1,2-bis-(*p*-Methoxyphenyl)-cyclohexane, III.—The mixture of bis-(*p*-methoxyphenyl)-cyclohexenes, 3.2 g., in 50 ml. of acetone was shaken with 0.5 g. of 10% palladium-on-charcoal catalyst for six hours at 50 p. s. i. of hydrogen. Following filtration and removal of acetone the residue was crystallized from alcohol, giving 2.9 g. (90%) of 1,2-bis-(*p*-methoxyphenyl)-cyclohexane, m. p. 67–69°. *Anal.* Calcd. for $C_{20}H_{24}O_2$: C, 81.02; H, 8.17. Found: C, 80.92, 80.91; H, 8.06, 7.92. Hydrogenation, likewise, of the pure isomeric bis-(*p*-methoxyphenyl)-cyclohexenes, Ia and IIa, resulted in the same cyclohexane from each in comparable yields.

1,2-bis-(*p*-Hydroxyphenyl)-cyclohexane, IV.—Demethylation of 8.0 g. of 1,2-bis-(*p*-methoxyphenyl)-cyclohexane with 20 g. of potassium hydroxide in 150 ml. of alcohol at 200–210° for twenty-four hours yielded 7.0 g. of acid-precipitated product, m. p. 176–178°. Two recrystallizations from 50% aqueous methyl alcohol, with

(19) This was prepared by dehydration of the carbinol, *cf.* Sherwood, *et al.*, *J. Chem. Soc.*, 1832 (1932); 323 (1936), and the melting point was as given by v. Braun, *Ann.*, **472**, 1 (1929).

(20) All micro-melting points were observed at fifty magnifications in the Kofler apparatus as supplied by the Arthur H. Thomas Co., Philadelphia, Pa., and calibrated in terms of standard samples accompanying the instrument.

addition of Norite, gave 6.5 g. (88%) of the phenol, m. p. 177.5–179.5°, which produced no color with ferric chloride. *Anal.* Calcd. for $C_{18}H_{20}O_2$: C, 80.54; H, 7.53. Found: C, 80.56, 80.54; H, 7.41, 7.20.

1,2-bis-(*p*-Acetoxyphenyl)-cyclohexane, m. p. 114.8–116.2° (micro), was prepared and purified just as described for the corresponding unsaturated compounds. *Anal.* Calcd. for $C_{22}H_{24}O_4$: C, 74.96; H, 6.88. Found: C, 74.88, 75.00; H, 6.81, 6.75.

Physiological Activity.—On subcutaneous injection into rats[22] of an oil solution, bis-(*p*-hydroxyphenyl)-cyclohexene, Ib, showed 300 I. U./mg.; bis-(*p*-hydroxyphenyl)-cyclohexene, IIb, 150 I. U./mg.; and 1,2-bis-(*p*-hydroxyphenyl)-cyclohexane, 200 I. U./mg. of estrogenic activity.

(22) We are grateful to Parke Davis and Company, Detroit, Michigan, for testing these compounds.

Summary

1,2-bis-(*p*-Hydroxyphenyl)-cyclohexane and two intermediate cyclohexenes together with their methyl and acetyl derivatives have been prepared. The phenols have moderate estrogenic activity. The hindrance to ring closure of 1,6-diarylhexamethylene derivatives has been indicated and the formation of a polypinacol discussed.

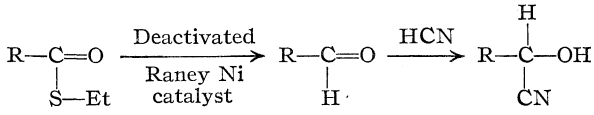
Steroid Acids and their Transformation Products. VI. Some New Aldehydes and Their Derived Cyanohydrins

BY A. VERN MCINTOSH, ANNA MAE SEARCY, ELIZABETH M. MEINZER AND ROBERT H. LEVIN

Preparation of steroid aldehydes by the desulfurization of thiol esters of 3β-hydroxy-5-cholenic acid, 3β-hydroxybisnor-5-cholenic acid and desoxycholic acid with acetone deactivated W-1[1] Raney nickel catalyst has been reported in previous papers of this series.[2] We have now prepared aldehydes starting with the thiol esters of nor-desoxycholic acid, lithocholic acid, 12α-hydroxycholanic acid, and 3α-hydroxy-11-cholenic acid, in yields of 39 to 78%. These aldehydes have been converted to cyanohydrins in excellent yields, completing the sequence of reactions



Ethyl 3α,12α-diacetoxynorthiolcholanate has been used as a model for the study of variations in the desulfurization procedure. The information gained from the experiments on the desulfurization of this compound is summarized very briefly below, excluding data which have been previously reported in this series.

A number of attempts were made to prepare 3α,12α-diacetoxynorcholan-23-al from the thiol ester without deactivation of the nickel. It was found that five parts of W-4 Raney nickel, or twenty parts of W-1 or commercial active Raney nickel, would reduce the thiol ester in alcohol quantitatively to 3α,12α-diacetoxynorcholan-23-ol at either room temperature or at reflux. When ten parts of W-1 Raney catalyst was heated with one part of ester in alcohol solution, a mixture of 3α,12α-diacetoxynorcholan-23-ol and ethyl 3α,12α-diacetoxynorthiolcholanate was obtained, besides about a 1% yield of aldehyde isolated as the semicarbazone.

Next, an experiment was devised to analyze the products obtained by use of Raney nickel which had been deactivated by reaction with the thiol ester. A mixture of Raney nickel and Celite filter-aid was placed in a chromatogram column and a solution of the thiol ester was filtered through and collected in portions. When 10 g. of W-4 Raney nickel was used, 2.1 g. of very pure 3α,12α-diacetoxynorcholan-23-ol was obtained in the first several fractions, then alcohol–ester mixtures followed. The time of contact of the solution in the column was about a minute, indicating a very rapid reaction at room temperature. Using W-1 Raney nickel, a little less than half the yield of alcohol given by the W-4 nickel was obtained, followed by some gummy mixtures, then the pure thiol ester. A very small amount of aldehyde semicarbazone was obtained on working up the mixtures, besides both alcohol and ester.

Without deactivation of the Raney nickel before the reaction with the thiol ester not more than 1% of aldehyde was obtained, isolated as the semicarbazone. Pretreatment of the Raney nickel in acetone under reflux proved by far the most suitable of the methods of deactivation tried.[2] When deactivated with acetone W-1 and W-4 Raney nickels, prepared in this Laboratory, and a commercial active Raney nickel[3] were used successfully as desulfurizing agents. A commercial pelleted Raney catalyst was found to be entirely inactive. Within experimental error the yields obtained when the commercial active Raney nickel was used were the same as were obtained with the W-1 catalyst. The W-4 catalyst gave consistently lower yields of aldehyde although different deactivation and reaction times were tried. However, for reduction of thiol esters to alcohols the W-4 nickel was best, giving nearly quantitative

yields in a few minutes at room temperature with alcohol or ether as the solvent.

In several less thorough series of experiments with thiol esters of other steroid acids the results were similar to those outlined above.

Commercial active Raney nickel[3] has been used in the desulfurization of most of the thiol esters reported in this series of articles,[2] in every case successfully. The conditions were those reported for ethyl 3α,12α-diacetoxynorthiolcholanate in the experimental section of this paper. Variation of the amount of catalyst used by about 20% in some cases slightly improved the yield. When the thiol ester is not sufficiently soluble in aqueous acetone[4] it may be added in dry acetone or dioxane.

Two examples of the separation of the aldehyde

(4) The water is not necessary for the reaction, but makes the reaction mixture easier to work up.

from the by-products of the reaction through formation of the sodium bisulfite complex[5] are given in the experimental section. Bisulfites of some steroid aldehydes, especially those containing free hydroxyl groups, tend to be both water soluble and relatively difficult to decompose with aqueous sodium carbonate. This is the case with 3α,12α-diacetoxynorcholan-23-al. When the complex is highly insoluble, *e. g.*, with 3α-formoxycholan-24-al, the aldehyde is more easily worked up.

The steroid aldehydes not previously reported are listed in Table II. Semicarbazones and 2,4-dinitrophenylhydrazones are included in the same table.

Cyanohydrins were prepared from the aldehydes described in this paper, as well as from several aldehydes reported previously.[2] These are listed in Table III. Three methods of preparation were investigated. In one the aldehyde bisulfite was suspended in excess 1.25% aqueous potassium cyanide and heated on the steam-bath five to ten minutes, then stirred for an hour and extracted with ether to obtain the product.[6] In a second the aldehyde was dissolved in a mixture of alcohol and acetic acid and treated with excess potassium cyanide at 0°.[7] The first method gave a good yield of cyanohydrin from 3β-acetoxy-5-cholen-24-al, but did not work well with 3α,12α-diacetoxynorcholan-23-al. Using the second method these results were reversed. In a third variation the aldehyde was dissolved in a small amount of dioxane and stirred with 40% aqueous sodium bisulfite, then excess solid potassium cyanide was added and the mixture was heated five minutes on the steam-bath, allowed to cool, and poured into water. This method gave good results with all the steroid aldehydes used, and is described in the experimental section.

3α,12α-Diacetoxynorcholan-23-al cyanohydrin and 3β-acetoxy-5-cholen-24-al cyanohydrin were found to be stable when chromatographed over alumina. This contrasts with the behavior of 20-ketosteroid cyanohydrins which Sarett[1] found to be dehydrated or split by passage over alumina columns.

A number of new steroid thiol esters prepared in the course of this research are listed in Table I.

Experimental[8]

Thiol Esters.—Six new thiol esters are listed in Table I. These were prepared by treating the corresponding steroid acid chlorides with ethyl mercaptan in the presence of pyridine,[9] with the exception of ethyl 3α-hydroxythiolcholanate which was obtained by passing ethyl 3α-formoxythiolcholanate[9] over Fisher adsorption alumina.[9,10]

12α-Formoxy- and 12α-acetoxycholanic acids, used as starting materials, have not been reported previously. These were prepared from 12α-hydroxycholanic acid[11] by formylation following Moffett's procedure[12] and by acetylation in acetic anhydride–acetic acid mixture using anhydrous perchloric acid as a catalyst.[13]

12α-Formoxycholanic acid was crystallized from 1–1 dioxane–formic acid mixture, m. p. 145–147°; $[\alpha]^{24}D$ +75° (203.7 mg. in 10 ml. of chloroform, *l*, 1 dm.; αD +1.53).

Anal. Calcd. for $C_{25}H_{40}O_4$: C, 74.22; H, 9.97. Found: C, 73.91; H, 10.08.

12α-Acetoxycholanic acid melted at 214–215° after crystallization from glacial acetic acid; $[\alpha]^{25}D$ + 71° (233.9 mg. in 10 ml. of chloroform, *l* 1 dm.; αD + 1.67°).

Anal. Calcd. for $C_{26}H_{42}O_4$: C, 74.60; H, 10.12. Found: C, 74.70; H, 10.16.

The Desulfurization Reaction.—The aldehydes prepared by treatment of steroid thiol esters with deactivated Raney nickel are listed in Table II. Two examples of the method are given below.

3α,12α-Diacetoxynorcholan-23-al.—A suspension of 30 g. of commercial active Raney nickel (washed alkali free) in 90 ml. of acetone was stirred and heated under reflux an hour, then 30 ml. of water was added, followed by a solution of 3.0 g. of ethyl 3α,12α-diacetoxynorthiolcholanate in 60 ml. of acetone. The reaction mixture was heated an hour, then was filtered hot. The Raney nickel was washed with hot acetone and the filtrate and washings concentrated *in vacuo* till a heavy precipitate formed. The precipitate (2.67 g.) was dissolved in a mixture of 45 ml. of ether and 40 ml. of methanol, then 100 ml. of 40% aqueous sodium bisulfite was added and the mixture was shaken for ten minutes. On standing three layers separated (some water may be required). The aldehyde bisulfite complex was richest in the middle layer. The two lower layers combined were brought to *p*H 10 by addition of saturated aqueous sodium carbonate and extracted with ether to give 1.76 g. of crystalline aldehyde. The ether layer, extracted a second time with bisulfite, gave 0.36 g. of aldehyde. A residue of 0.61 g. remained after evaporation of the ether. The crude aldehyde was crystallized from aqueous acetic acid to give 1.82 g. (69%) of 3α,12α-diacetoxynorcholan-23-al, m. p. 115–121°. After crystallization from Skellysolve "B" the aldehyde melted at 128–131°.

3α-Formoxycholan-24-al.—Desulfurization of 2.7 g. of ethyl 3α-formoxythiolcholanate with 30 g. of Raney nickel was carried out as described above. The acetone solution of the aldehyde was concentrated *in vacuo* to less than 30 ml. An oil separated. Water was added and the mixture was extracted with ether. The ether solution was concentrated to 30 ml., then 30 ml. of methanol and 75 ml. of saturated aqueous sodium bisulfite were added and the mixture was shaken ten minutes. A white precipitate formed, and was separated by centrifuging. The precipitate was shaken with ether and ice water and again centrifuged, then was suspended in 10% aqueous sodium carbonate under ether and agitated thirty minutes with a stream of nitrogen. The ether layer was washed with water, dried, and evaporated under nitrogen to give 1.50 g. (62%) of 3α-formoxycholan-24-al, m. p. 95–98°. After crystallization from Skellysolve "B," then aqueous acetic acid, the m. p. was 98–100°.

3α,12α-Diacetoxynorcholan-23-ol and Derivatives.—In the desulfurization of ethyl 3α,12α-diacetoxynorthiolcholanate the material remaining in the ether solution after extraction with aqueous sodium bisulfite was dissolved in benzene and passed over Fisher adsorption alumina. The fraction eluted with benzene consisted of ethyl 3α,12α-diacetoxynorthiolcholanate; a second fraction eluted with 2% methanol in benzene consisted of 3α,12α-diacetoxynorcholan-23-ol. When the yield of alde-

hyde was highest the proportion of the two by-products was roughly equal, but even when the Raney nickel–ester ratios were varied from 5–1 to 20–1 both products were present.

The identity of the alcohol was checked by preparation of 3α,12α-diacetoxynorcholan-23-ol by direct reduction of ethyl 3α,12α-diacetoxynorthiolcholanate with W-4 Raney nickel in alcohol at room temperature.[2] The two alcohols were identical. The compound was crystallized both from aqueous alcohol and chloroform–hexane mixture; m. p. 148.5–151°; $[\alpha]^{26}D$ + 110° (100.0 mg. in 10 ml. of $CHCl_3$, *l* 1 dm.; αD +1.10°).

Anal. Calcd. for $C_{27}H_{44}O_5$: C, 72.30; H, 9.89. Found: C, 72.49; H, 9.95.

3α,12α-Diacetoxynorcholan-23-ol refluxed for two hours in 1–1 pyridine–acetic anhydride gave a 70% yield of 3α,-12α,23-triacetoxynorcholane, m. p. 108–110° from aqueous acetic acid.

Anal. Calcd. for $C_{29}H_{46}O_6$: C, 70.98; H, 9.45. Found: C, 71.05; H, 9.38.

3α,12α-Diacetoxynorcholan-23-ol was allowed to stand seven hours in a 5% solution of potassium hydroxide in 80% alcohol at room temperature. The product was precipitated by the addition of water, chromatographed and crystallized from aqueous alcohol to give a 70% yield of 3α,23-dihydroxy-12-acetoxynorcholane, m. p. 181.5–182°.

Anal. Calcd. for $C_{25}H_{42}O_4$: C, 73.85; H, 10.41. Found: C, 73.89; H, 10.32.

Hydrolysis of 3α,12α-diacetoxynorcholan-23-ol in 10% alcoholic potassium hydroxide under reflux for three hours gave 83% of 3α,12α,23-trihydroxynorcholane, m. p. 194–200°. On recrystallization from ethanol the compound melted at 209.5–211°.

Anal. Calcd. for $C_{23}H_{40}O_3$: C, 75.77; H, 11.06. Found: C, 75.67; H, 10.96.

The dinitrophenylhydrazones and semicarbazones reported in Table II were prepared as described in previous papers in this series.[2]

Cyanohydrins.—The preparation of the steroid aldehyde cyanohydrins listed in Table III is illustrated by the method used for **3α-acetoxycholan-24-al cyanohydrin.** A mixture of 0.500 g. of 3α-acetoxycholan-24-al, 1.5 ml. of dioxane, and 3 ml. of saturated aqueous sodium bisulfite was stirred at room temperature for thirty minutes, then 0.5 g. of solid potassium cyanide was added and the mixture was heated for five minutes on the steam-bath, then allowed to cool to room temperature for thirty minutes, with occasional stirring. The reaction mixture was poured into 50 ml. of water giving a gummy precipitate. This was crystallized from aqueous acetic acid to give 0.476 g. (85%) of crystals melting at 148–152°. After several crystallizations from aqueous acetic acid the m. p. was 154.5–156°.

Summary

3α-Hydroxycholan-24-al, its 3-acetyl and 3-formyl derivatives, 12α-acetoxycholan-24-al, 3α,-12α-diacetoxynorcholan-23-al, 3α-acetoxy-11-cholen-24-al, and 3β-formoxy-5-cholen-24-al have been prepared by the desulfurization of the corresponding thiol esters with acetone deactivated Raney nickel catalyst.

The cyanohydrins have been obtained by treating these aldehydes with sodium bisulfite and potassium cyanide in dioxane–water.

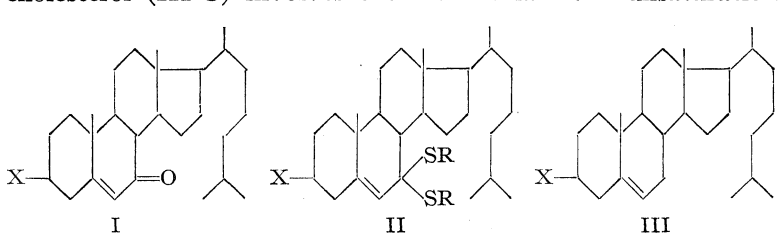
Addition of Mercaptans to Unsaturated Steroid Ketones

BY JACK W. RALLS,[1] R. M. DODSON[2] AND BYRON RIEGEL

Cholesterol that has been labeled with isotopic carbon in the nucleus would be useful for many biological investigations. A method for the introduction of the carbon isotopes into ring B of cholesterol (III-C) involves the intermediate 7-ketocholesterol (I-C). The final step would be the reduction of the 7-keto group to give the labelled cholesterol. This critical step was studied in some detail. Classical methods of reduction require strongly acid or basic conditions, which will cause the elimination of the group at the 3-position[3] with the formation of a second conjugated ethylenic linkage. Reduction of a carbonyl group without the simultaneous reduction of the α,β-unsaturation limits the methods that may be employed. The Wolff–Kishner reduction is unsatisfactory.



I II III

X A AcO—

C HO—

Recently Hauptmann[4] has prepared 4-cholestene from cholestenone by desulfurizing the dibenzyl mercaptole derivative. This method has also been used for the reduction of saturated steroid ketones[5] where the carbonyl group occupies the 3, 7, 12 and 17 positions.

The mercaptoles of 7-ketocholesteryl acetate (II-A) do not form readily. The best yield (40%) was obtained using ethanedithiol in

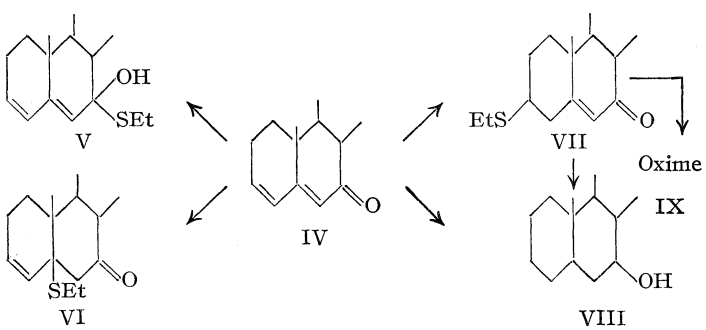
absolute ether with dry hydrogen chloride as the catalyst. The ethanedithiol derivative, melting at 188.2–188.8°, was reduced to cholesteryl acetate (III-A) which was isolated as the dibromide in a 40% yield. Because of the low yields on these final steps, this method did not appear feasible for the preparation of labelled cholesterol.[6]

However, when 7-ketocholesteryl acetate (I-A) was treated with ethyl mercaptan in an acetic–hydrochloric acid mixture, a good yield of a crystalline solid melting at 152–153° with a specific rotation of −106° was obtained. This compound was not the desired mercaptole. The elucidation of its structure and the course of the reaction established a new 1,6-addition.

The analytical data indicated that the substance resulted from the addition of one mole of ethyl mercaptan to 3,5-cholestadien-7-one (IV). Such a product could form if the 7-ketocholesteryl acetate had lost the elements of acetic acid to give 3,5-cholestadien-7-one which then added ethyl mercaptan. When 3,5-cholestadien-7-one was treated with ethyl mercaptan, a product identical with that from 7-ketocholesteryl acetate was obtained. The most likely compounds that would be formed by the addition of ethyl mercaptan to 3,5-cholestadien-7-one are V, VI and VII.

The presence of a carbonyl group was established when it was found that the adduct formed an oxime (IX). The addition product was unstable when heated with dilute methanolic potassium hydroxide solution. Under these conditions the adduct gave ethyl mercaptan and 3,5-cholestadien-7-one. This reversal of addition in the presence of bases is characteristic of compounds formed by 1,4-addition of mercaptans to α,β-unsaturated ketones.[7] By treating the addition product with Raney nickel in dioxane–water at 120° for twenty-four hours, complete removal of sulfur was accomplished and the product isolated was identified as 7-cholestanol (VIII). The formation of 7-cholestanol was found to be compatible with structures VI and VII when it was shown that 3,5-cholestadien-7-one gave a good yield of 7-cholestanol when reduced under the desulfuration conditions.



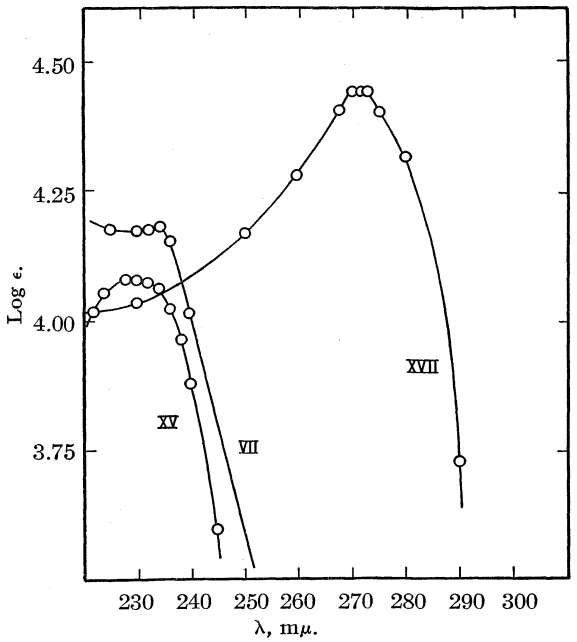


Fig. 1.—Ultraviolet absorption spectra of 3-ethylthio-5-cholesten-7-one (VII), 3-ethylsulfonyl-5-cholesten-7-one (XV), and 3-ethylthio-3,5-cholestadiene (XVII). All taken in dry ether.

An assignment of structure was made on the basis of the absorption spectrum of the adduct shown in Fig. 1. The spectrum indicates that structure VII is correct, since it is very similar to the spectra of 7-ketocholesteryl acetate and other α,β-unsaturated steroid ketones.[8] This compound, 3-ethylthio-5-cholesten-7-one (VII), would result from a 1,6-addition of ethyl mercaptan to 3,5-cholestadien-7-one. Since this type of addition has not been observed previously, a more rigorous structure proof was required.

The adduct (VII) was oxidized to a sulfone (XV) using excess hydrogen peroxide in dioxane at 100°. This compound melted at 190.0–192.0° and had a specific rotation of −64°. It would seem reasonable to expect that the sulfone (XV) would show absorption characteristics similar to VII. The absorption spectra are given in Fig. 1. The spectra are similar but the evidence was not as conclusive as we had hoped. Recently Fehnel and Carmack[9] have given an excellent presentation of the ultraviolet absorption spectra of organic sulfur compounds. However, they did not report a sulfur compound where the sulfur is attached to a bridgehead carbon atom.

(6) Further work on these reactions was terminated when we learned from Dr. Seymour Lieberman that a similar study is in progress at the Sloan-Kettering Institute for Cancer Research.

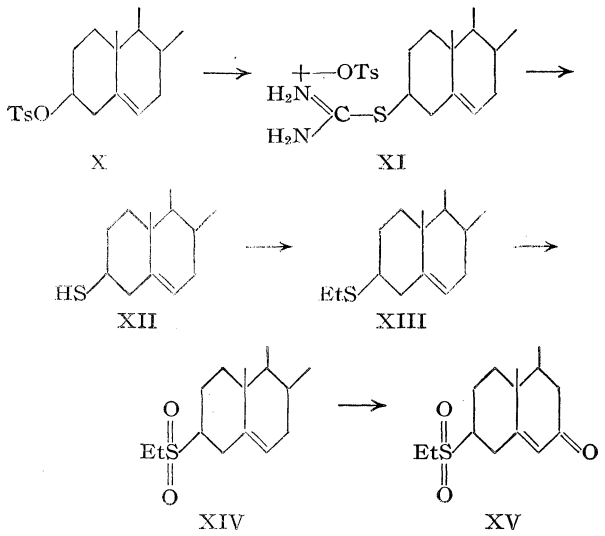
To place the structure proof on a firm chemical basis, an independent synthesis of XV was carried out. The structures given in X to XV outline the method employed. By a modification of the



method of King, Dodson and Subluskey,[10] 3β-mercapto-5-cholestene (XII) was prepared. There seems to be little possible doubt that the structure of "thiocholesterol" is 3β-mercapto-5-cholestene. It has been prepared by several routes,[11–13] all of which yield the same isomer. The replacement reactions of 3β-toluenesulfonoxy-5-cholestene (X) have been studied extensively. It has been established that such replacements can lead to two isomeric products depending on the reaction conditions. Under basic (or buffered) conditions the product is predominantly the *i*-structure. Acid conditions favor replacement without inversion. In the reaction of 3β-toluenesulfonoxy-5 cholestene with thiocyanate[12] and thiourea[10] the authors have presented ample evidence that the products do not have the *i*-structure. These facts are the basis for the configurations assigned to the compounds reported in this paper. Additional evidence for these designations will be cited.

Alkyl cholesteryl sulfides are relatively unknown. The only such compound reported in the literature is the 3β-benzylthio-5-cholestene prepared by Wagner–Jauregg and Lennartz.[12] We have found that 3β-sodiothio-5-cholestene can be alkylated in excellent yield by ethyl bromide to give 3β-ethylthio-5-cholestene (XIII). This method appears to be a general one but we have not explored other possibilities. Compound XIII was prepared previously in this laboratory by the acid catalyzed rearrangement of *i*-cholesteryl methyl ether in a mixture of ethyl mercaptan and benzene.[14] Since this rearrangement is stereospecific,[15] the assignment of configuration of all the compounds reported in this paper is very probably correct.

The oxidation of 3β-ethylthio-5-cholestene (XIII) to the sulfone (XIV) was accomplished smoothly to give a compound melting at 150.8–151.6°. The sulfone when subjected to the allylic oxidation procedure[16] gave the 3β-ethylsulfonyl-5-cholesten-7-one (XV), m. p. 190.2–192.0°, $[\alpha]_D$ −64°. This material was identical with the sulfone obtained from the oxidation of the adduct formed from the addition of ethyl mercaptan to 3,5-cholestadien-7-one. Therefore, the 1,6-addition of an alkyl mercaptan to a multiple conjugated system has been established.

This type of 1,6-addition has not been observed previously. The addition of mercaptans to cinnamylideneacetophenone is stated to be a 1,4-addition,[17] although no proof of the structure of the adduct is presented. Since cinnamylideneacetophenone undergoes only 1,4-addition with a variety of reagents,[18] there is little question that the addition of mercaptans is also of this type. The 1,6-addition of ethyl mercaptan to 3,5-cholestadien-7-one is clearly a case of steric factors influencing the mode of addition. A 1,4-addition would necessitate the formation of an angular alkylthio group. Apparently the energetics of such a formation prohibit a 1,4-addition under mild conditions. This interpretation is consistent with the observation that cholestenone will not undergo a 1,4-addition of alkyl mercaptans.[4]

The generality of the reaction of 3-substituted 7-ketosteroids with ethyl mercaptan in an acetic–hydrochloric acid mixture was extended when it was found that 3β-chloro-5-cholesten-7-one (I-B) gave VII in good yield. These results suggest that this reaction may be used as a test for 7-ketosteroids which are oxygenated or halogenated in the 3-position. The applicability of this technique to mixtures has not been investigated. It has been found that cholesteryl acetate is unaffected by the reaction conditions employed. When *i*-cholestanone is treated under these conditions, only 3β-chloro-6-cholestanone results. 3-Cholestanone gives the diethyl mercaptole when the reaction time is extended. These data indicate that only the 3-ketosteroids form diethyl mercaptoles under mild conditions.

The smooth 1,6-addition of ethyl mercaptan under acid conditions was somewhat surprising. The analogous 1,4-addition of mercaptans to unsaturated ketones proceeds best when base catalyzed.[7a,19] When ethyl mercaptan was allowed to

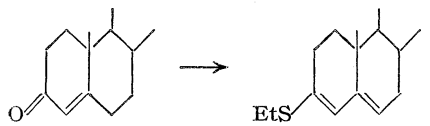
react with 3,5-cholestadien-7-one under basic conditions, 3-ethylthio-5-cholesten-7-one was obtained but the yield was poor. Hauptmann[4] has reported that cholestenone (XVI) does not add benzyl mercaptan under basic conditions. We have found that ethyl mercaptan does not add to cholestenone under the same basic conditions which lead to 3-ethylthio-5-cholesten-7-one from the addition of ethyl mercaptan to 3,5-cholestadiene-7-one.

Under the acid conditions generally employed in this work, cholestenone (XVI) combined with ethyl mercaptan to give a good yield of the sub-



XVI XVII

stance previously reported by Bernstein and Dorfman.[5a,20] They tentatively assigned structure XVII or 3-ethylthio-3,5-cholestadiene to this material. Evidence that this structure was the correct one was obtained from the rotation and the absorption spectrum. The specific rotation of −129° was that expected of a 3-substituted 3,5-cholestadiene.[21] The absorption spectrum is reproduced in Fig. 1. The auxochromic effect of the –SEt group is apparent as the maximum of 238 mμ shown by 3-acetoxy-3,5-cholestadiene[3a] is shifted toward the higher wave lengths to a degree consistent with the effect in simpler compounds.[22]

Acknowledgment.—The authors would like to express their appreciation to Professor Irving M. Klotz for helpful discussions in the determination and interpretation of the absorption spectra.

Experimental[23]

5,6-Dibromocholestanyl Acetate from 7-Ketocholesteryl Acetate.—A solution of 1.0 g. of 7-ketocholesteryl acetate[16] and 2.0 g. of ethanedithiol (b. p. 59° (30 mm.)) in 20 ml. of dry ether was prepared. A slow stream of hydrogen chloride gas was passed into the solution. A crystalline solid started to precipitate after twenty minutes. More dry ether was added to maintain a constant volume, and the addition of hydrogen chloride was continued until a red color started to develop (thirty minutes). The crystalline solid was removed by filtration and washed with cold methanol. The yield of material melting at 188.2–188.8° was 0.48 g. (40%). This compound could be crystallized from methanol without changing the m.p.; it gave a positive test for sulfur and a negative test for chlorine.

The desulfuration of this derivative was carried out in two experiments. A. A solution of 0.30 g. of mercaptole was prepared in 50 ml. of a two-year old Raney nickel suspension containing 9.6 g. of the catalyst. After the addition of 5 ml. of water, the mixture was heated under reflux for nine hours. The nickel components were removed by filtration and washed with ether. Removal of the solvents *in vacuo* gave a mixture of solid and gum. The solid was taken up in 20 ml. of 95% ethanol; the gum (0.037 g.) was insoluble. Diluting the ethanolic solution and cooling gave 0.065 g. of an amorphous solid which melted over a wide range (109–122°). It was thought that alcoholysis of the acetyl group had taken place. The very poor yield of organic material indicated that considerable adsorption of the steroid fraction to the catalyst had taken place. With these preliminary results available a second experiment was run.

B. A mixture of 0.178 g. of the ethanedithiol addition product, 3.0 g. of freshly prepared Raney nickel catalyst,[24] 25 ml. of purified dioxane[25] and 5 ml. of water was heated under reflux for eight hours. The catalyst was removed by filtration and washed with two portions of hot dioxane. Removal of the solvents *in vacuo* gave 0.111 g. of amorphous solid which melted at 75–95°, gave a negative test for sulfur and a positive Liebermann–Burchard reaction. A solution of 0.074 g. of this material in 5 ml. of ether–acetic acid (2:3) was treated with a dilute solution of bromine in acetic acid until a slight excess of bromine was present. Removal of the ether by evaporation, addition of a few drops of water, and cooling gave 0.052 g. of crystalline solid melting at 112–114°. The mixed m. p. with an authentic sample of cholesteryl acetate dibromide was 112–114°.

3-Ethylthio-5-cholesten-7-one (VII).—A. To a solution of 1.0 g. of 7-ketocholesteryl acetate in 25 ml. of glacial acetic acid there was added 2.0 ml. of concentrated hydrochloric acid. The steroid was precipitated. Complete solution was effected by adding 10 ml. of acetic acid and warming slightly. The solution was cooled to room temperature and 5.0 ml. of ethyl mercaptan was added. A red color developed immediately and after five minutes a crystalline solid began to deposit. After standing for thirty minutes, the solid was removed by filtration and washed with cold methanol. The dried crystalline solid weighed 0.73 g. and melted at 148–149°. Cooling the filtrate and washings gave an additional 0.10 g. melting at 146–148°. Total yield was 0.83 g. (83%). Crystallization from acetone–methanol gave long needles which melted at 152.2–152.8°; $[\alpha]^{25.4}D$ −105.8° (44.6 mg. made up to 2 ml. with $CHCl_3$, $\alpha = -4.73°$, l, 2 dm.); $\lambda_{max.} = 234$ mμ ($\log \epsilon = 4.19$); solvent, dry ether.

Anal. Calcd. for $C_{29}H_{48}OS$: C, 78.32; H, 10.88; S, 7.21. Found: C, 78.25; H, 11.02; S, 7.00.

B. A solution of 0.50 g. of 3,5-cholestadien-7-one[3a] in 18 ml. of glacial acetic acid and 1.0 ml. of concentrated hydrochloric acid was treated with 2.5 ml. of ethyl mercaptan. The color immediately changed to red-orange. After five minutes a solid formed. The mixture was cooled for thirty-five minutes in an ice-bath. The solid was removed by filtration (after the solvent had melted) and washed with cold methanol. The air dried material weighed 0.53 g. (91%) and melted at 148–150°. There was no depression in melting point when this material was mixed with the product from A.

C. The preparation starting with 3β-chloro-5-cholesten-7-one[3b] was carried out as above. From 1.0 g. of the steroid there was obtained 0.95 g. of crystalline solid melting at 144–149°. This material gave a negative Beilstein test for halogen and was not depressed in melting point when mixed with the products described above. Recrystallization from methanol–acetone gave 0.84 g. (80%) melting at 147–149°.

D. A solution of 0.50 g. of 3,5-cholestadien-7-one in 20 ml. of pyridine was treated with 5.0 ml. of ethyl mercaptan. After two hours at room temperature 0.20 g. of

(24) The catalyst was prepared according to the directions of R. Mozingo, *Org. Syn.*, **21**, 15 (1941), except after the addition of the alloy the mixture was allowed to stand at 25–30° for fourteen to sixteen hours before washing. The alkali-free catalyst was dried by azeotropic distillation with purified dioxane.

(25) L. F. Fieser, "Experiments in Organic Chemistry," 2nd ed., D. C. Heath & Co., New York, N. Y., 1941, p. 368.

commercial sodium methoxide powder was added. After an additional two and one-half hours of standing, the orange mixture was poured onto cracked ice. The orange solid was taken up in ether and the ether layer washed with three portions of water. The ether layer was dried over anhydrous sodium sulfate and the ether removed. The yellow gummy solid was dissolved in 40 ml. of methanol–acetone (3:1). On cooling, a deposit of small crystals formed; these were collected and washed with cold methanol. The yield was 0.20 g. (36%), m. p. 141–146°. The filtrate and washings gave some additional material on concentration and cooling. This melted at 95–105° and was apparently a mixture of starting material and adduct.

Desulfuration of 3-Ethylthio-5-cholesten-7-one.—**A.** A mixture of 0.50 g. of 3-ethylthio-5-cholesten-7-one, 3.0 g. of Raney nickel catalyst, 40 ml. of purified dioxane, and 2 ml. of water was heated under reflux for three hours. The catalyst was removed by filtration and washed with warm dioxane. Removal of the solvents *in vacuo* gave 0.498 g. of white solid which melted at 106–135°. This material was dissolved in 125 ml. of boiling methanol. After standing for twenty-four hours at room temperature 0.24 g. of crystalline solid (m. p. 148–149°) had deposited. After standing at −10° for twenty-four hours, the filtrate deposited 0.050 g. of crystals melting at 142–145°. The filtrate was evaporated to a volume of 30 ml. When cooling to room temperature produced no precipitate, the solution was heated to boiling and water added to the point of turbidity. Cooling the solution gave 0.18 g. of white solid which melted at 100–108°. Crystallization of this material from methanol–butanone gave 0.10 g. of white solid which melted at 104–110°. Later observations indicated the more soluble fraction consisted largely of 7-cholestanol (m. p. 119–120°) mixed with 3-ethylthio-5-cholesten-7-one. On the basis of the recovery of 60% of relatively pure 3-ethylthio-5-cholesten-7-one, it was estimated that only about 25% desulfuration had taken place under these conditions.

B. A mixture of 0.500 g. of 3-ethylthio-5-cholesten-7-one, 5 g. of Raney nickel catalyst, 35 ml. of purified dioxane, and 1.0 ml. of water was sealed in an 100-ml. Carius tube. The mixture was heated in a bomb furnace at 120 ± 1° for twenty-four hours. There was a slight positive pressure on opening the tube. The nickel components were removed by filtration and the solvent removed *in vacuo*. A white solid remained. This was taken up in ether, the ether solution dried over anhydrous sodium sulfate and the ether removed. The crystalline solid which remained weighed 0.424 g. (96.5%) and melted at 109–112°. This material was sulfur free. Recrystallization of 0.40 g. from ethanol gave 0.227 g. (55%) of needles melting at 119–120° which had an $[\alpha]^{26}D + 38.1°$. This substance gave a negative Liebermann-Burchard reaction. These constants were somewhat different from those reported by Heilbron and co-workers[26] who give the melting point of 7-cholestanol as 119° and the rotation as +50.6°. The identity was proven by oxidation of the alcohol to 7-cholestanone following the directions of Marker, *et al.*[3b] From 0.20 g. of the alcohol there was obtained 0.16 g. of shiny plates which melted at 116.2–117.0°. This ketone was reduced to 7-cholestanol by the method of Heilbron, *et al.* The material was difficult to purify and after several crystallizations the needles obtained melted at 116.2–116.8°. This substance showed a marked depression in melting point when mixed with the starting ketone. A mixture with the alcohol (m. p. 119–120°) melted at 116.4–118.8°.

Stability of 3-Ethylthio-5-cholesten-7-one to Acid Conditions.—**A.** A mixture of 0.20 g. of 3-ethylthio-5-cholesten-7-one, 30 ml. of 95% ethanol, and five drops of concentrated hydrochloric acid was heated under reflux for three hours. When cooled the solution deposited long needles (0.20 g.) which melted at 150.8–151.8°. A mixed melting point with the starting material gave no depression.

(26) I. Heilbron, W. Shaw and F. Spring, *Rec. trav. chim.*, **57**, 529 (1938).

B. A mixture of 0.20 g. of 3-ethylthio-5-cholesten-7-one, 15 ml. of 95% ethanol and 5 ml. of concentrated hydrochloric acid was heated under reflux for six hours. The mixture had a faint red tinge and a mercaptan odor. After cooling 0.16 g. (80%) of starting material was recovered.

3-Ethylthio-5-cholesten-7-one Oxime (IX).—A mixture of 0.335 g. of 3-ethylthio-5-cholesten-7-one, 5 ml. of pyridine, 5 ml. of dry ethanol, and 0.50 g. of hydroxylamine hydrochloride was heated under reflux. Complete solution was effected when the mixture reached reflux temperature. After an eight-hour reflux period, considerable solid had formed. The mixture was cooled and the solid removed by filtration. This was washed with water and cold methanol and crystallized from dioxane–water to give 0.32 g. (92%) of crystalline solid which melted at 146–147°. The mixed melting point with the starting material was 119–129°. Recrystallization from 2-propanol gave micro needles which melted at 147.2–148.0°. The oxime gave a positive test for sulfur.

Anal. Calcd. for $C_{29}H_{49}OSN$: N, 3.05. Found: N, 3.22.

Reversal of Mercaptan Addition by Base.—A suspension of 0.40 g. of 3-ethylthio-5-cholesten-7-one in a solution of 0.50 g. of potassium hydroxide in 25 ml. of methanol was prepared. After standing for fourteen hours at room temperature, the mixture was heated under reflux. Complete solution was effected after one and one-half hours. The orange solution smelled strongly of ethyl mercaptan. After an additional one and one-half hours of heating, the solution was poured onto cracked ice and the organic material extracted with ether. The ether layer, after washing, drying, and evaporation yielded an orange solid. This substance was crystallized from methanol to give as a first crop (0.203 g.) of yellow crystalline material which melted at 105–107°. The mixed melting point with 3,5-cholestadien-7-one was 105–109°. The reversal was not complete under these conditions. The mixture was proven to be composed of the mercaptan adduct and 3,5-cholestadien-7-one when it was found that 0.190 g. of the mixture gave 0.189 g. of pure 3-ethylthio-5-cholesten-7-one melting at 150–151.5°. A second crop of 0.056 g. melting at 100–104° was obtained but was not investigated further.

7-Cholestanol.—The reduction of 3,5-cholestadien-7-one was carried out as described for 3-ethylthio-5-cholesten-7-one. The crude alcohol was recrystallized from ethanol and gave 0.30 g. (60%) of crystalline solid which melted at 119.2–120.2°. When the filtrate was evaporated and the residue crystallized from acetone, an additional 0.145 g. (29%) was obtained. This material melted at 115.5–117.0°. When mixed with the first fraction, the melting point was 116.0–117.5°. The total yield was 0.445 g. (89%).

Cholesterylisothiouronium *p*-Toluenesulfonate (XI).[10]—A suspension was prepared from 10.8 g. (0.02 mole) of 3β-*p*-toluenesulfonoxy-5-cholestene, 8.0 g. (0.105 mole) of thiourea and 140 ml. of 99% 2-propanol. The mixture was heated under reflux for four hours. Water (50 ml.) was added to the clear boiling solution at a rate which maintained ebullition. The resulting suspension was cooled to room temperature and then allowed to stand overnight in the cold room. The crystalline product was removed by filtration and washed with two 25-ml. portions of acetone (25°). The solid was dried for one hour in the air and for four hours *in vacuo* over phosphorus pentoxide at room temperature (30°). The yield of material melting at 227.5–229.0° was 11.8 g. (96%).

3β-Mercapto-5-cholestene (XII) was prepared according to the directions of King, Dodson and Subluskey.[10] From 9.84 g. of cholesterylisothiouronium *p*-toluenesulfonate there was obtained 6.10 g. (95%) of 3β-mercapto-5-cholestene, m. p. 88–95°. This material gave satisfactory results in the following preparation.

3β-Ethylthio-5-cholestene (XIII).—A solution of sodium ethoxide was prepared from 1.0 g. of sodium metal dissolved in 50 ml. of absolute ethanol. To this solution

there was added 4.10 g. (0.010 mole) of 3β-mercapto-5-cholestene. The mixture was heated to reflux temperature and the resulting solution cooled. Cold ethyl bromide (20 ml., 0.126 mole) was added and the resulting mixture heated under reflux for two hours. The mixture was poured onto 500 g. of ice and the resulting suspension extracted with ether. The ether layer was washed with water, 1.2 *N* hydrochloric acid, water, 5% sodium bicarbonate, and water. The dried ether layer was evaporated and the solid crystallized from acetone–ethyl acetate (4:1). The yield of material melting at 129.8–131.6° was 4.30 g. (98%). Recrystallization from acetone gave an analytical sample, m. p. 131.6–132.6°, $[\alpha]^{30}D$ −30.1° (0.0369 g. made up to 2.0 ml. with chloroform, αD −1.11°).

Anal. Calcd. for $C_{29}H_{50}S$: C, 80.85; H, 11.70. Found: C, 81.08; H, 11.76.

3β-Ethylsulfonyl-5-cholestene (XIV).—A solution of 2.15 g. (0.005 mole) of 3β-ethylthio-5-cholestene in 50 ml. of purified dioxane was prepared. The solution was cooled and 5.0 ml. of 30% hydrogen peroxide was added. The mixture was allowed to stand at room temperature for twenty-three hours and then heated under reflux for eight hours after the addition of 3.0 ml. of 30% hydrogen peroxide. The resulting solution was cooled and poured onto cracked ice. The suspension was extracted with two 200-ml. portions of ether. The ether layer was washed with 5% sodium bicarbonate and then with water. The solid resulting from the removal of the ether was dissolved in 110 ml. of 95% ethanol. Cooling produced a crystalline solid which melted at 149–152°. The yield was 1.4 g. (60%). Recrystallization from acetone gave an analytical sample, m. p. 150.8–151.6°, $[\alpha]^{33}D$ −18.9° (0.0456 g. made up to 2.0 ml. with chloroform, α −0.86).

Anal. Calcd. for $C_{29}H_{50}SO_2$: C, 75.27; H, 10.91. Found: C, 75.68; H, 10.98.

3β-Ethylsulfonyl-5-cholesten-7-one (XV): **A. Oxidation of the Adduct.**—A solution of 0.37 g. (0.864 mmole) of the adduct in 39 ml. of purified dioxane was prepared. After the addition of 3.0 ml. of 30% hydrogen peroxide, the mixture was allowed to stand for twenty-three hours at room temperature and then heated under reflux for nine hours. The resulting solution was poured onto ice. After standing overnight, the solid was removed by filtration. Crystallization from acetone–methanol gave 0.21 g. (52%) of solid melting at 186.5–188.5°. Another crystallization gave the analytical sample m. p. 190.0–192.0°, $[\alpha]^{27}D$ −64.2° (0.0340 g. made up to 2.0 ml. with chloroform, α −2.18°).

Anal. Calcd. for $C_{29}H_{48}SO_3$: C, 73.06; H, 10.15. Found: C, 72.91; H, 10.05, $\lambda_{max.}$ = 229 mμ, log $\epsilon_{max.}$ = 4.08 (in dry ether).

B. Oxidation of 3β-Ethylsulfonyl-5-cholestene.—A suspension of 1.00 g. (2.2 mmole) of 3β-ethylsulfonyl-5-cholestene in 15 ml. of glacial acetic acid was stirred vigorously and maintained at 55–58° while a solution of 0.75 g. of chromic oxide in 0.5 ml. of water and 1.5 ml. of glacial acetic acid was added over a period of forty minutes. The mixture was stirred and heated for an additional three hours. After addition of ethanol (1 ml.) to destroy the excess oxidizing agent, the warm solution was carefully diluted with 10 ml. of water. After standing overnight at 5°, the suspension was filtered and the solid washed with small portions of cold methanol until it was nearly colorless. The slightly grey solid was crystallized from acetone–methanol (1:2) to yield 0.25 g. (24%) of solid melting at 190.2–192.0°. The mixed melting point with the product from A gave no depression. The rotation was $[\alpha]^{33}D$ −64.2° (0.0385 g. made up to 2.0 ml. with chloroform, α −2.47°).

Reaction of Other Steroids with Ethyl Mercaptan in Acetic Acid–Hydrochloric Acid: A. Cholesteryl Acetate.—One gram of cholesteryl acetate was dissolved in a mixture of 35 ml. of acetic acid and 2 ml. of concentrated hydrochloric acid. Then 5 ml. of ethyl mercaptan was added to the cooled solution and the mixture allowed to stand for two hours at 0°. The solid was removed by filtration and washed with cold methanol. The dry solid (0.90 g., 90%) melted at 113–115°. Mixed melting point with starting material was 114–115°.

B. *i*-Cholestanone (3β-Chloro-6-cholestanone).—A solution of 0.105 g. of *i*-cholestanone[27] in 10 ml. of acetic acid and 0.5 ml. of ethyl mercaptan was prepared. Twenty drops of concentrated hydrochloric acid were added to the cold solution. After fifteen minutes, 5 ml. of methanol was added and the solution cooled. When no solid resulted from this treatment, water was carefully added. This resulted in the separation of a white solid. The mixture was cooled for two hours and the solid was removed by filtration and washed with cold methanol. After air drying, the solid melted at 127–129°. The mixed m. p. with 3β-chloro-6-cholestanone[15] was 127–128°. The yield was 0.090 g. (80%).

C. 3-Cholestanone (3-Cholestanone Diethyl Mercaptole).—A mixture of 0.49 g. of 3-cholestanone, 18 ml. of acetic acid, and 1.0 ml. of ethyl mercaptan was prepared. Addition of five drops of concentrated hydrochloric acid gave a cloudy suspension. Cooling for forty minutes gave a solid mixture. Addition of 15 ml. of methanol caused the solid to change to an oil. Cooling for an hour and scratching produced a solid. This was removed by filtration and washed with cold methanol. The air dried solid weighed 0.56 g. (93%) and melted at 76–78°. This was 3-cholestanone diethyl mercaptole.[5a]

D. Cholestenone (3-Ethylthio-3,5-cholestadiene).—Ten drops of concentrated hydrochloric acid was added to a mixture of 20 ml. of acetic acid, 2 ml. of ethyl mercaptan, and 1.10 g. of cholestenone. The solution soon became cloudy. Scratching and cooling gave a white solid. The mixture was cooled for one-half hour. The solid was removed by filtration and washed with three 5-ml. portions of cold methanol. The finely divided solid weighed 1.08 g. (88%) and melted at 94–95°. Recrystallization from 35 ml. of acetone gave 0.95 g. (78%) of crystalline solid melting at 97.4–98.2°. The analysis of the material corresponded to that reported by Bernstein and Dorfman[5a] when calculated on the basis of the correct formula, $C_{29}H_{48}S$; $[\alpha]^{26.4}D$ −128.8° (69.3 mg. made up to 4.93 ml. with $CHCl_3$, α −4.93°, *l*, 2 dm.); $\lambda_{max.}$ = 272 mμ (log ε = 4.41), taken in dry ether.

Summary

1. The keto group of 7-ketocholesteryl acetate has been reduced by converting to the ethylene mercaptole and desulfurizing.

2. In an acetic–hydrochloric acid solution, 7-ketocholesteryl acetate, 7-ketocholesteryl chloride and 3,5-cholestadien-7-one react with ethyl mercaptan to give 3-ethylthio-5-cholesten-7-one. 3,5-Cholestadien-7-one is the common intermediate for this reaction.

3. The reaction of ethyl mercaptan with 3,5-cholestadien-7-one is a new 1,6 addition.

4. The structure of 3-ethylthio-5-cholesten-7-one was established by conversion to 3-ethylsulfonyl-5-cholesten-7-one which was prepared by an independent synthesis.

5. Improved procedures are described for the preparation of 7-cholestanol, diethyl mercaptole of 3-cholestanone and for 3-ethylthio-3,5-cholestadiene (from cholestenone).

A Spectrophotometric Study of Ferric Thiocyanate in Isodielectric Mixtures of Various Aqueous–non-Aqueous Solvent Pairs[1]

BY SIDNEY BALDWIN AND W. J. SVIRBELY

Woods and Mellon[2] recently made a spectrophotometric study of ferric thiocyanate in acetone–water solutions at various volume concentrations. Their work showed that as the volume per cent. of acetone in the solution was increased, the corresponding absorption curve, plotted as per cent. transmittancy *versus* wave length, had a consistently deeper minimum. This decrease in transmittancy with increasing concentration of acetone was attributed to the lower dielectric constant of the solution.

The present study was undertaken in order to clarify the role of the dielectric constant of the medium in the ferric thiocyanate system. It would seem that if the intensity of color is solely a function of the dielectric constant of the solvent, with the other variables, such as concentrations and temperature kept constant, the absorption curves for this system should be identical in all isodielectric mixtures, regardless of the solvent pair. Accordingly, the absorption spectra of ferric thiocyanate was investigated at various fixed dielectric constants in the following solvent pairs: acetone–water, methanol–water, ethanol–water, isopropyl alcohol–water, ethylene glycol–water and dioxane–water.

Materials

Nitric Acid.—J. T. Baker Analyzed nitric acid was distilled from an all-glass apparatus, collecting the middle 50%. The distillate was allowed to remain twenty-four to thirty-six hours under a hood to remove dissolved nitrogen dioxide. A nitric acid solution, 6.04 *N*, was prepared from the distillate. The standardization was with sodium tetraborate decahydrate, using methyl red as an indicator; d^{25}_4 1.1933. The solution was stored in a dark, cool place.

Ferric Nitrate.—J. T. Baker Analyzed (99.8% pure) iron wire (0.1 g.) was dissolved in about 10 ml. of the 6.04 *N* acid. Hydrogen peroxide (30%) was added to insure complete oxidation to ferric ion. The solution was evaporated to dryness on a steam-bath. The residue was dissolved in exactly 10 ml. of 6.04 *N* nitric acid and diluted to 1 liter. A 100-ml. aliquot portion of this solution was diluted to 250 ml., giving a solution containing 40 p. p. m. of iron in 0.024 *N* nitric acid. The solution was stored in a cool, dark place; d^{25}_4 1.0015.

Ammonium Thiocyanate.—J. T. Baker Analyzed salt was used without further purification: 100 g. of ammonium thiocyanate was dissolved in 400 g. of water. The resulting solution contained 20% of ammonium thiocyanate by weight; d^{25}_4 1.0452. It was stored in a cool, dark place.

Methyl Alcohol.—A liter of Mallinckrodt acetone-free methanol was refluxed[3] over 15–20 g. of magnesium turnings for three hours. The methanol was then fractionally distilled through a 50-in. Fenske column. The middle 500-ml. portion was collected: $n^{20}D$ (obsd.) 1.3285, $n^{20}D$ (lit.) 1.3288.

Ethyl Alcohol.—A liter of U. S. Industrial commercial absolute alcohol was refluxed[4] over 7 g. of sodium and 27.5 g. of diethyl phthalate for one hour. It was then fractionally distilled, collecting the middle 500-ml. portion, $n^{20}D$ (obsd.) 1.3610, $n^{20.5}D$ (lit.) 1.3610.

Acetone.—About 2.5 liters of J. T. Baker Analyzed acetone was treated[5] with 100 ml. of 85% phosphoric acid. The acetone was distilled through an 18-in. Vigreux column, collecting the middle 2-liter portion. This portion was dried for forty-eight hours over anhydrous potassium carbonate and then fractionally distilled, collecting the middle 1500-ml portion: $n^{20}D$(obsd.) 1.3586; $n^{20}D$ (lit.) 1.3591.

Dioxane.—About 2 liters of U. S. Carbon and Carbide dioxane was purified by a standard procedure.[4] The middle 1-liter portion was collected after fractionation: $n^{20}D$(obsd.) 1.4215; $n^{20}D$(lit.) 1.4221.

Isopropyl Alcohol.—About 2 liters of Eastman Kodak Co. (98–99%) isopropyl alcohol was fractionally distilled, collecting the middle 80%. This was then dried for eighteen hours over anhydrous sodium sulfate in a refrigerator. It was then refractionated; $n^{20}D$(obsd.) 1.3768, $n^{20}D$(lit.) 1.3776.

Ethylene Glycol.—About 2 liters of Eastman Kodak Co. Technical grade was fractionated. The fraction boiling between 197–198° was collected and dried over sodium sulfate for a week in a refrigerator. This portion was then vacuum-distilled and the fraction boiling between 107–108° at 9.5 mm. pressure was collected: $n^{20}D$ (obsd.) 1.4309; $n^{20}D$ (lit.) 1.4318.

Experimental Method

The weight percentage of water at 25°, corresponding to dielectric constants of 30, 40, 50, 60 and 70, were obtained from the literature.[5] From calculations involving density data, the correct volumes of organic solvent and water required to give the desired dielectric constant were determined.

After the reagents had attained thermal equilibrium in a thermostat, the following procedure was used in preparing a solution: five ml. of ferric nitrate solution, 5 ml. of nitric acid solution and 2 ml. of ammonium thiocyanate solution were placed, in the order listed, in a thermostated, calibrated, 50-ml. volumetric flask. Allowing for the water already present in the reagents used, the calculated volumes of organic solvent and water required to give a definite dielectric constant were added to the flask. Dilution, to the mark, was made by a previously prepared mixture of the solvent-pair having the desired dielectric constant. The above procedure allowed the maintaining of a constant iron concentration of 4 p. p. m. in all cases and also kept the *p*H of the solution within the desirable limits[2] of 0.70 to 0.25. The solution was thoroughly mixed and the absorption data were obtained within one-half hour after development of the color. Very little fading was observed in that time limit. The blank consisted of a solution of the same solvent-pair made up to the same dielectric strength.

All absorption measurements were made with a Beckman Model D U Quartz Spectrophotometer, using specially matched corex cells. These cells, 0.998 cm. in depth, were thoroughly rinsed 3 or 4 times with the solution to be measured, and the faces wiped dry with a lintless cloth. Per cent. transmittancy values were read at 10 mμ inter-

vals from 400 to 540 mμ and at 20 mμ intervals from 540 to 700 mμ. The instrument was operated at maximum sensitivity and at narrow slit width (0.02 mm.). Two runs were made at each dielectric strength for each solvent pair. If the values checked within 1–2% at each wave length, no further runs were made. The average of the two runs was used.

A Coleman Model 4D *p*H meter was used for measuring the acidity of the solutions after the transmittancy curves were taken in order to check the *p*H.

The wave length scale of the spectrophotometer was not calibrated. The photometric scale was checked using a solution of potassium chromate in 0.05 *N* potassium hydroxide. The values obtained checked very well with those reported by previous workers.[6]

During absorption measurements, the cuvettes were not temperature controlled, due to conditions not under our control. The room temperature was essentially constant during each run. The temperature range, in which all the measurements were made, was 28.0 ± 1.2°. The calculated volumes of non-aqueous solvent and water used in the various mixtures, gave the desired dielectric constant at 25°. It was realized that, owing to the dissolved electrolytes and to the difference in temperatures, the value of the existing dielectric constant would differ from the desired value. Nevertheless, it was assumed that, since the same concentrations of reagents were used in all the determinations, and since the experimental temperatures in all except a few cases were reasonably close

to 28°, both effects would cause almost an equal variation in any fixed, calculated, dielectric constant. Consequently, the solutions prepared should have the same relative dielectric strength even if the absolute values referred to in our data are not strictly valid.

Discussion of Data

The spectrophotometric curves for the six solvent pairs are shown in Figs. 1–6. In all cases, the absorption decreases as aqueous conditions are approached. In general, there is a larger difference between the minima at the higher dielectric constant values than at the lower values. Figures 1–6 also show that there is a slight hypsochromic effect, *i. e.*, there is a shift in the peak of the absorption band toward lower wave lengths as aqueous conditions are approached. This is in agreement with the work of Woods and Mellon[2] in acetone–water solvents. It contradicts the observations of Schlesinger and Van Valkenburgh,[7a] who claim that there is no difference in the absorption spectra of aqueous solutions of ferric thiocyanate and of non-aqueous solutions of ferric thiocyanate.

TABLE I

WAVE LENGTHS WHERE MINIMA OCCUR

Solvent pairs	Dielectric constant 30	40	50	60	70
Acetone–water		490	483	480	480
Methanol–water			492	483	480
Ethanol–water		490	487	485	480
Isopropanol–water	485	485	480	480	480
Ethylene glycol–water			503	488	480
Dioxane–water	495	490	490	483	480

Our data for the hypsochromic effect are summarized in Table I.

An examination of the transmittancy curves for the various isodielectric mixtures also shows that acetone–water mixtures have lower per cent. transmittancy values than any of the other corresponding isodielectric media. Furthermore, reference to Table I shows that the minima did not usually occur at the same wave length in the various isodielectric media. Thus it is evident that specific solvent effects are also in operation in addition to any operating dielectric effect.

Before attempting to explain the above observations, we would like to call attention to Table II, which is a summary of conclusions concerning the nature of the species causing the color in the ferric thiocyanate system. In regard to absorption work, the following observations have been made. Frank and Ostwalt[7g] showed that the positive complex $Fe(SCN)^{++}$ had an absorption minimum at about 447.5 mμ. Woods and Mellon[2] observed that as the ammonium thiocyanate added was increased from 0.5 to 5.0 ml., (SCN^-/Fe^{+3} changed from 76 to 765), the intensity increased and the peak of the absorption band shifted from 460 to 480 mμ. They also observed that the absorption band of a solution obtained by extracting the ferric thiocyanate complex with a mixture of equal volumes of amyl alcohol and ethyl ether had about the same intensity as that of an acetone solution of the same concentration of iron. However, the peak of the absorption band of the extract was at 500 mμ. Since in non-aqueous solvents[7a,e] the iron exists as the dimer, $Fe_2(SCN)_6$, one concludes that the absorption maximum at 500 mμ must be due to the dimer. Absorption maxima between 447 mμ and 480 mμ depend on the nature of the complex ion present.

TABLE II

SUMMARY OF CONCLUSIONS CONCERNING NATURE OF COLORED SPECIES

Reference 7	Solvent	Fe^{+3} (*M*)	SCN^{-1} (*M*)	$\frac{SCN^{-1}}{Fe^{+3}}$	Nature of colored species
a	Aqueous				$Fe(SCN)_6^{-3}$
a	Ether or benzene				$Fe[Fe(SCN)_6]$
b	Aqueous				$Fe(SCN)^{++}$, $Fe(SCN)_2^+$, $Fe(SCN)_3$ and possibly $Fe(SCN)_4^-$ at high thiocyanate concn.

Compound	450 mμ Regression equation[a]	δest_T[b]	480 mμ Regression equation[a]	δest_T	520 mμ Regression equation	δest_T
Acetone	$\log T = 0.0117D + 0.700$	0.74	$\log T = 0.0177D + 0.216$	0.51	$\log T = 0.0161D + 0.446$	0.31
	$T = 8.56 \times 10^{-7}D^4 + 13.2$	.57	$T = 9.47 \times 10^{-7}D^4 + 6.29$	.26	$T = 11.6 \times 10^{-7}D^4 + 10.1$	1.33
Ethanol	$\log T = 0.00641D + 1.10$	.81	$\log T = 0.010D + 0.808$	.39	$\log T = 0.0103D + 0.893$	0.50
Methanol	$\log T = 0.00617D + 1.12$	1.07			$\log T = 0.0116D + 0.774$	0.54
	$T = 5.04 \times 10^{-7}D^4 + 23.5$	0.56	$T = 6.52 \times 10^{-7}D^4 + 15.5$	.10		
Glycol	$\log T = 0.00671D + 1.12$	.82	$\log T = 0.0121D + 0.699$	.32	$\log T = 0.0162D + 0.498$	1.87
	$T = 5.92 \times 10^{-7}D^4 + 25.2$	.10				
Dioxane	$\log T = 0.00549D + 1.17$	.90	$\log T = 0.0101D + 0.818$	1.30	$\log T = 0.0109D + 0.862$	1.06
Isopropanol	$T = 7.24 \times 10^{-7}D^4 + 21.8$	.82	$T = 7.96 \times 10^{-7}D^4 + 16.4$	0.57	$T = 9.50 \times 10^{-7}D^4 + 21.7$	0.67

[a] Where D = dielectric constant. T = per cent. transmittancy; [b] δest_T = unbiased standard error of estimate of T found from the regression equation.

Therefore, based on the hypsochromic effect, in light of the conclusions of other investigators concerning the nature of the colored species, we can conclude that in this investigation (the ratio of thiocyanate to iron was 1540) the color forming species is mainly a mixture[8] of $Fe_2(SCN)_6$ and various negative complex ions. On approaching non-aqueous conditions, $Fe_2(SCN)_6$ predominates,[7d,e] while on approaching aqueous conditions, the negative complexes, in particular $Fe(SCN)_6^{-3}$ become more important.

If one assumes that the following equilibrium reaction exists $Fe(SCN)_6^{-3} + Fe^{+3} \leftrightarrows Fe_2(SCN)_6$, (1) then the increase in color intensity on approaching non-aqueous conditions is explainable if the color of $Fe_2(SCN)_6$ is assumed to be more intense than that of the negative complex. Furthermore, the equilibrium serves to explain the specific solvent effects. If there is a tendency for the solvent to donate a free electron pair to Fe^{+3}, then a strong electron donating solvent would favor the dissociation of $Fe_2(SCN)_6$ into ions, while a weaker electron donating solvent would favor association into $Fe_2(SCN)_6$, thereby producing a greater color intensity. Acetone, according to this study, thus would have a weak electron donating tendency compared to the other organic solvents used. The concept that acetone is a poorer electron donor is tantamount to saying that it is a weaker base than the other organic solvents used in this study. Measurements of Koch[9] based on solvation activity coefficients of Ag^+ in various solvents, placed the solvents in the following order of decreasing basicity: methanol, ethanol and acetone. The same order holds equally well for the basicity with respect to H^+ and it seems reasonable to expect it to hold also for Fe^{+3}. Although there are no values listed for the other organic solvents used in this study, it appears likely that they should have electron donating tendencies not too far different from methanol and ethanol. Thus, acetone should favor the equilibrium in reaction (1) to the right to a much greater extent than any of the other solvents used.

In trying to correlate per cent. transmittancy with some property of the solvent, we obtained two general empirical relations, if the dielectric constant was treated as the independent variable, namely

$$T = mD^4 + b \quad (1)$$

$$T = a10^{cD} \text{ or } \log T = \log a + cD \quad (2)$$

where T is the per cent. transmittancy, D is the dielectric constant and m, b, a and c are empirical constants which were evaluated by the method of least squares. The results are given in Table III. We would like to state, however, that it is impossible to distinguish between specific solvent effects and dielectric effects. These equations serve to generalize the data. No trend was observed when either weight per cent. or mole-fraction of water was used as the independent variable.

Acknowledgment.—The authors are indebted to Dr. A. Kramer of the Department of Horticulture, University of Maryland, for his permission to use the Beckman Spectrophotometer in that department.

Summary

1. The absorption curves for ferric thiocyanate at an iron concentration of 4 p. p. m., at relative dielectric constants of 30, 40, 50, 60 and 70 have been measured in the range of 400 to 700 mμ in the following solvent pairs: methanol–water, ethanol–water, isopropyl alcohol–water, ethylene glycol–water, dioxane–water, and acetone–water. The work was carried out at about 28° with a Beckman Model DU Spectrophotometer.

2. In general, on approaching aqueous conditions a decrease in intensity of color and a shifting of the absorption peak to a lower wave length are observed. These experimental observations are accounted for by postulating that $Fe_2(SCN)_6$ and $Fe(SCN)_6^{-3}$ are the species causing the color and that the former has a more intense color than the latter.

3. The increased intensity in acetone–water solutions compared to other solvent–water mixtures is attributed to the feeble, basic character of acetone compared to the other organic solvents used.

4. Equations have been obtained empirically showing the correlation of per cent. transmittancy with the dielectric strength of the solution.

(8) The possibility of existence of other complex ions is not denied. In light of the work summarized in Table II, it appears that in our case the highly negative complexes would be the most important.

