected were found to lie between the values of c calculated for these two positions.

Calculations of $K_{A_xB_0}$.—The conventions used in carrying out the calculations for the present paper were, with a few exceptions, the same as those used by Sarmousakis. An attempt was made, however, to carry out the calculations without any arbitrary adjustment of parameters such as was used by Sarmousakis. The focal radius c calculated from structural considerations was used instead of the arbitrarily adjusted focal radius used by Sarmousakis. In calculating the focal radius the position of the proton was taken for the phenols as an average position with free rotation about the C–O bond and the position for the benzoic acids was taken to be the average extended position described above. The distance r was calculated trigonometrically instead of using the value $\sqrt{3}c$ for the value of r. The location of the center of the dipole was taken for all cases at the mid-point of the line from the benzene ring to the projection of the outermost atom on the axis of the ring, instead of locating the dipole for polyatomic substituents at the position of the iodo group dipole.

The dipole moments for the halogenobenzenes were taken from Hurdis and Smyth,[8] for nitro-

(8) Hurdis and Smyth, THIS JOURNAL, 64, 2212 (1942).

benzene from Smyth[9] and for toluene from Baker and Groves.[10] The bond distances and angles and the atomic radii were selected from the values given by Pauling,[11] Branch and Calvin[12] Maxwell.[13] The dielectric constant of water was taken as 78.5[14] and the value 2.00 used by Kirkwood and Westheimer and by Sarmousakis was again used for D_i. $K_{A_xB_0}$ values calculated in this way are shown in the third column of Table I.

Experimental Values of $K_{A_xB_0}$.—In order to compare the calculated and experimental values of log $K_{A_xB_0}$ it was necessary to select with as much consistency as possible a single set of values for the dissociation constants of the meta- and parasubstituted phenols and benzoic acids in aqueous solution. The values selected by Elliott and Kilpatrick[15] for comparison with their data in alcohol solution were used for the benzoic acids. The values reported in the previous paper were used for the nitrophenols, and the data given by Boyd[16] were used to calculate $K_{A_xB_0}$ for the cresols. The values for the chlorophenols were calculated from an average of the values in the previous paper and the values of Abichandani and Jatkar.[17] Except for *p*-fluorophenol, the values for the other halogenophenols, which differed only slightly from the values for the corresponding chlorophenols, were calculated from the average difference between the reported constants for the halogenophenols and the constants reported by the same investigator for the corresponding chlorophenol. The data of Hodgson and Smith[18] were used for the halogenophenols in addition to the sources cited for the chlorophenols. The measured value for *p*-fluorophenol, which was quite different from the value for *p*-chlorophenol, was taken directly from the previous paper. The accepted experimental values are listed in the second column of Table I.

Calculations with Adjusted Parameters.—The calculated values in the third column of Table I are consistently lower than the observed values. An arbitrary adjustment of parameters was therefore required. Instead of changing the focal radius *c*, the internal dielectric constant D_i was arbitrarily adjusted to provide the best possible agreement between the calculated and observed values for the metasubstituted halogenophenols and halogenobenzoic acids. The revised calculated values shown in the fourth column were obtained with D_i equal to 1.54. It was found that the same value of D_i selected to give agreement for the *m*-chloro, *m*-bromo and *m*-iodophenol also gave the best agreement for the corresponding *m*-halogenobenzoic acids.

The increase in the absolute value of $K_{A_xB_0}$ obtained by changing D_i from 2.00 to 1.54 clearly would not improve the agreement with the observed values for the metasubstituted nitro and methyl derivatives. Since the true location of the dipole in these polyatomic substituents was not known, it was possible to adjust this position so as to bring about better agreement between the observed and calculated values for the metasubstituted phenols and benzoic acids. In these cases it was not possible to bring about exact agreement for both the phenols and the benzoic acids so a compromise adjustment was made. The position selected for the dipole in the nitro group was at a distance of 1.26 Å. from the ring, compared to a distance of 1.46 Å. from the ring to the nitrogen atom and a distance of 1.99 Å. to the projection of the oxygen atom on the line of the C–N bond. For the methyl group the dipole was located 1.35 Å. from the ring, compared to a distance of 1.50 Å. to the methyl carbon atom and 1.83 Å. to the projection of the methyl hydrogen atom.

Resonance Contributions.—Sarmousakis calculated values of Δ log $K_{A_xB_0}$ for the parasubstituted benzoic acids from the difference between the observed and calculated values. This term Δ log $K_{A_xB_0}$ was considered to be a measure of the resonance contribution to the acid strength of the parasubstituted acid. In the present calculations the treatment is slightly more complicated because the calculated values have not been adjusted to bring exact agreement with the observed values for each individual acid. For this reason Δ log $K_{A_xB_0}$ was calculated by subtracting the difference between the observed and calculated values for the meta acid from the difference between the observed and calculated values for the para acid.

These methods of calculating resonance contributions are based on the assumption that there is no resonance in the metasubstituted acid. Actually it can be seen that in Table I there is a larger difference between the observed and calculated values for *m*-fluorophenol than for the other *m*-halogenophenols. This appears to be due to a resonance effect whose magnitude can be estimated by subtracting the average difference between the observed and calculated values for the remaining *m*-halogenophenols from the difference for *m*-fluorophenol. The resonance contributions estimated similarly for the other *m*-halogen acids were very small.

While the *m*-halogen acids can be considered from the point of view of the differences from one halogen to another, it is not so easy to tell from the measured $K_{A_xB_0}$ values whether there is any resonance in the acids with nitro and methyl substituents in the meta position. The differences

between the observed and calculated values for these metasubstituted acids may also be due in part to resonance effects.

The calculated values of the resonance contribution term are shown in Table II. While the general ideas involved in predicting the effects of resonance on the strength of acids have been presented in several places[19] and the effects for aromatic acids have been studied in particular detail,[19a] the resonance structures required to explain the effects in the acids considered here do not appear to have been formulated explicitly in any one place.

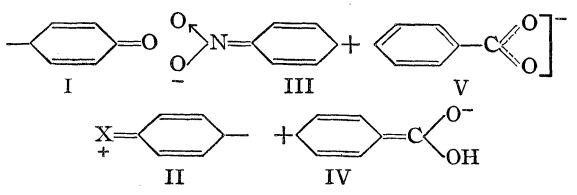
TABLE II

$\Delta \log K_{A_xB_0}$

	Phenols		Benzoic acids	
	m	*p*	*m*	*p*
F	−0.18	−0.40	−0.04	−0.18
Cl	.00	− .07	− .01	− .05
Br	− .02	− .08	.01	− .05
I	.02	− .01	− .01	....
CH_3	....	− .20		− .13
NO_2	....	1.81		.29

The resonance in phenol between the aromatic ring and the anion of the acidic group (I) is more important than the resonance involving the corresponding form of the free acid. This leads to an acid strengthening resonance effect in phenol. The resonance between the ring and an alkyl or halogen group in the para position (II) tends to weaken the resonance of the acidic group (I) and thereby weaken the acid. The resonance between the ring and the para nitro group (III) enhances the resonance (I) and is acid strengthening.

The resonance between the carbonyl group and the ring in benzoic acid (IV) tends to weaken the resonance between the carbonyl group and the anion of the acidic group (V) and is acid weakening. The resonance of the para nitro group (III) with the ring decreases the resonance (IV) and is acid strengthening while the resonance of the methyl or halogen group (II) increases (IV) and is acid weakening.



I III V

II IV

The resonance in the halogen-substituted acids is observed to increase in magnitude from the iodo to the fluoro group. The increase for the *p*-fluoro acid over the value for the *p*-chloro acid is particularly marked and shows that the magnitude of the resonance term cannot be predicted from the mesomeric moment[20] alone, since the mesomeric moments of the halogenobenzenes increase more or less uniformly from one halogen group to the next.

While resonance effects are not usually encountered in metasubstituted acids, the resonance effect in *m*-fluoro acids has been observed previously and explanations have been offered to account for it.[21]

Specific Ortho Effects.—The Legendre polynomials required for the calculation of D_ξ and D_ϕ for orthosubstituted acids have not been evaluated because the series converge too slowly. Some other method of treatment must be used to find out whether the experimental data can be interpreted to show the presence or absence of specific ortho effects.

Jenkins[22] has reported that for the halogeno- and nitrobenzoic acids the logarithm of the dissociation constant for three isomeric substituted benzoic acids and the unsubstituted acid is proportional to a function F which represents the field strength which would exist at the number one carbon atom of the ring due to the substituent dipole if the dielectric constant were unity. The function F is calculated from the equation

$$F = \mu\sqrt{1 + 3\cos^2\theta}/r^3 \qquad (3)$$

where r, μ and θ have the same meaning as in equation (1). According to this treatment log $K_{A_xB_0}$ should be a constant for the three isomeric acids if the effects are entirely inductive. The values of this ratio are shown in Table III for the substituted benzoic acids.

TABLE III

$\log K_{A_xB_0}/F$ FOR BENZOIC ACIDS

Subst.	Ortho	Meta	Para
F	2.2	3.2	0.8
Cl	3.3	3.7	3.1
Br	3.8	4.0	3.3
I	4.1	3.9	....
CH_3	6.0	−4	−15
NO_2	3.3	4.0	6.1

The dissociation constants were taken from the same sources as those used for Table I and the field strength was calculated using the same conventions and the same physical constants as were used to calculate log $K_{A_xB_0}$ from the Sarmousakis treatment. The function F was considered positive in all cases so that an increase in the algebraic value of the ratio in the table always corresponds to an acid strengthening.

The assumption involved in this treatment is that the acid group may be regarded more or less as a perfect conductor so that the ring carbon atom is the center determining the free energy of ionization. Since the resonance effect in the metasubstituted acids is relatively small, deviations of the ratios in Table III from the value for

(19) (a) Ref. 12, Chapter VI; (b) Wheland, "The Theory of Resonance," John Wiley and Sons, Inc., New York, N. Y., 1944.

(20) Groves and Sugden, *J. Chem. Soc.*, 1992 (1937).

(21) Dippy and Lewis, *ibid.*, 644 (1936).

(22) Jenkins, *ibid.*, 640 (1939).

the corresponding metasubstituted acid may be considered to indicate the presence of effects other than inductive.

The resonance effects of the parasubstituted acids indicated by the variations in Table III are in qualitative agreement with the resonance effects which were measured quantitatively by the Sarmousakis treatment. An acid strengthening resonance effect is shown for *p*-nitrobenzoic acid and an acid weakening resonance for *p*-toluic acid and the *p*-halogenobenzoic acids. The *o*-nitrobenzoic and *o*-toluic acids show deviations from the meta-substituted acids in the opposite direction from the deviations shown by the para-substituted acids. This may be considered evidence of a specific ortho effect, acid strengthening for *o*-toluic acid and acid weakening for *o*-nitrobenzoic acid. The *o*-halogenobenzoic acids have ratios between those of the meta- and the parasubstituted acids. In this case the presence or absence of specific ortho effects is not clearly demonstrated.

Jenkins had concluded that the absence of specific ortho effects was proven by the approximate agreement in these ratios for the three corresponding acids, except for the toluic acids in which case he admitted that a specific ortho effect was indicated. It must be admitted that if the values of log $K_{A_xB_0}$ are plotted against F, as was done by Jenkins, the discrepancies are not quite so obvious as when the ratios are calculated as in Table III. As an example the data for the nitrobenzoic acids are shown in Fig. 1. Since the theoretical basis of the treatment is not clearly established, there is certainly a question how large a deviation is required to be significant. Since the differences between the ratios in Table III for the meta- and parasubstituted acids can be interpreted satisfactorily in terms of resonance effects in the parasubstituted acid, the interpretation of the deviations for the orthosubstituted acids in terms of chelation or of resonance of a different type from that found in the parasubstituted acid seems justified.

Jenkins also plotted the logarithm of the dissociation constant against the electric potential at the number one carbon atom.[23] In a plot of the potential ψ against log $K_{A_xB_0}$ for a set of isomeric substituted benzoic acids, a line is obtained quite similar to that obtained in plotting against the field strength, but this line does not pass through the origin. In treating the phenols Jenkins plotted against the potential and found that the data for the ortho- and para-substituted halogenophenols in alcohol–water mixtures formed a line passing through the origin, that is, the point representing the unsubstituted acid. He then argued that the relative magnitude of resonance and inductive effects should be the same in the ortho- and para-substituted acids and that this linear relationship therefore indicated the

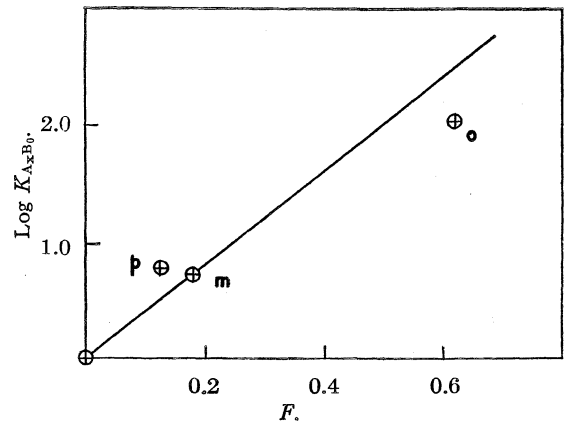


Fig. 1.—Dissociation constants of nitrobenzoic acids.

absence of specific ortho effects in the halogenophenols. There are three objections which can be taken to Jenkins' treatment of the halogenophenols. First, no reason was given to explain why the plot against potential should necessarily go through the origin when it had been shown that the plot for the halogenobenzoic acids did not go through the origin. Without the origin as a fixed point there is no obvious significance to a line through the points for two of the isomeric acids. Second, no proof has been given that the relative effects of resonance are the same in the ortho- and parasubstituted acids although this is probably acceptable as an approximation. Third, the value used in Jenkins' paper for *p*-fluorophenol in alcohol–water solution does not agree with the value in the paper of Bennett, Brooks and Glasstone[24] from which it was reported to have been taken. Using the value from the original paper the data for the fluorophenols does not fit the relationship proposed by Jenkins.

Abichandani and Jatkar[17] returned to the use of the field strength as a measure of the inductive effect in the phenols and used the method of Jenkins' first paper. They plotted the data for the halogenophenols in water and in alcohol–water mixtures against the field strength to show the existence of specific ortho effects in the halogenophenols. Using this same treatment, the ratio log $K_{A_xB_0}/F$ has been calculated for the halogen-, nitro- and methyl-substituted phenols in aqueous solutions using the same sources of data used in the application of the Sarmousakis treatment, with the

TABLE IV

log $K_{A_xB_0}/F$ OF PHENOLS

Subst.	Ortho	Meta	Para

(23) Jenkins, *J. Chem. Soc.*, 1137 (1939).

(24) Bennett, Brooks and Glasstone, *ibid.*, 1821 (1935).

addition of the dissociation constant for *o*-fluorophenol from Bennett, Brooks and Glasstone. The large acid weakening effects in *p*-cresol and *p*-fluorophenol, the less marked weakening in the other *p*-halogenophenols and the large acid strengthening in *p*-nitrophenol are clearly shown just as for the comparable treatment of the benzoic acids and as for the more quantitative treatment by the Sarmousakis method. There is further a marked acid weakening effect in *o*-chloro-, *o*-bromo- and *o*-iodophenol. This effect is distinctly different from the resonance effect in the *p*-halogenophenol which is small except for the fluorophenol. There is also an acid weakening effect in *o*-nitrophenol shown and, in the case of *o*-cresol, there is an acid strengthening which at least compensates for the acid weakening resonance which appears in *p*-cresol.

The theoretical weakness of the treatment based on the field strength at the number one carbon atom is recognized. The basis for suggesting the further use of this treatment for the study of deviations from the normal inductive effects is that the effects indicated by this treatment for the phenols and benzoic acids can all be accounted for in terms of resonance forms which are reasonable in the light of our present knowledge.[19] Except for the effects in *o*-halogenophenols and in *o*-nitrobenzoic acid, these deviations from the inductive effect have been previously accepted. The effect in *o*-nitrobenzoic acid is small and therefore not definitely established. The effect in the *o*-halogenophenols is clearly established if this method of treatment is valid.

Summary

The Sarmousakis modification of the Kirkwood–Westheimer method of calculating the ratio of the dissocation constant of a substituted acid to that of the unsubstituted acid has been used to calculate values for the meta- and parasubstituted phenols and benzoic acids. Using a consistent set of assumptions it has been possible to adjust the parameters so that agreement could be obtained between the calculated and the observed values for aqueous solutions for both the metasubstituted phenols and the metasubstituted benzoic acids. The differences between the calculated and observed values for the parasubstituted acids have been calculated as a measure of resonance effects.

Following a suggestion made by Jenkins, values of log $K_{A_xB_0}/F$ were calculated relating the ratio between the dissociation constants to the field strength at the ring carbon atom due to the dipole. Differences in this ratio for the corresponding ortho-, meta- and parasubstituted acids have been interpreted qualitatively in terms of resonance and chelation effects.

Preparation and Polymerization of Unsaturated Quaternary Ammonium Compounds[1,2]

BY GEORGE B. BUTLER AND ROBERT L. BUNCH

The absence of information in the literature concerning the polymerization of unsaturated quaternary ammonium compounds prompted us to study the preparation and polymerization of compounds of this type as a possible source of water insoluble polymers containing strongly basic groups. Products of this nature should be capable of absorbing negative ions from neutral salt solutions.

Since the presence of nitrogen in organic compounds quite often exhibits an inhibitory effect on peroxide catalyzed polymerization, there was some doubt that polymerization of these compounds could be accomplished. However, since quaternary ammonium halides are salts of strong bases and strong acids, it appeared likely that polymerization of these neutral salts would occur under the proper conditions. This was found to be the case as described in detail below.

In order for a cross-linked polymer to result from vinyl type polymerization of a pure unsaturated quaternary ammonium salt, the presence of at least two unsaturated groups in the molecule is essential. Therefore, all of the compounds studied have contained at least two unsaturated groups, while some have contained three or four. The compounds were prepared by reaction of unsaturated tertiary amines, several of which had not been prepared previously with the appropriate alkyl halides. The majority of the compounds were prepared as the bromides, and were found to have rather high melting points. Introduction, however, of relatively high molecular weight radicals such as benzyl usually lowered the melting point. Most of the salts were found to be rather hygroscopic and are very soluble in water, low molecular weight alcohols, and formamide, fairly soluble in hot ketones, but insoluble in most other organic solvents.

(1) The work described in this manuscript was done under the sponsorship of the Office of Naval Research, and was abstracted from a dissertation presented by Robert L. Bunch to the Graduate School of the University of Florida in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

(2) This material was presented in part before the Organic Division of the American Chemical Society, St. Louis, Missouri, Sept., 1948.

TABLE I

UNSATURATED TERTIARY AMINES

Compound	Formula	B. p. °C.	Mm.	d^{25}_{25}	$n^{25}D$	Nitrogen analyses, % Calcd.	Found	Yield, %

[a] Picrate, m. p. 118°; chloroplatinate, m. p., 183.5°; picrolonate, m. p. 213°. N-Allylmorpholine was prepared by (1) reaction of morpholine and allyl bromide and (2) reaction of allylamine and β,β'-dichloroethyl ether. [b] Picrate, m. p. 254° (d); chloroplatinate, m. p. 280°. [c] Prepared from organic halide and diallylamine. [d] Previously reported without physical constants Brauchli and Cloetta [*Chem. Zentr.*, 99, I, 2732 (1928)].

The high melting points of these compounds made it necessary to attempt polymerization either in solution, or by addition of some component to lower the melting points. Their solubility in water suggested the use of water soluble catalysts such as hydrogen peroxide, ammonium or potassium persulfate. However, attempts to obtain polymerization of aqueous solutions of these compounds using these catalysts were unsuccessful. Attempted polymerizations using benzoyl peroxide and di-*t*-butyl peroxide as catalysts were also unsuccessful.

Addition of suitable components for lowering the melting point to a desirable range proved to be quite valuable in some cases. Equal quantities of triallylbenzylammonium bromide, which melts at 132°, and several of the higher melting compounds when thoroughly mixed resulted in solids which fused to clear liquids in the range of 85–95°. Addition of a small quantity of *t*-butyl hydroperoxide to these fused masses resulted in copolymerization of the mixture.

Further polymerization studies revealed the fact that fusion temperatures of these compounds could be lowered tremendously by the addition of extremely small amounts of water or formamide. Examples illustrating these methods of polymerization are given under the experimental section.

The polymers and copolymers of these compounds have been found to undergo the ion exchange reactions as predicted. The complete cycle is illustrated in the following series of reactions

$$n\mathrm{R_4NBr} \xrightarrow[\text{hydroperoxide}]{t\text{-Butyl}} (\mathrm{R_4NBr})_n$$

(R groups may be equal or different. At least two groups are unsaturated.)

Cross-linked, water insoluble polymer. (Washed free of soluble bromides)

$$(\mathrm{R_4NBr})_n + n\mathrm{KOH} \longrightarrow (\mathrm{R_4NOH})_n + n\mathrm{KBr}$$

Continued until no halogen present in filtrate. Resin washed until neutral filtrate obtained.

$$(\mathrm{R_4NOH})_n + n\mathrm{KCl} \longrightarrow (\mathrm{R_4NCl})_n + n\mathrm{KOH}$$

Filtrate was very strongly basic.

Experimental

Materials.—Piperazine hexahydrate and piperidine (practical grade) were obtained from Eastman Kodak Company and used as received. The *n*-butylamine and morpholine were obtained from Carbide and Carbon Chemical Company and used without further treatment. The diallylamine, allyl chloride, β-methylallyl chloride, and di-*t*-butyl peroxide were obtained through the courtesy of Shell Chemical Company. The allyl chloride and β-methylallyl chloride were redistilled before use. The allyl bromide was obtained from Dow Chemical Company and used without further purification. The *t*-butyl hydroperoxide was obtained as a 60% solution through the courtesy of Union Bay State Company.

Preparation of Unsaturated Tertiary Amines.—The unsaturated tertiary amines required for this work were prepared by a modification of the procedure outlined in "Organic Syntheses"[3] for preparation of benzylaniline. The secondary amine was treated with a 0.05 mole excess of the appropriate halide in presence of a 0.25 mole excess of sodium bicarbonate in aqueous solution. The amines were purified by distillation after separation from the aqueous solution and drying.

Since the number of unsaturated tertiary amines recorded in the literature is surprisingly small, many of these are new compounds. The properties, analyses and yields of these new tertiary amines are summarized in Table I.

Preparation of Quaternary Ammonium Salts.—An equimolecular quantity of the appropriate alkyl or alkenyl halide was added dropwise, with stirring, to a hot solution of the unsaturated tertiary amine in acetophenone. Stirring was continued, and the solution was refluxed gently for approximately two hours. In most cases the products were insoluble in the solvent and crystallized on cooling. Purification was accomplished by recrystallization from ketones, alcohol–ether mixtures, or formamide–acetone mixtures. The products were stored under anhydrous conditions to prevent absorption of moisture. The properties, analyses, and yields of these compounds are summarized in Table II.

Polymerization Studies.—The following experiments will serve to illustrate the methods of polymerization and the ion-exchange properties of the polymers:

(1) One-half gram of triallylbenzylammonium bromide and 0.5 g. of tetraallylammonium bromide were mixed well and placed in a bath at 110°. Fusion of the mixture began at 85° and was complete at 95°, a clear solution being obtained. When the temperature of the liquid reached 108°, five drops of 60% *t*-butyl hydroperoxide was added with stirring, and the reaction vessel removed from the bath. Polymerization began immediately as was evidenced by a temperature rise to 140°. A rubbery mass having a reddish-brown color was formed. When the exothermic reaction was over, the vessel was returned to the bath and heating continued at 125° for two hours. The polymer was insoluble in water.

(2) Ten grams of tetraallylammonium bromide, 0.94 g. of formamide and 0.22 g. of 60% *t*-butyl hydroperoxide were mixed well and placed in an oven at 75°. Fusion was

[a] Previously reported as decomposing at 80°, Grosheintz [*Bull. soc. chim.*, [2] **31**, 391 (1879)]. [b] This is a flash m. p.; no true melting point on slow heating. [c] β-Methylallyl bromide was the reacting halide in this case. [d] The compound prepared was the chloride. Allyl chloride was the reacting halide. The reported analytical values are % chlorine.

complete at this temperature. After a short time, the liquid became a dark brown, glassy solid. After twenty hours in the oven at 75°, the polymer was removed and washed with hot water, 7.6 g. of a granular, water insoluble substance being obtained.

(3) Ten grams of triallylbutylammonium bromide, 0.39 g. of distilled water and 0.11 g. of 60% *t*-butyl hydroperoxide were mixed well and placed in an oven at 100°. After twelve hours, the temperature was raised to 125° and held for twelve hours. The polymer was obtained in a 52.5% yield as a light brown, granular, water insoluble product.

(4) The copolymer obtained from triallylbenzylammonium bromide and tetraallylammonium bromide was washed with hot distilled water until the filtrate no longer gave a test for halogen. It was then treated with a 1% solution of potassium hydroxide, stirred at room temperature for several minutes and filtered. The filtrate, after acidifying with halogen-free nitric acid, gave a precipitate of silver bromide upon addition of silver nitrate, showing that the polyquaternary ammonium bromide was being converted to the polyquaternary ammonium hydroxide and releasing bromide ions. This treatment was continued until the acidified filtrate was found to be halogen-free, indicating that replacement of the halogen ion with hydroxyl ion was complete. This was shown to be correct by decomposing a sample of the dried polymer by sodium fusion and testing for halogen in the filtrate, no precipitate of silver bromide being formed. The product was washed with distilled water until a neutral filtrate was obtained. Upon treatment of the polymer with a neutral solution of potassium chloride, a strongly basic filtrate was obtained, showing that chloride ions were removed from solution by the polymer, and hydroxide ions released.

Acknowledgment.—We are indebted to Mr. A. E. Potter, Mr. J. L. Wester and Mr. R. L. Goette of this Laboratory for many of the analyses reported here, as well as for additional valuable assistance.

Summary

Several new unsaturated tertiary amines and quaternary ammonium salts have been prepared and characterized.

These unsaturated quaternary ammonium halides have been polymerized to water insoluble polymers, and it has been shown that these polymers may be converted to the polyquaternary ammonium hydroxides by an ion exchange reaction with potassium hydroxide resulting in the formation of a series of strongly basic ion exchange resins.

Equilibrium Studies on N-Chloro Compounds. II. The Base Strength of N-Chloro Dialkylamines and of Monochloramine[1]

BY IRA WEIL AND J. CARRELL MORRIS

A knowledge of the possible basic or acidic nature of the chlorine substitution products of ammonia, monochloramine (NH_2Cl), and dichloramine ($NHCl_2$) is of great importance in analyzing the behavior of these compounds in water solution. Moreover, such information is of theoretical interest, since it would provide a knowledge of the change in acid or base strength produced by the substitution of a chlorine atom for a hydrogen on an ammonia-type molecule. This paper presents the results of an attempt to evaluate the base strength of the monosubstituted compound, NH_2Cl, and of its alkyl homologs.

In the water system, substitution of a chlorine for a hydrogen has a strong acidifying effect which is roughly comparable to that produced by substitution of an acetyl group. Thus, the acid ionization constant of HOCl is 3×10^{-8} and that of CH_3COOH is 2×10^{-5}, as compared with 2×10^{-16} for water itself. The effect of the acetyl group in this case is accentuated by the large amount of resonance in the acetate ion. In the ammonia system the acetyl group has a base-weakening effect of the same order of magnitude, for the base strength of CH_3CONH_2 is only (3×10^{-15})[2] whereas that of ammonia is 2×10^{-5}. By analogy one might predict roughly that NH_2Cl and its alkyl homologs should also be very weak bases with ionization constants in the neighborhood of 10^{-15}.

Unfortunately a direct measurement of an ionization constant of this magnitude for monochloramine appears impossible, since the basic properties would be manifested to a measurable extent only in very acid solutions, and monochloramine disproportionates very rapidly under such conditions. However, by working with the N-chlorodialkylamines it has been possible to eliminate this side reaction and to obtain a direct measurement of the base strengths of N-chlorodimethylamine and N-chlorodiethylamine. From these, reasonable estimates of the base strength of monochloramine can be made.

The method employed for the direct determinations was to measure the ultraviolet absorption spectra of the N-chlorodialkylamines in solutions of varying acid concentration. It was observed that as the acid concentration of solutions of these substances is increased above 0.01 *M* the characteristic absorption bands for the N-chlorodialkylamines are increasingly diminished in intensity. These changes in the absorption spectra are not accompanied by any changes in the oxidizing-chlorine titers, and the absorption bands can be made to appear and disappear rapidly by alternate addition of alkali and acid. Consequently, the observed spectral changes were attributed to ionization processes, and the quantitative measurements are based upon this interpretation.

Experimental

Materials.—The distilled water and the acid and base solutions used in the determinations were all made "chlorine-demand-free"[3] to insure that no reducing materials remained.

Stock chlorine solutions were obtained by bubbling gaseous chlorine into distilled water and diluting the solution until the desired strength was obtained, approximately 1.3×10^{-3} molar. The solutions were checked daily by addition of potassium iodide followed by titration with sodium thiosulfate.

Dimethylammonium chloride and diethylammonium chloride (Eastman Kodak Company) were dried and weighed to prepare stock solutions which contained 7×10^{-3} mole per liter. The concentrations of these solutions were checked by Kjeldahl nitrogen determinations, which gave values within 0.5% of those obtained from the weights of the salts.

Perchloric acid and sodium hydroxide solutions were standardized with reagent-grade potassium acid phthalate.

Procedure.—Equivalent quantities of the chlorine and amine solutions at 25° were mixed at a *p*H of 10.7 to form the N-chlorodialkylamine. At this *p*H, the time for 99% reaction is less than one minute.[4] Fifty ml. of the resulting solution, which was approximately 4×10^{-4} molar, was diluted with perchloric acid and sodium hydroxide to obtain the desired acid concentration and ionic strength and was then made up to 100 ml. in a volumetric flask. One portion of this solution was placed in the quartz cell of the spectrophotometer and a second portion was titrated to obtain the exact concentration of N-chlorodialkylamine.

The absorption data were obtained with a Beckman ultraviolet spectrophotometer, Model DU. In all the determinations 10-cm. quartz cells which had been calibrated against one another were used. In place of the conventional cell holder there was substituted a cell block which permitted the cells to be kept at a constant temperature of 25.0 ± 0.3° by the circulation of water from a constant temperature bath.

The absorption for each sample was measured from 220 to 300 mμ, against a blank which contained the same quantities of acid and base as the chloramine sample. Transmission values near the absorption maximum were measured three or four times on each sample and were found to check within an average deviation of ±0.002 in terms of optical density. Readings were taken at 5 mμ intervals with band widths varying from 0.3 to 1.4 mμ.

The absorption spectra of the N-chlorodialkylamine bases were determined on solutions prepared at *p*H 10.7. Three concentrations, 1×10^{-4}, 2×10^{-4} and 3×10^{-4} *M* were employed. Values of the molar extinction coefficients for the three concentrations, calculated from the transmission data, agreed within 2 to 3 units at practically

all wave lengths. Absorption spectra of the acidified solutions were determined at a total chloramine concentration of 2×10^{-4} M.

The reliability of the dissociation constant values calculated from the spectra depends largely on the accuracy of differences in the extinction coefficient values, as shown by equation (5). On the basis of the estimated errors in the individual extinction coefficient values, the largest error in any one value of K_c is 14%, the minimum error, about 3%. The final average values of K_a are believed to be accurate to ± 5%.

Results and Discussion

Absorption Spectra.—Values of ϵ, the molar extinction coefficient, for N-chlorodimethylamine and N-chlorodiethylamine in the region 220 to 300 mμ are shown as the upper curves in Figs. 1 and 2, respectively. These were computed from the transmission data on solutions at *p*H 10.7 by means of the usual formula, $\epsilon = (1/lM) \log I_0/I$, l being in cm. and M in moles per liter. N-Chlorodimethylamine has an absorption maximum at 263 ± 2 mμ and N-chlorodiethylamine shows one at 262 ± 2 mμ. Determinations of the ionization constants were based on measurements at 265 mμ for N-chlorodimethylamine and at 260 mμ for N-chlorodiethylamine. At these wave lengths the molar extinction coefficients, which are very close to the maximum values, are 366 ± 3 and 312 ± 3, respectively.[5]

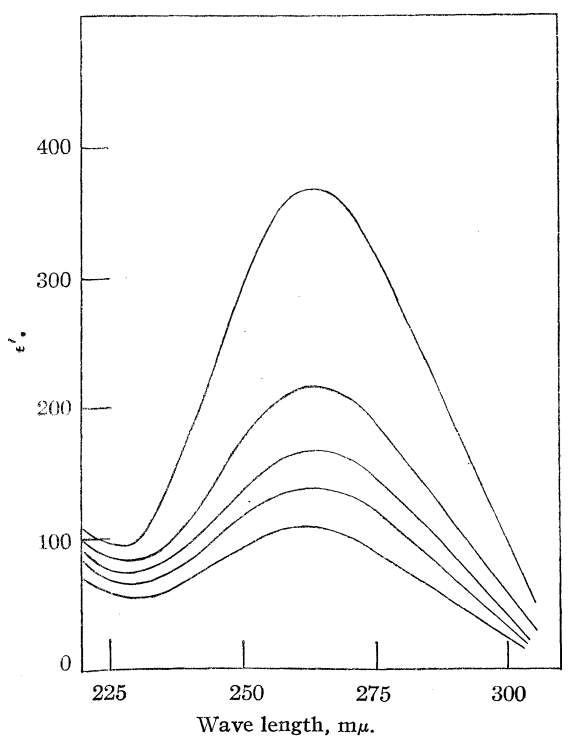

Fig. 1.—Absorption spectra of N-chlorodimethylamine at different acid concentrations. The uppermost curve is at a *p*H of 10.7. For the others in descending order, $[H^+]$ = 0.125, 0.224, 0.322, and 0.519, respectively.

(5) Metcalf, *J. Chem. Soc.*, 148 (1942), gives λ_{max} = 263 mμ and ϵ_{max} = 300 for both substances.

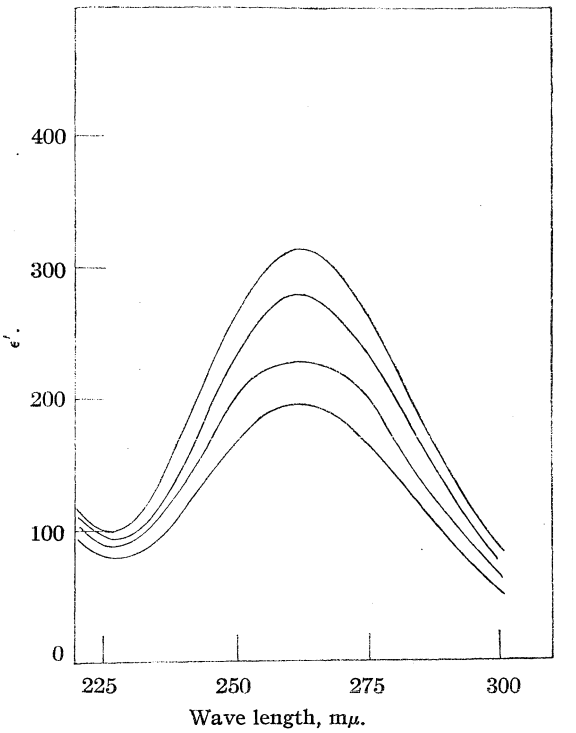

Fig. 2.—The absorption spectra of N-chlorodiethylamine at different acid concentrations. The uppermost curve is at a *p*H of 10.7. For the others in descending order, $[H^+]$ = 0.0100, 0.0298, and 0.0495, respectively.

The other curves in Figs. 1 and 2 depict typical absorption spectra for acidified solutions of these chloramines. The curves have been computed from the transmission data in terms of "apparent molar extinction coefficients," ϵ', defined as $\epsilon' = (1/lM_0) \log I_0/I$, M_0 being the total chloramine concentration, whether present as base or ion. The decreasing absorption with increasing acidity is evident.

Concentration Dissociation Constants.—For a solution containing both free base and ion the Beer–Lambert law becomes

$$(1/l) \log I_0/I = \epsilon_B [B] + \epsilon_{BH^+} [BH^+] = \epsilon' M_0 \quad (1)$$

Combination of this expression with the relation $M_0 = [B] + [BH^+]$ gives for the ratio of the molarity of chloramine to that of chlorammonium ion

$$[B]/[BH^+] = (\epsilon' - \epsilon_{BH^+})/(\epsilon_B - \epsilon') \quad (2)$$

At constant ionic strength the dissociation constant or acidity for the reaction

$$BH^+ \rightleftarrows B + H^+ \quad (3)$$

may be expressed in terms of concentrations as

$$K_c = [H^+][B]/[BH^+] \quad (4)$$

Combination of this with equation (2) then gives

$$K_c = [H^+] (\epsilon' - \epsilon_{BH^+})/(\epsilon_B - \epsilon') \quad (5)$$

Values of ϵ_B and ϵ' for substitution in this equation were taken from the data at 265 mμ for N-

chlorodimethylamine and at 260 mμ for N-chlorodiethylamine. However, direct evaluation of the ϵ_{BH^+} terms was not practical and so an indirect technique was used. Rearrangement of equation (5) gives the expression

$$\epsilon_{BH^+} = \epsilon' - K_c(\epsilon_B - \epsilon')/[H^+] \qquad (6)$$

Consequently, evaluation of ϵ_{BH^+} may be accomplished by plotting values of ϵ' for a constant ionic strength against the function $(\epsilon_B - \epsilon')/[H^+]$ and determining the intercept of the straight line drawn through the points.

Determination of ϵ_{BH^+} in this way for both N-chlorodialkylammonium ions is shown in Fig. 3. The intercepts give $\epsilon_{BH^+} = 30 \pm 5$ for N-chlorodimethylammonium ion at 265 mμ and $\epsilon_{BH^+} = 15 \pm 5$ for N-chlorodiethylammonium ion at 260 mμ.

Tables I and II show values of K_c for N-chlorodimethylamine and N-chlorodiethylamine obtained by means of equation (5) with the preceding values for ϵ_{BH^+}. At fixed ionic strength the figures are constant within the experimental error, but vary with the ionic strength of the solutions.

Activity Dissociation Constants.—Evaluation of the true acidity constant defined as

$$K_a = ([H^+]f_{H^+}[B]f_B)/([BH^+]f_{BH^+}) = K_c f_B f_{H^+}/f_{BH^+} \qquad (7)$$

requires a knowledge of or method of estimation for the activity coefficient ratio, $f_B f_{H^+}/f_{BH^+}$. The high ionic concentrations make it impossible to use the Debye–Hückel limiting law. Previous investigators[6] have made the assumption that f_B/f_{BH^+} is independent of the base employed, and have made corrections on that basis, although it is readily apparent from a consideration of the extended forms of the Debye–Hückel equation that this is only an approximation. However, the assumption should have increased validity if it is applied to bases of essentially the same nature and size. Hence in the present case it was assumed that the activity coefficient ratios for the N-chlorodialkylamines are the same as those for trimethylamine, which have been determined by Harned and Robinson,[7] and their values were used in the calculation of ionic strength corrections for the chloramines.

The data reported by Harned and Robinson are in the form $(f_B/f_{BH^+}f_{OH^-})^{1/2}$. These values were squared and then multiplied by the activity coefficient product of water[8] to yield $f_B f_{H^+}/f_{BH^+}$. The values so obtained were then plotted against the ionic strength and correction factors for the

desired ionic strengths were read from the smooth curve drawn through the points.

Table III shows the application of these corrections to the K_c data to obtain values for K_a. The consistency of the figures indicates that the procedure employed is a suitable one. A weighted average, which takes into account the number of determinations and the estimated error at each ionic strength, gives for N-chlorodimethylammonium ion, $K_a(25°) = 0.345$, and for N-chlorodiethylammonium ion, $K_a(25°) = 0.095$ mole/liter.

TABLE III

Basic Ionization Constants.—The basic ionization constants, K_b, corresponding to the process

$$B + H_2O \rightleftharpoons BH^+ + OH^- \qquad (8)$$

are related to K_a by the equation $K_b = K_w/K_a$, in which K_w is the activity product for water. Application of this expression gives for N-chlorodimethylamine, $K_b(25°) = 2.9 \times 10^{-14}$ and for N-chlorodiethylamine, $K_b(25°) = 1.06 \times 10^{-13}$.

By comparison of the basic ionization constants of the dialkylamines with those of the N-chlorodialkylamines, an estimate of the decrease in basicity resulting from substitution of a chlorine on a nitrogen atom can be obtained. The change in ionization constant produced by chlorine substitution for dimethylamine is from 6.0×10^{-4}[9] to 2.9×10^{-14} or a factor of 5×10^{-11}; for diethylamine it is from 1.3×10^{-3}[10] to 1.06×10^{-13} or a factor of 8×10^{-11}. It may reasonably be assumed that the basic ionization constant of NH_2Cl is smaller than that of ammonia by a similar factor. Since K_b for ammonia is 1.8×10^{-5}, the basic ionization constant for monochloramine should be approximately 1×10^{-15}.

Acknowledgment.—The authors wish to express their appreciation for the help of Miss Frances R. Tibbetts and Miss Alice E. Ozanian in obtaining the data for this paper.

Summary

Basic ionization constants for N-chlorodimethylamine, $(CH_3)_2NCl$, and N-chlorodiethylamine, $(C_2H_5)_2NCl$, have been determined from measurements of the ultraviolet absorption spectra of acidified solutions of these compounds. The values obtained for the activity ionization constants at 25° are $K_b = 2.9 \times 10^{-14}$ for N-chlorodimethylamine and $K_b = 1.06 \times 10^{-13}$ for N-chlorodiethylamine.

On the assumption that substitution of a chlorine for a hydrogen on the nitrogen atom has the same effect on base strength for ammonia as for the N-chlorodialkylamines, it has been estimated that $K_b = 1 \times 10^{-15}$ for monochloramine, NH_2Cl.

The ultraviolet absorption spectrum of N-chlorodimethylamine has a maximum at 263 mμ with a molar extinction coefficient, $\epsilon = 370$; that for N-chlorodiethylamine has a maximum at 262 mμ with $\epsilon = 315$.

A New Apparatus for Measuring Diffusion in Solutions*

BY ROBERT B. DEAN

When a solute diffuses into a solvent the concentration will vary with time and distance in a unique manner depending on the boundary conditions and the diffusion coefficient. If either the concentration, c, or the gradient of concentration, dc/dh, is known as an empirical function of the time, t, and distance, h, the diffusion coefficient D, can be calculated.[1,2] When c is known as a function of h and t for free diffusion, D can be calculated directly from Boltzmann's equation[1,3]

$$D = -\frac{1}{2}\, dy/dc \int_0^c y\, dc \qquad (1)$$

where $y = h/\sqrt{t}$ (see also ref.[4]).

Any method for measuring c as a function of t and h should preferably do so without disturbing the diffusing system. This logically suggests optical methods. When the solute absorbs light its diffusion can be followed by obvious colorimetric methods.[5-7] Colorless solutes can be followed by observing the refractive index of the diffusion column. Nakamura[8] was apparently the first to measure the concentration by the critical angle of reflection at one face of the diffusion cell. He used a cell which was 1 cm. thick and formed the initial boundary by flowing the solution under the pure solvent. His initial boundary cannot have been sharp and convection currents would be hard to eliminate in such a thick cell. Furth and his co-workers[6,9,10,11] pioneered in the use of thin chambers which minimize convection but they formed the initial boundary by withdrawing a sliding partition. Any sliding surface inevitably produces mixing and the results from Furth's school show fluctuations of more than 10% in the estimation of D. Zuber's optical arrangement[9] was furthermore limited by the precision of his goniometer. Instead of recording the entire refractive index–height curve he measured the angle of extinction at a number of selected heights. The short optical path of his apparatus also limits the possible precision of his method.

The apparatus described in this paper was designed to produce a direct record of the variation of concentration with height and at the same time eliminate convection and sliding boundaries.

The apparatus (see Fig. 1) consists of a thin chamber (approximately 4 cm. square) formed between one face of a 60° prism and a special fused glass cell.[12] The glass plate which forms the distal wall of the diffusion chamber terminates in a horizontal "knife-edge" at the top. This plate is backed up by a glass cell having a capacity one hundred times that of the diffusion chamber. The glass cell is attached to the prism face with stopcock grease and pressed on to a tight fit. The central portion of the chamber is parallel to the prism to within one wave length of sodium light in a vertical direction. It is inclined to the prism face about six wave lengths (3×10^{-4} cm.) per cm. in the central region. The cell is 0.03 cm. thick and parallel walled to 0.1% in the direction of diffusion. A mask on the exit face of the prism limits the effective object to the central portion of the diffusion cell. At the edges of the cell the departures from parallel walls are two to three times greater than in the center.

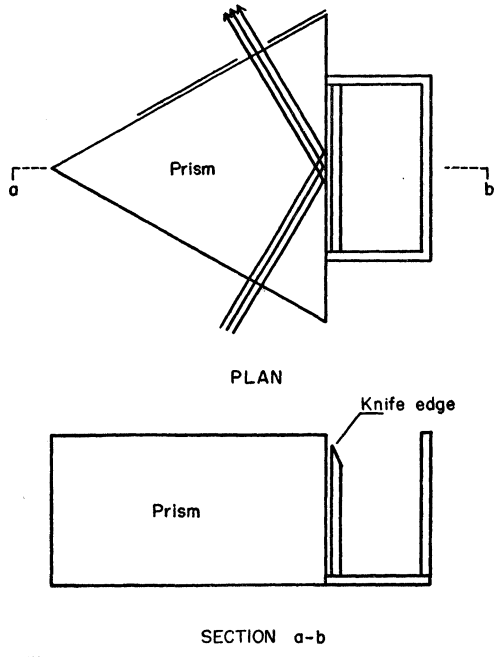

Fig. 1.—Diagram of diffusion cell and prism.

To start a diffusion run the chamber is filled with the 0.4 ml. of the more concentrated solution. The cell is then filled with 40 ml. of the more dilute solution, frequently water, at 25° and the time at which the top of the "knife-edge" floods is taken as zero time. As the solute in the chamber diffuses up to the "knife-edge" it falls over and sinks to the bottom of the large chamber. Approximately 20% of the contents of the chamber will have diffused into the outer cell when the concentration at the bottom falls to 99% of its original value. When this happens the boundary conditions no longer correspond to free diffusion in a semi-infinite prism and the run is ordinarily stopped. This quantity of solute will produce a

maximum change of 0.02% in the concentration of the outer chamber if mixing is perfect. It is likely that mixing will not be perfect in the outer chamber and the concentration change will be correspondingly less. Convection cannot occur in the actual diffusion chamber because the walls are close together (0.3 mm.). Furthermore the density of the solution in the lower part of the cell is about 4% greater than at the top for 1 *N* potassium chloride. A temperature difference of 1° produces a density difference of only 0.02% so the possibility of thermal convection in the diffusion column can be ruled out for aqueous salt systems.

The lens system (see Fig. 2) consists of a plano cylindrical plus 2 diopter eyeglass lens (f = 50 cm.) and a plano spherical plus 2 diopter lens. The plane sides of the lenses face out and they are approximately 1 cm. apart. The focal line of the cylindrical lens is in the center of diffusion chamber and its axis is horizontal. The focal point of the spherical lens is on the photographic plate. There is a 0.6 cm. vertical slit mask on the exposed prism face and a 0.6 cm. horizontal slit mask between the lenses. The prism is illuminated through its third unpolished face by light from a mercury sun-lamp filtered through glass filters to isolate the green line at 5461 Å.

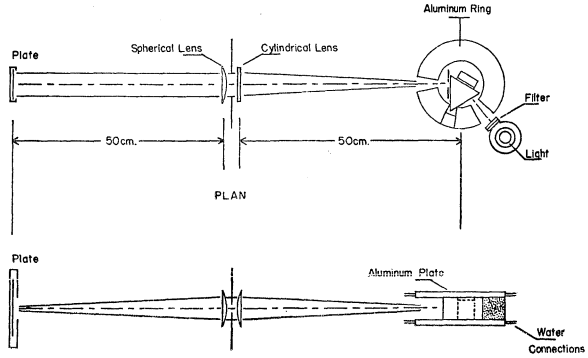

Fig. 2.—Plan and elevation (sectional) of optical bench.

Light entering the prism through the fine-ground face is scattered to produce even illumination over the entire diffusion chamber. Light striking the chamber at less than the critical angle is partially reflected and partially transmitted into the chamber where it is lost. Light striking at the critical angle or greater is totally reflected. In the horizontal plane the cylindrical lens is inoperative and the spherical lens focusses the parallel ray reflected at the critical angle, or any other angle, to a point on the plate corresponding to the angle of reflection. In the vertical plane light arising from any level in the diffusion cell is rendered parallel by the cylindrical lens and focussed to a corresponding level by the spherical lens.

The image thus consists of two fields differing in illumination. The location of the boundary between these fields depends upon the angle of total reflection in the prism which in turn depends upon the ratio of the refractive indices of the glass prism and the solution in the diffusion chamber. The critical angle for pure water against crown glass, n = 1.51, is 61° 59′. Light reflected at the critical angle reaches the exit face of the prism virtually perpendicular and undergoes only slight deviation at that face. For organic liquids a flint prism would be preferable. The variation in the critical angle is practically linear with the refractive index of the solutions in contact with the glass for the range of concentrations available. A 10% solution of most solutes produces a deviation of about 2 cm. on the photographic plate.

The aperture width of 0.6 cm. was chosen as the best compromise between diffraction and lack of focus. Since the object plane is necessarily inclined at 60° to the optical axis it is impossible to focus light from the cell exactly on a plane. The requirements of horizontal focussing are incompatible with those of vertical focussing and a sharp focus can only be obtained by narrow apertures which, however, introduce diffraction errors. For the dimensions chosen the optimum aperture is about 0.6 cm. which limits the theoretical resolution to 13″ of arc or approximately 0.003% salt solution. The observed resolution is not yet as good as this; it is possible to locate a boundary to within 0.02 mm. corresponding to 0.01% salt solution. Various Eastman Kodak Co. photographic plates have been used successfully including IVG and VG spectroscopic plates and Wratten Metallographic plates all used with Eastman D-19 developer to produce maximum contrast. Figure 3 shows a contact print of one of the plates.

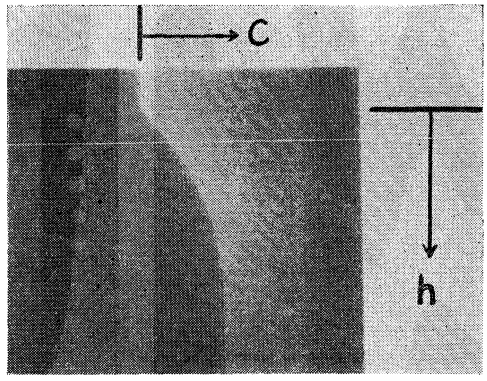

Fig. 3.—Print of a negative showing the variation of concentration with height in the diffusion cell.

The apparatus is mounted at one end of an optical bench which rests on a concrete pier. The prism and cell sit on a copper carrying plate which in turn sits on a hollow aluminum plate 8 in. in diameter. The prism and cell are surrounded by sections of a square cross section aluminum ring which is cut away to permit light to enter and leave the prism. Another hollow aluminum plate sits on top of the ring. Water is circulated by a centrifugal pump, from a tank containing heating and cooling coils, through the top plate of the prism, then through a glass tube containing a mercury thermoregulator and back through the lower plate to the tank. The heater is regulated by a thyratron controlled by the thermoregulator and operated from a 6-v. transformer. This thermostat maintains the temperature of the solution in the cell to within 0.02° or better. Care is taken not to let the mercury light shine on the cell except when a picture is being taken. Except for the mercury lamp the entire apparatus is housed in a plywood box with removable walls.

The image developed on the photographic plate should be measured with a coördinate comparator. Not all the parts for such a comparator have been received yet and the pictures obtained so far have been measured with a travelling microscope and eye-piece micrometer using a low magnification objective. This method is subject to errors caused by distortion of the image field and is furthermore very inconvenient. The results obtained are therefore of a preliminary nature and no attempt has been made to calculate D by Boltzman's equation, 1.

An estimate of D on the assumption that D is independent of c can be made conveniently by using probability paper. Since the concentration at the "knife-edge" is maintained essentially constant the boundary conditions in the initial stages correspond to diffusion into a semi-infinite prism. This is identical with one half of the case of diffusion from an initially sharp boundary into an infinite prism. The relation between c, h and t is given by the following equation for these

conditions (1)

$$\frac{c}{c_0} = \frac{1}{\sqrt{4\pi D_0 t}} \int_{\infty}^{h} e^{-\frac{h^2}{4D_0 t}} \, dh \qquad (2)$$

This is identical in form with the equation for the probability integral

$$Z = \frac{1}{\sqrt{2\pi\sigma^2}} \int_{\infty}^{h} e^{-\frac{h^2}{2\sigma^2}} \, dh \qquad (3)$$

where z varies from zero to 1. From equations 2 and 3 it is evident that

$$\sigma^2 = 2D_0 t \text{ or } D_0 = \frac{\sigma^2}{2t} \qquad (4)$$

Values of z as a function of h are readily available in tables and it is also possible to purchase probability graph paper[13] ruled from 0 to 100% in such a way that a plot of z *vs.* h is a straight line. The value of σ is equal to the difference in the h intercepts at 50% and either 15.87 or 84.13%. D_0 can of course be estimated from the 15.87 or the 84.13% intercept alone but it has been found safer to plot the values of c *vs.* h on probability paper and draw the best straight line through the points to obtain the h intercepts. To do this the c values are converted to C' values from 50 to 100 by the relation

$$C' = (50c/c_0) + 50 \qquad (5)$$

or the equivalent reaction for values from 0 to 50

$$C' = 50 - (50c/c) \qquad (6)$$

Figure 4 shows data from two photographs of one run with 1 N potassium chloride. The D values obtained, 1.8 and 1.9 $\times 10^{-5}$, show satisfactory agreement with the integral value of 1.85 $\times 10^{-5}$, calculated from the data given by Vinograd and McBain[14] corrected according to Gordon.[15] This

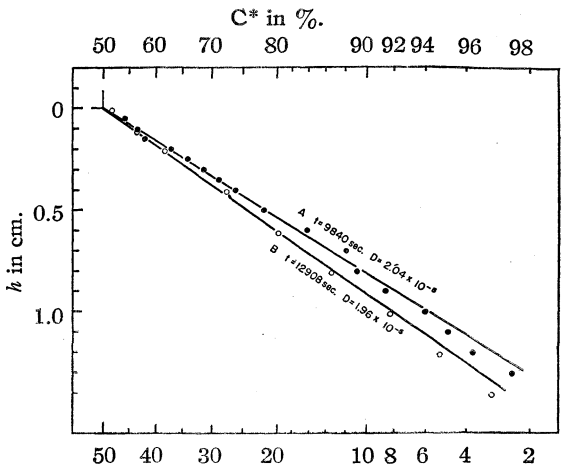

Fig. 4.—Diffusion of 1 N KCl at 25° plotted on probability paper.

agreement is partially fortuitous since D for potassium chloride varies by 10% over the range from 0 to 1 N. The probability integral method is essentially equivalent to the height and area method for analysing curves of dc/dh obtained by the scale method.[16]

Summary

1. An apparatus is described in which diffusion takes place in a narrow chamber along one face of a prism into an effectively infinite volume of solvent.

2. The initial boundary is formed by flooding the top of the thin chamber.

3. The concentration of diffusing material is determined from the angle of total reflection which is recorded photographically.

4. The apparatus is suitable for solutions containing of the order of 1% solute.

Studies of Protein Foams Obtained by Bubbling[1]

BY WILLIAM C. THUMAN,[2] A. G. BROWN[2] AND J. W. MCBAIN

Introduction

The foaming of protein solutions is of theoretical interest, and also has wide applications in the baking industry and in fire fighting practice. It is known to be greatly dependent upon pH and the presence of salts, though but little systematic work has been published in this field.

(1) (a) This investigation was conducted under Contract N-7onr 321 between The Stanford Research Institute and the Office of Naval Research, supervised by Professor J. W. McBain; (b) presented at the 115th meeting of the American Chemical Society, San Francisco March, 1948.

(2) Present address: Stanford Research Institute, Stanford, California.

Recently it was shown by Perri and Hazel[3] that a soybean protein solution exhibited a maximum foaming capacity in the neighborhood of the isoelectric point. Barmore[4] in studying the properties of egg white foams as a problem of the baking industry reported that organic acids and acid salts considerably increase foam stability. Peter and Bell[5] found the stability of foams from the protein of whey to be increased by addition of

alkali, sodium sulfite, or a mixture of calcium chloride with calcium hydroxide. In the results of Clark[6] with hydrolyzates of blood protein the maximum foam volume was obtained from a solution near the isoelectric point.

Most of the work on the foaming capacity of protein solutions has been carried out with protein materials of uncertain composition or consisting of obvious mixtures. Thus, it seemed desirable to extend the work of Perri and Hazel employing other pure proteins. For the present study purified egg albumin and salmine sulfate were selected. With the egg albumin, previous work could be greatly extended. Salmine sulfate was chosen because its isoelectric point is at a *p*H of 12, in sharp contrast to both α-soybean protein and egg albumin with isoelectric points respectively 4.1 and 4.6 to 4.8.

Preliminary experiments were carried out by Irving M. Abrams,[7] who found that single bubbles on salmine sulfate solutions show a sharp maximum in lifetime at about *p*H 10. We have found that the foaming capacity of 0.5% salmine solutions is a maximum around this same *p*H and that solutions of egg albumin also show a maximum in foaming capacity slightly on the acid side of the isoelectric point.

The effects of *p*H and of added electrolytes have been examined in some detail for the purified egg albumin.

Materials.—The two proteins used in these experiments were a protamine sulfate (salmine sulfate) supplied by Eli Lilly and Company and a sample of hen egg albumin from the laboratories of the Harvard Medical School. As we received it, the latter sample had been recrystallized three times and dialyzed against water and dried. Freshly prepared solutions of protein were used each day. The concentrations in these experiments were 0.05% for the albumin and 0.5% for the protamine. This concentration of egg albumin approximates in nitrogen value the soybean solution used by Perri and Hazel.[3] The higher concentration of the protamine was necessary due to its poor foaming characteristics.

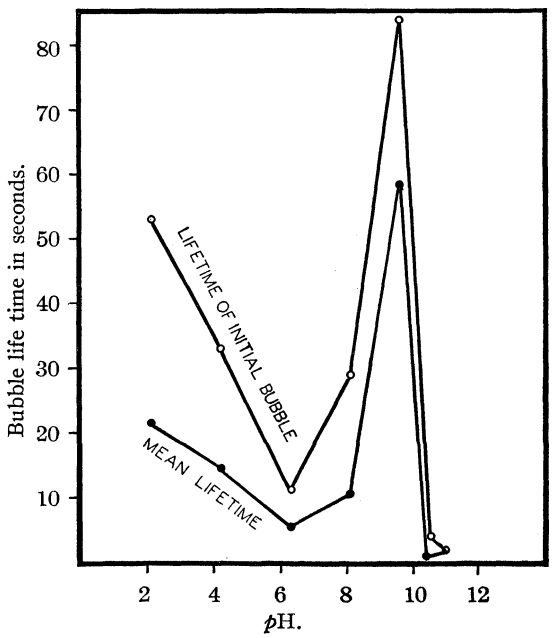

Fig. 1.—Effect of *p*H on lifetime of single bubbles on 0.5% salmine sulfate.

Method.—For determinations of foaming capacity, 1.0 cc. of liquid was transferred to the porous plate of a modified Stiepel type foam meter[8] by means of a Blodgett pipet. During foam formation the rate of air flow through the porous plate was maintained at 16 cc. per minute until there was no further increase in the volume of the foam. This maximum volume was recorded. While individual values for foaming capacity are probably subject to an error, in the extreme, of 2 cc., most curves were obtained as the result of several independent determinations in order to minimize errors in foam volume and also errors in *p*H caused by fouling of the glass electrode by the protein.

Except where otherwise indicated, the protein was dispersed in distilled water and made up to volume with the required solution of electrolyte. For some experiments, clear solutions of the protein were obtained by dissolving the protein in a minimum volume of 10^{-3} *M* hydroxide and making it to volume with sufficient solution of electrolyte to give the required electrolyte concentration.

When a range of *p*H values was desired, the first *p*H of a solution to be tested was that of the solution as prepared. Subsequent determinations on the acid side of this first value were made after stepwise additions of hydrochloric acid; on the alkaline side by additions of potassium hydroxide. Determination of *p*H was made with a Model G Beckman glass electrode *p*H meter employing standard or blue glass electrodes in the appropriate ranges.

In those experiments requiring conditions free from carbon dioxide, boiled distilled water was used in preparation of the solutions. Access of carbon dioxide to the solution during the experiment was prevented by a current of air free from carbon dioxide flowing into and out of the container in which the solution was enclosed. Air flow, adjustment of *p*H, and removal of the sample by means of the Blodgett pipet was made possible by an opening in the top of the container. In those experiments requiring saturated solution of carbon dioxide, the solution was enclosed in the above container, and carbon dioxide from dry ice was allowed to flow into and out of the vessel during the experiment.

Experiments on Life of Single Bubbles by I. M. Abrams.—Preliminary experiments were carried out on the life-time of single bubbles released from an orifice and floating to the surface of 0.5% protamine solutions at different *p*H values. These experiments were carried out in closed vessels to exclude dust and minimize evaporation.

The effect of *p*H on bubble lifetime as indicated by the lifetime of initial bubbles at different *p*H values and by the average lifetime at these values is shown in Fig. 1 for 0.5% protamine solutions. While the variation of bubble life at any observed *p*H was very great, a sharp maximum in stability was observed somewhat on the acid side of the isoelectric point. Stability was at a minimum at about *p*H 6 and increased again at low *p*H values.

Foams with Salmine Sulfate.—The results with single bubbles suggested the desirability of extending the investigation to actual foams, both of the protamine and of albumin. The results for the foaming capacity of 0.5% protamine solutions at different *p*H values are shown in Fig. 2. At the concentration used (0.5%) the foams obtained were weak and poorly characterized. However, a broad maximum in foaming capacity does appear somewhat on the acid side of the isoelectric point.

Foams with Egg Albumin

Standard Foaming Capacity Curve.—Well-defined foams were obtained using a 0.05% aqueous solution of albumin at different *p*H values, especially in the region of maximum foaming capacity. Greatest foaming occurs on the acid side (*p*H 3.7 to 4.0) of the normal isoelectric point of albumin (*p*H 4.6 to 4.8), and at very high and very low *p*H values, as shown in Fig. 3. The absence of foam between *p*H's 6 and 11 is very striking. Figure 3 will appear dotted for reference in all later figures.

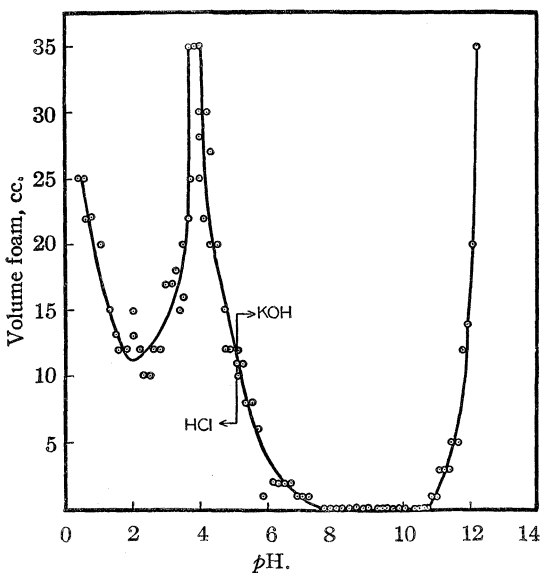

Fig. 3.—Effect of *p*H on foaming capacity of 1.0 cc. of 0.05% egg albumin.

These solutions were exposed to air and therefore contained carbon dioxide. However, determinations of foaming capacity in the *absence* of carbon dioxide give values which, within experimental error, appear to fall on the same standard curve. Saturating the solutions with carbon dioxide slightly decreases the amount of foam produced near the isoelectric point. These results are shown in Fig. 3a.

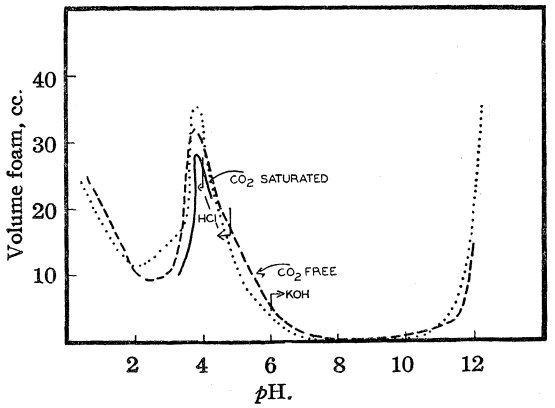

Fig. 3a.—Effect of *p*H on foaming capacity of 1.0 cc. of 0.05% egg albumin in absence of carbon dioxide. Effect of saturating the solution with carbon dioxide.

Effect of Added Weak Acids at Various *p*H's Adjusted with Potassium Hydroxide or Hydrochloric Acid.—The effect of anions on the maximum foaming capacity was investigated in the region of the isoleectric point by foaming 1.0 cc. of 0.05% albumin in 10^{-3} *M* salt solutions, adding hydrochloric acid or potassium hydroxide as required. Arrows on the accompanying figures indicate initial *p*H values. It is to be noted that the characteristics of albumin in the region of the isoelectric point are of interest to the baking industries. The effects of adding acetic acid, potassium acid tartrate, citric acid and phosphoric acid are shown in Figs. 4 and 5. The curve for a saturated solution of carbon dioxide has been mentioned previously (Fig. 3a).

Effect of Added Salts.—The effect of cation valence at different salt molarities is shown in Table I. The results

TABLE I

EFFECT OF CATIONS ON FOAM CAPACITY OF 0.05% EGG ALBUMIN

Molarity of added salt	KCl *p*H	KCl Foam, cc.	$CaCl_2$ *p*H	$CaCl_2$ Foam, cc.	$Ca(NO_3)_2$ *p*H	$Ca(NO_3)_2$ Foam, cc.	$Th(NO_3)_4$ *p*H	$Th(NO_3)_4$ Foam, cc.
0	5.09	10	5.09	10	5.2	12	5.2	12
10^{-1}	5.45	12	5.85	12	5.0	14	2.3	25
10^{-2}	5.1	14	6.0	12	4.9	14	2.9	50
10^{-3}	5.2	12	5.8	10	4.9	11	3.3	45
10^{-4}	5.1	12	5.0	10	4.8	12	4.0	6
10^{-5}							4.2	6
10^{-6}							5.0	17
10^{-7}							5.2	14

were not at all similar to those which might have been expected from the work of Perri and Hazel, and it became obvious that salt effects should be investigated over a range of *p*H values for each concentration of salt. Such studies are shown in Fig. 6 for 10^{-2}, 10^{-3} and 10^{-4} *M* potassium chloride and for 10^{-3} *M* calcium chloride. The curve for the calcium chloride–potassium hydroxide system (Fig. 6) was obtained later and will be discussed in connection with Fig. 9.

Effect of Degree or Kind of Dispersion of the Albumin.—Albumin "solutions" as ordinarily made up, and as used in all the above experiments, were obtained by simply dissolving the albumin in distilled water. These solutions had a *p*H of 5.05 to 5.1 and were slightly turbid. *Clear* solutions were obtained by dissolving the protein in 10^{-3} *M* potassium hydroxide. Foaming capacities of such solutions were determined over a range of *p*H values obtained by additions of hydrochloric acid or further potassium hydroxide and are shown in Fig. 7. Access of carbon dioxide

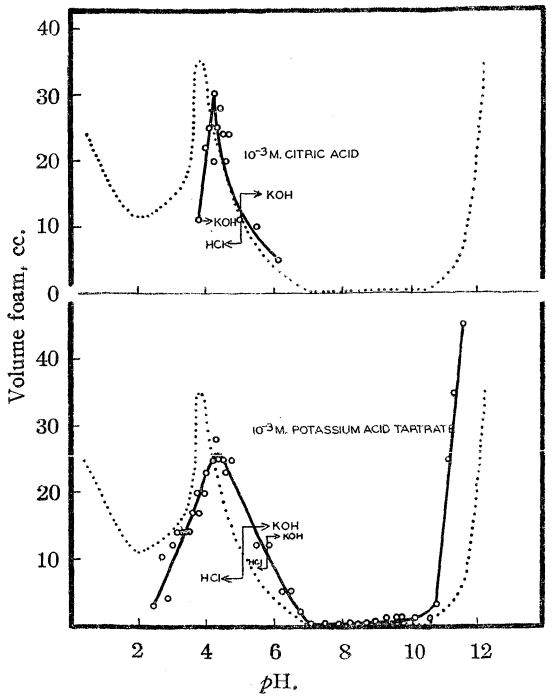

Fig. 4.—Effect of 10^{-3} M potassium acid tartrate or 10^{-3} M citric acid on foaming capacity of 1.0 cc. of 0.05% egg albumin at different pH values.

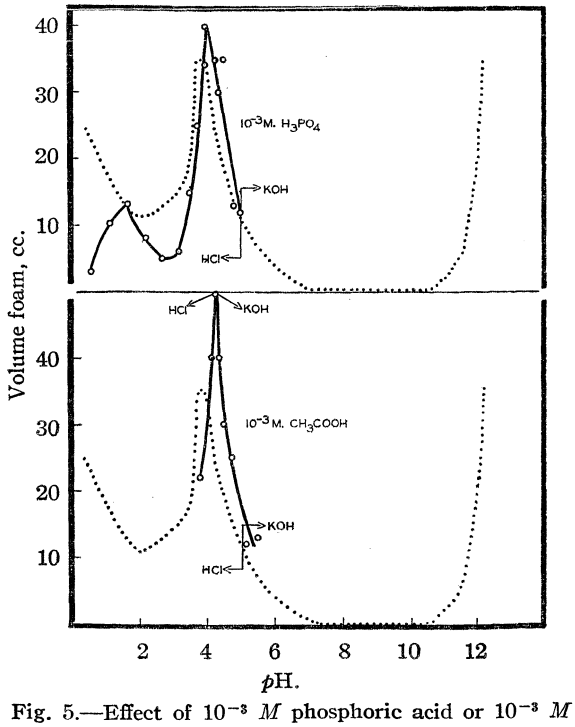

Fig. 5.—Effect of 10^{-3} M phosphoric acid or 10^{-3} M acetic acid on foaming capacity of 1.0 cc. of 0.05% egg albumin at different pH values.

to these solutions was prevented. For comparison, results are shown also in Fig. 7 for the foaming capacity of a *clear* solution of albumin dissolved in 5×10^{-4} M potas-

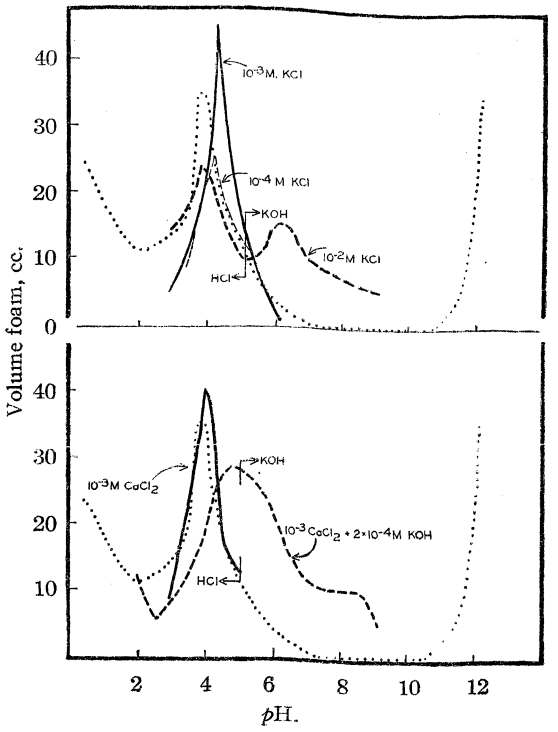

Fig. 6.—Effect of various concentrations of potassium chloride on foaming capacity of 1.0 cc. of 0.05% egg albumin at different pH values. Effect of 10^{-3} M calcium chloride on the foaming capacity of 1.0 cc. of 0.05% albumin solution at various pH values; comparison of the foaming of egg albumin originally dispersed in 10^{-3} M calcium chloride solution at pH 5.95 with the foaming of egg albumin originally *dissolved* in 10^{-3} M potassium hydroxide and then made 2×10^{-4} M in potassium hydroxide and 10^{-3} M in calcium chloride.

sium carbonate, to which hydrochloric acid or potassium hydroxide was then added to adjust the pH.

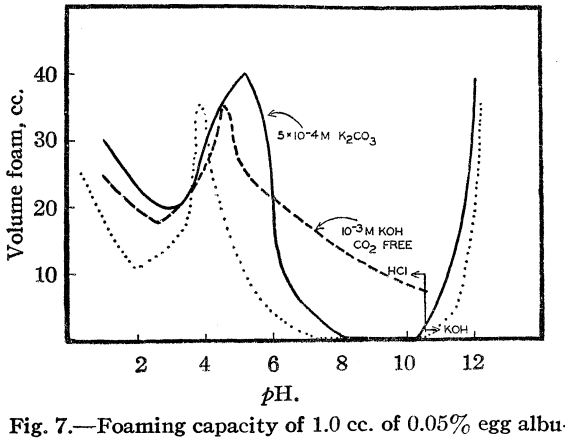

Fig. 7.—Foaming capacity of 1.0 cc. of 0.05% egg albumin showing effect of *dissolving* the albumin in 10^{-3} M potassium hydroxide or in 5×10^{-4} M potassium carbonate, access of carbon dioxide from the air prevented at all times.

It is apparent that much more foam is produced in the alkaline region when the protein is first dissolved in alkali.

The lesser foaming in potassium carbonate solution as compared to potassium hydroxide solution may be due to a depressing effect of carbonate or bicarbonate ion or it may be due to an effect of the slightly lower initial *p*H of the potassium carbonate solution.

Experiments with Dissolved Egg Albumin in Presence of Barium Ion.—After showing the importance of first *dissolving* the egg albumin in 10^{-3} *M* potassium hydroxide, a series of experiments was carried out with egg albumin *dissolved* in a minimum volume of 10^{-3} *M* barium hydroxide (50 mg. albumin in 20 cc.) and then adjusted to various concentrations of barium ion by adding water or concentrated barium hydroxide, making the albumin 0.05%. Access of carbon dioxide was prevented. Adjustment of *p*H was made with hydrochloric acid. The five curves are presented in Fig. 8. The very great increase in foaming caused by the barium ion in the alkaline range is strikingly evident. Near *p*H 4, on the contrary, foaming decreases regularly with increasing concentrations of barium salt.

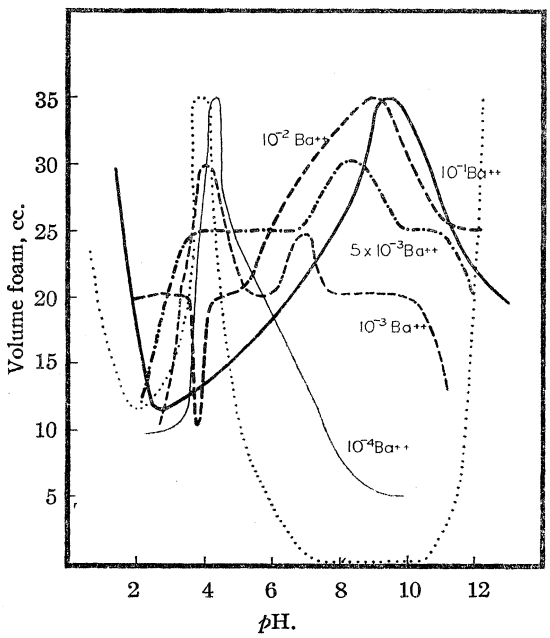

Fig. 8.—Foaming of 0.05% egg albumin *dissolved* originally in barium hydroxide and kept carbonate free, with *p*H adjusted by adding hydrochloric acid, showing decrease in foaming at *p*H 4 caused by barium salt and great increase at *p*H's 7 to 10.

Dispersed and Dissolved Egg Albumin in Presence of Barium Chloride.—Figure 9 shows the results of further experiments in which on the one hand, 0.05% egg albumin was initially *dispersed* in 10^{-3} *M* barium chloride at *p*H 5.4, and *p*H's adjusted with potassium hydroxide or hydrochloric acid; and, on the other, initially *dissolved* in a minimum of 10^{-3} *M* potassium hydroxide, then adjusted to 2×10^{-4} *M* potassium hydroxide and 10^{-3} *M* barium chloride, with further adjustments of *p*H by adding hydrochloric acid. The initial point of each series is indicated by a cross on the curve in Fig. 9. A similar effect for calcium chloride is shown in Fig. 6. It is seen that the degree or kind of dispersion of the protein and the presence of alkaline earth ion are both important in promoting foaming in the alkaline range.

Effect of Sea Water.—Ability of a material to foam in sea water is of importance in certain special foam applications. In this connection the egg albumin, dissolved at a concentration of 0.05 % in synthetic sea water (*p*H 8.2), gave 15 cc. of foam by the bubbling method; whereas, after adjusting the *p*H by small additions of hydrochloric acid or potassium hydroxide, the following foam volumes were obtained: *p*H 7.2, 17 cc.; *p*H 9.0, 32 cc.; *p*H 10.0, 20 cc. In distilled water at these *p*H values the foaming capacity of the pure albumin is negligible (Fig. 3). It is interesting that the sea water causes a maximum in foaming in about the same *p*H region as does barium ion at a concentration equivalent to the total alkaline earth concentration of the sea water (Fig. 8).

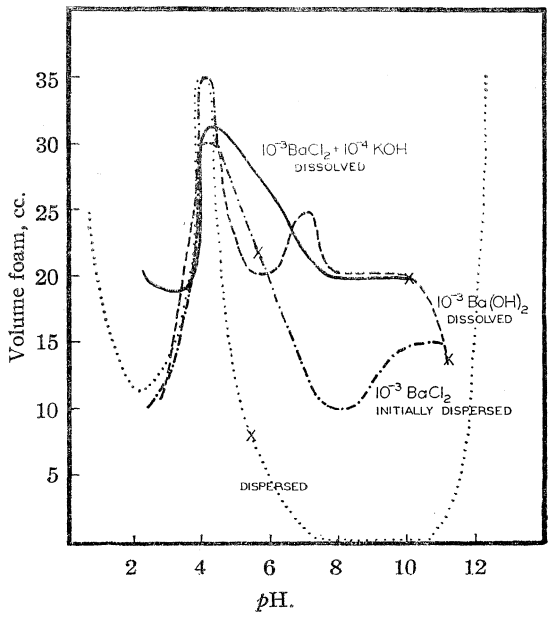

Fig. 9.—Results in presence of 10^{-3} *M* barium ion, in absence of carbon dioxide. Comparison of effect of barium ion on egg albumin initially *dispersed* at *p*H 5.4 (marked by cross) with effect of egg albumin initially *dissolved* at *p*H 10.1 (marked by cross) and with the effect of barium ion on egg albumin originally dissolved at *p*H 11.2 (marked by cross) in 10^{-3} *M* barium hydroxide. The dashed line as in Fig. 8 represents solutions made in barium hydroxide with *p*H's adjusted by adding hydrochloric acid; the full line, solutions made in 10^{-3} *M* potassium hydroxide diluted to 2×10^{-4} *M* potassium hydroxide and kept 10^{-3} *M* barium chloride with *p*H's adjusted by hydrochloric acid; the heavy dot-dash line refers to a dispersion containing 10^{-3} *M* barium chloride with *p*H's adjusted by potassium hydroxide or hydrochloric acid.

Discussion

It is seen that the foaming properties of proteins are complex and necessitate isolating the various factors by obtaining series of experiments over the whole *p*H range while studying one factor at a time. This is illustrated by the different curves in our figures.

The first point noticed is the pronounced maximum in the foaming of the albumin and protamine solutions at a *p*H slightly on the acid side of the isoelectric point. The albumin solutions also showed high foaming capacity at very high and very low *p*H values. The foaming capacity at this maximum appears to be the same whether the albumin was originally dispersed at *p*H 5 or originally dissolved at *p*H 10 (in 10^{-3} *M* potassium

hydroxide or 10^{-4} *M* barium hydroxide) although the position of the maximum is slightly shifted.

In the alkaline ranges albumin originally *dissolved* in potassium or barium hydroxide froths freely; whereas, if the albumin is first merely dispersed in water at *p*H 5–5.4 and the *p*H increased by adding potassium hydroxide, the albumin does not froth at all between *p*H's 7 and 11.

If sufficient barium ion is added to albumin dissolved in 10^{-3} *M* hydroxide, the frothing at *p*H 9 equals the maximum normally observed near the isoelectric point, but additional barium salt did not improve the foaming further. However, at *p*H 4, barium salt has the opposite effect, and lessens the foaming, as is seen in Fig. 8. Barium is seen to be much more effective than calcium or potassium in promoting foaming in the alkaline range. With increasing amounts of barium ion, maximum foaming occurs at increasingly higher *p*H values.

There appears to be a significant correlation between denaturation and maximum foaming. When foaming was a maximum, either at *p*H 4 for the "standard" curve or at *p*H 9 through the influence of barium ion, a residue which could not be redissolved was observed after collapse of the foam; when foaming was weak, no such denatured residue was found. Adam[9] has discussed denaturation in connection with protein films obtained either by spreading the protein on the surface of water or by adsorption of the protein at the air–protein solution interface, and has associated the effect with the "unfoldment" of the protein molecule in the surface film. It would appear from our results that only under conditions of optimum foaming is the protein adsorbed at the air–solution interface in the form of a fully extended coherent film.

Some further insight as to the nature of the adsorbed albumin film in the foam may be gained from the fact that, under conditions of optimum foaming, the air–liquid surface area produced was estimated by bubble size measurements to be of the order of magnitude of one square meter for each 5 mg. of albumin present in the original solution (surface tension 62 dynes/cm.). Comparisons with the results of Hughes[10] for the spreading of albumin at the air–water interface suggest that, under conditions of maximum foaming, the adsorbed surface film is of the "gel" type.

It therefore appears that the essential condition for maximum foaming is that the protein solution be capable of yielding readily a fully extended, semi-rigid, coherent protein film adsorbed at the air–solution interface. It would seem to be suggested that this condition is fulfilled when there is a minimum net charge on the protein complex—at very high and very low *p*H values due to suppression of ionization of the protein, at the isoelectric point due to "self-neutralization," and at intermediate values due to neutralization of free COO^- or NH_3^+ groups by cations or anions, respectively. Our results actually depart from this idealized concept in two respects. Maximum foaming actually appeared on the acid side of the isoelectric point and anion effects were not apparent. It is possible that the isoelectric point of albumin in an "unfolded" or extended condition at the air–water interface may be slightly different from that of the protein in solution although the possibility of a shift due to the presence of electrolytes is not completely eliminated. The reason the expected anion effect did not appear in our results may be that in this *p*H range (below *p*H4 for albumin) the weak acids involved were almost completely undissociated.

It is interesting to note that Gorter and coworkers[9] have found that the rate of spreading of proteins at the air–water interface is a maximum at the isoelectric point and at very high and very low *p*H values. They showed that in the alkaline range cations improve spreading according to a typical lyotropic series and also that anions had similar effects on the acid side of the isoelectric point.

Zhukov and Bushmakin[11] observed a maximum stability of benzene emulsions stabilized with gelatin at the iso-electric point, *i. e.*, where the surface tension and viscosity are at a minimum. Two minimum stability points were observed at *p*H 2.5 and 9.5 coinciding with maximum viscosities. They concluded that non-hydrated and undissociated gelatin molecules serve best for emulsification.

Our results appear to amplify and extend those of Perri and Hazel[3] and offer possible explanations for those of others. Thus Barmore observed a maximum foaming capacity of fresh whole egg white at *p*H 8, which may be due to inorganic cations, although globulins are of course also present. In so far as whey proteins may be compared with egg albumin, the results of Peter and Bell[5] correlate satisfactorily with ours.

It appears from this work that in any study of the foaming properties of proteins it is important to be aware of electrolytes, either added or originally present in the protein, to consider the degree or kind of dispersion of the protein and to observe the foaming characteristics over a wide range of *p*H values for each concentration of electrolyte used.

Summary

1. Proteins produce maximum foam somewhat on the acid side of the isoelectric point. This is shown by single bubbles and by frothing for egg albumin (*p*H 4) and protamine (*p*H 10).

2. This maximum is enhanced by dissolving the egg albumin in 10^{-3} *M* acetic acid.

3. If egg albumin is merely dispersed to a somewhat turbid "solution" at *p*H 5, it does not foam in the range *p*H 7 to 11.

(11) I. I. Zhukov and I. N. Bushmakin, *J. Russ. Phys.-Chem. Soc.*, **59**, 1061 (1927).

4. If first dissolved in 10^{-3} *M* alkali (potassium hydroxide or barium hydroxide) it foams freely in the alkaline range.

5. Alkaline earth ion or salt greatly promotes foaming in the alkaline range, but may minimize it on the acid side.

6. The data presented, considered in the light of previous knowledge, indicate that different proteins follow a general pattern in their foaming behavior and that this pattern is similar to that exhibited by other properties of proteins.

The Preparation and Properties of Vanadium Nitrosyl Chlorides

BY ARTHUR GREENVILLE WHITTAKER[1] AND DON M. YOST

In connection with an investigation of vanadium tetrachloride, VCl_4, it was observed that a beautiful, dark purple, coarsely crystalline substance forms readily when dry nitric oxide is passed through a solution of vanadium tetrachloride in carbon tetrachloride. Similar crystalline materials result when dry nitric oxide reacts with pure vanadium tetrachloride in either the liquid or vapor state. Although compounds containing the NO group have been previously studied,[2] the reaction products herein described do not appear to have been mentioned in the literature and are therefore new.

Experimental

The vanadium tetrachloride was prepared as described in a previous paper.[3] Nitric oxide was prepared by slowly adding 50% sulfuric acid to a solution which was four formal in potassium nitrite and one formal in potassium iodide.[4] The gas was purified and dried by passing it through successive tubes containing potassium hydroxide, calcium chloride and magnesium perchlorate.

In preparing these new compounds, three different sets of conditions were tried, yielding three different sets of principal reaction products. In all cases a number of products were formed, but the principal ones were the dark purple crystals and vanadium trichloride. Small amounts of nitrosyl chloride and vanadium oxytrichloride were always produced, however. The three sets of reaction conditions and principal products are: (1) Nitric oxide reacting with vanadium tetrachloride in the vapor phase gave the solid $V_2Cl_8(NO)_5$, and a large fraction of vanadium trichloride; (2) Nitric oxide passed into liquid vanadium tetrachloride resulted in the precipitation of the compound V_2Cl_7NO; (3) The insoluble solid VCl_4NO was formed when nitric oxide was passed into a dilute (say 10%) carbon tetrachloride solution.

All reactions were started at room temperature, but as considerable heat is evolved the exact temperatures during reaction cannot be specified. No attempt was made to estimate the heat of reaction. The compounds were purified by subliming them from one end of a pyrex tube (50 cm. × 2.5 cm.), which was filled with dry air or carbon dioxide at one atmosphere, to the other. Although sublimation begins at about 45°, the hot end of the tube was maintained at 135° and the cold end at room temperature. The residue at the hot end of the tube was always vanadium trichloride. Before the crystals were removed from the tube the collection end was placed in a furnace at 50° overnight to distill any liquid away from the crystals

Densities were determined pycnometrically; carbon tetrachloride served as the liquid. Magnetic susceptibility measurements were made by the Gouy method.

Extensive analyses of the various preparations were made using the following methods: (1) Vanadium was determined, in sulfuric acid solution, with standardized permanganate. (2) Chlorine was precipitated as silver chloride and weighed. (3) Nitrogen was determined by first oxidizing to nitrate with alkaline permanganate the nitric oxide or nitrous acid formed when the purple crystals react with water. The excess permanganate was reduced with hydrogen peroxide and the manganese dioxide filtered off. Nitrogen in the filtrate was determined by the Kjeldahl method, using aluminum metal in sodium carbonate solution as a reducing agent.

Results and Properties of the Compounds.—The average values of the results of the analyses and of the measurements of the densities and magnetic susceptibilites are presented in Table I. As indicated there the results of the analyses were best satisfied by compounds with the empirical formulas VCl_4NO, V_2Cl_7NO and $V_2Cl_8(NO)_5$.

All the compounds gave off a colorless gas and ultimately yielded a blue solution when placed in water. The blue solution was due to vanadyl ion, VO^{++}, and the gas was identified as nitric oxide. The amount of nitric oxide liberated by each compound is indicated in Table I. In the case of V_2Cl_7NO the rate of solution was slower and it was possible to observe a brown solution in the immediate vicinity of the crystals as they reacted with water. The brown color was much like that due to VO^+ which one gets on dissolving vanadium trichloride in water.

Long, dark purple, opaque crystals were formed by each of the compounds. Microscopic examination revealed that dark purple light was transmitted by small crystals. Also, the crystals were birefringent, and they show parallel extinction. The crystals of VCl_4NO and $V_2Cl_8(NO)_5$ were needle-like, and had a tendency to form penetration twins. The crystals of V_2Cl_7NO were shorter prisms that tended to form hemispherical tufts of the prisms like pins in a pin cushion.

TABLE I

SOME PROPERTIES OF THE VANADIUM NITROSYL CHLORIDES

Compound	Percentage composition: V	Obsd. Cl	NO	Theory: V	Cl	NO	NO lib. by H_2O, %	Density at 28°	χ_m[a] ($\times 10^6$) 25.3°
VCl_4NO	23.1	62.5	11.9[b]	22.9	63.6	13.5	13.5	2.32	2340
V_2Cl_7NO	26.8	65.8	7.8	22.6	65.6	7.8	2.5	2.50	4180
$V_2Cl_8(NO)_5$	19.0	52.6	23.9[b]	19.0	53.0	28.0	3.0	2.15	2470

[a] χ_m is the molal susceptibility. [b] These results are known to be low.

Moisture in the air reacts readily with all of the preparations to give nitric oxide and vanadyl chloride. Subjected to pressure of about 0.1 mm. at room temperature, the compounds simply sublimed from a retort tube to a cold trap. Such experiments gave a rough measure of the relative volatility of the compounds. Listed in order of increasing volatility they are: V_2Cl_7NO, VCl_4NO and $V_2Cl_8(NO)_5$.

Efforts were made to decompose the compounds by heating them rather suddenly to 400 to 500° in an apparatus consisting of a reaction tube, a cold trap at −78°, and a pneumatic trough to catch gases that did not condense in the cold trap. The compound VCl_4NO did not appear to decompose since it could be sublimed repeatedly from one end of the reaction tube to the other without leaving a residue. The compound V_2Cl_7NO showed some decomposition in that the cold trap caught a small amount of nitrosyl chloride, and a small residue of vanadium trichloride remained. In the case of $V_2Cl_8(NO)_5$ decomposition took place to some extent giving NOCl and perhaps NO, some of which reacted with oxygen in the apparatus and condensed in the cold trap as a mixture of NO_2 and N_2O_3. A residue of V_2O_5 appeared to be formed. In all cases the pneumatic trough caught no significant amount of gas other than that due to expansion of the air on heating. At the elevated temperature all the compounds appeared to react slowly with oxygen in the air to give vanadium oxytrichloride.

The compounds were found to be insoluble in the dried liquids, carbon tetrachloride, *n*-butyl alcohol, ether, dioxane and nitrobenzene. All were soluble to the extent of a few per cent. in carbon tetrachloride at 100° while enclosed in a sublimation tube. Efforts to dissolve the compounds in boiling carbon tetrachloride at atmospheric pressure in a test-tube resulted in the decomposition of the compounds.

Discussion.—Unfortunately, the various preparation methods do not produce results which were clear cut. With all three some of the preparations turned out to be mixtures of two or more of the compounds. In some, but not all, cases the properties of the mixtures could be resolved into those of the components by using a simple additivity relation based on the chemical analysis and the probable pure components. As the procedure did not always yield sensible results, the existence of a fourth compound in the group is not precluded. At any rate one or more pure samples of the above described compounds were independently produced.

The results of the magnetic susceptibility measurements deserve further mention. It is interesting that two of these compounds, namely, VCl_4NO and V_2Cl_6NO are examples of "even molecules" which are paramagnetic. For example, in the case of VCl_4NO the odd electron of the vanadium does not appear to couple with that of the NO group. Complete coupling would produce a diamagnetic substance, which is certainly not the case here.

If it is assumed that this compound obeys the Curie–Weiss law for the odd electrons per molecule, then the Curie temperature turns out to be −99°. This is not an unreasonable value. The other compounds are too complicated to make a reasonable guess as to how their paramagnetism arises.

Since these compounds are not reported elsewhere in the literature, the following names are proposed: VCl_4NO can be named vanadium nitrosyl tetrachloride, V_2Cl_7NO can be named divanadium nitrosyl heptachloride, and $V_2Cl_8(NO)_5$ can be named divanadium pentanitrosyl octachloride.

We are greatly indebted to Mr. David L. Douglas for helpful discussion and careful study of the results of the experiments. The work was kindly supported by a grant from the Research Corporation.

Summary

1. Three new compounds are reported as resulting from reactions between vanadium tetrachloride and nitric oxide. These compounds have the empirical formulas VCl_4NO, V_2Cl_7NO and $V_2Cl_8(NO)_5$; they have been named vanadium nitrosyl tetrachloride, divanadium nitrosyl heptachloride, and divanadium pentanitrosyl octachloride, respectively.

2. Various properties of the compounds are reported. These include reaction with water, qualitative solubilities where no reaction takes place with the solvent, and their behavior at reduced pressure and when suddenly heated to about 450°. All the compounds have very nearly the same general appearance, and all sublime readily.

3. The density of each compound was measured, and found to be 2.32, 2.50 and 2.15 g./cc. for VCl_4NO, V_2Cl_7NO and $V_2Cl_8(NO)_5$, respectively.

4. The magnetic susceptibility of each compound was measured at 25.3° and found to be 2340×10^{-6}, 4180×10^{-6} and 2470×10^{-6} per mole for VCl_4NO, V_2Cl_7NO and $V_2Cl_3(NO)_5$, respectively.

The Kinetics of the Thallium(I)–Thallium(III) Exchange Reaction

BY RENÉ J. PRESTWOOD[1] AND ARTHUR C. WAHL

Harbottle and Dodson[2] and the authors[3] have previously reported that the rate of the exchange reaction between thallium(I) and thallium(III) in acid solution is measurable. Harbottle and Dodson found that in perchloric acid the rate was proportional to the first power of the concentration of each reactant. They also found that the rate increased when lithium perchlorate was added, varied when the acid concentration was varied, being a maximum at about 1 f., and was greater in hydrochloric acid than in perchloric acid. The authors found the rate was greater in nitric acid than in perchloric acid, increased with increasing nitric acid concentration (1.0–1.5 f.) and decreased with increasing perchloric acid concentration (1.5–3.5 f.). This paper describes our studies of the kinetics of the thallium(I)–thallium(III) exchange reaction.

Experimental

Radioactivity.—The 3.5-year Tl^{204} was used as tracer in all experiments. Part of the Tl^{204} was produced by the n,γ reaction and was obtained from the Clinton Laboratories on allocation from the U. S. Atomic Energy Commission; part was produced by the d,p reaction in the Washington University cyclotron. The activity produced in the cyclotron was purified by solution of the bombarded metal in dilute nitric acid, oxidation with aqua regia, ether extraction of thallium(III) chloride from 6 f. hydrochloric acid containing lead(II) carrier, precipitation of thallium(III) hydroxide from copper(II) and zinc(II) carriers with ammonium hydroxide, solution of the hydroxide in nitric acid, reduction with sulfite, precipitation of added iron(III) carrier with ammonium hydroxide, oxidation of the supernatant with aqua regia, and reprecipitation and solution of thallium(III) hydroxide. Thallium(III) oxide was purified prior to irradiation in the Oak Ridge pile by solution of thallium metal in dilute nitric acid, precipitation of thallium(I) chloride, oxidation with aqua regia, ether extraction of thallium(III) chloride from 6 f. hydrochloric acid, and precipitation and reprecipitation of thallium(III) hydroxide with ammonium hydroxide. The hydroxide was dried at 150–200°. The irradiated thallium(III) oxide was dissolved in nitric acid, the solution oxidized with aqua regia to be certain all the Tl^{204} was in the plus three oxidation state, and thallium(III) hydroxide precipitated and dissolved in the appropriate acid. The specific activity of this thallium was the same as that of an aliquot further purified from added lead and mercury carrier. Aluminum absorption curves of the radiation from either n,γ or d,p produced Tl^{204} agreed with the curve reported by Fajans and Voight.[4] The initial half-thickness was 30 mg. per cm.^{2}, the range 310 mg. per cm.^{2}, the beta to gamma ratio about 10^4.

Chemicals.—With the exception of the materials used in the preliminary studies of separation methods, all reaction mixtures were made up from the following solutions.

0.100 f. thallium(I) perchlorate (inactive)
0.100 f. thallium(III) perchlorate (radioactive) in 2.50 f. perchloric acid
5.00 f. perchloric acid
5.00 f. sodium perchlorate
5.00 f. sodium nitrate

Thallium(I) perchlorate was prepared by evaporation of a perchloric acid solution of Fisher pure thallium(I) nitrate and recrystallization of thallium(I) perchlorate three times from water. The thallium(III) perchlorate solution was prepared by solution of a mixture of active and inactive thallium(III) oxide in 9.3 f. perchloric acid and dilution. The inactive thallium(III) oxide was prepared by the method used to purify the oxide prior to neutron irradiation. Both thallium perchlorate solutions were assayed for thallium gravimetrically by precipitation of thallium (I) hexachloroplatinate(IV). The excess acid in the thallium(III) perchlorate solution was assayed by addition of excess standard sodium hydroxide, centrifugation of thallium(III) hydroxide, and back-titration with standard acid. Mallinckrodt "Analytical Reagent Grade" 60 or 71% perchloric acid and dried sodium nitrate and G. Frederick Smith anhydrous sodium perchlorate were used to prepare the remaining solutions. Mallinckrodt "Analytical Reagent Grade" ammonium hydroxide, sodium bromide, sodium chromate, sodium cyanide, and hexachloroplatinic acid (10% solution) were used in various solutions employed in the separation of the reactants.

Measurement of Radioactivity.—All precipitates were mounted by filtration on a tared, 18-mm. diameter piece of Whatman No. 42 filter paper, dried at 110°, weighed, mounted on a 2 × 2.5 in. cardboard card with scotch tape placed directly over the sample, and counted on a Geiger–Müller counter. During the filtration the filter paper was clamped between a glass chimney, 2.5 in. high and 14 mm. inside diameter, and a Hirsch funnel, without sides and with its surface ground flat. In order to obtain uniform deposits, the precipitate was allowed to settle on the filter paper before suction was applied. The Geiger counter[5] had an 8 mg./cm.^{2} dural side window, 1.0 in. in diameter. The sample was placed directly below and 0.5 cm. from the window. The counter pulses were fed directly into the discriminator of an Instrument Development Laboratories' Model 161 scaler (scale of 256). The counter was stable, had a 100 v. plateau which was flat within 1% statistical error, and had a background of 50 counts per minute inside a lead shield. The response of the counter was linear to within about 2% up to the maximum counting rate measured (3000 counts per minute).

Since samples of the same weight, composition and

(5) The details of the construction and operation of the Geiger counter will be reported in a later publication.

thickness were always compared, and since the scotch tape was of uniform thickness (9 mg./cm.^{2}), no absorption or scattering corrections were made. This procedure appears to be justified because good agreement between duplicate samples was always obtained. For example the average deviation between the measured specific activities (counts per min./mg. Tl_2CrO_4) of duplicate samples, prepared for the determination of the equilibrium specific activities of twenty-five reaction mixtures, was 0.9%, a deviation consistent with known counting and weighing errors.

Procedure.—All components of a reaction mixture except the active thallium(III) solution (*ca.* 10% of the total volume) were mixed, the solution allowed to reach temperature equilibrium in a constant temperature (±0.1°) water-bath, and the thallium(III) solution added at room temperature. Less than fifteen minutes was required for the reaction mixture to regain temperature equilibrium, a time short compared to the exchange half-times (five to twelve hundred hours). Aliquots were removed at known time intervals, the reactants separated, and specific activity measurements made. Two aliquots were removed immediately after the solutions were mixed for measurement of the apparent zero-time exchange (see Separation-Induced Exchange and Coprecipitation Effects under Results), and six aliquots were removed at time intervals chosen so that 20–60% exchange had occurred in the solution. Concentrations were calculated on the volumes of the solutions at 25°. (Corrections for volume changes would be less than 1%.)

Four procedures for the separation of thallium(I) from thallium(III) were studied.

(1) **Hydroxide Separation.**—Thallium(III) hydroxide was precipitated with 15 f. ammonium hydroxide. Thallium(I) chromate was precipitated from the supernatant, washed, and mounted for the specific activity determination of the thallium(I) fraction. Thallium(III) hydroxide was converted to thallium(I) chromate by solution in acid, reduction with sulfurous acid, and precipitation with sodium chromate from an ammoniacal solution. This latter thallium(I) chromate precipitate was mounted for the specific activity determination of the thallium(III) fraction. Since the hydroxide separation was used only when the concentrations of thallium(I) and thallium(III) were equal, the equilibrium specific activity, S_∞, was taken as the average specific activity of each pair of samples.

(2) **Bromide Separation.**—Thallium(I) bromide was precipitated with 2 f. sodium bromide and mounted for the specific activity determination of the thallium(I) fraction. Thallium(III) remaining in the supernatant was converted to thallium(I) bromide by precipitation of thallium(III) hydroxide, solution in acid, reduction with sulfurous acid and precipitation with sodium bromide. The latter thallium(I) bromide was mounted for the specific activity determination of the thallium(III) fraction. The equilibrium specific activity was taken as the average specific activity of each pair of samples.

(3) **Chromate Separation.**—Thallium(I) chromate was precipitated and thallium(III) complexed with cyanide by addition of an aliquot of the reaction mixture to a solution 0.5 f. in sodium chromate, 1.0 f. in sodium cyanide, and 7.0 f. in ammonium hydroxide.[6] Since thallium(I) chromate can be filtered more readily if allowed to remain in contact with its supernatant for some time, it was allowed to stand fifteen minutes, then filtered and mounted for the specific activity determination of the thallium(I) fraction. The equilibrium specific activity, S_∞, was taken as the average specific activity of all the thallium in the reaction mixture. The average specific activity measurements were made on duplicate thallium(I) chromate samples prepared by the above procedure after thallium(III) had been reduced with sulfurous acid. The sizes of the aliquots were chosen so that in any run all thallium(I) chromate samples had the same weight. The equivalence of the average and equilibrium specific activities was checked in several runs by measurement of the specific activity of the thallium(I) fraction at a time when radioactive atoms were randomly distributed. An indirect check on the amount of thallium(III) coprecipitated with thallium(I) chromate was made by preparation of fourteen thallium(I) chromate samples by the same procedure. Seven were precipitated in the presence of thallium(III) ([Tl(I)] = [Tl(III)] = 10 mf.) and seven in the absence of thallium(III). The average weight of the samples precipitated in the presence of thallium(III) was 12.5 ± 0.1 mg. compared to 12.4 ± 0.1 mg. for those precipitated in the absence of thallium(III). Therefore little if any coprecipitation occurred.

(4) **Hexachloroplatinate Separation.**—Thallium(I) hexachloroplatinate was precipitated with hexachloroplatinic acid and mounted for the specific activity determination of the thallium(I) fraction. The equilibrium specific activity was taken as the average specific activity of all the thallium in the reaction mixture.

Errors.—The principal sources of error were the statistical fluctuations in the counting rate (± *ca.* 1%), uncertainty in the weight of the counted samples (± *ca.* 1%), and uncertainty in the concentrations of the solutions (± *ca.* 1%). The error in specific activities due to nonuniform distribution of the samples has been discussed and was considered negligible. We believe the probable error in the rates is not over 3%. The internal consistency of the data indicate the precision may be somewhat higher than 3%.

Results

Separation-Induced Exchange and Coprecipitation Effects.—The exponential exchange law[7,8] expressed in its logarithmic form for the thallium(I)–thallium(III) exchange is

$$Rt = -\frac{[Tl(I)][Tl(III)]}{[Tl(I)] + [Tl(III)]} \ln (1 - F) \qquad (1)$$

The exchange rate, R, is the rate at which thallium (I) becomes thallium(III) and at which thallium(III) becomes thallium(I). R is a constant when thallium(I) and thallium(III) are uniformly dispersed in the same phase and all conditions, except the distribution of the radioactive atoms, are constant. Square bracketed quantities indicate concentrations in gram atoms per liter, and t is the time the exchange of radioactive atoms is followed (time after addition of tagged thallium(III) to the rest of the reaction mixture). The fraction exchange, F, is a measure of the extent of the exchange of radioactive atoms and approaches an equilibrium value of 1.0. Since thallium(I) was initially inactive, F may be expressed as

$$F = \frac{S_{(I)}}{S_\infty} = \frac{S_{(III)} - S_{(III)0}}{S_\infty - S_{(III)0}} \qquad (2)$$

where the specific activity, S, is defined as the ratio of radioactive to total thallium atoms in the indicated oxidation state or chemical fraction, subscripts (I) and (III) referring to the oxidation states of thallium, and subscripts 0 and ∞ referring to the time the specific activity was measured. As can be seen from equation 1, $(1 - F)$ should decrease exponentially with time so that if 50% exchange occurred in time t, 75% exchange would occur in time $2t$, etc., and a semi-logarithmic

(6) Harbottle and Dodson[2] used a similar solution containing ethanol with good results.

(7) H. A. C. McKay, *Nature*, **142**, 997 (1938).

(8) R. B. Duffield and M. Calvin, THIS JOURNAL, **68**, 557 (1946).

plot of $(1 - F)$ against time should be a straight line passing through 1.0 at zero time.

If some of the thallium(I) can be separated free of thallium(III) and if no exchange occurs during the separation, then the specific activity of the thallium(I) fraction is equal to the specific activity of the thallium(I) in the reaction mixture just prior to the separation and may be used to calculate the fraction exchange that occurred in solution. However, if the thallium(I) fraction contains some thallium(III) and if exchange occurs during the separation, the specific activity of the thallium(I) fraction will not be equal to the specific activity of the thallium(I) in solution prior to the separation but will be a function of the amounts of thallium(I) and thallium(III) in the separated chemical fraction, their specific activities prior to separation, and the extent of the separation-induced exchange. Similar statements apply to a thallium(III) fraction.

It is shown in the appendix that *when the separation-induced exchange and the incomplete separation effects are reproducible* the following simple relations are true.

$$F = \frac{S - S_0}{S_\infty - S_0} = \frac{F' - F_0'}{1 - F_0'} \qquad (3)$$

S and S_0 are the specific activities of a chemical fraction, enriched in one of the exchange reactants separated at time t and time zero, respectively. F' and F_0' are the fraction exchange observed after separation at times t and zero, respectively. Substitution for F in equation 1 gives

$$\ln (1 - F') = -\frac{[\mathrm{Tl(I)}] + [\mathrm{Tl(III)}]}{[\mathrm{Tl(I)}][\mathrm{Tl(III)}]} Rt + \ln (1 - F_0') \qquad (4)$$

$$\ln (S_\infty - S) = -\frac{[\mathrm{Tl(I)}] + [\mathrm{Tl(III)}]}{[\mathrm{Tl(I)}]\,[\mathrm{Tl(III)}]} Rt + \ln (S_\infty - S_0) \qquad (5)$$

Therefore semi-logarithmic plots of $(1 - F')$ *vs.* t and $(S_\infty - S)$ *vs.* t should be straight lines with intercepts of $(1 - F_0')$ and $(S_\infty - S_0)$, respectively, at $t = 0$. The slopes and half-values of these plots will be the same as those of a semi-logarithmic plot of $(1 - F)$ *vs.* t, and the exchange rate, R, may be calculated from the half-value, $t_{1/2}$ (half-time of the exchange reaction occurring in the solution; $t = t_{1/2}$ when $F = 0.5$), of any of these plots.

$$R = \frac{[\mathrm{Tl(I)}][\mathrm{Tl(III)}]}{[\mathrm{Tl(I)}] + [\mathrm{Tl(III)}]} \times \frac{0.693}{t_{1/2}} \qquad (6)$$

Figure 1, curves A, B and C, shows semi-logarithmic plots of $(1 - F')$ *vs.* t for three different separation procedures applied to identical reaction mixtures. Curve D is a plot of $(1 - F)$ *vs.* t, F having been calculated from the F' and F_0' values plotted in curves A, B and C.

The specific activity values used in calculations of the fraction exchange were in units of *counts per min./mg. of sample* and were not the ratio of *radioactive to total thallium atoms* as defined.

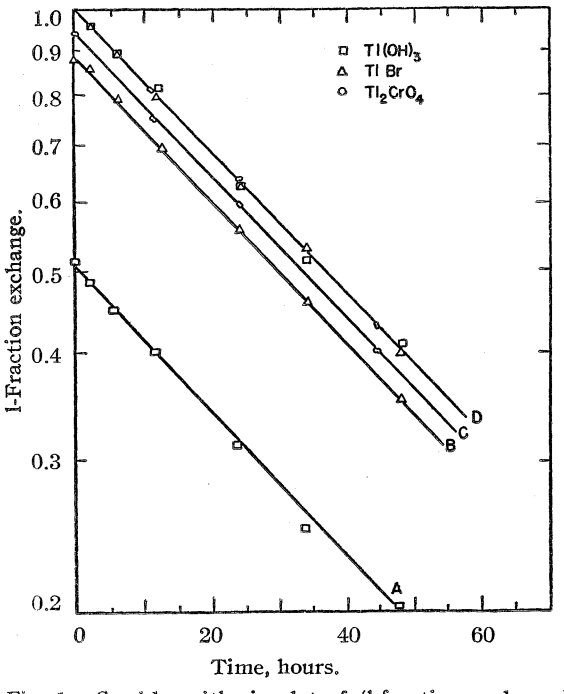

Fig. 1.—Semi-logarithmic plot of (1-fraction exchange) against time, reaction solution: 24.4 mf. $TlClO_4$, 24.4 mf. $Tl(ClO_4)_3$, 1.50 f. $HClO_4$, 24.8°. Curve A: Reactants separated by precipitation of $Tl(OH)_3$; 0.5 ml. 15 f. NH_4OH added to 2.0 ml. aliquots. Curve B: Reactants separated by precipitation of TlBr; 2.0 ml. aliquots added to 0.5 ml. 2.0 f. NaBr. Curve C: Reactants separated by precipitation of Tl_2CrO_4; 2.0 ml. aliquots added to 2.0 ml. 0.5 f. Na_2CrO_4, 1.0 f. NaCN, 7.0 f. NH_4OH. Curve D: Points of curves A, B and C corrected by equation 3.

However, since ratios of specific activities are always used in these calculations, this substitution is justified provided the counting efficiencies and compositions of all the samples from a given run are the same. The agreement of the data with the predicted exponential exchange law is a good indication that the above procedure was justified. Further justification in the case of the chromate separation procedure is given in the experimental section where it is shown that (1) the counting efficiencies of duplicate thallium(I) chromate precipitates are the same and (2) that little if any thallium(III) is coprecipitated with thallium(I) chromate. The latter is evidence that thallium(I) chromate samples have the same composition whether prepared for measurement of the specific activity of the thallium(I) fraction or the average thallium specific activity.

Several separation procedures were studied in order to find one which gave small and reproducible values of F_0'. A brief summary of the results of this study is given in Table I.

As can be seen from the data presented in Table I, only a small and reproducible apparent zero-time exchange occurred during the chromate separation. Therefore this method of separation

was used in all the kinetic studies of the homogeneous exchange. Since the thallium(I) chromate precipitate was allowed to stand for fifteen minutes in contact with its supernatant, a check was made to see if the standing increased the apparent zero-time exchange due to the heterogeneous exchange reaction between $Tl_2CrO_4(s)$ and $Tl(CN)_6^{\equiv}$. As seen from the results in Table II, the heterogeneous exchange is very slow.

The heterogeneous exchange between freshly precipitated thallium(III) hydroxide and thallium(I) ion in ammonium hydroxide solution was also measured. The fraction exchange was 22% for a ten-minute contact at room temperature.

Homogeneous Exchange—Procedure.—The general procedure has been described in the experimental section. The ionic strength (concentrations expressed in moles per liter) of all reaction mixtures was adjusted to 3.68 with sodium perchlorate. The reactants were separated by the chromate method. The measured fraction exchanges were corrected by equation 3, and the rates were calculated from the half-times obtained from semi-logarithmic plots of $(1 - F)$ *vs.* t. All points fell on straight lines passing through 1.0 at $t = 0$. A typical plot is shown in Fig. 2.

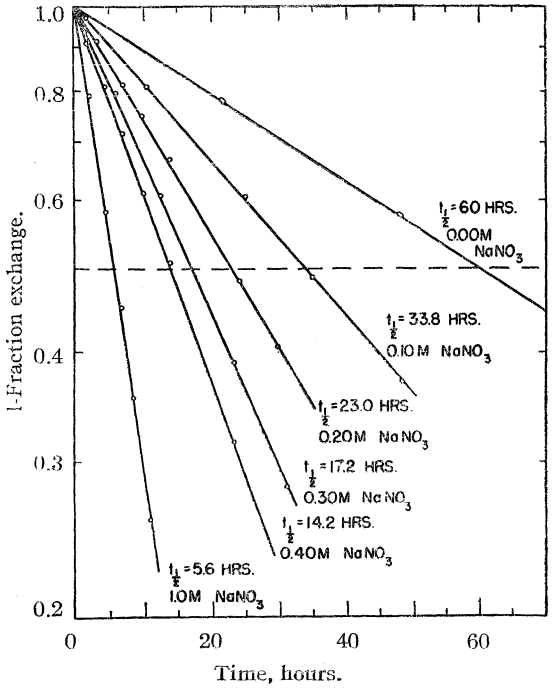

Fig. 2.—Semi-logarithmic plot of (1-fraction exchange) against time at various $NaNO_3$ concentrations (10.0 mf. $TlClO_4$, 10.0 mf. $Tl(ClO_4)_3$, 2.50 f. $HClO_4$, 37.3°, μ adjusted to 3.68 with $NaClO_4$).

Homogeneous Exchange.—[Tl(I)], [Tl(III)] Dependence.—Table III shows the dependence of the exchange half-time on the thallium(I) and thallium(III) concentrations.

10.0	10.0	189	50.0
10.0	5.0	248	66.7

If the exchange reaction is bimolecular, $R = k[Tl(I)][Tl(III)]$, substitution of $k[Tl(I)][Tl(III)]$ for R in equation 6 gives

$$t_{1/2} = \frac{0.693}{[Tl(I)] + [Tl(III)]} \times \frac{1}{k} \qquad (7)$$

Figure 3, a plot of the data in Table III, shows that the half-time of the exchange is inversely proportional to the total thallium concentration, as predicted from equation 7 for a bimolecular reaction.

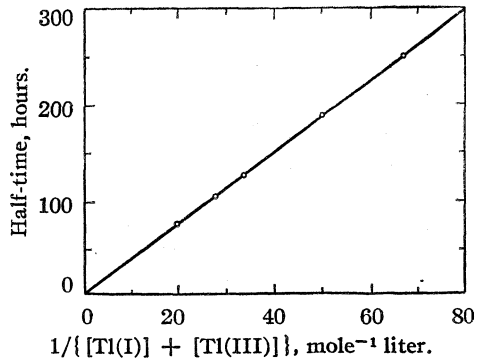

Fig. 3.—Effect of total thallium concentration on the half-time of the exchange (2.50 f. $HClO_4$, 24.9°, μ adjusted to 3.68 with $NaClO_4$).

Homogeneous Exchange—[H^+] Dependence.—Table IV summarizes the data from sixteen runs made at various acid concentrations and at various temperatures. At any one temperature plots of log $R/[Tl(I)]\,[Tl(III)]$ *vs.* log $[H^+]$ resulted in curves whose slopes approached zero at high acid concentration. However, plots of $R/[Tl(I)][Tl(III)]$ against $1/[H^+]$ (see Fig. 4) resulted in straight lines. This suggests that there are two paths for the exchange, one hydrogen ion independent and one hydrogen ion dependent.

$$R = [Tl(I)][Tl(III)]\left\{k + \frac{k'}{[H^+]}\right\} \qquad (8)$$

The intercepts of the lines give the values of k at the various temperatures, and the slopes of the lines give the values of k'.

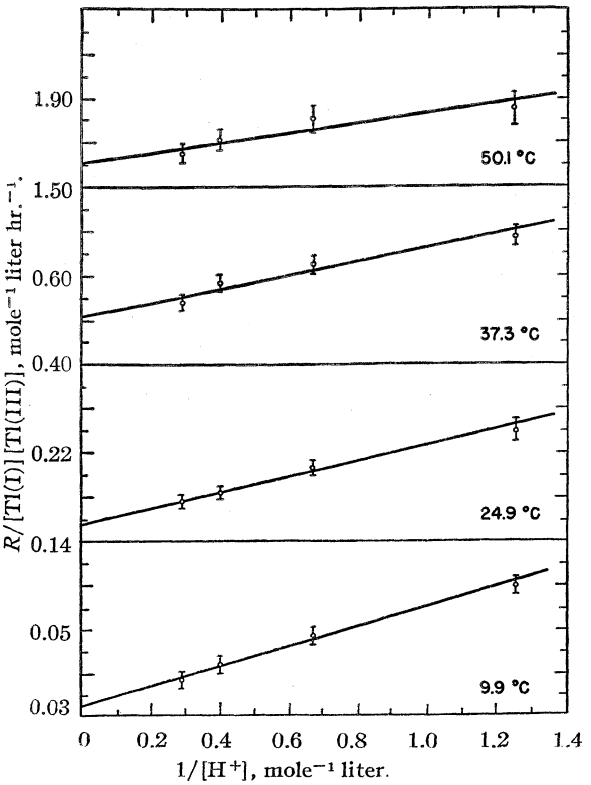

Fig. 4.—Effect of acid concentration on the exchange rate (μ adjusted to 3.68 with $NaClO_4$).

Curves A and B, Fig. 5, are semi-logarithmic plots of k and k' against the reciprocal of the absolute temperature. The experimental activation energies determined from these plots are 17,600 ± 400 cal. for the hydrogen ion independent path and 10,300 ± 1,600 cal. for the hydrogen ion dependent path. The rate constants may be expressed as

$$k = 3.8 \times 10^8\, e^{-17{,}600/RT} \text{ mole}^{-1}\text{·liter·sec.}^{-1} \qquad (9)$$

$$k' = 790\, e^{-10{,}300/RT} \text{ sec.}^{-1} \qquad (10)$$

where R is the gas constant and T is the absolute temperature.

Homogeneous Exchange—[NO_3^-] Dependence.—Five runs were made at 37.3° in which the sodium nitrate concentration was varied from 0.100 to 1.00 f. and the other conditions were held constant. The experimental exchange curves obtained along with the curve for the ex-

TABLE V

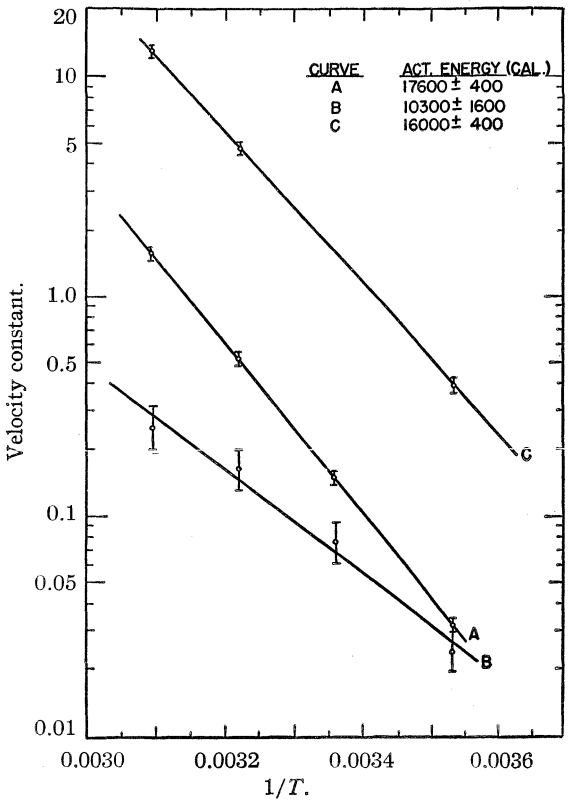

Fig. 5.—Temperature dependence of the three exchange paths. Curve A: $[H^+]$ independent path (k *vs.* $1/T$). Curve B: $[H^+]$ dependent path (k' *vs.* $1/T$). Curve C: $[NO_3^-]$ dependent path (k'' *vs.* $1/T$).

change in the absence of sodium nitrate are shown in Fig. 2. Table V is a summary of these data, and Fig. 6 is a plot of the rate against the sodium nitrate concentration.