Applications of Radioactive Chlorine to the Study of the Mechanisms of Reactions Involving Changes in the Oxidation State of Chlorine

BY HENRY TAUBE AND HAROLD DODGEN

In the chlorine system of oxidation states in water solution representatives of each of the stages between −1 and +7, the +2 and +6 only excepted, are known. Thus each of the substances Cl^-, Cl_2, $ClO^-(HOCl)$, $ClO_2^-(HClO_2)$, ClO_2, ClO_3^- and ClO_4^- persists in water solution and can be well characterized. The reactions of these substances offer a rich field for kinetic investigations and unusual opportunities for reaching a detailed understanding of mechanisms. In this paper is presented an account of experiments which have been done on the mechanisms of some of the reactions using radioactive chlorine as a tracer. The changes studied were oxidation–reduction reactions, and in all cases both the oxidizing and the reducing agents contained chlorine. Experiments have been carried out on the following reactions: (a) the interaction of chlorous acid and chlorate ion, (b) the interaction of chlorine (or hypochlorite) and chlorite, (c) the interaction of chloride ion and chlorate (and the reverse reaction), and (d) the disproportionation of chlorous acid. Included also are experiments on the exchange of chlorine atoms between hypochlorite and chlorite ions and between chlorine and chlorate ion in acid solutions.

Some of the reactions here studied have been investigated kinetically by other workers. While the published data are for the most part incomplete and often conflicting, they are of value in reaching conclusions about the mechanisms of the reactions. In no case do the observations made thus far, including those reported here, suffice to establish mechanisms, but they do in every case lead to significant conclusions. It will be shown that the observations on reactions (b), (c) and (d) require that the activated complex be unsymmetrical in every case, and that the observations for the three reactions can be correlated if an intermediate of the type  (or Cl—O—Cl—O) is assumed to be present.

The present paper includes a discussion of earlier work as well as of that performed by us. It is offered as an orienting survey of the reactions in this field, and will be amplified by further experiments. These will include detailed studies of stoichiometry and rates, and will make further applications of isotopes as tracers.

An interesting feature of the reactions in acid solution is that chlorine dioxide is frequently a product. Although not a stable end-product, it persists for long periods of time; both the rate at which it disproportionates and the rate at which it reacts with chlorine in other oxidation states in acid at room temperature are slow. Chlorine dioxide appears in the disproportionation of chlorate in acid, in the reduction of chlorate by chloride ion, the oxidation of chlorite by chlorine or hypochlorous acid and in the disproportionation of chlorite in acid. The feature that chlorine dioxide is present in the system, or that it can readily be generated from some of the substances present, has greatly simplified the work. Chlorine dioxide can readily be separated from other chlorine species using extraction procedures, and most of the tests for radioactivity were therefore made with it. Experiments reported earlier[1] have established the necessary facts about the exchange of activity between chlorine dioxide and chlorine in other oxidation states.

General Experimental Procedures, Conditions, Definitions.—For the tracer experiments the isotope $_{17}Cl^{38}$ was used. It was produced by exposing the appropriate chlorine containing substance to the slow neutron radiation of the University of Chicago cyclotron. For experiments which required the radioactivity to be present in Cl^- or Cl_2, aqueous solutions of hydrogen chloride and of chlorine were exposed. The oxalic acid method previously described was applied in the preparation of Cl^*O_2.[1] A solution containing the chlorine radioactivity as ClO_3^- was prepared by disproportionation of radioactive chlorine in aqueous phosphate buffer at 95°, the chloride ion then being removed by adding silver ion and filtering off the precipitate of silver chloride.

Account of activity was kept in terms of specific activity,[1] $I_0/(100C)$. I_0 is the counting rate expressed in arbitrary units, and C is the concentration expressed as gram atoms per liter of the species containing radioactive chlorine. In all cases solutions in carbon tetrachloride were counted. Chlorine and chloride exchangeable activity were removed from solutions of Cl^*O_2 in carbon tetrachloride by extraction with portions of an aqueous solution 0.5 M in potassium chloride containing also phosphate buffer at a pH above 7. Where activity was present in Cl^-, the specific activity was established by exchanging with chlorine added in known amount, then counting chlorine in carbon tetrachloride and determining the concentration of chlorine in the solutions.

Unless otherwise stated, the temperature at which the experiments were conducted was 25 ± 2°.

The data used in calculating equilibrium constants, with the exception of those for ClO_2^- and

(1) Dodgen and Taube, THIS JOURNAL, 71, 2501 (1949).

$HClO_2$, are taken from Latimer "Oxidation Potentials."[2] For ClO_2^- and $HClO_2$ the newer values reported by Fontana and Latimer[3] are used. In all changes involving chlorine dioxide, the values for the equilibrium constants refer to the gas as the standard state for this substance. The value of the coefficient for the distribution of chlorine dioxide[4] between gas and water has been measured in these laboratories. The concentration in solution is 25 times as great as the concentration in the gas phase at 25°.

Results and Discussion

The Reaction: $2H^+ + ClO_2^- + ClO_3^- = H_2O + 2ClO_2$ (g). The present interest in the system ClO_2^-, ClO_3^-, and ClO_2 in acid was to learn something about the rate at which ClO_2^- and ClO_3^- interact in acid. Since the position of equilibrium and the rate of the reverse reaction are pertinent to a consideration of the rate of the forward reaction, a brief discussion of the observations on these aspects of the reaction is presented.

The equilibrium constant for the reaction as represented in the heading is 36. For the net change with $HClO_2$ replacing $H^+ + ClO_2^-$, it is 0.36. These constants show that at equilibrium in neutral solution chlorine dioxide would be almost completely disproportionated, and that even in fairly acid solution the disproportionation would be largely complete. It is known, however that the change is slow except in alkaline solution. For example, a solution in the dark at 0° initially 0.155 *M* in ClO_2, 0.0011 *M* in H^+ and also containing the catalyst chloride ion at 0.001 *M* was observed by Bray[5] to decompose only about 1% in seven weeks. The rate law for the disproportionation in alkali for concentrations of chlorine dioxide in excess of about 10^{-3} *M* was observed to be[5]

$$-d(ClO_2)/dt = k(ClO_2)^2(OH^-)$$

with the specific rate at 0° equal to 330 $l.^2$ $mole^{-2}$ $min.^{-1}$ and the temperature coefficient 1.81. These data show that disproportionation by this path in acid will be very slow, amounting to only about 10^{-80}% in one hour at 25° for a solution 0.1 *M* in ClO_2 and 1 *M* in H^+.

The rate of the forward reaction, $ClO_2^- + ClO_3^-$, has been the subject of considerable discussion. Bray[5] has reviewed the evidence which suggests that the reaction proceeds at an appreciable rate, and has concluded that there is but a single observation which supports this view. This observation[6] is that ClO_3^- enhances the rate at which chlorine dioxide is formed in an acidified solution of chlorite. However, the data reported in his paper indicate no appreciable difference in the rate of decomposition of $HClO_2$ for two solutions in which the concentrations of ClO_3^- are widely different.

The fact that the rate of hydrolysis of chlorine dioxide is very slow in acid, coupled with the fact that the equilibrium constant is about unity requires that the rate at which $HClO_2$ and ClO_3^- react must also be very slow. A direct experimental demonstration, necessary perhaps because the equilibrium constants are probably not very accurate, that ClO_2 and $HClO_2 + ClO_3^-$ do not enter into a rapidly established equilibrium is our observation[1] that no measurable exchange takes place between ClO_2 and ClO_3^- in acid in a period of an hour. An even more direct check has been attempted—to discover whether any of the ClO_2 which forms when ClO_2^- disproportionates in acid in the presence of ClO_3^- is derived from the chlorate ion. This was done by using inert ClO_2^- mixed with radioactive ClO_3^- and testing for the appearance of radioactivity in the product ClO_2.

Experiment.—The initial composition of the reaction mixture of volume 23 cc. was: 0.14 *M* $Cl^*O_3^-$, 0.037 *M* chlorite, 0.73 *M* H_2SO_4 and 0.1 *M* H_3PO_4. After fifteen minutes had elapsed, during which time about 20% of the chlorite decomposed, 20 cc. of carbon tetrachloride was added and the mixture shaken. The carbon tetrachloride layer was drawn off, and chloride exchangeable activity removed by two successive washings with 5-cc. portions of the chloride + buffer solution. The specific activity of the chlorine dioxide was found to be 0 ± 10. To establish the specific activity of ClO_3^-, the residual chlorite in the water layer was decomposed by acidifying with hydrochloric acid, the chlorine dioxide formed removed with carbon tetrachloride, then $Cl^*O_3^-$ was reduced to Cl^*O_2 by making the solution strongly acid with sulfuric acid. The specific activity of the chlorine dioxide (which will be almost identical with that of chlorate ion—see below) was measured and found to be 2000 ± 61.

This experiment shows that in acid solution, the reaction of $HClO_2$ with ClO_3^- is very much slower than is the disproportionation of $HClO_2$. Under the conditions of our experiments, less than 3% of the chlorine dioxide was formed by the former reaction. If both are second order in the chlorine species, the specific rate of the $HClO_2 + ClO_3^-$ reaction is less than 1/100 that of the $HClO_2 + HClO_2$ reaction. The experiment confirms the conclusion for which other evidence has been cited above, that ClO_3^- and $HClO_2$ even in acid react only very slowly. The contrast in this respect for the system $HClO_2$–ClO_2–ClO_3^- with the analogous one in nitrogen chemistry is striking: HNO_2 is outstanding among ordinary reducing agents for the speed at which it reduces NO_3^-.

The Reaction of Chlorite (ClO_2^- or $HClO_2$) with Chlorine and with Hypochlorite.—Both chlorine dioxide and chlorate ion are products when chlorine reacts with chlorite in acid solu-

4	$HCl^*O + 2ClO_2^- = 2ClO_2 + Cl^- + OH^-$	5×10^{-8}	26 ± 11	583	5 ± 2
5	$HCl^*O + 2ClO_2^- = 2ClO_2 + Cl^- + OH^-$	10^{-8}	81 ± 8	1780	4.6 ± 0.5
6	$HCl^*O + ClO_2^- = ClO_3^- + Cl^- + H^+$	10^{-8}	156 ± 10	1780	8.8 ± 0.6

[a] Temperature 25°. Perchloric acid was used in the strongly acidic solutions, phosphate buffer for those of higher *p*H. [b] Calculated for random distribution among the chlorine atoms present as Cl^-, Cl_2, HClO, $HClO_2$, ClO_2, ClO_3^-.

tion. In neutral or weakly alkaline solution, the chlorine is largely present as HClO and Cl^-. Under these conditions both ClO_2 and ClO_3^- still appear as products, but the ratio of ClO_3^- to ClO_2 is greater than for acid solutions. Typical observations on the stoichiometry with halogen in excess are the following. In a solution initially 0.4 *M* in perchloric acid, 0.020 *M* chlorine and 0.024 *M* chlorite, 7.8% of the chlorite is oxidized to ClO_3^-, the remainder to ClO_2. In a solution at *p*H about 7.5, with initial HClO at 0.020 *M*, and initial ClO_2^- at 0.024 *M*, 28% of the chlorite is oxidized to chlorate.

The equations expressing the net changes in acid are

$$Cl_2 + 2HClO_2 = 2ClO_2 + 2Cl^- + 2H^+ \quad \Delta F^0 = -6490$$

$$Cl_2 + HClO_2 + H_2O = ClO_3^- + 2Cl^- + 3H^+ \quad \Delta F^0 = -7050$$

and for solutions near the neutral point

$$HOCl + 2ClO_2^- = 2ClO_2 + Cl^- + OH^- \quad \Delta F^0 = -27{,}000$$

$$HOCl + ClO_2^- + OH^- = ClO_3^- + Cl^- + H_2O \quad \Delta F^0 = -31{,}870$$

From the values tabulated for the standard free energy changes, it is evident that equilibrium is far to the right in ordinary acidity ranges for all the changes represented.

The changes in acid and neutral solutions proceed very rapidly. Chlorine dioxide appears instantly in large amount when the solutions are mixed, and with one of the reactants in excess, the other is consumed almost completely within a minute or so after mixing. In very alkaline solution, however (*e. g.*, 0.1 *M* OH^-), where ClO^- rather than Cl_2 or HClO is the principal species, the reaction is very slow—periods of time of the order of hours being required for appreciable reaction to take place. Nothing appears to have been published on the kinetics of the reactions of chlorine and hypochlorite with chlorite, and in view of the high reaction rates, quantitative work would be difficult.

Two essentially distinct types of mechanism may be considered for this and for similar changes. In one of these, both reactants on primary interaction change to an oxidation state in which they become equivalent, and the intermediate substance thereby produced undergoes further change. In a second type of mechanism, the chlorine atom from the Cl_2 or HOCl at all stages remains distinct from the chlorine atom in ClO_2^-. Experiments making use of radioactive chlorine were undertaken to discover which of these two types operates. A report of these experiments follows.

Experiments.—For each experiment a solution containing radioactive chlorine was mixed with a solution containing non-radioactive chlorite. After reaction, the solution was buffered to a *p*H of 7–8 (unless already at that *p*H), carbon tetrachloride was added, the mixture shaken. The carbon tetrachloride layer was then treated as described earlier to measure the specific activity of the chlorine dioxide. The specific activity of the original chlorine was determined on a solution in carbon tetrachloride. Table I summarizes the results of the experiments.

The experiments show that for the most part in the three reactions studied, the atoms present initially in chlorine or hypochlorite appear as chloride ion, and those present in chlorite as chlorine dioxide. A small transfer of activity from chlorine or hypochlorite to the product chlorine dioxide is noted, however, and the effect appears to be real. In experiment 3 of Table I the extractions of the carbon tetrachloride solutions of chlorine dioxide by the aqueous Cl^- buffer solution were continued, the specific activity being measured after each extraction. No change in specific activity was observed —258 ± 6, 257 ± 9, 255 ± 12 — thus proving that the activity was present as chlorine dioxide. The possibility that Cl^*O_2 was formed in the bombardment of chlorine or chloride ion is ruled out on the basis of experiments reported elsewhere.[1] Irradiated chlorine shows no immediate exchange with chlorine dioxide. The relatively high transfer of activity noted in the reaction producing ClO_3^- is probably a result of the procedure followed in the experiment. After reaction, the chlorine dioxide was washed out, and the chlorate ion reduced to chlorine dioxide by adding sulfuric acid. The chloride ion was radioactive and, as is shown below, a slight transfer takes place in the $ClO_3^- + Cl^-$ reaction. The high value for the percentage transfer, 8.8, is probably due to the additional opportunity for exchange in generating chlorine dioxide from chlorate ion in the mixture.

The experiments prove that for the most part at

least, the reactions do not proceed by a path in which on primary interaction of chlorine or hypochlorous acid with chlorite a symmetrical intermediate is formed. Thus the mechanisms having as first steps

$$Cl_2 + ClO_2^- = \overset{O}{\diagdown}Cl\text{—}Cl\overset{O}{\diagup} \text{ (or } 2ClO) + Cl^-$$

$$HOCl + ClO_2^- + H^+ = \overset{O}{\diagdown}Cl\text{—}Cl\overset{O}{\diagup} \text{ (or } 2ClO) + H_2O$$

do not account for the major part of the reaction. The principal path must be one in which the chlorine atoms remain distinct, as for example one involving the intermediate $Cl\text{—}Cl\langle^{O}_{O}$ or Cl—O—Cl—O. There are at present no observations which distinguish the two formulations, and the reactions will be written for the substance $Cl\text{—}Cl\langle^{O}_{O}$.

Simple steps involving this intermediate which satisfy the observations on stoichiometry and those reported above are

$$Cl^*_2 + ClO_2^- = Cl^*Cl\langle^{O}_{O} + Cl^{*-}$$

or

$$H^+ + HOCl^* + ClO_2^- = Cl^*Cl\langle^{O}_{O} + H_2O$$

For the production of ClO_2, the following reaction may be formulated as

$$2Cl^*Cl\langle^{O}_{O} = Cl^*_2 + 2ClO_2$$

and for the production of chlorate ion as

$$Cl^*Cl\langle^{O}_{O} + H_2O = Cl^{*-} + ClO_3^- + 2H^+$$

The slight transfer of activity from Cl^*_2 or $HOCl^*$ to the product may result from the oxidation of $Cl^*Cl\langle^{O}_{O}$ to $ClO_2 + Cl^*O_2$, or from isomerization of $Cl^*Cl\langle^{O}_{O}$ to the symmetrical intermediate.

Test for Exchange in the System $ClO^- + ClO_2^-$.—An experiment was performed in which radioactive hypochlorite was mixed with chlorite ion in alkaline solution and the substances left in contact for a period of time. The rate of reaction is very slow when (OH^-) is as high as 0.1 *M*. The initial concentrations of ClO^-, ClO_2^- Cl^- and OH^- were 0.0171, 0.0478, 0.0171 and 0.1 *M* in order. At the end of forty-three minutes the solution was acidified, whereupon chlorine dioxide was liberated from the chlorite by hypochlorite. The specific activity of the chlorine dioxide was then measured as described above. It was observed to be 40 ± 13; if the activity had been uniformly distributed among Cl^-, ClO^- and ClO_2^-, the specific activity of the chlorine dioxide would have been 583.

The experiment shows that there was little transfer of activity from ClO^- to ClO_2^-. The slight amount appearing in the chlorine dioxide may be attributed to the transfer in the reaction of Cl^*_2 or $HOCl^*$ with ClO_2^- (see above). It may be concluded that the rate of exchange between ClO^- and ClO_2^- is very slow, less than 5% at the concentration above in forty-five minutes. Exchange could conceivably occur by oxygen atom transfer from one group to another. The experiment does not exclude the possibility that such exchange may occur in acid solution.

The System $4H^+ + 2Cl^- + 2ClO_3^- = Cl_{2aq} + 2ClO_2 + 2H_2O$.—The equilibrium constant for this reaction at 25° is 4.7×10^{-7}; thus, appreciable reduction of chlorate ion by chloride ion can be expected only in solutions of high acidity. The forward reaction proceeds fairly rapidly even at room temperature in solutions of high acidity when the concentrations of ClO_3^- and Cl^- are of the order of tenth molar. For example, in 4 *M* $HClO_4$, with ClO_3^- and Cl^- each 0.2 *M*, the color of ClO_2 becomes quite marked in about a minute. In the range of low chloride ion concentrations, the stoichiometry corresponds to that expressed by the equation above. At high chloride ion concentrations, however, relatively more chlorine is formed.

Considerable work on the kinetics of the forward reaction has been reported; much however is conflicting, and none as yet leads to any unambiguous conclusions about mechanism. Among the observations on kinetics which appear well established are the following. The reaction is inhibited by the product chlorine, but not by chlorine dioxide.[7] At low chlorine concentration a limiting rate is reached, and under these conditions the reaction is eighth order[8]

$$-d(ClO_3^-)/dt = k(H^+)^4(Cl^-)^2(ClO_3^-)^2$$

In the presence of iodide ion[9] the reaction reduces to one of simpler order

$$-d(ClO_3^-)/dt = k(H^+)^2(Cl^-)(ClO_3^-)$$

Since ClO_2^- and Cl_2 or $HOCl$ are known to react to give ClO_3^- and Cl^- (as well as other products) it may be fruitful to consider the interaction of ClO_3^- and Cl^- in relation to the mechanism suggested for the above reaction. All the observations are consistent with a mechanism of this type formulated in the following way

$$Cl^- + ClO_3^- + 2H^+ \underset{(1')}{\overset{(1)}{\rightleftharpoons}} H_2O + Cl\text{—}Cl\langle^{O}_{O} \qquad \begin{matrix}\text{Equilibrium I}\\ \text{reaction (1) forward}\\ \text{reaction (1') reverse}\end{matrix}$$

$$2Cl\text{—}Cl\langle^{O}_{O} \longrightarrow Cl_2 + 2ClO_2 \qquad (2)$$

Reaction 1 (*i. e.*, I in the forward direction) is the reverse of that written for the formation of chlo-

(9) Bray, *J. Phys. Chem.*, **7**, 112 (1903).

rate in the oxidation of ClO_2^- by Cl_2 or HOCl. It is evident that the pair $Cl^- + ClO_3^-$ can lead to the same intermediate as the pair $HOCl + ClO_2^-$ or $Cl_2 + ClO_2^-$. The mechanism as written leads to the eighth order rate law observed by Luther and MacDougall. The effect of chlorine on the rate may be explained as was done by Luther and MacDougall,[8] or by the assumption that chlorine or HOCl can reoxidize $Cl—Cl\langle^{O}_{O}$. The mechanism is consistent also with Bray's rate law if it be supposed that I^- reacts rapidly with $Cl—Cl\langle^{O}_{O}$ so that the forward reaction in Equilibrium I becomes rate determining. Finally, it may be pointed out that there is no inconsistency in stating that in the present system the substance $Cl—Cl\langle^{O}_{O}$ formed by reaction 1 reverts mainly to ClO_3^- and Cl^- by the reaction 1′ rather than reacting in the second step (this condition is necessary if I is to be maintained as an equilibrium) while in the system $Cl_2 + ClO_2^-$, it reacts principally to form $Cl_2^- + ClO_2$. The reaction $Cl_2 + ClO_2^-$ is much more rapid than is $Cl^- + ClO_3^-$, so that in the former system the steady state concentration of $ClClO_2$ is greater and the 2nd order reaction leading to the products $Cl_2 + ClO_2$ would therefore be favored above the first order reaction of the intermediate to give ClO_3^-.

These considerations show that the observations in the present system may be understood by postulating the same intermediate, $Cl—Cl\langle^{O}_{O}$ (or Cl—O—Cl—O), as was assumed for the reaction of chlorite with chlorine and hypochlorite. As a consequence of this type of mechanism, it would be expected that for the most part, the chlorine atoms in chloride and chlorate would remain distinct on interaction of the two ions, but that a small amount of exchange would occur. An account of the experiments testing this view follows.

Experiments.—Radioactive chloride ion was mixed with inert chlorate in strong acid (4.5 *M* H_2SO_4), the chlorine dioxide separated, and its specific activity determined as described above. In one experiment, with $(Cl^-)/(ClO_3^-)$, initially at 2, the specific activity of the chlorine dioxide liberated was found to be 7 ± 3; that calculated for random distribution among the chlorine atoms in the system 258. These numbers correspond to 3 ± 1% exchange. In a second experiment, $(Cl^-)/(ClO_3^-)$ was initially 0.5; the observed specific activity of the chlorine dioxide, and that calculated for complete exchange in the products were 8 ± 3 and 135, respectively, corresponding to 6 ± 2% of exchange.

As in the reaction of chlorine or hypochlorite with chlorite ion, the chlorine atoms for the most part remain distinct. Slight exchange is noted, however, about the same in magnitude as was observed for the previous reaction. It seems possible therefore that this small degree of exchange is the property of an intermediate common to both systems.

Only incomplete data on the rate and kinetics of the reverse reaction have been published, but those reported by Bray[10] suffice to show that over a limited range of the ratio $(ClO_2)/(Cl_2)$, the stoichiometry corresponds to that expressed by the equation. His data show, furthermore, that the rate of interaction is slow; thus at 18° in a solution in which ClO_2 and Cl_2 are initially of the order of tenths molar, (H^+) and $(Cl)^-$ 5×10^{-3} *M* and 2×10^{-3} *M*, respectively, only a few per cent. of ClO_2 reacts in eight days. Since the equilibrium constant is known, the specific rate and rate law for the forward reaction fix those for the reverse reaction (if the assumption be accepted that the rate law for the reverse reaction will be of the simplest form). The rate law proposed by Bray, similar in form to that found by Sand[11] at higher temperatures and agreeing with data published by Schacherl[12,13] taken together with the equilibrium constant would require a much higher rate for the $Cl_2 + ClO_2$ reaction than was observed by Bray. The observations can, however, be reconciled if the findings by Luther and MacDougall that the forward reaction is inhibited by chlorine is accepted.

An attempt was made to learn something about the rate of the reverse reaction for a system in which the concentrations of reactants and products approach equilibrium values. This was done by introducing radioactive chlorine dioxide into such a system, and observing the change in specific activity with time.

Experiment.—A solution was prepared containing initially 1 *M* $NaClO_3$, 4.2 *M* H_2SO_4 and 0.22 *M* HCl. This remained at room temperature for one day, after which time the concentrations of ClO_2 and Cl_2 were found by analysis to be 0.142 and 0.032 *M*, respectively. To 13 cc. of this solution was added 10 cc. of a carbon tetrachloride solution 0.098 *M* in Cl^*O_2 of known specific activity, and 0.074 *M* in Cl_2. The resulting mixture after shaking was allowed to stand for 86 min. and the specific activity of the chlorine dioxide determined. The results were as follows: the observed final specific activity of the ClO_2 was 81 ± 3, that expected if the only effect were dilution with the inert ClO_2 in the original aqueous solution 89 ± 3; that expected including also complete exchange with ClO_3^-, 19.

The experiment shows that in the time of the experiment, the exchange of chlorine dioxide with chlorate ion is far from complete, and that therefore the rate of reaction of chlorine and chlorine dioxide under the conditions of the experiment is

(10) Bray, *Z. anorg. allgem. Chem.*, **48**, 228 (1904).

slow. It should be pointed out that any decrease in specific activity observed sets only an upper limit on the rate of reaction, since adding carbon tetrachloride lowered the concentrations of chlorine and chlorine dioxide, and the net change while probably slight, proceeded in the direction of forming chlorine dioxide from inert chlorate ion. The slow rate observed is not compatible with the rate for the forward reaction far from equilibrium and the equilibrium constant, but is explained if the inhibiting effect of chlorine on the rate of the forward reaction is accepted.

Non-exchange in the System $Cl_2 + ClO_3^-$.—It has been shown that the equilibrium between $ClO_3^- + Cl^-$ and $ClO_2 + Cl_2$ is slow; furthermore, the chlorine atoms originating in ClO_3^- and Cl^- tend to remain distinct. It is also known that chlorine disproportionates to $ClO_3^- + Cl^-$ only slowly in acid. These facts made it seem worthwhile to reinvestigate the exchange between chlorine and chlorate ion in acid, since the rather rapid exchange noted by Libby[14] would therefore seem to imply some mechanism other than these orthodox equilibria for transfer of activity.

A record of the experiment on the exchange of Cl_2 and ClO_3^- is presented in Table II.

TABLE II

EXCHANGE IN THE SYSTEM $Cl_2^* + ClO_3^-$ IN STRONG ACID

($NaClO_3$)	(Cl_2^*)	(H_2SO_4)	Temp., °C.	Time, min.	$I_0/100C$ obsd.	$I_0/100C$ calcd.

.75	.015	4.5	25	83	290 ± 9	12
1.0	.0261	3.0	25	2	4250 ± 30	211
1[a]	.0261	3	93	32	3500 ± 150	211
1[a]	.0261	3	93	58	3600 ± 150	211

[a] Heated in sealed tubes.

The experiments were performed by using chlorine solutions of known specific activity, separating chlorine from the reaction mixture at the end of the experiment and determining its specific activity. The data show that at room temperatures there is no significant change in specific activity for periods of time up to approximately one and one-half hours. Even at 93°, the change in specific activity is slight, and probably is for the most part apparent rather than real. At this temperature, about 50% of the chlorine had disappeared at the end of the experiment, and the cell contents were colored slightly yellow. This yellow color was undoubtedly due to chlorine dioxide formed from the chlorate. Since the analysis did not distinguish between Cl_2 and ClO_2, the formation of chlorine dioxide would reduce the apparent specific activity of the chlorine.

The Disproportionation of Chlorite in Acid.—Chlorite is unstable and in acid solution it decomposes fairly rapidly. The principal products of the disproportionation reaction over the whole range of acid concentration in which the rate is appreciable are chlorine dioxide and chlorate ion as higher oxidation states and chloride ion as the lower oxidation state. If the chloride ion concentration remains low, the net change[15] approaches that expressed by the equation

$$4HClO_2 = Cl^- + 2ClO_2 + ClO_3^- + 2H^+ + H_2O$$

However, under most conditions the proportion of chlorate formed is somewhat in excess of that represented above. Small amounts of chlorine are also reported as products.[5] This is surprising in view of the rapid reaction of chlorine and chlorite ion. In an experiment done in this laboratory, differing from Barnett's in that the concentration of acid was much greater (1 *M* H^+ as compared to a maximum of about 0.2 *M* H^+ in Barnett's experiments), no measurable amount of chlorine was observed.

Experiment.—The solution was initially 1 *M* H_2SO_4 and 0.0540 *M* in total chlorite. After one and one-half hours had elapsed, the chlorine and chlorine dioxide were removed by repeated extraction with carbon tetrachloride. The carbon tetrachloride solution on analysis proved to have no noticeable amount of chlorine. The oxidizing agent which is left in the aqueous solution and which responds to iodide at low acid is chlorite. The chlorate formed is therefore measured by the decrease in total oxidizing power. Perchlorate ion is not a product in this reaction. The concentrations at the end of the time interval were: ClO_2, 0.0171 *M*; ClO_3^-, 0.0100 *M*; ClO_2^-, 0.0178 *M*; Cl_2, 0.000 *M*.

A study of the kinetics of the decomposition has been made by Barnett. His experiments were for conditions of fairly low acidity ($(ClO_2^-) > (HClO_2)$) and covered a range about twenty-fold in (ClO_2^-) and 3- to 4-fold in ($HClO_2$). The rate law was found to be

$$-d(HClO_2)/dt = k(HClO_2)^2$$

and the value of k at 25°, 1.41. mole^{-1} min.$^{-1}$.

Chloride ion catalyzes the disproportionation of $HClO_2$, and changes the stoichiometry of the reaction. Thus, in an experiment in which the solution was initially 0.472 *M* HCl and 0.0280 *M* $NaClO_2$, after eight minutes had elapsed, the total chlorite had fallen to 0.0149 *M*, and the concentrations of the products ClO_2 and ClO_3^- were 0.0091 and 0.0012 *M*, respectively. The fraction of the chlorite ion appearing as chlorate ion is much less in the chloride catalyzed reaction than it is in the uncatalyzed change.

The observations may all be understood on the basis that in the uncatalyzed reaction, the primary step is

$$2HClO_2 \longrightarrow HClO + H^+ + ClO_2^-$$

and in the catalyzed reaction

$$HClO_2 + Cl^- + H^+ \longrightarrow 2HClO$$

The oxidation of chlorite by HClO or chlorine as

(14) Libby, THIS JOURNAL, 62, 1930 (1940).

(15) Barnett, Thesis, University of California, 1935.

follow reaction yields mainly chlorine dioxide and accounts for the observed stoichiometry.

We have performed experiments to establish whether for the catalyzed reaction the chlorine atoms in the chloride ion remain distinct from those appearing in the product ClO_2. On the basis of the mechanism proposed above for the change, it is expected that they do remain distinct, since very little transfer of activity from HCl*O or Cl_2* to ClO_2 takes place in the reaction of these with ClO_2^-.

The experiments are outlined below, and show that in fact little mixing of activity between Cl^- and ClO_2^- is observed when the former acts as catalyst for the disproportionation of chlorite ion. The slight amount of exchange, about the same in extent as in the oxidation of chlorite by chlorine or hypochlorite, supports the view that the same intermediate is involved in both reactions.

Experiment.—The concentration of hydrochloride in each experiment was 0.58 *M*. The chloride ion was radioactive and its specific activity was determined before the reaction. After considerable chlorine dioxide had been formed, it was separated from other species as described above, and its specific activity determined. In one of the experiments, the specific activity of the chlorine dioxide formed was 4 ± 4, that expected if exchange with the halogen in the system were complete 50; in a second, these numbers were 27 ± 15 and 336. The results in the second experiment correspond to 8 ± 5% exchange. Thus the amount of exchange which takes place is about the same as in the oxidation of chlorite by chlorine or HOCl. Since the mechanism proposed includes as a step the oxidation of chlorite by HOCl or chlorine, slight transfer of activity to the product ClO_2 is expected.

Acknowledgment.—The cyclotron was operated with the aid of funds from the Office of Naval Research (N60NR-20, Task Order III). The authors wish to express their appreciation also to Joseph Halperin for help with some of the experiments.

Summary

By experiments using radioactive chlorine as a tracer, the following observations have been made. (a) The oxidation of chlorite by chlorate in acid is much slower than the disproportionation of chlorite. (b) In the reaction of chlorite with chlorine (or hypochlorous acid) to form chlorine dioxide or chlorate and chloride ion, most of the chlorine atoms in the chlorine dioxide or chlorate are derived from the chlorite. (c) In the reaction of chloride ion with chlorate ion in acid to produce chlorine and chlorine dioxide, the chlorine atoms in the chlorine dioxide are for the most part derived from the chlorate. (d) In the disproportionation of chlorite in acid catalyzed by chloride ion, the chlorine atoms in the chlorine dioxide are for the most part derived from the chlorite. (e) In each of the changes under (b), (c) and (d), a small but definite degree of mixing of the chlorine atoms in the products has taken place. (f) The reverse reaction in the system (c) near its equilibrium composition is very slow. (g) The exchange of chlorine activity between ClO^- and ClO_2^- in base is very slow. (h) The exchange of chlorine with chlorate ion in acid at room temperature and at elevated temperatures is very slow.

The significance of these observations in relation to other published observations and in relation to reasonable mechanisms for the reactions has been discussed. An unsymmetrical intermediate, Cl—Cl$\langle^{O}_{O}$ (or Cl—O—Cl—O), common to the systems (b), (c) and (d) is postulated.

The Apparent and Partial Molal Volume of Copper Sulfamate in Aqueous Solutions

BY ELTON M. BAKER

The object of this investigation was to determine the apparent and partial molal volume of copper sulfamate at 25° for various concentrations of solutions from accurate density measurements. At infinite dilution the apparent molal volume becomes the partial molal volume. The literature contains limited data for salts of the type contained in this study.

Experimental

The experimental procedure consisted of determining densities of aqueous solutions of copper sulfamate in calibrated weld precision pycnometers of approximately 25 ml. capacity. These were calibrated using distilled water. The deviation was less than 0.005%. The density obtained for each concentration is the average of three determinations. The maximum deviation between values in any series was 0.005%. The densities were determined at 25 ± 0.02°. The temperatures were determined by a long mercurial thermometer of short range, calibrated by the National Bureau of Standards. Calibrated weights were used and weighings could be reproduced to ±0.05 mg. All weights were corrected to vacuum. Weighing was done in a room at 25 ± 1°.

Copper sulfamate was prepared by the interaction of C. P. sulfamic acid and basic copper carbonate. The blue copper sulfamate was recrystallized three times from distilled water. The copper content was determined by allowing an excess of potassium iodide to reduce weighed samples of the stock solution of copper sulfamate in an acid buffer. The released iodine was titrated using standard thiosulfate solution with potassium thiocyanate added

near the end-point. The accepted value was the average of three analyses in which the maximum deviation between analytical results for any concentration was less than 0.07%.

Molal concentrations were then obtained and molar concentrations were calculated with the use of densities.

A saturated solution was prepared by allowing a warm concentrated copper sulfamate solution to cool to 25°, then permitting it to come to equilibrium with the solid phase which separated. Weighed samples of the supernatant liquid were analyzed as before. The solubility was found to be 74.73 (±0.05) g. per 100 g. of water.

Treatment of Results.—The apparent molal volumes were calculated from the observed densities by means of the equation proposed by Gucker[1]

$$\phi(V_2) = 1000/c - 1/d_1[1000d/c - M_2] \quad (1)$$

where $\phi(V_2)$ is the apparent molal volume, M_2 is the molecular weight of the copper sulfamate, d_1 and d are the densities of the solvent and solution, respectively, and c is the concentration (moles of solute per liter of solution). The absolute density of water was used as 0.99707 g./ml. The densities and the corresponding values of concentration and apparent and partial molal volumes are shown in Table I.

TABLE I

Density	Concentration Molal	Concentration Molar	$\bar{V}_2$	$\phi(V_2)$	$d\phi(V_2)$
1.01340	0.08348	0.08283	59.86	58.77	−0.30
1.02316	.13394	.13250	60.40	59.00	− .10
1.10238	.56471	.54394	65.33	62.31	+ .02
1.18428	1.0484	.97910	68.86	64.72	+ .18
1.22814	1.3315	1.2199	71.14	66.51	− .27
1.28484	1.7130	1.5304	73.09	67.90	− .13
1.36007	2.2627	1.9495	75.54	69.74	− .05
1.44351	2.9221	2.4140	77.36	71.01	+ .38

(1) Gucker, *J. Phys. Chem.*, **38**, 307 (1934).

From the data a second order equation expressing $\phi(V_2)$ as a function of c was found. The value of the coefficients was obtained by the method of averages[2]

$$\phi(V_2) = 56.08 + 7.07c^{1/2} + 1.92c \quad (2)$$

In Column 6 are shown the deviations, $d\phi(V_2)$, of the observed values from those calculated from the equation.

Partial molal volumes were obtained using concentrations and calculated apparent molal volumes by the relation proposed by Gucker[1]

$$\bar{V}_2 = \phi(V_2) + c^{1/2}\left[\frac{1000 - c\,\phi(V_2)}{2000 + c^{3/2}\frac{\partial\phi(V_2)}{\partial c^{1/2}}}\right]\frac{\partial\phi(V_2)}{\partial c^{1/2}} \quad (3)$$

where $\phi(V_2)$ is the apparent molal volume and

$$\partial\phi(V_2)/\partial c^{1/2} = 7.07 + 3.84c^{1/2} \quad (4)$$

as obtained from equation (2).

The partial molal volume of copper sulfamate at zero concentration was determined as 56.08 ml. per gram molecular weight by the evaluation of the first constant in equation (2).

Summary

1. Densities at 25 ± 0.02° of copper sulfamate solutions ranging from 0.08 to 2.4 molar have been determined.

2. The solubility of copper sulfamate at 25° was determined: 74.73 g. per 100 g. of solvent.

3. The apparent and partial molal volumes of the solute have been calculated.

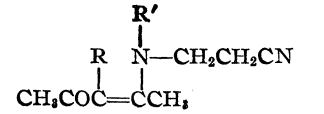
Infrared Spectra of Amino-substituted α,β-Unsaturated Ketones

BY NORMAN H. CROMWELL, FOIL A. MILLER,[1] AGATHA R. JOHNSON, ROBERT L. FRANK AND DAVID J. WALLACE

A recent study of some cyclizations involved the preparation of 4-(2′-cyanoethyl)-amino-3-penten-2-one (I), 4-(2′-cyanoethyl)-amino-3-methyl-3-penten-2-one (II) and 4-N-(2′-cyanoethyl)-methylamino-3-penten-2-one (III) and the possibility of their ring closure by the aldol condensation. The properties of these substances



I, R = R′ = H
II, R = CH_3, R′ = H
III, R = H, R′ = CH_3

have proved to be unusual and have prompted us to undertake a study of their infrared absorption spectra and those of a number of previously reported related compounds.

(1) Present address: Mellon Institute, Pittsburgh, Pennsylvania.

Preparation and Properties

Compounds I, II and III were readily prepared by condensation of the appropriate β-aminopropionitrile with acetylacetone or 3-methylacetylacetone. Assignment of the double bond in these structures to the position α,β to the carbonyl rather than β,γ between the carbon and nitrogen atoms, is based on their ultraviolet absorption maxima in the region characteristic of α,β-unsaturated carbonyl compounds and on a comparison of their infrared spectra with those of compounds VII through IX of known structure.

It is of interest that ammonia and β-aminopropionitrile fail to condense with 3,3-dimethylacetylacetone, a case in which the double bond of the product cannot take the position α,β to the carbonyl group.[2]

These amino ketones are structurally vinylogs of amides, and have been found to behave chemically more like amides than ketones. Our experiments performed mostly on 4-(2′-cyanoethyl)-amino-3-penten-2-one (I), show, for example, that they do not form phenylhydrazones; they fail to give a positive haloform reaction under the usual conditions; they fail to cyclize under conditions favorable for aldol condensation. Hydrolysis occurs in aqueous acid but not readily in water or aqueous alkali. Reaction with picric acid occurs only accompanied by cleavage to yield the picrate of the β-aminopropionitrile.

The preparation and properties of compounds IV,[2] V,[3] VI,[4] VII,[5] VIII,[5] IX,[5] X,[4] XI,[6,8,9] XII,[6,8,9] XIII,[5] XIV[7] and XV[9] have been described previously as indicated by the references.

Experimental

β-Aminopropionitrile.—The method of Ford, Buc and Greiner[10] was employed using 106 g. (2.00 moles) of acrylonitrile and 1 l. of 28% ammonium hydroxide. The yield was 81 g. (63%), b. p. 66–69° (5 mm.); $n^{20}D$ 1.4400. Its picrate had m. p. 178° (lit.,[11] 178°).

β-Methylaminopropionitrile.—The method of Whitmore and co-workers[11] for β-ethylaminopropionitrile was applied using 106 g. (2.00 moles) of acrylonitrile and 300 ml. of 35% aqueous methylamine (3.00 moles of amine), and gave 117.5 g. (70%) of product, b. p. 90° (30 mm.); $n^{20}D$ 1.4318.

4-(2′-Cyanoethyl)-amino-3-penten-2-one (I).—Addition of 13.5 g. (0.19 mole) of β-aminopropionitrile to 20.0 g. (0.20 mole) of acetylacetone resulted in an exothermic reaction. The product solidified on cooling to give a quantitative yield, 28.8 g.; m. p. 88°. An analytical sample was prepared by two recrystallizations from benzene–petroleum ether (3:1) to form white needles, m. p. 89.5–90°. These gave a purple color with ethanolic ferric chloride.

Anal.[12] Calcd. for $C_8H_{12}N_2O$: C, 63.16; H, 7.89. Found: C, 63.35; H, 7.68.

An alternative preparation involved the solution of 200 g. (2.00 moles) of acetylacetone in 150 ml. of 28% ammonium hydroxide, followed by addition of 106 g. (2.00 moles) of acrylonitrile. The mixture was refluxed for four hours and the excess water then removed under reduced pressure to yield several crops of crystals totaling 76 g. (25%), m. p. 88°.

The ultraviolet absorption spectrum was determined by Mrs. Calvin Brantley with a Beckman Model D spectrophotometer. A maximum occurs at 308 mμ with log ε = 4.265, where ε, the molecular extinction coefficient, is given by log $I_0/I = \epsilon \times c$ (moles/l.) × d(cm.). The solution employed contained 0.0006 g./l. in 95% ethanol.

Experiments designed to cyclize this compound to a dihydropyridine involved refluxing ethanolic solutions with piperidine, piperidine carbonate, sodium hydroxide, and sodium ethoxide; heating it with zinc chloride; heating it alone at temperatures up to 240°; and allowing it to stand with hydrochloric acid, acetic anhydride, and acetyl chloride. None of these attempts yielded a cyclized product. In most cases the starting material was recovered, although refluxing with 4% hydrochloric acid caused hydrolysis to β-aminopropionitrile hydrochloride.

Reaction with phenylhydrazine and with sodium hypoiodite according to the directions of Shriner and Fuson[13a,b] gave negative results. Reaction with picric acid[13c] gave the picrate of β-aminopropionitrile, m. p. 178° (lit.,[11] 178°).

4-(2′-Cyanoethyl)-amino-3-methyl-3-penten-2-one (II).—Mixing of 7.0 g. (0.060 mole) of 3-methylacetylacetone and 4.0 g. (0.057 mole) of β-aminopropionitrile and cooling of the hot reaction mixture gave the solid product. Recrystallization from benzene gave 9.0 g. (92%) of colorless needles, m. p. 109–110°. The compound forms a red color with ethanolic ferric chloride.

Anal. Calcd. for $C_8H_{14}N_2O$: C, 65.03; H, 8.43. Found: C, 65.25; H, 8.36.

The ultraviolet absorption spectrum, measured as reported for the preceding compound, had a peak of 327 mμ (log ε = 4.048; concentration 0.0092 g./l. in 95% ethanol).

4-N-(2′-Cyanoethyl)-methylamino-3-penten-2-one (III).—Twenty grams (0.20 mole) of acetylacetone and 17.0 g. (0.20 mole) of β-methylaminopropionitrile were mixed and heated on a steam cone for one half-hour. White needles (32.5 g., 98%) formed on cooling, m. p. 69–70°. These gave a purple color with ethanolic ferric chloride.

Anal. Calcd. for $C_8H_{14}N_2O$: C, 65.03; H, 8.43. Found: C, 64.85; H, 8.61.

The ultraviolet absorption spectrum, measured as described for the preceding compounds, had a maximum at 306 mμ (log ε = 4.357; concentration 0.0006 g./l. in 95% ethanol).

Infrared Absorption Spectra

The infrared spectra of compounds I-XV were measured from 650 to 3800 cm.$^{-1}$ with a Perkin-Elmer model 12B recording infrared spectrometer employing a sodium chloride prism. Table I summarizes the results. The samples were in the form of Nujol mulls, so the strong bands of Nujol at 1378, 1458 and about 2920 cm.$^{-1}$ appear in all the spectra. Since these bands are due to aliphatic C–H bending and stretching vibrations,[14] they would doubtless be present in the spectra of the compounds alone. They have therefore been included in the table and marked with an asterisk. Nujol also has a weak band at 720 cm.$^{-1}$ which probably would not be exhibited by the compounds. This has been observed in some of the spectra, and is also marked in the table. The accuracy of the wave length measurement is estimated to be ±1 cm.$^{-1}$ at 1000 cm.$^{-1}$, ±4 cm.$^{-1}$ at 1500 cm.$^{-1}$ ± 7 cm.$^{-1}$ at 2000 cm.$^{-1}$, and ±17 cm.$^{-1}$ at 3000 cm.$^{-1}$.

XVI

Compounds I-X.—We shall consider first the 1500–1700 cm.$^{-1}$ region of the spectra of compounds I-X. Here one expects to find bands due to the phenyl group, the carbonyl group, to C=C bonds, and to the N–H bending of amines. The phenyl bands occur very nearly at 1500 and 1600 cm.$^{-1}$.[15] They are characteristic and are rather easily identified by their intensity and shape. The carbonyl stretching vibration in ketones is found quite consistently at the following wave numbers

(a) Unconjugated ketones,[15a]  1705–1720[16,17,18,19]

(b) α,β-Unsaturated ketones, (including aryl ketones)  1665–1700[16,17,18,19]

(c) α,β,α′,β′-Unsaturated ketones, (including diaryl ketones)  1650–1670[16,17,18]

It is noteworthy that further extension of the conjugation to the γ,δ bond  has little additional effect on the carbonyl frequency. The C=C band is to be expected at 1600–1625 cm.$^{-1}$ in these compounds since it is in every case conjugated with the carbonyl group, and in some cases is also conjugated with a phenyl group.[15] The intensity of this band is known to vary greatly from one compound to another. Primary amines exhibit an N–H bending absorption at 1580–1640 (usually only one band is observed).[15] Little information seems to be available on secondary amines. Finally one often observes "extra" bands in this region which are due to combination tones and overtones. Their intensity may be enhanced by Fermi resonance so that they occasionally appear to be moderately intense.

Since our compounds I-X contain both keto and amino groups, it is convenient for discussion to classify them in several categories

	Examples
(1) α-Amino-α,β,α′,β′-unsaturated ketones	
(a) N-Disubstituted	V, VI
(2) β-Amino-α,β-unsaturated ketones	
(a) N-Unsubstituted	IV
(b) N-Monosubstituted	I, II
(c) N-Disubstituted	III
(3) β-Amino-α-β,α′,β′-unsaturated ketones	
(a) N-Monosubstituted	VII, VIII, IX
(b) N-Disubstituted	X

We now consider the bands which are observed experimentally in the double bond region. These are reproduced in Fig. 1 in the form of a line chart. The height of a line is a measure of the band intensity. The cross-hatched areas indicate the regions in which the carbonyl bands are expected to appear.

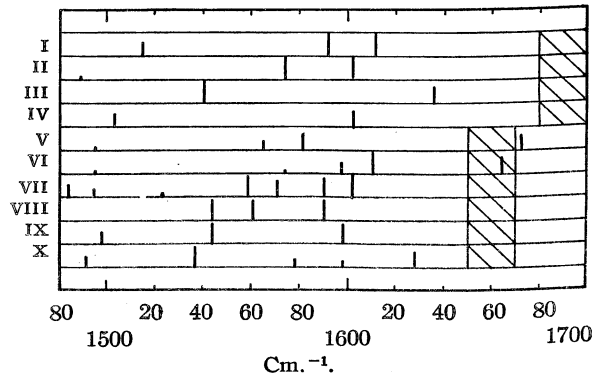

Fig. 1.—Infrared absorption spectra.

Only the two α-amino-α,β,α′,β′-unsaturated ketones (V and VI) have carbonyl bands in the expected range. The phenyl bands are rather

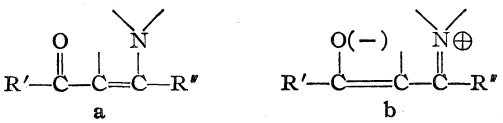
easily located in these two compounds, and the 1610 band in VI may well be due to the C=C vibration. The only puzzling questions are the explanation of 1565 cm.$^{-1}$ in V and the whereabouts of the C=C band in V.

In all the remaining compounds (I-IV and VII-X) the highest band in the 1500–1700 cm.$^{-1}$ region, which is presumably the C=O band, is lower than expected by from 20 to 80 cm.$^{-1}$. It is well known[19d] that hydrogen bonding will lower a carbonyl frequency. This effect can not be operative in III or X, however (nor in V or VI), because they are tertiary amines. One must therefore conclude that the substitution of an amino group in the beta position of these α,β-unsaturated ketones lowers the carbonyl frequency. This is particularly striking when one compares VI and X, since these compounds are identical except for the position of substitution.

Compound III should possess a C=C band. The only band in the double bond region besides the carbonyl band is an intense one at 1541, which is 60 cm.$^{-1}$ lower than expected. It can scarcely be due to a combination tone because of its marked intensity. In X one finds an analogous band in nearly the same position, 1537 cm.$^{-1}$. There are in addition phenyl bands at 1491 and 1598, and an unexplained band at 1578.

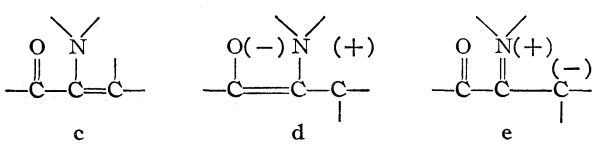
Let us now consider why in compounds III and X the carbonyl band is low, why the C=C band is missing, and what may be the origin of the band near 1540. One possibility is that the high band

is not really due to the C=O group, but that it is due to C=C and that the C=O band is missing. This is unlikely because (a) the carbonyl band is almost invariably a strong band, and (b) the 1540 band must still be explained. Another possibility is that with the amino group substituted on the β carbon atom, the ionic resonance form (b) can contribute appreciably to the ground state.



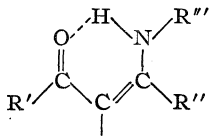
a b

This would have the effect of lowering the C=O frequency, lowering the C=C frequency, and raising the C—N frequency. Thus it does qualitatively fit the observed results. The 1540 band would then be explained as either the lowered C=C or the enhanced C—N frequency —probably the former. This explanation also makes it understandable that the α-amino ketones (V and VI) do not exhibit these anomalies, since the ionic resonance structures that one can write in this case (d and e) would be expected to contribute much less to the actual ground state of the molecule.[20]



c d e

The remaining compounds (I, II, IV, VII, VIII and IX) are further complicated by hydrogen bonding. It has been shown[21] that hydrogen bonding will lower a carbonyl frequency, and it has already been mentioned that this bonding cannot occur in compounds III, V, VI, nor X because they are tertiary amines. Now it is precisely in compounds III and X that the anomalous lowering of the carbonyl frequency is smallest. In the other β-amino ketones the effect of hydrogen bonding is apparently superimposed on this first effect. This is supported by the fact that no N–H stretching frequency is observed in the usual region around 3300 cm.$^{-1}$. The N–H band has probably been broadened and lowered to around 3000 cm.$^{-1}$ where it is hidden by the C–H bands. The spectrum of II was measured in chloroform solution and no shift to higher frequencies was observed. The hydrogen bonding must therefore be largely intramolecular. It will be noted that these compounds offer favorable opportunities for chelation.



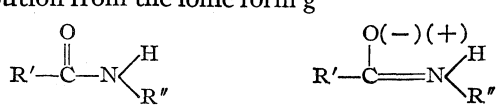
In general the spectra of these remaining β-amino ketones show the same features as those of III and X except for having lower carbonyl bands. The phenyl bands can usually be found readily, and the C=C not at all if one assigns the highest frequency to C=O. Extra bands appear in many cases which may be due to the N–H bending vibration. And finally there is in nearly every case a strong band somewhere in the range 1500–1560 whose explanation is puzzling. We can think of no explanation for this other than the one already advanced.

When the spectra of compounds I-IV and VII-X were first measured, the compounds were suspected of being monosubstituted amides because of this strong band around 1540 cm.$^{-1}$. Richards and Thompson[22] give some general results for amides in the solid state

	Band "B"	C=O
R—CO—NH_2	1630	1655
R—CO—NHR	1530–1570	1640–1680
R—CO—NR_1R_2	....	1650

Band "B" near 1540 cm.$^{-1}$ is so characteristic of monosubstituted amides that it, in conjunction with an N–H stretching band near 3270 cm.$^{-1}$, serves as an excellent test for this class of compounds. We have already pointed out, however, that our compounds I-IV and VII-X are not amides but are vinylogs of amides.

The question now arises as to whether this 1540 cm.$^{-1}$ band might not have the same explanation in the monosubstituted amides and in the vinylogs. The origin of band "B" in amides is not settled. Richards and Thompson[22] discuss four possible explanations and conclude that it is due to the N–H bending motion. This is supported by its absence in disubstituted amides. These authors have pointed out that deuterization experiments should provide a critical test of this explanation. Should it be disproved, a possible alternative is to explain band "B" as the C-N stretching frequency enhanced by a large contribution from the ionic form g



f g

The analogy to the vinylogs (structures a and b) is evident, and affords some support for this idea. Nevertheless there are certain difficulties with this explanation. In the first place the ionic form must make a very important contribution

(20) Additional ionic resonance forms besides d and e are of course possible in the cases having phenyl groups attached to this system.

(21) The work of Thompson, *et al.*, reference 19d indicates that simple hydrogen bonding can lower the carbonyl frequency in some cases. Rasmussen, *et al.*, reference 19c, have found that intramolecular hydrogen bonding as in diacetone alcohol has almost no effect on the carbonyl vibrational frequency. On the other hand these latter authors state that "conjugated chelation" as in enolyzed beta-diketones produces a major shift of the carbonyl infrared band to about 1613 cm.$^{-1}$ with a considerable increase in intensity. The analogy between the structures of β-secondary or primary amino α,β-unsaturated ketones and the enols of β-diketones is obvious.

(22) Richards and Thompson, *J. Chem. Soc.*, 1248 (1947).

to the final ground state if the C–N stretching frequency is to be as high as 1540 cm.$^{-1}$. This should at the same time lower the carbonyl frequency markedly, since it acquires a large amount of single bond character. This frequency is indeed lower in amides than in aldehydes and unconjugated ketones, but by nowhere nearly the amount expected. Secondly one wonders why the 1540 cm.$^{-1}$ band is found only in monosubstituted amides, whereas with the vinylogs the 1500–1560 band appears regardless of whether the amine group is unsubstituted, monosubstituted, or disubstituted. We are therefore inclined to feel that the origin of the 1540 band is fundamentally different in the amides and in their vinylogs. Conversely if the origin is actually different, several of our unsaturated ketones might be expected to exhibit *two* bands between 1500 and 1600 cm.$^{-1}$ (in addition to any phenyl bands) ... namely the characteristic band at 1500–1560 cm.$^{-1}$ due to the resonance effect already described, and a second band due to the N–H bending in a secondary amine. Two bands are found in compounds I, VII and VIII, although there is only one in II and IX.

Compounds XI–XV.—Compounds XI and XII have been indicated to be the *trans* and *cis* modifications, respectively, of 1-benzyl-2-phenyl-3-*p*-toluylethyleneimine,[6,8,9] and it is of interest that while the *trans* form (XI) exhibits a carbonyl band in the normal region for α,β-unsaturated carbonyls (including aromatic unsaturation), the *cis* form (XII) has a band about 25 cm.$^{-1}$ below this region. These spectra help settle the relationship of the configuration of structure XIII to that of XI, inasmuch as its band in the α,β-unsaturated carbonyl region, 1680–1700 cm.$^{-1}$, resembles that of XI rather than XII.

Compound XV is the structure shown for the reaction product of phenylhydrazine with the ethyleneimine XII,[9] but the possibility was considered that the correct structure might instead be represented by XVI. A comparison of its infrared spectrum with that of the other four compounds (XI–XIV) confirms the previous conclusion that it has the pyrazoline structure (XV) rather than the ethyleneimine form (XVI). Thus for example it has the moderately strong bands at 1138 and 1394 cm.$^{-1}$ which have counterparts in XIV but not in XI, XII, nor XIII. Moreover it does not exhibit the strong bands at 1020–1060, 1175–1185, 1220–1240 and 1325–1360 cm.$^{-1}$ shown by each of XI, XII and XIII.

Summary

1. Certain β-amino α,β-unsaturated ketones have been shown to behave chemically more like amides, of which they are vinylogs, than like ketones or vinyl amines.

2. Infrared spectra of fifteen unsaturated amino ketones or derivatives thereof have been studied and their peculiarities discussed. The presence of an amino group (either substituted or unsubstituted) on the beta carbon atom of an α,β-unsaturated ketone lowers the carbonyl band by 20–80 cm.$^{-1}$.

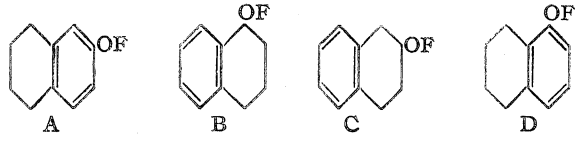
The Catalytic Dehydrogenation of 2-Substituted Tetrahydronaphthalene Derivatives

BY MELVIN S. NEWMAN AND J. ROGER MANGHAM[1]

The following report describes a continuation of studies designed to obtain more information about the liquid phase dehydrogenation over palladium-on-charcoal of oxygenated hydroaromatic compounds. The previous reports,[2,3] respectively, dealt with 6-substituted 1,2,3,4-tetrahydronaphthalenes, A, and 1-substituted 1,2,3,4-tetrahydronaphthalenes, B, where OF indicates the oxygenated function. Since the oxygenated functions of A and B differed both in their positions with respect to the point of ring fusion and in their relative positions with respect to the hydrogen to be removed, it is necessary to study compounds of type C and D before a complete discussion can be attempted. In this paper we describe the behavior of 2-substituted-1,2,3,4-tetrahydronaphthalenes, C, under the above conditions.



A B C D

In the discussion R will be used to designate the 1,2,3,4-tetrahydro-2-naphthyl radical and R′, the 2-naphthyl radical. In Table I are summarized the results with the following compounds: $RCOOCH_3$, I; RCH_2OH, II; RCH_2OCOCH_3, III; RCHO, IV; $R\overline{CHOCH_2CH_2O}$, V; $RCOCH_3$, VI; RCH_2COCH_3, VII; and $RCH_2CH_2COCH_3$, VIII.

(1) This work was taken from the dissertation submitted by J. R. Mangham to The Ohio State University in partial fulfilment of the requirements for the Ph.D. degree, December, 1948.

[a] The yields of hydrogen are based on the assumption that each mole of tetralin derivative will evolve two moles of hydrogen during dehydrogenation. [b] Yields represent purified naphthalene derivatives, except as noted. [c] The theoretical amount of gas is four moles ($3H_2$ + 1 CO) per mole. [d] Yield based on index of refraction measurements. Recovered 9.0% of original acetate. [e] A portion of the yield was derived from a saponification equivalent determination. [f] The theoretical amount of gas is three moles ($2H_2$ + 1 CO) per mole. [g] Probably contaminated with 2-methyltetralin. Recovered 50.5% of the original acetal. [h] Yield based on slightly impure material.

Experimental[4]

Methyl 1,2,3,4-Tetrahydro-2-naphthoate, I.—A large scale synthesis of 1,2,3,4-tetrahydro-2-naphthoic acid, involving a modification of Baeyer's synthesis,[5] was carried out in 12 gallon Pyrex solution bottles. A solution of potassium hypochlorite was prepared from 8.11 kg. of commercial calcium hypochlorite (H. T. H., Mathieson Alkali Co.), 5.66 kg. of potassium carbonate, 1.62 kg. of potassium hydroxide and 43 l. of water. Since the 2.50 kg. (14.2 moles) of methyl 2-naphthyl ketone to be oxidized was much greater than that previously used,[6] it was added portionwise, during two hours, to the vigorously stirred oxidizing solution,[7] held between 60 and 70° by external cooling. After an additional one and one-half hours of stirring at this temperature, a solution of 1.40 kg. of sodium bisulfite in 3.5 l. of water was added. The 2-naphthoic acid was precipitated by the addition of 7.4 l. of concentrated hydrochloric acid and the liquid was removed by suction filtration with fritted filter sticks. The damp acid was dissolved in 18 l. of solution containing 825 g. of potassium hydroxide. With carbon dioxide bubbling in to control the basicity of the reducing medium,[5,8] 37.8 kg. of 3% sodium amalgam was added during eight hours. At this point reduction to the dihydro acids[9] was complete as indicated by an oxidation test[5] with cold dilute potassium permanganate. This solution was filtered free of insoluble material and combined with 9.2 l. of 18 *N* sulfuric acid. After removal of the liquid, the damp mixture of dihydro acids was dissolved in 28 l. of solution containing 4.83 kg. of sodium hydroxide. To this solution was added 4.46 kg. of Raney nickel–aluminum alloy[10] in portions during thirty hours. After removal of the nickel catalyst by filtration, the alkaline solution was divided into two equal amounts, each of which was allowed to siphon slowly into 19 l. of vigorously stirred concentrated hydrochloric acid. After the batches of precipitated acid had been freed of filtrate, dissolved in a total of 30 l. of water containing 650 g. of potassium hydroxide and combined, the solution was cooled to about 10° by the addition of ice. Potassium permanganate was added until no further decolorization occurred (500 ml. of saturated solution). After clarification with saturated sodium bisulfite solution, the solution was siphoned slowly into 4.5 l. of vigorously stirred concentrated hydrochloric acid. The solid was washed with water until free of aluminum salts.

Further purification was accomplished by fractional precipitation from alkaline solution.[9] After six fractions of impure acid had been obtained by addition of successive portions of 50 ml. of concentrated hydrochloric acid, the remainder of the product was precipitated, dried, and recrystallized from petroleum ether (b. p. 65–69°). The yield of 1,2,3,4-tetrahydro-2-naphthoic acid (RCOOH) from the last fraction was 1200 g., m. p. 96.0–96.6°. Fractions 1–6 were fractionally precipitated individually by a similar procedure and yielded an additional 179 g. of pure acid. The total yield was 1379 g. (53.2%). The methyl ester, I, boiled at 102–105° (1 mm.), $n^{20}D$ 1.5314.

The acid chloride boiled at 122–126° at 2 mm. The amide melted at 138.0–138.8°.

Anal.[c] Calcd. for $C_{11}H_{13}ON$: N, 8.2. Found: N, 8.0.

Methyl 1,2,3,4-Tetrahydro-2-naphthyl Ketone, VI.—Into a solution made from 16.5 g. of metallic lithium, 200 g. of methyl iodide, and 900 ml. of ether[11] was slowly added a solution of 35.0 g. (0.2 mole) of RCOOH in 1.4 l. of ether. The mixture was treated with water and the neutral portion was distilled to yield 21.4 g. (61.7%) of the desired ketone, VI, as a colorless oil, b. p. 135–138° (4 mm.), $n^{20}D$ 1.5426. The semicarbazone melted at 192.0–193.2° with dec.

method,[12] the reaction requiring two hours for evolution of 84% of the theoretical amount of hydrogen chloride gas. Upon vacuum distillation the aldehyde[13] was obtained as a colorless oil, b. p. 90–92° (0.5 mm.), which solidified rapidly at room temperature. This solid product was probably the trimer since it broke down readily at elevated temperatures to yield the oily aldehyde. The semicarbazone melted at 194.8–196.8° with dec.

2-(1,2,3,4-Tetrahydro-2-naphthyl)-1,3-dioxolane, V.—A mixture of 54.5 g. (0.34 mole) of aldehyde IV, 40 ml. of ethylene glycol, 500 ml. of benzene and a trace of *p*-toluenesulfonic acid was refluxed for three days under a fractionating column with a special take-off head for removing the bottom layer of distillate.[14] After the acid catalyst had been removed by washing with sodium bicarbonate solution, 54.5 g. (78.5%) of the acetal, V, was obtained as a colorless oil, b. p. 126–128° (1 mm.), $n^{20}D$ 1.5423.

Anal.[e] Calcd. for $C_{13}H_{16}O_2$: C, 76.4; H, 7.9. Found: C, 75.9, 76.0; H, 7.8, 7.9.

1,2,3,4-Tetrahydro-2-naphthylcarbinol, II.—During one hour a solution of 194 g. (0.95 mole) of ethyl 1,2,3,4-tetrahydro-2-naphthoate, prepared by esterification of RCOOH with ethanol, in 1 l. of ether was dropped into an ethereal solution of 20 g. (0.52 mole) of lithium aluminum hydride.[15] After the reaction mixture had been decomposed with water and dilute sulfuric acid, 147.2 g. (95.5%) of the desired carbinol, II, was obtained as a colorless oil, b. p. 114–116° (1 mm.), $n^{20}D$ 1.5559. Its 1-naphthylurethan melted at 108.6–109.2°.

Anal.[k] Calcd. for $C_{11}H_{14}O$: C, 81.4; H, 8.7. Found: C, 81.4, 81.4; H, 8.8, 9.2. Calcd. for $C_{22}H_{21}O_2N$: C, 79.7; H, 6.4; N, 4.3. Found: C, 79.9, 79.9; H, 6.1, 6.0; N, 4.4, 4.3.

The corresponding acetate, III, was formed in 94% yield by heating the carbinol, II, in benzene with acetic anhydride and a trace of *p*-toluenesulfonic acid. It formed a colorless oil, b. p. 124–126° (1.5 mm.), $n^{20}D$ 1.5238.

Anal.[k] Calcd. for $C_{13}H_{16}O_2$: C, 76.4; H, 7.9. Found: C, 76.8, 76.7; H, 8.2, 8.5.

1-(1,2,3,4-Tetrahydro-2-naphthyl)-2-propanone, VII.—To a cooled solution of 224.0 g. (1.38 moles) of carbinol, II, 109.0 g. (1.38 moles) of dry pyridine and 250 ml. of dry toluene was added slowly 164 g. (1.38 moles) of purified thionyl chloride. After heating the reaction mixture on the steam-bath overnight, the yield of chloride, RCH_2Cl, b. p. 114–118° (1.5 mm.), was 233.8 g. (93.8%). As a structure proof of the product, a portion was refluxed for thirty-six days with potassium acetate and a trace of sodium iodide in anhydrous ethanol. The acetate, thus formed, was readily hydrolyzed by aqueous alkali and the product (68% from the chloride) was shown to be identical with authentic 1,2,3,4-tetrahydro-2-naphthylcarbinol, II, by comparison of the 1-naphthylurethans, m. p. 108.2–108.6 and mixed m. p. 108.5–109.2°.

The Grignard reagent prepared from 54.2 g. (0.3 mole) of the chloride, RCH_2Cl, was added over a period of two hours to a solution of 57.0 g. (0.56 mole) of acetic anhydride in 57 ml. of ether cooled by an external Dry Ice–acetone-bath at −78°.[16] After the reaction mixture has been treated with ammonium chloride solution, 44.3 g. (78.6%) of the ketone, VII, was obtained as a colorless oil, b. p. 114–117° (1 mm.), $n^{20}D$ 1.5362. The semicarbazone melted at 199.8–201.6° with dec.

Anal.[e] Calcd. for $C_{13}H_{16}O$: C, 82.9; H, 8.6. Found: C, 82.4, 82.5; H, 8.5, 8.7. Calcd. for $C_{14}H_{12}ON_3$; N, 17.1. Found: N, 16.9.