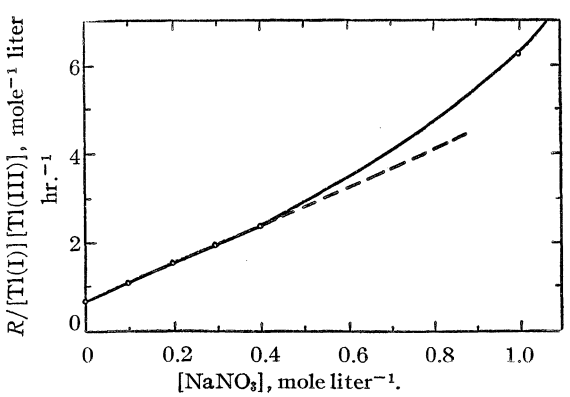

Fig. 6.—Effect of sodium nitrate concentration on the exchange rate (10.0 mf. $TlClO_4$, 10.0 mf. $Tl(ClO_4)_3$, 2.50 f. $HClO_4$, 37.3°, μ adjusted to 3.68 with $NaClO_4$).

Below 0.4 f. sodium nitrate the exchange rate is a linear function of the sodium nitrate concentration which suggests still a third path for the exchange in the presence of nitrate.

$$R = [Tl(I)][Tl(III)]\{k + (k'/[H^+]) + k''[NO_3^-]\} \quad (11)$$

The temperature dependence of k'' was investigated by measurement of the exchange rates at 9.9 and 50.1° (10 mf. $TlClO_4$, 10 mf. $Tl(ClO_4)_3$, 2.50 f. $HClO_4$, 0.400 f. $NaNO_3$, μ adjusted to 3.68 with $NaClO_4$). The half-time at 9.9° was 179 hours and at 50.1°, 5.03 hours. From the previously determined values of k and k', values of k'' were calculated at the various temperatures. A plot of k'' *vs.* $1/T$ is shown in Fig. 5, curve C. The experimental activation energy of the nitrate dependent path is 16,000 ± 400 cal. The rate constant may be represented as

$$k'' = 2.5 \times 10^8\, e^{-16{,}000/RT}\ \text{mole}^{-2}\cdot\text{liter}^2\cdot\text{sec.}^{-1} \quad (12)$$

A summary of the experimentally determined rate constants is given in Table VI.

TABLE VI

SUMMARY OF EXPERIMENTAL RATE CONSTANTS

(10.0–25.0 mf. $TlClO_4$, 5.0–25.0 mf. $Tl(ClO_4)_3$, 0.80–3.50. f. $HClO_4$, 0.00–0.40 f. $NaNO_3$, μ adjusted to 3.68 with $NaClO_4$)

Temp., °C.	k, mole^{-1}·liter·hr.$^{-1}$	k', hr.$^{-1}$	k'', mole^{-2}·liter^2·hr.$^{-1}$
9.9 ± 0.1	0.032 ± 0.002	0.023 ± 0.004	0.38 ± 0.02
24.9 ± .1	.154 ± .008	.07 ± .01	(1.60)[a]
37.3 ± .1	.510 ± .025	.15 ± .03	4.7 ± 0.2
50.1 ± .1	1.61 ± .08	.24 ± .05	13.0 ± .5

[a] Calculated from equation 12.

Heterogeneous Catalysis.—The exchange reaction at 37.3° (solution 10.0 mf. $TlClO_4$, 10.0 mf. $Tl(ClO_4)_3$, 2.50 f. $HClO_4$, μ adjusted to 3.68 with $NaClO_4$) was run in the presence of a three inch length of 0.01 inch platinized platinum wire. A similar experiment was run in the presence of five grams of pulverized silica gel. The solutions in both experiments were stirred during the runs. The half-time of the exchange in the presence of the platinum black was 1.6 hours and in the presence of silica gel 61.5 hours. These values may be compared with the half-time of 60.0 hours obtained under the same conditions in the absence of solid catalysts. The small increase in half-time in the presence of silica gel is probably not real and may be due to inaccuracies in the calculated specific activities caused by contamination of the thallium(I) chromate with silica. As the run progressed the silica became increasingly difficult to separate from the solution, and the thallium(I) chromate samples became increasingly heavy. The large decrease in the half-time of the exchange in the presence of platinum black is real and indicates the exchange may occur more rapidly in the presence of a conductor.

Discussion

Separation-Induced Exchange and Coprecipitation Effects.—It is of interest to know what proportion of the apparent zero-time exchange is due to separation-induced exchange and what proportion to incomplete separation. The large, *ca.* 50%, apparent zero-time exchange caused by precipitation of thallium(III) hydroxide is dif-

ficult to explain purely on the basis of incomplete separation. For such an explanation it would be necessary to postulate *ca.* 25% cross contamination of the thallium(I) and thallium(III) fractions. Such a figure appears at least an order of magnitude too large in view of the very low solubility of thallium(III) hydroxide in ammonium hydroxide and the clear and colorless appearance of the supernatant and wash resulting from centrifugation of the hydroxide. Also the color of thallium(I) chromate prepared for counting directly from the ammoniacal supernatant and wash was very sensitive to small amounts of thallium(III) impurity; we estimate a few per cent. of thallium(III) gave the chromate a distinctly brown color. Therefore we believe that most (> 90%) of the apparent zero-time exchange caused by the hydroxide separation was due to separation-induced exchange.

The coprecipitation of thallium(III) with thallium(I) chromate in the chromate separation was discussed in the experimental section, and it was concluded that little if any coprecipitation occurred. Therefore separation-induced exchange again seems to be the important factor in the apparent zero-time exchange.

In the bromide and hexachloroplatinate separations no attempt was made to resolve the separation-induced exchange and coprecipitation effects.

The rates of heterogeneous exchange between freshly precipitated thallium(III) hydroxide and thallium(I) ion and between freshly precipitated Tl_2CrO_4 and $Tl(CN)_6^{\equiv}$ were not sufficiently large to account for the observed separation-induced exchanges. Therefore it seems likely that most of the separation-induced exchange occurred while the precipitates were forming.

Separation-induced exchange may be an important factor in many isotopic exchange studies. At the present time there seems to be no reason to believe it need be zero or measurable. When chemical methods of separation are used and when the apparent zero-time exchange is 100%, there is no way of telling whether the rapid exchange occurred in solution prior to the separation or whether it occurred during the separation. Therefore unless physical methods of separation were used, reports of instantaneous complete exchange should be interpreted with caution.

Homogeneous Exchange.—Thallium(I) perchlorate and thallium(I) hydroxide are strong, soluble electrolytes, so essentially all thallium(I) in perchloric acid solution must exist as Tl^+. Sherrill and Haas[9] found that the solubility of thallium(III) hydroxide in perchloric acid was proportional to the cube of the hydrogen ion concentration, indicating that most thallium(III) present in perchloric acid solution exists as Tl^{+++}.

(9) M. S. Sherrill and A. J. Haas, Jr., THIS JOURNAL, **58**, 953 (1936).

The kinetic data, which are well represented by the rate law given in equation 11, indicate that in perchloric acid solution containing sodium nitrate the exchange between thallium(I) and thallium(III) proceeds via three independent paths. The following simple mechanism is consistent with the experimental rate law.

Path (1).—Two electrons are transferred directly from Tl^+ to Tl^{+++}

$$Tl^+ + Tl^{*+++} \underset{k}{\overset{k}{\rightleftharpoons}} Tl^{+++} + Tl^{*+} \qquad (13)$$

Path (2).—A small fraction[10] of one of the reactants (probably Tl^{+++}) is hydrolyzed, and two electrons are transferred between the hydrolysis product and the other reactant (the OH^- may or may not be transferred when the transition state decomposes)

$$Tl^{*+++} + H_2O = Tl^*OH^{++} + H^+ \quad K_h \text{ (rapid, reversible)} \qquad (14)$$

$$\left.\begin{aligned} &Tl^+ + Tl^*OH^{++} \xrightarrow{k_1} Tl^{+++} + Tl^*OH \text{ (rate determining)} \\ &Tl^*OH + H^+ \longrightarrow Tl^{*+} + H_2O \text{ (rapid follow reaction)} \end{aligned}\right\} \qquad (15a)$$

or

$$Tl^+ + Tl^*OH^{++} \underset{k_1}{\overset{k_1}{\rightleftharpoons}} TlOH^{++} + Tl^{*+} \text{ (rate determining)} \qquad (15b)$$

$$k' = K_h k_1 \qquad (16)$$

Path (3).—A small fraction[11] of one of the reactants (probably Tl^{+++}) is complexed with nitrate ion, and two electrons are transferred between the nitrate complex and the other reactant (the NO_3^- may or may not be transferred when the transition state decomposes)

$$Tl^{*+++} + NO_3^- = Tl^*NO_3^{++} \quad K \text{ (rapid, reversible)} \qquad (17)$$

$$\left.\begin{aligned} &Tl^+ + Tl^*NO_3^{++} \xrightarrow{k_2} Tl^{+++} + Tl^*NO_3 \text{ (rate determining)} \\ &Tl^*NO_3 \longrightarrow Tl^{*+} + NO_3^- \text{ (rapid follow reaction)} \end{aligned}\right\} \qquad 18)a)$$

or

$$Tl^+ + Tl^*NO_3^{++} \underset{k_2}{\overset{k_2}{\rightleftharpoons}} TlNO_3^{++} + Tl^{*+} \text{ (rate determining)} \qquad (18b)$$

$$k'' = Kk_2 \qquad (19)$$

The large increase in the exchange rate caused by the presence of platinum black indicates that

(10) If a large fraction of one of the reactants (Tl(III)) were hydrolyzed, the concentration of the unhydrolyzed reactant (Tl^{+++}) would decrease with decreasing hydrogen ion concentration and the curves in Fig. 4 would bend downward. The experimental points may indicate some deviation in this direction, but the deviation is within the experimental error.

(11) If a large fraction of one of the reactants (Tl(III)) were complexed by nitrate ion, the concentration of the uncomplexed reactant (Tl^{+++}) would decrease with increasing nitrate ion concentration and the curve in Fig. 6 would bend downward. The high point at 1 f. $NaNO_3$ in Fig. 6 may indicate that paths involving two or more nitrate ions may be becoming important (*e. g.*, reaction between $Tl^*(NO_3)_2^+$ and Tl^+).

in the presence of a conductor the transfer of electrons may be accomplished by still a fourth path, the electrons presumably being transferred through the conductor.

The entropy of activation for reaction 13, calculated from the experimental rate constants by use of the absolute rate theory,[12] in a solution of ionic strength 3.68 is −20 E. U. That predicted[12] for a reaction between +1 and +3 ions at zero ionic strength is about −30 E. U. The predicted entropy of activation will increase as the ionic strength of the solution increases, but no quantitative calculation has been attempted because of the known large deviations from the Debye–Hückel limiting law at high ionic strengths. (The velocity constants and heats and entropies of activation for reactions 15 and 18 cannot be calculated because the unknown equilibrium constants and heats of reactions 14 and 17 are included in the measured quantities.)

The mechanisms of electron transfer reactions and the relative importance of factors which determine the rates of such reactions are not well understood.[13] Although our study of the thallium(I)–thallium(III) exchange does little to clarify this important subject, it does point out certain inadequacies in some of the current theories.

The "equi-valence change" hypothesis proposed by Shaffer[14] and modified by Remick[15] predicts, among other things, that oxidizing and reducing agents which gain or lose the same number of electrons will react rapidly. The slow thallium(I)–thallium(III) exchange reaction is not consistent with this portion of the theory. Perhaps the theory should be modified to require a reasonable free energy decrease if a two electron transfer reaction is to be rapid.

The "coulombic-repulsion" hypothesis of Gorin[16] and Weiss[17] predicts that reactions between ions with charges of like sign will be slow. The slowness of the thallium exchange reaction and the catalytic effect of a conductor in the solution are consistent with this theory. However, the rapid oxidation[18] of tin(II) by thallium(III) in 3 f. perchloric acid appears to be inconsistent with the theory, unless it is assumed that Sn^{++} was in equilibrium with small but appreciable amounts of neutral molecules such as $Sn(OH)_2$ or that an undetected trace of catalytic impurity was present. An obvious difference between the thallium(I)–thallium(III) exchange reaction and the tin(II)–thallium(III) reaction is the over-all free energy change involved. Although there is no general correlation between the rate and the over-all free energy change of a reaction, this factor may be of importance in electron transfer reactions.

Appendix

Correction for Incomplete Separation of Reactants and Separation-Induced Exchange.—Consider an exchange reaction between the molecular species A and B in which atoms of element X, which is common to both species, are exchanged. Define specific activity as the ratio of radioactive X atoms to the total number of X atoms in the same molecular species or chemical fraction. Let

S_A = Specific activity of reactant A at time t and prior to the separation

S_{A_0} = Specific activity of reactant A at time zero and prior to the separation

S_B = Specific activity of reactant B at time t and prior to the separation

S_{B_0} = Specific activity of reactant B at time zero and prior to the separation

S_∞ = Equilibrium specific activity of A and B

S = Specific activity of the chemical fraction enriched in A and separated from the reaction mixture at time t

S_0 = Specific activity of the chemical fraction enriched in A and separated from the reaction mixture at time zero

a = Atoms of element X that were contained in species A prior to the separation and that appear in the chemical fraction enriched in A

b = Atoms of element X that were contained in species B prior to the separation and that appear in the chemical fraction enriched in A

F = Fraction exchange at time t prior to the separation

$$= \frac{S_A - S_{A_0}}{S_\infty - S_{A_0}} = \frac{S_B - S_{B_0}}{S_\infty - S_{B_0}}$$

F' = Fraction exchange observed after separation at time t

$$= \frac{S - S_{A_0}}{S_\infty - S_{A_0}}$$

F_0' = Fraction exchange observed after separation at time zero

$$= \frac{S_0 - S_{A_0}}{S_\infty - S_{A_0}}$$

Assume that under a given set of exchange and separation conditions a and b are independent of the time of separation, *i. e.*, that the separation-induced exchange and the degree of separation of the reactants are reproducible.

$$S = \frac{aS_A + bS_B}{a + b} \quad (1)$$

$$S_0 = \frac{aS_{A_0} + bS_{B_0}}{a + b} \quad (2)$$

$$S_\infty - S = \frac{aS_\infty + bS_\infty - aS_A - bS_B}{a + b} = \frac{a(S_\infty - S_A) + b(S_\infty - S_B)}{a + b} \quad (3)$$

$$S_\infty - S_0 = \frac{a(S_\infty - S_{A_0}) + b(S_\infty - S_{B_0})}{a + b} \quad (4)$$

$$\frac{S_\infty - S}{S_\infty - S_0} = \frac{a(S_\infty - S_A) + b(S_\infty - S_B)}{a(S_\infty - S_{A_0}) + b(S_\infty - S_{B_0})} \quad (5)$$

From the definition of F

$$1 - F = \frac{S_\infty - S_A}{S_\infty - S_{A_0}} = \frac{S_\infty - S_B}{S_\infty - S_{B_0}} \quad (6)$$

$$(S_\infty - S_A) = (1 - F)(S_\infty - S_{A_0}) \quad (7)$$

$$(S_\infty - S_B) = (1 - F)(S_\infty - S_{B_0}) \quad (8)$$

Substitution of equations 7 and 8 in 5 gives

$$\frac{S_\infty - S}{S_\infty - S_0} = \frac{(1 - F)[a(S_\infty - S_{A_0}) + b(S_\infty - S_{B_0})]}{a(S_\infty - S_{A_0}) + b(S_\infty - S_{B_0})} = 1 - F \quad (9)$$

Therefore

$$F = 1 - \frac{S_\infty - S}{S_\infty - S_0} = \frac{S - S_0}{S_\infty - S_0} \quad (10)$$

Alternatively from the definitions of F' and F_0'

$$1 - F' = \frac{S_\infty - S}{S_\infty - S_{A_0}} \quad (11)$$

$$1 - F_0' = \frac{S_\infty - S_0}{S_\infty - S_{A_0}} \quad (12)$$

$$\frac{1 - F'}{1 - F_0'} = \frac{S_\infty - S}{S_\infty - S_0} = 1 - F \quad (13)$$

$$F = 1 - \frac{1 - F'}{1 - F_0'} = \frac{F' - F_0'}{1 - F_0'} \quad (14)$$

Summary

1. In aqueous perchloric acid solution a slow exchange between Tl(I) and Tl(III) has been observed. The exchange rate in aqueous solutions 0.8 to 3.5 f. $HClO_4$, 0.0 to 0.4 f. $NaNO_3$, 10–25 mf. $TlClO_4$, 5–25 mf. $Tl(ClO_4)_3$, 10 to 50°, and μ adjusted to 3.68 with $NaClO_4$ is well represented by

$$R = [Tl(I)][Tl(III)]\left\{k + \frac{k'}{[H^+]} + k''[NO_3^+]\right\}$$

where

$$k = 3.8 \times 10^8\, e^{-17{,}600/RT}\ \text{mole}^{-1}\cdot\text{liter}\cdot\text{sec.}^{-1}$$

$$k' = 7.9 \times 10^2\, e^{-10{,}300/RT}\ \text{sec.}^{-1}$$

$$k'' = 2.5 \times 10^8\, e^{-16{,}000/RT}\ \text{mole}^{-2}\cdot\text{liter}^2\cdot\text{sec.}^{-1}$$

2. The presence of platinum black in the exchange solution caused a marked increase in the exchange rate; the presence of finely divided silica gel caused no measurable change in the rate.

3. Four precipitation methods for the separation of Tl(I) and Tl(III) were studied. All caused measurable and reproducible apparent zero-time exchanges due to coprecipitation or separation-induced exchange or both. It was found that separation-induced exchange was the predominant effect for at least two of the methods studied.

4. The following expression is derived which relates F, the fraction exchange that occurs in solution in time t, to F', the observed fraction exchange at time t, and F_0', the observed fraction exchange at time zero (apparent zero-time exchange).

$$F = (F' - F_0')/(1 - F_0')$$

This expression is valid as long as the separation-induced exchange and the degree of separation are reproducible in a given exchange run. The expression has been checked experimentally.

A Magnetic Study of Sulfur Vapor[1,2]

BY ALLEN B. SCOTT

By comparison with O_2, it has long been assumed that diatomic sulfur molecules are in the $^3\Sigma$ state and are thus paramagnetic. Neel[3] has measured the susceptibility of sulfur vapor at several temperatures, and, basing his calculation of the concentration of S_2 upon the vapor density measurements of Preuner and Schupp,[4] showed that this assumption was approximately correct, though his value for $\chi_M T$ was about 40% different from the theoretical value, and varied considerably with temperature. He was unable to conclude whether the disagreement was due to error in his magnetic data, error in the vapor equilibrium data, or was really an indication that S_2 was not truly in the triplet state.

An attempt has been made in this Laboratory to reinvestigate the susceptibility of sulfur vapor as a step in elucidating the complex equilibrium among the aggregates in sulfur vapor. If it can be established that S_2 has the theoretical moment of the triplet state, the measurement of susceptibility will then suffice to determine the concentration of S_2 in the presence of higher aggregates. In this paper are reported the results of a determination of the susceptibility of sulfur vapor at several temperatures between 550 and 850° which indicate that S_2 has the correct moment for the triplet state.

Experimental

The method was essentially that used in the measurement of the susceptibility of thermally dissociated iodine vapor.[5] A method for detecting the amount of displacement of the balance beam, consisting of a micro-

metrically adjustable scale in place of the photographic recording device, was found time-saving and gave more consistent results. By means of a micrometer, the scale could be positioned so that the oscillations of the slit image were symmetrical about the scale index, as viewed through a telescope; after applying the field or lifting the calibrating weight, the scale was again positioned and the difference between micrometer readings was proportional to the displacing force.

In practice, it was found that small changes in the location of the bulb in the field caused a significant change in the force of the field upon the bulb. In the previous work with iodine errors due to slight positional changes were overcome by taking a large number of measurements over an extended period of time. In order to save time and eliminate constructively the source of these errors, the height of the bulb was adjusted by always bringing the balance beam to the same initial position by means of a small solenoid acting upon a fine iron wire at the end of the beam opposite the bulb suspension. The current through the solenoid was adjusted manually to bring the slit image to a constant initial scale position; the current was maintained while the field was applied, and the new scale position obtained.

The furnace was made of somewhat larger (19 mm. o.d.) quartz tubing, which necessitated less lagging in order that it could be placed between the magnet poles. The variation in temperature throughout the length of the bulb was 33°. The average temperature was obtained from several measurements along the length of the bulb and was correct within about 5°. The thermocouples used were chromel–alumel, calibrated at the freezing points of C. P. $K_2Cr_2O_7$, KCl, and NaCl.

C. P. sulfur was recrystallized twice from redistilled carbon disulfide and then twice distilled in a stream of nitrogen. At each distillation approximately one-fourth of the original amount was rejected. On the second distillation, the vapor was condensed in the Vycor tube, of 10 mm. i. d., to be used in the magnetic measurements, and the tube was evacuated and sealed. The mass of sulfur contained was determined after the experiments by evaporating all sulfur out of the tip of the bulb, breaking the tip, weighing before and after driving the sulfur out at 500° in the muffle furnace. Two samples were used in the measurement, one of volume 9.90 cc. containing 57.0 mg. S, and the other 9.85 cc. containing 46.7 mg.

The field strength was 8080 oersteds.

The force due to the magnetic field upon the bulb alone was taken as the force on the bulb and contents at room temperature, since the force upon small amounts of solid sulfur condensed in the tips of the bulb in regions of approximately constant field strength is negligible. The temperature independence of susceptibility of the Vycor tubing used was verified by measurements at room temperature and 850° upon an empty bulb. The force upon the empty bulb was, within the average deviation, the same at both temperatures.

Results and Discussion

At 850° and vapor density 5.76 mg./cc., the force of the field upon the sulfur vapor, after correcting for the force due to the bulb, was 1.69 mg. in the direction of paramagnetism. The cross-sectional area of the bulb was 0.785 sq. cm. The calculated volume susceptibility was 6.47×10^{-8} c. g. s. unit. The volume susceptibility due to the diamagnetism of sulfur may be calculated from the mass susceptibility which was assumed to be -0.49×10^{-6} c. g. s. unit; this leads to a diamagnetic volume susceptibility at this density of -2.8×10^{-9} c. g. s. unit. Thus the paramagnetic volume susceptibility, κ, was 6.75×10^{-8} unit.

In the same manner were calculated the susceptibilities at other temperatures and those for the sample of density 4.74 mg./cc. The cross-sectional area of the second bulb was 0.810 sq. cm. These data are tabulated in Table I.

In order to compute the molar susceptibility of S_2, it is necessary to evaluate its partial pressure in the mixed vapor. Preuner and Schupp[2] have determined the equilibrium constants for the reactions

$$S_8 = 4S_2 \quad (1)$$
$$S_6 = 3S_2 \quad (2)$$

at several temperatures, including 550, 650 and 850°, and these constants were used directly. A plot of log κ against $1/T$ from 450 to 850° is very nearly linear in both cases, and the constants at 750°, obtained from the plot, were: (1) $K_{mm.} = 1.5 \times 10^{12}$ and (2) $K_{mm.} = 5.1 \times 10^{7}$. These direct constants differ somewhat from those calculated from the standard free energy equations of Kelley,[6] since his equations are based on the average data in a lower temperature range; however the difference is not of great significance in view of the relatively large probable error in the magnetic measurements.

It must be noted also that the above data were obtained at pressures generally below 1000 mm., while the present work necessitated pressures up to six times as high to obtain sufficient force on the sample. In the absence of thermodynamic data for the vapor species present it is impossible to evaluate what error is introduced by making this extrapolation; however, since the temperatures are high, it is unlikely that the error is of serious consequence. Similarly, it was necessary to assume ideal behavior for the computation of total pressures.

For the case of density 5.76 mg./cc., at 850°, the equilibrium data give the proportion of S_2 in the vapor as 90.2 weight per cent. This leads to a molar paramagnetic susceptibility of 8.3×10^{-4} c. g. s. unit and a Curie constant, $\chi_M T$, of 0.93. Similar results for the other cases are tabulated in Table I. The susceptibilities given are the paramagnetic part only, as in each case the observed volume susceptibility was corrected for the diamagnetism of the entire mass of sulfur present.

(6) Kelley, *U. S. Bur. Mines, Bull. No.* **406** (1937).

In Fig. 1 is shown the observed variation of combined paramagnetic and diamagnetic volume susceptibility with temperature, compared to that calculated by the use of the Van Vleck equation, the diamagnetism of sulfur, and the equilibrium constants of Preuner and Schupp.

The relative probable error in the measurements based solely upon the distribution of values of the force of the field upon the sample, as a result of four or five determinations at each temperature, was about 3% at 850° and increased progressively to about 20% at 550° where the force was much smaller. Errors in temperature, field strength, and equilibrium data would increase the relative error at 850° to perhaps 7% but would be swamped by the observational error at the lower temperature. The error in the average $\chi_M T$ (excluding values at 550°) is thus about 10%.

The theory of Van Vleck[7] predicts that the molar susceptibility of molecules in the $^3\Sigma$ state, having small multiplet intervals, is

$$\chi_M = \frac{N\beta^2}{3KT}[4S(S+1)] = \frac{0.993}{T}$$

At 850° this leads to a value of 8.83×10^{-4} unit, in good agreement with the observed average of the two samples, $9.0 \times 10^{-4} \pm 0.6 \times 10^{-4}$. Neel[3] reported 5.4×10^{-4} unit.

The average value of $\chi_M T$, excluding the values at 550°, is 0.91 ± 0.09, compared to the theoretical value of 0.993.

These data serve to show that the ground state of diatomic sulfur is undoubtedly the triplet state, and further that the equilibrium data of Preuner and Schupp predict quite satisfactorily the proportion of S_2 in sulfur vapor between 550 and 850°.

A similar study of the ground state of Se_2 is to be undertaken by this laboratory in the near future.

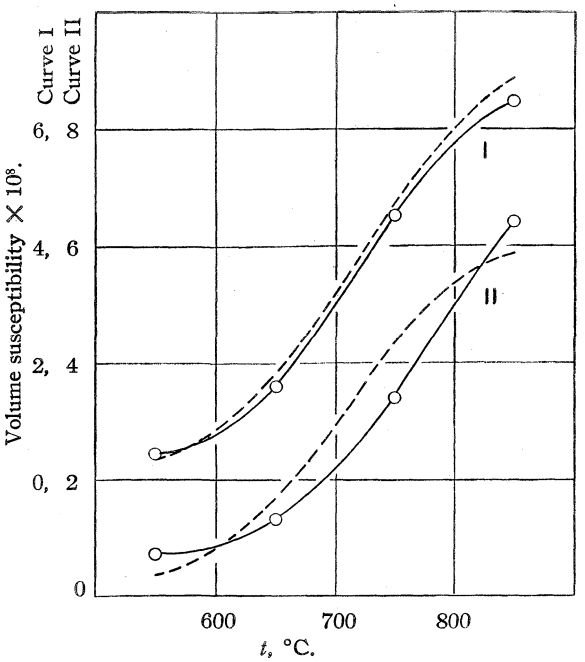

Fig. 1.—Volume susceptibility of S vapor: I, density 5.76 mg./cc.; II, density 4.74 mg./cc.; broken curves, calculated.

Summary

The molar susceptibility of S_2 at temperatures between 550 and 850° has been measured and found to agree with the theoretical value within the limits of experimental error. The existing equilibrium data predict satisfactorily the proportion of S_2 in sulfur vapor between 550 and 850°.

The Solubility of Nitrogen in Carbon Disulfide, Benzene, Normal- and Cyclo-hexane, and in Three Fluorocarbons

BY J. CHR. GJALDBAEK[1] AND J. H. HILDEBRAND

Introduction.—The extraordinary solubility relations of fluorocarbons have been the subject of three recent papers from this Laboratory; Scott[2] assigned figures for the "solubility parameters" needed in order to apply the modern theory of regular solutions, and showed their general consistence with the initially fragmentary data. Benesi and Hildebrand[3] determined the solubility of iodine in perfluoro-*n*-heptane, finding a value which, although only 0.027 of its solubility in normal heptane, is nevertheless consistent with theory. Hildebrand and Cochrane[4] determined liquid–liquid solubility curves for perfluoromethylcyclohexane with five organic liquids and likewise found reasonably good agreement with theory. The most illuminating investigation to undertake next appeared to us to be the solvent powers of these substances for gases. Their exceedingly low solvent power for a substance such as iodine implies high solvent power for gases, but there remained the question

whether the gases, at the one end of the scale, would fit the theory as well as does iodine, at the other.

Since the theory has been derived from a model process in which two pure liquids are mixed, the reference of the activity of a gas to a hypothetical liquid above its critical temperature has made the values for ideal solubility[5] heretofore used rather uncertain. An additional uncertainty is introduced by the large discrepancy between the molal volumes of nitrogen and the solvents, particularly the fluorocarbons.

Apparatus and Procedure.—The apparatus and procedure were approximately those of Lannung.[6] The volume of the gas buret was 7 cc., that of the flask, 55 cc. The temperature of the air thermostat was constant within 0.05° in the range 25–50° and within 0.1° at the lowest temperatures, which were in the neighborhood of 2°.

Materials.—The nitrogen was from Stuart Oxygen Co. (99.996% N_2). The three fluorocarbons, from E. I. du Pont Co., were fractionated by distilling in a Vigreux column and the middle portions used showed the following boiling points: perfluoro-*n*-heptane (C_7F_{16}) 82.3–82.4° (753.7 mm.), perfluoromethylcyclohexane (C_8F_{14}) 76.5–76.6° (760.0 mm) and perfluorodimethylcyclohexane (C_8F_{16}) 102.4–102.6° (760.0 mm.). Carbon disulfide ("analytical reagent") by Mallinckrodt showed a negative test for polysulfides and a fraction was used boiling at 45.80–45.85° (750.1). *n*-Hexane ("research grade") by Phillips Petroleum Company was used without further treatment. Cyclohexane by Paragon Testing Laboratories was fractionated by distillation and a portion with boiling point 80.63–80.66° (755.7 mm.) was taken. The benzene was that used by Benesi and Hildebrand.[3]

It is necessary to know the vapor pressure of the solvent in each experiment in order to calculate the solubility of the solute gas at a partial pressure of one atmosphere. For the three fluorocarbons we used the values given by Fowler and co-workers.[7] Their values for perfluoro-*n*-heptane are in good agreement with those of Barber.[8] For the other solvents, we used the values given in "International Critical Tables."

The densities of perfluoro-*n*-heptane were those of Grosse and Cady[9]; for perfluoromethylcyclohexane we determined $d^{25.0}$ 1.7859, and for perfluorodimethylcyclohexane $d^{25.0}$ 1.8400, $d^{35.1}$ 1.8126 and $d^{46.8}$ 1.7834. The other densities needed were taken from the "International Critical Tables."

Results.—The results are expressed in Table I in terms of the Bunsen absorption coefficient, $\alpha = 760\ V^g/pV^l$; V^g referring to the volume of the gas measured at the temperature of the experiment in the volume, V^l that of the solvent. Pressure is in mm. mercury. An example of the calculation is given in detail in an earlier paper.[10] The table gives, also, values of x_2, the mole fraction of the dissolved gas, at 0, 25, and 50°, derived from the observed values.

[a] (1) indicates that the experiment was performed from the same charge of solvent and gas; (2) indicates experiments with a new charge.

Guerry[11] reported $\alpha = 0.213$ for nitrogen in *n*-hexane at 25° and 0.149 in cyclohexane, both lower than our values. Just[12] reported $\alpha = 0.0526$ for its solubility in carbon disulfide, much lower than our figure. These redeterminations were made because of gross discrepancies[5] for other gases between Guerry and McDaniel, on the one hand, and Just and Horiuti,[13] on the other. One may infer from a comprehensive survey of the data on gas solubilities that all the results published by McDaniel and by Just are somewhat low, due possibly to insufficient degassing of solvents. Our figure for benzene, $\alpha = 0.124$, agrees well with the one found by Horiuti, 0.121.

Correlation with Theory.—The senior author[14] pointed out, in 1916, that Raoult's law, $p = p^0x = 1$ atmosphere, could be used to define an "ideal" gas solubility, even above the critical temperature of the gas, by obtaining a fictitious value for p^0 by plotting log p *vs.* $1/T$ for the vapor pressure of the gas. This gives a practically straight line right up to the critical point,[5] and its extrapolation to still higher temperatures yields values of p/p^0 which are close to the measured solubilities of gases in solvents of low internal pressure such as hexane. He showed, further, that the solubility falls off regularly with increasing internal pressure of the solvent. We had long ago obtained in this way, for nitrogen $p^0 = 1000$ atmospheres and $x^i = 0.0010$ when $p = 1$ atmosphere, while Guerry reported 0.00125 in *n*-hexane.

In order to take into account the different internal pressures of the solvents, we may use the equation[15]

$$-\ln x_2 = -\ln x_2^i + (\bar{v}_2/RT)(\delta_1 - \delta_2)^2 \qquad (1)$$

where the subscript 2 now refers to the solute gas and subscript 1 to the solvent, and the δ's are "solubility parameters," defined, for liquid components, as the square roots of their energy of vaporization per cc. The senior author[16] found that an equation of this type, with a semi-empirical adjustment of parameters, could account well for the solubilities of argon, and Gonikberg[17,5] applied it successfully to the solubilities of hydrogen.

When pure normal liquids are mixed, the expansion is ordinarily very small, and we can set $\bar{v}_2 = v_2$ with but little error. In the case of nitrogen solutions at 25° we have no pure liquid volume but we can use the values of $\bar{v}_2$ determined by Horiuti,[13,5] who found 53 cc. per mole in both benzene and carbon tetrachloride, and values not significantly different from 53 in other solvents. Although ideally one would wish to calculate solubility from the properties of the pure components, the values obtained by Horiuti for all the gases in this class can be used in combination with the other necessary data for the practical task of calculating the solubilities of these gases in new solvents. The proper value of δ_2 to use for nitrogen solutions can best be determined, for practical purposes, from the data themselves, but if we adjust one uncertain parameter in order to fit the data we might as well adjust another also. It is possible to use $x_2^i = 10^{-3}$ and $\bar{v}_2 = 53$ cc. and to select empirically a value for δ_2 which permits the calculation of solubilities agreeing rather well with the measured ones in all solvents except the fluorocarbons, where the calculated values are definitely too small. This suggests introducing a correction of the Flory–Huggins[18] type based upon the ratio of molal volumes, which alters Eqn. 1 to

$$-\log x_2 = -\log x_2^i + \log(\bar{v}_2/v_1) + 0.434(1 - \bar{v}_2/v_1) + \bar{v}_2(\delta_1 - \delta_2)^2/4.575T \qquad (2)$$

We have set $x_2^i = 1.6 \times 10^{-3}$, $\bar{v}_2 = 53$ cc., and $\delta_2 = 5.2$ to obtain the calculated values of solubility given in the fourth column of figures in Table II.

TABLE II

CS_2	60	10.0	3.65	3.69	+ .04	3.60	− .05

[a] With $-\log x_2^i = 2.70$.

The differences, Δ_2, between calculated and experimental values in the next column, give an idea of the errors involved. Going from C_7F_{16} to CS_2, the value of $\log \bar{v}_2 - \log v_1 + 0.434(1 - \bar{v}_2/v_1)$ increases from −0.30 to 0.00 while the value of $\bar{v}_2(\delta_1 - \delta_1)^2/4.575T$ increases from 0.02 to 0.90. We see that Eqn. 2 accounts for solubilities greater than the ideal value in liquids with large v_1, and for solubilities less than the ideal value in liquids with large δ_1, while Eqn. 1 is only able to account for solubilities less than the ideal value since the term $\bar{v}_2(\delta_1 - \delta_2)^2/4.575\,T$, is always positive. The degree of agreement yielded by this equation with "best" values of the parameters is shown in the last two columns of Table II. A few polar but not associated liquids are included in Table II.

From a practical standpoint, the solubility of any of the super-critical gases can now be approximately predicted in any new non-polar solvent from the δ-value of the latter by simple interpolation with known solvents, since we are in possession of data for all of these gases in a series of solvents. It will be seen that the order of the measured solubilities in Table II closely follows the δ-values of the solvents. It is obvious, nevertheless, from the data in this paper, that there is much room for refinement in the present theory of gas solubility.

We may note that, having measured the solubility of nitrogen in two of the solvents at more

(14) J. H. Hildebrand, THIS JOURNAL, **38**, 1452 (1916); **42**, 1067 (1919); also, N. W. Taylor and J. H. Hildebrand, *ibid.*, **45**, 682 (1923).

(15) For the history of this equation see ref. 5, Chapter VII.

(17) M. G. Gonikberg, *J. Phys. Chem., USSR*, **14**, 582 (1940).

(18) For an account of this development, see ref. 5, also, J. H. Hildebrand, *J. Chem. Phys.*, **15**, 225 (1947).

than one temperature, we are in a position to calculate the heat of solution of nitrogen in these solvents by the aid of the relation

$$\left(\frac{\partial \ln x_2}{\partial T}\right)_{p_2} = -\left(\frac{\partial \ln x_2}{\partial \ln p_2}\right)_T \left(\frac{\partial \ln p_2}{\partial T}\right)_{x_2} = \frac{-\bar{H}_2}{RT^2}$$

since the nitrogen obeys Henry's law in these very dilute solutions and therefore $(\partial \ln x_2/\partial \ln p_2)_T = 1$. The values in Table I yield $\bar{H}_2 = -140$ cal. in perfluoro-*n*-heptane and -260 cal. in perfluorodimethylcyclohexane. These values are small and obviously subject to considerable percentage error.

A few remarks may be added concerning the point mentioned above, that of stretching a theory based upon mixing liquids to cover the solubility of a gas above its critical temperature. First it would be quite possible to go back to an early step in the derivation of Eqn. 1 where the potential energy of a liquid mixture relative to its two gaseous components is expressed in terms of the liquid structure, and to subtract therefrom only the potential energy of the pure liquid solvent, which would give an expression for the partial molal energy of the solution of the gas. Its free energy of solution at the equilibrium pressure and composition is of course zero. If we had a satisfactory expression for the entropy of solution of the gaseous component, the problem would be solved, but unfortunately we have not been able to express the entropy of this process as satisfactorily as we have the entropy of mixing two liquids to form a regular solution.

Acknowledgment.—We express our gratitude to Dr. J. M. Tinker, Director of the Jackson Laboratory, E. I. du Pont de Nemours Co., for the substituted perfluoro-cyclohexanes used in this research, and to the Office of Naval Research for financial support.

Summary

1. Values for the solubility of nitrogen have been determined, expressed as Bunsen coefficient. In *n*-perfluoroheptane, 0°, 0.411; 25°, 0.385; 50°, 0.360; perfluoromethylcyclohexane, 25°, 0.375; perfluorodimethylcyclohexane, 25°, 0.328; 50°, 0.317; *n*-hexane, 25°, 0.239; cyclohexane, 25°, 0.156; benzene, 25°, 0.124; carbon disulfide, 25°, 0.0823.

The above data are tabulated with existing data for six other solvents and it is shown that the order of solubility, expressed as mole fraction, closely parallels the order of the "solubility parameters," defined as the square roots of their energies of vaporization per cc.

3. The solubility equation for regular solutions, with a semiempirical adjustment of its parameters, yields calculated values in fair agreement with the experimental ones, except in the case of the fluorocarbons, where the experimental values are larger. This discrepancy is attributed to the unusually large molal volumes of these solvents because it is considerably reduced by introducing a correction of the Flory–Huggins type.

Ultraviolet Absorption Study of the Ionization of Substituted Phenols in Ethanol

BY NORMAN D. COGGESHALL AND ALVIN S. GLESSNER, JR.

It is well known that the ultraviolet absorption spectra for the anions or cations of many polar substituted aromatic materials are markedly different from the spectra obtained for the compounds themselves. The spectra of the ions generally exhibit a large bathochromic shift of the absorption ascribed to the phenyl ring chromophore. In addition the intensity of absorption is increased. Since the spectral shift is large, often of the order of 20 mμ or larger, it provides a method whereby dissociation constants may be determined. Ordinarily these cannot be calculated from the spectrophotometric data alone but depend also on separately determined values of *p*H or on previously determined equilibrium constants which are pertinent to the processes involved.

In this manner Stendstrom and co-workers[1,2] demonstrated that the shift of the phenol spectrum induced by the addition of sodium hydroxide is due to the creation of the phenolate ions. From their data they obtained a value of the dissociation constant for phenol. Using the same procedure, Flexser, Hammett and Dingwall[3] calculated the ionization constants for benzoic acid, 2,4-dinitrophenol and acetophenone. More recently Ewing and Steck[4] have utilized this phenomenon in studies of the acidic and basic properties of quinolinols and isoquinolinols. Similar studies were made of various 4-aminoquinolines by Irvin and Irvin.[5]

The present studies are of the substituted phenols. The substituted phenols may be divided into three classes according to their steric hindrance to inter-molecular hydrogen bonding.[6] Phenols with the ortho positions either unsubsti-

tuted or occupied by a small group such as a methyl are known as unhindered phenols. Those with one ortho position occupied by a large group such as a *t*-butyl and the other either unsubstituted or occupied by a small group are known as partially hindered phenols. Those with both ortho positions occupied by large groups are known as the hindered phenols. It is well known that the same type of hindrance that influences intermolecular hydrogen bonding is effective in hindering intermolecular association effects which influence the ultraviolet absorption spectra of the phenols.[7] The hindered phenols, for example, exhibit quite small spectral changes between examination in paraffin and in polar solvents such as ethanol whereas large changes are observed for the unhindered and partially hindered phenols. The differences have been interpreted as due to the different degrees of proximity possible between the hydroxyl groups of the phenols and the polar groups of the solvent.

In view of the above results it is to be expected that the behavior of the various phenols in a solvent containing a strong base such as sodium hydroxide will vary in accordance with the steric hindrance of the above type. Since the formation of a phenolate ion involves the removal of the hydrogen nucleus from the hydroxyl group any shielding such as offered by large groups on the ortho positions would be expected to be effective in reducing the ionization. It is important to evaluate such effects not only as a method of determining the relative acidity of the various phenols, but also in order to provide information pertinent to a detailed consideration of the ionization processes in the liquid phase. The present report is of a study of the ultraviolet absorption spectra of a series of substituted phenols in ethanol and in ethanol containing sodium hydroxide. The data are interpreted in terms of the influence of steric hindrance on the ionization.

Experimental

All of the absorption spectra were obtained with the use of a Beckman Quartz Spectrophotometer equipped for work in the ultraviolet. In some of the preliminary investigations a study was made of the dependence of spectral changes on temperature. For this the temperature controlled absorption cell compartment previously described[7] was used. A Precision Scientific Company constant temperature bath was employed to provide the water used to regulate the temperature of this compartment.

With the exception of the simpler ones, the substituted phenols studied were prepared in this Laboratory.[8,9] There was evidence that each compound used was at least 99% pure. Such other chemicals as were used were the best available commercially and were, when necessary, further purified by recrystallization. Absolute ethanol was used as the solvent in all cases. Effects due to benzene in the ethanol were eliminated by using the same solvent in the comparison cell as used in the sample cell.

In these studies the ethanol solutions containing hydroxyl ions were prepared by the use of aqueous solutions containing one mole/liter or more of sodium hydroxide or of other bases. Solutions containing other inorganic materials were prepared in the same general manner. In every case the reference cell was filled with the same combination solvent as used for the particular phenol being investigated. In this manner any errors or discrepancies which might have been introduced through impurities in the sodium hydroxide or other inorganic material were avoided.

Data and Discussion

Preliminary Experiments.—In examining the literature on the subject of changes of ultraviolet absorption spectra of polar substituted aromatics induced by addition of specific types of ions in the solvent, it was apparent that sufficient proof that the shifted spectra are due to ionized solute was lacking. It was desirable to obtain further data to verify that this explanation is correct and the effect is not due to intermolecular effects such as hydrogen bonding or the formation of transient complexes between neutral molecules and ions. For that reason a number of experiments were performed on phenols in ethanol containing various inorganic materials. The fact that the present work was done with ethanol as the solvent instead of water, as was the case for most of the previous work, made it further desirable that such experiments be done. This was to verify that the processes were the same for the two solvents.

p-Cresol was examined in solutions containing the bases sodium hydroxide, lithium hydroxide, potassium hydroxide, calcium hydroxide, barium hydroxide, and ammonium hydroxide. The same spectral shift was observed in every case although with differences in degree of ionization. For a concentration of 3×10^{-4} mole/liter of *p*-cresol in solution a concentration of about 12 moles/liter of the weak base ammonium hydroxide was required for complete ionization whereas for lithium, sodium and potassium hydroxides, concentrations of less than one tenth mole/liter were sufficient. These data confirm previous work, but do not rule out the possibilities of complexes being responsible for the shift. Hence to determine if the phenomenon depended specifically upon the addition of hydroxyl ions data were obtained for *p*-cresol in solutions containing sodium chloride and hydrogen chloride. The resulting spectra were virtually indistinguishable from the spectrum obtained with pure ethanol as the solvent. Next a reversal procedure was tested on several phenols. In this the spectra were shifted by the addition of sodium hydroxide and then brought back to that observed

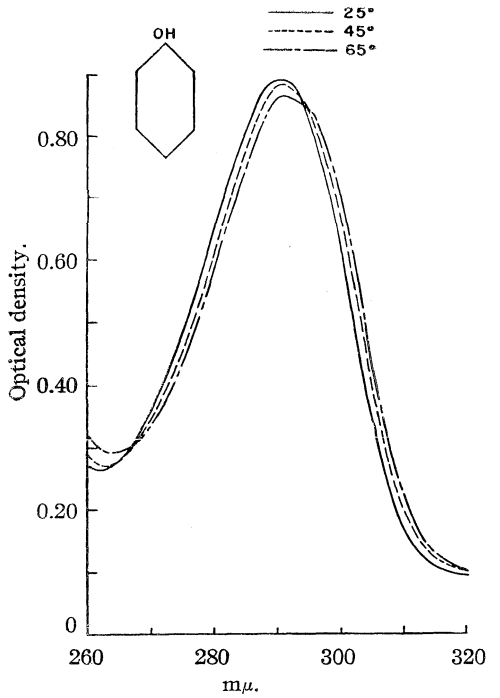

Fig. 1.—Ultraviolet absorption spectra of 2.8×10^{-4} mole/liter of phenol at various temperatures in ethanol containing 1.0×10^{-1} mole/liter of sodium hydroxide.

for pure ethanol solvent by the addition of hydrogen chloride to the same solutions. A complete reversal was achieved for each of the phenols tested, namely, *p*-cresol, 2-methyl-4,6-di-*t*-butylphenol and 2,4,6-tri-*t*-butylphenol.

nol and dioxane in a carbon tetrachloride solution is very strongly reduced by an increase of temperature from 20 to 55°. It would be expected that the energy per intermolecular hydrogen bond or complex between a phenol molecule and an ion would be of the same order of magnitude as for the complexes studied by Errera and Sack. Therefore, if the spectral shift considered here were due to such effects we would get at least a partial reversion to that observed for the ethanol solution when the temperature was elevated. In Fig. 1 may be seen the results for such a test on 2.8×10^{-4} mole/liter of phenol in an ethanol solution containing one-tenth mole/liter of sodium hydroxide. Here the optical density is plotted *versus* wave length. The optical density D is defined by $D = \log I_0/I$, where I_0 and I are the incident and transmitted energies, respectively. It may be seen that the rise in temperature to 65° produces only a very minor change and it is in the opposite direction to that which would be expected if the spectral changes were due to intermolecular effects. The same results were also obtained for 2-methyl-4,6-di-*t*-butylphenol and for 2,6-di-*t*-butyl-4-ethyl phenol. The preliminary experiments therefore all definitely confirm the ionization explanation for the spectral shift observed for the phenols.

Unhindered Phenols.—In Fig. 2 may be seen the data for three of the unhindered phenols examined. Here are given the spectra for the materials in pure ethanol and in ethanol containing one-tenth mole/liter of sodium hydroxide. The concentration of absorbing material is about the same in each case being 2.5×10^{-4} mole/liter for the *p*-*t*-butylphenol, 2.0×10^{-4} mole/liter for

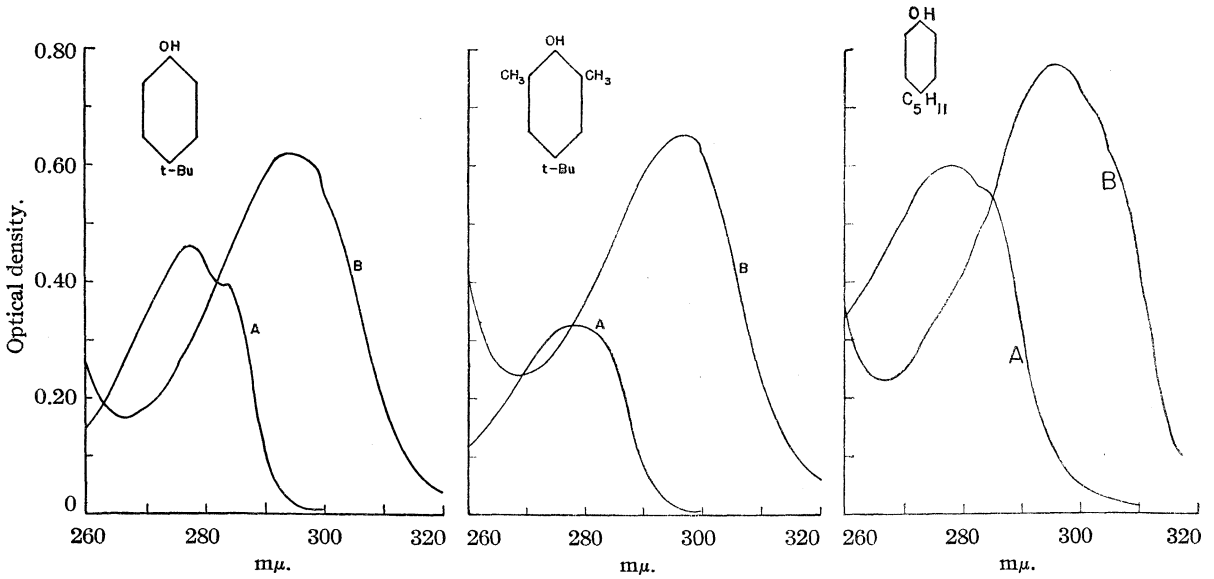

Fig. 2.—Ultraviolet absorption spectra of three unhindered phenols in: A, pure ethanol; B, ethanol containing 1.0×10^{-1} mole/liter of sodium hydroxide.

Errera and Sack[10] have shown that the population of intermolecular complexes between etha-

the 2,6-dimethyl-4-*t*-butylphenol, and 2.0×10^{-4} mole/liter for the *p*-*t*-amylphenol. It is to be noted that in each case there is a complete spectral

(10) J. Errera and H. Sack, *Trans. Faraday Soc.*, **34**, 728 (1938).

shift. By this is meant that the spectra observed for the solutions containing sodium hydroxide show no evidence for any un-ionized phenol molecules, *i. e.*, no maxima at the wave lengths at which the maxima occur for the compounds in pure ethanol solutions.

For solutions containing lower concentrations of sodium hydroxide two absorption maxima are observed, one representing the un-ionized phenol molecules, and one representing the phenolate ions. For the unhindered phenols a sodium hydroxide concentration of less than 1.0×10^{-1} mole/liter is sufficient to produce the complete spectral shift. However, as will be discussed below, the concentrations of sodium hydroxide at which the shifts become apparently complete were not determined as there are difficulties in utilizing these data in a quantitative manner. The sodium hydroxide concentration of 1.0×10^{-1} mole/liter was chosen as a convenient reference for comparison between the different classes of phenols. In Table I may be seen the wave lengths of maximum absorption for the various unhindered phenols in pure ethanol and in ethanol plus 1.0×10^{-1} mole/liter of sodium hydroxide. The spectral shift $\Delta(1/\lambda)$, calculated from these wave lengths, is also given. As the absorption bands are broad the maxima are only given to the nearest mμ. The values of $\Delta(1/\lambda)$ are therefore only reliable to two significant figures.

TABLE I

WAVE LENGTHS OF MAXIMUM ABSORPTION FOR UNHINDERED PHENOLS IN ETHANOL AND ETHANOL PLUS SODIUM HYDROXIDE AND $\Delta(1/\lambda)$ VALUES

Compound	λ max. (mμ) (ethanol)	λ max. (mμ) (ethanol plus NaOH)	$\Delta(1/\lambda)$ cm.$^{-1}$
p-Cresol	280	299	2200
p-*t*-Butylphenol	278	294	2000
p-*t*-Amylphenol	278	295	2100
m-Cresol	274	291	2100
o-Cresol	274	291	2100
2,6-Di-methyl-4-*t*-butylphenol	278	297	2300
Average value of $\Delta(1/\lambda)$ =			2100

Partially Hindered Phenols.—In Fig. 3 may be seen the behavior of three partially hindered phenols. The concentrations were: 1.5×10^{-4} mole/liter of 2-methyl-4,6-di-*t*-butylphenol, 1.7×10^{-4} mole/liter of 2,4-di-*t*-butylphenol, and 2.0×10^{-4} mole/liter of 2-*t*-butyl-4-methylphenol. It is immediately evident that a concentration of 1.0×10^{-1} mole/liter of sodium hydroxide which produced a complete spectral shift for the unhindered phenols, produces only a partial shift in the present cases. This is evident from the fact that the B curves all show maxima representative of the un-ionized material. In each case it is seen that these maxima are shifted to the red as compared to the maxima for the A curves. This is believed to be the result of an actual change in the absorption frequencies of the un-ionized material and of the geometrical superposition of the independent effects of the ionized and un-ionized materials. The latter effect was confirmed in a number of cases by the numerical construction of such intermediate curves. This was done by making suitable combinations of the data for the case of ethanol alone and the data for the 5.0×10^{-1} mole/liter of sodium hydroxide solutions wherein complete shifts were exhibited. The concentration of 5.0×10^{-1} mole/liter was somewhat more than necessary to produce the complete spectral shift, but was chosen as a convenient reference for comparisons between the various classes of phenols. In Table II are the values of the absorption maxima and of the $\Delta(1/\lambda)$'s.

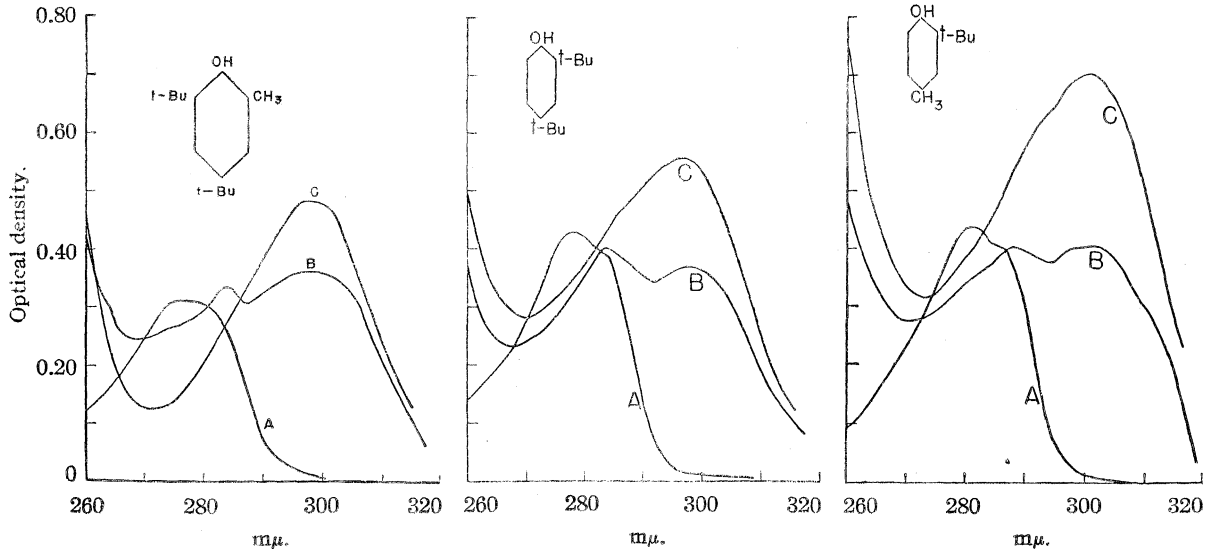

Fig. 3.—Ultraviolet absorption spectra of three partially hindered phenols in: A, pure ethanol: B, ethanol plus 1.0×10^{-1} mole/liter of sodium hydroxide, and C, ethanol plus 5.0×10^{-1} mole/liter of sodium hydroxide.

TABLE II

WAVE LENGTHS OF MAXIMUM ABSORPTION FOR PARTIALLY HINDERED PHENOLS IN ETHANOL AND ETHANOL PLUS SODIUM HYDROXIDE AND $\Delta(1/\lambda)$ VALUES

Compound	λ max. (mμ) (ethanol)	λ max. (mμ) (ethanol + NaOH)	$\Delta(1/\lambda)$ cm.$^{-1}$
2-Methyl-4,6-di-*t*-butylphenol	277	298	2500
2-*t*-Butyl-4-methylphenol	281	301	2300
2,4-Di-*t*-butylphenol	278	297	2300
3-Methyl-6-*t*-butylphenol	276	294	2200
Average value of $\Delta(1/\lambda)$ =			2300

Hindered Phenols.—In Fig. 4 may be seen the data for three hindered phenols. In each case the concentration of the phenol is approximately 1.7×10^{-4} mole/liter. It may be seen that a sodium hydroxide concentration of 1.0×10^{-1} mole/liter produces only minor spectral changes and that a concentration of 5.0×10^{-1} mole/liter which produces a complete shift for the partially hindered phenols is responsible here for only a partial shift. In the D curves are given the spectra for the phenols in the presence of 5.0 mole/liter of sodium hydroxide. Even this concentration does not produce a complete ionization.

TABLE III

WAVE LENGTHS OF MAXIMUM ABSORPTION FOR HINDERED PHENOLS IN ETHANOL AND ETHANOL PLUS SODIUM HYDROXIDE AND $\Delta(1/\lambda)$ VALUES

Compound	λ max. (mμ) (ethanol)	λ max. (mμ) (ethanol + NaOH)	$\Delta(1/\lambda)$ cm.$^{-1}$
2,6-Di-*t*-butyl-4-methylphenol	277	303	3100
2,6-Di-*t*-butyl-4-cyclohexylphenol	275	300	3100
2,4,6-Tri-*t*-butylphenol	275	302	3300
2,6-Di-*t*-butyl-4-ethylphenol	276	303	3200
2,6-Di-*t*-butyl-4-phenylphenol	266	302	4500
Average value of $\Delta(1/\lambda)$ =			3400

Discussion.—It is obvious from the data given in the figures that great differences exist between the three classes of phenols as regards their ease of ionization in ethanol solution. These differences are ascribed to the steric hindering effects of the large ortho substituents. Although one-tenth mole/liter of sodium hydroxide was sufficient to achieve complete ionization for the unhindered phenols it resulted in only partial ionization of the partially hindered phenols. A sodium hydroxide concentration of 5.0×10^{-1} mole/liter was sufficient to produce complete ionization for the latter compounds but definitely only produced a partial ionization of the hindered phenols. In addition the hindered phenols were not completely ionized by as much as 5.0 mole/liter of sodium hydroxide. This positively establishes the role of the large ortho groups in hindering the ionization.

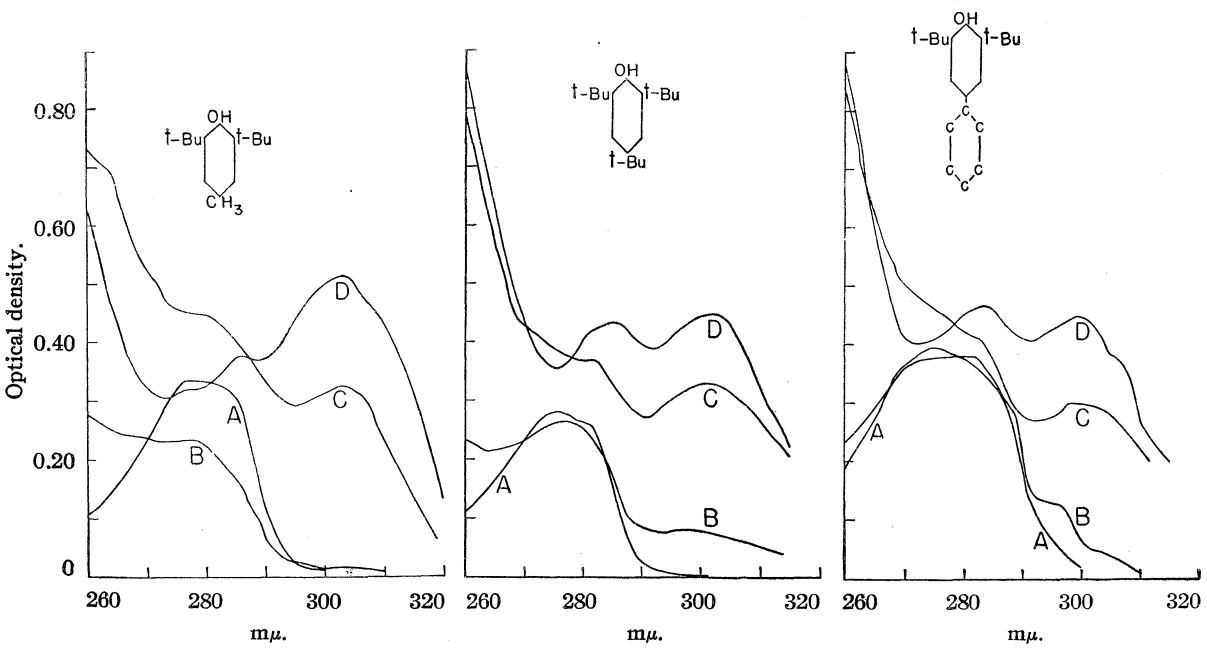

Fig. 4.—Ultraviolet absorption spectra of three hindered phenols in: A, pure ethanol; B, ethanol plus 1.0×10^{-1} mole/liter of sodium hydroxide; C, ethanol plus 5.0×10^{-1} mole/liter of sodium hydroxide, and D, ethanol plus 5.0 mole/liter of sodium hydroxide.

With the dilution scheme used it was impossible to go over about 5.0 mole/liter of sodium hydroxide due to the precipitation of sodium hydroxide. Hence the complete ionization of the unhindered phenols cannot be achieved in this manner. In Table III may be seen the wave lengths of maximum absorption and the $\Delta(1/\lambda)$ values.

There is a very interesting implication in the above data regarding the processes of ionization. The data show that the large groups on the ortho position sterically hinder the ionization. They are large in spatial extension and therefore shield the phenolic hydroxyl group from close approach by other molecules or ions. Since they also hinder the ionization, we may therefore assume that the ionization process is a result of a close approach or collision between a phenolic hydroxyl group and other molecules or ions. With this assumption the primary factors affecting ionization are the details of geometry and electric fields of the molecules and ions involved rather than gross dielectric properties.

It is evident from the data in the tables that there is a further difference between the spectral behavior of the phenols. The difference in frequency of maximum absorption $\Delta(1/\lambda)$ between the molecules and the phenolate ion is in each case expressed in wave numbers. This provides a measure of the differences of transition energies between the ground and first excited electronic states. As was stated above the wave lengths of maximum absorption are only reliable to about 1 mμ. Hence the $\Delta(1/\lambda)$ values are reliable to only two significant figures. Despite this limitation it is clear that a definite difference exists between the unhindered and partially hindered phenols. For the former the average value of $\Delta(1/\lambda)$ was 2100 cm.$^{-1}$, whereas it was 2300 cm.$^{-1}$ for the latter. This implies that the size of the ortho substituent affects the transition energy for the phenolate ion. This implication is further confirmed by a comparison between the partially hindered and the hindered phenols. The average value of $\Delta(1/\lambda)$ for the latter was 3200 cm.$^{-1}$, excluding a consideration of 2,6-di-*t*-butyl-4-phenylphenol. This compound has an anomalously high $\Delta(1/\lambda)$ value presumably due to some effect of the conjugation of the phenyl rings.

The data then show that the large groups on the ortho positions affect the energy of transition between the ground and the first excited electronic states of the phenolate ions. This may be explained as the result of the energy of polarization of the *t*-butyl groups by the electric fields resulting from the polar resonance forms of the first excited state. This carries a further implication that in the polar resonance forms which contribute the most to the first excited state there is an accumulation of electric charge on the number one position of the phenyl ring. This is necessary since it is the ortho substituents that affect the energy. Such an accumulation of charge would create large fields which would polarize the ortho substituents.

The above results make another tool available for the determination of molecular structure of phenols of unknown composition. Since the behavior of the three classes is different for each, a phenol of unknown composition may be examined under the various conditions and thereby assigned to one of the classes. Another application has been made to analytical problems. Ordinarily it is impossible to quantitatively analyze a mixture of mononuclear aromatic hydrocarbons and phenols by ultraviolet absorption. This is because the absorption is approximately the same for each class, being due to the phenyl ring chromophore. The addition of sodium hydroxide however results in the ionization of the phenols with the resultant spectral shift. This allows data to be obtained independently for the aromatics and for the phenols. Similar considerations apply to other polar substituted aromatics. If the material in question is basic the addition of an acid will result in ionization and the same type of spectral shift.

Acknowledgment is gratefully made to Dr. Donald R. Stevens and Dr. G. Stillson for furnishing some of the substituted phenols examined. Appreciation is also due Dr. Paul D. Foote, Executive Vice-President of Gulf Research & Development Company, for permission to publish this material.

Summary

A study has been made of the ultraviolet absorption spectra of substituted phenols in ethanol solutions containing sodium hydroxide. Preliminary work was done to verify that the spectral shift which occurs when sodium hydroxide is added is due to the formation of phenolate ions. This comprised tests with different bases, acids and salts; the reversal of the effect by the addition of acid to a basic solution; and a study of the temperature dependence of the spectral shift. The unhindered phenols gave evidence of complete ionization in solutions containing 1.0×10^{-1} mole/liter of sodium hydroxide. The partially hindered phenols were only partially ionized at this concentration of sodium hydroxide, but demonstrated complete ionization for a concentration of 5.0×10^{-1} mole/liter of sodium hydroxide. The hindered phenols were neither completely ionized with the latter concentration of sodium hydroxide nor for the much larger concentration of 5.0 mole/liter. These results demonstrate the great differences in acidity between the different classes of phenols and show that ionization is hindered by the presence of large ortho substituents. This leads to the conclusion that the process of ionization is the result of a collision or of a small distance of approach between the phenolic hydroxyl and other molecules or ions. The difference of energy of transition between the ground and first excited state for the neutral molecule and for the phenolate ion depends upon the type of phenol. An explanation is given which is based on the energy of polarization of the large ortho groups. Applications of the phenomenon to analytical and molecular structure problems are given.

The Reaction of Acetylene–Air Mixtures with Supported Silver Nitrate

BY K. A. KRIEGER

In the course of a study of methods for the removal of traces of acetylene from air, we have investigated the reaction of silver nitrate on various inert supports with air–acetylene mixtures.[1] These studies suggest the existence of a critical lower limit for the concentration of active component. We find that the concentration of silver nitrate required to produce measurable activity is a function of the surface area of the support material and is relatively independent of the structure of the support.

Experimental

Materials.—Silver nitrate was J. T. Baker C. P. grade, used without further purification.

Activated Alumina and Tabular Alumina were obtained from the Alumina Ore Company and used as received.

Prest-O-Lite acetylene was used usually without further treatment, but sometimes purified by passage through sodium bisulfite and sodium hydroxide solutions. No difference in behavior was observed. Measured quantities were introduced into steel pressure cylinders and made up to a total pressure of about 3000 lb./sq. in. with compressed air.

The oil used in the oil saturator was Socony-Vacuum DTE Heavy.

Catalysts were prepared by impregnation of the support with cold aqueous solutions of silver nitrate, followed by slow evaporation of the excess water at its boiling point and final drying at 100°. In all the preparations the weight of support and volume of impregnating solution were kept approximately constant, the concentration of solution being varied to give the desired final silver content. Activation was by heating in air for two hours at 200°, except as noted.

Methods and Apparatus.—As the primary purpose of this program was to find catalysts suitable for the removal of acetylene from air of composition similar to that at the output of oil lubricated compressors designed for air liquefaction equipment, the catalytic apparatus was set up to simulate these conditions. Air–acetylene mixtures were introduced into the apparatus through a reducing valve and rotameter, then passed through water saturator, oil saturator and reaction chamber, each electrically heated. The reaction chamber was a short length of stainless steel pipe provided with a thermocouple well. The water saturator was maintained at 65° and the oil saturator and catalyst chamber at 149°. Temperature could be controlled to about ±2°. In all runs the space velocity was 100,000 (S.T.P.) per hour, and the pressure 100 lb./sq. in. gage. Twenty cc. of catalyst was used in each run.

Known volumes of gas were collected for analysis through by-passes located immediately before and after the catalyst chamber, and acetylene was determined by a modification of the Ilosvay procedure.[2]

The operation of the apparatus has been described elsewhere.[1]

The catalytic activities reported are the results of at least two determinations and the reproducibility is of the order of ±3%.

Surface areas were measured with nitrogen using the BET method[3] and apparatus described by Krieger.[4]

X-Ray data were obtained with a Norelco X-ray Spectrometer using Cu Kα radiation.

Results and Discussion

The data obtained with Activated Alumina F-10 as support are shown in Table I. In this table the surface area has been calculated on two bases, S_c being the area per gram of catalyst and S_s the area per gram of support. S_{cx} is the area of the "exhausted" catalyst per gram of catalyst. The catalytic activity is expressed as per cent. acetylene removed from the air–acetylene mixture, A_3 being the activity after three hours operation and A_0 the activity at the beginning of the run. Under X are recorded the relative concentrations of silver nitrate and under Y those of metallic silver, as

determined by the intensity of X-ray diffraction, the subscripts f and x referring, respectively, to fresh catalysts and those partially exhausted by four hours of use.

The rapid decline in catalytic activity with use as shown by the differences between A_0 and A_3 raises the question as to whether the reaction is actually catalytic. Although under these conditions the total acetylene removed has never exceeded the ratio of one mole of acetylene to one of silver nitrate, other experiments[5] with higher acetylene and lower oxygen pressures have given a ratio greater than one. Since catalytic action is normally preceded by the formation of a complex between reactant and substrate, our conclusions would not, moreover, be affected even if the reaction were not truly catalytic.

Silver Concentration and Activity.—The very sudden rise in A_3 beginning at about 5% and approaching a maximum at about 12% is a striking feature of these data (Fig. 1), and as it can be calculated from the dimensions of the silver nitrate

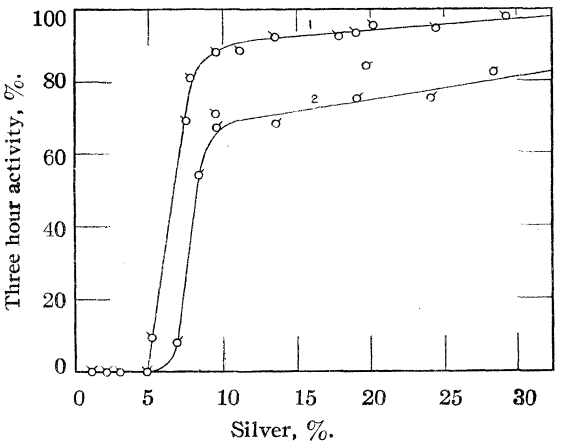

Fig. 1.—Catalytic activity *vs.* silver concentration on activated alumina F-10: ♉ 1, with 4–6 p. p. m. of acetylene; ♂, 2–10 p. p. m. of acetylene.

unit cell that about 12% silver would be required to produce a monolayer of the salt, it is tempting to ascribe the maximum to the completion of such a layer. Such a layer would not, however, be expected to yield a sharp diffraction pattern and Figure 2 shows that a strong pattern is produced considerably before 12% silver concentration is attained. As all of the diffraction patterns exhibited sharp lines we are compelled to conclude that even at the lowest concentrations which yield diffraction lines the silver nitrate crystals contain at least several hundred silver atoms, and that the failure to detect them at lower concentrations is to be attributed to limitations imposed by the sensitivity of the method itself. A comparison of A_0 with A_3 will show, furthermore, that the correspondence of X-ray detectable silver nitrate with catalytic activity does not hold where the activity

(5) To be published.

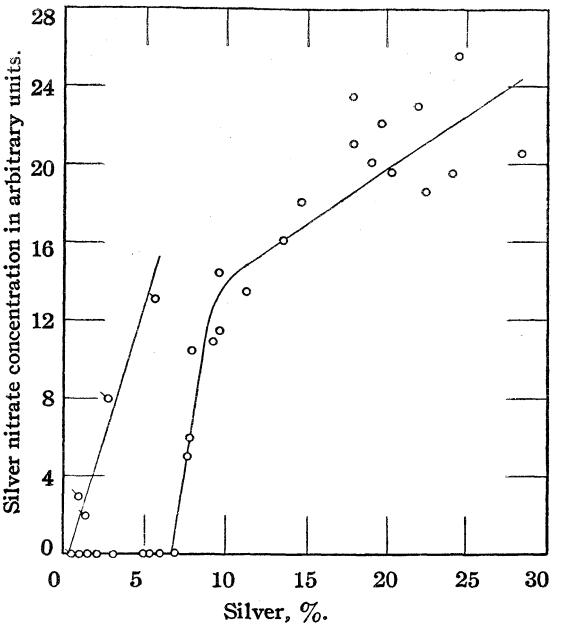

Fig. 2.—Crystalline silver nitrate content as a function of total silver concentration: O on F-10; ♉ on T-72.

is measured at the beginning of the run. The behavior of a second series of catalysts in which Tabula Alumina T-72 was used as support provides additional evidence against the monolayer hypothesis. Since the area of this support is about 0.2 sq. m./g. compared with nearly 130 sq. m./g. for F-10, maximum catalytic activity, if conditioned exclusively by the completion of a monolayer, should appear at about 1/600 of the silver concentration required to produce it on the high area support. The data of Table II demonstrate, however, that on T-72 maximum activity is not reached until the silver concentration is at least one-fifth of that required on F-10. This latter observation strongly suggests that in the case of the high area porous support a very considerable fraction of the silver nitrate is contained in pores so small that it

is catalytically inactive because diffusion limits access of the reactants to, or removal of the products from, the active surface. Taken in conjunction with these facts the similar maximum activities of catalysts prepared upon supports of such widely different areas points to catalytic activity confined to the "external" surface of the granules and practically precludes the possibility of specific effects due to differences in the support materials.

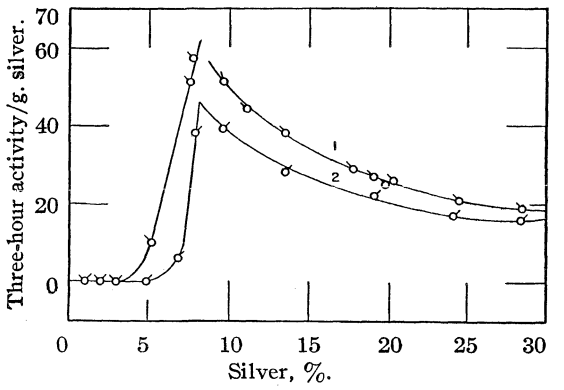

Fig. 3.—Catalytic activity per gram of silver *vs.* silver concentration: 1, with 4–6 p. p. m. of acetylene on activated alumina F-10; 2, with 8–10 p. p. m. of acetylene on activated alumina F-10.

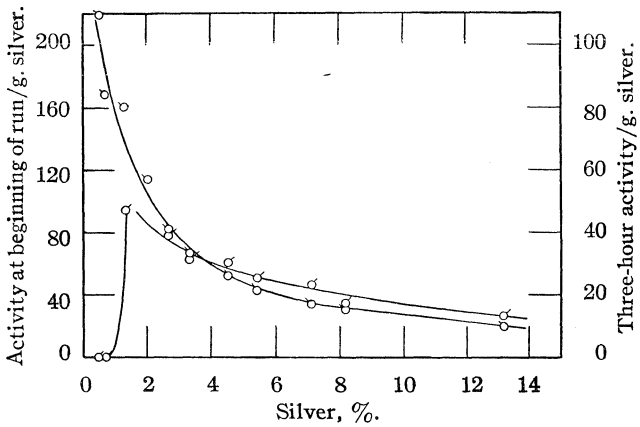

Fig. 4.—Catalytic activity as a function of silver concentration on T-72; 5 p. p. m. of acetylene: ○, A_0; ●, A_3.

The fact that the ratio of silver concentrations required to give measurable X-ray diffraction intensities on the two supports (Fig. 2) is of the same order as that needed to produce maximum values of A_3 seems to support the belief that the carriers are almost entirely non-specific in their action, functioning merely to provide more or less extended areas upon which the silver nitrate may be spread.

Although the close correspondence between the silver concentration required to give detectable diffraction effects and that at which A_3 is greater than zero must be regarded as fortuitous, the fact that the break in the curve for F-10 supported catalysts (Fig. 2) corresponds in silver concentration to the leveling off in Fig. 1 may be interpreted to mean that the thickness of the silver nitrate layer has become sufficiently great so that the lower layers contribute little either to catalytic activity or to diffraction intensity.

All of these data require that an explanation other than the completion of a monolayer be found for the sudden increase in activity with rising concentration. The nature of the problem can perhaps be clarified by plotting the specific activity (per gram of silver) as a function of silver concentration. This has been done in Figs. 3 and 4, inspection of which will show that there are two distinct regions to be accounted for. The higher concentration range, where the specific activity decreases with increasing concentration, is the more easily understood. Recent work[6] has shown that the specific activity of copper oxide and of chromia on alumina steadily decreased with increasing concentration of the active component and that at least in the case of chromia there was a distinct correlation between activity and dispersion as indicated by measurements of magnetic susceptibility. Selwood very reasonably interprets these results to mean that a high degree of dispersion is favorable to good catalytic activity. Though our data at higher concentrations support these experimental findings, the probability of occlusion of part of the silver nitrate in pores of the support or by overlying additional layers of the salt appears to offer an alternative explanation for the decrease in specific activity at the higher concentrations. The latter explanation may be offered with greater confidence in the case of catalysts supported on T-72, since even at the lowest concentrations studied there is enough silver nitrate present to furnish a covering ten "molecules" thick, and it is difficult to understand how the effective dispersion could change much in the higher concentration range.

The abrupt rise in activity (A_3) at lower concentrations is remarkable in that it does not begin at the concentration origin but is delayed to about 5 and 1% silver on F-10 and T-72, respectively. This observation would not be surprising if the supports themselves possessed any catalytic activity, since examples of this sort of promoter action are well known. Separate experiments have shown, however, that neither support has measurable activity by itself, and we have been unable to discover similar phenomena in the literature. It is worth noting that Selwood, whose measurements dealt in part with the same variables considered here, though in very different chemical systems, did not find a maximum.

There are several possible explanations for the delayed appearance of catalytic activity. The assumption might be made that a certain minimum "crystal" size of active component is necessary for activity. Such an assumption is not in itself un-

(6) Selwood and Dallas, THIS JOURNAL, **70**, 2145 (1948); Eischens and Selwood, *ibid.*, **70**, 2271 (1948); **69**, 2698 (1947).

reasonable, for it is generally recognized that heterogeneous reactions are normally preceded by an activated adsorption resulting from the operation of rather strong forces between catalyst and reactant. As these forces are clearly of the same general kind as those responsible for crystal growth, and are therefore probably coöperative in nature, it might be expected that they will not reach important magnitudes until the crystals attain sizes larger than those which correspond to the collection of but a few molecules. It should be emphasized that this picture does not conflict with Selwood's arguments in favor of a direct relationship between dispersion and activity, but simply serves to set a lower limit to the permissible dispersion. If this assumption is to be entertained, however, it is pertinent to inquire why Selwood did not find a similar maximum, and the explanation is perhaps to be found in the very different properties of the active materials in his experiments. Chromia and copper oxide are obviously substances in which the cohesive forces are very much greater than those in silver nitrate, as is evidenced, for example, by their much higher melting points and greater thermal stabilities, and it is quite possible that these cohesive forces are great enough to entirely prevent dispersion to the extent required to produce a diminution in activity or at least to limit such dispersion to still lower concentration ranges than those reported. It is a corollary of this explanation that maxima such as we have found ought to occur most readily when the active material is of low melting point.

Alternative explanations for the delayed rise in activity are possible, however. Since both oil vapor and acetylene, to a lesser extent, are known to cause a decrease in activity with time, it might be argued that the effects observed are due merely to the inactivation of the surface by these means. But experiments in which the time of exposure to oil vapor was purposely varied produced no appreciable effect and since the acetylene concentration does not much affect the position of maximum specific activity (Fig. 1), it does not appear that the observations can be accounted for exclusively by these processes.

A second explanation requires the assumption that small quantities of silver nitrate are lost by reaction with the support material to yield a compound not catalytically active. Although it is practically impossible to entirely rule out this possibility, since very small amounts of impurity might under certain circumstances have large effects, it is difficult to believe that the loss of as much as 5% silver could be accounted for by this means, and still more difficult to explain the relationships observed on high and low area supports in this way.

On the whole the catalytic evidence strongly suggests that crystal size has an important role in determining activity.

Surface Area and Activity.—The variation of surface area, per gram of support (S_s of Table I) with silver content is shown in Fig. 5, where the solid line is the least squares line calculated from all the points except "A." A decrease in area with rising concentration of active component has been observed before[6] and is what would be expected where a substance of low specific area covers pores in one of much higher area. Because of the scatter of experimental points, it is difficult to be sure that the slight rise in area up to about 3% silver is real, but there can be no question that other straight lines drawn through point "A" would not fit the data nearly so well, and it seems quite safe to say that the area does not begin to decrease significantly below about 5% silver. This observation again suggests that at low concentrations the crystals of silver nitrate are too small to effectively close the pores of the support.

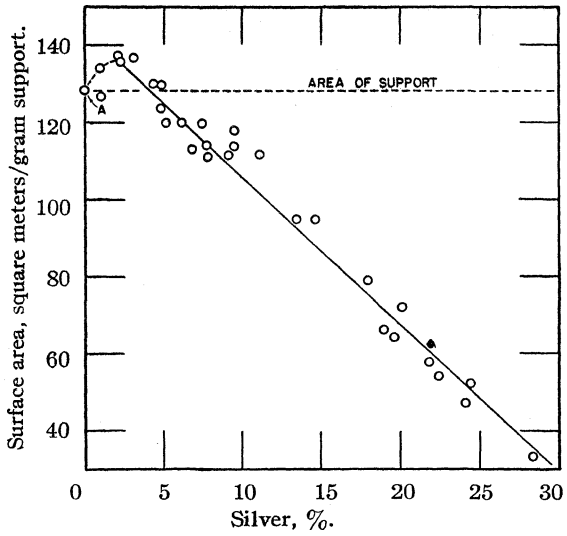

Fig. 5.—Surface area as a function of silver concentration on activated alumina F-10.

The effects of concentration on catalytic activity and surface area are all consistent with a picture of the catalyst as a collection of silver nitrate crystals, held mechanically on the carriers, whose size depends upon the surface concentration of the salt and whose activity in turn depends strongly upon size below a certain minimum size. At silver concentrations below about 12% on F-10 and about 2% on T-72 these crystals are discrete, but at higher concentrations they substantially cover the external surface of the supports.

Activation Temperature and Activity.—The effect of alterations on the time and temperature of activation are shown in Fig. 6. Both relative shapes and relative placement of the curves for one and two hour activation times indicate that the decline in activity occurring beyond the maximum is due to decomposition of the silver nitrate. In this connection the rise in area is significant; since it is found to correspond closely with the decrease in activity it may be interpreted to represent the gain in area resulting from the

decomposition of relatively compact silver nitrate crystals. Separate experiments have shown only a very slight decrease in the area of the support itself over the 200–400° temperature change. The sharp rise in activity to the maximum is probably associated with dehydration of the silver nitrate.

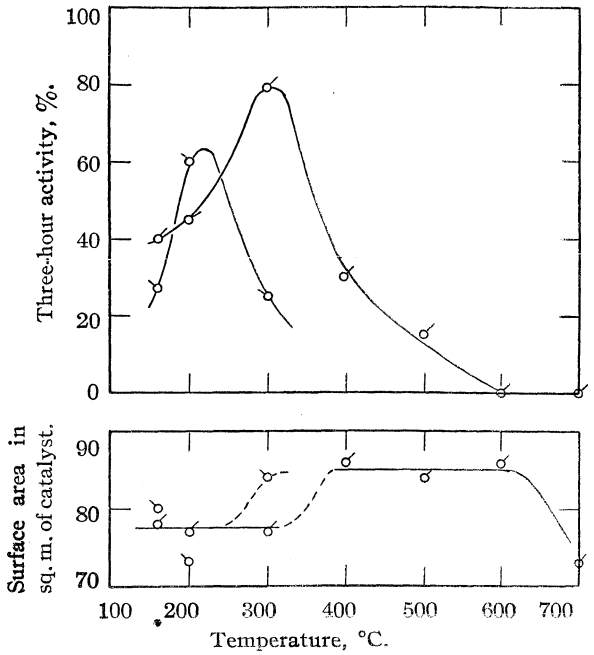

Fig. 6.—Activity and surface area as a function of time and temperature of activation, F-10, 5 p. p. m. C_2H_2: σ, 1 hr. activation; ϭ, 2 hr. activation.

Exhausted Catalysts.—During operation, changes in surface area and partial conversion of silver nitrate to metallic silver occur. Figure 7 (X_x and Y: of Table I) illustrates the latter change. Comparison of these data with those of Fig. 2 demonstrates that the minimum silver concentration required to yield detectable silver nitrate in fresh catalysts is very nearly the same as that required for metallic silver in an exhausted one and that for concentrations up to about 15% no crystalline silver nitrate is left unconverted by four hours of operation. That the diffraction intensity of silver does not continue to rise with increasing silver content means that conversion of silver nitrate to silver proceeds only to a fixed depth, no doubt because the silver itself protects the lower layers from attack. The slight but measurable decrease in silver intensity, coincident with the first appearance of unreduced silver nitrate at about 15% total silver, is probably due to the solvent effect of silver nitrate. The curve for silver nitrate intensity *vs.* total silver is practically congruent with that found for fresh catalysts (Fig. 2) but is translated to about 10% higher total silver concentrations; the magnitude of this translation sets only an upper limit to the amount of silver nitrate decomposed during operation,

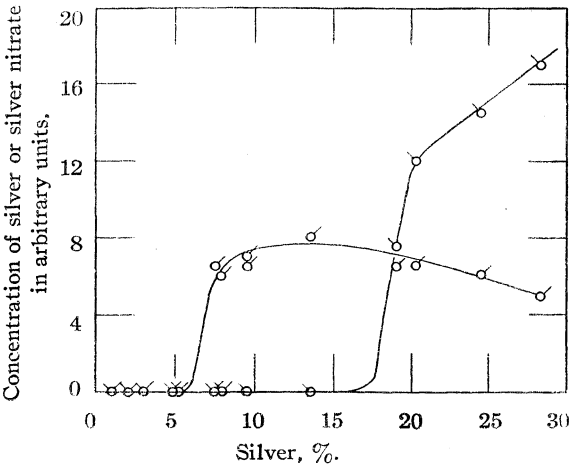

Fig. 7.—Crystalline silver and silver nitrate concentration on exhausted catalysts as a function of total silver concentration on F-10, 5 p. p. m. of C_2H_2: σ, silver; ϭ, silver nitrate.

because a correction of unknown size would have to be applied to the diffraction intensities observed in exhausted samples on account of the screening effect of the overlying layer of metallic silver. Data for a similar set of catalysts run with 10 p.p.m. of acetylene (Table I) give curves indistinguishable, within the experimental error, from Fig. 7.

Changes in surface area with use are shown in Table I and Fig. 8. The decrease in area at low silver concentrations is to be attributed to covering of exposed support surface by deposited oil vapor. As the silver concentration rises, so that more and more of the support surface is protected from oil vapor by silver nitrate, the decrease in area becomes less, and at about 12% silver the

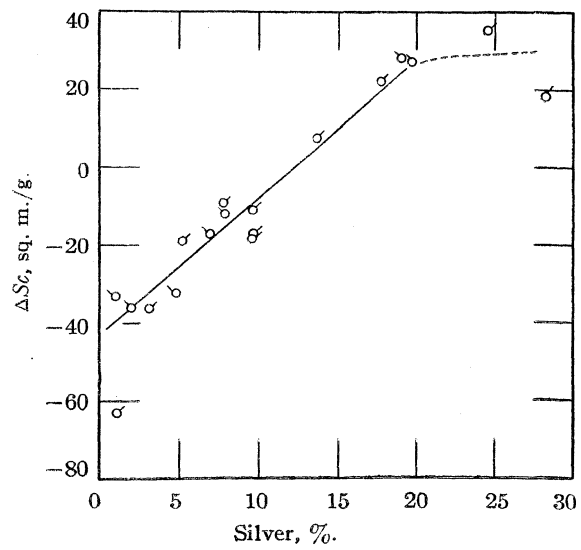

Fig. 8.—Change in surface area during use as a function of total silver content on F-10: σ, 5 p. p. m. of acetylene; ϭ, 10 p. p. m. of acetylene.

area does not change during use. It is noteworthy that this is about the silver concentration at which the catalytic activity levels off. The increase in area at still higher concentrations is probably due to increases in the area of the upper layers of the silver nitrate itself, accompanying its reduction to metallic silver, which has already been shown to occur. If this latter supposition is correct the increase in area might be expected to become nearly constant at the higher concentrations since data presented earlier indicate that only a limited amount of decomposition can occur. The points lying above 15% total silver which represents the largest amount of silver nitrate which can be decomposed under these conditions, do in fact suggest such a leveling off with ΔS_c equal to about 30 sq. m./g.

Acknowledgment.—The author wishes to express his thanks to the Thermodynamics Research Laboratory of the University of Pennsylvania and its sponsors the Navy Department, Bureau of Ships, for the support of this project, to Dr. T. A. Geissman for the design of the apparatus and for many contributions to the planning of the program, and to Messrs. D. Y. Dolman, R. F. Cree, Philip Mahoney and E. A. Fiero for much of the experimental work.

Summary

1. The activity of silver nitrate supported on alumina for reaction with acetylene–air mixtures has been studied as a function of silver nitrate concentration, area of support, temperature of activation, and acetylene concentration. Surface areas and X-ray diffraction patterns have been determined.

2. The activity is found to depend upon the ratio of surface area of support to concentration of silver nitrate, and arguments are advanced to show that maximum activity is attained when the support is covered with a multi-layer of silver nitrate.

3. Evidence is presented which leads to the hypothesis that a certain minimum crystal size is required for reactivity.

4. The effect of changes in activation temperature is related to chemical changes in the silver nitrate.

5. Factors causing decreased activity during the reaction are analyzed, and reduction of silver nitrate in the active layer is shown to occur to a limited extent. The change in surface area during use is found to be related to the decline in activity.

New Synthetic Methods for the Preparation of Lysine[1]

BY DAVID CYR SAYLES[2] WITH ED. F. DEGERING

Many syntheses of lysine have been published,[3] but only the von Braun[4] method and its improvement by Eck and Marvel[5] and Galat[6] seem to have commercial application. More recently, two closely related syntheses of DL-lysine, using dihydropyran as starting material[7,8] have been published by Rogers[7] and Gaudry.[8]

During this research, several methods were investigated. The first involves the splitting of ϵ-caprolactam[9] by hydrochloric acid and neutralization to give 6-aminohexanoic acid.[10] The rest of the process is similar to that developed by Eck and Marvel.[11] The ammonolysis of 2-bromo-6-benzoylaminohexanoic acid, however, is effected by the use of aqueous ammonia and ammonium carbonate in the presence of cuprous chloride, with a decided increase in yield.

Several methods which entail the use of 1-bromo-4-chlorobutane and 1-chloro-4-nitrobutane were investigated. These intermediates are prepared by direct chlorination of 1-bromobutane and 1-nitrobutane, respectively, in yields of 30–40%. Their utilization in the preparation of lysine are indicated by: n-BuBr $\rightarrow$ $Cl(CH_2)_4Br$ (35%) $\rightarrow$ $Cl(CH_2)_4CH(CO_2Et)_2$ (65%) $\rightarrow$ $Cl(CH_2)_4CBr(CO_2Et)_2$ (70%) $\rightarrow$ $Cl(CH_2)_4CHBrCO_2H$ (50%) $\rightarrow$ lysine dihydrochloride (55%).

n-$BuNO_2$ $\rightarrow$ $Cl(CH_2)_4NO_2$ (35%) $\rightarrow$ $O_2N(CH_2)_4CH(CO_2Et)_2$ (20%) $\rightarrow$ $O_2N(CH_2)_4C(:NOH)CO_2Et$ (25%) $\rightarrow$ $H_2N(CH_2)_4CHNH_2CO_2Et$ (9%) $\rightarrow$ lysine dihydrochloride (5%).

1,4-Dichlorobutane was first converted to 1-chloro-4-phenoxybutane, as indicated by: $Cl(CH_2)_4Cl$ $\rightarrow$ $PhO(CH_2)_4Cl$ (60%) $\rightarrow$ $PhO(CH_2)_4CHAcCO_2Et$ (40%) $\rightarrow$ $PhO(CH_2)_5CO_2H$ (50%) $\rightarrow$ $PhO(CH_2)_4CHBrCO_2H$ (85%) $\rightarrow$ $Br(CH_2)_4CHBrCO_2H$ (87%) $\rightarrow$ lysine dihydrochloride (81%).

An alternative method is: $PhO(CH_2)_5CO_2H \rightarrow Br(CH_2)_4CO_2H$ (60%) $\rightarrow Br(CH_2)_4CHBrCO_2H$ (85%) $\rightarrow$ lysine dihydrochloride (81%).

Reduction of monoethyl adipate, either catalytically using copper chromite and hydrogen or sodium and alcohol, yields a mixture of 6-hydroxyhexanoic acid and its lactone which can be converted to 6-bromohexanoic acid and finally lysine.

Experimental

Ammonolysis of 6-Benzoylamino-2-bromohexanoic Acid.—Ammonium hydroxide (250 ml., d. 0.98, 3.75 moles), ammonium carbonate (75 g., 0.9 mole), cuprous chloride (1 g., 0.005 mole) and 6-benzoylamino-2-bromohexanoic acid[11] (70 g., 0.22 mole) are placed in a shaking autoclave and heated at 100 to 150° for twelve to fourteen hours. The solution is then boiled for thirty minutes to decompose the ammonium carbonate, cooled, crystallized, filtered by suction, and washed with alcohol (50 ml.) and then with ether (50 ml.). The aqueous filtrate is evaporated to dryness under reduced pressure, the residue washed with two portions of water (50 ml.), then with ethanol (25 ml.), and finally with ether (25 ml.) to give 55 g. of product (m. p. 260–265°, 98–99%).

Lysine Dihydrochloride.—This compound can be prepared according to the method of Eck and Marvel.[11]

1-Bromo-4-chlorobutane.—A mixture of 1-bromobutane (1000 g., 7.4 moles), sulfuryl chloride[12] (1000 g., 7.4 moles), and benzoyl peroxide (20 g., 0.16 mole) is refluxed for ten to twelve hours until the evolution of gases ceases. The reaction product is then separated by distillation under diminished pressure. The final cut (b. p. 100 to 120° at 100 mm.) is fractionated through a 36-inch glass-packed column (b. p. 110–112° at 100 mm., yield 360 g., 35% of theory).

1-Bromo-4-chlorobutane.—1-Bromobutane (1000 g., 7.4 moles) was placed in a dispersion tube,[13] which was equipped with a condenser attached to a dry ice trap and a hydrogen chloride absorber. Chlorine (519 g., 7.3 moles) is bubbled slowly through the solution, which is illuminated by six 150-watt Mazda light bulbs. The unreacted chlorine is recycled. After complete addition of the chlorine, carbon dioxide is passed through the reaction product to displace the hydrogen chloride. The resulting product is fractionated through a 36-inch column (yield 350 g., 35% of theory, b. p. 110–112° at 100 mm.).

Diethyl 4-Chlorobutylmalonate.—Sodium (96 g., 3.0 moles) is dissolved in absolute alcohol (1000 g.) in a three-necked three-liter flask which is fitted with a mercury-seal stirrer, reflux condenser, dropping funnel, and drying tubes. Then, in order, are added diethyl malonate (480 g., 3.0 moles) and 1-bromo-4-chlorobutane (518 g., 3.0 moles). The reaction mixture is refluxed for four to five hours, the alcohol removed by distillation, and water added to the residue to dissolve the sodium bromide. The oil is separated and the aqueous solution is extracted with ether. The combined organic material is washed with water and dried over anhydrous sodium sulfate. The ether is evaporated, and the residue is distilled under diminished pressure through a 36-inch glass-packed column (500 g., 65% conversion, b. p. 145–148° at 10 mm.).

Diethyl 4-Chlorobutylbromomalonate.—A mixture of diethyl 4-chlorobutylmalonate (550 g., 2.2 moles) and chloroform (1000 ml.) is placed in a three-liter three-necked flask which is fitted with a stirrer, dropping funnel, reflux condenser, and drying tubes. Iodine (5 g.) is added, and then bromine (365 g., 2.3 moles) dissolved in chloroform (200 ml.) is added dropwise. The reaction mixture is then refluxed on a steam-bath for two to three hours until the evolution of hydrogen bromide ceases. The chloroform is recovered and the residue distilled under diminished pressure (b. p. 147–155° at 30 mm., yield 340 g., 70% of theory).

(12) Kharasch and Brown, THIS JOURNAL, **61**, 2142 (1939).

(13) Degering, *Ind. Eng. Chem.*, **24**, 181 (1932).

2-Bromo-6-chlorohexanoic Acid.—Diethyl 4-chlorobutylbromomalonate (387 g., 1.2 moles) is refluxed with concentrated hydrochloric acid (1500 ml., 9.8 moles) containing zinc chloride (100 g., 0.5 mole) for eighteen to twenty-four hours. The reaction mixture is cooled, extracted with benzene, and the benzene extract filtered. The filtrate is then extracted with aqueous sodium carbonate, and the alkaline solution is cooled and acidified with concentrated hydrochloric acid. The organic layer is taken up in ether, and the aqueous solution is then extracted with ether. The combined organic material is washed with water, dried over anhydrous sodium sulfate, and the ethereal solution is filtered, the ether recovered, and the residue distilled under reduced pressure (b. p. 93–95° at 5 mm., yield 135 g., 50% of theory).

Lysine Dihydrochloride.—Ammonium hydroxide (250 ml., 3.75 moles), ammonium carbonate (75 g., 0.87 mole), cuprous chloride (1 g.) and 2-bromo-6-chlorohexanoic acid (57 g., 0.25 mole) are placed in a shaking autoclave and heated at 175–200° for twelve hours. The contents of the autoclave are removed and filtered, the filtrate evaporated to dryness under diminished pressure, and concentrated hydrochloric acid (1000 ml., 6.6 moles) is added to the residue, which is then warmed for ten to fifteen minutes on a steam-bath. The solution is then evaporated, hot absolute alcohol (200 ml.) is added, the solution is filtered, then cooled to 10–15°. A small quantity of absolute ether is added to the filtrate to precipitate any ammonium bromide which is dissolved in the alcohol, and then filtered. Anhydrous ether (200 ml.) is slowly added with continuous stirring to the filtrate. The solid which separates is collected by filtration and dried (m. p. 183–185°, yield 30 g., 55% of theory).

1-Chloro-4-nitrobutane.—1-Nitrobutane (870 g., 7.7 moles) is placed in a dispersion tube[13] equipped with a reflux condenser, which is connected to a Dry Ice trap for the recovery of unreacted chlorine. Phosphorus pentoxide (30 g., 0.1 mole) is added, and chlorine (628 g., 8.9 moles) is slowly bubbled through the solution which is illuminated with nine 150-watt Mazda bulbs. Reaction occurs slowly, with a brief induction period, and the chlorination temperature ranges from 70–80°. The hydrogen chloride is then displaced by a stream of carbon dioxide. The product is poured into water, washed several times with water, and dried over anhydrous sodium sulfate. The material is distilled under reduced pressure (b. p. 100–105° at 10 mm. 370 g., 35% of theory).

Ethyl 2-Acetyl-6-nitrohexanoate.—Sodium (48.3 g., 2.1 moles) is dissolved in absolute alcohol (400 ml.) in a two-liter three-necked flask which is fitted with a mercury-seal stirrer, reflux condenser, dropping funnel, and drying tubes. Ethyl acetoacetate (273 g., 2.1 moles) is added, followed by the slow addition of 1-chloro-4-nitrobutane (214 g., 1.6 moles). The reaction mixture is refluxed on a steam-bath for four to six hours. The alcohol is then distilled, the residue diluted with water, the organic material separated, and the aqueous solution extracted with ether. The combined organic material is washed with water and dried over anhydrous sodium sulfate. The ether is evaporated, and the residue is distilled under diminished pressure (b. p. 153–158° at 9 mm., yield 67 g., 20% conversion).

Ethyl 6-Nitro-2-oximidohexanoate.—Ethyl 2-acetyl-6-nitrohexanoate (160 g., 0.7 mole), chilled to 0°, is mixed with *n*-butyl nitrite (120 g., 1.2 moles), chilled to 0°, and the mixture is then added gradually to a solution of sodium (20 g., 0.95 mole) in cold absolute alcohol (400 ml.) in a one-liter, three-necked flask, which is fitted with a mercury-seal stirrer, dropping funnel, reflux condenser, and drying tubes. The reactants are maintained at −10° for twenty-four to thirty hours by the use of an ice-salt-bath, then permitted to warm up to room temperature, and stirred an additional two to three hours. The alcohol is recovered under diminished pressure, the residue diluted with water, and the organic layer separated. The aqueous solution is extracted with ether, and then the aqueous solution is cooled and acidified with dilute sulfuric acid. The organic layer is again separated, and the aqueous

solution is extracted with ether. The combined organic material is washed with water, and then dried over anhydrous sodium sulfate (yield 38 g., 25% conversion).

Lysine Dihydrochloride.—Tin (60 g., 0.5 mole), water (60 ml.) and ethyl 6-nitro-2-oximidohexanoate (10 g., 0.046 mole) are placed in a 500-ml. three-necked flask, which is equipped with a stirrer, dropping funnel, and reflux condenser. Hydrochloric acid (100 ml., 0.65 mole) diluted with water (150 ml.) is slowly added, and the reaction mixture is then refluxed for four to six hours. The excess tin is removed by filtration, the aqueous solution is extracted once with ether, the filtrate is evaporated to dryness, and the residue is dried in a vacuum desiccator over concentrated sulfuric acid. The residue is then transferred to a Soxhlet thimble and extracted with absolute alcohol. The solvent is evaporated, and the residue is refluxed with 50% aqueous alcohol (100 ml.) containing sodium hydroxide (10 g., 0.25 mole) for four to five hours. The alcohol is recovered, the residue is acidified with hydrochloric acid and the solvent is then evaporated under diminished pressure. The residue is dissolved in a small quantity of alcohol, picric acid in alcohol is added, and the monopicrate is isolated. The product darkens above 215° and decomposes at about 233° (yield 0.9 g., 7% of theory).

4-Phenoxybutyl Chloride.—A mixture of water (1000 g.), 1,4-dichlorobutane (320 g., 2.5 moles), and phenol (185 g., 2.0 moles) is placed in a three-liter, three-necked flask which is equipped with a mercury-seal stirrer, reflux condenser, and a dropping funnel. The mixture is heated to boiling, a solution of sodium hydroxide (75 g., 1.9 moles) in water (250 ml.) is slowly added during one to two hours, and the reaction mixture is refluxed for seven to nine hours. The lower layer is separated, washed twice with 10% aqueous sodium hydroxide to remove any unreacted phenol, then washed with water, and finally dried over anhydrous sodium sulfate. The product is then distilled under diminished pressure (b. p. 135–138° at 12 mm., yield 200 g., 60% conversion).

Ethyl 4-Phenoxybutylacetoacetate.—Absolute ethanol (500 ml.) is placed in a two-liter three-necked flask, which is fitted with a mercury-seal stirrer, reflux condenser, dropping funnel, and drying tubes. Sodium (58 g., 2.5 moles) is added. After complete reaction, freshly distilled ethyl acetoacetate (325 g., 2.5 moles) is added dropwise while the reaction mixture is maintained under gentle reflux, and the mixture is then refluxed ten to twelve hours. The solvent is distilled, the residue is diluted with water, the organic material is separated, and the aqueous solution is extracted with ether. The combined organic material is washed with water, dried over anhydrous sodium sulfate, the ether recovered, and the residue distilled under diminished pressure. The distillate consists of unreacted materials, whereas the residue is crude ethyl 4-phenoxybutylacetoacetate, which is an oily, low melting solid (yield 240 g., 40% conversion).

6-Phenoxyhexanoic Acid.—Ethyl 4-phenoxybutylacetoacetate (110 g., 0.4 mole) is heated on a steam-bath for seven to nine hours with a mixture of potassium hydroxide (110 g., 2.0 moles), water (80 ml.) and ethanol (100 ml.)., while vigorously stirring throughout. The mixture is allowed to cool, diluted with water, extracted with ether to remove the alkali-insoluble material, and the alkaline solution boiled with Norite (1 g.) for one-half hour. The solution is filtered, the filtrate cooled in an ice-bath, then acidified with dilute hydrochloric acid, and the solid which separates is filtered, washed with water, and dried in a vacuum desiccator (m. p. 69°, yield 40 g., 50% of theory).

2-Bromo-6-phenoxyhexanoic Acid.—6-Phenoxyhexanoic acid (100 g., 0.5 mole) is placed in a one-liter three-necked flask, which is equipped with an efficient stirrer, reflux condenser, dropping funnel, and drying tubes. Red phosphorus (15 g.) is then added, followed by the cautious addition of a slight excess of bromine (93.5 g., 0.55 mole). The reaction mixture is then heated on a steam-bath for five to six hours, allowed to stand overnight, the product poured into water, and the mixture heated on a steam-bath to ensure the complete hydrolysis of the acid bromide. The acid is dissolved in aqueous sodium carbonate, acidified with dilute aqueous hydrochloric acid, and the acid which separates is filtered, dried in a vacuum desiccator, and crystallized from hexane (m. p. 114–7°, yield 117 g., 85% of theory).

2,6-Dibromohexanoic Acid.—A mixture of 2-bromo-6-phenoxyhexanoic acid (20 g., 0.07 mole) and aqueous hydrobromic acid (200 ml., 48%, 1.7 moles) is refluxed for eight to ten hours. The phenol is steam distilled, the residue is allowed to cool, the acid separated by extraction with ether, and the ethereal solution extracted with dilute aqueous sodium carbonate. The aqueous extract is extracted with ether, and the alkaline solution is acidified with dilute hydrochloric acid. The oil which separates is extracted with ether, the ethereal extract washed with water, dried over anhydrous sodium sulfate, the ether evaporated, and the residue is distilled under diminished pressure (b. p. 144–146° at 2 mm., yield 17.4 g., 87% of theory).

Lysine Dihydrochloride.—A mixture of ammonium hydroxide (110 ml., 1.7 moles), ammonium carbonate (48 g., 0.5 mole), 2,6-dibromohexanoic acid (27.4 g., 0.1 mole) and cuprous chloride (1 g.) is placed in a hydrogenation bomb and heated at 125–150° for eighteen to twenty-four hours. The solution is then removed from the bomb, boiled for ten to twenty minutes to decompose the ammonium carbonate, and then evaporated to dryness under diminished pressure. The residue is treated with hydrochloric acid, evaporated to a thick sirup, dissolved in hot alcohol, and filtered. The filtrate is cooled to 15 to 20°, and absolute ether is slowly added. The solid which separates is collected by filtration, and dried (m. p. 185–189°, yield 18 g., 81% of theory).

6-Bromohexanoic Acid.—This compound can be prepared by the method of Marvel[14] in yields of 60 to 65%, or according to the method of Brown and Partridge[15] in 80% yields, or by the reaction of aqueous hydrogen bromide on 6-hydroxyhexanoic acid and its lactone which is prepared by the reduction of monoethyl adipate.

6-Hydroxyhexanoic Acid.—Monoethyl adipate (180 g., 1.0 mole) is neutralized with potassium hydroxide (30% aqueous), the solution is evaporated to dryness under diminished pressure and then dried in a vacuum desiccator over concentrated sulfuric acid and finally over phosphoric anhydride. Potassium ethyl adipate (106 g., 1.0 mole) is placed in a three-liter, three-necked flask, which is fitted with a reflux condenser, mercury-seal stirrer, and drying tubes. Absolute ethanol (1500 ml.) is added, the solution refluxed to effect as complete solution as possible, and sodium (80 g., 3.5 moles) is then added in small quantities. After the complete disappearance of the sodium metal, the alcohol is removed by distillation, leaving a crude residue of 6-hydroxyhexanoic acid and its lactone in almost quantitative yields.

6-Hydroxyhexanoic Acid.—Monoethyl adipate (200 g., 0.85 mole) and copper chromite catalyst (20 g.) are placed in a hydrogenation bomb. Hydrogen at a pressure of 2000 pounds per square inch is introduced, and the temperature is rapidly raised to 225–250°. Hydrogen is then introduced at intervals so that the hydrogen pressure is maintained above 2000 pounds pressure. The bomb and contents are then allowed to cool to room temperature, the contents removed, the catalyst removed by filtration, and the solvent recovered, yielding a crude residue of 6-hydroxyhexanoic acid and its lactone in almost quantitative yields.

The crude 6-hydroxyhexanoic acid and its lactone are converted directly into 6-bromohexanoic acid.[15]

Summary

Several methods for the synthesis of lysine dihydrochloride have been developed during the course of this research.

The most promising method in this study for the

(14) Marvel, THIS JOURNAL, **46**, 2841 (1924).

(15) Brown and Partridge, *ibid.*, **66**, 839 (1944).

commercial production of this essential amino acid appears to involve the use of ϵ-caprolactam.

The second most practical method involves the reduction of monoethyl adipate, and conversion to 6-bromohexanoic acid.

The conversion of tetramethylene chlorobromide, tetramethylene chloride, 1-nitro-4-chlorobutane to lysine may be somewhat inferior methods but are significant in case raw material values change and the by-products formed in the reactions can be utilized.

Acrylic Esters of Amino Alcohols

BY C. E. REHBERG AND W. A. FAUCETTE[2]

According to the patent literature, several amino alcohols have been converted into the acrylic[3] or methacrylic[4] esters. Gilman and co-workers[5] prepared diethylaminoethyl acrylate hydrochloride, but, since their interest was in its physiological activity, they did not prepare the free ester or make any attempt to polymerize the salt.

Our principal object in preparing the aminoalkyl acrylates was to copolymerize them with alkyl acrylates and thus obtain acrylic elastomers containing basic functional groups. However, they did not readily polymerize alone, nor did they copolymerize with ethyl acrylate. Hence, their properties were not extensively studied.

It has been stated that aminoalkyl methacrylates act as polymerization inhibitors and are difficult to polymerize with benzoyl peroxide[4b] but are readily polymerized by ultraviolet light.[4b] Diethylaminoethyl methacrylate has been reported[4b,d,e] to polymerize spontaneously at 0° in the absence of light or catalysts. In general, these observations were confirmed in the present work with acrylic esters.

Experimental

Amino Alcohols.—The diethyl- and dibutylaminopropanols were obtained from Eastman Kodak Company; dimethylaminoethanol and 2-N-morpholinoethanol were kindly supplied by the Carbide and Carbon Chemicals Corporation, and we are indebted to Sharples Chemicals, Inc., for diethyl- and dibutylaminoethanol and ethyldiethanolamine. All were used after a simple distillation.

TABLE I

PREPARATION AND PROPERTIES OF AMINOALKYL ACRYLATES

Acrylate	Boiling point °C.	Mm.	Yield, %	$n^{20}D$	d^{20}_4	Mol. refraction Calcd.	Mol. refraction Found	Nitrogen Calcd.	Nitrogen Found

N-Ethyl-N-(2-hydroxyethyl)-aminoethyl	77	.2	76	1.4662	1.0211	50.41	50.79	7.4	8.3

The aminoalkyl acrylates (Table I) were prepared readily, and usually in high yield, by the alcoholysis of methyl or ethyl acrylate. This method had been used previously in the preparation of alkyl,[6] alkenyl[7] and alkoxyalkyl[8] acrylates.

Monomeric Acrylates.—The esters were prepared by the alcoholysis of methyl or ethyl acrylate. Aluminum isopropoxide was used as a catalyst and phenyl-β-naphthylamine as a polymerization inhibitor. In one experiment, no inhibitor was used, and a lowered yield of monomer, together with a large distillation residue, was obtained. The procedure and equipment have been described in previous papers.[6-8]

In the one experiment in which ethyldiethanolamine was used, only one mole of methanol was produced in the reaction. The molecular refraction of the constant-boiling product agreed with the expected value for the monoacrylate. The nitrogen analysis was somewhat high for the monoacrylate, indicating that some free amine was present. However, two fractional distillations through a 3-ft. Vigreux column failed to effect any separation.

The esters were colorless liquids having mild, ammoniacal odors and appreciable water solubility.

Polymerization Experiments.—Addition of benzoyl peroxide (1%) to the monomers or to their solutions (10%) in ethyl acetate resulted in instant discoloration. Sub-

sequent heating at 90–100° had no effect. Addition of benzoyl peroxide or ammonium persulfate to aqueous emulsions of the esters had a similar result. Several attempts to copolymerize diethylaminoethyl and ethyl acrylates (weight ratio 1:10) in ethyl acetate solution and in aqueous emulsion, with benzoyl peroxide and ammonium persulfate, respectively, as catalysts, resulted in discoloration of the monomer but no appreciable polymerization. Diethyl- and dibutylaminoethyl acrylates were sealed in glass tubes and heated at 90° for one week without visible change. The tubes were than irradiated with ultraviolet light. Viscous, liquid polymers were thus formed.

No polymerization occurred when a 10% aqueous solution of the acetate of diethylaminoethyl acrylate containing 1% of benzoyl peroxide was refluxed for twenty-four hours. A 10% aqueous solution of the acrylate (salt) of diethylaminoethyl acrylate containing 0.06% (based on ester) of ammonium persulfate was placed in sunlight. After a few hours it polymerized vigorously, the entire solution being converted to a soft, pasty solid. This was soluble in water, from which it could be precipitated by sodium chloride. A sample of the polymer which had been precipitated from dilute hydrochloric acid and then from water was analyzed: N, found 2.95% (calcd. 5.75%).

A 1% aqueous solution of morpholinoethyl polyacrylate (prepared from polymer formed spontaneously while in the refrigerator) was added to a 1% aqueous solution of polyacrylic acid. A voluminous precipitate formed instantly. When dried it was hard and brittle.

Summary

The acrylic esters of eight alcohols containing tertiary amino groups were prepared by the alcoholysis of methyl or ethyl acrylate.

All attempts to polymerize the esters with benzoyl peroxide, ammonium persulfate or heat, whether in bulk, in solution or in aqueous emulsion, were failures. Ultraviolet light was effective in promoting polymerization.

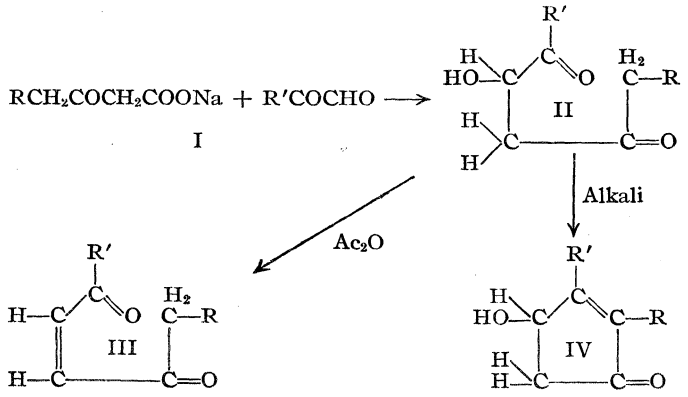
Constituents of Pyrethrum Flowers. XXIII. Cinerolone and the Synthesis of Related Cyclopentenolones[1]

BY MILTON S. SCHECHTER, NATHAN GREEN AND F. B. LAFORGE

Of the two substituted cyclopentenolones, pyrethrolone and cinerolone, the chrysanthemum acid esters of which constitute the principal insecticidal constituents of pyrethrum flowers, cinerolone, 2-(2-butenyl)-4-hydroxy-3-methyl-2-cyclopenten-1-one, possesses the simplest structure. When it is re-esterified with *d-trans*-chrysanthemum monocarboxylic acid, the resulting cinerin I has been shown to be of about the same order of toxicity[2] as pyrethrin I, and it has the added advantage of decidedly greater stability. For these reasons cinerolone has been given first consideration from the standpoint of synthesis.

In previous articles[3,4] the synthesis of 2-*n*-butyl-4-hydroxy-3-methyl-2-cyclopenten-1-one (*dl*-dihydrocinerolone) and the corresponding 2-*n*-amyl compound (*dl*-tetrahydropyrethrolone) has been described. The method employed consisted in the introduction of bromine in the 4-position of dihydrocinerone and tetrahydropyrethrone, respectively, by the agency of N-bromosuccinimide and the replacement of the halogen by hydroxyl. This method failed[5] when the side chain was unsaturated, as it is in cinerone and pyrethrone.

It has been shown[6] that 3-methyl-2-cyclopentenones with a side chain in position 2 are readily obtained by the cyclization of 1,4-diketones con-



a, R = *n*-C_4H_4; R′ = $-CH_3$.
b, R = $-CH_2CH{=}CHCH_3$; R′ = $-CH_3$.
c, R = $-CH_2CH{=}CH_2$; R′ = $-CH_3$.
d, R = $-CH_2C(CH_3){=}CH_2$; R′ = $-CH_3$.
e, R = $-CH_2CH_2CH{=}CH_2$; R′ = $-CH_3$.
f, R = $-CH_2CH{=}C(CH_3)_2$; R′ = $-CH_3$.
g, R = $-H$; R′ = $-CH_3$.
h, R = $-CH_2CH{=}CH_2$; R′ = $-C_6H_5$.

taining a $-CH_2-$ group in the 5-position. If 2-hydroxy-1,4-diketones also having a $-CH_2-$ group in the 5-position could be prepared, they might be expected to cyclize with the elimination of a molecule of water to 2,3-disubstituted-4-hydroxy-2-cyclopenten-1-ones. It will be shown that this

route can, in fact, be used to prepare a variety of substituted cyclopentenolones.

Only two 2-hydroxy-1,4-diketones appear to have been described in the literature—3-hydroxy-2,5-hexanedione ($CH_3COCHOHCH_2COCH_3$) and 2-hydroxy-1-phenyl-1,4-pentanedione (C_6H_5CO-$CHOHCH_2COCH_3$)—the chemistry and biochemistry of which have been extensively studied by Henze and colleagues.[7] They were obtained by the aldol condensation of methylglyoxal (pyruvaldehyde) and phenylglyoxal, respectively, with sodium acetoacetate in faintly alkaline aqueous solution at room temperature. In addition, Shaffer, Friedemann, and co-workers,[8] who were also interested in antiketogenesis, investigated the reaction of a number of aldehydes, glyoxal, etc., on alkali acetoacetate both with and without the addition of peroxide, but they failed to isolate or characterize the reaction products.

Henze represented his reaction as proceeding *via* an intermediate condensation product containing a carboxyl group (as the sodium salt), which had to be decarboxylated by warming with acid in order to produce the hydroxydiketone. We have found that the decarboxylation proceeds spontaneously under the conditions of the reaction, the final product being the hydroxydiketone, which can be extracted directly from the alkaline reaction mixture. We have also shown that the reaction can be carried out under acidic conditions, in which case carbon dioxide is liberated instead of being converted to alkali bicarbonate.

Hunsdiecker and Blaise[6] specified that a $-CH_2-$ group in the 5-position of 1,4-diketones is an essential condition for their cyclization to cyclopentenones, and that hence a compound such as acetonylacetone cannot be cyclized. This rule probably holds true in the case of 2-hydroxy-1,4-diketones, since we were unable to cyclize Henze's ketol, 3-hydroxy-2,5-hexanedione (IIg).

Preparation of 2-Hydroxy-1,4-diketones (Formula II).—Convenient methods for the preparation of saturated and unsaturated β-keto esters with a $-CH_2-$ group in the γ-position are described elsewhere[9,10] and in this article. With these esters as starting materials, a number of 2-hydroxy-1,4-diketones of the general formula II have now been prepared by the condensation of pyruvaldehyde with the alkali salts of the β-keto acids of formula I. Also, 2-hydroxy-1-phenyl-7-octene-1,4-dione (IIh), has been prepared by the condensation of phenylglyoxal with the potassium salt of Ic.

(10) Green and LaForge, *ibid.*, **70**, 2287 (1948).

Although the reactions can be carried out under acid conditions, we have generally prepared the hydroxydiketones by the reaction of a substituted glyoxal, R'COCHO, with a faintly alkaline aqueous solution of an alkali salt of a β-keto acid, RCH_2COCH_2COOH, in substantially equimolecular proportions, the final solution being adjusted so that it is near *p*H 8. It is inadvisable to have the solution too alkaline or too acidic. If it is too alkaline, some of the substituted glyoxal may dismutate to a hydroxy acid, whereas, if it is too acidic, some of the β-keto acid may decompose; in either case, the yield of desired product will be lowered. In order to carry out the reaction under acid conditions, buffers may be used or acid may be added as the reaction proceeds. Provided that the reaction is not made too acidic nor too alkaline at first, the *p*H will tend to adjust itself to a suitable value because of the production of alkali bicarbonate. The reactions are practically complete in about six hours at room temperature but they may be allowed to proceed for a day or two. In general, the hydroxydiketones were isolated in about 50–75% yields by extraction with ether and distillation *in vacuo*.

With the exception of 2-hydroxy-1-phenyl-7-octene-1,4-dione, IIh, which is a colorless, crystalline solid, all of the hydroxydiketones are practically colorless liquids. They all reduce Fehling solution rapidly in the cold.

Attempts to prepare acetates by treatment with acetic anhydride and sodium acetate led instead to the formation of anhydro compounds of formula III. The anhydro compounds form disemicarbazones almost instantaneously upon treatment with semicarbazide hydrochloride in pyridine–ethanol solution. In contrast to this behavior, the hydroxydiketones form semicarbazone derivatives very slowly. However, the semicarbazone derivatives of the hydroxydiketones are identical with those from the corresponding anhydro compounds as shown by analysis and mixed melting point behavior. Furthermore, these semicarbazones show dimorphism when recrystallized from different solvents, ethanol usually giving a higher melting form than acetic acid. We were not able to obtain the simple disemicarbazones of our hydroxydiketones; in every case dehydration occurred. The possibility of pyrazoline formation as noted by Henze[7g] is not excluded.

It is interesting to note that the formation of the hydroxydiketones from pyruvaldehyde and salts of β-keto acids takes place under what is considered to be physiological conditions and there is a possibility that the synthesis of pyrethrolone and cinerolone may proceed via a similar mechanism in the pyrethrum plant. In fact, there is a strong resemblance between this reaction and the elegant "physiological" synthesis of tropinone by Schöpf and Lehmann.[11]

(11) Schöpf and Lehmann, *Ann.*, **518**, 1 (1935); see also Schöpf and Arnold, *ibid.*, **558**, 109 (1947), and Schöpf and Thierfelder, *ibid.*, **518**, 127 (1935).

Cyclization of 2-Hydroxy-1,4-diketones (II) to 4-Hydroxycyclopentenones (IV).—The cyclization is accomplished by agitation of the hydroxydiketones with aqueous alkali at room temperature yielding the substituted cyclopentenolones. Employing about 10–20 volumes of 1 to 10% sodium hydroxide solution for several hours, yields of about 50–65% were obtained. The distilled products are practically colorless oils except IVh, which is crystalline. When pure, they do not reduce Fehling solution in the cold but only on warming.

Among the cyclopentenolones prepared, the one of formula IVb, obtained by the cyclization of the hydroxydiketone IIb, merits special consideration because it corresponds to the structure assigned to cinerolone.[12] The synthetic 2-(2-butenyl)-4-hydroxy-3-methyl-2-cyclopenten-1-one (IVb) was characterized by the preparation of the semicarbazone, acetate semicarbazone and the 3,5-dinitrobenzoate. The corresponding derivatives prepared from natural *dl*-cinerolone, with the exception of the semicarbazone, have melting points near those derived from the synthetic cyclopentenolone. In each case, however, mixed melting points of the corresponding derivatives from the two sources showed very definite depressions leaving no doubt as to their non-identity (see Table I).

Catalytic hydrogenation of the synthetic compound IVb furnished as the major product 2-butyl-4-hydroxy-3-methyl-2-cyclopenten-1-one (*dl*-dihydrocinerolone) identical with the compound (IVa) obtained by direct synthesis. The identity of the hydrogenated compound with compound IVa and also with *dl*-dihydrocinerolone prepared by the hydrogenation of *dl*-cinerolone from the natural source, has been established by mixed melting point determinations of the corresponding semicarbazones, the 3,5-dinitrobenzoates, and the 2,4-dinitrophenylhydrazones. The identity of the semicarbazones was further confirmed by a comparison of their X-ray diffraction patterns.

The possibility that the crotyl halide and hence all of the subsequent intermediates employed in the synthesis of 2-(2-butenyl)-4-hydroxy-3-methyl-2-cyclopenten-1-one (IVb), contained any considerable amount of the methyl vinyl carbinyl isomer due to an allylic rearrangement[13] has been excluded by the hydrogenation result. The only remaining explanation for the difference between this synthetic cyclopentenolone (IVb) and natural *dl*-cinerolone seems to be that of *cis–trans* isomerism. Harper[14] has also attributed the lack of identity of synthetic 2-(2-butenyl)-3-methyl-2-cyclopenten-1-one with cinerone obtained from natural cinerolone to geometric isomerism. In addition to isomerism due to the allylic rearrangement, crotyl halides may exist as mixtures of *cis* and *trans* isomers but there is scant information on this point.[15] However, it is probable that crotyl halides exist predominantly in the *trans* form, and that hence our synthetic product (IVb) has a *trans* configuration at the double bond in the side chain, whereas natural cinerolone is probably the *cis* isomer.

All of the substituted cyclopentenolones described in this article have been esterified[16] with natural *d-trans*-chrysanthemum monocarboxylic acid yielding esters analogous to cinerin I. In addition, two of them, IVb and IVc, have been esterified with synthetic *dl-cis-* and *dl-trans*-chrysanthemum monocarboxylic acids.[17]

Most of these esters exhibited a high order of insecticidal activity, with associated knock-down and paralytic effects characteristic of pyrethrum extracts. Some of them (those of IVc and IVd) exceeded the reference test standard (pyrethrin I + cinerin I 50%, pyrethrin II + cinerin II 50%) in their toxic action against house flies when tested by the turntable method.[18] Natural *d-trans*-chrysanthemum monocarboxylic acid yielded esters more toxic than the synthetic *dl-cis–trans* mixture.

The processes for the preparation of these substituted cyclopentenolones utilize starting materials which are readily available commercially. Although the yields are fair, they undoubtedly could be increased by systematic study. Campbell and Harper[19] have recently improved the synthesis of chrysanthemum monocarboxylic acid and it is possible that other acids may be found that might replace it in the synthesis of insecticidally active esters. A technical synthesis of insecticides of the pyrethrum type now seems to have been brought within the realm of possibility.

Experimental

All melting points are corrected.

α-Alkenyl Acetoacetic Esters

Ethyl α-Allylacetoacetate.[20]—A solution of sodium ethoxide prepared by dissolving 46 g. (2 moles) of sodium in 700 ml. of absolute ethanol was cooled to 15° and 286 g. (2.2 moles) of ethyl acetoacetate was added to the stirred solution. After one-half hour 153 g. (2 moles) of allyl chloride was added at once, and the stirring was continued for a short time. The reaction was then allowed to proceed overnight, and completed by refluxing for one hour. After the sodium chloride had been removed by filtration, and most of the ethanol by distillation, the reaction product was distilled and a fraction collected between 85 and 105° (15 mm.), yield of crude product 250–300 g. The purity as calculated from ethoxyl determinations was found to range from 75–90%. This fraction, which contained some unreacted ethyl acetoacetate, was generally employed for the preparation of 5-hexen-2-one (allyl acetone). Pure ethyl α-allyl acetoacetate obtained by

Ethyl α-Crotylacetoacetate.[5]—The method employed was essentially the same as in the previous preparation, the proportions in a typical experiment being 260 g. (2 moles) of ethyl acetoacetate, 23 g. of sodium (1 mole) dissolved in 600 ml. of absolute methanol and 135 g. (1 mole) of crotyl bromide that had been fractionated through a glass helix-packed column, b. p. 106–109° (765 mm.), $n^{25}D$ 1.4786, d^{25}_4 1.3357. The constants reported[13] for crotyl bromide are b. p. 107° (760 mm.), $n^{25}D$ 1.4795, d^{25}_4 1.3335.

The excess of the solvent and the ethyl acetoacetate were removed by vacuum distillation and the 203 g. of residue was employed for the preparation of 5-hepten-2-one, any ester exchange which might have occurred being of no importance.

Ethyl α-methallylacetoacetate was prepared by the same procedure from 286 g. (2.2 moles) of ethyl acetoacetate, 46 g. (2 moles) of sodium dissolved in 600 ml. of absolute ethanol, and 181 g. (2 moles) of methallyl chloride. After removal of the solvent and the excess of ethyl acetoacetate, the residue was distilled and the fraction b. p. 98–112° (15 mm.) collected, $n^{26}D$ 1.4408; yield 280 g. (77%).

Anal. Calcd. for $C_{10}H_{16}O_3$: OC_2H_5, 24.4. Found: OC_2H_5, 24.0.

Methyl Alkenyl Ketones

5-Hexen-2-one (Allyl Acetone).[21]—Three hundred grams of crude ethyl α-allylacetoacetate (92% pure) was added to an aqueous solution of 112 g. of potassium hydroxide (100% basis) in 1 l. of water at 0° and the suspension was stirred until all but a small residue had dissolved. The solution was then kept in the refrigerator for three days. After the small amount of undissolved oil had been removed with petroleum ether, 60 ml. of sulfuric acid in 100 ml. of water was added to the aqueous solution in a flask equipped with a water condenser and the flask was heated on the steam-bath until no more carbon dioxide evolved. The separated oil was removed and the aqueous solution, after saturation with sodium chloride, was extracted with petroleum ether. The extract was combined with the separated oil, and the solution was washed with dilute alkali and with saturated salt solution. After drying the solution over potassium carbonate and removing the solvent, the residue was distilled; yield 93 g. (60% based on 92% ester, 48% based on the allyl chloride), b. p. 127–132° (760 mm.).

By the same procedure 170 g. (1 mole) of the pure ester yielded 83 g. (85%) of allyl acetone, b. p. 127–132° (760 mm.), $n^{27}D$ 1.4170.

5-Hepten-2-one (Crotyl Acetone).[5,21b]—Two hundred and three grams of crude ethyl α-crotylacetoacetate dissolved in 1 l. of a cold aqueous solution of 73 g. of potassium hydroxide (100% basis) after three days in the refrigerator furnished crude crotyl acetone on decarboxylation and isolation in the manner described for allyl acetone. Fractionation through a concentric tube column gave a forerun of 2.4 g., b. p. 148–151°, and 90.2 g. (81% overall yield based on crotyl bromide) of the desired product, b. p. 151–154° at 770 mm., $n^{25}D$ 1.4280.

5-Methyl-5-hexen-2-one (Methallyl Acetone).[21b]—This compound was prepared by saponification of 280 g. (1.52 moles) of ethyl α-methallylacetoacetate with 96 g. (1.71 moles) of potassium hydroxide (100% basis) in 650 ml. of water for four days in the refrigerator. The ketone was obtained in the usual manner. Fractionation gave 15 g. of forerun and 117 g. (69% yield) of the desired product, b. p. 142–154° at 760 mm., 90% of which distilled at 145–150°, $n^{27}D$ 1.4278. The **semicarbazone** was prepared, **m. p. 136–137°.**

Anal.[22] Calcd. for $C_8H_{14}ON_3$: N, 24.83. Found: N, 24.98.

Ethyl Esters of 3-Oxo-alkenoic Acids

The preparation of ethyl β-oxocaprylate and of ethyl 3-oxo-6-octenoate by carbethoxylation of 2-heptanone and 5-hepten-2-one, respectively, by the agency of sodium hydride has been described in previous articles.[5,9] By the same procedure the following esters have been prepared.

Ethyl 3-Oxo-6-heptenoate.—The proportions of the reactants were 90 g. (0.92 mole) of 5-hexen-2-one (allyl acetone), 44 g. (1.84 moles) of sodium hydride, and 218 g. (1.84 moles) of ethyl carbonate: yield 120 g. (77%), b. p. 107–111° (14 mm.), $n^{28}D$ 1.4393.

Anal. Calcd. for $C_9H_{14}O_3$: OC_2H_5, 26.5. Found: OC_2H_5, 25.8.

This ester has also been prepared by the forced condensation method. Ethyl carbonate, 350 g. (3 moles), and commercial sodium methylate, 30 g. (0.55 mole), were placed in a 2-l. flask equipped with a dropping funnel, a thermometer, a stirrer having a lubricated rubber seal, and a short column surmounted with a total reflux take-off head. Employing a vacuum of about 100 mm., 49 g. (0.5 mole) of allyl acetone was added dropwise over a period of three hours while about 100 ml. of distillate was collected using a take-off ratio of about 1 to 4. The temperature of the bath was about 90° and of the vapor about 62°. Two 50-ml. portions of ethyl carbonate were added at intervals of one hour during the distillation. A part of the remaining ethyl carbonate was distilled off; the solution was cooled and acidified with a slight excess of glacial acetic acid. Water was then added and the produced isolated in the usual manner to yield 60.7 g. (70.6%).

Ethyl 6-Methyl-3-oxo-6-heptenoate.—One hundred and twelve grams (1.04 moles) of 5-methyl-5-hexen-2-one (methallyl acetone), 50 g. (2.08 moles) of sodium hydride, and 248 g. (2.1 moles) of ethyl carbonate were employed in one experiment: yield 134 g. (70%), b. p. 119–125° (16 mm.), $n^{27}D$ 1.4468.

Anal. Calcd. for $C_{10}H_{16}O_3$: OC_2H_5, 24.4. Found: OC_2H_5, 24.1.

Ethyl 7-Methyl-3-oxo-6-octenoate.—This compound was obtained from 126 g. (1 mole) of 6-methyl-5-hepten-2-one,[23] 48 g. (2 moles) of sodium hydride, and 236 g. (2 moles) of ethyl carbonate: yield 141 g. (71%), b. p. 135–136° (15 mm.), $n^{25}D$ 1.4519.

Anal. Calcd. for $C_{11}H_{18}O_3$: OC_2H_5, 22.7. Found: OC_2H_5, 23.2.

The refractive indices of some of these β-keto esters were observed to change on standing due to a shift of the keto-enol ratio.

β-Keto Acids

β-Oxocaprylic Acid (Ia).—This acid was prepared by the method of Locquin,[24] m. p. 75–76° (dec.).

3-Oxo-6-octenoic Acid (Ib).—Twenty-eight grams of the ethyl ester was saponified for three days at about 5° with 100 ml. of 10% aqueous potassium hydroxide. Upon acidification to congo red with hydrochloric acid the free acid was obtained in crystalline form, m. p. (air dried) 71–72° (dec.). This acid and the previous one, Ia, are stable for months in the refrigerator but slowly decompose at room temperature with the liberation of carbon dioxide.

Anal. Calcd. for $C_8H_{12}O_3$: mol. wt., 156. Found: mol. wt. (titration), 160.

3-Oxo-6-heptenoic Acid (Ic).—This compound was prepared in the same manner but isolated as an oil. It is crystalline when cooled with dry ice, but melts with slow decomposition on warming to room temperature.

2-Hydroxy-1,4-diketones of Formula II

The general procedures used in the preparation of the

hydroxydiketones will be outlined, and supplementary details will be described for each experiment when necessary.

In **Procedure A** the β-keto acid was isolated, stored in a desiccator in the refrigerator until ready to be used, and then mixed with ice-cold water and exactly neutralized with cold 10% sodium hydroxide solution. The pyruvaldehyde prepared by a modification of the method of Riley[25a,b] usually dissolved in a little water, was added, and the alkalinity adjusted to approximately *p*H 8. It is immaterial whether or not the pyruvaldehyde has polymerized on storage in the refrigerator, for either it dissociates on standing in dilute aqueous solution[25b] or else the equilibrium shifts to the monomer as it reacts. If the reaction medium is too alkaline, some of the substituted glyoxal may be converted to a hydroxy acid before it can react with the salt of the β-keto acid. In those cases where the hydroxydiketones are difficultly soluble, the reaction mixture turns cloudy in about two hours, and during several more hours the oily reaction product separates almost completely. The hydroxydiketones of lower molecular weight may separate partially or not at all, depending on their solubility and the volume of the reaction mixture. In these cases the solution was saturated with sodium chloride before extraction. After about sixteen hours to several days the reaction mixture was extracted with peroxide-free ether. The ether solution was washed with saturated salt solution, and after drying over sodium sulfate the solvent was removed and the residue distilled in high vacuum. There was little or no forerun, but a fraction, not further investigated, having a considerably higher boiling point than the desired compound was present in all the preparations.

Procedure B was the same as A except that the β-keto ester was saponified with a slight excess of a 5 to 20% potassium hydroxide solution for several days in the refrigerator. The excess alkali was neutralized with dilute sulfuric acid, the pyruvaldehyde solution added, and the alkalinity finally adjusted to approximately *p*H 8.

Procedure C was the same as procedure B except that, instead of neutralizing the alkaline solution of the β-keto acid with dilute sulfuric acid, the solution was saturated with carbon dioxide employing a porous disperser. The excess alkali was thereby converted to bicarbonate, giving a suitable *p*H, and the pyruvaldehyde solution could be added without further adjustment of the alkalinity.

3-Hydroxy-2,5-decanedione (IIa). (Procedure A).— Thirty grams (0.19 mole) of β-oxocaprylic acid, Ia, mixed with 50 ml. of cold water in a glass-stoppered flask was kept cold in an ice-bath and titrated with 10% sodium hydroxide solution until just alkaline to phenolphthalein. The stoppered flask was shaken vigorously near the end of the titration. Eighteen grams of pyruvaldehyde (87.6% assay[26]) (0.22 mole) was added and rinsed in with a little water. The alkalinity of the reaction mixture was adjusted to approximately *p*H 8 by the careful addition of a little 10% sodium hydroxide solution. The total volume of the reaction mixture was 200 ml. After about two hours at room temperature the solution turned milky and the oily reaction product rose to the surface. By placing the solution in a graduated cylinder the progress of the reaction could be measured by noting the increase in volume of the oil layer. After two days the reaction mixture was still faintly alkaline. It was extracted several times with ether, the extracts were combined and washed several times with saturated sodium chloride solution and, after drying over anhydrous sodium sulfate, the ether was distilled off leaving a residue of 32 g. of yellow oil which was distilled *in vacuo*. After a small forerun the main fraction was collected at 89–95° (0.05 mm.), most of it distilling at 93–95°, $n^{25}D$ 1.4514, yield 23 g. (65%). There was also a higher boiling fraction, b. p. 150–155° at 0.15 mm., which was not investigated. After redistillation, the 3-hydroxy-2,5-decanedione, $n^{25}D$ 1.4508, d^{25}_4 0.9967, was analyzed.

Anal. Calcd. for $C_{10}H_{18}O_3$: C, 64.48; H, 9.74; MR_D, 49.93. Found: C, 64.10; H, 9.56; MR_D, 50.29.

An aliquot of the reaction mixture, after it had been extracted with ether, was titrated for sodium bicarbonate, using 1 *N* sulfuric acid solution and methyl orange indicator, the solution being boiled near the end of the titration. The theoretical amount of sodium bicarbonate was found.

A similar experiment was performed with 10.2 g. (0.065 mole) of β-oxocaprylic acid and 18.1 g. (0.065 mole) of pyruvaldehyde-sodium bisulfite compound[27] (instead of pyruvaldehyde) with final adjustment of the alkalinity to approximately *p*H 8. After standing for two days very little oil separated. The reaction mixture was acidified to congo red with dilute sulfuric acid (1:4) and heated for fifteen minutes on the steam-bath under a reflux condenser in order to decompose any bisulfite addition compounds. The product was isolated as usual by extraction with ether and distillation *in vacuo*, giving only a 19% yield of 3-hydroxy-2,5-decanedione.

Another experiment was performed with commercially available pyruvaldehyde.[28] Procedure B was used. Ninety-nine grams (0.53 mole) of ethyl β-oxocaprylate was mixed with 195 ml. of an ice-cold solution containing 39 g. of potassium hydroxide (86% assay) (0.60 mole). After standing for three days in the refrigerator, the excess alkali was approximately neutralized by the slow addition of dilute sulfuric acid (1:4). One hundred and forty grams of commercial pyruvaldehyde (30%) (0.58 mole) was added, and the solution was adjusted to approximately *p*H 7.5 to 8 by the addition of 10% potassium hydroxide solution. The total volume of the reaction mixture was 537 ml. In ninety minutes the reaction product began to separate as an oil. After four hours 104 ml. had separated, after which there was no further increase. The product was isolated in the usual manner by extraction with ether and distillation to yield, after a small forerun, 50.9 g. (52%), b. p. 105–110° at 0.4 mm., $n^{25}D$ 1.4532. Redistillation gave 41.7 g., b. p. 90–98° at 0.05 mm., $n^{25}D$ 1.4528.

To illustrate that these reactions can be run under acidic conditions, a solution of sodium β-oxocaprylate (0.05 mole) was mixed with a slight excess of pyruvaldehyde in the presence of a buffer consisting of a solution of citric acid (0.1 mole) partially neutralized with sodium hydroxide. The initial *p*H of the reaction mixture was 4.9. The reaction was allowed to proceed for twenty-four hours during which time carbon dioxide was evolved and the reaction product separated as an oil, the final *p*H being 5.1. Extraction and distillation as usual yielded 5.5 g. (59%) of 3-hydroxy-2,5-decanedione.

Sometimes, after several weeks, the formation of crystals in some preparations of 3-hydroxy-2,5-decanedione was noticed. The crystals were filtered off and recrystallized from petroleum ether (b. p. 60–70°) to give colorless plates, m. p. 91–91.5°.

Anal.[22] Calcd. for $C_{20}H_{34}O_5$: C, 67.76; H, 9.67. Found: C, 68.26, 68.24; H, 9.66, 9.61.

Derivatives of 3-Hydroxy-2,5-decanedione (IIa)

The **anhydrodisemicarbazone** was prepared by treatment of IIa with a 50% excess of semicarbazide hydrochloride in pyridine–ethanol. The reaction required several days for completion, as did all the analogous derivatives described later. The anhydrodisemicarbazone was filtered off, washed, and dried, and after recrystallization from acetic acid was colorless, m. p. 224–225° (dec.).[29]

(28) This product was supplied as an approximate 30% aqueous solution. It contained formaldehyde, acidic substances, and other unknown impurities.

(29) The melting point behavior of many of the semicarbazone derivatives reported in this article was variable. Differences of as much as 5° were sometimes observed, depending on the rate of heating and the temperature at which the capillaries were inserted in the

Anal. Calcd. for $C_{12}H_{22}O_2N_6$: C, 51.04; H, 7.86. Found: C, 50.62; H, 7.65.

It was found to be identical with the disemicarbazone of 3-decene-2,5-dione described below. The analysis indicated that water had been eliminated. Hence the compound may be a pyrazoline derivative, as suggested by Henze[7g] for the analogous derivative of his ketol.

3,5-Dinitrobenzoate.—This derivative was obtained by using 3,5-dinitrobenzoyl chloride in benzene in the presence of pyridine. After isolation in the usual manner, the ester crystallized when kept in the refrigerator for several days and was recrystallized several times from methanol, m. p. 67–68°. The compound was unstable on storage.

Anal. Calcd. for $C_{17}H_{20}O_8N_2$: C, 53.68; H, 5.30. Found: C, 53.53; H, 5.00.

The 2,4-dinitrophenylhydrazone derivative was prepared by refluxing the hydroxydiketone for thirty minutes with an excess of 2,4-dinitrophenylhydrazine in ethanol acidified with concentrated hydrochloric acid. The compound was filtered off, washed with ethanol, dried and recrystallized from chloroform (other solvents were not as satisfactory) giving red crystals, m. p. 226–227°.

3-Decene-2,5-dione (IIIa).—To IIa was added twice its weight of acetic anhydride plus a little anhydrous sodium acetate. The following day the solution was warmed at 100° for ten minutes and the excess acetic anhydride removed under reduced pressure. The residue was dissolved in ether and washed with water, dilute sodium bicarbonate solution, and saturated sodium chloride solution. After the ether solution was dried over anhydrous sodium sulfate, the solvent was evaporated. The residue (practically theoretical yield) crystallized on standing and was recrystallized from low-boiling petroleum ether to give pale yellow crystals, m. p. 52–53°.

Anal. Calcd. for $C_{10}H_{16}O_2$: C, 71.39; H, 9.59. Found: C, 71.27, 70.86, 71.40; H, 9.44, 9.40, 9.33.

The compound (IIIa) reacted almost immediately with semicarbazide hydrochloride in pyridine–ethanol to give a yellow **disemicarbazone**, which was filtered off, washed with water and ethanol, and dried, m. p. 228–229° (dec.). This derivative was obtained in two forms. Recrystallization by solution in a large volume of boiling 95% ethanol and concentration gave one form, yellow, m. p. 228–229° (dec.).

Anal. Calcd. for $C_{12}H_{22}O_2N_6$: C, 51.04; H, 7.86. Found: C, 51.39; H, 7,94.

Recrystallization from acetic acid gave another form, colorless, m. p. 224–225° (dec.). The mixed melting point[29] of either form with the anhydrodisemicarbazone obtained from 3-hydroxy-2,5-decanedione (m. p. 224–225° dec.) was 224–225° (dec.) in each instance, indicating that the semicarbazone derivatives from the two sources are identical and that the lower melting form is the more stable one.

3-Hydroxy-8-decene-2,5-dione (IIb).—Procedure A was used. From 50.4 g. (0.27 mole) of 3-oxo-6-octenoic acid, Ib, and 29.5 g. of pyruvaldehyde (90% assay) (0.37 mole), the time of reaction being three days and the total volume 290 ml., 44.7 g. (75%) of distilled product, b. p. 97–100° at 0.1 mm., $n^{25}D$ 1.4679, was obtained.

Anal. Calcd. for $C_{10}H_{16}O_3$: C, 65.19; H, 8.76. Found: C, 64.75; H, 8.79.

The **anhydrodisemicarbazone** was prepared and recrystallized from acetic acid, giving a yellow product, m. p. 227–228° (dec.).

Anal. Calcd. for $C_{12}H_{20}O_2N_6$: C, 51.41; H, 7.19. Found: C, 51.47; H, 7.02.

3,8-Decadiene-2,5-dione (IIIb).—This compound was prepared from IIb in the same manner as IIIa. Recrystallization from low-boiling petroleum ether gave pale yellow crystals, m. p. 52–53°.

Anal. Calcd. for $C_{10}H_{14}O_2$: C, 72.26; H, 8.49. Found: C, 71.74; H, 8.35.

3-Hydroxy-8-nonene-2,5-dione (IIc).—Procedure A was used, starting with 50 g. (0.35 mole) of 3-oxo-6-heptenoic acid and 32.2 g. of pyruvaldehyde (90% assay) (0.40 mole). The time of reaction was three days and the total volume 270 ml.; 35 g. (58%) of distilled product, b. p. 85–90° (mostly 86–89°) at 0.07 mm., $n^{25}D$ 1.4657, was obtained.

Anal. Calcd. for $C_9H_{14}O_3$: C, 63.51; H, 8.29. Found: C, 62.82; H, 8.05.

There was also a higher boiling fraction, 5.2 g., b. p. 142–152° at 0.5 mm., $n^{25}D$ 1.4977, which was not investigated.

The **anhydrodisemicarbazone** of IIc was prepared and recrystallized from acetic acid, giving a yellow compound, m. p. 228–229° (dec.), identical with the disemicarbazone of 3,8-nonadiene-2,5-dione described below.

Anal. Calcd. for $C_{11}H_{18}O_2N_6$: C, 49.61; H, 6.81. Found: C, 49.65; H, 6.85.

3,8-Nonadiene-2,5-dione (IIIc).—This compound was prepared from IIc in the same manner as the other analogs. The oily product crystallized in the refrigerator but melted on warming to room temperature.

Its **disemicarbazone** was obtained in two forms. By solution in a large volume of boiling 95% ethanol and concentration, a bright yellow compound was obtained, m. p. 231–232° (dec.). Recrystallization from acetic acid gave the bright yellow lower-melting form, m. p. 228–229° (dec.). A mixed melting point of the latter with the anhydrodisemicarbazone of IIc was 228–229° (dec., no depression).

An experiment to determine the feasibility of using pyruvaldehyde diethyl acetal as a source of the pyruvaldehyde proceeded satisfactorily. Seventeen and a half grams (0.12 mole) of pyruvaldehyde diethyl acetal was refluxed for one hour with 1.6 g. of concentrated sulfuric acid in 60 ml. of water. The solution was cooled in an ice-bath and neutralized by the slow addition of about 3 g. of sodium bicarbonate. Procedure C was used. Starting with 17 g. (0.10 mole) of ethyl 3-oxo-6-heptenoate, saponified in the usual manner with 7.1 g. of potassium hydroxide (87.5% assay) (0.11 mole) in 80 ml. of water, and the hydrolyzed pyruvaldehyde diethyl acetal solution, after two days, 10.6 g. (62%) of distilled product (IIc), $n^{25}D$ 1.4660, was obtained. Pyruvaldehyde diisopropyl acetal[30] was also used successfully in a similar manner.

3-Hydroxy-8-methyl-8-nonene-2,5-dione (IId).—Procedure C was used. From 44 g. (0.24 mole) of ethyl 6-methyl-3-oxo-6-heptenoate and 24 g. of pyruvaldehyde (76% assay) (0.25 mole), the time of reaction being twenty-four hours and the total volume 254 ml., 25.7 g. (58%) of distilled product, b. p. 98–102° at 0.3 mm., $n^{25}D$ 1.4687, was obtained.

Anal.[22] Calcd. for $C_{10}H_{16}O_3$: C, 65.19; H, 8.76. Found: C, 65.28; H, 8.38.

The **anhydrodisemicarbazone** was prepared in the usual manner and when recrystallized from acetic acid was bright yellow, m. p. 225–226° (dec.).

Anal.[22] Calcd. for $C_{12}H_{20}O_2N_6$: C, 51.41; H, 7.19. Found: C, 50.76; H, 6.80.

3-Hydroxy-9-decene-2,5-dione (IIe).—Procedure C was used. Starting with 50 g. (0.27 mole) of methyl 3-oxo-7-octenoate,[14] and 32.2 g. of pyruvaldehyde (72.4% assay) (0.32 mole), the time of reaction being sixteen hours and

bath. Some of the differences in the values given in the literature may be due to this factor in addition to the usual thermometer inaccuracies. Where comparisons and mixed-melting-point determinations were made, the capillaries containing the individual samples and the mixture were placed adjacent to the thermometer and all three run at the same time in a modified type of Hershberg apparatus. It was found that results were more reproducible when the capillaries were inserted in the bath about 10–15° below the expected melting point and the temperature raised about 10° per minute.

(30) Guest, MacDowell and McNamee, U. S. Patent 2,421,559 (1947).

the total volume 255 ml., 38.4 g. (77%) of distilled product, b. p. 94–97° at 0.2 mm., $n^{25}D$ 1.4675, was obtained.

The **anhydrodisemicarbazone** was prepared in the usual manner. It was obtained in two forms, m. p. 214–215° (dec.) from acetic acid, and m. p. 220–221° (dec.) from 95% ethanol, both of which were pale yellow. The latter form was analyzed.

Anal. Calcd. for $C_{12}H_{20}O_2N_6$: C, 51.41; H, 7.19. Found: C, 51.70; H, 6.98.

The **3,5-dinitrobenzoate** was prepared and recrystallized from ether plus low-boiling petroleum ether to give the pale yellow crystalline ester, m. p. 60–61°. The derivative is unstable on storage.

3,9-Decadiene-2,5-dione (IIIe).—This compound was prepared by treating IIe in the same manner as the other analogs. The oily product crystallized in the refrigerator but melted on warming to room temperature. The **disemicarbazone** occurred as a low-melting form, m. p. 214–215° (dec.), when recrystallized from acetic acid and as a high-melting form, m. p. 220–221°, when recrystallized from 95% ethanol, both of which were pale yellow. A mixed melting point of the latter with the high-melting form of the anhydrodisemicarbazone of 3-hydroxy-9-decene-2,5-dione, IIe, was 220–221° (dec., no depression).

3-Hydroxy-9-methyl-8-decene-2,5-dione (IIf).—Procedure C was used. Starting with 47.5 g. (0.24 mole) of ethyl 7-methyl-3-oxo-6-octenoate and 25 g. of pyruvaldehyde (76% assay) (0.26 mole), the time of reaction being one day and the total volume 300 ml., 32.2 g. (68%) of distilled product, b. p. 106–109° at 0.5 mm., $n^{25}D$ 1.4715, was obtained.

Anal.[22] Calcd. for $C_{11}H_{18}O_3$: C, 66.64; H, 9.15. Found: C, 66.80; H, 8.75.

The **anhydrodisemicarbazone** was prepared and recrystallized from acetic acid, m. p. 238–239° (dec.).

3-Hydroxy-2,5-hexanedione (Henze's Ketol, IIg).—Procedure C was used, starting 65 g. (0.50 mole) of ethyl acetoacetate and 41.4 g. of pyruvaldehyde (88.6% assay) (0.51 mole). After three days the solution was saturated with sodium chloride (no separation of oil) and extracted with ether in a continuous extractor. It was not necessary to acidify and heat the solution as Henze[7a,g,h,i] specified; therefore, decarboxylation must have taken place spontaneously during the reaction as in the other analogous reactions described in this article. The ether was distilled off and the residue dried by refluxing with benzene by use of a Dean–Stark trap. The benzene was removed with a water pump and the residue distilled in high vacuum. The yield of distilled product was 24.1 g. (37%), b. p. 62–67° (mostly 65–67°) at 0.5 mm., $n^{25}D$ 1.4497.

2-Hydroxy-1-phenyl-7-octene-1,4-dione (IIh).—Procedure B was used. Since phenylglyoxal hydrate is not readily soluble in water, the reaction mixture was shaken for five hours and then allowed to stand overnight. Starting with 28 g. (0.16 mole) of ethyl 3-oxo-6-heptenoate and 22.5 g. (0.17 mole) of phenylglyoxal hydrate,[31] m. p. 83–84°, the total volume of reaction mixture being 210 ml., 23.3 g. (68%) of distilled product, b. p. 154–157° at 0.8 mm., was obtained.

Anal. Calcd. for $C_{14}H_{16}O_3$: C, 72.39; H, 6.94. Found: C, 71.71; H, 6.74.

A small amount was cooled in dry ice to obtain seeds, and then the main product was recrystallized from ether plus low-boiling petroleum ether, filtered, and washed with low-boiling petroleum ether, to give colorless crystals, m. p. 38.5–39°.

Anal. Calcd. for $C_{14}H_{16}O_3$: C, 72.39; H, 6.94. Found: C, 72.56; H, 6.85.

Cyclopentenolones (Formula IV)

General Procedure for Cyclizing 2-Hydroxy-1,4-diketones to Cyclopentenolones.—The hydroxydiketone was placed in a glass-stoppered Erlenmeyer flask or bottle, and 10 to 20 volumes of 1 to 10% sodium hydroxide solution were added. Although other alkaline cyclizing agents, such as potassium hydroxide, barium hydroxide and piperidine, can be used, sodium hydroxide was found to give uniformly good yields and was generally employed. The air was displaced with nitrogen and the slightly lubricated stopper inserted. (If further precautions against oxidation are desired, boiled water may be used in making up the alkali solution, and a small amount of hydroquinone may be added to the reaction mixture.) It was then shaken for one to four hours on a shaking machine, occasionally somewhat longer. The reaction mixture turned yellow as soon as the alkali was added and usually became darker as the reaction proceeded. After extraction with peroxide-free ether (in the case of the lower molecular weight cyclopentenolones, after saturation with salt), the extract was washed several times with saturated salt solution and after drying over sodium sulfate the solvent was removed and the residue distilled in high vacuum. Sometimes there was a small forerun. In each case, as in the distillation of the hydroxydiketones, there was a fraction, not further investigated, boiling considerably higher than the desired compound.

2-Butyl-4-hydroxy-3-methyl-2-cyclopenten-1-one (IVa, Synthetic *dl*-Dihydrocinerolone).—Fourteen grams of IIa was shaken overnight with 140 ml. of 2% sodium hydroxide solution. By the general procedure, 8.0 g. (63%) of the distilled product, b. p. 110–113° at 0.07 mm., $n^{25}D$ 1.4920, was obtained. The compound was purified by regeneration from the semicarbazone, b. p. 111–113° at 0.2 mm., $n^{25}D$ 1.4945 (literature values[3] are $n^{22}D$ 1.4958 and $n^{25}D$ 1.4955).

Anal. Calcd. for $C_{10}H_{16}O_2$: C, 71.39; H, 9.59. Found: C, 71.10; H, 9.64.

The **semicarbazone** was prepared in pyridine–ethanol and recrystallized from methanol–ethyl acetate, m. p. 199–200° (dec.).

Anal. Calcd. for $C_{11}H_{19}O_2N_3$: C, 58.64; H, 8.50. Found: C, 58.79; H, 8.29.

A sample of *dl*-dihydrocinerolone semicarbazone prepared from natural *dl*-cinerolone had a melting point of 195–196° on our thermometer[29] instead of 185° as previously reported.[3] It probably was slightly impure, but the amount available was too small to purify further. A mixed melting point[29] of this semicarbazone with that of the synthetic dihydrocinerolone, IVa (m. p. 199–200°, dec.), was 195–196° (dec., no depression).

The **3,5-dinitrobenzoate** of IVa was prepared in benzene in the presence of pyridine and was recrystallized from methanol, m. p. 111.5–112°.

Anal. Calcd. for $C_{17}H_{18}O_7N_2$: C, 56.35; H, 5.01. Found: C, 56.27; H, 4.81.

The mixed melting point with the 3,5-dinitrobenzoate[3] *dl*-dihydrocinerolone from the natural source was 111.5–112°.

The **2,4-dinitrophenylhydrazone** of IVa was prepared and recrystallized from 95% ethanol, m. p. 140.5–141.5°.

2-(2-Butenyl)-4-hydroxy-3-methyl-2-cyclopenten-1-one (IVb).—Instead of shaking as in the general procedure, the reaction was carried out with stirring. To 500 ml. of a 1% sodium hydroxide solution in a nitrogen-swept flask fitted with a Hershberg stirrer and dropping funnel, 25 g. of IIb was added over a period of thirty minutes. Stirring was continued for another hour, after which the reaction was worked up as usual. Fourteen grams (62%) of distilled product, b. p. 110–114° at 0.15 mm., $n^{25}D$ 1.5143, was obtained.

Anal. Calcd. for $C_{10}H_{14}O_2$: C, 72.26; H, 8.49. Found: C, 71.75; H, 8.40.

The **semicarbazone** was prepared in pyridine–ethanol and recrystallized from methanol–ethyl acetate, m. p. 222–223° (dec.).

Anal. Calcd. for $C_{11}H_{17}O_2N_3$: C, 59.17; H, 7.68. Found: C, 59.29; H, 7.51.

ating the cyclopentenolone and then preparing the semicarbazone of the acetate. Recrystallized from ethyl acetate, it melted at 155–155.5° (without dec.).

Anal. Calcd. for $C_{13}H_{19}O_3N_3$: C, 58.85; H, 7.22. Found: C, 58.70; H, 7.16.

The **3,5-dinitrobenzoate** was prepared and recrystallized from 95% ethanol, m. p. 125–126°.

Anal. Calcd. for $C_{17}H_{16}O_7N_2$: C, 56.66; H, 4.48. Found: C, 56.16; H, 4.53.

A comparison of synthetic 2-(2-butenyl)-4-hydroxy-3-methyl-2-cyclopenten-1-one (IVb), the natural product *dl*-cinerolone, and their derivatives is presented in Table I. The very definite depressions of the mixed melting points of the corresponding derivatives leaves no doubt as to their non-identity.

The **3,5-dinitrobenzoate** (not previously reported) of natural *dl*-cinerolone was prepared and recrystallized from methanol, m. p. 119.5–121.5°.

Anal. Calcd. for $C_{17}H_{16}O_7N_2$: C, 56.66; H, 4.48. Found: C, 57.26; H, 4.86.

TABLE I

MELTING POINTS OF SYNTHETIC AND NATURAL *dl*-2-(2-BUTENYL)-4-HYDROXY-3-METHYL-2-CYCLOPENTEN-1-ONES AND THEIR DERIVATIVES

	n_D	Semicarbazone, m. p., °C. (dec.)	Acetate semicarbazone, m. p., °C.	3,5-Dinitrobenzoate, m. p., °C.
Synthetic[a]	1.5143 (25°)	222–223	155–155.5	125–126
Natural[b]	1.5240 (28°)	199–200	151–152	.....
Natural[a]	.....	196–197	154–156	119.5–121.5
Natural + synthetic[a]	.....	192–193	143–149	100–108

[a] Melting points taken on our thermometer.[29] [b] Literature values [LaForge and Barthel, *J. Org. Chem.*, **10**, 106, 114 (1945)].

Hydrogenation of Synthetic 2-(2-Butenyl)-4-hydroxy-3-methyl-2-cyclopenten-1-one (IVb).—Three and one-half grams of IVb in ethanol was hydrogenated with Adams platinum oxide catalyst until 570 ml. of hydrogen at normal temperature and pressure (20% excess over that required to saturate one double bond) was absorbed. After filtration from the catalyst, 3.25 g. of crude semicarbazone, m. p. 191–192° (dec.), was prepared directly from the concentrated solution. Recrystallization from ethanol gave 2.65 g., m. p. 197–198° (dec.).

From 2.0 g. of the recrystallized semicarbazone 1.4 g. of 2-butyl-4-hydroxy-3-methyl-2-cyclopenten-1-one was regenerated, b. p. 109–110° at 0.2 mm., $n^{25}D$ 1.4927.

When the semicarbazone, 3,5-dinitrobenzoate and 2,4-dinitrophenylhydrazone of the hydrogenated compound were mixed with the corresponding derivatives of 2-butyl-4-hydroxy-3-methyl-2-cyclopenten-1-one (IVa), there was no depression of the melting points.[29] Mixed melting points of the semicarbazone and 3,5-dinitrobenzoate with the corresponding derivatives of *dl*-dihydrocinerolone from the natural source also did not show any depression.

The semicarbazones of IVa and of hydrogenated IVb showed the same X-ray diffraction patterns.[32] These patterns agreed with that of *dl*-dihydrocinerolone semicarbazone from the natural source except for moderate shifts in some of the lines attributable to impurities in solid solution in the latter sample. The X-ray diffraction patterns of the three semicarbazone derivatives, therefore, further confirmed their identity.

2-Allyl-4-hydroxy-3-methyl-2-cyclopenten-1-one (IVc).—Twenty-five grams of IIc was shaken for one hour with 200 ml. of 10% sodium hydroxide solution. By the general procedure 13.3 g. (59%) of distilled product, b. p. 100–103° at 0.15 mm., $n^{25}D$ 1.5141, was obtained.

(32) Grateful acknowledgment is made to E. L. Gooden of this Bureau for the X-ray diffraction data.

2-Allyl-4-hydroxy-3-phenyl-2-cyclopenten-1-one (IVh).—Treatment of 15 g. of IIh with 225 ml. of 2% sodium hydroxide solution for four hours according to the general procedure yielded 7.0 g. (51%) of distilled compound, b. p. 153–156° at 0.6 mm., $n^{25}D$ 1.5975. When purified by regeneration from the semicarbazone, it crystallized. Recrystallization from benzene–petroleum ether gave colorless crystals, m. p. 97.5–98.5°.

Anal. Calcd. for $C_{14}H_{14}O_2$: C, 78.48; H, 6.59. Found: C, 78.49; H, 6.56.

The **semicarbazone** recrystallized from acetic acid melted at 212–213° (dec.).

Anal. Calcd. for $C_{15}H_{17}O_2N_3$: C, 66.40; H, 6.32. Found: C, 66.43; H, 6.37.

Attempted Cyclization of Henze's Ketol, 3-Hydroxy-2,5-hexanedione.—Fifteen grams of II g. was dissolved in 300 ml. of 2% sodium hydroxide solution with the addition of 0.1 g. of hydroquinone. The flask was filled with nitrogen and allowed to stand for four hours. After saturation with sodium chloride, the reaction mixture was extracted with ether in a continuous extractor for twenty-four hours. The ether was distilled off and the residue dried by refluxing with benzene by use of a Dean–Stark trap. The benzene was removed with a water pump, and the residue fractionated in a high vacuum to give three fractions as follows: (1) 0.90 g., b. p. 39–41° at 0.3 mm., $n^{25}D$ 1.4387; (2) 0.65 g., b. p. 92–103° at 0.3 mm., $n^{25}D$ 1.5104; (3) 1.75 g., b. p. 118–128° at 0.3 mm., $n^{25}D$ 1.5342. Only fraction (1) gave a semicarbazone (it precipitated immediately), but the amount was too small to characterize. It was evident from the distillation that the reaction was not clear cut and that cyclization had not taken place. By analogy with the other cyclopentenolones, which have a little higher boiling point than the respective hydroxydiketones from which they are prepared, the cyclized product from 3-hydroxy-2,5-hexanedione, if any were formed, would have an estimated boiling point in the region of 70–85° at 0.3 mm. No such fraction was obtained. If any cyclized product were formed, its detection would require a more rigorous search. The degradation of Henze's ketol by alkali apparently leads to a complex mixture of products.

Acknowledgment.—We wish to express our appreciation for samples of methallyl chloride received from the Shell Chemical Corp., for pyruvaldehyde from the Carbide & Carbon Chemicals Corp., for selenium dioxide from C. Tennant, Sons & Co., and for sodium hydride from E I. du Pont de Nemours and Co.

Summary

The reaction between substituted glyoxals of the type R'COCHO and salts of substituted acetoacetic acids of the type RCH_2COCH_2COOH, yields 2-hydroxy-1,4-diketones, which cyclize upon treatment with alkali to 2,3-disubstituted-4-hydroxy-2-cyclopenten-1-ones. The chrysanthemum monocarboxylic acid esters of certain of these cyclopentenolones exceed the pyrethrins in insecticidal activity to house flies.

Synthetic 2-(2-butenyl)-4-hydroxy-3-methyl-2-cyclopenten-1-one appears to be a geometric isomer of natural *dl*-cinerolone.

The Nitration of 1,1,1-Trichloro-2,2-bis-(*p*-methoxyphenyl)-ethane

BY DAVID A. SHIRLEY, THEODORE N. GOREAU AND FRED S. EISEMAN, JR.

1,1,1 - Trichloro - 2,2 - bis - (*p* - methoxyphenyl)-ethane (methoxychlor) has recently become available commercially because of its favorable properties as an insecticide. We have investigated the nitration of methoxychlor because of the usefulness of this reaction as a route to various derivatives whose biological properties are of interest. We were primarily interested in the possible activity of methoxychlor derivatives, particularly the amino derivatives, as anti-tubercular chemotherapeutic agents in view of the observation reported by Kirkwood and Phillips[1] of the high anti-tubercular activity *in vitro* of 1,1,1 - trichloro - 2,2 - bis - (*p* - aminophenyl)-ethane and 1,1-dichloro-2,2-bis-(*p*-aminophenyl)-ethylene.

Nitration of methoxychlor (I in Fig. 1) with concentrated nitric acid in glacial acetic acid solution produced a dinitro derivative. This dinitro compound was shown to be 1,1,1-trichloro-2,2-bis-(3-nitro-4-methoxyphenyl)-ethane (II in Fig. 1) by the methods indicated below.

Treatment of the dinitro derivative II with alcoholic base effected dehydrohalogenation to 1,1 - dichloro - 2,2 - bis - (3 - nitro - 4 - methoxyphenyl)-ethylene (III). Oxidation of this compound with chromic anhydride in glacial acetic acid gave 3,3'-dinitro-4,4'-dimethoxybenzophenone (VII). This ketone has been reported by several workers[2] and its melting point reported as 205°,[2a] 193°,[2d] 190°[2c] and 189–190°.[2b] Our product VII reached a maximum melting point of 187–187.5°[3] after a total of eight recrystallizations from a variety of solvents.

Conclusive proof of the structure of II was given by two independent methods. The first of these was by the condensation of chloral hydrate and *o*-nitroanisole to a product identical with II, indicating that the nitro groups in II were ortho to the methoxyl groups. In addition the nitration product (VI) of DDT (V), shown by Backeberg and Morris[4] to be 1,1,1-trichloro-2,2-bis-(3-nitro-4-chlorophenyl)-ethane, on treatment with alcoholic sodium methoxide caused dehydrohalogenation and replacement of the para chlorine atoms by methoxyl groups giving a product identical with III.

Reduction of the nitro groups in III gave the corresponding diamine, 1,1-dichloro-2,2-bis-(3-amino-4-methoxyphenyl)-ethylene, IV.

Preliminary *in vitro* tests were carried out on compounds II, III and IV by the Parke, Davis

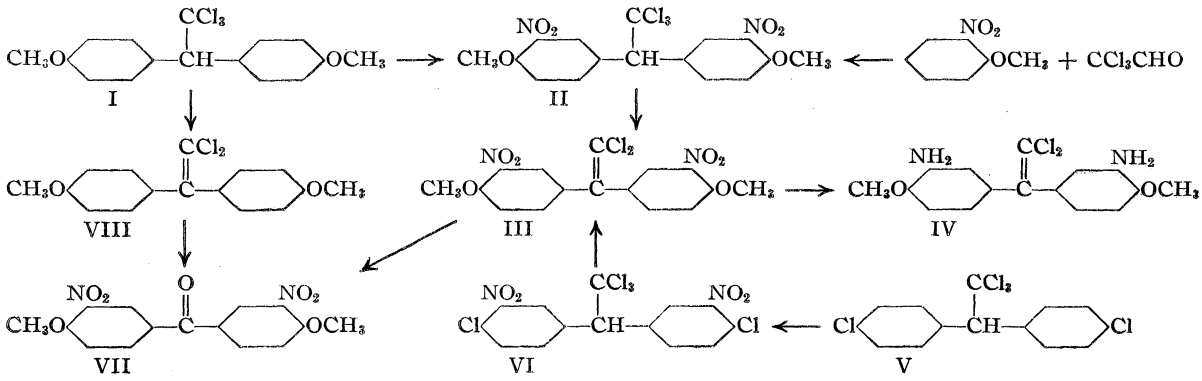
Fig. 1.—Summary of reactions.



Co. for activity against the H37Rv strain of human tuberculosis bacillus.[5] None of the compounds was active.

Experimental

1,1,1-Trichloro-2,2-bis-(3-nitro-4-methoxyphenyl)-ethane (II).—Five grams (0.0145 mole) of methoxychlor (I), prepared in essential accordance with the procedure of Schneller and Smith,[6] was dissolved in 50 ml. of glacial acetic acid and heated to reflux while a solution of 25 ml. of concentrated nitric acid was added dropwise over a period of thirty minutes. Reflux was continued for an additional hour, and the mixture allowed to stand for five hours. The reaction mixture was poured into excess water and the precipitated solid filtered off, dried, and recrystallized from alcohol. The product was 4.3 g. (68%) of small lemon yellow prisms, m. p. 166–167°. Another recrystallization from a mixture of alcohol and benzene gave 3.7 g. melting at 167–168°.

Anal. Calcd. for $C_{16}H_{13}Cl_3N_2O_6$: N, 6.43; Cl, 24.42. Found: N, 6.27 and 6.48; Cl, 24.45 and 24.40.

A mixture of 75.5 g. (0.50 mole) of *o*-nitroanisole, 37 g. (0.25 mole) of chloral hydrate, and 50 g. of concentrated sulfuric acid was stirred while 100 g. of 20% fuming sulfuric acid was added over a thirty-minute period. The temperature of the mixture increased to 65–70°. The mixture was stirred for one and one-half hours longer and then poured into excess water. The precipitated brown semi-solid mass was filtered off, washed with water, and recrystallized from glacial acetic acid and then from alcohol–benzene mixture to give 12.5 g. (12%) of yellow prisms, m. p. 168°. A mixed melting point between this material and that formed above by nitration of methoxychlor showed no depression.

1,1-Dichloro-2,2-bis-(3-nitro-4-methoxyphenyl)-ethylene (III).—A solution of 44 g. (0.10 mole) of II in a mixture of 250 ml. of alcohol and 75 ml. of benzene was heated to reflux and stirred while a solution of 8.6 g. (0.15 mole) of potassium hydroxide in 80 ml. of alcohol was added slowly. After a ten-minute reflux period, the hot mixture was filtered to remove the precipitated potassium chloride. Cooling the filtrate precipitated 31 g. (78%) of yellow prisms, m. p. 160–161°.

Anal. Calcd. for $C_{16}H_{12}Cl_2N_2O_6$: N, 7.03; Cl, 17.8. Found: N, 7.07 and 7.09; Cl, 17.4 and 17.4.

1,1-Dichloro-2,2-bis-(3-amino-4-methoxyphenyl)-ethylene (IV).—Raney nickel catalyst[7] suspended in alcohol was added to a hot solution of 8.0 g. (0.02 mole) of III in 100 ml. of alcohol. The mixture was agitated under a hydrogen pressure of 40 lb. until absorption of hydrogen was complete (about thirty minutes). The catalyst was removed by filtration, and the filtrate evaporated to a volume of 30–40 ml. Cooling precipitated 3.4 g. (50%) of the amine, m. p. 108.5°.

Anal. Calcd. for $C_{16}H_{16}Cl_2N_2O_2$: N, 8.26. Found: N, 8.39.

Oxidation of 1,1-Dichloro-2,2-bis-(3-nitro-4-methoxyphenyl)-ethylene (III).—The ethylene derivative III (2.0 g.) was oxidized with chromium trioxide in glacial acetic acid in general accordance with a procedure used by other workers[1,8] to give 1.1 g. of crude 3,3′-dinitro-4,4′-dimethoxybenzophenone, m. p. 178–180°. Eight recrystallizations utilizing ethanol, benzene, ethyl acetate, methanol and acetophenone as solvents gave a product with a constant and maximum melting point of 187–187.5°.[2]

Anal. Calcd. for $C_{15}H_{12}N_2O_7$: N, 8.43. Found: N, 8.38 and 8.42.

Treatment of 17 g. (0.055 mole) of 1,1-dichloro-2,2-bis-(*p*-methoxyphenyl)-ethylene (VIII), prepared by dehydrohalogenation of methoxychlor,[8b] with concentrated nitric acid (75 ml.) in glacial acetic acid (200 ml.) at the reflux temperature (one hour) gave 8 g. of 3,3′-dinitro-4,4′-dimethoxybenzophenone (VII) which was shown to be identical by the method of mixed melting points with the material isolated above. This indicated that both dinitration and oxidation to the ketone had occurred.

1,1-Dichloro-2,2-bis-(3-nitro-4-methoxyphenyl)-ethylene (III) from 1,1,1-Trichloro-2,2-bis-(3-nitro-4-chlorophenyl)-ethane (VI).—DDT (V) (10 g.) was nitrated in essential accordance with the procedure of Forrest, Stephenson and Waters[8a] to form 1,1,1-trichloro-2,2-bis-(3-nitro-4-chlorophenyl)-ethane (VI) in 91% yield. The product melted at 143–144°.[8a,9]

To a solution of 2.3 g. (0.0052 mole) of the nitration product (VI) in 100 ml. of methanol was added a solution of 0.6 g. (0.026 g. atom) of sodium in 60 ml. of methanol. The mixture was refluxed for two hours and then filtered to remove the precipitated sodium chloride. The solvent was removed from the filtrate by distillation to one-half volume, and upon cooling yellow prisms precipitated. These were recrystallized from ethanol to give 0.6 g. (27%) of 1,1-dichloro-2,2-bis-(3-nitro-4-methoxyphenyl)-ethylene (III), m. p. 161–162°. A mixed melting point with a sample of III prepared as described above by dehydrohalogenation of the nitration product of methoxychlor showed no depression.

Summary

Nitration of 1,1,1-trichloro-2,2-bis-(*p*-methoxyphenyl)-ethane (methoxychlor) forms 1,1,1-trichloro - 2,2 - bis - (3 - nitro - 4 - methoxyphenyl)-ethane.

Two independent methods of proof showed that the structure of the nitration product is that indicated in the above name.

1,1-Dichloro-2,2-bis-(3-amino-4-methoxyphenyl)-ethylene and its precursors showed no activity *in vitro* when tested against *M. tuberculosis*.

Racemic Glucose

BY M. L. WOLFROM AND H. B. WOOD

Racemic glucose was described as a sirup by Fischer.[1] Its purported occurrence in jute leaf[2] requires further experimental substantiation. The excellent synthesis of Sowden and Fischer[3] now makes L-glucose a readily available substance. We have succeeded in crystallizing a racemic form of this sugar. Hudson[4] has discussed the possible anomeric forms of a racemic mutarotating sugar and Fletcher and Hudson[5] have shown how these may be distinguished by acylative and crystallographic technics. Applying these criteria to our substance, we find that the X-ray powder diffraction pattern (Table I) for the racemic form of glucose isolated by us, is sensibly identical with the data reported by Sponsler and Dore[6] for anhydrous α-D-glucose. Since enantiomorphs exhibit like patterns, this is definitive proof that the racemic glucose is α-D,α-L-glucose and that it is a racemic mixture and not a true racemic compound. Supporting indirect evidence for this deduction is obtainable by acetylation technics. The racemic glucose was acetylated at low temperature with acetic anhydride and pyridine[7] and the crystalline product was characterized. L-Glucose was employed to prepare its hitherto unknown α and β pyranoid pentaacetates. These were admixed with equal quantities of their enantiomorphs and the crystalline racemic substances were characterized by melting point and X-ray powder diffraction pattern. The data of Table I show that the two racemic pentaacetates have a different crystal structure than is exhibited by either enantiomorph. Therefore α-D,α-L-glucopyranose pentaacetate (m. p. 140.5–141°) and β-D,β-L-glucopyranose pentaacetate (m. p. 125–126°) are true racemic compounds. The former was identical with the product obtained by the low temperature acetylation of the racemic glucose. This is further evidence that the racemic glucose is α-D,α-L-glucopyranose. The required assumption that the ring or anomeric structure of the sugar did not change on acetylation, while eminently probable, is not rigorous and this evidence is therefore equivocal.

cose was dissolved in 100 ml. of warm, absolute methanol. Crystallization was effected on slow solvent removal in a desiccator over sulfuric acid. Pure material was obtained on recrystallization (or elution) from methanol or ethanol and drying was effected under reduced pressure over phosphorus pentoxide at 56°; m. p. 112–113.5°, $[\alpha]^{20}D$ 0° (no mutarotation). It crystallized as fine needles.

Anal. Calcd. for $C_6H_{12}O_6$: C, 40.00; H, 6.66. Found: C, 39.90; H, 6.72.

α-D,α-L-Glucopyranose Pentaacetate.—α-D,α-L-Glucose (0.200 g.) and 2 ml. of anhydrous pyridine were cooled to 0° and 1.4 ml. of acetic anhydride was added slowly under mechanical stirring while maintaining the same temperature. The suspension was stirred at 0° for twenty hours after which time the solution was poured slowly into 10 ml. of ice and water. The crystalline material was removed by filtration, washed with water and recrystallized from 95% ethanol; yield 0.258 g. (61%), m. p. 140–140.5°. The substance formed complex rhombic crystals.

Anal. Calcd. for $C_{16}H_{22}O_{11}$: C, 49.22; H, 5.68. Found: C, 49.21; H, 5.75.

This product showed the same X-ray powder diffraction diagram (Table I) as that obtained by recrystallizing equal amounts (0.2000 g.) of the α-D and the below-described α-L-glucose pentaacetate from 95% ethanol; m. p. 141–141.5°, mixed melting point unchanged; m. p. 113–115° on admixture with the below-described β-D,β-L-pentaacetate of m. p. 125–126°.

α-L-Glucopyranose Pentaacetate.—α-L-Glucose[3] (0.40 g.) was acetylated as described above for the α-D,α-L isomer and the crude crystalline product (0.77 g., 89%, m. p. 108–110°) was recrystallized from ethanol–water; m. p. 112–113°, $[\alpha]^{25}D$ −101° (*c* 4.4, chloroform) in agreement (opposite sign) with those cited by Hudson and Dale[8] for α-D-glucose pentaacetate.

Anal. Calcd. for $C_{16}H_{22}O_{11}$: C, 49.22; H, 5.68. Found: C, 49.29; H, 5.30.

(8) C. S. Hudson and J. K. Dale, THIS JOURNAL, **37**, 1264 (1915).

β-L-Glucopyranose Pentaacetate.—α-L-Glucose[3] (0.20 g.) was heated on a steam-bath with freshly fused sodium acetate (0.12 g.) and acetic anhydride (2.0 ml.) and heating was maintained for two hours after solution, which required about thirty minutes. The crystalline material (0.38 g., 88%, m. p. 130–131°) obtained on pouring the reaction mixture into 20 ml. of ice and water, was recrystallized from 95% ethanol; m. p. 131–132°, $[\alpha]^{25}D$ −3.9° (*c* 2.9, chloroform) in agreement (opposite sign) with those cited by Hudson and Dale[8] for β-D-glucose pentaacetate.

Anal. Calcd. for $C_{16}H_{22}O_{11}$: C, 49.22; H, 5.68. Found: C, 49.30; H, 5.32.

β-D,β-L-Glucopyranose Pentaacetate.—Equal amounts (0.1000 g.) of β-D- and β-L-glucose pentaacetate were recrystallized from 95% ethanol; m. p. 125–126°, needles.

Anal. Calcd. for $C_{16}H_{22}O_{11}$: C, 49.22; H, 5.68. Found: C, 49.60; H, 5.43.

Summary

1. A crystalline form of racemic glucose has been prepared.

2. The crystalline pyranoid pentaacetates of α-L-, β-L-, α-D,α-L- and β-D,β-L-glucose are described.

3. X-Ray powder diffraction diagrams of the above compounds have been obtained.

4. Mild acetylation of the racemic glucose produces α-D,α-L-glucopyranose pentaacetate.

5. The D,L-glucose (m. p. 112–113.5°) described is a racemic mixture of the α-D and α-L forms of glucose, probably pyranoid.

6. The described pyranoid pentaacetates of α-D,α-L- and β-D,β-L-glucose are true racemic compounds.

Liquid–Vapor Equilibrium of Ethanol–Methylcyclohexane Solutions

BY CARL B. KRETSCHMER AND RICHARD WIEBE

In two recent publications results on the liquid–vapor equilibria of ethanol–isoöctane[2] and ethanol–toluene[3] solutions were described. The work has now been extended to solutions of ethanol in methylcyclohexane. The only previous measurements on this system are those of Isii,[4] who measured the total vapor pressure at 0 to 30°.

Experimental

The apparatus, method and purification of the ethanol have been described fully in previous articles.[2,3] A commercial grade of methylcyclohexane was fractionally distilled in an efficient column and percolated through a column of silica gel. Facilities for a determination of the freezing point were not available but the physical properties, d^{25}_4 0.76496, $n^{25}D$ 1.42059, are in satisfactory agreement with the values given by Forziati[5] for a sample containing 0.10 mole per cent. impurity, *viz.*: d^{25}_4 0.76501, $n^{25}D$ 1.42056.

Since the densities of the two liquids differ by only 0.02, solutions were analyzed by means of their refractive indices for the green mercury line (5461 Å.). A Bausch and Lomb precision refractometer was used. In order to establish the relation between composition and index of refraction, solutions were made up by weight as previously described.[2] Because of the theoretical and practical interest in the change of volume on mixing, the densities of these solutions were measured as well as their refractive indices. Table I gives the resulting values. The volume changes are all positive and are remarkably close to the values for

ethanol–isoöctane solutions at the same temperature. Compositions of the liquid and vapor samples were calculated from their indices of refraction with the aid of the indices listed in Table I. The accuracy of such analyses is believed to be about 0.1 unit in the percentage by weight.

The results of the liquid–vapor equilibrium measurements at 35 and 55° are given in Table II. The vapor pressures for pure ethanol were taken from our previous work[3]; those for methylcyclohexane were calculated from the equation published by Willingham and co-workers.[6] Since the vapor pressure curves for this system are similar to those for the other systems studied, they are not reproduced here.

Discussion

The vapor compositions were fitted by the empirical equation previously used[3]

$$y(1-x)/[x(1-y)] = \alpha = (A - Bx)/[(x + C)(1 - 2C + Cx)] \quad (1)$$

where x and y are the mole fractions of ethanol in liquid and vapor, respectively. The following values of the constants were found to represent the data for ethanol–methylcyclohexane solutions: at 35°, $A = 1.131$, $B = 1.003$, $C = 0.020$; at 55°, $A = 1.339$, $B = 1.179$, $C = 0.028$. That the fit is satisfactory is shown by the deviations listed in Table II. Fig. 1 illustrates the method of fitting this equation. The quantity $q = \alpha(x + C)(1 - 2C + Cx)$ is plotted against x for various values of C, and that value of C is chosen which makes the points lie closest to a straight line, bearing in mind that the points must be given weights proportional to $y(1 - y)/q$ if all the values of y are assumed equally accurate.

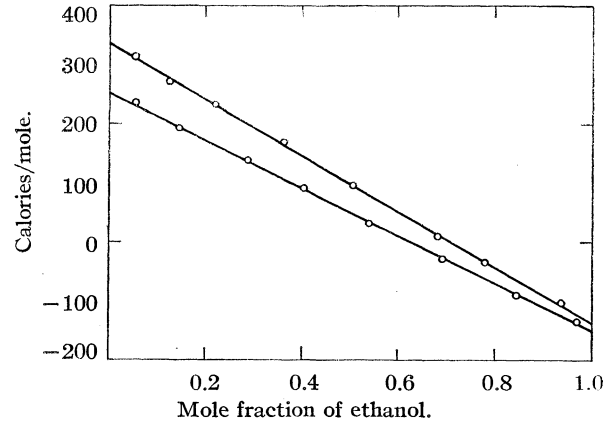

Fig. 1.—Relative volatilities of ethanol–methylcyclohexane solutions: upper curve, 55°, $C = 0.028$; lower curve, 35°, $C = 0.020$.

Equation (1) was substituted into the Gibbs–Duhem relation in the form given as equation (3) of our previous paper,[3] and used to calculate the vapor pressure at mole fractions of 0.5 and 1, for both temperatures. The liquid molal volumes and second virial coefficients for ethanol were the same as used previously.[3] For methylcyclohexane, the critical constants given by Kay,[7] were used with the equation of state of Keyes, Smith and Gerry in the form used by Scatchard and Raymond,[8] to give the following values of the second virial coefficient: at 35°, −3361; at 55°, −2592 cc./mole. Liquid molal volumes were calculated from the density equation of Massart.[9] The calculated vapor pressures differ from observed values by

(7) W. B. Kay, THIS JOURNAL, **69**, 1273 (1947).
(8) G. Scatchard and C. L. Raymond, *ibid*, **60**, 1278 (1938).

0.8% or less. This result may be taken to indicate a satisfactory degree of thermodynamic consistency in our data.

Redlich and Kister[10] have developed the following equation to represent the behavior of solutions containing an associating component such as an alcohol.

$$\log(\gamma_1/\gamma_2) = A'(K,x) + B'(1-2x) + C'[6x(1-x)-1] \quad (2)$$

Here γ_1 and γ_2 are the activity coefficients of alcohol and hydrocarbon, respectively. We have used primes to distinguish the notation from that of equation (1). A' is a function of x and of K, the equilibrium constant for the association reaction $ROH + (ROH)_n \rightleftarrows (ROH)_{n+1}$. The form of the function $A'(K,x)$ is given in reference (10b), equation (20). In equation (2) above, the terms in A' and B' are odd functions of $(1-2x)$, while the term in C' is, of course, an even function.

To test the applicability of equation (2) to the present data, the values of log γ_1 and log γ_2 listed in Table II were calculated from the experimental data by use of the relation

$$\log\gamma_i = \log(y_i p/x_i p_i) + (1/2.303RT)(\beta_i - v_i)(p - p_i) \quad (3)$$

Here x_i and y_i are the mole fractions of component i in liquid and vapor; p_i, β_i and v_i are the vapor pressure, second virial coefficient, and liquid molal volume of component i, and p is the vapor pressure of the solution. Values of log (γ_1/γ_2) were plotted against x, and the resulting curve was resolved into odd and even functions of $(1-2x)$ by means of the relation

$$f(x) = \tfrac{1}{2}[f(x) - f(1-x)] + \tfrac{1}{2}[f(x) + f(1-x)] \quad (4)$$

It was found that the odd function could be represented quite accurately by the odd terms of equation (2). However, the even function is represented poorly by the term $C'[6x(1-x)-1]$. This is shown in Fig. 2, where the plotted points have been taken from the experimental curve of log (γ_1/γ_2) *vs.* x, and the curve is calculated for $C' = -0.111$. The deviations represent errors in y of up to 0.015 mole fraction. The following values of the parameters were found for ethanol–methylcyclohexane solutions: at 35°, $K = 16$, $B' = 1.350$, $C' = -0.111$; at 55°, $K = 16$, $B' = 1.331$, $C' = -0.111$. The ethanol–toluene system[3] at 35° can be represented by $K = 6$, $B' = 0.994$, $C' = -0.130$, with deviations very similar to those shown in Fig. 2. The above values of K are anomalous in that one would reasonably expect K to decrease appreciably between 35 and 55°. Furthermore, the theory behind equation (2) requires that K have the same value for solutions of the same alcohol in different hydrocarbons at the same temperature. However, it has been emphasized[10] that K is very sensitive to experimental errors, and also, we might add, to deviations from the simplifying assumptions necessarily introduced in deriving equation (2).

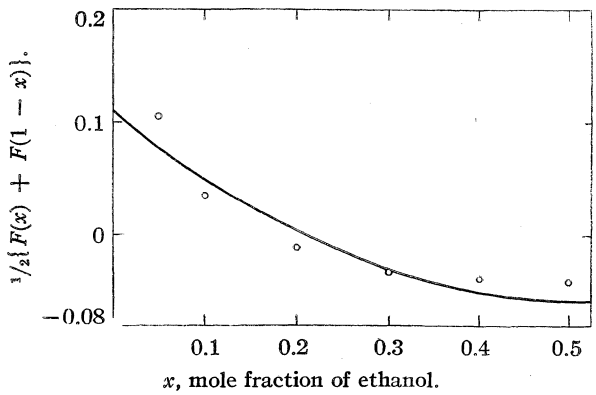

Fig. 2.—Ethanol–methylcyclohexane solutions at 55°: points, even component of log(γ_1/γ_2); curve, $0.111[1 - 6x(1-x)]$.

TABLE III

EXCESS THERMODYNAMIC FUNCTIONS OF ETHANOL–METHYLCYCLOHEXANE SOLUTIONS IN CALORIES/MOLE

Mole fract. ethanol	G^E, 35°	G^E, 55°	TS^E, 35°	H^M
0.0528	95	91	79	174
.1251	186	183	42	228
.2205	263	263	− 9	254
.3621	323	327	−62	261
.5071	334	341	−92	242

.7792	231	235	−79	152
.9347	86	87	−29	57

The excess thermodynamic functions in Table III and Fig. 3 were calculated from the experimental values of y and p by the usual method.[3] The behavior is similar to that of the ethanol–toluene system, as well as various systems containing methanol which have been studied and discussed by Scatchard and co-workers.[11] Little

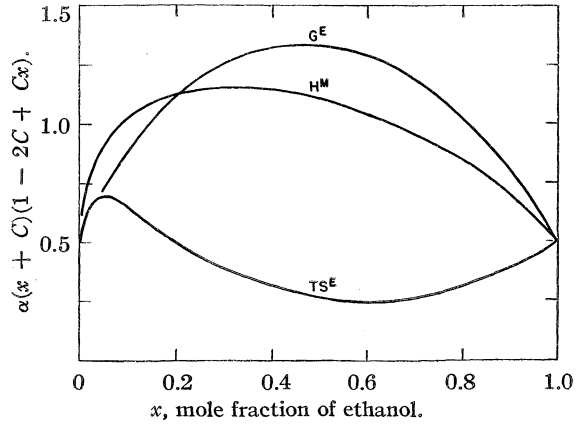

Fig. 3.—Excess thermodynamic functions of ethanol-methylcyclohexane solutions at 35°.

(10) (a) O. Redlich and A. T. Kister, *J. Chem. Phys.*, **15**, 849 (1947); (b) *Ind. Eng. Chem.*, **40**, 345 (1948).

(11) G. Scatchard, S. E. Wood and J. M. Mochel, THIS JOURNAL, **68**, 1957, 1960 (1946); S. E. Wood, *ibid.*, **68**, 1963 (1946); *J. Chem. Phys.*, **15**, 358 (1947).

can be added to their discussion except to say that a completely satisfying theory of the behavior of such solutions is not yet possible, and to emphasize again the fact that interactions between the unlike molecules are involved, in addition to the type of association of the alcohol postulated by Redlich and Kister.[10]

Summary

For the system ethanol–methylcyclohexane, densities and refractive indices have been measured at 25°. Total and partial vapor pressures have been determined at 35 and 55°. Thermodynamic consistency of the data was found to be satisfactory.

Vapor compositions are represented by the empirical equation previously developed by the authors, to within 0.005 mole fraction. They can be represented by an equation developed by Redlich and Kister, with somewhat less accuracy, and with rather anomalous values of the equilibrium constant involved.

The excess free energy, entropy and enthalpy have been calculated from the data, and exhibit a similar behavior to that of other alcohol–hydrocarbon systems.

The Fractional Separation of Zirconium and Hafnium by Extraction with Thenoyltrifluoroacetone[1]

BY E. H. HUFFMAN AND L. J. BEAUFAIT

The synthesis of thenoyltrifluoroacetone,  —CO—CH_2—CO—CF_3, has recently been reported by Reid and Calvin[2] and a study of the extraction of its zirconium chelate into benzene has been reported by Connick and McVey.[3] The work reported in this paper on the separation of zirconium and hafnium by means of this β-diketone was undertaken at the suggestion of M. Calvin and G. T. Seaborg. A study has been made of some differences in the extractions of zirconium and hafnium by benzene solutions of thenoyltrifluoroacetone (referred to as HT in equations and tables) from aqueous 2 *M* perchloric acid and the results applied to separations of these elements.

Zirconium is generally regarded as being in the form of ZrO^{++} in acid solutions. The complexing of zirconium by the diketone is negligible in the aqueous phase and the only important species in the benzene phase is ZrT_4.[3] The reaction then is expressed by the equation

$$ZrO^{+2} + 4HT = ZrT_4 + H_2O + 2H^+$$

and, assuming constant acid concentration, the equilibrium constant by

$$\log K = \log [ZrT_4]/[ZrO^{+2}] - 4 \log [HT] = \log R - 4 \log [HT]$$

where *R* is the extraction coefficient. If the zirconium is in the form of the simple Zr^{+4} ion in 2 *M* perchloric acid, as recently reported,[4] the expression for the equilibrium constant is not changed, providing that the zirconium ion is monomeric. Values for *R* and *K* have previously been determined[3] for zirconium using trace amounts of radioactive Zr^{95}.

The close similarity of zirconium and hafnium in chemical behavior makes it logical to assume that the above equations apply to both elements. The determination of values for *R* and *K* for both zirconium and hafnium, using macro quantities and concentrations for which the zirconium ions has been shown to be a monomer in 2.0 *M* perchloric acid,[4] has been carried out in this work in the thenoyltrifluoroacetone concentration range of 4×10^{-3} to 3×10^{-2} for zirconium and 10^{-2} to 7×10^{-2} for hafnium.

Experimental

Materials.—Thenoyltrifluoroacetone of 99.5% purity was obtained from M. W. Davis and H. R. Lehman of this Laboratory. Weighed amounts were dissolved in reagent thiophene-free benzene to give solutions of the desired concentrations.

Zirconium solutions were prepared in a manner similar to that of Connick and McVey.[3] Recrystallized $ZrOCl_2 \cdot 8H_2O$ was dissolved in 2.0 *M* perchloric acid to prepare a stock solution of approximately 0.09 *M* zirconium.

Tracer zirconium solutions were prepared from carrier-free Zr^{95} in 5% oxalic acid which was received from the Isotopes Branch, United States Atomic Energy Commission. This solution was made about 10 *M* in nitric acid and carrier zirconium added from the above stock solution. The solution was purified by the following treatment.[3] A small amount of 0.1 *N* potassium permanganate was added to precipitate manganese dioxide which carries the radioactive columbium but not zirconium. This precipitation was carried out three times to remove both oxalic acid and columbium. The zirconium solution was then diluted to about 1 *M* nitric acid and extracted with 0.02 *M* thenoyltrifluoroacetone in benzene, and the benzene phase washed twice with 2 *M* perchloric acid. The benzene solution was removed to a platinum dish and fumed with sulfuric acid with the addition of small amounts of 30% hydrogen peroxide to destroy organic matter. It was then diluted and zirconium hydroxide precipitated with ammonium hydroxide. The precipitate was dissolved in hydrochloric acid and the

[a] Analysis by tracer Zr^{95}.

zirconium hydroxide precipitated twice more to remove sulfate. Concentrated hydrochloric acid was then used to dissolve the hydroxide and this solution diluted to 6–7 *M* hydrochloric acid to precipitate $ZrOCl_2 \cdot 8H_2O$. A weighed amount of this salt was then dissolved in 2 *M* perchloric acid to give a stock solution approximately 0.003 *M* in zirconium.

Hafnium solutions were prepared from hafnium dioxide which contained 0.4% zirconium. This material was prepared from a commercial product, containing 5% zirconium, during preliminary extractions with 0.02 *M* thenoyltrifluoroacetone to explore the possibilities of the separation method. The zirconium content before and after purification was based on spectrographic analyses, as reported below. A weighed amount of the dioxide was warmed with concentrated nitric acid and a small amount of 48% hydrofluoric acid in a platinum dish until a clear solution was obtained which was then evaporated to near dryness. About 0.5 ml. of concentrated sulfuric acid was added and fumed for five to ten minutes. The preparation of $HfOCl_2 \cdot 8H_2O$ then followed the method given above for tracer $ZrOCl_2 \cdot 8H_2O$, beginning with dilution of the sulfuric acid solution. Tracer Hf^{181} solutions were prepared in the same way, using hafnium dioxide obtained from the Isotopes Branch, United States Atomic Energy Commission.

Analysis.—Colorimetric analyses were made with a Beckman spectrophotometer by G. Iddings who adapted the following method from that of Liebhafsky and Winslow[5] to correct for the effects of the organic substances and perchloric acid present. One-half ml. of saturated alizarin is added to a 25 ml. volumetric flask and then, in order, 10 ml. of 95% ethanol, 4 ml. of 2 *M* perchloric acid including that to be added from the sample, 1.0 ml. of 0.02 *M* thenoyltrifluoroacetone in benzene including that to be added from the sample, benzene or aqueous phase sample containing 25–90 μg of Zr or 25–125 μg of Hf, and 1 ml. of 2 *M* hydrochloric acid. After mixing, ammonium hydroxide is added carefully until the red color just appears and the mixture allowed to stand for five minutes. One normal hydrochloric acid is added until the red color disappears and then 0.10 ml. of 7 *M* hydrochloric acid is added in excess. The volume is made to 25 ml. with 95% ethanol and the mixture allowed to stand for four hours before the spectrophotometer reading is taken. Standard curves prepared by this procedure show that the zirconium and hafnium are colorimetrically equivalent, on a mole basis, in contrast to previous results.[5] The difference is probably due to the variation in the method of forming the lakes.

Radioactive analyses of zirconium were made using micropipets to obtain samples containing 500–1500 counts per minute. The samples were evaporated on platinum discs under an infrared lamp and counted in a Geiger counter, first with an aluminum absorber of 30 mg./sq. cm. and then with one of 150 mg./sq. cm. The differences in the two counts give that of the zirconium alone without the count of the active columbium which had grown in. The ratio of count to weight was obtained by evaporating a larger sample of the stock solution, igniting to zirconium dioxide and weighing. Hafnium radioactive analyses were made in a similar manner but counted without absorbers.

For the determination of extraction coefficients micropipets were used to obtain approximate weights of zirconium or hafnium from the stock solutions and the volume made to 5 ml. with 2 *M* perchloric acid. Five ml. of a benzene solution of thenoyltrifluoroacetone was then added and the mixture shaken for eighty minutes, although equilibrium was found to be reached within forty minutes for these amounts. Aliquots of the benzene and aqueous phases were then taken for analysis.

Results

Table I gives the results found for zirconium on the distribution ratios and equilibrium constant. Columns one, two and three give, respectively, the molar concentrations of diketone added, the micrograms per ml. of zirconium in the benzene phase and the micrograms per ml. in the aqueous phase at equilibrium. The free diketone concentration, not allowing for solubility in the aqueous phase, is obtained by multiplying the molar concentration of zirconium found in the benzene phase by four and subtracting the product from the molar concentration of diketone added. This answer is then multiplied by 0.974 to correct for solubility in 2 *M* perchloric acid[4] and to obtain the diketone concentration in the benzene phase. In column four are given the activity coefficients for these cor-

(5) H. Liebhafsky and E. Winslow, THIS JOURNAL, **60**, 1776 (1938).

rected diketone concentrations.[6] These also represent the activity coefficients of the chelate.[3] Column five gives the diketone activities found by multiplying the corrected concentrations by the corresponding activity coefficients. The distribution ratios in column six are obtained by multiplying the ratios of values from columns two and three by the activity coefficients of column four. Table II gives similar results for hafnium.

[a] Analysis by tracer Hf^{181}.

The dependence of the extraction coefficients on the diketone activities for zirconium and hafnium are given in the figure. The straight lines are drawn with a slope of four and corresponding to the average values found for the equilibrium constants.

A good separation of hafnium was carried out on a solution in 2 *M* perchloric acid containing 22.9 mg. of hafnium and 13.6 mg. of zirconium in 150 ml. Two extractions were made with 150-ml. portions of 0.025 *M* thenoyltrifluoroacetone and 6.31 mg. of hafnium was recovered in the aqueous phase, as determined by tracer count. The zirconium present in the aqueous phase was then too small to be determined by a combination of colorimetric and tracer Hf^{181} analysis. Spectrographic analysis, made on the perchloric acid solution, showed the presence of less than 1.2% zirconium based on the hafnium present. Calculations from the curves show that about 1% zirconium should be present.

In another separation, carried out before the data for the curves were obtained, 78.6 mg. of hafnium and 3.93 mg. of zirconium, from a commercial hafnium dioxide, were dissolved in 300 ml. of 2 *M* perchloric acid. This solution was then extracted with three 300-ml. portions of 0.02 *M* thenoyltrifluoroacetone. Precipitation and ignition of the oxide from the aqueous solution gave a recovery of 39.4 mg. of hafnium. Spectrographic analysis of a hydrofluoric acid solution of this product showed a 0.4% zirconium content, which is the value calculated from the curves. This is the material which was used in preparing hafnium solutions to obtain the data for the curve. Spectrographic analyses were made by J. Conway and M. Moore of this Laboratory who report that such analyses are more sensitive when carried out on hydrofluoric acid solutions than when on perchloric acid solutions.

(6) E. L. King and W. H. Reas, UCRL BC-69, July, 1947.

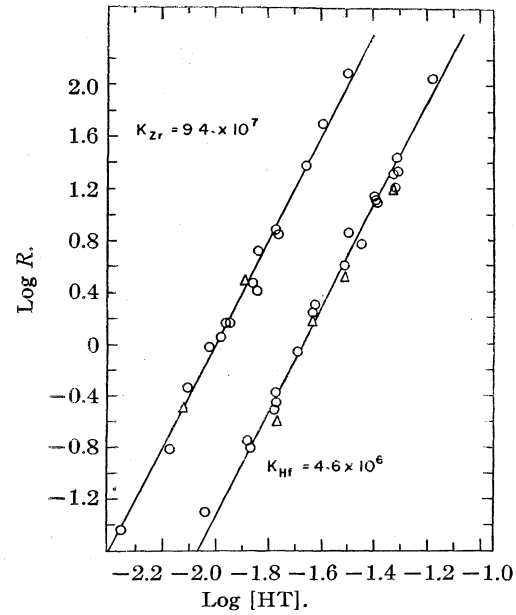

Fig. 1.—Dependence of distribution ratios on thenoyltrifluoroacetone activities: upper curve, zirconium; lower curve, hafnium; O, colorimetric analysis; △, radioactive tracer analysis.

The similarity of zirconium and hafnium makes it unlikely that better separations would be attained at other acidities and temperatures, but it is possible that higher concentrations could be worked with at higher acidities where the monomeric state is retained.

Summary

Distribution ratios for zirconium and hafnium have been found for extraction from 2 *M* perchloric acid with benzene solutions of thenoyltrifluoroacetone of varying concentration. The equilibrium constants for the zirconium and hafnium extractions were found to be 9.4×10^7 and 4.6×10^6, respectively, at this acidity.

Two extractions with 0.025 *M* thenoyltrifluoroacetone of a solution containing 59% as much zirconium as hafnium yielded 27% of the original hafnium with a content of less than 1.2% zir-

conium. Three extractions with 0.02 *M* thenoyltrifluoroacetone of a solution containing 5.0% zirconium, based on the hafnium content, gave a recovery of 50% of the hafnium with zirconium content of 0.4%.

The Aqueous Chemistry of Zirconium[1]

BY ROBERT E. CONNICK AND WILLIAM H. MCVEY[2]

Although the chemistry of zirconium has been the subject of numerous investigations since its discovery in 1789, practically nothing is known about the species existing in aqueous solutions of its salts. Typical is the fact that not even the formula of the uncomplexed zirconium(IV) ion, present in perchloric acid solutions, has been identified. The formulas of several complex ions in aqueous solutions such as $ZrO(SO_4)_2^{=}$ [3] and $ZrOCl_4^{=}$ [4] have been reported but the data could be interpreted equally well by assuming other species. From a search of the literature we have been forced to the conclusion that the formula of not a single aqueous zirconium(IV) species has been unambiguously identified up to the present time.

The existing information on the chemistry of zirconium was collected in 1921 by Venable[5] and more recently by Pascal.[6] Nearly all of this work, as well as that published since 1931, deals with the identification of solid phases rather than the study of ions in solution.

The purpose of the present research was to determine the formulas of the zirconium species existing in acidic aqueous solutions and to study the complexing of zirconium(IV) by a number of the more common anions

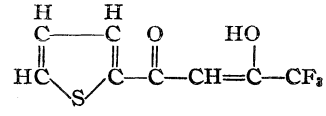
Experimental Method

The usual procedures for the determination of the formulas of species in solution, such as cell measurements, freezing point lowering, spectrophotometric analysis, *p*H determinations, solubility studies, etc., are not readily applicable in the case of zirconium because of the great tendency for hydrolysis to take place except in quite acidic solutions.

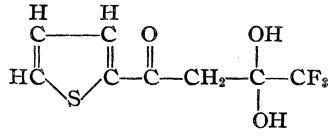
The experimental method employed involves the measurement of an equilibrium in which zirconium(IV) is distributed between the aqueous phase being investigated and an organic phase containing a chelating agent. The zirconium is inappreciably complexed by the chelating agent when in the aqueous phase, yet forms a chelate which is soluble in the organic phase and which is in equilibrium with whatever species exist in the aqueous phase. Any complexing of species in the aqueous phase is quantitatively reflected in a decrease of the extraction of the zirconium into the organic phase.

The method used in the present study is clearly a powerful one and it should find application in the study of many similar systems.

Calvin[7] has investigated the complexing properties of several chelating agents and the particular chelating agent used in this work, thenoyltrifluoroacetone was one prepared by Calvin and Reid.[8] This compound, hereafter referred to as TTA, is a weak acid having the following structure in the enol form



When TTA is equilibrated between dilute acid and benzene, the principal species in the aqueous phase is the hydrate[9]



while in the benzene phase, about 15% occurs in the hydrate form and 85% in the enol form. The keto form apparently is not an important species in this system. In aqueous solution TTA is a weak acid with an ionization constant[10] of 6.7×10^{-7}.

The distribution coefficient of TTA between benzene and a dilute acidic, aqueous phase favors the benzene phase, *i. e.*, at low TTA concentrations

$$(TTA)_b/(TTA)_{aq} = 40$$

The activity coefficient of TTA in benzene has been measured by King and Reas[9] who found it to decrease significantly below unity at TTA concentrations above 0.01 *M* in the benzene phase.

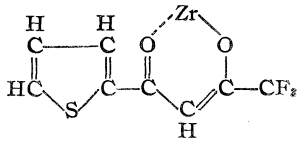
The zirconium chelate species which is extracted into the benzene phase is a neutral molecule consisting of a zirconium ion bonded to four TTA ions. Presumably each TTA ion is attached by two oxygens in the following manner



with the two double bonds in the zirconium ring capable of resonating between the two carbon–oxygen and carbon–carbon bonds.

Materials and Analytical Procedures.—In most of the experiments carrier-free, radioactive Zr^{95} tracer was employed. In some experiments macro concentrations of inactive zirconium were used and in a few of the runs both radioactive and macro amounts of inactive zirconium were present. The inactive zirconium was obtained from City Chemical Corporation as $ZrOCl_2 \cdot 8H_2O$ and was recrystallized several times from concentrated hydrochloric acid in the form of large crystalline needles of $ZrOCl_2 \cdot 8H_2O$. This solid was dissolved in 1.00 *M* perchloric acid to give a 0.1 *M* solution of zirconium(IV) containing 0.2 *M* chloride ion. The solution was clear except for a slight Tyndall beam and remained so over a period of many months.

The Zr^{95} tracer, which was obtained from Oak Ridge, decays[11] with a 65 day half-life to Cb^{95} by emission of a beta particle and gamma rays. The columbium in turn decays with a 35 day half-life to stable Mo^{95} with the emission of a beta particle and a gamma ray. A small fraction of the columbium appears to be formed in an excited state, which drops to the ground state with a 90 hour half-life.

The zirconium tracer, containing radioactive columbium, was received in a 5% oxalic acid solution. The solution was made 10 *M* in nitric acid and a small amount of 0.1 *N* potassium permanganate added to precipitate manganese dioxide, which was removed by centrifugation. This process was repeated several times, the potassium permanganate being reduced by water in the later precipitations. The purification served the dual purpose of eliminating the oxalic acid and the radioactive columbium, which is carried by manganese dioxide. Further purification from columbium and removal of nitric acid were achieved by extracting the zirconium into a benzene–TTA solution and washing the benzene phase repeatedly with 2.0 *M* perchloric acid. Columbium is not as readily extracted into the organic phase as is zirconium. Finally the benzene phase was diluted ten-fold with benzene, to lower the TTA concentration, and the zirconium was re-extracted into a small volume of 2.00 *M* perchloric acid.

In the analysis for radioactive zirconium, aliquots from both phases, usually 0.100 ml. in size, were mounted on 22-mm. square glass cover slides and counted, either using a Geiger counter with a mica-window tube or an ionization chamber attached to a vibrating reed electrometer. The reproducibility of these analyses was generally of the order of 2 to 3%. The samples were counted through an approximately 10 mg. per sq. cm. aluminum absorber in an effort to minimize the activity from columbium, which grows into the samples from the decay of zirconium; the columbium beta particles are considerably less energetic than those of zirconium. The activity and counting times were such as to give a probable counting error of approximately 0.7% in those experiments where the extraction coefficient was about unity.

A colorimetric method, developed by Liebhafsky and Winslow[12] and capable of determining quantitatively a few micrograms of zirconium, was used for the analysis of macro amounts of zirconium. The reproducibility of the analysis was fairly good, *i. e.*, of the order of 3%; however, the process of lake formation was greatly slowed down in the presence of TTA. The apparent concentration of zirconium increased slowly over a period of several hours. Attempts to improve the analysis by destruction of the TTA with bromine, chlorine and sodium hydroxide were unsuccessful. The spectrophotometer reading used for calculating the zirconium concentration was the nearly constant value obtained after the solution had stood for several hours.

Perchloric acid solutions were prepared by diluting G. Frederick Smith double vacuum distilled perchloric acid with conductivity water. The solutions were standardized by the mercuric oxide–potassium iodide method. Lithium perchlorate, used in the hydrolysis experiments to maintain constant ionic strength, was purified by recrystallizing G. Frederick Smith $LiClO_4 \cdot 3H_2O$ from water. The solution was analyzed by evaporating aliquots with sulfuric acid, igniting and weighing as anhydrous lithium sulfate. Pure, vacuum distilled TTA was kindly furnished by Dr. James C. Reid. The benzene was thiophene-free. All other chemicals were of reagent or C. P. grade and were used without further purification.

The experiments were carried out by mixing 25-ml. portions of the two phases, aqueous and benzene, in 100-ml. volumetric flasks. A mechanical shaker was so arranged that the flask was immersed in a water thermostat at 25.00 ± 0.05°. The shaking was vigorous, the flasks going through 1520 up and down movements per minute with a stroke of 2.5 cm.

All concentrations are expressed in moles per liter of solution, designated by the symbol *M*.

Nature of Extraction Equilibrium

Formula of Zirconium Chelate and Evidence for Non-complexing of Zirconium by TTA in Aqueous Phase.—Before the zirconium chelate extraction equilibrium can be used in the study of zirconium species in aqueous solutions, it is necessary to determine the formula of the chelate compound extracted into benzene and to establish that there is no appreciable complexing of zirconium by TTA in the aqueous phase. These facts may be ascertained from a study of the extraction coefficient as a function of the TTA concentration at constant acidity.

One possible equation for the extraction of zirconium is

$$Zr^{+4}(aq) + 4HK(b) = ZrK_4(b) + 4H^+(aq) \quad (1)$$

where HK has been used to represent TTA. However, the zirconium in the aqueous phase may be hydrolyzed and complexed by TTA, and the chelate in the benzene phase may contain hydroxide as well as TTA groups. To include all possibilities we write the general equation for the reaction

$$Zr(OH)_nK_m^{+4-n-m} + (p - m)HK = Zr(OH)_{4-p}K_p + (4 - m - n)H^+ + (n + p - 4)H_2O \quad (2)$$

and we may define the equilibrium constants

$$K_{m,n,p} = \frac{[Zr(OH)_{4-p}K_p][H^+]^{4-m-n}[H_2O]^{n+p-4}}{[Zr(OH)_nK_m^{+4-n-m}][HK]^{p-m}} \quad (3)$$

Brackets have been used to represent activities of the enclosed species. (Parentheses will be used to indicate concentrations.) The designation of the phase in which each species exists has been omitted to simplify the writing of the equation. The spe-

(11) G. T. Seaborg and I. Perlman, "Table of the Isotopes," Department of Chemistry and Radiation Laboratory, University of California, Report UCRL-179, August, 1948.

(12) H. Liebhafsky and E. Winslow, THIS JOURNAL, **60**, 1776 (1938).

cies $Zr(OH)_nK_m^{+4-n-m}$ and H^+ occur in the aqueous phase while the species $Zr(OH)_{4-p}K_p$ and HK are components of the benzene phase. All species in the benzene phase have been assumed to be neutral molecules because of the low dielectric constant of this solvent. The letter K has been used to indicate both an equilibrium constant and the ion of TTA; however, there should be no confusion as in the latter case it will always appear within brackets.

An extraction coefficient expressed in terms of activities is defined as the sum of the activities of zirconium species in the benzene phase divided by the sum of the activities of zirconium species in the aqueous phase, *i. e.*

$$E_a = \frac{\sum_p [Zr(OH)_{4-p}K_p]}{\sum_n \sum_m [Zr(OH)_nK_m^{+4-n-m}]} \quad (4)$$

From equation (3) the relationship holds

$$[Zr(OH)_nK_m^{+4-n-m}] = \frac{[ZrK_4][H^+]^{4-m-n}[H_2O]^n}{K_{m,n,4}[HK]^{4-m}} \quad (5)$$

From equations (3) and (5)

$$\frac{[ZrK_4][H^+]^{4-m-n}[H_2O]^n}{K_{m,n,4}[HK]^{4-m}} = \frac{[Zr(OH)_{4-p}K_p][H^+]^{4-m-n}[H_2O]^{n+p-4}}{K_{m,n,p}[HK]^{p-m}} \quad (6)$$

Solving for the activity of the general species in the benzene phase

$$[Zr(OH)_{4-p}K_p] = \frac{[ZrK_4][H_2O]^{4-p}K_{m,n,p}}{[HK]^{4-p}K_{m,n,4}} \quad (7)$$

Since this equation holds for any set of values of m and n, we shall for simplicity choose m and n to be zero. Then

$$[Zr(OH)_{4-p}K_p] = \frac{[ZrK_4][H_2O]^{4-p}K_{o,o,p}}{[HK]^{4-p}K_{o,o,4}} \quad (8)$$

Substituting equations (8) and (5) into equation (4), one obtains

$$E_a = \frac{\sum_p \frac{[ZrK_4][H_2O]^{4-p}K_{o,o,p}}{[HK]^{4-p}K_{o,o,4}}}{\sum_m \sum_n \frac{[ZrK_4][H^+]^{4-m-n}[H_2O]^n}{K_{m,n,4}[HK]^{4-m}}} \quad (9)$$

The factor $[ZrK_4]$ cancels completely between the numerator and denominator. Taking the partial derivative of the logarithm of E_a with respect to the logarithm of the activity of HK and substituting from equations (8) and (5) gives

$$\frac{\partial \ln E_a}{\partial \ln [HK]} = \frac{\sum_p (p-4)[Zr(OH)_{4-p}K_p]}{\sum_p [Zr(OH)_{4-p}K_p]} - \frac{\sum_m \sum_n (m-4)[Zr(OH)_nK_m^{+4-m-n}]}{\sum_m \sum_n [Zr(OH)_nK_m^{+4-m-n}]} \quad (10)$$

Limits may be placed on the values of m and p on the basis of the size of the zirconium ion. It is found both theoretically and experimentally that the maximum coördination number of Zr^{+4} for oxygens does not exceed eight.[13] Assigning two coördination positions to each chelate group then limits the maximum possible number values of m and p to four. With this assumption equation (10) may be rewritten in the form

$$\partial \ln E_a / \partial \ln [HK] = -4f_0 - 3f_1 - 2f_2 - f_3 + 4f_0' + 3f_1' + 2f_2' + f_3' \quad (11)$$

where each f is the fraction of the total activity of that phase contributed by species containing the indicated number of chelate groups. The unprimed f's refer to the benzene phase and the primed f's to the aqueous phase. It should be pointed out that in performing the differentiation leading to equation (11) it was necessary that the activity of water and of hydrogen ion remained constant.

An equation having exactly the same form as (11) may be derived on the basis of an extraction coefficient, E', defined as the ratio of the sum of the activities of the zirconium species in the benzene phase to the total concentration of zirconium in the aqueous phase. The f's represent fractions of the total zirconium activity in the benzene phase and the f''s fractions of the total zirconium concentration in the aqueous phase. An additional restriction is imposed on the differentiation, *i. e.*, that the activity coefficients of all species in the aqueous phase remain constant.

This equation corresponds to the experimental conditions used in the determination of the dependence of the extraction coefficient on TTA activity, but unfortunately only E_c, the extraction coefficient expressed in concentrations, and not E' can be determined experimentally.

The activity coefficients of the individual zirconium chelate species in the benzene phase as a function of the TTA concentration are not known. For simplicity it will be assumed that they all behave like γ_{ZrK_4}, the activity coefficient of ZrK_4, and that this in turn is equal to γ_{UK_4} measured by Reas.[14] No appreciable error should be introduced by these assumptions since γ_{UK_4} varies little over the range of TTA concentration used. On this basis $E' = E_c\gamma_{ZrK_4}$.

From the slope of the line obtained by plotting the logarithm of the extraction coefficient E' *versus* the logarithm of the activity of TTA (see equation (11)), one should be able to determine the number of TTA groups present in the zirconium species in the benzene phase and in the aqueous phase. (Experiments in which only the TTA activity is varied provide no information about the number of hydroxide groups or other anions associated with the various zirconium species.) For any slope less than four, a number of combinations of the various f's and f''s would fit the data. The important point is that, should the slope be four, there is only one combination which will fit the

(13) L. Pauling, "The Nature of the Chemical Bond," Cornell University Press, Ithaca, N. Y., 1939.

(14) W. H. Reas, unpublished work, this Laboratory.

data and that is for all of the f's to be zero, and all of the f''s to be zero except f_0' which must be unity, *i. e.*, $p = 4$ and $m = 0$. Then the equation for the reaction must be written

$$Zr(OH)_n^{+4-n} + 4HK = ZrK_4 + (4 - n)H^+ + nH_2O \quad (12)$$

Experimental Results

The experiments designed to test the dependence of the extraction coefficient on the TTA concentration were carried out in 2.00 M perchloric acid. The conditions and results are presented in Table I.

[a] Value obtained when new aqueous phase was equilibrated with benzene phase of previous experiment, in order to eliminate columbium; see text.

In the first column is given the TTA concentration (moles per liter) in the benzene phase at equilibrium, calculated from the known concentration of TTA added and a distribution ratio of 35 for TTA between the benzene phase and the aqueous phase. (The distribution coefficient decreases from 40 in 0.1 M hydrochloric acid[9] to 35 in 2 M perchloric acid relative to benzene.) In column two is listed the value of the activity coefficient of TTA[9] corresponding to the concentration in column one. Reas[14] found that the activity coefficient of uranium(IV) chelate in benzene at various TTA concentrations was, within experimental error, the same as for TTA itself, hence the values of column two also represent γ_{ZrK_4} in benzene. In column three is given the ratio of the concentrations of zirconium in the benzene and aqueous phases as determined from the zirconium radioactivity. In columns four and five are listed the values of the activity of TTA and E', calculated from the relationships $[HK] = (HK)\gamma_{HK}$ and $E' = E_c\gamma_{ZrK_4}$, respectively. The logarithms of the values of the activity of TTA and E', given in columns six and seven, are plotted in Fig. 1. In the experiments of Table I and all following experiments, both phases were analyzed as a function of time in order to make certain that equilibrium had been established.

The straight line in Fig. 1 has been drawn with a slope of four. It can be seen that the experimental points, indicated by solid circles fit this slope within experimental error up to a TTA activity of 10^{-2}, but, from there on, the points appear to fall off to a smaller slope. That this effect is not real, but arises from radioactive columbium impurity in the stock tracer, is shown by the point at highest TTA activity (designated by an open circle in Fig. 1) which falls on the line of slope four. In this experiment columbium was eliminated by reëquilibrating the benzene phase of the experiment at 0.02918 M TTA with a fresh aqueous phase. The columbium was removed along with the first aqueous phase as it is not extracted appreciably into benzene under these conditions. Presumably the other points which deviate would also be brought into line if the columbium were eliminated. No attempt was made to calculate a correction for these experiments because columbium is radio-colloidal in such solutions and probably does not behave reproducibly. The correction for columbium becomes small, *i. e.*, of the order of magnitude of the experimental accuracy in the experiments where the extraction coefficient is low.

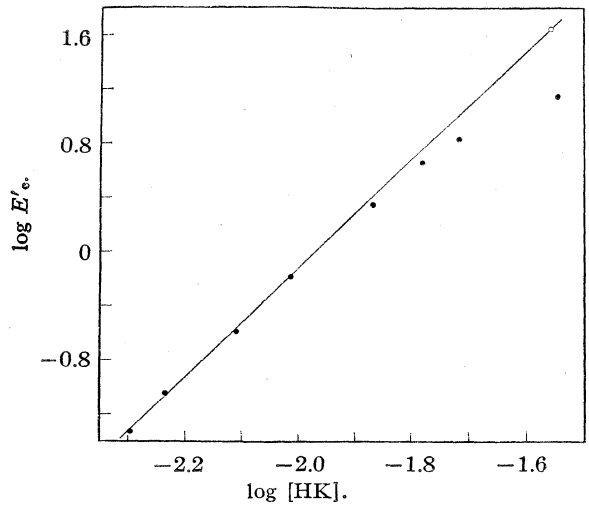

Fig. 1.—Dependence of extraction coefficient on TTA activity.

From the above results the extraction coefficient appears to follow a fourth power dependence on TTA activity within the accuracy of the measurements. Therefore the zirconium species in the aqueous phase are not appreciably complexed by TTA, and the only important species in the benzene phase is ZrK_4.

Comparison of Extraction Coefficients of Trace and Macro Amounts of Zirconium.—Experiments performed with macro amounts of zirconium to check the trace results gave somewhat greater coefficients, as shown in Table II. The concentration of TTA in column 2 has been corrected for that used up in forming the chelate. The extraction coefficients, corrected to the same TTA concentration as in the first experiment, are given in the last column as $E_{cor.}$

The increase in the extraction coefficient at macro zirconium concentrations seems best explained by assuming the presence of a small

TABLE II

5.1×10^{-4} M	.00861	.56	.91

amount of impurity which partially complexed the trace zirconium. At high zirconium concentrations the effect would become small if the total amount of impurity were small compared to the total zirconium. If it is assumed that the amount of impurity was the same in each experiment, certain deductions may be made. Since the extraction coefficient of the second experiment is greater than for the trace experiment, an appreciable part of the impurity must have been tied up in the second experiment. The relatively small change in extraction coefficient for a ten-fold increase in zirconium concentration in going from the second to the third experiment indicates that nearly all of the impurity must be complexed by zirconium in the third experiment. Therefore the concentration of the impurity must be of the order of 10^{-4} to 10^{-5} M. Further, it may be concluded that the extraction coefficient in the last experiment is near the value that would be obtained in the absence of the impurity and that about 40% of the zirconium(IV) in the aqueous phase is complexed by the impurity in the first experiment.

A strenuous effort was made to eliminate the impurity. Different sources of all reagents were tried. The magnitude of the effect varied somewhat but in no case was the effect eliminated. It was shown by a study of their complexing power that none of the substances listed in Table VI were responsible.

Impurities in the radioactive tracer were not interfering as experiments with and without tracer gave the same results and the radioactive analysis agreed with the colorimetric analysis.

Radio-colloid formation did not appear to be a likely explanation since addition of 0.01 M silicic acid did not decrease the extraction coefficient greatly (see Table VI). Polymer or true colloid formation would have caused a decrease in extraction coefficient with rising zirconium concentration.

At the present time neither the identity nor the source of the impurity is known. Its presence introduces an uncertainty into the interpretation of the data of the trace experiments. The identification of the various zirconium complexes present in the aqueous phase is believed to be correct, but the calculated stabilities of these species may be somewhat in error. It should be noted that the fourth power TTA dependence of the extraction coefficient is not affected provided the amount of impurity remained the same in all of the TTA dependence experiments.

Hydrolysis

In order to determine the degree of hydrolysis of zirconium the extraction coefficient was measured as a function of the hydrogen ion concentration. Ignoring for the moment the perturbing effect of the unknown impurity, the equation for the net reaction may be written

$$Zr(OH)_n^{+4-n} + 4HK = ZrK_4 + (4 - n)H^+ + nH_2O \quad (13)$$

assuming that perchlorate ion, in conformity with its general chemical behavior, does not complex zirconium. Equilibrium quotients expressed in concentrations may be written for equation (13)

$$K_n = \frac{(ZrK_4)(H^+)^{4-n}}{(Zr(OH)_n^{+4-n})(HK)^4} \quad (14)$$

An extraction coefficient is defined in terms of concentrations

$$E_c = \frac{(ZrK_4)}{\sum_n (Zr(OH)_n^{+4-n})} \quad (15)$$

Proceeding as before gives (for constant activity coefficient and TTA concentration)

$$\partial \ln E_c^0 / \partial \ln (H^+) = -4 + f_1 + 2f_2 + 3f_3 + \ldots \quad (16)$$

Each f is equal to that fraction of the total zirconium in the aqueous phase which has the number of hydroxide groups per zirconium indicated by the subscript. In the experiments, it was necessary to vary the TTA concentration as the acidity was varied in order to obtain measurable extraction coefficients. Therefore all measured values of E_c were corrected to a common basis, *i. e.*, the values the extraction coefficients would have had at unit activity of TTA and at $\gamma_{ZrK_4} = 1$. This quantity, E_c^0, is defined by the equation

$$E_c^0 = E_c \gamma_{ZrK_4} / (HK)^4 \gamma_{HK}^4 \quad (17)$$

It was assumed that the activity coefficients of all species in the aqueous phase remained essentially constant since the ionic strength was maintained at 2.0 by adding lithium perchlorate as the perchloric acid concentration was decreased. Some justification is obtained from the fact that the activity coefficient of hydrochloric acid in lithium chloride solutions does not change measurably from 10^{-3} M hydrochloric acid to 3 M hydrochloric acid at a total molality of 3 M.[15]

In equation (13) it has been assumed that there is no complexing of zirconium in the aqueous phase by TTA over the whole acidity range studied. This has already been shown to be the case at 2.0 M hydrogen ion. From the hydrolysis data it appears that complexing by hydroxide ion does occur to some extent in the 2 M hydrogen ion region and therefore the hydroxide ion has a stronger tendency than the chelate ion to complex zirconium under these conditions. Since the

(15) H. S. Harned and B. B. Owen, "The Physical Chemistry of Electrolytic Solutions," Reinhold Publishing Corporation, New York, N. Y., 1943, p. 457.

ratio of chelate ion concentration to hydroxide ion concentration decreased in going to the experiments at lower acidity, it seems likely that no appreciable complexing by TTA occurred in any of the experiments.

In the trace experiments samples from the aqueous phase could not be evaporated directly for counting because of the self-absorption by lithium perchlorate. To circumvent this difficulty, the zirconium in samples from the aqueous phase was extracted completely into a benzene–TTA solution and aliquots of this phase were mounted to give plates free of solid. This procedure also served to eliminate any columbium impurity.

The experimental results are shown in Fig. 2 where log E_c^0 is plotted against log (H^+). According to equation (16) the average number of hydroxides per zirconium is the slope minus four. The two straight lines in Fig. 2 are drawn with slopes of -2 and -3 corresponding to $Zr(OH)_2^{++}$ and $ZrOH^{+3}$.

The three types of symbols in Fig. 2 represent experiments with trace amounts of zirconium in uncoated glass vessels, trace experiments in coated glass vessels and experiments with macro amounts of zirconium in uncoated glass vessels. In some of the experiments the glass was coated with "Dri-Film" to prevent the zirconium from sticking to the walls of the vessels at low acidity. "Dri-Film," which is $SiCl_2(CH_3)_2$, is hydrolyzed, by the thin film of water always present on a glass surface that has been air-dried, to give a hydrocarbon surface which is not wet by water. The coating was quite successful in preventing the sticking of zirconium to the glass but the possibility of radio-colloid formation on particles in solution was, of course, still present.

The extraction coefficients at low acidity did not fall on a smooth curve, which fact suggested the formation of a radio-colloid. This was confirmed by centrifuging experiments. Therefore the data of Fig. 2, for acidities below 0.1 *M*, should be regarded only as lower limits for the extraction coefficient.

The curve drawn through the points of the trace experiments was calculated assuming that the only important species were $ZrOH^{+3}$ and $Zr(OH)_2^{++}$. The significance of such a calculation is doubtful, however, because of the unknown effect of the impurity. If the impurity is the ion of a strong acid the break from slope -3 to -2 should have occurred at higher acidity than shown by the data. If the complexing impurity is the ion of a weak acid (which seems more likely since no ions of strong acids were found to complex zirconium strongly in 2 *M* perchloric acid), then the slope of the curve should be steeper everywhere, corresponding to less hydrolysis of the zirconium.

The macro experiments, which were run with approximately 3×10^{-4} *M* zirconium(IV) in the aqueous phase, all show higher extraction coefficients than the trace experiments. Presumably this arises from the complexing action of the impurity in the trace experiments. The two points at highest acidity in the macro runs give a slope between three and four, indicating a mixture of Zr^{+4} and $ZrOH^{+3}$. The falling off of the points for the macro experiments at low acidity may be caused by polymer formation. The discrepancy in the two points at log $(H^+) = 0.4$ may arise from the same cause, since the concentration of zirconium in the aqueous phase of the higher point was only 0.4 times that in the other experiment.

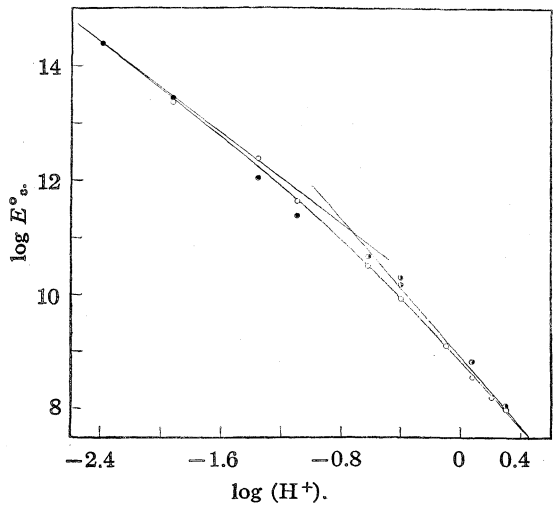

Fig. 2.—Dependence of extraction coefficient on hydrogen ion concentration: trace Zr(IV) in uncoated vessel, O; trace Zr(IV) in "Dri-Film" coated vessel, ●; macro Zr(IV) in uncoated vessel, ◑.

From the results of the hydrolysis experiments it seems likely that at low zirconium concentrations the average zirconium species in 2 *M* perchloric acid has somewhere between zero and one hydroxide group attached, *i. e.*, lies between Zr^{+4} and $ZrOH^{+3}$.

Hydrolysis data reported in the literature give evidence of polymer formation at higher concentrations of zirconium and/or lower acidity.

Complexing

Sulfate Complexing.—The stability of the sulfate complexes of zirconium was determined by measuring the extraction coefficient as a function of sulfate concentration at constant acidity. The general equation may be written

$$Zr(OH)_n^{+4-n} + mHSO_4^- = Zr(OH)_x(SO_4)_m^{+4-x-2m} + (n-x)H_2O + (x-n+m)H^+ \quad (18)$$

The principle sulfate species in 2 *M* H^+ is HSO_4^-. Equilibrium quotients and an extraction coefficient are defined in terms of concentrations

$$K_{n,m,x} = \frac{(Zr(OH)_x(SO_4)_m^{+4-x-2m})(H^+)^{x-n+m}}{(Zr(OH)_n^{+4-n})(HSO_4^-)^m} \quad (19)$$

				Av. of last two values	7.79×10^7	$-\infty$	7.891

$$E_c = \frac{(ZrK_4)}{\sum_m \sum_x (Zr(OH)_x(SO_4)_m^{+4-x-2m}) + \sum_n (Zr(OH)_n^{+4-n})} \quad (20)$$

Proceeding as before one obtains

$$\partial \ln E_c^0 / \partial \ln (HSO_4^-) = -f_1 - 2f_2 - 3f_3 \ldots \quad (21)$$

Each f in equation (21) is equal to the fraction of the total zirconium in the aqueous phase which is complexed by the number of sulfate groups indicated by the subscript numbers. The equations apply to conditions of constant hydrogen ion and TTA concentrations and constant values of all activity coefficients. When log E_c^0 is plotted against log (HSO_4^-) the slope of the curve gives the average number of sulfate groups per zirconium.

To obtain measurable extraction coefficients it was necessary to vary the TTA concentration. Therefore the measured extraction coefficients, E_c, were corrected to the value they would have had at unit activity of TTA and unit activity coefficient of ZrK_4, according to equation (17).

The aqueous solutions were prepared by mixing the appropriate volumes of 2.00 M perchloric acid and 1.95 M sulfuric acid, which gave solutions of essentially constant ionic strength. It was assumed that, over the range of mixtures studied, all activity coefficients of species in the aqueous phase remained constant.

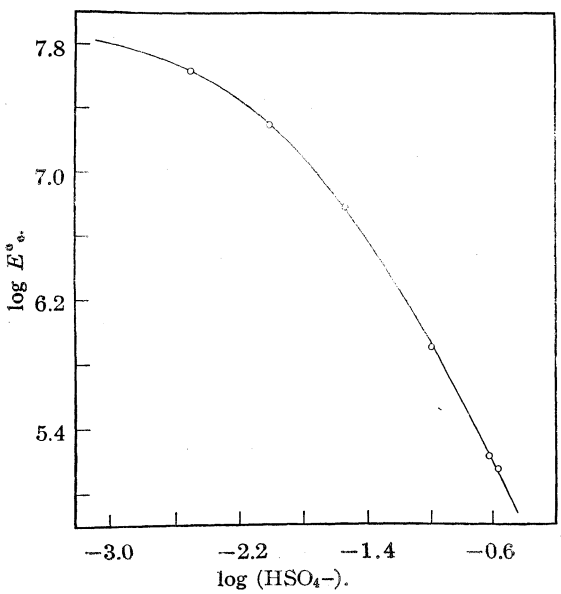

Fig. 3.—Dependence of extraction coefficient on bisulfate ion concentration.

The experimental data are presented in Table III and plotted in Fig. 3. From the slope of the curve it is found that there is an average of one sulfate per zirconium at 0.013 M HSO_4^- and an average of two sulfates at 0.3 M HSO_4^-. At neither of these points is just one species present, but rather several species, of which the predominant one is that with one and two sulfates, respectively. A mixture is obtained because the successive complexing constants do not differ greatly in magnitude.

It is not possible to determine from the data the number of hydroxide groups associated with each complex since the experiments were performed at constant acidity; however, some reasonable deductions may be made. The hydrolysis experiments indicated that zirconium in 2 M perchloric acid had between zero and one hydroxide groups attached, and therefore had little tendency to hold a second hydroxide when one was already present. It would be expected that, when a sulfate group is bonded to a zirconium ion, there would be little tendency for a hydroxide group to be attached in addition. Thus the sulfate complexes in 2 M hydrogen ion are not expected to contain hydroxide groups.

Further, it is believed that it is sulfate rather than bisulfate ion which is present in these complexes. The attachment of Zr^{+4} to a bisulfate ion should make the hydrogen ion readily ionizable, just as the attachment of one hydrogen ion in sulfuric acid makes the other hydrogen a strong acid.

The solid line drawn in Fig. 3 is a theoretical curve based on the equations

$$Zr^{+4} + HSO_4^- = ZrSO_4^{++} + H^+ \qquad K_1 = 4.6 \times 10^2$$
$$ZrSO_4^{++} + HSO_4^- = Zr(SO_4)_2 + H^+ \qquad K_2 = 53$$
$$Zr(SO_4)_2 + HSO_4^- = Zr(SO_4)_3^= + H^+ \qquad K_3 = 1$$

The equilibrium quotients were evaluated from the data by a modification of the method described

[a] Factor by which E_c is to be multiplied to give the value it would have at 2.00 M H^+.

by Leden.[16] The first is almost certainly too small because of the impurity. Comparison of the last two experiments of Table III with the last experiment of Table II indicates this error to be about 30%. In addition, it was assumed that all of the uncomplexed zirconium was Zr^{+4} which, if not true, again causes the first equilibrium quotient to be low. The values of K_2 and K_3 should not be affected by the presence of the impurity and should be correct provided the right species have been chosen. The precision in determining K_2 is estimated to be ±8% while K_3 could be evaluated only approximately at the bisulfate concentrations used, and may be in error by a factor of two.

Fluoride Complexing.—Experiments similar to the sulfate series were performed to establish the zirconium species present in acidic solutions containing hydrofluoric acid. The following equation may be derived

$$\partial \log E_c^0/\partial \log (HF) = -f_1 - 2f_2 - 3f_3 - \ldots \quad (22)$$

where each f represents the fraction of the zirconium which has the indicated number of fluoride ions attached.

The data are given in Table IV and plotted in Fig. 4. The solutions were prepared by adding small aliquots of a sodium fluoride solution to 2.00 M perchloric acid. A small acidity correction, for dilution of the perchloric acid and formation of HF, was applied (see column 5 of Table IV).

At the high concentrations of TTA used in some of the experiments there would probably be complexing of zirconium by TTA in the aqueous phase if there were no hydrofluoric acid present, and there is the possibility that the zirconium is complexed by both fluoride ion and TTA. However, in view of the extreme stability of the fluoride complexes, it seems unreasonable that there could be much competition by TTA for the zirconium in the presence of hydrofluoric acid, especially since the HF concentration was increased much more than the TTA concentration. To settle this point, it would be necessary to measure the TTA dependence in the presence of hydrofluoric acid. In the present experiments a fourth power TTA dependence was assumed in correcting the extraction coefficients to unit activity of TTA.

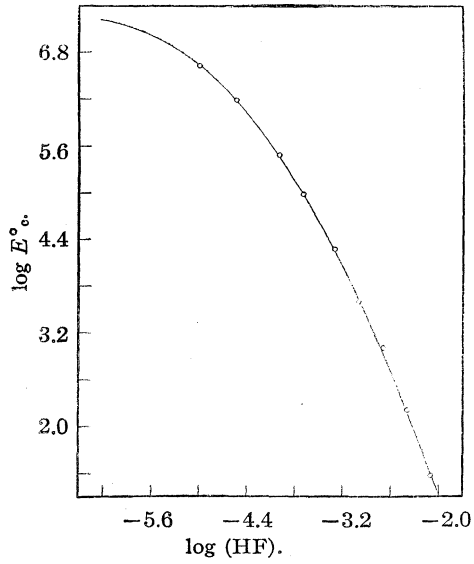

Fig. 4.—Dependence of extraction coefficient on hydrofluoric acid concentration.