1-(1,2,3,4-Tetrahydro-2-naphthyl)-3-butanone, VIII.—The preparation of VIII from RCH_2Cl by way of the aceto-acetic ester synthesis failed. The low boiling material obtained probably resulted from dehydrohalogenation of the starting alkyl chloride. Alternately, gaseous formaldehyde was passed into the Grignard reagent[17] made from 161.9 g. (0.895 mole) of RCH_2Cl until the color test[18] for the Grignard reagent was negative (about thirty minutes). After decomposition of the reaction mixture with dilute sulfuric acid, there was obtained 96.4 g. (61%) of 2-(1,2,3,4-tetrahydro-2-naphthyl)-ethanol as a colorless oil, b. p. 123–127° (1 mm.), $n^{20}D$ 1.5490.

Anal.[e] Calcd. for $C_{12}H_{16}O$: C, 81.7; H, 9.2. Found: C, 81.8; H, 9.4.

By a process similar to one above, the alcohol was treated with thionyl chloride to yield the corresponding chloride (93.1%) as a colorless oil, b. p. 104–109° (0.5 mm.). In a reaction similar to one above involving the Grignard reagent from 42.5 g. (0.22 mole) of the chloride, RCH_2CH_2Cl, and 42.4 g. (0.415 mole) of acetic anhydride there was obtained 27.4 g. (62%) of the desired butanone, VIII, as a colorless oil, b. p. 124–126° (1 mm.) $n^{20}D$ 1.5320. The semicarbazone melted at 171.4–173.4° with dec.

Anal.[e] Calcd. for $C_{14}H_{18}O$: C, 83.1; H, 9.0. Found: C, 82.1, 82.4; H, 9.2, 9.0. Calcd. for $C_{15}H_{21}ON_3$: N, 16.3. Found: N, 16.4.

Dehydrogenation Experiments

Palladium-on-Charcoal Catalyst.—The catalyst used in this work was similar to that of the previous investigations.[2,3] A check on the activity of the catalyst was made by dehydrogenation of methyl 1,2,3,4-tetrahydro-6-naphthoate as before.[2] About the same amount of hydrogen was evolved in about the same amount of time.

General Description of Dehydrogenations.—The apparatus made for the dehydrogenations was designed to improve on the two-flask technique in the previous investigations.[2,3] It consisted of a 50-ml. Claisen flask with a condenser and receiver sealed onto its horizontal side arm. In the verticle side-arm was sealed a coil-type condenser through which water was circulated during those dehydrogenations in which water was not liberated. In the dehydrogenation experiments where water was evolved, acetic acid vapor was refluxed through the sealed-in coil. The heated coil served to allow the water to distill from the reaction mixture and prevent excessive splattering and to condense the organic vapors. The remainder of the dehydrogenation procedure was essentially the same as before.

Three duplicate runs were made on each compound, the first served as a pilot run. In the second and third the products were isolated as nearly quantitatively as possible and served as checks on the reproducibility of the results obtained. Since the results of the last two were in substantial agreement, a description is given only for the third run. In each case 0.07 mole ± 0.01 g. of the compound was dehydrogenated. Table I summarizes the experimental details recorded. In working up the products of the reactions, the material was always vacuum distilled from the catalyst prior to further treatment.

$RCOOCH_3$, I.—The distilled dehydrogenated ester was saponified and the acid was recrystallized from ethanol. It melted, alone and mixed with authentic 2-naphthoic acid, at 183.4–185.0°.

RCH_2OH, II.—The product from 11.36 g. of II was fractionated under reduced pressure. The first fraction, 2.47 g. (27.6%), naphthalene, was obtained by careful sublimation into a chilled receiver. A portion, after recrystallization from ethanol, melted at 78.6–80.2°,

mixed m. p. 79.0–80.4°. The second fraction, 5.96 g. (59.8%), b. p. 69–74° (1 mm.), formed a picrate, m. p. 115.8–116.4°, mixed m. p. not depressed with picrate of 2-methylnaphthalene.

A gas analysis[19] showed that the gas evolved was a mixture of carbon monoxide and hydrogen. The amounts of carbon monoxide and naphthalene obtained corresponded rather closely, but a quantitative balance was not undertaken.

RCH_2OCOCH_3, III.—The product obtained from 12.41 g. of III was separated into three fractions by vacuum distillation. Fraction 1, 7.26 g. (73.0%), b. p. 126–131° at 23 mm., formed 2-methylnaphthalene picrate, m. p. and mixed m. p. 116.4–117.4°. Fraction 2, 1.58 g., b. p. 131–177° at 23 mm., was shown by a saponification equivalent determination (assuming the molecular weight of III) to consist of about 40% of ester and 60% of 2-methylnaphthalene. The picrate of 2-methylnaphthalene was isolated and identified. Fraction 3, b. p. 177–180° at 23 mm., weighed 1.06 g. After a portion had been saponified, the carbinol product boiled at 120–125° at 2 mm. The 1-naphthylurethan which was prepared melted at 102–106°, which indicated a mixture of the two 1-naphthylurethans, that of 1,2,3,4-tetrahydro-2-naphthylcarbinol (m. p. 108.6–109.2°) and that of 2-naphthylcarbinol (m. p. 141.2–142.8°). The latter was prepared from 2-naphthylcarbinol,[20] m. p. 81.2–82.0°, obtained by reduction of 2-naphthoic acid with lithium aluminum hydride.[21] Authentic 2-naphthylmethyl acetate,[22] m. p. 57.2–57.8°, was prepared by refluxing 2-naphthylcarbinol with acetic anhydride and a trace of *p*-toluenesulfonic acid in benzene. Mixtures of III and 2-naphthyl acetate were made and their refractive indices determined.

% 2-naphthylmethyl acetate	$n^{20}D$
20	1.5344
40	1.5479
50	1.5530

Since the refractive index of Fraction 3 was $n^{20}D$ 1.5473, it contained about 40% 2-naphthylmethyl acetate and 60% unchanged III. Thus, in all, there was obtained 3.0% of 2-naphthylmethyl acetate, 82.5% of 2-methylnaphthalene and 9.0% of III based on the starting 14.21 g. of III.

RCHO, IV.—Pure naphthalene was obtained by direct sublimation from the catalyst. By analysis[19] the gas collected was shown to contain carbon monoxide, hydrogen and methane. The amounts of carbon monoxide and methane obtained account reasonably well for the amount of naphthalene obtained in the experiment; however, a quantitative balance was not established.

$RCHOCH_2CH_2O$, V.—The product from 14.30 g. of V was separated into two main fractions by vacuum distillation. Fraction 1, 1.58 g. (15.9%), b. p. 104–109° at 6 mm., yielded 2-methylnaphthalene picrate. Since the yield of picrate was somewhat lower (54%) than that from authentic 2-methylnaphthalene prepared in a similar manner (68%), we conclude that Fraction 1 probably contained a small amount of 2-methyltetralin. Fraction 2, b. p. 157–160° at 6 mm., weighed 7.21 g. A portion was hydrolyzed by boiling with dilute aqueous alcoholic hydrochloric acid and the product converted to its semicarbazone in 72% over-all yield. The semicarbazone melted alone and mixed with the semicarbazone of 1,2,3,4-tetrahydro-2-naphthaldehyde at 191–194° with dec. Fraction 2, then, was essentially unchanged V and represents a 50.5% recovery of the starting material. In addition to the two fractions, there remained 3.3 g. of residue.

$RCOCH_3$, VI.—The addition of 0.10 g. of fresh catalyst, after an hour's heating, caused a considerable increase in the pace of the dehydrogenation reaction. The distilled material from 12.20 g. of VI was separated into two main fractions by vacuum distillation. The first fraction, 4.24 g. (38.7%), b. p. 70–77° (0.5 mm.), formed a picrate which melted at 76–78° alone and mixed with the picrate of authentic 2-ethylnaphthalene. The second fraction, 6.58 g. (55.2%), b. p. 95–99° (0.5 mm.), after recrystallization from an alcohol–water mixture, melted alone and mixed with authentic methyl 2-naphthyl ketone at 53–54°. The semicarbazone of the second fraction melted alone and mixed with the semicarbazone of authentic methyl 2-naphthyl ketone at 222.0–223.4°.

RCH_2COCH_3, VII.—The slow rate of evolution of hydrogen from 13.18 g. of VII was not increased by the addition of a fresh portion of catalyst at the end of two hours of heating. After removal of the product from the catalyst by vacuum distillation, there remained 3.4 g. of high boiling residue. The product was separated into two fractions by distillation at reduced pressure. Fraction 1, 1.55 g. (15.6%), b. p. 66–129° (1 mm.), consisted mainly of 2-methylnaphthalene as judged by the ready formation of the picrate. Fraction 2, 7.02 g. (54.5%), b. p. 129–131° (1 mm.), was shown to be 2-naphthyl-2-propanone by comparison with an authentic sample. A portion of Fraction 2, after recrystallization from petroleum ether (b. p. 30–60°), melted alone and mixed at 36.0–37.2°. Its semicarbazone melted at 182.8–184.4° with dec.; a mixed melting point showed no depression.

The previously unknown 2-naphthyl-2-propanone was synthesized in 42% yield from 2-naphthylacetic acid[23] and methyl lithium by a procedure similar to that described in the experimental discussion above. It boiled at 131.5–132.5° at 1.5 mm. and after recrystallization from petroleum ether (b. p. 30–60°) melted at 36.0–37.2°. The semicarbazone melted at 183.0–184.6° with dec.

Anal.[c] Calcd. for $C_{13}H_{12}O$: C, 84.7; H, 6.6. Found: C, 84.9; H, 6.5. Calcd. for $C_{14}H_{15}ON_3$: N, 17.4. Found: N, 17.3.

$RCH_2CH_2COCH_3$, VIII.—With the catalyst remained 2.8 g. of resinous material. The product from 14.16 g. of VIII was fractionated. Fraction 1, 1.71 g. (15.6%), b. p. 76–80° (1 mm.), was shown to be 2-ethylnaphthalene by formation of its picrate which, after one recrystallization from ethanol, melted at 75.2–76.8° alone and mixed with an authentic sample. Fraction 2, 8.73 g. (62.8%), b. p. 139–142° (1 mm.) was shown to be 1-(2-naphthyl)-3-butanone by its melting point, after recrystallization from petroleum ether (b. p. 30–60°), of 48.4–49.0° (lit.[24] 50°), of its semicarbazone, 171.2–172.8° (lit.[24] 173°) and of its oxime, 119.4–120.8° (lit.[24] 115–116°).

Discussion of Results

A number of the compounds in this dehydrogenation study contained the same oxygenated substituents as those of the previous studies.[2,3] *The carbomethoxy group* (*-$COOCH_3$*) was unharmed in all three cases by the hydrogen which was eliminated from the ring. It is, therefore, concluded that a carboxyl group in a hydroaromatic compound may be protected easily during dehydrogenation over palladium-on-charcoal by conversion to its methyl ester.

In the cases of the compounds containing the *carbinol group* (*-CH_2OH*) the results of the three studies show graded differences. The primary alcohol group on the beta position of the benzenoid ring[2] was hydrogenolyzed to the methyl group, whereas this same group on the alpha position of the saturated ring[3] lost both hydrogen and carbon

monoxide to yield naphthalene almost quantitatively. Hydrogenolysis of the alcohol group to 1-methylnaphthalene occurred only to the extent of 4%. The compound containing the carbinol group on the beta position of the hydrogenated ring lost water in part and carbon monoxide in part, giving 2-methylnaphthalene and naphthalene in the approximate ratio of 2:1. The last results show some similarity to those of each of the others. It seems, therefore, that the fate of the primary alcohol function is dependent both on its position with respect to the point of ring fusion and on the type of ring to which it is bound.

The results of the dehydrogenation of the compounds containing the *ketonic group*, (*-COCH*$_3$) show graded differences. When the compound bearing this group attached to the beta position of the aromatic ring[2] was dehydrogenated, the carbonyl group was reduced to a methylene group; only a small amount of the corresponding naphthyl ketone being obtained. In contrast, the ketone function was not attacked by hydrogen when attached to the alpha position of the hydroaromatic ring.[3] In the latter case, the ring itself was resistant to dehydrogenation and only a small amount of the methyl 1-naphthyl ketone was obtained. The compound bearing the ketonic group at the beta position of the saturated ring, was partially converted to the 2-ethylnaphthalene and partially dehydrogenated to methyl 2-naphthyl ketone. The ratio of the amounts of 2-ethylnaphthalene and methyl 2-naphthyl ketone was approximately 2:3. The results in the last case cited are similar to some extent to those of both of the others. It may be concluded that the behavior of the ketonic group directly bound to the ring depends both upon the type of ring to which it is attached and upon its position relative to the point of ring fusion.

The *aldehyde function* (*-CHO*), when attached to the beta position of the aromatic ring[2] and when attached to the beta position of the hydroaromatic ring, lost carbon monoxide almost quantitatively. However, the decarbonylation reaction is undoubtedly catalyzed by the palladium and is not affected by the removal of hydrogen from the ring.

The two *acetates*, (having the group *-CH*$_2$*OCOCH*$_3$), differing in the position of the ester function on the hydrogenated ring, gave dehydrogenation products that differed in degree but not in kind. The oxygenated function was protected to the extent of 26% in the dehydrogenation of the alpha isomer[3] and only to the extent of 3% in the dehydrogenation of the beta isomer. The other products in each case resulted from hydrogenolysis of the acetate function. It thus appears that it is not feasible to attempt a catalytic dehydrogenation of a compound bearing an alcohol function either free or acetylated.

The two isomeric *propanones*, having the ketone group removed from the saturated ring by a methylene group, yielded somewhat different products. The alpha substituted compound gave a high yield of the corresponding aromatic propanone,[3] whereas the beta substituted compound gave only a fair yield of the corresponding naphthalene derivative. The difference in yields is accounted for by the formation of 2-methylnaphthalene and resinous material in the latter case. Since the beta substituted isomer was heated about 30° higher and about twice as long as the alpha derivative before hydrogen evolution had ceased, the lower yields of aromatic ketone from the former may have been due to pyrolytic decomposition rather than to a dehydrogenation effect.

The differences between the dehydrogenation products of the two butanones, having the ketone group removed from the hydrogenated ring by two methylene groups, are quite a bit greater than those of the propanones described above. The alpha compound[3] in this case was resistant to dehydrogenation and yielded only a small amount (16%) of the corresponding naphthalene ketone, whereas the beta compound dehydrogenated slowly but steadily to give a fair yield (62.8%) of its corresponding naphthalene ketone. The hydrocarbons, isolated from the reaction products, represented the loss of a three carbon fragment (1-methylnaphthalene) from the alpha-butanone and the loss of a two carbon fragment (2-ethylnaphthalene) from the beta-butanone. The hydrocarbon side reaction products presumably resulted from pyrolysis and do not therefore indicate a difference in hydrogenolysis effects resulting from the different relative positions of the parent functional groups on the hydrogenated ring.

Protection of the aldehyde function by formation of its cyclic acetal with ethylene glycol has been tried in only the present case. The only dehydrogenated product isolated, 2-methylnaphthalene, was in low yield. The remainder of the product consisted of high boiling material and unchanged starting material (50.5%). From these results it would appear that this method of protection of aldehydes from decarbonylation during catalytic dehydrogenation has little value.

Summary

The liquid phase catalytic dehydrogenation over a palladium-on-charcoal catalyst of eight oxygenated 2-substituted-1,2,3,4-tetrahydronaphthalenes is described.

The methyl ester, $C_{10}H_{11}COOCH_3$, was converted in high yield into the corresponding naphthalene derivative while the theoretical amount of hydrogen was evolved.

The primary alcohol, $C_{10}H_{11}CH_2OH$, was partially degraded to naphthalene by the loss of hydrogen and carbon monoxide and partially converted to 2-methylnaphthalene by loss of hydrogen and water.

Hydrogenolysis of the acetate function of $C_{11}H_{10}CH_2OCOCH_3$ occurred as the main reaction.

The aldehyde, $C_{10}H_{11}CHO$, readily lost carbon monoxide.

The cyclic acetal, $C_{10}H_{11}\overset{\Big\lceil}{C}HOCH_2CH_2O\overset{\Big\rceil}{}$, did not dehydrogenate smoothly. The only dehydrogenated product isolated, 2-methylnaphthalene, resulted from hydrogenolysis of the acetal.

The ketones $C_{10}H_{11}COCH_3$, $C_{10}H_{11}CH_2COCH_3$ and $C_{10}H_{11}CH_2CH_2COCH_3$ gave fair yields of the corresponding aromatic ketones. The ketonic group of the first was reduced to a methylene group to a considerable extent. Small amounts of the last two were pyrolyzed to form hydrocarbons, with a resulting loss of a two-carbon fragment in each case.

Pyrolysis of Butadiene[1]

BY MARY THOMAS MURPHY[2a] AND ANN CHARLES DUGGAN[2b]

In the pyrolysis of unsaturated hydrocarbons in this Laboratory, it has been observed that the liquid products are frequently colored yellow. This was noted particularly in the pyrolyses of butadiene, isoprene,[3] and isobutylene,[4] where it appeared in the C_7-C_8 region of products. Similar observations were reported in 1932 by Frey and Hepp[5] in a study of the production of aromatic oils from the pyrolysis of simple paraffins. At 850° and atmospheric pressure, butane gave benzene, toluene, xylenes, and a number of olefins and diolefins, principally butadiene and cyclopentadiene. A few degrees above the boiling point of toluene a bright yellow hydrocarbon was obtained; another yellow hydrocarbon appeared in the xylene fraction. Neither of these was identified because they were present in such small amounts.

The first step in this investigation has been to pyrolyze large quantities of butadiene in order to isolate the yellow fraction in amounts large enough to analyze.

Experimental

The apparatus used for the pyrolysis was a quartz furnace 60 × 3 cm., connected to a series of traps, a manometer, a glycerol-filled vacuum pump and a gas meter. The traps were cooled to −78°. To prevent clogging, the first trap was cooled only to −10°. The furnace was heated by two external resistance heaters, and the temperature at the center was measured with a chromel–alumel thermocouple. The temperature was maintained within 10° during a given run. The pressure did not vary more than 2 mm.

The butadiene obtained from Shell Oil Company was of better than 98% purity; it was used without further purification. The hydrocarbon was introduced to the furnace from a pressure bottle kept in an ice-salt-bath, the input rate, usually a mole an hour, being regulated by a needle valve, and the amount put through determined by the loss in weight of the bottle. The tar, largely naphthalene, collected in the first trap, while the lower aromatic fractions condensed mainly in the second and third traps. Nearly all of the unchanged butadiene condensed in the traps, but 2–5% of the total volume was detected in the effluent gases. The gaseous products (insoluble in glycerol, except acetylene to some extent) passed through the gas meter and escaped into the air. During the course of a run several samples were taken for analysis. At the end of each run the products collected were transferred to weighed bottles and stored at −15° until they were analyzed.

Five runs were made in all. In Table I are given the data for run 3. The analysis of the products was made as follows:

The gases were determined on a modified Hempel apparatus developed in this Laboratory.[6] The reagents for the absorption of the various gases were: acetylene, potassium mercuric iodide; isobutylene, 62.5% sulfuric acid; butenes, 71% sulfuric acid; propylene, 82.5% sulfuric acid; ethylene, fuming sulfuric acid. The different concentrations of acid were those recommended by Hurd and Spence[7] for the detection of the various hydrocarbons. Butadiene was determined by its reaction with maleic anhydride.[8] Since, according to Hurd and Spence, butadiene would be absorbed in both the propylene and isobutylene reagents, the values reported for the C_3 and C_4 hydrocarbons are affected by this amount. The saturated portion of the gas was analyzed for hydrogen by oxidation over copper oxide at 285°. The average value, 25%, checked analyses by combustion data which gave 25.8% for hydrogen and 12% for methane.

The tar in the first trap was collected over several runs and distilled. It was found to contain naphthalene and a small yellow fraction boiling above naphthalene, which we have not yet identified.

An approximate analysis from mass spectrometer data[9] for the liquid samples from the other traps showed, in agreement with Staudinger[10] that the liquids are almost exclusively aromatic. The relative abundance of the compounds was as follows: benzene, > 90%; toluene, ≦ 1%; indene, < 1%; dihydroindene, < 1%; tetralin, < 0.5%; styrene, < 1%; ethylbenzene, ≤ 1%. Other peaks not accounted for occurred at 83, 85, 117 and 119. It will be noticed that the benzene/toluene ratio of 90/1 found by the mass spectrometer differs widely from the ratios reported in Tables I and II (15.4/1.0 and 10.8/1.0, respectively), but no explanation for this deviation is apparent.

Carbon (tar)	.075	.264
Carbon in furnace	.075	.264

The liquid products were analyzed by distillation at both ordinary and reduced pressures. In run 3, the liquid products were hydrogenated, before distillation on an 11-mm. Podbielniak column.

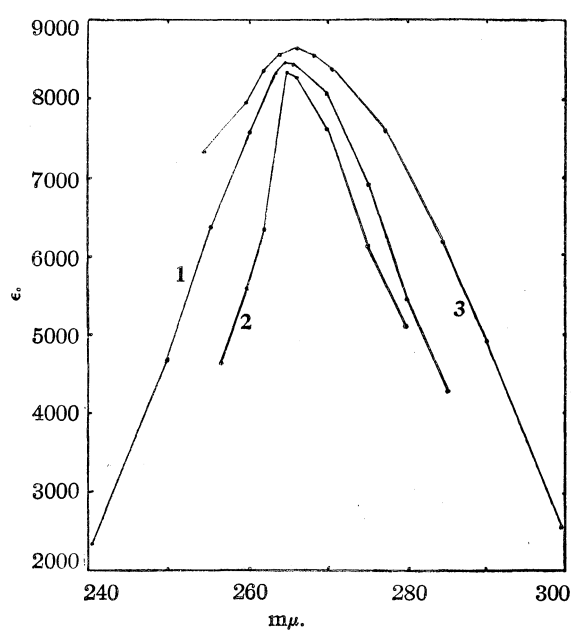

Fig. 1.—Ultraviolet absorption spectra of dimethylfulvene and yellow pyrolysis product: 1, dimethylfulvene in 2,2,4-trimethylpentane; 2, pyrolysis product in *n*-hexane; 3, pyrolysis product in 2,2,4-trimethylpentane.

In Table II are given data for the distillation of the liquid products of run 2. In this case the distillation was carried out on a 35-cm. vacuum-jacketed Vigreux column. The first part of the distillation was run rapidly to prevent polymerization of the dimethylfulvene; 25 cc. of hexadecane was added before the distillation to serve as column hold-up. This distillation showed the presence of cyclopentadiene as well as the aromatic products previously reported in butadiene pyrolysis[10] and indicated that the main yellow product was a C_8 compound. It was subsequently identified as dimethylfulvene by its absorption spectra, hydrogenated products and oxygen derivative.

The sample used for the absorption spectra measurements was obtained by fractional crystallization of the liquid products. After most of the dissolved butadiene had been removed by distillation at room temperature, the remaining liquid was cooled to −80° and filtered through a suction funnel likewise cooled. The process of cooling and filtering was repeated until no more solid could be separated from the yellow liquid. Further separation of the residue was accomplished in a bulb to bulb distillation at 1–2 mm., the receiver being cooled in liquid air. In this way 2.5 cc. of bright yellow liquid was obtained for the absorption spectra measurements.

The absorption in the visible and ultraviolet were measured with a Beckmann Model DU quartz spectrophotometer. Since the work on the spectrum of dimethylfulvene[11] had been done before conventions were established for the reporting of spectral data, it seemed advantageous to repeat the work in this Laboratory in order to facilitate the comparison of the dimethylfulvene spectrum with that of our yellow compound. Accordingly, dimethylfulvene was synthesized by the method of Thiele.[12] Solutions were made from a sample which boiled at 46–48° under 11 mm. pressure and had a freezing point of 0.9°. The 2,2,4-trimethylpentane used as a solvent was distilled over sodium hydroxide and filtered through silica gel. The graphs for the spectra of dimethylfulvene and our yellow compound are shown in comparison in Fig. 1. The absorption maxima, 270 and 365 mμ, are the same as those reported by Stark and his co-workers.

Hydrogenation was carried out under the conditions recommended by Pines and Ipatieff.[13] Three hundred twenty grams of pyrolysis product, including unchanged butadiene, was hydrogenated over Raney nickel at 30 atm. and 25–125°. Distillation was then carried out on a Podbielniak fractionating column. Small amounts of the expected hydrogenation products of dimethylfulvene were obtained: 1.5 cc. isopropylcyclopentene, b. p. 120–122°; 1.8 cc. isopropylcyclopentane, b. p. 126–127.5°, m. p. −113°.

The presence of the fulvene was further substantiated by the formation of its oxide. A dilute solution was allowed to stand in air for a month. At the end of this time a flocculent white precipitate had formed. The solution was centrifuged and the precipitate washed with ether and dried. At 80–90° it reacted in the same way as the oxide of dimethylfulvene[14] which had formed in the same manner. Both oxides exploded when heated to 125°.

The yellow substance also gave a positive color reaction with sulfuric and acetic acids. This test described by Thiele[15] is given by all the simple fulvenes.

The mass spectrometer data indicated the presence of indene, dihydroindene and tetralin, but the small amounts which may have been present were not isolated.

Summary

Butadiene has been pyrolyzed at low pressures in order to study the formation of yellow hydrocarbons produced in the pyrolysis. In addition to

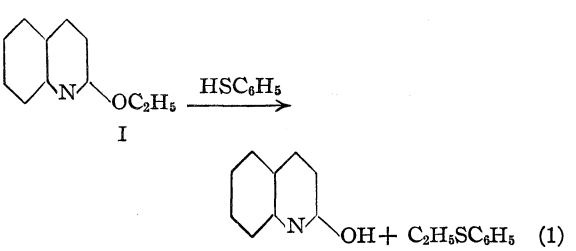
The Reactions of Thiols with Some Alkyl and Aryl Heterocyclic Ethers

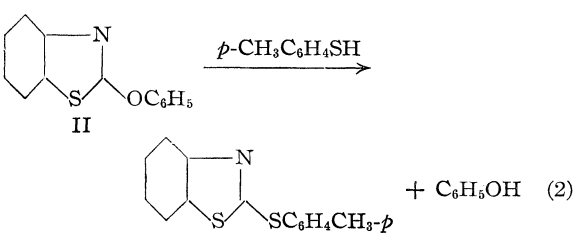
BY GABRIELLO ILLUMINATI AND HENRY GILMAN

Recent work[1] on the action of organolithium compounds on some 2-substituted quinolines has emphasized the special character of the 2-position in quinoline. The present study describes the reactions of aryl thiols on some alkyl and aryl 2- and 4-quinolyl ethers and on corresponding derivatives of 2-benzothiazolyl and 2-benzoxazolyl ethers.

The 2-ethoxy compounds of quinoline (I), benzothiazole and benzoxazole are known to be cleaved by hydrogen chloride[2] to form ethyl chloride and the corresponding 2-hydroxy derivatives. We have now found that a similar cleavage occurs by the action of aryl thiols on these ethoxy compounds at 150–170°, in accordance with the following typical reaction.



This alkylating reaction appears to be general, for 2-benzyloxyquinoline behaves in an analogous manner. However, with aryloxy compounds, the following representative cleavage reaction takes place.



From the results given in Table I it appears that the ease of cleavage of the heterocyclic types varies as follows:

2-Quinolyl > 2-Benzothiazolyl > 2-Benzoxazolyl.—An alkylating reaction appears not to occur with 4-alkoxyquinolines, for 4-ethoxy-7-chloroquinoline (III) reacts in essential accordance with reaction (2).

These reactions generally take place in good yield (see Table I) when aryl thiols like thiophenol, *m*- and *p*-thiocresol and β-thionaphthol are used. An exception in the experiments carried out was *o*-thiocresol, which did not react appreciably with (I), possibly because of steric hindrance. Some reagents containing an acidic hydrogen, other than aryl thiols, have given corresponding exchange reactions with 2-alkoxyquinolines.[3] The fact that benzyl mercaptan cleaved (I) to a small extent (see Table I, Expt. 6) may be accounted for by the lower acidic character of the benzyl mercaptan as compared with that of the aryl thiols.

Aryl thiols can also effect a related reaction with the chlorine atom in the activated positions of quinoline and benzothiazole. For example,

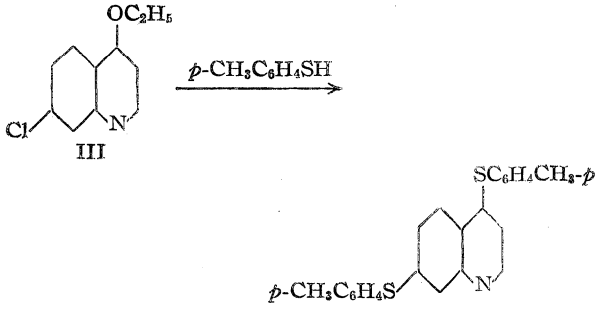
(3) Unpublished studies; see, also, ref. 2.

2-chloroquinoline was converted by thiophenol to phenyl 2-quinolyl sulfide in 79% yield. Surprisingly, this type of reaction was also observed in (III), in which the supposedly stable 7-chlorine in the benzenoid ring was replaced by a *p*-thiocresoxy group to form 4,7-di-(*p*-thiocresoxy)-quinoline.



Compound (III) was obtained quantitatively from 4,7-dichloroquinoline and sodium ethoxide, even when the latter reagent was used in excess.[3a]

A discussion of the course of cleavage of the ethers examined warrants a consideration of an intermediate addition product to the azomethine linkage, in view of the tendency of the ring system of quinoline to form isolable 1,2-dihydro-2-substituted derivatives with some organometallic reagents.[4] However, in our work, no experimental evidence has been found to support such an hypothesis. Also, the conditions in which reactions with organometallic reagents are carried out are different from those used in our experiments, in which we used higher temperatures and no solvent. We have observed that a mixture of thiophenol and 2-ethoxyquinoline, stirred for three days at room temperature, underwent no reaction and no change in color; the starting materials were recovered at low temperature by high vacuum distillation.

Because of a possible relationship between extent of cleavage of the ether and acidity of reagent used and by comparison with other related observations, it appears rather likely that thiols act as nucleophilic cleavage reagents on ethers containing an especially weakened carbon–oxygen bond. Thus ethyl benzyl ether was cleaved to an extent of 2.5% by *p*-thiocresol to give benzyl *p*-tolyl sulfide. This reaction was promoted, as expected, by either sulfuric acid or anhydrous aluminum chloride to give 50 and 75% yields, respectively, of the same sulfide. In an analogous manner thiols react with compounds like ethylene oxide[5] to yield sulfides of the type $HOCH_2CH_2SR$. In addition, ether linkages are cleaved in lignin by mercaptoacetic acid, in presence of hydrogen chloride, to form sulfides of the type $RSCH_2COOH$.[6]

Depending on the firmness of attachment of the groups to the oxygen of the ether, the bond may be cleaved on either side, as we have observed with the alkyl and aryl ethers reported in Table I. It is interesting to note that ethyl β-naphthyl ether, unlike 2-ethoxyquinoline, does not react with thiophenol, even after prolonged treatment. From this point of view the weakening effect of the aromatic ring nitrogen on the carbon–oxygen bond resembles that of the nitro groups in polynitro aromatic ethers.[7] However, a weak ether bond has also been found in piperidinomethyl ethyl ether,[8] in which the tertiary nitrogen bears no double bond.

Experimental

Cleavage by Thiols.—A mixture of the compound to be cleaved and the thiol, in a molar ratio 1:2 to 1:3, was stirred for twenty-four to forty-eight hours, at 150–170°, in a dry nitrogen atmosphere. In the experiments 1 to 9 (see Table I), the 2-hydroxy derivative crystallized at the end of the reaction after cooling and was isolated by filtration. The crystals were washed with a little diethyl ether or petroleum ether (b. p. 32–35°) to give a practically pure compound.

The reaction mixture, or the filtrate, was diluted with diethyl ether or petroleum ether (b. p. 32–35°) and extracted with a 5% sodium hydroxide solution. This alkaline extract contained the unreacted thiol and, for the experiments 10 and 11, the phenol formed as one of the cleavage products. In some cases, as, for instance, in the experiments 1 to 6, it was possible to extract completely the unreacted heterocyclic compounds with hydrochloric acid, so the ether-soluble fraction consisted of cleavage products only (sulfides). Usually, however, the ether-soluble fraction contained more or less large amounts of the disulfide corresponding to the thiol used.

2-Benzyloxyquinoline.—To a solution of 0.16 mole of sodium benzyloxide in benzyl alcohol, 24.4 g. (0.15 mole) of 2-chloroquinoline was added, and the mixture was stirred at 120° overnight. After cooling, the reaction product was diluted with ether and washed with water. After removal of the ether, the excess benzyl alcohol was removed by distillation at reduced pressure. The residue was distilled at 170° at 0.8 mm. to give 28 g. (80%) of a solid melting at 46–48°, which was purified by crystallization from ethanol to form white crystals (m. p. 48.5–49.5°).[9]

Anal. Calcd. for $C_{16}H_{13}ON$: N, 5.95. Found: N, 5.87.

2-Phenoxybenzothiazole.—To a solution of 0.3 mole of sodium phenoxide in hot phenol, 33.8 g. (0.2 mole) of 2-chlorobenzothiazole was added, and the mixture was stirred at 120° overnight. After cooling, the reaction product was taken up in ether and the excess phenol was extracted with 5% sodium hydroxide solution. The residue obtained from the ether layer was distilled at 147° at 1 mm. to give 42 g. (94.6%) of a solid (m. p. 51–52.5°), which was purified by crystallization from ethanol as white crystals (m. p. 51.5–52.5°).

[a] The times selected for many of these reactions were arbitrary. [b] The solid cleavage products were identified by the method of mixed m. p.; the liquids by determining the b. p., density and refractive index. The compounds without corresponding yields were only identified qualitatively. [c] Not reported in literature; b. p. 216–219° (735 mm.); d^{25} 0.9947; $n^{15}D$ 1.5610. *Anal.* Calcd. for $C_9H_{12}S$: S, 21.05. Found: S, 20.63. [d] The authentic specimen was prepared according to the directions given in the Experimental. [e] Not reported in literature; b. p. 250° (0.5 mm.); m. p. 101–101.5°. *Anal.* Calcd. for $C_{23}H_{19}S_2N$: S, 17.17; N, 3.75. Found: S, 17.14; N, 3.77.

Anal. Calcd. for $C_{13}H_9ONS$: S, 14.08. Found: S, 13.95.

4-Ethoxy-7-chloroquinoline.—To a solution of 0.22 mole of sodium ethoxide in hot ethanol, an alcoholic solution of 39.8 g. (0.20 mole) of 4,7-dichloroquinoline was added and the mixture was refluxed and stirred for four hours. After cooling, the reaction product was diluted with ether and washed with a large volume of water. The residue from the ether layer was a white solid melting at 100–102° (95%) which by recrystallization from petroleum ether (b. p. 65–67°) gave bright colorless prisms (m. p. 103°). The same results were obtained when 0.22 mole of sodium ethoxide was allowed to react with 0.10 mole of the dichloro compound over a period of twenty-four hours.

Anal. Calcd. for $C_{17}H_{16}ONCl$: Cl, 17.07. Found: Cl, 16.91.

Phenyl 2-Quinolyl Sulfide.—This compound was prepared from 8.1 g. (0.050 mole) of 2-chloroquinoline and 0.055 mole of sodium thiophenoxide in ethanol solution by refluxing and stirring the mixture for four hours. The crude product was obtained in 80% yield by vacuum distillation (b. p. 164–166° at 0.6 mm.). Recrystallization from ethanol gave colorless crystals melting at 48–49°.

Anal. Calcd. for $C_{15}H_{11}NS$: S, 13.49. Found: S, 13.28.

***p*-Tolyl 2-Benzothiazolyl Sulfide.**—To a solution of 0.22 mole of sodium *p*-thiocresoxide in ethanol, 32.8 g. (0.20 mole) of 2-chlorobenzothiazole was added, and the mixture was refluxed and stirred for four hours; 48.4 g. (94%) of crude product (m. p. 69–71°) was obtained. The pure compound crystallizes from ethanol and melts at 71–72°.

Summary

Some alkyl and aryl 2-quinolyl, 2-benzothiazolyl and 2-(benzoxazolyl) ethers are cleaved extensively by aryl thiols. The alkyl ethers have an alkylating action; for example, 2-ethoxyquinoline and thiophenol give ethyl phenyl sulfide and 2-hydroxyquinoline. The aryl ethers yield heterocyclic aryl sulfides.

Aryl thiols react with the 2-chloro compounds to form the aryl heterocyclic sulfides.

Both 4,7-dichloroquinoline and 4-ethoxy-7-chloroquinoline react with *p*-thiocresol to give 4,7-di-(*p*-thiocresoxy)-quinoline.

An interpretation of the course of some of these reactions has been considered.

Quaternary Carbon Compounds. III. Trialkylcarbinyl Isocyanates and Trialkylcarbinamines

BY NATHAN SPERBER AND ROSEMARIE FRICANO

It has been reported that trialkylacetamides[1] (I), trialkylethylamines[2] (II) and trialkylacetic acids[3] (III), in which R is a 3, 4 or 5 carbon atom alkyl group and R_3 totals 12–18 carbon atoms, possess musculotropic antispasmodic activity equal to or greater than papaverine. In order to establish whether the structural requirements for antispasmodic activity observed for I, II and III are generally applicable to highly branched, aliphatic compounds, we prepared a series of trialkylcarbinamines (IV) for pharmacological testing: $R_3C—R'$, I, R'—$CONH_2$; II, R'—CH_2NH_2; III, R'—COOH; IV, R'—NH_2.

Low molecular weight trialkylcarbinamines[4] have been prepared by the Hofmann degradation of the corresponding acetamides (VI) and subsequent acidic hydrolysis of the resulting isocyanates (VII). Trialkylcarbinamines having one long chain alkyl and two methyl groups and aralkyldialkylcarbinamines[5] have been reported. Tertiary alkyl primary amines have also been prepared[6] by the abnormal reaction of one molar equivalent of a nitrile with two molar equivalents of allylmagnesium bromide. This method results in carbinamines containing at least one allyl or propyl group. Recently Ritter and Kalish[7] have described several *t*-carbinamines prepared by the hydrolysis of N-*t*-alkyl formamides.

In this study, the carbinamines (IV) were synthesized by a series of transformations

$$R_3C—CN \xrightarrow{H_2SO_4} R_3C—CONH_2 \xrightarrow{NaOBr}$$
V VI

$$R_3C—NCO \xrightarrow{HCl} IV$$
VII

The trialkylacetonitriles[8] (V) were hydrolyzed to the corresponding acetamides[2] (VI) with hot 80% sulfuric acid and the amides converted to the corresponding isocyanates[4] (VII) in 80–90% yields. The isocyanates (VII) were hydrolyzed to the carbinamines[9] (IV) when heated with 20% hydrochloric acid. The trialkyl isocyanates (Table I) form ureas upon reaction with various amines. In Table II are listed the amines prepared in this investigation.

In general, the trialkylcarbinamines were less spasmolytic and more toxic than the corresponding trialkylethylamines. N,N'-bis-(1,1-Dibutylamyl)-urea was inactive, whereas N-1,1-dibutylamylurea and N-1,1-dibutylamylacetamide possess musculotropic antispasmodic activity in the range of papaverine.

Experimental

The preparation of 1,1-dibutylamylamine will illustrate the general procedures.

Trialkylcarbinyl Isocyanates.[4]—In a 500 cc., three-necked flask cooled in an ice–salt-bath and fitted with an efficient stirrer, condenser and dropping funnel, was placed an ice cold solution of 24 g. of sodium hydroxide in 200 cc. of water. To the rapidly stirred solution, 8 cc. of bromine was added slowly. When the bromine color had disappeared, 22.7 g. (0.1 mole) of finely powdered tributylacetamide was added in one portion and the suspension was stirred vigorously for four hours at 0°. Within one hour, the solid was transformed into an oil. The oil was extracted with ether, the ether layer washed with water, dried over sodium sulfate, the solvent removed *in vacuo* and the residue fractionated. The isocyanate was then redistilled for analysis.

The isocyanate was fairly stable at room temperature, but slowly deposited N,N'-bis-(1,1-dibutylamyl)-urea. The latter was formed by the reaction of 1,1-dibutylamyl isocyanate and 1,1-dibutylamylamine and melted at 127–128°. This urea was also prepared by warming a mixture of 1,1-dibutylamyl isocyanate and 1,1-dibutylamylamine and melted at 127–127.5° after recrystallization from ethanol–water. A mixed melting point of the two samples showed no depression.

Anal. Calcd. for $C_{27}H_{56}N_2O$: N, 6.60. Found: N, 6.43.

The following derivatives of 1,1-dibutylamyl isocyanate were prepared.

N-1,1-Dibutylamylurea.—A mixture of 12 g. of 1,1-dibutylamyl isocyanate and 55 cc. of concentrated ammonia water (28%) was stirred for six hours and stored for four days in a refrigerator. The oily precipitate was filtered, washed with cold, dilute ethanol and recrystallized from a mixture of ethanol–water; weight 4 g.; m. p. 153–153.5°.

Anal. Calcd. for $C_{14}H_{30}N_2O$: N, 11.56. Found: N, 11.75.

N-(β-Diethylaminoethyl)-N'-(1,1-dibutylamyl)-urea hydrochloride: A cold solution of 11.3 g. (0.05 mole) of 1,1-dibutylamyl isocyanate in 25 cc. of benzene was added to a cold solution of 5.8 g. (0.05 mole) of β-diethylaminoethylamine in 25 cc. of benzene. The resulting warm solution was cooled in an ice-bath until the reaction subsided. After standing overnight at room temperature,

[a] Yields are based on distilled products. [b] $n^{21}D$ 1.4349; literature,[6] b. p. 47–48° (5 mm.); $n^{20}D$ 1.4353.

the solution was refluxed for two hours and the solvent was removed *in vacuo*, leaving a gummy sirup. The latter was dissolved in ether and saturated with hydrogen chloride and upon removal of the ether, a gum remained, which was crystallized from ligroin; yield 11 g. (58%), m. p. 91–91.5°.

Anal. Calcd. for $C_{20}H_{44}N_3OCl$: N, 11.13. Found: N, 10.91.

N-Benzyl-N'-1,1-dibutylamylurea.—Upon mixing equivalent quantities of benzylamine and 1,1-dibutylamyl isocyanate the urea crystallized immediately. The solid was recrystallized from a mixture of alcohol and water and appeared as white needles, m. p. 127–128°.

Anal. Calcd. for $C_{21}H_{36}N_2O$: N, 8.40. Found: N, 8.30.

N-(2-Pyridyl)-N'-(1,1-dibutylamyl)-urea.—A solution of 4.7 g. (0.05 mole) of 2-aminopyridine and 12.7 g. (0.05 mole) of 1,1-dibutylamyl isocyanate in 50 cc. of benzene was refluxed for twenty-four hours. The benzene was removed and the residual oil crystallized slowly. The solid was recrystallized twice from a mixture of ethanol and water, m. p. 138–138.5°.

Anal. Calcd. for $C_{19}H_{33}N_3$: N, 13.85. Found: N, 13.53.

Trialkylcarbinamines.—A mixture of 20 g. (0.089 mole) of 1,1-dibutylamyl isocyanate and 70 cc. of 20% hydrochloric acid was heated and stirred for five hours on a steam-bath. Upon cooling 1,1-dibutylamylamine hydrochloride precipitated, yield 16.7 g.; m. p. 68–69°. To an aqueous suspension of the hydrochloride, there was added sodium hydroxide pellets, the liberated amine ether extracted and the ether extracts washed with water. After drying over anhydrous potassium carbonate, the solvent was removed and the residue distilled. A colorless, free-flowing liquid was obtained. In other experiments, the amine hydrochloride was not isolated. After completion of the hydrolysis of the isocyanate to the carbinamine, the mixture was neutralized with sodium hydroxide pellets and the free base taken up in ether and distilled.

The time required for the hydrolysis varied with the molecular weight of the isocyanate. 1,1-Dipropylamyl isocyanate hydrolyzed immediately upon contact with hydrochloric acid, whereas 1-heptyl-1-butyloctyl isocyanate required seven hours to complete the hydrolysis.

N-1,1-Dibutylamylacetamide.—To a solution of 1 cc. of 1,1-dibutylamylamine dissolved in 5 cc. of dry pyridine was added dropwise 2 cc. of acetic anhydride. The warm solution was allowed to stand one hour and then decomposed on ice and water. The white solid was recrystallized from a mixture of ethanol and water, m. p. 80.5–81.5°.

Anal. Calcd. for $C_{15}H_{31}NO$: N, 5.81. Found: N, 5.79.

Acknowledgment.—The authors wish to express their appreciation to Dr. Richard Tislow and Mrs. Annette LaBelle for the pharmacological examination of these compounds.

Summary

The preparation of a series of trialkylcarbinyl isocyanates and trialkylcarbinamines by the Hofmann degradation of the corresponding acetamides is described.

The trialkylcarbinamines exhibit weaker antispasmodic activity than the corresponding trialkylethylamines.

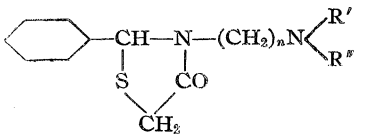
4-Thiazolidones. IV. The Preparation of Some 3-Alkylaminoalkyl-2-aryl Derivatives

BY ALEXANDER R. SURREY

The observation[1] that several of the 2-aryl-3-dialkylaminoalkyl-4-thiazolidones (I) showed promising local anesthetic activity suggested that



I, R′ = R″ = alkyl

II, R′ = H, R″ = alkyl, cycloalkyl, aralkyl

it would be of interest to study the activity of some 2-aryl-3-alkylaminoalkyl derivatives (II). A series of these compounds has been synthesized and is reported in the present communication.

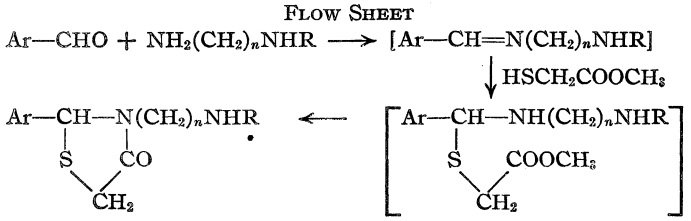
The compounds described in Table III were prepared by essentially the same procedure reported for the tertiary aminoalkyl derivatives.[1] The appropriate benzaldehyde and secondary–primary diamine (see Tables I and II) were condensed to form the corresponding Schiff base which in turn was allowed to react with methyl thioglycolate (see flow sheet). With the exception of benzylidene-*n*-propyl-(and *n*-butyl)-aminopropylamine, none of the Schiff bases was isolated. Attempts to purify several of them by vacuum distillation resulted in considerable decomposition.

FLOW SHEET



It has been reported that trimethylene-1,3-diamines[3] and 1,3-dianilinopropane[4] react with aldehydes to yield hexahydropyrimidines. In these instances, both amino groups were either primary or secondary. With a primary–secondary diamine, as is the case in the present series, the reaction with aldehydes does not give the heterocyclic compound but rather a Schiff base as shown by the ultraviolet absorption spectrum[5] (see Fig. 1) and molecular refraction of benzylidene-*n*-propylaminopropylamine.

In order to determine the effect of substitution in the 5-position of the thiazolidone nucleus, 3-(3-butylaminopropyl)-5-ethyl-2-phenyl-4-thiazolidone hydrochloride was prepared according to the above described procedure by the reaction of benzylidene-*n*-propylaminopropylamine with methyl α-mercapto-*n*-butyrate. In addition, two of the thiazolidones, 2-(4-chlorophenyl)-3-(3-pentylaminopropyl)-4-thiazolidone and 3-(3-butylaminopropyl)-2-phenyl-4-thiazolidone were oxidized to the corresponding 1-dioxides with potassium permanganate. Good yields of the desired products were obtained when the reaction was carried out in acetic acid solution at 5–10°.

Pharmacology.—The anesthetic activity of the present series of 2-aryl-3-alkylaminoalkyl-4-thiazolidones was investigated by the Pharmacology Division of this Institute.[6] The results of this study showed that most of the compounds possessed a high degree of activity in producing sciatic nerve block in guinea pigs and spinal anesthesia in rabbits. Good results were also obtained in intracutaneous wheal tests in man. It was observed that increasing the length of the terminal N-alkyl group increased the local anesthetic activity. The optimum was reached at 5–6 carbon atoms after which the solubility decreased rather sharply. Substitution of the 4-butoxy for the 3,4-methylenedioxy group in the benzene ring increased the tissue irritation properties of the compound.

Experimental[7]

N-Cyclohexylhexamethylenediamine-1,6.—The procedure employed was that described by Pearson, Jones and Cope[8] for the preparation of N-cyclohexylethylenediamine. The product distilled at 115–118° (0.7–0.8 mm.); $n^{25}D$ 1.4756.

Anal. Calcd. for $C_{12}H_{26}N_2$: N, 14.13. Found: N, 14.35.

3-(6-Cyclohexylaminohexyl)-2-(3,4-methylenedioxyphenyl)-4-thiazolidone.—The following is an example of the general procedure employed for the preparation of most of the compounds listed in Table III.

A mixture of 18.5 g. of N-cyclohexylhexamethylenediamine-1,6 and 14 g. of piperonal in 100 ml. of Skellysolve E was refluxed until no more water was collected in a separator connected to the apparatus. Methyl thioglycolate (10 g.) was then added and refluxing was continued at a gentle rate until no more methanol was collected in the separator. After cooling, the solvent[9] was decanted from the oil which separated and the latter was dissolved in ether and extracted with 1 *N* hydrochloric acid. The acid extracts were combined, basified, and the oil extracted with ether. The ether was dried over Drierite and removed by distillation. The residue (24 g.) was dissolved in 120 ml. of acetone, filtered with Norite and to the filtrate was added alcoholic hydrogen chloride solution. The solid (1 g.) which separated melted at 223–226° (uncor.) and did not depress the melting point of a sample of dihydrochloride prepared from N-cyclohexylhexamethylenediamine-1,6.

Ether was added to the acetone filtrate and a crystalline solid separated on standing (9 g.). It was recrystallized once from isopropyl alcohol, dissolved in hot water and the solution basified. The solid base was collected, washed with water and then recrystallized from a mixture of ethanol and ether.[10]

2-(4-Butoxyphenyl)-3-(3-propylaminopropyl)-4-thiazolidone Hydrochloride.—A mixture of 26.7 g. of 4-butoxybenzaldehyde and 17.4 g. of N-propylpropanediamine-1,3 in 100 ml. of dry benzene was refluxed until no more water separated. After removing the solvent *in vacuo*, the crude Schiff base was dissolved in 100 ml. of Skellysolve E and the reaction was continued according to the general procedure described above.

3-(3-Butylaminopropyl)-2-(4-nitrophenyl)-4-thiazolidone Hydrochloride.—Fifteen grams of 4-nitrobenzaldehyde and 13 g. of N-butylpropanediamine-1,3 in 100 ml. of dry benzene[11] were refluxed for one and one-half hours while removing the water as it formed. Methyl thioglycolate (11 g.) was added and refluxing was continued for three and one-half hours. After standing overnight some tarry material had separated. Additional benzene was added to the reaction mixture and the benzene solu-

(9) In most instances the solvent was distilled off under reduced pressure.

(10) Where the preparation of a particular compound was repeated, the isolation of the product could be simplified considerably by seeding the reaction mixture with the solid base where available or with the hydrochloride after the addition of alcoholic hydrogen chloride and acetone. The solid base or hydrochloride was obtained in this manner directly from the reaction mixture.

(11) When Skellysolve E was used as a solvent excessive decomposition occurred.

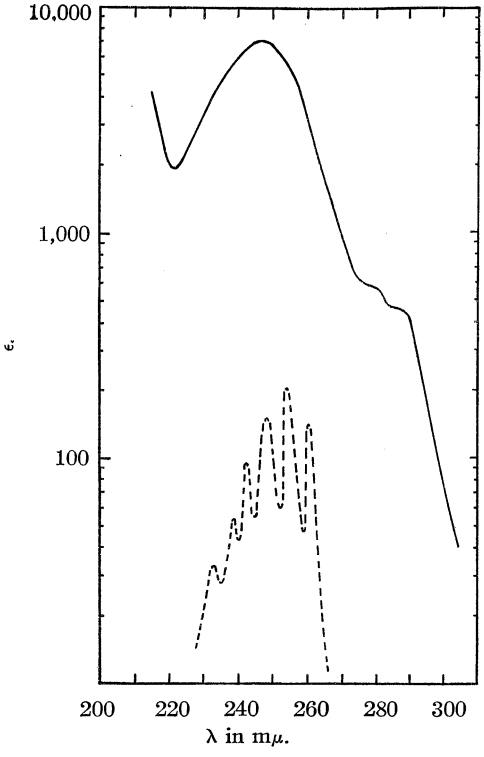

Fig. 1.—Absorption curves of benzylidene-*n*-propylminopropylamine in 95% ethanol: —, benzene in 95% ethanol: ---, as constructed from data of Campbell, Linden, Godshalk and Young, THIS JOURNAL, 69, 881 (1947).

tion was extracted with 1 *N* hydrochloric acid. The solid hydrochloride which separated from the combined acid extracts was recrystallized from isopropyl alcohol and triturated with acetone; yield, 14 g.

2-(4-Aminophenyl)-3-(3-butylaminopropyl)-4-thiazolidone Hydrochloride.—A mixture of 7 g. of 3-(3-butylaminopropyl)-2-(4-nitrophenyl)-4-thiazolidone, 28 g. of iron filings, 50 ml. of ethanol, 25 ml. of water and 1 ml. of glacial acetic acid was refluxed with efficient stirring for three hours. The solution was made alkaline with sodium carbonate, more ethanol added, and the resulting solution was filtered hot. After removing the ethanol by distillation, the amino compound was extracted with chloroform. The crude base, after removal of the solvent, was converted to the hydrochloride.

Benzylidene-3-propylaminopropylamine.—This compound was prepared from benzaldehyde and N-propylpropanediamine-1,3 by refluxing the reactants in benzene and removing the water as it formed. After washing the benzene solution with sodium bicarbonate solution and then water, the product distilled at 107° (0.3 mm.); $n^{27}D$ 1.5272, d^{27} 0.9697.

Anal. Calcd. for $C_{13}H_{26}N_2$: N, 13.72; mol. ref., 65.24. Found: N, 13.70; mol. ref., 64.80.[12]

(12) The molecular refraction calculated for the isomeric hexahydropyrimidine is 63.65.[3]

Benzylidene-3-butylaminopropylamine.—The compound distilled at 113–117° (0.4–0.5 mm.).

Anal. Calcd. for $C_{14}H_{22}N_2$: N, 12.85. Found: N, 12.97.

3-(3-Butylaminopropyl)-5-ethyl-2-phenyl-4-thiazolidone Hydrochloride.—A mixture of 13.4 g. of methyl α-mercaptobutyrate[13] and 21.8 g. of benzylidene-3-butylaminopropylamine in 100 ml. of Skellysolve E was treated according to the general procedure described above. The crude base (26 g.) was dissolved in 250 ml. of acetone, filtered with Norite and the calculated amount of alcoholic hydrogen chloride was added. After adding dry ether to the solution, 12 g. (34%) of solid hydrochloride separated. Two recrystallizations from ethyl acetate followed by drying at 95° for two hours gave a product melting at 125.2–126.5°.

Anal. Calcd. for $C_{18}H_{28}N_2OS{\cdot}HCl$: S, 8.98; Cl^-, 9.93. Found: S, 9.07; Cl^-, 10.21.

2-(4-Chlorophenyl)-3-(3-pentylaminopropyl)-4-thiazolidone-1-dioxide Hydrochloride.—A solution of 8.6 g. of potassium permanganate in 300 ml. of water was added dropwise with stirring at 5–10° to a solution of 8.5 g. of 2-(4-chlorophenyl)-3-(3-pentylaminopropyl)-4-thiazolidone in 30 ml. of glacial acetic acid. The addition required thirty minutes. Sodium bisulfite solution was added to the reaction mixture and the colorless solution treated with an excess of ammonium hydroxide. The solution was extracted with chloroform, dried, and the solvent was removed by distillation. The residue (7 g.) was converted to the hydrochloride, which after recrystallization from ethanol melted at 198.5–200°.

Anal. Calcd. for $C_{17}H_{25}ClN_2O_3S{\cdot}HCl$: S, 7.83; Cl^-, 8.66. Found: S, 7.93; Cl^-, 8.60.

Summary

A series of 3-alkylaminoalkyl-2-aryl-4-thiazolidones has been prepared by the reaction of methyl thioglycolate with several benzylidene-alkylaminoalkylamines. Methyl α-mercaptobutyrate has been employed for the preparation of 3-(3-butylaminopropyl)-5-ethyl-2-phenyl-4-thiazolidone. Two of the thiazolidones were oxidized with potassium permanganate to yield the 1-dioxides.

Most of the compounds reported showed high local anesthetic activity in the production of sciatic nerve block in guinea pigs and spinal anesthesia in rabbits.

RENSSELAER, NEW YORK RECEIVED MAY 9, 1949

(13) The ester was obtained by refluxing the corresponding acid in methanol with concentrated sulfuric acid. The product was taken up in ether and the ether solution was washed with water, sodium bicarbonate solution and again with water. After drying, the ether was distilled off. Maltotriose and its Crystalline β-D-Hendecaacetate

BY J. M. SUGIHARA[1] AND M. L. WOLFROM

In previous communications[2] there was described the isolation of a crystalline trisaccharide hendecaacetate (m. p. 134–136°, $[\alpha]^{25}D$ + 86° in chloroform) from the acetylated enzymic (malt amylases) hydrolyzate of waxy maize starch (amylopectin). The acetate chromatographic technics[3] developed in this Laboratory made the separation of the pure compound from the complex mixture possible, although it was present only in small quantities.

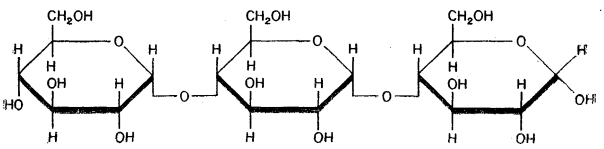
Herein evidence is presented to demonstrate that this trisaccharide hendecaacetate is β-maltotriose hendecaacetate (a trisaccharide with two α-D 1,4 linkages). The acetate was first converted into the corresponding amorphous hendecamethyl ether of unknown and probably mixed anomeric form, by employing three different technics in succession. The general procedure (dimethyl sulfate and alkali) of Haworth, Hirst and Webb[4] was employed initially and this was followed by that of Purdie and Irvine[5] using silver oxide and methyl iodide. Essentially the theoretical methoxyl content was then attained by a final treatment using sodium in liquid ammonia followed by reaction with methyl iodide as described by Muskat[6] and modified by Hendricks and Rundle.[7] The sirupy methyl ether exhibited $[\alpha]^{25}D$ + 122° and $[\alpha]^{25}$ 578 + 128° in chloroform, the latter value being in agreement with that cited by Freudenberg and co-workers[8] for a similar product (of unknown anomeric constitution) prepared by the methylation of a starch acetolyzate.

Acid hydrolysis of the methyl ether gave a sirup which was chromatographically separated into two crystalline compounds, 2,3,6-trimethyl-D-glucose and 2,3,4,6-tetramethyl-D-glucose, characterized by melting point, mixed melting point, rotation and the crystalline derivatives 2,3,6-trimethyl-β-D-glucose 1,4-diacetate and 2,3,4,6-tetramethyl-D-glucose anilide. The chromatographic technic employed[3] allowed this separation to be effected utilizing only 1 g. of the crystalline acetate. The molar ratio of the 2,3,6-trimethyl-D-glucose to 2,3,4,6-tetramethyl-D-glucose was 2 to 1 with the recovery of the chromatographed, crystalline substances of good purity being approximately 90%. This demonstrates that there are two 1,4-D-glucosidic linkages per molecule, assuming the normal pyranoid rings in each D-glucose unit.

The deacetylation of the crystalline hendecaacetate yielded the free sugar, obtained as an amorphous solid, which to date has resisted crystallization; $[\alpha]^{23}D$ + 160° (water). This sugar was not fermented by a commercial bakers' yeast that did not ferment maltose. Myrbäck and co-workers[9,10] have stated that sirupy products assumed by them to be or to contain maltotriose were fermented by a maltose-fermenting yeast.

One mole of the free sugar was partially hydrolyzed by a commercial maltase preparation at 26–27° in forty-four hours into 1.7 moles of D-glucose and 0.2 mole of maltose with recovery of 0.1 mole of the original trisaccharide, as determined by weights of the products isolated. The products of hydrolysis as well as the unchanged sugar were isolated as acetates using a chromatographic technic.[3] The free sugar was not hydrolyzed by emulsin. The fact that the sugar was hydrolyzed by maltase but not by emulsin establishes the two 1,4-D-glucosidic linkages as being α-D. The conversion to maltose gives final support to the assignment of the maltotriose structure to the trisaccharide. The experiments further illustrate the value of chromatographic technics in the analysis and separation of sugar mixtures.

Since the acetate of maltotriose was prepared[2] by the hot sodium acetate acetylation procedure and since it exhibits a specific rotation of $[\alpha]^{25}D$ +86° in chloroform, we have considered the compound to be the β-D-anomer of 4-[4-(α-D-glucopyranosyl)-α-D-glucopyranosyl]-β-D-glucopyranose hendecaacetate.



Experimental[11]

Methyl Decamethylmaltotrioside.[12]—Following the general procedure of Haworth, Hirst and Webb,[4] 1.000 g. of maltotriose hendecaacetate (m. p. 134–136°, $[\alpha]^{25}D$ +86° in chloroform)[2] was dissolved in 3 ml. of acetone in a conical, four-necked flask fitted with a mechanical stirrer, a condenser, two dropping funnels and a capillary to introduce nitrogen. While maintaining an atmosphere of ni-

(12) Anomeric composition unknown.

trogen and an external bath at 30–35° and vigorously stirring, 3 ml. of 30% sodium hydroxide and 2 ml. of dimethyl sulfate were added through the dropping funnels in small quantities over a period of two hours. The bath temperature was raised to 35–40° and vigorous stirring was continued until a small aliquot of the reaction mixture did not reduce Fehling solution (about four hours after adding the methylating reagents). The temperature of the bath was then increased to 55° and 5 ml. of dimethyl sulfate and 9 ml. of 30% sodium hydroxide were added in portions over a period of one and one-half hours with continued stirring. The bath temperature was then raised to 100° for one-half hour. The reaction flask was cooled and the solution was neutralized with 6 *N* sulfuric acid, sufficient water being added to dissolve any precipitated sulfate. This aqueous solution was extracted four times with 5-ml. portions of chloroform. Solvent removal from the combined, dried chloroform extracts left a sirup which was dried to constant weight in a vacuum desiccator containing Dehydrite (anhydrous magnesium perchlorate); yield 414 mg.

The aqueous solution remaining after chloroform extraction was evaporated to a thick slurry. Absolute ethanol (25 ml.) was added and the precipitated sodium sulfate was removed by filtration. The filtrate was again evaporated to a slurry, and a second portion of 25 ml. of absolute ethanol was added. Filtration and concentration of the filtrate to 3 ml. was followed by remethylation with 3 ml. of dimethyl sulfate and 5 ml. of 30% sodium hydroxide at 55°. This treatment was followed by reaction at 100° for one-half hour. The aqueous solution obtained was treated as previously described; yield of dried sirup 81 mg.

The sirups obtained were combined (495 mg.) and subjected to the general methylation procedure described by Purdie and Irvine.[5] The combined material was dissolved in 10 ml. of methyl iodide and placed in a flask fitted with a mechanical stirrer and a reflux condenser. An amount of 2 g. of silver oxide was added under gentle refluxing maintained subsequently for four hours. Excess methyl iodide was allowed to evaporate and the residue was repeatedly extracted with anhydrous ether (total volume 50 ml.). Evaporation of the ether left a sirup which was dried to constant weight over Dehydrite under reduced pressure; yield 490 mg.

This sirup (490 mg.) was dissolved in 5 ml. of liquid ammonia in an unsilvered Dewar flask and subjected to the Muskat[6] methylation procedure as modified by Hendricks and Rundle.[7] A solution of 60 mg. of sodium in 20 ml. of liquid ammonia was added in portions such that the blue color of the liquid ammonia solution persisted for one hour after the last addition (total volume 10 ml.). Excess methyl iodide (5 ml.) was added in portions and the ammonia was allowed to evaporate. The reaction mixture was transferred to a 25-ml. round-bottomed flask fitted with a reflux condenser. A further amount of 5 ml. of methyl iodide was added under gentle refluxing maintained for four hours. The mixture was then held overnight at room temperature. Excess methyl iodide was allowed to evaporate and the residue was extracted repeatedly with anhydrous ether. The combined ether solution (50 ml.) was treated with activated charcoal. Solvent removal left a sirup which was dried to constant weight at 78°, under reduced pressure, over phosphorus pentoxide; yield 488 mg. (72%), $[\alpha]^{25}D$ +122° (*c* 1.91, chloroform), $[\alpha]^{25}578$ +128° (*c* 1.91, chloroform). Freudenberg and co-workers[8] report: $[\alpha]^{18}_{578}$ +129.9° (*c* 1.57, chloroform) for a preparation of methyl decamethylmaltotrioside of undetermined anomeric admixture.

Anal. Calcd. for $C_{18}H_{21}O_5(OCH_3)_{11}$: C, 52.87; H, 8.26; OCH_3, 51.8. Found: C, 53.05; H, 8.30; OCH_3, 51.0.

Hydrolysis of Methyl Decamethylmaltotrioside.—The general procedure described by West and Holden[13] was applied. An amount of 98.5 mg. of methyl decamethylmaltotrioside was dissolved in 1 ml. of chloroform and 2.5 ml. of 2 *N* hydrochloric acid was added. Steam, generated at atmospheric pressure, was bubbled into the mixture. The chloroform was rapidly distilled leaving the methylated trisaccharide in a state of fine suspension. The reaction vessel was submerged in a bath, maintained at 104–106° and the current of steam was passed through for two and one-half hours at such a rate as to maintain the volume constant at 3–5 ml. The cooled solution was neutralized with silver carbonate and residual silver ion was removed with hydrogen sulfide. Distillation of the solution under reduced pressure left a sirup which was dried to constant weight in a vacuum desiccator over Dehydrite; yield 99 mg. This sirup (99 mg.) was dissolved in 25 ml. of chloroform containing 0.5% ethanol and the solution was placed on a chromatographic column packed with acid-washed[14] Magnesol[15]–Celite[16] (5:1 by wt.) (200 × 35 mm. diam.[17]) and developed with 350 ml. (5 column lengths) of benzene–ethanol (100:1 by vol.). Extrusion of the column and streaking with a permanganate indicator (1 part of potassium permanganate, 10 parts of sodium hydroxide and 100 parts of water) located two zones, the first about one-fifth of a column length from the top and the second near the middle of the column. These zones were sectioned and each section was eluted with 50 ml. of acetone. From the eluate of the top zone, solvent removal left 61 mg. (92%) of crystalline material; m. p. 112–114°, $[\alpha]^{24}D$ +65° (*c* 1.78, methanol, equilibrium). This substance was recrystallized from ether; yield 45.3 mg., melting point and mixed melting point with authentic 2,3,6-trimethyl-D-glucose 117.5–118°, $[\alpha]^{27}D$ +67.5° (*c* 1.69, methanol, equilibrium).[18]

An amount of 17.0 mg. of this material was acetylated by heating at 98° with acetic anhydride (5 ml.) and anhydrous sodium acetate (25 mg.). The product obtained on pouring the cooled reaction mixture into an excess (150 g.) of ice and water was extracted with chloroform and the washed (with aqueous sodium bicarbonate) and dried extract was concentrated to a sirup; yield 50.2 mg. This sirup was dissolved in 25 ml. of benzene and placed on a chromatographic column packed with acid-washed[14] Magnesol[15]–Celite[16] (5:1 by wt.) (200 × 35 mm. diam.[17]) and developed with two column lengths (130 ml.) of benzene–ethanol (100:1 by vol.). A zone near the middle of the extruded column was located by means of the permanganate streak indicator. This was sectioned and eluted with 50 ml. of acetone. Evaporation of the solvent left 36.9 mg. of a sirup, which when dissolved in a minimum of petroleum naphtha (b. p. 90–100°)-ether (4:1 by vol.) and allowed to stand overnight in the cold gave crystals; yield 15 mg., m. p. 57–61°. Pure material was obtained on further crystallization from the same solvent; m. p. 66–66.5°. Micheel and Hess[19] reported for 2,3,6-trimethyl-β-D-glucose 1,4-diacetate, m. p. 67–68°. A mixed melting point with an authentic sample showed no depression.