The solid curve of Fig. 4 was plotted using the following values of the equilibrium quotients for the indicated equilibria

$Zr^{+4} + HF = ZrF^{+3} + H^+ \quad K_1 = 6.3 \times 10^5$

$ZrF^{+3} + HF = ZrF_2^{+2} + H^+ \quad K_2 = 2.10 \times 10^4$

$ZrF_2^{+2} + HF = ZrF_3^{+} + H^+ \quad K_3 = 6.7 \times 10^2$

(16) I. Leden, *Z. physik. Chem.*, **188**, 160 (1941). The following modifications were made. The logarithm of the function on the left of Leden's equation (6) was plotted *versus* the logarithm of the HSO_4^- concentration. In the region where only the first and second complexes are important this curve has a universal shape, approaching a constant value at low HSO_4^- concentrations. This value is related to the first association constant and was determined by obtaining the best fit of the data to a theoretical plot. To get the second constant, the first constant was subtracted from the left side of (6) and this quantity divided by the HSO_4^- concentration. The logarithm of this quantity was plotted *versus* log (HSO_4^-) and now the same universal curve results, as long as complexes containing more than three sulfates are unimportant. The constant was determined as before. The process may be repeated to give higher constants.

The method of evaluating the equilibrium quotients was the same as in the preceding section; the estimated precision in evaluating K_1 and K_2 is $\pm 10\%$, while that for K_3 is $\pm 30\%$.

To illustrate the stability of the fluoride complexes, one calculates from the data of Table IV that in 10^{-5} M hydrofluoric acid, 78% of the zirconium is complexed by fluoride and that in 8×10^{-3} M hydrofluoric acid, all but 0.00012% of the zirconium is complexed. From the slope of the curve of Fig. 4 and equation (22) the average number of fluoride groups per zirconium ion is found to be one at 2×10^{-5} M hydrofluoric acid, two at 5×10^{-4} M hydrofluoric acid and three at 10^{-2} M hydrofluoric acid. The same considerations apply here as in the case of the sulfate complexes regarding the validity of the equations and the values of the equilibrium quotients. Again, the successive complexing constants differ so little that all solutions contain appreciable amounts of several species.

It was thought that hydrofluoric acid would attack the glass walls of the container and be converted to fluosilicate ion or some hydrolyzed form of this ion. Therefore all of the above experiments were run in vessels coated with "Dri-Film" to prevent the hydrofluoric acid from coming in contact with the glass. In no case was there any evidence of attack of the glass and the extraction appeared to come to equilibrium and remained steady thereafter. Several preliminary experiments were run in non-coated glass vessels, but even here there was no sign of attack, as the extraction coefficients were about the same as with the coated vessels. Apparently the hydrofluoric acid does not attack silica at this rather high acidity (2.0 M) and relatively low concentration of hydrofluoric acid.

Chloride and Nitrate Complexing.—The extraction coefficient of trace zirconium was measured in mixtures of hydrochloric and perchloric acids at a total hydrogen ion concentration of 2.00 M. Similar experiments were carried out with mixtures of nitric acid and perchloric acid. The data are given in Table V. The per cent. uncomplexed was assumed to be equal to the extraction coefficient for the given solution divided by the extraction coefficient in 2.00 M perchloric acid. This presumes that there are no significant differences in activity coefficients in the various solutions studied.

TABLE V

CHLORIDE AND NITRATE COMPLEXING AT 25° AND 2.00 M H^+

$HClO_4$ moles/l.	HCl, moles/l.	HNO_3, moles/l.	Fraction Zr uncomplexed
0.80	1.20	..	0.29
.00	2.00	..	.19
.80	..	1.20	.30
.00	..	2.00	.20

Without specifying the nature of the uncomplexed and complexed zirconium species, the following equations may be written

$$Zr(IV) + xCl^- = Zr(IV)Cl_x \quad (23)$$

$$K = (Zr(IV)Cl_x)/(Zr(IV))(Cl^-)^x \quad (24)$$

Equating the equilibrium quotients for two different chloride concentrations one obtains

$$\frac{(Cl^-)_1}{(Cl^-)_2^x} = \frac{(Zr(IV)Cl_x)_1(Zr(IV))_2}{(Zr(IV)Cl_x)_2(Zr(IV))_1} \quad (25)$$

Substituting the data of Table V, x is found to be 1.08 for chloride ion and 1.06 for nitrate ion, in the corresponding expression. Therefore there is approximately one chloride ion and one nitrate ion present in the respective complexes in the range of conditions studied. Assuming x to be 1.00 the value of the equilibrium quotient for equation (24) is 2.0 for both the nitrate and chloride complexes. Elimination of the impurity would tend to raise these values about 30%.

Miscellaneous Complexes.—Single extraction experiments were run in the presence of a number of substances to ascertain the order of magnitude of their complexing action on zirconium at trace concentration. From one experiment, it is of course impossible to identify the species present. The results are presented in Table VI. Data for sulfuric and hydrofluoric acid are included for comparison. The fraction of zirconium uncomplexed was again assumed to be equal to the measured extraction coefficient divided by the extraction coefficient in 2.00 M perchloric acid.

TABLE VI

COMPLEXING ABILITY OF VARIOUS SUBSTANCES FOR ZIRCONIUM

Trace Concentrations of Zirconium, 2.00 M $HClO_4$, 25°

Substance	Concn. M	% Zr uncomplexed
Bisulfate, ion, HSO_4^-	0.0031	56
Hydrofluoric acid, HF	10^{-5}	22
Oxalic acid, $H_2C_2O_4$	0.001	0.36
Malonic acid, HOOC—CH_2—COOH	0.01	100
Succinic acid, HOOC—$(CH_2)_2$—COOH	0.005	100
Glutaric acid, HOOC—$(CH_2)_3$—COOH	0.1	94
Fumaric acid, HC—COOH ‖ HOOC—CH	0.05	88
Maleic acid, HC—COOH ‖ HC—COOH	0.05	74
Orthophosphoric acid, H_3PO_4	0.012	68
Orthoboric acid, H_3BO_3	0.1	100
Metasilicic acid, H_2SiO_3	0.01	87
Acetic acid, CH_3COOH	1.0	100
Trifluoroacetic acid, CF_3COOH	0.11	51
Carbonic acid, H_2CO_3	1 atm. CO_2	90
Hydrogen peroxide, H_2O_2	0.015	63

The fluoride complex is by far the most stable studied. In the series of aliphatic dibasic acids

from oxalic to glutaric, only oxalic showed any strong complexing tendency. The apparent value of 6% of the zirconium complexed by glutaric acid may not be significant. Oxalic acid has a much greater complexing power relative to the other members of the series than can be accounted for simply by comparison of the acid dissociation constants. Geometry considerations cannot be too important since the carboxyl groups of all the acids are able to assume very nearly the same relative configuration. The explanation for the great difference in complexing ability must lie in more complicated effects.

The two unsaturated dibasic acids, fumaric and maleic, seem to have some complexing tendencies, with the *cis* configuration showing a slightly greater complexing power. The result of the experiment with phosphoric acid probably has little significance since there was a continual decrease with time in the zirconium concentration; the per cent. zirconium uncomplexed, given in this table, was one determined early in the experiment.

There was no indication of any complexing by either 0.1 *M* boric acid or 1 *M* acetic acid. Trifluoroacetic acid complexed approximately half of the zirconium when present at a concentration of 0.11 *M*. It should be pointed out that the presence of a very small amount of hydrofluoric acid in the trifluoroacetic acid could account for the observed results. The experiment with the silicic acid solution, which was very cloudy, probably does not indicate complexing but rather the formation of a small amount of radio-colloid. It is believed that little significance should be attached to the apparent value of 10% complexing when carbon dioxide gas was present in the extraction flask at a pressure of one atmosphere.

It has been observed[17] that plutonium(IV) at macro concentrations forms complexes with hydrogen peroxide involving two plutonium atoms in the complex ion. Zirconium at trace concentrations apparently forms a complex with hydrogen peroxide, which must certainly contain only one zirconium atom in the complex ion. It would be interesting to study the zirconium peroxide complexes at higher concentrations of zirconium, to see if peroxy complexes containing two zirconium ions are formed.

A correlation of the stability of the various zirconium complexes will be presented in a later paper.

(17) R. E. Connick and W. H. McVey, THIS JOURNAL, **71**, 1534 (1949).

Summary

The nature of the zirconium(IV) species existing in aqueous solutions has been investigated by means of a two phase distribution equilibrium. The zirconium is partially extracted into benzene as the neutral chelate of thenoyltrifluoroacetone and the formulas of the zirconium species in the aqueous phase are deduced from the quantitative variation of the extraction coefficient as a function of the aqueous solution composition.

In 2 *M* perchloric acid at 25° and low zirconium concentrations, the average number of hydroxide ions attached to each zirconium ion lies between zero and one. The composition is not known precisely because of the interference in the experiments of an unidentified impurity.

The stabilities of several of the complexes formed with sulfate and fluoride ions were measured in 2 *M* perchloric acid solution. At bisulfate concentrations of 10^{-2} and 0.3 *M* there are on the average one and two sulfate groups in the complex, respectively. At hydrofluoric acid concentrations of 2×10^{-5}, 5×10^{-4} and 10^{-2} *M* the average number of fluorides per zirconium ion is one, two and three, respectively. In both cases the equilibrium constants for the formation of the successive complexes are so close together that any solution always contains appreciable amounts of several complexes.

Chloride and nitrate ions form only weak complexes of about the same stability in 2 *M* perchloric acid. Peroxide forms a moderately stable complex under the same conditions. The oxalate complex is very stable, while the next three members of the aliphatic, dibasic acid series show little tendency towards complex formation.

An Example of the Difficulty in Obtaining Equilibrium Corresponding to a Macrocrystalline Non-volatile Phase. The Reaction $Mg(OH)_2 \rightleftarrows MgO + H_2O(g)$

BY W. F. GIAUQUE

Recently Torgeson and Sahama[1] measured the heat of solution of magnesium hydroxide in hydrochloric acid solution. They selected conditions of experiment, including final concentrations, to correspond to the work of Shomate and Huffman,[2] on the heat of solution of magnesium oxide.

Combining the results they obtain

$$Mg(OH)_2(c) = MgO(c) + H_2O(l)$$
$$\Delta H_{298.16^\circ K} = 8850 \pm 25 \text{ cal. mole}^{-1}$$

Torgeson and Sahama prepared their $Mg(OH)_2$ by reaction of MgO with steam(saturated) at 150 p. s. i. Shomate and Huffman prepared MgO by heating $Mg(OH)_2$ in a silica flask for one hundred hours, during which the temperature was raised from 400 to 1000°. Torgeson and Sahama consider both substances to have been crystalline and we see little reason to doubt that they were approximately macrocrystalline with respect to their properties.

Giauque and Archibald[3] measured the heats of solution of $Mg(OH)_2$ and MgO in hydrochloric acid solution and obtained a result of $\Delta H_{298.16} = 9739 \pm 25$ cal. mole.$^{-1}$ for Reaction 1, however, with the MgO in a different physical state.

They prepared crystals of $Mg(OH)_2$ with an average diameter of 0.2 mm. by slowly cooling a solution of $MgCl_2$ in concentrated potassium hydroxide from 210°. There is no reason for believing that the $Mg(OH)_2$ used by Torgeson and Sahama was appreciably different in its macroscopic properties from the visible crystals used by Giauque and Archibald.

The MgO prepared by Giauque and Archibald was made by dehydrating the above $Mg(OH)_2$ crystals, *in vacuo*, at a relatively low temperature. Decomposition was attempted at 200°, but was so slow that the temperature was raised to 300°, and for a short period to 350° at the end of ten days of heating *in vacuo*. This treatment decomposed 95% of the material, which was in the form of a fine powder. The above data lead to the result

$$MgO(\text{crystalline}) = MgO \text{ (finely divided)} \quad (2)$$
$$\Delta H_{298.16} = 888 \text{ cal. mole}^{-1}$$

Giauque and Archibald[3] were not primarily interested in the properties of either MgO or $Mg(OH)_2$ and were using these substances only as a means of determining the entropy of $H_2O(g)$ by use of the third law of thermodynamics and the decomposition equilibrium

$$Mg(OH)_2 = MgO + H_2O(g)$$

For this reason they considered it desirable to prepare and investigate the heat content and heat capacity of MgO under approximately the same conditions as those existing during their study of the decomposition pressures.

The heat capacity of the finely divided MgO was found to be higher than that of the crystalline material, which had been investigated by Parks and Kelley.[4] ΔC_p was about 1% at ordinary temperatures and this increased to about 6% at 90°K.

Giauque and Archibald were aware that the heat content of the powder should be somewhat higher than that of large crystals, due to increased surface energy, but had no idea that the difference would be a large quantity such as 888 cal. mole.$^{-1}$ We believe that it would be proper to describe the MgO powder prepared at about 300° as colloidal.

Our attention has been called to an equivalent result of Taylor and Wells[5] who decomposed $Mg(OH)_2$ at various temperatures, with a heating period of two and one-half hours.

Taking the heat of solution results at their lowest and highest temperatures

$$MgO_{(\text{formed at } 1425^\circ)} = MgO_{(\text{formed at } 450^\circ)} \quad (3)$$
$$\Delta H_{298.1^\circ K} = (36{,}670 \pm 70) - (35{,}720 \pm 30) = 950 \text{ cal. mole}^{-1}$$

This value and the 888 cal. mole.$^{-1}$ value given above agree within the limits of error of the measurements. Taylor and Wells[5] made X-ray diffraction patterns of their various samples and found no change in crystal structure. They ascribed their results as due "mainly to differences in surface."

The Decomposition Pressure of $Mg(OH)_2$.—The principal purpose of this paper is to ask the following question: How often have experimenters recorded equilibrium data which did not correspond to the macrocrystalline properties of the phases present?

Giauque and Archibald[3] studied the decomposition pressure of $Mg(OH)_2$ with unusual care at 463.1 and 485.0°K., waiting as long as two weeks for equilibrium. The equilibrium pressures at these temperatures were approached from both below and above, with results which were identical to an unusually high degree of accuracy. Moreover, there can be no reasonable doubt that they obtained an equilibrium value for the phases present, since the entropy of $H_2O(g)$ calculated from their calorimetric and equilibrium data, and the third law of thermodynamics, agrees very closely

with the result which is known accurately from band spectroscopy.

Let us assume that the results of Torgeson and Sahama[1] had been available to Giauque and Archibald, and that the entropy of crystalline MgO had been used in their calculations, the resultant free energy would have differed by the following amount

$$\text{MgO(crystals)} = \text{MgO(fine powder)}$$
$$\Delta F = \Delta H - T\Delta S \qquad (4)$$
$$\Delta F_{474^\circ K} = (\sim 900) - 474 \times (\sim 0.2)$$
$$= 800 \text{ cal. mole}^{-1}$$

where F, H and S refer to free energy, heat content and entropy.

We have used 474°K. as the average temperature of the experimental results and have estimated roughly that the finely divided MgO had a larger entropy by about 0.2 cal. deg.$^{-1}$ mole.$^{-1}$

This means, that had the pressure of H_2O been calculated from the calorimetric results on the macroscopic MgO, decomposition pressures greater by some 130%, than the values which were observed with a reproducibility of 0.1%, would have been expected.

Discussion of the Results—The above facts cannot be explained by assuming that the H_2O was in equilibrium with surface material on particles, which had macroscopic thermodynamic properties inside, since all of the material was dissolved when the heat of solution was measured. Similarly the $\int_0^T C_p \, d \ln T$ corresponds to the average entropy per mole of interior and surface material.

We conclude that the MgO came to complete equilibrium throughout the particles and thus had the same free energy per mole in the interior as on the surface.

It is often assumed that the excess of some property such as heat content, heat capacity or entropy of a system with considerable surface can be allocated to the surface. This idea is based on the assumption that the substance in the interior has retained the properties of the substance in bulk. This assumption would certainly not hold in the present case. Strictly speaking it is never possible to consider the properties within a particle as separable from those of the surface material. If such an approximation is made, as a matter of convenience, the equilibrium proved in the present case implies that

$$F = H(\text{inside}) - TS(\text{inside}) = H(\text{surface}) - TS(\text{surface}) \qquad (5)$$

By a thermodynamic artifice it is possible to obtain an approximate value for the free energy of small drops of liquid. In this case consideration of the increase in free energy of the interior material due to pressure caused by the surface tension, leads to the well known formula, $dF = 2V\,d(\gamma/r)$ which gives the change of free energy with size.[6] V represents the molal volume, and r and γ are the radius and surface tension, respectively, of the drop.

A similar consideration may be applied roughly to the MgO particles leading to the equation

$$\Delta F(\text{in calories}) \times 4.8 \times 10^7 = 2\gamma V \text{ ergs}/r$$
$$V = 11.1 \text{ cm.}^3 \text{ mole}^{-1}$$

from which

$$\frac{2\gamma}{r} = \frac{800 \times 4.8 \times 10^7}{11.1}$$
$$= 35 \times 10^8 \text{ dynes cm.}^{-2}$$

If one assumes spherical particles, this is equivalent to an inside pressure of 3500 atmospheres. We have no information concerning either γ or r of the finely divided material obtained in the equilibrium measurements. A search was made for a sample of the material used but it was probably discarded. It would have been interesting to obtain an electron-microscopic photograph of the material. If the particles were large enough to be seen in an ordinary microscope, they would have to possess some open type of structure, such as a loose aggregation of small units. It is difficult to see how such a reversible equilibrium, as that observed, could have been reached unless the unit particles had assumed something approximating a spherical shape.

It is, however, not any exact knowledge of particle dimensions which interests us here, but rather the fact that the usual tests of attainment in a chemical equilibrium are no guarantee that it corresponds, even approximately, to the thermodynamic properties of macroscopic phases.

It is not difficult to see why the dehydration of crystalline $Mg(OH)_2$ should produce particles of MgO which become detached before they reach macroscopic dimensions, and it is difficult to escape the conclusion that this is a fairly commonplace occurrence in other cases, although usually in lesser degree.

For example it seems probable that anhydrous salts, or the lower hydrates of salts, formed by the decomposition of multihydrated forms, in the absence of a solution, can be expected to produce finely divided material. The higher free energies of substances in this form should give lower decomposition pressures than do macroscopic phases.

(6) *E. g.*, "Thermodynamics and the Free Energy of Chemical Substances," Lewis and Randall, McGraw-Hill Book Co., Inc., New York, N. Y., 1923, p. 252. Lewis and Randall make an impractical statement on p. 248 with respect to surface effects as follows: "If we start with a given amount of liquid and increase its surface, the molal free energy in the body of the liquid does not necessarily change, and if we maintain equilibrium the total free energy in the surface formed must be the same as in the body of the liquid. Therefore the molal free energy multiplied by the total number of moles remains constant, but the total free energy is increased by $\gamma d\sigma$." We believe that it is impossible to devise a procedure in which the surface, and thus the surface energy, of a system is changed, under equilibrium conditions, without an equivalent change in the free energy of the substance or substances of which the system is composed. The total free energy of any system at equilibrium is always equal to the free energy per mole times the number of moles, summed over all components.

When the equilibrium decomposition pressure is sufficiently close to the saturation pressure, so that adsorption is considerable, equilibrium may be facilitated among solid phases. However, when the dissociation pressure of water is very small compared to that of the saturated solution, the attainment of macroscopic equilibrium may be excessively slow, and a rather definite metastable equilibrium can exist as a consequence.

When very fine particles are themselves nonvolatile, and lack a reconstituting mechanism, such as some equilibrium volatile compound which can transport material from them, they can only be expected to give equilibrium results consistent with their own free energy. At sufficiently high temperatures, sintering will produce macroscopic properties but the $Mg(OH)_2$ dissociation pressure would reach considerable values at temperatures below those required to sinter the MgO produced. We conclude that many measurements on systems involving equilibrium between gases and dry solid phases should be accepted with considerable caution in correlating thermodynamic data.

Summary

It is shown that the true dissociation pressure in the reaction $Mg(OH)_2$(cry.) = MgO(cry.) + H_2O(g), as determined from the third law of thermodynamics, is some 130% higher than accurately measured values which were reproducible to 0.1%.

The above result is attributed to the colloidal nature of the magnesium oxide produced under equilibrium conditions.

Giauque and Archibald have shown previously that the third law gives accurate agreement with the measured equilibrium pressures, when the entropy and heat content are measured on the actual finely divided magnesium oxide in equilibrium. Thus the colloidal particles approached essentially zero entropy at very low temperatures and evidently approximated a perfect crystalline structure.

For the finely divided material obtained during equilibrium dissociation, MgO(cry.) = MgO (finely divided); $\Delta H_{25} = 888$ cal. mole.$^{-1}$

It is concluded that neither reproducibility of equilibrium measurements based on approach from each side nor agreement with the third law of thermodynamics, can be accepted as proof that an equilibrium corresponds to the thermodynamic properties of macrocrystalline phases.

It seems impossible to escape the conclusion that many equilibrium measurements involving gases and finely divided dry solid phases, produced by the evolution of gases, or formed by reaction with gases, do not correspond to the properties of macroscopic materials.

The Infrared Spectrum of Dimethylcadmium

BY H. S. GUTOWSKY[1]

In a previous publication,[2] the infrared and Raman spectra of dimethylmercury and dimethylzinc were presented and interpreted as supporting a linear C–M–C structure of D_{3h}' symmetry, with essentially free internal rotation of the methyl groups. Similar data for dimethylcadmium are of interest in verifying this interpretation and in providing force constants which, with those for mercury and zinc, afford a basis for relating molecular properties to atomic parameters of the Group IIb metals.

Experimental

Preparation of Sample.—Attempts to produce dimethylcadmium by heating dimethylmercury with cadmium metal were unsuccessful. The sample used was prepared by Mr. A. R. Bader, under the direction of Professor E. G. Rochow, from cadmium iodide and methylmagnesium bromide in ether solution. Their coöperation in furnishing the sample is gratefully acknowledged. It was purified by bulb to bulb distillation in a vacuum system until it was infrared spectroscopically free from ether.

Infrared Spectrum.—The region from 430 to 650 cm.$^{-1}$ was observed with a KRS-5 prism in conjunction with a lithium fluoride mirror using the Harvard spectrometer.[3] The gaseous sample of dimethylcadmium was at its room temperature vapor pressure of 3.6 cm., in a 30-cm. cell with potassium bromide windows. The region from 625 to 5000 cm.$^{-1}$ was run at the same pressure in a 5-cm. sodium chloride cell on a Baird Associates spectrometer. The observed spectrum is summarrized in Table I. Its general appearance is similar to that of dimethylzinc,[2] with the exception that the structure of the bands at 1140 and 1305 cm.$^{-1}$ in dimethylcadmium is not nearly as distinct as the corresponding bands in dimethyl zinc.

Frequency Assignment

A generally satisfactory frequency assignment has been made, using D_{3h}' symmetry. The Raman data of Fehér, Kolb and Leverenz[4] are in-

[a] The numbers after the band frequencies are relative apparent intensities. The appearance and polarization are indicated for the Raman lines by the letters s (scharf), b (breit) and a second set of numbers.

cluded in Table I as well as the infrared observations and the details of the frequency assignment. The infrared band intensities listed are merely relative values. The numerals in parentheses after the Raman line frequencies are intensity and polarization, respectively. The assignment of fundamental frequencies is summarized in Table II.

The Raman active A_1' fundamental frequencies are readily assigned as the three strongest lines which are polarized. The infrared active A_2'' fundamentals ν_6 and ν_7 are obtained by comparison with the corresponding A_1' frequencies. The E'' Raman active fundamentals are selected from the remaining unassigned lines. 2963 cm.$^{-1}$ is assigned as ν_{12} since it does not overlap the C–H stretching frequencies in the infrared spectrum. In the CH_3 deformation region the Raman line at 1448 cm.$^{-1}$ coincides with the infrared band at 1435 cm.$^{-1}$ so they are assigned as ν_9, which leaves the 1384 cm.$^{-1}$ line as ν_{13}. ν_{14} is taken to be the Raman line at 642 cm.$^{-1}$ as this value is intermediate between the corresponding values for dimethylmercury and dimethyl zinc. Moreover, there are no other unassigned lines in the expected frequency range. The polarization value of 0.77 given for this line is sufficiently close to the depolarized value that this assignment is not precluded. The E' fundamentals are both infrared and Raman active and ν_8 is assigned as the coincidence in frequencies at about 2885 cm.$^{-1}$. The intense infrared band at 705 cm.$^{-1}$ is undoubtedly ν_{10}, and the only observed frequency low enough to be the C–Cd–C bending frequency, ν_{11}, is the doubtful 150 cm.$^{-1}$ line reported by Kolb and Leverenz.[4]

The remaining bands are interpretable as combinations or overtones with the exception of the weak Raman line at 520 cm.$^{-1}$. Assuming this line to be real, it might be the asymmetric skeletal stretching frequency, ν_7, the selection rule prohibiting its appearance in the Raman spectrum being relaxed by Coriolis interaction with the skeletal bending ν_{11}. The relatively high intensity of the infrared bands at 1305 and 1325 cm.$^{-1}$ is a bit surprising for combinations but their assignment as fundamental frequencies is not supported by any other considerations.

Normal Coördinate Analysis and Force Constants

Valence-type force constants have been determined from the above frequency assignment following the symmetry coördinate methods of Wilson[5] and using the G and diagonal F matrices

given previously[2] for a linear CH_3–M–CH_3 molecule. These force constants, as given in Table II, are in terms of the internal coördinates α, β, γ, r and η which are defined as small displacements in the H–C–H, H–C–Cd, C–Cd–C bond angles and the C–H, C–Cd bond lengths, respectively. In the computations, tetrahedral angles were assumed for the methyl groups and 1.10 Å. was adopted as the C–H bond distance, *d*. No measurement of the C–Cd bond distance, *D*, appears to be available, so a value estimated from the covalent radii to be 2.15 Å. was used.

The F_{ii} values in Table II are the numerical values used in the diagonal *F* matrices for the various factors in computing the frequency of the corresponding vibration. No attempt was made to introduce off-diagonal terms in the *F* matrix. The values of the force constants given in terms of the internal coördinates are derived from F_{ii} using the relations previously reported[2]; the numerical values for the C–H stretching, f_r and f_{rr}, and the H–C–H angle distortion, d^2f_α, are also adopted from the previous work.

Discussion

Configuration and Internal Rotation.—On the basis of the evidence reported herein for dimethyl cadmium and the earlier data[2] for dimethylmercury and dimethylzinc, it appears that the dimethyl compounds of the group IIb metals have a linear C–M–C skeleton. Moreover, there are sufficient coincidences between the infrared and Raman frequencies assigned as E′ fundamentals to confirm the nonexistence of the staggered orientation of the methyl groups; such a D_{3d} configuration would have a center of symmetry and the fundamentals could be active only in either the infrared *or* Raman spectrum. The simplest interpretation of all the spectral data is in terms of either an eclipsed D_{3h} orientation of the methyl groups or a D_{3h}' model in which the methyl groups are free to rotate internally about the C–M bonds. Inasmuch as the staggered configuration is generally considered[6,7] to be the stable form when there is hindrance to internal rotation, it appears that a more or less free internal rotation exists in these dimethyl compounds. The application of an empirical inverse fifth power law[6] to the potential restricting the internal rotation suggests the barrier to such rotation is of the order of 15 cal./mole. The theoretical calculations of Lassettre and Dean[7] give a value of 31 cal./mole for the barrier to internal rotation in dimethyl acetylene; this indicates the possibility of a somewhat higher barrier in the metal alkyls than the 15 cal./mole from the empirical calculation. In any event, the spectral results are in general accord with the calculated barriers; both suggest that hindrance to internal rotation in these compounds is slight at most.

Force Constants and Electronegativities of the Group IIb Metals.—In Table III there are summarized the force constants directly related to the C–M bonds in the Group IIb dimethyl alkyls. A number of more or less empirical expressions have been proposed, relating bond stretching force constants, bond lengths, position in the periodic table, type of compound, and similar parameters. In this connection, it is of some

interest to consider the recent extensive discussion by Gordy[8] who proposed the equation $k = aN(X_AX_B/d^2)^{3/4} + b$. k is the bond stretching force constant in 10^5 dynes/cm.; a and b are empirical constants with the values 1.67 and 0.30 for stable molecules in their normal covalent state; N is the bond order; X_A and X_B are the electronegativities of the bonded atoms; and d is the bond length in angstroms. Electronegativities are given in Table IV for zinc, cadmium and mercury, computed with this equation using the $f\eta$ force constants in Table II and also the force constants of the dihalides from their Raman spectra in solution.[9,10] Included for comparison are the electronegativities proposed by Gordy[8] from the force constants in the diatomic hydrides and also values suggested by Haissinsky[11] from thermal data. While some of the differences between the computed electronegativities may result from the approximation of several of the bond lengths, the differences between the values from the alkyls and those from the halides and hydrides are too large not to be real.

TABLE IV

I	2.40	..	2.50	0.91	[c]2.55	1.73	2.45
Gordy[8]		1.2		1.1		1.0	
Haissinsky[11]		1.5		1.5		1.9	

[a] Bond lengths are estimated from convalent radii by comparison with the corresponding compounds of mercury. [b] L. O. Brockway and H. O. Jenkins, THIS JOURNAL, 58, 2036 (1936). [c] H. Braune and S. Knoke, *Z. physik. Chem.*, B23, 163 (1933).

Part of the disagreement may lie in the bond order. For the alkyls, hyperconjugation of the methyl groups could increase the bond order from 1.0 to perhaps as high as 1.2. This is still inadequate to bring the corresponding electronegativities into agreement with the values from the halides and hydrides. The thermal electronegativities of Haissinsky[11] differ from the alkyl values by a fairly narrow range, from 0.43 to 0.76 indicating the force constants could be fitted fairly well by Gordy's equation, with a different value of b or else a bond order of about 1.4. However, it is particularly difficult to reconcile the very wide scatter of electronegativity values for mercury without introducing an excessive number of new empirical constants.

Summary

1. The infrared spectrum of dimethylcadmium is reported and a frequency assignment proposed. Valence-type force constants are computed from a normal coördinate analysis. The results support a linear C–Cd–C structure of D_{3h}' symmetry with free internal rotation of the methyl groups, consistent with similar conclusions made previously for dimethylzinc and dimethylmercury.

2. A comparison of electronegativity values computed from the bond stretching force constants in the dimethyl alkyls and dihalides of the Group IIb metals, using an empirical relation proposed by Gordy, suggests the difficulty of applying the relation to additional types of compounds.

The Conversion of Fibrinogen to Fibrin. I. Influence of Hydroxyl Compounds on Clotting Time and Clot Opacity[1]

BY JOHN D. FERRY AND SIDNEY SHULMAN

The reaction between fibrinogen and thrombin to form a solid structure of fibrin is modified by the presence of glycerol or other hydroxyl compounds so that the clotting time is prolonged and the clot opacity, a measure of coarseness of structure, is markedly decreased.[2] It has been suggested that hydroxyl compounds reduce the attractive forces between fibrinogen molecules and diminish their tendency toward side-by-side association during clotting, resulting in a network of fine rather than coarse strands.

This phenomenon has now been further studied by examining the effects of a large number of hydroxyl compounds on clotting time and clot opacity. Correlations are drawn between molecular structure and effectiveness in modifying the clotting process, and tentative conclusions can be reached concerning the nature of the interactions involved.

Materials and Methods

Bovine fibrinogen (Fraction I[3]) and thrombin were furnished through the kindness of Dr. J. D. Porsche of Armour and Company, to whom we are deeply indebted for the gift of these materials. In Fraction I preparation C-185A the protein was 79% fibrinogen, as determined by the assay method of Morrison[4]; in preparation C-739, it was 65%. Thrombin preparation C-173B had an activity[5] of 4.7 units per mg.

Glycerol, mannitol, pentaerythritol, trimethylene glycol and pinacol were obtained from the Eastman Kodak Company; 2-methyl-1,3-pentanediol, 2-methyl-2,4-pentanediol, 1,3-butanediol, and bis-(2-hydroxyethyl) sulfide from Carbide and Carbon Chemicals Corporation[6]; pentamethylene glycol, hexamethylene glycol, and polyvinyl alcohol (Elvanol 72-51) from E. I. du Pont de Nemours and Co.; and tetrahydrofurfuryl alcohol from the Quaker Oats Co.[6] A sample of tetramethylene glycol was kindly given us by Professor Homer Adkins. The other compounds were commercial products of reagent grade. Most of the reagents were used without further purification. Trimethylene glycol, tetrahydrofurfuryl alcohol and pentamethylene glycol were redistilled.

Fibrinogen solutions were prepared by dissolving the stock powder (which had been dried from a frozen solution in citrate buffer) in water at a concentration of about 3% protein, dialyzing against a large volume of sodium chloride solution (usually 0.45 *M*) with several changes for twenty-four hours to remove citrate, and clarifying by filtration through filter pads. After filtration, each stock solution was assayed[4] for fibrinogen, and the *p*H was measured. Aliquots were then diluted to give samples with chosen concentrations of fibrinogen, salt, and added reagent. The reagents (hydroxyl compounds) were added in the form of moderately dilute solutions containing 0.45 *M* sodium chloride (the *p*H having been adjusted to 6.3 if necessary), to minimize possible injurious effects of local changes in composition. In every case, the *p*H of the mixture containing the highest concentration of reagent differed by not more than ±0.1 unit from the corresponding control with no reagent. Thrombin solutions were prepared by dissolving the stock powder in 0.45 *M* sodium chloride, usually at a concentration of 20 unit/cc.

Each sample, after addition of thrombin, had a volume of 5 cc. and contained 5 g./l. of fibrinogen, 1 unit/cc. of thrombin, and 0.45 *M* sodium chloride. The clotting time was taken as that required to develop a characteristic rigidity in a test-tube of 1.40 cm. i.d. The opacity,[2] or extinction coefficient, was measured in the same tube at a wave length of 6000 Å. with a Beckman spectrophotometer[7] at intervals, sometimes before as well as after the moment of clotting. The clots were kept at room temperature, which varied from 22 to 25°.

Results

Effect of *p*H and Ionic Strength.—Since previous studies[2] of the dependence of clot opacity and clotting time on reaction conditions had been made with human rather than bovine fibrinogen and thrombin, preliminary experiments were made to show that the effects of *p*H and ionic strength were qualitatively the same for both species. For the bovine, as for the human system, both opacity and clotting time decreased with increasing *p*H; with increasing ionic strength, clotting time increased and opacity passed through a minimum. However, at *p*H 6.3 and ionic strength 0.45, the bovine clotting time was roughly twice as long and the clot opacity twice as great as the human; a higher *p*H, and/or a higher salt concentration, was required for bovine than for human fibrinogen to effect the changes in properties representing the transition from coarse to fine structure.[2] This difference has also been noted by Edsall and Lever.[8]

Preliminary experiments showed that, with bovine as with human fibrinogen, addition of glycerol prolonged the clotting time and diminished clot opacity. These effects were observed at various values of *p*H and ionic strength. At the average unadjusted *p*H of our solutions, 6.3, the sensitivity of opacity to added glycerol was greatest near an ionic strength of 0.45, the value selected for all experiments with other reagents.

In various successive stock solutions prepared as described above, the clotting times without added reagent varied from six to nine minutes for

(8) J. T. Edsall and W. F. Lever, private communication.

preparation C-185A, and from eleven to fourteen minutes for C-739. The corresponding opacities (six hours after addition of thrombin) varied from 0.5 to 1.2 cm.$^{-1}$ for C-185A, and from 1.0 to 1.2 cm.$^{-1}$ for C-739. Most of the data reported here were obtained with the latter preparation, whose opacity was more nearly reproducible. In any case, the relative effects of different added reagents could be expressed independently of the variability of the stock solutions, by the methods of calculation described below.

Clotting Time.—Most of the hydroxyl compounds prolonged the clotting time (t_C); a plot of log t_C against concentration of reagent (c, in g./l.) gave a straight line at low concentrations (Fig. 1). At higher concentrations, the slope usually decreased somewhat. Two reagents—starch and polyvinyl alcohol—decreased the clotting time; here also log t_C was a linear function of c (Fig. 1).

[a] Fraction I Preparation C-185A. [b] No straight line; initial slope estimated. Slope falls off sharply above 4 g./l. [c] (moles monomer residue per liter)$^{-1}$.

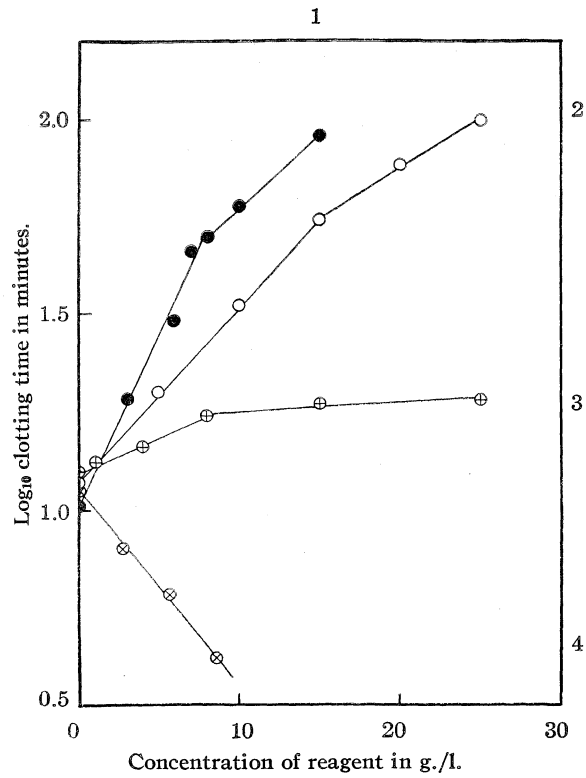

Fig. 1.—Logarithm of clotting time (in minutes) plotted against concentration of reagent in g./l.: 1, hexamethylene glycol; 2, 1,3-butanediol; 3, ethylene glycol; 4, starch.

The initial slopes of plots such as Fig. 1 were taken as measures of the effectiveness of the various reagents in altering the clotting time. They are summarized in Table I in decreasing order. Except where noted, only those experiments in which at least three points fell on a straight line are included; some other experiments, in which erratic results were obtained, have been omitted.

With the same reagent, different stock fibrinogen solutions usually gave lines with similar slopes, as shown by the fair agreement in values of d log t_C/dc in successive experiments. The slopes are recorded both as d log t_C/dc and d log t_C/dm, where m is the concentration in moles per liter. Since most of the compounds do not differ greatly in molecular weight, the order of decreasing values is about the same in both cases. The extremes represent rather marked effects; thus, hexamethylene glycol at a concentration of 5 g./l. prolongs the clotting time by a factor of 2.5, while polyvinyl alcohol at the same concentration shortens the clotting time by a factor of 3. At higher concentrations, beyond the linear range, far greater changes are observed; polyvinyl alcohol shortens t_C by as much as a factor of 10, and hexamethylene glycol prolongs it indefinitely. How-

ever, these larger effects are not so convenient for characterizing reagents.

Change of Clot Opacity with Time.—In the course of the conversion process, the opacity rises steadily before the moment of clotting and continues to rise for a long time thereafter.[2] Its increase with time is illustrated in Figs. 2 and 3 for systems containing varying amounts of 1,3-butanediol. In the early stages (Fig. 2) the opacity rises linearly with time; the moment of clotting, indicated by a cross, occurs during this linear increase.[9] In the later stages (Fig. 3) the opacity appears to approach a limiting value, but in the presence of higher concentrations of glycol the opacity is still rising after twenty-four hours.

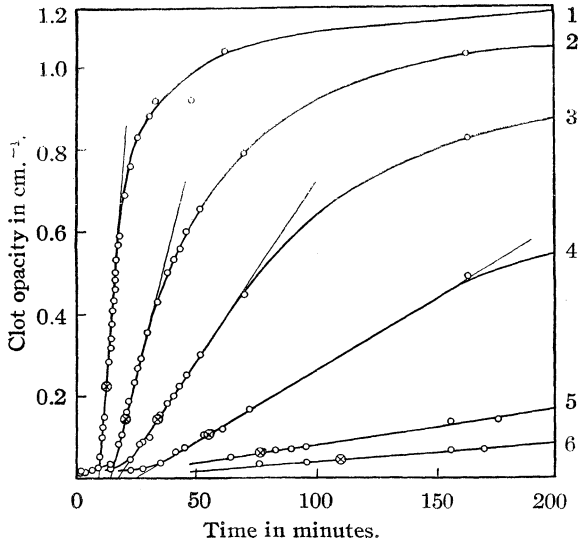

Fig. 2.—Clot opacity plotted against time, for different concentrations of 1,3-butanediol in g./l. as follows: 1, 0; 2, 5; 3, 10; 4, 15; 5, 20; 6, 25. The crosses denote clotting times.

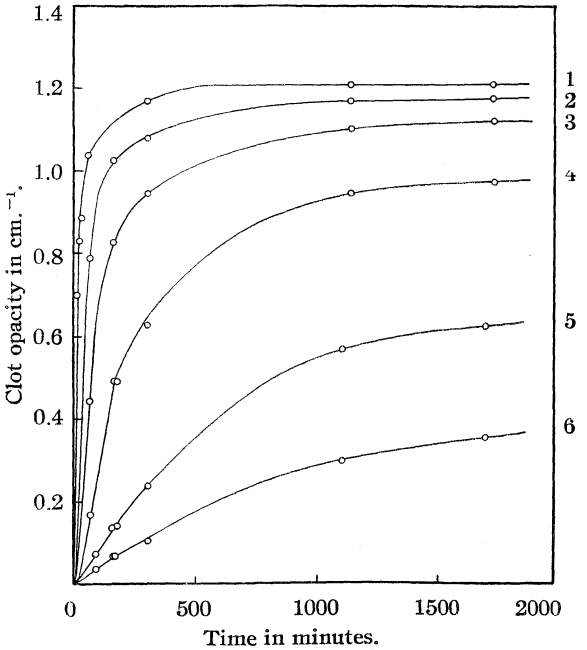

Fig. 3.—Clot opacity plotted against time, for different concentrations of 1,3-butanediol (for longer time periods). Key to curves same as in Fig. 2.

Change of Clot Opacity with Concentration of Added Reagent.—The butanediol decreases markedly the slope of the linear portion of the opacity–time curve, and it also decreases the opacity attained after a given time interval. This result may be partly attributed to a decrease in the rate of formation of the fibrin structure (as measured by the prolonged clotting time) and partly to a change in the character of the structure itself. We seek a measure of the latter effect alone. It could be provided by a comparison of the final opacity values after conversion is complete. However, it is difficult to ascertain when the opacity attains its maximum value; in the presence of relatively high concentrations of hydroxyl compounds, the rise may continue for several days, and it is undesirable to prolong experiments for such periods because of possible instability and bacterial action.

Accordingly, to gage the effect of added reagents on the clot structure, we have adopted the procedure of comparing opacities *at the clotting time*

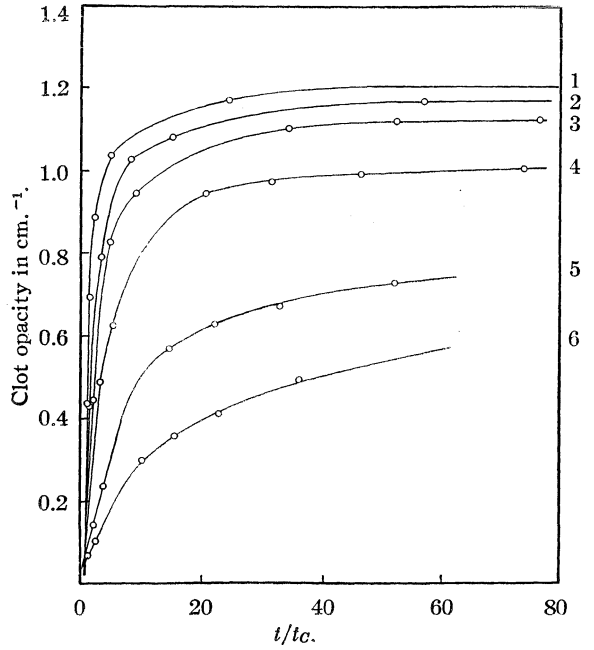

Fig. 4.—Clot opacity plotted against t/t_c for different concentrations of 1,3-butanediol. Key to curves same as in Fig. 2.

(9) Oster (*J. Colloid Sci.*, **2**, 291 (1947)) has shown that the opacity should increase linearly with time when molecules are growing by condensation polymerization, provided the molecular sizes are all small compared with the wave length of light. However, it cannot be inferred that the conversion of fibrinogen to fibrin is a condensation polymerization, because the above provision is not satisfied.

($t = t_C$) or at equal multiples thereof.[10] When the opacity data of Figs. 2 and 3 are plotted against t/t_C instead of t, the influence of the glycol appears less pronounced (Fig. 4). Here its effectiveness in decreasing coarseness of structure has been isolated, as a first approximation, from its effectiveness in decreasing the rate of the conversion process.

[a] Fraction I Preparation C-185A. [b] Depresses the opacity by 13% at $c = 25$ g./l. [c] Depresses the opacity by 11% at $c = 40$ g./l. [d] Depresses the opacity by 14% at $c = 40$ g./l.

(10) It would be preferable to compare opacities at equal extents of reaction, corresponding to times when a given proportion of fibrinogen had been converted to fibrin. However, this is impractical, if not impossible, to determine at present.

The effects of different concentrations at time intervals which are equal multiples of the clotting time are represented by intersections of the curves of Fig. 4 with vertical lines. Opacities obtained in this way are plotted against the concentration in Fig. 5 for $t/t_C = 1$, 10, 30 and 50. The sigmoid shape of the upper curves was characteristic of most of the other reagents studied.

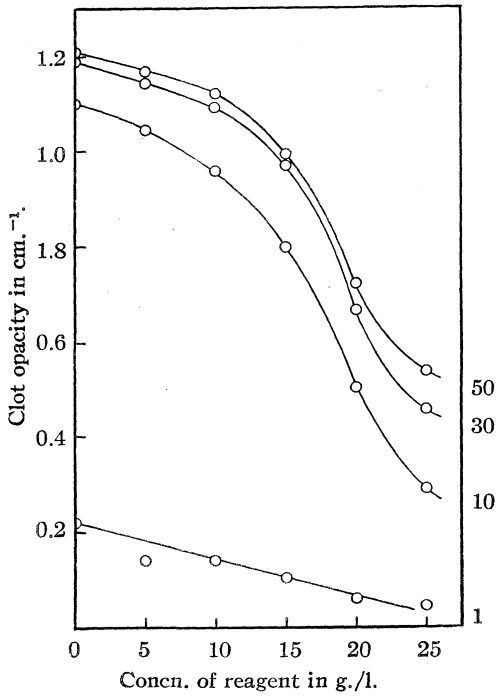

Fig. 5.—Opacity plotted against concentration of 1,3-butanediol, at various values of t/t_C as indicated.

Comparison of Reagents.—To provide a simple comparison, the concentrations of reagents in g./l. required to reduce the capacity to half the control value (with no added reagent) at $t/t_C = 1$ (*i.e.*, at the moment of clotting) and at $t/t_C = 10$ were interpolated from graphs of the type of Fig. 5. These results are given in Table II, together with the corresponding concentrations expressed as moles per liter. Fewer values are available at $t/t_C = 1$ because of the difficulty of making numerous opacity measurements in a short time interval in the vicinity of the clotting time. At $t/t_C = 10$, they range from 2 to 3 g./l. (0.02 *M*) for bis-(2-hydroxyethyl) sulfide to 70 g./l. (0.6 *M*) for diethylene glycol. This particular comparison is striking because the two molecules differ only in the central atom, which is oxygen and sulfur, respectively. Several compounds at the end of the table are so weakly effective that the opacity is not diminished to one-half the control value within the concentration range studied. In some cases the range was limited by solubility.

The two compounds of high molecular weight, starch and polyvinyl alcohol, which shorten the

clotting time, increase the opacity when compared at constant t but are without effect when compared at constant t/t_C.

Inhibition.—Several of the most effective reagents, at moderate concentrations, inhibit clotting altogether. These compounds can be characterized by the minimum inhibiting concentration required to prevent clotting for at least twenty-four hours (Table III); this is practically equivalent to inhibition indefinitely, since mixtures unclotted after one day have been observed to remain unclotted for weeks. It is surprising that these simple alcohols interfere so effectively with the reaction between fibrinogen and thrombin, while others at higher concentrations permit clotting within an hour or less: mannitol and glucose at 80 g./l., and ethylene glycol and glycerol at 200 g./l.

TABLE III

MINIMUM INHIBITING CONCENTRATIONS[a]

Reagent	c, g./l.	m, moles/l.
Hexamethylene glycol	32–43	0.27–0.36
Pentamethylene glycol	48–60	.46– .58
bis-(2-Hydroxyethyl) sulfide	61–81	.50– .66

[a] The first concentration is the highest observed that permits clotting, and the second is the lowest that prevents clotting for at 24 hours, at pH 6.2–6.4, ionic strength 0.45.

Reversibility of Effects of Hydroxyl Compounds.—The reagents studied do not appear to cause any irreversible changes in either fibrinogen or thrombin, as shown by the following experiments with several of the more powerful compounds. (*a*) Solutions of fibrinogen with the standard concentration, pH, and ionic strength, containing hexamethylene glycol, pentamethylene glycol, and bis-(2-hydroxyethyl) sulfide at concentrations somewhat above their minimum inhibiting levels, were allowed to stand six hours and then dialyzed against large volumes of sodium chloride–phosphate buffer of ionic strength 0.45. The dialyzed solutions showed no evidence of precipitation, and, upon addition of thrombin, clots of normal opacity and clotting time were obtained. (*b*) Similar solutions of fibrinogen were dialyzed against large volumes of 0.45 M sodium chloride without buffer. In this case, the pH fell to 5.5, (as did that of fibrinogen solution with no reagent present), and portions tested with thrombin did not clot; but, after the pH was readjusted to 6.2, clots of normal opacity and clotting time were obtained. (*c*) Solutions of thrombin (20 units/cc.) containing the above inhibitors at concentrations somewhat above their minimum inhibiting levels were allowed to stand twenty hours and then used to clot fresh fibrinogen solutions with the standard procedure. Since the concentration of reagent was reduced twenty-fold in mixing with the fibrinogen, its influence should have been slight unless the thrombin had been inactivated; clots of nearly normal opacity and clotting time were in fact obtained, showing that the thrombin had not been affected. (*d*) Mixtures of fibrinogen and thrombin containing the inhibitors which had been kept without clotting for as long as a month were dialyzed against 0.45 M sodium chloride. Clotting soon took place, although the opacity was of course lower than normal because the inhibitor had not been completely removed.

When opaque control clots, formed with the standard procedure in cellophane tubing, were dialyzed against 0.45 M sodium chloride containing pentamethylene and hexamethylene glycols at their minimum inhibiting concentrations, no changes in opacity were apparent, showing that once the coarse structure is established these reagents are powerless to alter it.

When transparent clots, formed in cellophane tubing from fibrinogen solutions containing slightly less than the minimum inhibiting concentrations of the above reagents, were dialyzed against 0.45 M sodium chloride, a gradual increase in opacity occurred after one or two days. It is not yet certain whether this represents a coarsening of the fine structure already established or a continued polymerization of smaller units which had remained unattached to the network structure.

Discussion

Interpretation of these results will be based on the concepts previously developed,[2] that the conversion of fibrinogen to fibrin is essentially a polymerization; that the rod-like fibrinogen molecules (about 35 × 700 Å.) enter the fibrin structure without any profound changes in their own shape; and that their end-to-end junction is accompanied by varying degrees of side-by-side association. The more lateral association, the coarser are the strands of the final network.

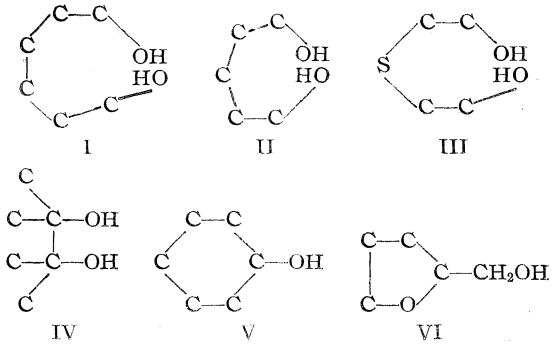
Since the hydroxyl compounds studied do not produce any irreversible change in fibrinogen or thrombin, it may be concluded that their effects on the clotting process are due to interaction involving van der Waals forces. This interaction might interfere with the primary reaction between fibrinogen and thrombin, or it might modify the normal interactions between fibrinogen molecules which determine the geometrical details of polymerization. In either case, the simplest assumption is that the volume of the reagent molecule prevents the two protein molecules from approaching closely enough for their normal combination to occur.

Modification of the geometry of polymerization would cause differences in structure, which are measured roughly by changes in opacity at constant t/t_C (Table II). Interference with the fibrinogen–thrombin reaction would affect the clotting time (Table I), but the latter could also be changed by differences in association geometry, so that both influences must be considered in interpreting the effects of reagents on the time of

clotting.[11] Actually, the orders of effectiveness in the two tables are rather similar.

Relation of Effectiveness to Structure.—As Pauling has emphasized,[13] in van der Waals interactions steric factors are overwhelmingly important; and it should be possible to correlate the observed effects with molecular shape and arrangement of hydroxyls. The most profound effect is complete inhibition by hexamethylene glycol (I), pentamethylene glycol (II), and bis-(2-hydroxyethyl) sulfide (III). Their similarity in structure is evident, with two terminal hydroxyls separated by a chain about 8 to 9 Å. long when fully extended.

The above three compounds appear near the top in Table I and Table II, together with pinacol (IV), cyclohexanol (V), and tetrahydrofurfuryl alcohol (VI). These six molecules present rather similar contours if the glycols are in the ring configuration with the hydroxyls aligned in a hydrogen bond



It seems probable that this is the configuration which interacts strongly with one of the proteins to impede clotting; it represents a bulky mass of paraffin material with either one hydroxyl or two associated hydroxyls at one side.

Near the bottom of each table appear ethylene and propylene glycol and glycerol, with other compounds containing a relatively high proportion of hydroxyl to carbon. From the relative inactivity of these reagents, it appears that the non-polar areas of the more powerful substances are essential to their interaction; it may be supposed that the site on the protein which is blocked involves both a non-polar side chain and a hydrogen bond-forming group.

The compounds mannitol, pentaerythritol, glucose, and sucrose, which are bulky but carry many hydroxyls, are anomalous in that they strongly decrease opacity but have relatively little effect on the clotting time except at quite low concentrations.

Interpretation of Opacity Changes.—Since most of the effective reagents not only prolong clotting but also decrease the opacity at constant t/t_C, it seems probable that they interact with fibrinogen rather than with thrombin, and moreover that they interfere with side-by-side association of fibrinogen molecules even more than with end-to-end junction.[14] It is easy to see how the existence of several sites for interaction with reagent could produce this result (Fig. 6); when a moderate proportion of sites is covered, the probability of finding an unimpeded side is less than that of finding an unimpeded end. The picture of Fig. 6 also explains qualitatively the shape of the curves of opacity against concentration (Fig. 5). If the interaction between sites and reagent can be expressed by an association constant k, then the probability of a free side (and hence the opportunity for association to give coarse network strands) is proportional to $1/(1 + kc)^n$, where c is the concentration and n the number of sites on a side. With increasing c, this fraction at first decreases slowly, and then falls rather rapidly toward zero.

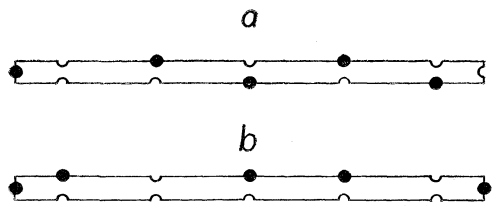


Fig. 6.—Illustration of greater interference, by reagents, with side-by-side than with end-to-end combination. If there are n interaction sites on each side of a fibrinogen molecule and 1 on each end, and a proportion p is blocked by reagents, the probability of a free end (a) is $1 - p$ but the probability of a free side (b) is $(1 - p)^n$.

Effect of Starch and Polyvinyl Alcohol.—The two reagents of high molecular weight are clearly in a class by themselves. Their effect in decreasing the clotting time is shared by a number of other macromolecules, termed "fibrinoplastic" by Ferguson.[15] No more detailed interpretation is offered than the possibility suggested previously[2] that the polymer molecules serve as additional cross-links which permit the network to be established at an earlier stage of the reaction.

Summary

1. The effects of twenty-five hydroxyl compounds on the conversion by thrombin of bovine fibrinogen to fibrin have been investigated by measurements of clotting time and clot opacity.

2. All the reagents except two prolong the

(11) This discussion implies that the extent of reaction at the moment of clotting or gel point[12]—*i. e.*, the proportion of fibrinogen which has been converted to fibrin, or the proportion reacted of whatever specific groups on the fibrinogen molecule are involved—does not depend greatly on the presence of modifying reagents. It is impossible to test the validity of this assumption at present; it probably does not invalidate any of the qualitative conclusions drawn here.

(12) P. J. Flory, *J. Phys. Chem.*, **46**, 132 (1942); *cf.* J. D. Ferry, "Advances in Protein Chemistry," Vol. IV, p. 60 ff.

(13) L. Pauling, in K. Landsteiner, "The Specificity of Serological Reactions," Cambridge, Mass., 1947, Chapter VIII.

(14) This conclusion is supported by preliminary electron micrographs of fibrinogen which has been allowed to react with thrombin in the presence of hexamethylene glycol; very long thin isolated fibers are observed.

(15) J. H. Ferguson, *Ann. N. Y. Acad. Sciences*, **49**, 486 (1948).

clotting time (t_C), and diminish the opacity both compared at constant time (t) after addition of thrombin and at constant t/t_C. The exceptions, starch and polyvinyl alcohol, shorten the clotting time.

3. The effectiveness in prolonging clotting time (expressed by d log t_C/dc, where c is concentration) and in diminishing opacity (expressed by the value of c at which opacity at constant t/t_C is one-half the control value) is generally greatest for compounds with one or two hydroxyls and several methylene or methyl groups, although specific characteristics are apparent.

4. Three reagents—hexamethylene glycol, pentamethylene glycol, and bis-(2-hydroxyethyl)-sulfide—prevent clotting entirely at moderate concentrations but cause no apparent irreversible changes in either fibrinogen or thrombin.

5. The results are interpreted as due to van der Waals association of the reagents with fibrinogen, and consequent steric interference with both end-to-end and side-by-side union of fibrinogen molecules.

Cyclization of α-Phenylglutaric Anhydride

BY E. C. HORNING AND A. F. FINELLI[1]

From an extensive study by Attwood, Stevenson and Thorpe[2] on the cyclization of dicarboxylic acids derived from γ-phenylbutyric acid, the generalization was drawn that substitution in the β-position (with respect to the ring) was necessary for cyclization. For example, both β-benzylglutaric acid and α-benzylsuccinic acid gave tetralones on treatment with sulfuric acid; it was postulated that anhydride formation occurred first, and that cyclization then followed under the influence of concentrated acid. The effect of a β-substituent was not clearly defined, but since every instance in which cyclization occurred included this structural feature, the generalization seemed valid.

In the course of work on the synthesis of certain substituted tetralones, we have investigated the cyclization of α-phenylglutaric anhydride. This compound was prepared from phenylacetonitrile by the following steps. Carbethoxylation of phenylacetonitrile with diethyl carbonate by a modification of the usual method[3] gave ethyl phenylcyanoacetate (I). Addition of acrylonitrile to the latter compound provided α-phenyl-α-carbethoxyglutaronitrile (II); this was hydrolyzed and decarboxylated to the corresponding glutaric acid, which was then converted to the anhydride with acetic anhydride. Treatment of α-phenylglutaric anhydride (III) with sulfuric acid gave 4-keto-1,2,3,4-tetrahydro-1-naphthoic acid (IV) in 57% yield.

It was recognized by the English workers that α-phenylglutaric acid or its anhydride should be investigated as a simple test case for their generalization, but unfortunately the method of Fichter and Merckens[4] for the preparation of the acid could not be repeated. Since the original work, instances in which this generalization does not hold have been found; for example, Robinson[5] has described the cyclization of 5-carboxy-4-carboxymethyl-7-phenylheptanoic acid with sulfuric acid to the corresponding tetralone. The present method provides a satisfactory way of obtaining α-phenylglutaric anhydride, and its successful cyclization confirms the view that substitution in the β-position with respect to the ring is not a prerequisite for cyclization. At the same time, the conditions of cyclization may determine the nature of the product. When the anhydride was treated with aluminum bromide in benzene, an intermolecular reaction occurred with formation of α-phenyl-γ-benzoylbutyric acid. It has recently been demonstrated[6] that benzene is a suitable solvent for intramolecular Friedel–Crafts reactions, and this result indicates that sulfuric acid may give results different from those obtained under Friedel–Crafts conditions.

Acknowledgment.—We are indebted to the Research Corporation for a grant in support of this work, and to Mrs. Sarah M. Woods for the analytical data.

Experimental

All melting points are corrected.

Ethyl Phenylcyanoacetate.—Sodium ethoxide was prepared from 12.0 g. (0.52 mole) of sodium and 300 ml. of anhydrous ethanol in a 1-l. three-necked, round-bottomed flask fitted with a reflux condenser and drying tube. After the sodium dissolved, the excess ethanol was removed by heating the flask on a steam-bath while the system was maintained at the pressure obtained with an ordinary aspirator.

As rapidly as possible, after removal of the ethanol, the flask was fitted with a stirrer, a dropping funnel, a distilling head with thermometer, and a condenser arranged for distillation into a flask protected by a calcium chloride tube. There was added 300 ml. of dry diethyl carbonate, 80 ml. of dry toluene, and 58.5 g. (0.50 mole) of phenylacetonitrile. The flask was heated with good stirring and when distillation started, dry toluene was added dropwise at about the same rate as that of distillation. Approximately 200–250 ml. of toluene was added over a period of two hours while stirring and distillation was continued.

The mixture was cooled, transferred to a beaker, and after addition of 300 ml. of cold water, the aqueous phase was acidified with 35–40 ml. of acetic acid. The layers were separated, and the water solution was extracted with three 75-ml. portions of ether. The organic solutions were washed with 100 ml. of water, and then dried over magnesium sulfate. The low-boiling solvents were removed by distillation at atmospheric pressure, and the residue was distilled under reduced pressure through a short (15 cm.) Vigreux column. After a 1–5 g. forerun, the product was collected as a colorless liquid at 125–135° (3–5 mm.). The yield was 66–74 g. (71–79%), $n^{25}D$ 1.5012–5019.

α-Phenyl-α-carbethoxyglutaronitrile.—A solution of 57.0 g. (0.30 mole) of ethyl phenylcyanoacetate in 80 ml. of *t*-butyl alcohol was heated to 40°, and with stirring the dropwise addition of a solution of 33.0 g. (0.62 mole) of acrylonitrile in 30 ml. of *t*-butyl alcohol was started. After the addition of about 10–15 drops, 1.0 ml. of 30% methanolic potassium hydroxide was added, and the temperature was maintained at 40–45° by occasional external cooling while the remaining solution was added slowly. When about one-half of the acrylonitrile was added an additional 1.0 ml. of potassium hydroxide solution was added. When the temperature was no longer maintained above 40° by the exothermic reaction, a hot-water-bath was employed to keep the mixture at 40–45° for one hour and it was then allowed to stand overnight.

The solution was diluted with 250 ml. of water, and acidified with 10% hydrochloric acid (30–40 ml.). The product was separated with 100 ml. of ether, and the aqueous solution extracted with two 50-ml. portions of ether. The combined extracts were washed with 50 ml. of water and dried over magnesium sulfate. The ether was distilled at atmospheric pressure, and the residue was distilled under reduced pressure through a short (15-cm.) Vigreux column. After a forerun of a few grams, the product was collected as a colorless viscous oil at 157–167° (0.5–1 mm.). The yield was 50–61 g. (69–83%), $n^{25}D$ 1.5100–5103.

Anal. Calcd. for $C_{14}H_{14}O_2N_2$: C, 69.40; H, 5.82. Found: C, 69.59; H, 6.04.

α-Phenylglutaric Anhydride.—A mixture of 48.4 g. (0.20 mole) of α-phenyl-α-carbethoxyglutaronitrile, 225 ml. of hydrochloric acid (sp. gr. 1.19) and 50 ml. of acetic acid was heated under reflux for ten hours. After cooling, the solution was diluted with 300 ml. of water. The α-phenylglutaric acid was extracted with five 100-ml. portions of ether–ethyl acetate (1:1). The extracts were combined and dried over magnesium sulfate. The solvents were removed as completely as possible by heating on a steam-bath, and the residue was transferred to a 200-ml. flask. Acetic anhydride (50 ml.) was added, and the solution was heated under gentle reflux for one hour. The excess acetic anhydride was removed by distillation at atmospheric pressure, and the residue was distilled under reduced pressure through a short (15 cm.) Vigreux column. The product was collected at 178–188° (0.5–1 mm.). The yield was 32.7 g. (86%); m. p. 90–94°.

This material was recrystallized from ethyl acetate–hexane to give a colorless crystalline product, m. p. 95–96°. The acid and its anhydride have been reported by Fichter and Merckens.[4]

α-Phenyl-γ-benzoylbutyric Acid.—To a solution of 14.4 g. (0.06 mole) of anhydrous aluminum bromide in 30 ml. of dry benzene there was added a solution of 3.8 g. (0.02 mole) of α-phenylglutaric anhydride dissolved (with warming) in 20 ml. of dry benzene. After the ensuing exothermic reaction the mixture was refluxed for twenty minutes and allowed to stand overnight.

The solution was decomposed with ice and concentrated hydrochloric acid. Approximately 30 ml. of ether was added to aid in the separation. The aqueous layer was extracted with three 30-ml. portions of ether. The combined organic extracts were washed with water. The organic layer was filtered and extracted with six 25-ml. portions of 10% sodium carbonate solution. The alkaline extract was filtered and acidified with hydrochloric acid (10%) to precipitate the organic acid. The mixture was chilled for two hours, filtered, and the product washed with cold water and dried at room temperature to yield 3.6 g. (67%) of crude colorless acid; m. p. 119–125°. Recrystallization from benzene–cyclohexane gave the acid as colorless needles, m. p. 130–131°.

Anal. Calcd. for $C_{17}H_{16}O_3$: C, 76.10; H, 6.01. Found: C, 76.00; H, 6.09.

4-Keto-1,2,3,4-tetrahydro-1-naphthoic Acid.—α-Phenylglutaric anhydride (4.0 g.) was dissolved with slight warming in 25 ml. of concentrated sulfuric acid, and the solution was kept at 60–70° for thirty minutes. This was allowed to stand overnight at room temperature. The solution was poured on chopped ice and allowed to stand until separation of the colorless solid product was complete. The crude material was removed by filtration and dried to yield 2.3 g. (57%); m. p. 91–92°. Recrystallization from ethyl acetate–pentane gave colorless needles, m. p. 93–95°.

Anal. Calcd. for $C_{11}H_{10}O_3$: C, 69.46; H, 5.30; neut. equiv., 190. Found: C, 69.57; H, 5.40; neut. equiv., 192.

The colorless **semicarbazone** melted at 237° (dec.).

Anal. Calcd. for $C_{12}H_{13}O_3N_3$: C, 58.29; H, 5.30. Found: C, 58.46; H, 5.20.

The orange **2,4-dinitrophenylhydrazone** was recrystallized from benzene; m. p. 255–256 (dec.).

Anal. Calcd. for $C_{17}H_{14}O_6N_4$: C, 55.13; H, 3.81. Found: C, 55.12; H, 3.68.

Summary

The preparation and cyclization of α-phenylglutaric anhydride to 4-keto-1,2,3,4-tetrahydro-1-naphthoic acid is described.

Studies in the Indole Series. XI. The Reduction of Certain Oxindoles with Lithium Aluminum Hydride

BY PERCY L. JULIAN AND HELEN C. PRINTY

This investigation had its origin in the need for rather large quantities of N-methylyobyrine[1] and certain 5-ethoxylated indole derivatives. To secure the necessary starting materials, namely, 1-methylindole and 1-methyl-5-ethoxyindole, it seemed appropriate to study the reduction of the corresponding and very readily accessible oxindole analogs[2] with lithium aluminum hydride.[3] The method has been applied to several N-methylated oxindoles, and appears generally applicable for the reduction of these derivatives to indoles.

Even with the reverse addition of one mole of lithium aluminum hydride in ether to two moles of the oxindole suspended or dissolved in the same solvent, there always arose about 10–15% of the corresponding indoline. Easily removed from the indole by washing with dilute acid, its presence, nevertheless, gave another example of the reduction of isolated double bonds by lithium aluminum hydride.[4]

In view of the ease with which the reduction of N-substituted oxindoles and indoles took place, it was surprising that the reaction was an almost complete failure with unsubstituted oxindoles. Little or no indole could be obtained from oxindole even when the reaction was carried out at elevated temperatures in butyl ether, dioxane, or tetrahydrofuran. Likewise, unsubstituted indoles were not reduced to indolines by the reagent, a fact we have been able to utilize in the selective reduction of certain groups in more complex indole derivatives.[5]

Analogous results were noted in the behavior of dioxindoles: dioxindole was reduced to oxindole, with small amounts of indole resulting, whereas 1-methyldioxindole was reduced to 1-methylindole.

With ample quantities of 1-methylindole at our disposal, the preparation of 1-methyltryptamine was carried out according to the elegant method of Snyder and Eliel[6]; however, we were able to improve the yield by catalytic reduction[7] of the 1-methylindolylacetonitrile. N-Methylyobyrine was prepared from 1-methyltryptamine by the method already described for yobyrine.[8]

Experimental[9]

Reduction of 1-Methyloxindoles with Lithium Aluminum Hydride.—Twelve grams of lithium aluminum hydride in 600 ml. of anhydrous ether was added in forty minutes to a stirred suspension of 100 g. of 1-methyloxindole in 1 liter of anhydrous ether. The mixture was stirred another ten minutes, 250 ml. of water was added slowly, then 250 ml. of 4% hydrochloric acid. The reaction products were shaken out with ether, and the ether washed with 1 liter of 3% hydrochloric acid. The ether extract was concentrated, then steam-distilled until 4 liters of distillate was obtained. This was extracted with ether, dried over sodium sulfate, and the ether distilled. Fifty-five grams (61.8%) of 1-methylindole, a pale yellow oil, was obtained. This gave a red picrate, m. p. 146–147° dec. (lit.[10] 150°).

The residue from steam-distillation was extracted with ether, washed, dried and concentrated. Fourteen grams of 1-methyloxindole, m. p. 82–85°, was obtained.

The acid washes were treated with sodium hydroxide pellets until strongly alkaline, then steam-distilled until 1 liter of distillate was obtained. This was extracted with ether, which was dried over sodium sulfate, and the ether was distilled. Eleven grams (12%) of pale yellow oil was obtained. This oil distilled at 100–102° at 14 mm., and gave a picrate, shiny yellow plates, m. p. 171–172° dec. Carrasco[11] reports a melting point of 165° for 1-methylindoline picrate.

1,3-Dimethyloxindole was reduced by the metal hydride to 1,3-dimethylindole, b. p. 132–139° (16 mm.), picrate m. p. 141–142° dec., in 85.8% yield. A 13% yield of 1,3-dimethylindoline, a yellow oil, was also obtained. This gave a yellow picrate which crystallized from methanol, m. p. 111–112° dec.

Anal. Calcd. for $C_{16}H_{16}O_7N_4$: C, 51.06; H, 4.28. Found: C, 51.06; H, 4.15.

1-Methyl-5-ethoxyoxindole was reduced in 60% yield to 1-methyl-5-ethoxyindole; 6% of 1-methyl-5-ethoxyindoline was obtained, and 27% of 1-methyl-5-ethoxyoxindole, m. p. 88–90°,[12] recovered. 1-Methyl-5-ethoxyindole was, surprisingly, a higher-melting compound than we expected. It was obtained, on recrystallization from methanol, as shiny white plates, m. p. 86–87°.

Anal. Calcd. for $C_{11}H_{13}ON$: C, 75.39; H, 7.47. Found: C, 75.74; H, 7.70.

This compound gave a very soluble picrate which crystallized from methanol in fine red needles, m. p. 95–96° dec.

Anal. Calcd. for $C_{17}H_{16}O_8N_4$: C, 50.49; H, 3.98. Found: C, 50.90; H, 4.10.

For purposes of comparison, 1-methyl-5-ethoxyindole was prepared from pyruvic acid and *p*-ethoxyphenylmethylhydrazine.[13] The indole obtained this way was identical with that from 1-methyl-5-ethoxyoxindole.

1-Methyl-5-ethoxyindoline was an oil which was isolated as the picrate. This crystallized from methanol in shiny yellow plates, m. p. 142–144° dec.

Anal. Calcd. for $C_{17}H_{18}O_8N_4$: C, 50.24; H, 4.46. Found: C, 50.30; H, 4.61.

Dehydrogenation of the Indolines to Indoles.—This was effected by refluxing a solution of 4 g. of the indoline in 80 ml. of xylene with 7.5 g. of chloranil. The yields of indole were approximately 50%, the remainder of the material apparently forming a complex with chloranil.[14]

Reduction of Indoles with Lithium Aluminum Hydride.—A solution of 4.68 g. of indole in 50 ml. of anhydrous ether was added to a stirred suspension of 1.0 g. of lithium

aluminum hydride in 50 ml. of ether, and stirred for one and one-half hours. Water was added, the aluminum hydroxide dissolved in 3% hydrochloric acid, and the ether layer washed, concentrated and steam-distilled. From the steam-distillate, 4.3 g. of indole was recovered. No indoline was formed. Under these same conditions both 1-methylindole and 1,3-dimethylindole were converted to the respective indolines in 25–30% yields.

Reduction of Dioxindoles.—From 3.72 g. of dioxindole, treated in essentially the same manner, 2.05 g. of oxindole, and, surprisingly, 0.41 g. of indole were obtained. On the other hand, 3.2 g. of 1-methyldioxindole on reduction yielded 1.2 g. of 1-methylindole and 0.5 g. of the oxindole.

Preparation of N-Methylyobyrine.—The following compounds were prepared as previously described.[8b]

***o*-Tolylacetyl-1-methyltryptamine** crystallized from ether in creamy white plates, m. p. 103.5°.

Anal. Calcd. for $C_{20}H_{22}ON_2$: C, 78.39; H, 7.23. Found: C, 78.52; H, 6.97.

N-Methyldihydroyobyrine picrate, crystallized in yellow needles from benzene, m. p. 205–206° dec.

Anal. Calcd. for $C_{26}H_{23}O_7N_5$: C, 60.34; H, 4.48. Found: C, 60.72; H, 4.47.

N-Methylyobyrine (picrate, m. p. 233° dec.) crystallized from ether–methanol as shiny white needles, m. p. 106°.[1]

Anal. Calcd. for $C_{20}H_{18}N_2$: C, 83.88; H, 6.33; N, 9.78. Found: C, 83.72; H, 6.30; N, 9.85.

The over-all yield, in large (4 g.) runs of N-methylyobyrine from *o*-tolylacetyl-1-methyltryptamine, was 30%.

Summary

1-Methyloxindoles are reduced in good yields to the corresponding indoles with lithium aluminum hydride.

The preparation of N-methylyobyrine is described.

Studies in the Indole Series. XII. Yohimbine (Part 3). A Novel Synthesis of the Yohimbine Ring Structure

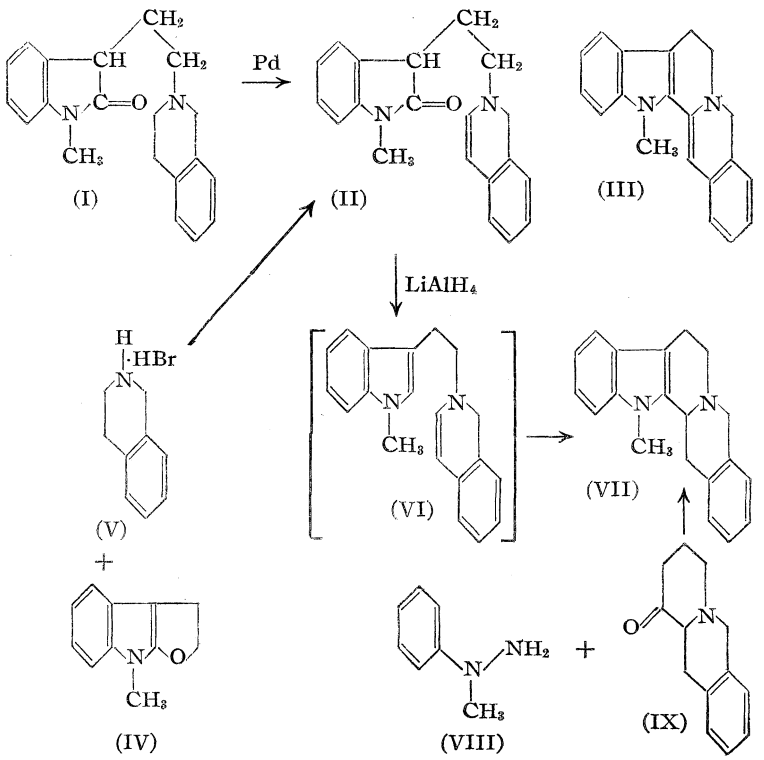
BY PERCY L. JULIAN AND ARTHUR MAGNANI

In an earlier communication dealing with the preparation and properties of 3-(N-tetrahydroisoquinolylethyl)-1-methyloxindole (I),[1] it was shown that dehydrogenation of I with palladium black yielded a 182° melting compound which could not be cyclicized, with the usual dehydrating agents, to III, a substance possessing the basic ring structure of yohimbine.

Largely because of this failure at ring closure, and also because of the difficulties hitherto experienced by various workers in attempts to prepare 1,2-dihydroisoquinolines like II, we expressed the opinion that our dehydrogenation product did not have the constitution II, despite the correct analyses and molecular weight. Certainly its preparation from the dihydrofuroindole (IV) and tetrahydroisoquinoline hydrobromide (V) was, to say the least, not a comfortable basis for ascribing to it the constitution II.

Our subsequent investigations, however, have shown that failure to secure ring closure represents no criterion for or against structure II, and further that the 182° melting dehydrogenation product of I actually does have the structure II, despite the considerations recorded above and in an earlier communication.[1]

Moreover, reduction of II with lithium aluminum hydride, a procedure which we have demonstrated converts 1-alkyl oxindoles smoothly to the corresponding indoles,[2] resulted in spontaneous cyclization of the intermediate (VI) to VII, a compound possessing the basic ring structure of



(1) Julian, Magnani, Pikl and Karpel, THIS JOURNAL, **70**, 174 (1948).

(2) Julian and Printy, *ibid.*, **71**, 3206 (1949).

yohimbine. Thus a novel synthesis of this structure is revealed, the potential usefulness of which is far-reaching.

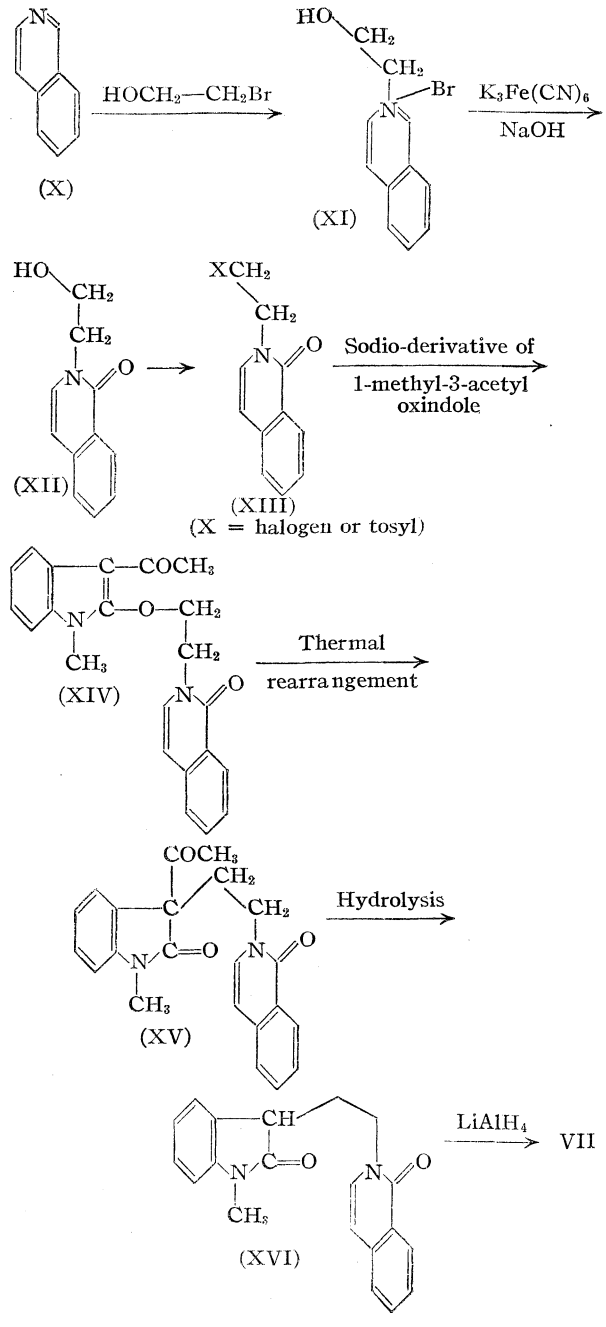
The structure of VII was demonstrated in several ways. First of all it was synthesized quite readily from VIII and IX by a procedure suggested by Clemo and Swan.[3]

The second verification of the structure of VII, demonstrated further the usefulness of this novel method of ring closure to yohimbine derivatives and afforded, in addition, some new insight into the 3-alkylation of oxindoles.[4] In an attempt to prepare compounds of the type represented by II and which indisputably possessed a double bond in the 3,4-position of the isoquinoline nucleus, we prepared the isoquinolone (XVI). All attempts to close the ring here through dehydration, involving enolization of the hydrogen atom in the 3-position of the oxindole, failed as had similar attempts on compound II. On reduction, however, with lithium aluminum hydride, XVI was readily converted into VII, the oxindole carbonyl being reduced as well as the carbonyl group of the isoquinolone.

Further verification of the structure of VII was obtained by its conversion to N-methylyobyrine[2] by treatment with palladium black, a reaction now well identified with compounds containing the yohimbine ring skeleton.[5]

As stated above, the preparation of XVI gave us our first insight into the mechanism of 3-alkylation of 1-methyl-3-acetyloxindole, a type of alkylation we have frequently employed over the past several years.[1,4] The quaternary adduct from ethylene bromohydrin and isoquinoline was converted in good yield with alkaline potassium ferricyanide to the isoquinolone alcohol (XII). The tosylate of the latter or the corresponding chlor-compound (XIII) reacted with the sodio-derivative of 1-methyl-3-acetyloxindole to yield a readily crystallizable O-alkyl derivative, to which we tentatively ascribe formula XIV. The experimental basis for this structure is diffuse and will be the subject of a separate communication. Suffice it to say that structure XIV has been chosen primarily on the basis of analogy in ultraviolet spectrum and other properties to the 1-methyl-2-methoxy-3-formyl indole prepared several years ago.[6]

Thermal rearrangement of this O-alkyl derivative (XIV) yields a C-alkyl acetyl derivative (XV), which could not be induced to crystallize, but which on hydrolysis gave the crystalline 1-methyl-3-(1-oxo-isoquinolylethyl)-oxindole (XVI). Thus we have one of the relatively rare cases where the O-alkyl intermediate in C-alkylation of 1,3-dicarbonyl compounds can be cleanly isolated and thermally rearranged into its C-alkyl isomer.



The further exploitation of this interesting type of ring closure for the simplest type of synthesis of the yohimbine ring structure yet reported, involving the addition of β-indolylethyl bromide and β-N-methylindolylethyl bromide to isoquinoline, is being studied and will be reported in another communication.

Experimental

Reduction of 1-Methyl-3-[2-N-(1,2-dihydroisoquinolylethyl)]-oxindole (II) to the Yohimbine Ring Skeleton (VII) with $LiAlH_4$.—The dihydroisoquinolylethyloxindole (II) was obtained by dehydrogenating the tetrahydroisoquinolylethyloxindole (I) with palladium black.[1] The

dihydroisoquinolylethyloxindole (0.45 g., m. p. 180–182°) was dissolved in 5 ml. of dry dioxane and diluted with 30 ml. of absolute ether. Over a five-minute period with agitation there was added a solution of 70 mg. of lithium aluminum hydride in 25 ml. of absolute ether. The reaction mixture was allowed to stand for one hour at room temperature, cautiously decomposed by the addition of water, and then acidified with dilute acid. The aqueous acidic solution was extracted with ether to remove any non-basic material. The basic fraction (0.4 g.) obtained by basifying and extracting with ether was distilled. The fraction distilling as a yellow oil at 180–185° bath temperature (0.008 mm.) was collected and amounted to 0.3 g. Upon treatment in methanol with picric acid, there was obtained 0.25 g. of orange picrate, m. p. 198–202° dec. It was identical with the picrate of the base VII obtained from the Fischer indole synthesis involving the ketone IX, and after crystallization from methanol melted at 205–207° dec. The picrate (0.18 g.) upon decomposition with alkali yielded the base VII (85 mg.) melting at 132–135°. By heating 60 mg. of the base with palladium black as described below, N-methylyobyrine was isolated as the picrate (44 mg., m. p. 230–233° dec.).

Fischer Indole Synthesis of the Base VII.—The method and procedure used were essentially those described by Clemo and Swan.[3] The hydrazone prepared from α-methylphenylhydrazine (VIII) and the ketone (IX) was crystallized from aqueous methanol as yellow plates, m. p. 93°.

Anal. Calcd. for $C_{20}H_{23}N_3$: C, 78.65; H, 7.59; N, 13.76. Found: C, 78.83; H, 7.47; N, 13.45.

The phenylhydrazone (0.44 g.) was ring closed by heating for twenty minutes on the steam-bath with 15 ml. of 5% sulfuric acid. The red aqueous solution was diluted with water, made alkaline, and extracted several times with ether. The ethereal solution was washed with water, dried over sodium sulfate, and the solvent removed. The residual reddish oil could not be crystallized at this point. It was dissolved in methanol, treated with a methanolic solution of 0.30 g. of picric acid, and concentrated on the steam-bath until crystallization of the picrate began. After cooling, the picrate was filtered and washed with methanol. There was obtained 0.32 g. of the picrate of the ring-closed-base VII, m. p. 206–208° dec. Recrystallization from methanol gave yellow needles, m. p. 209° dec.

Anal. Calcd. for $C_{26}H_{23}N_5O_7$: C, 60.34; H, 4.48; N, 13.54. Found: C, 60.40; H, 4.37; N, 13.26.

The free base VII was obtained from the picrate (0.3 g.) by shaking a suspension of it in ether with alkali until complete solution resulted. The ethereal solution was washed well with water, dried over sodium sulfate, and the solvent removed. The partially crystalline residue (0.14 g.) was distilled as a yellow oil (0.11 g.) collected at 0.002 mm. and 165–170° bath temperature. Slow crystallization from warm aqueous methanol gave the base VII as white plates; yield 88 mg., m. p. 135°.

Anal. Calcd. for $C_{20}H_{20}N_2$: C, 83.29; H, 6.99; N, 9.72. Found: C, 83.20; H, 6.92; N, 9.66.

The base VII (30 mg.) was heated with 30 mg. of palladium black for twenty minutes at 215 to 225° and at 10–15 mm. pressure. The product was extracted with hot methanol and treated with norite. The methanol solution, upon treatment with 25 mg. of picric acid, yielded, on concentration, 25 mg. of the yellow picrate of N-methylyobyrine, m. p. 230–232° dec. After decomposition of the picrate with alkali, N-methylyobyrine (10 mg.) was readily obtained by crystallization from a concentrated solution in ether–petroleum ether as white rods, m. p. 105–106°. When this product was mixed with an authentic sample of N-methylyobyrine[2] (m. p. 105–106°), there was no depression of the melting point.

β-Hydroxyethyl-isoquinolinium Bromide (XI).—A mixture of 17.7 g. of ethylene bromohydrin and 20 g. of isoquinoline was heated on the steam-bath until an exothermic reaction darkened the solution and rapidly raised the temperature of the mixture to 190°. When allowed to cool slowly the reddish liquid set to a mass of crystals which was digested with acetone and filtered. The isoquinolinium bromide (34 g.) was dissolved in 34 ml. of hot methanol and crystallized by adding 340 ml. of hot acetone. There was obtained 26.2 g. of the isoquinolinium bromide, m. p. 154–156°. Further crystallizations raised the melting point to 157°.

Anal. Calcd. for $C_{11}H_{12}ONBr$: C, 51.99; H, 4.76; N, 5.51. Found: C, 51.86; H, 4.70; N, 5.42.

2-β-Hydroxyethyl-1-isoquinolone (XII).—The isoquinolinium bromide was oxidized to the isoquinolone in 60% yield with potassium ferricyanide by the method of Elpern and Hamilton.[7] The crude isoquinolone was isolated by filtration or by chloroform extraction and distilled. From 26 g. of the isoquinolinium bromide there was obtained 14.2 g. of a yellow oil which crystallized readily, b. p. 190–200°, bath temperature (2.5 mm.). The isoquinolone was dissolved in 10 ml. of methanol, 50 ml. of warm benzene was added and the solution concentrated to a volume of 35 ml. It crystallized as white plates; yield 11.8 g.; m. p. 114–116°. For analysis it was recrystallized from benzene, m. p. 116°.

Anal. Calcd. for $C_{11}H_{11}O_2N$: C, 69.83; H, 5.86; N, 7.40. Found: C, 69.73; H, 5.54; N, 7.31.

Tosylate of 2-β-Hydroxyethyl-1-isoquinolone (XIII).—The tosylate of the isoquinolone was best prepared by employing a large excess of tosyl chloride. To a suspension of 2.85 g. of the isoquinolone (finely divided) in 25 ml. of benzene was added 3.0 g. of tosyl chloride. The mixture was cooled in an ice-bath, and with vigorous agitation there was added 10 ml. of 30% sodium hydroxide over a period of five minutes. This mixture was agitated for five minutes, and the addition of tosyl chloride and sodium hydroxide was repeated twice. The slightly gummy precipitate of the tosylate changed to a finely divided precipitate which was collected on a filter and washed well with water and ether. There was obtained 4.0 g. of the tosylate, m. p. 160–164°. It is sparingly soluble in ether or benzene. For recrystallization, it was dissolved in a small amount of chloroform, diluted with hot benzene, and then concentrated until crystallization began, m. p. 166°.

Anal. Calcd. for $C_{18}H_{17}O_4NS$: C, 62.96; H, 4.99; N, 4.08. Found: C, 63.06; H, 4.96; N, 4.14.

2-β-Chloroethyl-1-isoquinolone (XIII).—Thionyl chloride (4 ml.) was cautiously added to 2.1 g. of the hydroxyethylisoquinolone covered with 6 ml. of petroleum ether (30 to 60°) and the resulting yellow layers allowed to stand for twenty minutes. This mixture was heated on the steam-bath until a homogeneous solution resulted, and the remaining petroleum ether and excess thionyl chloride were removed *in vacuo*. The residual yellow oil was dissolved in ether, and the solution washed with dilute alkali and water. The chloroethylisoquinolone was crystallized from ether–petroleum ether; yield 2.2 g., m. p. 102–105°. Recrystallization from the same solvents gave white needles, m. p. 109°.

Anal. Calcd. for $C_{11}H_{10}ONCl$: C, 63.62; H, 4.85; N, 6.74. Found: C, 63.88; H, 4.77; N, 6.62.

The same chloroethylisoquinolone was prepared from the tosylate. To 250 mg. of the tosylate in 10 ml. of dry alcohol-free acetone 50 mg. of lithium chloride was added and the mixture refluxed for one hour. The acetone was removed *in vacuo* and the residue was dissolved in ether and washed with water. The chloroethylisoquinolone (120 mg.) thus isolated melted at 107–109°.

2-β-Bromoethyl-1-isoquinolone (XIII).—Reaction of hydroxyethylisoquinolone with thionyl bromide yielded a mixture of products and very little of the bromoethylisoquinolone. The latter, however, was readily prepared from the tosylate as described for the chloroethylisoquinolone. From 0.5 g. of the tosylate and 0.5 g. of lithium bromide there was obtained 0.4 g. of the bromoethylisoquinolone, m. p. 109–110°. Recrystallization from ether–petroleum ether gave white needles, m. p. 112°.

(7) Elpern and Hamilton, THIS JOURNAL, 68, 1436 (1946).

Anal. Calcd. for $C_{11}H_{10}ONBr$: C, 52.40; H, 4.00. Found: C, 52.65; H, 4.10.

Reaction of Isoquinolones (XIII) with Sodio-derivative of 1-Methyl-3-acetyloxindole (a) with Tosylate of 2-β-Hydroxyethyl-1-isoquinolone.—A mixture of 2.5 g. of the tosylate and 2.1 g. of the sodium salt of the acetyloxindole in 50 ml. of alcohol-free acetone was refluxed vigorously for one hour under anhydrous conditions. The thick paste first formed was gradually replaced by a fine precipitate of the sodium salt of the sulfonic acid. This mixture was diluted with ether and washed with water. The reddish ethereal solution was concentrated and the last of the solvents removed *in vacuo*. The remaining oil was then crystallized from acetone–ether yielding 1.45 g. of the compound XIV resulting from O-alkylation of the acetyloxindole, m. p. 157–160°. Recrystallization from acetone–ether gave white needles, m. p. 161°.

Anal. Calcd. for $C_{22}H_{20}O_3N_2$: C, 73.31; H, 5.60; N, 7.77. Found: C, 73.37; H, 5.82; N, 7.40.

The compound XIV is sparingly soluble in ether and in the extraction described above will precipitate from the ethereal solution if all of the acetone is removed by washing.

(b) **With 2-β-Chloroethyl-1-isoquinolone.**—A mixture of 7.0 g. of the chloroethylisoquinolone, 14.0 g. of the sodio-derivative of 1-methyl-3-acetyloxindole, 1.0 g. of sodium iodide, and 70 ml. of dry dioxane was heated for 17 hours on the steam-bath with frequent shaking. The thick paste of solids slowly thinned as the reaction progressed. After cooling, water was added to dissolve the unchanged sodium salts and the mixture was extracted with ether. From the aqueous portion 5.6 g. of the acetyloxindole was recovered by acidification. The ethereal solution was washed free of alkali with water, small amounts of acetone being added to prevent precipitation of the sparingly soluble O-alkyl product. The product (XIV) was isolated and crystallized as previously described; yield, 3.1 g.; m. p. 158–160°.

(c) **With 2-β-Bromoethyl-1-isoquinolone.**—The same O-alkyl product (XIV) was obtained by refluxing 1.1 g. of the bromoethylisoquinolone, 2.2 g. of sodio-derivative of acetyloxindole, and 0.3 g. of sodium iodide in 25 ml. of dioxane for five hours. The work-up was the same as that described in (b); yield 0.35 g., m. p. 158–160°.

Hydrolysis of O-Alkyl Product (XIV).—Upon treatment of the O-alkyl product (XIV) with sodium ethoxide several products were obtained. To 1.45 g. of XIV in 10 ml. of ethanol a solution of 0.2 g. of sodium in 5 ml. of ethanol was added and the mixture heated for ten minutes on the steam-bath. The purple solution was diluted with ether and washed with water and dilute hydrochloric acid to remove most of the color. The ethereal solution was dried, concentrated, and taken to dryness. The residue (1.0 g.) crystallized readily from ether–petroleum ether to give 0.8 g. of crystals, m. p. 88–94°, which proved to be a mixture of two compounds. They were separated by fractional crystallization. One product crystallized as white plates, m. p. 116°, and proved to be 2-β-hydroxyethyl-1-isoquinolone. The other product crystallized as white rods, m. p. 110°, and by analysis appeared to be 2-β-ethoxyethyl-1-isoquinolone.

Anal. Calcd. for $C_{13}H_{15}O_2N$: C, 71.89; H, 6.91; N, 6.45. Found: C, 71.54; H, 6.77; N, 6.70.

Ether extraction of the acidified aqueous alkaline washes gave 1-methyl-3-acetyloxindole which crystallized as needles from aqueous methanol, m. p. 108–110°. By alkaline extraction of residues from the fractional crystallizations more of the acetyloxindole was obtained.

Thermal Rearrangement of the O-Alkyl Compound (XIV) and Hydrolysis to XVI.—The O-alkyl compound (1.3 g.) was heated in a metal-bath for ten minutes at 220–230° for the rearrangement. The red melt was allowed to cool and dissolved in ether but could not be induced to crystallize. By distillation (230–250° bath temperature, 0.5 mm.) there was obtained 1.1 g. of a red oil (XV) which again could not be obtained crystalline. It was dissolved in 5 ml. of ethanol and refluxed for ten minutes with a solution of 0.3 g. of sodium in 8 ml. of ethanol for deacetylation. After cooling and diluting with water, the product was extracted with ether and washed with water. Removal of the ether gave a reddish oil which crystallized readily from ether–petroleum ether yielding 0.7 g. of the 1-methyl-3-[2-N-(1-oxo-1,2-dihydroisoquinolylethyl)]-oxindole (XVI), m. p. 120–124°. Recrystallization gave fine white needles, m. p. 126°.

Anal. Calcd. for $C_{20}H_{18}O_2N_2$: C, 75.45; H, 5.70; N, 8.80. Found: C, 75.38; H, 5.76; N, 8.95.

Attempts to Ring Close 1-Methyl-3-[2-N-(1-oxo-1,2-dihydroisoquinolylethyl)]-oxindole (XVI).—A solution of 0.3 g. of the isoquinolylethyloxindole in 4 ml. of phosphorus oxychloride was refluxed for one hour. The oxychloride was removed *in vacuo* and the remaining viscous residue was dissolved by digestion with water. The acidic aqueous solution was rendered alkaline and extracted with ether. From the ethereal solution there was recovered 0.24 g. of the original compound, m. p. 121–124°. No other product was isolable. The same results were obtained when a longer refluxing time was used. Similarly, by using phosphorus pentoxide in xylene, the original compound was recovered. With phosphorus trichloride followed by treatment with aluminum chloride only the starting material was isolated from the halogen-containing products.

Reduction of 1-Methyl-3-[2-N-(1-oxo-1,2-dihydroisoquinolylethyl)]-oxindole (XVI) with $LiAlH_4$ to VII.—Two grams of the oxo-dihydroisoquinolylethyl oxindole was dissolved in 10 ml. of dioxane and diluted with 50 ml. of absolute ether. There was added with agitation a solution of 0.4 g. of lithium aluminum hydride in 50 ml. of absolute ether over a five-minute period. After standing for one hour the reaction mixture was worked up as described for the reaction with the dihydroisoquinolylethyloxindole (II). The crude basic fraction (1.5 g.) was purified by distillation. The fraction distilling at 180–210° bath temperature and at 0.01 mm. (0.8 g.) was redistilled and the pale yellow oil (0.55 g.) distilling at 180–190° at 0.01 mm. collected. Upon treating the oil in methanol with 0.45 g. of picric acid there was readily obtained 0.75 g. of crude picrate melting at 180–190° dec. After two crystallizations from methanol, the picrate (0.3 g.) melted at 205–207° dec. and gave no melting point depression when admixed with the picrate of the base VII obtained by the Fischer indole synthesis. Upon decomposition of 100 mg. of the picrate with alkali there was obtained 40 mg. of the base VII (m. p. 132–135°) which upon treatment with palladium black gave N-methylyobyrine, isolated as the picrate (29 mg., m. p. 232–234° dec.).

Summary

A novel synthesis of the yohimbine ring structure is reported which comprises the spontaneous ring closure of a 3-[2-N-(1,2-dihydroisoquinolylethyl)]-indole.

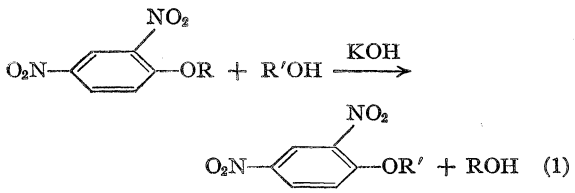
Nucleophilic Substitution in Aromatic Ethers. I. Ethers in which Nucleophilic Substitution is Possible

BY YOSHIRO OGATA[1] AND MASAYA OKANO

Just like *p*-nitrochlorobenzene, *p*-nitroanisole is converted to *p*-nitrophenetole when boiled in ethyl alcohol in the presence of caustic alkali.[2] The substitution may be called an ether interchange. In an attempt to extend this reaction, we studied the interchange of *p*-nitroanisole with polyhydric alcohols and alcohols of the C_3–C_4 range. It was found that little or no reaction occurred. When an alkoxyl group was activated by the introduction of nitro groups into the 2 and 4 positions of anisole, however, substitution occurred readily



(1)

In this paper a number of such substitution reactions are described.

The reaction was found to be reversible when the group R was alkyl but irreversible when R was aryl (Equation 1). In the same way, 2,4-dinitroanisole or 2,4-dinitrodiphenyl ether reacted with aniline, forming 2,4-dinitrodiphenylamine.[3] Benzyl methyl ether, benzhydryl methyl ether, anisole or anisoles substituted with electronegative groups other than nitro (*e.g.*, CH_3CO) were incapable of interchange.

Experimental

Ether Interchange.—The experiments summarized in Table I were carried out according to a standardized procedure which may be illustrated by the preparation of 2,4-dinitrophenyl isobutyl ether. In 30 cc. of isobutyl alcohol was dissolved 0.2 g. of potassium hydroxide by boiling. To this solution was added 3 g. of 2,4-dinitroanisole (m. p. 88°) and the mixture was boiled under a reflux condenser for ten hours. After removing the alcohols by distillation and evaporation, the residue was cooled and washed with water. The crude 2,4-dinitrophenyl isobutyl ether (m. p. 27–29°) weighed 2.8 g. (77%). It was recrystallized from ethanol to which a drop of concentrated hydrochloric acid was added. The product separated in the form of laminae, m. p. 34–35°, and recrystallization involved about a 10% loss of material.

Anal. Calcd. for $C_{10}H_{12}O_5N_2$: C, 50.00; H, 5.04; N, 11.66. Found: C, 49.58; H, 4.93; N, 10.9.

The same product (m. p. 33–35°) was isolated from the reaction of 2,4-dinitrochlorobenzene with sodium isobutoxide. A mixed melting point determination of this material with the product obtained from the ether interchange reaction showed no depression.[4]

Under approximately the same conditions anisole, *p*-acetylanisole, *p*-chloroanisole, 2,4,6-tribromoanisole and potassium *p*-methoxybenzenesulfonate did not react with ethanol. Similarly *p*-nitroanisole did not undergo interchange with isopropyl alcohol, isobutanol, allyl alcohol, ethylene glycol, or phenol. In boiling aniline solution, however, 2,4-dinitrodiphenyl ether and 2,4-dinitrophenyl β-naphthyl ether gave good yields (80 and 97%, respectively), of 2,4-dinitrodiphenylamine, m. p. 156–157°. 2,4-Dinitroanisole also reacted, but a large amount of amorphous material was formed. The yield of 2,4-dinitrodiphenylamine was less than 20%.

In the run in which glycerol was employed, the general procedure was modified to the extent that the reaction mixture was heated with stirring at 160–180° in an oil-bath.

[a] Blanksma and van der Weyden, *Rec. trav. chim.*, **39**, 629 (1940). [b] New compound; see the Experimental part. [c] The melting point of this compound agrees with that of the monoglycol ether $(NO_2)_2C_6H_3OCH_2CH_2OH$, recently found by Blanksma and Fohr, *Rec. trav. chim.*, **65**, 706, 711 (1946); *cf. C. A.* **41**, 5484 (1947).

(1) Present address: Kyoto University, Yoshida, Kyoto, Japan.

(2) Oliverio, *C. A.*, **33**, 9302 (1939).

(3) For the reaction of 2,4-dinitroanisole with ammonia, see Salkowski, *Ber.*, **5**, 872 (1872).

(4) The tarry matter inevitable to the reaction of 2,4-dinitrochlorobenzene with sodium alkoxides is never produced in the ether interchange. It should therefore prove to be a better general method for the preparation of higher 2,4-dinitrophenyl ethers.

Summary

The methoxyl group of 2,4-dinitroanisole is convertible to another alkoxyl group, by boiling dinitroanisole in the presence of caustic alkali with polyhydric alcohols or alcohols of the C_2–C_4 range. Aniline leads to 2,4-dinitrodiphenylamine.

Similar reactions are possible with some other 2,4-dinitrophenyl alkyl or aryl ethers.

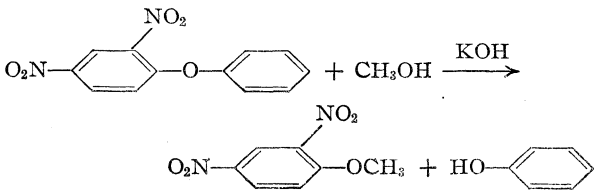
Nucleophilic Substitution in Aromatic Ethers. II. Kinetics of the Methanolysis of 2,4-Dinitrodiphenyl Ethers

BY YOSHIRO OGATA AND MASAYA OKANO

In the preceding paper[1] it was shown that 2,4-dinitroanisole is formed irreversibly, when a solution of 2,4-dinitrodiphenyl ether is boiled in alkaline methanol



In the present paper, the rate of reaction and the effect of structure on the rate were studied. The rate was determined by taking out aliquots of the reaction mixture after suitable time intervals, and estimating the phenol produced iodometrically.

Experimental

Materials.—Methanol (b. p. 64.5–65°) was purified by repeated rectifications from calcium oxide and silver nitrate. The 2,4-dinitrodiphenyl ethers were prepared by the condensation of 2,4-dinitrochlorobenzene with the corresponding sodium phenolates. They were recrystallized (twice) slowly from acetone or, with the α- or β-naphthyl derivatives, from a mixture of acetone and methanol. Among them, the 4′-chlorophenyl, 4′-nitrophenyl, α-naphthyl and β-naphthyl ethers were prepared in methanol (many hours boiling was necessary in the case of the nitro or naphthyl derivatives). The melting points agreed with those in the literature[2] as follows. 2,4-Dinitrodiphenyl ether, 70–71°; 2′-methyl, 89–90°; 3′-methyl, 72–73.5°; 4′-methyl, 91–92.5°; 4′-chloro, 122–123.5°; 4′-nitro, 115–116°; α-naphthyl 127–128°; β-naphthyl, 93–94.5°.

Apparatus and Procedure.—About 0.0025 mole of one of the ethers was weighed out and dissolved in 200 cc. of methanol. The solution was poured into a four-necked flask and placed in a thermostat (20 ± 0.1°) until temperature equilibrium was established. The flask was fitted with a stirrer[3] in its central neck, and in the other three were placed a thermometer, a tube suitable for withdrawing samples, and a tube into which air could be blown for pushing out the sample. The proper amount of potassium hydroxide was then dissolved in boiling methanol and its concentration was determined by titration with 0.05 *N* oxalic acid. An accurately measured amount of this solution (50 cc.) was taken out and kept in the thermostat until temperature equilibrium was reached and was then poured into the flask with gentle agitation (250–300 r. p. m.). This time was taken as the beginning of the reaction. A 25-cc. sample was taken out at regular intervals and run into a glass-stoppered flask containing 3 cc. of concentrated hydrochloric acid and 50 cc. of water. Twenty cc. of 0.1 *N* bromine water (a solution prepared from potassium bromate and bromide), were then added, the flask was stoppered tightly, and it was allowed to stand for fifteen seconds or thirty minutes before analysis.[4] The mixture was then treated with 5 cc. of 20% potassium iodide solution, and the freed iodine was titrated with 0.05 *N* sodium thiosulfate. The difference between the needed volume of thiosulfate solution and the blank test corresponded to the amount of phenol formed.

Results and Calculations

The bimolecular rate constants shown in Tables I and II were calculated by means of the following equation

$$k = \frac{2.303}{60t(b-a)} \log \frac{a(b-x)}{b(a-x)} \text{ (l./moles} \times \text{sec.)}$$

Here, a is the initial concentration of ether (moles/l.), b that of alkali (moles/l.), x the concentration of phenol after t minutes (mole/l.).[5] In Table I is shown the effect of changes in concentration on the second order rate constant of the methanolysis of 2,4-dinitrodiphenyl ether. It is evident that the rate of formation of phenol is proportional to the product of the concentration of the original ether and methylate ion.

In Table II are shown the rate constants for a number of runs in which various changes were made in the 2,4-dinitrodiphenyl ether molecule. It will be observed that the substitution of an electron attracting group (*e. g.*, NO_2) in the 4′ posi-

(1) Ogata and Okano, THIS JOURNAL, **71**, 3211 (1949).

(2) (a) Raiford and Colbert, *ibid.*, **48**, 2652 (1926); (b) Bost and Nicholson, *ibid.*, **57**, 2368 (1935).

(3) Agitation was necessary, for the methanol solution tended to become heterogeneous when it was allowed to stand for a long time.

(4) From the results obtained with pure materials under these conditions, it was found that standing for thirty minutes is too long for *o*-, *m*-, *p*-cresol, and α- or β-naphthol. Even when the potassium iodide solution was added after fifteen seconds, the estimations of *o*- and *p*-cresol showed that the values were about 103 and 104% of the theoretical values. These estimations were, therefore, carried out rapidly and corrected by dividing the results by 1.04 and 1.03, respectively. See Day and Taggert, *Ind. Eng. Chem.*, **20**, 545 (1928).

(5) It should be noted that phenol and *m*-cresol consume 3 moles of bromine per mole. *p*-Substituted phenols and β-naphthol consume 2 moles, but α-naphthol reacts with 1 mole. Moreover, with *o*- and *p*-cresol, x should be divided by 1.03 and 1.04, respectively; see ref. 4.

tion of 2,4-dinitrodiphenyl ether increases the rate of reaction and the introduction of an electron releasing group (*e. g.*, CH_3) in the 2′- or 4′-position decreases the rate of reaction. This behavior resembles the effect of a substituent upon the reactivity of 4-substituted 2,6-dinitroanisoles with *p*-methoxydimethylaniline.[6] It is probaby due to the fact that the electron attracting group not only makes the formation of the activated complex I easier,[7] but also it facilitates fission of the carbon–

(I)

oxygen bond a. By inserting into Hammett's equation, $\log k/k_0 = \rho\cdot\sigma$,[8] the average values of k and k_0 shown in Table II, the values for ρ shown in Table III were calculated using Hammett's σ values. From the average value of ρ (1.46 ± 0.04), the σ value of the α-naphthyl group in α-naphthyl 2,4-dinitrophenyl ether was calculated to be 0.084.

TABLE III

Substituent	log (k/k_0)	ρ
4′-NO_2	1.1354	1.46
4′-Cl	0.3665	1.61
β-C_4H_4	.2347	1.38
3′-CH_3	− .1078	1.56
4′-CH_3	− .2215	1.30
	Av.	1.46 ± 0.04[9]

From this average value of ρ, the σ value of α-naphthyl was calculated to be +0.084.

Summary

The rates of exchange of the substituted phenoxy group of substituted 2,4-dinitrodiphenyl ethers for a methoxy group were measured. It was found that the rate is proportional to the product of the concentration of the original ether and methylate ion. Electron-attracting groups in the 4′-position of the ether increase the rate. Electron-releasing groups in the 2′- or 4′-position decrease it. The effect of the substituent on the rate constant of this reaction satisfied Hammett's equation, giving a σ value of + 1.46 ± 0.04.

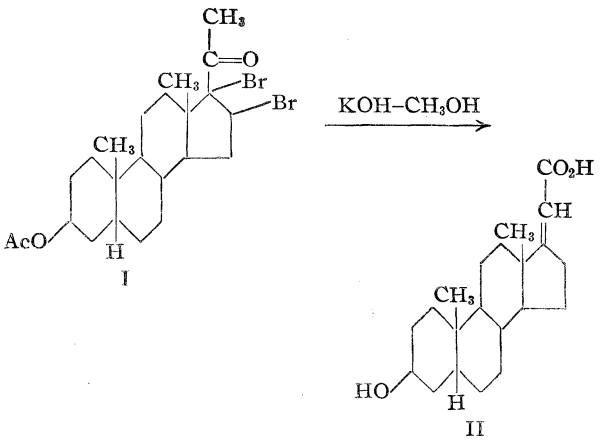
Rearrangement of α,β-Dibromoketones[1]

BY R. B. WAGNER

During the course of studies of certain steroidal bromoketones, it was found that 16,17-dibromopregnan-3(β)-ol-20-one acetate (I) under vigorous alkali treatment yields 3(β)-hydroxy-Δ^{17-20}-pregnen-21-oic acid (II) by a rearrangement which had not been previously observed.[2]

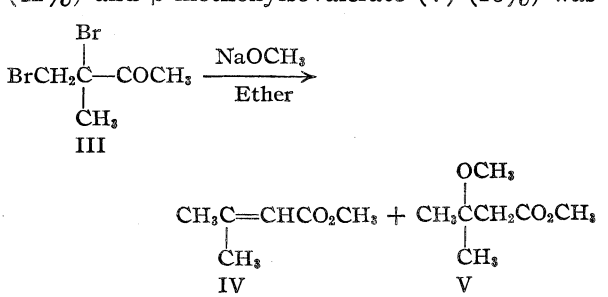


I II

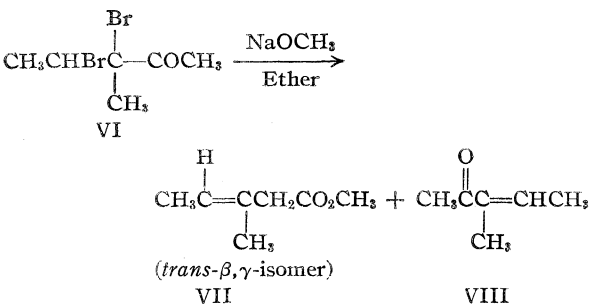
The present paper describes the extension of this rearrangement to aliphatic and simpler alicyclic α,β-dibromoketones, namely, 3,4-dibromo-3-methyl-2-butanone (III), 3,4-dibromo-3-methyl-2-pentanone (VI) and 1-acetyl-1,2-dibromocyclohexane.

The dibromo compounds were prepared by the reaction of equimolar quantities of bromine and the corresponding α,β-unsaturated ketones. The adjacent positions of the bromine atoms in these compounds are indicated by their almost quantitative removal with hot methanolic sodium iodide to give the original unsaturated ketone.[2]

When 3,4-dibromo-3-methyl-2-butanone (III) was added to an ether suspension of two moles of sodium methoxide at 10–20° and the products were allowed to stand for thirty hours, a mixture of the methyl esters of β,β-dimethylacrylate (IV) (42%) and β-methoxyisovalerate (V) (16%) was obtained; with a reaction time of two and a half hours, a mixture consisting of 64% of IV and 2% of V was obtained.



Similarly, using the shorter reaction time, 3,4-dibromo-3-methyl-2-pentanone (VI) gave 3-methyl-3-penten-2-one (VIII) (15%) and the methyl ester of *trans*-3-methyl-3-pentenoic acid (VII) (55%); none of the corresponding isomeric unsaturated ester could be isolated. Under the same conditions, 1-acetyl-1,2-dibromocyclohexane yielded exactly analogous products, namely, the methyl ester of 1-cyclohexenylacetic acid (34%) and methyl 1-cyclohexenyl ketone (19%).



The methyl esters from these rearrangements were characterized by hydrogenation, saponification and oxidation procedures and, in each case, direct comparison with synthetic products and their derivatives were made. With the exception of the β-methoxy ester (V), the products could be obtained by procedures described in the literature.[3,4]

Methyl β-methoxyisovalerate (V) has been synthesized in small yields by the addition of methanol to methyl β,β-dimethylacrylate (IV) in the presence of sodium methoxide. It has been shown that the addition of alcohols to methyl acrylate is a general reaction for the preparation of β-alkoxypropionates.[5] However, the reaction of the disubstituted acrylate is much slower.

None of the corresponding γ-methoxy isomer, methyl γ-methoxyisovalerate, was detected among the rearrangement products from III. For comparison purposes, this compound has been synthesized by the following series of reactions.

The γ-methoxy ester and its acid are completely different from the rearrangement product (V) and its acid.

It is noteworthy that the double bond in the unsaturated esters from the last two mentioned rearrangement reactions is in the β,γ-position,

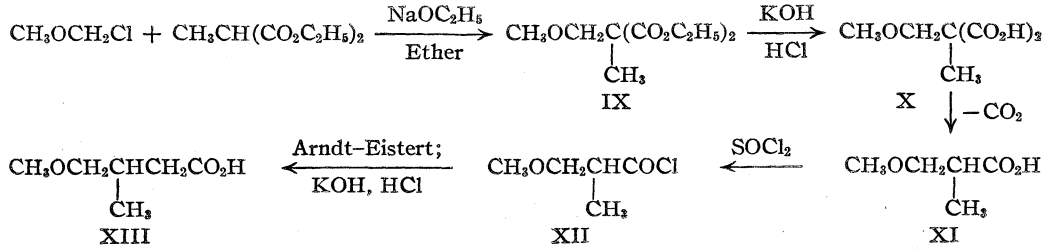
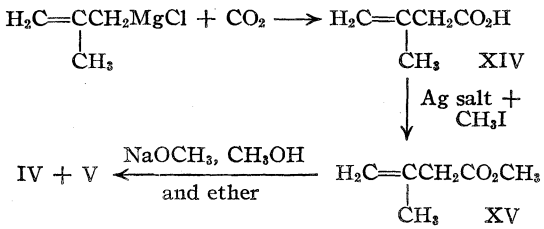
(4) Auwers and Ellinger, *Ann.*, **387**, 200 (1912); these authors report for methyl 1-cyclohexenylacetate, b. p. 93° (15 mm.), $n^{20}D$ 1.4679 and d^{20} 1.002.

(5) Rehberg, Dixon and Fisher, THIS JOURNAL, **68**, 544 (1946).



whereas the first reaction gives an ester having α,β-unsaturation. This anomaly in this series has been investigated further and it has been found that the corresponding β,γ-isomer (XV) of methyl β,β-dimethylacrylate when placed under conditions similar to those used for the bromoketone rearrangement *undergoes a shifting of the double bond to the α,β-position.* In addition, methyl β-methoxyisovalerate (V) is formed during this reaction in the same proportions as noted in the rearrangement reaction. From this experiment, it may be concluded that if the β,γ-unsaturated ester is formed here as in the other cases, it would immediately undergo a secondary reaction to give the α,β-isomer (IV) and the β-methoxy ester (V). Furthermore, since methanol adds to the α,β-isomer (IV) under these conditions of long and short reaction periods to form the β-methoxy ester (V) in 24 and 8% yields, respectively, this source (IV) for the latter (V) is indicated in both the isomerization and the rearrangement reaction. On the other hand, the double bond in the higher β-alkylated-β,γ-unsaturated esters, homologs of XV, does not migrate under these mild conditions; in fact, even under more vigorous alkali treatment, the "equilibrated" mixture favors the β,γ-isomer.[3] However, it should be noted that the double bond in the steroidal unsaturated acid (II) is in the α,β-position, which again appears to be the more stable position.

The β,γ-isomer (XV), methyl 3-methyl-3-butenoate, has been synthesized for these studies by the carbonation of methallyl Grignard reagent followed by esterification of the resulting acid through its silver salt. This ester is readily differentiated from the rearrangement ester (IV).



The mechanism by which the rearrangement occurs is not definitely settled although suggestions have been made.[6,7]

Acknowledgment.—Combustion analyses (C, H, N) were performed by R. N. Walters.

Experimental[8]

Unsaturated Ketones.—(a) **3-Methyl-3-buten-2-one** was prepared by the dehydration of 3-methyl-4-butanol-2-one, b. p. 80° (10 mm.), $n^{20}D$ 1.4340, d^{20} 0.9951. The crude ketol prepared by the procedure of Morgan and Griffith[9] was found to be satisfactory for dehydration. The reaction was carried out by adding 1 kg. of the ketol, preheated to 95°, continuously in a slow stream to a hot mixture of 50 g. of fused potassium bisulfate and 4 g. of hydroquinone contained in a flask equipped with the usual Claisen distilling head and condenser. The reaction mixture was heated during the addition causing the distillation of the olefinic ketone and water mixture. When the addition of the ketol was complete and the head temperature had risen to 110°, the reaction was stopped and the product layers were separated. The organic mixture was fractionated through a column with a 45 × 1.8 cm. section packed with $^3/_{32}$" glass helices, removing additional water in the fore-cut. There was obtained an 80% yield of the unsaturated ketone, b. p. 58° (200 mm.), $n^{20}D$ 1.4232 and d^{20} 0.8540.[10]

(b) **3-Methyl-3-penten-2-one** was prepared in an 87% yield by distilling directly from a reaction mixture consisting of 290 g. of 3-methyl-4-pentanol-2-one, 2 cc. of 38% aqueous hydrobromic acid and 2 g. of hydroquinone. The crude olefinic ketone was fractionated to give material having b. p. 97° (200 mm.), $n^{20}D$ 1.4489 and d^{20} 0.8758.

The pure ketol, b. p. 76° (10 mm.), $n^{20}D$ 1.4350 and d^{20} 0.9704, was prepared in a 67% yield from methyl ethyl ketone and acetaldehyde by the procedure of Kyrides[11] using satisfactorily five times the stated quantities. The reaction mixture was concentrated by a flash evapora-

TABLE I

DIBROMO KETONES

[a] This material could be distilled in 10-g. batches without serious decomposition. [b] 1-Acetyl-1,2-dibromocyclohexene (formula not shown) was prepared by brominating the unsaturated ketone dissolved in an equal volume of chloroform. Most of the solvent was removed at a bath temperature of 20° and the remainder at 15 mm. during three days at 30°. The crystalline dibromide was triturated and washed with cold pentane. A sample of this material was heated under reflux for one hour with excess sodium iodide in methanol. The liberated iodine (titrated with standard sodium thiosulfate) corresponded to the theoretical quantity for the complete removal of both bromine atoms. The original olefinic ketone was isolated as its semicarbazone, m. p. and mixed m. p., 217°.

[a] 1-Acetyl-1,2-dibromocyclohexane (formula not shown). [b] Exaltations for the conjugated systems in these compounds would raise the calculated values (*cf.* ref. 4). [c] Yields in parentheses are those obtained when the reaction mixture was allowed to stand thirty hours.

tion technique[12] and distilled through a column with a 53 × 1.8 cm. section packed with 1/8" glass helices.

(c) **1-Acetyl-1-cyclohexene** was prepared in a 50% yield from cyclohexane, acetyl chloride and anhydrous aluminum chloride by the directions of Christ and Fuson[13] and was purified by fractionation through a column with a 53 × 1.8 cm. section packed with 3/32" glass helices; b. p. 88.5° (20 mm.) and $n^{20}D$ 1.4904.[14]

Preparation of the Dibromo Ketones.—The unsaturated ketone, 2–3 moles, contained in a 1-liter three-necked flask which was equipped wth a stirrer, dropping funnel and thermometer and surrounded by an ice–salt-bath, was treated in a dropwise manner with an equimolar quantity of bromine at 0° during six hours. Additional data are summarized in Table I.

Reaction with Sodium Methoxide.—To a suspension of 4 moles of sodium methoxide (Mathieson Alkali Works, 95%) in anhydrous ether was added 2 moles of the dibromo ketone. The reaction mixture was stirred vigorously and was cooled by a salt–ice-bath. The addition was completed in one and one-half hours, keeping the temperature at 20°. An acid–base titration of a 2-ml. aliquot showed the almost complete absence of the basic reagent. After stirring an additional hour, the mixture was poured onto ice, the layers were separated, and the water layer was ether extracted. The total ethereal solution was dried over anhydrous potassium carbonate and the ether was removed through a column. The concentrate was rapidly distilled *in vacuo* through a Claisen apparatus to free it from any high-boiling and bromine-containing material. The crude distillate was then carefully fractionated through a column with a 43 × 1.8 cm. section packed with 3/32" glass helices. Additional data are summarized in Table II.

Identification of Products from the Rearrangement Reactions.[15] (a) **Methyl β,β-Dimethylacrylate (IV).**—Hydrogenation of IV using Adams catalyst gave methyl 3-methylbutanoate, b. p. 116° (732 mm.), $n^{20}D$ 1.3920, d^{20} 0.8807, further characterized by its *p*-toluide, m. p. and mixed m. p., 109–110°. Saponification gave dimethylacrylic acid, m. p. and mixed m. p., 70°, and methanol, b. p. 64° (739 mm.) and $n^{20}D$ 1.3265. Oxidation with magnesium permanganate gave acetone isolated as its 2,4-dinitrophenylhydrazone, m. p. and mixed m. p., 126–127°.

The anilide was crystallized from ether as needles, m. p. and mixed m. p. with an authentic sample, 131–132°.

The *p*-toluide was crystallized from ethanol as needles, m. p. and mixed m. p. with an authentic sample, 106–107°.

Anal. Calcd. for $C_{12}H_{15}ON$: N, 7.40. Found: N, 7.59, 7.58.

(b) **Methyl β-Methoxyisovalerate (V).**—The properties of V are the same as those for the product synthesized by the route described below.

Anal. Calcd. for $C_7H_{14}O_3$: $2CH_3O$, 42.4; sapn. equiv., 146. Found: $2CH_3O$ (Zeisel), 42.4; sapn. equiv., 149.

The *p*-toluide was crystallized from benzene–pentane as needles, m. p. and mixed m. p., 51–52°.

Anal. Calcd. for $C_{13}H_{19}O_3N$: N, 5.90. Found: N, 6.14.

(c) **3-Methyl-3-penten-2-one (VIII).**—The properties of VIII agree with those for the product synthesized as described above. The **semicarbazone** was crystallized from ethanol, m. p. and mixed m. p., 200–201°.[16]

(d) **Methyl *trans*-3-Methyl-3-pentenoate (VII).**—Hydrogenation of VII using Adams catalyst gave methyl 3-methylpentanoate isolated as its anilide which was crystallized from benzene–pentane, m. p. and mixed m. p., 86–87°. Ozonolysis gave acetaldehyde isolated as the 2,4-dinitrophenylhydrazone, m. p. and mixed m. p., 167–168°.

Anal. Calcd. for $C_7H_{12}O_2$: sapn. equiv., 128. Found: sapn. equiv., 128.

The amide was crystallized from benzene–pentane as plates, m. p. 130–131°.

The *p*-toluide was crystallized from aqueous ethanol as plates, m. p. and mixed m. p. with the *p*-toluide of the *trans*-isomer, 91–92°.

The anilide was crystallized from benzene–pentane as needles, m. p. and mixed m. p. with the anilide of the *trans*-isomer, 99–100°.

(e) **Methyl 1-Cyclohexenylacetate.**[4]—Saponification gave methanol, b. p. 64° (739 mm.) and $n^{20}D$ 1.3268.

The anilide was crystallized from aqueous ethanol as long needles, m. p. and mixed m. p. with an authentic sample,[17] 118–119°.

Anal. Calcd. for $C_{14}H_{17}ON$: C, 78.10; H, 7.96. Found: C, 77.38; H, 7.82.

The *p*-toluide was crystallized from aqueous ethanol as needles, m. p. and mixed m. p. with an authentic sample,[17] 101–102°.

Anal. Calcd. for $C_{15}H_{19}ON$; C, 78.56; H, 8.35. Found: C, 78.59; H, 8.14.

(f) **Methyl 1-Cyclohexenyl Ketone.**—The semicarbazone was crystallized from ethanol, m. p. and mixed m. p., 221°.[14]

3-Methyl-3-butenoic Acid (XIV) and Reactions.—Methallylmagnesium chloride was prepared in an 81% yield by treating 900 g. (10 moles) of methallyl chloride in 10 liters of anhydrous ether with 243 g. (10 moles) of magnesium turnings at 14–16° during ten hours. The reaction was carried out with vigorous stirring in a three-

(15) All derivatives were prepared by the methods described by Shriner and Fuson, "Identification of Organic Compounds," John Wiley and Sons, Inc., New York, N. Y., 2nd ed., 1940.

(16) Hinkel, *J. Chem. Soc.*, 818 (1931), reports the semicarbazone, m. p. 201°.

(17) The 1-cyclohexenylacetic acid used for the preparation of these derivatives was prepared from cyclohexylideneacetic acid by the procedure of Beesley, Ingold and Thorpe, *J. Chem. Soc.*, 1080 (1915); b. p. 136° (12 mm.).

gallon copper vessel. The Grignard reagent was obtained as a solid suspended in the ether. This was added with vigorous stirring during thirty minutes to 10 kg. of powdered Dry Ice contained in a second copper vessel equipped with a large vent to the hood. The resulting complex was decomposed with ice and concentrated hydrochloric acid mixture (requires 1 liter of concd. hydrochloric acid). After saturating the water layer with sodium chloride, the ether layer was separated and the acid portion was extracted by washing with a solution of 600 g. of sodium carbonate (final *p*H of wash, 8.01). The alkaline extract was layered with 6 liters of ether and acidified by vigorous stirring with 1 liter of concd. hydrochloric acid (final *p*H, 1.5). The ethereal solution was evaporated, and the residue was dried by removing the water as an azeotropic mixture with benzene and then distilled through a Claisen apparatus to give 400 g. of material (40% yield) boiling 68–70° (5 mm.), m. p. 20.2–21.3° and $n^{20}D$ 1.4308.

Anal. Calcd. for $C_5H_8O_2$: neut. equiv., 100. Found: neut. equiv., 100, 101.

Ozonolysis of this material yielded formaldehyde isolated as its dimedone derivative.

(a) **Conversion to the Methyl Ester (XV).**—To a stirred solution of 213 g. (2.13 moles) of 3-methyl-3-butenoic acid in 4 liters of distilled water was added 85 g. (2.13 moles) of C. P. sodium hydroxide dissolved in 2 liters of distilled water followed by a solution of 392 g. (2.31 moles) of silver nitrate in 1 liter of distilled water. The precipitate was filtered and triturated twice successively with water, absolute ethanol and ether. The silver salt suspended in 2.5 liters of anhydrous ether contained in a 5-liter, three-necked flask, equipped with a stirrer and condenser, was treated with excess methyl iodide (2.3 moles) under reflux for seventy-two hours. After twenty-four hours a yellow precipitate of silver iodide predominated. The reaction mixture was filtered, the ether was evaporated, and the product was fractionated through a column with a 43 × 1.8 cm. section packed with $^3/_{32}$″ glass helices to give entirely one product, 115 g., b. p. 41° (27 mm.), $n^{20}D$ 1.4168 and d^{20} 0.931; 47% yield. *M*D calcd., 31.10; obs., 31.18.

Anal. Calcd. for $C_6H_{10}O_2$: C, 63.13; H, 8.83. Found: C, 62.94; H, 9.10.

The *p*-toluide was prepared from the ester and crystallized from aqueous ethanol as needles, m. p. 95°. A mixture with the *p*-toluide of β,β-dimethylacrylic acid, m. p. 107°, melted 68–90°.

Anal. Calcd. for $C_{12}H_{15}ON$: N, 7.40. Found: N, 7.40.

(b) **Conversion to β,β-Dimethylacrylic Acid.**—A mixture of 10 g. of 3-methyl-3-butenoic acid, 20 ml. of dry ether and 10 g. of 90% sulfuric acid was allowed to stand at room temperature for forty-eight hours. The reaction mixture was diluted with water and extracted with ether, after saturating the water layer with ammonium sulfate. The acid fraction was then transferred to the aqueous sodium salt solution and back to an ethereal solution, which was evaporated to yield 9.7 g. of dimethylacrylic acid, crystallized from water; m. p. and mixed m. p., 68–70°; 97% yield.

(c) **Conversion to Methyl β,β-Dimethylacrylate and Methyl β-Methoxyisovalerate.**—For reasons discussed above, this reaction was carried out under conditions similar to those used for the rearrangement of the bromo ketones. Since the formation of the unsaturated ester is accompanied by an equimolar quantity of methanol, this was added. Thus a mixture 109 g. (0.96 mole) of methyl 3-methyl-3-butenoate, 32 g. (1.0 mole) of methanol, 10 g. of sodium methoxide and 500 ml. of ether was stirred at room temperature for thirty hours. The reaction mixture was processed as before and the product on fractionation gave 60 g. (0.55 mole) of methyl β,β-dimethylacrylate, b. p. 60° (50 mm.), $n^{20}D$ 1.4381 (53% yield) and 32 g. (0.22 mole) of methyl β-methoxyisovalerate, b. p. 66° (20 mm.), $n^{20}D$ 1.4157 (23% yield).

Under similar conditions using a two and a half-hour reaction time, the yield of the unsaturated ester was 80 and 10% for the β-methoxy ester.

When methyl β,β-dimethylacrylate was treated under the same conditions, the yields were 63% of the unsaturated ester and 24% of the β-methoxy ester for the long reaction period and 81 and 8%, respectively, for the short time.

Methyl β-Methoxyisovalerate (V).—A solution of 3 g. of sodium in 32 g. (1.0 mole) of methanol was added to 83 g. (0.85 mole) of methyl β,β-dimethylacrylate at 28° during ten minutes. The mixture was kept at room temperature for four days, then acidified with 15 cc. of concd. hydrochloric acid and filtered. The filtrate was fractionated to give starting material and 15 g. (0.11 mole) of methyl β-methoxyisovalerate, b. p. 67° (20 mm.), $n^{20}D$ 1.4161 and d^{20} 0.9777; *M*D calcd., 37.8; obs., 37.5.

Anal. Calcd. for $C_7H_{12}O_3$: $2CH_3O$, 42.4; C, 57.5; H, 9.65. Found: $2CH_3O$ (Zeisel), 44.0, 44.2; C, 58.1; H, 10.0.

The *p*-toluide was prepared and crystallized from benzene–pentane as needles, m. p. 51°. This gave no depression in melting point with the *p*-toluide of the corresponding rearrangement product.

Synthesis of γ-Methoxyisovaleric Acid (XIII). (a) **Ethyl Methoxymethylmethylmalonate (IX).**—Finely divided sodium, 115 g. (5 atoms) in 2 liters of anhydrous ether was treated with 855 g. (5.0 moles) of ethyl methylmalonate.[18] The mixture was refluxed and stirred for eight hours at which time all of the sodium had reacted. To the semi-solid sodio-derivative was added 440 g. (5.5 moles) of monochloromethyl ether,[19] b. p. 60–65° (739 mm.), during one hour at reflux temperature. The reaction was vigorous and the mixture became more fluid with the formation of sodium chloride; it was stirred overnight at room temperature.

Titration of a 1-ml. aliquot indicated that only 0.33 mole of base remained. The mixture was acidified with 30 ml. of acetic acid and then treated with water. The ethereal solution was dried rapidly with anhydrous calcium chloride and distilled rapidly through a Claisen apparatus. Material boiling between 94 and 120° (50 mm.), was carefully fractionated to give a 50% yield of product, b. p. 115–117° (16 mm.), $n^{20}D$ 1.4220.

(b) **Methoxymethylmethylmalonic Acid (X).**—To a solution of 300 g. (7.5 moles) of sodium hydroxide in 200 ml. of water and 1 liter of 95% ethanol was added 530 g. (2.43 moles) of the above ester during one hour at room temperature. The mixture was stirred for two hours and allowed to stand overnight. After dissolving the solid mass in 400 ml. of water, the solution was concentrated to one liter on the steam-bath with air passing through it to remove the alcohol. The concentrate was cooled and acidified with 235 ml. (4.2 moles) of concentrated sulfuric acid dissolved in an equal volume of water and then continuously extracted with ether for four days. The ether extract was evaporated and the residue was crystallized; 393 g. (2.40 moles); yield, 99% of crude acid. An aliquot was recrystallized from ether–pentane, m. p. 104–105°.

Anal. Calcd. for $C_6H_{10}O_5$: C, 44.44; H, 6.22; neut. equiv., 81.0. Found: C, 44.53; H, 6.49; neut. equiv., 81.4, 82.4.

(c) **β-Methoxyisobutyric Acid (XI).**—The above crude acid, 383 g. (2.36 moles), was heated under a column with a 53 × 1.8 cm. section packed with $^1/_4$″ glass helices at 150–160° until the evolution of carbon dioxide ceased. The product was fractionated to give 228 g. (1.93 moles) of monocarboxylic acid, b. p. 83° (3 mm.) and $n^{20}D$ 1.4192; 82% yield.

Anal. Calcd. for $C_5H_{10}O_3$: CH_3O, 26.3; neut. equiv., 118. Found: CH_3O (Zeisel), 26.3, 26.6; neut. equiv., 118, 119.

(d) **β-Methoxyisobutyryl Chloride (XII).**—A mixture of 118 g. (1.00 mole) of XI and 144 g. (1.20 moles) of pure thionyl chloride was warmed at 40° for forty-five minutes and then at 60° for an additional forty-five minutes. The excess thionyl chloride was removed *in vacuo* and the

(18) Cox and McElvain, *Org. Syntheses*, Coll. Vol. II, 279 (1943).

(19) Marvel and Porter, *ibid.*, Coll. Vol. I, 377 (1941).

product was distilled to give material boiling at 48–59° (15 mm.), 122 g. (0.90 mole), representing a 90% yield.

Anal. Calcd. for $C_5H_9O_2Cl$: Cl, 26.0. Found: Cl (Stepanoff), 26.2, 26.2.

(e) **γ-Methoxyisovaleric Acid (XIII).**—The above acid chloride, 114 g. (0.84 mole), was treated in three batches with an ethereal solution of diazomethane and then with a methanol slurry of silver oxide according to the Arndt–Eistert[20] procedure. The resulting product consisted of a mixture of the chloro ketone and the desired methyl ester, 25 g., b. p. 69° (20 mm.); 25% yield.

Although the saponification equivalent agreed closely with the theoretical value, a chlorine analysis showed that the ester was contaminated with the chloro ketone. The latter was removed by converting the above methyl ester, 24 g., to the corresponding acid by refluxing with excess 10% alcoholic potassium hydroxide. The product was isolated in the usual manner and fractionated to give the γ-methoxy acid; 16 g., b. p. 123–125° (20 mm.), $n^{20}D$ 1.4235, d^{20} 1.034; M_D calcd., 33.09; obs., 32.52.

Anal. Calcd. for $C_6H_{12}O_3$: OCH_3, 23.5. Found: OCH_3 (Zeisel), 23.6.

β-Methoxyisovaleric Acid.—For comparison purposes, the ester, 21 g., was hydrolyzed with excess 20% alcoholic potassium hydroxide as above and the product was fractionated to give the β-methoxy acid, b. p. 125° (20 mm.), $n^{20}D$ 1.4333, d^{20} 1.045; M_D calcd., 33.09; obs., 32.81.

Anal. Calcd. for $C_6H_{12}O_3$: neut. equiv., 132. Found: neut. equiv., 132.

***cis*- and *trans*-3-Pentenoic Acid.**—These acids were prepared by general procedures described in the literature[3] and converted to their derivatives, not previously described, for comparisons with the corresponding derivatives of the rearrangement products. Ethyl β-methyl-β-hydroxyvalerate, b. p. 83–88° (13 mm.), prepared by the Reformatsky reaction according to the procedure of Natelson and Gottfried,[21] was converted to the acid by careful alkaline hydrolysis, avoiding the presence of a large excess of base at any time. For this the ester, 280 g. (1.75 moles), in 200 ml. of 95% ethanol was treated at reflux temperature with a solution of 70 g. (1.75 moles) of C. P. sodium hydroxide in 150 ml. of water in a dropwise manner, maintaining a faint coloration with phenolphthalein indicator. The mixture was concentrated by air passing through the hot solution. The cold concentrate was acidified with dilute sulfuric acid and ether extracted to give 200 g. (1.75 moles) of crude acid. This was dehydrated with acetic anhydride according to Wallach[22] to give a mixture of the *cis*- and *trans*-isomers of both the α,β- and β,γ-unsaturated acids. The non-crystalline material,[23] 80 g. (0.70 mole) was partially esterified during twelve hours at room temperature to separate the α,β- and β,γ-isomers as acid and ester, respectively.[2] The former, 53 g. (0.47 mole), was treated with 260 g. (4.65 moles) of potassium hydroxide in 750 ml. of water at 100° for three days; an equilibrium mixture of the *cis*- and *trans*-α,β-acids and the *cis*-β,γ-acid resulted (the *trans*-β,γ-acid is not present to any large extent).[3] The mixture was partially esterified with ethanol to give an acid fraction consisting of the α,β-isomers and a neutral fraction which was the desired ethyl *cis*-3-methyl-3-pentenoate, b. p. 61° (13 mm.), $n^{20}D$ 1.4298 and d^{20} 0.9183; wt., 25 g. (0.16 mole).

Ozonolysis of this material gave acetaldehyde, isolated as its 2,4-dinitrophenylhydrazone, m. p. and mixed m. p., 165–168°.

The *cis*-*p*-toluide was crystallized from aqueous ethanol as needles, m. p. 100.5–101.5°. A mixture with the *p*-toluide from the rearrangement product (IV) or the authentic *trans*-*p*-toluide described below showed a melting point depression of thirty degrees.

Anal. Calcd. for $C_{13}H_{17}ON$: C, 76.80; H, 8.43. Found: C, 76.94; H, 8.47.

The *cis*-anilide was crystallized from aqueous ethanol as needles, m. p. 99–100°. A mixture with the anilide of *trans*-3-methyl-3-pentenoic acid (m. p. 101°) melted 97–98°, a slight depression.

Anal. Calcd. for $C_{12}H_{15}ON$: C, 76.15; H, 7.91. Found: C, 76.30; H, 8.00.

The *cis*-amide was crystallized from benzene–pentane as plates, m. p. 126–127°. A mixture with the amide from the rearrangement product (m. p. 131°) melted 127–130°.

Anal. Calcd. for $C_6H_{11}ON$: N, 12.38. Found: N, 12.13.

The *trans*-acid and its derivatives were obtained by dehydrating a second batch of the hydroxy ester, 256 g. (1.60 moles), with a suspension of 170 g. (1.25 moles) of phosphorus pentoxide in 750 ml. of dry benzene,[24] hydrolyzing the unsaturated esters, and partially esterifying the crude acids, 103 g. (0.90 mole), during five hours at room temperature.[3] The resulting mixture of β,γ-unsaturated esters, 49 g. (0.31 mole), b. p. 62–65° (16 mm.), was treated with a slight excess of 10% ethanolic potassium hydroxide for four days at room temperature. The acid fraction was isolated and crystallized from pentane to give the desired *trans*-acid, m. p. 35°; wt., 10 g.

Anal. Calcd. for $C_6H_{10}O_2$: neut. equiv., 114. Found: neut. equiv., 113, 114.

Ozonolysis of this material gave acetaldehyde, isolated as its 2,4-dinitrophenylhydrazone, m. p. and mixed m. p., 165–168°.

The *trans* *p*-toluide was crystallized from aqueous ethanol as flat needles, m. p. 91.5–92.5°; this did not depress the melting point of the *p*-toluide of the rearrangement product (VII).

Anal. Calcd. for $C_{13}H_{17}ON$: N, 6.91. Found: N, 7.17.

The *trans* anilide was crystallized from aqueous ethanol as needles, m. p. 100–101°; this did not depress the melting point of the *p*-toluide of the rearrangement product (VII).

Anal. Calcd. for $C_{12}H_{15}ON$: N, 7.41. Found: N, 7.38.

Summary

1. Treatment of α-alkyl-α,β-dibromoketones with a suspension of sodium methoxide in ether causes a rearrangement to give the methyl ester of a β-alkyl-β,γ-unsaturated acid. In addition, the original olefinic ketone may be regenerated.

2. The simplest compound in this series, namely, 3,4-dibromo-3-methyl-2-butanone (III), takes an anomalous course in giving methyl β,β-dimethylacrylate (IV) and methyl β-methoxyisovalerate (V). It has been shown that the corresponding β,γ-isomer, methyl 3-methyl-3-butenoate (XV), if formed in the rearrangement reaction, would undergo further reaction to give these products.

3. Methyl *trans*-3-methyl-3-pentenoate and the corresponding *cis*-isomer have been definitely characterized and the identity of the former with an ester from the rearrangement studies has been established.

4. Methyl β-methoxyisovalerate and its γ-methoxy homolog have been synthesized for comparison purposes.

Analgesics. III. Hydrochlorides of Phenylalkylamines[1]

BY L. H. GOODSON[2] AND R. B. MOFFETT[3]

As reported in the two earlier papers in this series,[4,5] our laboratory is interested in the synthesis of analgesic agents selected from the group of compounds known as the phenylalkylamines. The present paper is a continuation of our earlier work and describes thirty-one additional amines which are listed in Table I.

The synthetic methods used in the preparation of these compounds are not new, but are described briefly in the experimental part. The yields given usually do not indicate the best possible, but, rather, those actually obtained in one preparation.

These compounds have been screened for their analgesic activity by Dr. Harold G. Holck of the University of Nebraska, School of Pharmacy, and publication of results will appear elsewhere. Little or no analgesic activity was exhibited by any of these compounds when compared with morphine or isonipecaine.

Experimental

Amino Ketones and Esters, 1–13 (Table I).—The starting materials, desoxybenzoin, desoxyanisoin, α-cyclohexylacetophenone,[6] α-cyclohexyl-*p*-methoxyacetophenone,[7] 2-naphthyl benzyl ketone[8] and ethyl phenylacetate, were readily available or were prepared by the usual methods. These compounds were brominated by adding the calculated quantity of bromine to a solution of the compound in carbon tetrachloride. The resulting α-bromo compounds were freed of solvent and then used with or without distillation. Each of the crude bromo compounds in absolute ether or benzene was allowed to react with an excess of the appropriate amine, either by allowing the mixture to stand at room temperature for one week or by refluxing for two hours. The product was separated from the excess of reactants by treating the reaction mixture with aqueous sodium hydroxide, washing the organic layer with water, and evaporating to dryness, finally at 80° *in vacuo*. The base was taken up in absolute ether and the hydrochloride was precipitated by passing in hydrogen chloride.

Amino Alcohols, 14–17 (Table I).—These compounds were prepared from the corresponding amino ketones by reduction of the free bases with aluminum isopropoxide in absolute isopropyl alcohol. The slow distillation of the isopropyl alcohol was continued until no trace of acetone was observed in the distillate (eight to fourteen hours). The isopropyl alcohol was then removed under reduced pressure and the residue was shaken with ether and water. The ether layer was dried over potassium carbonate, and dry hydrogen chloride was passed in.

Amino Alcohols, 18–19 (Table I).—These compounds were prepared by the method of Erlenmeyer,[9] in which benzaldehyde is condensed with glycine in the presence of alcoholic alkali to give iso-1,2-diphenylethanolamine. In the present reactions, 2,3-dimethoxybenzaldehyde and 3,4-dimethoxybenzaldehyde were used in place of benzaldehyde. By analogy with the literature we have designated these DL-pairs as *iso* compounds, although we have no evidence concerning the spatial relationships; the so-called normal forms are not yet described.

Amino Alcohol, 20, and Amine, 27 (Table I).—The benzene solution of anisoin or desoxyanisoin was mixed with the amine (ethanolamine or benzylamine), a drop of acetic acid added and the mixture refluxed using a continuous water separator until no more water was liberated. The benzene was removed and the resulting crude ketimine was reduced by dissolving it in absolute ethanol and adding five times the theoretical quantity of sodium required to reduce the double bond. The alcohol was removed and the basic organic material was separated, dried, dissolved in absolute ether, and treated with hydrogen chloride.

Amines, 21–23 (Table I).—These compounds were prepared from 2-acetonaphthone and dibenzyl ketone by use of the Leuckart reaction.[4] The amines used were β-(4-morpholino)-ethylamine and ethanolamine and during the reaction time of three hours the temperature was raised from 170 to 200°. The formyl derivative was hydrolyzed and the products isolated as described earlier.

Amines, 24–26 (Table I).—These compounds were prepared from the corresponding 1,2-di-(*p*-methoxyphenyl)-ethylamines by dissolving them in 48% hydrobromic acid, and boiling them for one-quarter to two hours, then separating the demethylated fraction first by its solubility in alkali and then by recrystallization of the demethylated material after its conversion to its hydrochloride or hydrobromide.

Amine, 28 (Table I). α-Phenyl-2-hydroxy-5-cyclohexylacetophenone and Oxime.—A mixture of 88.1 g. (0.5 mole) of *p*-cyclohexylphenol and 77.3 g. (0.5 mole) of phenylacetyl chloride was warmed on a boiling water-bath until no more hydrogen chloride was evolved (about one and one-half hours). This crude ester was mixed with 84 g. (0.63 mole) of anhydrous aluminum chloride and heated in an oil-bath. At a temperature of 120°, hydrogen chloride was rapidly evolved and at 140° the mixture became very thick. After fifteen minutes at this temperature, it was cooled and decomposed with ice and hydrochloric acid. The product was taken up in ether, washed with water, and after removing the ether, it was distilled first from a Claisen flask and then through a six-inch glass helices-packed column. The fraction, boiling at 120–130° (0.007 mm.), was a light yellow viscous liquid which crystallized on standing. Recrystallization from petroleum ether gave 53.8 g. (37%) of material, m. p. 55–58°.

The oxime was prepared by refluxing for one and one-half hours a solution of 20 g. of the ketone and 20 g. of hydroxylammonium chloride in 50 ml. of ethanol and 50 ml. of pyridine. On evaporation and dilution with water, the oxime crystallized, and a sample was recrystallized from ethanol, m. p. 138.5–140°.

Anal. Calcd. for $C_{20}H_{23}NO_2$: N, 4.53. Found: N, 4.64.

1-(2-Hydroxy-5-cyclohexylphenyl)-2-phenylethylamine (28).—To a solution of 22.4 g. of the crude oxime in 1 l. of absolute ethanol was added 69 g. of sodium. When

A.*, **4**, 2634 (1910), report the formation of a compound HOCHPhCHPhNC$_5$H$_{10}$, m. p. 156–157°, but they do not describe a hydrochloride. R. E. Lutz, J. A. Freek and R. S. Murphey, THIS JOURNAL, **70**, 2016 (1948), report both racemates of this compound and report the m. p. of this isomer as 259–260° *in vacuo*. [dd] Emil Eidebenz, German Patent 671,786; *C. A.*, **33**, 6527 (1939). [ee] The free base distills at 130–149° at 0.1 mm. [ff] Melting points determined using a thermometer calibrated for 76-mm. immersion.

the reaction was complete, it was acidified with hydrochloric acid, distilled nearly to dryness *in vacuo*, and shaken with 500 ml. of water. The solid hydrochloride was collected on a filter, washed with ether and water, and dried; yield, 7.3 g., m. p. 224–227°. Recrystallization from ethanol did not raise the melting point.

N-Methyl-α-cyclohexylbenzylamine (29).—The method of preparation was similar to that previously described.[5] Cyclohexylmagnesium bromide was prepared from 14 g. (0.6 mole) of magnesium, 100 g. (0.62 mole) of cyclohexyl bromide and 200 ml. of absolute ether. To this was added 24 g. (0.2 mole) of benzalmethylamine, and the mixture was refluxed for one and one-quarter hours. The base was distilled twice from a Claisen flask, b. p. 89° (0.135 mm.); yield, 10.2 g. (25.2%); $n^{25}D$ 1.5287. It was converted to the hydrochloride by saturating its alcoholic solution with hydrogen chloride and diluting with absolute ether. The crystalline solid was boiled with isopropyl alcohol,

cooled, and filtered from a small amount of insoluble material. Dilution of the filtrate with absolute ether gave the pure hydrochloride, m. p. 251–253°.

1-(4-Chlorophenyl)-2-phenyl-2-aminopropanol (30).—This was prepared by the reaction of a Grignard reagent with an oxime.[10] In this case, 27 g. of 4-chloropropiophenone oxime[11] was heated to 140–145° for one-half hour with an excess of phenylmagnesium bromide. The products were separated and purified as described by Campbell, *et al.*[10]

1,2-Di-*p*-methoxyphenylbutylamine (31).—Ninety grams of α-ethyldesoxyanisoin oxime[12] was dissolved in 3 l. of absolute methanol and treated with 300 g. of sodium. The resulting solution was boiled two hours and poured into 6 l. of 10% hydrochloric acid. The first crop of crystals was yellow, m. p. 60–80°. The second crop weighed 27 g., m. p. 252–258°. Treatment of the filtrate with alkali gave a gummy material, which, on treatment with 5% hydrochloric acid, crystallized to give 15 g., m. p. 200–225°. Crystallization of the second crop of crystals from dilute hydrochloric acid, then alcohol, and finally, distilled water, gave material, m. p. 269–271°.

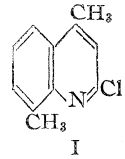
Derivatives of 2-Amino-4,8-dimethyl- and 4-Amino-3,8-dimethylquinoline[1]

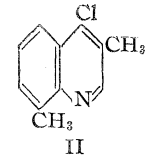
BY DONALD E. EICHINGER[2] AND C. G. STUCKWISCH

In an attempt to find new types of compounds that exhibit antimalarial activity 2-substituted-4,8-dimethylquinolines and 4-substituted-3,8-dimethylquinolines were investigated.[3]

The key intermediate for the first series of compounds, 2-chloro-4,8-dimethylquinoline (I), was prepared by the reaction of phosphorus oxychloride with 2-hydroxy-4,8-dimethylquinoline. The latter was obtained in essential accordance with the procedure of Roos.[4] 4-Chloro-3,8-dimethylquinoline (II) was prepared as described by Steck, *et al.*[3]



I



II

Compounds I and II were condensed with morpholine, piperidine, 1-hydroxymethylpropylamine and 4-diethylamino-1-methylbutylamine. Table I of the experimental section lists the properties of the compounds obtained.

TABLE I

DERIVATIVES OF DIMETHYLQUINOLINES

Compound	Yield, %	Solvent	M. p., °C.	Analyses, % Carbon Calcd.	Carbon Found	Hydrogen Calcd.	Hydrogen Found	Nitrogen Calcd.	Nitrogen Found

4-Chloro-3,8-dimethylquinoline (II).—The sequence of reaction for the preparation of 4-chloro-3,8-dimethyl-

(1) Abstracted in part from a Master's Thesis by D. E. Eichinger.

(2) Present address: E. I. Du Pont de Nemours & Co., Philadelphia, Pennsylvania.

(3) Since the inception of this work in September, 1945, 3,8-dimethyl-4-dimethylamino-1-methylbutylaminoquinoline has been described by Steck, Hallock and Holland, THIS JOURNAL, **68**, 132 (1946).

(4) Roos, *Ber.*, **21**, 624 (1888).

quinoline has been described in the literature.[3] Our yields and melting points agreed essentially with those reported.

Derivatives of Dimethylquinolines.—The compounds described in Table I were prepared by refluxing the chloro compound with an excess of the appropriate amine as the solvent. The reflux time was eight to ten hours. The reaction mixture was then poured on ice. The 4-diethylamino-1-methylbutylamino derivative was extracted from the water with ether and was purified by distillation; whereas the solid piperidino, morpholino and 1-hydroxymethylpropylamino derivatives were filtered off and crystallized.

Summary

1. 2-Chloro-4,8-dimethylquinoline has been prepared.

2. Some derivatives of 2-amino-4,8-dimethylaminoquinoline and 4-amino-3,8-dimethylquinoline are described.

WICHITA, KANSAS RECEIVED APRIL 12, 1949

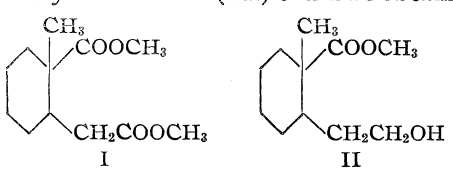
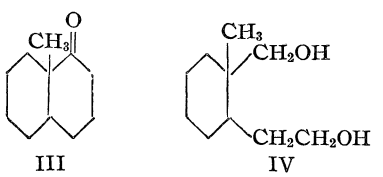
Reduction of a Diester to a Hydroxyester by Lithium Aluminum Hydride. Application to the Construction of Rings

BY W. E. BACHMANN AND ANDRE S. DREIDING[1]

No instance of the reduction of one of two ester groups by lithium aluminum hydride has been reported. Nystrom and Brown were unable to reduce one of the two primary carboxy groups of sebacic acid and its half ester at the boiling point of ether and suggested experimentation at lower temperatures.[2] We were interested in reducing selectively the primary ester group of the dimethyl ester of *cis*-2-methyl-2-carboxycyclohexaneacetic acid (I) to the alcohol (II) from which, after a malonic ester synthesis and cyclization, *cis*-9-methyl-1-decalone (III) could be obtained.





Accordingly we examined the reduction of the diester (I) with an amount of lithium aluminum hydride sufficient to reduce only one ester group at low temperatures. Below −15° no visible change occurred. When the reaction mixture was kept near −15° the reagent was used up in reducing the primary carbomethoxy group to yield *cis*-β-2-methyl-2-carbomethoxycyclohexaneëthanol (II). The crude product was converted to the bromoester by the action of phosphorus tribromide. Condensation with sodiomalonic ester followed by hydrolysis and decarboxylation yielded *cis*-γ-2-methyl-2-carboxycyclohexanebutyric acid. Its dimethyl ester underwent the Dieckmann cyclization, hydrolysis, and decarboxylation to give *cis*-9-methyl-1-decalone (III) in a 15% over-all yield from I. These reactions represent a new synthesis of the bicyclic ketone (III) from the diester (I) and the procedure may prove to be generally applicable for the construction of rings since the starting acetic esters are frequently available through the Reformatsky reaction or malonic ester synthesis. Recently we described the preparation of the ketone (III) from the ester (I) through two successive Arndt–Eistert reactions followed by cyclization.[3]

Reduction of the diester (I) with sufficient lithium aluminum hydride to reduce both ester groups yielded *cis*-β-2-methyl-2-hydroxymethylcyclohexaneëthanol (IV). The same product (IV) was obtained when the diester (I) was treated with an excess of sodium in boiling ethanol.

Experimental

Reduction of the Diester (I) to the Hydroxyester (II).—A 0.15-g. piece of lithium aluminum hydride (Metal Hydrides Inc., Beverly, Massachusetts) was softened by allowing it to rest in 15 cc. of boiling anhydrous ether for twenty minutes, while excluding moisture and carbon dioxide. It was broken up with a stirring rod and the resulting supension was refluxed again for twenty minutes. The remaining undissolved particles were crushed and brought into solution almost completely by boiling for another twenty minutes. To the solution, cooled to −60° in a Dry Ice–acetone-bath, a solution of 1.8 g. of the dimethyl ester of *cis*-2-methyl-2-carboxycyclohexaneacetic acid (I, made from the corresponding diacid[4] by esterification with diazomethane) in 10 cc. of ether was added in small portions so that the temperature did not rise above −40°. The colorless solution, which contained only a small amount of undissolved solids, stood at −60° for five hours and was allowed to warm up slowly. At −15° a colorless gelatinous precipitate appeared. The mixture was kept at −15 to −10° for twenty minutes by reinserting the flask in the cold bath from time to time with swirling. After standing at room temperature for three hours, a small amount of 10% sodium hydroxide and then excess hydrochloric acid was added. The ethereal layer was washed with a saturated sodium chloride solution and concentrated, and the crude residue was evaporatively distilled. The colorless camphoraceous oil (0.83 g. or 53%, presumably *cis*-β-2-methyl-2-carbomethoxycyclohexaneethanol, II), which was collected at 70–80° (0.4 mm.), was

(2) Nystrom and Brown, THIS JOURNAL, **69**, 2548 (1947).

(3) Bachmann and Dreiding, *J. Org. Chem.*, **13**, 317 (1948).

(4) Chuang, Tien and Huang, *Ber.*, **68**, 866 (1935); Bachmann and Kushner, THIS JOURNAL, **65**, 1963 (1943).

treated in the cold with 0.13 cc. of phosphorus tribromide in 10 cc. of benzene. After standing for four hours at 0° and fifteen hours at room temperature, the mixture was diluted with ether, washed with 10% sodium hydroxide and water, and concentrated. The residue, which had a fruity odor, was evaporatively distilled, and the bromoester (0.73 g. or 71%), which was collected at 75–95° (0.3 mm.), was added to a suspension of the sodium salt of diethyl malonate (made from 0.11 g. of sodium, 1.5 cc. of ethanol, and 0.88 g. of diethyl malonate) in 7 cc. of benzene. The mixture was refluxed for fifteen hours, cooled, and treated with dilute hydrochloric acid. The organic layer was separated and concentrated and the residue saponified in 20% aqueous methanolic potassium hydroxide for eight hours. The clear yellow solution was concentrated, washed with ether, and acidified in the cold. The oily malonic acid derivative, isolated by means of ether, was decarboxylated at 180–210° for eight minutes. A solution of the melt in 10% sodium hydroxide was washed with ether and acidified. The precipitated *cis*-γ-2-methyl-2-carboxycyclohexanebutyric acid was taken up in ether, washed with water, and esterified with diazomethane. The ethereal solution was extracted with 5% sodium hydroxide, the solvent evaporated and the residual diester was evaporatively distilled at 90–115° (0.2 mm.); yield, 0.47 g. (66%). The distillate was subjected to a Dieckmann cyclization, hydrolysis, and decarboxylation according to the described method.[3] Evaporative distillation of the product at 60–80° (0.4 mm.) gave *cis*-9-methyl-1-decalone (III) as a colorless camphoraceous liquid; yield, 0.2 g. (66%). The 2,4-dinitrophenylhydrazone, crystallized twice from an ethanol–ethyl acetate mixture, melted at 158–163° alone and when mixed with an authentic sample (m. p. 164–165°).[3] The oxime crystallized from methanol as colorless prisms, m. p. 110–112° alone and when mixed with an authentic sample (m. p. 114–115°).[3]

Reduction of the Diester (I) to the Glycol (IV). (a) By Lithium Aluminum Hydride.—To a solution of 88 mg. of lithium aluminum hydride in 18 cc. of anhydrous ether (prepared as described above) was added in small portions a solution of 0.45 g. of the dimethyl ester of *cis*-2-methyl-2-carboxycyclohexaneacetic acid (I, prepared by esterification of the acid[4]) at room temperature over a period of fifteen minutes; a colorless gelatinous precipitate appeared immediately. After standing at room temperature for twenty minutes, 10% aqueous sodium hydroxide was added, followed by solution of the salts in excess hydrochloric acid. Evaporation of the ethereal layer gave ***cis*-β-2-methyl-2-hydroxymethylcyclohexaneëthanol** (IV), which crystallized from ether–petroleum ether (b. p. 30–60°) in colorless needles; yield, 0.27 g. (80%), m. p. 112–116°; after another recrystallization, 116–117°.

Anal. Calcd. for $C_{10}H_{20}O_2$: C, 69.72; H, 11.71. Found: C, 69.55; H, 11.80.

(b) By Sodium and Alcohol.—To a boiling solution of the diester (I) in 50 cc. of dry ethanol was added 5 g. of sodium in small slices over a period of fifteen minutes. The mixture was kept refluxing for three hours, when all the sodium had reacted. The cooled mixture was treated with ice and water and the product was extracted with ether. The ethereal solution was washed with a saturated sodium chloride solution, dried over magnesium sulfate, and concentrated. Evaporative distillation of the residue at 120–140° (0.4 mm.) gave 3.5 g. (95%) of a colorless glass which crystallized when covered with a small amount of ether, m. p. 114–116°. On recrystallization from 1:1 ether–petroleum ether (b. p. 30–60°) the glycol (IV) melted at 116–117°.

Summary

The selective reduction of the primary carbomethoxy group in the dimethyl ester of *cis*-2-methyl-2-carboxycyclohexaneacetic acid (I) by lithium aluminum hydride and its application to a synthesis of *cis*-9-methyl-1-decalone (III) is described.

Alkylamine Esters of 7-Aminofluorenone-2-carboxylic Acid

BY H. F. OEHLSCHLAEGER[1] AND IAN R. MACGREGOR

Alkylamine esters of fluorene and fluorenone carboxylic acids have been reported to possess local anesthetic action. For example, the alkylamine esters of fluorene-9-carboxylic acid have been investigated and patented as local anesthetics.[2,3]

Ray and Rieveschl[4,5] prepared the β-diethylaminoethyl ester of fluorene-2-carboxylic acid as well as a series of alkylamine esters of fluorenone-1, -2 and -4 carboxylic acids. Of the series, the esters of fluorenone-2-carboxylic acid proved to be the most active as local anesthetics and as antispasmodics. The water solubility of these esters, however, is low. Subsequent attempts by Ray and MacGregor[6] to produce more soluble anesthetics based on the fluorene nucleus and using a ketone linkage rather than the ester linkage did not appreciably alter the water solubilities.

In this investigation we hoped to increase the effectiveness of the alkylamine esters of fluorenone-2-carboxylic acid by the introduction of an amino group in the 7-position of the fluorenone molecule. Generally the presence of a free amino group in a position para to the ester linkage in compounds of the procaine type has an advantageous effect. There is a noticeable increase in activity with no apparent increase in toxicity in compounds containing the para-amino group over compounds devoid of this group.[7] A series of alkylamine esters of 7-nitrofluorenone-2-carboxylic acid, and 7-aminofluorenone-2-carboxylic acid were prepared.

A modification of a Friedel–Crafts reaction used by Broisman and MacGregor[8] gave 60–65%

yields of 7-nitro-2-acetylfluorene from 2-nitrofluorene, acetyl chloride, and aluminum chloride in nitrobenzene solvent. The purified 7-nitro-2-acetylfluorene was readily oxidized in glacial acetic acid by sodium dichromate to 7-nitrofluorenone-2-carboxylic acid, m. p. 324° (uncor.). Some controversy existed over the melting point of the acid since Stockton[9] had reported it as melting at 220°, while Broisman[8] had reported the melting point as 233°. Proof of structure of the 7-nitrofluorenone-2-carboxylic acid was established by reduction of the nitro group to the amine and deamination by diazotization and treatment with hypophosphorous acid to yield the known fluorenone-2-carboxylic acid. The nitrocarboxylic acid formed a reddish-orange phenylhydrazone when refluxed with phenylhydrazine in alcohol solution.

An intermediate compound in the oxidation of 7-nitro-2-acetylfluorene was 7-nitro-2-acetylfluorenone which was easily isolated from the 7-nitrofluorenone-2-carboxylic acid by virtue of the insolubility of the former in aqueous potassium hydroxide.

The carboxylic acid was converted to the corresponding 7-nitrofluorenone-2-carbonyl chloride, by reaction with thionyl chloride. Esterification of 7-nitrofluorenone-2-carbonyl chloride with several amino alcohols was carried out in very good yields using inert solvents such as chlorobenzene or toluene. The resulting 7-nitrofluorenone-2-carboxylates were reduced satsifactorily to the corresponding alkylamine esters of 7-aminofluorenone-2-carboxylic acid by means of ammonium hydroxide and hydrogen sulfide. The reaction was accompanied by some tar formation which accounted for the erratic yields. The esters of the nitro- and aminofluorenonecarboxylic acids that were prepared are listed in Table I.

Experimental

7-Nitro-2-acetylfluorene.—To a well-stirred suspension of 97 g. (0.46 mole) of crude 2-nitrofluorene[10] were added 500 cc. redistilled nitrobenzene and 113 g. (0.85 mole) of anhydrous aluminum chloride. A deep red color developed as the suspension was warmed to 40°. During a period of one-half hour, 40 cc. (0.56 mole) of acetyl chloride was added dropwise, the temperature being maintained between 40 and 50°. The mixture was stirred and warmed to 50–55° for an additional four hours. The dark green mixture was hydrolyzed by pouring it portionwise into a strongly stirred mixture of 20 cc. of hydrochloric acid, 200 g. of ice and 800 cc. of water. The water layer was poured off and the oily precipitate was extracted twice with 750 cc. of ether to remove the excess nitrobenzene. The residue was collected on a Büchner funnel, pressed dry, and recrystallized from glacial acetic acid. The straw colored needles melted at 228°; the yield was 62.8%.

Anal. Calcd. for $C_{15}H_{11}O_3N$: N, 5.53. Found: N, 5.50.

7-Nitrofluorenone-2-carboxylic Acid.—To a solution of 30 g. (0.12 mole) of 7-nitro-2-acetylfluorene in 2000 cc. of glacial acetic acid was added, in small quantities, 150 g. (0.50 mole) of powdered sodium dichromate. After refluxing the mixture for two hours, 100 cc. of acetic anhydride was added slowly after which refluxing was continued for four hours longer. The reaction mixture was poured into 2.5 gallons of hot water, into which was passed live steam to coagulate the oxidation products. The suspension was filtered, washed with very dilute acid and pressed dry. The entire solution was warmed with 1000 cc. of 0.5% potassium hydroxide and filtered while hot. The filtrate was acidified with an excess of 1:1 hydrochloric acid, and the heavy yellow flocculent precipitate of the carboxylic acid was isolated by filtration, washed with water and recrystallized from glacial acetic acid. The alkali insoluble material was reoxidized with 75 g. of sodium dichromate in 1200 cc. of glacial acetic acid, yielding an additional amount of the acid after treatment in the same manner as the first oxidation reaction solution. The total crude product obtained from the oxidation was 20 g. (62.5% theoretical). Two recrystallizations from glacial acetic acid yielded a yellow crystalline product which melted at 322–324°.

Anal. Calcd. for $C_{14}H_7O_5N$: N, 5.20. Found: N, 5.14.

A solution of 1.0 g. of 7-nitrofluorenone-2-carboxylic

(10) Kuhn, "Organic Syntheses," John Wiley and Sons, Inc., New York, N. Y., Vol. XIII, 1943, p. 74.

acid in 100 cc. of ethyl alcohol was refluxed for fifteen minutes with 2.0 cc. (2.19 g., 0.02 mole) of phenylhydrazine. The mixture was cooled in an ice-bath and water was added dropwise to the solution until 100 cc. had deen added. The resulting precipitate was isolated by filtration and recrystallized from ethyl alcohol. The recrystallized phenylhydrazone melted at 264–265°.

7-Aminofluorenone-2-carboxylic Acid.—To a suspension of 10 g. (0.04 mole) of 7-nitrofluorenone-2-carboxylic acid in 600 cc. of ethyl alcohol was added 80 cc. of concentrated ammonium hydroxide. The suspension was heated to its boiling point and hydrogen sulfide gas was passed into it for one hour during which time the solid material dissolved and the solution took on a dark red color. The solution was boiled an additional half hour to remove excess hydrogen sulfide and ammonia. After cooling the solution it was filtered and the filtrate poured into 800 cc. of water. Acidification of the aqueous solution with 1:5 hydrochloric acid gave a dark red solid. The crude product was dissolved in 400 cc. of hot 2% potassium hydroxide and 0.5 g. of Darco. After filtration the hot filtrate was acidified by dropwise addition of 20 cc. of hydrochloric acid (1:5), the product separating as a precipitate. The resulting dark red powder did not melt below 360°. The yield was 7.5 g. (85%).

Anal. Calcd. for $C_{14}H_9O_3N$: C, 70.29; H, 3.77; N, 5.85. Found: C, 69.89; H, 4.00; N, 5.73.

7-Nitro-2-acetylfluorenone.—The alkali insoluble material from the oxidation described above was recrystallized twice from glacial acetic acid and once from xylene. The product formed as fine lemon-yellow needles, melting sharply at 234°.

Anal. Calcd. for $C_{15}H_9O_4N$: N, 5.24. Found: N, 5.08.

7-Nitrofluorenone-2-carbonyl Chloride.—Fifteen grams (0.056 mole) of crude 7-nitrofluorenone-2-carboxylic acid was refluxed with 400 g. of redistilled thionyl chloride for twelve hours, provision being made to trap the escaping sulfur dioxide and hydrochloric acid. The excess thionyl chloride was removed by distillation and the residue recrystallized from toluene or chlorobenzene. The yield of acid chloride was 15.0 g. (99 + % theoretical). The bright yellow crystalline compound melted at 246–248°.

Anal. Calcd. for $C_{14}H_6O_3NCl$: N, 4.87; Cl, 12.34. Found: N, 5.16; Cl, 12.42.

β-Diethylaminoethyl-7-nitrofluorenone-2-carboxylate Hydrochloride.—This preparation is typical of the method used for the preparation of the esters used in this work. To a solution of 6.5 g. (0.023 mole) of 7-nitrofluorenone-2-carbonyl chloride in 350 cc. of dry chlorobenzene in reflux was added dropwise over a period of one half hour a solution of 3.2 cc. (2.8 g., 0.025 mole) of β-diethylaminoethanol in 25 cc. of chlorobenzene. The hydrochloride of the alkylamine ester separated as a yellow crystalline solid which was collected and washed twice with 30-cc. portions of ether. The yield of the crude product was 8.5 g. (92.4 %). A portion, recrystallized from methyl alcohol, melted with decomposition at 230–232°.

The free base, prepared by dropwise addition of sufficient ammonium hydroxide to neutralize the hydrochloride, separated as bright yellow crystals which, recrystallized from a methyl alcohol–water mixture, melted at 134–136°.

Anal. Calcd. for $C_{20}H_{20}O_5N_2$: N, 7.61. Found: N, 7.67.

The nitric acid salt was prepared as a finely crystalline, water insoluble, yellow material by adding 5 cc. of dilute nitric acid (6 *N*) to a solution of 0.1 g. of the ester hydrochloride in 250 cc. of hot water. The product melted sharply at 214–215°.

Anal. Calcd. for $C_{20}H_{21}O_8N_3$: N, 9.75. Found: N, 10.03.

β-Diethylaminoethyl-7-aminofluorenone-2-carboxylate.—Six grams (0.015 mole) of β-diethylaminoethyl-7-nitrofluorenone-2-carboxylate was dissolved in 400 cc. of hot ethyl alcohol and 8 cc. of ammonium hydroxide. Hydrogen sulfide was bubbled into the hot solution over a period of one half hour, the solution changing to a dark red color. A solution of 50 cc. of 12 *N* hydrochloric acid in 400 cc. of water was added to the warm reaction mixture. The hot acid solution was filtered twice to remove free sulfur and then made alkaline with 6 *N* ammonium hydroxide and allowed to stand overnight. The bright red, finely divided precipitate which separated was recrystallized from an alcohol–water solution yielded 2.5 g. (50% theoretical) of the amine as red needles which melted at 215–216°.

Anal. Calcd. for $C_{20}H_{22}O_3N_2$: N, 8.28. Found: N, 8.02.

Summary

1. A series of alkylamino esters of 7-nitrofluorenone-2-carboxylic acid and 7-aminofluorenone-2-carboxylic acid have been prepared for evaluation as topical anesthetics or for possible antispasmodic action.

2. The preparation of pure 7-nitrofluorenone-2-carboxylic acid and the proof of its structure has resolved the question of its correct melting point.

Lower Iodides of Boron

BY WALTER C. SCHUMB, E. LEE GAMBLE AND MARIO D. BANUS

Although numerous points of resemblance may be observed in the chemistry of boron and silicon compounds, up to the present time a striking exception in the behavior of boron has been the lack of halides other than the well-known series of trihalides, BX_3. Except for the compound B_2Cl_4, first reported by Stock,[1] who succeeded in isolating a drop of the unstable liquid, no binary halides with B–B bonds appear to have been prepared. From the known instability of Stock's B_2Cl_4, it seemed reasonable to believe that synthetic methods operating at elevated temperatures would probably fail to yield such compounds as B_2Br_4 or B_2I_4 unless some means of "freezing-out" the desired products could be resorted to, whereby their decomposition might be held in check.

Preliminary experiments in which it was planned to prepare a lower iodide of boron, such as B_2I_4, by reduction of boron triiodide under conditions favoring the prevention of decomposition of the desired product, included the use of the "hot–cold" tube devised by St. Claire Deville[2]

(1) Stock, Brandt and Fischer, *Ber.*, **58B**, 653 (1925).

(2) St. Claire Deville, "Leçons sur la Dissociation, Leçons de Chemie," Soc. Chim. de Paris, 1864–1865.

and successfully employed by various other experimenters.[3,4] When a mixture of the vapors of boron triiodide and hydrogen was passed through such an apparatus, indications of the formation of a sub-iodide on the cold element of the tube were obtained, but in exceedingly small yields, together with a copious deposit of elementary boron on the hot glass surfaces.

Again the reduction of boron triiodide by means of metallic silver in a reaction analogous to that for the preparation of Si_2I_6[5,6] led to the result that, contrary to the earlier reports of Moissan,[7] reaction is appreciable at as low a temperature as 185°, iodine being liberated which is converted by the silver present into silver iodide, and a black, non-volatile solid being formed which was not separated in a pure form but which, from its similarity in properties to preparations by other methods, described below, we believe contained the monoiodide, $(BI)_n$.

Furthermore, it had been noted in the preparation of boron triiodide that the pure white color of the freshly prepared compound changed to a dark color when the substance was melted and that when heated above the melting point in a sealed evacuated tube boron triiodide decomposed, liberating iodine and forming a dark-colored solid, the color deepening as the temperature was increased. That an equilibrium process was not involved was shown by the fact that the depth of color did not lessen when the temperature was lowered to just above the melting point and held for a long time. The dark solid formed from 4 g. of triiodide heated at 250° for twenty-four hours in the sealed tube, when separated from unchanged triiodide by volatilization of the latter, gave reactions consistent with a lower iodide of boron and closely resembled the product described below which was obtained by the action of the electrodeless discharge on the vapors of boron triiodide.

In view of the results obtained from the exploratory experiments it was concluded that in order to prepare tetraiododiborine, a method of reduction would be required that did not raise the temperature of the products above room temperature. In the method used, a radio-frequency electrodeless discharge supplied the "cold" energy for the reduction.

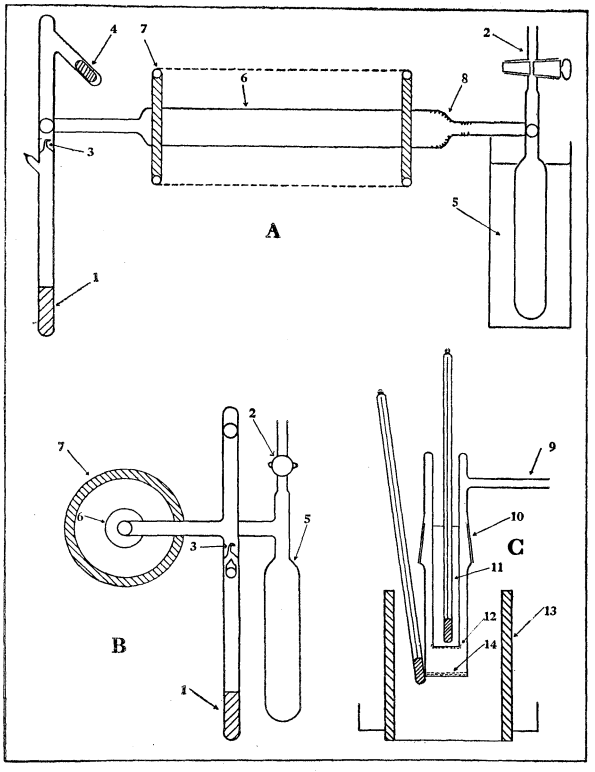

Fig. 1.—A and B: 1, Boron triiodide in sealed ampule; 2, outlet to pumping system; 3, break-off tip; 4, glass-covered steel magnetic breaker; 5, trap, cooled by liquid nitrogen; 6, 20 × 250 mm. glass tube; 7, 3″ copper solenoid, R. F. antenna; 8, crystals of yellow tetraiododiborine formed during reduction; C: 9, 9-mm. tubing to Hyvac-backed, mercury diffusion pump; 10, 29/42 ground joint; 11, ethanol cooled by Dry Ice to −20 to −30°; 12, pure tetraiododiborine as pale yellow sublimate; 13, Variac-controlled heating element; 14, crude tetraiododiborine from glow reduction.

Experimental

The electrodeless radio-frequency discharge apparatus used was that described by Schumb and Bickford[8] for use in the study of the dissociation of carbon dioxide at low temperatures. A 2000 v. d. c. power supply drove a 250-watt 204-A transmitting tube at frequencies from 4600 to 5200 k. c. with a tank current output of from 7–8 amp. R. F. The glass system (Fig. 1, A and B) made it possible to fill the boron triiodide ampule in the dry box with 4–8 g. of freshly sublimed boron triiodide followed by evacuation to <0.5 mm. and sealing, then to assemble the glass apparatus through the central 3″ solenoid. When the glass system was flame-dried and evacuated carefully by a Hyvac pump, the stopcock was closed, sealing the system. The break-off tip to the boron triiodide ampule was broken by the magnetic breaker allowing the iodide to sublime through the glow tube to the liquid nitrogen cooled trap. By keeping the boron triiodide supply at between 35 to 40°, a pressure of 1 to 3 mm. could be maintained in the glow tube, this vapor pressure giving an intense greenish-yellow glow when the R. F. transmitter was turned on. Under certain conditions, the glow would extend some distance beyond the ends of the glow tube in both directions. Free iodine along with the un-

reacted boron triiodide condensed in the liquid nitrogen, and the boron triiodide could be recovered later for reuse.

It required from four to six hours to sublime the boron triiodide through the discharge apparatus. Shortly after the glow started, fine yellow crystals could be seen at the exit constriction of the glow tube, gradually building up to a mass of yellow, crystalline material. Near its inlet, the glow tube gradually became coated with a black deposit which spread finally along the full length of the glow tube and back toward the boron triiodide supply, becoming so dense that it obscured the glow in the tube. When all the boron triiodide had passed through, the glow tube was sealed beyond the bends at both ends and placed in the dry box where it was opened carefully and the yellow crystals and black wall deposit scraped into weighed vials. The former, when sublimed at <0.1 micron and 60 to 70° in the molecular still (C, Fig. 1) gave a pale yellow sublimate and a trace of black residue. This yellow material had to be analyzed promptly since it decomposed even at room temperature. It could be kept undecomposed for a longer period in sealed evacuated ampules if refrigerated and kept out of the light. Analysis showed this compound to be B_2I_4. From the weight of solid products obtained in the reduction, it was calculated that 40% of the boron triiodide was reduced and recovered as lower iodides. One third of the reduced portion went to B_2I_4 according to the equation: $2BI_3 \rightarrow B_2I_4 + I_2$. The rest of the reduced boron triiodide was converted to the black deposit, a boron iodide or mixture of variable composition, B_xI_y, where $x > y$, according to the equation: $xBI_3 \rightarrow B_xI_y + (3x - y)/2I_2$.

Properties of the Lower Iodides.—Tetraiododiborine (B_2I_4) is a pale yellow, crystalline substance which at room temperature showed slow decomposition which increased rapidly with rising temperature and with exposure to sunlight. This decomposition occurred according to the equation: $xB_2I_4 \rightarrow yBI_3 + (BI)_{2x-y} + (x - y)I_2$. However, at room temperature only a trace of iodine was formed so that the decomposition became essentially a disproportionation. Larger quantities of iodine were formed at higher temperatures or under the action of sunlight. The decomposition of tetraiododiborine therefore proved to be an excellent method for preparing the monoiodide of boron, $(BI)_x$, a black, non-volatile, polymerized material. Tetraiododiborine dissolved in water with rapid, vigorous hydrolysis, forming an acid solution with strong reducing properties from which silver nitrate precipitated silver iodide, followed, on adding more of the reagent, by silver metal. On hydrolysis in 10% sodium hydroxide nearly the theoretical quantity of hydrogen was evolved according to the equation: $B_2I_4 + 8OH^- \rightarrow 2HBO_3^{=} + H_2 + 2H_2O + 4I^-$. Tetraiododiborine showed no melting point when heated in a sealed evacuated melting point tube, but started to decompose at about 80°, being completely decomposed by 250° with I_2 and BI_3 subliming to the top of the tube, leaving behind a black residue. It was not possible to detect any solubility of the iodide in carbon disulfide, carbon tetrachloride or cyclohexane, since these solvents slowly decompose the iodide with the liberation of iodine.

The black, polymerized monoiodide of boron was far more stable than the tetraiododiborine. It could be kept apparently indefinitely at room temperature if it were in a sealed, dry vial or ampule. Like tetraiododiborine, the $(BI)_x$ was apparently insoluble in carbon disulfide and carbon tetrachloride, with the solvents decomposing the iodide and giving a concentrated solution of iodine. The monoiodide was hydrolyzed by water to give a similar clear acid solution with strong reducing properties, but in this case the silver metal precipitated at the same time as did the silver iodide, giving a red-brown curd unlike the two-layer precipitate from the hydrolysis solution of the B_2I_4. In addition it was a much harder task to oxidize all the boron back to the trivalent state in the case of the monoiodide. On heating $(BI)_x$ in a sealed, evacuated, melting point tube it gave no melting point but did decompose above 125°, giving off iodine and leaving a black residue. On rapid heating in a micro flame a second sample appeared to be decomposed into boron and iodine. $(BI)_x$ had a vapor pressure of <0.1 micron at 110°.

The boron iodide of variable composition, B_xI_y, was very similar to $(BI)_x$ and was originally thought to be the latter compound. However, with larger samples and further study, indications of difference were found, especially with regard to their hydrolysis. B_xI_y when hydrolyzed gave the expected acid solution with strong reducing properties, but in addition it always gave varying amounts of a pale yellow, highly unreactive hydrolysis product which contained boron, iodine, oxygen and probably hydrogen. When the total analysis of boron and iodine from the solution and residue was made, the atomic ratio of boron to iodine varied between 1 and 3. The material may have been a mixture of $(BI)_x$ and another iodide but since the latter was apparently just as non-volatile and insoluble as the monoiodide no separation could be made. B_xI_y was found to be very stable to heat, giving only a trace of decomposition up to 260°; but with rapid higher heating in a free flame it decomposed to the elements. It was much more stable than the other iodides described toward the solvents carbon tetrachloride, cyclohexane and benzene, being only slowly decomposed over a period of several days. It did not show any tendency to dissolve, however.

Analysis of the Lower Iodides.—The iodides were analyzed by hydrolyzing weighed samples in 50-ml., glass-stoppered Erlenmeyer flasks, diluting to volume in volumetric flasks and taking two aliquots each for the boron

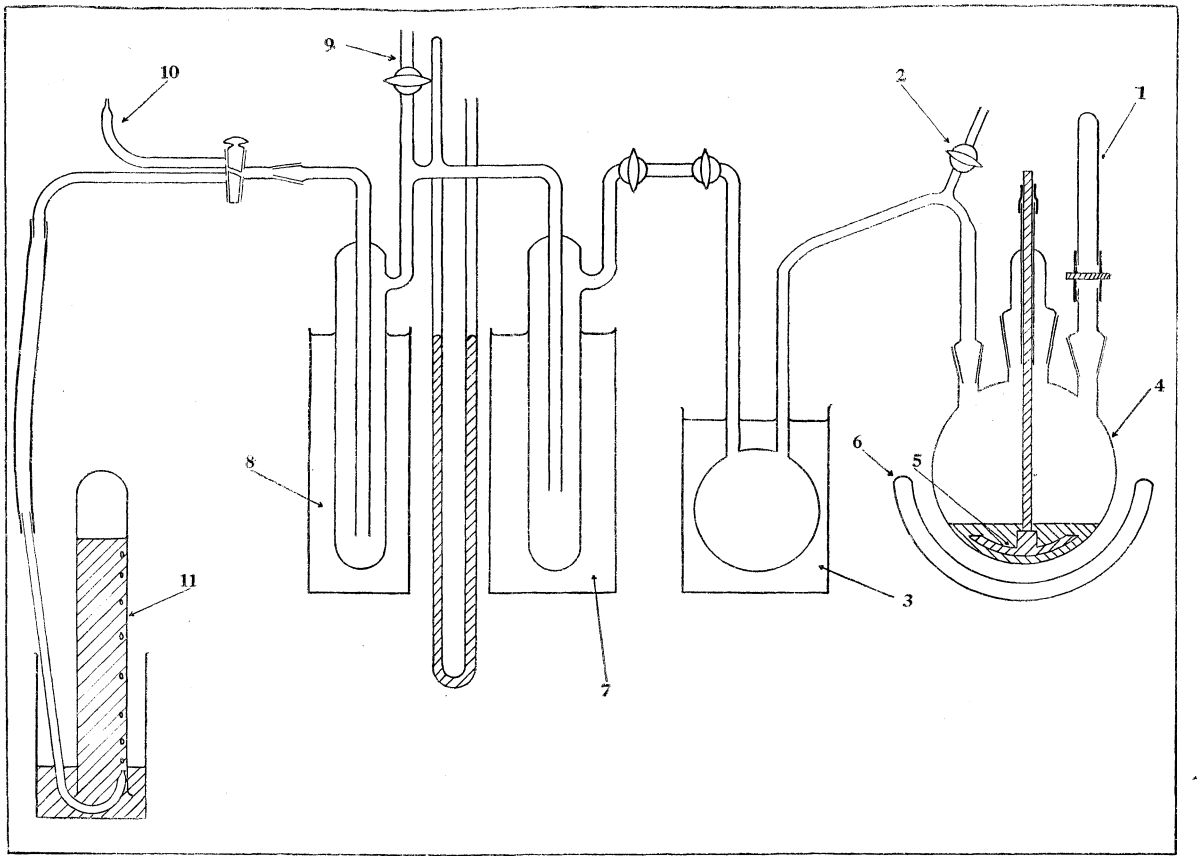

Fig. 2.—1, 20 × 170 mm. tube containing sodium or lithium borohydride; 2, inlet for dry purified nitrogen; 3, trap 1, 500-ml. flask cooled by ice; 4, 500-ml. 3-necked reaction flask containing the molten I_2; 5, nickel-shafted, Monel stirrer; 6, Variac-controlled Glas-col heating mantle; 7, trap 2, cooled by Dry Ice and ethanol; 8, trap 3, cooled by liquid nitrogen; 9, outlet to pumping system; 10, sweeping vent; 11, hydrogen measuring cylinder, 48 × 385 mm.

and iodine analyses. The aliquots were treated with 50% hydrogen peroxide and then made just basic to oxidize the boron. When the oxidation was complete, the excess hydrogen peroxide was destroyed by the use of platinum foil. For boron analysis the sample was made just acid to methyl red with sulfuric acid, then titrated to the methyl red end-point with standard base in a Koch microburet. Mannitol and phenolphthalein were added and the titration continued to the phenolphthalein end-point, giving the volume necessary for the boric acid. For iodine the sample was made acid with sulfuric acid excess, 0.2 *N* silver nitrate added, digested for one-hour hour and then filtered into weighed, fritted glass crucibles.

Preparation of Boron Triiodide.—The method developed for the preparation of boron triiodide used in the preparation of the lower iodides consisted of the reaction of sodium or lithium borohydride[9] with iodine, the reaction being carried out in a three-necked, round-bottom flask provided with an efficient mechanical stirrer and heated by means of an electric mantle. The temperature used in the case of sodium borohydride was about 200°; with lithium borohydride, 120–125°. Yields of 45–50% with the former compound and 64–66% on the basis of the boron involved with the latter were obtained. In a typical run from 5.1 g. of lithium borohydride (not recrystallized), 61 g. of BI_3 was obtained. The sodium borohydride was recrystallized before use from dried isopropylamine: the solution was centrifuged and decanted, the sodium borohydride freed from the amine by evaporation, followed by drying at 125° for thirty-six hours before it was finely powdered in an agate mortar. The reactions occurring between the borohydrides and iodine are somewhat complicated, but the principal over-all reaction deduced from the quantities of the respective products obtained may be represented as follows: $3NaBH_4 + 8I_2 \rightarrow 3NaI + 3BI_3 + 4H_2 + 4HI$; this main reaction being followed by side reactions involving reduction of boron to lower valences and to the element.

The preparation of boron triiodide was carried out in the apparatus shown in Fig. 2. Intermittent stirring was essential to high yields in the case of the preparation from sodium borohydride. On the other hand, temperature control to within the range mentioned was required for maximum yields with lithium borohydride so that a ther-

(9) We are indebted to the Ethyl Gas Corporation, Detroit, Mich., to Metal Hydrides, Inc., of Beverly, Mass., for the sodium borohydride, and to Linde Air Products Co., Tonawanda, N. Y., for the lithium borohydride used in this work.

mocouple well and thermocouple replaced the stirrer in this case. At the end of the run, all the boron triiodide and the excess iodine were sublimed into trap no. 1, now cooled by Dry Ice and then this trap was sealed at the inlet and cut out of the system between the pair of stopcocks at the outlet of trap no. 1.

Purification of boron triiodide as obtained from the borohydrides was effected first by dissolving it and some of the excess iodine in purest carbon disulfide, reduction of the iodine by mercury and zinc dust, filtering to get a clear solution, then vacuum evaporation of the carbon disulfide to get the crude BI_3. This was then further purified by slowly subliming it over a small quantity of mercury at a pressure of about a millimeter. The resulting crystalline product was of varying shades of pink due to admixed mercuric iodide. Resublimation at low pressure in a type of molecular still (C, Fig. 1) gave colorless, glistening crystals, melting at 49.9 ± 0.5°, the melt assuming a pale pink color. The melting point previously reported for BI_3 is 43°.[6] Analysis of this purified product agreed well with the theoretical requirements of BI_3. Found: B, 2.78; I, 96.95. Calcd.: B, 2.77; I, 97.23.

Summary

1. Tetraiododiborine, B_2I_4, and a lower iodide of boron, B_xI_y, where $x > y$, have been prepared by the action of an electrodeless discharge at room temperature upon the vapors of boron triiodide at 1 to 3 mm. pressure. The decomposition is irreversible and is accompanied by a brilliant yellowish-green glow. Free iodine is formed and is trapped out by liquid nitrogen. Forty per cent. of the boron triiodide is reduced in one pass through the glow; one-third of the reduced boron triiodide is recoverable as tetraiododiborine.

2. B_2I_4 is a well-crystallized, pale yellow solid, which is slowly decomposed at room temperature, forming BI_3 and a black non-volatile residue of a polymerized monoiodide, $(BI)_x$. Decomposition is hastened by higher temperature and by the action of sunlight.

3. The lower iodides of boron are hydrolyzed by water yielding strongly reducing solutions which react with silver nitrate precipitating metallic silver and silver iodide.

4. A new and satisfactory method for the preparation of boron triiodide has been developed, in which solid sodium or lithium borohydride reacts with iodine at 200 or 120°, respectively. Yields as high as 66% on the basis of the boron involved were obtained using lithium borohydride.

5. The reduction of boron triiodide to lower iodides has been shown to occur in other ways, such as by the action of silver wool at 185° or by means of hydrogen in a "hot–cold" tube apparatus. These methods, however, are less satisfactory for preparative purposes than those employing the electrodeless discharge.

Trichloroaminoalcohols. I. 1,1,1-Trichloro-3-aminopropanol-2 and Derivatives

BY MARYANN COMPTON,[1] HARVEY HIGGINS,[2] LORNE MACBETH,[3] JANE OSBORN[4] AND HOWARD BURKETT

In 1942 Malkiel and Mason[5] described the synthesis of a compound (I), m. p. 167.4–167.7° (cor.), by the catalytic hydrogenation of 1,1,1-trichloro-3-nitropropanol-2 (II). They reported I to be 1,1,1-trichloro-3-aminopropanol-2 (III). The synthesis of III, m. p. 123°, was first reported[6] in 1935. In addition to III, Chattaway and Witherington also described and reported analyses for its hydrochloride, sulfate and oxalate salts and the mono- and di-acetyl derivatives.

Upon repeating the work of Malkiel and Mason, we obtained a product, m. p. 159–159.5° (uncor.), which was apparently the same as I. It was noted in our work that about 3.8–3.9 moles of hydrogen was consumed per mole of the nitro compound and that the product was much more soluble in water than was expected. Moreover, this product gives instantly a copious precipitate with aqueous silver nitrate. It was suspected that one of the chlorine atoms had been removed by hydrogenolysis, forming 1,1-dichloro-3-aminopropanol-2 hydrochloride (IV), which would give nearly the same nitrogen analysis as III. We have prepared the free amine and the N-benzoyl and O,N-dibenzoyl derivatives from this product, all of which give the correct analysis for the dichloro compound. As further confirmation of its structure, IV has also been synthesized as represented by the following equations.

$$Cl_2CHCH(OC_2H_5)_2 \longrightarrow Cl_2CHCHO$$

$$\downarrow CH_3NO_2$$

$$Cl_2CHCOHCH_2NH_2.HCl \longleftarrow Cl_2CHCHOHCH_2NO_2$$

The mixed melting point of this latter product with that from the catalytic hydrogenation of II is not depressed. From this evidence, it is thought that the compound reported by Malkiel and Mason was IV and not III.

Chattaway and Witherington prepared III by the reduction of II with tin and hydrochloric acid but they did not report the yield. A similar re-

(6) Chattaway and Witherington, *J. Chem. Soc.*, **137**, 1623 (1935).

duction by us gave a poor yield. We have synthesized III in good yield, using stannous chloride and hydrochloric acid, and prepared several of its derivatives.

Malkiel and Mason describe the preparation of a benzoyl derivative, m. p. 167.4°, from their crude reduction mixture. It is confusing to note that this melting point is different from that of the mono- or di-benzoyl derivatives of either the dichloro- or trichloro-compound prepared in our work. The product obtained by us upon benzoylating the crude hydrogenation mixture, in the same manner[7] as they, was N-benzoyl-1,1-dichloro-3-aminopropanol.

Experimentation on the synthesis of II[5,8,9,10] by the base-catalyzed condensation of chloral hydrate and nitromethane has culminated in a procedure which gives a high-quality product in 92–98% yield. Attempts to make the benzoyl and *p*-nitrobenzoyl derivatives of II failed.

The N-acyl and O,N-diacyl derivatives of III are easily prepared. However, numerous attempts to synthesize O-acyl 1,1,1-trichloro-3-aminopropanol-2 hydrochloride by acylation of the hydrochloride[11–14] or by the rearrangement of the N-acyl 1,1,1-trichloro-3-aminopropanol-2[12,14] have been unsuccessful.

Pharmacology.—Several of these compounds were tested by Eli Lilly and Company for local anesthetic, pressor, analgesic and chemotherapeutic action and were found to have none.

Experimental

All melting points are uncorrected. Analyses were done by one of us (L. M.).

1,1,1-Trichloro-3-nitropropanol-2.—In a 250-ml. erlenmeyer flask were placed 165.5 g. (1 mole) of chloral hydrate and 73.2 g. (1.2 moles) of nitromethane. After the chloral hydrate had dissolved by warming to 50°, 1.9 g. of anhyd. potassium carbonate was added in portions with vigorous stirring so that the temperature remained at 70–80°, cooling in ice as necessary. The stirring was continued until the mixture had cooled to room temperature. Then, the product was washed three times with 50-ml. portions of water. The combined water washes were extracted with ether and the ether added to the main portion of the product. After the solvent had been removed under reduced pressure with warming on the steam-bath, the residue was distilled through a 15-cm. Vigreux column. The colorless fraction, boiling at 105.5–106.5° at 3.5 mm., amounted to 204.3 g. (98%). Upon standing, it gradually solidified, m. p. 44–46°.

1,1-Dichloro-3-aminopropanol-2 Hydrochloride (from 1,1,1-Trichloro-3-nitropropanol-2).—A mixture of 10.4 g. (0.05 mole) of 1,1,1-trichloro-3-nitropropanol-2, 75 ml. of ethanol and about 6 g. of Raney nickel was hydrogenated in the Adams machine, using an initial pressure of 50 p.s.i. In thirty-five minutes, a pressure drop corresponding to 0.190 mole of hydrogen was observed. The catalyst was filtered off and the filtrate evaporated to a small volume. The solid, obtained upon the addition of ethyl acetate and cooling, was recrystallized from ethanol and washed with ether, yielding 3.1 g. (34.7%) of white product, m. p. 159–159.5°.

Anal. Calcd. for $C_3H_7ONCl_2 \cdot HCl$: N, 7.75. Found: N, 7.49.

In another experiment, in which 3.9 moles of hydrogen was consumed per mole of compound, an aliquot of the reduced mixture was treated with an excess of silver nitrate solution. The amount of precipitated silver chloride indicated 1.19 equivalents of chloride ion per mole of compound reduced.

1,1-Dichloro-3-aminopropanol-2.—A small sample of the hydrochloride described in the previous section was recrystallized from butanol-1. This material, m. p. 162–163°, was dissolved in abs. alcohol and an excess of dry ammonia was added. Addition of anhyd. ether caused the precipitation of ammonium chloride, which was removed by filtration. The filtrate was evaporated to dryness at room temperature under reduced pressure. The residue was extracted with anhyd. ether and this solution evaporated to a small volume. After cooling in the refrigerator, the white crystalline product, m. p. 57–58°, was filtered off. It was somewhat hygroscopic and began to turn yellow in a few days.

Anal. Calcd. for $C_3H_7ONCl_2$: N, 9.69. Found: N, 9.49.

A sample of this amine was dissolved in anhyd. ether and dry hydrogen chloride was added. The resulting precipitate melted at 162–163° and gave no depression of the mixed melting point with the original hydrochloride, proving that there were no deep-seated changes in the compound.

1,1-Dichloro-3-aminopropanol-2 Hydrochloride (from Dichloroacetaldehyde).—To a mixture of 12.7 g. (0.112 mole) of dichloroacetaldehyde[15] (obtained from dichloroacetal[16]), 2.03 g. (0.112 mole) of water and 8.25 g. (0.135 mole) of nitromethane was added 0.22 g. of anhydrous potassium carbonate in portions. After an initial exothermic reaction, the temperature was kept at 80° for a few minutes. The cool reaction mixture was washed twice with small portions of water. The aqueous portions were extracted with ether and the combined organic materials were dried for a few seconds over anhyd. sodium carbonate and distilled. The portion (6.13 g.) boiling at 103–107° at 5 mm. was added to a solution of 47.6 g. of stannous chloride (hydrated) in 33 ml. of concd. hydrochloric acid. The reaction mixture was heated to 90°, at which temperature it darkened considerably. It was evaporated to dryness at 60° under reduced pressure and the residue was dissolved in water. The tin was removed by adding ammonium hydroxide and hydrogen sulfide and filtering. The solid residue, obtained upon evaporating the filtrate to dryness, was extracted thoroughly with boiling butanol-1. After evaporation to one-fourth volume and cooling, a crude product was obtained. One crystallization from butanol-1 yielded 0.24 g. of pure white product, m. p. 161–162°. The melting point of this product with that from the hydrogenation of 1,1,1-trichloro-3-nitropropanol-2 was 161–162°.

N-Benzoyl-1,1-dichloro-3-aminopropanol-2.—The reaction mixture from a hydrogenation identical to that described previously was evaporated to dryness under reduced pressure. The residue was mixed with a little water and 10 ml. of benzoyl chloride; then, with continuous stirring and cooling as necessary, 75 ml. of 10% sodium hydroxide was added in 20-ml. portions. After cooling and filtering, the solid was thoroughly extracted with warm ethyl acetate. The crude product, precipitated by adding petroleum ether, was crystallized twice from ethyl acetate–

petroleum ether, yielding 2.3 g. of white product, m. p. 131.3–132.5°.

Anal. Calcd. for $C_{10}H_{11}O_2NCl_2$: N, 5.67. Found: N, 5.87.

O,N-Dibenzoyl-1,1-dichloro-3-aminopropanol-2.—To 0.694 g. (0.0038 mole) of 1,1-dichloro-3-aminopropanol-2 hydrochloride suspended in 8 ml. of dry benzene was added, with cooling and stirring, 1.40 g. (0.0138 mole) of triethylamine; then, 1.94 g. (0.0138 mole) of benzoyl chloride, keeping the temperature below 30°. After the addition of the benzoyl chloride, the mixture was warmed to 40–45° for one hour. Filtration of the warm reaction mixture and addition of petroleum ether to the filtrate gave an oil, which upon two crystallizations from ethanol–water afforded 0.211 g. of white solid, m. p. 87–88°. The filtrates yielded 0.6 g. more of slightly less pure product.

Anal. Calcd. for $C_{17}H_{15}O_3NCl_2$: N, 3.95. Found: N, 3.75.

Treatment of the N-benzoyl-1,1-dichloro-3-aminopropanol-2, obtained from the crude hydrogenation mixture, in a similar manner gave the same product, m. p. 87–88° (mixed m. p. 87–88°).

1,1,1-Trichloro-3-aminopropanol-2.—In an erlenmeyer flask 580 g. (2.57 moles) of stannous chloride (hydrated) was dissolved in 400 ml. of concd. hydrochloric acid. With good stirring, 82.3 g. (0.394 mole) of 1,1,1-trichloro-3-nitropropanol-2 was added in one portion. The temperature rose spontaneously to 106°. When the temperature began to drop, the mixture was heated to boiling (114°) for a few minutes; then allowed to cool slowly. After finally cooling for three hours in an ice-bath, the tin-containing salt was filtered off and air-dried. A solution of this in 800 ml. of water was saturated with hydrogen sulfide and filtered. The filtrate was evaporated to dryness. To a solution of the resultant white solid in 85 ml. of water was added concd. ammonium hydroxide until no more precipitate formed. After cooling in an ice-bath and filtering, there was obtained 48.7 g. (69.4%) of product, m. p. 115.3–116.5°. Sublimation at 2 mm. pressure gave a pure product, m. p. 118–119°.

Anal. Calcd. for $C_3H_6ONCl_3$: N, 7.85. Found: N, 7.66.

In another preparation the tin-containing salt was thoroughly dried and analyzed.

Anal. Calcd. for $C_3H_6ONCl_3 \cdot H_2SnCl_4$: N, 3.28. Found: N, 3.40.

N-Benzoyl-1,1,1-trichloro-3-aminopropanol-2.—To a suspension of 5 g. (0.028 mole) of 1,1,1-trichloro-3-aminopropanol-2 in 50 ml. of benzene was added 3.75 g. (0.037 mole) of triethylamine; then, dropwise with stirring, 4.14 g. (0.029 mole) of benzoyl chloride. When the odor of benzoyl chloride was gone, the cooled reaction mixture was filtered. Thorough washing with water, followed by crystallizing from ethanol–water, yielded 6.65 g. (84%) of product, m. p. 144–144.5°.

Anal. Calcd. for $C_{10}H_{10}O_2NCl_3$: N, 4.96. Found: N, 4.96.

N-*p*-Nitrobenzoyl-1,1,1-trichloro-3-aminopropanol-2.—To a solution of 4.5 g. (0.025 mole) of 1,1,1-trichloro-3-aminopropanol-2 in 15 ml. of pyridine was added 4.6 g. (0.025 mole) of *p*-nitrobenzoyl chloride in small portions with stirring and cooling. After standing overnight, the mixture was warmed gently for thirty minutes, cooled and poured into water. The tan solid was filtered and was crystallized three times from ethanol–water and once from methanol, furnishing 1.6 g. (19.5%) of white solid, m. p. 134–136°.

Anal. Calcd. for $C_{10}H_9O_4N_2Cl_3$: N, 8.54. Found: N, 8.37.

O,N-Di-*p*-nitrobenzoyl-1,1,1-trichloro-3-aminopropanol-2.—To a solution of 4.0 g. (0.0224 mole) of 1,1,1-trichloro-3-aminopropanol-2 in 40 ml. of dry benzene and 4.95 g. (0.049 mole) of triethylamine was added 8.7 g. (0.047 mole) of *p*-nitrobenzoyl chloride in small portions with stirring so that the temperature did not rise above 30°. After standing for two days at room temperature, the mixture was refluxed for thirty minutes, cooled and filtered. The solid was washed thoroughly with water and crystallized twice from acetone–water, affording 6.8 g. (63.9%) of white product, m. p. 207.5–208.5°,

Anal. Calcd. for $C_{17}H_{12}O_6N_3Cl_3$: N, 8.81. Found: N, 8.70.

N-Phenylacetyl-1,1,1-trichloro-3-aminopropanol-2.—Handling 3.7 g. (0.0208 mole) of 1,1,1-trichloro-3-aminopropanol-2, 7.0 ml. (0.05 mole) of triethylamine and 5.6 ml. (0.042 mole) of phenylacetyl chloride by the same procedure as the preceding experiment yielded a product which sintered at 120° and melted at 129°.

Anal. Calcd. for $C_{11}H_{12}O_2NCl_3$: N, 4.74. Found: N, 4.86.

O,N-Di-diphenylacetyl-1,1,1-trichloro-3-aminopropanol-2.—This compound was made in the same manner as the preceding one from 1.78 g. (0.01 mole) of 1,1,1-trichloro-3-aminopropanol-2, 3 ml. of triethylamine and 4.9 g. (0.021 mole) of diphenylacetyl chloride. After one crystallization from ethanol, there was obtained 4.3 g. (77%) of white product, m. p. 142–143°.

Anal. Calcd. for $C_{31}H_{26}O_3NCl_3$: N, 2.47. Found: N, 2.32.

N-Benzenesulfonyl-1,1,1-trichloro-3-aminopropanol-2.—To a suspension of 3.56 g. (0.02 mole) of 1,1,1-trichloro-3-aminopropanol-2 in 15 ml. of water was added 7.77 g. (0.044 mole) of benzenesulfonyl chloride and 24 ml. of 10% aqueous sodium hydroxide in small portions alternately with stirring so that the temperature did not rise above 30° and the mixture was at no time strongly basic. When the odor of the benzenesulfonyl chloride was almost gone, the product was filtered, washed with water and crystallized from ethanol–water, yielding 3.7 g. (58%) with m. p. 162–163°.

Anal. Calcd. for $C_9H_{10}O_3NSCl_3$: N, 4.41. Found: N, 4.52.

Summary

Evidence for the identity of 1,1-dichloro-3-aminopropanol-2 hydrochloride was presented.

The synthesis of 1,1,1-trichloro-3-aminopropanol-2 and several of its derivatives were described.

GREENCASTLE, INDIANA RECEIVED DECEMBER 21, 1948

[CONTRIBUTION FROM THE DEPARTMENT OF CHEMISTRY, DUQUESNE UNIVERSITY]

A Synthesis of S-Benzyl-*dl*-cysteine

BY OSCAR GAWRON AND ANDREW J. GLAID, III

Wood and du Vigneaud[1] previously have synthesized S-benzyl-*dl*-cysteine from benzylthiolmethyl chloride and sodiophthalimidomalonic ester and subsequently[2] have converted it into *dl*-cystine.

In view of the use of S-benzyl-*dl*-cysteine as an intermediate in the preparation of *dl*-cystine and continued interest[3] in the synthesis of *dl*-cystine, we have synthesized S-benzyl-*dl*-cysteine from benzylmercaptoacetaldehyde by a modified Strecker synthesis.

Benzylmercaptoacetaldehyde has previously been found by Herbst[4] among the products of a reaction between S-benzyl-*l*-cysteine and pyruvic acid and was characterized by several derivatives. Fromm and Landmann[5] mention it as one of the decomposition products obtained when 1,2-dibenzylmercaptoethylene is treated with sulfuric and acetic acids. For our purpose, we have synthesized benzylmercaptoacetaldehyde by treating the sodium salt of benzylmercaptan with the dimethyl acetal of bromoacetaldehyde and hydrolyzing the obtained dimethyl acetal of benzylmercaptoacetaldehyde.

Treatment of benzylmercaptoacetaldehyde with sodium bisulfite and sodium cyanide yielded β-benzylmercapto-α-hydroxypropionitrile and this on treatment with gaseous ammonia at 100° was converted to β-benzylmercapto-α-aminopropionitrile. Hydrolysis of the latter with hydrochloric acid, followed by neutralization, yielded S-benzyl-*dl*-cysteine.

Application of the Bücherer hydantoin synthesis to benzylmercaptoacetaldehyde yielded 5-benzylmercaptomethylhydantoin. Preliminary attempts at hydrolysis of this hydantoin resulted in decomposition without yielding S-benzyl-*dl* cysteine and so no further attempts were made at obtaining S-benzyl-*dl*-cysteine by this method.

Experimental

Benzylmercaptoacetaldehyde Dimethyl Acetal.—Under reflux, 23 g. (1 gram-atom) of sodium was added slowly to 500 ml. of absolute ethanol. After solution of the sodium, 124 g. (1 mole) of benzyl mercaptan[6] was slowly added with stirring. The reaction mixture was then cooled and to it, with stirring, 169 g. (1 mole) of the dimethyl acetal of bromoacetaldehyde[7] was added over a period of ten minutes. The reaction mixture was then heated gently, the reaction proceeding vigorously at the start, and then refluxed for three hours. After cooling and filtering free of sodium bromide, 250–300 ml. of alcohol was removed by distillation. The concentrated solution was treated with 500 ml. of water and thoroughly extracted with ether. The combined ether extracts were washed once with water and dried over anhydrous sodium sulfate. After evaporation of the ether, the product was distilled at 140–141° (6 mm.); yield, 148 g. (70%) of a colorless liquid; d^{22}_4 1.0757; $n^{22}D$ 1.5303.

Anal. Calcd. for $C_{11}H_{16}O_2S$: C, 62.28; H, 7.55. Found: C, 62.55; H, 7.72.

Benzylmercaptoacetaldehyde.—One hundred ten grams (0.52 mole) of the dimethylacetal of benzylmercaptoacetaldehyde was heated with 350 ml. of 1 *N* sulfuric acid for one and one-half hours under reflux and with stirring. The reaction mixture was then cooled and extracted with ether. The ether extract was washed once with water and dried over anhydrous sodium sulfate. After evaporation of the ether, the product was distilled at 125.5–127° (6 mm.); yield, 65 g. (75%) of a colorless liquid; d^{22}_4 1.1105; $n^{22}D$ 1.5699.

Anal. Calcd. for $C_9H_{10}OS$: S, 19.28. Found: S, 19.01.

The aldehyde forms a crystalline bisulfite derivative and a crystalline yellow 2,4-dinitrophenylhydrazone, melting at 155–156°.[8] The semicarbazone, prepared in the usual fashion, consists of small white needles, melting at 105–107°.[9]

Anal. Calcd. for $C_{10}H_{13}N_3OS$: C, 53.81; H, 5.82; N, 18.82; S, 14.35. Found: C, 53.88; H, 5.47; N, 18.98; S, 14.26.

β-Benzylmercapto-α-hydroxypropionitrile.—Thirty-five grams (0.21 mole) of the aldehyde was added slowly and with shaking to a solution of 23 g. (0.22 mole) of sodium bisulfite in 75 ml. of water. After shaking for ten minutes, a pasty mass of the bisulfite derivative was obtained. To this was added, portionwise and with shaking, a solution of 11 g. (0.23 mole) of sodium cyanide in 30 ml. of water. Shaking was continued for thirty minutes after addition of the final portion of cyanide solution. The oily cyanohydrin was extracted four times with 75-ml. portions of benzene. The combined benzene extracts were washed once with a small amount of bisulfite solution, dried over anhydrous sodium sulfate and then vacuum concentrated. The crude cyanohydrin was a colorless oil which slowly turned yellow; yield 35.5 g. (86% of theory). No attempt was made at further purification, the crude cyanohydrin being used as such.

β-Benzylmercapto-α-aminopropionitrile.—Essentially the method of Pierson, *et al.*,[10] was used to prepare the aminonitrile. Thirty-five and one-half grams of crude β-benzylmercapto-α-hydroxypropionitrile was placed in a small flask arranged in a distillation setup. The flask was heated to 100° and anhydrous ammonia was bubbled through for one-half hour, the water distilling as formed. After cooling, the reaction mixture was dissolved in 100 ml. of benzene and extracted with 50-ml. portions of 10% hydrochloric acid. The combined extracts were made alkaline with concentrated ammonia and extracted three times with 75-ml. portions of benzene. The benzene extracts were combined and washed once with water, then dried over anhydrous sodium sulfate and concentrated *in vacuo*. The crude aminonitrile (23.0 g., 65%) was a yellowish oil. No attempt was made at further purification.

S-Benzyl-*dl*-cysteine.—Twenty-three grams of the crude aminonitrile was heated, under reflux, at 100° with 100 ml. of concentrated hydrochloric acid for four hours and then the reaction mixture was vacuum concentrated

to 50 ml. To this was added 75 ml. of water and concentrated ammonia to alkalinity, followed by acetic acid to *p*H 4.5. The S-benzyl-*dl*-cysteine was filtered off and partially purified by suspending in 70 ml. of water followed by the addition of sufficient 10% sodium hydroxide to cause solution. The brown solution was filtered free of gummy material and the product was precipitated with acetic acid. Repetition of this treatment followed by a crystallization from water yielded 17 g. (67.5% of theory) of S-benzyl-*dl*-cysteine, melting at 209–211°. Another recrystallization gave material melting at 213–214°, no depression of the melting point with synthetic S-benzyl-*l*-cysteine, melting 213–214°, prepared according to du Vigneaud, *et al.*[11]

Anal. Calcd. for $C_{10}H_{13}NO_2S$: N, 6.64; S, 15.18; neut. equiv., 211. Found: N, 6.64; S, 15.26; neut. equiv.,[12] 213.

5-Benzylmercaptomethylhydantoin.—The procedure used was similar to that of Pierson, *et al.*,[10] for the preparation of 5-(β-methylmercaptoethyl)-hydantoin.

Twenty grams (0.12 mole) of benzylmercaptoacetaldehyde, 57 g. (0.59 mole) of ammonium carbonate, 12.7 g. (0.26 mole) of sodium cyanide and 340 ml. of 50% ethyl alcohol were heated under reflux, and with stirring, at 40–45° for four hours. The reaction mixture was cooled and filtered and the filter cake was washed with a small amount of 95% alcohol. The filtrate and washings were combined and concentrated *in vacuo* to one-half volume. The concentrated solution was heated under reflux to 100° and then 25 ml. of concentrated hydrochloric acid was added. The reaction mixture was allowed to remain at this temperature for ten minutes. It was then cooled and the hydantoin filtered off and recrystallized from hot water to yield 20 g. (70% of theory) of 5-benzylmercaptomethylhydantoin, white needles, m. p. 118–119°.

For purposes of comparison by mixed melting points, the *levo* 5-benzylmercaptomethylhydantoin, melting at 129–130°, was prepared from S-benzyl-*l*-cysteine and was racemized with dilute aqueous sodium hydroxide solution. The *dl*-form prepared in this fashion melted at 118–119° and showed no depression of the melting point on admixture with the hydantoin prepared from benzylmercaptoacetaldehyde.

Preliminary attempts at hydrolysis of 5-benzylmercaptomethylhydantoin with alkali or ammonium sulfide or acid resulted in decomposition without yielding S-benzyl-*dl*-cysteine.

Anal. Calcd. for $C_{11}H_{12}N_2O_2S$: C, 55.90; H, 5.12; N, 11.88; S, 13.58. Found: C, 56.10; H, 4.94; N, 11.87; S, 13.32.

(11) du Vigneaud, Audrieth and Loring, *ibid.*, **52**, 4500 (1930).

(12) The determination was carried out by a modified formol titration. The compound was dissolved in excess standard sodium hydroxide in the presence of formaldehyde and the excess sodium hydroxide was titrated with standard acid.

Summary

Benzylmercaptoacetaldehyde has been synthesized and used as a starting material for the preparation of S-benzyl-*dl*-cysteine by a modified Strecker reaction.

NOTES

Carbonyl-cyanyls of Nickel(0)

BY ANTON B. BURG AND JUNE CHASE DAYTON[1]

The compound $K_4Ni(CN)_4$, discovered by Eastes and Burgess,[2] has been interpreted as an analog of nickel carbonyl, in that the cyanide ion is isoelectronic with carbon monoxide, and could replace it in complex compounds.[3] Such cyanide complexes, having the central atom in oxidation state zero, have been designated as "cyanyls" by Ormont.[4] In a search for chemical reality in this analogy, we have carried on reactions in which cyanide ion displaces carbon monoxide from nickel carbonyl, and others in which carbon monoxide displaces cyanide ion from $K_4Ni(CN)_4$. Under the conditions of the experiments, neither reaction could be brought to completion, and the products appeared to be mixtures of the intermediate compounds $KNiCN(CO)_3$, $K_2Ni(CN)_2(CO)_2$, and possibly $K_3Ni(CN)_3CO$.

Reaction of $Ni(CO)_4$ with KCN.—The first experiments showed that a yellow to orange solid (containing no dark material) is formed with the evolution of carbon monoxide when nickel carbonyl is allowed to react with solid potassium cyanide at ordinary temperatures. The solid product proved to be soluble in methyl cyanide, which then was adopted as the reaction medium. The solubility of potassium cyanide (0.03%) aided the reaction but was too low to interfere with the isolation of the product.

The apparatus employed for the reaction is shown in Fig. 1. Potassium cyanide was placed at A and dried by evacuation of the apparatus. Then methyl cyanide and nickel carbonyl were distilled in from the high-vacuum system with A at −196°, and warmed to room temperature. After three days, the carbon monoxide was removed through a trap at −196°, collected by a Töpler pump and measured. With the methyl cyanide solution at −196°, the lower part of the apparatus was sealed off *in vacuo* at D. Now the solution was melted and decanted into the weighed tubes designated as 1, 2 and 3. Next the solvent and any excess nickel carbonyl were distilled off through a vacuum tube-opener[5] operating at F, with the sample tubes 1, 2 and 3 in ice–salt to avoid decomposition of the solid product. Finally at half-hour intervals, the sample tubes were sealed off at E (leaving a tip suitable for the tube-opener) and the contents subjected to analysis. The sample-weight (usually about 0.3 g.) was determined as the gain in weight of the sealed tube and joint-socket.

The first step of the analysis was decomposition *in vacuo* at 200°, with collection and measurement of carbon

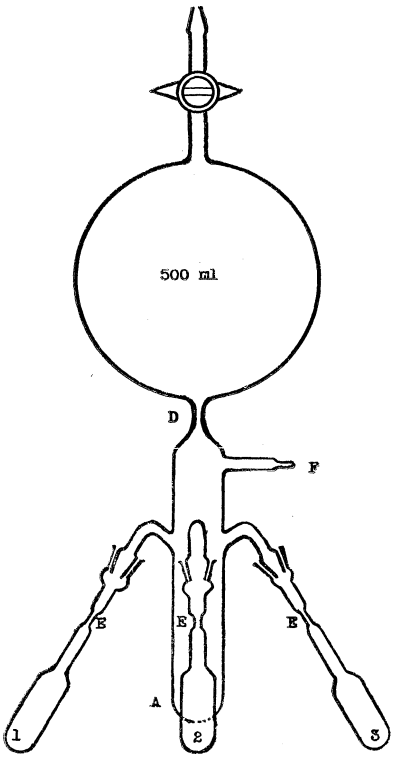

Fig. 1.—Apparatus used for the preparation of carbonyl-cyanyl compounds.

monoxide. Nickel carbonyl (perhaps due to disproportionation of a cyanyl-carbonyl) was condensed in a trap and decomposed on a hot glass surface, with collection and measurement of carbon monoxide. Finally all solids were dissolved in concentrated hydrochloric acid and analyzed for nickel by dimethylglyoxime and potassium by the cobaltinitrite method,[6] using aliquots of the solution.

One result was 43.4% KCN, 25.9% Ni, and 31.3% CO, corresponding perfectly to the formula $(KCN)_3Ni_2(CO)_5$. This could mean equal molar proportions of $K_2Ni(CN)_2(CO)_2$ and $KNiCN(CO)_3$. The average of all the results was: 39.8% KCN, 26.3% Ni, and 35.6% CO, corresponding to $(KCN)_4Ni_3(CO)_8$, or two moles of $KNiCN(CO)_3$ to one of $K_2Ni(CN)_2(CO)_2$. These simple formulas probably are fortuitous since the mixtures seem to vary continuously as indicated by measurements of carbon monoxide evolved in numerous experiments in which the composition of the solute was not determined.

It is also to be noted that in some experiments an insoluble yellow solid was obtained. This was not collected for analysis.

Reaction of $K_4Ni(CN)_4$ with CO.—The displacement of cyanide ion from $K_4Ni(CN)_4$ by the action of carbon monoxide was qualitatively demonstrated as follows. A sample of the salt $K_4Ni(CN)_4$ was prepared by the reaction of $K_6Ni(CN)_4$ with potassium in liquid ammonia.[2] After evaporation of all the ammonia *in vacuo*, methyl cyanide was distilled into the reaction tube, partially dissolving the copper-colored solid. Carbon monoxide now was introduced to a total pressure of 726 mm. During a week, at constant temperature (25°), the pressure fell to 654 mm. and a white precipitate (presumably KCN) appeared. A yellow solid apparently distinct from $K_4Ni(CN)_4$ also was noticed. More carbon monoxide was added and the pressure fell to the same point, 656 mm. Although the question of an established equilibrium was quite uncertain in this and preceding experiments, the fact that carbon monoxide could be either absorbed or evolved depending upon the conditions left no doubt of the reversibility of a series of displacements.

(6) L. V. Wilcox, *Ind. Eng. Chem., Anal. Ed.*, **9**, 137 (1937).

Discussion.—In view of the higher base strength of cyanide ion, it would seem surprising that carbon monoxide is capable of displacing it. The apparent similarity in the strength of bonding to nickel can be understood in terms of the double bonded situation in nickel carbonyl and the argument that the cyanide is chiefly single bonded.

Preparation of Arylethynylcarbinols[1]

BY E. T. CLAPPERTON AND W. S. MACGREGOR

Vanillin, veratraldehyde, 4-ethoxy-3-methoxybenzaldehyde and piperonal were converted to the corresponding arylethynylcarbinols by reaction with sodium acetylide in liquid ammonia.[2,3,4] The yields, Table I, ranged from 77 to 93% only when anhydrous conditions were carefully maintained. Hurd and McPhee[5] found that 0.0032 mole of water in a one-fifth mole reaction of acetone with sodium acetylide reduced the yield of dimethylethynylcarbinol from 86 to 49%. In the reaction of benzaldehyde 0.02 mole of water reduced the yield of phenylethynylcarbinol in a one-half mole reaction to 17.5%. The water in this case caused incomplete reaction and induced side reactions yielding nitrogen-free polymers, benzoic acid and benzyl alcohol.

When sodium acetylide and a nine-fold excess of benzaldehyde reacted in the presence of excess acetylene, 139% of phenylethynylcarbinol (based on sodium) was isolated. The high yield would be expected if the anion of phenylethynylcarbinol and acetylene were in equilibrium with the free carbinol and the acetylide anion as suggested by Campbell, Campbell and Eby.[2]

Acknowledgments.—The authors wish to express their appreciation of a grant from Research Corporation in support of this work.

Experimental

General Procedure.—The procedure used was adapted from those previously described.[2-5] The reactions were run in a 2-liter 3-neck flask fitted with a Hershberg stirrer having a hollow shaft for introducing gases. All outlets were protected from atmospheric moisture by Drierite tubes. Commercial acetylene, passed through water, a calcium chloride tube and a Dry Ice trap, was bubbled through a stirred mixture of one-half mole of sodium and 500 ml. of refrigeration-grade ammonia. After the blue

color was dispelled a solution of 0.5 mole[6] of the aldehyde in anhydrous ether was added dropwise and the mixture stirred six hours. The flow of acetylene was continued throughout the reaction period. Ammonium chloride (0.5 mole) was then added and the ammonia evaporated overnight under nitrogen. The carbinol was separated from the salt with ether and recovered from the washed and dried ether solution in a suitable manner. In the reaction with benzaldehyde the carbinol was recovered by fractional distillation. The crude carbinols from veratraldehyde and 4-ethoxy-3-methoxybenzaldehyde, which were crystalline and only slightly soluble in ether, were separated by filtration and purified by recrystallizing from ethanol. The dried ether solutions from the reactions with piperonal and vanillin were added to petroleum ether to precipitate the carbinols as oils which crystallized. The carbinol from piperonal was purified by distillation and that from vanillin by several recrystallizations from toluene.

The acetyl derivatives were prepared using excess acetic anhydride in pyridine at room temperature and the mercury derivatives were obtained by the procedure of Johnson and McEwen.[7]

(6) In the case of vanillin one-fourth mole was used because one equivalent of sodium acetylide was lost through reaction with the phenolic hydroxyl.

Steric Inhibition of Resonance in Pentachlorostyrene

BY TURNER ALFREY, JR., AND W. H. EBELKE

Ross[1] has recently reported that the ultraviolet absorption spectrum of 2,6-dichlorobenzoic acid shows characteristics which may be attributed to steric inhibition of resonance.

We have studied the copolymerization behavior of pentachlorostyrene, with styrene and with methyl methacrylate. Our results indicate a similar steric effect in pentachlorostyrene. Apparently the two ortho chlorine atoms and the vinyl group are sufficiently large so that the latter is forced out of the plane of the benzene ring, reducing the extent of conjugation and therefore the reactivity of this styrene derivative with free radicals. (Lewis and Mayo[2] have postulated a similar steric inhibition of resonance in esters of maleic acid, to explain the low copolymerization reactivities of maleates as compared with the corresponding fumarates.)

The low reactivity of pentachlorostyrene is apparent from the reactivity ratios and particularly from the low Q value reported below. The Q–e values indicate that the substitution of chlorine atoms in the ring has made the vinyl double bond more positive, as expected, but has *reduced* the average reactivity to about 20% of that of styrene. Since in other ring chlorinated styrenes either a slight increase, or no change, in reactivity is observed, the suggestion of steric inhibition of resonance in pentachlorostyrene seems reasonable. We would expect a similar reduction in copolymerization reactivity in the case of 2,6-dichlorostyrene. Marvel and co-workers[3] have reported copolymerization of 2,6-dichlorostyrene with butadiene at a single monomer ratio; their results are in harmony with this expectation, although the point cannot be definitely established from this single measurement.

Experimental

Pentachlorostyrene, provided by Dr. S. Ross and the Sprague Electric Company, was purified by recrystallization (m. p. 110.5–112°) and was copolymerized to low conversion at 70° with styrene and methyl methacrylate, using benzoyl peroxide as catalyst. Copolymers were precipitated with methanol, and monomers were removed by extraction with ether and repeated precipitation from benzene. Copolymer composition was determined by chlorine analysis, using a Parr Bomb method. Reactivity ratios were evaluated graphically with the aid of the well-known copolymerization equation

$$\frac{d[M_1]}{d[M_2]} = \frac{[M_1]}{[M_2]} \cdot \frac{r_1[M_1] + [M_2]}{r_2[M_2] + [M_1]}$$

Q and e values for pentachlorostyrene were also estimated graphically, using as reference standards the values initially assigned to styrene and methyl methacrylate by Alfrey and Price[4] in their semi-empirical scheme for resolving the copolymeriza-

Heterocyclic Basic Compounds. XII. 7-Bromo- and 7-Iodo-quinolines[1]

BY A. E. CONROY,[2] HARRY S. MOSHER[3] AND FRANK C. WHITMORE[4]

Various workers[5–8] have synthesized N-substituted 4-amino-7-halogen quinolines, certain of which possess considerable antimalarial activity. Outstanding among these is 4-(7-chloro-4-quinolylamino)-2-diethylaminomethylphenol,[9] SN 10,751.[10] The present note describes the synthesis of the 7-bromo- (SN 13,167) and the 7-iodo- (SN 13,168) analogs, which were obtained by coupling, according to Burckhalter, *et al.*,[9] 4-amino-2-diethylaminomethylphenol and the appropriate 4-chloro-7-haloquinoline. The 4-chloro-7-haloquinolines were prepared by the method of Price and Roberts[7] starting with the *m*-haloaniline and ethoxymethylenemalonic ester. The intermediate 4-hydroxy-7-haloquinolines and 4-chloro-7-haloquinolines have also been prepared by Surrey and Hammer[6] by another method. The melting points reported by these authors do not agree in certain cases with those found in this work.

Experimental[11]

3-Carbethoxy-4-hydroxy-7-bromoquinoline.—The intermediate ethyl α-carbethoxy-β-*m*-bromoanilinoacrylate was obtained in 40% yield (45 g.) by allowing a mixture of 50 g. of *m*-bromoaniline[12] and 63 g. of ethoxymethylenemalonic ester[13] to stand overnight. The resulting solid mass was twice recrystallized from a 1:1 solution of ether and ligroin; white needles, m. p. 70–71°. This material, 40 g., was cyclized by refluxing in diphenyl ether according to Price and Roberts.[7] After recrystallization from diphenyl ether, followed by thorough washing with diethyl ether, there was obtained a 44% yield (15 g.) of 3-carbethoxy-4-hydroxy-7-bromoquinoline as a white powder, m. p. 307–309°.

Anal. Calcd. for $C_{12}H_{10}O_3NBr$: C, 48.65; H, 3.38. Found: C, 48.74; H, 3.54.

3-Carbethoxy-4-hydroxy-7-iodoquinoline.—The intermediate ethyl α-carbethoxy-β-*m*-iodoanilinoacrylate was obtained in 43% yield (78 g.) by allowing a mixture of 90 g. of *m*-iodoaniline[12] and 89 g. of ethoxymethylenemalonic ester to stand overnight. The resulting solid mass was recrystallized once from acetone and once from a 1:1 solution of ether and ligroin; white needles, m. p. 92–93°. The product, 70 g., was cyclized and purified as in the above case. There was obtained a 45% yield (28 g.) of 3-carbethoxy-4-hydroxy-7-iodoquinoline as a white powder, m. p. 302–304°.

Anal. Calcd. for $C_{12}H_{10}O_3NI$: C, 42.00; H, 2.92. Found: C, 42.44; H, 3.17.

4-Hydroxy-7-bromoquinoline.—The intermediate 4-hydroxy-7-bromoquinoline-3-carboxylic acid was obtained in 70% yield (8 g.) by the hydrolysis of 13 g. of the 3-carbethoxy-4-hydroxy-7-bromoquinoline with 5% sodium hydroxide solution according to the method of Price and Roberts[7]; light yellow powder, m. p. 266° dec. The decarboxylation of 7 g. of this material was carried out by heating at 300° until the evolution of carbon dioxide ceased. The resulting crystalline cake was recrystallized from 95% ethanol giving 4 g. (68%) of 4-hydroxy-7-bromoquinoline as light tan crystals, m. p. 289–291° (lit.[6] 279–281°).

Anal. Calcd. for C_9H_6ONBr: C, 48.20; H, 2.68. Found: C, 48.01; H, 2.76.

4-Hydroxy-7-iodoquinoline.—The intermediate 4-hydroxy-7-iodoquinoline-3-carboxylic acid was obtained in 66% yield (15 g.) by the hydrolysis of 25 g. of the 3-carbethoxy-4-hydroxy-7-iodoquinoline with 5% sodium hydroxide solution; light grey powder, m. p. 263° dec. The

decarboxylation of 13 g. of this material was carried out by heating at 330° until the evolution of carbon dioxide ceased. The resulting crude 4-hydroxy-7-iodoquinoline was recrystallized from 50% ethanol; 6 g. (54%) of light yellow powder, m. p. 306–308° (lit.[6] 346–348°).

Anal. Calcd. for C_9H_6ONI: C, 39.85; H, 2.22. Found: C, 40.31; H, 2.55.

4-Chloro-7-bromoquinoline.—Three grams of the 4-hydroxy-7-bromoquinoline was converted to 4-chloro-7-bromoquinoline by treatment with phosphorus oxychloride essentially as described by Surrey and Hammer.[6] After recrystallization from 95% ethanol there was obtained a 61% yield (2.0 g.) of the 4-chloro-7-bromoquinoline as white crystals, m. p. 105–106° (lit.[6] 100.5–101.5°).

Anal. Calcd. for C_9H_5NClBr: C, 44.50; H, 2.06. Found: C, 44.76; H, 2.35.

4-Chloro-7-iodoquinoline.—This was obtained in an analogous manner from 4 g. of 4-hydroxy-7-iodoquinoline. Recrystallization from 75% ethanol gave a 35% yield (1.5 g.) of light yellow crystals, m. p. 101–102° (lit.[5] 101°; lit.[6] 95.5–97°).

4-(7-Bromo-4-quinolylamino)-2-diethylaminomethylphenol.—The hydrolysis of 35.4 g. of 2-diethylaminomethyl-4-acetylaminophenol[14] was accomplished by refluxing for two hours with 300 ml. of 6 *N* hydrochloric acid. The *p*H of the solution was adjusted to approximately 3 with 105 ml. of a 40% sodium hydroxide solution. To 250 ml. of this solution was added 22 g. of 4-chloro-7-bromoquinoline and the reaction mixture was refluxed for three and one-half hours according to the method of Burckhalter and co-workers.[8,15] The viscous oil which separated was removed, dissolved in methanol, and reprecipitated by dilution with dilute ammonia solution. The product, after twice recrystallizing from a 1:1 solution of 95% ethanol and acetone, was obtained in 55% yield (20 g.) as a light yellow powder, m. p. 206–208° dec.

Anal. Calcd. for $C_{20}H_{22}ON_3Br$: C, 60.00; H, 5.50. Found: C, 59.96; H, 5.73.

4-(7-Iodo-4-quinolylamino)-2-diethylaminomethylphenol.—This was prepared and purified in a similar manner from 16 g. of 4-chloro-7-iodoquinoline; 49% yield (12 g.), light yellow powder, m. p. 196–198° dec.

Anal. Calcd. for $C_{20}H_{22}ON_3I$: C, 53.70; H, 4.92. Found: C, 54.18; H, 5.16.

N-(Hydroxylethylmethylaminoethyl)-phenothiazine SC 1923: a New Antihistaminic

BY JOHN W. CUSIC

Many derivatives of phenothiazine have recently been made and studied for their anti-histaminic properties.

The 8-chlorotheophyllin salt of N-(dimethylaminoethyl)-phenothiazine was made by the author and tried clinically by Gay and Carliner.[1] Halpern[2] has reported extensively on several phenothiazines and recently N-pyrrolidylethylphenothiazine has been reported by Hunter, *et al.*[3]

Non-exchange of Sulfur between Carbon Disulfide and Hydrogen Sulfide in Benzene Solution

BY DAVID L. DOUGLAS, ROBERT A. COOLEY AND DON M. YOST

The recent communication of Edwards, *et al.*,[1] in which they mention a study of the exchange of $S^{=35}$ in aqueous solution with carbon disulfide as a separate phase, prompts us to report some work done in this laboratory in 1941. We undertook the investigation of the exchange of S^{35} between H_2S^{35} and carbon disulfide in benzene solution. Our experiments, detailed in Table I, showed that no exchange greater than the experimental error (1%) occurs between carbon disulfide and hydrogen sulfide in benzene solution after ninety-five hours at 120°.

TABLE I

THE NON-EXCHANGE BETWEEN CARBON DISULFIDE AND HYDROGEN SULFIDE IN BENZENE SOLUTION[2]

Temp., °C.	Time of exchange, hr.	Concns. of reactants, moles/liter × 10^3 H_2S	CS_2	Observed activity, counts/min. H_2S	CS_2	% exchange, max.
97	1	4.2	108	411 ± 3	0 ± 1	0.3
120	95	4.2	108	178 ± 1	0 ± 2	.8
120	95	4.2	108	181 ± 1	0 ± 1	.3

Experimental.—The source of the active sulfur and the counting technique are described in a previous paper.[3] A CS_2–C_6H_6 solution was made up by weighing out reagent grade carbon disulfide and mixing it with reagent benzene in a volumetric flask. The H_2S^{35}–C_6H_6 solution was prepared and analyzed by standard methods.

In a typical experiment 1 ml. of each of the two solutions were pipetted into a glass bulb of 5–10 ml. capacity. This was immediately immersed in liquid air and sealed off. The bulb was then placed in boiling water or a thermostated oven for a measured period of time. On completion of the run the hydrogen sulfide was trapped in 1 *N* sodium hydroxide and precipitated as silver sulfide. The carbon disulfide in the benzene was separated as potassium xanthate and precipitated as copper xanthate. The

method is described by E. S. Johnson[4] and Harding and Doran.[5] The activities of the precipitates were measured, no account being taken of differences in self absorption or back scattering. Multiplying the total measured activity for a run by the ratio of the equivalents of sulfur in the carbon disulfide to the total equivalents gave the expected activity. The ratio of the activity observed in the copper xanthate to that expected gave the "% exchange."

The Exchange between Br_2^* and $HgBr_2$ in Carbon Disulfide Solution

BY DAVID L. DOUGLAS, ROBERT A. COOLEY AND DON M. YOST

The exchange of bromine atoms between bromine and various inorganic bromides has been previously reported.[1-3] In view of the lack of published quantitative data and because of the general usefulness of the reaction in preparing samples of pure radioactive bromine, we are reporting some work done in this Laboratory in 1941. A study was made of the exchange of Br^{82} atoms between Br_2^* and $HgBr_2$ in carbon disulfide solution. The results of six experiments showed that the exchange is complete within at least two and one-half minutes at somewhat less than 0°. Table I contains the details of the experiments and results.

TABLE I

EXCHANGE OF BROMINE BETWEEN MERCURIC BROMIDE AND BROMINE IN CARBON DISULFIDE AT 0°[4]

245	6.82	1.67	1136 ± 10	274 ± 2	1.00	99 ± 2
266	6.82	1.67	992 ± 8	362 ± 3	0.854	121 ± 2
324	1.34	1.67	82 ± 1	252 ± 6	.406	100 ± 3
290	1.34	1.67	130 ± 1	250 ± 5	.650	100 ± 3
245	6.26	1.67	3066 ± 18	1160 ± 7	.666	96 ± 1
157	6.26	1.67	2863 ± 16	1318 ± 9	.593	102 ± 1

Experimental.—Radioactive bromine was prepared in the usual manner by irradiating *n*-butyl bromide with neutrons from a Rn–Be source. A solution of the active bromine in reagent carbon disulfide was prepared and analyzed by standard methods. The mercuric bromide solution was prepared by weighing out the pure solid into a known volume of carbon disulfide.