Solvent removal from the acetone eluate of the second zone of the above-described chromatogram left 30.6 mg. (87%) of crystals; m. p. 81–86°, $[\alpha]^{22}D$ +89.5° (*c* 2.24, ethanol, equilibrium). Recrystallization from petroleum naphtha (b. p. 90–100°)–ether (3:1 by vol.) left 22.3 mg.

(13) E. S. West and R. F. Holden, THIS JOURNAL, **56**, 930 (1934).

(14) A mixture of 5 parts (by wt.) of Magnesol and 1 part of Celite was suspended with efficient stirring in a solution composed of 1 part (by vol.) of concentrated hydrochloric acid and 3 parts of water. The amount of Magnesol–Celite added to the diluted acid was regulated so that a very thin paste resulted. After stirring for sixty minutes the slurry was filtered and washed free of chloride ion and the water was displaced with acetone. The material was dried at room temperature overnight and then for two hours at 110°. The adsorbent was cooled, and only that portion which passed a 200-mesh (per linear inch) sieve was used in the chromatographic procedures.

of material, melting point and mixed melting point with authentic 2,3,4,6-tetramethyl-D-glucose 91–92°, $[\alpha]^{26}D$ +84.3° (*c* 1.62, ethanol, equilibrium).[5] An amount of 17 mg. of this material was converted to the anilide according to the procedure of Irvine and Moodie[20]; m. p. 134–135°, unchanged on admixture with an authentic specimen of like melting point.

Evaporation of the effluent from the above-described chromatogram left 4.0 mg. of an unidentified sirup.

Maltotriose.—Two grams of β-maltotriose hendecaacetate was dissolved in 40 ml. of absolute methanol and cooled to 0°. A solution of 2.4 ml. of 0.4 *N* barium methoxide was added, and the whole was kept at 0° for twenty-four hours. Then to the solution 200 ml. of cold water was added and the ionic material was removed by passage through Amberlite[21] resins IR-100 and IR-4. The effluent was concentrated to a sirup under reduced pressure. The residual water was removed by repeatedly stirring with absolute ethanol and evaporating to dryness at room temperature in a vacuum desiccator containing anhydrous calcium chloride. All attempts to crystallize the amorphous solid have failed; $[\alpha]^{23}D$ +160° (*c* 2.36, water).

Anal. Calcd. for $C_{18}H_{32}O_{16}$: C, 42.86; H, 6.39. Found: C, 42.32; H, 6.39.

The free sugar was not hydrolyzed by emulsin and was not fermented by bakers' yeast,[22] which also failed to ferment maltose but fermented D-glucose rapidly.

Hydrolysis of Maltotriose by Maltase.—An amount of 98.0 mg. (1 mole) of maltotriose was dissolved in 0.5 ml. of 0.1 *N* acetate buffer (*p*H 4.7) and 0.5 ml. of an aqueous solution containing 1 mg. of a commercial purified maltase (Maltase 20[23]) preparation. The resultant solution was diluted to a volume of 2.52 ml. The enzymic reaction was followed polarimetrically. After twenty-six hours at 26–27°, hydrolysis to D-glucose was 71% complete; after forty-four hours, 82% complete (as determined polarimetrically). At the end of the latter period, the solution was evaporated to a sirup under reduced pressure. Residual water was removed by azeotropic distillation with absolute ethanol at reduced pressure. To the solids remaining were added 5 ml. of acetic anhydride and 50 mg. of anhydrous sodium acetate. Acetylation was conducted at 110–120° for one hour. The solution was then cooled and poured into 100 g. of ice and water. After hydrolysis of the excess acetic anhydride was complete, the aqueous solution containing suspended material was extracted with three 5-ml. portions of chloroform. The combined chloroform solution was repeatedly washed with a saturated aqueous solution of sodium bicarbonate, dried over anhydrous sodium sulfate, and evaporated to a solid; yield 196 mg. This crude product was dissolved in 25 ml. of benzene and placed on a chromatographic column packed with Magnesol[15]–Celite[16] (5:1 by wt.) (200 × 35 mm. diam.[17]) and developed with 200 ml. of benzene–ethanol (100:1 by vol.). A zone about one-third of a column length from the bottom of the extruded column was located by means of the permanganate streak indicator. This was sectioned and eluted with 50 ml. of acetone. Evaporation of the solvent left 140 mg. of crystals which were recrystallized from methanol; yield 128 mg. (1.7 moles), melting point and mixed melting point with β-D-glucopyranose pentaacetate 129–130°, $[\alpha]^{25}D$ +5° (*c* 3.58, chloroform).

A second zone about one-third of a column length from the top was sectioned and eluted with 50 ml. of acetone. Solvent removal left 30 mg. (0.2 mole) of material which crystallized from 95% ethanol; melting point and mixed melting point with β-maltose octaacetate 152–153.5°, mixed melting point with β-D-glycopyranose pentaacetate 114–119°, mixed melting point with β-maltotriose hendecaacetate 121–129°. A third zone at the top of the column was treated in the same fashion to yield 21 mg. (0.1 mole) of material which crystallized from 95% ethanol; melting point with β-maltotriose hendecaacetate 131–133°, mixed melting point with β-D-glucopyranose pentaacetate 105–109°, mixed melting point with β-maltose octaacetate 123–130°.

Acknowledgment.—The assistance of Dr. Alva Thompson and of Mr. I. L. Miller in the preparation of material is acknowledged, as is also the assistance of Mr. T. T. Galkowski in some of the enzyme experiments.

Summary

A crystalline trisaccharide hendecaacetate isolated from the acetylated enzymic hydrolyzate of amylopectin in the form of waxy maize starch[2] was shown to be β-maltotriose hendecaacetate. The methylation and acid hydrolysis of the acetate yielded crystalline 2,3,6-trimethyl-D-glucose and crystalline 2,3,4,6-tetramethyl-D-glucose, separated by chromatographic technics, and further characterized as the crystalline 2,3,6-trimethyl-β-D-glucose 1,4-diacetate and 2,3,4,6-tetramethyl-D-glucose anilide. The molar ratio of 2,3,6-trimethyl-D-glucose to 2,3,4,6-tetramethyl-D-glucose was 2:1.

Amorphous maltotriose, prepared through its crystalline β-hendecaacetate, was not fermented by bakers' yeast, was not hydrolyzed by emulsin, and was partially hydrolyzed by a maltase preparation into D-glucose and maltose (identified as the crystalline β-D-acetates separated chromatographically).

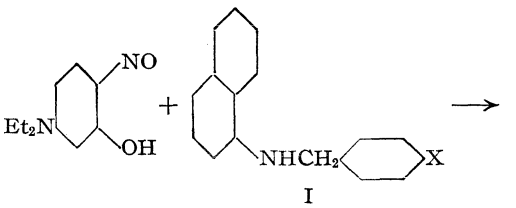
Halogenated Benzophenoxazine Dyes[1,2]

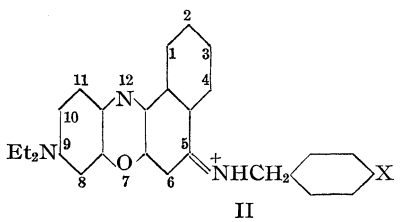
BY HENRY A. SLOVITER

The discovery[3] that certain oxazine dyes stain and inhibit the growth of cancer cells when administered to living animals stimulated the investigation of related compounds. Since these oxazine dyes showed some selective affinity for tumor tissue, the present work was undertaken to prepare derivatives which might ultimately be used as "carriers" of radioactivity when radioactive isotopes were incorporated in the molecule. The halogens were selected as the intended radioactive isotopes because of their availability and because their emission characteristics are suitable for the intended biological studies.

Since one of these dyes, 5-benzylamino-9-diethylaminobenzo[a]phenoxazine[4] (II, X = H) was found to have optimal physiologic activity, its halogen derivatives (II, X = Cl, Br, I) were prepared by the reaction



I

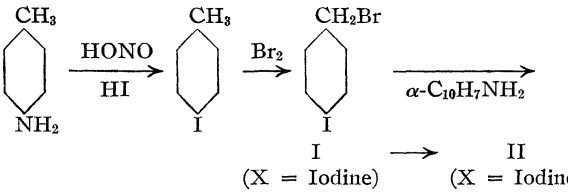


II

The N-(*p*-halobenzyl)-α-naphthylamines (I) have not been described previously. They were prepared by treating the proper *p*-halobenzyl halide with a large excess of α-naphthylamine in a manner similar to that described[5] for the preparation of the N-(nitrobenzyl)-α-naphthylamines.

The preparation of *p*-iodobenzyl bromide[6,7] by the bromination of *p*-iodotoluene without a solvent was found to give the product in poor yield and accompanied by considerable tarry matter. Good yields of pure *p*-iodobenzyl bromide were obtained by the modification of a procedure[8] used for the study of the photochemical bromination of *p*-iodotoluene in carbon tetrachloride.

In a complete synthesis of II where X is radioactive iodine, the sequence of reactions is



This synthesis has been successfully carried out and has yielded a product whose radioactivity is of the order of 0.5 millicurie per gram. The details of this preparation will be described in a subsequent report.

Since this synthesis involves carrying the radioactive iodine through four steps, an attempt was made to develop a shorter method of preparation. Accordingly, the preparation of I (X = Iodine) was attempted, without success, by replacement with iodine of the amino group of N-(*p*-aminobenzyl)-α-naphthylamine. The hydrochloride of the latter compound was prepared as described previously[5] by reduction of N-(*p*-nitrobenzyl)-α-naphthylamine. The product of this reduction on treatment with nitrous acid and iodide did not yield the desired N-(*p*-iodobenzyl)-α-naphthylamine.

An attempt was also made to prepare a benzo[a]phenoxazine dye containing a halogen atom in the ring structure. The reaction of 5-bromo-1-naphthylamine with 2-nitroso-5-diethylaminophenol which might have been expected to yield 1-bromo-5-amino-9-diethylaminobenzo[a]phenoxazine resulted in a substance which was apparently not a benzophenoxazine compound.

N-Allyl-α-naphthylamine was prepared with the intent of adding two atoms of iodine to obtain N-(2,3-diiodopropyl)-α-naphthylamine, from which the corresponding benzophenoxazine dye containing two atoms of iodine per molecule could be prepared. Thus far, N-(2,3-diiodopropyl)-α-naphthylamine has not been successfully isolated. However, 5-allyl-9-diethylaminobenzo[a]phenoxazine has been prepared.

Experimental

***p*-Iodobenzyl Bromide.**—Sixteen grams (5.4 ml.) of bromine in 50 ml. of pure carbon tetrachloride was added to 19 g. of freshly distilled *p*-iodotoluene (m. p. 35.0–35.3°) in 50 ml. of carbon tetrachloride. The flask was attached to an efficient reflux condenser and then illumi-

Allyl[a]	Chloride	$C_{13}H_{13}N$	95		110–120	[d]	[d]

[a] Distills as colorless liquid, rapidly becomes light amber. [b] Parr bomb method. [c] Chromic–sulfuric acid digestion, gravimetric. [d] Calcd.: iodine no., 139; N, 7.65. Found: iodine no. (two minutes contact with Wijs soln.), 144; N, 7.74.

nated by two 200-watt clear Mazda lamps placed almost in contact with the flask. Heat was applied to maintain the mixture at gentle reflux whereupon copious evolution of hydrogen bromide took place. After two hours the evolution of hydrogen bromide had almost ceased, and no vapors of bromine were visible in the reaction flask. The heat and light were continued for thirty minutes more. The flask was cooled, and 5 g. of potassium iodide in 50 ml. of water was added. Sodium thiosulfate solution (approximately 0.1 *N*) was added in slight excess (about 80 ml.). The carbon tetrachloride layer was separated and washed with water. After removal of the carbon tetrachloride by distillation, the residue solidified rapidly on cooling to a clean white crystalline mass. Recrystallization from ethanol yielded 15 g. (60% yield) of clean white crystals, m. p. 78.5–79.5°. The *p*-bromobenzyl bromide was similarly prepared.

N-(*p*-Halobenzyl)-α-naphthylamines.—To a solution of 14.3 g. (0.1 mole) of α-naphthylamine in 50 ml. of ethanol was added a solution of 0.03 mole of *p*-halobenzyl halide in 50 ml. of ethanol. The solution was refluxed for two hours and the alcohol was removed by distillation. About 100 ml. of hot water was added to the viscous residue and, after swirling the mixture, 1:1 hydrochloric acid was added dropwise until the aqueous phase became clear. The supernatant liquid was removed by siphon. This procedure was repeated two times, and the residue was then washed with hot water. This procedure served to remove most of the excess α-naphthylamine. The residue was then cooled in an ice-bath, whereupon it hardened sufficiently so that remaining water could be drained off. It was then washed with about 10 ml. of cold ethanol to remove water adhering to the flask and residue. The residue was then recrystallized from ethanol. The product tended to separate as an oil but very slow cooling and seeding gave clean, almost white crystalline products. The amines could be distilled under reduced pressure prior to recrystallization. The yields thus obtained were somewhat lower and the products were white, but the melting points were the same in both cases.

The yields, properties and analyses of these amines are listed in Table I. The melting points shown are corrected values.

N-Allyl-α-naphthylamine.—This was prepared in the same manner as the *p*-halobenzyl-α-naphthylamines using 25 g. of α-naphthylamine and 5 ml. of allyl chloride. After removal of the excess α-naphthylamine, the crude product was dissolved in ether and washed with water. After removal of the ether, the product was distilled under reduced pressure.

5-(N-Substituted Amino)-9-diethylaminobenzo[a]phenoxazine Chloride.—A mixture of 0.02 mole of N-substituted-α-naphthylamine, 5 ml. of concentrated hydrochloric acid and 30 ml. of ethanol was warmed gently until a clear solution was obtained. To this was added a solution of 5.8 g. (0.03 mole) of 2-nitroso-5-diethylaminophenol[9] in 15 ml. of ethanol, and the mixture was boiled under reflux for three hours. After standing overnight, the mixture was cooled in ice, and the crystalline dye was filtered, washed with a small quantity of cold ethanol and finally with ether. The products were pure as shown by analysis (Table II) and adsorption chromatograms on paper. The dyes could be recrystallized in small batches from ethanol containing a trace of hydrochloric acid.

TABLE II

5-R-9-DIETHYLAMINOBENZO[a]PHENOXAZINE CHLORIDES

R	Formula	Yield, %	Analyses, % Calcd.		Found
p-Chlorobenzylamino	$C_{27}H_{25}ON_3Cl_2$	75	Cl	14.84	14.77[a]
p-Bromobenzylamino	$C_{27}H_{25}ON_3ClBr$	80	Br	15.30	15.08[b]
p-Iodobenzylamino	$C_{27}H_{25}ON_3ClI$	88	I	22.29	22.43[c]
Allylamino	$C_{23}H_{24}ON_3Cl$	40			

[a] Parr bomb method. [b] Robertson method followed by weighing of mixed silver halides and after conversion of silver bromide to silver chloride. [c] Chromic–sulfuric acid digestion, gravimetric.

Attempts to prepare the sulfates of these dyes always yielded a resinous product which could not be crystallized.

Reaction of N-(*p*-Aminobenzyl)-α-naphthylamine with Nitrous Acid and Iodide.—A suspension of 5 g. of N-(*p*-aminobenzyl)-α-naphthylamine dihydrochloride[5] in a mixture of 40 ml. of water and 5 ml. of 1:1 hydrochloric acid was kept below 5°, and a solution of 0.75 g. of sodium nitrite in 10 ml. of water was added dropwise until a slight excess was present (starch–iodide paper). A clear solution resulted. To this was added slowly a solution of 1.75 g. of potassium iodide in 10 ml. of water. A dark brown precipitate formed slowly which floated to the surface. The mixture was kept below 5° for two hours and allowed to warm to room temperature overnight. The mixture was filtered and washed with water. The very dark brown powdery product was not appreciably soluble in water, dilute hydrochloric acid, alcohol or acetone.

Attempted Preparation of 1-Bromo-5-amino-9-diethylaminobenzo[a]phenoxazine Chloride.—To a boiling solution of 2 g. of 5-bromo-1-naphthylamine[10] in a mixture of 15 ml. of glacial acetic acid, 10 ml. of water and 3 ml. of 1:1 hydrochloric acid was added 2.2 g. of 2-nitroso-5-diethylaminophenol in small portions. The mixture was kept near boiling for one hour during which time it became almost black in color. After standing overnight, it was filtered, washed with water until the washings were only faintly colored and allowed to dry. This almost black, granular product gave a blue solution in glacial acetic acid and a cherry red solution in xylene. It was insoluble in water and dilute hydrochloric acid.

Acknowledgment.—The author is indebted to Mr. Louis Goldberg for the preparation of several batches of 2-nitroso-5-diethylaminophenol and for assistance with the analyses, and to Dr. Milton H. Paul and Mr. Bernard Shapiro for assistance in the preparation of adsorption chromatograms.

(9) Mohlau, *Ber.*, **25**, 1060 (1892), reports m. p. 84°; we consistently obtained m. p. 89–90°.

Summary

1. The 5-(*p*-halobenzylamino)-9-diethylaminobenzo[a]phenoxazine chlorides and corresponding 5-allylamino compound have been prepared. The intermediates, N-(*p*-halobenzyl)-α-naphthylamines and N-(allyl)-α-naphthylamine, have been prepared.

2. The attempted preparation of N-(*p*-iodobenzyl)-α-naphthylamine by treatment of N-(*p*-aminobenzyl)-α-naphthylamine with nitrous acid and iodide was unsuccessful.

3. The reaction of 5-bromo-1-naphthylamine with 2-nitroso-5-diethylaminophenol does not yield a benzophenoxazine dye.

The Reduction of Terminal Epoxides[1]

BY MELVIN S. NEWMAN, GERALD UNDERWOOD AND MARY RENOLL

Although the reduction of the epoxide function has been studied,[2] little systematic work has been done on the production of primary alcohols from terminal epoxides. The formation of *n*-propyl, *n*-butyl[3,4] and β-phenylethyl alcohols by catalytic reduction of the corresponding epoxide by hydrogen has been mentioned in the patent literature.

In this paper we report the successful reduction of 1,2-epoxydecane and of styrene oxide to the corresponding primary alcohols by catalytic methods. Reductions involving sodium amalgam and lithium aluminum hydride[5] gave mainly secondary alcohols and hence were not studied in detail.

mixtures analyzed by comparison with the standard curves at suitable wave lengths. The values cited are approximate only. We have checked several results qualitatively by formation of the phenyl urethans. Our qualitative results checked the infrared results about as well as could be expected. [c] Raney nickel prepared as described in "Organic Syntheses," Vol. XXI, John Wiley & Sons, Inc., New York, N. Y., 1941, p. 15. [d] Presence of this component judged qualitatively either by $n^{20}D$ and b. p. or by formation of phenyl urethan. [e] Attempted hydrogenolysis by adsorbed hydrogen as in desulfurization reactions. [f] Raney nickel prepared as by Pavlic and Adkins, THIS JOURNAL, **68**, 1471 (1946). [g] Average of two identical runs, per cent. calculated from infrared analysis; see *b*. [h] Reductions with added phosphoric acid much more sluggish. [i] Higher pressure to attempt speedier reduction, however, still sluggish. [j] Some compound other than styrene oxide was also present. [k] At the higher temperature the ring reduced yielding cyclohexane derivatives.

gave mainly primary alcohol but in the presence of as little as 0.1 g. of acid or base in over 100 cc. of solution primary alcohol formation was markedly decreased.

Experimental

1-Decene was converted to 1,2-epoxydecane, b. p. 82–83.5° at 10 mm., by reaction with peracetic acid.[6] 1-Decanol, b. p. 111.5–113.5° at 11 mm., and 2-decanol, b. p. 104.5–106.0° at 13 mm., were prepared by treating *n*-octylmagnesium bromide with ethylene oxide and acetaldehyde. The corresponding phenylurethans melted at 58.5–59.5 and 37–38°.

A commercial sample of styrene oxide (Dow) was rectified to yield pure styrene oxide, b. p. 81.5° at 15 mm., $n^{20}D$ 1.5350. Pure rectified α-phenylethyl alcohol, $n^{20}D$ 1.5272, formed a phenylurethan which melted at 93–94° and pure rectified β-phenylethyl alcohol, $n^{20}D$ 1.5325, formed a phenylurethan which melted at 78–79°.

General Procedure for Catalytic Reduction.—A mixture of 10 g. of 1,2-epoxydecane, 2.5 g. of wet catalyst (wet with absolute alcohol but containing 1 g. dry weight of catalyst), and 115 cc. of absolute alcohol was reduced in standard high pressure equipment. After reduction the catalyst was removed by filtration and washed well with solvent. The solvent was stripped and the residue was vacuum distilled without attempting fractionation. The entire distillate which usually amounted to 8.5 g. was weighed and its index of refraction determined. Part of the sample was then sealed in a glass ampoule and sent to the Goodrich Company for infrared analysis. In several cases the reaction mixture was treated with excess phenyl isocyanate and the melting point of the mixed phenylurethans taken. For runs which analysis indicated to consist of mainly primary alcohol there was no difficulty in isolating fairly good yields of the phenylurethan of the primary alcohol. The same was true for the phenylurethan of the secondary alcohol in mixtures rich in this compound. From reaction mixtures which analysis indicated a mixture of about equal parts, no pure urethan was isolated.

In the catalytic reductions involving styrene oxide conditions were the same as above except that only 100 cc. of alcohol was used.

Chemical Reduction of 1,2-Epoxydecane.—To a solution of 10 g. of epoxide in 100 cc. of water and 200 cc. of ethyl alcohol was added 500 g. of 3% sodium amalgam. After standing at room temperature for sixteen hours with occasional shaking and neutralization of excess alkali with carbon dioxide the product was isolated as above. The reduction, incomplete under these conditions, yielded mainly 2-decanol.

When 1,2-epoxydecane was treated with an equivalent amount of lithium aluminum hydride[5] in dry ether the product consisted exclusively of 2-decanol except for some unreacted epoxide.

Summary

On catalytic hydrogenation over Raney nickel 1,2-epoxydecane yields mainly 1-decanol. In the presence of small amounts of sodium hydroxide, however, mainly 2-decanol results. With sodium amalgam and lithium aluminum hydride 2-decanol is the main product.

Styrene oxide yields β-phenylethyl alcohol exclusively on catalytic reduction over Raney nickel either with or without added sodium hydroxide. The addition of phosphoric acid retards the reduction markedly and causes complications but primary alcohol is still the main product.

The Polymorphism of Saturated 1,3-Diglycerides

BY F. J. BAUR, F. L. JACKSON, D. G. KOLP AND E. S. LUTTON

Introduction

Malkin, Shurbagy and Meara[1] have described the polymorphism of both even and uneven monacid saturated 1,3-diglycerides of the series dicaprin through distearin. They have reported two sets of long spacings which give two straight lines if spacings are plotted against chain length. For the lower members, including dilaurin (LL) and dimyristin (MM), the greater long spacings were reported to be associated with short spacings of a type specified as "a"; the lesser long spacings were associated with short spacings of type "b." In the case of dipalmitin (PP) and distearin (SS) only the lesser long spacings were observed and these were associated, oddly, with "a" instead of "b" short spacings.

In the present paper are reported results of a reexamination of the even diglycerides, dilaurin through distearin, in the course of which two long spacing values were found uniformly for each compound, and the lesser and greater long spacings were respectively associated with "a" and with "b" type short spacings.

Experimental

The dipalmitin used in this study was prepared according to the directed rearrangement procedure described by Eckey and Formo.[2] Cottonseed oil stearin containing approximately 35% of saturated fatty acids was rearranged

TABLE I

CONSTANTS FOR 1,3-DIGLYCERIDES

	M. p., °C.	Hydroxyl value Found	Hydroxyl value Calcd.	Saponification value Found	Saponification value Calcd.	% monoglyceride[4] Found	% monoglyceride[4] Calcd.
Distearin	78.2, 78[1]	89	90	179.4	179.7	0.1	0.0
Dipalmitin	72.9, 72.5[1]	98	99	197.3	197.2	.2	.0
Dimyristin	66.5, 65.5[1]	109	109	216.8	218.5	<.1	.0
Dilaurin	56.8, 56.5[1]	119	123	245.7	245.7	<.1	.0

with 8% glycerol, representing a slight excess over the theoretical quantity required to convert all triglycerides to diglycerides. The crude diglyceride was purified by 6 recrystallizations from hexane and hexane–alcohol. The distearin, dimyristin, and dilaurin were prepared by a modification of this procedure.[3] Constants for the diglycerides are given in Table I.

Thermal examination was carried out in the manner of previous investigations in this Laboratory[5] but with one additional procedure to register a "cloud point." For this observation sealed 1-mm. capillary tubes containing the diglyceride were lowered in temperature about 2° per minute until the temperature of clouding was observed. This value is reproducible within about 0.5°. The test was run to see whether diglycerides like mono- and triglycerides show a supercooling limit near their lowest m. p. level. Such behavior would indicate the occurrence of alpha-type forms. "Rapid c. m. p." was determined on a freshly chilled sample by a "thrust-in" technique and "regular c. m. p." by raising the bath temperature 0.2° per minute.

X-Ray diffraction patterns were obtained as previously described[5] on chilled, aged and solvent crystallized samples.

Thermal and diffraction data are recorded in Tables II and III.

TABLE II

THERMAL DATA FOR 1,3-DIGLYCERIDES

Thermal point	Distearin	Dipalmitin	Dimyristin	Dilaurin
Cloud point (beta-a?)	73.5	67.0	60.5	50.0
Rapid c. m. p. (beta-a)	77.2	71.8	64.3	54.0
Regular c. m. p. (beta-a and beta-b)	78.2	72.9	66.5	56.8
Time required for transformation (beta-a to beta-b) at reg. c. m. p. −2°	5 hr.	2 hr.	1 min.	1–5 min.

Discussion

The reëxamination of this glyceride series reveals a close resemblance of the members to each other in polymorphic behavior as would be expected from their homologous molecular structures. Previously reported discontinuities between dimyristin and dipalmitin[1] were not confirmed.

Two forms were obtained for each diglyceride, each form having a strong 4.6 Å. short spacing line. A nomenclature has been adopted which is consistent on one hand with that established for triglycerides[6] (and stemming originally from the work of Malkin) and on the other hand with Malkin's distinction between "a" and "b" short spacing types for diglycerides.[1] Both forms are labeled "beta" on the basis of their strong 4.6 spacings, and distinguished as "a" or "b" on the basis of other important short spacings. Thus the two different forms here reported are named as follows—beta-a with characteristic short spacings 4.6 Å. VS, 3.9 M, 3.7 S; beta-b with characteristic short spacings 4.6 Å. VS, 3.75 S^+. This corresponds to the nomenclature of Sidhu and Daubert[7] for mixed diglycerides.

A feature of significance in clarifying the polymorphism of these compounds is illustrated in Fig. 1. In contrast to the data of Malkin, *et al.*,[1] it is shown that the beta-a short spacings are uniformly associated with the lesser long spacing for each of the four homologs; similarly beta-b is associated with the greater long spacing.

Beta-a is invariably obtained on cooling a melt. It is extremely stable at room temperature, in no case having been observed to transform at that level. It transforms to beta-b at a temperature within 2° of the melting point at rates which are, in general, inversely related to chain length. Rate of transformation is controlled by purity of sample, increasing with purity of constituent saturated acids and with increasing number of crystallizations. The corresponding monoglyceride, however, actually promotes transformation while triglyceride exerts a negligible retarding effect. It would seem that mixed diglycerides might be responsible for the slowing down of conversion in less pure samples. Such mixed glycerides are thought to account for the slower transformation rate of dilaurin relative to dimyristin, indicated in Table II. Beta-a is frequently obtained by solvent crystallization, being favored by lower temperatures, by more polar solvents and by presence of impurities (not monoglycerides), but the conditions are not clearly established.

Beta-b, as has been said, may be obtained from beta-a. Since the tranformation has not been observed to be reversible, beta-b appears to be the only thermodynamically stable form. It is favored in solvent crystallization by higher temperatures and less polar solvents. (Beta-b was not reported for dipalmitin and distearin by Malkin, *et al.*[1])

Beta-a, when formed from the melt by chilling, gives a "rapid c. m. p." (by "thrust-in" technique) about 2° below the solvent crystallized m. p. This signifies a certain degree of imperfection of the rapidly formed crystallites. A "regular c. m. p." on a chilled sample is within 0.5° of the maximum m. p. value and solvent crystallized beta-a appears

to melt as high as beta-b. (Of course, it may be that beta-a transforms to beta-b very rapidly near the m. p.)

It is a matter of speculative interest, at least, that certain analogies exist between the diffraction patterns of saturated di- and triglycerides. Thus, as pointed out by Malkin, *et al.*,[1] both beta-a diglyceride forms and beta-2 triglyceride forms show 4.6, 3.9, and 3.7 Å. short spacings (4.6 strongest). Likewise, beta-b (diglyceride) and beta-3 (triglyceride) have 4.6 and 3.75 Å. short spacings (3.75 strongest) in common. Moreover, just as beta-b forms exceed corresponding beta-a forms by about 2 Å. in long spacings, so beta-3 long spacings (when compared on a double-chain length basis) are 2 Å. greater than beta-2 values.[8] It should be noted, however, that beta-a long spacings exceed corresponding beta-2 long spacings by 5 Å.

A notable feature of these diglycerides is their apparent lack of alpha forms (single strong spacing near 4.2 Å.). While each compound shows approximately 5° of supercooling, in no case is a m. p. observable in the neighborhood of the supercooling limit. Therefore one characteristic common to the alpha forms of 1-mono- and triglycerides, namely, the close agreement of supercooling limit and lowest melting point, is here lacking. This fact and failure to obtain alpha patterns show that if alpha forms do occur at all for these diglycerides, they are extremely fleeting.

Acknowledgment.—The authors wish to express their appreciation to those of this laboratory who have assisted in the experimental work.

(8) In the terms of a previous publication,[6] $2/3\ (L\beta)_{T'} = (L\beta)_D + 2$.

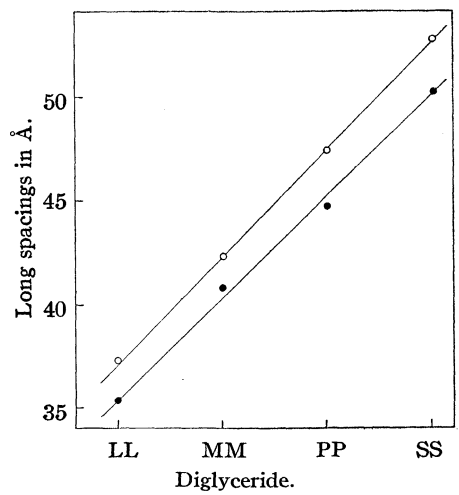

Fig. 1.—Diglyceride long spacings: ●, beta-a (metastable); ○, beta-b (stable).

Summary

A reëxamination of the polymorphism of the even, saturated 1,3-diglycerides, dilaurin through distearin, has revealed a uniformity of behavior which does not confirm the discontinuities reported by Malkin, *et al.*[1]

Each diglyceride has two forms, both classified as beta-like on the basis of strong 4.6 Å. spacings. After a suggestion of Malkin, the two forms are called beta-a and beta-b and are readily distinguishable by differences in short spacings in the

3.8 Å. region. For a given glyceride the beta-b long spacing exceeds that of beta-a by about 2 Å.

Beta-a is invariably obtained from the melt and may sometimes be obtained by solvent crystallization. Highly stable at room temperature, it transforms to beta-b near the m. p. Beta-b, apparently the only thermodynamically stable form, is obtained by transformation of beta-a and commonly by solvent crystallization.

It is notable that no alpha-like patterns were observed, although they are readily obtained with 1-mono- and triglycerides.

Purely on the basis of similarity in X-ray diffraction patterns, it is suggested that a structural similarity may exist between beta-a diglyceride forms and beta-2 triglyceride forms and between beta-b (diglyceride) and beta-3 (triglyceride).

Sulfur-Containing Amines. VIII.[1] Local Anesthetics. III

BY R. O. CLINTON, U. J. SALVADOR AND S. C. LASKOWSKI

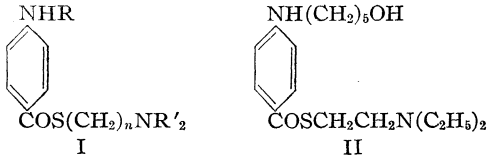
In extending previous investigations[2,3] there have been prepared a number of dialkylaminoalkyl thiol esters derived from various nuclei, for testing as local anesthetics.

In comparison to the oxygen analogs, very few local anesthetics of the dialkylaminoalkyl thiol ester type have appeared in the literature. Karjala and McElvain[4] have recorded the preparation of 3-(2-methylpiperidyl-1)-propyl thiolbenzoate hydrochloride, the thiol analog of Metycaine, by a four step synthesis *via* 3-bromopropyl thiolbenzoate. Lischer and Jordan[5] prepared a short series of 3-dialkylaminopropyl 4-aminothiolbenzoate hydrochlorides *via* 3-chloropropyl 4-nitrothiolbenzoate, in which the terminal tertiary amino group varied from diethylamino to diamylamino. Sergievskaya and Kropacheva[6] investigated a series of diethylamino-ethyl, -propyl and -butyl naphthalene-1-thiolcarboxylates and 4-aminonaphthalene-1-thiolcarboxylates. These compounds were reported by the authors to possess high anesthetic potency without irritation or other untoward effects. Further, a patent[7] reported the properties of three diethylaminoethyl 4-alkoxythiolbenzoate hydrochlorides, prepared by the action of a 4-alkoxybenzoyl chloride on 2-bromoethanethiol and subsequent reaction with a secondary amine.

An important advantage of simple local anesthetics of the types of Apothesine and Metycaine is the lack of PABA interference in clinical usage. It was felt in the present work that simple thiolbenzoates and thiolcinnamates might, while satisfying this condition, in addition possess lowered toxicity while retaining activity. Certain examples of these types have been prepared.

A few additional examples of diphenylthiolacetates[3,8] were prepared, since pharmacological screening has indicated that these compounds are strong local anesthetics, in analogy with other antispasmodics of related type.

A further interesting type of thiol ester is that related to Thiocaine.[2,9] This ester possesses a high therapeutic index in relation to Procaine[9]; similar high activity in analogous types is reported by Lischer and Jordan.[5] This series has therefore been widely extended, through variation of the dialkylaminoalkyl grouping. Of greater interest, insofar as activity is concerned, are the dialkylaminoalkyl thiol esters, (I), related to Tetracaine. A series of these compounds was prepared,



I II

either by reductive alkylation of the parent 4-aminothiolbenzoate, or by the reaction between a dialkylaminoalkanethiol and a 4-alkylaminobenzoyl chloride hydrochloride. A new example of this type was prepared by using 5-hydroxypentanal as the alkylating agent, to yield the compound II. The effect on activity of the inclusion of a hydroxyl group in this position of the nucleus has not been previously determined.

Several thiol esters derived from 2-butyloxyquinoline-4-carboxylic acid were also prepared, to determine whether the high toxicity and irritation associated with the Nupercaine series could be decreased through inclusion of a sulfur linkage in the ester group. Further, two examples of the 4-alkoxythiolbenzoate type[7] were prepared from the acid chloride and a thiol, to enable evaluation in comparison with the 4-aminothiolbenzoate analogs.

In most of the above series an attempt has been made to vary the basic ester portion of the molecule sufficiently to ascertain variations of toxicity and activity accompanying such changes.

Complete pharmacological data will be published at a later date by Dr. F. P. Luduena and Dr. T. J. Becker of these laboratories.

Experimental[10]

3-Dialkylaminopropanols.—Substantial improvements in yield were made in the synthesis of certain 3-dialkylaminopropanols, through modification of the conventional secondary amine-trimethylene chlorohydrin procedure of Adams, *et al.*[11,12] This synthesis is illustrated by the description in detail of the preparation of **3-(2-methylpiperidyl-1)-propanol**. A mixture of 770 g. (7.78 moles) of 2-methylpiperidine,[13] 368 g. (3.89 moles) of trimethylene chlorohydrin, 800 ml. of absolute alcohol and 30 g. of sodium iodide or potassium iodide, was refluxed with stirring for twenty-four hours. The stirred reaction mixture, after cooling, was treated with a solution of 90 g. (3.9 moles) of sodium in 1500 ml. of absolute alcohol, filtered, and the filtercake was washed well with ether. The filtrate was distilled at atmospheric pressure, with mechanical stirring, through a twelve-inch Vigreux column to a head temperature of 122°, reserving the fraction of b. p. 105–122° for recovery of 2-methylpiperidine. The still residue was diluted with three volumes of ether, filtered, and distilled, first at atmospheric pressure and then *in vacuo*. Redistillation gave 582 g. (95% yield based on trimethylene chlorohydrin or 92% yield based on recovered 2-methylpiperidine) of colorless product, b. p. 105–108° at 10–11 mm., $n^{25}D$ 1.4769 (lit.,[14] 60% yield, b. p. 112° at 15 mm., $n^{20}D$ 1.4780).

In a similar manner **3-(4-morpholinyl)-propanol** was prepared in 92% yield (twice distilled), b. p. 109–111° at 7–8 mm., $n^{25}D$ 1.4745 (lit.[15] 75% yield, b. p. 147–149° at 21 mm., $n^{25}D$ 1.4743), and **3-(1-piperidyl)-propanol** was prepared in 93% yield (twice distilled), b. p. 93.5–95° at 9 mm., $n^{25}D$ 1.4755 (lit.[12], 82% yield, b. p. 149° at 68 mm.; see also Brill[16]).

Dialkylaminoalkanethiols.—The two new dialkylaminoethanols used in the present work were prepared by the reaction between a secondary amine and ethylene oxide in boiling methanol, by a method similar to that of Pollard.[17] The alcohols were converted to the chloride hydrochlorides by treatment with thionyl chloride in chloroform solution. The thiols were then prepared by methods previously outlined.[18] The new compounds are listed in Table I.

Dialkylaminoalkyl Thiolbenzoates, Thiolcinnamates and Diphenylthiolacetates.—These compounds were prepared with little difficulty by the usual method. The thiol ester hydrochlorides were usually obtained crystalline directly from the reaction; however, in certain cases (*e. g.*, 2-(2-methylpiperidyl-1)-ethyl diphenylthiolactate) it was necessary to purify the isolated base by transference from acid to base twice, with appropriate washings. The hydrochlorides were crystallized from absolute alcohol–ethyl acetate or acetone–ethyl acetate. These compounds are listed in Table II.

2-(2-Methylpiperidyl-1)-ethyl 4-butyloxythiolbenzoate hydrochloride was prepared in quantitative yield by the reaction between 2-(2-methylpiperidyl-1)-ethanethiol and 4-butyloxybenzoyl chloride[19] in dry benzene. The compound crystallized from absolute alcohol in rosets of white needles, m. p. 171.4–173.0°.

Anal. Calcd. for $C_{19}H_{30}ClNO_2S$: Cl, 9.53; S, 8.61. Found: Cl, 9.32; S, 8.74.

In a similar manner there was obtained **2-diethylaminoethyl 4-hexyloxythiolbenzoate hydrochloride**, as white needles from ethyl acetate, m. p. 125.0–126.3°.

Anal. Calcd. for $C_{19}H_{32}ClNO_2S$: C, 61.02; H, 8.62; S, 8.57. Found: C, 61.13; H, 8.58; S, 8.65.

Dialkylaminoalkyl 4-Alkylaminothiolbenzoates.—The preparation of the intermediate dialkylaminoalkyl 4-nitrothiolbenzoates was effected by the reaction between 4-nitrobenzoyl chloride and the thiol in cold benzene, or in a chloroform–water–sodium bicarbonate admixture.[18] These compounds are listed in Table II. Reduction to the 4-aminothiolbenzoates was preferably carried out by a method similar to that of West,[21] since the ferrous sulfate–ammonia method used with similar types[18] offered no evident advantages in this case. Certain of the resulting dialkylaminoalkyl 4-aminothiolbenzoates (see Table II) were obtained crystalline. In the case of 2-(2-methylpyrrolidyl-1)-ethyl 4-nitrothiolbenzoate, a pure 4-amino base could not be isolated, nor were pure salts obtained from this compound.

The dialkylaminoalkyl 4-alkylaminothiolbenzoates were prepared either by reductive alkylation of the 4-amino compounds with an aldehyde in the presence of zinc dust and acetic acid, or directly from a 4-alkylaminobenzoyl chloride hydrochloride and a dialkylaminoalkanethiol. The former method was found preferable, since purification was more easily effected. The bases thus obtained were in most cases mobile, pale yellow oils, which readily yielded crystalline salts. The dialkylaminoalkyl 4-butylaminothiolbenzoates are listed in Table II; other homologs and a representative example of the reductive alkylation procedure appear below.

2-Diethylaminoethyl 4-Butylaminothiolbenzoate.—A stirred mixture of 20.0 g. (0.079 mole) of 2-diethylaminoethyl 4-aminothiolbenzoate,[2] 20.6 g. (0.32 mole) of zinc dust, 19.5 g. (0.33 mole) of glacial acetic acid and 100 ml. of benzene was brought to reflux on the steam-bath. During the course of twenty minutes there was added dropwise a solution of 6.9 g. (0.096 mole) of *n*-butyraldehyde in 20 ml. of benzene. After the addition was complete, refluxing and stirring were continued for an additional hour. The resulting mixture was filtered and the zinc–zinc acetate precipitate was washed thoroughly with warm dilute acetic acid and with benzene. The cooled filtrate, after being made basic to litmus with 35% sodium hydroxide solution, was filtered if necessary and the benzene layer separated. A further extraction of the aqueous layer with benzene, followed by concentration of the dried benzene extract *in vacuo*, gave 23.0 g. of residual mobile, pale yellow oil.

2-Diethylaminoethyl 4-propylaminothiolbenzoate, from the 4-amino compound[2] and propionaldehyde; the **picrate** crystallized from alcohol in canary-yellow needles, m. p. 129.5–131.3°.

Anal. Calcd. for $C_{22}H_{29}N_5O_8S$: N,[22] 5.35. Found: N,[22] 5.22.

The **dihydrochloride** crystallized from absolute alcohol–acetone–ethyl acetate in massive, pale yellow prisms, m. p. 152.4–153.5°.

Anal. Calcd. for $C_{16}H_{28}Cl_2N_2OS$: Cl, 19.30; S, 8.73. Found: Cl, 19.30; S, 8.77.

2-Diethylaminoethyl 4-Amylaminothiolbenzoate, Method A.—Reductive alkylation of ethyl 4-aminobenzoate with *n*-valeraldehyde gave a 95% yield of **ethyl 4-amylaminobenzoate,** white prisms from Skellysolve B, m. p. 54.0–55.0°.

Anal. Calcd. for $C_{14}H_{21}NO_2$: N, 5.95. Found: N, 6.05.

Saponification of the ester with aqueous-alcoholic sodium hydroxide solution gave a 99% yield of **4-amylaminobenzoic acid,** white needles from dilute alcohol, m. p. 135.5–136.5°.

Anal. Calcd. for $C_{12}H_{17}NO_2$: N, 6.76. Found: N, 6.65.

The acid was converted to the chloride hydrochloride either by the phosphorus pentachloride procedure of Graf and Langer[23] or the thionyl chloride procedure of Mndzhoyan[24]; the resulting 4-amylaminobenzoyl chloride hydrochloride was used without purification because of instability. Condensation with 2-diethylaminoethanethiol in benzene gave, after several purifications by crystallization and conversion to the base, a 45% yield of 2-diethylaminoethyl 4-amylaminothiolbenzoate as a pale yellow oil.

Method B.—The reductive alkylation of 2-diethylaminoethyl 4-aminothiolbenzoate[2] with *n*-valeraldehyde gave a 90% yield of an easily purified base.

The **picrate** formed pale orange needles from alcohol, m. p. 120.2–121.2°.

Anal. Calcd. for $C_{24}H_{33}N_5O_8S$: N,[22] 5.08. Found: N,[22] 4.83.

A crystalline dihydrochloride was also isolated, but its extreme hygroscopicity prevented purification for analysis.

2-Diethylaminoethyl 4-heptylaminothiolbenzoate citrate, prepared from the base (reductive alkylation with *n*-heptaldehyde) and citric acid monohydrate in acetone, crystallized in rosets of tiny white needles from absolute alcohol–ethyl acetate, m. p. 123–124° (dec.).

Anal. Calcd. for $C_{26}H_{42}N_2O_8S$: N, 5.16; S, 5.91. Found: N, 4.70; S, 6.04.

2-Diethylaminoethyl 4-(5-hydroxyamylamino)-thiolbenzoate, from the 4-amino base[2] and 5-hydroxypentanal,[25,26] crystallized from benzene–Skellysolve B in large white prisms, m. p. 72.3–73.6°.

Anal. Calcd. for $C_{18}H_{30}N_2O_2S$: N, 8.28; S, 9.47. Found: N, 8.15; S, 9.53.

(25) Woods and Sanders, THIS JOURNAL, **68**, 2111 (1946); *Org. Syn.*, **27**, 43 (1947). Comparable yields were obtained when the preparation was modified by saturation of the neutralized hydrolysis mixture with ammonium sulfate, followed by a single ether extraction. This obviates the continuous ether extraction.

(26) The final reflux period, after the addition of the hydroxyaldehyde, was extended to two hours.

The **picrate** formed tiny orange-yellow needles from alcohol, m. p. 96.6–98.2°.

Anal. Calcd. for $C_{24}H_{33}N_5O_9S$: N,[22] 4.94. Found: N,[22] 4.79.

The **phosphate** crystallized from alcohol-acetone in rosets of white cottony needles, m. p. 163.6–164.4°.

Anal. Calcd. for $C_{18}H_{33}N_2O_6PS$: S, 7.35; H_3PO_4, 22.46. Found: S, 7.34; H_3PO_4, 22.51.

Summary

There has been described the preparation of a series of dialkylaminoalkyl thiol esters derived from the benzoyl, cinnamoyl, 4-aminobenzoyl, 4-alkylaminobenzoyl, 4-alkoxybenzoyl and 2-butyloxyquinoline-4-carbonyl nuclei. Modifications in the preparation of certain intermediates, leading to increased yields, have also been described.

On an Alkaloid of *Kopsia Fruticosa*. I

BY A. BHATTACHARYA, A. CHATTERJEE[1] AND P. K. BOSE

Kopsia fruticosa, A.D. (*Apocynaceae*) is a large, evergreen shrub of the East Indies, which has been now naturalized in India. It was used as an arrow poison. All *Kopsia* species so far investigated have been found to contain alkaloids. Thus, a crystalline alkaloid has been isolated from the seeds of *K. flavida* Bl.[2]; the presence of three other alkaloids has been reported in *K. arborea* Bl., *K. albiflorum*, Bl., and *K. Roxburghii*[2] Bl. From *K. fruticosa* we have obtained a new alkaloid, kopsine, $C_{22}H_{26}N_2O_4$, m. p. 217–218° (dec.), $[\alpha]^{20}D$ +16.4° (in ethyl alcohol), and we wish to report its isolation and properties. Our mature leaves contained 0.12% kopsine and in the bark 0.06% was found (on the basis of dry weight). Thus, for large scale extraction, the leaves were preferred. Kopsine (in alcohol) is neutral to litmus. The solution shows green fluorescence. Its molecular extinction curve is represented in Fig. 1. The curve shows the maxima at 240 and 283 mμ and minima at 264, 279 and 286 mμ. The absorption spectra of kopsine are similar to those of indole alkaloids.[3,4] Kopsine does not show a coloration with ferric chloride but it gives the following reactions: concentrated sulfuric acid, colorless in the cold, pinkish upon heating; Erdmann reagent, gradual appearance of apple-green color; Fröhde reagent, solution slowly turns pink; Mandelin reagent, dissolves the alkaloid with permanganate-like color which gradually turns olive-green.

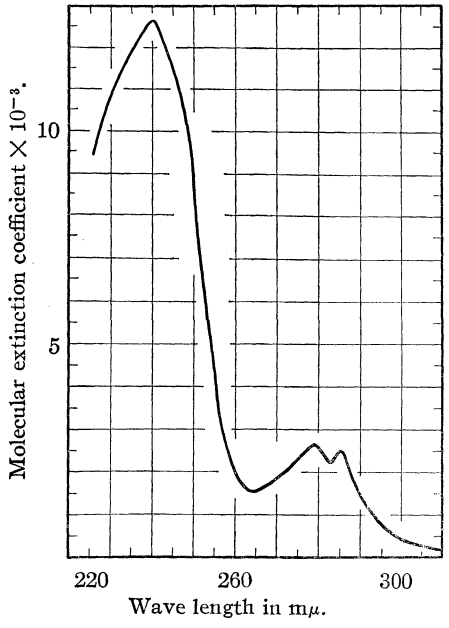

Fig. 1.—Molecular extinction curve of kopsine in alcohol.

A solution of kopsine in hydrochloric or sulfuric acid produces an orange precipitate with potassium bismuth iodide, a yellow precipitate with picric acid and a white precipitate with potassium mercuric iodide. (So far it has not been possible to prepare kopsine salts with some common mineral acids (HCl, HNO_3 and H_2SO_4, etc.) because of resinification). It forms, however, well defined

(1) Née Mookerjee.

(2) M. Greshoff, *Ber.*, **23**, 3537 (1890).

(3) M. S. Kharasch, D. W. Stanger, M. A. Bloodgood and R. R. Legault, *Science*, **83**, 36 (1936).

(4) W. A. Jacobs, L. C. Craig and A. Rothen, *ibid.*, **83**, 166 (1937).

salts with perchloric, picric, oxalic, chloroauric and chloroplatinic acids and then behaves as a monoacidic base. Both the base and its salts taste bitter. Kopsine contains one methoxyl. Dioxymethylene, carbonyl, hydroxyl and N-methyl groups are absent. The presence of two active hydrogens has been observed. On catalytic hydrogenation dihydrokopsine is formed. Kopsine readily yields a methiodide and gives negative tests for primary and secondary amino groups which suggests that the basic nitrogen atom is tertiary.

Kopsine is insoluble in cold alkali but is decomposed by hot ammonia to give a new base, kopsidine, $C_{20}H_{24}N_2O_3$, m. p. 142°, $[\alpha]^{25}D$ +30.2° (in alcohol), which yields a well crystallized picrate, m. p. 190° (dec.). Kopsidine dissolves in concentrated sulfuric acid and shows the following reactions: Erdmann reagent, olive-green; Fröhde reagent, the colorless solution slowly turns pink; Mandelin reagent, the purple solution gradually turns bottle-green.

Kopsidine contains the O-methyl group. On the basis of the empirical formulas kopsidine might be a deacetylation product of kopsine; however, kopsidine cannot be acetylated to kopsine.

Experimental

Isolation of Kopsine.—The coarsely powdered leaves (5 kg.) were extracted in a percolator with alcohol (10 liters, acidified with 10 ml. of glacial acetic acid) for four weeks. The deep green extract was concentrated to 100 ml. *in vacuo*. The viscous residue was poured into 0.5 liter of iced water. Overnight a thick, dark, tarry mass separated. The clear supernatant liquid was decanted and the tarry mass digested with 5 × 50 ml. of water (shaking). The filtrate was combined with the bulk of the decanted liquid, cooled in ice-water and basified with sodium bicarbonate. The separated kopsine was taken up in 200 ml. of chloroform; the extract was washed with water, dried over sodium sulfate and concentrated to 25 ml. This solution was diluted with 1 vol. of alcohol and kept overnight. Pale-yellow, glistening crystals of kopsine (6 g.), coated with a slimy mass, were thus obtained. On several crystallizations from acetone, alcohol, benzene and ethyl acetate, the m. p. increased from 198–220° to 208–210° (dec.). The base was dissolved in 100 ml. of 1% hydrochloric acid, filtered from the slimy mass and basified with sodium bicarbonate. The alkaloid crystallized from alcohol in colorless plates, m. p. 213–214° (dec.). By repeating this procedure thrice, it was obtained in the pure state, m. p. 217–218° (dec.). Samples regenerated from the picrate or oxalate showed the same m. p. Kopsine is freely soluble in chloroform, sparingly in methanol, ethanol, ethyl acetate, benzene and ether; it is insoluble in petroleum ether or water.

Anal. Calcd. for $C_{22}H_{26}N_2O_4$: C, 69.10; H, 6.80; N, 7.30; OCH_3, 8.11. Found: C, 69.35, 69.56; H, 6.43, 6.25; N, 7.47, 7.44; OCH_3, 8.28, 8.32.

Kopsine picrate was prepared by adding an ethereal solution of kopsine to picric acid (in ether). The yellow precipitate crystallized from alcohol in glistening yellow rods, m. p. 230° (dec.).

Anal. Calcd. for $C_{22}H_{26}N_2O_4 \cdot C_6H_3O_7N_3 \cdot 2C_2H_5OH$: N, 9.96. Found: N, 10.2.

Kopsine Oxalate.—An ethereal solution of anhydrous oxalic acid (0.2 g.) was added to 0.2 g. of kopsine (in ether). The colorless precipitate (0.15 g.) was washed acid-free and recrystallized from alcohol and acetone; prisms, m. p. 154° (dec.). It is highly soluble in water, acidic to litmus and liberates iodine from potassium iodide and potassium iodate.

Anal. Calcd. for $C_{22}H_{26}N_2O_4 \cdot C_2H_2O_4$: N, 5.93; Found: N, 6.1.

Kopsine Perchlorate.—One-quarter gram of powdered alkaloid was added slowly to perchloric acid (5 ml., 70%) diluted with 1 vol. of water. The colorless precipitate (0.27 g.) crystallized from water containing a little perchloric acid in needles, m. p. 284° (dec.).

Anal. Calcd. for $C_{22}H_{26}N_2O_4 \cdot HClO_4 \cdot 5H_2O$: Cl, 6.19. Found: Cl, 5.9.

Kopsine chloroplatinate was prepared by adding an aqueous solution of platinic chloride (5%) to a faintly acidic solution (HCl) of kopsine. Upon crystallization from water containing a little hydrochloric acid, glistening orange colored rods separated, which did not melt but decomposed above 150°.

Anal. Calcd. for $(C_{22}H_{26}N_2O_4)_2 \cdot H_2PtCl_6$: Pt, 16.6. Found: Pt, 16.12.

Kopsine Chloroaurate.—One-half gram of kopsine was dissolved in hydrochloric acid (2 *N*, 5 ml.) and an aqueous solution of auric chloride was added until precipitation was complete. The golden yellow rods were recrystallized from water containing a little hydrochloric acid; m. p. 203–205° (dec.).

Anal. Calcd. for $C_{22}H_{26}N_2O_4 \cdot HAuCl_4$: Au, 27.30. Found: Au, 27.30.

Kopsine Methiodide.—0.15 g. of kopsine was dissolved in dry acetone (8 ml.). Freshly distilled methyl iodide (1 ml.) was added and the mixture was kept overnight. The solution was concentrated *in vacuo* to a viscous residue which crystallized from alcohol; colorless plates, m. p. 200° (dec.).

Anal. Calcd. for $C_{22}H_{26}N_2O_4 \cdot MeI$: NMe, 5.54. Found: NMe, 4.83.

Determination of Active Hydrogen in Kopsine (Zerewitinoff).—0.05 g. of kopsine in 5 ml. of dry pyridine yielded 6 ml. of methane (0°, 760 mm.).

Anal. Calcd. for $C_{22}H_{26}N_2O_4$: H, 0.526. Found: H, 0.53.

Catalytic Hydrogenation of Kopsine.—Kopsine (0.2736 g.), dissolved in glacial acetic acid (10 ml.), was treated with hydrogen and Adams platinum oxide catalyst (0.15 g.) which had been previously saturated with hydrogen. The absorption of hydrogen (17 ml. at 30°, 760 mm.) corresponded to two atoms of hydrogen per mole. The solution was filtered, diluted with water and basified with sodium bicarbonate. The base was taken up in 100 ml. of ether. The colorless ethereal digest was washed with water, dried over sodium sulfate and distilled. The residue was successively crystallized from acetone, ethanol, ethyl acetate and benzene; colorless crystals, m. p. 218° (dec.). Dihydrokopsine showed a m.p. depression of 26° when mixed with kopsine.

Anal. Calcd. for $C_{22}H_{28}N_2O_4$: C, 68.75; H, 7.29; N, 7.29. Found: C, 68.32; H, 7.50; N, 7.62.

Hydrolysis of Kopsine and Isolation of Kopsidine.—A half gram of kopsine in alcohol (5 ml.) was refluxed with 10% ammonia (2 ml.) for six hours. The clear solution deposited overnight colorless prisms, m. p. 140–142°. After recrystallizations from ethanol, ethyl acetate and acetone, the m. p. was found to be 142°. Kopsidine is soluble in methanol, ethanol, ether, ethyl acetate or benzene and is insoluble in petroleum ether and water; $[\alpha]^{25}D$ +30.2° (in alcohol).

Anal. Calcd. for $C_{20}H_{24}N_2O_3$: C, 70.59; H, 7.05; N, 8.26; OMe, 9.12. Found: C, 70.28; H, 6.75; N, 7.92; OMe, 8.82.

Acknowledgment.—The authors wish to express their thanks to Professor L. Zechmeister for the laboratory facilities granted.

Summary

From *Kopsia fruticosa* a new alkaloid, termed kopsine, $C_{22}H_{26}N_2O_4$, m. p. 217–218° (dec.), has

been obtained. The isolation and properties of this alkaloid have been studied. On hydrolysis, it yields a base, kopsidine, $C_{20}H_{24}N_2O_3$, m. p. 142°; and on hydrogenation, a dihydro derivative, m. p. 218° (dec.).

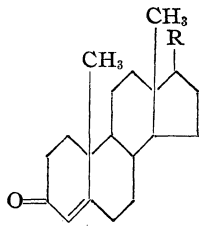
A New Series of Testosterone Esters

BY ARAM MOORADIAN, C. J. CAVALLITO, A. J. BERGMAN,[1] E. J. LAWSON AND C. M. SUTER

The literature is replete with attempts by workers in the field to prepare esters of testosterone which would show both more intensive and more prolonged androgenic action than testosterone itself. It was shown in early studies[2] that the lower aliphatic acid esters are most effective; as one increases the length of the carbon chain in the fatty acid residue, the effect becomes more prolonged but the intensity decreases rapidly. Ruzicka,[3] by his preparation and testing of the acetate and benzoate esters, initiated work which resulted in the general adoption of testosterone propionate as an activated form of testosterone. These workers[4] prepared a long series of aliphatic acid esters. Miescher's group[5] made a study of halogenated, aminated, and unsaturated aliphatic esters as well as carbonate esters. This latter group of workers[6] also studied the enol diesters of testosterone. Rabold and Dietrich[7] have made a study of the glucoside and tetraacetyl glucoside. The patent literature[8] describes a sulfonic acid and a phosphoric acid ester.

However, since it was felt that the field had not been combed thoroughly enough in view of the importance of the problem, there has been prepared a new series of esters several of which show activities surpassing testosterone propionate in rat tests where the weight increase of the seminal vesicles and the prostate was studied. A preliminary summary of the results obtained is shown in Table III. More complete biological results will be published[9] at a later date.

Esters of the general types



I, R = —OCOR′
II, R = —OCOR″—Y—R‴
III, R = —OCOR″OCOR‴

have been prepared (Table III) where R′ is of the carbocyclic or heterocyclic type, R″ and R‴ are various aliphatic or aromatic radicals and Y is oxygen or sulfur. Types I and III have been prepared from the acid chlorides and type II from the acid chlorides and anhydrides.

The acids shown in Table I were prepared by three methods. Method A involves the reaction of the appropriate sodium alkoxide or mercaptide with a halogenated acid. The second method, B, was used only to make ethyl or methylmercapto acids by the alkylation of the appropriate mercapto acid with ethyl or methyl sulfates. Method C involves hydrolysis of the corresponding nitrile.

In preparing the acid chlorides shown in Table II, both thionyl chloride (D) and phosphorus trichloride (E) were used. Phosphorus trichloride possesses the advantage that a colorless product almost always results. This is of decided advantage in the preparation of a color-free ester. Furthermore, in some instances in which thionyl chloride results in tar formation, phosphorus trichloride gives a fair yield of product. From the viewpoint of yield, however, thionyl chloride is usually to be preferred.

Some of the acids and acid chlorides described are old compounds but are included where the characterization is somewhat more complete than that described in the literature. Those acids which were obviously used but not described may be found elsewhere in the literature.

Experimental

n-**Butylmercaptoacetic Acid (Method A).**—To 21.6 g. of *n*-butylmercaptan (0.24 mole) dissolved in 200 cc. of 18% sodium hydroxide solution was added 20.8 g. of chloroacetic acid (0.22 mole) dissolved in 100 cc. of 18% sodium hydroxide. The mixed solutions were heated for two hours on a steam-bath. The solution was then cooled and acidified and the product extracted with ether and distilled. Distillation gave 29 g. of product, b. p., 136–137° at 10 mm.

2-Ethylmercaptopropanoic Acid (Method B).—A solution of 43.5 g. (0.41 mole) of 2-mercaptopropanoic acid was prepared by dissolving it in a solution containing 36 g. (0.9 mole) of sodium hydroxide in 45 cc. of water. While this solution was being stirred and heated on a steam-bath 63.2 g. (0.41 mole) of diethyl sulfate was added dropwise. Heating was continued until a single phase resulted. The solution was cooled, acidified with dilute sulfuric acid, and extracted with ether three times. The ether was evaporated and the residue distilled, yielding 24.5 g. of product, b. p. 111–113° at 8 mm.

4-Methylmercaptobutanoic Acid (Method C).—Eighteen grams of methyl mercaptan (0.37 mole) was dissolved

[a] Using thionyl chloride, only tar results. [b] Decomposes violently on standing at room temperature for some time.

in 125 cc. of 35% sodium hydroxide solution and 125 g. of crushed ice. To this was added 25.8 g. (0.25 mole) of 4-chlorobutanenitrile in 100 cc. of 95% ethanol. The solution was refluxed for two and one-half hours. After diluting the reaction mixture with water, it was extracted with ether to remove unhydrolyzed nitrile. The alkaline solution was then acidified with hydrochloric acid and again extracted with ether. There resulted 18.6 g. of product, b. p. 129–130° at 9 mm.

***n*-Butylmercaptoacetyl Chloride (Method D).**—A mixture of 23.8 g. (0.16 mole) of *n*-butylmercaptoacetic acid and 29 cc. of thionyl chloride was heated gently on a steam-bath until evolution of hydrogen chloride ceased. The residue was distilled to give 24.2 g. of product, b. p., 83–84° at 8 mm.

2-Ethylmercaptopropanol Chloride (Method E).—A mixture of 21.3 g. (0.16 mole) of 2-ethylmercaptopropanoic acid and 8.8 g. (0.064 mole) of phosphorus trichloride was allowed to stand overnight and then heated on a steam-bath for one hour. The product was decanted from the sirupy phosphoric acids. Distillation gave 15.4 g. of product, b. p. 56–57°, at 8 mm.

Ethylmercaptoacetic Anhydride.—A solution of 370 g. (3.1 mole) of ethylmercaptoacetic acid in 1100 g. of acetic anhydride was refluxed for six hours and then fractionally distilled. The product was collected at 100–103° at 0.1 mm., yield 166 g.

Testosterone *n*-Butoxyacetate.—Six-tenths gram of testosterone was dissolved in 25 cc. of dry ether with 4 cc. of dry pyridine. To this was added 1 g. of *n*-butoxyacetyl chloride in 10 cc. of dry ether. A solid immediately precipitated. The suspension was refluxed for one-half hour and poured into water. The ether extract was washed with dilute sodium carbonate solution, dilute sulfuric acid and water. The ether was evaporated and the residue taken up in Skellysolve A containing about 20% of ether.

[a] Activity is measured by the effect on growth of seminal vesicles and prostate of castrated male rats. Daily subcutaneous injection for 3 days sacrificed 24 hours after last injection. Estimated activity based on testosterone propionate as 100%. All results based on 3 rats except starred results which indicate 10 rats were used. [b] All run in 1% w/v solution in U. S. P. grain alcohol except the rotation of the furoate ester which was run in the same concentration of C. P. chloroform. [c] Uncorrected m. p. [d] Yield varied from 30 to 90%.

The solution was passed through a column of activated alumina (Aluminum Ore Co., minus 80 mesh). The absorbed product was then washed off the alumina with 1:1 Skellysolve A–ether. This process of adsorption and elution was repeated several times giving 0.5 g. of a white crystalline mass. This was recrystallized from Skellysolve A to give one fraction, m. p. 61.5–63° (0.32 g.), a second fraction, m. p. 58–59° and a residual sirup. Analysis of the first fraction showed it to be pure ester.

Testosterone Ethylmercaptoacetate.—A mixture of 0.75 g. of testosterone in 1 cc. of ethylmercaptoacetic anhydride was heated for two hours on a steam-bath. The reaction mixture was poured into water and allowed to stand overnight. It was then extracted with ether and the extract washed with dilute sodium carbonate solution. The ether was diluted with three parts of Skellysolve A and the solution passed through a column of activated alumina. The adsorbed ester was eluted from the alumina with 1:1 ether–Skellysolve. This process was repeated three times. The solvent was evaporated, almost to dryness, diluted with a little Skellysolve A, and the product allowed to crystallize. These crystals were filtered off and recrystallized from Skellysolve B; yield 0.80 g., m. p. 99–100°.

Summary

A series of new alkoxy and alkylmercapto acids and their acid chlorides have been prepared. These have been used in the preparation of the corresponding testosterone esters.

The Preparation and Reactions of Some α-(4-Quinolyl)-phenylacetonitriles[1]

BY ROYAL A. CUTLER, ALEXANDER R. SURREY AND JOHN B. CLOKE

The object of the present investigation was the preparation of a variety of α-(4-quinolyl)-phenylacetonitriles and products derived therefrom to make them available for pharmacological testing.

The nitriles described in this paper were prepared by the condensation of phenylacetonitrile and α-substituted phenylacetonitriles with 4-chloro, 4,5-dichloro[2] and 4,7-dichloroquinolines.[2] Inasmuch as most of the preliminary experimental work was carried out with compounds derived from 4,7-dichloroquinoline, the following discussion will be confined mainly to this series.

The condensation of 4,7-dichloroquinoline (I) with phenylacetonitrile (II) to give α-(7-chloro-4-quinolyl)-phenylacetonitrile (III) was tried under a variety of conditions in order to obtain optimum yields. When the condensation of I and II with sodamide was carried out according to the procedure of Hancock and Cope[3] for the preparation of cyclohexylphenylacetonitrile, excessive decomposition occurred at the high temperatures employed; at temperatures below 35° no decomposition was apparent. However, only a 50% yield of the nitrile (III) was obtained and half of the 4,7-dichloroquinoline was recovered. It was observed that during the reaction a red precipitate formed which appeared to be the sodio derivative of III. The formation of such a derivative at the expense of the sodio salt of the less acidic phenylacetonitrile would explain the recovery of half of the dichloro compound. The explanation is apparently correct for, when I was allowed to react with two moles each of sodamide and phenylacetonitrile, practically quantitative yields of III resulted. This procedure was equally effective with other 4-chloroquinolines.