The actual exchange reaction and separation were carried out as follows: 5 ml. of the solutions of Br_2^* and $HgBr_2$, cooled to 0°, were pipetted into a 250-ml. distilling flask which was surrounded by an ice-bath. As soon as the solutions were mixed thoroughly the bromine and carbon disulfide were distilled off in a vacuum and collected in a trap at −78°. The time elapsed from the moment of mixing to the completion of the distillation is recorded in column 1 of Table I. Clearly the temperature dropped below 0° during this time; however, no attempt was made to measure this drop.

The bromine was reduced and precipitated as silver bromide. The mercuric bromide residue in the flask was dissolved in nitric acid and the bromine precipitated as silver bromide. The activities of the precipitates were measured by counting techniques. Determination of the fraction of the bromine which was actually trapped was accomplished by analyzing the silver bromide precipitate.

The activities were corrected for time of measurement and background—the short lived activity being allowed to decrease to a negligible value before use. The "% exchange" was calculated thus

$$\%\ \text{exchange} = \frac{\text{Activity from } HgBr_2}{\text{Fraction of } Br_2 \text{ measured}} \times \frac{100}{\text{Mole fraction } Br_2 \text{ in } HgBr_2\text{–}Br_2 \times \text{Sum of activities}}$$

p-Chloro-α-(trichloromethyl)-benzyl Alcohol and a Chlorination Apparatus

BY EDWARD M. FRY

At the time the insecticidal value of 1,1,1-trichloro-2,2-bis-(*p*-chlorophenyl)-ethane became evident very little was known of its toxicology and as part of a program aimed at evaluating these properties a synthesis designed to utilize isotopic carbon at the point of attachment of the two chlorophenyl rings was undertaken. However, rapid and widespread use of DDT soon revealed its low toxicity with respect to humans and the project was discontinued, the synthesis being halted at *p*-chloro-α-(trichloromethyl)-benzyl alcohol. Carbon dioxide containing isotopic carbon was not used in this investigation and as none of the intermediate compounds are new, nor were any new or improved synthetic procedures used, the work is of interest only with respect to the method used with brief mention of experimental conditions. The scheme is as follows

$$ClC_6H_4MgBr \xrightarrow{CO_2} ClC_6H_4COOH \xrightarrow[(2)\ CH_2N_2\ (3)\ HCl]{(1)\ SOCl_2} ClC_6H_4COCH_2Cl$$

90%

$$ClC_6H_4COCH_2Cl \xrightarrow[125°]{Cl_2} ClC_6H_4COCCl_3 \xrightarrow{Al(i\text{-}PrO)_3} ClC_6H_4CHOHCCl_3$$

88% 93% 95% (70% from $BaCO_3$)

Carbon dioxide generated from barium carbonate reacted in a threefold excess of 1 *N* Grignard reagent to give the acid. The acid chloride in benzene solution reacted with cold ethereal diazomethane, then in the cold with dry hydrogen chloride to give *p*,α-dichloroacetophenone. The ketone in an equal volume of trichloroacetic acid on treatment with chlorine for two days at 120–125° gave *p*,α,α,α-tetrachloroacetophenone which, on reduction with a small excess of 3 *N* aluminum isopropoxide in isopropyl alcohol, gave the alcohol.

Chlorobenzoic acid has been prepared in the above manner,[1] and also from the corresponding lithium compound.[2] p,α-Dichloroacetophenone has been made by the action of chlorine on p-chloroacetophenone,[3] and by the action of chloroacetyl chloride on chlorobenzene.[4] p,α,α,α-Tetrachloroacetophenone has been made by the action of chlorine on p,α,α-trichloroacetophenone,[3] and p-chloro-α-(trichloromethyl)-benzyl alcohol by the condensation of chloroform with p-chlorobenzaldehyde.[5] This alcohol was also found to be a constituent of technical DDT.[6]

The apparatus described below was constructed so that the effect of solvent, temperature and light on chlorine reactions could be followed manometrically. Circulation of the gas is required for the removal of hydrogen chloride, and the corrosive action of moist chlorine makes a glass apparatus necessary. Circulation is achieved by means of an aspirator actuated by a stream of carbon tetrachloride–water which also serves to remove hydrogen chloride. The diagram shows the aspirator unit on the left, the reaction flask with a small condenser in the center, and the chlorine reservoir on the right. Movement of chlorine is in a clockwise direction and its absorption is followed by means of a manometer shown at the center hole of the reservoir stopper. The device proved a valuable index to the rate of chlorination under varying conditions and gave an estimate of the amount reacted. Sources of error are diluents such as air and gaseous decomposition products.

Construction and Operation.—Although a single five-gallon bottle is shown as the reservoir, more than one connected in series may be more convenient. The rubber stopper was substantially unaffected after several months in contact with chlorine. Chlorine is appreciably soluble in the carbon tetrachloride–water mixture used in the aspirator unit, and when the aspirator is shut off its pressure must be high enough so that its subsequent absorption by the cooling carbon tetrachloride–water does not result in manometer water being sucked into the reservoir. The manometer is long enough to measure a pressure of about 80 cm. of water. Chlorine should be added only when the aspirator flask is hot. Otherwise expulsion of chlorine from the hot carbon tetrachloride–water might cause such an increase in pressure as to blow the water from the manometer and release chlorine into the room. A drop in atmospheric pressure or a rise in room temperature can have the same effect if the apparatus is operated too closely to the pressure limit of the manometer. Changes of this nature during a run are observed and corrected for by means of a blank manometer (not shown). If dry chlorine is desired, calcium chloride is used to fill the enlarged portion of tubing extending to the bottom of the bottle.

To fill the apparatus, flask A, equipped with an electric heating jacket and containing carbon tetrachloride and water, is heated until its contents begin to boil. Chlorine is then slowly admitted through stopcock E, stopcock D being turned so as to deflect the chlorine into the reservoir and allow the displaced air to escape into the hood. The displacement of air is followed visually and when completed stopcock D is turned to the illustrated position and the pressure in the system brought to the desired level. Stopcocks B and C are for the purpose of isolating the reaction flask so that it can be removed with negligible chlorine loss.

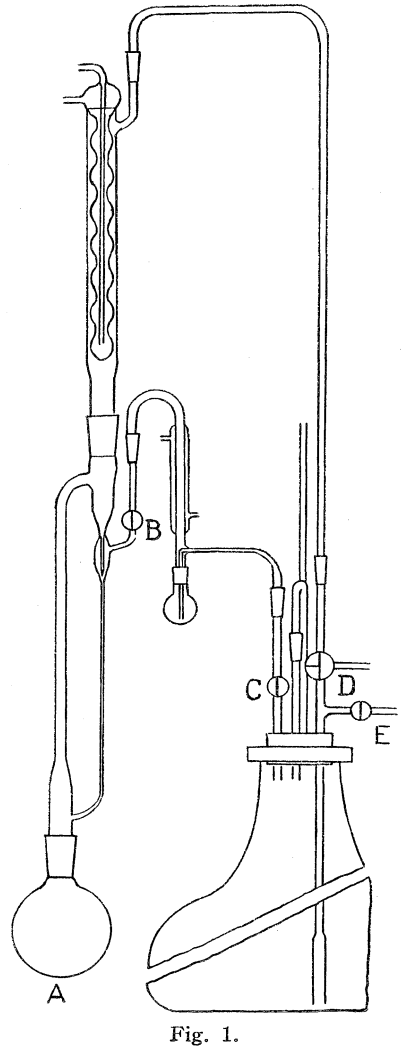

Fig. 1.

The various parts of the apparatus are connected with 24/40, 10/30, and 14/20 joints, lubricated with Dow-Corning silicone grease, and in the two smaller sizes held together with rubber bands secured between hooks (not shown). It is felt that ball-type joints would be more satisfactory than the 10/30 joints in that the apparatus could be allowed to stand unused for longer periods of time without danger of freezing at these relatively fragile junctures. The lubricant is slowly hardened by chlorine. The only construction feature requiring care is that of the aspirator unit. The tube should be symmetrically placed in the throat taper and about 1 mm. in diameter at the tip. Four mm. O. D. tubing was used for both the inner aspirator tube and for the discharge column which was found to operate best at a length of 20 cm., the range for satisfactory operation being between 15 and 25 cm. A rate of from 60–80 bubbles a minute against a head of 5 cm. of water was realized and the efficiency of the aspirator appears to be greatest with a moderate rate of reflux.

The Reaction between Carboxylic Acid Chlorides and Salts of *p*-Toluenesulfinic Acid

BY H. T. HOOKWAY

During the course of an investigation of a series of α-methylene sulfones[1] it was found desirable to attempt the synthesis of α-ketosulfones, and an examination was made of the reaction between carboxylic acid chlorides and salts of *p*-toluenesulfinic acid.

By analogy with the reaction between *p*-toluenesulfonyl chloride and sodium *p*-toluenesulfinate to give an α-disulfone,[2] the reaction between benzoyl chloride and sodium *p*-toluenesulfinate was expected to follow the course shown below

$$C_6H_5COCl + C_7H_7SO_2Na = C_6H_5COSO_2C_7H_7 + NaCl$$

Ethereal solutions of benzoyl and acetyl chlorides respectively were heated under pressure with sodium *p*-toluenesulfinate dihydrate and in both cases the products isolated were the corresponding carboxylic acids and di-*p*-tolyl disulfoxide (shown to be a thiolsulfonate, $C_7H_7SO_2SC_7H_7$[3,4]; no trace of a ketosulfone could be detected.

Since it does not appear possible to dehydrate sodium *p*-toluenesulfinate dihydrate without decomposition, this salt was used in the two experiments described above: presumably the acid chloride was first hydrolyzed to carboxylic acid and hydrochloric acid; the latter then liberated free *p*-toluenesulfinic acid which forms di-*p*-tolyl disulfoxide on heating alone or, more readily in the presence of aqueous acids[5,6]

$$C_7H_7SO_2H + C_7H_7SO_2H + C_7H_7SO_2SC_7H_7$$

p-Nitrobenzoyl chloride was then heated with sodium *p*-toluenesulfinate: it was anticipated that this chloride, containing a strongly electron attractive nitro-group, would be more resistant to hydrolysis under the conditions obtaining in these experiments than either acetyl or benzoyl chlorides. Again, no ketosulfone was obtained, but a small amount of disulfoxide was isolated.

An attempt was made to avoid the use of a hydrated salt by preparing silver *p*-toluenesulfinate. This salt is stated to be anhydrous when obtained by precipitation by addition of silver nitrate to an aqueous solution of the sodium sulfinate.[7] The analysis of the silver salt used in these experiments indicated that it still contained a small amount of water. When the silver salt and benzoyl chloride were heated together in ether, di-*p*-tolyl disulfoxide was obtained.

It is interesting to note Kohler and MacDonald claimed that by heating an ethereal solution of benzoyl chloride with sodium *p*-toluenesulfinate an α-ketosulfone was obtained as an ether soluble oil which readily gave a solid hydrate on trituration with water[2]

$$C_6H_5COCl + C_7H_7SO_2Na \xrightarrow{H_2O} C_6H_5COSO_2C_7H_7 = C_7H_7C(OH)_2SO_2C_7H_7$$

A similar reaction was also stated to take place when other acid chlorides were used, but the properties of the reaction products were not described. It must also be noted that Kohler and MacDonald did not state whether they had prepared and used anhydrous sodium *p*-toluenesulfinate or a hydrated material in their experiments. These authors stated that their products gave crystalline derivatives with typical ketone reagents, such as hydroxylamine and phenylhydrazine. Reaction of di-*p*-tolyl disulfoxide with 2,4-dinitrophenylhydrazine in methanolic sulfuric acid, under conditions such that a ketone gives the corresponding dinitrophenylhydrazone, gave only unchanged disulfoxide. When di-*p*-tolyl disulfoxide was warmed with hydroxylamine in an acetic acid–sodium acetate buffer, however, amongst other products, di-*p*-tolyl disulfide was obtained. A similar breakdown of the disulfoxide was observed with phenylhydrazine in buffered solution: these observations will be the subject of a further communication.

Acknowledgment.—The author wishes to express his indebtedness to Dr. J. Kenyon, F.R.S., for his interest in this work.

Experimental

Reaction between Sodium *p*-Toluenesulfinate and Benzoyl Chloride.—Sodium *p*-toluenesulfinate dihydrate (4.0 g., 0.019 mole) was suspended in ether (10 cc.) in a stout walled glass tube and benzoyl chloride (3.0 g., 0.021 mole) was added. The tube was then sealed and heated at 100° for thirty-six hours. After cooling, the contents of the tube were extracted with sodium carbonate solution (25 cc. of 3 *N*); the residual ethereal solution after drying and evaporation to small bulk gave di-*p*-tolyl disulfoxide; yield, 1.0 g., m. p. 78.5–79° (after three recrystallizations from 96% ethanol). Found: C, 60.6; H, 4.7; S, 22.6. Calcd. for $C_{14}H_{14}O_2S_2$: C, 60.5; H, 5.04; S, 23.0. Mixed m. p. with authentic specimen of di-*p*-tolyldisulfoxide[8] 78.5°. The alkaline extract on acidification gave 2.5 g. of benzoic acid, m. p. 122° (theoretical yield from hydrolysis of benzoyl chloride, 2.6 g.).

Reaction between Sodium *p*-Toluenesulfinate and Acetyl Chloride.—Sodium *p*-toluenesulfinate dihydrate (2.0 g., 0.009 mole) was suspended in ether (10 cc.) in a stout walled glass tube and acetyl chloride (0.84 g., 0.011 mole) was added. The tube was then sealed and heated at 100° for thirty-six hours. The reaction mixture was worked up as described in the previous experiment; yield of di-*p*-tolyl disulfoxide, 0.97 g., m. p. 78.5–79°; mixed m. p. with authentic specimen, 78°.

Reaction between Sodium *p*-Toluenesulfinate and *p*-Nitrobenzoyl Chloride.—Sodium *p*-toluenesulfinate dihydrate (8.0 g., 0.037 mole) was suspended in ether (100 cc.) in a stout-walled glass bottle and *p*-nitrobenzoyl chloride (6.92 g., 0.037 mole) was added. The reaction mixture was heated at 100° for twelve hours and gave 1.57 g. of di-*p*-tolyl disulfoxide, m. p. 78°, on working up.

Reaction between Silver *p*-Toluenesulfinate and Benzoyl Chloride.—Silver *p*-toluenesulfinate was prepared from the sodium salt and silver nitrate by precipitation from aqueous solution. The precipitated silver salt was washed with water and acetone and air dried. Found: Ag, 39.9. Calcd. for $C_7H_7O_2SAg$: Ag, 41. The silver salt (2.00 g., 0.0076 mole) was suspended in ether (20 cc. of sodium dried) in a stout-walled glass tube and benzoyl chloride (1.07 g., 0.0076 mole) was added. The tube was then sealed and heated at 100° for twelve hours. The reaction mixture yielded 0.2 g. of di-*p*-tolyl disulfoxide, m. p. 78°. All m. p.'s are uncorrected. Kohler and MacDonald quote 80° as m. p. for the keto-hydrate $C_{14}H_{14}O_4S$.

The Influence of Substituents on the Ultraviolet Absorption Spectrum of Styrene

BY Y. HIRSCHBERG

In view of the recent paper by Murray and Gallaway,[1] the following measurements on the spectra of some substituted (ortho-, alpha- and beta-positions) styrenes may be recorded (alcohol as solvent).

Hydrocarbon	Max., Å.	Log ε	Max., Å.	Log ε	Max., Å.	Log ε	Max., Å.	Log ε
Styrene	2910	2.77	2820	2.88	2730	2.88	2440	4.23
β-Methylstyrene[a,b]	2930	2.84	2840	2.99			2460	4.25
α-Methylstyrene[a]							2435	3.96
α,β-Dimethylstyrene							2440	3.94
o-Methylstyrene[c]	2980	2.03					2460	3.36
o,α-Dimethylstyrene[d,e]	No maximum between 2100–3000 Å.							

[a] Ramart-Lucas and Amagat, *Bull. soc. chim.*, [4] **51**, 108 (1932); [5] **1**, 719 (1934). [b] Hillmer and Schorning, *Z. physik. Chem.*, **A167**, 407 (1934). [c] Ramart-Lucas and Hoch, *Bull. soc. chim.*, [5] **2**, 327 (1935). [d] Ref. (1). [e] Ramart-Lucas and Hoch, *Bull. soc. chim.*, [5] 5, 848 (1938). [f] Campbell and co-workers, THIS JOURNAL, **69**, 880 (1947).

Introduction of a methyl group into the β-position of styrene has very little influence on the resonating system, whilst α-substitution, and to a minor degree *o*-substitution,[f] destroys the resonance. This is particularly clear for the *o*,α-dimethylstyrene for which no absorption maximum at all has been observed. It is reasonable to assume that the phenyl group is crowded out of the plane of the exocyclic double bond, and the monoplanarity required is thus destroyed.[2]

Materials

α-Methylstyrene was prepared according to Staudinger and Breusch,[3] the β-isomer from ethylphenylcarbinol with acetic anhydride, according to Spaeth and Koller.[4] For the synthesis of α,β-dimethylstyrene,[5] acetophenone was converted by reaction with ethylmagnesium bromide into phenylmethylethylcarbinol and the crude product dehydrated with boiling acetic anhydride: b. p. 107–109° (21 mm.); yield 75.5%. *o*-Methylstyrene was obtained by reaction of *o*-tolylmagnesium bromide with acetaldehyde and adding the carbinol obtained (b. p. 120–130° (29 mm.)) dropwise to molten potassium hydrogen sulfate, containing 1% of hydroquinone, at a bath temperature of 200° and in a vacuum of 100 mm.[6] The product which distilled off immediately, was fractionated, b. p. 75–78° (21 mm.).[7] Analogous reaction of *o*-tolylmagnesium bromide with *acetone* gave *o*-tolyldimethylcarbinol, b. p. 120–122° (25 mm.) and dehydration of the latter with boiling acetic anhydride, *o*,α-dimethylstyrene, b. p. 83–85° (25 mm.) in 70% yield.[8]

The Behavior of 1-Naphthyl Tetraacetyl-β-D-glucoside toward Diazotized *p*-Nitroaniline

BY CHARLES D. HURD AND WILLIAM A. BONNER

This note describes attempts to couple 1-naphthyl tetraacetyl-β-D-glucopyranoside (I) with diazo compounds. The ease of coupling should compare with that of 1-methoxynaphthalene.

Meyer and Lenhardt[1] record difficulty in coupling diazotized *p*-nitroaniline with anisole but claim that 4-(*p*-nitrophenylazo)-1-methoxynaphthalene, m. p. 169°, is formed on coupling with 1-methoxynaphthalene.

Attempts to couple (I) with aqueous solutions of diazotized *p*-nitroaniline led to difficulties caused by the insolubility of the acetylated glucoside. When a solution of *p*-nitrobenzenediazonium sulfate was prepared in glacial acetic acid after the manner of Hodgson and Walker[2] and mixed with a solution of the acetylated glucoside in acetic acid, a slight color developed. In the course of several days, however, this mixture assumed the intense purple coloration characteristic of control experiments with 1-methoxynaphthalene. The only product found was 4-(*p*-nitrophenylazo)-1-naphthol in 22% yield, showing cleavage as well as coupling. About half of the starting glucoside was recovered. It has frequently been observed[3] that phenolic ethers couple with partial or complete dealkylation.

In view of this result we studied 1-methoxynaphthalene under approximately identical con-

(1) Meyer and Lenhardt, *Ann.*, **398**, 78 (1913).

(2) Hodgson and Walker, *J. Chem. Soc.*, 1620 (1933).

(3) K. H. Saunders, "The Aromatic Diazo Compounds," Edward Arnold and Co., London, 1936, p. 112.

ditions. Here too, coupling took place with substantial cleavage of the ether. We were also unable to duplicate the results of Meyer and Lenhardt[1] using their 50% aqueous acetic acid solution. Coupling again was accompanied by demethylation, an observation which is in line with that of Jambuserwala and Mason[4] who found that 2-methoxy-3-naphthoic acid coupled with diazotized *p*-nitroaniline with complete removal of methoxyl.

Since the above coupling was conducted under strongly acid conditions, it seemed advisable to duplicate the process under conditions whereby the acidity of the sulfuric acid was neutralized by sodium acetate. When the acetic acid solution of *p*-nitrobenzenediazonium sulfate and (I) stood in contact with sodium acetate for several days, a red product was obtained on dilution with water. This was separated by adsorption methods into an amber glass, a red solid, and 1,3-bis-*p*-nitrophenyltriazene. The first two substances were not characterized. While the evidence here neither indicated nor precluded complete cleavage, it is pertinent to note that 1-methoxynaphthalene coupled with cleavage under these same buffered conditions.

Experimental

Coupling of 1-Naphthyl Tetraacetyl-β-D-glucopyranoside with Diazotized *p*-Nitroaniline.—Finely powdered sodium nitrite (1.7 g.) was added to 12 ml. of cold sulfuric acid. The mixture, warmed to about 70°, was stirred until completely dissolved, then was cooled to 20°. *p*-Nitroaniline (3 g.) was dissolved in hot acetic acid (36 ml.), and the mixture was cooled rapidly to room temperature. This solution was added slowly with stirring to the first solution.

One gram of 1-naphthyl tetraacetyl-β-D-glucopyranoside was dissolved in 20 g. of acetic acid. Into this mixture (at 20°) was added 15 ml. of the above diazonium solution. A pink coloration appeared. After standing for forty hours, the solution became intensely purple. On pouring into water (300 ml.), an orange solid resulted which rapidly became gummy. Extraction with ether (300 ml.) dissolved the gum but left a small amount of red solid which was filtered. The ether extract was washed with water and evaporated. The residue was redissolved in ether, and again a small amount of red solid remained undissolved. It was separated and combined with that above. The ether extract was dried over anhydrous sodium sulfate, filtered, and evaporated. There resulted 0.78 g. of reddish solid. This was recrystallized from 2-propanol to yield about 0.5 g. of the starting glucoside in slightly impure condition; m. p. 172–175°, mixed m. p. 175–177°.

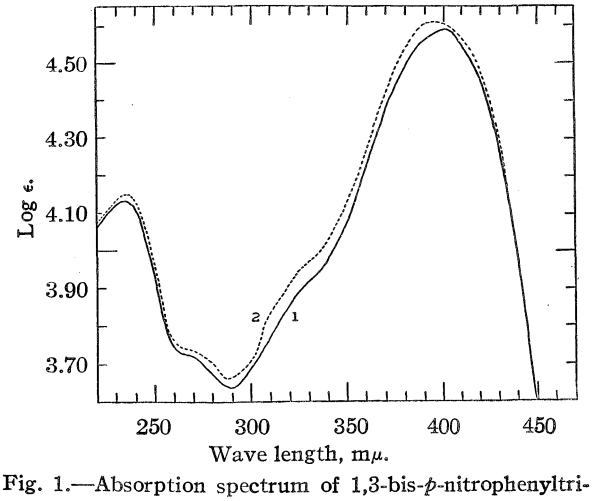

Fig. 1.—Absorption spectrum of 1,3-bis-*p*-nitrophenyltriazene: 1, known sample; 2, suspected sample.

The ether-insoluble red solids weighed 0.13 g. They were triturated with ether, air-dried, and found to melt at 275–278°. A mixed melting point of this material with 4-(*p*-nitrophenylazo)-1-naphthol (m. p. 284–285° (cor.)) gave the value 278–280°.

Attempts to couple 1-naphthyl tetraacetyl-β-D-glucoside with diazotized aniline or *p*-aminobenzoic acid under conditions comparable to those above led only to the isolation of starting material.

Several attempts were made to conduct the above coupling under well-buffered conditions. In a typical experiment 1-naphthyl tetraacetyl-β-D-glucoside (1.0 g.) in acetic acid (20 ml.) was treated with one-third (15 ml.) of the acetic acid solution of *p*-nitrobenzenediazonium sulfate prepared as described above. Anhydrous sodium acetate (12.3 g.) was added, the mixture shaken to an emulsion and permitted to stand for four days. The original yellow color became deep red, once the mixture was poured into water. The crude red solid was collected on a filter, suspended in water, collected again, and dried over phosphoric anhydride; yield, 1.80 g. Half a gram of this was dissolved in ethyl acetate (10 ml.) and ether (30 ml.). The red solution was filtered, and the filtrate was introduced into a column of alumina wet with ether. The absorbed band was developed with ether, but only a very thin orange band separated; this was not investigated. The effluent was evaporated to yield 0.19 g. of a reddish, amber glass, $[\alpha]^{25}D$ −48.5° (*c*, 1.90; chloroform). Attempts were made to crystallize this from 2-propanol, but only gummy crystals resulted. The main adsorbed band was extracted from the adsorbent in a Soxhlet thimble with ethyl acetate. Removal of the solvent left 0.22 g. of red solid. This was digested with methanol and filtered, leaving a gray-brown solid, m. p. 225–230° (dec.).

About 0.8 g. of the crude yield was digested twice with a total of 55 ml. of hot methanol, leaving 0.15 g. of orange solid, m. p. 228–229° (dec.). This was recrystallized from a mixture of acetone and water to give a yellow-gray solid, m. p. 229.5–230° (dec.). This was proven by melting point, mixed melting point, absorption spectrum (Fig. 1) and analysis to be 1,3-bis-*p*-nitrophenyltriazene.

Anal. Calcd. for $C_{12}H_9N_5O_4$: C, 50.2; H, 3.16; N, 24.4. Found: C, 49.62; H, 3.25; N, 24.56.

Coupling of 1-Methoxynaphthalene with Diazotized *p*-Nitroaniline.—1-Methoxynaphthalene (1 ml.) was dissolved in acetic acid (5 ml.) and sodium acetate (*ca.* 0.5 g.) was added. About 5 ml. of the non-aqueous diazo solution described above was added giving an immediate intense purple coloration. The homogeneous mixture was poured into water (100 ml.). A red product precipitated, which was collected on a filter and washed. A portion of the product was separated by means of its relative insolubility in hot ethanol. It was impure 4-(*p*-nitrophenylazo)-1-naphthol, m. p. 272–280°. The alcohol solution deposited solid on standing, m. p. around 120–125°. This was possibly a mixture of the previous high-melting solid plus the more soluble 4-(*p*-nitrophenylazo)-1-methoxynaphthalene of m. p. 169°.

The directions of Meyer and Lenhardt[5] for preparing *p*-nitrophenylazo-1-methoxynaphthalene are not specific, but it is stated that the coupling is carried out in 50% acetic acid. We attempted to duplicate these conditions by dissolving 1-methoxynaphthalene (1 ml.) in acetic acid (4 ml.) containing water (1 ml.) and adding this solution to a portion of the above diazo solution (3 ml.) diluted with water (13 ml.). A red solid formed instantly.

(4) Jambuserwala and Mason, *J. Soc. Dyers Colourists*, **46**, 339 (1930).

This proved quite insoluble in ethanol and was treated as above. The recrystallized portion melted at 277–282°, and the alcohol-insoluble portion had an indistinct m. p. above 280°.

In an attempt to encourage coupling without cleavage by buffering, 1-methoxynaphthalene (2 ml.) was treated with a mixture of 15 ml. of the non-aqueous diazo solution, 15 ml. of acetic acid, and 12.3 g. of anhydrous sodium acetate. After addition of more acetic acid (15 ml.), the red-black mixture was shaken thoroughly and poured into water. The red solid was filtered, rinsed, and washed by suspension in methanol and refiltration. The insoluble portion, when dry, melted at 275–280°.

1,3-bis-*p*-Nitrophenyltriazene.—The procedure used in this preparation was a modification of that of Meldola and Streatfield.[5] *p*-Nitroaniline (2.76 g., 0.02 mole) was dissolved with heating in concd. hydrochloric acid (50 ml.). The solution was cooled and a solution of sodium nitrite (0.69 g., 0.01 mole) in water (5 ml.) was slowly added dropwise with stirring. Water (20 ml.) was added to the mixture, which then stood for nineteen hours. The clear yellow solution was thrown into excess water, and on standing fine yellow needles formed. These were filtered and dried *in vacuo;* yield, 0.70 g., m. p. 224–228° (dec.). The mother liquors deposited a second crop, weight 0.05 g., m. p. 228–230° (dec.).

In order to establish without doubt the identity of this material and the product from the previous buffered coupling reaction involving the 1-naphthyl tetraacetyl-β-D-glucoside, absorption spectra of both samples were measured and found identical (Fig. 1). Solutions 10^{-3} molar in each sample were made for the measurements. In taking the readings, it soon became apparent that Beer's law was failing to apply. Thus at 440 mμ the 10^{-3} molar solution of each sample had a density reading on the Beckman Model DU Spectrophotometer of 1.84. A 10^{-4} molar solution at the same wave length had a density of 0.860 instead of 0.184. Similarly, at 410 mμ the density of the 10^{-4} molar solution was 1.800, while that of a 10^{-5} molar solution was 0.360. As the wave length region between 445 and 400 mμ was crossed, the density readings for 10^{-3} molar and 10^{-4} molar solutions approached constant values within the range of the spectrophotometer scale, and it was necessary to use 10^{-5} molar solutions in order to cover the lower visible and ultraviolet spectrum. These effects were observed on two different spectrophotometers. They are probably attributable to the ionization of dinitrodiazoaminobenzene in alcoholic solution, and are currently under more extensive study.

The Dissociation of Lead Chloride in Ethylene Glycol–Water Mixtures

BY J. C. JAMES

Norman and Garrett[1] have recently reported measurements of the conductance of lead chloride solutions at 25° in ethylene glycol–water mixtures, and conclude that activity and conductance data for such solutions show deviations from the Debye–Hückel and Onsager theories which cannot be accounted for by the assumption of incomplete dissociation. Discrepancies between theoretical and experimental values were attributed to differences between the macro and micro dielectric constants of the solutions, and "effective micro-dielectric constants" were calculated by comparison of experimental slopes with those predicted by the Debye–Hückel and Onsager theories.

These conclusions are surprising, as in aqueous solution previous workers[2–4] have assumed that the intermediate ion $PbCl^+$ was present, and have derived dissociation constants of the order of 0.02–0.03 from activity and conductance data; also, Fromherz and Kun-Hou Lih[5] have shown that the ultraviolet absorption spectra indicated presence of this ion. Similarly, conductance data for the salts zinc malonate, zinc sulfate and lanthanum ferricyanide in glycol–water mixtures have been accounted for satisfactorily by assuming dissociation to be incomplete.[6]

Norman and Garrett[1] have rejected this treatment on the grounds that as curves for the plots of both Λ *vs.* $\sqrt{m}$ and γ *vs.* $\sqrt{m}$ were straight in the lower concentration regions, a constant degree of dissociation would result in any solvent. Such behavior, however, does not necessarily imply complete dissociation, as the effect of actual variation in α may be cancelled out almost completely by the effect of higher terms neglected in the limiting Debye–Hückel and Onsager equations. Thus it has been shown by Davies[7] that dissociation is not complete in calcium mandelate solutions, although the Λ *vs.* $\sqrt{m}$ plot is linear up to $m = 0.02$, far beyond the limits of Onsager's equation. It is shown in this Note that the data of Norman and Garrett can be given an alternative explanation on the assumption that the intermediate ion $PbCl^+$ is formed in solution by the process $Pb^{++} + Cl^- \rightleftarrows PbCl^+$, further association to give the neutral salt being negligible.

Activity Data.—Dissociation constants for lead chloride in water at 25° have been calculated from the activity data of Carmody[8] using the method described by Davies,[9] and are given in Table I, γ being the stoichiometric activity coefficient, and f the true mean ionic activity coefficient. Dissociation constants in glycol–water mixtures have been calculated by the same method from the activity data of Garrett, Bryant and Kiefer,[10] up to concentrations of 0.006 N and are summarized in Table III. Mean ionic activity coefficients have been obtained from the empirical equation

$$-\log f = S\left[\frac{\sqrt{\mu}}{1+\sqrt{\mu}} - 0.20\,\mu\right]$$

where S is the limiting Debye–Hückel slope;

this equation fits the data of Knight, Masi and Roesel[11] for the activity of hydrogen chloride in glycol–water mixtures to $\mu = 0.02$ with a maximum deviation of 2%, and is sufficiently accurate for the purpose. Molal quantities have been converted to molar quantities, assuming the densities of the solutions to be equal to those of the pure solvent mixtures.

TABLE I

$m \times 10^4$ (molality)	γ	f	K
3.3333	0.912	0.966	(0.016)
10.000	.847	.926	.019
20.000	.791	.888	.022
26.666	.764	.869	.023
33.333	.740	.850	.024
100.00	.604	.729	.025
200.00	.505	.619	.025
266.66	.464	.568	.024
308.67	.443	.542	.023

Conductance Data.—Dissociation constants have been calculated in water from the data of Norman and Garrett,[1] by the method of Righellato and Davies,[2] evaluating mobility terms from the empirical equations

$$[\Lambda\ (Pb^{++}) + \Lambda\ (Cl')] = \Lambda_0 - bf_{2-1}\ (\mu)$$

and

$$[\Lambda\ (PbCl^{+}) + \Lambda\ (Cl')] = \Lambda' - b'f_{1-1}\ (\mu)$$

where b, b' are the respective Onsager slopes. For $f_{1-1}(\mu)$ values have been given by Robinson and Davies,[12] and for $f_{2-1}(\mu)$ values were calculated from the data of Shedlovsky and Brown[13] for calcium and magnesium chlorides, which have been assumed to be completely ionized. The mobility of the intermediate ion $PbCl^+$ at zero concentration has been estimated as 45 at 25°, from the value used by Righellato and Davies[2] at 18°. Values for the ionization constant K were derived from the equation

$$\log K = \log \frac{\alpha(1+\alpha)}{(1-\alpha)} m - 2\left[\frac{\sqrt{\mu}}{1+\sqrt{\mu}} - 0.20\,\mu\right]$$

and are given in Table II.

TABLE II

$m \times 10^4$ (molarity)	α	K
4.5284	0.971	0.025
4.8136	.970	.026
5.9780	.964	.026
6.9169	.963	.028
11.930	.935	.026
24.020	.884	.025
27.646	.886	.028
49.688	.819	.026
53.523	.815	.028

In glycol–water mixtures, the values summarized in Table III have been calculated up to concentrations of 0.002 N, using the limiting forms of the Onsager and Debye–Hückel equations, and assuming that the transport numbers of the ions do not change with the change in solvent. Limiting conductance values have been re-extrapolated by the method of Onsager,[14] as the values given by Norman and Garrett were obtained by Kohlrausch's square-root method, which is known to give Δ_0 values that are too high for incompletely dissociated electrolytes.[15]

TABLE III

% Glycol (ω/ω)	Mean K (conductance data)	Mean K (activity data)
0	0.026	0.023
20	.023	.030
40	.025	.025
60	.012	.015
80	.0083	.0095
100	.0026	∞

Dissociation constants calculated for lead chloride in glycol–water mixtures from conductance and activity data are in good agreement except in 100% glycol, for which the anomalously high activity coefficients appear to indicate complete dissociation. (Similar discrepancies have been noted by Garrett and Vellenga[16] with thallium chloride at high glycol concentrations.)

The results are of interest as lead chloride is one of the few inorganic salts which have been studied in a binary solvent mixture over the entire range of composition. Moelwyn-Hughes[17] has applied the Wynne-Jones equation[18]

$$\left[\frac{\mathrm{d}\ln K}{\mathrm{d}\ (1/D)}\right]_{T,P,} = \frac{z_A z_B \epsilon^2}{rkT}$$

to dissociation constants calculated from conductance data for silver nitrate in various solvents, plotting ΔG as a function of $1/D$ and obtaining a straight line, from the slope of which a value for r the sum of the ionic radii, was found. Application of this procedure to the data for lead chloride gave a linear plot leading to the value $r = 5.6$ Å. For $K = 0.025$ in water, the Bjerrum equation,[19] however, gives a value of 1.85 Å. for r. The observed decrease in K with decrease in D is considerably less than is to be anticipated from this treatment, which predicts $K = 2.5 \times 10^{-5}$ in 100% glycol, assuming r to remain unchanged. From the abnormally low dissociation constant in water and from the ultraviolet absorption spectra of lead chloride solutions, it appears possible that the ionic interaction goes further than can be explained by Coulomb's law, and that in consequence the

The Liberation of Diazotizable Amine from Pteroylglutamic Acid[1]

BY B. KOFT AND M. G. SEVAG

During a study of the possible role of pteroylglutamic acid (PGA)[2] and *p*-aminobenzoic acid (*p*-ABA) on the inhibition by sulfonamides of the growth of *Lactobacillus arabinosus* strain 17-5 and other bacteria, certain inconsistancies have been observed by us. These inconsistencies suggested the possibility that pteroylglutamic acid was undergoing decomposition in the sterile medium. Certainly, if this were so, it would have considerable bearing on the interpretations of the results of physiological experiments with pteroylglutamic acid.

TABLE I

RATE OF THE DECOMPOSITION OF PTEROYLGLUTAMIC ACID (PGA)

Pteroylglutamic acid solutions[a]	μg *p*-ABA/1000 μg of PGA[c] 0 hr.	20 hr.	40 hr.	64 hr.	120 hr.	168 hr.

4 *M*/30 KH_2PO_4 *p*H 4.5[b]	1.36	2.18	2.72	3.36	4.32	5.45
5 Growth medium (*p*H 7.0) (used for *L. arabinosus*[3])	2.50	3.82	6.18	14.54	18.86	45.44
6 Medium as in (5) without PGA	0	0	0	0	0	0
7 1 μg *p*-ABA/ml. of *M*/30 phosphate buffer of *p*H 7.3	1	1	1	1	1	1

[a] All solutions were autoclaved for ten minutes at 10 lb. pressure. Systems 1 to 5 contained 500 μg of PGA/ml. The solutions were then kept in a constant temperature incubator at 30°. [b] Pteroylglutamic acid dissolves on autoclaving and a precipitate forms on cooling; determinations for *p*-ABA were made on uniform suspensions. [c] *p*-ABA content of the various systems were determined according to Bratton and Marshall[4] using Klett–Summerson photoelectric colorimeter with filter No. 54, 1 μg of *p*-ABA/10 ml. reaction system gives a colorimetric reading of 22.

(1) This investigation was supported, in part, by a research grant from the Division of Research Grants and Fellowships of the National Institute of Health, U. S. Public Health Service.

(2) The authors are indebted to Dr. C. W. Waller, Lederle Laboratories, Pearl River, New York, for a freshly recrystallized sample of PGA. It contained 1 μg of *p*-ABA/1000 μg of PGA.

(3) T. D. Luckey, G. M. Briggs, Jr., and C. A. Elvehjem, *J. Biol. Chem.*, **152**, 157 (1944).

(4) A. C. Bratton and E. K. Marshall, Jr., *ibid.*, **128**, 537 (1939).

The data presented in Table I pertain to this observation.

It can be seen from the table that PGA decomposes at a regular rate on incubation at 30°. A very great rate of decomposition occurs in the sterile medium which has been generally used for the growth of *Lactobacillus arabinosus* 17-5. In this medium, 6.18 to 14.54 μg. of diazotizable amine calculated as *p*-ABA per 1000 μg. of PGA are liberated during an incubation period of from forty to sixty-four hours. The diazotizable component liberated in this medium is significantly greater than the amounts liberated in either aqueous or neutral phosphate buffer solutions of PGA. These results indicate that certain substances in the sterile medium accelerate the decomposition of PGA. The nature of these substances is under investigation.

Lithium Borohydride as a Reducing Agent

BY ROBERT F. NYSTROM, SAUL W. CHAIKIN AND WELDON G. BROWN

Lithium borohydride shares with lithium aluminum hydride the property of solubility in ether and other organic solvents. In ether solution it is a more powerful reducing agent than sodium borohydride (in water or alcohol solution) but is milder than lithium aluminum hydride. This combination of properties, together with the prospect of early commercial availability, suggests useful applications for lithium borohydride particularly in the execution of selective reductions.

Solid lithium borohydride has been known to flash on exposure to humid air, some samples being more prone than others, and for this reason transfers of the solid should be conducted in a dry atmosphere. However, solutions of lithium borohydride are relatively insensitive to moisture and in the experiments to be described no special precautions were taken to exclude moisture. Otherwise the procedures followed in lithium borohydride reductions were generally similar to those employed in reductions by lithium aluminum hydride. Tetrahydrofuran proved advantageous as a solvent, since more concentrated solutions of the hydride could be used, *viz.*, 3.5 *M* as compared with 0.5 *M* in diethyl ether.

The aldehydes and ketones (*cf.* Table I) were reduced rapidly at room temperature in exothermic reactions whereas the esters reacted slowly and the mixtures were heated to reflux for periods up to six hours. In the selective reduction of the ketone groups of the keto-esters, and of *m*-nitroacetophenone, ice-bath cooling was employed to enhance selectivity. The attempted selective reduction of ethyl acetoacetate gave rise to a borate complex from which the reduction product could not be

isolated. Similar difficulties have been encountered in the reduction of keto-acids by sodium borohydride.[1]

TABLE I

REDUCTIONS BY LITHIUM BOROHYDRIDE

Compound	Product	Yield, %
n-Heptaldehyde	*n*-Heptanol	83
Benzaldehyde	Benzyl alcohol	91
Crotonaldehyde	Crotyl alcohol	70
Methyl ethyl ketone	*s*-Butanol	77
Benzophenone	Benzhydrol	81
n-Butyl palmitate	*n*-Hexadecanol	95
Ethyl benzoate	Benzyl alcohol	62
Ethyl sebacate	Decamethylene glycol	60
β-Benzoylpropionic acid	γ-Phenylbutyrolactone	78
Ethyl levulinate	γ-Valerolactone	44
m-Nitroacetophenone	α-(*m*-Nitrophenyl)-ethanol[a]	93

[a] This product was obtained in an unstable crystalline modification, m. p. 25°, reverting on melting to the stable form, m. p. 61.5°; reported [Lund, *Ber.*, **70**, 1520 (1937)] m. p. 62.5°.

The action of lithium borohydride on carboxylic acids is complex. Benzoic acid caused decomposition of the hydride with the evolution of some diborane, but the benzoic acid was recovered unchanged. Butyric acid, after one half hour, was reduced to butyl alcohol to the extent of 8% and 75% of the acid was recovered. Crotonic acid, refluxed two hours, was recovered to the extent of 45%, the only isolable products being butyl alcohol (4%) and butyric acid (10%).

Nitrobenzene, after refluxing for eighteen hours with excess lithium borohydride in an ether–tetrahydrofuran mixture, furnished 22% aniline, 30% of an intractable dark red oil, and 30% unchanged nitrobenzene.

As the examples given in Table I show, neither the nitro group (*m*-nitroacetophenone) nor the free carboxyl group (β-benzoylpropionic acid) seriously interferes in the reduction of carbonyl groups.

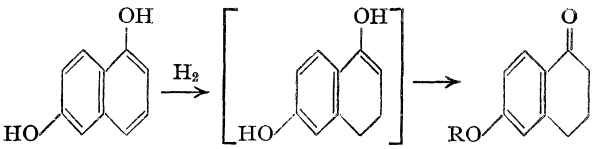
6-Methoxy-1-tetralone

BY DOMENICK PAPA

The selective hydrogenation of β-naphthol and β-naphthyl methyl ether[1] to the corresponding aryl-tetrahydro derivatives has been the most favored approach to the synthesis of 6-methoxy-1-tetralone[2] (IV). In addition, ring closure of γ-arylbutyric acids[2,3] and alkali fusion of tetralin-6-sulfonic acid[4] have given intermediates for the synthesis of IV.

Recently it has been reported[5] from these laboratories that 1,6-dihydroxynaphthalene (I) on treatment with Raney nickel–aluminum alloy in aqueous alkaline solution affords good yields of 6-hydroxy-1-tetralone (III). This reaction may be assumed to proceed either through the intermediate dihydro compound II, which rearranges to the tetralone III, or through the formation of 1,6-dihydroxytetralin (V) and subsequent dehydrogenation of V to III.[6]



I II III R = H IV R = CH_3

The failure of the alloy procedure to reduce III even after prolonged treatment with large excesses of nickel–aluminum alloy suggested that mild catalytic hydrogenation of I would yield III. Hydrogenation of I in 2% aqueous sodium hydroxide solution with Raney nickel catalyst at room temperature and a pressure of 2–3 atmospheres gave an uptake of one mole of hydrogen within one to one and one-half hours. The crude tetralone III was converted to IV with dimethyl sulfate in an over-all yield of 72%.

Preliminary experiments indicate that the noble metal catalysts give better yields of IV, as the semicarbazone, from I in acidic than in neutral or alkaline medium. As yet, we have not succeeded in isolating (IV) in pure form from the catalytic reduction with the noble metals. We are continuing our studies of the reduction of I and 6-methoxy-1-naphthol by cata ytic and chemical methods.

Experimental

Hydrogenation with Raney Nickel.—To a solution of 16.0 g. (0.1 mole) of 1,6-dihydroxynaphthalene[7] (m. p. 137–138°) in 300 cc. of 2% sodium hydroxide, there was added 5 cc. of Raney nickel catalyst.[8] The hydrogenation was carried out in the conventional Parr apparatus at room temperature at an initial pressure of 35–40 lb. After one and one-half hours[9] the hydrogen absorption ceased

(6) Compare Schwenk, Papa, Whitman and Ginsberg, *J. Org. Chem.*, **9**, 1 (1944). Although this sequence of reactions is not very probable, the action of Raney nickel–aluminum alloy on V is being studied.

(7) Generous samples of 1,6-dihydroxynaphthalene have been obtained from National Aniline Division of Allied Chemical and Dye Corporation through the courtesy of Mr. B. M. Helfaer of the Buffalo plant.

(8) The Raney nickel catalyst was prepared at 50° essentially as described by Mozingo, Wolf, Harris and Folkers, THIS JOURNAL, **65**, 1015 (1943), and was washed once with distilled water after decanting off the alkaline solution.

(9) In one instance the hydrogenation was quite sluggish, possibly due to the poisoning of the catalyst. In this case the nickel catalyst was filtered off and a fresh sample added. The hydrogenation then proceeded normally.

and corresponded to one mole of hydrogen. The alkaline solution was filtered to remove the nickel catalyst, diluted to 500 cc. with 25% sodium hydroxide solution. To this solution there was added 50 cc. of dimethyl sulfate and the methylation was carried out as usual. The alkaline solution was then extracted with two 100-cc. portions of ether and the combined ether extracts washed and dried. After removing the ether, the residue was distilled; yield 12.7 g. (72%), b. p. 135–139° (1 mm.), m. p. 75–77°. The semicarbazone, prepared in the usual manner, melted at 235.5–236.5° after recrystallization from aqueous alcohol.

Anal. Calcd. for $C_{12}H_{15}O_2N_3$: N, 18.01. Found: N, 18.06.

Reduction with Platinum Oxide Catalyst.—To 16.0 g. (0.1 mole) of 1,6-dihydroxynaphthalene in 150 cc. of acetic acid, there was added 200 mg. of Adams platinum oxide catalyst. The hydrogenation was carried out as described for the nickel catalyst and at the end of approximately three hours one mole of hydrogen had been absorbed. After filtering the platinum catalyst, the acetic acid was removed *in vacuo* and the residue dissolved in 300 cc. of 10% sodium hydroxide. Methylation of the crude hydroxy tetralone and isolation of the methylated product was carried out as described above. In this case, distillation yielded 6.8 g. of a pale yellow liquid, b. p. 130–144° (1 mm.) from which no crystalline material could be isolated. One gram of the distilled product was treated with semicarbazide hydrochloride and 0.16 g. of semicarbazone was isolated. The semicarbazone, after recrystallization from aqueous alcohol, melted at 230–232° and showed no depression on admixture with the product obtained by the nickel catalyst reduction. We are continuing our studies of this reduction procedure in order to establish the nature of the non-ketonic material.

Sulfanilamido-quinoxalines

BY BERTIE C. PLATT AND THOMAS M. SHARP

A paper by Wolf, Pfister, Beutel, Wilson, Robinson and Stevens[1] has appeared almost simultaneously with one by us[2] on sulfonamides derived from substituted quinoxalines. It is possible by inspection of the melting points quoted by Wolf,[1] *et al.*, to identify some of the compounds which were not fully identified by them.

In Table III[1] two 2-amino-6(or 7)-methylquinoxalines are described (a) m. p. 178–180° and (b) m. p. 171–173°. The former must be 2-amino-6-methylquinoxaline since it was prepared from 2-chloro-6-methyl-quinoxaline identified by Platt[3] by an unambiguous synthesis of 2-hydroxy-6-methylquinoxaline from 4-nitro-*m*-tolylglycine and conversion to the corresponding chloro and amino derivatives. The compound (b) m. p. 171–173° appears to be a mixture of 2-amino-6-methyl and 2-amino-7-methylquinoxalines since it was prepared from an impure 2-chloro-7-methylquinoxaline m. p. 56–57°. Pure 2-chloro-7-methylquinoxaline has m. p. 76° (Platt[3]). Platt[3] found 2-amino-6-methylquinoxaline, prepared by a method which could yield only one isomer, to have m. p. 181–182°, and 2-amino-7-methylquinoxaline, prepared in a similar manner to have m. p. 178–180°. A mixture of the two in approximately equal proportions had m. p. 172–174°. It is well known that mixtures of isomers in the quinoxaline series are very difficult to separate.

2-Chloro-5(or 8)-methylquinoxaline, m. p. 92–93°, of Table II[1] is identified as 2-chloro-5-methylquinoxaline which we[3] have synthesized rationally (m. p. 95°) and converted to 2-amino-5-methylquinoxaline (m. p. 201–2°). 2-Amino-5(or 8)-methylquinoxaline (m. p. 202–3°) of Table III[1] is therefore the 5-methyl isomer. (The isomeric 2-amino-8-methylquinoxaline we find to melt at 129°). The corresponding N^4-acetylsulfanilamide, m. p. 228–229°, and the N^1-sulfanilamide, m. p. 205–206° (Tables IV and V[1]) accordingly have the methyl groups in the 5-positions.

2-(2-Chloroethoxy)-ethyl Acetate and 2-Chloroethyl Vinyl Ether

BY C. E. REHBERG

Dioxane is the principal impurity in the crude 2-chloroethyl vinyl ether prepared by the method of Cretcher.[2] Cretcher considered that the two formed an azeotrope which boiled at 107°. This azeotrope appeared remarkable in that its boiling point was between those of the two components of the azeotropic mixture.

In the work reported here, chloroethyl vinyl ether was prepared in 60% yield by Cretcher's method. When the crude product was distilled through a column having 60 theoretical plates, dioxane was obtained at 101–102°, a mixture of dioxane and ether at 102–108°, and finally, pure ether at 108°. Since both pure dioxane and pure ether were distilled from the mixture, it is evident that no azeotrope was formed.

The ether was also distilled at reduced pressure (120 mm.). Dioxane distilled at 52–53°, and chloroethyl vinyl ether at 59°; a mixture of variable composition was obtained between the pure components.

The following properties were observed with chloroethyl vinyl ether[3]: b. p., 108°, 59° (120 mm.); $n^{20}D$ 1.4378; d^{20}_4 1.0475.

(2-Chloroethoxy)-ethyl Acetate.—An effort was made to produce chloroethyl vinyl ether by

(2) Cretcher, Koch and Pittenger, THIS JOURNAL, **47**, 1173 (1925).

(3) Cretcher reported b. p., 109° (740 mm.); d^{15}_{15} 1.0525; W. Chalmers reported b. p. 108°, $n^{20}D$ 1.4362; d^{20}_4 1.044 (*Can. J. Research*, **7**, 464 (1932)).

the pyrolysis of 2-(2-chloroethoxy)-ethyl acetate. Since the latter is a new compound, its preparation and pyrolysis are described. Diglycol chlorohydrin was acetylated with acetic anhydride, and the product (94% yield) was purified by distillation: b. p. 80° (1 mm.); d^{20}_4 1.1546; $n^{20}D$ 1.4398. Found: $M^{20}D$ 38.02; C, 43.3; H, 6.8. Calcd.: $M^{20}D$ 38.07; C, 43.3; H, 6.7. Pyrolysis over Pyrex glass at 500 and 550° (contact time, 8 sec.) decomposed 32 and 83%, respectively, of the ester but produced little if any chloroethyl vinyl ether. Most of the products were gases.

Alkoxy-*s*-triazines. III

BY WILLIAM M. PEARLMAN, JACQUELINE DOWNS MITULSKI AND C. K. BANKS

In the search for antihistaminic compounds of the triazinyl ether type the alkyl 2,4-diamino-6-*s*-triazinyl ethers were found to have a peak of activity at the *n*-propyl compound.[1] A subsequent investigation of the methyl and butyl ethers of thirty substituted-aminotriazines disclosed no regular progression of activity as was noted in the first series.[2] Subsequently, an examination of the previously determined antihistaminic activities indicated that certain miscellaneous alkyl ethers should be prepared to determine if any products of appreciable activity had been overlooked. The ethers were prepared by previously described methods[1,2] from 2-chlorotriazines already described.[3]

The compounds were tested by Dr. Graham Chen and Mr. Charles Ensor of our laboratories by the histamine-aerosol technique of Dr. E. R. Loew.[2] The physical properties and effective antihistaminic values are recorded in the accompanying table.

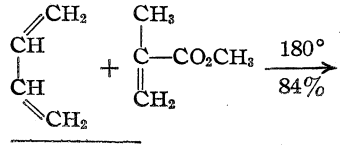
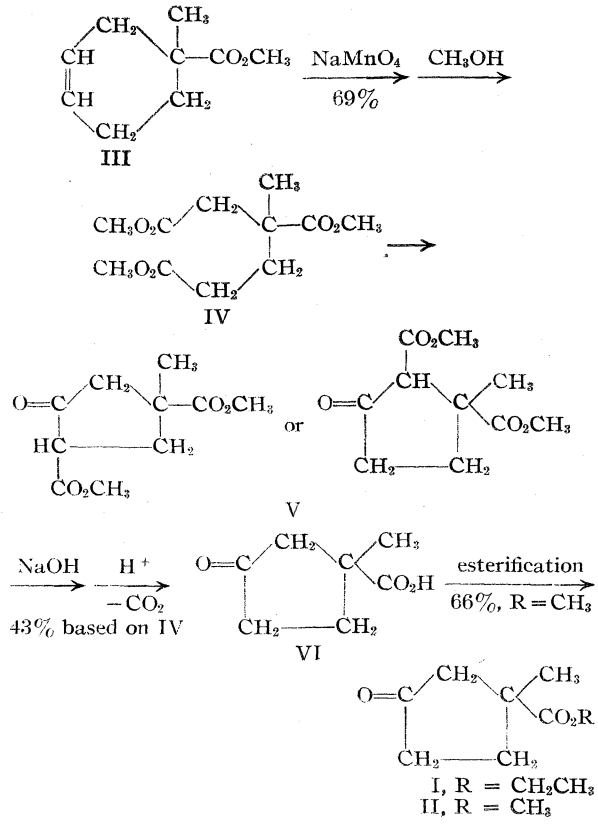
Synthesis of 3-Carbomethoxy-3-methylcyclopentanone

BY JOHN D. ROBERTS, A. K. JEYDEL AND ROSE ARMSTRONG

Ruzicka[1] has reported the preparation of 3-carbethoxy-3-methylcyclopentanone (I) through several steps from ethyl levulinate. In the present investigation, a shorter synthesis of the corresponding methyl ester (II) was achieved from the adduct of butadiene with methyl methacrylate by the following route.



(1) Ruzicka, *Ber.*, **50**, 1362 (1917).



Experimental

4-Carbomethoxy-4-methylcyclohexene (III).—A mixture of 100 g. (1.0 mole) of methyl methacrylate, 108 g. (2 moles) of butadiene and 1 g. of hydroquinone[2] was heated in a steel hydrogenation bomb at 180° for fifteen hours. The viscous product was distilled from a Claisen flask under reduced pressure to separate the polymeric materials and the distillate fractionated through a 2 × 40 cm. glass-helix packed column. The yield of III, b. p. 64–65° (10 mm.), $n^{20}D$ 1.4600, was 130 g. (84%).

Anal. Calcd. for $C_9H_{14}O_2$: C, 70.10; H, 9.15. Found: C, 70.34; H, 9.28.

In other runs at 180° for five and six hours, the yields were 64 and 71%, respectively.

Hydrolysis of III with potassium hydroxide gave **4-carboxy-4-methylcyclohexene**, m. p. 78–79° after crystallization from ligroin.

Anal. Calcd. for $C_8H_{12}O_2$: C, 68.55; H, 8.63. Found: C, 68.56; H, 8.63.

Dimethyl 3-Methyl-3-carbomethoxyadipate (IV).—A mixture of 145 g. (0.94 mole) of III and 2600 ml. of water was placed in a 12-l. flask equipped with a stirrer, dropping funnel and a thermometer extending close to the bottom of the flask. The contents of the flask were stirred vigorously and a solution of 457 g. (2.3 moles) of sodium permanganate trihydrate in 2600 ml. of water added during four hours. During the addition the reaction mixture was kept saturated with carbon dioxide by adding lumps of Dry Ice every few minutes. The temperature was kept below 50° by external cooling with an ice-bath. The manganese dioxide was reduced by passing in sulfur dioxide, the solution was filtered and extracted with ether in a large continuous extractor for five days. The ether was distilled from the extract and the residue was dried by distillation with benzene using a water separator. The viscous acid remaining after distillation of the benzene was refluxed for three days with 600 g. of methanol containing 2% of dry hydrogen chloride. The excess methanol was distilled, the residue dissolved in ether, and washed with water and sodium carbonate solution. The ethereal solution was dried over magnesium sulfate and distilled through a 30-cm. Vigreux column. The yield of IV was 145 g., b. p. 120–121° (0.7 mm.), $n^{25}D$ 1.4443. An additional 9 g. of IV was obtained by esterification of the tribasic acid recovered by acidification and extraction of the sodium carbonate washings of the crude ester. The total yield was 154 g. (70%).

Anal. Calcd. for $C_9H_{18}O_6$: C, 53.65; H, 7.37; sapon. equiv., 82.1. Found: C, 53.87; H, 7.26; sapon. equiv., 83.7.

3,5(or 2,3)-Dicarbomethoxy-3-methylcyclopentanone (V).—The following procedure gave better results than the one used by Ruzicka.[1] In a three-necked creased flask equipped with a stirrer, reflux condenser and dropping funnel was placed 100 ml. of dry toluene, 100 ml. of dry xylene and 3.6 g. (0.15 mole) of clean sodium. The flask was flushed with nitrogen, the contents heated to refluxing and 64 g. (2.0 moles) of methanol added dropwise. After all of the sodium had reacted, 50 ml. of the solvent was distilled to remove most of the excess methanol. To the hot reaction mixture was added 24.6 (0.1 mole) of IV over a forty-five-minute period. The mixture was heated under reflux for two hours, then cooled and 10 ml. of acetic acid added. The mixture was treated with 150 ml. of 1 *N* hydrochloric acid and the organic layer separated, washed with water, sodium carbonate solution and dried over magnesium sulfate. After distillation of the solvent under reduced pressure the residue was fractionated through a short Vigreux column. The yield of V (which may be a mixture of isomers) was 14.6 g. (68%); b. p. 145–151° (7 mm.); $n^{25}D$ 1.4628.

Anal. Calcd. for $C_{10}H_{14}O_5$: C, 56.07; H, 6.59. Found: C, 56.35; H, 6.83.

3-Carboxy-3-methylcyclopentanone (VI) and 3-Carbomethoxy-3-methylcyclopentanone.—The over-all yield of VI, b. p. 140–145° (2 mm.), from IV by the previously reported procedure[1] was 43%. Esterification of VI with methyl iodide instead of ethyl iodide[1] gave 66% of II; b. p. 96° (7.5 mm.), $n^{25}D$ 1.4523.

Anal. Calcd. for $C_8H_{12}O_5$: C, 61.52; H, 7.75. Found: C, 61.34; H, 8.03.

DEPARTMENT OF CHEMISTRY
MASSACHUSETTS INSTITUTE OF TECHNOLOGY
CAMBRIDGE 39, MASS. RECEIVED APRIL 27, 1949

(2) Much lower yields (20–55%) were obtained if no hydroquinone was used; *cf.* Shortridge, Craig, Greenlee, Derfer and Boord, THIS JOURNAL, **70**, 946 (1948), for similar observations.

The Catalytic Reduction of Dinitroneopentane[1]

BY JACK ROCKETT AND FRANK C. WHITMORE

The reduction of primary aliphatic nitro compounds has been found to yield, other than the primary amines, substances which are presumably reduction intermediates. These are the oxime,[2] the aldimine,[3] the nitrile,[3] and the N-hydroxylamine[4] corresponding to the nitro compound.

Among the products resulting from the hydrogenation of dinitroneopentane with Raney nickel catalyst, we have found the expected diaminoneopentane (67%) and, also, the diamide of dimethylmalonic acid (5%). The latter type substance has

(1) This work was completed by J. R. after the untimely death of Dean Frank C. Whitmore. Thanks are due to Dr. Thomas S. Oakwood who served as adviser after the death of Dean Whitmore.

(2) Johnson and Degering, THIS JOURNAL, **61**, 3194 (1939).

(3) Kohler and Drake, *ibid.*, **45**, 1286 (1923).

(4) Hoffman and Meyer, *Ber.*, **24**, 3528 (1891).

not previously been found to result directly from the reduction of a nitro compound.

The work of Paul[5] has demonstrated that aliphatic aldoximes in contact with Raney nickel will spontaneously rearrange upon gentle heating to the corresponding amides. It is therefore likely that some of the intermediate oxime (un-isolated) rearranged in the course of the present reduction

$$Me_2C(CH_2NO_2)_2 \xrightarrow[Ni]{H_2} Me_2C(CH{=}NOH)_2 \begin{cases} \rightarrow Me_2C(CONH_2)_2 \\ \rightarrow Me_2C(CH_2NH_2)_2 \end{cases}$$

It is possible that the reduction of a nitro compound or an oxime to an amine proceeds by way of the intermediate amide. However, the difficulty of reducing amides to amines[6] would indicate that this is probably not the most important reaction.

Experimental

Reduction of Dinitroneopentane.—A solution of 97.2 g. (0.6 mole) of dinitroneopentane in 750 ml. of absolute alcohol was placed in a hydrogenation bomb with 6 g. of Raney nickel catalyst. The hydrogenation proceeded at 1000 p. s. i. and 60°, requiring about two hours for completion. The contents of the bomb were placed in a beaker and allowed to stand at room temperature for twenty-four hours. The crystalline material and the catalyst were then filtered, and the crystalline material was removed from the mixture of extraction with hot water. Cooling the hot water solution gave white crystals, m. p. 268–269°, after one recrystallization from water. A second crop of the above compound was obtained by partly evaporating the alcohol from the original reaction mixture.

Anal. Calcd. for $C_5H_{10}O_2N_2$: C, 46.15; H, 7.69; N, 21.54. Found: C, 46.54; H, 7.84; N, 21.63.

The compound was shown to be the diamide of dimethylmalonic acid by comparison with a sample of that substance prepared from dimethylmalonic acid through the acid chloride, and subsequent treatment with liquid ammonia.

Diaminoneopentane.—The diaminoneopentane from the above reduction was obtained by treating the alcoholic solution above with anhydrous hydrogen chloride, which caused the separation of the di-hydrochloride. The hydrochloride was recrystallized from alcohol, m. p. 256–257°.

Anal. Calcd. for $C_5H_{16}N_2Cl_2$: Cl, 40.50. Found: Cl, 40.54.

This compound prepared in another way has been reported as having the m. p. 280–281°.[7] However, the picrate of the compound agreed with that prepared by these authors (m. p. 240°).

The recrystallized hydrochloride was dissolved in 300 ml. of methanol and methanolic potassium hydroxide was added. After filtering the potassium chloride formed, the diaminoneopentane was separated by distillation in an efficient column. It was a mobile water white liquid, fuming in moist air, b. p. 151–153° (737 mm.); $n^{20}D$ 1.4566.

Evidence for a Solid Dihydrate of Hexafluoroacetylacetone[1]

BY BOYD G. SCHULTZ AND EDWIN M. LARSEN

In the final step in the production of hexafluoroacetylacetone according to the process of Staniforth[2] in which the solvent and product are separated by fractional distillation, we continually obtained a white crystalline residue with corresponding poor yields of the low boiling product.

The white crystalline product was very soluble in ether, slightly soluble in benzene and petroleum ether, and slowly soluble in water. The water solution of this compound was acid to litmus and slowly liberated carbon dioxide from a solution of sodium hydrogen carbonate. It had a pungent odor and was very volatile as evidenced by substantial sublimation occurring even at room temperature. No melting point was observed as the compound sublimed completely before reaching 115°. On the basis of the following experimental results we have concluded that the material obtained is the dihydrate of hexafluoroacetylacetone.

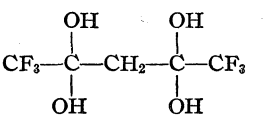
Experimental

For analysis the compound was recrystallized from ether, washed with benzene to remove any diketone present, and dried at room temperature under 0.1 mm. pressure. A qualitative elementary analysis confirmed the presence of carbon and fluorine, and the absence of any metallic elements. From the results of the quantitative analysis for carbon,[3] hydrogen[3] and fluorine, the empirical formula of the compound was calculated to be $C_5H_6O_4F_6$.

Anal. Calcd. for $C_5H_6O_4F_6$: C, 24.58; H, 2.47; F, 46.71. Found: C, 24.48; H, 2.54; F, 46.3.

The neutral equivalent of this compound as determined by titration of an aqueous solution with 0.1 *N* NaOH solution gave a value which corresponded to the molecular weight of the compound, $C_5H_6O_4F_6$: calcd. mol. wt., 244.10; exptl. neutral eq., 245.

Since the fluorine was all present in the starting material as trifluoromethyl groups, it was considered unlikely that the fluorine could be arranged in any other manner, and therefore on the basis of these data it was concluded that this compound was hexafluoroacetylacetone dihydrate



As one would expect, if the proposed formulation were correct, the dihydrate in ether solution was incapable of forming the copper chelate derivate directly. However, a small amount of the enol form must be present in both the ether and water solution of the dihydrate, because on standing in contact with a copper acetate solution for twenty-four hours, a greenish tint, characteristic of the copper chelate, was observed in the ether layer, and after several days the intensity of the coloration increased.

Additional experiments were conducted to test the possibility of dehydration as expressed in the reaction

$$CF_3C(OH)_2CH_2C(OH)_2CF_3 \rightleftharpoons CF_3C(OH){=}CH{-}CO(CF_3) + 2H_2O$$

(2) Henne, Newman, Quill and Staniforth, THIS JOURNAL, **69**, 1819 (1947).

(3) Analyses by Clark Microanalytical Laboratory, Urbana, Ill.

An ether solution of the dihydrate was treated with phosphorus pentoxide, and samples taken at intervals during a twenty-four-hour period were tested for the presence of hexafluoroacetylacetone.[4] Upon standing for a short time, no test for the hexafluoroacetylacetone was obtained, although after twenty-four hours an immediate test was obtained. The dehydration process progressed rapidly when an ether solution of the dihydrate was refluxed over phosphorus pentoxide for one hour, and then fractionally distilled. The fraction coming over above 35° gave an immediate test for the diketone.

Similarly, an increase in the *p*H of an aqueous solution resulted in a shift of the equilibrium to the right. Thus, an aqueous solution which had been brought up to a *p*H of 7 with 0.1 *N* sodium hydroxide, when treated with a copper acetate solution, gave immediately the ether extractable derivative.

The equilibrium could also be reversed as evidenced by the fact that when an ethereal solution of the hexafluoroacetylacetone was shaken with water, an immediate test for the diketone could not be obtained.

(4) The presence of hexafluoroacetylacetone was determined by shaking the test solution with aqueous copper acetate. The appearance of a green ethereal layer was taken as evidence of the formation of bis-(1,1,1,5,5,5 hexafluoro-2,4-pentanediono)-copper. This was confirmed by analyses of such copper derivatives recovered by evaporation of the ether solution. *Anal.* Found Cu, 13.4; F, 46.7; m. p. 114–116°. Calcd. Cu, 13.3; F, 47.8; m. p. 113–115°.

Resolution of DL-Tryptophan

BY A. C. SHABICA[1] AND MAX TISHLER

Although a number of excellent methods for the preparation of DL-tryptophan have been reported,[2] no equally satisfactory procedure for the resolution of the DL-mixture is known. We wish to report[3] a method of resolution developed by us several years ago which is simpler than the chemical procedures already reported.[4]

In this method N-acetyl-DL-tryptophan, an intermediate in a few of the recent syntheses, is resolved by brucine. The brucine salt of N-acetyl-D-tryptophan separates cleanly from ethanol and the L- form is obtained from the mother liquor. The N-acetyl enantiomorphs are hydrolyzed to the optically active amino acids by heating with 2*N* hydrochloric acid for about two hours. Both D- and L-tryptophan can be obtained in pure form and in good yields.

Brucine Salt of D- and L-N-Acetyltryptophan.—A mixture of 123 g. of N-acetyl-DL-tryptophan, 208 g. of brucine and 1750 cc. of absolute ethanol was boiled under reflux until solution was effected. After cooling, seeding and storing for twelve hours, the crystalline product was separated and slurried twice with small quantities of ethanol: Weight of dried product, 161 g.; $[\alpha]^{25}D$ − 16.5 ± 1°. Recrystallization from 320 cc. of hot ethanol gave 146 g. of pure brucine salt of N-acetyl-D-tryptophan ($[\alpha]^{25}D$ − 18.4°) as was indicated by its constant rotation when subjected to further recrystallization.

The brucine salt of N-acetyl-L-tryptophan was obtained from the resolution mother liquor by concentration of the solution to dryness under reduced pressure, dissolution of the residue in 320 cc. of hot methanol, charcoal treatment of the solution, dilution of the latter with 325 cc. of dry ether, seeding and storage of the mixture for several hours. The crystalline brucine salt was subjected again to the same recrystallization procedure whereby 139 g. of product was obtained; $[\alpha]^{25}D$ + 1.3 ± 1° (*c*, 1% in water). *Anal.* Calcd. for $C_{36}H_{40}O_7N_4$: C, 67.48; H, 6.29; N, 8.74. Found: C, 67.54; H, 6.13; N, 8.69.

L- and D-Tryptophan.—To a mixture of 49 g. of the recrystallized brucine salt of N-acetyl-L-tryptophan in 170 cc. of water was added 70 cc. of cold 1*N* sodium hydroxide solution. The salt dissolved readily and very soon brucine separated. After cooling in ice for a few hours, the mixture was filtered and the brucine washed with cold water. The combined filtrate and washings were neutralized with hydrochloric acid to *p*H 7.0, concentrated under reduced pressure to 140-cc. volume, treated with charcoal and finally acidified with hydrochloric acid *p*H 3.0. The N-acetyl-L-tryptophan was collected and slurried twice with cold water; weight 16.1 g. (85% yield); $[\alpha]^{25}D$ + 29° (*c*, 1% in H_2O + 1 equivalent NaOH).

A mixture of the product with 160 cc. of 2*N* hydrochloric acid was boiled under reflux for two and one-half hours and the resulting solution was concentrated under reduced pressure to dryness. The residue was dissolved in 40 cc. of hot water and the solution was treated with charcoal. A solution of 7 g. of sodium acetate in 20 cc. of water was added to the product solution and the mixture was stored at 5° for fourteen hours. The product was recrystallized by dissolution in 84 cc. of water containing 2.8 g. of sodium hydroxide, acidifying the warmed solution (at 70°) with 4.5 cc. of acetic acid and storing the mixture at 5° for fourteen hours. The pure L-tryptophan was collected and washed with small amounts of 50% ethanol followed by ethanol and then dry ether; weight, 10.9 g.; 82% yield; $[\alpha]^{25}D$ −31.90 (*c*, 1% in water + 1 equivalent of NaOH).

D-Tryptophan was obtained from the brucine salt of its N-acetyl derivative following the same procedure. The over-all yields were slightly better, however.

The Reduction of Methyl Cyclopropyl Ketone to Methylcyclopropylcarbinol

BY V. A. SLABEY AND P. H. WISE

In the course of an investigation of the syntheses of alkylcyclopropanes from methyl cyclopropyl ketone it was necessary to prepare a quantity of methylcyclopropylcarbinol. The reduction of methyl cyclopropyl ketone with sodium and ethanol[1] was found to be unsatisfactory because of the low yields of carbinol obtained. Methylcyclopropylcarbinol of good purity was obtained in good yield by the use of lithium aluminum hydride, but the method was abandoned because of the difficulties encountered in applying it to large-scale work.

Catalytic reductions were considered most desirable because of their applicability to preparations of any size. Consequently, reductions with hydrogen in the presence of Raney nickel and copper chromite catalysts were attempted. Hydrogenation with Raney nickel was found to yield nearly equal quantities of methylcyclopropylcarbinol and pentanol-2, as well as unconverted ketone. In the presence of a barium-promoted copper chromite catalyst, hydrogenation of the ketone at 150° and 1500 to 2000 p.s.i. of hydrogen gave a 76% yield of the desired carbinol which was contaminated with a close-boiling impurity believed to be pentanol-2. When the temperature was reduced to 100°, however, the yield of methylcyclopropylcarbinol increased to 90%, and ring cleavage to yield pentanol-2 was no longer evident. No difficulty was experienced in determining when the reaction was complete, because hydrogen consumption dropped to virtually nothing as soon as sufficient hydrogen to convert carbonyl to carbinol was absorbed (Fig. 1).

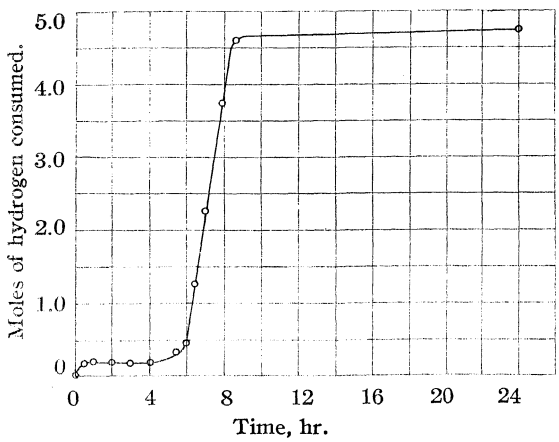

Fig. 1.—Rate of hydrogenation of 5 moles of methylcyclopropyl ketone at 100° in the presence of copper chromite catalyst.

The physical constants, carbon–hydrogen analysis, and infrared spectrum were determined on a center cut of the product obtained from the copper chromite reduction at 100°. These data are presented in Tables I and II.

The use of copper chromite as a catalyst for 1,2-hydrogenation of "conjugated" cyclopropane systems appears to be generally applicable.[2] Copper chromite has previously been used to hydrogenate the "conjugate" isopropenylcyclopropane to isopropylcyclopropane.[3]

Experimental

The methyl cyclopropyl ketone[4] was fractionated and only center-cut material was used in this work ($n^{20}D$ 1.4250–1.4252).

Reduction with Sodium and Ethanol.—Fourteen gram atoms (322 g.) of sodium in 0.25-inch cubes was added piecewise to 5 moles (420 g.) of methyl cyclopropyl ketone, 1500 ml. of ethanol and 500 ml. of water in a 3-liter flask equipped with a mercury-seal stirrer and a reflux condenser. During the addition of the sodium the reaction mixture was cooled to 10 to 15° by means of an ice-bath. When the addition was completed, the reactants were allowed to warm to room temperature to permit complete dissolution of the sodium. The mixture was then hydrolyzed by slowly adding 2 liters of cold water. The products were extracted from the water layer with ether and dried over anhydrous sodium sulfate. The dried ether solution was fractionated to yield 181 g., 42% yield, of methylcyclopropylcarbinol, b. p. 120–122°.

Reduction with Lithium Aluminum Hydride.—Five moles of methyl cyclopropyl ketone was added to a solution of approximately 2 moles (76 g.) of lithium aluminum hydride in 2 l. of dry ether in accordance with a previously described procedure.[5] The reaction mixture was stirred overnight and then hydrolyzed by the addition of 200 ml. of water and subsequently 1800 ml. of 10% sulfuric acid

solution. The ether layer was washed with saturated sodium bicarbonate solution, dried over "Drierite," and fractionated to yield 291 g. of carbinol, b. p. 121–122°. An additional 38 g. of carbinol was obtained by re-working the fore-run fractions; total yield was 76%.

Catalytic Reduction with Raney Nickel.—Five moles of methyl cyclopropyl ketone, 200 ml. of ethanol and approximately 25 g. of Raney nickel were sealed in a 1.25-l. rocking autoclave, and hydrogen was admitted to 1200 p. s. i. at room temperature. The reactants were gradually heated to 90° at which temperature hydrogenation began. Maximum temperature reached was 125°. The hydrogenation was stopped when the theoretical amount of hydrogen had been consumed. The product was fractionated to yield 46 g. of unconverted ketone, 131 g. of pentanol-2, and 145 g., 34% yield, of methylcyclopropylcarbinol, b. p. 120–122°.

Catalytic Reduction with Copper Chromite.—Three hydrogenations were run in essentially the same manner as follows with the exception of a difference in temperature: Five moles of methyl cyclopropyl ketone and 42 g. of a commercial barium-promoted copper chromite catalyst[6] were sealed into the previously mentioned hydrogenation vessel, and hydrogen was admitted to 1750 p. s. i. at room temperature. The reactants were heated to 100°, and after an induction period of about five hours, hydrogenation began. The reaction was completed within about four hours as indicated by the hydrogen consumption dropping to virtually nothing. With the exceptions of about 20 g. of fore-run the product consisted of 390 g., 90% yield of methylcyclopropylcarbinol, b. p. 121–122°. The 3,5-dinitrobenzoate was prepared, m. p. 88.5–89.0° (uncor.). *Anal.* Calcd. for $C_{12}H_{12}O_6N_2$: N, 10.00. Found: N, 9.86.

When the hydrogenation was carried out at 120°, the yield of carbinol was 374 g., or 87%. At 150° the yield was 326 g., 76% yield of carbinol, b. p. 118–120°. From the refractive index it was evident that a close-boiling impurity of lower index than methylcyclopropylcarbinol was present. The impurity was assumed to be pentanol-2.

Preparation of Organopolysiloxanes from Sodium Trimethylsilanolate[1,2]

BY LEO H. SOMMER, LARRY Q. GREEN AND FRANK C. WHITMORE

The availability of trimethylsilanol in good yield and high purity from the controlled hydrolysis of trimethylfluorosilane, and its rapid and complete reaction with sodium to give sodium trimethylsilanolate,[3] led to a study of the latter as an intermediate for further synthesis.

In the present work sodium trimethylsilanolate was found to readily undergo Williamson type reactions with diethyldichlorosilane, ethyltrichlorosilane and silicon tetrachloride, according to the general equation

$$R_xSiCl_{4-x} + (4-x)(CH_3)_3SiONa \longrightarrow R_xSi[(CH_3)_3SiO]_{4-x} + (4-x)NaCl$$

By this method there were synthesized diethyldi-(trimethylsiloxy)-silane (I), ethyltri-(trimethylsiloxy)-silane (II), and tetra-(trimethylsiloxy)-silane (III). Alternate names by the siloxane nomenclature are somewhat more cumbersome, *i. e.*, 1,1,1,5,5,5-hexamethyl-3,3-diethyltrisiloxane (I).

$(C_2H_5)_2Si[OSi(CH_3)_3]_2$ (I)

$C_2H_5Si[OSi(CH_3)_3]_3$ (II)

$Si[OSi(CH_3)_3]_4$ (III)

Compounds I and II are new organopolysiloxanes of a type not readily obtained in good yields by other methods which comprise cohydrolysis of the appropriate pair of monomers. Compound III was previously prepared in 27% yield by the cohydrolysis of ethyl orthosilicate and trimethylethoxysilane with aqueous sodium hydroxide.[4]

In the present work compound III was also prepared by reaction of trimethylsilanol with ethyl orthosilicate in the presence of a small amount of sodium.

$$4\,(CH_3)_3SiOH + (C_2H_5O)_4Si \longrightarrow Si[OSi(CH_3)_3]_4 + 4\,C_2H_5OH$$

[a] Melting point, *ca.* −60°. [b] Constants reported previously for compd. III (ref. 4) are $n^{25}D$ 1.3865, b. p. 91° (9 mm.). In a private communication Dr. M. J. Hunter informs us that the density given in ref. 4 should be changed to d^{25} 0.8630. [c] Calculated by the Lorentz-Lorenz equation. [d] Calculated by the method of Warrick, THIS JOURNAL, 68, 2455 (1946).

In Table I are listed the three organopolysiloxanes and some of their physical properties.

Comparison of compounds I and II with the previously reported octamethyltrisiloxane and methyl-(trimethylsiloxy)-silane,[5] respectively, shows that boiling points, densities and refractive indices are greater in compounds I and II by amounts approximating those to be expected from the substitution of ethyl for methyl.

A more interesting comparison is given by the highly-branched compound III and its linear isomer, dodecamethylpentasiloxane.[5] In compound III, boiling point, refractive index and density are

lower, and the melting point is higher. The differences are: b. p., 9°; $n^{20}D$ 0.0030; d^{20} 0.0078; m. p. 24°.

Viscosity measurements were similar to those of other organopolysiloxanes with respect to the temperature dependence of viscosity.

Experimental

Syntheses with Sodium Trimethylsilanolate.—The synthesis of tetra-(trimethylsiloxy)-silane will be described as representative of the procedure employed. In a 1-liter round-bottomed flask fitted with a reflux condenser there were placed 500 cc. of dry benzene and 110 g. (1.2 moles) of trimethylsilanol.[3] To this was added 30.1 g. (1.3 moles) of sodium cut into small pieces. Immediate reaction occurred, accompanied by evolution of hydrogen. Since a good deal of heat was evolved, the reaction flask was cooled externally in order to prevent the reaction from becoming too violent. After reaction had slackened heat was applied for two hours, causing a gentle reflux of benzene, in order to insure complete reaction. At this point the solution was slightly opalescent, but no sodium trimethylsilanolate separated. After cooling, the solution was decanted from the excess sodium into the flask in which the siloxane preparation was to be carried out. The remaining sodium was washed twice with small portions of benzene and the washings added to the bulk of the silanolate solution. The unreacted sodium weighed 2.3 g., indicating that the theoretical quantity, 27.8 g., had reacted with the silanol.

Reaction of the benzene solution of sodium trimethylsilanolate with silicon tetrachloride was performed in a 1-liter three-necked flask fitted with an efficient stirrer, reflux condenser and dropping funnel. The silicon tetrachloride, 42.5 g. (0.25 mole) was distilled directly into the dropping funnel, care being taken to exclude moisture. It was added to the silanolate during forty-five minutes while cooling the reaction flask in an ice-bath. After completion of the addition, the mixture was heated to reflux temperature for forty hours resulting in the separation of a considerable amount of sodium chloride. Sufficient water was then added to dissolve all solid material, the benzene layer separated, and the aqueous layer extracted with two 100-cc. portions of benzene. The benzene solution of the product was dried over anhydrous potassium carbonate and the benzene removed by distillation. Fractional distillation of the residue in a glass-helix packed column of about twelve theoretical plates gave 36.3 g. (0.095 mole) of tetra-(trimethylsiloxy)-silane, b. p. 96° (13 mm.), a yield of 38%. Table II gives pertinent data for the three syntheses.

TABLE II

Cpd.	Yield,[a] %	Mol. wt. Calcd.	Mol. wt. Found[b]	Si, % Calcd.	Si, % Found
I	52	264.5	264	31.8	31.8
II	44	324.5	327	34.6	34.3
III	38	384.7	386	36.5	36.2

[a] Yields are based on the quantity of chlorosilane, sodium trimethylsilanolate being present in approximately 20% excess. [b] Cryoscopically in benzene.

An attempted preparation of diethyldi-(trimethylsiloxy)-silane from the silanolate and diethyldichlorosilane in ethyl ether solution resulted in failure, thus indicating the need for a higher boiling solvent in these preparations.

Tetra-(trimethylsiloxy)-silane from Trimethylsilanol and Ethyl Orthosilicate.—A preliminary experiment indicated that ethanol and trimethylsilanol form an azeotropic mixture boiling in the range 62–70°. Since this would prevent the reaction from effectively being driven to completion by slow removal of ethanol, a large yield of tetra-(trimethylsiloxy)-silane was not expected.

In a 200-cc. round-bottomed flask were placed 41.7 g. (0.20 mole) of ethyl orthosilicate, 90 g. (1.00 mole) of trimethylsilanol, and a small amount (*ca.* 0.2 g.) of sodium. The mixture was heated at reflux temperature in a fractionating column for twenty-two hours. Fractionation in a glass-helix packed column of about twelve theoretical plates gave 14 g. of slightly impure tetra-(trimethylsiloxy)-silane, b. p. 215° at 732 mm. (uncor.), $n^{20}D$ 1.3889, mol. wt., 391 (calcd., 384.7), d^{20} 0.868, a yield of 18%. Other fractions obtained, b. 195–215°, 29.8 g., likely consist of products resulting from incomplete replacement of ethoxy groups by trimethylsiloxy groups.

Physical Properties.—Boiling points were determined in a modified Cottrell apparatus.[6] Densities were measured with pycnometers of about 5-cc. capacity. Viscosities were determined in Cannon–Fenske viscometers.[7]

Acknowledgment.—We thank Dr. F. Fischl of Standard Oil Development Co., Elizabeth, N. J., for the determination of the melting point of tetra-(trimethylsiloxy)-silane.

STATE COLLEGE, PA. RECEIVED FEBRUARY 25, 1949

Di-*t*-butyl-di-aminoalkyl Silicates[1]

BY PHILIP A. DI GIORGIO,[2] LEO H. SOMMER AND FRANK C. WHITMORE

Di-*t*-butoxydiaminosilane[3] reacts with amino alcohols to yield di-*t*-butyl-di-aminoalkyl silicates.[4] The following equation is illustrative of the reaction.

$$(t\text{-BuO})_2Si(NH_2)_2 + 2HOCH_2CH_2NH_2 \longrightarrow (t\text{-BuO})_2Si(OCH_2CH_2NH_2)_2 + 2NH_3$$

By this method we have synthesized six new di-*t*-butyl-di-aminoalkyl silicates whose properties are listed in Table I.

For the syntheses, generally a solution of one mole of di-*t*-butoxydiaminosilane and two moles of amino alcohol was refluxed for one to three hours at approximately 150–200°. After the theoretical weight of ammonia had been evolved, the crude product was purified by distillation under reduced pressure. The yields of di-*t*-butyl-di-aminoalkyl silicates ranged from 40 to 70%.

The products were viscous, water-white liquids having little or no odor. The 2-aminoethyl and 2-(β-aminoethylamino)-ethyl compounds were found to be very soluble in water, but the other compounds were substantially insoluble. Di-*t*-butyl-di-(2-aminoethyl) silicate dissolved readily in ligroin, benzene, carbon tetrachloride, 95% ethanol, ether, acetone and pyridine. This silicate did not react with molten sodium. Most of the

[a] The 100% excess amino alcohol used was recovered and in later runs was shown to be unnecessary. In a run which was stopped before it went to completion, there was isolated 70 g. of material boiling at 130° at 12 mm., $n^{20}D$ 1.4261, d^{20} 0.9180, MR_D 85.56, equivalent weight 154. Theoretical values for di-*t*-butoxy-(2-diethylaminoethoxy)-aminosilane, $(t\text{-BuO})_2(Et_2NCH_2CH_2O)SiNH_2$ are: equivalent weight 153 and MR_D 85.35. [b] These physical properties are those of a center fraction of the distillation flat which was taken as purified product. [c] Micro-Dumas by Mr. R. N. Walter. [d] Micro-Kjeldahl reported by Dr. P. M. Althouse as the average of three or more determinations with repeated cross-checks through tryptophan and urea standards. [e] A solution of the sample in aqueous methanol was titrated with 0.1 *N* hydrochloric acid to the methyl red end-point. [f] The calculated values were obtained by use of bond refractions given by Denbigh, *Trans. Faraday Soc.*, 36, 936 (1940), and by Warrick, THIS JOURNAL, 68, 2455 (1946). Similar results may be obtained by use of the method of Sauer, *ibid.*, 68, 954 (1946). The average deviation was 0.26 ml. when the sign was disgarded and 0.04 ml. when the sign was considered. Molecular refractions calculated for the alternate structure having the amino alcohol residue attached to silicon through nitrogen with the hydroxyl free showed an average deviation of 0.39 ml. when the sign was disregarded and 0.31 ml. when the sign was considered.

compounds prepared were sufficiently basic to be titrated completely with hydrochloric acid using methyl red indicator.

It is very improbable that the amino alcohol residues were attached to silicon through nitrogen rather than through oxygen. The structures involving attachment through oxygen were assigned for the following reasons: (1) 2-diethylaminoethanol, which contains no hydrogen atoms attached to nitrogen, reacted with the diaminosilane in a manner analogous to other amino alcohols containing unsubstituted amino groups; and the product obtained with 2-diethylaminoethanol had properties analogous to those of compounds obtained with amino alcohols possessing free amino groups; (2) if the nitrogen were attached to silicon, it is unlikely that it would be sufficiently basic to be titrated quickly and completely with hydrochloric acid using methyl red indicator; (3) the inertness of the di-*t*-butyl-di-(2-aminoethyl) silicate toward molten sodium indicates the absence of free hydroxyl groups.

Experimental

Intermediates. A. Amino Alcohols.—Sharples Co. 2-ethylaminoethanol and Eastman Kodak Co. 2-aminoethanol, 2-diethylaminoethanol, and 2-amino-2-methylpropanol were distilled before use. Commercial Solvents 2-aminobutanol, Dow 1-amino-2-propanol, and Eastman 2-(β-aminoethylamino)-ethanol were used as received. The properties of the intermediate known amino alcohols as used are listed below.

Compound	B. p., uncor. °C.	Mm.	$n^{20}D$	d^{20}
$NH_2CH_2CH_2OH$	83–86	21	1.455	1.016
$C_2H_5NHCH_2CH_2OH$	165	740	1.4411	0.9162
$(C_2H_5)_2NCH_2CH_2OH$	56–57	15	1.4412	0.8921
$CH_3C(CH_3)(NH_2)CH_2OH$	75	16	1.4482	
$CH_3CH_2CH(NH_2)CH_2OH$			1.4524	
$CH_3CH(OH)CH_2NH_2$			1.4479	
$NH_2CH_2CH_2NHCH_2CH_2OH$			1.486	

B. Di-*t*-butoxydiaminosilane.—This intermediate was used as received from the Minnesota Mining and Manufacturing Co. The material had equivalent weight 107, $n^{20}D$ 1.4200 and d^{20} 0.9281. Distillation of a portion indicated over 95% purity. A center fraction had the following properties: b. p. 104° at 20 mm., $n^{20}D$ 1.4199, d^{20} 0.9276. The observed MR_D was 56.28 and the value calculated as indicated in Table I was 55.68.

Anal. Calcd. for $C_8H_{22}O_2N_2Si$: equivalent weight, 103; N, 13.58. Found: equivalent weight 106; N (Dumas), 13.58.

Synthesis of Di-*t*-butyl-di-aminoalkyl Silicates.—All six compounds were prepared in essentially the same manner. The following detailed description of the synthesis of di-*t*-butyl-di-(2-amino-1-methyl-ethyl) silicate (III) is representative of the method used. Yields, properties, and analyses of the six new compounds prepared may be found in Table I.

A solution of 231 g., 3.1 moles, of 1-amino-2-propanol and 309 g., 1.5 moles, of di-*t*-butoxydiaminosilane was refluxed for one hour in a two-liter, round-bottom flask equipped with water-cooled reflux condenser. Since at the end of this period the weight loss of the reactants corresponded to the theoretical weight of ammonia expected, the reaction was considered to have gone to completion. (Some of the other amino alcohols required a three-hour reflux period for completion of the reaction.) The equivalent weight of the crude product was 155, while the calculated equivalent weight of the expected product was 161. Distillation of the crude product at reduced pressure gave 345 g., 1.1 moles, of di-*t*-butyl-di-(2-amino-1-methyl-ethyl) silicate III.

Other compounds prepared by this method were: di-*t*-butyl-di-(2-aminoethyl) silicate I, di-*t*-butyl-di-(2-diethylaminoethyl) silicate II, di-*t*-butyl-di-(2-aminobutyl) silicate IV, di-*t*-butyl-di-(2-amino-2-methyl-propyl) silicate V, and di-*t*-butyl-di-[2-(β-aminoethylamino)-ethyl] silicate VI.

For a number of the syntheses the material balances on distillation were consistently low. In one run the volatile material lost was shown to be *t*-butyl alcohol by its melting point, boiling point, refractive index, water solubility, and conversion to *t*-butyl chloride with concentrated hydrochloric acid. Higher boiling fractions from a number of the syntheses had a high refractive index and low equivalent weight indicative of ester-interchange between *t*-butoxy groups and amino alcohol molecules.

The reaction of 2.0 moles of 2-ethylaminoethanol with 1.0 mole of di-*t*-butoxydiaminosilane repeatedly gave an anomalous result. The theoretical weight loss was attained in one and one-half hours; however, distillation of the crude product gave, as indicated by equivalent weights, an approximately equimolar mixture of di-*t*-butyl-di-(2-ethylaminoethyl) silicate, b. p. 165° at 16 mm. and $n^{20}D$ 1.423, and *t*-butyl-tri-(2-ethylaminoethyl) silicate, b. p. 185° at 19 mm. and $n^{20}D$ 1.435. The high refractive index of the higher boiling material precludes its being hexa-*t*-butoxydisilazane resulting from the condensation of di-*t*-

butoxy-diaminosilane. The presumed di-*t*-butyl-di-(2-ethylaminoethyl) silicate boiled at 285° at 740 mm. and did not decompose appreciably upon being refluxed at this temperature for one hour. Variation of conditions by adding the diaminosilane to the refluxing amino alcohol and *vice versa* appeared to give no improvement in eliminating or minimizing the formation of the side-product arising presumably by ester-interchange.

Solubility and Specific Rotation of *l*-Ascorbyl Palmitate and *l*-Ascorbyl Laurate

BY DANIEL SWERN

Renewed interest in *l*-ascorbyl palmitate,[2] resulting from its recently reported antiscorbutic activity,[3] non-toxicity[4] and commercial availability[5] has prompted us to determine its solubility at 25° in some typical organic solvents, water, and cottonseed and peanut oils. For purposes of comparison, we also determined the solubility of *l*-ascorbyl laurate[2] in the two vegetable oils. We have also determined the specific rotation of both *l*-ascorbyl palmitate and laurate. With the exception of water and petroleum naphtha, the temperature coefficient of solubility is high. Benzene and ethyl acetate are two of the best crystallizing solvents for purifying the esters.

Experimental

Solubility Determinations.[6]—Solubility in petroleum naphtha, boiling range 63–70°, and water was determined on saturated solutions obtained by shaking the solvent with excess solute until equilibrium, ascertained by analysis, was attained. With all the other solvents, equilibrium was approached from the solution side by allowing excess solute to crystallize. Dissolved ester was determined either by titration with 0.1 *N* sodium hydroxide[2] or by evaporation of solvent. At least two determinations were run; precision of duplicates was about five parts per thousand. Solubility of *l*-ascorbyl palmitate in glycerol could not be determined because the solution was a thick gel. Its solubility, however, appeared to be low. Results are summarized in Table I.

Specific Rotation.—Specific rotation was determined with a Bellingham and Stanley Glass Seale polarimeter that could be read directly to 0.01°. A 5–10% solution of the ester in 95% alcohol and a 4.00-dm. tube were employed.

l-Ascorbyl palmitate: $[\alpha]^{25.5}D + 23.3°$ (8.086 g. per 100 ml. of 95% ethanol solution). *l*-Ascorbyl laurate: $[\alpha]^{25.5}D + 26.6°$ (5.014 g. per 100 ml. of 95% ethanol solution).

TABLE I

SOLUBILITY AT 25 ± 0.10°: *l*-ASCORBYL ESTERS

Solvent	Sol.[a] g./100 g.	Solvent	Sol.[a] g./100 g.

Preparation of Fluorothiophene

BY ROBERT T. VANVLECK

Chloro- and bromothiophene are offered in the industrial market and iodothiophene is reported in the literature, but no reference has been made to fluorothiophene. This compound has been prepared in these Laboratories in small yields by the reaction of antimony trifluoride with iodothiophene in the presence of nitromethane as a solvent. The preparation of fluorothiophene from 2-iodothiophene indicates that the fluoro compound is the 2-isomer.

Nitroethane, nitropropane and *t*-butylthiophene were found not suitable as solvents for the reaction. Various other methods for preparing fluorothiophene proved unsuccessful; they include the reaction of antimony trifluoride with either chloro- or bromothiophene, the reaction of aluminum trifluoride with chlorothiophene, and the reaction of fluoboric acid with thiophene diazonium chloride. This last reaction was studied in an unsuccessful attempt to adapt Flood's synthesis of fluorobenzene[1] to the preparation of the thiophene analog. It is possible that the diazonium chloride was not obtained due to the instability of the aminothiophene.

Experimental

A mixture of 150 g. (0.72 mol) of iodothiophene and 43 g. (0.24 mole) of antimony trifluoride in 250 ml. of nitromethane was heated in a flask at reflux temperature (90–100°) for five hours; the product fluorothiophene distilled over through a small column as formed plus some

Extraction of Cerium(IV) Nitrate by Butyl Phosphate[1a]

BY JAMES C. WARF[1b]

The extraction of inorganic compounds by organic solvents sometimes affords a unique method for rapidly and easily separating compounds of certain metals from common impurities. Well-known examples include the characteristic extraction of iron(III) chloride and the chlorides of a few other metals by ether, the extraction of uranyl nitrate by ether, the extraction of silver perchlorate by toluene,[2] and more recently the extraction of thorium nitrate by methyl isobutyl ketone and other solvents.[3] The extraction of cerium(IV) nitrate by ether was employed by Imre,[4] who observed that the solvent was attacked, generating heat and necessitating cooling, and that high nitric acid concentrations were required for efficient extraction. Pure ceria, however, could be produced.

A number of solvents expected to be resistant to the strong oxidizing action of cerium(IV) nitrate were tested, and nitromethane and tri-*n*-butyl phosphate found to be most satisfactory. The extent of removal of the cerium from the aqueous phase was also investigated.

Ammonium hexanitratocerate(IV) from the G. Frederick Smith Chemical Co. was employed. Tri-*n*-butyl phosphate from the Eastman Kodak Co. was vacuum distilled, the portion boiling at 145–150° (8 mm.) being collected separately; it was saturated with water before use.

The degree of stability of the solvent toward oxidation by the solute was established by permitting portions of solutions 0.5 *F* in ammonium hexanitratocerate(IV) and 1.0 *F* in nitric acid to stand at room temperature with the solvent for increasing periods of time, after which the cerium(IV) content was determined by titration with iron(II) sulfate solution using tris-(1,10-phenanthroline)-iron(II) sulfate as indicator.

The extent of extraction of the cerium(IV) nitrate was determined similarly by separating layers and titrating each immediately. The solvent layer was scrubbed several times with a solution 1.0 *F* each in nitric acid and ammonium nitrate before re-extraction of the cerium.

The rate of reduction of the cerium(IV) nitrate by butyl phosphate under the conditions described is indicated by the following results: After 1.6 hours, 1% of the total cerium(IV) was reduced; after 35 hours, 5%; after 120 hours, 10%; after 500 hours, 31%; and after 820 hours, 45%.

Conditions for favorable extraction were found to cover a wide range, 98–99% of the cerium entering the solvent when equal phase volumes were employed, regardless of the ammonium nitrate and nitric acid concentrations. The presence of nitric acid was found necessary to promote clean separation of the layers. At extreme dilution (0.001 *F* Ce(IV)) less favorable partition was observed, only 60–70% being extracted. Solutions of ammonium hexanitratocerate(IV) in 1.0 *F* nitric acid were used most frequently. Aqueous phases after extraction were colorless, and a few per cent. of the cerium(IV) was reduced to cerium(III) during the course of the operations. Addition of ammonium acetate or perchlorate to the aqueous phase had little effect on the degree of extraction, but ammonium sulfate caused serious interference.

Recovery of the cerium from the butyl phosphate by re-extraction with water or dilute nitric acid was slow and laborious, although the use of ammonium sulfate solutions was feasible. Generally the cerium(IV) was quickly and quantitatively re-extracted through reduction to cerium(III) by hydrogen peroxide; hydroxylamine, formaldehyde or glucose also were employed. Evaporation of aqueous solutions of the recovered cerium(III) salts and ignition yielded gray or black products, owing to the presence of pyrophosphates. This difficulty was avoided by washing the water phase thoroughly with benzene or carbon tetrachloride, to remove the small quantity of dissolved butyl phosphate, before evaporation or precipitation of cerium(III) oxalate. Cerium(IV) oxide resulting on ignition after such treatment was practically pure white, and contained negligible amounts of phosphorus.

Over 99.5% of the cerium could be removed from cerium(III) nitrate solutions by first oxidizing electrolytically as recommended by Smith, Frank and Kott,[5] in three steps, each followed by a butyl phosphate extraction. It was found more convenient to perform the oxidation chemically, using bromates in strong nitric acid solution, a procedure first employed by Schuman.[6] In order to realize quantitative removal of the cerium, a small continuous extractor was used.

A U-tube stirrer-extractor, described by Huzise,[7] was constructed. It was charged with 100–150 ml. of a solution 0.2 *F* in cerium(III) nitrate, 8–10 *F* in nitric acid, and 3 *F* in sodium nitrate. Small portions of solid sodium bromate were added over a period of two to three hours, using a total of 3 g., while butyl phosphate was run

through the extractor, a total of 300 ml. being employed. The solvent was well dispersed by the stirrer, and rose to form a static layer in the exit arm of the U-tube, from which it drained at the same rate at which fresh solvent was added. Qualitative tests showed no detectable cerium remaining in the water phase. The butyl phosphate extracted bromine as well as cerium.

Uranyl and thorium nitrates were observed to be readily extracted by butyl phosphate. These elements can be separated by extraction of cerium(III) solutions. The extraction of iron, zirconyl and lanthanum nitrates by butyl phosphate was also studied. The results showed that excellent separation from iron, fair separation from zirconium, and rather poor separation from lanthanum can be expected.

Iron(II) nitrate solutions, containing 1 mg. to 5 g. of iron per 100 ml., and 1.0 *F* in nitric acid, were extracted with butyl phosphate, the organic layer washed with ammonium nitrate–nitric acid solution, and re-extracted with hydrogen peroxide. The amount of iron thus recovered was determined spectrophotometrically with 1,10-phenanthroline and the ratio of the amount of iron in the original aqueous phase to the amount from the organic phase taken as a "separation factor." This factor varied from 2000 for low iron concentrations to 1.6×10^6 for the high concentrations. Similar experiments with zirconium, using a radioactive isotope (Zr^{95}, half-life 65 days) showed separation factors of 200 to 600, while with lanthanum (La^{140}, half-life 40 hours), factors of only 80 to 100 were observed. Lanthanum nitrate solution (500 mg. of La per 100 ml.) was extracted exhaustively by the stirrer U-tube technique described above, using sodium bromate, when 4 to 7% was found to be carried over.[8]

The high degree of extraction by butyl phosphate over a wide range of conditions suggested formation of a compound between the solvent and cerium(IV) nitrate.

Absorption spectra of aqueous and butyl phosphate solutions each 0.05 *F* in cerium(IV) nitrate were identical except for a slight shift toward the longer wave lengths for the non-aqueous solution. The absorption curves had no maxima, and both solutions were transparent for wave lengths above 580 mμ. The solvents were non-absorbing for wave lengths above 400 mμ. Kjeldahl analyses of the organic phase showed that no ammonium compound was present. Treatment of small known quantities of the solvent with a large excess of cerium(IV) nitrate solution, followed by extraction with carbon tetrachloride and determination of the Ce(IV) content, showed Bu_3PO_4/Ce ratios of 2.5 ± 0.1. Butyl phosphate extracts of ammonium hexanitratocerate(IV) from solutions containing no additional nitric acid were analyzed for nitrate by the nitron method,[9] and for cerium(IV), which gave NO_3/Ce ratios of 3.3 ± 0.2. While these values do not coincide with the ratios demanded by a simple formula, there was also no assurance of complete conversion of the reactants into a single compound. The analytical work was not pursued sufficiently to establish unambiguously the identity of the extracted substance or substances.

(8) Electrolytic oxidation is preferred to the use of bromates, for the latter seemed to permit greater extraction of iron, zirconium, and lanthanum. This may be attributable to the formation of bromides. It was observed that the behavior of zirconyl halides toward butyl phosphate extraction was quite different from that of the nitrate.

NEW COMPOUNDS

The Diacetate of 2-Methyl-1,3-pentanediol

Investigations in this Laboratory led to the preparation of the diacetate of 2-methyl-1,3-pentanediol. This new compound is of interest as it was reported by previous investigators[1] that the reaction of 2-methyl-1,3-pentanediol with acetic anhydride yields only the monoacetyl derivative.

Procedure.—One-half mole of 2-methyl-1,3-pentanediol and one-half mole of acetic anhydride were refluxed with a trace of sulfuric acid for three hours. At the end of this period, toluene was added to the reaction flask and a water-trap placed in the reflux system. The water from the reaction was then removed by refluxing with the toluene. The glycol diacetate was recovered in good yield after removal of the toluene and subsequent fractionation through a five-bulb Snyder column.

The physical constants of the diacetate of 2-methyl-1,3-pentanediol are: b. p., 225° (uncor.); d^{20}_4 1.0025; $n^{20}D$ 1.4253; *anal.* 99% ester content as the diacetate of 2-methyl-1,3-pentanediol; mol. ref. 51.68 found; 51.56 calcd.

Esters of 5-Methyl-2-thenoic Acid

The esters of 5-methyl-2-thenoic acid listed in Table I were prepared by refluxing 10 g. (0.07 mole) of the acid[1] in an excess (125 ml.) of the required alcohol containing 6–7 ml. of concd. sulfuric acid. After refluxing for four hours, the esters were worked up in the usual manner, and vacuum-distilled.

Some Quaternary Salts of Carbamates of Amino Alcohols[1]

A series of compounds of the general formula $[R_3'N—A—OCONR_2]^+I^-$ has been prepared (Table I). The unsubstituted carbamates (both R = H) were prepared by method 1, the N-methylcarbamates (R = CH_3, and R = H) by method 2, and the N,N-dimethylcarbamates (both R = CH_3) by method 3.

(1) Reaction of a dialkylamino alcohol with phosgene gave the dialkylaminoalkyl chloroformate, which reacted with ammonia to give the urethan. Condensation with an alkyl iodide gave the quaternary salt.[2]

$$R_2N(CH_2)_nOH \xrightarrow{COCl_2} R_2N(CH_2)_nOCOCl \xrightarrow{NH_3} R_2N(CH_2)_nOCONH_2 \xrightarrow{RI} [R_3N(CH_2)_nOCONH_2]^+I^-$$

(2) Reaction of a dialkylamino alcohol with methyl isocyanate gave a carbamate, which reacted with an alkyl iodide to give the quaternary salt.

$$R_2N(CH_2)_nOH \xrightarrow{CH_3NCO} R_2N(CH_2)_nOCONHCH_3 \xrightarrow{RI} [R_3N(CH_2)_nOCONHCH_3]^+I^-$$

(3) Reaction of a chloro alcohol and phosgene gave the chloroalkyl chloroformate, which was converted to the iodoalkyl carbamate by reaction first with dimethylamine and then with sodium iodide in acetone. Condensation of the iodoalkyl carbamate with a tertiary amine gave the quaternary salt.[3]

$$Cl(CH_2)_nOH \xrightarrow{COCl_2} Cl(CH_2)_nOCOCl \xrightarrow{(CH_3)_2NH} Cl(CH_2)_nOCON(CH_3)_2 \xrightarrow{NaI} I(CH_2)_nOCON(CH_3)_2 \xrightarrow{R_3N} [R_3N(CH_2)_nOCON(CH_3)_2]^+I^-$$

Stilbestrol Esters

Since a new series of testosterone esters[1] was found to have greater androgenic activity than testosterone propionate, similar stilbestrol esters have been prepared to determine whether these esters have any advantage over stilbestrol dipropionate. Two representative esters have been prepared.

Diethylstilbestrol Di-ethoxyacetate.—A solution of 1 g. of diethylstilbestrol (1 mole) in 15 cc. of dry ether and 6 cc. of dry pyridine was prepared. To this was added 2 cc. of ethoxyacetyl chloride (5 mole) in 10 cc. of dry ether. The reaction mixture was refluxed for one hour and 100 cc. more ether was added. This was poured into water and the ether layer separated, washed with dilute sulfuric acid, dilute sodium carbonate solution and water. Evaporation of the ether left 1.40 g. of reddish white powder, m. p. 129–136°. The product was taken up in a large amount of ether and filtered through activated alumina (Aluminum Ore Co. mm. 80 mesh). The red color was adsorbed on the alumina. Evaporation of the ether left a residue which was twice crystallized from 95% ethanol giving a product (1.05 g.) melting at 136.5–137.5°.

Anal. Calcd. for $C_{26}H_{32}O_6$: C, 70.89; H, 7.32. Found: C, 71.16; H, 7.57.

(1) Mooradian and Lawson, in press.

Diethylstilbestrol Di-ethylmercaptoacetate.—This ester was prepared just as was the preceding ester. The purification was carried out by evaporating the ether extract to dryness and taking the residue up in 10 cc. of ether and 40 cc. of Skellysolve A. This solution was passed through activated alumina and the alumina was then extracted with 1:4 ether–Skellysolve A. The extract was evaporated and the absorption-elution process carried out twice more. Finally the crude product (1.05 g.) was crystallized once from Skellysolve B and twice from 95% ethanol giving a yellowish product 0.30 g., m. p. 99–101°.

Anal. Calcd. for $C_{26}H_{32}O_4S_2$: C, 66.04; H, 6.83; S, 13.57. Found: C, 66.01; H, 6.73; S, 13.83.

THE USE OF CADMIUM IODIDE IN STARCH–IODINE COLORIMETRIC PROCEDURES

Sir:

In the course of an investigation[1] on methods of analysis for trace amounts of selenium in water, it was found that cadmium iodide and starch form a stable solution which may be used as a colorimetric reagent for a number of oxidizing substances. The reduction potential of the iodide in such a solution is a function of the *p*H. By proper adjustment of the *p*H, the iodide may be "exposed" to oxidation by oxidizing agents for controlled periods of time and in this way it was found possible to determine one oxidizing agent in the presence of others.

Cadmium iodide crystals may have a brownish discoloration which is shown by reaction with starch to be free iodine. However, after an aqueous solution of cadmium iodide is boiled for ten or fifteen minutes, a colorless solution is obtained. This solution may be added to a solution of starch to give a mixture that is apparently stable indefinitely to atmospheric oxygen and diffused sunlight.

In neutral solution, only the very strongest oxidizing agents, such as chlorine or hypochlorite, are capable of oxidizing the iodide to iodine and producing the blue starch–iodine color. At lower *p*H values, weaker oxidizing agents are able to oxidize the iodide; *e. g.*, nitrous acid is capable of oxidizing the iodide if the *p*H is below about 4.0 but the *p*H must be in the neighborhood of 1.0 or lower before selenious acid is able to react. Dissolved oxygen attacks the cadmium iodide reagent only in the most highly acid solutions, and very slowly even then.

The linear starch "A-fraction" isolated by Schoch[2] gives the best results although commercial soluble starches can be used. The color of the A-fraction starch–iodine complex produced by selenious acid in concentrations from 0.1 to 2.0 p. p. m., as selenium, follows Beer's law quite closely. The absorption band is broad with maximum absorption occurring at about 615 mμ.

Cadmium iodide in aqueous solution has been shown to form one or more auto-complexes, the nature of which has been the subject of several investigations. The complex anion may be CdI_3^-, $CdI_4^=$ or $CdI_5^{\equiv}$, with the cation Cd^{++} or CdI^+.

This reagent is undergoing further investigation in connection with the development of colorimetric methods of determining traces of substances having oxidizing properties, particularly selenium as selenious acid.

We wish to thank T. J. Schoch of the Corn Products Refining Company for providing generous samples of the linear starch A-fraction.

GERMIDINE AND GERMITRINE, TWO NEW ESTER ALKALOIDS FROM *VERATRUM VIRIDE*

Sir:

Recent evidence[1,2] indicates that powdered roots and rhizomes of *Veratrum viride* may produce marked reductions of arterial pressure in patients with essential hypertension. We have isolated from this material two new, highly active ester alkaloids derived from the alkamine germine, which we have named germidine and germitrine.[3]

(1) E. D. Freis and J. R. Stanton, *Am. Heart J.*, **36**, 723 (1948).

(2) E. D. Freis, *et al.*, *J. Clin. Investigation*, **28**, 353 (1949).

(3) Drs. E. D. Freis, J. A. Stanton and F. C. Moister of the Robert Dawson Evans Memorial, Massachusetts Memorial Hospitals, and the Department of Medicine, Boston University School of Medicine, have evaluated more than 100 of our individual alkaloidal fractions in patients with essential hypertension. Their results will be published elsewhere.

Preliminary fractionation of the benzene-extractable alkaloids by the excellent procedure of Jacobs and Craig[4] yielded the five known crystalline alkaloids and a large amorphous fraction; only the latter was active as a hypotensive agent at low dosage. Further fractionation of this material guided by assay[3] in hypertensive patients yielded a highly active concentrate, which on 24-plate Craig distribution, using 2 *M* acetate buffer at *p*H 5.5 and benzene as the immiscible phases, exhibited two discrete peaks. The material having a peak at tube 15 ($K = 1.67$) showed activity when administered orally in doses of 0.6–0.8 mg. per patient, while the material from the second peak, at tube 6 ($K = 0.35$), was active at about 4 mg. These fractions crystallized readily from methanol–water and ethanol–water respectively, yielding germidine (m. p. 220–223° (cor.); $[\alpha]^{25}D + 13°$ (*c*, 1.67 in chloroform)) and germitrine (m. p. 197–199° (cor.); $[\alpha]^{25}D + 11°$ (*c*, 1.54 in chloroform)).

Room temperature hydrolysis of germidine with 0.1 *N* aqueous methanolic alkali afforded germine ($C_{27}H_{43}O_8N$),[5] acetic acid and α-methylbutyric acid. The former was identified by rotation, analysis and conversion into monoacetonylgermine hydrochloride.[6] The acids, after conversion into the *p*-phenylphenacyl esters followed by chromatography on alumina, yielded *p*-phenylphenacyl α-methylbutyrate[7] (m. p. 71–72° (cor.)) and *p*-phenylphenacyl acetate[8] (m. p. 109–110° (cor.)). Analysis of the free base and the crystalline thiocyanate (m. p. 242–244° dec. (cor.)) indicates germidine to be an ester of germine with one mole each of the above acids.

Hydrolysis of germitrine yielded germine, α-methylbutyric acid and methyl-ethylglycolic acid. The phenylphenacyl ester of the latter (m. p. 119–120° (cor.); $[\alpha]^{25}D + 5°$ (*c*, 0.64 in chloroform)) was identical with an authentic sample.

Analysis of the free base and the thiocyanate (m. p. 228–231° dec. (cor.)) indicates that germitrine is probably a mono-α-methylbutyrate dimethylethylglycolate of germine.

The specific rotations of the branched-chain acids (isolated from the total amorphous fraction because of an insufficient supply of the crystalline alkaloids) showed these materials to be *l*-α-methylbutyric and *d*-methylethylglycolic acids. Germidine and germitrine, injected intravenously in doses of 0.6–0.8 γ per kg., markedly lowered the blood pressure of anesthetized dogs and cats.[9]

THE BIO-OXYGENATION OF 11-DESOXYCORTICOSTERONE AT C-11[1]

Sir:

A number of chemical processes[2] have been elaborated for introducing an oxygen function at C_{11} in the partial synthesis of adrenal cortical hormones. We wish to report a biochemical process, different from any hitherto described, which leads to the production of corticosterone from 11-desoxycorticosterone.

Using methods previously reported,[3,4] it was found that after perfusing 11-desoxycorticosterone (DOC) through isolated adrenal glands the perfusate contained large amounts of glycogenic activity.[5] The method of assay employed was that of Olson, *et al.*[6] The increased glycogenic activity was observed whether plasma or blood was used as the perfusion medium, and in the absence of adrenocorticotrophic hormone (ACTH). The activity could not be accounted for in terms of DOC recovered from the perfusates. Neither perfusion of the gland in the absence of DOC and ACTH,[4] nor the circulation of DOC in the absence of the gland led to significant activity; nor was it possible to demonstrate a synergistic action of DOC upon the glycogenic steroids present in adrenal extracts (Upjohn).

These observations strongly suggested that the isolated adrenal introduced an 11-oxygen function into desoxycorticosterone. Further work has resulted in the isolation from these perfusates of corticosterone, m. p. 173.3–180° (178–180.5°),[7] $[\alpha]^{30}D + 227°$ (*c*, 0.240, ethanol), as the principal crystalline transformation product. The identity was established conclusively by the melting point, 173–181°, of a mixture with an authentic sample of corticosterone (Upjohn), m. p. 173–179° (176.5–181°), and by the formation of an acetate, m. p. 150.5–152.5°, whose mixture with authentic corticosterone 21-acetate, m. p. 151.5–152.5°, melted at 150.5–152°.

Similar perfusion experiments employing 11-desoxycorticosterone 21-acetate also yielded corticosterone, the ester group apparently being hydrolyzed in the course of the perfusion.

These studies have been extended to a variety of steroids including progesterone, 4-androstene-3,17-dione, 17-hydroxyprogesterone, epi-androsterone, androsterone, 17-hydroxy-11-desoxycorticosterone and 5-pregnen-3-ol-20-one, and the

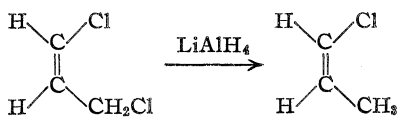
THE CONFIGURATION OF THE 1,3-DICHLOROPROPENES

Sir:

Considerable interest has been shown[1] in the structure of the two isomeric 1,3-dichloropropenes and there has not been complete agreement as to which isomer should be assigned the *cis* configuration and to which the *trans* configuration. This difference of opinion has been caused, in part, by the lack of an unequivocal proof of structure. The configuration of each of the two isomers of 1,3-dichloropropene has now been determined by chemically transforming each isomer into a compound the configuration of which has been established.

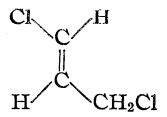
The low boiling isomer of 1,3-dichloropene (b. p. 57.5° (150 mm.), $n^{25}D$ 1.4652, d^{25}_4 1.2048) was refluxed for four hours with sufficient lithium aluminum hydride in isopropyl ether[2] to replace one chlorine atom with a hydrogen atom. By this treatment there was obtained a 50% conversion with a 46% yield of *cis*-1-chloropropene-1 having the following constants: b. p. 32.5° (749 mm.), $n^{20}D$ 1.4054 (lit.[3] b. p. 32.0–32.2° (747 mm.), $n^{20}D$ 1.4053). Similar treatment of the high boiling isomer of 1,3-dichloropropene (b. p. 112.2° (760 mm.), $n^{25}D$ 1.4712, d^{25}_4 1.2139) gave a 56% conversion with a 50% yield of *trans*-1-chloropropene-1, b. p. 37.2° (750 mm.), $n^{20}D$ 1.4048 (lit.[3] b. p. 36.7° (747 mm.), $n^{20}D$ 1.4054). In neither reaction was there any indication of the formation of a mixture of *cis*- and *trans*-1-chloropropene-1.

From these experimental data it follows that the low boiling isomer of 1,3-dichloropropene has the following configuration



Low-boiling 1,3-dichloropropene — *cis*-1-Chloropropene-1

while the high boiling isomer has the remaining configuration



High-boiling 1,3-dichloropropene

This assignment of configuration is in agreement with that proposed by Andrews and Kepner[1b] and not that proposed by Hatch and co-workers.[1a,c]

This method of ascertaining configuration is also being applied to other allylic chlorides which yield compounds of known structure upon replacement of the allylic chlorine atom by a hydrogen atom.

PREPARATION OF ADRENAL CORTICAL HORMONES

Sir:

We have made certain observations in the partial synthesis of adrenal cortical hormones which show that it is possible to introduce the 17α-hydroxy group in 11,20-diketo steroids. In addition we have studied the preparation of the dihydroxyacetone side-chain as exemplified by Reichstein's Compounds S and P. Since the reactions appear to be generally applicable, it is possible to prepare adrenal cortical hormones of both the 11-keto series such as Kendall's Compound E and its 11-desoxy analog, Reichstein's Compound S, both of current interest in their medical application.