On standing in concentrated sulfuric acid at room temperature for fifteen hours, the nitrile (III) was converted quantitatively to α-(7-chloro-4-quinolyl)-phenylacetamide (IV). An attempted preparation of α-(7-chloro-4-quinolyl)-phenylacetic acid by hydrolysis of the nitrile (III) in refluxing aqueous potassium hydroxide yielded only amide[4] (IV). Complete hydrolysis of the nitrile (III) or the amide (IV) by refluxing for one hour with 60% sulfuric acid[5] resulted in the formation of 4-benzyl-7-chloroquinoline (V). The synthesis of 4-benzylquinoline by this method is simpler and gives superior yields to those described in the literature for its preparation.[6] The methiodides of the 4-benzylquinolines (VI) were prepared by the general method described by Alekseeva.[7] It is interesting to note that, whereas no difficulty was encountered in the preparation of the unsubstituted and 7-chloro-4-benzylquinoline methiodides, attempts to dry the 5-chloro compound overnight in a vacuum desiccator resulted in its decomposition. The presence of a strong odor of benzaldehyde indicated that oxidation had occurred at the methylene group.

The preparation of esters of α-(7-chloro-4-quinolyl)-phenylacetic acid by alcoholysis of the corresponding nitrile was unsuccessful when attempted by customary procedures. Thus, on refluxing the nitrile (III) with concentrated sulfuric acid and absolute ethanol for three hours, about 90% of the starting material was recovered unchanged. Extension of the refluxing time to twenty-two hours resulted in a practically quantitative yield of 7-chloro-4-benzylquinoline (V). Similarly, when dry hydrogen chloride was passed into a refluxing solution of the nitrile in absolute alcohol for four hours, a mixture consisting of some unchanged nitrile (III), amide (IV) and 4-benzyl-7-chloroquinoline (V) was obtained. After a period of eight hours, only the benzylquinoline (V) was recovered.

The passage of dry hydrogen chloride for six hours into a solution of the nitrile (III) in absolute methanol, initially at room temperature and without external cooling, gave a quantitative yield of the amide (IV). However, when the nitrile was added to a previously saturated solution of methanolic hydrogen chloride cooled to room temperature and the passage of hydrogen chloride continued for six hours, a 12% yield of the desired methyl ester (VII) was obtained, the remainder of the product consisting of amide (IV). By allowing the reaction mixture to stand for six days at room temperature, 23% of the theoretical amount of ester resulted.

It is well known that the hydrochloride of imido esters (see Chart II, C), intermediates in the alcoholysis of nitriles in the presence of hydrogen

(1) This paper is an abstract of a thesis submitted by Royal A. Cutler to the Faculty of Rensselaer Polytechnic Institute in partial fulfillment of the requirements for the degree, Doctor of Philosophy, June, 1947. The experimental work was carried out in the laboratories of Sterling-Winthrop Research Institute. The paper was presented before the Organic Division at the Washington, D. C., meeting of the American Chemical Society on August 30, 1948.

(4) It is interesting to note that when the nitrile (III) was hydrolyzed by means of sodium hydroxide and 75% ethanol, the sodium salt of IV separated from the reaction mixture in the form of pale pink needles. Treatment of this product with dilute hydrochloric acid gave the free amide (IV).

(5) When 80% sulfuric acid was used, a 40% yield of a monosulfonated 4-benzyl-7-chloroquinoline was obtained in addition to the expected product. The position of the sulfonic acid group was not determined.

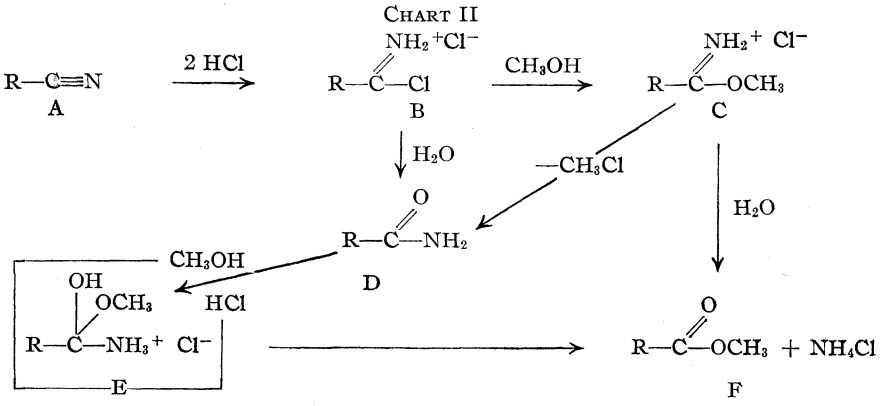
R′ = R and $-CH_2CH_2N(CH_3)_2$

chloride, lose the elements of alkyl halide upon heating to give amides (D).[8] The kinetics of this reaction for a number of imido ester hydrochlorides have been studied.[9] Furthermore, it has been demonstrated that the presence of highly negative groups in the position alpha to the nitrile group increases greatly the ease with which this type of reaction occurs. Thus trichloroacetonitrile,[10a] dichloroacetonitrile[10b] and nitroacetonitrile[10c] when treated with hydrogen chloride in methanol split out methyl chloride from the intermediate imido ester hydrochlorides, even at temperatures below 0°, to form the corresponding amides.

It was apparent, therefore, that in the alcoholysis of the nitrile (III) the negativity of the 4-quinolyl group combined with that of the phenyl group was sufficiently great to facilitate the split of methyl or ethyl chloride even at room temperature.[11] This accounts satisfactorily for the formation of large amounts of amide (IV) in the above-described experiments.

CHART II



Consideration of the mechanism for the formation of esters (F) from the intermediate imido ester hydrochloride (C) indicates that a molecule of water is necessary for the removal of the imido group by hydrolysis. In the usual alcoholysis of nitriles, this water is provided by pouring the

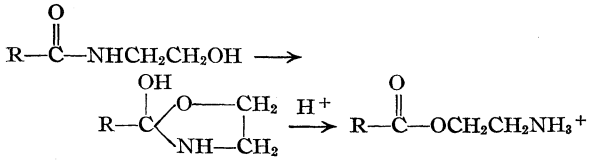
(11) The ease of formation of amide under non-hydrolytic conditions is shown by treating an ice-cooled solution of nitrile (III) in dry chloroform containing two equivalents of absolute ethanol with dry hydrogen chloride and allowing the solution to stand for three days at room temperature. The hydrochloride of the amide separated in quantitative yield.

reaction mixture into water after the imido ester hydrochloride has been formed. In the present series of nitriles (III), the intermediate imido methyl ester hydrochloride is too unstable to permit this type of treatment.[12] However, it was found that when water was incorporated into the reaction mixture, the rate of ester formation was materially increased. For example, when the nitrile (III) was added at room temperature to a solution of one part water and three parts of methanol, previously saturated with hydrogen chloride, and the passage of hydrogen chloride continued for six hours, a 32% yield of ester (VII) was obtained. On standing at room temperature for three days the yield was increased to 40% and after a period of three weeks to 70%.[13]

These results appear to indicate, according to the scheme outlined in Chart II, that the initial ester (F) formation results primarily from the hydrolysis of the imido ester hydrochloride (C). A considerable amount of amide (D) is formed concurrently due to the competing reactions; namely, the loss of methyl chloride from the imido ester hydrochloride (C) and probably also from the hydrolysis of some of the intermediate imido chloride hydrochloride (B). After the initial reaction, alcoholysis of the amide (D), to yield additional ester, proceeds at a slower rate. In order to test the latter hypothesis, the amide (IV) was subjected to the same conditions as described for the nitrile (III) to give an 18% yield of ester after six days and a 56% yield after three weeks. On employing anhydrous alcohols as the solvent a 7% yield of ester resulted from the amide after standing six days. The lower yield in the anhydrous media is probably due to the relative insolubility of the amide hydrochloride in this medium.

The alcoholysis of amides has been described previously. It is known that certain amides of β-aminoethanol rearrange in alcoholic solution under the influence of hydrogen chloride to give esters of β-aminoethanol. A possible mechanism for this type of reaction has been postulated by Phillips and Baltzly.[14] It was found that this reaction occurred rapidly even at room temperature. In one instance they reported an interconversion between the amide and ethanol, an example which still more closely resembles the present case. The authors found that, when the ethanolamide of phenylacetic acid was warmed with ethanolic hydrogen chloride, ethyl phenylacetate was obtained as one of the products.



Similar reasoning applied to the present problem would postulate that addition of methanol in the presence of excess hydrogen chloride would give the unstable addition compound, E (chart II). Loss of an ammonium ion would give the ester (F).

As an alternate method for the synthesis of ethyl α-(7-chloro-4-quinolyl)-phenylacetate, the condensation of ethyl phenylacetate with 4,7-dichloroquinoline was considered. The carbethoxylation of ethyl phenylacetate in 64% yield with ethyl carbonate or in 30% yield with ethyl chloroformate by means of sodamide in liquid ammonia has been reported.[15]

In the present work, 4,7-dichloroquinoline, ethyl phenylacetate and sodamide were stirred together at room temperature in dry benzene. After the temperature of the reaction mixture had risen to 50°, cooling was applied and the stirring continued overnight. From the reaction were isolated 20% of α-(7-chloro-4-quinolyl)-phenylacetamide (IV), about 1% of the desired ester (VII), a small amount of phenylacetamide and a 50% yield of ethyl α,γ-diphenylacetoacetate.[16] Apparently the ester is quite readily converted to the amide (IV) in the presence of sodamide. In order to avoid this latter action, sodium hydride was tried as the condensing agent. A mixture of sodium hydride, ethyl phenylacetate and 4,7-dichloroquinoline was refluxed for three hours in benzene to give a 75% yield of ethyl α,γ-diphenylacetoacetate and unchanged 4,7-dichloroquinoline. However, when a dilute benzene solution of ethyl phenylacetate was dropped very slowly into refluxing benzene containing 4,7-dichloroquinoline and an excess of sodium hydride, a 10% yield of ethyl α-(7-chloro-4-quinolyl)-phenylacetate was obtained. Inasmuch as suitable reaction conditions for the preparation of VII as well as for the corresponding ethyl ester by the alcoholysis of the nitrile (III) were finally worked out, as previously described, work on the above reaction was not pursued further.

Diethylaminoethyl α-(7-chloro-4-quinolyl)-phenylacetate (VIII) was prepared by the reaction of the corresponding methyl ester with diethylaminoethanol in refluxing Skellysolve E according to the procedure described by Surrey[17] for the *trans*-esterification of some methyl 4-quinolylmercaptoacetates. The presence of a trace of sodium decreased materially the reaction

(12) The imido ethyl ester hydrochloride is more stable. By passing hydrogen chloride into an absolute ethanol solution of the nitrile for six hours at 25° or into an aqueous-alcoholic solution cooled in an ice-salt-bath, the imido ester was obtained in good yield.

(13) The rate of alcoholysis of the nitriles in the three series studied showed a considerable variation. The rates in the order of decreasing velocity are as follows: unsubstituted > 7-chloro > 5-chloro. In the latter series only 56% of the ester was formed after five weeks whereas in the unsubstituted series a 90% yield of the ester was obtained after seventeen days.

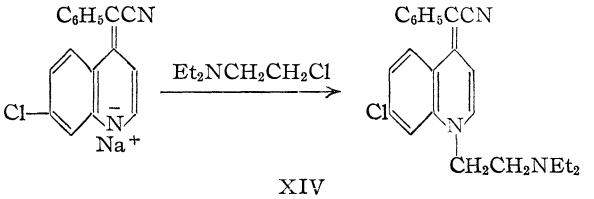
(15) Walker, Levine, Kibler and Hauser, *ibid.*, **68**, 672 (1946).

(16) A number of condensing agents have been used to prepare this compound. Its preparation in 82% yield by means of sodamide has recently been reported by Shivers, Dillon and Hauser, *ibid.*, **69**, 119 (1947).

(17) Surrey, *ibid.*, **70**, 2190 (1948).

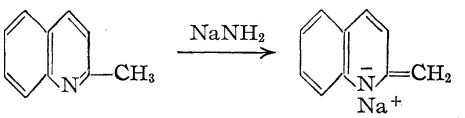
time and increased the yields. N-Diethylaminoethyl α-(7-chloro-4-quinolyl)-phenylacetamide (IX) was prepared similarly from the ester (VII) and N,N-diethylethylenediamine. The reaction was much slower than for the basic ester and was still slower in the presence of a trace of sodium. On the other hand, the presence of a little acid effectively catalyzed this reaction.

Attempts to prepare γ-diethylamino-α-(7-chloro-4-quinolyl)-phenylbutyronitrile (XI) by the condensation of the nitrile (III) with diethylaminoethyl chloride were unsuccessful. Instead, an isomeric compound was isolated in poor yield as its red-orange hydrochloride. The free base crystallized from Skellysolve B in two forms: namely, ruby-colored rectangular plates and long orange rods melting at 102–103° and 84–85°, respectively. These could be separated by mechanical means but on recrystallization either of the two forms again gave a mixture of the two crystalline modifications. The structure of the base is probably that of the N-alkylated compound (XIV) derived from the sodium salt whose structure is very likely that shown below.



XIV

Bergstrom[18] reported a similar type of salt formation in the case of 2-alkylquinolines. Treatment of the latter with alkali amides in liquid ammonia resulted only in salt formation with the enamic modification.



The preparation of γ-diethylamino-α-(7-chloro-4-quinolyl)-α-phenylbutyronitrile (XI) was accomplished in excellent yields by the condensation of 4,7-dichloroquinoline with γ-diethylamino-α-phenylbutyronitrile (X)[19] in the presence of sodamide. In addition it was found that phenyllithium in ether or sodium hydride in refluxing benzene also brought about the condensation.

Treatment of the nitrile (XI) with concentrated sulfuric acid at room temperature for four to five weeks gave a 90% yield of the amide (XII). After standing for three days only a 15% yield of XII was obtained. XII also resulted in 15% yield from refluxing the nitrile (XI) with sodium hydroxide in 70% ethanol for twelve hours. When the nitrile (XI) was refluxed with 60% sulfuric acid for one hour a 15% yield of the amide (XII) was isolated; after refluxing for twelve hours, a practically quantitative yield of 7-chloro-4-(3-diethylamino-1-phenylpropyl)-quinoline (XIII) was obtained. As would be expected, the rates of hydrolysis of the nitrile (XI) were much slower than for III. In the preparation of 5-chloro-4-(3-diethylamino-1-phenylpropyl)-quinoline, some of the intermediate amide was still present after refluxing for forty-eight hours.

Experimental[20]

α-(7-Chloro-4-quinolyl)-phenylacetonitrile (III).[21]—One hundred and ten grams (2.6 moles) of sodium amide[22] was added to a well-stirred, ice-cooled solution of 260 g. (2.2 moles) of phenylacetonitrile in one liter of dry benzene contained in a flask fitted with a soda-lime tube. The temperature rose gradually to 35° and the color of the solution changed from a pale yellow to a deep reddish black. After stirring for an hour, one mole (198 g.) of 4,7-dichloroquinoline was added portion-wise at a rate sufficient to maintain the temperature at 25–30° with strong external cooling. After the addition was complete, the ice-bath was removed and the reaction mixture stirred at room temperature for two hours. The bright red sodium salt of the product and excess sodium amide were decomposed by the cautious addition of water by means of a dropping funnel. The light reddish-orange benzene layer was washed once with water, followed by extraction with three 500-cc. portions of 9 *N* hydrochloric acid.[23] Ice was added to the acid extracts and the free base liberated by the addition of concentrated ammonium hydroxide. The red oil which formed was taken up in chloroform and dried over Drierite. Removal of the solvent gave a viscous oil which on treatment with ether and scratching yielded a pale yellow solid. In the case of IIIa[24] the oil was distilled at 0.1 micron, b. p. 140°, and the bright red distillate crystallized from a mixture of Skellysolve A and ether. Subsequent runs required no distillation.

The crude solids were obtained in practically quantitative yields and were used in subsequent reactions without further purification. Analytical samples were obtained by recrystallization from Skellysolve B or C.

α-(7-Chloro-4-quinolyl)-phenylacetamide (IV).—One part by weight of α-(7-chloro-4-quinolyl)-phenylacetonitrile was dissolved in four volumes of concentrated sulfuric acid and, after standing overnight at room temperature, the solution was poured into ice containing an excess of ammonium hydroxide. The solid amide was obtained in quantitative yield. Recrystallization from butanol gave a white crystalline solid. In the case of IVb,[24] ethanol was used as the recrystallization solvent.

7-Chloro-4-benzylquinoline (V).—Five parts by weight of the nitrile (III) and eight parts by volume each of concentrated sulfuric acid and water were refluxed vigorously for one hour. During the initial part of the reaction, carbon dioxide was evolved in copious amounts. At the end of the reaction, the yellow solution was poured onto ice

(20) All melting points are uncorrected. All analyses were performed by Mr. Auerbach and staff of these laboratories. Nitrogen, unless otherwise specified, was determined by means of a modified Kjeldahl procedure. Chlorine analyses, exceptions noted, were performed by means of the Parr-bomb method.

(21) The experimental procedures listed represent those for the compounds derived from 4,7-dichloroquinoline. The compounds in the unsubstituted and 5-chloro series were also prepared according to these methods with but few modifications which are noted.

(22) The sodamide used was prepared in the factory of Winthrop-Stearns, Inc. The granular material was stored under toluene and ground under benzene or toluene before use. The resulting finely divided material was pressed out between filter papers and quickly weighed, an excess being used in each case to make allowance for any solvent present.

(23) 6 *N* Hydrochloric acid was used for IIIa (see Table I). In the case of IIIb the solid hydrochloride tends to form during the extraction and may cause difficulty during separation.

(24) See Table I.

containing an excess of ammonium hydroxide. The product which separated was taken up in ether, dried over Drierite and the solvent evaporated to give a quantitative yield of a pale yellow oil which solidified on standing. Recrystallization from Skellysolve B gave long silky white needles.

In an initial experiment, 5 g. of the nitrile (III) was treated in a similar fashion using 12 cc. of concentrated sulfuric acid and 5 cc. of water. After extraction of the desired product (1.6 g.) with ether, acidification of the alkaline solution yielded 1.8 g. of a white solid which was purified by reprecipitation with acid from its sodium bicarbonate solution. Analysis indicated that it was a monosulfonated derivative of 7-chloro-4-benzylquinoline. The position of the sulfonic acid group was not determined.

Anal. Calcd. for $C_{16}H_{12}ClNO_3S$: Cl, 10.62; S, 9.60. Found: Cl, 10.51; S, 9.53.

7-Chloro-4-benzylquinoline Methiodide (VI).—The procedure was similar to the general method described by Alekseeva.[6] The product, obtained in quantitative yield, was recrystallized by stirring in 35 volumes of hot absolute alcohol followed by ice cooling, to give golden leaflets, m. p. 223–225° dec. Prolonged contact with hot alcohol results in considerable decomposition.

Anal. Calcd. for $C_{17}H_{15}ClIN$: I, 32.08; N, 3.54. Found: I, 31.60; N, 3.73.

4-Benzylquinoline methiodide obtained by the above procedure melted at 224–226° dec. (Rabe and Pasternack[6a] reported 226° dec.).

5-Chloro-4-benzylquinoline methiodide decomposed on drying in a vacuum desiccator overnight to give a dark brownish-red solid with a strong odor of benzaldehyde.

Methyl α-(7-Chloro-4-quinolyl)-phenylacetate (VII).—The following procedure gave the best yields of any method tried.

A solution of one part by volume of water in 3 parts by volume of methanol was saturated with gaseous hydrogen chloride with strong external cooling. The ice-bath was removed and one part by weight of the nitrile (III) added at 10–15°. The addition of hydrogen chloride was continued, the temperature rose to 35° and the solid soon dissolved completely to form a clear yellow solution. The white hydrochloride of the nitrile (III) soon separated and gradually redissolved over a period of two hours. (In the case of VIIa and VIIb[24] the hydrochloride of the corresponding nitrile did not separate.) The hydrogen chloride was bubbled slowly through the solution for a total of five or six hours. The resulting solution was stoppered and allowed to stand at room temperature for varying amounts of time. As ester formation occurred, ammonium chloride separated, the time required for the first appearance of this salt serving as a rough guide as to the rate of esterification. (The times required for the appearance of ammonium chloride for each of the compounds prepared were as follows: VIIa two to three hours; VII, ten to twelve hours; VIIb, about one week.) The reaction mixture was worked up by pouring into ice water and liberating the ester with aqueous sodium hydroxide in the presence of chloroform, care being taken to keep the solution cold by the addition of ice. Filtration at this point removed most of the amide present. The chloroform

layer upon separation, drying with Drierite, followed by evaporation, yielded the ester. The crude product was freed from small amounts of amide present[25] by dissolving in hot Skellysolve C (VIIb and VII) or a large volume of Skellysolve B (VIIa), filtering with charcoal, seeding and allowing to cool. The esters were recrystallized from the Skellysolves or methanol (VIIb) to give white crystalline solids. The crude yields of the three compounds prepared by this procedure are as follows: VIIa, 90% after standing seventeen days; VIIb, 56% after five weeks (yield after recrystallization from Skellysolve C); VII, 32% after six hours, 40% in three days, 70% after two weeks.

The methyl ester (VII) was also prepared from the amide (IV) by the same procedure. The yield of crude ester, after standing for six days, was 18% and 56% after three weeks.

Ethyl α-(7-Chloro-4-quinolyl)-phenylacetate.—This ester was prepared from the nitrile (III) according to the procedure outlined for the methyl ester. The yield after three days of standing was 54%, m. p., 125.5–126°, white thick needles.

Anal. Calcd. for $C_{19}H_{16}ClNO_2$: Cl, 10.88; N, 4.30. Found: Cl, 10.72; N, 4.24.

Ethyl α-(7-Chloro-4-quinolyl)-imidoacetate.—Twenty-eight grams (0.1 mole) of α-(7-chloro-4-quinolyl)-phenylacetonitrile (III) was added to 200 cc. of 95% ethanol, previously saturated with hydrogen chloride and thoroughly cooled in an ice–salt-bath. The passage of hydrogen chloride was continued with occasional shaking until solution was effected. After standing for three days in the ice-chest, the reaction mixture was diluted with two liters of ether, the resulting white crystalline precipitate collected on a filter and treated with dilute sodium bicarbonate solution. The mixture was shaken with chloroform and the insoluble amide (IV) collected on filter; yield, 5.5 g. The chloroform layer was separated from the filtrate, dried over anhydrous sodium sulfate, filtered with charcoal and the solvent removed by distillation to give 19.5 g. (0.06 mole) of almost white solid, m. p. 149–151°. Recrystallization from Skellysolve C, including treatment with charcoal, gave large white crystals, m. p. 155–157° (cor.).

Anal. Calcd. for $C_{19}H_{17}ClN_2O$: C, 70.25; H, 5.28; Cl, 10.92; N, 8.63. Found: C, 70.62; H, 5.13; Cl, 10.68; N (Dumas), 8.49.

The imido ester was also formed in good yield by adding the nitrile (III) to a saturated hydrogen chloride solution of absolute ethanol and passing in hydrogen chloride for six hours.

Diethylaminoethyl α-(7-Chloro-4-quinolyl)-phenylacetate (VIII).—A mixture of 15 g. (0.048 mole) of methyl α-(7-chloro-4-quinolyl)-phenylacetate (VII), 30 cc. of diethylaminoethanol, 110 cc. of Skellysolve E and a small piece of freshly cut sodium[26] about the size of a grain of wheat was placed in a 500-cc. round-bottomed flask fitted with a water separator, reflux condenser, and a drying tube. The mixture was refluxed (sixteen to twenty-four hours) at a rate just sufficient to allow the methanol formed in the reaction to distil over into the water separator. The cooled reaction mixture was diluted with an equal volume of ether and extracted with 0.5 *N* hydrochloric acid. The combined extracts were made just alkaline to litmus with 10% sodium hydroxide and extracted with ether to remove any unchanged ester together with small amounts of the 7-chloro-4-benzylquinoline formed due to the action of the sodium alkoxide present. The aqueous layer was then made alkaline to phenolphthalein with caustic, extracted with ether, the ether extracts dried with Drierite, and the solvent removed by distillation; yield, 16.35 g. (86%). In the case of VIIIa[24] and VIIIb the yields were 75 and 72%, respectively.

(25) In the preparation of VIIb, about one-quarter of the product at this point was amide because of the greater solubility of this compound in chloroform.

(26) A run made under similar conditions, but without sodium, gave only a 39% yield.

The free basic esters (VIIIa, VIIIb, and VIII) were all light orange-yellow oils. An attempted distillation of VIIIa was interrupted because of excessive decomposition. The mono-hydrochlorides of these compounds were readily obtained by dissolving the base in three volumes of acetone or isopropyl alcohol, adding slightly less than the calculated amount of alcoholic hydrogen chloride, diluting with ether just to turbidity and scratching or seeding to start crystal formation. Where necessary, the hydrochlorides were recrystallized from isopropyl alcohol or acetone. The hydrochlorides are stable, white crystalline substances easily soluble in water.

N-Diethylaminoethyl α-(7-Chloro-4-quinolyl)-phenylacetamide (IX).—The basic amide was prepared by the same procedure described above for the basic ester using N,N-diethylethylenediamine. In the presence of a trace of sodium the yield was 6%. Without the catalyst, the yields ranged from 20–25% and were increased to 65% when an acid catalyst (a trace of concentrated hydrochloric acid) was used. The product was recrystallized from Skellysolve B or C to give a white crystalline solid.

The monohydrochlorides of the bases (IXa,[24] IXb and IX) were prepared by the addition of slightly less than the equivalent amount of alcoholic hydrogen chloride to an isopropanol or acetone solution of the base.

Alkylation of α-(7-Chloro-4-quinolyl)-phenylacetonitrile. Preparation of XIV.—Sodamide (7 g.) was added to a stirred mixture of 40 g. of the nitrile (III) and 43 g. of diethylaminoethyl chloride in dry benzene at room temperature. The solution turned a ruby-red color as the red sodium salt of III separated. After stirring for thirty hours, the mixture was still a bright red; but, on standing for sixty hours more, it became black. After the cautious addition of water, the benzene layer was extracted with 1 *N* hydrochloric acid until the washings were but slightly colored. Evaporation of the benzene solution gave 17 g. of the starting material (III). The acid extracts were made just alkaline to congo red with sodium hydroxide, the black gum which separated was discarded and the solution filtered with charcoal to give a deep ruby-red filtrate. The latter was made alkaline to phenolphthalein, extracted with chloroform, the chloroform extracts dried over Drierite, filtered with charcoal and evaporated to give 30 g. of a black oil. This was taken up in ether, filtered from the solid which separated, and evaporated to give 20 g. of black oil which was in turn taken up in 60 cc. of isopropyl alcohol and 20 cc. of 3.6 *N* alcoholic hydrogen chloride added. On standing in the ice-chest, 2.6 g. of red needles separated. These were recrystallized from 200 cc. of isopropyl alcohol to yield 1.8 g. of fine red-orange needles, m. p. 215–216° dec. A mixed melting point with an authentic sample of γ-diethylamino-α-(7-chloro-4-quinolyl)-α-phenylbutyronitrile hydrochloride (m. p. 211–212°) melted at 175–190°. The analysis, however, indicated an isomeric compound.

Anal. Calcd. for $C_{23}H_{24}ClN_3 \cdot HCl$: Cl, 66.50; H, 6.07; Cl, 17.11. Found: C, 66.41; H, 5.97; Cl, 16.98.

Conversion of a sample of the above hydrochloride to the free base yielded a dark ruby viscous oil which was crystallized from Skellysolve B to give a mixture of dark ruby-red rectangular plates and orange rods. The two were separated by hand picking, the former melting at 102–103° and the latter at 84–85°. A mixed melting point appeared slightly moist at 82° but melted at 84–87°. Recrystallization of either solid from Skellysolve B resulted in the formation of a mixture of the two modifications. The ruby-red plates analyzed as follows:

Anal. Calcd. for $C_{23}H_{24}ClN_3$: C, 73.10; H, 6.40; N, 11.12. Found: C, 73.31; H, 6.18; N, 11.11.

γ-Dialkylamino-α-(7-chloro-4-quinolyl)-α-phenylbutyronitrile (XI).[27]—To a dry benzene solution (750 cc.)

(27) The γ-diethylamino and γ-dimethylamino compounds in this series (see Table II) were prepared in the same fashion and so will be treated under the general heading, γ-dialkylamino, exceptions being noted. The general procedure used in the preparation of these nitriles is similar to that described by Cloke, *et al.*, THIS JOURNAL, **53**, 2791 (1931), and Ziegler and Ohlinger, *Ann.*, **495**, 84 (1932).

of the 4,7-dichloroquinoline (0.5 mole) and one-half mole of γ-dialkylamino-α-phenylbutyronitrile[28] in a two-liter, three-necked flask fitted with a stirrer, thermometer, and drying tube was added 28 g. of fresh,[29] powdered sodamide. External cooling was applied when necessary to keep the temperature of the reaction mixture below 45°. At the end of two to three hours, the temperature had dropped to room temperature and stirring was continued for an additional four to five hours. Water was added cautiously and the dark colored solution changed to a light orange color. The benzene layer was washed twice with water and dried over Drierite. It was filtered with charcoal and evaporated to give a practically quantitative yield of the base. When the base was obtained as a viscous oil, it was stirred with a little ether to induce crystallization. Recrystallization from Skellysolve B or C yielded a pure sample of white crystalline solid.

The monohydrochlorides of the basic nitriles (see Table II) were prepared by dissolving the base in three to four volumes of warm isopropyl alcohol and adding slightly less than the calculated amount of alcoholic hydrogen chloride. In some instances ether was added to turbidity and the solution scratched to induce crystallization. The hydrochlorides were dried at 120° *in vacuo*.

γ-Dialkylamino-α-(7-chloro-4-quinolyl)-α-phenylbutyramide (XII).—A solution of one part by weight of the nitrile (XI) in four volumes of concentrated sulfuric acid was allowed to stand at room temperature for four to five weeks. The yellow solution was poured onto ice, treated with an excess of sodium hydroxide solution and extracted with chloroform. The combined extracts were dried over Drierite, filtered with charcoal and the chloroform distilled to give 80% yields or better of the amides. The crude products were crystallized from benzene or toluene to give white crystalline solids.

When the nitrile (III) was allowed to stand for three days in concentrated sulfuric acid, only a 15% yield of the amide was obtained. Refluxing the nitrile with an equal weight of sodium hydroxide in eight volumes of 70% ethanol for twelve hours or by heating 5 g. of the nitrile, 8 cc. of water and 8 cc. of concentrated sulfuric acid at reflux for one hour gave approximately 15% yields of the amide.

The monohydrochlorides were prepared by a procedure similar to that used in the preparation of the corresponding salts of the basic nitriles (XI). Larger volumes (5–20) of isopropyl alcohol were required to dissolve the amides. The salts were recrystallized from ethanol and dried *in vacuo* at 140°.

7-Chloro-4-(3-dialkylamino-1-phenylpropyl)-quinoline (XIII).—A solution of 30 g. of γ-dialkylamino-α-(7-chloro-4-quinolyl)-α-phenylbutyronitrile (XI) in 50 cc. of water and 50 cc. of concentrated sulfuric acid was refluxed for twelve to forty-eight hours. In some cases, the completeness of the reaction was determined by passing nitrogen over the surface of the reaction mixture and bubbling the escaping gases through barium hydroxide solution. When no cloudiness resulted after a minute or so, the reaction was regarded as complete. The reaction mixture was poured into ice containing an excess of sodium hydroxide solution, extracted with ether, the ether dried, filtered with charcoal and evaporated to give a pale yellow oil. In the case of XIIIb, some intermediate amide was isolated even after refluxing for forty-eight hours. This

(28) γ-Diethylamino-α-phenylbutyronitrile[19] and γ-dimethylamino-α-phenylbutyronitrile (Kwartler and Lucas, THIS JOURNAL, **68**, 2395 (1946)) were prepared in about 80–90% yields by the condensation of phenylacetonitrile with diethylaminoethyl chloride and dimethylaminoethyl chloride, respectively, under conditions similar to those described for the preparation of III.

(29) The use of sodamide which had been stored under toluene for long periods of time (four to six months) gave yields as low as 20%.

was removed by dissolving the oil in Skellysolve B, seeding with amide and allowing to stand twenty-four hours. Evaporation of the filtered solution gave the desired base. These bases could be converted to the monohydrochlorides without further purification or distilled under vacuum to give pale yellow tinted oils. The latter are all quite stable to heat but on standing for several days at room temperature, where dialkyl is diethyl, the bases develop a beautiful lavender or purple color. In two instances (see Table II) the bases solidified and were recrystallized from Skellysolve B.

The monohydrochlorides were prepared by dissolving the free base in three volumes of isopropyl alcohol and adding slightly less than the equivalent amount of alcoholic hydrogen chloride. In order to induce crystallization, ether was added to turbidity, the inside of the flask scratched and the solution allowed to stand. The analytical samples were dried *in vacuo* at about 120°.

The monohydrochloride of 7-chloro-4-(3-dimethylamino-1-phenylpropyl)-quinoline could not be induced to crystallize. A dihydrochloride, m. p. 215–217°, was prepared but gave an unsatisfactory analysis.

Summary

The condensation of phenylacetonitrile with 4-chloro-, 4,5-dichloro- and 4,7-dichloroquinoline has been investigated under a variety of conditions. The resulting α-(4-quinolyl)-phenylacetonitriles were converted to the corresponding α-(4-quinolyl)-phenylacetamides and 4-benzylquinolines.

The preparation of the methyl α-(4-quinolyl)-phenylacetates from the corresponding nitriles and some basic esters and basic amides is reported.

The reaction of γ-dialkylamino-α-phenylbutyronitrile with 4-chloroquinolines is also described. The nitriles so formed were converted to the corresponding amides and 4-(3-dialkylamino-1-phenylpropyl)-quinolines.

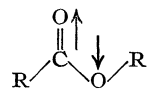
The Dipole Moment of Methyl Benzylpenicillinate

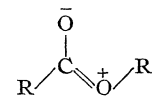
BY W. D. KUMLER, I. F. HALVERSTADT AND EDWARD L. ALPEN

Methyl benzylpenicillinate has been reported to have a dipole moment of approximately 8 from measurements in chloroform and anhydrous ethanol solutions.[1] It seems improbable that the molecule would have such a large moment if the commonly accepted structure of penicillin is correct. The large moment would mean that the individual moments were lined up in nearly the same direction, which is rather unlikely.

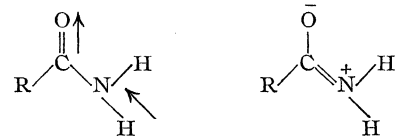
The group moments contributing to the over-all resultant moment are those of the ester (1.8), sulfide (1.6), amide (3.8)[2] and lactam (3.8 estimated). The moment of the lactam might be increased somewhat over an ordinary amide as a result of the ring formation, just as a lactone has a higher moment (4.1)[3] compared with an ester (1.8) but this increase in case of the lactam amide would be considerably less than in the case of the lactone. The ester is almost entirely in a form in which the ether dipole almost directly opposes the carbonyl dipole.



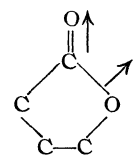
The molecule is held in this configuration by the contribution from the resonating form



which gives some double bond character to the carbonyl carbon–ether oxygen bond. The amides likewise are probably held in a similar configuration by resonance but here the moment of the amine portion (0.6–1.2) is not only smaller than that of the ether (1.3), but its resultant is not opposed to that of the carbonyl moment.



This effect is in part responsible for the dipole moment of amides being greater than that of a ketone (2.8), while that of an ester is considerably less. When an ester is bent around to form a lactone the moments are no longer directly opposed



but augment one another to some extent. However, when an amide is closed into a lactam there will not be nearly as much enhancement because there was originally not as much opposition to the

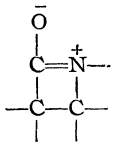
(1) O. S. R. D. Report Sh 4, 34 (1944) Shell Development Co. also the "Chemistry of Penicillin," Princeton University Press, Princeton, New Jersey, 1949, p. 407. This value was offered as an approximate value only. Although some workers interpreted this value as evidence for a zwitterion structure for penicillin, the Shell workers pointed out that although the value of 8 was intermediate between the moment of molecules without a separation of charge and the moment of zwitterion molecules, the fact that the molecule did not show a positive dielectric increment was evidence against its being a zwitterion.

(2) Kumler and Porter, THIS JOURNAL, **56**, 2549 (1934).

(3) Marsden and Sutton, *J. Chem. Soc.*, 1383 (1936).

carbonyl moment and the ring closure still leaves one of the N–H or N–C moments opposed to the carbonyl moment.

The lactam moment would also be reduced as a result of a decrease in the contribution of the resonating form



due to the additional strain in the four-membered ring caused by the double bond between carbon and nitrogen. There is evidence for this effect from the X-ray crystallographic studies. The carbonyl carbon–nitrogen distance in the lactam ring is given as 1.38 Å. and the carbonyl carbon–nitrogen distance in the amide as 1.33 Å.[4] The accuracy of the measurements is not sufficiently great to be certain of this difference but the reported distances are in the direction expected for less resonance in the lactam as compared with the amide. Not knowing the exact magnitude of either of these two effects we have assumed that the two cancel and the lactam has the same moment as the amide.

Taking the distances and angles given by the X-ray evidence for the solid, plus the above moments for the polar groups, we calculate the moment of methyl benzylpenicillin to be 5.2. The amide side-chain undoubtedly is not held in the same position in solution as it is in the solid. It would be expected to have some freedom of rotation, if not complete freedom of rotation, in solution. Assuming freedom of rotation for the amide side-chain the moment of the molecule is calculated to be 4.4. The expected moment of the compound is then somewhere between the two values.

The dipole moment of methyl benzylpenicillinate has been measured in dioxane solution at 25°. The method used in calculating the moment was that of Halverstadt and Kumler.[5] The ϵ_{12} values

$$p_{2_0} = \frac{3\alpha v_1}{(\epsilon_1 + 2)^2} + (v_1 + \beta)\frac{(\epsilon_1 - 1)}{(\epsilon_1 + 2)}$$

$$P_{2_0} = p_{2_0} M_2$$

$$\mu = 0.01281 \sqrt{(P_{2_0} - P_{E_{2_0}})T}$$

were linear with respect to ω_2. The v_{12} values departed somewhat from linearity on the first series of measurements. Four additional solutions were then measured and the v_{12} values of these were linear with respect to ω_2. The values of ϵ_1 and v_1 were obtained by extrapolating the ϵ_{12} and v_{12} values to $\omega_2 = 0$. $P_{E_{2_0}}$ values were obtained from the refractive index of the more concentrated solutions.

2.2147	0.97418	8.28	−0.209	550.8	93.0	4.73

The observed dipole moment of methyl benzylpenicillinate is 4.73 with an estimated accuracy of ±0.02. The value is within the range of the moment calculated using the accepted structure of benzylpenicillin. This value of the dipole moment is further confirmatory evidence for the correctness of the generally accepted structure of penicillin and removes any support which the higher reported dipole moment value of 8 gave to the previously proposed zwitterion-incipient azlactone structure for penicillin.[6]

Materials

Dioxane.—Dioxane was purified as before.[7]

Methyl Benzylpenicillinate.—Fifteen grams of potassium benzylpenicillin assaying 1577 units per mg. was treated by a modification of the procedure given in the Merck O.S.R.D. Report M-15b p. 1, and also in the "Chemistry of Penicillin," Princeton University Press, Princeton, New Jersey, 1949, p. 93. The ether solution of the free acid was dried by freezing out the ice at −70° and filtering. The solution was treated with a slight excess of diazomethane. Esterification was complete in fifteen minutes. The solution was concentrated *in vacuo* to an oily residue weighing 30 g. which was diluted with 70 g. of carbon tetrachloride and seeded with crystals by courtesy of D. S. Melstrom of Shell Development Co. After standing overnight the crystals were filtered off and dried; yield 10 g. Additional material was recovered to make a total of 11.26 g. This material was crystallized once from ether and once from carbon tetrachloride to yield 9.55 g. which softened at 94–95° and melted at 96–97° at 3° per min.

Summary

The dipole moment of methyl benzylpenicillinate was measured in dioxane and found to have a value of 4.73. This observed value is consistent with the calculated value using the usual group moments and the accepted structure of penicillin. Any support which the previously reported moment of 8 gave to the once proposed zwitterion-incipient azlactone structure for penicillin is thus removed.

The Rotatory Dispersions of Some *p*-Phenylazophenyl β-D-Glycosides[1]

BY WILLIAM A. BONNER

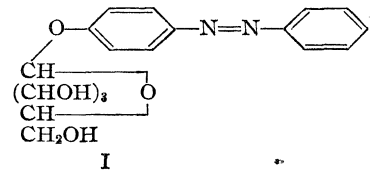
Measurements of rotatory dispersion shown by simple sugars and their derivatives have indicated that specific rotation varies with wave length in the visible spectrum according either to a simple Drude equation of the type

$$[\alpha]_\lambda = k/(\lambda^2 - \lambda_0^2) \qquad (1)$$

where k is the "rotation constant" and λ_0^2 the "dispersion constant," or to a more complex equation involving several terms similar to that in equation (1). In common with other optically active compounds, however, the simple or complex rotatory dispersions characteristic of measurements on sugars with visible light may become anomalous[2] in the ultraviolet regions as the wave length of the light approaches that corresponding to a specific absorption band in the molecule. It is known that the light absorbing group must be located in the close vicinity of the asymmetric center, and it is believed[2] that the asymmetric center imparts an induced dissymmetry to the chromophoric group which in turn contributes to the optical activity of the molecule, giving rise to anomalous dispersion when disturbed by light of the proper frequency. Thus the dispersion constant, λ_0^2, in equation (1) frequently corresponds to the wave length characteristic of an absorbing group near the asymmetric center.

There have been reported no experiments designed to test the possibility that absorbing groups further situated from an asymmetric center might also give rise to dispersion anomalies when coupled with the asymmetric center by appropriate conjugation. Experiments designed to test this possibility are reported in the present paper.

The absorption spectra of *p*-phenylazophenyl β-D-glycosides such as I have recently been measured.[3] Such spectra for a number of glycosides related to I have been found almost identical and, as was expected, quite similar to the spectra of the phenolic aglycone. Two distinct absorption bands were observed between 240 and 800 mμ: a relatively low intensity "R-band"[4] with a maximum around 436 mμ and a high intensity "K-band" with a maximum around 338 mμ. A third and more intense band below 240 mμ was also evident. It has been suggested[4] that the R-band in compounds such as I is due to the isolated azo linkage, and the K-band to the conjugated *p*-phenylazophenyl chromophore as a whole.



I

To the extent that this interpretation of the spectra of azo compounds is valid, one would expect the optical activity of compounds such as I to be affected by the *p*-phenylazophenyl chromophore causing the K-band, since this chromophore had its origin close to the first center of optical activity. We have attempted to determine if the azo chromophore causing the R-band might also affect the optical activity. At long wave lengths where solutions of I are transparent such an effect might not be expected, but it seemed reasonable to look for anomalous dispersion when wave lengths in the vicinity of the R-band were employed. Electronic disturbances of the azo chromophore by light of the R-band wave lengths might interact through the conjugation of the benzene ring with the first asymmetric center in I thus causing anomalous effects.

A serious experimental difficulty has prevented us from observing the optical effects we desired to study. The molar extinction coefficients of compounds such as I were in the neighborhood of 24000 for the high intensity K-band and 890 for the low intensity R-band.[3] These extinctions were so high that, even at high dilution, it was impossible to make polarimetric readings with light even in the longer wave length regions of the R-band. As soon as the initial R-band wave lengths were approached (*i. e.*, in the vicinity of 540 mμ) the optical densities of our solutions became so great that accurate polarimetric measurements were impossible. Thus with compounds such as I we have been unable to test the effect of distant chromophores which are conjugated with centers of optical activity on the rotations caused by these optically active centers. This problem is being studied at the present time with compounds whose absorption bands are characterized by lower extinction coefficients.

We have, however, been able to study the rotatory dispersion of compounds such as I for wave lengths above their R-band region. Since difficulties due to strong light absorption were anticipated, *p*-phenylazophenyl β-D-glucoside and *p*-phenylazophenyl β-D-galactoside were employed in these studies because of their relatively high specific rotations.[5] The dispersions of these compounds were measured in dioxane in the region from 667 to 524 mμ. The observed dispersions and their close similarities are illustrated graphically

in Fig. 1. The curves in Fig. 1 can be expressed mathematically with fair accuracy by means of the simple Drude formula of equation (1). On plotting the reciprocal of the observed specific rotation against the square of the wave length (Fig. 2) the linear relation characteristic of simple dispersion was found very nearly to hold. The slopes of the lines in Fig. 2 give rotation constants of −21.90 and −21.05, respectively, for *p*-phenylazophenyl β-D-glucoside and β-D-galactoside. Now knowing k of equation (1) for each compound it is possible, by substituting a measured specific rotation and wave length into the equation, to evaluate λ_0^2 and thus λ_0. This dispersion constant was determined to be 339 mμ for the glucoside and 342 mμ for the galactoside. These values are in striking agreement with the 338 mμ measured spectrophotometrically[3] for the position of maxima of the high intensity K-bands in compounds of type I. It is thus quite apparent that the conjugated *p*-phenylazophenyl chromophore is the one which affects the optical activity of type I compounds in the transparent regions of their spectrum. This observation, incidentally, is in accord with Burawoy's assignment[4] of the two absorption bands to their respective chromophores in the molecule.

As a further test of the simple dispersion observed in the transparent spectral regions we have used our values of k and λ_0 to calculate the specific rotation at each of our measured wave lengths. The calculated specific rotations, the observed specific rotations, and the average deviations from the means of the latter are recorded in Table I. With respect to the glucoside it is seen that the observed rotations agree with the calculated quite within the experimental error for longer wave lengths. From about 572 mμ downward, however, there seems to be a divergence in calculated and observed rotations which is beyond experimental error. This occurs in those very regions of the spectrum where the R-band absorption is just becoming evident and suggests that there is some interaction due to conjugation between the distant azo chromophore and the C-1 center of asymmetry as the electronic system of the azo chromophore becomes disturbed. It is most unfortunate that the high extinction coefficients characteristic of the absorption bands in our compounds prevented further polarimetric observation at the very point that this interesting divergence began to appear.

The agreement betwen observed and calculated specific rotations for the galactoside is not as satisfactory as in the case of the glucoside, due apparently to the fact that the dispersion of the galacto-

542[1]	122.2	138.1[d]	118.9	113.5		

Average deviation from mean value[2]: [a] 0.5 to 0.6; [b] 1.0 to 1.2; [c] 2.2; [d] 6.4; [e] 1.5 to 1.8; [f] 3.3; [g] 0.7 to 0.8; [h] 4.5.

[1] Measurements below 542 mμ were subject to such large experimental errors due to the high optical density of the solutions that the data are of doubtful significance and, therefore, not included.

[2] The deviation for an unlettered figure is that of the first lettered figure appearing above it.

side is not strictly simple. This trend away from simple dispersion is even more evident in *p*-phenylazophenyl tetraacetyl-β-D-galactoside, where the discrepancies in rotation between those observed and those calculated by equation (1) are even greater. It is interesting to note in Table I that the negative rotation of the unacylated glycosides become more negative with decreasing wave length, whereas the positive rotation of the acetylated galactoside becomes more positive. No attempts were made to extend dispersion measurements to other *p*-phenylazophenyl β-D-glycosides because of the comparatively low specific rotations of the known members of this class[5] and the high extinction coefficients of their absorption bands.[3]

Experimental Part

Dispersion measurements were made with a Lippich–Landolt precision polarimeter no. 80 and spectroscope monochromator no. 85[6] manufactured and calibrated by O. C. Rudolph and Sons. Solutions of the *p*-phenylazophenyl β-D-glycoside (10^{-1} molar for the glucoside and galactoside and 5×10^{-2} molar for the acetylated galactoside) were made in commercial dioxane and placed in a 10-ml. 1-dcm. polarimeter tube. Measurements were made at room temperature (*ca.* 23°) with no thermostating. Readings were taken at wave lengths indicated in Table I. The half-shade angle of the polarimeter was kept at 5 on its scale during all readings, and the slit widths on the monochromator were varied between 0.3 and 0.6 mm. depending upon the amount of light which would traverse the solution. Measurements were made at the concentrations indicated until increasing optical densities with decreasing wave length made matching of the polarimeter field impossible. At this point the solutions were diluted to 50% of their initial concentration with dioxane. Readings were continued until dilution was again necessary. One or two dilutions were usually sufficient to obtain data as in Table I. The dilution technique could not be employed to permit lower wave length readings as the observed rotation rapidly decreased with each dilution until the experimental errors of measurement made the results meaningless for comparative purposes.

Summary

Rotatory dispersion measurements on *p*-phenylazophenyl β-D-glucoside, β-D-galactoside, and tetraacetyl-β-D-galactoside have been conducted in order to see if the isolated azo chromophore of the aglycone might cause anomalous dispersion by interacting with the asymmetric centers through the conjugation of the benzene ring. The high extinction coefficients characteristic of the absorption bands in the aglycone, however, prevented dispersion measurements as the wave length of the first absorption band was approached.

In the transparent regions of the spectrum the dispersion of the unacylated glycosides was very nearly simple. Divergencies from simple behavior of possible significance were observed as the first absorption band of the aglycone was approached.

The wave length of the active absorption band calculated from a simple Drude equation agreed very well with the wave length of the ultraviolet absorption band as measured spectrophotometrically, indicating that the isolated azo chromophore in the aglycone had no effect on the rotation in the visible regions of the spectrum.

Thermal Data on Organic Compounds. XXV. Some Heat Capacity, Entropy and Free Energy Data for Nine Hydrocarbons of High Molecular Weight

BY GEORGE S. PARKS, GEORGE E. MOORE, MELVIN L. RENQUIST, BENJAMIN F. NAYLOR, LESLIE A. MCCLAINE, PAUL S. FUJII AND JOHN A. HATTON

In a series of investigations carried out at Stanford University between 1937 and 1944 heat capacity measurements were made upon twelve hydrocarbons of high molecular weight. From the data thus obtained the corresponding molal entropies were derived and in most instances the free energies of formation were also computed with the aid of available heats of combustion. Results for three of these hydrocarbons (11-*n*-decylheneicosane,[1] and *cis*- and *trans*-decahydronaphthalene[2]) have already been published in other connections. In the present paper we shall present similar results for the remaining nine compounds: *n*-hexadecane, *n*-octadecane, *n*-tetracosane, *n*-dotriacontane, ethylcyclohexane, *n*-heptylcyclohexane, *n*-dodecylcyclohexane, 11-cyclohexylheneicosane and 11-phenylheneicosane.

Materials

The hydrocarbon samples were the best obtainable at the time of these measurements, although more recently *n*-hexadecane and ethylcyclohexane have become available in much purer form. Most of the materials were also used in This Laboratory in determinations of the heats of combustion, in which work non-hydrocarbon impurities are especially serious. Accordingly, appropriate tests were run for ash content, the presence of halogens and in

some cases the carbon–hydrogen ratio. The results of such tests were entirely satisfactory for the materials used in this study. The observed melting points and the mole % purity, as estimated in the course of fusion determinations, are given in Table I. In all cases the impurities in the samples must have been primarily isomers or neighboring members of a homologous series, and these should not produce appreciable errors in the measured heat capacities except in the temperature region approaching the melting point.

TABLE I

MELTING POINTS AND ESTIMATED PURITY

Hydrocarbon	Formula	M. p., °K.	Purity, mole %
n-Hexadecane	$C_{16}H_{34}$	290.2	95.
n-Octadecane	$C_{18}H_{38}$	300.8	96.0
n-Tetracosane	$C_{24}H_{50}$	323.0	..
n-Dotriacontane	$C_{32}H_{66}$	342.7	..
Ethylcyclohexane	C_8H_{16}	161.2	99.1
n-Heptylcyclohexane	$C_{13}H_{26}$	232.0	97.1
n-Dodecylcyclohexane	$C_{18}H_{36}$	285.6	98.8
11-Cyclohexylheneicosane	$C_{27}H_{54}$	266.5	96.7
11-Phenylheneicosane	$C_{27}H_{48}$	294.0	97.7

The sources of our samples of *n*-hexadecane and *n*-octadecane were Eastman Kodak Co. materials, which were further purified in the procedures described, respectively, by Richardson and Parks[3] and by Parks[4] and coworkers. On the other hand, the Eastman *n*-tetracosane and *n*-dotriacontane were used without any additional purification. The ethylcyclohexane was part of a preparation from the laboratory of Professor C. E. Boord of Ohio State University. The samples of *n*-heptylcyclohexane and *n*-dodecylcyclohexane were prepared at Stanford University under the direction of Professor C. R. Noller, and their properties have been described in detail by Moore, Renquist and Parks.[5] The 11-cyclohexylheneicosane and 11-phenylheneicosane were compounds prepared in the work of American Petroleum Institute Research Project 42 at the Pennsylvania State College.[6]

Experimental Results

In principle, the method of Nernst was employed with an aneroid calorimeter in determining the "true" specific heats and the fusion data. The apparatus and details of experimental procedure have been fully described in other places.[7] In view of the accuracy of the various measurements involved, the absolute error in the experimental values thereby obtained is ordinarily less than 0.7%, except insofar as impurities in a sample may cause premelting at the upper temperatures of the crystals. The fortuitous errors are usually under 0.25%; and this latter figure may also be considered our probable *relative* error in making comparisons among these hydrocarbons.

Generally more than forty specific heat determinations in the temperature interval between 78 and 300°K. were made on each hydrocarbon. The results were then plotted on a large scale, a smooth curve through the experimental data was drawn, and specific heat values were read off from this curve for various even temperatures. For the sake of spatial economy and ease of comparison these derived values, rather than the more numerous experimental ones, are recorded in Table II. They and also the fusion data of Table III are expressed in terms of the *defined* conventional calorie[8] and with all weights reduced to a vacuum basis.

Three of these hydrocarbons exhibited small but distinct "humps" in the specific heat curves for the crystals. In the case of *n*-octadecane this hump came within the interval 228–240°K. and yielded a locally maximum C_p value of 0.365 cal. per gram at 237°. For *n*-tetradecane the hump range was 250–265° with a maximum of 0.420 cal. per gram for C_p at 262°, and for *n*-dodecylcyclohexane the range was 229–249° with a maximum of about 0.380 at 245°K.

Several of these liquid hydrocarbons could be supercooled to some extent, and in particular the ethylcyclohexane was first obtained as a typical glassy material at the temperature of liquid air. In this state it showed C_p values per gram of 0.175, 0.330 and 0.328 at 97, 100 and 110°K., respectively.

Apparently the recent investigation of the heat capacities of ethylcyclohexane by Huffman, Todd and Oliver[9] provides us with the only comparable data now available for any of these compounds. These investigators worked with a purer material than ours, and obtained specific heats which, outside of our premelting range, average 0.35% lower than our curve and a heat of fusion which is 0.68% above our mean value.

Entropy Data

Using the heat capacity data contained in the preceding section in conjunction with the third law of thermodynamics, we have calculated the entropies at 298.16°K. for these nine hydrocarbons. The detailed data are given in Table IV. In these calculations we have employed the extrapolation method of Kelley, Parks and Huffmann[10] for estimating the entropy increases of the crystals from 0 to 80°K. The various increments from 80 to 298.16°K., which appear in the next three columns, were obtained by the usual methods directly from the experimental data. The results for the total entropy are then given in the second column from the right under the designation "S^0_{298}"; they are probably reliable to within 1% in an absolute sense and to about half this figure for comparative purposes. In this connection it should be noted that the later and more ac-

TABLE III

FUSION DATA[a]

Hydrocarbon	M. p., °K.	Heat of fusion (cal. per g.) I	II	Mean
n-Hexadecane	291.1	54.40	...	54.40
n-Octadecane	301.3	56.68	56.93	56.80
Ethylcyclohexane	161.4	17.64	17.61	17.63
n-Heptylcyclohexane	232.8	28.97	29.29	29.13
n-Dodecylcyclohexane	285.8	43.42	43.36	43.39
11-Cyclohexylheneicosane	266.9	30.82	30.63	30.73
11-Phenylheneicosane	294.3	41.56	41.52	41.54

[a] In the calculation of these fusion values, the somewhat more rapid rise in the specific heat of the crystals as the melting point is approached was attributed to premelting; and the heat absorbed in this region in excess of that obtained by extrapolation of the specific heat data at lower temperatures was added to the heat absorbed at the melting point.

curate entropy result of Huffman[9] and co-workers for ethylcyclohexane is only about 0.23% less than our value tabulated here.

For the cases of n-octadecane and n-dotriacontane, which are crystalline substances at 298.16° K., we have also computed the entropy changes in the hypothetical fusion process at this temperature so as to be able to compare these compounds with others in the liquid state. In these computations we have used for the octadecane our own fusion data in Table III and for dotriacontane the estimate made by Parks and Rowe[11] for the heat of fusion.

The values of the entropies of formation (ΔS_f^0) given in the extreme right-hand column of Table IV represent simply the differences between the S_{298}^0 for each hydrocarbon and the corresponding values for the entropies contained therein. For this purpose we have used 31.211 e. u. for the entropy of hydrogen and 1.361 e. u. for C (β-graphite).[12]

While it is the intention of the senior author to present elsewhere in the near future a review of entropy regularities among both hydrocarbons and representative organic compounds containing oxygen, a few significant features relating to these tabulated S_{298}^0 values may be briefly noted here. Thus there is a fairly constant effect per CH_2 increment. Starting with the value of 70.76 e. u. as obtained by Douslin and Huffman[13] for liquid n-hexane, we find an average increase of 7.90 per CH_2 in going up the liquid paraffin series to n-hexadecane, 7.98 to n-octadecane and 8.05 e. u. to the hypothetical liquid n-dotriacontane. Likewise, there is an average increase of 7.98 e. u. per CH_2 increment in the liquid cyclohexane series from the ethyl to the dodecyl compound. By similar reasoning, the value of 51.3 e. u. may be assigned as the entropy contribution of the cyclohexyl group in a normal cyclohexane series involving liquids. On the other hand, the introduction of the cyclohexyl and phenyl groups in the middle of the heneicosane chain apparently produces entropy decreases, due to branching, of 7.6 and 5.4 e. u., respectively.

Free Energy Data

We have also calculated the free energies of formation of these hydrocarbons (except n-tetra-

The tabulated value for the enthalpy of formation (ΔH^0_f) of ethylcyclohexane has been taken from the work of Prosen, Johnson and Rossini.[14] That for *n*-hexadecane has been computed from a molal heat of combustion of 2557.50 kcal., which value represents a weighted (6 to 1) mean of the combustion determinations of Prosen and Rossini[15] and of Richardson and Parks.[3] The ΔH^0_f values for the remaining hydrocarbons have been taken from the combustion studies of Parks and co-workers,[3,4,5] with appropriate revisions, where necessary, to the present-day standards.[16]

In general, the free energies as derived from these ΔH^0_f quantities and the ΔS^0_f values in Table IV are probably reliable to within 0.05 or 0.06 kcal. per carbon atom, although in one or two instances, including that of *n*-heptylcyclohexane, the error may be appreciably greater than these figures. In this connection it should be noted that such calculations of free energy put a much heavier requirement for accuracy upon the measurement of the heat of combustion than upon the evaluation of the entropy. For example, in the case of 11-*n*-decylheneicosane an error of 1% in the molal entropy amounts to 2.62 e. u. and corresponds to 0.78 kcal. in free energy, while a mere 0.03% error in the heat of combustion corresponds to 1.47 kcal.

On the basis of these tabulated free energies we have deduced 1.21 kcal. for the average change in molal free energy per CH_2 increment in the series of liquid normal paraffins and normal alkylcyclohexanes. Likewise, through these and other data we have arrived at 12.8 kcal. as the approximate contribution of the cyclohexyl group in a series of liquid straight-chain compounds.

Summary

1. The specific heats of nine hydrocarbons of high molecular weight have been measured between 78 and 300° K. The corresponding heats of fusion have also been determined in seven cases.

2. The entropies of these hydrocarbons in the liquid or crystalline states at 298.16° K. have been calculated from the foregoing heat capacity data, and certain structural contributions have been noted.

3. The corresponding molal free energies have also been calculated. From these and other data values of 1.21 kcal. and 12.8 kcal. have been deduced for the respective contributions of a CH_2 increment and a cyclohexyl group in liquid straight-chain compounds.

Photochemical Studies. XLI. The Photochemistry of Dimethyl Mercury[1]

BY ROBERT GOMER[2] AND W. ALBERT NOYES, JR.

It was found during an investigation to be reported later that methyl radicals are almost certainly intermediates in the direct photochemical decomposition of ethylene oxide. The study of the reactions of CH_3 radicals with that molecule was, therefore, advisable and for this purpose the photochemical decomposition of $Hg(CH_3)_2$ was found to be convenient. Certain aspects of the decomposition of the latter molecule need further clarification.[3]

Experimental

Dimethyl mercury was prepared by the method of Gilman and Brown.[4] It was purified by fractional distillation in a column and then by bulb to bulb distillation at low temperatures. Vapor pressures agreed with the values of Linnett and Thompson.[5] The compound was degassed repeatedly after condensation by dry ice.

Two quartz reaction vessels were used: (a) 20 cm. length, 2.4 cm. inside diameter; (b) 3.5 cm. length, 2.0 cm. inside diameter. They were attached by quartz to Pyrex graded seals through mercury cut-offs to a line without stopcocks. The dead space during illumination was about 3 cc. In the case of the short cell it was necessary to replenish the $Hg(CH_3)_2$ periodically to prevent more than 10% decomposition.

The cells were placed in a brass cylinder about 10 cm. in diameter which could be heated electrically. Temperatures were read on thermometers placed in holes in the brass cylinder and by a thermocouple placed in a well in the vessel near the rear window. Extreme variations did not exceed three degrees.

Two different light sources were used: (a) a Hanovia medium pressure arc, S353; (b) a General Electric Company AH-6 high pressure arc. Filters were not used and radiation passing through a hole in a diaphragm next to the arc was made approximately parallel by a quartz lens, so that the cells were filled as completely and as uniformly as possible with radiation.

The absorption spectum of $Hg(CH_3)_2$ has been investigated by several authors, particularly Thompson and Linnett[6] and Terenin and Prileshayewa.[7] These authors agree that the spectrum is continuous in the neighborhood of 2500 Å., but long wave limits are placed at 2550 and 2800 Å., respectively.

The products uncondensed by liquid nitrogen (CH_4 with some C_2H_6) were separated from the $Hg(CH_3)_2$ by Toepler pumps. The remaining C_2H_6 and C_2H_4 (if any) were separated from $Hg(CH_3)_2$ by use of a modified Ward apparatus.[8] Combustions with oxygen over a heated platinum wire were usually used, but unsaturates were determined by fuming sulfuric acid, using a Blacet–Leighton apparatus.[9]

Light intensities with a given arc were varied by neutral density filters. These consisted of quartz plates, 1 mm.

in thickness, coated with a Cr–Al alloy by evaporation.[10] These filters were placed in such a way as to minimize local variations in density, although their uniformity was such as to render this precaution probably unnecessary.

Results

Table I shows data on rates of formation of CH_4 and of C_2H_6 in the large cell at 175° and at 220°. Table II shows similar data at 175° obtained in the small cell. Since the rate of C_2H_6 production is roughly proportional to the intensity, it can be seen that the intensity has been varied about 600-fold.

Table III shows data obtained in the large cell and over a range of temperature from 25 to 250° at approximately constant intensity.

TABLE III

RATES OF FORMATION OF METHANE AND OF ETHANE DURING PHOTOCHEMICAL DECOMPOSITION OF $Hg(CH_3)_2$

V = 590 cc. (for measurement of gas pressures of products); cell, 20 cm. long, 2.4 cm. diameter (V = 90.4 cc.); intensity constant; pressure of $Hg(CH_3)_2$ = 20.0 mm. (at 300°K.); arc – S 353; rates in microns/hr. (at 300°K.).

[a] Total C_2 hydrocarbons, C_2H_4 not determined. [b] 1.8 $\times 10^{-2}$ mm. C_2H_4 formed in addition.

Discussion

The data in Table III show that at constant intensity the rate of C_2H_6 formation increases markedly between 25 and 100° but that the change is very gradual as the temperature is increased further. This is in general agreement with the quantum yields determined by Linnett and Thompson[11] and the results of Cunningham and Taylor.[12] These facts may be connected with a decrease in stability of the $HgCH_3$ radical with increasing temperature. Thus if the primary process were $Hg(CH_3)_2 + h\nu = CH_3 + HgCH_3$ followed by a thermal decomposition of $HgCH_3$, $HgCH_3 = Hg + CH_3$, a recombination reaction could acccount for a low quantum yield of $Hg(CH_3)_2$ disappearance at low temperatures. The solid compound mercury methyl is, however, known not to be very stable even at room temperature.[13] The situation may resemble in important respects that found in acetone.[14] There is, however, evidence pointing to a reaction between CH_3 radicals and $Hg(CH_3)_2$ to give C_2H_6[15,19] and this may account for the gradual increase in $R_{C_2H_6}$ at higher temperatures.

The chief conclusions to be drawn in this paper are independent of the nature of the primary process provided, of course, CH_3 radicals are produced.[6,12]

For the sake of clarity of presentation it may be best to list at once the various steps in the mechanism and to follow them with evidence in their favor. It will be assumed in agreement with all other authors who have studied this molecule that CH_3 radicals are formed.[12]

$$CH_3 + CH_3 = C_2H_6;\ R_{C_2H_6}(1) = k_1(CH_3)^2 \quad (1)$$

$$CH_3 + Hg(CH_3)_2 = A;\ R_A = k_2(CH_3)(D) \quad (2)$$

$$A = CH_3 + Hg(CH_3)_2;\ -R'_A = k_3(A) \quad (3)$$

$$CH_3 + A = C_2H_6 + Hg + 2CH_3 \text{ (or } CH_3 + HgCH_3 \text{ or } Hg(CH_3)_2);\ -R''_A = k_4(CH_3)(A) \quad (4)$$

$$CH_3 + Hg(CH_3)_2 = CH_4 + H_2CHgCH_3;\ R_{CH_4} = k_5(CH_3)(D) \quad (5)$$

$$CH_3 + H_2CHgCH_3 = C_2H_5HgCH_3;\ R(6) = k_6(CH_3)(H_2CHgCH_3) \quad (6)$$

(D) = concentration of $Hg(CH_3)_2$.

The rate of CH_4 formation will be the rate of (5) and the rate of C_2H_6 formation will be the rate of (1) plus the rate of (4). If $R_{C_2H_6}(T)$ is the total rate of C_2H_6 formation, the following equation can be derived by assumption of the steady state for the intermediate A

$$\frac{R_{C_2H_6}(T)}{R_{CH_4}} = \frac{k_1 R_{CH_4}}{k_5^2(D)^2} + \frac{k_2 R_{CH_4}}{k_5} \frac{1}{(k_3 k_5(D)/k_4 + R_{CH_4}} \quad (7)$$

Equation (7) should be valid regardless of the units chosen for the various rates, but if comparison between constants for $Hg(CH_3)_2$ and for other molecules is desired, the rates should be expressed in standard units. For this purpose the rates have been converted to molecules cc.$^{-3}$ sec.$^{-1}$ with the assumption that CH_4 and C_2H_6 are produced uniformly throughout the reaction vessel. The validity of this assumption will be examined in a later paragraph.

It can be seen from the data in Tables I and II (Figs. 1 and 2) that a plot of $R_{C_2H_6}(T)/R_{CH_4}$ *vs.* R_{CH_4} gives a straight line except for low values of R_{CH_4} and that this straight line does not pass through the origin. The data for the short cell (Fig. 2) show more scatter than those for the long cell. This is due, undoubtedly, to the necessity for replenishing $Hg(CH_3)_2$ to prevent excessive decomposition during a run.

(10) The authors wish to express their appreciation to Dr. Harry Polster, Department of Optics, University of Rochester, for preparing these filters.

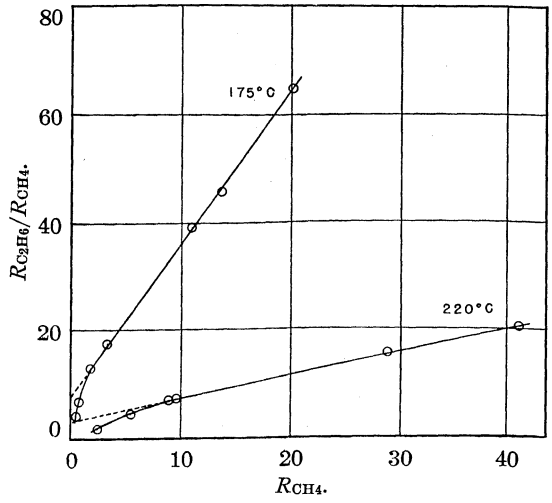

Fig. 1.—$R_{C_2H_6}/R_{CH_4}$ *vs.* R_{CH_4} in quartz cell 20.0 cm. long and 2.4 cm. internal diameter at 175° and at 220°C. The pressure of $Hg(CH_3)_2$ is 5.0 mm. (measured at 300°K.). Rates are in microns/hr. measured in a volume of 590 cc. at 300°K. Rates should be multiplied by 5.83×10^{10} to convert them to molecules/cc./sec. in the reaction vessel.

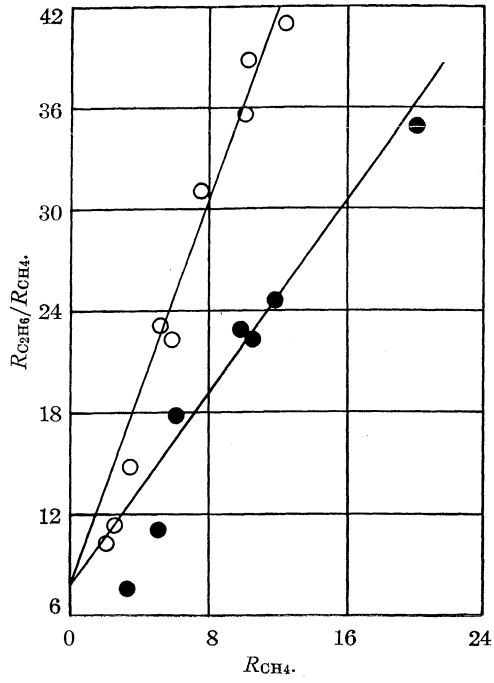

Fig. 2.—$R_{C_2H_6}/R_{CH_4}$ *vs.* R_{CH_4} in quartz cell 3.5 cm. long and 2.0 cm. internal diameter. Pressures of $Hg(CH_3)_2$ are 13.4 mm. (empty circles) and 20.1 mm. (solid circles) both measured at 300°K., $T = 175°$. The points are experimental and the lines are calculated from rate constants determined in the long cell at 175°C. (Fig. 1.). Rates are in micron/hr. and should be multiplied by 4.79×10^{11} to convert them to molecules/cc./sec.

A linear plot with positive intercept is obtained from equation (7) when $R_{CH_4} \gg k_3k_5(D)/k_4$. This situation would be obtained when the CH_3 concentration is sufficiently high to make (4) rapid compared to (3). The rate of formation of C_2H_6 by action of CH_3 on $Hg(CH_3)_2$ would be controlled by the rate of (2). The intercept would be k_2/k_5 and should be independent of (D) at constant temperature. This is seen to be true within experimental error (Fig. 2).

The slope of the linear plot would be $k_1/k_5^2(D)^2$ and hence should vary with $1/(D)$.[2] This is also found to be true within experimental error for the data in Tables I and II at 175°.

For this linear portion of the plot equations (2), (3) and (4) could be replaced simply by $CH_3 + Hg(CH_3)_2 = C_2H_6 + Hg + CH_3$, but the data necessitate a variable slope for low values of R_{CH_4} and the curve apparently tends toward the origin. This is satisfactorily accounted for by the complete mechanism embodied in equations (1) to (6) inclusive. While the authors have been unable to suggest any other mechanism which accounts for all of the facts, it should be emphasized that this does not constitute a proof that the proposed mechanism is a unique solution of the problem.

Equation (7) is, therefore, of the right form to fit the data in Tables I and II (Figs. 1 and 2). The smooth curves in Fig. 2 are calculated with the aid of rate constants obtained from the data in Table I and the fit to the experimental points adds strong support to the belief that the data are self-consistent.

It is not desired at the present time to enter into any detailed discussion of the theory of reaction rates, but a standard form of equation must be used for intercomparisons of various types of data. Hence the various rate constants are expressed in the form $aT^{1/2}e^{-E/RT}$ where $a = 2\sigma^2(\pi k/m)^{1/2}$ when the two colliding particles are identical (equation (1)) and $a = 2\sigma^2(2\pi k(m_1 + m_2)/m_1m_2))^{1/2}$ when the two colliding particles are different (equations (2), (4), (5), and (6)). k is the Boltzmann constant and σ^2 may be referred to as the "effective cross section" for the reaction.

If k_1 and k_5 are written in the above form it is seen that

$$\ln (k_1/k_5^2) = \ln (a_1/a_5^2) - {}^1/_2 \ln T - (E_1 - 2E_5)/RT \quad (8)$$

and $E_1 - 2E_5$ can be obtained from the slopes in Fig. 1 at two different temperatures. In this way it is found that $E_5 = 9000 + {}^1/_2 E_1$. This may be contrasted with approximately $5700 + {}^1/_2 E_1$ for the corresponding reaction of CH_4 formation in acetone.[16] The value of E_1 is not known precisely but is undoubtedly low.[17]

It is next possible to calculate a_1/a_5^2 and hence a relationship between the cross sections for C_2H_6 formation from radicals and for methane forma-

(16) L. M. Dorfman and W. A. Noyes, Jr., *J. Chem. Phys.*, **16**, 557 (1948).

(17) See ref. 12 and also S. Glasstone, K. J. Laidler and H. Eyring, "The Theory of Rate Processes," McGraw-Hill Book Company, Inc., New York, N. Y., 1941, p. 260.

tion. The results are: $a_5 = a_1^{1/2} \times 4.6 \times 10^{-9}$ (molecules^{-1} sec.$^{-1}$ cc.)$^{1/2}$; $\sigma_5^2 = 3.5 \times 10^{-11}\ \sigma_1$. In other words if $CH_3 + CH_3$ is a very fast reaction with a "normal" collision diameter of about 5 $\times 10^{-8}$ cm., the "effective cross section" for CH_4 formation is very low, roughly 10^{-3} times that which would be expected on a simple collision picture with 100% efficiency for each collision providing enough energy. It is interesting to note that the cross section obtained in this way is almost exactly the same as for the similar reaction in acetone[14,16] after suitable correction for the volume of the vessel.

The intercept of the straight line portion of the curves in Figs. 1 and 2 gives directly the ratio of $R_{C_2H_6}(4)/R_{CH_4}$, *i. e.*, the ratio of the rate of C_2H_6 formation to that of CH_4 formation when CH_3 radicals react with $Hg(CH_3)_2$. By use of the intercepts at two different temperatures one finds $E_5 - E_2$ to be approximately 9000 calories, *i. e.*, the energies of activation for C_2H_6 formation by the two different processes are about the same.

This result is somewhat surprising because reactions (2), (3) and (4) together could give rise to a chain reaction. Reaction (4) could be sufficiently exothermic to produce two CH_3 radicals.[18] The answer must be found in the very low a term for reaction (2), *i. e.*, it is found that $a_2 = 3.5 \times 10^{-4}\ a_5$. Since the same particles are involved the "cross section" for ethane formation from $CH_3 + Hg(CH_3)_2$ is also 3.5×10^{-4} times that for CH_4 formation. Thus in spite of a low activation energy the chain propagating step would be so slow as to be unimportant under most conditions.

Reference may now be made to the data in Table III to obtain a rough check on the energy of activation of the step leading to CH_4 formation. The CH_3 steady state concentration as obtained from the complete mechanism is

$$(CH_3) = -(k_5/2k_1)(D)(1 - (1 + 4I_a\, k_1/(k_5^2(D)^2)^{1/2}) \quad (9)$$

where I_a = number of quanta absorbed per cm.^{3} per second and two CH_3 radicals are assumed to be formed per quantum absorbed. From the rate of C_2H_6 formation a rough estimate can be made of I_a and this combined with the value determined above for k_1/k_5^2 indicates that $4I_ak_1/k_5^2(D) \gg 1$. Even the square root of this quantity is probably 10 to 100. Since $R_{CH_4} = k_5(CH_3)(D)$, one may write to a first approximation

$$R_{CH_4} = k_5 I_a^{1/2}(D)/k_1^{1/2} \quad (10)$$

At constant intensity and constant (D) a plot of ln R_{CH_4} *vs.* $1/T$ should give a straight line with slope $-(E_5 - {}^1/_2\, E_1)/R$. The assumptions made are probably least valid at high temperatures, but $E_5 - {}^1/_2\, E_1$ is found from the data in Table III to be approximately 10,000 cal., about as good a check as could be expected with the 9000 calories previously calculated from the data in Table I.

The mechanism postulated fits all of the data described in this article and as far as can be ascertained agrees well with data in the literature. A reaction between CH_3 radicals and $Hg(CH_3)_2$ to give C_2H_6 has been postulated frequently but the work of Harris and Steacie[19] affords the best proof for its occurrence. These authors studied the reaction of H atoms with $Hg(CH_3)_2$ and found that the ratio CH_4/C_2H_6 in the products was even less than unity under some conditions. If C_2H_6 were produced solely by combination of CH_3 radicals this ratio would have a minimum value of 2. It is necessary, therefore, to postulate a second method of formation of C_2H_6. Since the work just described seems to necessitate reactions (2), (3) and (4) for this method, it may or may not correspond to a simple inversion. Little more can be said about this matter at the present time.

The calculations which have been made are based on a uniform distribution of CH_3 radicals throughout the vessel, although they would be approximately valid (with minor changes in numerical values) if the distributions were similar from one run to another. Dr. T. L. Hill[20] has made approximate calculations of CH_3 distribution in a cell in the case of acetone where a situation similar to that in $Hg(CH_3)_2$ is encountered. The character of the distribution is very markedly dependent on the fate of radicals when they reach the walls, *i. e.*, under the conditions used in most of these experiments gas phase reactions will not be fast enough to prevent diffusion of many radicals to the walls. If the radicals are totally reflected a reasonably uniform distribution in a given cross section of the vessel is to be expected, although there will be a progressive decrease in concentration as the distance from the window through which the radiation is incident on the vessel increases.

Very little quantitative information is available on the fate of CH_3 radicals when they encounter walls under conditions obtaining in experiments of the type herein described. It appears probable, although the data are not exact enough to warrant a definite conclusion, that a very large fraction of encounters between CH_3 radicals and walls must lead to reflection. Otherwise the data would not be as consistent as they seem to be. More positive information on this point would certainly be of great value. The self-consistency of data in two different cells and the further fact that the addition of several hundred millimeters of carbon dioxide in one experiment did not affect the results, offer evidence that the methods of calculation used are justified.

In conclusion it should be reëmphasized that the pre-exponential factors in the rate constants for reactions (5) and (2) are very low. For many bimolecular reactions $aT^{1/2}$ is of the order of magnitude of 10^{13} to 10^{14} if concentrations are expressed in moles/cc. For reaction (5) (CH_4 forma-

(20) Private communication.

tion) $aT^{1/2}$ is about 2×10^{11} in these units and low values of this magnitude are found for other similar reactions if the assumption is made that the association reaction for CH_3 radicals is "normal." If the latter is low the constant for CH_4 formation will be reduced even further. For reaction (2) (the rate determining step for C_2H_6 formation from CH_3 and $Hg(CH_3)_2$), $aT^{1/2}$ is about 7×10^6, a very low value compared to most other bimolecular reactions.

Summary

1. The rates of formation of C_2H_6 and of CH_4 during irradiation of $Hg(CH_3)_2$ have been studied as functions of intensity, pressure, and temperature.

2. At temperatures below 250° CH_4 seems to be formed solely by the reaction $CH_3 + Hg(CH_3)_2 = CH_4 + CH_2HgCH_3$.

3. Ethane must be formed by at least two processes, one of which is the combination of CH_3 radicals and the other of which is a reaction of CH_3 radicals with $Hg(CH_3)_2$ which apparently proceeds through an unstable intermediate addition complex.

4. The pre-exponential factor in the rate constant for CH_4 formation is very much smaller than for ethane formation by radical combination.

5. The activation energy for reaction of CH_3 radicals with $Hg(CH_3)_2$ to form C_2H_6 is very low, about the same as for C_2H_6 formation by radical combination, but the pre-exponential factor is so low that the rate is small and a chain reaction is of relatively minor importance.

6. A mechanism consistent with the facts has been proposed.

The Heats of Reaction of Lithium, Sodium, Potassium and Cesium with Ammonium Ion in Liquid Ammonia at −33°

BY LOWELL V. COULTER AND ROBERT H. MAYBURY

The thermochemistry of oxidation–reduction reactions involving the alkali metals in liquid ammonia is of twofold interest. From a long range view the heats of reaction of the metals with ammonium ion in liquid ammonia, for example

$$M + NH_4^+ = M^+ + NH_3 + {}^1/_2H_2 \qquad (1)$$

may provide basic thermal values which when combined with corresponding free energy changes permit evaluation of relative partial molal ionic entropies in this solvent. In addition to the use of ionic entropies in the calculation of oxidation–reduction potentials not measurable directly, these ionic properties also permit evaluation of relative entropies of solvation of ions in liquid ammonia in a manner developed by Latimer[1] for water solutions. The existing scarcity of accurate free energy data for reactions occurring in liquid ammonia imposes temporary restrictions on the development of a set of reliable ionic entropies for this medium. However, the presumably simpler nature of liquid ammonia as compared with water arising from weaker hydrogen bonding would appear to simplify somewhat the theoretical treatment of the solvation process in this medium and therefore justify the exploration of this solvent.

Of immediate interest is the utilization of thermal data for the above reaction for the comparison of the nature of liquid ammonia solutions of the ammonia soluble metals. Prevailing concepts of these systems, while differing with regard to the equilibria involved in the more concentrated solutions and though incomplete as to the exact nature of the ammoniated electron, agree that the dilute solutions consist of solvated metal ions and single electrons resulting from essentially complete ionization in the dilute range of concentration. An exact similarity for these solutions has been observed by Gibson and Argo,[2] who have reported identical absorption spectra for dilute solutions of lithium, sodium, potassium and cesium. It is to be expected that these systems would likewise possess identical thermochemical properties for reactions involving the solvated electron of these solutions with a common oxidizing agent, as for example

$$e^-_{(am)} + NH_4^+{}_{(am)} = {}^1/_2H_{2(g)} + NH_{3(l)}$$

Direct measurement of the thermal effect associated with this reaction has not seemed experimentally feasible. It may be obtained indirectly, however, as the difference between the heat of solution of the metal in pure liquid ammonia and the heat of reaction of the metal with ammonium ion in liquid ammonia. The latter heat of reaction for solid lithium, sodium, potassium and cesium determined in this research combined with the literature values for the heats of solution of the metals has made possible the evaluation of the heat of this reaction. For dilute solutions of each of these metals we have obtained heats of reaction ranging from 39.7 kcal. for potassium to 41.6 kcal. for cesium with a mean of 40.4 kcal. This we regard as indicative of a common reaction for these solutions involving the solvated electron which energetically appears identical within experimental error in all cases.

Experimental

The calorimeter employed was essentially of the type used by Kraus and Schmidt[3] but differed in size and method of collecting the gaseous products of the reaction, hydrogen and vaporized ammonia. The calorimeter I of Fig. 1 consisted of a Pyrex vacuum-jacketed test-tube capped with a removable top G by means of a ground glass joint. The top was connected through F to a manifold and served as a point of suspension for the thermocouple well E, sample crushing rod K and the reciprocating stirrer B-J suspended by the spring A. Intermittent energizing of the solenoid C provided a stirring rate of 60 strokes per minute.

Sample bulbs of the metals were held near the bottom of the calorimeter in a platinum stirrup L located directly below the sample crushing rod K to which the holder was loosely attached. The crushing rod extended beyond the calorimeter top through a gas tight seal at D. A fine mesh platinum gauze enclosed the sample bulbs and served as a bubble trap whereby continuous contact of metal and solution was prevented and a controlled reaction rate obtained. The calorimeter was thermostated by boiling liquid ammonia contained in the closed Dewar vessel M of Fig. 1.

The gas collecting system consisted of a six-liter flask P thermostated at 25.0 ± 0.1°, and a manometer Q which were connected to the manifold through a small metal needle valve O. Withdrawal of gas from the calorimeter into the evacuated collecting system was made by manual adjustment of the valve during the reaction period. The entire gas collecting system had a total volume of 6715 ml. The connecting lines which were not thermostated amounted to about 1% of the total volume.

For each thermochemical measurement a weighed amount of ammonia, usually between 110 and 120 g., was introduced at N and condensed in the calorimeter to a liquid depth of about 14 cm. as indicated by the dotted line in Fig. 1. Temperature measurements were made with a copper–constantan thermocouple, calibrated at the sublimation point of carbon dioxide and the freezing point of mercury. Potentials were measured with a Type K-2 Leeds and Northrup potentiometer with a matched galvanometer having a sensitivity of 20 mm. per microvolt for a scale at a distance of 15 ft. from the galvanometer.

Commercial anhydrous liquid ammonia of 99.2% purity, according to the supplier, was used for the thermostating liquid. Stock ammonia for the calorimeter reaction medium was prepared by distillation of the ammonia from the large commercial cylinders into a small cylinder containing sodium metal as a drying agent.

The metals employed in the research were of the following grades as indicated by the supplier and were used without further purification except for cesium which underwent a distillation in the process of sample preparation: lithium, Lithaloy, low sodium quality (typical analysis as furnished by the supplier, N, 0.15; Si, 0.05; Fe, 0.02; Al, 0.01; Ca, 0.10; Na, 0.15; K, 0.05%); sodium, Baker, Analytical Reagent; potassium, Baker, C. P.; cesium, Fairmount Chemical Co.; C. P. Baker Analytical Reagent ammonium chloride and bromide dried at 100° were the oxidizing agents in the reactions. Samples of oxide-free sodium and potassium for the reaction were prepared in small thin-walled glass bulbs in the manner described by Kraus.[4] The cesium samples were prepared by a high vacuum distillation of the metal from the shipping ampoules into the weighed sample bulbs. Lithium samples with clean surfaces were prepared by cutting cylinders of the metal from the ingots under oil followed by removal of the oil with dried benzene rinses.

Procedure.—The net measured heat effect associated with reaction (1) was a composite of heat absorbed by the vaporization of ammonia during the reaction and the thermal change resulting from the temperature change of the calorimeter and contents. The experimental determination of the first of these quantities involved the withdrawal

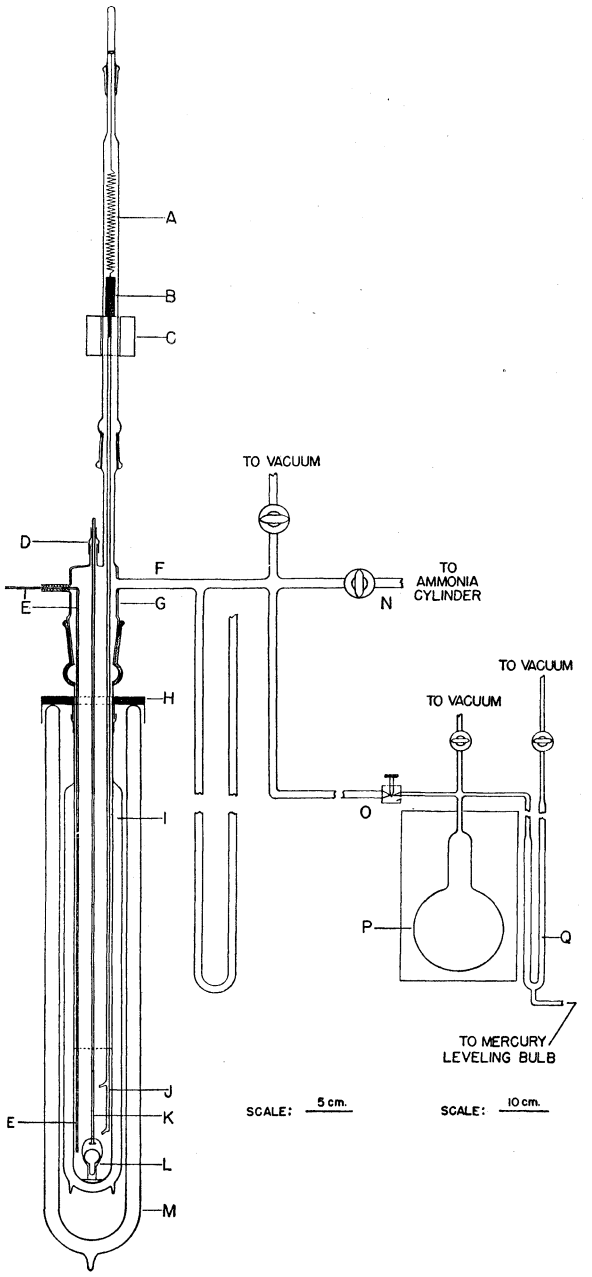

Fig. 1.

of gas during the reaction period from the calorimeter manifold into the calibrated gas collecting system through the manually controlled needle valve at such a rate as to maintain a constant pressure in the calorimeter. The second of these quantities was obtained from the measured temperature change of the calorimeter, as determined by the thermocouple measurements, and the total heat capacity of the calorimeter and contents.

Following the assembly of the calorimeter containing the reactants and liquid ammonia the temperature of the calorimeter was allowed to approach a steady state value.

When a constant temperature or temperature drift was attained, usually less than a thousandth of a degree per minute the sample bulb was fractured by a downward thrust of the crushing rod which initiated the reaction. During the reaction period withdrawal of vaporized ammonia and product hydrogen from the manifold into the

gas collecting system was accompanied by approximate temperature readings of the calorimeter in order to establish the temperature–time pattern from which the graphically determined mean temperature was calculated. During the post reaction period regular temperature measurements were again recorded for a period of fifteen to thirty minutes during which time a steady temperature drift was apparent. The corrected temperature change taking into account radiation heat gain was calculated from the temperature patterns so obtained in the usual manner for this type of calorimeter.[5] Although the reactions studied were exothermic, a temperature lowering of the calorimeter always occurred because of the release of gaseous hydrogen within the liquid. The mean calorimeter temperature was approximately −33°.

From the known volume, temperature and pressure of the gas collected in the gas collecting system the weight of ammonia vaporized was calculated by means of Berthelot's equation of state and the critical constants for ammonia.[6] The vaporization heat effect was determined from the net amount of ammonia vaporized and the specific heat of vaporization of ammonia[7] at the mean calorimeter temperature. Pressures were determined by a mercury manometer read by a cathetometer to 0.05 mm. Correction was made for the hydrogen gas liberated by the reaction and collected along with the ammonia in the manifold or gas collecting system on the assumption that the hydrogen gas behaved ideally. A correction was also applied to the weight of ammonia vaporized in those experiments having a net pressure change in the calorimeter system.

The heat capacity of the calorimeter was determined in a fashion similar to a heat measurement except that an electric heater was substituted for a sample of metal. To reproduce the temperature pattern as nearly as possible, hydrogen gas was measured into I through a side arm not shown in Fig. 1 and allowed to bubble through the solvent ammonia in the calorimeter simultaneously with the introduction of measured quantities of electrical energy. The dependence of the calorimeter heat capacity on depth was determined electrically at 25° with water in the calorimeter. For a depth of 15 cm. the heat capacity of the calorimeter was 21 cal. per degree at −33°.

Specific heats for liquid ammonia and the alkali metals were taken from the work of Overstreet and Giauque[8] and the compilation by Kelley.[9] A specific heat of 0.2 cal./g. was assumed for Pyrex glass in evaluating the small contributions of sample containers and glass rod to the total heat capacity of the calorimeter.

The heat effect associated with the crushing of an evacuated sample bulb containing no sample was determined in a manner identical with the reaction heat measurements. No pressure or temperature change (±0.01°) was found associated with the process.

Discussion

The observed heat effects for each of the thermochemical measurements are summarized in Table I. The total heat capacity and corresponding corrected temperature change of the calorime-

ter resulting from the reaction are tabulated in columns 4 and 5. The thermal effect, q_1, associated with the temperature change follows in column 6. The vaporization effect, q_2, listed in column 8 has been calculated from the grams of ammonia vaporized, tabulated in column 7 and the specific heat of vaporization of ammonia at the mean reaction temperature. The total net heat effect per sample and the change in heat content per gram atom for eq. (1) appear in columns 9 and 11, respectively. The values for the latter have been corrected only in the case of lithium for an effective 0.5% impurity.

Comparison of the heats of reaction fail to reveal any significant dependence of the reaction heat on concentration in the range investigated. In the case of lithium the mean of the values for experiments F and E is almost identical with the mean of G and C in which the concentrations were more than doubled. A further increase in concentration does appear, however, to give a slightly decreased reaction heat as evidenced by the mean of experiments 15 and 16 which is about 1.5% less. An analogous trend is to be observed for sodium. Experiment 6, for example, has a heat of reaction about 2% smaller than experiments 4 and 5 in which the dilution was greater. However, in view of an experimental error of at least 1% which must be assigned these values, we are inclined at the present to regard the dilution heat effects to be within the final experimental error to be assigned these measurements. By analogy with similar aqueous systems it is to be noted that dilution heat effects arising from differences in relative heat contents at these concentrations, approximately 400 moles of solvent per mole of solute, are considerably less than 1% of the heats of reaction measured in this research. We shall, consequently, employ these values at this time as the heats of reaction for infinite dilution. On this assumption the heats of reaction for each metal have been averaged and summarized in column 2 of Table II.

[a] Kraus and Schmidt, THIS JOURNAL, 56, 2298 (1934). [b] This research. [c] Schmidt, Studer and Sottysiak, *ibid.*, 60, 2780 (1938).

The heats of solution of the alkali metals in pure liquid ammonia at low concentrations have been determined by Kraus and Schmidt,[10] and Schmidt, Studer and Sottysiak[11] at −33° and are tabulated for convenience in column 3 of Table II as ΔH_2 values. Subtraction of the solution reaction

$$M_{(s)} = M^+_{(am)} + e^-_{(am)} \qquad (2)$$

and the associated heat of solution, ΔH_2, from our measured heats of reaction, ΔH_1, has given for each metal solution the molar heat effect, ΔH_3, for the common reaction

$$e^-_{(am)} + NH_4^+{}_{(am)} = NH_{3(l)} + {}^1/_2H_{2(g)} \qquad (3)$$

These values are tabulated in the last column of Table II.

It has been assumed in writing the foregoing equations that essentially complete dissociation of the metals and electrolytes involved occurs in liquid ammonia. That such may not be the case with electrolytes is indicated by their conductance in liquid ammonia. Gur'yanova and Pleskov[12] have found the Debye–Onsager theory inadequate for these systems and have accounted for conductance properties with some success on the basis of ion pairs. However, as is to be seen from a comparison of the reaction heats of sodium with the two ammono acids, ammonium chloride and ammonium bromide, appreciable differences in ionic association leading to energy effects are not revealed in the concentration range investigated. This is also evident from the apparent independence of the heats of reaction on concentration in general.

Calculation of ΔH_3 for the lithium solution based on the heat of solution reported by Kraus and Schmidt,[10] and Schmidt and co-workers,[11] led to the value −42.5 kcal. designated as lithium–ammonium bromide-1 in Table II, differing by about 6% from the mean obtained for sodium and potassium. Since this appeared to exceed a reasonable experimental error of 1 to 2% on the basis of a similarity for all alkali metal solutions we redetermined the heat of solution of lithium in pure liquid ammonia and obtained a heat of solution of 9.55 kcal. (see expt. J of Table I) which when combined with ΔH_2 gave for ΔH_3 −40.9 kcal. in better agreement with the values for sodium and potassium solutions. Further measurements in connection with other work now in progress substantiate this observation. We have not been able to account for this discrepancy in the heat of solution of lithium in a satisfactory manner.

The possibility that a heat of amide formation was contributing to our heat of solution does not appear likely in view of the observed stability of the solution. The nature of the temperature–time pattern for the heat of solution of the metal in comparison with other reactions likewise gave no indication of a significant side reaction.

Since our disagreement with previous workers on the heat of solution of lithium could be accounted for on the basis of instrumental and procedural differences, we remeasured the heat of solution of ammonium bromide which has also

(10) Kraus and Schmidt, THIS JOURNAL, 56, 2298 (1934).
(11) Schmidt, Studer and Sottysiak, *ibid.*, 60, 2780 (1938).
(12) Gur'yanova and Pleskov, *J. Phys. Chem.* (*U. S. S. R.*), 8, 345 (1936).

been studied by Schmidt and co-workers[13] in the same calorimeter employed for the lithium measurements. We have obtained 9.50 kcal. for the exothermic heat of solution of ammonium bromide at a concentration of 147 moles of ammonia per mole of ammonium bromide. This value is 2.5% lower than the interpolated value of 9.76 obtained from a large scale plot of values obtained by Schmidt. Since these two values are essentially in agreement on the basis of a 1% error for each value, it does not appear that the difference for lithium amounting to about 20% can be ascribed to instrumental differences. It is our intention, however, to redetermine the heat of solution of this metal along with others in a larger calorimeter now under construction which will afford an opportunity to examine these heat effects at much lower concentrations and at the same time eliminate any radiation effect on the solution reaction which might conceivable be involved with the partially jacketed calorimeters employed so far in liquid ammonia studies.

The slightly higher values obtained for ΔH_3 of the cesium solution, -41.5 kcal., which exceeds the mean for lithium, sodium and potassium, -40.2 kcal., by 3% may be indicative of some difference between this solution and the other alkali metals. However, in view of the fact that a few tenths of a per cent. impurity of one of the lighter alkali metals or calcium can account for this observed deviation, it does not appear appropriate to assign any uniqueness to the dilute ammonia solutions to cesium at this time.

In general, then, it appears that all of the dilute alkali metal solutions investigated in this research are energetically identical within about 1 kcal. Weighting all values equally we obtain for the reaction represented by eq. (3) at $-33°$: $\Delta H = -40.4 \pm 1$ kcal.

This heat of reaction will now furnish a basis for the investigation of the nature of solutions of the alkaline earth metals, calcium in particular. On the basis of the absorption spectra[2] and the magnetic susceptibility[14] of dilute calcium ammonia solutions, a difference appears to exist between calcium and the alkali metals in the first instance and between calcium and barium in the second. Measurements are now in progress to determine whether or not the heat of reaction of the calcium solution with ammonium ion indicates normal ionization of calcium or the formation of Ca_2^{++} and one electron ionization per gram atom of calcium as proposed by Yost and Russell.[15]

The relative partial molal ionic entropies of the alkali metal ions in liquid ammonia may now be calculated from the measured heats of reaction for eq. 1 and the corresponding free energy changes derived from cell measurements by Pleskov and Monoszon.[16] These values appear in column 3 of Table III along with our measured heats of reaction from which the partial molal ionic entropies relative to $\bar{S}^0_{NH_4^+} = 0$ at $-33°$ have been calculated in the usual manner.[1] It does not appear that the free energy changes employed in the calculation are above criticism because of the presence of liquid junction potentials in the cells employed by Pleskov and Monoszon and in view of the approximation of activity coefficients made for the solutes in the cell solutions in obtaining the standard electrode potentials.

TABLE III

IONIC AND SOLVATION ENTROPIES IN LIQUID AMMONIA AT $-33°$

Ion	ΔH^0 kcal.		ΔF^0 kcal.	$\bar{S}^0_{246}$°K. cal./deg.	ΔS of solvation cal./deg.
Li^+	$(-66.380)^a$	-50.6	-51.4	-26.8	-52
Na^+	$(-57.520)^a$	-38.7	-42.4	-9.5	-38
K^+	$(-60.340)^a$	-39.7	-45.6	$+2.6$	-27
Rb^+	$(-61.210)^a$	-40.0^b	-44.4	-2.4	-34
Cs^+	$(-62.040)^a$	-41.6	-44.9	-3.0	-42

[a] Corresponding values for the reaction $M + H_3O^+_{(aq)} = M^+_{(aq)} + \frac{1}{2}H_2 + H_2O$ at 25° [Latimer, *Chem. Rev.*, 18, 349 (1936)]. [b] Estimated from value for potassium.

Comparison of the ionic entropies obtained for the metal ions indicates a departure of $\bar{S}^0_{Rb^+}$ and $\bar{S}^0_{Cs^+}$ from the consistent and expected trend for lithium, sodium and potassium. This is emphasized in a consideration of the relative solvation entropies of each of the ions in the last column of Table III, where ΔS of solvation $= \bar{S}_{M^+} - S_{(\text{gas ion})}$. Although smaller negative values for the solvation entropy of Rb^+ and Cs^+ are expected in comparison with K^+ because of the larger ionic radius and consequently less ordering effect on the solvent, the reverse occurs. The admitted uncertainties in the standard potentials undoubtedly will account for these inconsistencies. It is of interest that solvation entropies of the lithium, sodium and potassium ions appear to be linearly dependent on the reciprocal of the ionic radius as already observed for aqueous ions by Latimer[1] and Buffington[17] and that the slope of the curve is approximately the same as obtained for these ions in water solution.[1]

For comparison purposes we have included in Table III the reaction heats of the alkali metals with hydronium ion in water solution. These values appear in parentheses with the corresponding values in column 2 obtained in this research for the reaction represented by eq. (1). It is to be noted that in both systems a minimum value is obtained for $-\Delta H$ for the sodium reaction. Although the difference between the reaction heats in the two systems is about constant at 20 to 21 kcal. for potassium, rubidium and cesium, the dif-

ference in the case of lithium amounts to only 16 kcal., thereby indicating a relatively greater interaction energy of the lithium ion with ammonia than with water.

Acknowledgment.—We wish to express our appreciation to the Research Corporation for a Frederick Cottrell grant in aid of research which made this investigation possible. We are also indebted to the Sigma Xi for an earlier grant supporting exploratory work. We acknowledge the assistance of Mr. Sumner P. Wolsky who performed some of the calibration experiments.

Summary

The heats of reaction of lithium, sodium, potassium and cesium metals with dilute solutions of ammonium bromide and ammonium chloride have been determined in a liquid ammonia calorimeter at −33°. Combination of these heats of reaction with the known heats of solution of the metals in pure liquid ammonia has given the heat of reaction of each dilute metal solution with ammonium ion. Exothermic heats of reaction varying from 39.7 to 41.6 kcal. (mean 40.4 ± 1 kcal.) indicate within experimental error an identical reaction in each case and, therefore, a close similarity in the nature of the dilute solutions of the alkali metals in liquid ammonia. A redetermination of the heat of solution of lithium in liquid ammonia gave −9.6 kcal. for ΔH instead of the reported value −8.0 kcal. From the measured heats of reaction and corresponding free energy changes relative partial molal ionic entropies and entropies of solvation of the alkali metal ions in liquid ammonia have been calculated.

The Relationship between Homoserine and its Lactone[1]

BY MARVIN D. ARMSTRONG

The preparation of the optical isomers of homoserine (α-amino-γ-hydroxybutyric acid) was described in a previous publication[2] and a brief review was made of its earlier literature. Since the first synthesis of homoserine by Fischer and Blumenthal in 1907[3] little appeared to have been added to our knowledge of the physical and chemical properties of the compound and its derivatives. The purpose of the present investigation was to examine some of these properties, particularly the relationship of homoserine to its γ-lactone and its diketopiperazine.

The early studies of homoserine by Fischer and Blumenthal indicated that in acid solutions it possibly existed only in the lactone form; the conversion to a lactone is in analogy with the behavior of homocysteine which forms the corresponding thiolactone.[4] Fischer and Blumenthal also prepared free α-aminobutyrolactone from its hydrochloride and found that it reacts with itself to form a diketopiperazine. The formation of a diketopiperazine is likewise similar to the reaction of homocysteine thiolactone which reacts with itself in neutral solution to form homocysteine diketopiperazine.[5] It thus was of interest to find whether homoserine could exist in the open form in acid solutions and whether the lactone of homoserine reacted in aqueous solution to form the corresponding diketopiperazine as well as opening to form homoserine.

The nitrous acid amino nitrogen determination showed both homoserine and its lactone to contain the calculated amount of amino nitrogen; homoserine diketopiperazine showed no amino nitrogen under the conditions of the determination. Solutions, ranging from 1 N in sodium hydroxide to 6 N in hydrochloric acid, of the free acid after standing for several days suffered no loss in their content of amino nitrogen; this indicated that no measurable amount of diketopiperazine was formed from homoserine itself. Solutions of the lactone behaved somewhat differently; in the presence of even a slight amount of base the lactone ring opened to form homoserine, and its solutions showed no loss of amino nitrogen. Dilute (1%) neutral or slightly acidic (less than 1 mole of acid/mole of lactone) solutions of the lactone did not show the formation of any significant amount of diketopiperazine; more concentrated neutral or slightly acidic solutions of the lactone, however, showed the formation of a mixture of homoserine and its diketopiperazine. The formation of homocysteine diketopiperazine in good yield from homocysteine thiolactone may be understood to occur as a result of the much greater insolubility of this diketopiperazine in water; this would speed the formation of diketopiperazine at the expense of the reaction forming homocysteine.

The availability of optically active homoserine and its lactone hydrobromide made it appear likely that the relationship of the free amino acid to its lactone could be studied polarimetrically,

(1) This research was supported by a grant from the United States Public Health Service. Presented in part before the Division of Biological Chemistry at the 112th meeting of the American Chemical Society, New York, September 16, 1947.

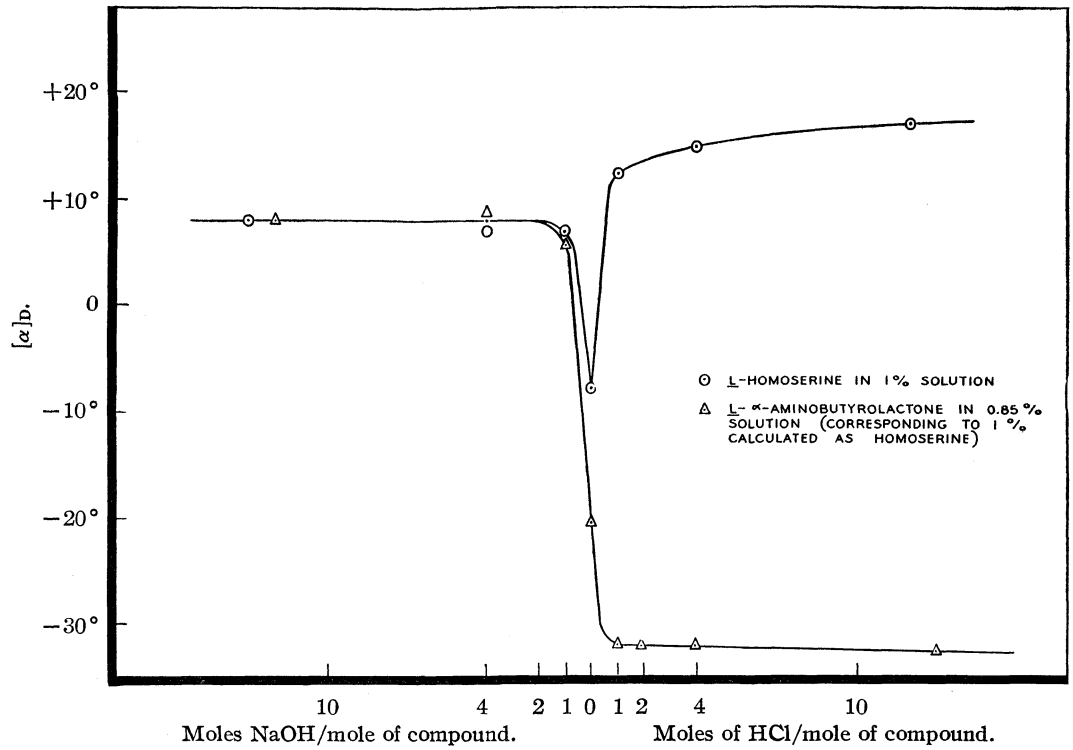

Fig. 1.—The effect of acid and alkali on the rotation of L-homoserine and its lactone.

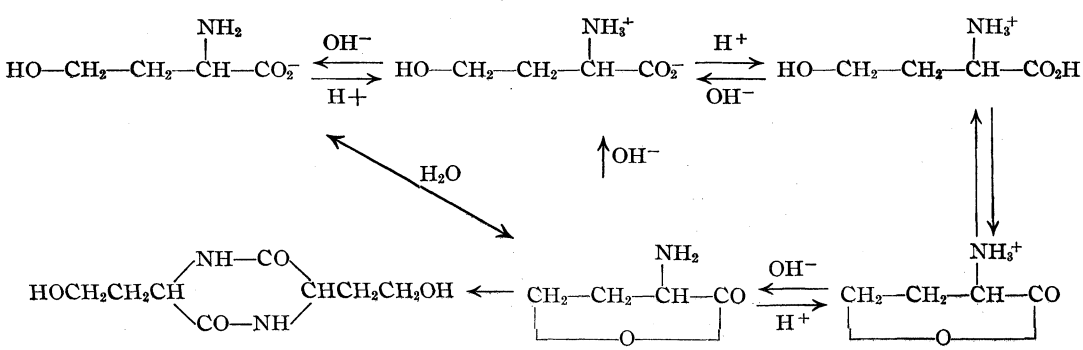
provided the initial rotations of homoserine and its lactone were widely enough separated. Accordingly, measurements were made of the rotations of L-homoserine and of L-α-aminobutyrolactone in solutions containing varying amounts of acid and alkali. For convenience a concentration of the lactone hydrobromide equivalent in molarity to a 1% solution of homoserine was used and the specific rotations are reported on this basis. The results (Fig. 1) show that the specific rotation of L-homoserine is affected by acid and alkali in the same manner as that of the other natural amino acids. L-α-Aminobutyrolactone, on the other hand, shows a quite different behavior. In the presence of 1 mole of base the lactone ring is immediately opened to yield a salt of homoserine; 1 mole of acid causes it to exhibit a negative maximum of rotation which is not increased significantly at higher acid concentrations.

Mutarotation was found to occur in acidic solutions of the amino acid or its lactone. The change in rotation with respect to time is shown in Fig. 2 for three concentrations of acid; the speed with which equilibrium was reached varied with the strength of acid. With the use of the observed initial rotations of homoserine and of its lactone (extrapolated to zero time) it became possible to calculate the percentage of each present in an equilibrium mixture. In Fig. 3 is shown the effect of acid concentration on the percentage of homoserine present in such a solution.

The above data indicate that in solutions of homoserine the following changes may occur.



Experimental

L- and DL-homoserine, L- and DL-α-aminobutyrolactone hydrobromide, and inactive homoserine diketopiperazine were prepared in the manner previously described.[1]

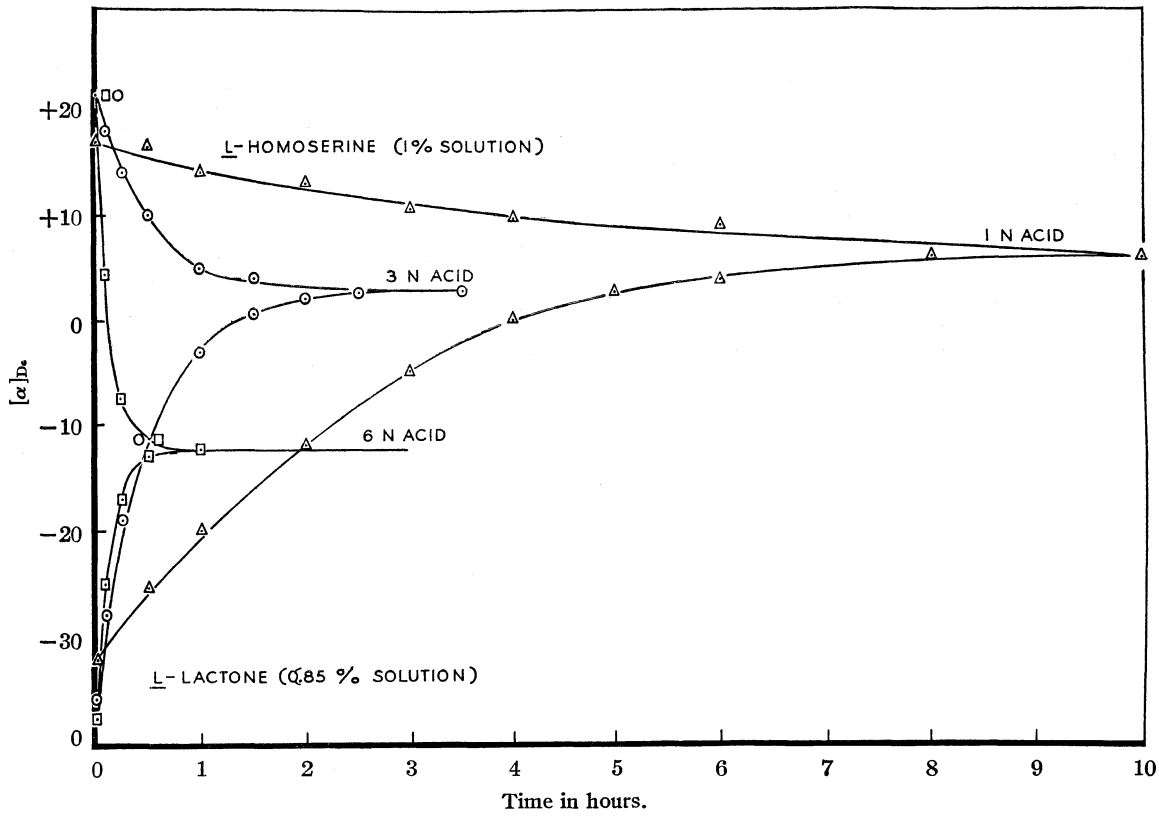


Fig. 2.—The effect of acid concentration on the equilibration of homoserine and its lactone.

The Solubility of L- and DL-Homoserine.—Because of the high solubility of these compounds in water and the unavailability of a considerable amount of the optically active compound for experimentation, a roughly quantitative estimate of their solubility was made as follows: 500.0 mg. of the compound was placed in a tared flask and distilled water was added dropwise to the flask until most of the compound had dissolved. The flask was shaken for a period of two hours between the addition of each drop of water. The amount of water necessary just to dissolve the compound was determined by reweighing the flask. DL-Homoserine: temperature, 30°; 504.4 mg. required 400 mg. of water; solubility, 125 g. of DL-homoserine in 100 g. of water. L-Homoserine: temperature, 30°; 404.4 mg. required 367 mg. of water for complete solution; solubility, 110 g. of L-homoserine in 100 g. of water. It will be noted that this approximation gives a minimum value for the solubility of the compounds.

Test for Diketopiperazine Formation from Homoserine and α-Aminobutyrolactone.—Analytical data were determined for homoserine and its derivatives:

TABLE I

	N Calcd., %	N Found, % Kjeldahl	Amino	Ninhydrin
Homoserine	11.76	11.93	11.77	11.78
α-Aminobutyrolactone hydrobromide	7.69	7.75	8.15[6]	0
Homoserine diketopiperazine	13.86	13.81	0	0

One per cent. solutions of homoserine and of α-aminobutyrolactone[7] were allowed to stand for several days with varying amounts of acid or alkali; at the end of this time the solutions showed no change in amino nitrogen content.

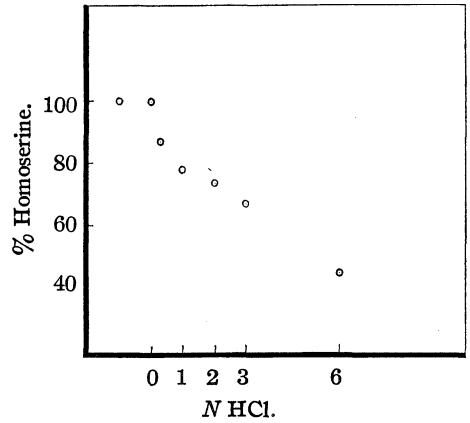

Fig. 3.—The effect of acid concentration on the composition of an equilibrium mixture of homoserine and its lactone. One per cent. solutions were used.

Opening of the Lactone Ring of α-Aminobutyrolactone in Aqueous Solution.—An attempt was made to follow the experimental conditions which gave a 95.5% yield of homocysteine diketopiperazine from homocysteine thiolactone hydrochloride.[5] To a solution of 10.0 g. of DL-α-

(6) After standing under conditions which open the lactone ring, a value of 7.72% amino N is found.

(7) Solutions of α-aminobutyrolactone were obtained by adding the calculated amounts of standard acid or alkali to a solution of its hydrobromide.

aminobutyrolactone hydrobromide in 100 ml. of water was added 4.62 g. of sodium bicarbonate. The resulting solution was allowed to stand overnight at room temperature. No precipitate had formed at this time so the solution was evaporated on a steam-bath to yield a thick semi-crystalline sirup. This sirup was dissolved in 18 ml. of water and the resulting solution was diluted with 100 ml. of absolute ethanol and let stand overnight in a refrigerator. The crystalline product was collected on a filter, washed with absolute alcohol, and was air dried; yield, 5.0 g.; m. p., 160–163° dec. An additional 0.6 g. of product having the same melting point was obtained by reworking the mother liquors.

The combined fractions were recrystallized by dissolving them in 20 ml. of hot water, adding 40 ml. of absolute ethanol, and allowing the solution to stand for several days in a refrigerator; 0.7 g. of flat parallelograms, m. p. 197–200°, was obtained. This compound gave a negative ninhydrin test and a mixed melting point with *meso*-homoserine diketopiperazine (m. p. 200–202°) showed no depression.

Anal. Calcd. for $C_8H_{14}O_4N_2$: N, 13.86. Found: N, 13.61.

The filtrate from this compound was diluted with 20 ml. of absolute ethanol and was allowed to stand in a refrigerator several more days: 1.4 g. of well formed flat needles was obtained, m. p. 183–185° dec. This compound gave a strongly positive ninhydrin test and a mixed melting point with DL-homoserine (m. p. 186–187°) showed no depression.

Anal. Calcd. for $C_4H_9O_3N$: N, 11.76. Found: N, 11.75.

A solution of homoserine in water was evaporated to dryness on a steam-bath in the same manner as in the above experiment. After it was redissolved in water an amino nitrogen determination showed that no loss in amino nitrogen had occurred, hence no diketopiperazine had formed under the conditions used.

The Optical Rotation of L-Homoserine and L-α-Aminobutyrolactone.—Rotation was measured using a 2-dm. tube and monochromatic light from a sodium vapor lamp. A 1% solution of homoserine was used in aqueous solutions containing varying amounts of acid and alkali; a 1.53% solution of α-aminobutyrolactone hydrobromide (equimolar with the 1% solution of homoserine) was used in a corresponding manner. The proper ratios of acid and alkali to the compounds were obtained by previously preparing standardized solutions containing the correct amounts of acid or alkali. The finely powdered compounds were dissolved in the solvent, placed in a polarimeter tube and the rotations of the solutions were measured as quickly as possible and thereafter at intervals. In cases where rapid mutarotation occurred the rotations at zero time were estimated by extrapolation. All rotations were measured at 25 ± 3°; there is no measurable error over this amount of variation in temperature due to a temperature coefficient for these compounds.

The results of the experiments are shown graphically in Figs. 1, 2 and 3.

Summary

The relationships between homoserine, its lactone and its diketopiperazine have been studied.

In basic and in neutral aqueous solution homoserine itself is stable and does not transform into either its lactone or diketopiperazine. In acidic solution homoserine is in equilibrium with its lactone; increasing amounts of the lactone are present in more strongly acid solutions.

In basic solution the lactone ring of α-aminobutyrolactone is opened to form homoserine; in solutions containing 1 mole or more of acid per mole of lactone the lactone is in equilibrium with homoserine. In dilute neutral solution the lactone ring opens to form homoserine and in dilute solutions containing less than 1 mole of acid per mole of lactone the lactone is in equilibrium with homoserine; in more concentrated neutral and slightly acidic solutions a mixture of homoserine and its diketopiperazine is formed.

The Synthesis of Pseudoconhydrine[1]

BY LÉO MARION AND WILLIAM F. COCKBURN

Pseudoconhydrine, one of the Hemlock group of alkaloids, occurs in the common hemlock, *Conium maculatum* L., along with coniine, N-methylconiine, γ-coniceine and conhydrine. It was discovered in the residues from the isolation of coniine and found to be an isomer of conhydrine, with the empirical formula $C_8H_{17}ON$.[2] Further investigation showed the base, like conhydrine itself, to be an hydroxyconiine,[3] while a study of the exhaustive methylation demonstrated that the hydroxyl group occupies position 5 of the piperidine nucleus.[4] Pseudoconhydrine is thus 5 - hydroxy - 2 - *n* - propylpiperidine[4] (VI), a structure now confirmed by the total synthesis of the alkaloid, the resolution of the synthetic base into its optical isomers and the preparation of derivatives.

Attempts to sulfonate conyrine (2-propylpyridine) in the 5-position with oleum and a mercury catalyst were largely unsuccessful, apparently owing to oxidation of the propyl side-chain, with the formation of tarry by-products. A small amount of impure material was isolated, but the method was not considered sufficiently profitable and was abandoned. The following scheme, however, proved successful.

2-Methylpyridine-5-sulfonic acid (I) was obtained by sulfonation of α-picoline[5] and converted to 5-hydroxy-2-methylpyridine (II) by potash fusion.[6] Addition of ethereal diazomethane to an aqueous–methanolic solution of II yielded the

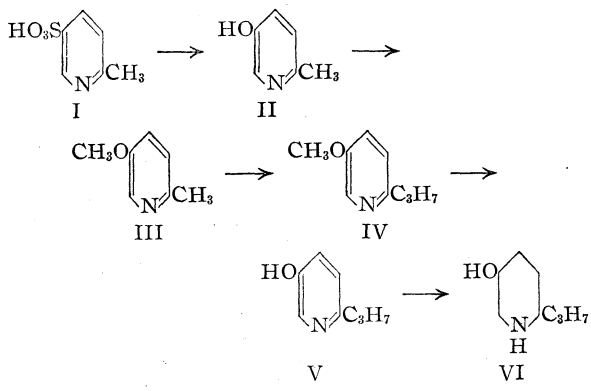
methyl ether (III) which was condensed with ethyl chloride in the presence of freshly prepared



potassamide to give 5-methoxy-2-propylpyridine (IV). Although the yield for this last reaction was only 22% for a single run, most of the unchanged α-picoline derivative could be recovered in a pure state and recycled, raising the "conversion" to 66%. A similar experiment employing phenyllithium as condensing agent gave only a 5% yield of the desired compound contaminated with other material, while sodium triphenylmethide failed to effect any conversion at all. Demethylation of IV was brought about by refluxing with 48% hydrobromic acid in glacial acetic acid, and the resulting phenolic compound (V) hydrogenated at 50 lb. pressure in presence of Adams catalyst. The hydrogenation product (VI) was obtained as a yellowish semi-crystalline mixture, fairly readily separable by vacuum distillation into approximately equal amounts of a white crystalline solid and a colorless oil. These are presumably the two racemic diastereomers to be expected on the basis of the two asymmetric carbon atoms in the molecule of pseudoconhydrine. The solid isomer, like the natural alkaloid, appears to hydrate very readily, and was dried by vacuum-sublimation at 70° (0.05 mm.) being then pure, m. p. 91.5–92°. Since the natural alkaloid melts at 105–106°, it seemed probable that this isomer was racemic pseudoconhydrine.

This compound, like synthetic conhydrine,[7] failed to form a crystalline salt with *d*-tartaric acid, and was therefore resolved with the optically active 6,6′-dinitro-2,2′-diphenic acids[8–10] into *l*- and *d*-pseudoconhydrine. Measurement of the optical activity gave $[\alpha]^{26}D$ − 10.75° and $[\alpha]^{23}D$ + 11.09° for the *l*- and *d*- isomers, respectively, the latter value being in excellent agreement with the values of +10.98 and +11.06° recorded for the natural alkaloid.[2] The melting points of the free base, 105–106°, the hydrochloride, 214–215°, and the N-benzoyl derivative, 131–132°, also correspond to those obtained by Löffler[3] and Späth[4] for the natural product and the corresponding derivatives, and identity is assumed.

Acknowledgment.—The authors wish to acknowledge with thanks their indebtedness to the Goldsmiths' Company of London, England, for the award of a Travelling Fellowship to one of them (W. F. C.).

Experimental

2-Methylpyridine-5-sulfonic Acid (I).—α-Picoline was sulfonated with oleum in presence of a mercury catalyst as described by McElvain and Goese.[5] The free sulfonic acid was obtained as a tan-colored crystalline solid, m. p. 334–338° (uncor.).[11] McElvain reports this as 338–341° (cor.); yield 54%.

5-Hydroxy-2-methylpyridine (II).—The free sulfonic acid (I) was fused with excess potassium hydroxide in a nickel crucible, with some iron filings as catalyst.[6] After cooling, the melt was dissolved in water and partly neutralized with hydrochloric acid, neutralization being completed with carbon dioxide. The precipitated phenolic compound was filtered off, dried in a desiccator, and extracted with ether in a Soxhlet. The aqueous mother liquors were also extracted overnight in a liquid–liquid extractor, and the two extracts combined and concentrated. The crude 5-hydroxy-2-methylpyridine which crystallized was purified by sublimation in a large Pyrex tube at 130° (0.1 mm.) being obtained as an almost white crystalline solid m. p. 167–169°. This is reported as 164–166°.[6] It gave a red color with aqueous ferric chloride.

Anal. Calcd. for C_6H_7ON: C, 66.06; H, 6.46. Found: C, 66.22, 66.34; H, 6.40, 6.30.

5-Methoxy-2-methylpyridine (III).—Ten grams (0.10 mole) of 5-hydroxy-2-methylpyridine was dissolved in 150 ml. of methanol containing 10% of water, and the solution chilled in an ice–salt-bath. A solution of 11.0 g. (0.26 mole) of diazomethane in 300 ml. of ether was added slowly with swirling from a dropping funnel, the stem of which projected below the surface of the liquid. A brisk effervescence accompanied the addition, which was interrupted several times in order to boil off the accumulated ether. If the latter procedure, which serves to keep the polarity of the solution at a maximum, was omitted, or more nearly equivalent quantities of phenol and methylating agent employed, the yield of methyl ether was much lower, although a greater recovery of unchanged phenol was possible. After being allowed to stand in the ice-box overnight, the methanol solution was acidified with hydrochloric acid, and most of the ether and methanol removed by concentration on the steam-bath. The resulting sirup was diluted with water and the solution exhausted with ether. It was then alkalized with sodium hydroxide pellets, and again extracted with ether. This second extract was dried over potassium hydroxide pellets, the ether removed by distillation, and the residual oil vacuum distilled. The product was a colorless oil, b. p. 43–45° (1 mm.) or 188–189° (760 mm.), $n^{25}D$ 1.5088.

Anal. Calcd. for C_7H_9ON: C, 68.28; H, 7.36. Found: C, 68.30, 68.37; H, 7.17, 7.35.

The maximum yield obtained was 40%, but some of the phenol was recoverable, the amount depending on the exact procedure followed.

5-Methoxy-2-propylpyridine (IV).—Potassium (5 g., 0.128 atom) was converted to potassamide in liquid ammonia (80 ml.) with ferric nitrate (0.2 g.) as catalyst. The reaction was carried out in a 100-ml. three-necked, ground-glass flask equipped with a stirrer and a cold-finger Dry Ice condenser with nitrogen inlet, while the third neck was closed with a stopper and used for the addition of reagents. When all the metal had been converted to amide, the ammonia was allowed to evaporate past the

(11) All melting points are corrected, unless otherwise stated.

loose stopper, the last traces being driven off by warming under nitrogen in a water-bath. The solid cake of potassamide was carefully broken up with a spatula in a strong stream of nitrogen, and the cold-finger filled with Dry Ice. Ten grams (0.081 mole) of 5-methoxy-2-methylpyridine was added, and allowed to stir for fifteen minutes, during which time the solution developed a deep purplish-red color. To the mixture was added 9.5 ml. (0.135 mole) of ethyl chloride from a cooled graduated pipet in 0.3-ml. portions at five-minute intervals, the condenser being kept cold by fresh additions of Dry Ice. After several hours, the flask was immersed in an ice-bath and stirring continued overnight. The ice-bath was then removed, fresh Dry Ice added to the condenser, and stirring continued at room temperature for a further ten hours. The total reaction time was thirty hours.

About 40 ml. of ether was added to the mixture, and the unreacted potassamide decomposed by the cautious addition of water from a dropping funnel. The ether layer was separated, extracted thoroughly with dilute hydrochloric acid, and the acid extract combined with the acidified aqueous portion of the reaction mixture. The combined solutions were repeatedly extracted with ether to remove non-basic impurities, alkalized with sodium hydroxide, and again extracted with ether. This second extract was dried with potassium carbonate, the ether removed by distillation and the residue vacuum distilled in a Vigreux–Claisen flask. The product was a water-white oil with a penetrating odor reminiscent of oil of aniseed, b. p. 60–61° (0.7 mm.). The yield was 2.6 g. (22%), 67% of the starting material being recovered.

The analysis results were slightly low, presumably due to the presence of unchanged 5-methoxy-2-methylpyridine, so the product of several runs was carefully fractionated at about 1 mm. pressure in a column (23 cm. long and 1 cm. dia.) packed with wire gauze, and equipped with a heated jacket and Whitmore and Lux still-head.[12] Two sharp fractions were obtained at 37–40° and 60–62°, corresponding to unchanged starting material and the desired product, respectively.

Anal. Calcd. for $C_9H_{13}ON$: C, 71.48; H, 8.66. Found: C, 71.45, 71.48, 71.50; H, 8.87, 8.76, 8.63; $n^{25}D$ 1.5012.

Treatment with the theoretical amount of picric acid in methanol gave a picrate in pale greenish-yellow needles, m. p. 113–114°.

Anal. Calcd. for $C_9H_{13}ON \cdot C_6H_3O_7N_3$: C, 47.37; H, 4.24. Found: C, 47.47, 47.67; H, 4.24, 4.30.

5-Hydroxy-2-propylpyridine (V).—For the demethylation, 4.30 g. (0.028 mole) of 5-methoxy-2-propylpyridine was refluxed for ninety hours with 200 ml. of glacial acetic acid containing 90 ml. of 48% hydrobromic acid. After cooling, the solution was diluted with its own volume of water and extracted four times with twice its own volume of ether. It was then basified with sodium hydroxide pellets and extracted with ether again. This extract yielded 0.13 g. of starting material (3%).

The aqueous solution was made just acid with concentrated hydrochloric acid, then basified with excess ammonium hydroxide, and the solution extracted continuously overnight with ether. The extract was dried with Drierite and concentrated to 10 ml. on the steam-bath. A white crystalline solid separated on cooling, and a further quantity could be obtained from the mother liquors by slow and repeated addition of petroleum ether (b. p. 50–60°). The product was readily purified by crystallization from ether–petroleum ether, being obtained as a white crystalline solid m. p. 93–93.5°. It is much more soluble in ether than 5-hydroxy-2-methylpyridine, and like the latter gives a deep red color with aqueous ferric chloride.

(12) F. C. Whitmore and A. R. Lux, THIS JOURNAL, **54**, 3448 (1932).

Anal. Calcd. for $C_8H_{11}ON$: C, 70.06; H, 8.08. Found: C, 70.01, 70.20; H, 7.84, 7.93.

The final yield was 2.60 g. (66%).

5-Hydroxy-2-propylpiperidine (VI).—One gram (0.0073 mole) of 5-hydroxy-2-propylpyridine was hydrogenated at 44 lb. pressure in 50 ml. of glacial acetic acid containing 250 mg. of Adams catalyst, the reaction time being sixteen hours. The solution was diluted with its own volume of water, filtered from the catalyst, acidified with 5 ml. of concentrated hydrochloric acid, and most of the acetic acid removed by ether extraction. The solution was basified with sodium hydroxide and extracted continuously overnight with ether. The extract was dried with potassium carbonate, and the ether removed by distillation, leaving a yellow oil which partially crystallized on cooling. The mixture had a pleasant sweetish smell reminiscent of crushed leaves. Yield was 1.008 g. (96%).

***dl*-Pseudoconhydrine.**—A bulb was blown in the end of a 30-cm. length of 12 mm. Pyrex tubing, and an ether solution of 1 g. of 5-hydroxy-2-propylpiperidine introduced into it. The ether was removed at the water-pump, and the residue slowly vacuum distilled from an air-bath, the portion of the tube outside the bath being wrapped with asbestos to provide a temperature gradient. The compound distilled at 70–75° (0.1 mm.) giving white crystals in the hotter part of the tube, and a colorless oil in the cooler part, the two being separated by breaking the tube between the fractions. The solid could be crystallized from ethyl acetate–petroleum ether in fine felted needles, but still had a diffuse melting point, probably due to hydrate formation. It was again sublimed *in vacuo*, being obtained in feathery white needles, m. p. 91.5–92°. It gave no color with aqueous ferric chloride, and depressed the melting point of 5-hydroxy-2-propylpyridine by over 50°.

Anal. Calcd. for $C_8H_{17}ON$: C, 67.11; H, 11.96. Found: C, 67.30, 67.24; H, 11.71, 11.76.

***l*- and *d*-Pseudoconhydrine.**—For the resolution, 0.685 g. of the racemic base was treated with 1.590 g. of *d*-6,6′-dinitro-2,2′-diphenic acid in 30 ml. of hot water. On cooling, 0.854 g. of yellow crystals separated. These were recrystallized from water nine times, giving 0.132 g. of salt, m. p. 238–240° (dec.).

Anal. Calcd. for $C_8H_{17}ON \cdot C_{14}H_8O_8N_2$: C, 55.56; H, 5.30. Found: C, 55.49, 55.35; H, 5.06, 5.14.

The free base was liberated and distilled at 70° (0.05 mm.) being obtained in feathery white crystals m. p. 105–106° (in vacuum tube); $[\alpha]^{26}D$ −10.75° (c = 1.675 in absolute ethanol). The hydrochloride was prepared and crystallized from methanol–acetone in silvery-white needles, m. p. 214–215°.

The free base was recovered from the mother liquors of the above resolution and treated with *l*-6,6′-dinitro-2,2′-diphenic acid. The same treatment as above yielded *d*-pseudoconhydrine m. p. 105–106°; $[\alpha]^{23}D$ +11.09° (c = 1.715 in absolute ethanol).

Treatment with 1 mole of benzoyl chloride in ether solution yielded the N-benzoyl derivative, which was recrystallized from ether in white nodules, m. p. 131–132°.

Summary

1. The structure assigned to pseudoconhydrine has been confirmed by a total synthesis of the alkaloid from α-picoline.

2. The 5-hydroxy-2-propylpiperidine so obtained has been separated by fractional distillation into two racemic diastereomers, of which the solid isomer has been resolved into its optical antipodes by means of its salts with the optically active 6,6′-dinitro-2,2′-diphenic acids.

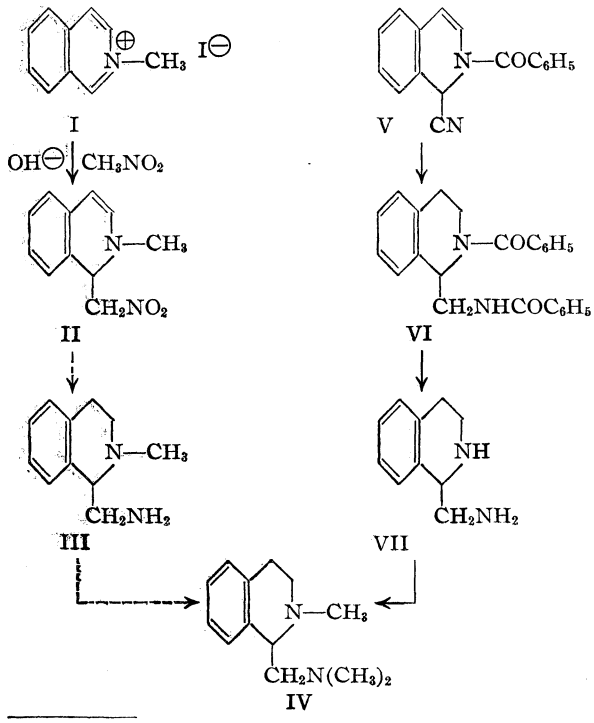
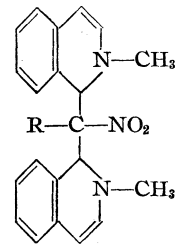
Reactions of Nitroparaffins with Isoquinolinium Compounds

BY NELSON J. LEONARD AND GERHARD W. LEUBNER[1,2]

One method for the synthesis of substituted 1-aminomethyltetrahydroisoquinolines (*e. g.*, III, IV), which are of pharmacological interest,[3] would appear to be the condensation of nitroparaffins with isoquinolinium salts in the presence of alkali, followed by stages of reduction and alkylation. For example, the mono-condensation product (II) of nitromethane with 2-methylisoquinolinium iodide (I) should be convertible to 1-dimethylaminomethyl-2-methyl-1,2,3,4-tetrahydroisoquinoline (IV). Positive comparison of this product with that obtained (VI → VII → IV)[4] from Reissert's isoquinoline compound (V)[5] would serve to establish the structure of the compounds in the nitroparaffin series. Surprising results were encountered in the proposed synthesis of II in that *2-nitronaphthalene* (XV) was obtained from the reaction of nitromethane with 2-methylisoquinolinium iodide in the presence of alkali. In addition, the alkaline condensation of nitromethane with I furnished some disubstituted nitroparaffin to which has been assigned the structure VIIIa. The alkaline condensation of nitroethane and 1-nitropropane with I yielded VIIIb and VIIIc.