When the dienol acetate derived from 3α-hydroxypregnane-11,20-dione (m. p. 200–201°; $[\alpha]^{33}D$ +105° (chloroform); $C_{27}H_{38}O_6$, calcd.: C, 70.71; H, 8.35; found: C, 70.80; H, 8.21) is treated with perbenzoic acid according to the procedure of Kritchevsky and Gallagher[1] the reaction product after saponification yielded 3α,17α-dihydroxypregnane-11,20-dione, m. p. 198–201°; $[\alpha]^{32}D$ +66° (acetone). The monoacetate of this compound, m. p. 202–204°, $[\alpha]^{34}D$ +81° (acetone), upon oxidation with chromic anhydride yielded 3α-acetoxyetiocholane-11,17-dione identical in all respects with the known compound. The enol of the 11-keto group therefore either does not react or reacts to such a negligible extent that isolation of the desired product in good yield is easily possible. This establishes the formation of a 17α-hydroxy derivative from a 20-keto steroid with an 11-keto group.

The preparation of the dihydroxy acetone side-chain characteristic of the most active adrenal hormones is illustrated by the reactions leading to the formation of Reichstein's Compounds P and S. Bromination of 3α-acetoxy-17α-hydroxyallopregnan-20-one with one mole of bromine yielded the 21-bromo derivative, m. p. 184–187°; $C_{23}H_{35}O_4Br$, calcd. Br, 17.76; found: Br, 17.47. Hydrolysis

with 0.05 *N* sodium hydroxide in 60% ethanol at room temperature in a nitrogen atmosphere for ten minutes resulted in replacement of halogen by a hydroxyl group. Acetylation yielded the diacetate of Reichstein's Compound P, m. p. 206–207°; $[\alpha]^{25}D$ +48° (chloroform).

The preparation of Reichstein's Compound S was achieved by the following reactions: 3α-formoxy-17α-hydroxypregnan-20-one (m. p. 184–185°; $[\alpha]^{34}D$ +68° (ethanol), $C_{22}H_{34}O_4$, calcd.: C, 72.89; H, 9.45; found: C, 73.00; H, 9.63) was brominated as in the preceding experiment yielding the 21-bromo compound as a solvate, m. p. 188–190°; $[\alpha]^{35}D$ +75° (ethanol). The formate was converted to the hydroxy compound, m. p. 202–204°, with methanol and dry hydrogen chloride at 5° for fourteen hours. Oxidation of 3α,17α-dihydroxy-21-bromopregnan-20-one with N-bromoacetamide yielded 17α-hydroxy-21-bromopregnan-3,20-dione, m. p. 203–204°; $[\alpha]^{33}D$ +81° (ethanol); $C_{21}H_{31}O_3Br$, calcd.: C, 61.31; H, 7.60; Br, 19.43; found: C, 61.02; H, 7.65; Br, 19.59. Hydrolysis of the halogen was accomplished by the procedure described above and, without isolation, the reaction product was acetylated, yielding 21-acetoxy-17α-hydroxypregnan-3,20-dione, m. p. 195–197°; $[\alpha]^{32}D$ +81° (ethanol). Bromination in acetic acid yielded the 4-bromo derivative (m. p. 196–203°; $[\alpha]^{36}D$ +83° (chloroform); $C_{23}H_{33}O_5Br$, calcd.: Br, 17.03; found: Br, 17.62) which was dehydrobrominated by a modification of the Mattox and Kendall[2] procedure to yield Reichstein's Compound S acetate, m. p. 237–241°; $[\alpha]D$ +116° (acetone); ϵ_{2410} = 17,400 (methanol).

SEPARATION OF ZIRCONIUM AND HAFNIUM WITH ANION EXCHANGE RESINS[1]

Sir:

During the course of an investigation of the behavior of negatively charged metal complexes on anion exchange resins, an attempt was made to separate zirconium and hafnium. These elements are generally considered to form negatively charged complexes[2] with certain complexing agents, particularly fluoride and oxalate ions. These elements, furthermore, are generally believed to be in true solution (rather than colloidal solutions) only if they are in the form of ionic complexes.

A separation based on their ability to form negatively charged complexes thus would have the advantage of being specifically designed for operation under conditions where true solution is most probable and complications due to hydrolysis (colloid formation or precipitation) minimized.

The experiments which have been carried out have demonstrated that separation of Zr(IV) and Hf(IV) by anion exchange is feasible, although the separation achieved is by no means at its optimum. Experiments are now under way to improve the efficiency of separation.

Partial separation of Zr(IV) and Hf(IV) at room temperature was achieved using a 107-cm. column of 200–230-mesh Dowex-1 (a quaternary amine anion exchanger) of 0.0226 sq. cm. cross section, and a mixture of 0.5 *M* hydrofluoric acid–1.0 *M* hydrochloric acid as eluent. Flow rates of *ca.* 0.3 ml./sq. cm./min. were used. Under these conditions elutions are relatively rapid (complete elution in *ca.* one and one-half days). The experiments were carried out with tracer concentrations of zirconium and 0.2 mg. of hafnium, using Zr^{95} (β-emitter, $T_{1/2}$ = 65 days[3]) and Hf^{181} (β-emitter, $T_{1/2}$ = 55 days[3]) as tracers. Zirconium and hafnium were identified radiochemically and in particular the hafnium content of the various elution fractions was determined by delayed coincidence counting taking advantage of the metastable daughter Ta^{181} (γ-emitter, $T_{1/2}$ = 20μsec.[4]) of Hf^{181}.[5]

The results of a typical experiment are shown in Table I. It may be noticed that the earlier fractions are highly depleted of hafnium, while the last fractions are practically pure hafnium.

SYNTHETIC CURARE SUBSTITUTES FROM ALIPHATIC DICARBOXYLIC ACID AMINOETHYL ESTERS

Sir:

The recent publication by Bovet and co-workers[1] of extensive work on synthetic curare substitutes derived from aliphatic dicarboxylic acid aminoethyl esters leads us to record briefly at this time results obtained in these laboratories simultaneously and independently.

Stimulated by the work of Barlow and Ing,[2] and of Paton and Zaimis[3] in discovering powerful curare-like activity in a series of straight-chain polymethylene bis-quaternary ammonium salts we sought to produce compounds of similar activity by duplicating the favorable chain length, found by them to be ten atoms, between the quaternary nitrogens. We did this first by making a series of bis-(β-dimethylaminoethyl) esters of aliphatic dicarboxylic acids, the bis-amino esters then being converted to bis-quaternary salts by reaction with the appropriate alkyl iodide.

The amino esters were obtained in poor or moderate yields by ester exchange reactions of the corresponding methyl or ethyl esters with a small excess of β-dimethylaminoethanol in the presence of a trace of dissolved sodium. The quaternary salts were best made in an inert solvent such as ether or acetone, as use of an alcohol solvent gave poor yields usually, probably because of reversal of the ester exchange process under these conditions.

bis-Dimethylaminoethyl succinate (b. p. 130–135° at 1 mm.); its bis-methiodide (m. p. 254–255°; calcd.: C, 30.87; H, 5.55. Found: C, 30.82; H, 5.45); bis-ethiodide (m. p. 203–204°; calcd.: C, 33.55; H, 5.99. Found: C, 33.56; H, 6.00); bis-*n*-propiodide (m. p. 132–133°; calcd.: C, 35.98; H, 6.38. Found: C, 36.47; H, 6.40); bis-dimethylaminoethyl glutarate (b. p. 145–150° at 1 mm.); its bis-methiodide (m. p. 214–217°; calcd.: C, 32.24; H, 5.79. Found: C, 32.52; H, 5.85); bis-ethiodide (m. p. 151–153°; calcd.: C, 34.79; H, 6.19. Found: C, 35.07; H, 6.10); and bis-dimethylaminoethyl adipate (b. p. 153–158° at 1 mm.) and its bis-methiodide (m. p. 138–139°; calcd.: I, 44.35. Found: I, 42.50) were prepared in this way.

The first compound made, the bis-dimethylaminoethyl succinate bis-methiodide, has ten atoms interposed between the quaternary salt groups, and showed a curariform activity equal in intensity to that of *d*-tubocurarine chloride as determined by its ability to block neuro-muscular transmission in the cat, but the effect was of much shorter duration than that produced by *d*-tubocurarine. This shorter duration of action was tentatively attributed to the action of choline esterases based on the similarity between this substance and two molecules of acetylcholine coupled at the α-carbon. Independent investigations by the pharmacological group of our laboratories confirm the findings of Bovet and co-workers[1] and further work is being carried on with the most active members of this series.

THE TETRAMETHYLPLATINUM–BENZENE COMPLEX

Sir:

Tetramethylplatinum forms a crystalline benzene complex.[1] Since Pt(IV) has six low energy orbitals and forms six interatomic links even in tetramethylplatinum,[1] it seemed possible that benzene was acting as a Lewis base, bonded to platinum, perhaps in the manner suggested by Winstein and Lucas for the silver perchlorate–benzene complex.[2] The nature of such a linkage has not been demonstrated, but is currently interesting due to speculation on π-bonding in organic reaction mechanisms, particularly by Dewar.[3]

Crystals of the benzene complex have the composition $(CH_3)_4Pt \cdot {}^1/_2C_6H_6$, as determined by loss of weight in going to the unsolvated form. A composition $(CH_3)_4Pt \cdot 2C_6H_6$ would be expected if benzene satisfied all platinum orbitals. Evidence, outlined below, indicates that the complex contains the tetramer, $(CH_3)_{16}Pt_4$, with molecular configuration unaltered.[1] There are then two benzene molecules per tetramer.

The tetramer configuration permits only methyl–benzene contacts, suggesting that the complex is held together by van der Waals forces, probably augmented by good crystal packing of these highly polarizable molecules.

Molecular Weight in Benzene.—The cryoscopically determined molecular weight in benzene is 1070 ± 100, *versus* 1021 expected for the tetramer. If benzene were bonded to platinum it would be expected that the methyl bridges of the tetramer would be broken, leading to a lower molecular weight.

Ultraviolet Absorption in Benzene and Cyclohexane.—The ultraviolet absorption of tetramethylplatinum in benzene and cyclohexane solutions, determined with a Beckmann spectrophotometer, are identical. Presumably the absorption would be considerably altered by any significant interaction of benzene with platinum.

Crystal Structure.—The benzene complex is orthorhombic, $a_0 = 16.83$, $b_0 = 21.08$, $c_0 = 8.92$ kX. ρ (obsd.) = 2.4, 16 $(CH_3)_4Pt$ and 8 benzenes per unit, with space group, as determined by Weissenberg and procession diagrams, C_{2v}^9–Pn2a or D_{2h}^{16}–Pnma. If the higher space group, Pnma,

is correct, and if the molecular configuration of the tetramethylplatinum tetramer is unaltered,[1] y-parameters of all platinum positions are determined. Intensities of (0k0) reflections can then be calculated, and are in good agreement with observation (Table I). One could not achieve this agreement if the molecular structure of the tetramer were seriously altered by complexing with benzene.

HYDROLYSIS OF THE α-1,6-GLUCOSIDIC LINKAGE IN ISOMALTOSE BY CULTURE FILTRATE OF *ASPERGILLUS NIGER* NRRL 330

Sir:

The α-1,6-glucosidic linkage in the amylopectin fraction of starch is resistant to hydrolysis by the action of the more common amylolytic enzymes. Inasmuch as the linkage between the two glucose residues in isomaltose is of the α-1,6 type, it was of interest to test the ability of a culture filtrate of *Aspergillus niger* NRRL 330 to hydrolyze this disaccharide. Isomaltose is now available in crystalline form. The sample of sugar used in these experiments was prepared from starch by the method of Montgomery, Weakley and Hilbert[1] and characterized as 6-(α-D-glucopyranosyl)-α-D-glucose monohydrate, rotating +120° in water (anhydrous). This particular strain of *A. niger* was selected because it elaborates, when grown in submerged culture, an enzyme capable of hydrolyzing maltose in large amounts.

To 20 ml. of 0.06 M isomaltose monohydrate, buffered at pH 4.4 (acetate buffer, 0.3 M), was added 10 ml. of culture filtrate. The reaction mixture was held at 50°. The extent of hydrolysis was measured at two and five hours by the increase in reducing power as determined by the method of Somogyi.[2] The glucose formed in the reaction mixture after five hours was identified biologically by "fermentation" at pH 8.8 with an excess of yeast by the procedure of Somogyi.[3] A collection of some of our experimental data is given in Table I.

(2) M. Somogyi, *J. Biol. Chem.*, **160**, 61 (1945).
(3) M. Somogyi, *ibid.*, **119**, 741 (1937).

TABLE I

Reaction mixture no.		1	2	3
Culture filtrate diluted		Un-	1:1 50%	1:3 25%
Two hr.	Isomaltose hydr./ml. culture filt., mg.	27.4	19.4	14.3
	Hydrolysis, %	63.4	44.9	33.1
Five hr.	Isomaltose hydr./ml. culture filt., mg.	39.0	35.1	29.0
	Hydrolysis, %	90.2	81.2	67.1
"Fermentable" glucose per ml. cult. filt., mg.		37.5	33.0	25.7

It will be noted that the undiluted culture filtrate hydrolyzed 90.2% or 39.0 mg. of the isomaltose per ml. of culture filtrate in five hours. The amount of fermentable glucose produced, 37.5 mg., per ml. of culture filtrate checks reasonably well with this figure. (The hydrolysis of isomaltose proceeds more slowly than the hydrolysis of maltose as indicated by the fact that 38.2 mg. of maltose is hydrolyzed per ml. of culture filtrate in one hour at 30°). In addition, the sugar formed in a reaction mixture identical to No. 1 in Table I, but incubated for six hours, was isolated as crystalline α-D-glucose monohydrate; $[\alpha]^{25}D$ +47.8° (c, 4 in water); m. p., 82.8°[4]; yield, 83.4%.

Further work on characterization of the enzyme system responsible for the hydrolysis of isomaltose is in progress.

DERIVATIVES OF DIBORINE

Sir:

Although tetrachlorodiborine, B_2Cl_4, first prepared by Stock, Brandt and Fischer (*Ber.*, **58**, 855 (1925)) by striking an arc across zinc electrodes immersed in liquid boron trichloride, is a compound of considerable potential interest, the original preparative method gave such poor yields (about 1%) of material of such low purity (less than 90%) that detailed study of the compound was not feasible.

Much better results have now been obtained by passing gaseous boron trichloride at 1 to 2 mm. through a glow discharge established between mercury electrodes. The mercurous chloride and other non-volatile products remain in the discharge tube; the volatile material is passed through a −78.5° trap, which retains the tetrachlorodiborine and allows the unchanged trichloride to pass. The latter is repeatedly subjected to the action of mercury in the discharge tube, since the amount converted per pass is small. The yield, however, is approximately 50%. There is evidence that other less volatile boron–chlorine compounds are obtained.

Tetrachlorodiborine is completely hydrolyzed by aqueous sodium hydroxide at 70°.

$$B_2Cl_4 + 6NaOH \longrightarrow 2NaBO_2 + 4NaCl + 2H_2O + H_2$$

Determination of the amounts of hydrogen, boron and chlorine in the hydrolysate of an unweighed sample by the usual methods gave the following results: H, 74.64 cc.; B, 0.0727 g.;

Cl, 0.481 g., corresponding to the atomic ratio H:B:Cl = 1.98:2.00:4.03. A 0.0995-g. sample gave 0.0131 g. of boron and 0.0878 g. of chlorine, a total of 0.1009 g. The vapor density corresponds to a molecular weight of 163 (calcd., 163.5). The vapor tensions, measured between −63.5 and 22.5°, are satisfactorily reproduced by the equation: $\log P_{(mm.)} = -1753/T + 8.057$.

Liquid tetrachlorodiborine at room temperature for seventy-two hours undergoes 21% decomposition, yielding boron trichloride, a very slightly volatile red substance and a white solid. The latter two must be hitherto unknown boron chlorides of as yet undetermined composition. At 0° the decomposition is much slower.

The following reactions of tetrachlorodiborine have been studied in preliminary fashion. (1) It yields the hitherto unknown *tetrabromodiborine* by treatment with boron tribromide, but does not react with boron trifluoride. (2) With dimethyl or diethyl ether it forms a liquid monoetherate and a solid dietherate. The latter has an appreciable dissociation pressure and is somewhat soluble in the ether. (3) It yields the corresponding tetramethoxy and tetraethoxy derivatives on treatment with the appropriate alcohols. (4) It reacts with lithium borohydride and aluminum borohydride to give boron hydrides among which diborane and dihydrotetraborane (B_4H_{10}) have been definitely identified; pentaboranes and decaboranes are probably present. It does not seem to react with lithium aluminum hydride at 0°. (5) It absorbs hydrogen at room temperature, by which reaction all of the chlorine is converted to boron trichloride, and the residue is a compound or mixture of the approximate composition $BH_{1.37}$ ($B_{10}H_{14}$?). (6) It reacts with ammonia in complex fashion. These and other reactions, as well as the preparative method, will receive further intensive study.

We gratefully acknowledge the interest and financial support of the Office of Naval Research and the Naval Research Laboratory.

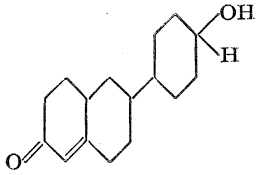
RECEIVED JULY 18, 1949

SYNTHESIS OF PHYSIOLOGICALLY ACTIVE ANALOGS OF TESTOSTERONE

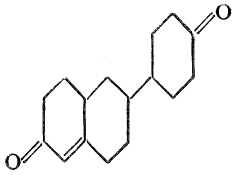
Sir:

The discovery of several hundred compounds possessing the physiological activity of the estrogenic hormones has prompted a number of investigators to search for synthetic analogs having activity similar to the other steroid hormones. While some claims of activity for such analogs have been made, particularly in patents, so far as we are aware no such claim has yet been substantiated [*cf.*, for example, the reported androgenic activity for certain reduction products related to diethylstilbestrol, apparently irrespective of configuration, Schoeller, Inhoffen, Steinruck and Höss, U. S. Patent 2,392,864 (Jan. 15, 1948)].

Since 1941 we have directed efforts toward the synthesis of analogs of the non-aromatic steroid hormones lacking ring C, and wish to report now the synthesis of two such analogs of the androgens: I, comparable to testosterone, and II, to androstenedione.



I



II

These α,β-unsaturated ketones were synthesized using the Robinson–Mannich base method [du Feu, McQuillin and Robinson, *J. Chem. Soc.*, 53 (1937)] with some modifications. Hydrogenation of 4,4′-dihydroxybiphenyl gave the three possible perhydro derivatives (m. p.'s 215–216°, 176.5–177° and 194–195°, all m. p.'s cor.). Half-oxidation of the first two stereoisomers with chromium trioxide afforded the same 4-(4′-hydroxycyclohexyl)-cyclohexanone (III, probably *trans*), m. p. 129–130°. *Anal.* Calcd. for $C_{12}H_{20}O_2$: C, 73.4; H, 10.3. Found: C, 73.6; H, 10.1. When sufficient 195° diol becomes available, it will presumably lead to the other possible isomer. More complete oxidation gave 4-(4′-ketocyclohexyl)-cyclohexanone (IV), m. p. 115–116° *Anal.* Calcd. for $C_{12}H_{18}O_2$: C, 74.2; H, 9.3 Found: C, 74.3; H, 9.2.

Formylation of the keto alcohol (III) with ethyl formate and sodium methoxide, reaction of the derivative with the methiodide of 1-diethyl aminobutanone-3 and cyclization with *ca.* 4% methanolic potassium hydroxide at room temperature gave 6-(4′-hydroxycyclohexyl)-Δ^{1-9}-octalone-2 (I), purified by chromatography on alumina and recrystallization from cyclohexane–ethyl acetate, m. p. 127–127.5°; max. 238.5 mμ (E_{molar} = 16,870). *Anal.* Calcd. for $C_{16}H_{24}O_2$: C, 77.4 H, 9.7. Found: C, 77.7; H, 9.8. The semicarbazone melted at 235–236° (dec.). *Anal.* Calcd. for $C_{17}H_{27}N_3O_2$: C, 66.9; H, 8.9. Found: C, 67.0; H, 8.7.

Similarly, monoformylation of the diketone (IV), reaction with the Mannich base methiodide and cyclization gave 6-(4′-ketocyclohexyl)-Δ^{1-}-octalone-2 (II), also obtained in small yield by oxidation of I (as the dibromide), m. p. 88.–89.5°; max. 238 mμ (E_{molar} = 16,400). *Anal.* Calcd. for $C_{16}H_{22}O_2$: C, 78.0; H, 9.0. Found: C, 77.9; H, 8.7. The disemicarbazone decomposed at 256–257°. *Anal.* Calcd. for $C_{18}H_{28}N_6$: C, 60.0; H, 7.8. Found: C, 59.9; H, 7.5.

Preliminary assays in day-old chicks, under the direction of Drs. R. K. Meyer and Elva G. Sh

ley of the Department of Zoology, have indicated androgenic activity for the diketone II at a total dose of 2.5 mg. (26 to 83% increase in comb weight over the controls). A total dose of 0.012 mg. of testosterone propionate resulted in 40% increase. The keto alcohol I has given inconclusive results. Further investigation of physiological effects in other species awaits the preparation of additional material.

RECEIVED JULY 20, 1949

SYNTHESIS OF VITAMIN A

Sir:

The appearance of an article by Schwarzkopf and collaborators[1] on the synthesis of vitamin A by the reduction of vitamin A esters with lithium aluminum hydride prompts us to record experimental work carried out in these laboratories.

Ethyl β-ionylidene acetate[2] was reduced with lithium aluminum hydride in 85% yield to β-ionylidene ethyl alcohol following the method of Milas and Harrington[3] [b. p. 112–114° at 0.4 mm.; $\lambda_{max.}^{isoöctane}$ 2840 Å., $E_{1\,cm.}^{1\%}$ 1205]; *trityl ether* (m. p. 132–134°) *anal.* Found: C, 88.13; H, 8.47; $\lambda_{max.}^{isoöctane}$ 2850 Å., $E_{1\,cm.}^{1\%}$ 733.

Oxidation of β-ionylidene ethyl alcohol with manganese dioxide by the method used to convert vitamin A to the aldehyde[4] produced a mixture of two stereoisomeric β-ionylideneacetaldehydes in 60% yield separable by chromatography into essentially equal amounts of *nor*-β-ionylideneacetaldehyde[5] [b. p. 90–95° at 10^{-2} mm.; $n^{25}D$ 1.5780; $\lambda_{max.}^{isoöctane}$ 2650 Å., $E_{1\,cm.}^{1\%}$ 567 and 3150 Å., $E^{1\%}$ 760, *anal.* Calcd. for $C_{15}H_{22}O$: C, 82.57; H 10.09. Found: C, 82.14; H, 10.36. *Semicarbazone:* m. p. 195–196°; $\lambda_{max.}^{chloroform}$ 3230 Å., $E_{1\,cm.}^{1\%}$ 1330; *anal.* Found: C, 69.56; H, 8.82; N, 15.29][6] and *iso*-β-ionylidene acetaldehyde[5] [b. p. 80–85° at 10^{-2} mm.; $n^{25}D$ 1.5780; $\lambda_{max.}^{isoöctane}$ 3180 Å., $E_{1\,cm.}^{1\%}$ 904. *Anal.* Found: C, 82.14; H, 10.33. *Semicarbazone:* m. p. 175–176°, $\lambda_{max.\ 3175}^{chloroform}$ $E_{1\,cm.}^{1\%}$ 1000. *Anal.* Found: C, 70.16; H, 9.07; N, 15.03].

nor-β-Ionylideneacetaldehyde was condensed with acetone in the presence of aluminum *t*-butoxide whereby the previously described C_{18}-ketone was obtained[7] in 80–85% yield; $\lambda_{max.}^{isöoctane}$ 3360 Å.; *semicarbazone:* m. p. 186–188°; $\lambda_{max.}^{chloroform}$ 3490 Å., $E_{1\,cm.}^{1\%}$ 1680. The C_{18}-ketone was converted by the Reformatsky reaction to the C_{20}-hydroxyester which was dehydrated by iodine to vitamin A ester and the latter saponified to vitamin A acid, m. p. 179–180°; $\lambda_{max.}^{ethanol}$ 3500 Å., $E_{1\,cm.}^{1\%}$ 1415. From *iso*-β-ionylideneacetaldehyde there was obtained a more difficultly characterizable C_{18}-ketone exhibiting a broad band at 3340–3370 Å. indicating a mixture of the *nor* and *iso* forms. This ketone afforded vitamin A acid in the same yield as that obtained from the *nor* series (25%); m. p. 180.5–181.5°; $\lambda_{max.}^{ethanol}$ 3530 Å., $E_{1\,cm.}^{1\%}$ 1510; mixed m. p. with acid from *nor* series, 180–181°. Both vitamin A acids on reduction with lithium aluminum hydride gave vitamin A exhibiting a single, well-defined maximum at 3260 Å., $E_{1\,cm.}^{1\%}$ 1330 (80% yield) as measured in isoöctane.

RECEIVED JULY 7, 1949

NEW BOOKS

Oxidation-Reduction Potentials in Bacteriology and Biochemistry. By L. F. HEWITT, Ph.D., B.Sc., F.R.I.C., Acting Director, Serum Research Institute, Carshalton, Surrey. Fifth Edition. Published by the London County Council, 1948, and may be purchased, either directly or through any Bookseller, from Staples, Ltd., 14, Great Smith Street, Victoria Street, Westminster, S.W.1. 130 pp. 17 × 25 cm. Price, 4s. 6d. By post, 4s. 10d.

The last previous edition of this small monograph was published in 1936. The present fifth edition follows the pattern of earlier ones. The first chapter contains a brief outline of the theory of oxidation–reduction reactions and the mathematical expressions relating oxidation–reduction potentials to the components of the reactions. The second chapter describes the methods for measuring oxidation–reduction potentials and gives tables of oxidation–reduction indicators. The third chapter deals with oxidation–reduction systems of biological interest. In the fourth chapter, the bacteriological applications of oxidation–reduction studies are described. This fourth chapter is the most important in the monograph, since it constitutes the best review of the work in this particular field—a field to which the author himself has made many contributions. The monograph concludes with two short

chapters, one on the polarograph and one entitled, "General Conclusions."

An excellent bibliography covering about twenty-four pages further increases the value of this monograph. The number of new contributions made in this field during the last decade is, however, conspicuously small and is probably in part due to a diversion of interests during the war years.

ERIC G. BALL

Kinetics of Chemical Change in Solution. By EDWARD S. AMIS. Formerly Associate Professor of Chemistry, Louisiana State University; also Senior Research Chemist, Carbide and Carbon Chemicals Corporation, Oak Ridge, Tenn. At present Professor of Chemistry, University of Arkansas. The Macmillan Company, 60 Fifth Avenue, New York, N. Y., 1949. ix + 332 pp. illustrated. 14 x 21.5 cm. Price, $5.00.

Amis presents a very good summary of his book in the preface. After discussing the order of reactions, he considers the Arrhenius equation. Because molecules often are polar and sometimes ionize, dielectric behavior is treated at length and chapter three which discusses the work in this field by Debye, Onsager, Kirkwood, Jaffé and others is a useful summary. Absolute rate theory is developed after a detailed presentation of earlier treatments. Photochemistry, chain reactions, homogeneous and heterogeneous catalysis are treated in the concluding chapters. A visit to the library verified the supposition that Lewis in the index meant G. N., W. K. or J. R., although by reading the text I could only find out that there was a G. N., which I knew before. Reaction kinetics shows almost infinite variety so that any treatment hits the high spots only. Amis has chosen a very interesting set of reactions to treat and has done the job well. This book is a valuable addition to the literature of reaction kinetics.

HENRY EYRING

An Introduction to the Chemistry of Carbohydrates. By JOHN HONEYMAN, Lecturer in Organic Chemistry, University of London, King's College. Oxford University Press, 114 Fifth Ave., New York 11, N. Y., 1949. 143 pp. 14.5 × 23 cm. Price, $4.50.

This small book serves as an excellent though brief textual summary of the present status of the chemistry of the carbohydrates. Most of the modern methods and techniques are delineated. It is intended to meet the needs of English students "reading for an Honours degree in Chemistry" but it should also be useful for others desiring to keep abreast of recent developments through a rapid survey of this field.

Polarographic Studies of Metal Complexes. I. The Copper(II) Tartrates

BY LOUIS MEITES

The first study of the polarographic behavior of copper(II) in a tartrate supporting electrolyte was made by Suchy,[1] who found a single wave, with a half-wave potential of −0.14 v. *vs.* the saturated calomel electrode, in a 10% (0.35 *M*) potassium sodium tartrate solution of unstated *p*H. Kolthoff and Lingane[2] found, in 0.5 *M* tartrate, $E_{1/2} = -0.10$ v., again at an unspecified *p*H value, and stated that the wave height corresponded to reduction to the metal. More recently, Lingane[3] has shown that the polarographic behavior of the system is significantly dependent on the *p*H: in particular, he found that the half-wave potential is displaced to very negative potentials in strongly alkaline solutions containing gelatin, in agreement with the earlier observation of Kolthoff and Lingane.[2]

Inasmuch as some preliminary experiments with alkaline tartrate solutions were in sharp disagreement with previous data, it was deemed desirable to make a complete study of the effects of *p*H and tartrate concentration on the system.

Experimental

The polarographic apparatus used was that described by Meites and Meites.[4] All measurements were made at 25.00 ± 0.02° in a water thermostat. The cell is a modification of the H-cell described by Lingane and Laitinen.[5] The solution compartment of this cell has a capacity of about 450 ml.; it is fitted with a no. 14 rubber stopper, through which are inserted the dropping electrode, a tube for leading oxygen-free hydrogen over the solution, the tips of two calibrated 10-ml. microburets, and the glass and calomel electrodes of a Beckman Model G *p*H meter. A known volume of air-free acid or base is added to the solution, which is then stirred briefly by a stream of gas, the *p*H is measured, and the polarogram is recorded; or, alternatively, one of the microburets may be filled with a standard solution of the metal ion and the diffusion current constant[6] measured by the technique previously described.[7-9] The entire time consumed is very little more than that required by the polarographic measurements themselves.

The Beckman *p*H meter used was set to read 3.57 in a saturated potassium hydrogen tartrate solution at 25°.[10] All *p*H values above 10 were measured with a Type E glass electrode, using as standard a potassium borate–boric acid buffer whose *p*H had been checked against the National Technical Laboratories buffer of *p*H 10.00. Suitable corrections for the alkali errors of the glass electrode have been made: they were minimized by the use of potassium hydroxide instead of sodium hydroxide.

Oxygen was removed from the tank hydrogen used by a vanadous sulfate wash train.[11]

Results and Discussion

Typical polarograms of copper(II) in potassium sodium tartrate solutions at varying *p*H values in the absence of gelatin are shown in Figs. 1, 2 and 3. In solutions containing the hydrogen tartrate ion at concentrations considerably greater than that of the copper(II), only a single wave is found. It is characterized by a very sharp maximum whose relative height decreases with increasing *p*H, but the plateau finally attained is very well defined. Lingane's data[3] indicate that the maximum in this wave is suppressed by as little as 0.005% gelatin.

The half-wave potential of this wave is only slightly affected by changes in *p*H: in 0.1 *M* tartrate $E_{1/2}$ is −0.003 v. at *p*H 1.70 and −0.084 v. at *p*H 5.73 (all potential measurements are referred to the saturated calomel electrode), and they are

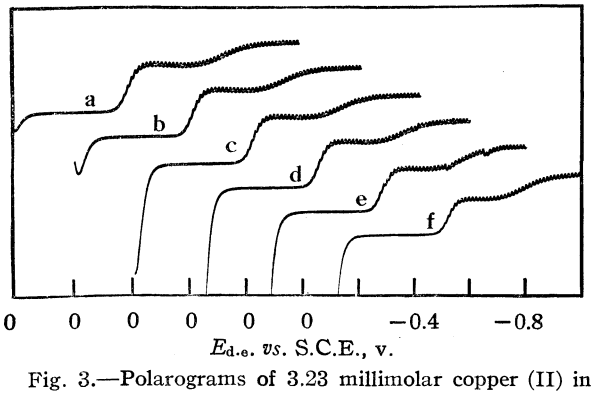

Fig. 3.—Polarograms of 3.23 millimolar copper (II) in 1.0 *M* potassium sodium tartrate at *p*H (a) 11.78, (b) 12.07, (c) 12.38, (d) 12.72, (e) 13.12, and (f) 13.50.

almost exactly the same in 0.5 or 1.0 *M* tartrate. This is in accordance with the fact that, in this *p*H range, the composition of the solution is determined, not by the total amount of tartrate present in the cell, but by the solubilities of sodium and potassium hydrogen tartrates. The presence of the maximum makes it impossible to attach any thermodynamic significance to the measured half-wave potentials.

As the *p*H is increased above about 6, the former single wave splits quite sharply into two waves. The first of these is fairly well defined, but the second has a maximum, sharper in 0.1 and 0.5 *M* tartrate than in 1 *M* tartrate (*cf.* curve *f*, Fig. 1, and Fig. 2), which again is suppressed by increasing *p*H. Concurrently, the height of the first wave is decreased, while that of the second increases. The sum of these two waves, at *p*H values near the bottom of this range, is about 10% smaller than the total wave height in more acid solutions where only one wave appears. The variation with *p*H of the relative heights of these waves in 0.5 *M* tartrate is shown in Fig. 4.

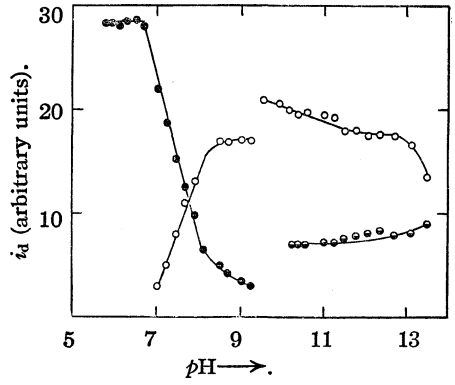

Fig. 4.—Effects of *p*H on the diffusion currents of the copper (II) waves in 1.0 *M* potassium sodium tartrate. Solid circles represent the first wave, open circles the second, and half-solid circles the third.

From Figs. 4, 5 and 6, which show the effect of *p*H on the half-wave potential of copper in tartrate solutions of various concentrations, the first indication of the appearance of two waves is found at *p*H 5.5 in 0.1 *M* tartrate, *p*H 6.3 in 0.5 *M* tartrate, and *p*H 6.7 in 1.0 *M* tartrate. The concentration of copper in all of these solutions was 3.23 millimolar, and from this datum and the values of K_1 and K_2 for tartaric acid given by Jones and Soper,[12] one calculates that the concentration of free hydrogen tartrate ion becomes equal to four times the copper concentration at *p*H 5.7 in 0.1 *M* total tartrate, at *p*H 6.4 in 0.5 *M* tartrate, and at *p*H 6.7 in 1.0 *M* tartrate. This appears to constitute conclusive proof that the complex formed in these acidic solutions has the formula $Cu(H\ Tart)_4^{=}$, a deduction further supported by the results of an amperometric titration shown in Fig. 7.

The second of these two waves increases in height at the expense of the first as the concentration of the hydrogen tartrate ion decreases with increasing *p*H until only a single wave is observed. Over a *p*H range whose lower limit is the first appearance of a double wave and whose upper limit is the point at which the wave begins a grad-

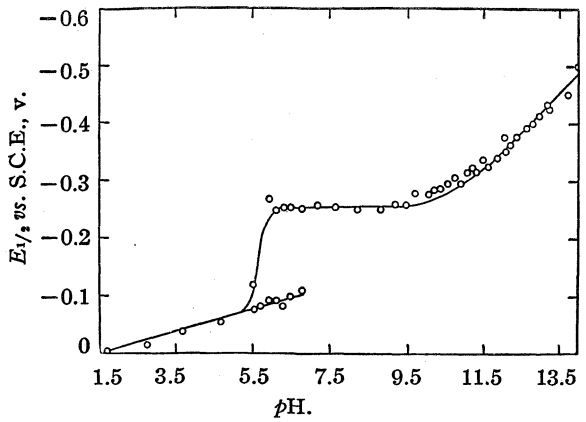

Fig. 5.—Effects of pH on the half-wave potentials of the copper (II) waves in 0.10 M potassium sodium tartrate.

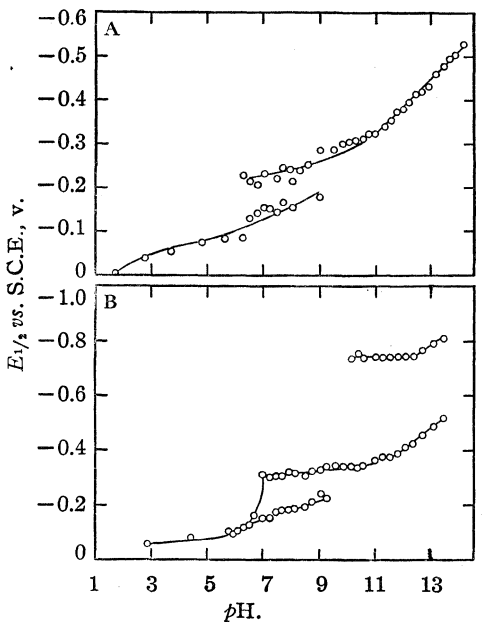

Fig. 6.—Effects of pH on the half-wave potentials of the copper(II) waves in (A) 0.50 M and (B) 1.0 M potassium sodium tartrate.

ual continuous shift to more negative values, the half-wave potential of this wave is fairly constant.

From measurements of the relative heights of the two waves in a similar critical region, Lingane[13] was able to establish the formula of the ferric hydrogen tartrate complex in solution as $Fe(HTart)_3$, and theoretically it should also be possible, if the tartrate and hydrogen tartrate complexes were sufficiently slowly interconvertible, to calculate the ratio of their dissociation constants from such diffusion current measurements. In the present case, however, the ratio secured exhibits a consistent trend with pH: this is the behavior which would be expected if the two species were in moderately rapid equilibrium at the surface of the drop.

(13) J. J. Lingane, THIS JOURNAL, **68**, 2448 (1946).

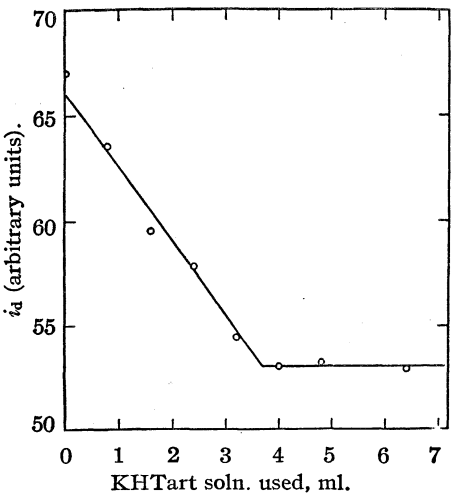

Fig. 7.—Amperometric titration of 250 ml. of 0.400 millimolar copper (II) in an 0.5 M acetate buffer of pH 3.59 with 20 millimolar potassium hydrogen tartrate, at $E_{d.e.} = -0.50$ v.

As the pH is further increased so that the concentration of hydroxyl ion becomes significant in comparison with the copper concentration, the wave begins the slow shift to more negative potentials described above. This shift is first observed at pH 9.0 in 0.1 M tartrate, at pH 9.5 in 0.5 M tartrate, and at pH 10.5 in 1.0 M tartrate. It is surprising that the hydroxyl ion concentration in every case is much too small to correspond to conversion of an appreciable fraction of the copper into a hydroxytartrate complex. Nevertheless, the waves observed in this region are very well defined and show, on mathematical analysis, none of the phenomena frequently observed[9,14] in systems where other evidence points to the co-existence of two ionic species in moderately slow equilibrium.

A comparison of the half-wave potentials of this wave at a constant hydroxyl ion activity gives results typified by those at pH 12, which are −0.346 v. in 0.1 M tartrate, −0.378 v. in 0.5 M tartrate, and −0.409 v. in 1.0 M tartrate. Applying to these data the theoretical equation for the reduction of metal complexes derived by Lingane,[15,16] one calculates that, in the generalized equation for the reduction

$$[Cu(OH)_p(Tart)_q]^{2-(p+2q)} + ne \longrightarrow Cu^{(2-n)}(OH)_r(Tart)_s^{2-(n+r+2s)} + (q-s)\,Tart^{=} + (p-r)OH^{-} \quad (1)$$

$(q - s)$ is equal to n. Lingane[3] and Kolthoff and Lingane[17] are agreed that the reduction of copper from these solutions proceeds all the way to the metal. In confirmation of this, the slopes of plots of $-E_{d.e.}$ against $\log[i/(i_d - i)]$ for the waves given by these solutions are uniformly 36 ± 2 mv., cor-

(14) J. J. Lingane and L. Meites, *ibid.*, in press.

(16) Ref. 2, pp. 161–165.
(17) Ref. 2, p. 280.

responding approximately to the expected value for a thermodynamically reversible two-electron reduction.[16] Therefore equation (1) becomes

$$[Cu(OH)_p(Tart)_2]^{-(2+p)} + 2e \longrightarrow Cu(Hg) + 2\ Tart^{=} + p\ OH^{-} \quad (2)$$

Now the rate of change of the half-wave potential with pH in this region is shown by Figs. 5 and 6 to be nearly linear, and from them the average values of $\Delta E_{1/2}/\Delta(p\mathrm{H})$ are estimated to be -50 mv. in 0.1 M tartrate, -60 mv. in 0.5 M tartrate, and -63 mv. in 1.0 M tartrate. The differences in these values may well be due to the effects of the changing ionic strength on the activity coefficients of the various species involved in the equilibrium. However, they are all in satisfactory agreement for the predicted effect of pH on the half-wave potential for $p = 2$ in equation (2), so that, finally

$$Cu(OH)_2(Tart)_2^{-4} + 2e \longrightarrow Cu(Hg) + 2\ Tart^{=} + 2OH^{-} \quad (3)$$

At pH 14.0, and at a total tartrate concentration of 1.0 M, the half-wave potential is -0.563 v. Then, neglecting, perforce, activity effects, we write, using the value for $E_{1/2}$ of the aquo-cupric ion given by Kolthoff and Lingane[18]

$$K = \frac{[Cu^{++}][OH^-]^2[Tart^=]^2}{[Cu(OH)_2(Tart)_2^{-4}} = 1.4 \times 10^{-10}$$

and, for the standard potential of the reduction corresponding to equation (3), by combining this value for K with the E_0 for the copper–cupric ion couple given by Lewis and Randall,[19] we secure

$$Cu + 2OH^- + 2\ Tart^= \longrightarrow Cu(OH)_2(Tart)_2^{-4} + 2e;\ E^0 = +0.24\ v.$$

corresponding to a standard free energy change of 13.4 kcal.

Jellinek and Gordon[20] report, from potentiometric measurements, that $K = [Cu^{++}]^2[OH^-]^4$.

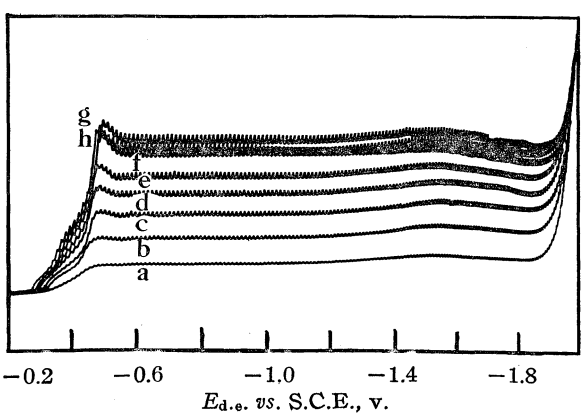

Fig. 8.—Polarograms of (a) 0.385, (b) 0.741, (c) 1.071, (d) 1.380, (e) 1.667, (f) 2.064 (g) 2.424, and (h) 2.86 millimolar copper (II) in 1.00 M potassium hydroxide.

(20) K. Jellinek and H. Gordon, *Z. physik. Chem.*, **112**, 207 (1924).

$[Tart^=]^2/[Complex]$ and state that $[Cu^{++}] = 10^{-15}\ M$ when $[OH^-] = 1\ M$ and the concentration of the complex is $10^{-3}\ M$. Latimer[21] has called attention to the uncertainty regarding the formula of the complex ion.

The second wave visible on the curves of Fig. 4 appears only at pH values above about 10. Since its height, although to some extent a function of the tartrate concentration, is never quite equal to that of the first wave, and in 1 M tartrate is only about one-third of the height of the first wave, it cannot indicate stepwise reduction of the copper, but must be due to the presence of a second complex in very slow equilibrium with the first. Its height is quite insensitive to gross changes in pH, and its half-wave potential is similarly independent of pH ($E_{1/2} = -0.744 \pm 0.004$ v. *vs.* the S.C.E. in 1.0 M tartrate) up to pH 12.5. Because it was thought that this wave might be due to the reduction of a cuprate ion, the polarograms shown in Fig. 8 were recorded. At low concentrations (0.4 millimolar) only a single wave, with a half-wave potential of -0.410 v., is observed. The value of $E_{3/4} - E_{1/4}$ for this wave is -42 mv., showing that the two-electron reduction to the metal proceeds somewhat irreversibly from these solutions. As the total copper concentration is increased, the wave appears to divide into two poorly separated waves nearly equal in height, of which the second is much more nearly reversible than the first, and at the same time a small maximum develops. These facts strongly indicate that the cuprate species which predominates in these solutions is reduced to the metal *via* an intermediate cuprite ion. At copper concentrations above 2.5 millimolar, a dark brown solid phase, presumably cupric oxide, separates, and further additions of copper then have little effect on the diffusion current observed. The complexity of the wave form does not appear to affect the constancy of i_d/C, as shown in Fig. 9, which shows a sharply defined limiting concentration of dissolved +2 copper of $2.18 \times 10^{-3}\ M$. This is considered more reliable than the solubility computed by Latimer.[22]

$$Cu(OH)_2 + 2OH^- \longrightarrow CuO_2^= + 2H_2O;\ K = 1.2 \times 10^{-3}$$

For the moment, we can at least conclude that the wave at -0.744 v. is not due to the reduction of a cuprate ion, but no better explanation has as yet suggested itself.

Lingane,[3] working with solutions containing 0.01% gelatin, found that the copper wave in 0.5 M tartrate containing 0.1 M sodium hydroxide was shifted to a very negative potential ($E_{1/2}$ = *ca.* $-$ 1.6 v.), while a small "pre-wave" was observed starting at about -0.4 v. He considered the "pre-wave" to be produced by the same species present in the neutral and slightly acid solutions, which, on the basis of the present discussion, is plainly impossible. The appearance of the main

(22) Ref. 21, p. 174.

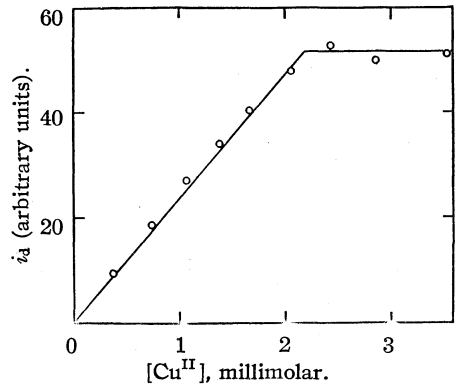

Fig. 9.—The diffusion current of copper (II) in 1.00 *M* potassium hydroxide. $E_{d.e.} = -0.80$ v.

wave at −1.6 v. is also in contradiction of the present data. The apparent controversy is resolved by Fig. 10, which shows the effect of adding 0.010% gelatin to a solution of +2 copper in 0.5 *M* tartrate containing 1 *M* potassium hydroxide. Similar effects are caused by the addition of gelatin to every other system discussed in this paper: a discussion of these effects is now in preparation. Once again it must be stressed that the indiscriminate addition of gelatin to a solution except for the specific purpose of suppressing a maximum, and then only in an amount barely sufficient to accomplish this purpose, is to be looked upon with the gravest suspicion.

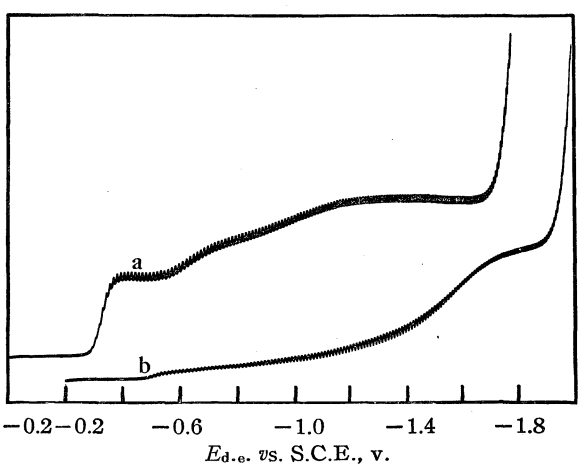

Fig. 10.—Polarograms of 3.2 millimolar copper (II) in 0.50 *M* potassium sodium tartrate and 1.0 *M* potassium hydroxide, (a) without gelatin, (b) with 0.010 % gelatin.

Figures 11, 12 and 13 show the effect of *p*H on the reduction of +2 copper from ammoniacal ammonium tartrate solutions: the values of $E_{1/2}$ are plotted in Fig. 14 as functions of the *p*H. Below *p*H 5.6 there appears to be no difference between the waves in these solutions and those in solutions containing only alkali metal ions, except that the maximum seems to be somewhat accentuated. The appearance of a double wave at *p*H

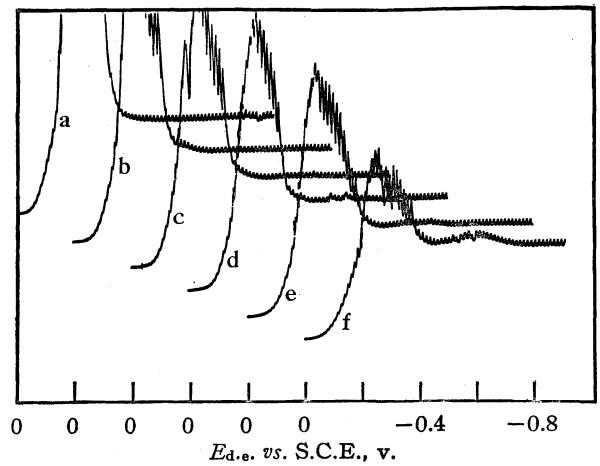

Fig. 11.—Polarograms of 3.23 millimolar copper (II) in 0.100 *M* ammonium tartrate at *p*H (a) 6.07, (b) 6.49, (c) 6.89, (d) 7.21, (e) 7.60, and (f) 7.95.

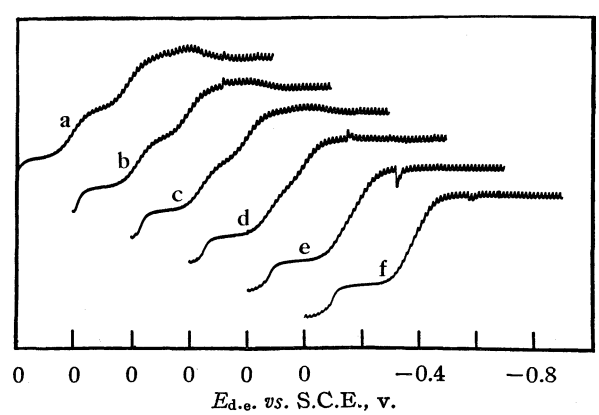

Fig. 13.—Polarograms of 3.23 millimolar copper (II) in 0.100 *M* ammonium tartrate at *p*H (a) 10.03, (b) 10.50, (c) 10.90, (d) 11.38, (e) 11.90, and (f) 12.22.

7.9 in 0.1 *M* ammonium tartrate, and at *p*H 8.2 in 0.25 *M* ammonium tartrate, is accompanied by the development of a very peculiar hump in the

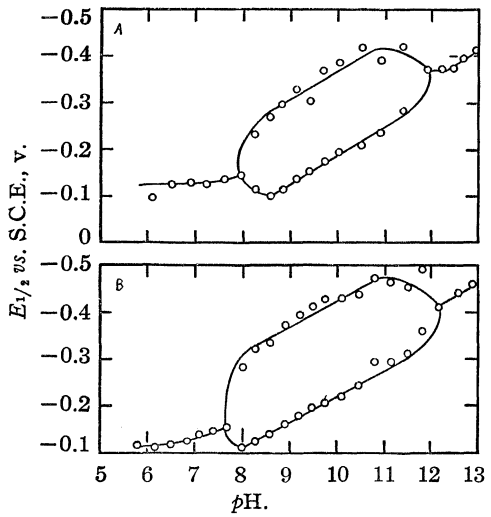

Fig. 14.—Effects of pH on the half-wave potentials of the copper (II) waves in (A) 0.10 M and (B) 0.25 M ammonium tartrate.

plateau of the second wave about 0.2 v. after this plateau is reached. This hump is observed at all pH values at which a double wave is found. These two waves are, within the limits of accuracy of the measurements, equal in height throughout this pH range, which indicates that reduction to the metal proceeds through the +1 state. For each of the waves $E_{3/4} - E_{1/4}$ is found to be -66 ± 4 mv., in approximate agreement with the expected value for a reversible one-electron reduction.

In 0.1 M ammonium tartrate, the half-wave potentials are given by the equations $E_{1/2}^{1} = 0.458 - 0.065$ (pH) (± 4 mv.) and $E_{1/2}^{2} = 0.273 - 0.065$ (pH) (± 14 mv.). The corresponding equations for 0.25 M ammonium tartrate solutions are $E_{1/2}^{1} = 0.359 - 0.0583$ (pH) (± 5 mv.) and $E_{1/2}^{2} = 0.156 - 0.0583$ (pH) (± 11 mv.). In each case the better agreement with the equation for the first wave is due to the considerably poorer definition of the second.

Now this effect of pH is exactly that to be expected if one molecule of ammonia is liberated in each one-electron reduction, so that the copper(II) complex must be formulated as $Cu(NH_3)_2(Tart)_x^{2-2x}$ and the copper(I) complex must be $Cu(NH_3)(Tart)_y^{1-2y}$. On making a correction of 0.40 pH unit to compensate for the different concentrations of ammonium ion, the half-wave potentials of the first waves (reduction to +1 copper) at the different concentrations of tartrate are found to be essentially equal (± 10 mv.) at equal concentrations of ammonia. Therefore we must conclude that tartrate ions are not involved in the first step of the reduction, and, in equations 4 and 5

$$Cu(NH_3)_2(Tart)_x^{2-2x} + e \longrightarrow Cu(NH_3)(Tart)_y^{1-2y} + NH_3 + (x - y)Tart^- \quad (4)$$

$$Cu(NH_3)(Tart)_y^{1-y} + e \longrightarrow Cu(Hg) + NH_3 + yTart^- \quad (5)$$

$x = y$. The same correction to the data for the second waves reveals that, at a constant concentration of ammonia, a 2.5-fold increase in the tartrate concentration shifts the half-wave potential corresponding to equation (5) to a value more negative by about 30 mv. This corresponds to 75 mv. for a tenfold increase in tartrate concentrations, in approximate agreement with the theoretical effect if $y = 1$ in equation 5. Correcting the observed data to solutions containing M ammonia and tartrate, we then have

$$Cu(NH_3)(Tart)^- + NH_3 \longrightarrow Cu(NH_3)_2(Tart) + e; \; E^0 = -0.04 \text{ v.}$$

and

$$Cu(Hg) + NH_3 + Tart^= \longrightarrow Cu(NH_3)(Tart)^- + e; \; E^0 = +0.20 \text{ v.}$$

At pH values above about 11, when the concentration of hydroxyl ion becomes of the same order of magnitude as the concentration of copper, the two waves coalesce into one which, because of the equality of the $E_{1/2}$ values, must be attributed to the reduction of the $Cu(OH)_2(Tart)_2^{-4}$ complex present in the ammonia-free tartrate solutions of the same pH.

Figure 15 illustrates the effect of gelatin on the waves in ammoniacal ammonium tartrate, and re-emphasizes the caution that must be observed in the use of gelatin.

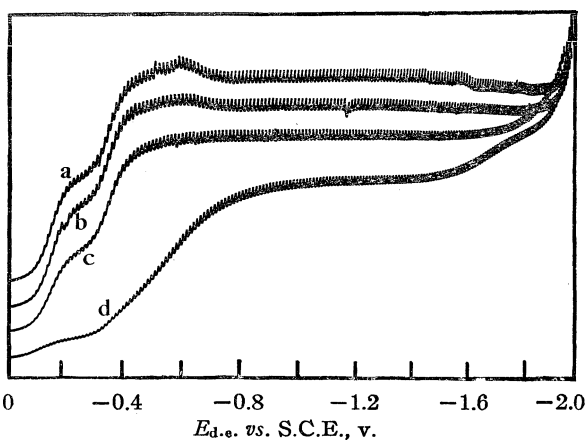

Fig. 15.—Polarograms of 3.2 millimolar copper (II) in 0.10 M ammonium tartrate, pH 9.55, with (a) 0, (b) 0.001, (c) 0.010, and (d) 0.050 % gelatin.

Summary

Acidic tartrate solutions of +2 copper contain the $Cu(H\ Tart)_4^=$ ion which is reduced directly to the metal at about −0.1 v. (*vs.* S.C.E.). At pH values between about 7 and 11, the copper is present mainly as a tartrate complex whose formula cannot be determined from polarographic measurements, and in still more alkaline solutions the $Cu(OH)_2(Tart)_2^{-4}$ ion is formed. The dissociation constant of this ion is 1.4×10^{-10}.

The same phenomena are found in ammonium tartrate solutions of pH below 7 or above 12, but

in the intermediate range an amminocupric tartrate ion is formed. This is reduced to the metal *via* the +1 state, the reactions being

$$Cu(NH_3)(Tart)^- + NH_3 \longrightarrow Cu(NH_3)_2(Tart) + e;\ E^0 = -0.04 \text{ v.}$$

and

$$Cu(Hg) = NH_4 + Tart''' \longrightarrow Cu(NH_3)(Tart)^- + e;\ E^0 = +0.20 \text{ v.}$$

The solubility of +2 copper in *M* hydroxide is 2.18×10^{-3} *M*.

Gelatin severely distorts the waves of all these species, especially at concentrations above 0.001%. Great stress is laid on the caution that should be observed in its use if polarographic data are to be considered to represent the true electrochemical behavior of substances in solution.

A Thermodynamic Study of Liquid Metallic Solutions. I. The System Lead–Gold

BY O. J. KLEPPA

Introduction

In a detailed experimental study of the thermodynamic properties of binary liquid alloy systems, there are two general ways of approach. One method is to evaluate the activity of a volatile component (Hg, Zn, Cd, Mg) from vapor pressure measurements. The other method depends on measuring the electromotive force in reversible galvanic cells of the type

$$A(l)/A^{n+}/(A + B)(l)$$

where A denotes the baser (more electropositive) metal, B the other metal.

If carried out over a sufficiently large composition and temperature range, both methods will give us, in principle, all the data required for a complete evaluation of the thermodynamic properties (*i. e.*, free energy, entropy and heat of mixing) for the mixture, using the pure components as reference states. Both methods have also found extensive application at moderately high temperatures during the past twenty to twenty-five years.[1]

It has not, however, so far been possible to tie the results of these researches in with any existing theory of solutions.[2] This paper is the first report on a series of investigations started in order, if possible, to arrive at a clearer understanding of the factors governing the properties of such liquid metallic solutions.

Experimental Method.—The system lead–gold is well suited for application of the electromotive force method.

Measurements of the electromotive force, E, of various liquid alloy compositions *versus* pure liquid lead immediately give us the relative chemical potential μ_{Pb} in the mixture through the relationship $\mu_{Pb} - \mu_{Pb}^0 = -2FyE$ where Fy is the faraday constant. The superscript^0 in this paper refers to the pure component.

The temperature gradient of the electromotive force, dE/dT, will give the relative partial molar entropy $\Delta\bar{S}$ in the mixture in a similar way, through the relationship

$$\Delta\bar{S} = \bar{S} - S^0 = 2Fy(dE/dT)$$

These quantities are thus directly available from measurements. Through the equation

$$\mu - \mu^0 = \bar{L} - T\Delta\bar{S}$$

we can also immediately calculate the relative partial molar heat content, $\bar{L}_{Pb}$, for lead in the mixture.

A knowledge of the partial molar properties for one of the components over the whole concentration range makes possible a calculation of the same properties for the other component by (graphical) integration of the Gibbs–Duhem–Margules equation

$$x_1 d\bar{Y}_1 + x_2 d\bar{Y}_2 = 0$$

where $\bar{Y}_1$ is any partial molar quantity for component 1, x_1 is the corresponding mole fraction (or here atomic fraction).

It should, however, be noted that in the case of lead–gold, where it was not possible to extend the measurements into the gold-rich region beyond an atomic fraction of gold of 0.79, the calculation of the partial molar properties for gold in the mixtures is associated with some uncertainty. This uncertainty is carried through in any calculation of the integral thermodynamic properties Y through the equation

$$Y = x_1\bar{Y}_1 + x_2\bar{Y}_2$$

Experimental Procedure

The type of cell used in this investigation was similar to the H-shaped cell extensively applied by H. Seltz and co-workers.[3] However, as the study of the lead–gold system required measurements up to 800–850°, temperatures at which Pyrex will no longer stand up, the cells were made from fused silica. Although extended heating at the highest temperatures caused some devitrification of the cell walls, it was found that these silica cells in general stood up quite well to the attack of the electrolyte used. This consisted of a eutectic mixture (m. p. 360°) of lithium

chloride and potassium chloride with some 5 wt. per cent. of lead chloride added.

The electrolyte was first melted down in the cell and degassed by heating to 700–800° for a short period of time. Weighed amounts (totaling 3–4 g.) of gold and lead, and of pure lead only, were then melted down in their separate halves of the cell, before the cell was placed in a larger silica tube heated in an electric tube furnace. To prevent temperature fluctuations, the silica tube contained a lead "bath" protected by a chloride melt, into which the cell was immersed.

Tungsten leads, protected from the electrolyte in the cell by close fitting alundum thermocouple tubes, were then inserted, the system closed off and evacuated. The assembled system is shown in Fig. 1.

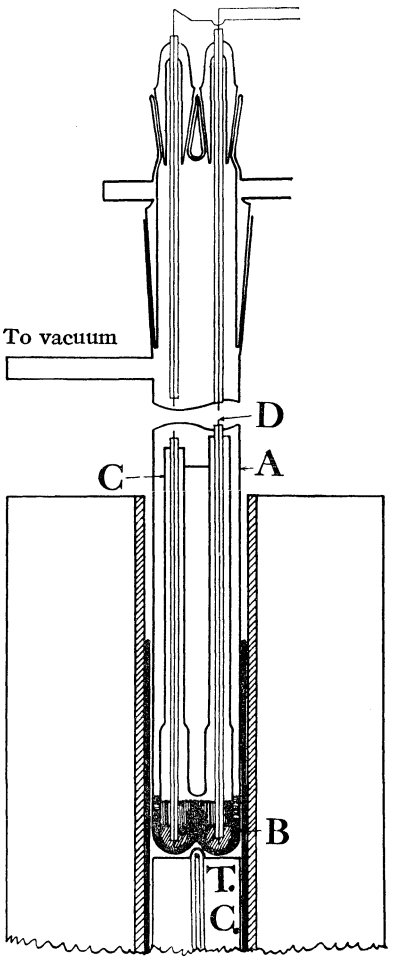

Fig. 1.—Experimental arrangement: A, outer silica tube; B, lead bath; C, silica cell; D, tungsten leads; T. C. thermocouple.

By using a constant voltage transformer for control of the power input it was possible to maintain constant temperature in the system to ±1° over a period of many hours.

The temperature was measured by a chromel-alumel thermocouple in contact with the outside bottom of the silica tube (see Fig. 1, T.C.). It was found in separate experiments that this thermocouple showed a practically constant amount of 2° less than the actual temperature of the lead-bath (in the temperature range used); the reported temperatures are corrected for this difference. The Chromel–Alumel thermocouples were checked at the melting points of lead, antimony and silver.

The electromotive forces, both for cell and thermocouple, were measured by a Rubicon (type B) potentiometer which could be read easily to 0.005 mv.

In a period of two to three days some 100–200 independent measurements of both temperature and electromotive force were carried out at 8–15 different temperatures. When the required data for one alloy composition had been obtained in this way, nitrogen was admitted into the system and additional weighed amounts of gold or lead were added to the alloy electrode. The experiment was then continued for another two to three days until the required data for the new composition had been recorded. After 2 or 3 such consecutive runs, the cell was removed from the system, and the alloy and reference electrodes removed from the cooled off cell for analysis.

It was found that the electromotive force measurements at moderately high temperatures (< 700°) could be reproduced to ±0.02–0.03 mv. At temperatures above 700°, however, scattering increased and the precision dropped to ±0.1–0.2 mv. When measurements were carried out above 850°, it was no longer found possible to get consistent results over any prolonged period of time. This prevented extension of the measurements to alloys richer in gold than about 80 atomic per cent.

The possible presence of gold in the reference electrodes was checked after completion of the runs by spectrographic methods. In all cases, except one, it was found that the gold content was less than 0.02%. This amount is quite negligible compared with other sources of error. In one case, however, 0.31% gold was found in the reference electrode, indicating accidental contamination of the reference electrode by transfer of metal from the alloy side to the pure metal side of the cell. The results of these runs are not reported.

Analysis by conventional analytical methods of the alloy electrodes showed, within the analytical error, no change in composition. The compositions reported are based on weighed-in amounts.

The lead used in this investigation was "Baker's Analysed" with a total of foreign non-volatile matter of 0.02%. The gold was "fine gold" (99.9% Au) supplied by Baker and Company.

Experimental Results

The measured electromotive forces for each alloy composition were plotted *vs.* temperature. Over a range of 200–300°, there was never a detectable change in the slope of any of these curves, and a graphical determination of the temperature gradient of the electromotive force was, therefore, simple. From the same set of curves the electromotive forces for the various compositions at one reference temperature, 600°, were obtained. As most of the experiments were performed at 450–700°, it was decided to use 600° as a reference temperature also for alloys which would not be liquid at this temperature (alloys with less than 32 atomic per cent. lead). This involved an extrapolation of the data for these alloys from higher temperatures, making use of the simultaneously determined temperature gradient of the electromotive force. The reference state for gold in all data reported below is the hypothetical undercooled liquid gold.

The experimental results for the various runs and the corresponding activities a_{Pb} and "entropy fractions"[4] x'_{Pb} are recorded in Table I.

Based on this set of experimental data, the electromotive forces and their temperature gradients for round figure atomic fractions were de-

(4) For an explanation of the term "entropy fraction," see below.

[a] The values in parentheses are based on extrapolation. The reference state for gold is the hypothetical undercooled liquid gold.

termined by graphical interpolation of the smooth curve drawn through the experimental points. The corresponding chemical potentials and partial molar entropies are recorded in columns 2 and 3, Table II.

In column 4 of this table are given the activities of lead at 600°, while column 5 gives the corresponding activities of gold, calculated by graphical integration of the atomic ratios *versus* activity coefficients. Columns 6 and 7 give, in a similar way, the "entropy fractions" for lead and gold, respectively.

The author, in another communication,[5] has suggested the use of the "entropy fraction" to indicate the deviations of the partial molar entropies from those of an ideal solution.

The entropy fraction x_i' is defined by the relationship

$$\Delta\bar{S}_i = -R \ln x_i'$$

It will be seen that this quantity is related to the partial molar entropy in the same manner as the activity is related to the chemical potential. If x' is different from x, the ratio of the two (x'/x) gives a numerical measure for deviations from the ideal partial molar entropy. The quantity (x'/x) might be termed "entropy fraction coefficient" and is particularly useful in graphical integrations involving the partial molar entropy. Like the chemical potential, the partial molar entropy goes numerically to infinity when x goes to zero, while the activity coefficient and (x'/x) of course remain finite. This has been made use of in the computation of the data of column 7.

Plots of activities and "entropy fractions" for both components are given in Fig. 2.

Columns 8, 9 and 10 finally give the calculated values for relative partial heat contents $\bar{L}$ and for the integral heats of mixing ΔH. These quantities are plotted in Fig. 3.

Limits of Error in Computed Data.—The limits of error in the basic data of Table II (columns 2 and 3) are estimated to generally less than $\pm 1\%$ for the chemical potentials and to ± 2–3% for the partial molar entropies. This estimation

(5) O. J. Kleppa, *Discussions Faraday Soc.*, **4**, 109 (1948).

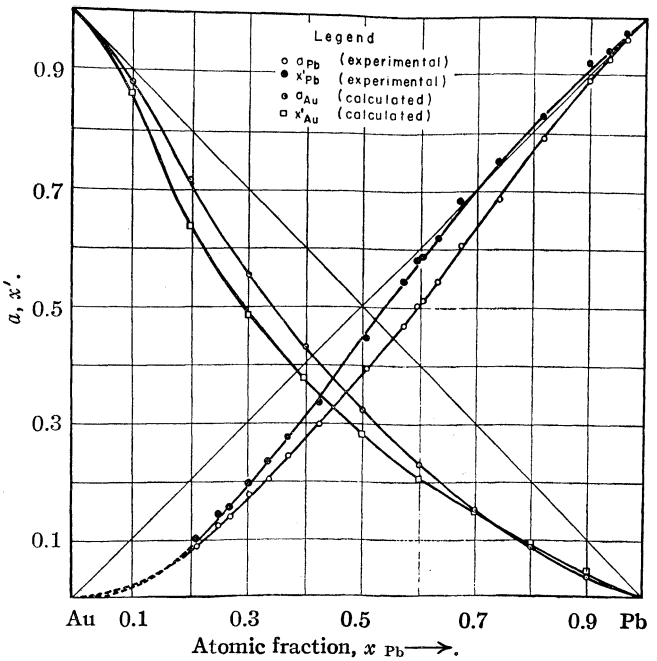

Fig. 2.—Activities and "entropy fractions" in the system Au (1)-Pb (1).

is based primarily on the reproducibility of the measurements, the temperature fluctuations during the experiments and on the possible error involved in the graphical interpolations.

These errors cannot seriously affect the calculated values for the activity and "entropy fraction" for lead. However, the relative partial molar heat content, $\bar{L}_{Pb}$, is derived as a difference between two large numbers, and may accordingly be associated with a considerably greater uncertainty.

In the subsequent calculations of the activities and "entropy fractions" for gold more serious error may also be involved, because of the required extrapolation of the data for lead into the most gold-rich region (bracketed values in columns 2 and 3) and the uncertainty associated with the graphical integration. What is said above about the uncertainty in the partial molar heat content, is even more the case for $\bar{L}_{Au}$ than for $\bar{L}_{Pb}$.

Comparison with Other Data.—Unfortunately, there are no calorimetric data available for the system lead-gold. These would have represented a very desirable check on the thermal data. However, by comparison with the equilibrium phase diagram, we have an independent method for determination of the chemical potential of gold in the liquid alloys rich in gold.

The phase diagram in this system was worked out by Vogel.[6] From his data we find that the liquid in equilibrium with the solid solution of lead in gold at 600° has an atomic fraction of lead of 0.314. As the solid solubility of lead in gold is probably of the order of 0.05% or less at 600°[7] we can neglect it in our calculations without introducing any appreciable error.

The equilibrium condition is then simply

$$\mu'_{Au}\ (\text{solid}) = \mu_{Au}\ (\text{in solution})$$

We must accordingly calculate the chemical potential of pure solid gold at 600°, referred to pure liquid undercooled gold of the same temperature. This immediately also gives the chemical potential of gold in the solution.

For the process Au(l) = Au(s) K. K. Kelley[8] gives $\Delta H = -3030$ cal. at the melting point of gold (1336°K.). In the lack of data for the specific heat of undercooled liquid gold, we make the reasonable assumption that $\Delta C_P = 0$ and find for the considered process

$$\mu'_{Au(s)} - \mu^0_{Au(l)} = 2.268T - 3030$$

whence

$$\log a_{Au} = 0.4957 - (662.3/T)$$

At 600° we calculate $a_{Au} = 0.546$ while this investigation gives $a_{Au} = 0.538$ for $x_{Pb} = 0.314$. In view of the assumptions made and the possible error involved in our computations of the activities of gold in the solutions, this agreement must be considered quite satisfactory.

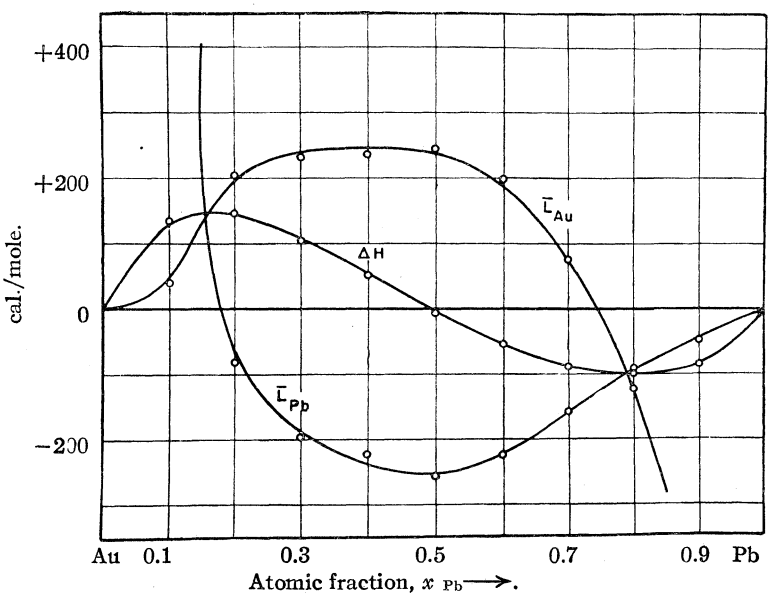

Fig. 3.—Relative partial molar and integral heats of mixing in the system Au (1)-Pb (1).

Thermodynamic Properties of Au_2Pb.—By further study of the phase diagram for lead–gold, it will be seen that between the temperatures 420 and 254°, various liquid mixtures are in equilibrium with solid Au_2Pb, and that between 254 and 215° other mixtures are in equilibrium with solid $AuPb_2$.

We shall use our thermodynamic data for the liquid extrapolated to the appropriate temperatures to calculate the free energy of formation ΔF for Au_2Pb(s), with reference to the pure liquid metals of the same temperatures. In these calculations it is assumed that there is no change in the partial molar entropies in the liquid with temperature. At equilibrium conditions

$$\mu'_{Pb} \text{ (in } Au_2Pb) = \mu_{Pb} \text{ (in solution)}$$
$$\mu'_{Au} \text{ (in } Au_2Pb) = \mu_{Au} \text{ (in solution)}$$

For the process

$$2Au(l, \text{undercooled}) + Pb(l) = Au_2Pb(s)$$

we then have

$$\Delta F = 2\,\mu_{Au} + \mu_{Pb}$$

The results of these calculations are recorded in Table III.

TABLE III

Atomic fraction, x_{Pb}	Equil. temp., °K.	$-\Delta F$ (Au_2Pb)	$-\Delta F/T$	$10^3 \times 1/T$
0.4382	696	4223	6.067	1.437
.4880	681	4268	6.267	1.468
.5381	656	4327	6.615	1.524
.5885	628	4407	7.017	1.592
.6390	593	4495	7.580	1.686
.6694	565	4526	8.010	1.769
.6899	548	4541	8.226	1.824

The data in the first two columns are taken from Vogel,[6] ΔF is calculated from the equation above after the appropriate extrapolation of our experimental data has been carried out. In Fig. 4, $\Delta F/T$ is plotted *versus* $1/T$ in the usual way, and from the slope we find

$$\Delta H = -6000 \pm 300 \text{ cal.}$$

Hence, for the entropy of formation at 692°K.

$$\Delta S = (\Delta H - \Delta F)/T = -2.6 \pm 0.5$$

In the lack of data for the specific heat of undercooled liquid gold and Au_2Pb, we shall not try to evaluate the standard heat of formation of Au_2Pb at room temperature.

Discussion

The thermodynamic properties of the liquid mixture of gold and lead can be summarized as follows. The heat of mixing is small (±100 cal.). The considerable deviation of the solution from Raoult's law can be attributed largely to an anomalously high entropy of mixing.

Any discussion trying to explain the properties of this mixture should perhaps be focused on the entropy of mixing rather than on the heat (energy) of mixing.[9] Unfortunately, the factors contributing to entropy deviations in metallic mixtures are even less understood than those deciding energetic deviations. Although theories exist which try to account for entropy deviations due to one single factor only, no attempt has been made so far to get a more complete understanding of their concerted effect. Among the single factors which, although not mutually independent, undoubtedly may play a role in the determination of the entropy of mixing are the following:

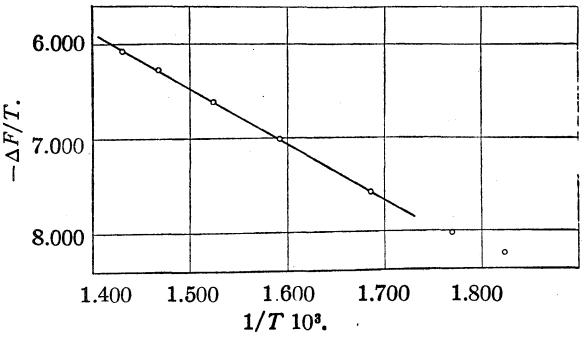

Fig. 4.

Factor	Effect on ΔS	Reference
Short range order	Neg.	Fowler and Guggenheim[10]
Net volume change on mixing $\Delta V > 0$	Pos.	Scatchard[11]
Net volume change on mixing $\Delta V < 0$	Neg.	
Diff. in space req. of each component	Pos.	Hildebrand[12]
Change in sp. heats on mixing	Pos. or neg.	...
Change in coördination no. on mixing	Pos. (?) or neg.	...

The only one of these factors on which we have any decisive information in the case of the gold–lead system, is the difference in space requirement of the gold atom and lead atom, respectively.

At the melting point the atomic volume of liquid lead is 19.4 cm.^{3} per g. atom, while the corresponding figure for gold is 11.5 cm.^{3} If a correction is introduced for the thermal expansion between the melting points and our reference temperature 600°, the difference between the two would be still greater.

It is found, however, that the formulas derived to correct the entropy of mixing for a difference in volume of the two components are quite unable to account for a positive deviation of our order of magnitude.[12]

If data had been available for the net volume change on mixing, the formulas derived by Scatchard[11] might perhaps have explained the excess entropy of mixing. However, without density measurements on liquid lead–gold mixtures, we

(9) A more complete discussion of the factors causing anomalous entropies of mixing in liquid metallic mixtures will be given in a later communication in this series.

Summary

The chemical potentials and partial molar entropies of mixing for lead in liquid lead–gold mixtures have been determined by the electromotive force method for compositions up to 79 atomic per cent. gold.

From these data have been calculated for both components activities at 600°, "entropy fractions," and relative partial and integral molar heats of mixing. It was found that the deviation of this mixture from Raoult's law can be largely attributed to a non-ideal entropy of mixing.

The heat and free energies of formation for Au_2Pb(s) from liquid lead and undercooled liquid gold at about 400° were calculated using information from the established equilibrium phase diagram of Au–Pb and from this investigation.

Composition of Ferric Thiocyanate at High Concentrations

BY STANLEY E. POLCHLOPEK[1] AND J. HAROLD SMITH

Several recent investigations[2–5] have established by a variety of methods that in dilute solution the composition of the ferric thiocyanate complex is $FeSCN^{++}$. Møller[6] used conductivity measurements to identify complexes such as $Fe(SCN)_2^+$ and $Fe(SCN)_4^-$, in more concentrated solutions. In an earlier study Schlesinger and VanValkenburg[7] had concluded that $Fe(SCN)_6^{\equiv}$ was responsible for the red color of ferric thiocyanate solutions on the basis of boiling point elevation and freezing point depression data and absorption spectra.

It has been the purpose of this investigation to study the formation of higher ferric thiocyanate complexes at high concentrations by means of the spectrophotometer, using the method developed by Job[8] and modified by Vosburgh and Cooper.[9] Gould and Vosburgh[5] used this method of continuous variations and found the 1:1 complex at low concentrations, but the method has never been applied to high concentrations of ferric thiocyanate probably because of the very intense color of a concentrated solution. This intense color made necessary the use of very thin absorption cells and the development of a technique for handling these cells.

Experimental

Ferric nitrate and potassium thiocyanate were selected as reactants to avoid the formation of other complexes. The ferric nitrate solutions were standardized against sulfato-ceric acid; the potassium thiocyanate solutions were standardized against silver nitrate. Potassium nitrate solutions were used to maintain constant ionic strength whenever possible. The determinations on 0.1 and 0.25 *M* solutions were made with the potassium thiocyanate solutions brought to the ionic strength and *p*H of the ferric nitrate. Check determinations were made without bringing the potassium thiocyanate to the *p*H of the ferric nitrate and it was found that the absorption maxima remained the same as with the *p*H adjusted potassium thiocyanate. In 1.0 *M* solutions it was not possible because of solubility considerations to bring potassium thiocyanate to the same ionic strength as the ferric nitrate and only the *p*H was adjusted. In the 2.0 *M* solutions studied neither the *p*H nor the ionic strength were adjusted. It should be noted that with the high acidity of the thiocyanate solution measurements of optical density had to be made immediately because of the instability of these solutions.

Absorption spectra were determined for solutions in which the ratio of iron(III) to thiocyanate ranged from 1:1 to 1:6 at 0.1 and 0.25 *M* concentrations. These spectra were determined by keeping the volume of the iron(III) solution constant and increasing the volume of thiocyanate. In order that the final volume of ferric thiocyanate be the same for each determination after mixing the components a potassium nitrate solution of the same ionic strength and *p*H was added each time in appropriate volume.

The absorption measurements were taken with a Beckman D. U. Quartz Spectrophotometer. The band widths used in the determinations ranged from 0.8 mμ of spectrum at a wave length of 400 to 4 mμ of spectrum at a wave length of 600 mμ according to data supplied by the manufacturer. The absorption cells used in these measurements were made from "special grade, colorless" microscope slides (A. H. Thomas Co.). Two thin slips of a plastic sheet (or thin cover glasses) were sandwiched between the microscope slides in such a manner that the plastic or glass separators were at both ends of the cell and the center area could be filled with liquid. The cells were clamped at both ends with spring back metal paper clamps. The

plastic separators used were approximately 0.0038 cm. thick and the glass separators were approximately 0.020 cm. Cells of like construction were used with distilled water to adjust the instrument at each wave length.

The slides used were cleaned by immersion in hot sulfuric acid–potassium dichromate cleaning solution, and then rinsed in several detergents and distilled water. If the water drained evenly and readily from the slide, it was accepted as clean. The slide was then polished with lens paper and handled through lens paper throughout the process of assembly. The plastic film and cover glasses used as separators were never touched by hand.

A cell so constructed was filled by capillarity with the ferric thiocyanate introduced into the top of the cell from a pointed medicine dropper. This procedure was found to fill the cell immediately and completely. That the cell was filled uniformly was indicated by the fact that optical density measurements on the same solution and at a specified wave length remained constant regardless of the position of the cell. It was noted that on standing the solution tended to flow slowly out of the cell. It was, therefore, necessary to refill the cell at more or less regular intervals. This was done by introducing the solution at the top of the cell slowly enough so that it completely replaced the original solution which was thus caused to drain out. These flushings had to be carried out very carefully in order not to soil the optical surface of the cell, for the cells could not be cleaned except by complete dismantling. Measurements on solutions of a given series were carried out in the same cell in order to better control the variables in the investigation. For the same reason in order to eliminate any possible effects which might be attributed to fading, all readings of optical density were taken immediately after mixing and, as with Frank and Oswalt's[4] investigation, no evidence of fading was found in freshly prepared solutions.

It must be noted that the absorption cells used in this investigation varied in thickness because the solution placed in the cell often formed a thin film over the separators, causing a very slight displacement. No way to overcome this difficulty was found, and consequently the values for the optical densities of the solution varied very slightly every time a new cell was used. The flushing technique proved so satisfactory, however, that it was possible to use the same cell for getting at least two sets of data for either a continuous variation study or an absorption spectrum without dismantling the cell. So long as the same cell was used, the variations in optical density were no more than those normally encountered when using standard one-cm. cells. The determinations of optical density were repeated several times, and the data presented represent the average of at least three determinations. It was observed that the data for any one study always gave the same shaped curves with the maxima occurring in the same place regardless of any slight variation of the thickness of the cells used.

Results and Discussion

Figure 1 presents the absorption curves for volume ratios of 1:1 to 1:6 of 0.100 *M* iron(III) to 0.100 *M* thiocyanate and indicates that maximum absorption does not occur at the same wave length for each ratio. It was determined that the absorption due to ferric nitrate was negligible at wave lengths higher than 350 mμ with the very thin cells used. This obviated the necessity of corrections for the absorption due to ferric ion at the wave lengths used. Since the total volume for each determination was kept the same by the addition of appropriate volumes of potassium nitrate of equivalent ionic strength, the absorption curves illustrate the mass action effect, and the change in the absorption may be attributed directly to the increase in the thiocyanate concentration. It was anticipated, and found, in view of the low stability of ferric thiocyanate, that absorption would increase as the concentration of thiocyanate increased. The shift in absorption maximum suggests that at high concentrations of thiocyanate higher complexes are being formed.

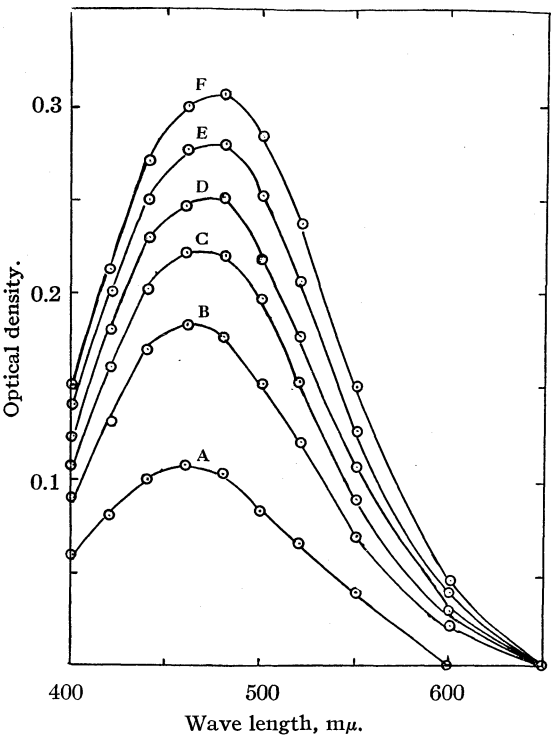

Fig. 1.—Absorption spectra of 0.100 *M* ferric nitrate and 0.100 *M* potassium thiocyanate mixed in ratios of 1:1 (A), 1:2 (B), 1:3 (C), 1:4 (D), 1:5 (E) and 1:6 (F). Iron(III) concentration was constant at 0.0143 *M*. Both solutions were at *p*H 1.7 and ionic strength 0.6. Constant volume was maintained by adding potassium nitrate of like *p*H and ionic strength in approximate amounts. The absorption cell was 0.0038 cm.

Because the absorption spectra show no tendency to intersect, the rules worked out by Vosburgh and Cooper[9] for the selection of wave lengths for a continuous variation study do not apply. The wave lengths used for the continuous variations study were those at which maximum absorption was noted and in addition several wave lengths on both sides of the maximum.

The results of the continuous variations studies for 0.100 *M* solutions are presented in Fig. 2. The fact that the maximum falls at a fraction of approximately 0.4 for iron and 0.6 for thiocyanate indicates presumably that 1.5 thiocyanate ions are associated with each ferric ion. A preferable interpretation is that the ferric thiocyanate solution resulting from mixing solutions of 0.100 *M* ferric nitrate and potassium thiocyanate contains not only the 1:1 complex but other, higher, complexes such as the 1:2.

A study of 0.250 *M* solutions of ferric nitrate

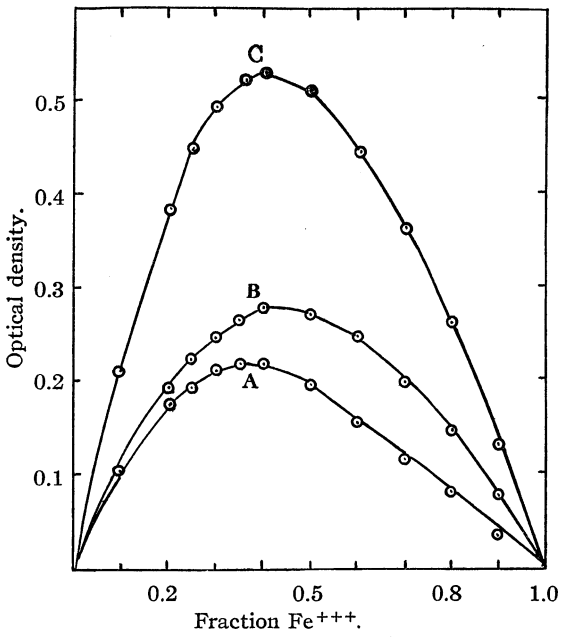

Fig. 2.—Continuous variations studies with 0.100 *M* ferric nitrate and 0.100 *M* potassium thiocyanate, each at *p*H 1.7 and ionic strength 0.6 at wave lengths of 550 mμ (A), 400 mμ (B) and 480 mμ (C). Data for wave lengths of 450 and 500 mμ follow similar plots. The absorption cell was 0.0038 cm.

and potassium thiocyanate showed (Fig. 3) that the absorption increases and the maximum shifts to higher wave lengths as the ratio of thiocyanate to iron(III) increases, thus again illustrating the mass action effect. The continuous variation study on the same solutions (Fig. 4) indicates that the maximum occurs at almost the same point as with the 0.100 *M* solutions, again indicating that the solution contains a mixture of complexes.

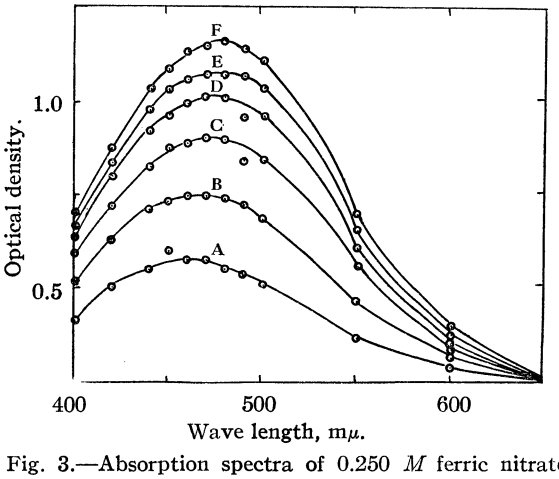

Fig. 3.—Absorption spectra of 0.250 *M* ferric nitrate and 0.250 *M* potassium thiocyanate each at *p*H 1.45 and ionic strength 1.5 mixed in ratios of 1:1 (A), 1:2 (B), 1:3 (C), 1:4 (D), 1:5 (E) and 1:6 (F). Iron(III) concentration was constant at 0.0357 *M*. Constant volume was maintained by adding potassium nitrate of like *p*H and ionic strength in appropriate amounts. The absorption cell was 0.0038 cm.

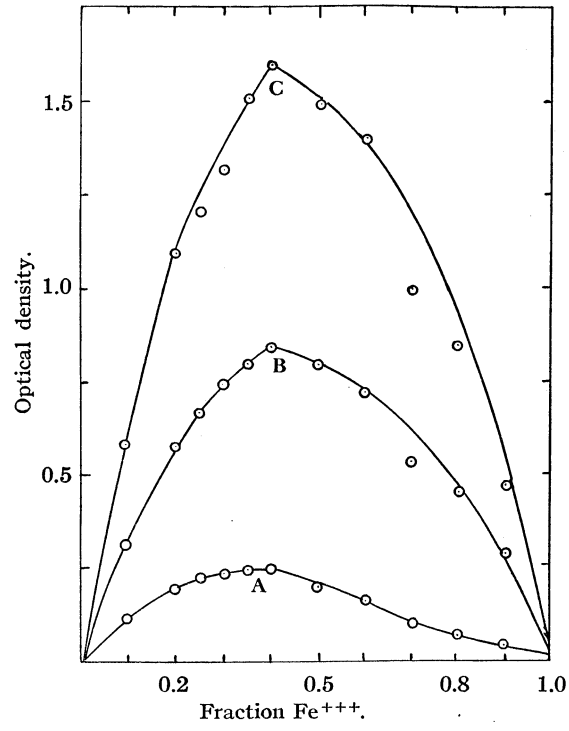

Fig. 4.—Continuous variations studies with 0.250 *M* ferric nitrate and 0.250 *M* potassium thiocyanate each at *p*H 1.45 and ionic strength 1.5 at wave lengths of 600 mμ (A), 400 mμ (B), and 450 mμ (C). Data for wave lengths of 500 and 550 mμ follow similar plots. The absorption cell was 0.0038 cm.

The optical densities of one and two molar solutions were so high that complete absorption data could not be obtained even with the thin cells used. Consequently, in order to study continuous variation, it was necessary to go to the longer wave lengths. Figure 5 shows the maximum for one molar solution at a ratio of thiocyanate to iron (III) of slightly more than 2:1. In other words, while the presence of some $FeSCN^{++}$ cannot be denied, it appears that the solution contains considerable $Fe(SCN)_2^+$ and that even higher complexes are present. A study of two molar solutions showed substantially the same thing, as indicated by Fig. 6. The ratio of thiocyanate to iron(III) at the maxima is slightly higher than for the one molar solutions. In the very concentrated solutions $Fe(SCN)_2^+$ is probably predominant. To check the effect of dilution, samples of the concentrated ferric thiocyanate solutions were occasionally diluted to 0.02 and 0.001 *M* and, as in earlier investigations,[2,3,4,5] only $FeSCN^{++}$ was found. Doubtless this is the predominant complex involved in colorimetric determinations of iron(III) where thiocyanate concentrations are generally very low.

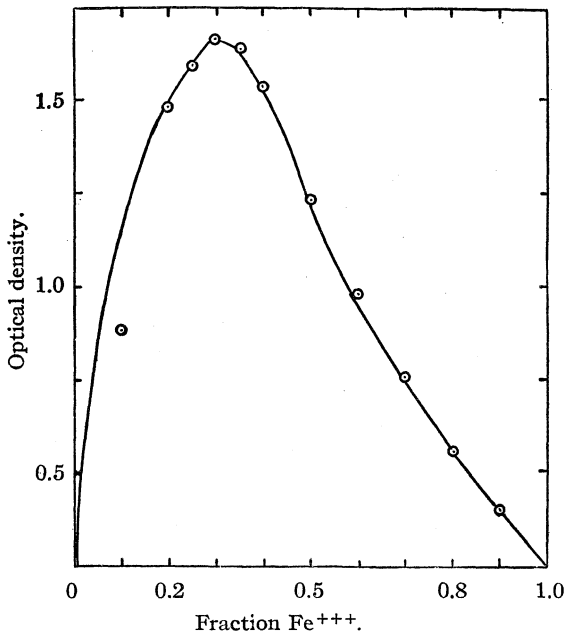

Fig. 5.—Continuous variations study using 1.000 *M* ferric nitrate and 1.000 *M* potassium thiocyanate, each at *p*H 0.75 at 600 mμ. Ionic strength was not controlled. The absorption cell was 0.0038 cm.

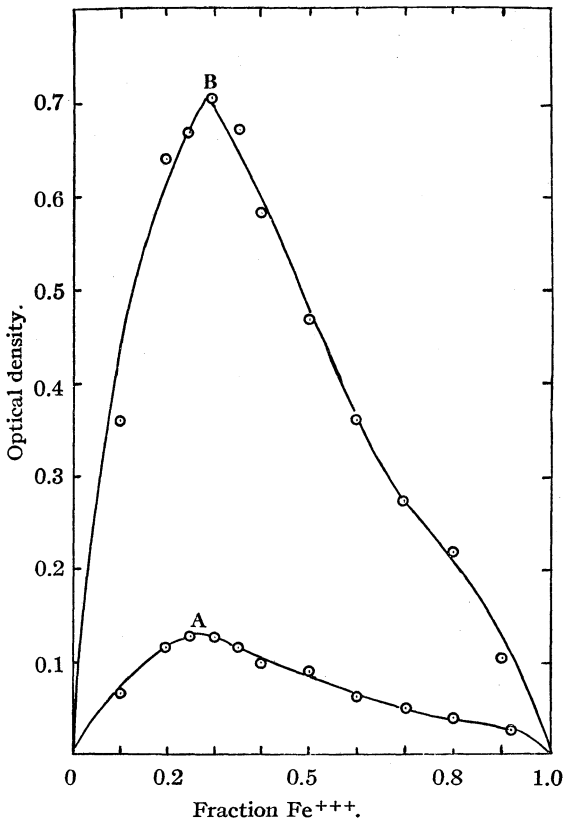

Fig. 6.—Continuous variations study using 2.000 *M* ferric nitrate and 2.000 *M* potassium thiocyanate at 700 mμ (A) and 650 mμ (B). Ionic strength and *p*H were not controlled. The absorption cell was 0.0038 cm.

Summary

1. Absorption spectra of ferric thiocyanate solutions with ferric ion at 0.0143 and 0.0357 molar and iron(III) to thiocyanate concentration ratios from 1:1 to 1:6 were determined, and are herewith presented. A shift of the absorption maximum toward longer wave lengths as the thiocyanate concentration is increased is noted and interpreted as an indication of higher complexes than $FeSCN^{++}$ which is found in dilute solution.

2. Data obtained by the method of continuous variations are presented which establish the existence of higher complexes. Definite evidence for higher complexes is found even at concentrations no higher than a few hundredths molar. The complex $Fe(SCN)_2^+$ is indicated as predominant in the 0.5 to 1.0 molar concentration range. Evidence for still higher complexes is presented.

3. In view of the complexity of the ferric thiocyanate system at the concentrations studied, no attempt was made to determine equilibrium constants. The several complexes apparently present in any given solution have absorption bands which overlap to such an extent as to make the study of any one particular higher complex extremely difficult, if not impossible, with a spectrophotometric method.

A Two Dimensional Representation of Quaternary Phase Systems

BY EDWARD V. SAYRE[1]

The solution of many phase separation problems in quaternary systems has been difficult because no single two dimensional diagram has been presented upon which graphical solutions of these problems may be obtained. Several ingenious methods have been described by which the concentration of all four components of a mixture may be represented in one plane. Some of the ways have been through a special use of polar coordinates,[2] or through the representation of a composition by a vector the length of which is determined by the concentration of one component and the position of which is determined by the concentrations of the other three components.[3,4] Blasdale[5] superimposed a Loewenherz and a Jaenecke projection at an arbitrarily convenient position so that the relations between them determined the solvent concentrations. Ricci and Loucks[6] suggested that an orthogonal projection of a three-dimensional Schreinemakers diagram and a Jaenecke projection may be used together in the same way. These methods of representation, however, do not lend themselves to the graphical solution of other than the most simple phase separation problems.

Most graphical methods of solution are performed with less complicated diagrams, which do not individually describe the systems with respect to all four components. Two or more of such separate diagrams are, therefore, required to arrive at a solution. Typical of such methods are the combined use of a vertical and a horizontal projection of a three dimensional Jaenecke isothermal diagram,[7-9] or the use of projections on two different planes through a solid Schreinemakers type diagram.[6,10]

The diagram described in this paper is the result of a double projection of the equilibrium surfaces of a solid Schreinemakers diagram[10] onto its base. These solid figures are, of course, a tetrahedron for additive systems and a pyramid for reciprocal salt pair systems. One projection is an orthogonal projection of the equilibrium points onto the base. The second figure is obtained by projecting the equilibrium points radially onto the base through lines originating at the solvent apex, *i. e.*, a Jaenecke projection. The two projections are superimposed in such a way that the ratio of the distance of an orthogonally projected point from the center of the diagram to the distance of the corresponding Jaenecke point from the center is exactly equal to the mole fraction of solvent present. Thus the diagram permits the indirect determination of solid phases through Schreinemakers' method of residues,[11] the extrapolation of tie lines. Hence by reverse application of this principle the diagram is well adapted for the graphical solution of problems of precipitation from supersaturated solutions. Also any two corresponding points in the double projections together describe a given mixture unambiguously in all four components.

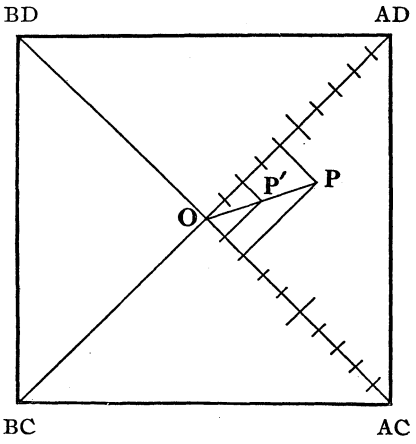

Fig. 1.—Jaenecke plot, P, and Schreinemakers plot, P', for solution of mol fractions 0.2 AD, 0.2 AC, 0.1 BD, and 0.5 solvent.

Construction of the Diagram

The orthogonal projection of a reciprocal salt pair system may be plotted by considering the four half diagonals of the square pyramid base as coördinate axes. As shown in Fig. 1, a point in the diagram quadrant, salt AC—center point O—salt AD, is located by plotting the mole fraction of AC in the total mixture as its abscissa outward along the half diagonal O(AC) and the mole fraction of AD as its ordinate along the half diagonal O(AD). If some of the salt BD, reciprocal to salt AC, is present, the position of the point in the O(AC) direction is plotted equal to mole fraction AC minus mole fraction BD. When the mole

fraction of total salts in the particular mixture plotted is increased by the simple removal of solvent, the mole fraction of each individual salt is increased in the same proportion. In this case, the representing point is extended outward along a straight line originating at the center O, where the mole fraction of total salt is zero. In the full three dimensional diagram, contained in a regular tetrahedral pyramid as illustrated in Fig. 2, the locus of these points representing change of solvent concentration alone is a radial line from the apex terminating on the base. A diagram can be thus radially projected through the Schreinemakers construction of a phase system onto the pyramid base, where total mole fraction of salts equals one. This projection can be plotted in the manner described above by substituting as coördinates the mole fractions of the individual salts in the total dry salts in place of mole fractions in the total salt–aqueous mixture. This figure is the two dimensional Jaenecke diagram of the phase system, and is identical with the figure obtained by the more conventional procedure of plotting mole fractions of ions as coördinates. If the number of moles of a given salt in a mixture is X, the total number of moles of salt Y and the number of moles of solvent Z, then the coördinate of the given salt in the orthogonal projection is $X/(Y+Z)$, and the coördinate in the Jaenecke projection is X/Y. The ratio of the orthogonal coördinate to the Jaenecke coördinate, $X/(Y+Z)/X/Y$, is then equal to the mole fraction of total salts, $Y/(Y+Z)$. Therefore, the ratio of the distance of the orthogonal point from the center origin to the distance of the Jaenecke point from the center is also equal to the mole fraction of total salts. And, since the Jaenecke point alone unambiguously specifies the molar ratios of the salts, the two points together completely define a given mixture. Any finite number of equilibrium data points may be so plotted, and thus a description of an isothermal four-component reciprocal salt pair system may be obtained in a plane.

Figure 3 presents the 25° isothermal diagram of the sodium nitrate–potassium chloride–water system, which is of importance in the manufacture of conversion saltpeter. For simplicity, all equilibrium surfaces have been considered planes and their intersections, therefore, straight lines. This assumption need not be made, since any finite number of data points describing the equilibrium surfaces may be plotted and contour lines drawn between them to represent the true equilibrium surfaces and lines within the accuracy of the available data. Primed figures will designate the orthogonally projected diagram; the unprimed ones the Jaenecke diagram. The data for this system were taken from Findlay and Campbell.[9] Point P completely describes the mixture 0.50 KNO_3, 0.40 $NaNO_3$, 0.10 KCl, 0.00 H_2O. If water is added to the mixture until its mole fraction is 0.8 (0.10 KNO_3, 0.08 $NaNO_3$, 0.02 KCl, 0.80 H_2O) points P and P′ are necessary to describe it. If the mole fraction of water is then halved (0.30 KNO_3, 0.24 $NaNO_3$, 0.06 KCl, 0.40 H_2O) points P and P″ will describe the solution. It is apparent that the distance PP″ is half the distance PP′. Henceforth, points in the Jaenecke diagram will be called base points, and those in the orthogonal diagram called projected points. They will always be designated by unprimed and primed letters, respectively.

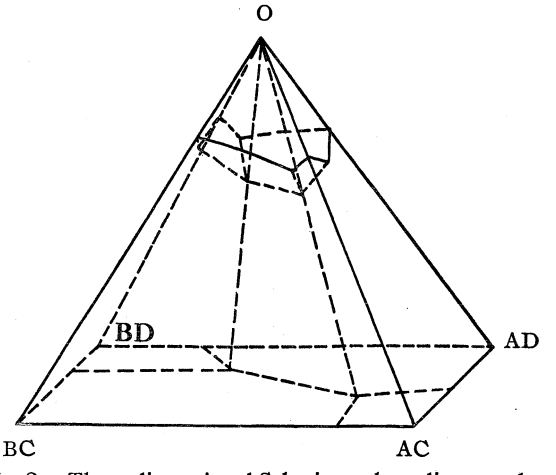

Fig. 2.—Three-dimensional Schreinemakers diagram showing Jaenecke projection on its base.

It is apparent that a solution is not uniquely defined if its base point lies at the center position O. The occurrence of a solution at this position, however, in general simplifies the solution of phase change problems by other methods. The properties of a system in this condition will be discussed later.

Solution of Phase Change Problems

When one determines in what planes a point pair might move through a pyramidal Schreinemakers diagram, the most apparent restriction is that they be planes containing both the base point and the projected point. Therefore, they are planes through the line connecting the base point to the water apex. Considering the point pair P and P′ in Fig. 3, since the position of the base point is in the potassium nitrate section, we know that if any solid phase crystallizes out it will be potassium nitrate. The plane of operation of this phase separation must, therefore, include the base corner point KNO_3. The projection of this plane, determined by points KNO_3, O, and P, is shown in Fig. 3, where it is drawn completely through the figure to point R, its intersection with the base line connecting the $NaNO_3$ and NaCl corners. Then R′, the projection of point R in the orthogonal diagram, is readily determined by the intersection of lines OR and ($NaNO_3$′)B′. Similarly, Q′, the intersection of the plane with the equilibrium line F′A′, is determined by the intersection of F′A′ with the line OQ, where Q is the intersection of the base lines FA and (KNO_3)R.

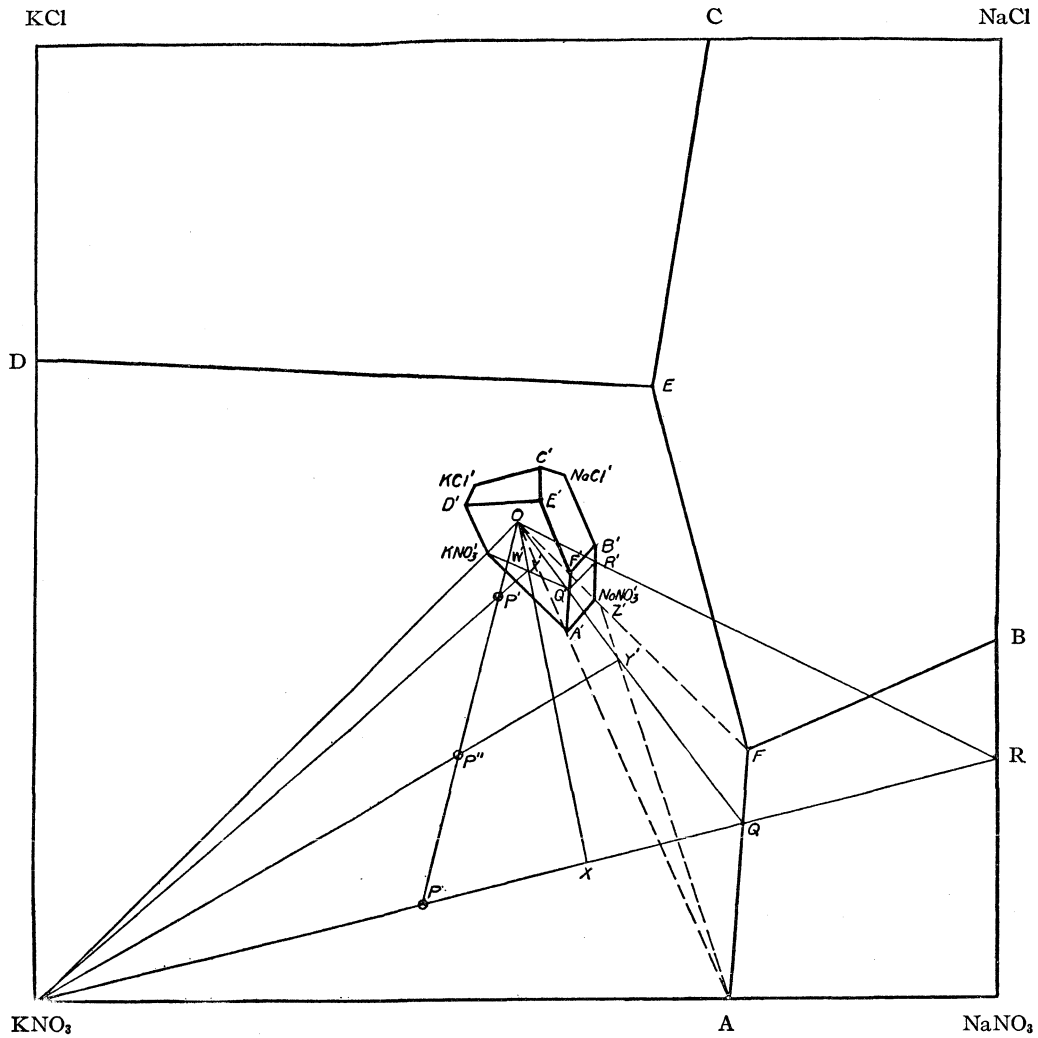

Fig. 3.—Isothermal diagram at 25° of system sodium nitrate, potassium chloride, water, with constructions determining precipitation from supersaturated solutions PP′ and PP″.

The lines $(KNO_3')Q'$ and $Q'R'$ then are the vertical projections of the intersection of plane $(KNO_3)RO$ with the equilibrium surfaces of the phase diagram. The intersection of line OP with line $(KNO_3')Q'$ then is the projection of the point at which OP pierces the equilibrium surface $(KNO_3')A'F'E'D'$. If the projected point along OP is closer to the origin O than this intersection, W′, the mixture represented is an unsaturated solution of salt mixture P; if the projected point is at W′, the solution is saturated with these salts; and if the projected point is below W′, as is P′, solid potassium nitrate will crystallize out.

Since all points along the base line $(KNO_3)R$ express a constant ratio of NaCl to $NaNO_3$, all points in the $(KNO_3)RO$ plane obviously must do likewise. (It has already been shown that a line in this plane originating at the water apex O represents mixtures of constant salt ratios differing only in their water contents.) Similarly, a line in this plane originating at base point KNO_3 fixes a constant ratio of water to mixture R, and motion along such a line correctly describes the addition or removal of pure potassium nitrate to the system. As one crystallizes potassium nitrate from the supersaturated solution of pair PP′, the projected point P′ moves along the line $(KNO_3)P'$ until it reaches the equilibrium surface at X′, the intersection of the operating line with $(KNO_3')Q'$. The base point will at the same time move along $(KNO_3)P$ until it reaches X, the point of intersection with a straight line through O and X′. Evaporation of water from the equilibrium mixture XX′ would move the projected point along the line segment X′Q′ while the base point would move to corresponding positions along XQ.

When potassium nitrate is separated from the supersaturated solution PP″, the base point reaches an equilibrium line on the Jaenecke diagram, *i. e.*, point Q on line AF, before the corresponding projected point Y′ has reached an equilibrium position on the orthogonal diagram. This

indicates that solution PP″ was supersaturated with respect to more than one salt. The crystallization path that such a solution would follow may be decided unambiguously by asking what would occur if water were added to it until the solution was in equilibrium, then this extra water evaporated away, the solution being allowed to follow an equilibrium course. In this particular problem this path would first involve the conversion of PP″ to PW′. Evaporation of water from PW′ would result in precipitation of potassium nitrate until composition QQ′ was reached. At this point a salt mixture of composition A would start crystallizing out, and the saturated solution proceed down path Q′F′. One may theoretically stop this process at any point, however, and remove the remaining added water in a non-equilibrium manner, leaving a supersaturated solution. If one did this upon reaching QQ′, the resulting supersaturated solution would be QY′, exactly the same point at which one arrives by the direct path P″Y′. Since the system is conservative, the simple direct path is as good for calculation as the one detouring over the equilibrium surface.

Similarly, therefore, one may assume upon reaching QY′ the supersaturated solution will separate only salt of composition A. The diagram points may be assumed then to move in the new plane OFA, which is determined by line OQ and base point A (see Fig. 3). The orthogonal projection of the intersection of this plane with the equilibrium surface is obviously A′F′. Again in this case the base point, moving inward along the extended line AQ, reaches a new position of equilibrium, the quintuple base point F, before its projected point, moving inward along line AY′, intersects the equilibrium surface. It is, of course, completely fortuitous that FF′ lies along the diagonal KCl–$NaNO_3$.

The new supersaturated solution FZ′ will crystallize out the triple component mixture of composition F. The position of the base point, F, may be assumed not to change during this process, while the projected point will move inward along line OF until it reaches the equilibrium position F′. Following the usual proportional balance the ratio of number of moles of solid crystallized out to number of moles of saturated solution remaining is given by the ratio of F′Z′ to Z′F.

An interesting special problem arises when the precipitating salt is hydrated. One would have then separate projected and base points representing the solid salt. In the problem of describing the separation of this salt from its supersaturated solution, the course of the projected point of the solution would be along the straight line originally connecting it to the projected point of the solid, while the course of the base point would be along the straight line connecting it to the base point of the solid.

In the solution to the problems presented above, two simplifying assumptions were made. One of them was that the equilibrium surfaces were planes and their intersections straight lines. This assumption may be easily avoided and in no way affects the fundamentals of the method presented above. For example, in Fig. 3 one might have plotted a number of experimental points of the surface A′(KNO_3′)D′E′F′ and drawn contour lines between these experimental points both in the orthogonal and Jaenecke projections. Then the intersections of line (KNO_3)Q with the contour lines on the base would determine the intersections of plane (KNO_3)OQ with the corresponding orthogonally projected contour lines. Hence the path of crystallization, (KNO_3′)Q′, would have been determined in its true curved form.

The second simplifying assumption was that the proportion of two salts precipitating along a line of two-fold saturation is constant. This is the same as assuming that, for example, Jaenecke line AF in Fig. 3 is straight. This assumption is fundamental to the procedure of solutions described, for without it one would have to move by trial and error in the curved surface OAF. The assumption is a very good approximation, however, since the degree to which line AF would vary from straightness would be no greater than the degree to which the activity coefficients of potassium nitrate and sodium nitrate would change at different rates along the path A′F′.

Limitations of the Method.—It is apparent that occasionally one would operate in a plane vertically intersecting a three dimensional Schreinemakers diagram. The projection of such a plane in the two dimensional diagram would be a straight line, on which it would be impossible to perform many of the geometric constructions described above. However, because all motion in this case is restricted to a straight line in the diagram, it is usually apparent where at least one of the composition points will come to rest, as it was in the case of motion along the line OF in Fig. 3. Phase separations from the special type of solution described above for which the base point lies directly beneath the center origin will always take place in such vertically placed planes. Therefore, if the original concentration is known, it is usually easy to calculate changes from it with the help of the diagram even though it is impossible to plot the original concentration in an unambiguous manner.

If the phase system is one of very insoluble salts, the orthogonal projection will be inconveniently close in toward the origin, and an extremely large diagram might be required for exact construction. This difficulty can be avoided by enlarging the center portion of the diagram containing all of the orthogonal projection into a second diagram. The intersection of lines in the normal diagram with the periphery of the center section in it chosen for enlargement, together with the equilibrium points concerned, give sufficient information for transfer-

ing lines from the normal to the enlarged partial diagram and vice versa.

Application to other Four-Component Systems.—The methods described above can be applied to systems composed of water and three salts with a common ion if the following method of plotting is followed. The figure appears in an equilateral triangular graph with vertices A, B and C and point of intersection of perpendiculars from these vertices to their opposite bases, O. Then a point is determined by plotting the mole fractions of salts A and B as coördinates along the axes OA and OB originating at the center O. The point is then moved parallel to the third axis OC, a distance equal to mole fraction of salt C.

Acknowledgment.—The author wishes to thank Professor J. J. Beaver for his constructive criticism of this paper.

Summary

A two-dimensional, quaternary phase diagram is presented in which compositions are described in all four constituents and in which graphical solutions to general phase separation problems may be made. The diagram is constructed by superimposing an orthogonal projection of a three dimensional Schreinemakers diagram upon a Jaenecke projection in such a way that the method of wet residues may be applied.

Properties of Electrolytic Solutions. XLIV. Conductance of Some Long Chain Salts in Ethylene Chloride, Pyridine and Nitrobenzene at 25°[1]

BY HAROLD L. PICKERING[2] AND CHARLES A. KRAUS

I. Introduction

Weaver[3] has measured the conductance of several long chain salts in ethylene chloride and nitrobenzene. In these solvents the salts behaved like normal electrolytes. It seemed worth while, therefore, to measure the conductance of a larger number of long chain salts. It was of particular interest to determine the limiting conductance of long chain ions and to find how the conductance of such ions depends on the number of carbon atoms that they contain, on the one hand, and their arrangement about the central nitrogen atom, on the other.

To this end, the conductance of a number of long chain salts was measured in ethylene chloride, pyridine and nitrobenzene. In addition, the conductance of several ordinary quaternary ammonium salts was determined in order to fill gaps in the list of ion conductances.

II. Experimental

1. **Salts.**—These were prepared according to conventional methods. It is important to use only well purified starting materials. Nitrates and picrates were prepared by metathesis of iodides with silver salts in methanol or ethanol. The following salts were prepared: (1) *n*-octadecylpyridonium nitrate (m. p., 79–80°), (2) di-*n*-octadecyldimethylammonium picrate (m. p., 75.5–76.2°), (3) di-*n*-octadecyldi-*n*-butylammonium picrate (m. p. 50.5–51.5°), (4) *n*-octadecyltri-*n*-butylammonium nitrate (m. p., 90.5–91.5°), (5) *n*-octadecyltri-*n*-butylammonium picrate (m. p., 42–43°), (6) *n*-octadecyltrimethylammonium iodide (m. p., 237–238.5°), (7) *n*-octadecyltrimethylammonium picrate (m. p., 134–135°), (8) *n*-propylpyridonium picrate (61–62°), (9) tetra-*n*-butylammonium picrate (m. p., 73.5–74.5°), (10) tetra-*n*-propylammonium picrate (m. p., 115–116°). Earlier preparations of tetra-*n*-butylammonium triphenylborofluoride (11) and formate (12) were measured after several recrystallizations.

The salts were recrystallized as follows: (1) hexane plus few drops of ethanol, (2) hot absolute ethanol, (3), (5) methanol plus few drops of ethanol, (4) dioxane–water followed by hexane–ethanol, (6), (7) absolute ethanol, (8) 99% ethanol, (9), (10), (12) 95% ethanol, (11) ethanol plus 10% hexane.

2. **Solvents.**—Solvents were prepared as described in earlier papers.[4] Solvent resistances were measured with a special parallel arm bridge permitting of precise measurements up to 10^7 ohms.

3. **Apparatus and Procedure.**—These were the same as those described in earlier papers of this series.[4]

III. Results

In Table I are given equivalent conductances at different concentrations (expressed in moles per liter of solution) for several salts in ethylene chloride. Similar data are given for solutions in pyridine in Table II and for solutions in nitrobenzene in Table III. All measurements were carried out at 25 ± 0.01°. In computations, the following values were employed for physical constants.

	Density	Viscosity	Diel. const.
Ethylene chloride	1.2455	0.00787	10.23
Pyridine	0.97792	.008824	12.01

[a] Measurements by Dr. C. J. Carignan.

by the method of Fuoss[5] and values of the limiting conductance, Λ_0, and the dissociation constant, K, have been obtained. These values are collected in Table IV, where limiting conductances are given in column 2, cation conductances as determined by the method of Fowler[5] in column 3 and dissociation constants in column 4. In Figs. 1 and 2 are shown Fuoss plots for several salts in ethylene chloride and pyridine, respectively.

As may be seen from the figures, the salts measured in ethylene chloride and pyridine conform to the Fuoss relation within the limit of experimental error, and successive series are in good agreement.

[a] Iodide and formate ions

[a] Privately communicated by Mr. E. J. Bair, of This Laboratory.

In ethylene chloride, the iodide and formate ions have rather low conductances; this is particularly true of the iodide. It is a striking fact that, in this solvent, the conductances of the chloride, bromide and iodide ions differ widely, being, respectively, 39.1, 33.8 and 29.9. The conductance of the iodide is 23% less than that of the chloride ion.