VIII (a, R = H; b, R = CH_3; c, R = C_2H_5)

The condensation of nitromethane with 2-methylisoquinolinium iodide in the presence of two molecular equivalents of potassium hydroxide has been described in the patent literature.[6] Kaufmann reported a product melting at 99°, but further characterization was lacking. In our hands, the same condensation in the presence of varying amounts of alkali invariably led to a non-homogeneous product, the components of which were difficult to separate. Recrystallization, sublimation, distillation and chromatographic adsorption of the crude reaction product were investigated. A single, pure chemical individual was isolated (in about 9% yield) by the methods of sublimation and chromatography. The pale yellow crystalline solid, m. p. 78–79°, thus obtained possessed a melting point and an analytical composition which were suggestive of 2-nitronaphthalene (XV); indeed, the product was found to be identical with an authentic sample of 2-nitronaphthalene. Moreover, it was converted by reduction and acetylation to acet-2-naphthalide, identical with an authentic sample of this compound.

Since the transformation of an isoquinoline ring system to a naphthalene ring system is unusual, it is interesting to speculate on the method whereby 2-nitronaphthalene is produced. A plausible series of reactions can be written in which the first step supposes the formation of 1-nitromethyl-2-methyl-1,2-dihydroisoquinoline (II) from 2-methylisoquinolinium hydroxide and nitromethane. Compound II has a Mannich base structure so that its conversion to the open chain nitroölefin (IX) might be expected to occur.[7] Hope and Robinson[8] have reported the isolation of a similar type of compound from the reaction of methyl iodide with anhydrocotarninenitromethane. The 1,3-shift of hydrogen corresponding to the conversion of a vinyl secondary amine (IX) to a Schiff

base (X) has been observed,[9] as has the addition of water (X → XI) to a nitroölefin.[10,11] The sequence of these and subsequent reactions is not to be considered inflexible. The conversion of the Schiff-base hydrolysis product (XIII) to XIV represents a common reaction of aldehydes with nitroparaffins[11] and the conversion of XI to XII represents a known reaction of nitroparaffins with imines.[12] The transformation of both XIV and XII to 2-nitronaphthalene (XV) would be expected to occur readily. Further study is planned to determine the scope and course of the over-all transformation.

Also obtained from the reaction of nitromethane and 2-methylisoquinolinium iodide in the presence of alkali was a compound, isolated as the monohydrochloride and monopicrate, which had a composition represented by the structure VIIIa. An analogous product was isolated as the free base (in 44% yield) from the condensation of nitroethane with two moles of 2-methylisoquinolinium iodide and potassium hydroxide and was assigned the structure, 1,1-bis-[1′-2′-methyl-1′,2′-dihydroisoquinolyl)]-nitroethane (VIIIb), on the basis of analysis and infrared absorption spectrum. A similar product, 1,1-bis-[1′-(2′-methyl-1′,2′-dihydroisoquinolyl)]-1-nitropropane (VIIIc) was obtained in a 21% yield using 1-nitropropane. Previously reported examples of the reaction of nitroparaffins with isoquinolinium compounds have never disclosed the formation of dicondensation products.[3b,6,8,13,14,15,16]

In the preparation of IV from Reissert's isoquinoline compound,[5] with certain modifications of the method of Rupe and Frey,[4] the intermediates VI and VII were isolated. The anhydrous hydrochloride of 1-aminomethyl-1,2,3,4-tetrahydroisoquinoline (VII) was obtained, rather than the hydrated salt, and the dipicrate of 1-dimethylaminomethyl-2-methyl-1,2,3,4-tetrahydroisoquinoline (IV) was formed from IV, rather than the monopicrate, as observed by Rupe and Frey.

Experimental[17]

Reaction of Nitromethane with 2-Methylisoquinolinium Hydroxide.—Fifty grams (0.185 mole) of 2-methylisoquinolinium iodide, m. p. 161–162°, and 33.8 g. (0.554 mole) of freshly distilled nitromethane[18] were dissolved in 250 ml. of hot absolute ethanol. To this was added a hot solution of 25 g. (0.38 mole) of potassium hydroxide pellets (85% KOH) in 100 ml. of absolute ethanol. The color of the solution changed immediately from yellow to red, and potassium iodide began to precipitate. After allowing the solution to stand for ten minutes, 250 ml. of water was added. The solution was cooled in an ice-bath and was acidified slowly with approximately 300 ml. of 5% aqueous acetic acid, with rapid stirring. The light brown solid which formed was allowed to settle and the supernatant liquid was decanted. The solid was stirred with water and the supernatant liquid was again decanted. After the washing process was repeated three times, the solid was collected and air-dried (25 g.). The wide melting range of the solid was not improved by recrystallization (ethanol, methanol, petroleum ether). In one run, a picrate was made from a filtered ether solution of the solid and an ethereal solution of picric acid. Four recrystallizations from ethylene dichloride–ethanol gave tiny yellow needles, which decomposed at 200° and were found to have an elementary composition corresponding to the **monopicrate of bis-[1-(2-methyl-1,2-dihydroisoquinolyl)]-nitromethane (VIIIa).**

Anal. Calcd. for $C_{27}H_{24}N_6O_9$: C, 56.25; H, 4.20; N, 14.58. Found: C, 56.28; H, 4.10; N, 14.16.

In a second run, using 1.1 moles of potassium hydroxide per mole of nitromethane and 2-methylisoquinolinium iodide, the crude dry product (1 g.) was dissolved in 100 ml. of ether and treated with anhydrous hydrogen chlo-

ride. The precipitated salt was recrystallized four times from absolute ethanol to yield 0.33 g. of colorless prisms, which decomposed at 184° after initial sintering and darkening at 170°. In elementary composition the compound corresponded to the **monohydrochloride of bis-[1-(2-methyl-1,2-dihydroisoquinolyl)]-nitromethane.**

Anal. Calcd. for $C_{21}H_{22}ClN_3O_2$: C, 65.70; H, 5.78; N, 10.95. Found: C, 65.74; H, 6.13; N, 11.00.

The **picrate** prepared from this hydrochloride salt was identical with that described above.

In a duplicate of the original run (two moles of potassium hydroxide per mole of nitromethane and 2-methylisoquinolinium iodide) the crude condensation product was dissolved in benzene and chromatographed on a column of Harshaw 2-350 aluminum oxide. The chromatogram was developed with benzene to give successive canary yellow, lighter yellow, and brown bands. The lowest yellow band was eluted with benzene and the benzene solution was evaporated to dryness. The light yellow crystalline solid, after purification by sublimation and recrystallization from water (as needles), melted at 78–79°. The analytical composition corresponded to the empirical formula $C_{10}H_7NO_2$.

Anal. Calcd. for $C_{10}H_7NO_2$: C, 69.36; H, 4.07; N, 8.09. Found: C, 69.70; H, 4.10; N, 7.72.

Analysis and melting point were suggestive of 2-nitronaphthalene.[19] An authentic sample of 2-nitronaphthalene, m. p. 78–79°, was prepared by the method of Hodgson, Birtwell and Marsden[19] from 2-nitro-1-naphthylamine. Mixtures of the two samples gave no depression in melting point. The $C_{10}H_7NO_2$ product was reduced by means of iron powder in acetic acid and acetic anhydride to give a product, m. p. 131–132°, which separated as colorless plates from aqueous ethanol. This product gave no depression in melting point when mixed with an authentic sample, m. p. 131–132°, of acet-2-naphthalide.[20] The amount of 2-nitronaphthalene isolated by means of chromatography corresponded to a yield of 9% based on the 2-methylisoquinolinium iodide used. Approximately the same yield of 2-nitronaphthalene, similarly characterized, was realized by sublimation of the crude condensation product of 2-methylisoquinolinium hydroxide and nitromethane. The sublimation was carried out in the range of 80–150° and 0.01–0.5 mm. No other pure compounds could be isolated by chromatography and sublimation methods. It is probable that the yield of 2-nitronaphthalene can be raised by further examination of the conditions of the reaction.

1,1-bis-[1′-(2′-Methyl-1′,2′-dihydroisoquinolyl)]-nitroethane (VIIIb).—To a hot solution of 75 g. (0.28 mole) of 2-methylisoquinolinium iodide, 62 g. (0.83 mole) of nitroethane and 30 ml. of methanol was added a heated solution of 27.4 g. (0.42 mole) of potassium hydroxide in 100 ml. of methanol. The solution was allowed to stand one-half hour and was then evaporated at 25° with a stream of dry air. After the crystalline material began to separate, evaporation was aided by mechanical stirring. A thick paste of crystals and dark red oil resulted. The oil was removed by repeated washing with cold methanol, and potassium iodide was removed by water washing. The colorless organic solid (22 g., 44% yield) crystallized as prisms from acetone; m. p. 210–212°.

Anal. Calcd. for $C_{22}H_{23}N_3O_2$: C, 73.11; H, 6.41; N, 11.63. Found: C, 73.14; H, 6.55; N, 11.72.

The infrared absorption spectrum agreed well with the structure assigned on the basis of analysis. The strong characteristic nitro absorption band was observed at 1535 cm.$^{-1}$, and the bands at 741 and 751 cm.$^{-1}$ were characteristic of the *o*-substituted phenyl grouping.

1,1-bis-[1′-(2′-Methyl-1′,2′-dihydroisoquinolyl)]-1-nitropropane (VIIIc).—The reaction between 1-nitropropane and 2-methylisoquinolinium iodide was carried out in the same manner as that described for nitroethane. When the reaction mixture was allowed to stand for several days at 25°, crystalline material separated. The solid (21% yield) was obtained as colorless prisms upon recrystallization from acetone; m. p. 201.5–202°.

Anal. Calcd. for $C_{23}H_{25}N_3O_2$: C, 73.57; H, 6.71; N, 11.19. Found: C, 73.58; H, 6.87; N, 10.99.

The infrared absorption spectrum was very similar to that observed for the lower homolog (VIIIb).

1-Aminomethyl-1,2,3,4-tetrahydroisoquinoline (VII) Hydrochloride.—The preparation of 1-cyano-2-benzoyl-1,2-dihydroisoquinoline (V) was effected by the method of Reissert[5] with some modifications. Hydrogenation of V in ethanol over Raney nickel catalyst at 150 atm. and 100° gave 1-benzoylaminomethyl-1,2,3,4-tetrahydroisoquinoline as an oil which was converted to solid 1-benzoylaminomethyl-2-acetyl-1,2,3,4-tetrahydroisoquinoline (VI), m. p. 196–197.5° (reported, 201°).[4] Hydrolysis of VI to 1-aminomethyl-1,2,3,4-tetrahydroisoquinoline (VII), b. p. 154–159° (15 mm.), $n^{20}D$ 1.5779, was effected with 20% hydrochloric acid. To a cooled solution of 11.5 g. (0.071 mole) of VII in 20 ml. of absolute ethanol was added slowly with stirring 6.8 ml. of absolute ethanol containing 2.6 g. (0.071 mole) of hydrogen chloride. The mixture containing some crystalline solid was heated, 25 ml. additional of absolute ethanol was added, and the material was allowed to crystallize. The monohydrochloride was obtained as colorless plates which darkened at 171° and melted at 179–184°. Recrystallization from absolute ethanol failed to improve the melting point.

Anal. Calcd. for $C_{10}H_{15}ClN_2$: C, 60.44; H, 7.61; N, 14.10. Found: C, 60.39; H, 7.37; N, 13.92.

Rupe and Frey[4] prepared the monohydrochloride in absolute ether and recrystallized from ethanol containing a small amount of water to obtain a dihydrate of the salt, m. p. 281° (dec.).

1-Dimethylaminomethyl-2-methyl-1,2,3,4-tetrahydroisoquinoline (IV).—The formaldehyde–formic acid method of methylation[21] was adapted to the conversion of VII to IV, rather than the methyl iodide–potassium hydroxide method of Rupe and Frey.[4] Twenty-one grams (0.13 mole) of 1-aminomethyl-1,2,3,4-tetrahydroisoquinoline (VII) was dissolved with cooling in 51.1 g. (0.97 mole) of 87.5% formic acid and to this was added 34.7 g. (0.43 mole of formaldehyde) of formalin. After a short period of heating on the steam-bath, the initially vigorous evolution of carbon dioxide subsided in fifteen minutes. Heating on the steam-bath was continued for eight hours, 23 ml. of 12 *N* hydrochloric acid was added, and the solution was then evaporated to dryness under reduced pressure. The sirup which remained was dissolved in water, and the cold aqueous solution was made strongly alkaline with sodium hydroxide. The alkaline mixture was extracted with ether, the ethereal solution was dried, and the ether was removed. Fractional distillation of the residue *in vacuo* gave 12.6 g. (48%) of colorless oil, b. p. 143–146° (16 mm.) (reported, b. p. 135° (12 mm.)[4]); $n^{20}D$ 1.5331.

Anal. Calcd. for $C_{13}H_{20}N_2$: C, 76.42; H, 9.87; N, 13.72. Found: C, 76.23; H, 9.78; N, 14.07.

The methiodide, recrystallized from ethanol, melted at 196–197° (reported, 199°).[4] Two new derivatives of 1-dimethylaminomethyl-2-methyl-1,2,3,4-tetrahydroisoquinoline were formed. The **dihydrobromide monohydrate** was prepared by the slow addition of 12.2 g. (0.072 mole of HBr) of 48% hydrobromic acid with stirring to an ice-cold solution of 7.4 g. (0.036 mole) of IV in 15 ml. of absolute ethanol. During the addition the crystalline salt began to separate. The mixture was heated and additional absolute ethanol was added to bring about solution. After filtration and cooling, 11.7 g. (88%) of colorless elongated prisms separated. Recrystallization from ethanol plus a small amount of water gave a 94% recovery of material which began sintering at 138° and melted with decomposition at 152–153°.

Anal. Calcd. for $C_{13}H_{24}Br_2N_2O$: C, 40.64; H, 6.30; N, 7.29. Found: C, 40.46; H, 6.48; N, 6.90.

(20) Leonard and Hyson, *J. Org. Chem.*, **13**, 164 (1948).

(21) "Organic Syntheses," **25**, 89 (1945).

A small sample was well crushed and dried in an Abderhalden apparatus over phosphorus pentoxide at 110° for ten hours. The melting point of the anhydrous dihydrobromide was 216–220°.

Anal. Calcd. for $C_{13}H_{22}Br_2N_2$: C, 42.64; H, 6.06. Found: C, 42.76; H, 6.31.

We were unable to isolate the monopicrate, m. p. 202°, described by Rupe and Frey,[4] but we obtained a dipicrate when the amine in ethanol was treated with a large excess of ethanolic picric acid. Recrystallization from acetone-ethanol gave yellow crystals which softened at 158° and melted at 171–174°.

Anal. Calcd. for $C_{25}H_{26}N_8O_{14}$: C, 45.32; H, 3.96; N, 16.91. Found: C, 45.56; H, 4.18; N, 17.17.

Summary

It has been established that 2-nitronaphthalene is produced from the condensation of 2-methylisoquinolinium iodide with nitromethane in the presence of potassium hydroxide, and a plausible series of reactions has been suggested to account for this unusual transformation. The alkaline condensation of 2-methyliosquinolium iodide with nitromethane also produced some bis-[1-(2-methyl - 1,2 - dihydroisoquinolyl)]-nitromethane, that with nitroethane produced 1,1-bis-[1′-(2′-methyl - 1′,2′ - dihydroisoquinolyl)]-nitroethane, and that with 1-nitropropane gave 1,1-bis-[1′-(2′-methyl-1′,2′-dihydroisoquinolyl)]-1-nitropropane.

URBANA, ILLINOIS RECEIVED APRIL 28, 1949

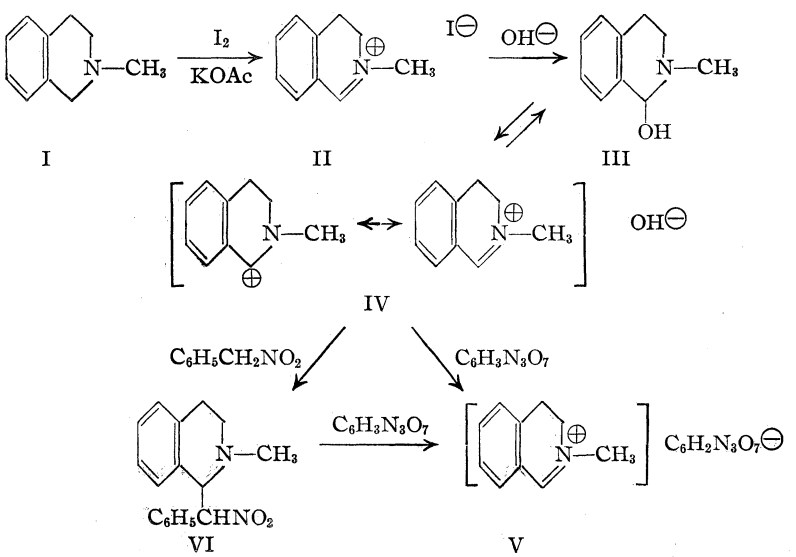
Reactions of Nitroparaffins with Pseudo Bases Related to Dihydroisoquinolinium Hydroxide

BY NELSON J. LEONARD AND GERHARD W. LEUBNER[1,2]

In an investigation[3] of the reaction of nitroparaffins with a pseudo base of type III,[4] the attempted characterization of the nitromethane product (analogous to VI) by picrate formation gave an unusual result. The supposed picrate derivative always reverted to the picrate of the pseudo base (V)! This observed elimination of nitromethane prompted a reëxamination of the picrate derivatives of anhydrocotarninenitromethane (VIII) and anhydrohydrastininenitromethane (VIII without methoxyl) reported by Hope and Robinson.[5] It has now been found that these reported derivatives are, in fact, cotarnine picrate (IX) and hydrastinine picrate (IX without methoxyl), both products of nitromethane elimination.



The method of synthesis of the pseudo base III required the initial preparation of 2-methyl-1,2,3,4-tetrahydroisoquinoline (I). The previously described directions for obtaining I by the reduction of 2-methylisoquinolinium iodide with tin and hydrochloric acid[6] or with sodium and ethanol[7] were less convenient than the formaldehyde–formic acid methylation[8] of 1,2,3,4-tetrahydroisoquinoline. 2-Methyl-1,2,3,4-tetrahydroisoquinoline (I) was oxidized to 2-methyl - 3,4 - dihydroisoquinolinium iodide (II) by means of iodine and potassium acetate. Compound II had been prepared previously, but by a degradation process.[9] The conversion of tetrahydro- to dihydro-compounds by iodine oxidation had been realized previously with several highly substituted tetrahydroisoquinolines,[10,11,12] but Schmidt had reported that iodine oxidation of tetrahydroisoquinoline itself gave iso-

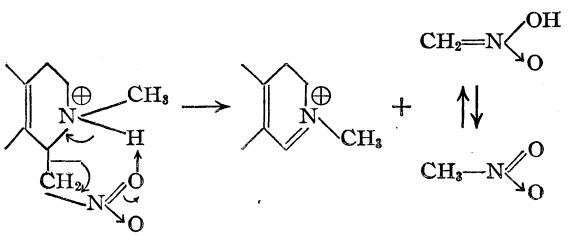
quinoline.[13] The conversion of I to II was found to proceed in satisfactory yield. Since the reaction of II with nitromethane in the presence of alkali did not produce any pure chemical individual, attention was turned to the pseudo base III, obtained from II by treatment with sodium hydroxide.

The combination of 1-hydroxy-2-methyl-1,2,3,-4-tetrahydroisoquinoline (III) with nitromethane in methanol led to the liberation of heat, but not to the formation of any crystallizable or distillable condensation product. Although the liberation of heat was indicative at a reaction between III and the nitroparaffin, as was the separation of water when the two were mixed in the absence of a solvent or in benzene, a picrate prepared from the reaction mixture was identified as 2-methyl-3,4-dihydroisoquinolinium picrate (V). The same picrate was prepared directly from the pseudo base (III) without the intervening nitromethane treatment. From these results it appeared that a transient nitromethane condensation product with III was produced, but that this product lost nitromethane readily at some stage. Further information was gained through the reaction of the pseudo base (III) with phenylnitromethane, since this combination produced a readily isolable solid product. The reaction is considered to proceed by combination of the carbonium species IV with the phenylnitromethane carbanion. An eighty-seven per cent. yield of 2-methyl-1-(α-nitrobenzyl)-1,2,3,4-tetrahydroisoquinoline (VI) was obtained merely by bringing the reactants together in methanol at 25°. When a picrate derivative was prepared from crystalline VI, the picrate was non-homogeneous as first precipitated, but heating in ethanol provided pure 2-methyl-3,4-dihydroisoquinolinium picrate (V). Phenylnitromethane must have been eliminated—and as a result of the picric acid.

The observed probable elimination of nitromethane and certain elimination of phenylnitromethane in these attempts to form picrates of condensation products of type VI suggested a reexamination of analogous derivatives of some of the isoquinoline alkaloids. Cotarnine (VII) forms a picrate (IX), m. p. 143–144°,[14] and a solid condensation product with nitromethane, called anhydrocotarninenitromethane (VIII).[5] The picrate of VIII prepared by Hope and Robinson[5] was described as melting at 136–137°, but no analysis was reported. It appeared from these close melting points that the nitromethane condensation product might have lost some nitromethane upon or after picric acid treatment. Following the procedure of Hope and Robinson, a picrate was prepared from anhydrocotarninenitromethane in aqueous acetic acid. This picrate melted at 134–136° when heated rapidly, and sintered at 140° and melted at 142–144° when heated slowly. The melting point of a mixture with authentic cotarnine picrate (IX) was 143–144°. Recrystallized "anhydrocotarninenitromethane picrate"[5] was definitely cotarnine picrate. When the picrate of VIII was prepared in anhydrous ether solution, a different picrate was obtained, m. p. 132–132.5°. This derivative, which was not recrystallized but was merely washed with ether as a means of purification, had the correct analysis for the normal picrate of anhydrocotarninenitromethane (VIIIa). Picrate VIIIa reverted to cotarnine picrate (IX), with elimination of nitromethane, when heated in acetone for recrystallization. The loss of nitroparaffin is parallel to that observed with 2-methyl-1-nitromethyl-1,2,3,4-tetrahydroisoquinoline and 2-methyl-1-(α-nitrobenzyl)-1,2,3,4-tetrahydroisoquinoline (VI). That the elimination of nitroparaffin is acid-catalyzed (X → XI) follows from the sensitivity of these pseudo base–nitroparaffin condensation products to acetic acid and to picric acid (especially in warm solution)



X XI

The alkaloid hydrastinine (VII without methoxyl) forms a picrate, m. p. 173°,[15] and a condensation product with nitromethane, called anhydrohydrastininenitromethane.[5] A picrate of anhydrohydrastininenitromethane was described by Hope and Robinson[5] as melting at 173–174°, but no analysis was reported. Because of the suggestive proximity of these melting points and by

(13) Schmidt, *Arch. Pharm.*, **237**, 561 (1899).

analogy to the three cases of nitroparaffin elimination described herein, we conclude that the derivative described as "anhydrohydrastinenitromethane picrate" is actually hydrastinine picrate.

Experimental[16]

2-Methyl-1,2,3,4-tetrahydroisoquinoline (I).—Hydrogenation of isoquinoline in absolute ethanol at 200 atm. and 200° over copper chromite catalyst gave a 98% yield of 1,2,3,4-tetrahydroisoquinoline. Methylation of 1,2,3,-4-tetrahydroisoquinoline by means of formaldehyde and formic acid[8] gave a 79% yield of 2-methyl-1,2,3,4-tetrahydroisoquinoline,[6,7] b. p. 84–85° (4 mm.), 103–105° (14 mm.), 223–224° (745 mm.); $n^{20}D$ 1.5422.

2-Methyl-3,4-dihydroisoquinolinium Iodide (II).—A solution of 73.5 g. (0.5 mole) of 2-methyl-1,2,3,4-tetrahydroisoquinoline and 54 g. (0.55 mole) of anhydrous potassium acetate (freshly fused) in 500 ml. of absolute ethanol was heated to refluxing, and to the solution was added slowly (four hours) with stirring a solution of 127 g. (0.5 mole) of iodine in 1.2 l. of absolute ethanol. When the addition was complete, the solution was refluxed for three hours. Ethanol (1.5 l.) was distilled from the reaction mixture and the residue was allowed to cool to room temperature. Potassium iodide was removed by filtration and the filtrate and washings were concentrated. After removal of the second crop of potassium iodide, the remaining ethanol and acetic acid were removed under reduced pressure on the steam-bath. The dark viscous residue was dissolved with heating in 125 ml. of acetone and 20 ml. of absolute ethanol. Cooling induced the separation of 54 g. (40%) of yellow prisms which were recrystallized from the same mixed solvent; m. p. 124–125° (reported, 125–128°).[9] Similar runs using smaller amounts (3 g.) invariably gave better yields (65–80%).

Anal. Calcd. for $C_{10}H_{12}IN$: C, 43.97; H, 4.43; N, 5.13. Found: C, 44.10; H, 4.36; N, 5.06.

1-Hydroxy-2-methyl-1,2,3,4-tetrahydroisoquinoline (III).—Fifty-four grams (0.2 mole) of crude 2-methyl-3,4-dihydroisoquinolinium iodide, m. p. 118–124°, was stirred with 90 ml. of water. After removal of the insoluble material (1.2 g.) by filtration, the orange solution was cooled to 0° and a cold solution of 32 g. (0.8 mole) of sodium hydroxide in 50 ml. of water was added slowly with stirring. An orange solid separated. The mixture was extracted with three 250-ml. portions of ether, the ethereal solution was concentrated by distillation and was finally allowed to evaporate at room temperature. The residue, which consisted of a mixture of red oil and beautiful elongated prisms, was stirred and crushed with cold acetone. The insoluble solid was collected and washed with cold acetone; yield, 14.2 g. (45%). Recrystallization from acetone gave colorless prisms, m. p. 101–103° (reported, 110–111°).[9,17]

Anal. Calcd. for $C_{10}H_{13}NO$: C, 73.59; H, 8.03; N, 8.58. Found: C, 73.48; H, 8.28; N, 8.46.

In an infrared spectrum determination no carbonyl absorption was observed, but a band (3093 $cm.^{-1}$) was found at the low frequency characteristic of strongly bonded O–H. Absorption bands at 1607 and 1491 $cm.^{-1}$ were characteristic of the phenyl group and that at 745 $cm.^{-1}$, of *o*-substituted phenyl.

2-Methyl-3,4-dihydroisoquinolinium Picrate (V).—Prepared in absolute ethanol from 1-hydroxy-2-methyl-1,2,3,4-tetrahydroisoquinoline and picric acid and recrystallized from absolute ethanol, the picrate was obtained as yellow elongated prisms, m. p. 147–148° (reported, 145°).[9]

Reaction of 1-Hydroxy-2-methyl-1,2,3,4-tetrahydroisoquinoline with Nitromethane.—The reaction of 2-methyl-3,4-dihydroisoquinolinium iodide with nitromethane in the presence of alkali led to non-homogeneous material from which neither a pure product nor a derivative could be isolated. There was apparently a reaction between nitromethane (0.56 g., 0.09 mole) and 1-hydroxy-2-methyl-1,2,3,4-tetrahydroisoquinoline (0.50 g., 0.03 mole) in methanol (1 ml.) since heat was liberated upon addition of the nitromethane. The solution was allowed to evaporate at room temperature. The light yellow oily residue could not be distilled or induced to crystallize. A picrate prepared in ethanol solution sintered at 103° and melted at 106–145°. Two recrystallizations from absolute ethanol gave yellow elongated prisms, m. p. 147–148°, which gave no depression when mixed with 2-methyl-3,4-dihydroisoquinolinium picrate.

Anal. Calcd. for $C_{16}H_{14}N_4O_7$: C, 51.34; H, 3.77. Found: C, 51.54; H, 3.89.

When the reaction between 1-hydroxy-2-methyl-1,2,3,-4-tetrahydroisoquinoline and nitromethane was run in the absence of a solvent or in benzene, water separated from the solution, thus indicating initial condensation before picrate formation. In a run employing 6 g. of pseudo base (III) with excess nitromethane, the theoretical quantity of water was collected by distillation after condensation.

Reaction of 1-Hydroxy-2-methyl-1,2,3,4-tetrahydroisoquinoline with Phenylnitromethane.—A solution of 0.5 g. (0.03 mole) of 1-hydroxy-2-methyl-1,2,3,4-tetrahydroisoquinoline in 1 ml. of methanol was treated with 1.23 g. (0.09 mole) of purified[18] phenylnitromethane. After one-half hour crystals began to separate, and the mixture was allowed to stand at 25° for twelve hours. After cooling, filtering and drying operations, 0.75 g. (87%) of colorless prisms were collected; m. p. 118–119°. Several recrystallizations from methanol did not alter the melting point of the product, 2-methyl-1-(α-nitrobenzyl)-1,2,3,4-tetrahydroisoquinoline (VI).

Anal. Calcd. for $C_{17}H_{18}N_2O_2$: C, 72.32; H, 6.42; N, 9.92. Found: C, 72.02; H, 6.75; N, 9.81.

The picrate prepared in ether solution melted over a range 135–145°. When this derivative was heated in ethanol solution for recrystallization, it was converted to a pure compound, isolated as yellow elongated prisms, m. p. 147–148°, and identified as 2-methyl-3,4-dihydroisoquinolinium picrate.

Cotarnine Picrate (IX).—Prepared in and recrystallized from absolute ethanol, cotarnine picrate was obtained as delicate yellow needles, m. p. 143–144°.[14]

Anhydrocotarninenitromethane (VIII).—To a hot solution of 1.0 g. (0.004 mole) of cotarnine chloride (Merck Stypticin) and 0.72 g. (0.012 mole) of nitromethane in 3 ml. of absolute ethanol was added a hot solution of 0.52 g. (0.008 mole) of potassium hydroxide in ethanol. The mixture was filtered hot to remove the by-product potassium chloride. From the cooled filtrate, 0.76 g. (69%) of anhydrocotarninenitromethane separated as colorless prisms, m. p. 125–126° (reported, 129°).[5]

The infrared absorption spectrum showed strong bands at 1549 and 1321 $cm.^{-1}$, characteristic of the nitro group. The strong band observed at 1620 $cm.^{-1}$ was due partially, at least, to the phenyl group, which also accounted for the band at 1498 $cm.^{-1}$. The strong absorption bands at 1123, 1095, 1077, 1061, 1050, 1033 and 1026 $cm.^{-1}$ were in the C–O vibration region.

Anhydrocotarninenitromethane Picrate (VIIIa).—The picrate was made by treating a saturated solution of anhydrocotarninenitromethane in ether with anhydrous picric acid in ether. The precipitated yellow prisms were collected and washed with ether; m. p. 132–132.5°.

Anal. Calcd. for $C_{19}H_{19}N_5O_{12}$: C, 44.80; H, 3.76; N, 13.75. Found: C, 45.19; H, 3.90; N, 13.52.

When heated in ethanol or acetone for recrystallization, this picrate was converted to cotarnine picrate, yellow needles, m. p. 143–144°, as established by mixed melting point.

(16) All melting points are corrected. The authors are indebted to Mr. Roger E. Beyler for assistance and to Mrs. James L. Johnson for determination of the infrared absorption spectra.

(18) Fieser and Gates, THIS JOURNAL, **68**, 2249 (1946).

Following Hope and Robinson's directions[5] for the preparation of anhydrocotarninenitromethane picrate, anhydrocotarninenitromethane was dissolved in aqueous acetic acid and an aqueous solution of picric acid was added. A solid picrate resulted which melted at 134–136°, when the melting point was taken with rapid heating, and sintered at 140° with melting at 142–144°, when the temperature was raised slowly. When mixed with cotarnine picrate, the melting point was 143–144°. A sample was submitted for analysis after two recrystallizations from absolute ethanol; yellow needles, m. p. 143–144°.

Anal. Calcd. for cotarnine picrate, $C_{18}H_{16}N_4O_{10}$: C, 48.22; H, 3.60; N, 12.50. Found: C, 48.35; H, 3.66; N, 12.14.

Summary

The elimination of nitromethane from 2-methyl-1-nitromethyl-1,2,3,4-tetrahydroisoquinoline and anhydrocotarninenitromethane and of phenylnitromethane from 2-methyl-1-(α-nitrobenzyl)-1,2,3,4-tetrahydroisoquinoline has been observed in the presence of picric acid.

Equilibrium Ratio of Rotational Isomers of *n*-Pentane: with Special Reference to its Difference from that of 1,2-Dichloroethane

BY SAN-ICHIRO MIZUSHIMA AND HIROATSU OKAZAKI

As shown in our preceding papers on the Raman effect, infrared absorption, dipole moment, and electron diffraction,[1] the molecules of 1,2-dichloroethane $ClH_2C–CH_2Cl$ in the gaseous and liquid states consist of the *trans* and the gauche forms, where the former is the configuration in which the two chlorine atoms are at the farthest distance apart and the latter differs from the former in an internal rotation by $\pm 120°$ about the C–C bond as axis.

We determined also the equilibrium ratio of these two "rotational isomers" in the gaseous state by the measurement of dielectric constant and of the intensity ratio of two Raman lines or of two infrared absorption lines, one assigned to the *trans* form and the other to the gauche form.[1] From this equilibrium ratio the energy of the gauche molecule was found to be greater than that of the *trans* molecule by an amount of $\Delta E = 1.20$ kcal./mole. The intensity measurement made for the liquid spectra tells us that the situation is quite different in the liquid state. The relative number of molecules in the gauche form was found much larger than was expected from the value of ΔE stated above.[1a] This was explained[2] as due to the electrostatic interaction between the molecules in the liquid state: *i. e.*—while the *trans* molecule has no dipole moment, the gauche molecule has a considerable one and in consequence the energy of the gauche molecule is lowered by the electrostatic interaction to approach to that of the *trans* molecule.[3] If this explanation be appropriate, we expect for a non-polar substance that the value of ΔE in the liquid state will not be much different from that in the gaseous state. It would, therefore, be very interesting to measure the intensity change of the Raman spectrum of a non-polar liquid with temperature. With this object in view we have measured the Raman spectrum of *n*-pentane at 32° and at −72°.

For *n*-pentane there can be considered three rotational isomers of skeleton: the first one corresponding to the planar, zigzag form (four consecutive carbon atoms forming the *trans* configuration), the second one containing one gauche structure, and the third one containing two gauche structures. Of these three forms the first one is the most stable and the third one the most unstable, since in the first form all the movable groups (*i. e.*, CH_3– or CH_2–groups) are at the farthest distance apart.

The identification of the Raman lines to be assigned to the first form can at once be made from

(1) The former part of this series of researches is summarized in: Mizushima and Morino, *Bull. Chem. Soc. Japan*, **17**, 94 (1942), (see also Mizushima, Morino and Takeda, *J. Chem. Phys.*, **9**, 826 (1941)) and the latter part is published in Mizushima, Morino, Watanabe, Simanouti, Yamaguchi, *etc.*, *Sci. Papers Inst. Phys. Chem. Research, Tokyo*, **39**, 387, 396, 401 (1942), **40**, 87, 100, 417, 425, 467 (1943), **42**, *Chem.*, 1, **5**, 27 (1944), **42**, *Chem.*, 51 (1946).

(2) Watanabe, Mizushima, and Masiko, *Sci. Papers Inst. Phys. Chem. Research, Tokyo*, **40**, 425 (1943).

(3) If we assume the same model of dielectrics as that of Onsager (THIS JOURNAL, **58**, 1486 (1936)) and consider a small cavity of radius a in the continuous medium of dielectric constant ϵ, a dipole of moment μ situated at the center of this spherical cavity will cause dielectric polarization in the continuous medium, which in turn exerts a field R (reaction field) upon the original dipole.

$$R = \frac{2(\epsilon - 1)}{2\epsilon + 1}\frac{\mu}{a^3}$$

Let us further assume that the gauche molecule can be represented by a sphere of radius a, at whose center the total permanent moment is located. The gauche molecule in the liquid state will then acquire an excess of electrostatic energy by an amount of

$$\Delta E' = \int_0^{\mu} -R\mathrm{d}\mu = -\frac{(\epsilon - 1)}{2\epsilon + 1}\frac{\mu^2}{a^3}$$

as compared with that in the gaseous state (*i. e.*, of the free molecule). The corresponding energy change of the *trans* molecule with no moment is negligible. Introducing the moment value of the gauche molecule (2.55 *D*) into μ of the above equation, we see that the value of $\Delta E'$ is almost equal to the value of ΔE, and therefore, the energy of the gauche molecule approaches to that of the *trans* molecule in the liquid state (see footnote (2)).

our previous observation[4] on the change of Raman spectrum on solidification, since the solid consists only of the molecules of the first form. Thus the Raman line observed at 865 cm.$^{-1}$ is assigned to the first form and that observed at 838 cm.$^{-1}$ to the second form or to the third. The intensity ratio of these two lines was obtained from the microphotometer tracings of the Raman spectra photographed at the two temperatures, and was found as

$$I(838)/I(865) = 1.21 \text{ at } 305°\text{K.}$$
$$= 0.77 \text{ at } 201°\text{K.}$$

Then the energy difference ΔE between the first form and another can at once be calculated from:[4a]

$$\frac{1.21}{0.77} = e^{-\frac{\Delta E}{R}\left(\frac{1}{305} - \frac{1}{201}\right)}$$

and we have

$$\Delta E = 0.53 \text{ kcal./mole}^{4b}$$

Similarly from a pair of lines at 865 and at 764 cm.$^{-1}$ we obtain a value of $\Delta E = 0.70$ kcal./mole which is somewhat larger than the preceding one. The difference may merely be due to the experimental error, but we cannot deny the possibility that the line at 764 cm.$^{-1}$ belongs to the rotational isomer different from what we stated above with regard to the line at 838 cm.$^{-1}$: *i. e.*, we may assign the line at 764 cm.$^{-1}$ to the third molecular form which is more unstable than the second one. We are not, however, sure whether this assignment is appropriate, since the number of lines seems to be too small to account for the coexistence of three molecular forms.[5]

TABLE I

OBSERVED INTENSITY RATIO OF PAIRS OF LINES AT ν AND 865 CM.$^{-1}$

ν	$I(\nu)/I(865)$ at 201° K.	at 305° K.	ΔE kcal./mole
764	0.27	0.49	0.70
838	.77	1.21	.53

We have not yet observed the temperature dependence of the intensity ratio in the gaseous state, the accurate determination of which would be considerably difficult, but we have reason to believe that the values of ΔE obtained above are not much different from that of a free molecule, since these values are of the magnitude which would be expected from the steric repulsion between the moving groups about the C–C bond as axis.[6]

In any case we are sure that on liquefaction the energy difference between the rotational isomers of *n*-pentane does not change so much as in the case of dichloroethane and it is, therefore, reasonable that we explained the difference in the spectral intensity between the gaseous and liquid dichloroethane mainly by the electrostatic interaction between polar molecules.

Summary

The relative intensity of the Raman lines of *n*-pentane was measured at 32° and at −72° and from this experimental result the energy difference between the rotational isomers was calculated as 0.5 kcal./mole.

(4) Mizushima and Simanouti, THIS JOURNAL, **71**, 1320 (1949).

(4a) See Langseth and Bernstein, *J. Chem. Phys.*, **8**, 410 (1940).

(4b) After the manuscript was submitted to the Editorial Board, Sheppard and Szasz (*J. Chem. Phys.*, **17**, 86 (1949)) reported the value of ΔE in excellent agreement with ours.

(5) The number of Raman lines observed for *n*-pentane is not larger than that observed for *n*-butane (see footnote (4)). It seems, therefore, probable to consider the coexistence of only two molecular forms for *n*-pentane as for *n*-butane. However, some Raman lines of *n*-pentane may escape detection because of their weak intensity and, therefore, we cannot deny the possibility of the coexistence of three molecular forms.

(6) The value of ΔE obtained by Pitzer (0.8 kcal./mole) in his calculation of entropies of *n*-butane and *n*-heptane is not much different from that obtained in the present experiment; see Pitzer, *Chem. Rev.*, **27**, 39 (1940), *J. Chem. Phys.*, **8**, 711 (1940).

The Synthesis of Pterorhodin (Rhodopterin)[1,1a]

BY PETER B. RUSSELL,[a] ROBERT PURRMANN,[b] WERNER SCHMITT[b] AND GEORGE H. HITCHINGS[a]

Pterorhodin is a violet-red substance which is formed during autoxidation of acid solutions of crude butterfly wing pigments,[2] and xanthopterin[3] and erythropterin[3] of natural origin. Both Schöpf[5] and Hopkins[3] suggested that it was formed from erythropterin, but the proportion of pterorhodin obtainable from this source diminishes with increasing purity of the erythropterin.[6] Moreover, xanthopterin is not the precursor since synthetic xanthopterin fails to yield the substance.[4,7]

A structural formula for pterorhodin (I) was suggested by Purrmann and Maas[4] primarily on the basis of degradative experiments in which leucopterin (II) and xanthopterin-7-carboxylic acid (III) were obtained as the products of oxida-

(1) Presented in part at the 115th meeting of the American Chemical Society at San Francisco, California, March 30, 1949.

(1a) Pterorhodin has been named first lepidoporphyrin,[2] then rhodopterin[3] by Hopkins, but Purrmann's proposal,[4] pterorhodin, is perhaps preferable since the substance is not a primary butterfly wing pigment.

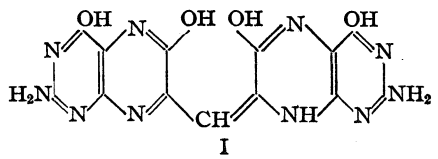
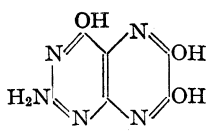
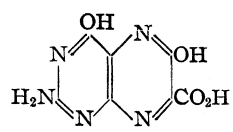
tion. This formulation is in agreement with the analytical data, the reversible reduction to a tetrahydro derivative by sodium amalgam, the cleavage by chlorine water to oxalylguanidine and other properties.[4] However, an alternative formulation (IV) could not be excluded by these properties and reactions.



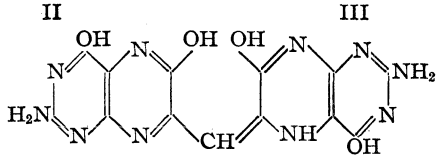
I



II

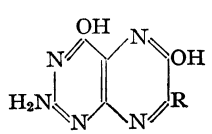


III



IV

The formulations (I) or (IV) for pterorhodin suggested a possible synthetic approach to the problem if the reactivities of the pyrazine moiety and attached methyl groups were sufficiently great to permit the oxidative condensation of xanthopterin (V) or iso-xanthopterin (VII) with the respective methyl derivatives (VI) (VIII).[8] Condensation of xanthopterin (V) with 7-methylxanthopterin (VI) would be expected to yield (I). Compound (IV) could be formed either from xanthopterin (V) and 6-methyl*iso*xanthopterin (VIII) or from iso-xanthopterin (VII) and 7-methylxanthopterin (VI), while a third isomer (IX) would be expected from the condensation of iso-xanthopterin (VII) and methyl*iso*xanthopterin (VIII). Pterorhodin, identical with that from natural



V R = H

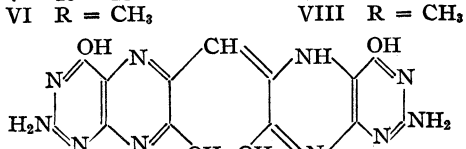
VIII R = CH_3

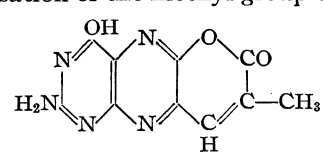


IX

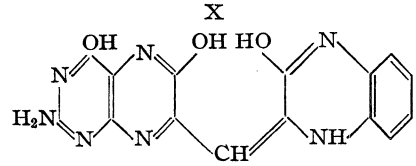
pterins of *C. argante* was in fact obtained by the condensation of xanthopterin with 7-methylxanthopterin. Moreover, iso-pterorhodin (IV) and *allo*-pterorhodin (IX) were obtained as predicted.

The formation of pterorhodin from xanthopterin may be carried out in a variety of ways. A mixture of xanthopterin and 7-methylxanthopterin in acid solution can be oxidized with air or with hydrogen peroxide, or 7-methylxanthopterin may be formed by the reaction of 2,4,5-triamino-6-hydroxypyrimidine with oxalacetic ester[9] and condensed with a further quantity of xanthopterin without isolation of the intermediate. Furthermore, appreciable quantities of pterorhodin are obtained when acid solutions of xanthopterin containing acetone or acetaldehyde are oxidized with hydrogen peroxide, and even during acetylation of xanthopterin with acetic anhydride.[10] Thus the methylene group of pterorhodin may have a variety of sources. However, in view of the close resemblance in properties of xanthopterin and 7-methylxanthopterin[8] it is highly probable that the latter is the precursor which is present in xanthopterin from natural sources.

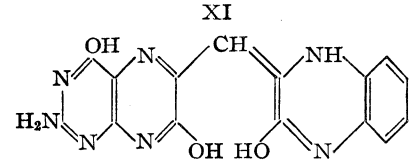
The reactivity of the methyl group which appears to be involved in these syntheses of pterorhodin (and its isomers) may be illustrated by other reactions of xanthopterin derivatives. In strongly acid solution, 2,4,5-triamino-6-hydroxypyrimidine and pyruvic acid give xanthopterin methacrylic acid lactone (X) which apparently arises through the condensation of the methyl group of 7-methyl-



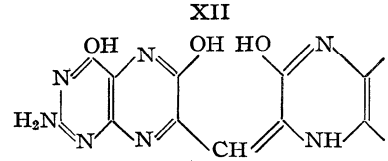
X



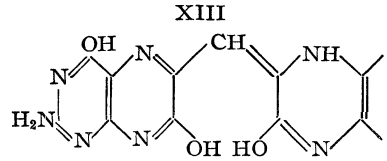
XI



XII



XIII



XIV

(8) Elion and Hitchings, THIS JOURNAL, **69**, 2553 (1947).

(9) The condensation of ethyloxalacetate with 4,5-diaminopyrimidines gives almost exclusively 6-hydroxy-7-methylpteridines in strong acid and 7-hydroxy-6-methylpteridines in acetic acid solution. The yields are superior to those obtainable with pyruvic acid (Elion, Russell and Hitchings, to be published).

(10) Purrmann, unpublished observations.

xanthopterin with a second molecule of pyruvic acid. Xanthopterin and iso-xanthopterin both condense oxidatively with 2-hydroxy-3-methylquinoxaline to give substances, XI and XII, respectively, similar to the pterorhodins. It is interesting in this connection that the absorption spectrum of XI (Fig. 1) has the general characteristics of that of pterorhodin (I) (Fig. 1) which thus seems to be correlated with the grouping (XIII). The spectrum of XII resembles that of

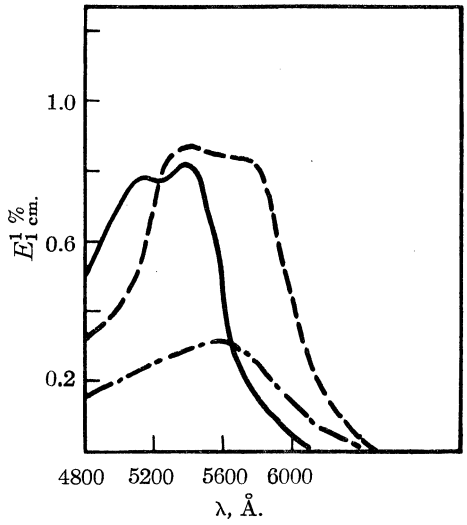


Fig. 1.—Absorption spectra of: isopterorhodin - - - - -; pterorhodin———; condensation product of xanthopterin and 3-methyl-2-quinoxalone —·—·— in concentrated sulfuric acid.

allo-pterorhodin (IX) (Fig. 2) and both substances contain the structure (XIV). Isopterorhodin (IV) which might be viewed as containing either or both of the structures XIII or XIV gives a spectrum more closely related to that of the pterorhodin series.

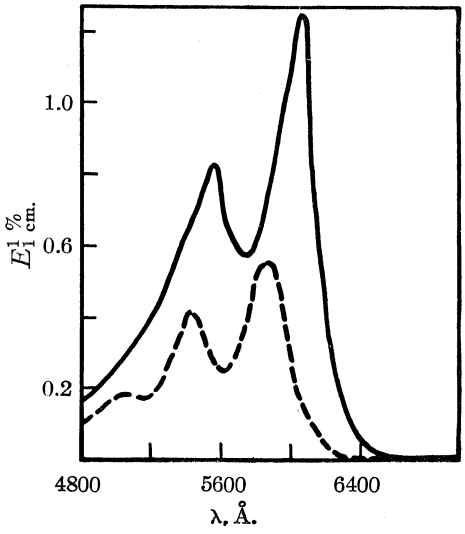

Fig. 2.—Absorption spectra of: *allo*-pterorhodin ——; the condensation product of iso-xanthopterin and 3-methyl-2-quinoxalone - - - - in conc. sulfuric acid.

The oxidative condensations of the xanthopterin derivatives perhaps are best viewed as (a) an acid catalyzed reversible addition of the active 7 (or 6) methyl group to the 7,8 (or 5,6) double bond to give aldol-like intermediates (A) followed by (b) dehydrogenation in the side-chain to give the products B. In the formation of pterorhodin from xanthopterin and acetone or acetaldehyde an intermediate carboxylic acid would be postulated (A or B, R = CO_2H) as arising from the carbonyl group by oxidation. Decarboxylation then would result in 7-methylxanthopterin (B, R = H). Some evidence for the formation of an intermediate of the postulated type was obtained. When xanthopterin and 7-methylxanthopterin are mixed in acid solution a rapid change in spectrum occurs after which an equilibrium state appears to be reached (Table I). At equilibrium the spectrum resembles that of a mixture of xanthopterin and dihydroxanthopterin and therefore approximates that which might be expected of a substance (A) containing isolated nuclei of this type.

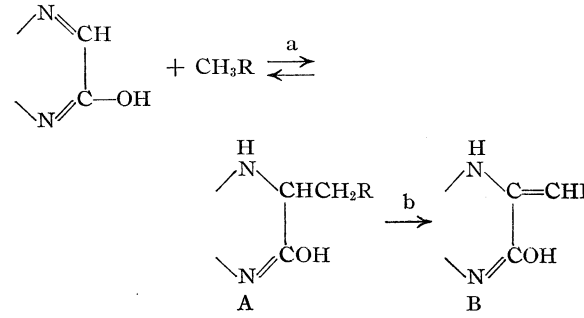

TABLE I

CHANGES IN ULTRAVIOLET ABSORPTION SPECTRUM DURING REACTION OF XANTHOPTERIN WITH 7-METHYLXANTHOPTERIN

	Substance	Reference spectra $E^{1\%}_{1\,cm.}$ 305 mμ / $E^{1\%}_{1\,cm.}$ 390 mμ	Time, min.	Reaction mixture[a] $E^{1\%}_{1\,cm.}$ 305 mμ / $E^{1\%}_{1\,cm.}$ 390 mμ
A	Xanthopterin	0.20	0	0.20
B	7-Methylxanthopterin	0.12	15	.51
C	β-Dihydroxanthopterin	∞	30	.61
			45	.63
	A + C	0.70	60	.63
	B + C	1.20	105	.70

[a] Equimolecular quantities of xanthopterin and 7-methylxanthopterin were dissolved in 2 *N* hydrochloric acid and the solutions were mixed. The optical densities of the mixtures were determined at 305 and 390 mμ immediately and after the indicated period at 60°.

This reaction mechanism appears to be consistent with the observed reactions. The resemblance of the pyrazine —C=N— (7,8 or 5,6) linkage, in the xanthopterin-type compound, to a carbonyl group[11] is brought out in the condensations, and

(11) Wieland and Purrmann, *Ann.*, **544**, 163 (1940).

also in the decarboxylations which occur both in the formation of the methylxanthopterins *via* oxalacetic ester and in the formation of pterorhodin from xanthopterin and acetaldehyde or acetone. In this respect isoxanthopterin and xanthopterin (6 and 7) acetic acids resemble β-keto acids. A parallel reaction has been observed in the quinoxaline field.[12]

The discovery that a synthetic 7,8-dihydroxanthopterin is not identical with the reduction product of xanthopterin[13] may or may not be inconsistent with this view of the potentialities of the pteridine —C=N— linkage. The reduction of xanthopterin may follow a course differing from that of the condensations, in fact, 1,4-addition (*i. e.*, addition at the 5,8-position) of hydrogen would appear probable. In any case, the two isomeric dihydroxanthopterins probably should be regarded as "stable tautomers"[13] and the significance of their existence will depend on further work on the fine structure of the reduction isomer. The existence of stable isomeric dihydropteridines differing in the position of the double bond in the pyrazine ring has been reported.[14]

Since the preparation of this manuscript Karrer and Schwyzer[15] have reported the synthesis of "methylpterin red" by the reaction of 2,4,5-triamino-6-hydroxypyrimidine and glyceric aldehyde. The published spectrum of this substance is very similar, but not identical, to that found for natural and synthetic pterorhodin (Fig. 3). A direct comparison of these substances appears to be desirable.

Experimental

Pterorhodin from Xanthopterin and 7-Methylxanthopterin. (a) **With Air.**—One-half gram of xanthopterin[16] was mixed with 0.5 g. of 7-methylxanthopterin[8] and the mixture dissolved in 200 ml. of *N* hydrochloric acid; the solution was filtered from a small amount of insoluble matter, heated to 90° in a water-bath and a stream of air passed through at a rate of about 200 bubbles per minute. After about one-half hour the solution began to redden and shortly thereafter a dark purple, almost black, solid began to separate. After two and one-half hours the solid was filtered off, washed with hot *N* hydrochloric acid and hot water. The solid was a mass of minute dark purple needles (sample I). Its absorption spectrum in concentrated sulfuric acid differed only slightly from that of an authentic sample of pterorhodin in the same solvent (Fig. 3). It appears likely that one or both samples contain trace impurities, which would account for the observed differences.

(b) **With Hydrogen Peroxide.**—One hundred and twenty milligrams each of the two reactants were dissolved in 100 ml. of 3 *N* hydrochloric acid. The solution was filtered and 10 ml. of a 15% hydrogen peroxide solution was added. On standing at room temperature a dark solid separated. After three and one-half hours it was filtered off (100 mg.). It proved to be amorphous but was identical with the above product in every other respect.

A portion was purified by solution in concentrated sulfuric acid and precipitated with water. It was dried at 150° *in vacuo* for analysis (sample IV). Several repetitions of the hydrogen peroxide oxidation, with or without added seeds, failed to produce pterorhodin in crystalline form.

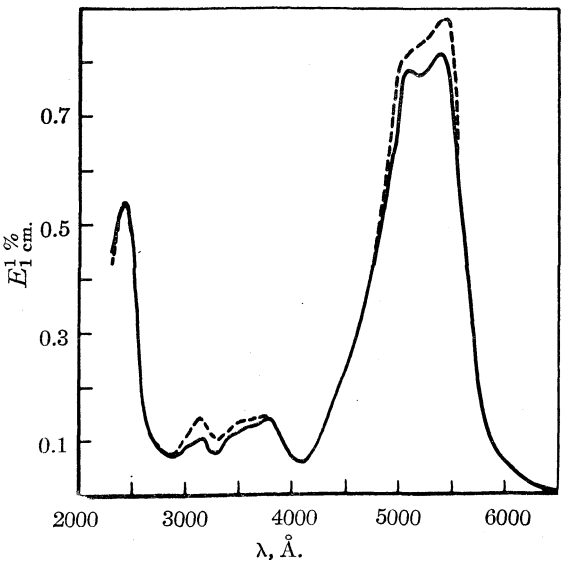

Fig. 3.—Absorption spectrum of pterorhodin in concd. sulfuric acid: natural - - - -; synthetic ——.

On standing, the mother liquors from the above oxidation deposited some bright red needles. These could be recrystallized from 3 *N* hydrochloric acid but too little was obtained to allow further examination.

Pterorhodin by Oxidation of the Condensation Product of 2,4,5-Triamino-6-hydroxypyrimidine and Ethyl Oxalacetate with Xanthopterin.—A solution obtained by treating 2 g. of 2,4,5-triamino-6-hydroxypyrimidine with 4 g. of sodium ethyl oxalacetate in 200 ml. of boiling 2 *N* sulfuric acid for one and one-half hours followed by filtration was treated with 1.5 g. of xanthopterin in 8 l. of 0.1 *N* hydrochloric acid. The solution was warmed and allowed to stand for three days after which time 1.35 g. of fine violet needles was collected (47%). After purification by precipitation from concentrated sulfuric acid with water and drying at 150° *in vacuo* the substance was analyzed (sample II).

In another experiment the original sulfuric acid solution was diluted to 1 l., the xanthopterin added and the solution heated on a water-bath while air was drawn through. The yield of violet-black needles was 1.15 g. (40%). This was analyzed (sample III) after drying at 150° *in vacuo*.

Anal. Calcd. for $C_{13}H_{10}O_4N_{10}$: C, 42.2; H, 2.7; N, 37.8. Found: Sample I: C, 41.5; H, 3.1; N, 37.4. Sample II: C, 42.4; H, 3.0; N, 34.4. Sample III: C, 42.2; H, 2.5; N, 37.2. Sample IV: N, 37.3.

Pterorhodin by Oxidation of Xanthopterin with Acetaldehyde or Acetone.—Three hundred milligrams of xanthopterin was dissolved in 20 ml. of warm *N* sulfuric acid and the solution filtered. To this solution was added 0.04 ml. of acetaldehyde in 4 ml. of water followed by 0.3 ml. of a 30% solution of hydrogen peroxide. The mixture was warmed for five minutes in a boiling water-bath and set aside for twelve hours. At the end of this time 56 mg. of purple material had separated. This was shown to be identical with pterorhodin after purification by precipitation from sulfuric acid with water.

When a solution of xanthopterin in 3 *N* hydrochloric acid was treated with acetone and hydrogen peroxide in a similar manner pterorhodin was obtained in about 20–30% yield.

Pterorhodin Sulfate.—Synthetic pterorhodin (100 mg., sample I) was converted to the sulfate by the method of Purrmann and Maas.[4] The sulfate (66 mg.) formed red

plates identical in appearance to a sample prepared from authentic pterorhodin. It was dried at 120° *in vacuo*.

Anal. Calcd. for $C_{13}H_{10}O_4N_{10}\cdot 2H_2SO_4$: C, 27.6; H, 2.5; N, 24.7. Found: C, 27.8; H, 2.6; N, 24.3.

Tetrahydropterorhodin Perchlorate.—Synthetic pterorhodin (sample I) was reduced with sodium amalgam following Purrmann and Maas.[4] The colorless hydrochloride was converted to the perchlorate which separated from the solution in rhombic prisms. It was dried at 150° for analysis.

Anal. Calcd. for $C_{13}H_{14}O_4N_{10}\cdot 2HClO_4$: C, 27.1; H, 2.8. Found: C, 27.6; H, 2.6.

The solid perchlorate began to turn purple rapidly on exposure to air. The mother liquors of the hydrochloride and perchlorate on dilution and oxidation with air gave pterorhodin.

Isopterorhodin.—One hundred milligrams each of 7-methylxanthopterin and isoxanthopterin[17] were treated with 30 ml. of 5 *N* hydrochloric acid. The isoxanthopterin did not dissolve completely. Air was drawn through the solution as previously described. After six hours the red micro-crystalline powder was filtered (75 mg.). It was visibly contaminated with some white material. Seventy milligrams of the red powder was dissolved in 1 ml. of concentrated sulfuric acid, the deep purplish-red solution was filtered through a sintered glass plate and 3 ml. of water added cautiously. The almost black crystalline precipitate (50 mg.) was collected by centrifugation, washed twice with 40% sulfuric acid, six times with acetic acid and finally several times with ether. It was dried at 150° *in vacuo*.

Anal. Calcd. for $C_{13}H_{10}O_4N_{10}\cdot H_2SO_4\cdot H_2O$: C, 32.1; H, 2.9; N, 28.8. Found: C, 32.1; H, 3.1; N, 28.5.

When the above preparation was carried out with xanthopterin and 6-methylisoxanthopterin[8] the same product was obtained.

Allopterorhodin.—One hundred milligrams each of isoxanthopterin and 6-methylisoxanthopterin were suspended in 30 ml. of 5 *N* hydrochloric acid and the suspension oxidized as previously described. The oxidation was continued for two days and the product filtered off at the end of this time (103 mg.). It was converted to the sulfate by solution in 4 ml. of concentrated sulfuric acid and dilution with 6 ml. of water. The purple sulfate separated as a crystalline powder. It was centrifuged off, washed with dilute sulfuric acid, acetic acid and ether. It was dried at 150° *in vacuo*.

Anal. Calcd. for $C_{13}H_{10}O_4N_{10}\cdot H_2SO_4$: C, 33.4; H, 2.6; N, 30.0. Found: C, 33.9; H, 2.8; N, 30.3.

Ethyl 2-Quinoxalone-3-acetate.—To a solution of *o*-phenylenediamine (5 g.) in 300 ml. of 2 *N* acetic acid was added 10 g. of sodium ethyl oxalacetate. Almost at once a yellow solid separated. The solution was heated for two hours on a steam-bath and then cooled and filtered. The yellow solid (9.0 g., 85%) was recrystallized from ethanol. It formed yellow needles, m. p. 210° (after softening from 205°). Ruhemann and Stapleton[12] described this compound, obtained by the condensation of *o*-phenylenediamine and ethyl acetylenedicarboxylate, as melting at 210° with previous softening.

3-Methyl-2-quinoxalone.—This compound was obtained in 80% yield by hydrolysis of the above ester with potassium hydroxide.[12] The acid decarboxylated spontaneously on acidification. The quinoxalone melted at 247–248° (dec.).[12,18]

Oxidative Condensation of 3-Methyl-2-quinoxalone with Xanthopterin.—Two hundred milligrams of each of the components was dissolved in 50 ml. of 3 *N* hydrochloric acid. Solution took place at once with the formation of a red color. The solution was warmed to 90° and air passed through as before. After about one hour the purple solid began to separate; at the end of four hours 125 mg. was collected. The product was converted to its sulfate by solution in 2.5 ml. of concentrated sulfuric acid and dilution with 2.5 ml. of water. The sulfate was separated by centrifugation, washed ten times with acetic acid and finally with ether. The red microcrystalline product was dried at 150°.

Anal. Calcd. for $C_{15}H_{10}O_3N_7\cdot H_2SO_4$: N, 22.7. Found: N, 22.9.

The sulfuric acid mother liquors deposited more amorphous material on dilution with water.

Oxidative Condensation of 3-Methyl-2-quinoxalone with Isoxanthopterin.—The reaction was carried out as above with isoxanthopterin and 3-methyl-2-quinoxalone. Isoxanthopterin was not soluble to any great extent and as a consequence the reaction mixture appeared as a suspension which on oxidation changed from gray to a reddish-brown. After four hours the brown solid was filtered off and washed with hot dilute hydrochloric acid and with hot water. The condensation product gave a greenish-red solution in concentrated sulfuric acid, the color changing to violet on addition of only a drop of water. Further dilution gave a precipitate of the violet sulfate which, on standing or on further addition of water, changed to the brownish-red free base. For analysis the process was repeated twice and the product dried at 150°.

Anal. Calcd. for $C_{15}H_{10}O_3N_7$: N, 29.0. Found: N, 29.3.

Xanthopterin Methacrylic Acid Lactone.—Five hundred milligrams of 2,4,5-triamino-6-hydroxypyrimidine bisulfite was treated with 30 drops of concentrated sulfuric acid and then warmed with 6 ml. of pyruvic acid for twenty minutes on the water-bath. On cooling the crystalline material (370 mg., 55%) was filtered, washed with acetic acid and crystallized twice from 5 ml. of concentrated sulfuric acid by addition of 5 ml. of water.

Anal. Calcd. for $C_{10}H_7O_3N_5\cdot H_2SO_4$: C, 35.0; H, 2.6; N, 20.5; SO_4, 28.0. Found: C, 35.3; H, 2.5; N, 18.6; SO_4, 30.3.

The free lactone was prepared by heating the sulfate with water. The precipitate was filtered and washed with water.

Anal. Calcd. for $C_{10}H_7O_3N_5$: C, 49.0; H, 2.8; N, 28.6. Found: C, 49.0; H, 2.8; N, 29.0.

Acknowledgment.—Our thanks are due Samuel W. Blackman for microanalyses, and Gertrude B. Elion for the determination of absorption spectra. The invaluable assistance of Dr. B. K. Blount in effecting contact between the German and the American authors is gratefully acknowledged.

Summary

1. Pterorhodin (rhodopterin) has been synthesized by the oxidative condensation of xanthopterin and 7-methylxanthopterin. This suggests the presence of 7-methylxanthopterin as an hitherto undetected constituent of the pterins of butterfly wings.

2. Two isomeric substances, isopterorhodin and *allo*-pterorhodin have been prepared by similar means. Isopterorhodin has been synthesized from xanthopterin and 6-methylisoxanthopterin and from isoxanthopterin and 7-methylxanthopterin. *Allo*-pterorhodin was obtained by the condensation of the two isoxanthopterin derivatives.

3. Studies on the reactivity of the 7-position of xanthopterin (6-position of isoxanthopterin) and of the methyl groups attached to these positions are reported.

Derivatives of 2-Amino-6-methoxybenzothiazole[1]

BY C. G. STUCKWISCH

p-Substituted anilines are readily converted to 2-amino-6-substituted benzothiazoles by reaction with alkali thiocyanates in the presence of bromine.[2] By modification of procedure we have obtained 2-amino-6-methoxybenzothiazole from *p*-anisidine in 87% yield.

In a search for types of compounds that might exhibit antimalarial activity several derivatives of 2-amino-6-methoxybenzothiazole were prepared.[3] Details are given in the experimental section.

Experimental

2-Amino-6-methoxybenzothiazole.—To a solution of 24.6 g. (0.2 mole) of *p*-anisidine and 77.6 g. (0.8 mole) of potassium thiocyanate in 360 ml. of 96% acetic acid was added dropwise, with stirring, 32 g. (0.2 mole) of bromine dissolved in 150 ml. of glacial acetic acid while the temperature was kept below 35°. After all the bromine solution had been added the mixture was stirred for ten hours and was then filtered and the residue washed with water. The combined filtrate and washings were neutralized with ammonium hydroxide. The precipitate was collected on a filter and dried. The yield of product melting at 158–161° was 31.5 g. or 87%. This material is pure enough for subsequent reactions. Larger runs do not affect the yield.

Further purification is most readily carried out by crystallization from a mixture composed of equal volumes of concentrated hydrochloric acid and 95% ethanol. The hydrochloride thus obtained is dissolved in water and the free base is precipitated with sodium carbonate. The recovery of 2-amino-6-methoxybenzothiazole, melting at 161–162°,[4] is nearly quantitative. An alternate method of purification is crystallization from benzene.