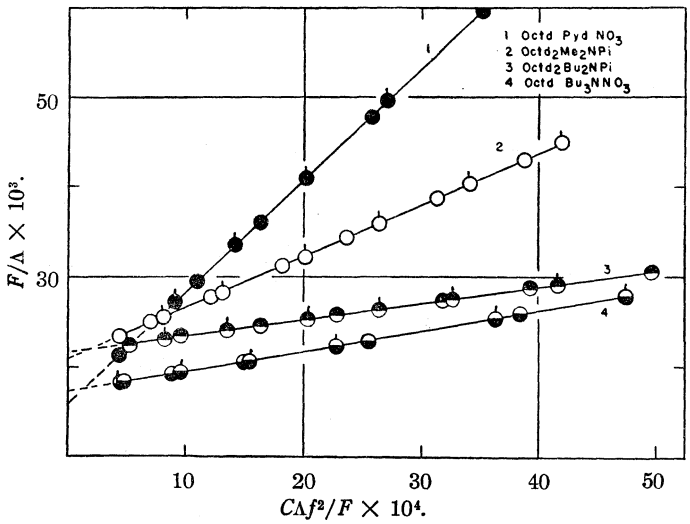

Fig. 1.—Fuoss plots for long chain salts in ethylene chloride.

The dissociation constant for octadecylpyridonium nitrate is about one half that of propylpyridonium picrate. The same is true of octadecyltributylammonium nitrate as compared with dioctadecyldi-*n*-butylammonium picrate. Octadecyltrimethylammonium formate is an especially weak salt, its constant being one-fifth that of the iodide.

The dissociation constants of the homologous series of quaternary ammonium picrates in ethylene chloride increase regularly with increasing numbers of carbon atoms in the substituent groups as Tucker has shown.[6] In this connection, it is of interest to note that the constant for dioctadecyldibutylammonium picrate is 2.61×10^{-4} as against 2.38×10^{-4} for tetra-*n*-amylammonium picrate. The constant for tetraethylammonium picrate is 1.59×10^{-4}.

In contrast to the regular change of the dissociation constant of the quaternary ammonium picrates in ethylene chloride, in pyridine the constant changes but little and, seemingly, irregularly. As may be seen from Table II, b, the constant for tetraethylammonium picrate is 10.4×10^{-4} while that for tetrabutylammonium picrate is 12.8×10^{-4}. But the constant for tetra-*n*-amylammonium picrate is only 11.3×10^{-4}, and that for dioctadecyldibutylammonium picrate is 12.0×10^{-4}. It is of interest to note that while in ethylene chloride the constant for tetra-amylammonium picrate is 7.4 times that of the corresponding tetramethylammonium salt, in pyridine the constants for the same two salts have a ratio of only 1.7. It is evident that the effect of chain length on the interaction of quaternary ions with the picrate ion in pyridine differs greatly from that in ethylene chloride. Whether the inversions found for the constants in pyridine are real or a result of experimental error remains uncertain as yet. Luder's conductance values for tetrabutylammonium picrate have subsequently been twice checked and confirmed independently. The symmetrical quaternary ammonium salts used in this investigation were the same as those used earlier by Tucker[1] except for their recrystallization.

2. Nitrobenzene.—Strong salts (*i. e.*, salts of large ions) are so highly dissociated in nitrobenzene that their dissociation constants cannot be evaluated. Values of Λ_0 may be determined by extrapolation of Λ–$\sqrt{C}$ plots. In Table V are given values of Λ_0 for the different salts measured; for the stronger salts, Λ_0 was obtained by extrapolation of the Λ–$\sqrt{C}$ plots. The weak salts were analyzed by the Fuoss method and values of the Λ_0 so obtained are given in column 2 and values of the dissociation constant, K, in the last column. Cation conductances are given in column 3. These are based on the conductance of the tetrabutylammonium triphenylborofluoride, it being assumed in accordance with Fowler[5b] that the two ions of this salt have the same conductance. Percentage deviations for the theoretical Onsager slope, Δ, are given in column 4.

Taylor and Kraus[7] measured the conductance of

TABLE V

CONSTANTS OF SOME QUATERNARY AMMONIUM SALTS IN NITROBENZENE

Salt	Λ_0	Λ_0^+	Δ%	$K \times 10^4$
Bu_4NPh_3BF	23.78	11.9	0.6	...
$Octd_2Bu_2NPi$	23.23	7.2	3.2	...
$OctdBu_3NPi$	24.64	8.6	4.1	...
$Octd_2Me_2NPi$	23.82	7.8	10.0	860
$OctdMe_3NPi$	26.50	10.5	19.4	430
$OctdPydNO_3$	33.39	10.8	146.	79

tetrabutylammonium triphenylborofluoride and found the slope of the Λ–$\sqrt{C}$ plot to be 4% less than the theoretical. It seemed worth while to measure this salt using another preparation.[8] The results of two series of measurements are shown graphically in Fig. 3. The slope of the plot is 0.6% below the theoretical. In other words, this salt conforms to the theoretical slope within the experimental error.

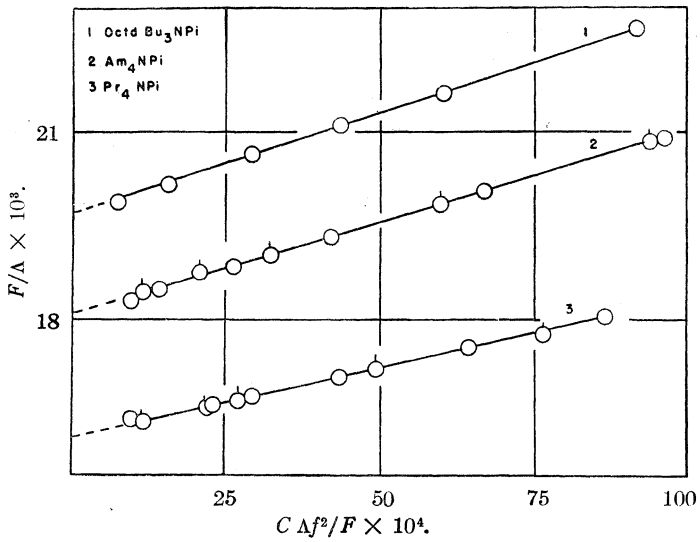

Fig. 2.—Fuoss plots for salts in pyridine.

The picrate ion in the ion pairs is smaller than the triphenylborofluoride ion. Dioctadecyldibutylammonium and octadecyltributylammonium picrate show slopes 3.2 and 4.1% greater than the theoretical. The picrates of the two methyl derivatives show markedly greater slopes. The slope of octadecylpyridonium nitrate is much greater than the theoretical. It may be pointed out that in ethylene chloride the dissociation constant of dioctadecyldimethylammonium picrate is approximately four times that of octadecylpyridonium nitrate; in nitrobenzene, the ratio of constants for the same two salts is approximately ten.

(8) Reynolds and Kraus, THIS JOURNAL, 70, 1704 (1948).

3. Conductance of Long Chain Cations.—Thompson[9] has suggested that in comparing the conductance of the symmetrical quaternary ammonium ions as a function of the number of carbon atoms in the substituent alkyl groups, it is better to compare the reciprocal of ion conductances rather than the ion conductances themselves. In other words, it is best to compare equivalent ion resistances. He has shown that with the symmetrical quaternary ammonium ions in ethylene chloride, the reciprocal ion conductances vary approximately as a linear function of the number of carbon atoms from tetraethyl- to tetra-amylammonium, inclusive.

In comparing ion conductances as a function of carbon atom content in different solvents it is helpful to take the viscosities of the solvents into account. Accordingly, in Fig. 4, we have plotted the reciprocals of the product of ion conductance and viscosity for a number of quaternary ammonium ions as a function of the number of carbon atoms that they contain, for ethylene chloride, nitrobenzene and pyridine. To avoid confusion in the plots, the origin for each succeeding solvent has been displaced 8 carbon atoms to the right as indicated in the figure.

As may be seen from Fig. 4, the tetramethylammonium ion meets with much greater resistance in proportion to the number of carbon atoms that it contains than do the larger ions. The resistance of this ion, when adjusted for the viscosity of the solvent, is very nearly the same in ethylene chloride and nitrobenzene but it is much smaller in pyridine. The resistance with which an ion meets in its motion through a solvent medium is made up of two parts: first, a normal Stokes

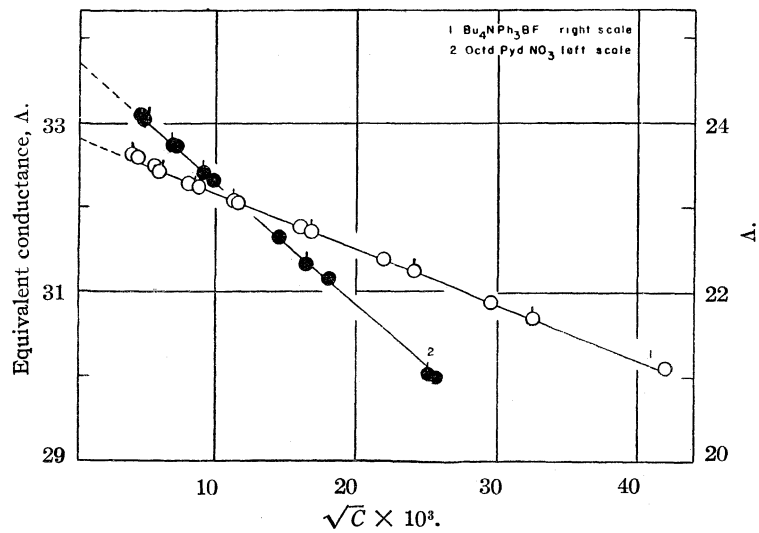

Fig. 3.—Λ-$\sqrt{C}$ plots for salts in nitrobenzene.

(9) W. E. Thompson, Thesis, Brown University, May, 1941.

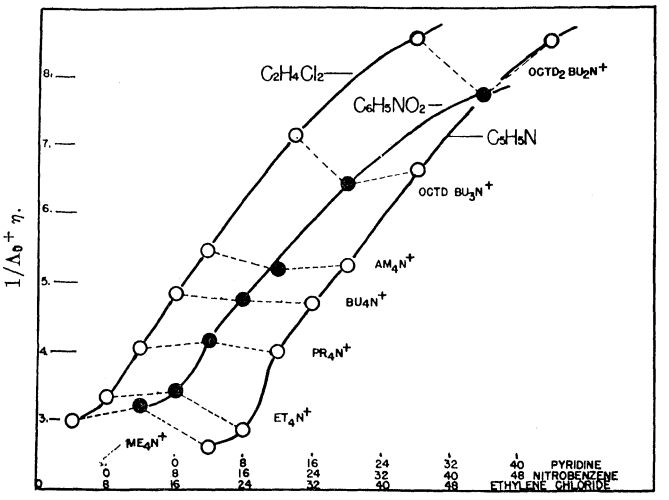

Fig. 4.—Plots of reciprocals of ion conductance–viscosity products for cations in ethylene chloride, nitrobenzene and pyridine as function of number of carbon atoms. (Note displacement of horizontal scales.)

frictional resistance and, second, a resistance due to the interaction of the charge on the ion with the dipole molecules of the solvent. The latter will depend on the size and shape of the ion and of the solvent molecules and the strength of the dipoles. It is to such factors that the tetramethylammonium ion owes its higher resistance in ethylene chloride and nitrobenzene as compared to that in pyridine.

In ethylene chloride, ion resistance varies as a linear function of the number of carbon atoms from the tetraethyl- to the tetra-amylammonium ion, inclusive. In other words, the introduction of a carbon atom causes the same increase in resistance, irrespective of the number of atoms already in the substituent groups. Even the octadecyltributylammonium ion deviates but little from the linear relation. With the dioctadecyldibutylammonium ion, the deviation is greater but not large.

For the smaller ions, the resistance curve in nitrobenzene parallels that in ethylene chloride. However, beginning with the tetrabutylammonium ion, the curve deviates from linearity and for the largest ion the deviation is very large. In contrast, the curve in pyridine deviates widely from that in ethylene chloride for smaller ions but parallels it for large ions. In going from the tetraethyl- to the tetrapropylammonium ion, the resistance change in pyridine is large in comparison with that in the other two solvents. The change in going from the tetramethyl- to the tetraethylammonium ion is exceptionally small. It would seem that the difference in ion resistance of smaller ions as between pyridine and the other two solvents must be ascribed to specific interaction of ions and solvent molecules. The difference in ion resistance for large ions as between nitrobenzene and the other two solvents may be ascribed to the compacting of the carbon atoms in the chains in the case of nitrobenzene. Indeed, the fact that the resistance of ions in ethylene chloride is proportional to the number of carbon atoms would seem to indicate that in this solvent the chains are extended. The same is true in pyridine but here we have differences in the case of smaller ions that must be attributed to other factors. In nitrobenzene, possibly due to weaker van der Waals interaction, the chains may no longer be extended and ion resistances would, accordingly, be smaller.

According to Walden's rule, the product of ion conductance and viscosity is a constant for large ions in solvents of different viscosities. From Fig. 4, it is evident that Walden's rule holds only as an approximation. Thus, for the seven quaternary ammonium ions, from tetramethyl- to dioctadecyldibutylammonium, inclusive, the maximum percentage differences for the $\Lambda_0\eta$ product in the three solvents is 19 (Me_4N^+), 16, 4, 3, 5, 10 and 9% ($Octd_2Bu_2N^+$). The product for the tetrabutyl- and the tetraamylammonium ions has the same value in pyridine and nitrobenzene while, for the dioctadecyldibutylammonium ion, it has the same value in ethylene chloride and pyridine. If Walden's rule is to be employed for the purpose of evaluating ion conductances in solvents where transport numbers cannot be determined experimentally, it would seem to be preferable to employ the tetrabutylammonium ion the $\Lambda_0{}^+\eta$ product of which is more nearly constant than is that of other ions. The tetraethylammonium ion yields unreliable results. The same can be said of the picrate ion as one of us has pointed out elsewhere.[10]

V. Summary

1. The conductances of seven long chain salts have been measured in ethylene chloride; five have been measured in nitrobenzene and one has been measured in pyridine. Cation conductances have been evaluated from the results of these measurements.

2. Several other salts have been measured in one or more of these solvents. Ion conductances have been derived from these measurements.

3. The conductance of tetrabutylammonium triphenylborofluoride in nitrobenzene has been remeasured. The slope of the Λ_0–$\sqrt{C}$ plot corresponds to the theoretical value within the limit of experimental error.

4. Plots are shown for the reciprocals of ion conductance viscosity products for the five symmetrical quaternary ammonium ions from tetramethyl- to tetraamyl, inclusive, and for octadecyltributyl- and dioctadecyldibutylammonium ions in ethylene chloride, nitrobenzene and pyridine.

(10) Kraus, *Ann. N. Y. Acad. of Sci.*, **51**, 789 (1949).

In ethylene chloride the equivalent resistance is a linear function of the number of carbon atoms from the tetraethyl- to the tetra-amylammonium ions, inclusive. Thereafter, resistance deviates slightly toward lower resistances as the number of carbon atoms increases. The resistance curve in nitrobenzene parallels that in ethylene chloride for smaller ions but deviates widely for large ions. The resistance curve for pyridine parallels that for ethylene chloride for large ions but deviates widely for small ions.

Amino Acid Composition of α-Casein and β-Casein[2]

BY WILLIAM G. GORDON, WILLIAM F. SEMMETT, ROBERT S. CABLE AND MYRON MORRIS

The heterogeneity of cow's milk casein has been established by solubility studies and electrophoretic analysis. Warner[3] reviewed earlier work on this problem and described the chemical separation of casein into two mutually distinct components,[4] α-casein and β-casein, which occur in unfractionated casein in the approximate ratio of 4:1. The fractions isolated by Warner, although not electrophoretically homogeneous over the entire *p*H range, were purified, so that neither fraction contained any of the other. Comparison of the nitrogen and phosphorus contents of the isolated fractions with those of whole casein showed some significant differences; the values for β-casein, the minor component, differed from the values for whole casein more markedly than did those for α-casein.

The present paper deals with the amino acid analysis of α-casein and β-casein. Whole casein was also analyzed by the same methods for purposes of comparison. It has been possible to account for essentially all the nitrogen of each protein in terms of known amino acid residues and amide nitrogen.

Experimental

Proteins Used.—The samples of whole casein, α-casein and β-casein were prepared by Dr. Warner according to his published directions.[3] Electrophoretic analysis showed that each fraction was free of the other. In preliminary experiments, two preparations of each protein were analyzed for total nitrogen, phosphorus, lysine, tryptophan, tyrosine and amino nitrogen. The results indicated that there was no significant difference in composition between the two preparations. Therefore, in all subsequent experiments no distinction was made between different preparations of the same protein.

Methods of Analysis.—All analyses were carried out on air-dried protein samples; moisture determinations were made as suggested by Chibnall, *et al.*[5] True ash was determined according to Warner,[3] total nitrogen by the Kjeldahl method as used by Miller and Houghton[6] and phosphorus by the method of Fiske and SubbaRow[7] after digestion with sulfuric and nitric acids. Amino nitrogen values were obtained by the Van Slyke method as modified by Doherty and Ogg,[8] and amide nitrogen was estimated in Conway micro-diffusion cells according to the procedure suggested by Warner and Cannan.[9] In the latter procedure, a series of Conway vessels, each containing 10 mg. protein in 1 ml. 1.5 *N* sodium hydroxide in the outer compartment and 1.5 ml. 2% boric acid in the inner chamber, was set up at 35°. At intervals which ranged from thirty-five to sixty-five hours, vessels were removed from the oven, and the distilled ammonia was titrated with 0.01 *N* hydrochloric acid. The value at each reaction time was determined in triplicate. A progressive increase in ammonia liberated with time was observed, so that a linear extrapolation of the values to zero time was made to obtain the amide nitrogen figures.

Unless otherwise noted, hydrolysis of the proteins was carried out in 6 *N* hydrochloric acid in an oil-bath at 120° for twenty hours.

Lysine was determined by means of a specific decarboxylase both on total hydrolyzates and on catholytes obtained by ionophoresis of aliquots of the same hydrolyzates. Hanke's adaptation[10] of Gale's method[11] to the Van Slyke–Neill manometric apparatus was used. Ionophoresis was employed for the primary purpose of securing catholytes suitable for photometric determinations of arginine and histidine. A three-compartment cell patterned after that of Albanese[12] was constructed, and the general procedure of Gordon, Martin and Synge[13] was followed, with hydrolyzates prepared from 0.5 g. of protein. Arginine and histidine were then determined by Macpherson's modifications[14] of the Sakaguchi–Weber and Pauly reactions on the catholytes obtained after repeated (4 times) ionophoresis.[15] The values obtained for lysine in these catholytes were consistently lower (6 to 9%) than those found in the original hydrolyzates. On the

(15) After our analyses for the basic amino acids had been completed, the comprehensive paper on this scheme of analysis by Macpherson appeared.[51] Our experience confirms (a) the need for repeated ionophoresis of the catholyte to effect complete purification of the basic amino acid fraction, and, (b) the increased precision of the colorimetric methods when standards are used instead of calibration curves. In our hands, however, determination of lysine by difference on the basis of nitrogen analyses on the catholyte was not entirely trustworthy.

[a] Obtained from the American Type Culture Collection. [b] Special samples of L-leucine and DL-isoleucine were obtained from Merck and Company through the courtesy of Dr. E. E. Howe; stated purity of the L-leucine was at least 99% and of the DL-isoleucine at least 96%, as determined by solubility tests. Other standard amino acids were of the "Analytically or Chemically Pure Grade" of Amino Acid Manufactures, University of California, Los Angeles. [c] In micrograms of L-amino acid per tube containing a final volume of 10 ml. [d] Range shown does not include glycine added to basal medium to overcome induction period.[29] [e] Modified by the addition of 250 mg. sodium citrate per tube containing a final volume of 10 ml. in order to enhance growth and acid production.[31,32] [f] Modified by the substitution of L-asparagine for aspartic acid.[33]

assumption that mechanical losses involved in repeated ionophoresis accounted for this discrepancy, the lysine determinations on original hydrolyzates were accepted as more nearly correct, and a correction based on lysine recovery was applied to all arginine and histidine values.

Tyrosine and tryptophan were determined on alkaline stannite hydrolyzates according to the Brand and Kassell adaptation[16] of the Millon-Lugg procedure. The corrections recommended by Brand and Kassell were applied to the results. Also, tryptophan analyses were made on the unhydrolyzed proteins by the glyoxylic acid reaction as applied by Shaw and McFarlane.[17] The tryptophan values obtained by the two methods were in good agreement.

Cystine determinations were made, by Kassell and Brand's modification[18] of the phosphotungstic acid reaction, on hydrochloric acid and hydrochloric acid–formic acid hydrolyzates, and by Vassel's adaptation[19] of the Fleming reaction, on hydrochloric acid–formic acid hydrolyzates, with concordant results. The occurrence of cysteine in casein in unlikely.[20]

Methionine was determined both as volatile iodide and as homocysteine after hydrolysis with hydriodic acid according to the Kassell and Brand modification[21] of Baernstein's method. The correction factors of Kassell and Brand were applied.

Serine was determined by oxidation with periodate and distillation of formaldehyde by the technique of Boyd and Logan[22] and estimation of formaldehyde photometrically with chromotropic acid according to MacFadyen.[23] Threonine was estimated by periodate oxidation and diffusion of acetaldehyde in Conway vessels by the method of Winnick.[24] Correction factors for decomposition of serine and threonine during acid hydrolysis have been worked out by Rees[25] for mixtures of amino acids. We have assumed that the factors (100/89.5 for serine and 100/94.7 for threonine) were applicable to hydrolyzates of casein and its fractions, and the serine and threonine values have been so corrected. The corrected figures for serine may still be low, in view of the greater lability to acid hydrolysis of serine combined as phosphoserine in phosphoproteins, as compared with that of free serine. Thus, Nicolet, *et al.*, give 7.38% as the probable serine content of casein, compared with 5.5% found on direct acid hydrolysis.[26] A correction factor based on these figures would be 100/74.5.

Glycine, valine, leucine, isoleucine, proline, phenylalanine, aspartic acid and glutamic acid were determined by microbiological assay. Our technique in general was patterned after that of Stokes and co-workers,[27,28] but differed with respect to the following minor variations. Cells for inoculum were suspended in a small volume of physiological saline and added to the basal medium previously sterilized by filtration through a Seitz filter. Five-ml. portions of the mixture were then pipetted into tubes containing 5-ml. aliquots of either standard amino acid or unknown, previously sterilized by autoclaving. Standards were run in quadruplicate at 10 levels of amino acid concentration and unknowns in quadruplicate at 5 levels. Lactic acid production was determined by titration (glass electrode). Conditions used in the assays are summarized in Table I; further deviations from published procedures are noted there.

Attempts to work out a microbiological assay method for alanine from suggestions in the literature[34–36] were unsuccessful. Likewise, attempts to determine alanine by the Alexander and Seligman method in its original form[37] or as applied to protein hydrolyzates by Michel and Michel[38] were unsatisfactory. Our values for alanine were obtained by the method of Aqvist,[39] which involves deamination to lactic acid, conversion of the lat-

ter to acetaldehyde and determination of the aldehyde with *p*-hydroxybiphenyl. The figures should be regarded only as approximations.

Comments on Methods.—Vickery[40] has stressed the need for maintaining certain specialized standards of accuracy in amino acid analysis of proteins. In conforming to these standards insofar as possible, we have made liberal use of the "standard proteins," β-lactoglobulin and bovine serum albumin, and of mixtures of amino acids, for control analyses. Each method of analysis was tested on a "standard protein" before it was adopted for use. In the microbiological assays, an analysis of lactoglobulin was made simultaneously with every run on unknown protein. With few exceptions, our results on lactoglobulin and serum albumin agreed closely with the analyses listed by Brand.[41]

Table II shows the divergent values for lactoglobulin, together with other figures from the recent literature. Alanine analyses of lactoglobulin by the Aqvist method, although they average 7.8%, a not unreasonable value, are not included in the table because the results were erratic.

TABLE II

AMINO ACID ANALYSES OF LACTOGLOBULIN, G./100 G. OF PROTEIN

	Brand[41]	Values from present work	Other values
Glycine	1.4	1.8	1.56 (Keston, *et al.*[42])
Isoleucine	8.4	7.1	5.86 (Stein and Moore[43])
Proline	4.1	4.8	4.84 (Keston, *et al.*[42])
Serine	5.0	4.3	4.07 (Rees[25])
Threonine	5.85	5.3	5.11 (Rees[25])

It will be obvious, especially to protein analysts, that to obtain results in agreement with reliable values in the literature within a few per cent., although reassuring, is no proof of accuracy. This is particularly true of the serine, threonine and other determinations which involve correction for destruction during hydrolysis, of the amide nitrogen determination, and of some of the microbiological procedures. Therefore analyses of casein, α-casein and β-casein were carried out under identical conditions and simultaneously whenever possible, so that observed differences in composition could be accepted as real, at least in a comparative sense.

Discussion

Averaged analytical results are listed in Table III. All have been corrected for moisture. Since true ash amounted to less than 0.4% in each protein, it was disregarded in the calculations. Corrections previously mentioned have been applied to the figures for methionine, tryptophan, arginine, histidine, serine, threonine and tyrosine.

α-Casein and β-casein differ in their content of most of the amino acids. Most striking, perhaps, are the observed differences in proline, tryptophan and tyrosine content, and the presence of less than 0.1% cystine in β-casein. Histidine, glutamic acid, threonine and, obviously, amide nitrogen are considered to be present in equal concentration within experimental error. The differences in glycine, isoleucine and serine content, although not large, are considered as probably significant, especially since any differences in composition relative to casein would be accentuated in β-casein, the minor component. Definite conclusions regarding alanine cannot be drawn from the available data; the figures for this amino acid are included only to show its approximate concentration.

There have been previous reports that casein fractions differ in phosphorus, tyrosine and tryptophan content but, as Warner[3] has pointed out, it is unlikely that the fractions analyzed were homogeneous. However, the alcohol-soluble casein containing little phosphorus, which was isolated by Osborne and Wakeman[44] and by Linderstrøm-Lang[45] may well be a distinct component of casein, with its own characteristic amino acid composition.[4]

In more recent studies, Mellander[46] has reported that α-casein, prepared by Warner's method, contained 6.8% serine, whereas his original casein contained 3.5%. And in an abstract by Hagberg and Swanson[47] it is stated that "α-casein contained a higher percentage of total phosphorus, aspartic acid, glutamic acid and tyrosine" (than β-casein, being implied). Our data, except for glutamic acid, are in accord with the latter statement. The comparison of Mellander regarding serine, however, seems questionable because of the low value of 3.5% for casein (*cf.* Rees[25]) and because of the following considerations.

If it is assumed that casein is composed of only α-casein and β-casein, and if the analyses for any common constituent differ significantly in the three proteins, then the relative amounts of α-casein and β-casein in casein may be calculated. Thus, using the figures for tyrosine in Table III, 6.3, 8.1 and 3.2%, one obtains a ratio of 63:37 for the proportion of α-casein to β-casein in casein. This calculation has been made for 14 of the constituents listed in Table III; the resulting ratios range from 58:42 to 78:22 and average 69:31. The ratio deduced by Warner from electrophoretic patterns was 80:20. Mellander's values do not fit any reasonable ratio of this kind, but if the value of 3.5% serine in casein is indeed low, the figure of 6.8% in α-casein is possible.

The completeness of the analyses as shown by the summations of nitrogen in Table III might

Tyrosine	6.3 (6.00–6.84) [17,2]	8.1 (7.82–8.28) [13,2]	3.2 (3.09–3.30) [7,2]	3.1	4.0	1.6
Total	115.8[g]	115.7[g]	117.4[g]	101.5	101.8	103.4

[a] These values are identical with those reported by Warner.[3] [b] Figures in brackets show the number of determinations, followed by the number of duplicative analyses in each determination; figures in parentheses are averages of the duplicative analyses and show the range of the individual determinations from which the final average value was calculated; in the microbioassays, analyses at 5 levels of unknown concentration are considered as duplicative analyses. [c] These values are provisional. [d] The figures listed are averaged results of two methods; found for casein by Brand–Kassell method, 0.35(0.30–0.39)[6,2]; and by Vassel method, 0.33(0.30–0.34)[6,2]; found for α-casein, by Brand–Kassell method 0.42(0.40–0.49)[7,2] and by Vassel method 0.43(0.41–0.45)[5,2]; less than 0.1% cystine was found in β-casein by either method. [e] Averaged results of 2 methods; found for casein by volatile iodide, 2.85(2.63–3.05)[5,2], and as homocysteine, 2.73(2.65–2.80)[5,1]; found for α-casein, 2.55(2.49–2.62)[4,2] and 2.53(2.47–2.66)[4,1]; found for β-casein, 3.42(3.38–3.46)[2,2] and 3.45(3.44–3.46)[2,1]. [f] Averaged results of 2 methods; found for casein by Brand–Kassell method, 1.23(1.06–1.37)[17,2] and by Shaw-McFarlane, 1.26(1.18–1.32)[12,2]; found for α-casein, 1.46(1.32–1.53)[13,2] and 1.65(1.56–1.75)[11,2]; found for β-casein, 0.74(0.72–0.77)[7,2] and 0.55(0.46–0.65)[5,2]. [g] Total includes amino acids, amide N calculated as ammonia (1.9%), and phosphorus calculated as phosphoric acid (2.7, 3.1 and 1.9%, respectively, for casein, α-casein and β-casein).

conceivably be the result of numerous compensating errors. The presence of other amino acids or other groups must be considered possible, although it is reasonably certain that they could not be present in large concentration. Additional evidence for the essential completeness of the analyses may be found in the summations by McMeekin, *et al.*,[48] of amino acid residue weights, 98.13, 98.12 and 99.15, for whole casein, α-casein and β-casein, respectively.

The values herein reported for the amino acid composition of whole casein are compared with figures from the literature (Table IV) in order to demonstrate that casein is fairly well characterized in spite of its heterogeneity. The selection of data from the great number of published values is admittedly arbitrary, as is also the omission of hydroxyproline and citrulline.

To show correlations between physical properties and amino acid composition, the data in Table III have been recalculated in terms of side chain groups (Table V). The treatment follows that of Brand, *et al.*,[34] with respect to grouping of side chain residues and calculating free α-amino, free α-carboxyl, free glutamic acid carboxyl and glutamine groups. It has been assumed that all the phosphorus is present as phosphoserine, the excess of serine being listed as free serine groups. The phosphoserine side chains are considered dibasic anionic groups. Incidentally, if they are considered monobasic anionic groups, and if the free α-amino and free α-carboxyl groups are not included in the summations, the figures for total groups become 845, 837 and 873 moles of amino acids per 10^5 g. of whole casein, α-casein and β-casein, respectively; the reciprocals of these totals, 118.3, 119.5 and 114.5, are

(48) McMeekin, Groves and Hipp, THIS JOURNAL, **71**, 3298 (1949).

TABLE IV

AMINO ACID COMPOSITION OF WHOLE CASEIN, G./100 G. OF PROTEIN

	Values from present work	Values from literature
Glycine	2.7	1.9[29]
Alanine	3.0	3.5[49]
Valine	7.2	7.2[30]
Leucine	9.2	10.3[30]
Isoleucine	6.1	7.6[30]
Proline	11.3	11.6[30]
Phenylalanine	5.0	5.5[30]
Cystine	0.34	0.34[20]
Methionine	2.8	3.1[20]
Tryptophan	1.2	1.2[50]

Threonine	4.9	4.6[25]
Tyrosine	6.3	6.2[30]
Total	112.8	115.0

then the respective approximate average residue weights.

An important difference in the properties of α-casein and β-casein, which has been utilized in this Laboratory in their separation, is the greater solubility of β-casein in ethanol–water mixtures. The larger proportion of non-polar groups in β-casein (Table V) may well account for this.

Differences in the electrophoretic mobilities of α-casein and β-casein observed by Warner[3] may be explained also on the basis of amino acid composition. In solutions, both acid and alkaline to the isoelectric points of the proteins, α-casein had the higher mobility. The higher proportions of cationic and anionic groups in α-casein fit in with this observation. The greater concentration of phosphoric ester residues in α-casein is also noteworthy because of the particular contribution of these groups to the higher mobility of α-casein in alkaline solution.

A correlation between amino acid composition and specific volume for each of these proteins is demonstrated by McMeekin, *et al.*[48]

Summary

A comparative analysis of the amino acid composition of whole casein and its two major components, α-casein and β-casein, has been made. Within the experimental error of the analytical methods, all the nitrogen of each protein has been accounted for in terms of known amino acids and amide nitrogen.

α-Casein and β-casein differ considerably in their content of many amino acids, and these differences are reflected in such physical properties as solubility and electrophoretic mobility.

Although heterogeneous, whole casein is a fairly well characterized protein with respect to amino acid composition.

Apparent Specific Volume of α-Casein and β-Casein and the Relationship of Specific Volume to Amino Acid Composition

By T. L. McMeekin, M. L. Groves and N. J. Hipp

The partial specific volumes of proteins are of great importance in determining their molecular weights by sedimentation and diffusion. The apparent specific volumes are calculated from the densities of the protein solutions and are identical with the partial specific volumes in dilute solutions. A value of about 0.750 has been reported for the partial specific volume of many proteins.[2] It has been suggested,[3,4] however, that the apparent specific volume of a protein is largely determined by the volume increments of the amino acid residues of which it is composed. The recent complete amino acid analyses of α-casein and β-casein by Gordon, *et al.*,[5] which show considerable differences in the composition of these proteins, offer the opportunity of comparing the specific volume calculated from the amino acid content with the experimentally determined specific volume.

Experimental

Casein Preparations.—The preparations were the same as those used by Gordon, *et al.*,[5] and described by Warner,[6] with the exception of β-casein, which was prepared by Hipp, *et al.*,[7] by a modification of the method devised by Warner. The β-casein was free from α-casein, as shown by electrophoresis, and contained 0.60% phosphorus and 15.3% nitrogen. The amino acid analysis of β-casein by Gordon, *et al.*, however, was made on the sample prepared by Warner. Consequently, our calculated specific volume of β-casein is based on one preparation, whereas our experimentally determined specific volume is based on another, a sample which has not been analyzed for amino acids. It is believed, however, that the electrophoretic analyses and the nitrogen and phosphorus content characterized β-casein well enough to make a valid comparison of the measurements of the two preparations.

Density Measurements.—The casein samples were dissolved in the minimum amount of dilute sodium hydroxide to give a *p*H of 6.4 to 6.9—approximately 4.6 cc. of 0.1 *N* sodium hydroxide for each gram of casein. Densities were determined at 25° in pycnometers of about 20-ml. capacity. The protein concentration was determined on aliquots of the solution by dry weight at 105°. The calculated amount of sodium present was subtracted in calculating the dry weight. The dry weight value agreed with the weight of casein used in making the solutions. Densities of solutions of whole casein were also determined in 6.66 molar urea solutions and in acid solutions of *p*H 3.1. Urea was purified by dissolving it in 70% alcohol at 40° and precipitated by chilling to −5°. The recrystallized urea was dried *in vacuo* at 50°. Casein solutions with a *p*H of 3.1 were prepared by dissolving casein in dilute sodium hydroxide and adding lactic acid rapidly with stirring until the desired *p*H was reached. In each case the density of a solution containing all the added ingredients, with the exception of the casein, was determined and used as the solvent density in calculating the apparent specific volumes.

Densities and Apparent Specific Volumes of Casein Solutions.—Table I gives the data on the densities and calculated apparent specific volumes of α-casein, β-casein and whole casein solutions. The equation of Svedberg and Chirnoaga[8] was used in calculating the apparent specific volumes: $V = [w - (1 - h)]/\rho h$, where w is weight of solvent in pycnometer, l is weight of solution, h is weight of protein, and ρ is density of solvent. No correction was made for ash because these preparations contained only small amounts of true ash.[6]

Calculation of the Specific Volumes of Caseins from the Volumes of the Amino Acid Residues.—The method of Cohn and Edsall[4] for calculating the apparent specific volume of proteins was followed in detail. The specific volume was calculated by the equation $V_p = \Sigma V_i W_i / \Sigma W_i$, where W_i is the per cent. by weight of the i'th amino acid residue in the protein as found by analysis, and V_i is the specific volume of this residue. The molecular weights and corresponding specific volumes of the amino acid residues were the ones given by Cohn and Edsall, with the exception of cystine. The cystine residue was considered to be cystine minus two molecules of water, resulting in a molecular weight for the residue of 204.18 instead of 222.18. Consequently, a value of 6.6 cc. was subtracted for the volume of the second molecule of water removed from cystine, giving a calculated molal volume for its residue of 128.8 cc. instead of 135.4 cc. When the molal volume of the residue is divided by the weight of the residue, a value of 0.63 is obtained for the specific volume of the cystine residue.

Phosphorus is present in casein in the form of a phosphoric acid ester of serine.[9] Values for the atomic volume of phosphorus and the oxygen atoms of phosphoric acid are not available for calculating the specific volume of serine phosphoric acid. Consequently, the molal volume of serine phosphoric acid was determined, and its residue volume in casein calculated. Serine phosphoric acid was made by the method of Levene and Schormuller,[10] as modified by Plimmer.[11] The product melted at 171.5° and contained 7.69% nitrogen and 17.1% phosphorus. Theoretical values for serine phosphate are 7.57% nitrogen and 16.76% phosphorus. Table II gives the values for the density and molal volume of aqueous solutions of serine phosphate.

TABLE II

MOLAL VOLUME OF SERINE PHOSPHATE

Concentration g. per 100 cc.	Density at 25°	Molal volume
2.002	1.00745	89.4
3.203	1.01359	89.9
4.004 (0.22 *M*)	1.01764	90.3

The value of 90.3 cc. for the molal volume of serine phosphate is used in calculating its residue volume, because the concentration of 0.22 *M* is close to the concentration of 0.25 *M*, used by Cohn and Edsall in their data on the molal volume of amino acids. In calculating the specific volume of serine phosphoric acid residue, 7.4 cc. was subtracted from 90.3 cc., and the result was divided by the molecular weight of the residue (167.07), giving a value of 0.50. The value of 7.4 cc. per mole change in volume caused by the formation of an amino acid from an amino acid residue in the protein was derived by Cohn and Edsall by adding the value of the atomic volumes of 2 hydrogen and 1 oxygen (6.6 cc.) to the calculated difference between the electrostriction and covolume effects (0.8 cc.).

Table III gives calculated values for the per cent. by volume of amino acid residues based on the amino acid analyses of Gordon, *et al.*,[5] for whole casein, α-casein and β-casein, as well as calculated values for their specific volumes.

Discussion

Several values have been reported for the partial specific volume of casein solutions. Chick and Martin[12] calculated the apparent density of the casein molecule in solution to be 1.39, or 0.720 for the apparent specific volume. Svedberg, Carpenter and Carpenter[13] gave the value of 0.750 for the partial specific volume of casein in solution. Our values for whole casein, as well as α-casein and β-casein, are between these two reported values. The accuracy of the value for the specific volume of a protein in solution is dependent on the accuracy of the method for determining the protein concentration. The concentrations of casein reported in Table I were determined in most cases by two methods—(1) by weighing the casein accurately before dissolving it and subtracting the moisture content, and (2) by determining the solids in the solution and subtracting the value for the dry weight of the material added to dissolve the casein. In all cases the values obtained by the two methods were in good agreement. The values for concentration reported in urea solutions were obtained from the weight of casein used.

The apparent specific volume of whole casein was 0.731 when it was dissolved in dilute alkali or in 6.66 *M* urea. When the whole casein was dissolved in lactic acid, the apparent specific volume varied considerably with the concentration of casein used. However, the extrapolated value of 0.730 for zero concentration is in agreement with the values obtained in alkali and urea solutions. The value of 0.728 for the apparent specific volume of α-casein is only slightly less than that for whole casein and is in fact within the experimental variation in determining the specific volume. This value, however, is in agreement with the expected value; Warner[6] has estimated that whole casein contains 80% α-casein and 20% β-casein and the value of the apparent specific volume of β-casein is 0.741.

The calculated specific volumes of the caseins based on the amino acid analyses of Gordon, *et al.*,[5] and the specific volumes of the amino acid residues are in good agreement with the experimentally determined specific volume in each case. These results confirm the hypothesis that the apparent specific volume of a protein is essentially determined by the volume of amino acid residues. These results indicate that if the value for the ap-

Specific volume, observed (Table I)					.731	.728	.741

parent specific volume of a protein as determined does not agree reasonably well with the value calculated from the specific volumes of the amino acid residues a redetermination should be made of either the apparent specific volume or the amino acid content. Thus Putnam, Lamanna and Sharp[14] have calculated from the volumes of the amino acid residue that the apparent specific volume of botulinus antitoxin is 0.738, while Kegeles[15] found 0.755 for this protein. Here the variation between the calculated value and the observed value appears to be greater than might be expected. A value of 0.746 for the apparent specific volume of β-lactoglobulin may be calculated from the amino acid analysis of Brand, *et al.*[16] This value is in good agreement with the determined value of 0.751 reported by Pedersen[17] and confirmed by Brand and Kassell.[18] (The value of 6.1% for the isoleucine content of β-lactoglobulin reported by Smith and Greene[19] was used instead of Brand's value of 8.4%.)

Summary

Values for the apparent specific volume of whole casein, α-casein and β-casein have been calculated from density determinations and from the volumes of the amino acid residues. The values calculated by the two methods are in good agreement, indicating that the apparent specific volume of a protein is largely determined by the volume of its amino acid residues.

Reduction of Steroid Ketones and other Carbonyl Compounds by Modified Wolff–Kishner Method

BY HUANG-MINLON[1]

According to Dutcher and Wintersteiner[2] the reduction of C_3-steroid ketones by the Wolff–Kishner method under usual conditions gives mainly the corresponding C_3-epimeric carbinols with small amounts of the expected C_3-methylenic products. In the case of the α,β-unsaturated ketone, cholestenone, the reduction follows a still more complex course. In addition to the epimeric unsaturated carbinols and a small amount of the normal product, Δ^4-cholestene, the saturated carbinols, α-coprosterol and β-cholestanol have also been isolated. The authors stated that the abnormal reduction can be explained by the assumption that the hydrazone or semicarbazone is partially hydrolyzed to free ketone, which is then reduced by sodium alcoholate to give the secondary alcohol. These possibilities are, however, eliminated by the modified Wolff–Kishner reduction,[3,4] in which the water is evaporated during the heating period. Moreover, the excess of hydrazine hydrate used in this reaction should keep the concentration of the regenerated ketone at a low level.[2] In fact all the C_3-steroid ketones so far investigated gave the normal C_3-methylenic compounds by the modified Wolff–Kishner reduction. The formation of carbinols has never been observed. This reaction proceeds also normally on keto groups at other positions, C_7, C_{12}, C_{17} and C_{20}, except at C_{11}, which remains unattacked. Thus, 3-hydroxy-11-ketoetiocholanic acid is unreduced. 3,α-Acetoxy-11,20-diketopregnane (I) gave a reduced product melting at 152–153° in which one of the two keto groups is unattacked. In view of the fact that the 20-keto compounds, such as Δ^5-pregnen-3(β)-ol-20-one (IV) and its hydrogenation product, allopregnan-3(β)-ol-20-one (VI) can be transferred to Δ^5-pregnan-3(β)-ol (V) and 3,β-hydroxyallo-pregnane (VII), respectively, the reduced product from I may be formulated as 3,α-hydroxy-11-ketopregnane (III). Δ^5-Pregnen-3(β)-ol (V), which has not previously been reported, is transferred to the known compound, allopregnan-3(β)-ol (VII) by catalytic hydrogenation. From the reaction products of 3,α-acetoxy-11,20-diketo-12-bromopregnane (II) two isomeric compounds could be isolated, one of which melts at 152–153° and is identical with III and the other melts at 109°. Both give the same analytical result, but the latter is more dextrorotatory and its structure is under investigation.

[c] Prepared from Δ^5-pregnenolone according to Plattner, Heusser and Angliker, *Helv. Chim. Acta*, **29**, 468 (1946). [d] Ruzicka, Meister and Prelog, prepared from dehydroepiandrosterone, *ibid.*, **30**, 867 (1947). [e] Butenandt and Tschering, *Z. physiol. Chem.*, **229**, 185 (1934); Prelog, Ruzicka and Wieland, *Helv. Chim. Acta*, **27**, 66 (1944). [f] Marker, Wittle and Tullar prepared from Δ^5-cholestene, THIS JOURNAL, **62**, 223 (1940). [g] Not depressed by admixture with authentic sample. [h] The residue of the methanolic mother liquor of (a) was dissolved in a mixture of benzine (30–60°) and benzene (4-1) and eluted with the same mixed solvents (3:1, 2:1, 1:1) and finally with pure benzene. This low melting isomer is isolated from the first crystalline fractions. [i] After acidifying with dil. HCl the crude product was washed with hot water to remove benzoic acid liberated from the starting material. [j] One sample is transferred to desoxycholic acid m. p. 170–171° not depressed by mixture with authentic sample. [k] On methylation of the crude reduced product with dimethyl sulfate. [l] Prepared according to "Org. Syntheses," **20**, 11 (1940). [m] Fieser and Hartwell obtained this product melting at 77–78° in lower yield from the same starting material by usual Wolff–Kishner reduction, THIS JOURNAL, **60**, 2555 (1938). [n] Ruzicka, Jeger and Ringnes [*Helv. Chim. Acta*, **27**, 932 (1944)] reduced this compound by usual Wolff–Kishner procedure, but the yield of friedelane is not given. [o] Drake and Jacobsen [THIS JOURNAL, **57**, 1570 (1935)] also obtained same reduced product, friedelane, from friedeline and cerine by Clemmensen reduction.

Similar smooth reduction of the carbonyl group in other compounds apart from the steroids, was also noted (see Experimental). One case, however, needs to be specially mentioned for its abnormal behavior. Thus the carbonyl compound (VIII) did not give the corresponding methylene compound by the modified Wolff–Kishner reduction but gave the indazole derivative (IX) in good yield. This, however, is not surprising since α-aceto-β-naphthol is known to react with hydrazine yielding indazole derivative.[5]

Acknowledgment.—I am indebted to Prof. L. F. Fieser for his encouragement in the pursuance of this investigation.

Experimental[6]

The reduction has been carried out by procedures similar to those described in previous papers.[3,4] Thus a mixture of the starting material, diethylene or triethylene glycol (Note 1), alkali hydroxide and 85% hydrazine hydrate (Notes 2 and 3) was refluxed for about half an hour and the condenser was then removed to allow the aqueous liquor to evaporate and the temperature of the reaction mixture to rise to about 200°. In cases where either the starting material or the reduced product is volatile a take-off adapter was used instead of removing the condenser to evaporate aqueous liquor. After refluxing at this temperature for about two hours the reaction mixture was cooled, diluted with water (Note 4) and the separated reaction product was filtered or extracted with ether (Note 5). The results are summarized in Table I (Notes 6 and 7).

Catalytic reduction of Δ^5-pregnen-3(β)-ol (V) to allopregnan-3(β)-ol (VII): 0.2 g. of Δ^5-pregnen-3(β)-ol in 30 cc. of alcohol containing 3 drops of hydrobromic acid (48%) was shaken with hydrogen in the presence of 0.05 g. of Adams catalyst until the calculated amount of hydrogen was absorbed. The reaction mixture was filtered and the filtrate was concentrated in vacuum to a small volume. On dilution with water allopregnan-3(β)-ol (VII) separated in plates. It was recrystallized from methanol, m. p. 136–137, not depressed by admixture with the Wolff–Kishner reduction product from VI; yield 0.18 g.

NOTE 1.—The amount of diethylene glycol or triethylene glycol used can be varied according to the solubility of the carbonyl compound or its hydrazone formed during the reaction so that a clear or nearly clear reaction mixture is obtained during the heating period. Sometimes it is advisable to dissolve the carbonyl compound in alcohol before addition of glycol and other reagents, *e.g.*, in the case of cholestanone and cholestenone.

NOTE 2.—The amount of alkali hydroxide used is about 10% to the volume of the glycol used and the amount of 85% hydrazine hydrate used is always in excess (3 moles or more).

NOTE 3.—In reduction of alkali-sensitive compounds such as aldehydes, α,β-unsaturated ketones and those carbonyl compounds in which the carbonyl group is adjacent to an asymmetric center it is advisable to reflux the glycol solution of starting material with hydrazine hydrate for about half an hour and then add a concentrated aqueous solution of alkali hydroxide slowly as described previously.[4]

NOTE 4.—If the reduced product is acidic, it is obtained by acidifying the cooled reaction mixture with dilute hydrochloric acid.

NOTE 5.—In cases where the starting material contains methoxy group the crude reduced product was remethylated with dimethyl sulfate.

NOTE 6.—Most of the technical steroid ketones[7] were recrystallized before reduction, since otherwise the yield is sometimes unsatisfactory. The yields of reduced products given in Table I are on the basis of pure products for which the melting points are given.

NOTE 7.—In cases where the carbonyl compound is unstable and difficult to purify such as α-naphthaldehyde the hydrazone or semicarbazone can be taken as starting material for reduction.

(6) The microanalyses were carried out by Shirley Katz of this Laboratory.

Summary

1. The modified Wolff–Kishner method has been applied to the reduction of a number of steroid ketones and a few other carbonyl compounds giving excellent or comparatively good yields.

2. In the case of the steroids the reduction proceeds normally on the keto groups at positions C_3, C_7, C_{12}, C_{17} and C_{20}, but the C_{11} keto group remains unattacked.

Drugs Effecting Muscular Paralysis. Some Substituted Dioxolanes and Related Compounds[1]

BY V. BOEKELHEIDE, L. LIBERMAN, J. FIGUERAS,[2a] C. KRESPAN,[2b] F. C. PENNINGTON AND D. S. TARBELL

The drugs which effect muscular paralysis may be divided into two classes, depending on whether the predominant action is peripheral or central in nature.[3] The usual curariform agents, including most natural alkaloids and certain quaternary ammonium salts, belong to the former class. The first important compounds to be discovered having a central action were *o*-toloxy-1,2-propanediol (myanesin) and certain related α-glyceryl ethers.[4] Recently,[5] it was found that another class of compounds, the 2-substituted-4-hydroxymethyl-1,3-dioxolanes, possessed an action similar to that of the α-glyceryl ethers. In fact, the results of testing in mice indicate that the best compounds of the dioxolane series exceed those of the α-glyceryl ether series both in degree of activity and in margin of safety. In an attempt to find the scope of activity and the effect of changes of structure on activity in the dioxolane series, a number of substituted dioxolanes have been prepared. In the present paper the synthesis of these dioxolanes is described and evidence is presented establishing the structures of several of the most active members of this series.[6]

The synthesis of the substituted dioxolanes was accomplished, in general, by heating the appropriate carbonyl compound with glycerol or ethylene glycol and an acid catalyst in the presence of a hydrocarbon solvent and with continuous removal

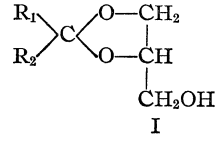
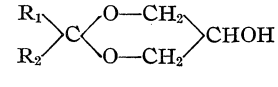
of the water formed. Those dioxolanes which were prepared and have not previously been reported, are listed in Tables I, II and III.

For the preparation of some of the compounds listed in Tables I, II and III, the general method could not be applied. Compound XX, 2-(1′-hydroxymethylamyl)-2-methyl-1,3-dioxolane, was prepared by the sodium and alcohol reduction of the corresponding ester, XIX. It was of interest that XX was the only compound prepared which had high physiological activity but did not have a hydroxymethyl group at the 4-position of the dioxolane ring. Compound XXV, 2-*n*-amyl-2-methyl-4-hydroxymethyl-1,3-dithiolane, was prepared by the condensation of methyl *n*-amyl ketone and 2,3-dimercapto-1-propanol (B. A. L.). Compound XXVI was obtained by the peroxide oxidation of 2,2-dimethyl-4-hydroxymethyl-1,3-dithiolane.

The condensation of a carbonyl compound with glycerol may yield either a dioxolane derivative (I) or a *m*-dioxane derivative (II). Although in



I



II

previous work[7–9] it has been assumed that ketones react with glycerol to give products having the dioxolane structure, this has apparently been established only for the condensation of acetone with glycerol.[10,11] An indication that ketones condense with glycerol to give dioxolane derivatives was obtained when it was found that methyl *n*-amyl ketone condensed readily with ethylene glycol but gave no product at all with trimethylene

glycol. Similar results have been cited by Dworzak and Herrmann[7] as evidence that ketones and glycerol give dioxolane derivatives. However, the work of Hibbert and his collaborators[12,13] has shown that such reasoning, when applied to the condensation of aldehydes with glycerol, is misleading. Therefore, the structures of the condensation products of glycerol with methyl *n*-amyl ketone and with methyl *n*-hexyl ketone were investigated and definitely shown to be of the dioxolane type.

The evidence for the dioxolane structure, I, was established as follows. The condensation product of glycerol and methyl *n*-hexyl ketone, on conversion to the corresponding methyl ether followed by acid hydrolysis, gave only α-methyl glyceryl ether. Thus, the condensation product must be 2-methyl-2-*n*-hexyl-4-hydroxymethyl-1,3-dioxolane, since the corresponding *m*-dioxane derivatives would yield a β-methyl glyceryl ether. Likewise the condensation product of glycerol and methyl *n*-hexyl ketone, on treatment with trityl chloride in pyridine under the usual conditions whereby primary but not secondary alcohol groups are etherified,[14] gave an 83% yield of the corresponding trityl ether. The condensation product of glycerol and methyl *n*-hexyl ketone must therefore be almost entirely 2-methyl-2-*n*-hexyl-4-hydroxymethyl-1,3-dioxolane.

Finally, a sample of 2-methyl-2-*n*-amyl-4-hydroxymethyl-1,3-dioxolane of known structure was prepared by the alkaline hydrolysis of the condensation product of methyl *n*-amyl ketone and 3-(3′,5′-dinitrobenzoxy)-1,2-propanediol. The infrared absorption spectrum of the 2-methyl-2-*n*-amyl-4-hydroxymethyl-1,3-dioxolane, thus prepared, was found to be identical within experimental error with that of the condensation product of glycerol and methyl *n*-amyl ketone. The absorption spectra are given in Fig. 1.

On the other hand, there is considerable evidence in the literature[15] that aldehydes condense with glycerol to give mixtures of the corresponding 4-hydroxymethyl-1,3-dioxolanes (I) and the corresponding 5-*m*-dioxanols (II). Since the condensation product of glycerol and heptanal possessed a fairly high degree of physiological activity, an investigation of its structure was made.

When the condensation product of glycerol and heptanal was allowed to react with trityl chloride in anhydrous pyridine, as before, there was obtained a 58% yield of the corresponding trityl ether. This rather low yield indicates that, while the product predominantly has structure I, there is also present some material having structure II.

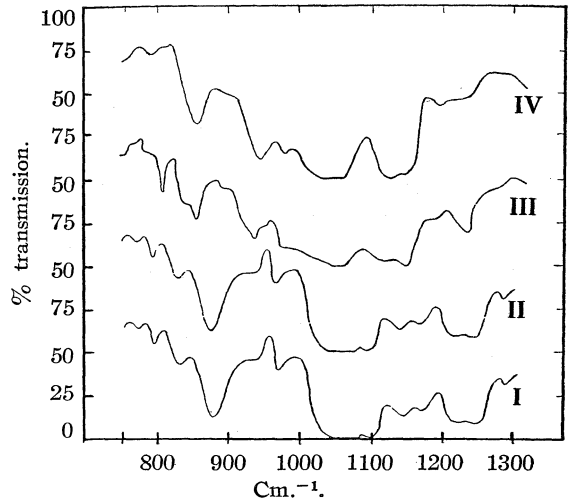

Fig. 1.—Infrared absorption spectra of the condensation product of glycerol and methyl *n*-amyl ketone (I); 2-*n*-amyl-2-methyl-4-hydroxymethyl-1,3-dioxolane (II); condensation product of glycerol and heptanal (III); and 2-*n*-hexyl-4-hydroxymethyl-1,3-dioxolane (IV). Spectra were obtained using 0.025 mm. cell.

Further evidence for this conclusion was obtained from infrared absorption spectra studies. A sample of 2-*n*-hexyl-4-hydroxymethyl-1,3-dioxolane of known structure was prepared by the alkaline hydrolysis of the condensation product of heptanal and 3-(3′,5′-dinitrobenzoxy)-1,2-propanediol. A comparison of the infrared absorption spectra (see Fig. 1) of this sample with that of the condensation product of glycerol and heptanal showed that, despite a close similarity of the two curves, there were certain real differences. The condensation product of glycerol and heptanal showed absorption peaks at 811 cm.$^{-1}$ and 1240 cm.$^{-1}$, which were not present in the spectra of the pure 2-*n*-hexyl-4-hydroxymethyl-1,3-dioxolane. However, until a pure sample of 2-*n*-hexyl-5-*m*-dioxanol is available for comparison, it is not possible to estimate accurately the amount of 2-*n*-hexyl-5-*m*-dioxanol present in the condensation product of glycerol and heptanal.

The infrared absorption spectra studies were initiated in the hope that some characteristic of the spectrum could be related to the dioxolane ring structure and that the infrared absorption spectra of these compounds could be used as a diagnostic test for the presence of the dioxolane ring. However, our knowledge of these spectra is still insufficient to allow such a diagnosis.

Experimental[16]

Formation of the Substituted Dioxolanes, Dioxaspiranes, and Dithiolanes Listed in Tables I, II and III.—With the

(16) Analyses by Mrs. G. L. Sauvage; all melting points are uncorrected.

exceptions and additions noted below, the compounds listed in Tables I, II and III were prepared by the condensation of the appropriate carbonyl compound with glycerol, ethylene glycol, or 2,3-dimercapto-1-propanol (B. A. L.) according to the following procedure. A mixture of the appropriate carbonyl compound (0.20 mole), double-distilled glycerol (0.25 mole), toluenesulfonic acid (0.5 g.) and toluene (100 ml.) was heated in a three-necked flask with stirring and with provision for continuous removal of water.[17] When the expected amount of water had separated or when no further separation of water occurred, the reaction mixture was cooled, washed successively with a 25-ml. portion of a 5% potassium carbonate solution and three 50-ml. portions of water. The toluene was removed under reduced pressure and the residual oil distilled.

(A) Sodium α-(2-Methyl-4-hydroxymethyl-1,3-dioxolan-2-yl)-caproate.—A mixture of 21.0 g. of 2-(1′-carbethoxyamyl)-2-methyl-4-hydroxymethyl-1,3-dioxolane (XVIII) and 65 ml. of a 5% sodium hydroxide solution was boiled under reflux until the solution became clear (four hours). After evaporation of the solution to dryness, the residue was taken up in a minimum amount of alcohol and reprecipitated by addition of ether. Recrystallization of the crude material from a mixture of alcohol and ether yielded 15.1 g. (75%) of a white powder, m. p. 240–245°.

Anal. Calcd. for $C_{11}H_{19}O_5Na$: Na, 9.05. Found (as Na_2SO_4): Na, 9.09; 9.70.

(B) 2-(1′-Hydroxymethylamyl)-2-methyl-1,3-dioxolane (XX).—To a solution of 26.3 g. of 2-(1′-carbethoxyamyl)-2-methyl-1,3-dioxolane (XIX) in 150 ml. of absolute alcohol, a total of 23.0 g. of sodium and 170 ml. of absolute alcohol, was added alternately in small portions. When the reaction of sodium with alcohol was complete, 75 ml. of water was added and most of the alcohol was removed under reduced pressure. The organic residue was extracted with ether, washed, and the ether was removed. Distillation of the residue yielded 9.9 g. (48%) of a colorless oil, b. p. 106° at 5 mm.

(C) 2-Hydroxymethyl-8-methyl-8-aza-1,4-dioxaspiro-4,5-decane.[18]—A solution of 1.0 g. of 1-methyl-4-piperidone hydrochloride,[19] 0.65 g. of glycerol, and 25 ml. of chloroform was heated in such a manner that as the chloroform slowly distilled, fresh chloroform was added to maintain constant volume. After two hours, the reaction was stopped and the chloroform was removed *in vacuo*. An excess of 45% potassium hydroxide was added to the residue, and the organic layer was extracted with ether, dried, and distilled. There was obtained 0.5 g. of a light yellow oil, b. p. 104–106° at 1 mm.

A **picrate** of the oil was prepared in ether and was obtained as light yellow crystals, m. p. 154–157°.

Anal. Calcd. for $C_{15}H_{20}N_4O_{10}$: C, 43.27; H, 4.84. Found: C, 43.01; H, 4.83.

(D) 2,2-Dimethyl-4-hydroxymethyl-1,3-dithiolanedisulfone (XXVI).—To a solution of 2.3 g. of 2,2-dimethyl-4-hydroxymethyl-1,3-dithiolane[20] in 5 ml. of acetic acid, there was added dropwise 4.5 ml. of a 30% hydrogen peroxide solution. The mixture was allowed to stand overnight and was then poured into 50 ml. of water. On partial evaporation of the solution crystals separated and they were collected on a filter. Recrystallization of the crude material from a mixture of benzene and hexane yielded 2.4 g. (79%) of white crystals, m. p. 110–112°.

Evidence for the Structure of the Condensation Products of Glycerol and Ketones

(A) Preparation and Hydrolysis of 2-*n*-Hexyl-2-methyl-4-methoxymethyl-1,3-dioxolane.—A solution of 2-*n*-hexyl-2-methyl-4-hydroxymethyl-1,3-dioxolane (39.5 g., 0.195 mole) in toluene (20 ml.) was slowly added to an excess of sodium (0.20 mole) in boiling toluene (100 ml.). After the reaction with sodium was complete, the solution was removed from the excess sodium by decantation and methyl iodide (42.6 g., 0.30 mole) was slowly added with stirring. The reaction mixture was then boiled under reflux for one hour. The sodium iodide, which precipitated, was removed by filtration, the solvent was removed *in vacuo*, and the residue was distilled. There was obtained 22.9 g. (54%) of a colorless oil; b. p. 79° at 1 mm.; $n^{20}D$ 1.4350; d^{20} 0.9364.

Anal. Calcd. for $C_{12}H_{24}O_3$: C, 66.63; H, 11.18. Found: C, 66.30; H, 11.76.

Hydrolysis of a sample of 2-*n*-hexyl-2-methyl-4-methoxymethyl-1,3-dioxolane (22.9 g., 0.11 mole) was accomplished by heating it for several hours with 25 ml. of a 1% solution of hydrochloric acid containing sufficient alcohol to produce a homogeneous solution. The alcohol was then removed *in vacuo*, and the solution was extracted with ether to remove any methyl *n*-hexyl ketone present. After neutralization of the solution with lead carbonate followed by filtration, the water was removed *in vacuo* and the residue was distilled. There was obtained 5.4 g. (45%) of a viscous oil; b. p. 63° at 0.05 mm.; $n^{20}D$ 1.4463; d^{20} 1.1138. The oil formed a diphenylcarbamate, m. p. 119–120°. These properties agree well with those reported for α-methyl glycerol ether.[21]

The presence of methyl *n*-hexyl ketone in the ethereal extract was established by formation of the 2,4-dinitrophenylhydrazone, m. p. 57–58°.[22]

(B) Formation of 2-*n*-Hexyl-2-methyl-4-triphenylmethoxymethyl-1,3-dioxolane.—A sample of 2-*n*-hexyl-2-methyl-4-hydroxymethyl-1,3-dioxolane (29.9 g., 0.148 mole) was treated with trityl chloride (42.6 g., 0.148 mole) in anhydrous pyridine (30 ml.) according to the procedure of Seikel and Huntress.[23] The product obtained did not crystallize and could not be distilled without decomposition. Purification was finally effected as follows. The oil was treated with pentane (100 ml.) to precipitate any triphenylcarbinol, the pentane was removed, and the resulting oil was recrystallized from ethanol using a dry-ice cooling-bath. There was obtained 53.0 g. (83%) of a viscous, colorless oil, $n^{21}D$ 1.5607.

Anal. Calcd. for $C_{30}H_{36}O_3$: C, 81.03; H, 8.10. Found: C, 80.79; H, 7.86.

(C) Preparation of 2-*n*-Amyl-2-methyl-4-hydroxymethyl-1,3-dioxolane of Known Structure.—A mixture of 3-(3′,5′-dinitrobenzoxy)-1,2-propanediol[24] (20.0 g., 0.07 mole), methyl *n*-amyl ketone (18.0 g., 0.14 mole), and benzene (70 ml.) was treated in the usual manner for preparing dioxolanes. The residual oil, which resulted, was treated with pentane and cooled to effect crystallization. There was obtained 19.3 g. (73%) of light yellow crystals, m. p. 43–48°. Repeated recrystallization of the crude material from a benzene–hexane mixture gave white crystals, m. p. 56–57°, liquid becomes clear at 60°.

Anal. Calcd. for $C_{17}H_{22}N_2O_7$: C, 53.40; H, 5.76. Found: C, 53.72; H, 5.66.

Since there are two diastereoisomeric forms possible for 2-*n*-amyl-2-methyl-4-(3′,5′-dinitrobenzoxy-methyl)-1,3-dioxolane, it seemed probable that the crude product represented a mixture of both forms. Evidence for this was obtained from the fact that a sample of the crude product, which had been crystallized once from acetonitrile and melted at 52–54°, gave as good an analysis (Found: C, 53.59; H, 5.87) as did the highest melting product previously obtained.

Hydrolysis of the 2-*n*-amyl-2-methyl-4-(3′,5′-dinitrobenzoxymethyl)-1,3-dioxolane was carried out on the crude mixture obtained above so that separation of diastereoisomers would not be effected by crystallization

and so that the hydrolysis product would be comparable for an infrared absorption study to that obtained by direct synthesis. A mixture of 2-*n*-amyl-2-methyl-4-(3′,5′-dinitrobenzoxymethyl)-1,3-dioxolane (9.7 g., 0.25 mole), potassium hydroxide (2.8 g.) and water (100 ml.) was boiled gently for one hour. The basic solution was dried, the ether was removed, and the residual oil was distilled yielding 3.0 g. (62.5%) of a colorless oil; b. p. 70–72° at 0.5 mm., $n^{21}D$ 1.4468, d^{21} 0.988. These physical properties and the infrared absorption spectra of this compound (see Fig. 1) are essentially identical with those obtained for the product from the direct reaction of methyl *n*-amyl ketone and glycerol.

Evidence for the Structure of the Condensation Product of Glycerol and Heptanal

(A) Treatment of the Condensation Product with Trityl Chloride in Pyridine.—The condensation product was treated with trityl chloride in anhydrous pyridine according to the procedure of Seikel and Huntress.[23] The reaction mixture was heated on the steam-bath for five minutes. From 18.8 g. of condensation product there was obtained, after one crystallization from alcohol, 26.0 g. (58%) of white crystals, m. p. 56–58°. This crude material apparently represents a mixture of the diastereoisomeric racemates, which are possible for 2-*n*-hexyl-4-(triphenylmethoxymethyl)-1,3-dioxolane. By repeated recrystallization of this material from alcohol a pure sample of white crystals, m. p. 70–71°, was obtained.

Anal. Calcd. for $C_{29}H_{34}O_3$: C, 80.93; H, 7.90. Found: C, 81.03; H, 7.81.

(B) Preparation of a Sample of 2-*n*-Hexyl-4-hydroxymethyl-1,3-dioxolane of Known Structure

2-*n*-Hexyl-4-(3′,5′-dinitrobenzoxymethyl)-1,3-dioxolane.—A mixture of 25.0 g. of 3-(3′,5′-dinitrobenzoxy)-1,2-propanediol,[24] 18.2 g. of heptanal and 80 ml. of benzene was heated in a flask connected to an ordinary water-eliminator. When the expected quantity of water had separated, the benzene was removed and the residue was triturated with hexane. The fluffy, white crystals, m. p. 65–68°, which separated, were collected on a filter and weighed 16.0 g. (48%). Since this crude material probably represents a mixture of the two possible diastereoisomeric racemates, it was employed without further purification in the hydrolysis experiment described below. Repeated recrystallization of the crude material from a mixture of benzene and hexane gave a pure sample of one of the racemates, m. p. 74–75°.

Anal. Calcd. for $C_{17}H_{22}N_2O_8$: C, 53.41; H, 5.76. Found: C, 53.43; H, 5.67.

2-*n*-Hexyl-4-hydroxymethyl-1,3-dioxolane.—A mixture of 14.0 g. of the crude 2-*n*-hexyl-4-(3′,5′-dinitrobenzoxymethyl)-1,3-dioxolane, m. p. 65–68°, and 90 ml. of a 5% potassium hydroxide solution was boiled under reflux for three hours. The organic layer was then extracted with ether, washed, dried, and the ether was removed. Distillation of the residue yielded 4.0 g. (58%) of a colorless oil; b. p. 80° at 0.2 mm.; $n^{21}D$ 1.4492; d^{21} 0.988; *M* calcd. 50.92; $M_{obsd.}$ 51.05.

Anal. Calcd. for $C_{10}H_{20}O_3$: C, 63.79; H, 10.71. Found: C, 63.83; H, 10.78.

Summary

Some substituted dioxolanes, dioxaspiranes and dithiolanes of possible interest as agents for effecting muscular paralysis have been prepared. On the basis of chemical evidence and infrared absorption spectra data, the condensation products of glycerol with methyl *n*-amyl ketone and methyl *n*-hexyl ketone have been assigned the structures of 2,2-dialkyl-4-hydroxymethyl-1,3-dioxolanes.

On the basis of similar evidence the condensation product of glycerol and heptanal is thought to be a mixture of which the predominant constituent is 2-*n*-hexyl-4-hydroxymethyl-1,3-dioxolane.

Analogs of Dibenzylacetic Acid[1]

BY ALFRED BURGER, DIETER G. MARKEES,[2] WILLIAM R. NES[3] AND WILLIAM L. YOST[4]

Certain dialkylaminoalkyl esters of dibenzylacetic acid abolish spasm produced by barium chloride or histamine several times as effectively as papaverine while their atropine-like activity against spasm caused by acetylcholine is generally low.[5] A comparison of analogous compounds in which the benzyl groups have been altered by cyclization or isosteric replacements promised to clarify further this relationship.

The first of our variations of the structure of dibenzylacetic acid (I) was concerned with a steric fixation of the two benzyl carbon atoms by incorporating them in a cyclopropane ring. The required 2,3-diphenylcyclopropanecarboxylic acids were prepared by adding ethyl diazoacetate to *cis*- and *trans*-stilbene, respectively, decomposing the intermediate pyrazoline derivative without isolation, and hydrolyzing the resulting esters. *trans*-Stilbene gave only one racemic acid (II), and only one of the two meso forms (III and IV) expected from *cis*-stilbene could be isolated from the reaction mixture. For further comparison, 2,2-diphenylcyclopropanecarboxylic acid (V) was

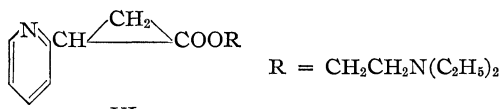
V

prepared from ethyl diazoacetate and 1,1-diphenylethylene.[6] The yields of the cyclopropane derivatives were low in all these cases, perhaps because of the aromatic character of the extracyclic double bond of the starting materials.

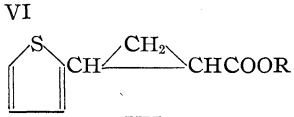
Dialkylaminoalkyl esters of the diphenylcyclopropanecarboxylic acids were prepared where the supply permitted.

We had available in this Laboratory 2-phenylcyclopropanecarbonyl chloride,[7] and converted it to the diethylaminoethyl ester. In an analogous manner, diethylaminoethyl 2-(2-pyridyl)- and 2-(2-thienyl)-cyclopropanecarboxylates were prepared (VI and VII). The acid moieties of these esters were obtained from ethyl diazoacetate and 2-vinylpyridine, and 2-vinylthiophene, respectively, by a series of reactions described for the phenyl prototype.[7]



R = $CH_2CH_2N(C_2H_5)_2$

VI



VII

In order to avoid the formation of stereoisomeric mixtures of these heterocyclic cyclopropanecarboxylic acids, purification through the acid chloride was chosen in each case. Basic esters were prepared from the chlorides and diethylaminoethanol.

This series was not further investigated when a basic ester of 2-phenyl-2-methyl-cyclopropanecarboxylic acid was described recently.[8]

Another approach to analogs of antispasmodics of the dibenzylacetic acid type was sought among basic esters (VIIIa) and amides (VIIIb) of diphenoxyacetic acid.

$(C_6H_5O)_2CHCOR$ VIII

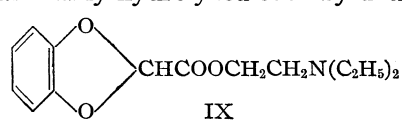
R = (a) $O(CH_2)_nNR_2$
(b) $NH(CH_2)_nNR_2$
(c) Cl

In these compounds, the oxygen atoms replace the isosteric methylene groups of the benzyl radicals. Since diphenoxyacetic acid is the diphenyl acetal of glyoxylic acid and is attacked readily by hydrolytic agents, it was considered possible that esters of the formula VIIIa may exert a short-lived antispasmodic activity which would give place to the antiseptic effect of phenol as the latter is liberated in analogy to Nencki's salol principle.

The preparation of these derivatives offered no difficulty. Diphenoxyacetyl chloride (VIIIc), prepared from the acid and thionyl chloride,[9] reacted smoothly with aminoalcohols and aminoalkyl dialkylamines. The resulting basic esters and amides could not be distilled without decomposition but were isolated as salts or hydrates. They were colorless substances most of which did not crystallize without some effort. Although stable for limited periods of time, they decomposed slowly after several months with a distinct odor of phenol.

It would have been shorter to prepare these basic esters from ethyl diphenoxyacetate by base-catalyzed ester interchange[10] but the materials decomposed at the high temperature of the reaction.

A much lower degree of stability was displayed by diethylaminoethyl *o*-phenylenedioxyacetate (IX) which decomposed in a sealed dark vessel within a few hours and could not be identified by analysis. It shares this instability with phenylenedioxyacetic acid and its simple alkyl esters which are easily hydrolyzed even by dilute alkali.



IX

Pharmacological Observations.—Several of the dialkylaminoalkyl esters described in this paper have been tested by Dr. E. J. Fellows. He reports that none of the phenylacetal-type esters exhibited antispasmodic activity in concentrations of 1×10^{-6} when tested by the isolated intestinal strip method. Only γ-(2-methylpiperidino)-propyl diphenoxyacetate hydrochloride protected guinea pigs from bronchospasm produced by aerosolized histamine in doses devoid of side effects. Several esters of this series (diethylaminoethyl, morpholinoethyl, and γ-(2-methylpiperidinopropyl)), as well as β-morpholinoethyl diphenoxyacetamide caused local anesthesia of a low order for 7.6 to 16.3 minutes when applied topically to rabbits' eyes in a 1% concentration but all of them showed signs of irritation. The same held true for β-diethylaminoethyl 2-phenylcyclopropanecarboxylate.

Acknowledgment.—We are grateful to Smith, Kline and French Laboratories for support of this work, and to Dr. E. J. Fellows of this Company for the pharmacological tests.

Experimental[11]

2-Aryl- and 2-Heteroarylcyclopropane-1-carboxylic Acids and Derivatives. General Procedures.—A mixture of 0.1 mole of the ethylene derivative and 0.1 mole of ethyl diazoacetate, and usually about two volumes of xylene was warmed to 120–130° until evolution of nitrogen began. The reaction proceeded exothermically except in the case of 1,1-diphenylethylene, and was completed by refluxing until no more gas was evolved. The solvent was

[a] Needles. [b] Hygroscopic. [c] The hygroscopic hydrochloride was decomposed with bicarbonate solution, the base extracted into ether, and the solvent allowed to evaporate slowly at room temperature in order to give the hydrated material. [d] The anhydrous ester is liquid, b. p. 165–175° (3 mm., dec.). [e] Flakes. [f] The 3-(α-methylpiperidino)-propanol used in the preparation of this compound was kindly supplied by Eli Lilly & Co.

stripped and the remaining oil was fractionated. The esters were hydrolyzed by refluxing with 3 to 12% ethanolic sodium hydroxide solution for four to six hours, most of the ethanol was removed, non-acidic products were extracted into ether, and the substituted cyclopropanecarboxylic acids were precipitated with hydrochloric acid as solids, or oils which usually solidified soon.

The amphoteric 2-(2-pyridyl)-cyclopropanecarboxylic acid could be obtained by neutralization of the saponification mixture to *p*H 6.6 and continuous extraction with ether. Hydrolysis of the ester with concentrated hydrochloric acid, evaporation of the reaction mixture and recovery of the hydrochloride of the carboxylic acid was more advantageous.

Stereochemically homogeneous samples were produced by boiling the acids with thionyl chloride in benzene solution for two hours, and reconverting the acid chlorides to the acids by hydrolysis with hot water.[7]

The esters, amides and anilides of the acids were prepared from the acid chlorides in benzene solution by treatment with the corresponding reagent.

Basic Esters and Amides of Diphenoxyacetic Acid.—Eight parts of diphenoxyacetic acid[12] was refluxed in benzene solution with seven parts of purified thionyl chloride for six to seven hours, and the mixture was allowed to stand overnight. Benzene and thionyl chloride were stripped under reduced pressure, and the crude acid chloride[9] was used in the next step.

Equivalent amounts of diphenoxyacetyl chloride and the dialkylaminoalkanol, or dialkylaminoalkylamine, respectively, were mixed in benzene solution. After an initial exothermic reaction the hydrochlorides of the reaction products precipitated, and usually solidified after some standing. In selected cases, the bases were liberated with sodium bicarbonate solution, and purified if they were more readily handled than the salts.

Isoamyl *o*-Phenylenedioxyacetate.—The preparation of this ester was patterned on that reported for the ethyl ester.[13] The preparative modification described here produced the isoamyl ester in a yield of 16.7% as compared with 8% reported for the ethyl ester.[14]

To a hot solution of 106 g. of sodium in 1200 cc. of dry isoamyl alcohol was added a suspension of 254 g. of catechol in 250 cc. of isoamyl alcohol with stirring in an atmosphere of nitrogen. The resulting viscous white mass was heated at 120° and treated gradually with 362 g. of ethyl dichloroacetate at such a rate that the exothermic reaction subsided after about one-half of the ester had been added. The reaction mixture became fluid and turned purple. It was refluxed another sixteen hours, 700 cc. of isoamyl alcohol was distilled off at 20 mm. pressure, and the dark viscous residue was dissolved in 2 liters of ether. The ether solution was washed with several liters of an ice-cold calcium chloride solution, and then with two 500-cc. portions of cold 2% sodium hydroxide solution. The dark red ether layer was dried over calcium chloride, the solvent was distilled, and the residual oil was fractionated several times. The colorless fraction boiling finally at 149–152° (20 mm.) weighed 90 g. (16.7%). It consisted of practically pure isoamyl *o*-phenylenedioxyacetate but gave a weak test for catechol. Repeated fractionation to b. p. 122–124° (2 mm.) furnished a satisfactory analytical sample.

Anal. Calcd. for $C_{13}H_{16}O_4$: C, 66.10; H, 6.78. Found: C, 66.05; H, 7.00.

***o*-Phenylenedioxyacetic Acid.**—A mixture of 13 g. of isoamyl *o*-phenylenedioxyacetate and 75 cc. of 8% sodium hydroxide solution was heated at 90° for forty-five minutes; isoamyl alcohol was extracted with ether, and the colorless solution was acidified and extracted with ether. After drying over sodium sulfate, the solvent was removed, and the residual oil was allowed to crystallize from petroleum ether. The yield of colorless flakes, m. p. 104–106°, was 6 g. (65.6%). The material gave no ferric chloride test for catechol, and did not depress the melting point of an authentic sample[13].

***o*-Phenylenedioxyacetamide.**—When dry ammonia was passed through isoamyl *o*-phenylenedioxyacetate at 100°, the ester became cloudy, and the product cleared and solidified after thirty minutes. The colorless amide crystallized from ether–petroleum ether, m. p. 105–106°. It gave no color test with ferric chloride, and could be hydrolyzed with 25% sodium hydroxide solution at room temperature.

Anal. Calcd. for $C_8H_7NO_3$: N, 8.41. Found: N, 8.62.

The amide could also be prepared in poor yields, from *o*-phenylenedioxyacetyl chloride which was obtained from the acid and thionyl chloride in benzene solution. This acid chloride could not be purified but served also as the starting material for the preparation of the unstable diethylaminoethyl *o*-phenylenedioxyacetate.

Summary

The condensation of several aromatically and heterocyclically substituted ethylene derivatives with ethyl diazoacetate furnished the ethyl esters of the corresponding cyclopropanecarboxylic acids. Dialkylaminoalkyl esters of some of these acids were prepared as potential antispasmodics.

A series of dialkylaminoalkyl diphenoxyacetates and diphenoxyacetamides was prepared for comparison with the isosteric derivatives of dibenzylacetic acid. The chemical stability of the acetal type derivatives of diphenoxyacetic acid was compared with that of similar compounds derived from *o*-phenylenedioxyacetic acid.

The Synthesis of Some 1-Cyclopentenealdehydes

BY JAMES ENGLISH, JR., AND GEORGE W. BARBER[1]

In many of the possible synthetic approaches[2] to molecules having structures analogous to auxin a[3] substituted 1-cyclopentenealdehydes are necessary starting materials. The preparation of such substances has therefore been undertaken with a view to their eventual utilization in a synthetic program.

1-Cyclopentenealdehyde itself has been prepared by the rearrangement of cyclohexene peroxide[4] and from adipic aldehyde obtained by ozonolysis of cyclohexene.[5] Urion obtained this substance also by treatment of divinylglycol with alumina at 300°.[6] These methods, however, are not easily adapted to the preparation of substituted 1-cyclopentenealdehydes and in our experience have given unsatisfactory yields. The process finally developed is shown in the equations.

The 3-*n*-propyl- and 3,5-di-*n*-propylpyrocatechols were prepared from the corresponding allyl derivatives by hydrogenation; the allyl pyrocate-

(1) Present address: Cox Medical Research Institute, University of Pennsylvania. Taken from a thesis submitted by George W. Barber to the Faculty of the Graduate School of Yale University in partial fulfilment of the requirements for the Ph.D. degree.

chols in turn were obtained from guaiacol and eugenol, respectively, as described in the literature. Pyrocatechol and its mono- and di-propyl derivatives were hydrogenated with Raney nickel to give the corresponding cyclohexanediols in 84–86% yields. No attempt was made to separate the *cis* and *trans* forms of these compounds, but the redistilled mixtures were oxidized with lead tetraacetate in benzene or chloroform. It was found that by the addition of anhydrous potassium carbonate to the reaction mixture to maintain neutrality, the losses in handling the resulting adipic aldehydes were much decreased in comparison with those experienced in the original procedure of Criegee.[7]

After considerable experimentation the method of Wohl and Schweitzer[5] was found most effective for the cyclization of adipic aldehydes and yields of about 50% of the corresponding 1-cyclopentenealdehyde were obtained directly from the lead tetraacetate oxidation mixture without the necessity of isolating the intermediate adipic aldehydes. In the case of 3,5-di-*n*-propyladipic aldehyde cyclization took place during the oxidation reaction, especially in chloroform solution, and a yield of 80% of 3,5-di-*n*-propyl-1-cyclopentenealdehyde was obtained directly.

The structures proposed for the cyclization products of the 3-*n*-propyl- and 3,5-di-*n*-propyladipic aldehydes are supported by the loss of water of the intermediate aldols during the cyclization. By analogy with other aldol condensations as reported in the literature,[8] no such dehydrations would have been expected if the cyclization had involved the tertiary alpha carbon atom. In analogous base-catalyzed cyclizations of the Dieckmann type a similar phenomenon is observed.[9] Here again a secondary alpha carbon atom rather than a tertiary one seems always to be involved.

Attempts were made to separate the 3,5-di-*n*-propyl-1-cyclopentenealdehyde into its *cis* and *trans* forms. The hydrogenation of pyrocatechol has been found[10] to give a mixture of isomers and similar behavior might have been expected in this case. However, neither extensive fractional crystallization of the semicarbazone or a careful fractional distillation produced any evidence of the existence of significant amounts of an isomer in the purified material. It therefore seems probable that this substance is homogeneous, and that the hydrogenation of disubstituted catechols leads to a predominance of one stereoisomer, probably *trans* with respect to the alkyl groups.

On standing at room temperature all three 1-cyclopentenealdehydes were observed to polymerize, becoming yellow and viscous in the course of a few days. Preliminary experiments indicate that the freshly prepared propyl-1-cyclopentenealdehydes react normally in the Reformatski reaction with ethyl bromoacetate.

Experimental[11]

3-*n*-Propylpyrocatechol.—A mixture of 442 g. of 6-propylguaiacol, b. p. 80–82° at 1.5 mm., prepared from 6-allylguaiacol[12] by hydrogenation with platinum oxide at 50 p. s. i. in ethanol, was refluxed for twelve hours in a solution of 750 g. 48% hydrobromic acid in 1 liter of glacial acetic acid. After removal of the excess hydrobromic acid and solvent the residue was distilled. There was obtained 382 g. (95% of theory) of colorless 3-propylpyrocatechol, b. p. 112–113° at 1.5 mm. On recrystallization from ethanol the product melted at 72°. Kurosawa[13] reported the melting point of this substance as 70–72°.

3,5-Di-*n*-propylpyrocatechol.—Diallylguaiacol, prepared by the method of Claisen and Eisleb[14] was hydrogenated in ethanol with platinum oxide at 60 p. s. i. The product, obtained in quantitative yield was 4,6-di-*n*-propylguaiacol, b. p. 107–108° at 1 mm., $n^{20}D$ 1.5123. A dinitrobenzoate was prepared m. p. 117.5°. *Anal.* Calcd. for $C_{13}H_{20}O_2$: C, 74.96; H, 9.68. Found: C, 75.13; H, 9.72. A mixture of 208 g. of this product was refluxed with 300 cc. of 48% hydrobromic acid and 800 cc. of glacial acetic acid for eight hours. After evaporation of the residual hydrobromic acid and solvent *in vacuo*, the product was distilled, b. p. 115–120° at 1 mm., as a viscous liquid that slowly crystallized. On recrystallization from petroleum ether (b. p. 30–60°) by cooling in Dry Ice there was obtained 169 g. (87%) of crystalline 3,5-di-*n*-propylpyrocatechol, m. p. 39–40°. The pure product melts at 41.5°.

Anal. Calcd. for $C_{12}H_{18}O_2$: C, 74.19, H, 9.34. Found: C, 74.18; H, 9.04.

Hydrogenation of Pyrocatechols.—Pyrocatechol and the above substituted pyrocatechols were hydrogenated in 100 g. batches with 50 cc. of absolute ethanol, 10 g. of Raney nickel and a pellet of sodium hydroxide.[15] The reaction was carried out at about 2000 p. s. i. and at a temperature of 140 to 160°. Six to nine hours were required for complete hydrogenation, the higher homologs requiring the longer times. The products were taken up in petroleum ether, washed with 10% sodium hydroxide to remove any unchanged pyrocatechol, and the residues distilled after evaporation of the solvent. The properties and yields of the mixtures of stereoisomeric cyclohexanediols obtained were:

3,5-Di-*n*-propyl-1,2-cyclohexanediols	135–150	2	86	

Adipic Aldehyde.[7]—Twenty grams (0.17 mole) of the above 1,2-cyclohexanediol preparation was dissolved in 200 cc. of dry benzene and 50 g. anhydrous potassium carbonate added. The mixture was stirred vigorously while 76 g. (0.17 mole) of lead tetraacetate was added in 5 g. portions over the course of one hour. A nitrogen atmosphere was maintained during the addition and subsequent distillations. The mixture was stirred for an additional hour after the addition was complete and then filtered. The mixture of salts was extracted thoroughly with benzene and the combined filtrates dried briefly over sodium sulfate. The benzene was then removed in vacuum and the product distilled. There was obtained 13.4 g. (68%) of colorless adipic aldehyde, b. p. 68–70 at 3 mm., $n^{20}D$ 1.4350. There was always observed a higher boiling fraction of polymerized material and a non-volatile residue.

1-Cyclopentenealdehyde.[5]—Nineteen grams of freshly distilled adipic aldehyde was heated with 115 cc. of distilled water in a bomb at 110° for five hours. After cooling, the solution was then extracted thoroughly with ether and the product isolated by distillation. There was obtained 10 g. of 1-cyclopentenealdehyde (62%), b. p. 57–59° at 23 mm., $n^{20}D$ 1.4866.

An over-all yield of 52% was obtained by treating the crude adipic aldehyde as obtained above on evaporation of solvent with water at 110° in the same manner. The product in both cases polymerized on standing. Urion reported the properties of this substance as: b. p. 48° at 11 mm., $n^{20}D$ 1.4828.

2-*n*-Propyladipic Aldehyde.—The 3-*n*-propylcyclohexane-1,2-diol mixture described above (30 g.) was oxidized in the same manner as described above for cyclohexanediol. There was obtained 19.5 g. (68%) of 2-*n*-propyladipic aldehyde, b. p. 124–127° at 15 mm. Careful fractionation gave a product b. p. 83° at 2 mm., $n^{20}D$ 1.4478, d_{20} 0.9580; molecular refraction calcd., 43.8; found, 43.6.

The 2,4-dinitrophenylhydrazone prepared in the usual manner melted at 178–179° after recrystallization from glacial acetic acid.

Anal. Calcd. for $C_{21}H_{24}N_8O_8$: C, 48.84; H, 4.68. Found: C, 49.42; H, 4.63.

2-*n*-Propyladipic acid[17] was prepared by heating 5.2 g. of 2-*n*-propyladipic aldehyde in 100 cc. of water and 50 cc. of alcohol with 20 g. of fresh silver oxide and 3 g. of sodium hydroxide. After two hours of refluxing and stirring the mixture was filtered and extracted with ether. After acidification with hydrochloric acid, the solution was again extracted with ether yielding, on removal of the solvent, an oil that crystallized partially after standing some time. On recrystallization from petroleum ether (b. p. 30–60°) 2-*n*-propyladipic acid m. p. 53–54° was obtained.

Anal. Calcd. for: $C_9H_{16}O_4$: C, 57.43; H, 8.57; neut. equiv., 94.1. Found: C, 57.38; H, 8.55; neut. equiv., 95.1.

3-*n*-Propyl-1-cyclopentenealdehyde.—A 63% yield of this substance was obtained from 15 g. of 2-propyladipic aldehyde by the procedure described above for 1-cyclopentenealdehyde. By treating the undistilled 2-propyladipic aldehyde directly with water at 110° as described above, an over-all yield of 52% of 3-propyl-1-cyclopentenealdehyde b. p. 86–88° at 15 mm. was obtained. The semicarbazone prepared in the usual manner and recrystallized from dilute ethanol melted at 188–189°.

Anal. Calcd. for $C_{10}H_{17}N_3O$: C, 61.51; H, 8.78; N, 21.52. Found: C, 61.58; H, 8.86; N, 20.91.

Steam distillation of a mixture of 7.8 g. of this semicarbazone with 7 g. of oxalic acid in 200 cc. of water yielded pure 3-*n*-propyl-1-cyclopentenealdehyde (3.5 g.), b. p. 54–55° at 2 mm., $n^{20}D$ 1.4780; d_{20} 0.9285; molecular refraction calcd. 41.11, found 42.13 (exaltation 2.5%). The 2,4-dinitrophenylhydrazone was obtained by crystallization from dilute alcohol as bright red needles, m. p. 149°.

3,5-Di-*n*-propylcyclopentenealdehyde.—Oxidation of 50 g. of the 3,5-di-*n*-propylcyclohexane-1,2-diol mixture in 300 cc. of dry chloroform containing 40 g. of anhydrous potassium carbonate in the same manner as described for the oxidation of cyclohexanediol, yielded on distillation 35.9 g. (80%) of 3,5-di-*n*-propyl-1-cyclopentenealdehyde b. p. 106–107° at 3.5 mm., $n^{20}D$ 1.4730. Under these conditions there seemed to be little if any of the di-*n*-propyl adipic dialdehyde formed. When benzene was substituted for chloroform, the details being otherwise the same, there was obtained 24.8 g. of material boiling at 95–120° at 2 mm.; refractionation yielded in addition to 3,5-di-*n*-propylcyclopentenylformaldehyde about 3 g. of a higher fraction, b. p. 112° at 2 mm., $n^{20}D$ 1.4554, which was presumably the di-*n*-propyladipic dialdehyde. This fraction was not further investigated. The semicarbazone, prepared in dilute alcohol and recrystallized from alcohol, melted at 124.5–125°.

Anal. Calcd. for $C_{13}H_{23}N_3O$: C, 65.79; H, 9.77; N, 17.71. Found: C, 65.72; H, 9.55; N, 17.57.

An attempt at separation of the possible stereoisomers by fractional crystallization of the semicarbazones yielded only the product described above and a small amount of non-crystalline oil. This oil may have contained other isomeric forms, but has not been investigated further. Careful fractional distillation of 35 g. of freshly prepared 3,5-di-*n*-propylcyclopentenylformaldehyde yielded an apparently homogeneous product, b. p. 89–90° at 3.5 mm., n 1.4735 to 1.4740; a total of 19 fractions were collected arbitrarily from a 40 cm. column packed with steel helices (about 25 theoretical plates) and 24.5 g. of material fell within the range given above. The remainder was largely polymerized residue in the still pot. Semicarbazones from these fractions melted at 124–125° as before. On standing at room temperature the free aldehyde became viscous due to polymerization.

Ethyl 3-(3-*n*-Propyl-1-cyclopentenyl)-3-hydroxypropionate.—A solution of 9 g. of 3-*n*-propyl-1-cyclopentenealdehyde and 16.7 g. of ethyl bromoacetate in a mixture of 16 cc. of dry benzene and 4 cc. of ether was added slowly under nitrogen to 7 g. of activated[18] zinc dust. The rate of addition was adjusted to maintain gentle reflux. After the addition the mixture was heated for one hour, the excess zinc removed and 100 cc. of ether added. The mixture was shaken alternately with dilute sulfuric acid and sodium bicarbonate until no cloudiness appeared on bicarbonate treatment and the product finally distilled under reduced pressure. After careful fractionation 6.6 g. (45%) of pure ethyl 3-(3-*n*-propyl-1-cyclopentenyl)-3-hydroxypropionate, b. p. 128 at 2 mm., $n^{20}D$ 1.4688, d_{20} 0.9975 was obtained.

Anal. Calcd. for $C_{13}H_{22}O_3$: C, 68.99; H, 9.80. Found: C, 68.46; H, 9.93.

Ethyl 2-(3,5-Di-*n*-propyl-1-cyclopentenyl)-3-hydroxypropionate.—This ester was prepared in the same way from 3,5-di-*n*-propylcyclopentenealdehyde and ethyl bromoacetate. The ester, obtained in 50% yield, was carefully fractionated in vacuum. Pure ethyl (3,5-di-*n*-propyl-1-cyclopentenyl)-3-hydroxypropionate boiled at 124° at 1 mm., $n^{20}D$ 1.4686, d_{20} 0.9688.

Anal. Calcd. for $C_{16}H_{28}O_3$; C, 71.60; H, 10.52. Found: C, 70.69; H, 10.17.

The free acids corresponding to both of the above hydroxy esters were prepared by hydrolysis in alcoholic potassium hydroxide at room temperature. Both were obtained as liquids which defied attempts at crystallization. The product obtained from the monopropyl analog gave

evidence of containing some lactone. The nature of these compounds will be further investigated.

Summary

A practical synthesis of substituted 1-cyclopentenealdehydes has been developed and applied to 1-cyclopentenealdehyde, 3-*n*-propyl-1-cyclopentenealdehyde and 3,5-di-*n*-propyl-1-cyclopentenealdehyde.

The substituted 1-cyclopentenealdehydes have been shown to undergo the Reformatski reaction.

NEW HAVEN, CONNECTICUT RECEIVED MARCH 17, 1949

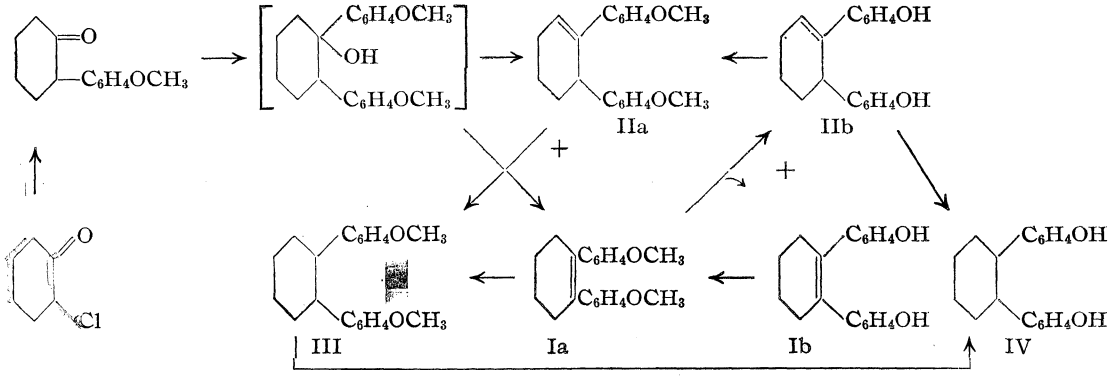
Synthesis of Cyclohexestrol[1]

BY GEORGE P. MUELLER AND ROY MAY[2]

Much of the search for new synthetic estrogens has consisted either of substituting groups within the essentially intact hexestrol skeleton, or of building other structures also supposedly capable of simulating the nuclear form of the estrogenic hormone. The synthesis of the cyclohexane analog, for which previous attempts have been reported,[3] has been completed.



The formation of 2-substituted cyclohexanones from 2-chlorocyclohexanones has been studied more recently by Mousseron[4] and by Newman[5] who have shown that the alkyl or aryl group from an attacking Grignard reagent may become attached either to the carbonyl or the halogen-bearing carbon. Our results indicate further either that a 2-substituted cyclohexanone or cyclohexene oxide is formed and subject to further attack as in the formation of tertiary alcohols from carboxylic esters, or that the halogen-bearing and carbonyl carbons are attacked simultaneously. Thus, although clean separations of products were difficult, a 2:1 mole ratio of *p*-methoxyphenylmagnesium bromide to 2-chlorocyclohexanone favored the formation of bis-(*p*-methoxyphenyl)-cyclohexenes, Ia and IIa, over that of 2-*p*-methoxyphenylcyclohexanone,[6] and conversely for a 1:1 ratio.

The mixture of cyclohexenes must have been formed by spontaneous dehydration during the reaction or on hydrolysis of the magnesium salts, since the isomer Ia was on one occasion crystallized directly from the crude products before application of the usual dehydrating conditions. Parmerter[7] obtained a 1,2-diphenylcyclohexene after dehydrating the crude hydrolysis product from phenylmagnesium bromide and 2-phenylcyclohexanone, but he did not confirm the actual presence of a carbinol. Further evidence of the activating effect of the *p*-methoxyphenyl group in this connection was observed during a synthesis of 2-*p*-methoxyphenylcyclohexanone through perbenzoic acid oxidation of 1-*p*-methoxyphenylcyclohexene. Here, distillation of the acid-free oxidation product to purify the 1-*p*-methoxyphenylcyclohexene oxide yielded instead the cyclohexanone. 1-Phenylcyclohexene oxide was reported however as being purified in this way and requiring acid catalysis to effect the rearrangement.[8]

Two bis-(*p*-methoxyphenyl)-cyclohexenes, Ia and IIa, were isolated and separately hydrogenated to the same cyclohexane, III, which was demethylated in alcoholic alkali to 1,2-bis-(*p*-hydroxyphenyl)-cyclohexane IV. We have called

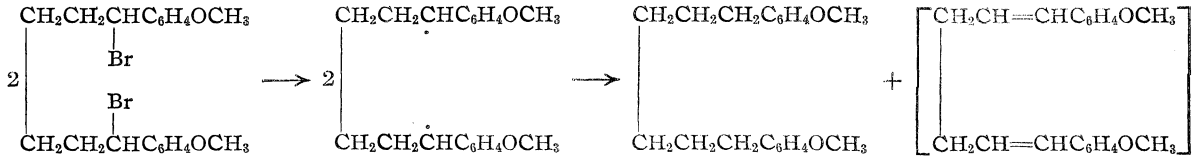
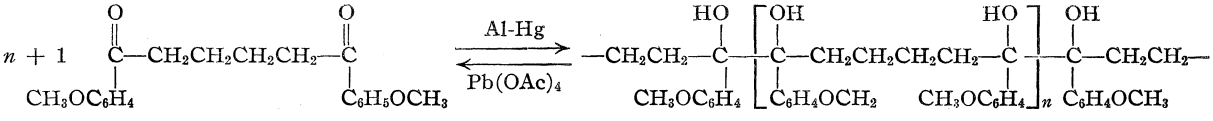
the latter "cyclohexestrol," although its low physiological activity may, perhaps, not warrant such a cognomen. Similar demethylation of the cyclohexene, Ia, gave both of the phenolic cyclohexenes, Ib and IIb, identified with the methoxy-iso-



mers by remethylation. The skeletal structure of the series was confirmed through dehydrogenation of the mixed bis-(*p*-methoxyphenyl)-cyclohexenes to 4′,4″-dimethoxy-*o*-terphenyl.[3b]

Placement of the double bond in the isomeric series, I and II, as shown is provisional. It seems likely that the carbinol intermediate would have a *trans* configuration favorable to the formation of Ia, as the preponderant isomer, by *trans* elimination of water.[9] Conflicting evidence arises from the appearance of the two phenolic cyclohexenes during alkaline demethylation at 200° of the isomer Ia. If there were not some doubt, arising from isolation difficulties and hence the qualitative nature of the experiment, one could only conclude that migration of the bond from the unsymmetrical to the symmetrical and completely conjugated position had occurred.[10] Establishment of these structures through oxidation studies is continuing.

The two phenolic cyclohexenes as well as cyclohexestrol were tested and found to possess defi-



nite, though weak, estrogenic activity. Whether the latter has the *dl* or *meso* configuration can only be inferred from hydrogenation experiments with diethylstilbestrol.[11] Up to this date the compound has eluded resolution.

Several attempts to synthesize cyclohexestrol by ring-closure of 1,6-bis-(*p*-methoxyphenyl)-hexane derivatives were unsuccessful but yielded curious results which illustrate the steric resistance offered by aryl substituents on the carbons to be joined. The methods tried were analogous to those previously used in preparing hexestrol, dienestrol and related compounds.[12]

Treatment of 1,6-bis-(*p*-methoxyphenyl)-1,6-dibromohexane with phenylmagnesium bromide and cobaltous chloride was expected to produce a 1,6-diradical and then a 1,2-bis-(*p*-methoxyphenyl)-cyclohexane. We submit that while the mechanism of free radical formation here was that previously suggested, the disposition of the radical itself may rather be the result of a disproportionation.[13]

The isolation and positive identification of 1,6-bis-(*p*-methoxyphenyl)-hexane, aside from the ever-present biphenyl and *p*-terphenyl, was all that could be accomplished with the intractable, highly unsaturated products. Again, treatment of the dibromohexane with sodium, magnesium and sodium amide led in each case to unsaturated oils from which no recognizable compound could be isolated.

Another approach to the ring-closure was the aluminum-amalgam reduction of 1,4-bis-(*p*-methoxybenzoyl)-butane to the anticipated 1,2-bis-(*p*-methoxyphenyl)-1,2-dihydroxycyclohexane.[14] Similar cyclic 1,2-diaryl pinacols have been formed in which the ring was already extant.[15] Only a polymeric product was recovered, however, despite attempts to isolate crystalline material from the purification liquors. This resin was poly-1,6-bis-(*p*-methoxyphenyl)-1,6-dihydroxyhexamethylene, as shown by its rapid and quantitative oxidation with lead tetraacetate to the original 1,6-diketone.

The formation of this interesting polypinacol under such mild conditions and the facile reversal of the reductive-polymerization offers attractive possibilities. The study of this reaction and of the chemical and physical properties of the product is continuing.

Experimental

Reduction of 1,4-bis-(*p*-Methoxybenzoyl)-butane.—1,4-bis-(*p*-Methoxybenzoyl)-butane, 25.0 g., was hydrogenated in 125 ml. of ethyl alcohol over copper-chromium oxide at 2000 p. s. i. and 100°, giving 22.4 g. of crystalline material, m. p. 100–140°. After three recrystallizations from methyl alcohol the melting point was 132–150°. Similar mixtures were obtained by using Raney nickel at 2000 p. s. i. and 130°. Aluminum isopropoxide reduction of 9.9 g. of the diketone and recrystallization of the product once from benzene gave 7.5 g. of solid, m. p. 105–140°. In order to confirm the reduction work, 48.6 g. of magnesium turnings, 216 g. of freshly-distilled tetramethylene bromide and 408 g. of anisaldehyde were treated in a man-

ner similar to that of Schmidt,[16] yielding 100 g. of the 1,6-glycols, m. p. 115–138°, after two recrystallizations from ethyl alcohol. Oxidation of 3.3 g. of such a product with 10 g. of concentrated sulfuric acid, 5 g. of potassium dichromate and 20 ml. of water at 100° for twenty-five minutes yielded 1 g. of 1,4-bis-(*p*-methoxybenzoyl)-butane, identified through mixed melting points of the diketone and its oxime with authentic samples. The glycols, therefore, were mixtures of *dl* and *meso* forms of 1,6-bis-(*p*-methoxyphenyl)-1,6-dihydroxyhexane.

1,6-bis-(*p*-Methoxyphenyl)-1,6-dibromohexane.—The mixture of 1,6-bis-(*p*-methoxyphenyl)-1,6-dihydroxyhexanes, 5 g., was suspended in 20 ml. of dry benzene and dry hydrogen bromide was introduced, causing solution of the glycol accompanied by slight warming. The water formed was removed and the solution cooled overnight; the white, crystalline powder was collected and weighed 5.5 g.; m. p. 99–102°. An additional recovery by concentrating the benzene solution *in vacuo* made the total yield 6.2 g. (88%). This bromide, recrystallized from anhydrous ether, melted at 102–103° with decomposition.

Anal. Calcd. for $C_{20}H_{24}O_2Br_2$: C, 52.65; H, 5.30. Found: C, 52.84; H, 5.36.

At room temperature the bromide decomposed in a few days, but was stable for several months under refrigeration. A dark green oil was the impurity associated with the bromide, either accompanying certain preparations or appearing on decomposition after standing or melting. Since the pure bromide was not greatly soluble in boiling ether, although more so in ether–acetone mixtures, from which it crystallized less completely, purification for preparative purposes was best accomplished by washing with a very little cold acetone and several times with ether. The colored material was thus removed, leaving generally 85–90% of white crystalline material from very impure-looking preparations. Decomposition accompanied attempts to recrystallize from hot benzene or ethyl alcohol. A pure sample precipitated silver bromide instantly from alcoholic silver nitrate.

The oily residues remaining from crystallization of the solid 1,6-glycols yielded 76% of the same pure dibromohexane.

1,6-bis-(*p*-Methoxyphenyl)-1,6-dichlorohexane.—The mixture of solid 1,6-glycols, 10 g., was suspended in 20 ml. of dry benzene and 20 ml. of petroleum ether (b.p. 95–96°); 8 g. of thionyl chloride was added and the solution warmed gently at reflux for forty-five minutes until gas evolution had ceased and the solid dissolved. After cooling overnight 7.2 g. (65%) of gray-white crystals were collected; m. p. 105–108°. After five recrystallizations from dry ether the dichlorohexane melted at 108–112°, or up to 116° upon rapid heating, with decomposition. *Anal.* Calcd. for $C_{20}H_{24}O_2Cl_2$: C, 65.40; H, 6.59. Found: C, 65.35; H, 6.79. It gave instantaneous precipitation in alcoholic silver nitrate. As before, the oily 1,6-glycols by the same procedure yielded 53% of the dichloro compound.

Attempts to Cyclize 1,6-bis-(*p*-Methoxyphenyl)-1,6-dibromohexane.—Using a procedure similar to that of Kharasch and Kleiman for coupling anethole hydrobromide,[11] the dibromohexane, 22.8 g., was suspended in 300 ml. of dry benzene and 300 ml. of dry ether. This suspension was added to a solution of 75 ml. of phenylmagnesium bromide (0.15 mole) in ether which had previously been treated with 1.0 g. of freshly-fused, powdered cobaltous chloride and cooled in ice–hydrochloric acid. The cooling bath was then removed, stirring continued five hours at room temperature and the mixture finally decomposed with 300 g. of ice and 10 ml. of concentrated hydrochloric acid. The dried ethereal extracts yielded 23.2 g. of an oil which was distilled to give 8.1 g. of biphenyl, b. p. 107–120° (8–11 mm.), m. p. 69–70° and 10.13 g. of an oil, b. p. 210–250° (1 mm.). Subjection of the latter fraction to a long series of distillations and crystallizations from toluene, ether, ligroin and methyl alcohol permitted isolation of 0.4 g. of *p*-terphenyl, m. p. 209–211°, and 0.5 g. of 1,6-bis-(*p*-methoxyphenyl)-hexane, m. p. 70.1–72.5°. The mixed melting points of the latter with biphenyl and with 1,2-bis-(*p*-methoxyphenyl)-cyclohexane (see below) were depressed, but not with a synthetic sample of the known 1,6-bis-(*p*-methoxyphenyl)-hexane,[17] for which compound the analysis also was correct.

Pinacol Reduction of 1,4-bis-(*p*-Methoxybenzoyl)-butane.—A suspension of 25 g. of the diketone in 400 ml. of moist ethyl acetate was added to 9.5 g. of aluminum foil, freshly amalgamated. The temperature remained at 38° with stirring, for two hours as the reaction proceeded slowly, then rose to 48° and finally had dropped back to 30° after four hours. The mixture was worked up in the usual way, the organic solution dried over anhydrous magnesium sulfate and evaporated *in vacuo* leaving 20.7 g. of a tan-colored glass, soluble in warm ethyl acetate and precipitated therefrom by benzene or petroleum ether. The product was not soluble in methyl alcohol, ethyl alcohol or acetone. It was dissolved in 100 ml. of ethyl acetate and the resulting solution filtered into 250 ml. of methyl alcohol. The freshly precipitated polymer was gummy, but on standing in the mother liquors became friable and when dried resembled colorless rosin. The dry polymer was introduced into 100 ml. of ethyl acetate where it first swelled, then formed a gel and finally dissolved on heating; it was precipitated again in 250 ml. of methyl alcohol, collected and dried. The powdered polymer was hygroscopic and difficult to dry to a constant weight even over phosphorus pentoxide. It melted at 170–185° with foaming until residual moisture had evaporated. The viscous amber liquid cooled to form a brittle glass. *Anal.* Calcd. for $C_{20}H_{24}O_4$: C, 73.15; H, 7.37. Found: C, 72.03; H, 7.39; redried: C, 72.14; H, 7.64. The finely-powdered polymer, 0.66 g. (0.002 mole), and 0.90 g. (0.002 mole) of lead tetraacetate gave a heavy, insoluble suspension in 5 ml. of glacial acetic acid. However, on stirring, the entire mass was brought into solution in two minutes. After centrifuging to remove traces of insoluble matter, this was poured into cold water and the precipitated solid collected and dried, giving 0.66 g. of ketone. This was recrystallized twice from ethyl acetate and melted at 144.0–146.0°, not depressing the melting point of an authentic sample of 1,4-bis-(*p*-methoxybenzoyl)-butane.

2-(*p*-Methoxyphenyl)-cyclohexanone.—The procedure used previously in preparing phenylmethylcyclohexanones served as a guide.[5] 2-Chlorocyclohexanone,[18] 41 g. (0.31 mole), in 100 ml. of dry ether was added with stirring and cooling to the Grignard reagent prepared from 56 g. (0.30 mole) of *p*-bromoanisole and 7.55 g. (0.31 mole) of magnesium in 100 ml. of ether. Xylene, 155 ml., was added to the mixture on the next day and ether distilled away until the internal temperature reached 95–100°, when heating was continued at total reflux with stirring for eight hours. The cooled mixture was hydrolyzed with ammonium chloride solution and the organic layer removed, washed, dried and distilled, yielding 19.9 g. (33%) of 2-(*p*-methoxyphenyl)-cyclohexanone; b. p. 156–166° (1 mm.), m. p. 88.5–89.5° after crystallization from ligroin. *Anal.* Calcd. for $C_{13}H_{16}O_2$: C, 76.43; H, 7.89. Found: C, 76.01, 75.97; H, 7.65, 7.77. This ketone failed either to form a bisulfite addition compound or to react with Schiff reagent. It did react slowly with Fehling solution and the usual ketone reagents. The 2,4-dinitrophenylhydrazone was prepared and recrystallized three times from ethyl alcohol; m. p. 143–144°. *Anal.* Calcd. for $C_{19}H_{20}O_5N_4$: C, 59.37; H, 5.25. Found: C, 59.10; H, 5.25. Its structure was confirmed by oxidizing 1.0 g. of the ketone suspended in 25 ml. of water and heated to 90° with the dropwise addition of 1.0 g. of potassium permanganate in 25 ml. of water. The cooled solution was extracted with ether and the residual ether removed from the aqueous solution which was then acidified with dilute sulfuric acid and permitted to stand in the cold until crystallization of the δ-(*p*-methoxy-

(18) Newman, Farbman and Hipsher, *Org. Syntheses*, **25**, 22 (1945).

benzoyl)-valeric acid was complete. This was collected and recrystallized successively from alcohol and ethyl acetate; 0.5 g., m. p. 127.0–127.5°,[17] neutral equivalent 238 (calcd., 236).

Another preparation of 2-(*p*-methoxyphenyl)-cyclohexanone involved oxidation of 1-(*p*-methoxyphenyl)-cyclohexene[19] with perbenzoic acid in chloroform solution. However, the oxidation products from 19.3 g. were oily and yielded as crystalline products 2 g. of an unidentified substance, m. p. 122–124° [*Anal.* Calcd. for $C_{15}H_{16}O_3$: C, 73.75; H, 6.60. Found: C, 73.65, 73.51; H, 6.77, 6.62] and only 2 g. of the desired cyclohexanone after distillation at 3 mm. of the unpurified oxide intermediate.

The bis-(*p*-Methoxyphenyl)-cyclohexenes, Ia and IIa.—A solution of 19 g. (0.093 mole) of 2-(*p*-methoxyphenyl)-cyclohexanone in 300 ml. of dry ether was added to the Grignard reagent prepared from 18 g. (0.096 mole) of *p*-bromoanisole and 2.34 g. (0.096 mole) of magnesium in 40 ml. of ether, slowly, to maintain gentle refluxing. The mixture stood overnight, was hydrolyzed with ammonium chloride solution and the crude product recovered as an oil from the dry ethereal extract. This oil was heated at reflux for one hour with 20 g. of acetic anhydride. Removal of the excess anhydride and acetic acid left an oil, separable into 10.9 g. of viscous, greenish-yellow oil, b. p. 209–214° (1 mm.), crystallizing slowly on dilution with alcohol. The yield was 9.1 g. (33%) of crystalline product, m. p. 75–87°. Microscopic observation showed two crystal forms present after eight recrystallizations from ethyl alcohol, which raised the melting point to 86–88°. The analysis was correct for a mixture of bis-(*p*-methoxyphenyl)-cyclohexenes; this mixture was almost entirely the isomer Ia with very little IIa.

Anal. Calcd. for $C_{20}H_{22}O_2$: C, 81.59; H, 7.54. Found: C, 81.30, 81.46; H, 7.39, 7.44.

In an alternative preparation 21 g. (0.16 mole) of 2-chlorocyclohexanone in 50 ml. of dry ether was added to the Grignard reagent prepared from 61 g. (0.32 mole) of *p*-bromoanisole and 7.9 g. (0.32 mole) of magnesium in 100 ml. of ether; 150 ml. of xylene was used in the manner described above. After hydrolysis and separation, the dried xylene extracts were treated with 10 ml. of acetic anhydride for three hours at room temperature and the solvent and acetic acid removed *in vacuo*. Fractional distillation yielded 2.1 g. (6.4%) of 2-(*p*-methoxyphenyl)-cyclohexanone and 17.8 g. of green oil, b. p. 210–215° (1 mm.), of which 9.2 g. (19.7%) crystallized readily from alcohol. This was the principal product, melting at 88.5–90.0° (micro)[20] after three recrystallizations. This was bis-(*p*-methoxyphenyl)-cyclohexene, Ia.

Anal. Calcd. for $C_{20}H_{22}O_2$: C, 81.59; H, 7.54. Found: C, 81.44; H, 7.43.

The mother liquors from purification of the isomer Ia yielded 0.25 g. of the other isomer, m. p. 88.0–89.5° (micro) after five crystallizations from alcohol. This was bis-(*p*-methoxyphenyl)-cyclohexene, IIa; a mixture of equal weights of Ia and IIa melted at 67–86°.

Anal. Calcd. for $C_{20}H_{22}O_2$: C, 81.59; H, 7.54. Found: C, 81.57; H, 7.49.

In an attempt to isolate the intermediate, 1,2-bis-(*p*-methoxyphenyl)-cyclohexanol, the acetic anhydride treatment was omitted, but instead the heavy oil remaining after removal of the xylene *in vacuo* allowed to stand until partly crystallized. With the aid of petroleum ether some crystals were freed from oil and purified from methyl alcohol. They proved to be the cyclohexene, Ia.

Dehydrogenation of 0.3 g. of the mixture of cyclohexenes, m. p. 75–87°, was accomplished by heating with 0.065 g. of sulfur for five hours at 200–250°. Zinc dust was added at 250° to destroy excess sulfur and the melt cooled and extracted with hot methyl alcohol. The recovery of white needles, m. p. 103–105° was 0.14 g.; when purified further from methyl alcohol this product melted at 105–106° and did not depress the melting point of 4′,4″-dimethoxy-*o*-terphenyl.[3b]

The bis-(*p*-Hydroxyphenyl)-cyclohexenes, Ib and IIb.—A solution of 3.0 g. of bis-(*p*-methoxyphenyl)-cyclohexene, Ia, m. p. 86–88°, in 25 ml. of ethyl alcohol and 10 g. of potassium hydroxide was heated in a steel autoclave at 200–210° for twenty-four hours.[13a] Acidification of the cooled, diluted solution precipitated 2.65 g. (98%) of crude phenols, m. p. 165–220°. Fractional crystallization from methyl alcohol finally gave two pure products, the first isolated being bis-(*p*-hydroxyphenyl)-cyclohexene, IIb, 0.4 g., crystallizing in long needles and subliming into short staffs at 224° just before melting at 226.6–228.6° (micro). *Anal.* Calcd. for $C_{18}H_{18}O_2$: C, 81.18; H, 6.81. Found: C, 81.14; H, 6.77. The diacetate resulted from heating 50 mg. of the phenol with 2 ml. of acetic anhydride and 0.1 g. of fused sodium acetate. It was purified from methyl alcohol; m. p. 149.0–150.4° (micro). *Anal.* Calcd. for $C_{22}H_{22}O_4$: C, 75.41; H, 6.33. Found: C, 75.07; H, 6.65. This phenolic cyclohexene, IIb, did not depress the melting point of 4′,4″-dihydroxy-*o*-terphenyl. However, 4′,4″-diacetoxy-*o*-terphenyl, m. p. 186°[3b] was clearly different from and depressed the melting point of the cyclohexane derivative. Moreover, saponification of the acetate, in 5% sodium hydroxide, m. p. 149–150°, gave the original phenol almost quantitatively. Methylation of 50 mg. of this phenol, m. p. 224–228°, by alternate addition in two portions of a total of 2 ml. of 20% sodium hydroxide and 2 ml. of dimethyl sulfate, destroying the excess with concentrated ammonia, yielded a gummy, white solid. This was recrystallized three times from methyl alcohol; m. p. 90.8–91.4° (micro); m. m. p. with bis-(*p*-methoxyphenyl)-cyclohexene, Ia, 70–87°; m. m. p. with the cyclohexene, IIa, 89.5–90.9° (micro). Hydrogenation of the phenolic cyclohexene, IIb, 18 mg., over 10% palladium-on-charcoal catalyst[21] in ethyl alcohol at 80 p. s. i. yielded 12 mg. of 1,2-bis-(*p*-hydroxyphenyl)-cyclohexane, IV, m. p. 177–179° (see below).

The second compound isolated from the demethylation products crystallized on slow evaporation of the liquors from phenolic cyclohexane IIb. This melted at 160–220° but finally yielded 0.5 g. of micro-needles, m. p. 171.0–173.5° (micro), from the same solvent. It depressed to 158° the melting point of 1,2-bis-(*p*-hydroxyphenyl)-cyclohexane and is bis-(*p*-hydroxyphenyl)-cyclohexene, Ib. *Anal.* Calcd. for $C_{18}H_{18}O_2$: C, 81.18; H, 6.81. Found: C, 81.33, 81.15; H, 6.90, 6.66. The diacetate, prepared as above, was purified from methyl alcohol; m. p. 140.5–141.5° (micro). *Anal.* Calcd. for $C_{22}H_{22}O_4$: C, 75.41; H, 6.33. Found: C, 75.45; H, 6.36. Methylation of this phenol in like manner furnished bis-(*p*-methoxyphenyl)-cyclohexene, Ia, m. p. 88.8–89.8° (micro); m. p., with the isomer Ia isolated from the Grignard reaction, 88.3–90.4° (micro).