2-Chloro-6-methoxybenzothiazole.—A solution of 18 g. (0.1 mole) of 2-amino-6-methoxybenzothiazole in 50 ml. of formic acid, 20 ml. of glacial acetic acid and 40 ml. of concd. hydrochloric acid was cooled to −5° and then 7 g. of sodium nitrite in 10 ml. of water was added dropwise with stirring. After addition was complete, stirring was continued for fifteen minutes at 0°. The mixture was then added slowly to an ice-cold vigorously stirred solution of 0.13 mole of cuprous chloride in 59 ml. of hydrochloric acid (sp. gr. 1.14). After one-half hour the mixture was heated to 60° on a steam-bath. When evolution of nitrogen ceased, the mixture was diluted with water and the solid was filtered off and extracted with hot ethanol. The alcohol extract was poured into water and the precipitated material collected on a filter and dried. Crystallization from dilute methanol gave 6 g. or 30% of 2-chloro-6-methoxybenzothiazole, m. p. 43–44°.

Anal. Calcd. for C_8H_6ONClS: Cl, 17.8. Found: Cl, 17.7.

[a] A mixture of 8 g. of mucic acid and 6 g. of 2-amino-6-methoxybenzothiazole was distilled from a 50-ml. Claisen flask evacuated to 2 mm. (Bell, *Ber.*, **10**, 1861 (1877)). [b] 2-Amino-6-methoxybenzothiazole and acetonylacetone were heated for five hours at 135°. [c] 2-Chloro-6-methoxybenzothiazole was refluxed with the requisite amine for two hours. [d] A mixture of 2-amino-6-methoxybenzothiazole, chloroacetyl chloride and dimethylaniline was heated on a steam-bath for an hour and was then poured into 500 ml. of dilute hydrochloric acid. The yellow precipitate was collected on a filter and dried. The crude material was heated with morpholine at 135° for four hours. [e] 2-Amino-6′-methoxybenzothiazole was condensed with *m*-nitrobenzoyl chloride in pyridine solution. [f] The corresponding nitro compound was reduced with tin and acetic acid. [g] 2-Amino-6-methoxybenzothiazole was diazotized as previously described and then coupled with N,N-dimethylaniline.

Summary

1. A procedure for the preparation of 2-amino-6-methoxybenzothiazole has been described.

2. Several derivatives of 2-amino-6-methoxybenzothiazole have been prepared.

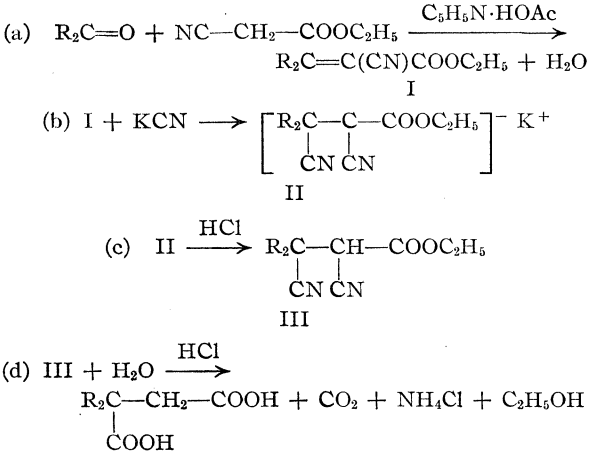
A Synthesis for Unsymmetrically Substituted Succinic Acids[1]

BY PETER A. S. SMITH AND JEROME P. HORWITZ[2]

A convenient and somewhat general procedure which we have developed for the synthesis of succinic acids of the type $HOOC-CR_2-CH_2-COOH$ is described here as applied to seven examples. The procedure, which consists of two laboratory steps, takes place according to the equations



Reaction (b) is combined with reaction (a), which is only partially complete at equilibrium, in order to draw reaction (a) more completely in the desired direction. This same effect was accomplished by Cope and Alexander,[3] who added hydrogen instead of potassium cyanide to the unsaturated ester (I). Reaction (a) may also be driven to completion by removal of the water by distillation.[4]

It is in the actual laboratory procedure that the method reported here represents an improvement over a stoichiometrically similar method described by Lapworth and McRae.[5]

Their procedure involves isolation of the alkylidene cyanoacetic ester before treatment with potassium cyanide. This gives from cyclohexanone and cyanoacetic ester, for example, a 53% yield of cyclohexylidenecyanoacetic ester; by the procedure reported in this paper, the corresponding hydrogen cyanide addition product is obtained in 75% yield from the same starting materials. The Lapworth and McRae procedure gives superior results, however, with aromatic aldehydes.

Our attention was directed toward this method when a need arose for a supply of α,α-dimethylsuccinic acid. The preparation of this acid according to Higson and Thorpe[6] by the condensation of acetone cyanohydrin with sodiocyanoacetic ester, followed by hydrolysis and decarboxylation of the α,α-dimethyl-β-carboethoxysuccinonitrile so produced, was found to be manipulatively inconvenient and sensitive to variations in conditions which are difficult to control. By the method described here we were able consistently to obtain α,α-dimethylsuccinic acid in two convenient steps in over-all yields above 50%. Because of this success, we were led to extend the method to the synthesis of some additional succinic acids. The satisfactory results with unhindered aliphatic ketones and aldehydes show that this procedure is of synthetic value for the preparation of alkyl- and α,α-dialkylsuccinic acids. The poor results with benzaldehyde and acetophenone, and the complete lack of reaction of diisopropyl ketone, are indicative of the probable limitations of the method.

Experimental

The condensation of the aldehydes and ketones with cyanoacetic ester and the hydrolysis and decarboxylation of the resulting dicyano ester was essentially the same in all the cases here reported. For this reason only the operations leading to α,α-dimethylsuccinic acid are described in detail; the results of the other preparations are given in the accompanying table. Analyses of new compounds are given in footnotes to the table.

Ethyl α,β-Dicyano-β-methylbutyrate.—A mixture of 58 g. (1 mole) of dry acetone, 113 g. (1 mole) of ethyl cyanoacetate, 79 g. (1 mole) of pyridine and 63 g. (1 mole) of glacial acetic acid was refluxed for one hour. Absolute ethyl alcohol (100 ml.) was then added, and as soon as active boiling subsided, 65 g. (1 mole) of potassium cyanide was added through the neck of the flask. The condenser was immediately replaced, and the refluxing which occurred because of the ensuing vigorous spontaneous reaction was continued by the application of heat when necessary for a total of one hour. It is important that the cyanide addition be made before the mixture has cooled appreciably below the temperature of active refluxing, for the reaction with the potassium cyanide cannot otherwise be made complete, and low yields and an impure product result.

The slurry which formed on cooling was then treated with 400 ml. of 1:3 hydrochloric acid, and swirled and gently warmed until all solid disappeared. The aqueous layer, after separation of the oil, was extracted with two 100-ml. portions of ether, and the combined organic layers were neutralized with sodium bicarbonate, dried over sodium sulfate, and distilled; yield 126 g. (70%), b. p. 136–141° (9 mm.).

α,α-Dimethylsuccinic Acid.—A mixture of 126 g. of ethyl α,β-dicyano-β-methylbutyrate and 600 ml. of concentrated hydrochloric acid was refluxed for five hours, after which 150 ml. more acid was added and the refluxing was continued three hours. Distillation to dryness under aspirator vacuum left a cake of α,α-dimethylsuccinic acid and ammonium chloride, from which the acid was extracted with several 100-ml. portions of boiling ether

Acetophenone	17	140–145	0.1	α-Phenyl-α-methylsuccinic acid[e]	60	157–158
Benzaldehyde	[f]	145–158	0.1	Phenylsuccinic[f] acid and α-cyanocinnamic acid	12	

[a] Higson and Thorpe[6] report ethyl α,β-dicyano-β-methylvalerate, b. p. 162° (20 mm.), and α-ethyl-α-methylsuccinic acid, m. p. 102–103°. [b] Dickens, Horton and Thorpe, *J. Chem. Soc.*, 125 (1934), report ethyl 1-cyanocyclohexylcyanoacetate, b. p. 210–212° (22 mm.), and (1-carboxycyclohexyl)-acetic acid, m. p. 132°. [c] Ethyl α,β-dicyanovalerate: *Anal.* Calcd. for $C_9H_{12}O_2N_2$: N, 15.56. Found: N, 15.62.[7] [d] Ethyl α,β-dicyano-γ-methylvalerate: *Anal.* Calcd. for $C_{10}H_{14}O_2N_2$: N, 14.43. Found: N, 14.41.[7] Von Braun and Reinhardt, *Ber.*, **62**, 2585 (1929), report isopropylsuccinic acid, m. p. 116°. [e] α-Phenyl-α-methylsuccinic acid: *Anal.* Calcd. for $C_{11}H_{12}O_4$: C, 63.45; H, 5.77; neut. equiv., 104. Found: C, 63.32; H, 5.82[6]; neut. equiv., 107. [f] The mixture of esters was hydrolyzed without separation to give phenylsuccinic acid and α-cyanocinnamic acid, which were separated by means of the solubility of the former in hot water, in 12% over-all yield each.

The product was obtained in a very pure state by evaporation to a volume of about 125 ml., heating to boiling with 1 l. of benzene, and allowing to stand until crystallization was complete (about one day); yield 77 g. (76%), m. p. 138–139° (lit. 139°[5]). The acid can also be recovered from the hydrolysis mixture more simply, but in lower yield (*ca.* 60%), by allowing crystallization to take place instead of distilling the mixture to dryness, and extracting the filtered solids with ether as described.

The hydrolyses of the other dicyano-esters reported in the table were essentially the same, except that 1-carboxycyclohexylacetic acid had to be precipitated from benzene solution by the addition of petroleum ether (60–75°), and α-phenyl-α-methylsuccinic acid was freed from ammonium chloride by crystallization from hot water.

(7) Analysis by Micro-Tech Laboratories, Skokie, Illinois.

Summary

A convenient synthesis for certain succinic acids is described which employs the condensation of aldehydes or ketones with cyanoacetic ester and potassium cyanide.

Synthetic Analogs of Oxytocic Drugs. II. β-Hydroxyphenethyl-β-alanine Esters[1]

BY RICHARD BALTZLY AND ARTHUR P. PHILLIPS

Oxytocic activity having been found in a family of phenethyl-β-alanine esters[2] the effect of introducing an hydroxyl group in the side-chain was studied. Data on the compounds prepared for this purpose and on new intermediates are presented in Table I.

Although the available methods of assay render any precise conclusions on the influence of the hydroxyl group questionable, its presence appears advantageous. While compounds IV and V were not clearly more active than the comparable substances without the hydroxyl group, compounds I–III are also of the same order of activity, whereas in the phenethyl series[2] maximum activity was observed only with two alkoxyl substituents on the aromatic ring.

The preferred method of synthesis was by the addition of the appropriate phenylalkanolamine to methyl acrylate

$$RCHOHCH_2NHMe + CH_2{=}CHCOOMe \longrightarrow RCHOHCH_2N(Me)CH_2CH_2COOMe$$

Under the conditions described in the experimental section this reaction appears to be quantitative. Compound I was prepared from *d,l*-ephedrine and ethyl-β-bromopropionate. Compound V was obtained from IV by ester exchange.[2]

The secondary amines required from compounds II–IV are known.[3,4] The intermediate for compound VI, N-methyl-β-hydroxy-β-(3,4-dimethoxyphenyl)-ethylamine (XI)[5] is less easily prepared than might be supposed. When the corresponding benzylmethylaminoketone hydrochloride (VIII) was hydrogenated with Adams catalyst in the expectation of obtaining XI, cleavage of the dimethoxyphenacyl group appeared to compete with debenzylation. A considerable quantity of neutral material less volatile than toluene was present in the reaction mixture and XI was iso-

lated with difficulty and in poor yield. A preferable course was to reduce the tertiary amino ketone base with aluminum isopropoxide and debenzylate the resultant tertiary amino alcohol

$$RCOCH_2NMeBz \xrightarrow{Al(i\text{-}PrO)_3} RCHOHCH_2\cdot NMeBz \xrightarrow[H_2]{Pd\text{–}C} RCHOH\text{—}CH_2NHMe$$

This sequence was also employed in preparing larger quantities of IV and proceeded smoothly and without complications.

This lability of a phenacyl group toward hydrogenolysis was unexpected to us at the time. Subsequently one of us (A.P.P.) observed a hydrogenolytic cleavage of a phenacylpyridinium salt and these facts taken together with the unusual speed of dehalogenation of phenacyl chloride[6] suggest that dephenacylation may resemble debenzylation generally. Some phenomena reported from Adkins' laboratory[7] may also be related. Further investigation is planned.

Experimental[8]

β-(2,5-Dimethoxyphenyl)-β-hydroxyethylbenzylmethylamine Hydrochloride (VII).—Thirty-two gram of α-benzylmethylamino-2,5-dimethoxyacetophenone hydrochloride was dissolved in water, and alkali was added to liberate the base. The ethereal solution of the base was dried over potassium carbonate and evaporated. The base so obtained was refluxed in isopropyl alcohol containing 22 g. of aluminum isopropoxide for five hours, the acetone formed being fractionated off. The reduction mixture was cooled and made strongly alkaline with sodium hydroxide solution and extracted five times with ether. The combined ethereal extracts were dried over potassium carbonate and added to an excess of ethanolic hydrogen chloride solution. An oil separated that crystallized on scratching. The crystalline product weighed 28 g. (a 90% yield) and melted at 166–167°. Recrystallization did not raise the melting point. The starting amino ketone hydrochloride melts at 167.5°[3] but a mixture melted at 148–154°.

β-Hydroxy-β-(2,5-dimethoxyphenyl)-ethylmethylamine Hydrochloride.—Seventy millimoles (23.6 g.) of the tertiary aminoalcohol was dissolved in methanol and hydrogenated with palladized charcoal. The catalyst was filtered off, the methanol and toluene evaporated *in vacuo* and the residue was crystallized from an ethanol–ethylacetate–ether mixture. The product weighed 17 g. (calcd. 17.3 g.) and melted at 151.5°.[3]

N-Methyl-N-(β-hydroxy-β-2,5-dimethoxyphenyl)-ethyl-β-alanine Methyl Ester Hydrochloride.—The base was liberated from the previous preparation, taken into benzene, dried over potassium carbonate and added to 45 g. of methyl acrylate (Eastman Practical Grade). The reaction mixture was allowed to stand at room temperature three days and warmed to about 50° for three hours. On cooling, the solution was poured into about 200 cc. of acetone to which 10 g. of 39% (wt./wt.) methanolic hydrogen chloride had been added. The solution was diluted with ether to the point of turbidity and seeded. The crystalline product weighed 21 g. and melted at 154.5–155°. After one recrystallization from methanol–acetone–ether mixture the m. p. was 156–156.5°, yield 20.5 g. The over-all yield in the last two operations was 90%.

The tertiary aminoketones VIII and IX were prepared by the reaction of 2 mols. of benzylmethylamine with one mol. of bromoacetoveratrone and α-brompropioveratrone, respectively. Compound IX was not employed in further syntheses.

All the compounds reported in Table I have the type of solubilities usual with amine hydrochlorides. The intermediates VII–XI were crystallized from ethanol–ether mixtures, sometimes with addition of ethyl acetate. The β-alanine esters, I–VI, were crystallized by solution in the esterifying alcohol and addition of acetone (or ethyl acetate with I and V) and ether to the point of turbidity.

Acknowledgment.—The authors wish to express their gratitude to Messrs. Walter S. Ide and Samuel Blackman for the microanalyses.

Summary

The preparation of some N-β-hydroxyphenethyl-N-methyl-β-alanine esters with oxytocic action is described.

Synthetic Analogs of Oxytocic Drugs. III. Homologs of the Phenethyl β-Alanine Type[1]

BY RICHARD BALTZLY AND ARTHUR P. PHILLIPS

Oxytocic activity having been observed in certain N-phenethyl-β-alanine esters[2] it seemed desirable to examine the effect of varying the length of the chains (a) between the ring and the amino nitrogen, and (b) between the amino group and the ester grouping. To this end were first prepared four phenethyl derivatives of glycine and α-alanine, Compounds I–IV, none of which proved of physiological interest. The β-alanine homolog of IV is quite active wherefore it is apparent that at least two carbons must intervene between the amino and carbalkoxyl groups.

The reverse operation, increase of the distance between amino and ester functions, produced no comparable change in physiological activity. Compounds VIII and IX were not significantly less potent than their β-alanine equivalents. Evidently there is no critical upper limit in this distance.

The variation of chain length between the amino groups and the ring was not studied in comparable detail since amines with more than two carbons in this chain were less accessible. Three substituted benzyl β-alanine esters, V–VII, were prepared and found to be inactive. At the same time alterations in the nitrogen substituent were made without affecting this result.

The compounds prepared and their analytical data are presented in Table I. Compounds V–VII were formed from the appropriate secondary amines and methyl acrylate as described in the first paper of this series.[2] The other amino esters were obtained by reaction of the required secondary amine with the appropriate halo ester. The yields by this method were in the range of 30–50% based on pure product. Compound II was prepared by heating I with ethanolamine.

Experimental[2a]

N-Methyl-N-homoveratryl Glycine Ethyl Ester (IV).—Nine grams of ethyl chloroacetate and 14.5 g. of N-methylhomoveratrylamine were refluxed together in absolute ethanol for five hours and the alcohol was then evaporated *in vacuo*. The residual sirup was dissolved in water, basified with sodium carbonate and the bases were taken into ether. After drying over potassium carbonate the bases were distilled at 11 mm. a fraction (4.3 g.) boiling at 192° being selected for further examination. This was dissolved in absolute ethanol, acidified with ethanolic hydrogen chloride and crystallized by addition of ether.

N-Methyl-N-(ξ-carbethoxyhexyl)-homoveratrylamine (IX).—Six hundredths mole of N-methylhomoveratrylamine (12.5 g.) was refluxed in 40 cc. of ethanol with 15 g. of ethyl ξ-bromoheptoate[3] for sixty hours. The alcohol was evaporated and the residual material was dissolved in water. The solution was basified with sodium hydroxide solution and the liberated bases were taken into ether and dried over potassium carbonate. The dry ethereal solution was then treated with portions (1–2 g.) of phenyl isocyanate until the odor of that substance persisted. The excess isocyanate was destroyed with alcohol, the urea filtered off, and the tertiary amine taken into water by extraction with dilute hydrochloric acid. The base was then liberated again, taken into ether, dried and precipitated by addition of ethanolic hydrogen chloride.

N-Methyl-N-phenethylglycine Ethanolamide (II).—Eleven grams (0.05 mole) of N-methyl-N-phenethyl glycine ethyl ester and 30 g. (0.5 mole) of ethanolamine was

heated under reflux with a thermometer in the liquid. Heating was applied by a metal-bath. The material, at first in layers, became homogeneous at about 90°. The temperature of the liquid when it began to boil was 154° (b. p. of ethanolamine, 172°) and this temperature fell during twenty minutes to 144° where it remained during forty-five minutes more of gentle refluxing. The contents of the flask was then distilled at 16 mm.; 22 g. of ethanolamine came over at 82°. The residue, which was not extracted from aqueous solution by ether, was acidified with hydrochloric acid (12 cc. of concentrated acid), iced and treated with 10 g. of sodium nitrite and 5 cc. more of concentrated hydrochloric acid. After standing an hour, the solution was evaporated *in vacuo*, dissolved in a minimum of water and basified with 20% sodium hydroxide solution. Repeated extraction with ether removed a sirupy base leaving most of the color behind. The ethereal extracts were dried over potassium carbonate and poured into an excess of ethanolic hydrogen chloride solution. A sirupy layer separated and crystallized slowly. The yield of purified material was 7 g.

The salts described in Table I had no unusual solubilities but the lower melting members were most advantageously recrystallized from acetone with a trace of the esterifying alcohol and with addition of sufficient ether to saturate the solution to the liquid phase. The acid oxalates, V and VII, were prepared because the hydrochlorides could not be induced to crystallize. The hydrobromide III was obtained directly from the reaction mixture in which it was formed.

Intermediates.—The secondary amines leading to compounds I, III, IV and IX, phenethylmethylamine and homoveratrylmethylamine are familiar. The precursor of VIII, N-methyl-2,5-dimethoxyphenethylamine was described by Buck.[4] The intermediates for compounds V–VII are shown in Table I. Veratrylmethylamine (XII),[5] veratrylbutylamine (XIII) and anisylethylamine (X) were prepared by hydrogenation of the corresponding Schiff bases in acetic acid with Adams catalyst; the yields were 75–80%. N-Methyl-4-methoxy-3-bromobenzylamine (XI) was prepared by brominating X in aqueous solution as its hydrobromide; the yield of recrystallized hydrobromide was 76%.

Acknowledgment.—The microanalyses here reported were performed by Messrs. Walter S. Ide and Samuel Blackman to whom we wish to express our gratitude.

Summary

A group of N-phenethyl glycine and N-benzyl-β-alanine derivatives as well as two higher homologs have been prepared for study of their oxytocic properties.

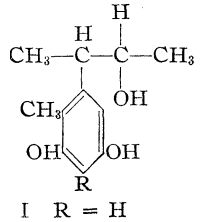
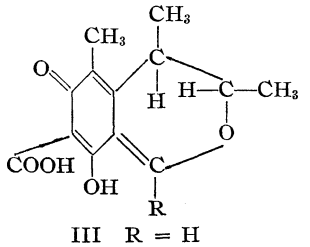
The Synthesis of Dihydrocitrinin and Citrinin

BY H. H. WARREN, GREGG DOUGHERTY AND EVERETT S. WALLIS

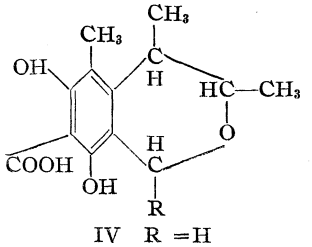
The synthesis of citrinin by Cartwright, *et al.*,[1] from the phenolic degradation product A (I), and the synthesis of the racemic form of A corroborates the structure, III, for citrinin advanced by Brown and co-workers.[2] In this Laboratory we have accomplished the synthesis of dihydrocitrinin (IV) from I by the cyclization of the carboxylic acid derivative, II, with methylal. The dihydrocitrinin thus prepared (m. p. 169.5–170.5° dec.) was readily converted to citrinin by oxidation with bromine in accordance with a method essentially the same as that recently published by Schwenk, Schubert and Stahl.[3]



I R = H
II R = COOH



III R = H



IV R = H

Preliminary observations from investigations now in progress on the synthesis of homologs and analogs of dihydrocitrinin and of citrinin for the purpose of determining the effect of variation in structure on physiological activity indicate that the cyclization is of general applicability for the preparation of derivatives of III and IV where R is methyl, ethyl, benzyl, etc., or substituted radicals of various structures. The results of these experiments will be described in a later paper.

Experimental Part

Compound A.—Citrinin was hydrolyzed with ammonium hydroxide according to the method of Schwenk.[3] Compound A was obtained in excellent yields. Recrystallization from hot chloroform gave a pure product of m. p. 128–130°.

Carboxylic Acid Derivative of Compound A.—The method used was similar to that described by Cartwright.[1] A mixture of 0.50 g. of compound A, 1.00 g. of potassium bicarbonate and 1.00 g. of glycerol was heated under an atmosphere of carbon dioxide in an oil-bath at 150° for five hours. After cooling, the material was dissolved in twice its volume of water and was extracted four times with ether to remove glycerol. Careful acidification of the

cold aqueous solution with dilute sulfuric acid yielded 0.38 g. of white crystalline material which, after three recrystallizations from ether and chloroform, melted at 178.3–179.8 (dec.).

Anal. Calcd. for $C_{12}H_{16}O_5$: C, 59.97; H, 6.71. Found: C, 59.70; H, 6.80.

Dihydrocitrinin.—A suspension of 0.20 g. of the carboxylic acid derivative of compound A in a solution of 0.40 g. of methylal and 4.0 ml. of benzene saturated with dry hydrogen chloride at room temperature was heated in a sealed tube at 60° for six hours. After standing overnight the tube was opened and the clear, slightly yellow liquid was decanted from a very small amount of oil, decolorized with Darco and evaporated nearly to dryness in a stream of nitrogen. Petroleum ether was added dropwise until a tarry precipitate started to form. The clear solution was decanted from the tar and upon further addition of petroleum ether a white crystalline material separated. Four recrystallizations from hot carbon tetrachloride and cyclohexane yielded a product which melted at 169.5–170.5 (dec.).

Anal. Calcd. for $C_{13}H_{16}O_5$: C, 61.87; H, 6.39. Found: C, 61.54; H, 6.15.

Citrinin.—To a solution of 0.030 g. of dihydrocitrinin in one-half ml. of chloroform was added dropwise a molar solution of bromine in chloroform until the bromine color persisted. After standing for ten minutes the solvent was evaporated at low temperature, yielding a dark orange tar which was dissolved in a minimum amount of ethanol. Addition of hot water initiated the formation of a lemon-yellow crystalline material, which after cooling was filtered and recrystallized. Crystals were obtained which melted at 175.8–176.3° (dec.). No depression of the melting point was observed when a sample of this material was admixed with an authentic sample of citrinin.

Anal. Calcd. for $C_{13}H_{14}O_5$: C, 62.39; H, 5.64. Found: C, 62.24; H, 5.47.

Acknowledgment.—We wish to take this opportunity to express our thanks to The Schering Corporation, Bloomfield, N. J., for the citrinin used in the preparation of Compound A, and to Merck and Company, Inc., Rahway, N. J., for the analyses published in this paper. We also wish to express our appreciation to The Standard Brands Corporation, New York City, N. Y. for a grant-in-aid which made this work possible.

Summary

A synthesis of dihydrocitrinin and of citrinin has been described.

Preliminary observations indicate that the synthesis is applicable to homologs and analogs and to other derivatives of similar structure.

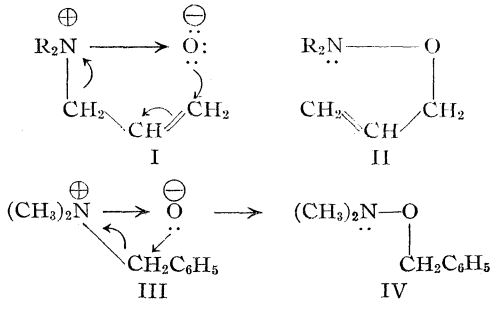
Rearrangement of Allyldialkylamine Oxides and Benzyldimethylamine Oxide[1]

BY ARTHUR C. COPE AND PHILIP H. TOWLE

Meisenheimer has shown that allylmethylaniline oxide and allylethylaniline oxide rearrange to O-allyl-N-alkyl-N-phenylhydroxylamines on heating with aqueous sodium hydroxide, and that benzylmethylaniline oxide rearranges to O-benzyl-N-methyl-N-phenylhydroxylamine under the same conditions.[2,3] These reactions have been interpreted as intramolecular, thermal rearrangements, because crotylmethylaniline was observed to rearrange with inversion of the crotyl group, yielding O-methylvinylcarbinyl-N-methyl-N-phenylhydroxylamine.[4] The fact that the rearrangement products are formed in high yield in the presence of sodium hydroxide indicates that the oxygen–carbon bond is formed essentially at the same time that the nitrogen–carbon bond is broken, for otherwise appreciable amounts of allyl alcohol and benzyl alcohol should be formed by reaction of the migrating groups (if momentarily free as carbonium ions) with hydroxyl ions. According to this interpretation, the sodium hydroxide has no function in the rearrangement other than to liberate the amine oxides from their salts.

Meisenheimer[3] reported that allyldimethylamine oxide and allyldiethylamine oxide did not rearrange on heating with aqueous sodium hydroxide, but were recovered unchanged except for small amounts which were cleaved into dimethylamine and diethylamine, respectively, and unidentified decomposition products. If the driving force for the rearrangement is a nucleophilic attack of an unshared electron pair of oxygen on the allyl or benzyl group, or the attraction of the positively charged nitrogen of the amine oxide for the electron pair attaching it to the allyl or benzyl group, the rearrangement would be expected to proceed in the aliphatic series as indicated:



A possible explanation for the difference in behavior of allyldialkylamine oxides and allylalkylaniline oxides on heating is the greater tendency of aliphatic amine oxides to hydrate,[5] since combina-

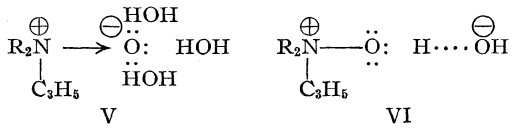
[a] Ref. 3 and Knorr and Roth, *Ber.*, **39**, 1428 (1906), report m. p. 95° for allyldimethylamine picrate (possibly a lower melting dimorphous form). [b] Ref. 3 reports m. p. 94–95.5° for allyldiethylamine picrate. [c] The picrate separated as an oil which failed to crystallize.

tion with water as hydrates such as V or hydroxides (VI) would be expected to reduce the reactivity of the unshared electron pairs of the amine oxide oxygen and interfere with the rearrangements if they proceed in the manner indicated in the equations.



V VI

Accordingly a number of aliphatic allyldialkylamine oxides (I) and benzyldimethylamine oxide (III) were investigated in order to determine whether they would rearrange under appropriate conditions to yield O-allyl-N,N-dialkylhydroxylamines (II) and O-benzyl-N,N-dimethylhydroxylamine (IV), respectively.

In beginning this work, Meisenheimer's observation[3] concerning the stability of allyldimethylamine oxide in alkaline aqueous solution was confirmed. After the amine oxide had been heated at the reflux temperature with approximately 25% aqueous sodium hydroxide for six and one-half hours, 7.4% decomposition to dimethylamine had occurred, as determined by titration of the volatile base formed and isolation of dimethylamine picrate, and 64% of the allyldimethylamine oxide was recovered from the alkaline aqueous solution as the crystalline picrate. The susceptibility of allyldimethylamine oxide to rearrangement then was determined under conditions less favorable for hydration. Allyldimethylamine was converted into the oxide by treatment with 10% aqueous hydrogen peroxide. The excess hydrogen peroxide was decomposed in the presence of platinum foil, and the allyldimethylamine oxide solution was concentrated to a viscous sirup, which was heated at 105–110° for one-half hour. During this period a water-insoluble, volatile product formed. Further heating and distillation completed the isomerization of the amine oxide, and after redistillation the rearrangement product, O-allyl-N,N-dimethylhydroxylamine (II, R = CH_3), was isolated in 51% yield. Its structure was established by analysis, analysis of its picrate and methiodide, and direct comparison (m. p. and mixed m. p.) of these solid derivatives with corresponding derivatives of an authentic sample of O-allyl-N,N-dimethylhydroxylamine prepared by methylation of O-allylhydroxylamine with dimethyl sulfate.

In order to determine whether other allyldialkylamine oxides rearranged in a similar manner, the tertiary amines listed in Table I were first prepared and characterized as solid derivatives (Table II). These amines and benzyldimethylamine were converted to the oxides by treatment with hydrogen peroxide. The use of concentrated aqueous hydrogen peroxide or an organic solvent, to produce homogeneous reaction mixtures, was required for the oxidation of the higher molecular weight amines. Allyldiethylamine was oxidized by 10% aqueous hydrogen peroxide, and allyldi-*n*-propylamine, allyldiisopropylamine and benzyldimethylamine were oxidized with 35% aqueous hydrogen peroxide. Allyldi-*n*-hexylamine re-

quired treatment with 35% aqueous hydrogen peroxide in acetone[6] or oxidation with perbenzoic acid for conversion to the amine oxide. All but one of the amine oxides were obtained in high yield, as indicated by the yields of their picrates (Table III). The yield of allyldi-*n*-hexylamine oxide could not be determined in this manner because its picrate failed to crystallize and its picrylsulfonate was crystallized with difficulty and consequent loss of material.

When the amine oxides were concentrated and heated under reduced pressure at temperatures of 80–165°, rearrangement to trialkylhydroxylamines occurred in each case. It was important to remove the excess hydrogen peroxide rather completely by treatment with platinum before the amine oxide solutions were concentrated. If substantial quantities of hydrogen peroxide remained in the solutions, explosive decomposition occurred in some cases when the residues were heated. The lower molecular weight amine oxides rearranged only after almost all of the water had been removed from their aqueous solutions, while the higher homologs rearranged in the presence of water during the distillation. The trialkylhydroxylamines which were formed were isolated in yields of 51 to 80%, and were differentiated easily from the isomeric, non-volatile amine oxides from which they were prepared by their physical properties (including volatility), and by preparation of solid derivatives.

From these results it is concluded that the rearrangement of allyl and benzyldialkylamine oxides is not essentially different from the rearrangement of allyl and benzylalkylaniline oxides.[2,3,4] It has been shown that the rearrangement takes place readily in the absence of alkali. The fact that removal of most of the water from the alkyldialkylamine oxides facilitates their rearrangement may be interpreted as indicating that hydration (represented in formulas V and VI) interferes with the rearrangement either sterically or by an effect on the dipole moment of the amine oxide or the dielectric constant of the solution. An alternate, less likely explanation which is not consistent with the case of rearrangement with inversion observed previously[4] would be isomerization by a bimolecular process, which would proceed more rapidly at higher concentrations, rather than by an intramolecular route.

Experimental[7]

Tertiary Amines (Table I).—Allyldimethylamine was prepared by a method similar to one described by Weston, Ruddy and Suter.[8] A 25% aqueous solution of dimethylamine (112 g.) and allyl chloride (38.3 g.) was weighed into each of six 8-oz. pressure bottles. To each bottle was added a solution of 4.8 g. of sodium hydroxide in 6 ml. of water. The bottles were capped and shaken with a mechanical shaker for eighteen hours. The mixtures became warm initially and cooled to room temperature within two hours. They were combined in a separatory funnel, and the amine layer was separated and combined with an additional quantity which separated when a solution of 60 g. of potassium hydroxide in 60 ml. of water was added to the aqueous phase. The aqueous solution was distilled, and the material boiling below 85° was added to the amine fraction, which was then distilled through an adiabatic, total condensation, variable take-off type column with a 1.1 × 30 cm. section packed with glass helices.

Allyldiethylamine was prepared by an adaptation of a procedure described by Menschutkin for similar preparations.[9] Allyl bromide (165 g., 1.37 moles) was added slowly with stirring to a solution of diethylamine (200 g., 2.74 moles) in 240 ml. of dry benzene in a 1-l. three-necked flask fitted with a stirrer, dropping funnel, reflux condenser and a thermometer dipping into the liquid. The flask was cooled intermittently to keep the reaction temperature from rising above 45–50°. After the addition was completed, the mixture was heated under reflux in a bath at 80° for two hours. After cooling, 150 ml. of concentrated hydrochloric acid and 100 ml. of water were added. The layers were separated, the benzene layer was extracted with two 50-ml. portions of 10% hydrochloric acid, and the combined acid extracts and aqueous phase were extracted with 50 ml. of benzene. The aqueous solution was made alkaline by adding a solution of 200 g. of sodium hydroxide in 500 ml. of water, and the non-aqueous phase was separated and combined with two 50-

(7) Melting points are corrected and boiling points are uncorrected. In calculation of molecular refractions the Eisenlohr values were used (Eisenlohr, *Z. physik. Chem.*, **75**, 605 (1911)), and 2.48 for nitrogen in the hydroxylamine derivatives (Bruhl, *Ber.*, **26**, 2508 (1893)). We are indebted to Mr. S. M. Nagy and Mrs. Louise W. Spencer for analyses.

ml. ether extracts of the water solution. The combined amine and ether extracts were dried over solid potassium hydroxide and fractionated through a 1.1 × 30 cm. helix-packed column. Other allyldialkylamines listed in Table I were prepared in essentially the same manner as allyldiethylamine. Benzyldimethylamine was obtained in 83% yield by methylation of benzylamine with formaldehyde and formic acid.[10]

Solid derivatives which were prepared from the tertiary amines are listed in Table II. They were made by heating the reactants briefly in 95% alcohol, and were recrystallized from absolute alcohol.

Amine Oxides.—The tertiary amines were converted to the oxides by reaction with hydrogen peroxide according to the following procedures. Small-scale preparations or aliquot portions of larger scale oxidations were treated with picric acid or picrylsulfonic acid in order to characterize the amine oxides which were formed, and to determine their yields by the weights of solid derivatives which were isolated (Table III).

Allyldimethylamine (20 g.) was added slowly to 171 g. (about 100% molar excess) of 10% aqueous hydrogen peroxide in a 500-ml. flask fitted with a stirrer, dropping funnel, thermometer and reflux condenser. During the addition the temperature of the mixture was maintained at 8–10° by cooling with an ice-bath. The turbid mixture became homogeneous after two hours, and was allowed to warm to room temperature and stirred for twelve hours. The solution was extracted with three 50-ml. portions of ether to remove any amine still present. Approximately 12 sq. cm. of platinum foil (cleaned by treatment with boiling dilute nitric acid, heated to redness in a flame, and cooled) was added to the solution to catalyze the decomposition of the excess hydrogen peroxide. The rate of evolution of oxygen decreased after one and one-half hours, and the decomposition was allowed to continue for twenty-four hours at room temperature. The solution was decanted from the platinum into a solution of 53.8 g. (0.24 mole) of picric acid in 1570 ml. of water at 80°. The solution was heated at 70–80° for fifteen minutes, cooled slowly, and after crystallization started was placed in an ice-bath and stirred until the crystallization appeared to be complete. The yield of allyldimethylamine oxide picrate, m. p. 135–136°, was 72.7 g. (94%). Allyldiethylamine oxide picrate was prepared in the same way. Allyldiisopropylamine (41.2 g.) was added to 35% hydrogen peroxide (82.4 g., about 200% molar excess) with stirring but without cooling. After nineteen hours the aqueous layer was separated and the amine was returned to the flask and again stirred with 80 g. of 35% hydrogen peroxide for twenty-one hours. The process was repeated a third time, and after five hours a homogeneous solution was obtained. The excess hydrogen peroxide in the combined aqueous solutions was decomposed by adding platinum foil at 0° and allowing the solution to stand, initially at 0° and finally at room temperature, until the oxygen evolution became very slow. An aliquot portion of the solution was used for the preparation of allyldiisopropylamine oxide picrate by the procedure described above. Allyldi-*n*-propylamine was oxidized in the same manner as its isomer, except that one treatment with 35% hydrogen peroxide proved to be sufficient to complete the oxidation, as evidenced by formation of a homogeneous solution. Allyldi-*n*-propylamine also was converted to the oxide (isolated as the picrate in 89% yield) by treatment with a 7% solution of hydrogen peroxide in *t*-butyl alcohol[11] for two days at room temperature. Allyldi-*n*-hexylamine (5.1 g.) in 21 ml. of acetone was oxidized by heating under reflux with 5 ml. of 35% aqueous hydrogen peroxide for five hours. The solution was cooled, platinum foil was added, and after oxygen evolution became slow the acetone was removed under reduced pressure. Water (15 ml.) was added to the residue, and the mixture (which formed two layers) was extracted with 10 ml. of pentane, which formed a third layer, to remove any allyldi-*n*-hexylamine which might be present. Allyldi-*n*-hexylamine oxide picrylsulfonate was prepared by adding picrylsulfonic acid in acetone, but it was isolated in poor yield, probably because of difficulties encountered in its crystallization. Allyldi-*n*-hexylamine oxide also was prepared by oxidation of the amine with perbenzoic acid in chloroform solution, and isolated in poor yield as the picrylsulfonate. Benzyldimethylamine (25 g.) was stirred with 35 g. of 35% aqueous hydrogen peroxide at room temperature. The mixture became homogeneous after one hour, and was stirred overnight. Excess hydrogen peroxide was decomposed by adding clean platinum foil and allowing the solution to stand until oxygen evolution became slow, and an aliquot portion of the solution was used for the preparation of benzyldimethylamine oxide picrate.

Stability of Allyldimethylamine Oxide in Alkaline Aqueous Solution.—Allyldimethylamine oxide hydrochloride was prepared from the picrate by a method used by Meisenheimer for similar conversions.[12] Allyldimethylamine oxide picrate (30 g., 90.9 millimoles) was shaken with 70 ml. of nitrobenzene, 70 ml. of ether and 15 ml. of concentrated hydrochloric acid until the picrate dissolved. Water (1 ml.) was added to facilitate separation of the layers, and the acid layer was withdrawn and combined with three successive 3-ml. portions of concentrated hydrochloric acid used to extract the ether–nitrobenzene solution. The acid solution was extracted with three 25-ml. portions of ether and diluted to 250 ml. with water. A Kjeldahl determination on an aliquot of this solution showed the presence of 1.080 g. of nitrogen (equivalent to 77.1 millimoles) in the solution (85% yield of allyldimethylamine oxide hydrochloride from the picrate). The allyldimethylamine oxide hydrochloride solution was placed in a 500-ml. round-bottomed flask, which was attached to a reflux condenser connected to two receivers in series containing standard hydrochloric acid. The inlet tubes to these receivers dipped below the surface of the acid, so that any base distilled into them would be absorbed. A solution of 120 g. of sodium hydroxide in 150 ml. of water was added to the allyldimethylamine oxide hydrochloride solution and the mixture was heated under reflux for six hours. After this period steam was passed through the reflux condenser while the basic solution was boiled for thirty minutes, so that any volatile bases would distil into the standard acid. The standard acid in the first receiver was diluted to 250 ml. Titration of aliquots showed that 5.6 millimoles of a volatile base had been neutralized, and Kjeldahl determinations on aliquots showed the presence of 0.081 g. of nitrogen (equivalent to 5.8 millimoles), in agreement with the acidimetric titration. The standard acid in the second receiver was found to have absorbed a negligible amount of volatile base, and was discarded. The volatile base was liberated by adding a solution of 30 g. of sodium hydroxide in 100 ml. of water to the acid solution (combined with the titrated samples), and steam distilled with about 40 ml. of water into a solution of 1.33 g. of picric acid in 26 ml. of alcohol. Dimethylamine picrate (1.5 g.) was obtained after concentration, and after recrystallization weighed 1.42 g. (5.2 millimoles), m. p. and mixed m. p. with a known sample 156–157°.

The original alkaline solution remaining after the period of reflux and distillation of the volatile base was neutralized with concentrated hydrochloric acid, concentrated to a volume of less than 1 l., and diluted to 1 l. with water. A Kjeldahl determination on an aliquot showed the presence of 0.985 g. of nitrogen (equivalent to 70.3 millimoles). After preliminary experiments on methods of isolating allyldimethylamine oxide picrate from small aliquots of the solution, the remainder was concentrated to dryness under reduced pressure, yielding sodium chloride containing some organic material. This residue was dried by refluxing with benzene and removing the water in the condensate with a continuous separator, and the benzene was then removed under reduced pressure. The residue

was extracted thoroughly with absolute alcohol, which was concentrated, leaving a residue which was dried with benzene as before and re-extracted with 50 ml. of absolute alcohol. The alcohol solution was concentrated to 10 ml., diluted with 50 ml. of water, and warmed with 14.5 g. of freshly precipitated silver oxide. The silver chloride which was formed and excess silver oxide were removed by filtration, and a solution of 15.9 g. of picric acid in 325 ml. of water at 80° was added to the filtrate. The allyldimethylamine oxide picrate which separated was recrystallized from alcohol; yield 14.8 g., m. p. 135.2–136.2°, which was not depressed by a known sample. This yield amounted to 64% of the amount of allyldimethylamine oxide hydrochloride employed, taking into account the aliquots removed for analyses and preliminary experiments.

Rearrangement of Allyldimethylamine Oxide to O-Allyl-N,N-dimethylhydroxylamine.—An aqueous solution of allyldimethylamine oxide prepared by oxidizing 20 g. (0.24 mole) of allyldimethylamine with 10% aqueous hydrogen peroxide, followed by decomposition of the excess hydrogen peroxide in the presence of platinum, was concentrated to a thick sirup under reduced pressure at a bath temperature of 60–65°. Two 50-ml. portions of absolute alcohol, three 50-ml. portions of benzene and finally 50 ml. of absolute alcohol were added and distilled under reduced pressure in order to remove water from the residue. The resulting pale yellow, viscous sirup was heated in a nitrogen atmosphere under a reflux condenser at a bath temperature of 105–110° for thirty minutes. The liquid became dark yellow and separated into two layers. The condenser was set for distillation, and the liquid was distilled by gradually raising the bath temperature to 140° during a period of four hours. The distillate, which collected in two layers, was separated, and the aqueous layer was extracted with 10 ml. of ether. The organic layer and the ether extract were combined, dried over potassium hydroxide and distilled through an adiabatic, total condensation, variable take-off type column with a 1.5 × 15 cm. section packed with glass helices. The yield of O-allyl-N,N-dimethylhydroxylamine was 12.2 g. (51%), b. p. 83°; $n^{25}D$ 1.3982; d^{25}_4 0.7939; M_D calcd. 30.05, found 30.77.

Anal. Calcd. for $C_5H_{11}NO$: C, 59.37; H, 10.96; N, 13.85. Found: C, 59.15; H, 10.73; N, 13.98.

O-Allyl-N,N-dimethylhydroxylamine picrate was prepared by heating the reactants in alcohol solution and was recrystallized from a mixture of alcohol and ether; m. p. 92.5–93.5°.

Anal. Calcd. for $C_{11}H_{14}N_4O_8$: C, 40.00; H, 4.27; N, 16.97. Found: C, 39.80; H, 4.26; N, 17.07.

O-Allyl-N,N-dimethylhydroxylamine (1 g.) and methyl iodide (1.4 g.) reacted to give a white, crystalline methiodide. The mixture was allowed to stand in a refrigerator for twenty-four hours, the solid was pressed dry on a suction filter, and recrystallized from a mixture of absolute alcohol and dry ether; m. p. 129° (dec.).

Anal. Calcd. for $C_6H_{14}NOI$: C, 29.64; H, 5.81; N, 5.76; I, 52.21. Found: C, 29.25; H, 5.95; N, 5.62; I, 53.00.

Synthesis of O-Allyl-N,N-dimethylhydroxylamine for Comparison with the Rearrangement Product.—Hydroxyurethan was prepared according to the method of Jones[13] and alkylated with allyl bromide under conditions similar to those employed previously.[4,13,14] It was found to be important to use moderately dilute solutions in the alkylation in order to obtain a high proportion of O-allylhydroxyurethan in the product; in concentrated solution the yield of this compound was less than 5% and O,N-diallylhydroxyurethan was the principal product. Hydroxyurethan (159 g.) in 330 ml. of absolute alcohol was converted into the potassium salt with a solution of 86.8 g. of potassium hydroxide in 330 ml. of absolute alcohol. Allyl bromide (195.5 g.) was added with cooling at room temperature, and the mixture was heated under reflux for two hours. After separation of the two products with 10% sodium hydroxide[4] the acidic fraction yielded 134.2 g. (61%) of O-allylhydroxyurethan, b. p. 107° (12.5 mm.), $n^{25}D$ 1.4429, and the neutral fraction yielded 25.2 g. of O,N-diallylhydroxyurethan, b. p. 91–92° (8.5 mm.), $n^{25}D$ 1.4436. O-Allylhydroxyurethan (134 g.) was hydrolyzed to O-allylhydroxylamine by heating with a solution of 120 g. of potassium hydroxide in 280 ml. of water for two hours under reflux. The product was steam distilled into dilute hydrochloric acid, and O-allylhydroxylamine hydrochloride was isolated by concentration under reduced pressure. After twice adding absolute alcohol and removing it under reduced pressure the yield was 91 g. (90%), m. p. 169–170°. After recrystallization from absolute alcohol and dry ether the m. p. was 170.6–170.8°.[4,15]

Freshly distilled dimethyl sulfate (52 g.) was added slowly with stirring and cooling to O-allylhydroxylamine hydrochloride (22.5 g.) in 200 ml. of 10% aqueous sodium hydroxide. The solution became turbid and two layers separated within three-quarters of an hour. An additional 5.2 g. of dimethyl sulfate and 40 ml. of 10% sodium hydroxide was added, and the mixture was heated under reflux for one-half hour and stirred at room temperature for twelve hours. The solution was extracted with 50- and 25-ml. portions of ether, which were dried over sodium sulfate and distilled. The O-allyl-N,N-dimethylhydroxylamine was converted into solid derivatives for comparison with derivatives prepared from O-allyl-N,N-dimethylhydroxylamine obtained by rearrangement. O-Allyl-N,N-dimethylhydroxylamine picrate was recrystallized from absolute alcohol; m. p. 92.6–93°, which was not depressed by mixture with the picrate obtained from the rearrangement product.

Anal. Calcd. for $C_{11}H_{14}N_4O_8$: C, 40.00; H, 4.27; N, 16.97. Found: C, 39.81; H, 4.23; N, 17.36.

Another sample of the O-allyl-N,N-dimethylhydroxylamine prepared by this synthesis was converted to the methiodide, which was recrystallized from a mixture of absolute alcohol and dry ether; m. p. and mixed m. p. with the methiodide prepared from the rearrangement product 129° (dec.).

Anal. Calcd. for $C_6H_{14}NOI$: C, 29.64; H, 5.81; N, 5.76; I, 52.21. Found: C, 29.60; H, 5.84; N, 5.66; I, 52.11.

Both samples of the methiodide decomposed suddenly within fifteen seconds when placed in a melting-point bath heated to 128–129°. If placed in the bath at a temperature below 120°, they darkened slowly and charred between 200 and 250°. If placed in the bath at temperatures between 120 and 128° they decomposed, but not within fifteen seconds and not always at the same temperature.

O-Allyl-N,N-diethylhydroxylamine.—An aqueous solution prepared by oxidizing 50 g. of allyldiethylamine with 10% aqueous hydrogen peroxide was treated with platinum to decompose the excess hydrogen peroxide and concentrated to a thick pale yellow sirup. The flask containing the sirup was attached to a condenser set for distillation, nitrogen was introduced through a capillary, and the flask was immersed in a bath at 125°. O-Allyl-N,N-diethylhydroxylamine began to distil along with water remaining in the amine oxide sirup within fifteen minutes, and the distillation was continued by raising the bath temperature as necessary until only a small dark residue remained. The product was separated, combined with two 15-ml. ether extracts of the aqueous layer, and dried over magnesium sulfate. The solution was distilled through a total condensation type column with a 1.5 × 15 cm. section packed with glass helices. The yield of O-allyl-N,N-diethylhydroxylamine was 33.9 g. (59%), b. p. 126°; $n^{25}D$ 1.4118; d^{25}_4 0.8018; M_D calcd. 39.28, found 40.07.

Anal. Calcd. for $C_7H_{15}NO$: C, 65.09; H, 11.70; N, 10.84. Found: C, 65.18; H, 11.60; N, 10.66.

O-Allyl-N,N-diethylhydroxylamine picrate was pre-

pared as a derivative and recrystallized from absolute alcohol; m. p. 78.8–79.4°.

Anal. Calcd. for $C_{13}H_{18}N_4O_8$: C, 43.58; H, 5.06; N, 15.64. Found: C, 43.22; H, 5.13; N, 15.42.

In two preparations, the rearrangement was conducted by concentrating the aqueous solution of allyldiethylamine oxide at atmospheric pressure. The solution was added from a dropping funnel to a distilling flask immersed in a bath at 150–155° as rapidly as water distilled from the solution. The O-allyl-N,N-diethylhydroxylamine distilled with steam after most of the water had distilled. The distillate was extracted with ether, which was dried over magnesium sulfate and fractionated. The yields were poorer (42 and 44%) than in the preparations in which the amine oxide was concentrated under reduced pressure before rearrangement.

O-Allyl-N,N-diisopropylhydroxylamine.—The aqueous solution of allyldiisopropylamine oxide (277 ml.) described under the preparation of the picrate was divided, 25 ml. being used for preparation of the picrate and the remainder for rearrangement according to the following procedure. The solution was heated in an oil-bath at 125° for twenty minutes, and then distilled rapidly at a pressure of 75 mm. The organic layer was separated from the distillate and combined with two 25-ml. extracts of the aqueous layer. After drying over magnesium sulfate the product was distilled through the total condensation type column with a 1.5 × 16 cm. section packed with glass helices. The yield of O-allyl-N,N-diisopropylhydroxylamine was 27.5 g. (67%), b. p. 92–93° (100 mm.); $n^{25}D$ 1.4248; d^{25}_4 0.8223; MD calcd. 48.52, found 48.88.

Anal. Calcd. for $C_9H_{19}NO$: C, 68.74; H, 12.18; N, 8.91. Found: C, 68.58; H, 12.23; N, 9.16.

O-Allyl-N,N-diisopropylhydroxylamine picrate decomposed on attempted recrystallization but was analytically pure as it crystallized on preparation in 95% alcohol; m. p. 86.4–87.2°.

Anal. Calcd. for $C_{15}H_{22}N_4O_8$: C, 46.63; H, 5.74; N, 14.50. Found: C, 46.41; H, 6.01; N, 14.59.

O-Allyl-N,N-di-*n*-propylhydroxylamine.—An aqueous solution of allyldi-*n*-propylamine oxide was prepared by oxidizing 50 g. of allyldi-*n*-propylamine with 35% hydrogen peroxide, treated with platinum to decompose hydrogen peroxide, and rearranged under the conditions described for preparation of O-allyl-N,N-diisopropylhydroxylamine. The yield of O-allyl-N,N-di-*n*-propylhydroxylamine was 44.5 g. (80%), b. p. 100–101° (100 mm.); $n^{25}D$ 1.4209; d^{25}_4 0.8125; MD calcd. 48.52, found 49.07.

Anal. Calcd. for $C_9H_{19}NO$: C, 68.74; H, 12.18; N, 8.91. Found: C, 68.78; H, 12.24; N, 9.05.

O-Allyl-N,N-di-*n*-propylhydroxylamine picrylsulfonate was prepared by heating the reactants in 95% alcohol and was recrystallized from the same solvent; m. p. 106.8–107.7°.

Anal. Calcd. for $C_{15}H_{22}N_4O_{10}S$: C, 40.00; H, 4.92; N, 12.44. Found: C, 40.27; H, 4.96; N, 12.47.

O-Allyl-N,N-di-*n*-hexylhydroxylamine.—Allyldi-*n*-hexylamine (5.1 g.) was oxidized with hydrogen peroxide in acetone by the procedure described under preparation of the amine oxide picrate. An aqueous suspension (two layers) of the amine oxide was concentrated under reduced pressure, with much difficulty because of foaming. The residue was heated with an electric heating mantle and distilled at 1 mm., also with foaming. The organic layer of the distillate was separated, combined with ether extracts of the aqueous layer, and redistilled through a short Vigreux column at 0.5 mm. Foaming interfered with the distillation, which was accomplished by heating the liquid as little as possible and directing an infrared lamp at its surface. The yield of O-allyl-N,N-di-*n*-hexylhydroxylamine was 3.73 g. (68%), b. p. 77–81° (0.5 mm.). A redistilled analytical sample had b. p. 93–94° (1 mm.); $n^{25}D$ 1.4381; d^{25}_4 0.8245; MD calcd. 76.23, found 76.79.

Anal. Calcd. for $C_{15}H_{31}NO$: C, 74.62; H, 12.94; N, 5.80. Found: C, 74.93; H, 12.87; N, 5.70.

Unsuccessful attempts were made to prepare the following derivatives of O-allyl-N,N-di-*n*-hexylhydroxylamine in crystalline form: picrate, picrylsulfonate, perchlorate, dilituarate, styphnate, methiodide and methyl *p*-toluenesulfonate.

O-Benzyl-N,N-dimethylhydroxylamine.—Benzyldimethylamine (25 g.) was oxidized by stirring with 35 g. of 35% aqueous hydrogen peroxide for five hours, while the mixture was immersed in a water-bath at room temperature to dissipate the heat of reaction. The solution was diluted with 25 ml. of water and stirred in the presence of platinum foil for two days. The aqueous solution was extracted with 10 ml. of pentane and concentrated under reduced pressure with a bath temperature of 45°. The residual sirup was dried by adding three successive 25-ml. portions of benzene and removing them under reduced pressure. The residue was distilled at a bath temperature of 85–165° and 15–10 mm. The organic layer was separated from the distillate, combined with ether extracts of the aqueous layer, and distilled through an adiabatic, total condensation type column with a 1.5 × 15 cm. Vigreux section. The yield of O-benzyl-N,N-dimethylhydroxylamine was 17 g. (61%), b. p. 79–80° (15 mm.); $n^{25}D$ 1.4920; d^{25}_4 0.9474; MD calcd. 45.38; found 46.30.

Anal. Calcd. for $C_9H_{13}NO$: C, 71.49; H, 8.66; N, 9.26. Found: C, 71.81; H, 8.76; N, 9.16.

O-Benzyl-N,N-dimethylhydroxylamine picrate was prepared by heating the reactants in 95% alcohol and was recrystallized from the same solvent; m. p. 111.6–112.4°.

Anal. Calcd. for $C_{15}H_{16}N_4O_8$: C, 47.37; H, 4.24; N, 14.73. Found: C, 47.10; H, 4.45; N, 14.96.

Summary

Allyldialkylamine oxides rearrange on heating, yielding O-allyl-N,N-dialkylhydroxylamines. Allyldimethylamine oxide does not undergo the rearrangement in alkaline aqueous solution, but does rearrange on heating after most of the water has been removed from its aqueous solution by distillation. Benzyldimethylamine oxide rearranges in a similar manner to yield O-benzyl-N,N-dimethylhydroxylamine. The rearrangement provides a satisfactory synthetic route for the preparation of O-allyl-N,N-dialkylhydroxylamines and O-benzyl-N,N-dimethylhydroxylamine.

Reaction of Chloroalkyl Sulfides with Sodium[1]

BY CHARLES D. HURD AND KENNETH WILKINSON

The present problem deals with the behavior of several chloroalkyl sulfides with sodium and other metals. Simple alkyl halides are known to react[2] with sodium, giving first the alkylsodium, RNa, then the paraffin, R–R. Some α,ω-dihalides behave similarly, the products of reaction[3] of 1,10-dichlorodecane in ether with sodium being decane, eicosane, triacontane, and so on up to heptacontane, $C_{70}H_{142}$. The only chloroalkyl sulfide whose behavior toward sodium has been reported is 2-chloroethyl sulfide or mustard gas. Like 1,10-dichlorodecane, it also is an α,ω-dihalide, but it is reported to be inert toward sodium either in ether[4] or in refluxing xylene.[5]

Mustard gas was reinvestigated in the present work along with several other chloro sulfides. The list includes sulfides of the general formula $RS(CH_2)_nCl$ wherein R was phenyl, ethyl, *n*-, *s*-, and *t*-butyl, 2-chloroethyl and 3-chloropropyl; and *n* was 1, 2, 3 or 4. These compounds were generally synthesized by reaction of thionyl chloride on the corresponding hydroxy sulfide. Three of the chlorides were new: *s*-butyl 2-chloroethyl sulfide, *t*-butyl 2-chloroethyl sulfide and *n*-butyl 4-chlorobutyl sulfide. The hydroxyalkyl sulfides from which these three compounds were made were new also. They were synthesized from the sodium alkyl sulfide by reaction with either ethylene chlorohydrin or tetramethylene chlorohydrin.

The yield of *t*-butyl 2-chloroethyl sulfide was considerably lower than that for the *n*- and *s*-butyl isomers, pointing to extensive cleavage at the C–S bond. Supporting this statement is the fact that a 25% yield of *t*-butyl chloride was isolated as a by-product.

Reaction of the alkyl (or aryl) 2-chloroethyl sulfides with sodium wire in refluxing toluene was rapid. A purple color formed on the surface of sodium and a gas was evolved, namely, ethylene. The non-volatile reaction products included sodium chloride, sodium alkyl (or aryl) sulfide, and 1,2-bis-(alkylthio)-ethane, $RSCH_2CH_2SR$. None of the 1,4-bis-(alkylthio)-butane, $RSCH_2CH_2CH_2CH_2SR$, was obtained, showing that no Wurtz reaction was involved. The following three equations provide an explanation for the four major products isolated.

$$RSCH_2CH_2Cl + 2Na \longrightarrow RSNa + C_2H_4 + NaCl \quad (1)$$

$$RSNa + RSCH_2CH_2Cl \longrightarrow RSCH_2CH_2SR + NaCl \quad (2)$$

$$RSCH_2CH_2SR + 2Na \longrightarrow 2RSNa + C_2H_4 \quad (3)$$

A transient alkylsodium, $RSCH_2CH_2Na$, may be an intermediate step in equation 1 but, if so, its decomposition into RSNa + C_2H_4 took precedence over a tendency for a reaction of the Wurtz type.

The rapidity of these reactions is portrayed graphically in Fig. 1, all experiments being carried out in refluxing toluene. No curve for the *t*-butyl analog is included in Fig. 1, since it was impracticable, because of the vigor of the reaction, to add the sulfide all at once as was done with the others. After the initial rapid spurt of gas, the *t*-butyl compound also gave a slow, prolonged evolution of ethylene.

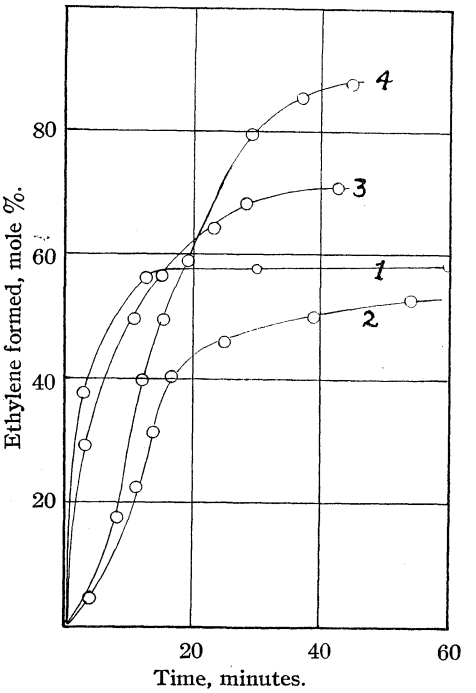

Fig. 1.—Effect of R on the reaction of $RSCH_2CH_2Cl$ with sodium: 1, R, ethyl; 2, R, butyl; 3, R, *s*-butyl; 4, R, phenyl.

All the curves in Fig. 1 depict experiments employing a mole ratio of sodium to the chloro sulfide of about 4:1. Lessening this ratio of 1.5:1 slackened the rate of evolution of ethylene from phenyl 2-chloroethyl sulfide below that of curve 2 for the first thirty-five minutes, passing curve 1 at fifty minutes, finally reaching 71 mole % of ethylene in two hours. This is considerably below the 90% mark reached in one hour when the ratio was 4.3:1.

Support for equation 3 was obtained by treating 1,2-bis-(phenylthio)-ethane with sodium, again in hot toluene. Ethylene was evolved steadily, though slowly; about 27 mole per cent. was collected the first hour and 62% after five hours.

Correlation may be drawn between the formation of ethylene in equation 1 and the last step of the well-known Swallen–Boord synthesis of olefins by reaction of ethyl 2-bromoalkyl ethers with zinc

$$BrCH_2CHROEt + Zn \longrightarrow CH_2{=}CHR + BrZnOEt$$

Zinc dust and zinc amalgam both were found capable of liberating ethylene from phenyl 2-chloroethyl sulfide. Magnesium did not react. As with sodium, the isolated products were ethylene, sodium phenyl sulfide, sodium chloride and 1,2-bis-(phenylthio)-ethane. The yield of ethylene, however, was low. Only 30–37 mole per cent. appeared during the first hour, and only 39–45% after five hours. Thiophenol was not found. This suggests that equation 2 consumed all the thiophenol derivative formed in equation 1, with no cleavage by zinc according to equation 3.

In studying the effect of the distance of halogen from sulfur in $RS(CH_2)_nCl$, butyl chloromethyl sulfide was selected for $n = 1$. This was the only example found where any Wurtz product was obtained, but even here only a trace of 1,2-bis-(butylthio)-ethane was found. The chief product was the mercaptal, bisbutylthiomethane. Lesser quantities of mercaptan and gas appeared also. Butylene was the major gaseous product, ethylene and paraffins being lesser products.

The reaction of 3-chloropropyl compounds with sodium produced cyclopropane, not propylene. Ethyl 3-chloropropyl sulfide, for example, gave rise to sodium chloride, cyclopropane, sodium ethyl sulfide and 1,3-bis-(ethylthio)-propane. Phenyl 3-chloropropyl sulfide yielded cyclopropane, sodium phenyl sulfide and bis-(phenylthio)-propane. There was no formation of Wurtz products. These reaction products are well summarized by an extension of equations 1–3.

The reaction of sodium with phenyl 4-chlorobutyl sulfide was less clear cut. Although the phenyl compound is more stable than the dialkyl analogs,[6] it tends to undergo ring closure, forming a sulfonium chloride. In its reaction with sodium, the chief gas evolved was *n*-butane (not cyclobutane). Appreciable quantities of ethylene and 1-butene were formed also. Other identified products of the reaction were sodium phenyl sulfide, 1,4-bis-(phenylthio)-butane, and sodium chloride. To show that the butane did not arise by hydrogen transfer from an aromatic hydrocarbon, the reaction of butyl 4-chlorobutyl sulfide with sodium in butyl ether also produced butane. This formation of butane resembles the formation of decane[3] from 1,10-dichlorodecane.

Two symmetrical chloroalkyl sulfides were studied also, namely, 2-chloroethyl sulfide and 3-chloropropyl sulfide. This work is of interest in view of the reported non-reaction of sodium and mustard gas. We have confirmed Helfrich and Reid's observation[4] of non-reaction in ethyl ether if strictly anhydrous ether was used, but reaction was initiated by using ether which contained only 0.2% of ethanol. Reaction in benzene, toluene or butyl ether at temperatures of 80–110° was slower than with the alkyl 2-chloroethyl sulfides but so definite that it is difficult to understand the reported non-reaction in hot xylene.[5] About twelve hours was necessary to complete the reaction in hot toluene, whereas it took one week in ethyl ether at 25°.

In refluxing toluene, ethylene was evolved to the extent of 148 mole per cent. in twelve hours. The sodium wire assumed a brilliant purple color which did not change color on treatment with alcohol but did change in water to a pale yellow, very insoluble solid melting at 158–160°. It contained no chlorine. Here again, there was no evidence for a product of the Wurtz type. The latter would demand a product with a carbon–sulfur ratio of 4:1, whereas a 2:1 ratio was found.

Equation 1 evidently holds for 2-chloroethyl sulfide as well as for the unsymmetrical analogs. If but one of the chloroethyl groups reacts with sodium, the products would be ethylene and sodium 2-chloroethyl sulfide (A), $ClCH_2CH_2SNa$, whereas if both groups participate, it would lead to sodium sulfide. Actually, some sodium sulfide was formed. The chief solid product, however, was the solid mentioned earlier. It was a polymer with this recurring unit, $(-CH_2CH_2S-)_n$. This might result by reaction of A with itself or with 2-chloroethyl sulfide (equation 2). The extent of equation 3 cannot be estimated but probably some chain-splitting at the C–S bonds occurred.

Oxidation of the polymer by nitric acid yielded a water-soluble polysulfoxide, with apparently a sulfonic acid end group. Oxidation by hydrogen peroxide gave rise to a water-insoluble substance which was believed to be a polysulfone.

Bennett[7] has described a polymer, $(C_2H_4S)_n$, of m. p. 177–180°, made by reaction of 2-hydroxy-1-ethanethiol with hydrochloric acid. Our repetition of Bennett's synthesis yielded a substance of m. p. 158–165°. Apparently, therefore, the polymers from the two sources are similar, although they may not be identical.

3-Chloropropyl sulfide also evolved a gas (cyclopropane) and produced a polymer by reacting with sodium in hot toluene. Gas evolution was complete in less than one hour.

$$(ClCH_2CH_2CH_2)_2S \xrightarrow{Na} [RSCH_2CH_2CH_2Na] \longrightarrow RSNa + \begin{array}{l} CH_2{-}CH_2 \\ \quad\diagdown\diagup \\ \quad\ CH_2 \end{array}$$

The polymer differed from that from 2-chloroethyl sulfide in melting lower (56°) and in being

(6) Bennett, Heathcoat and Mosses, *J. Chem. Soc.*, 2567 (1929).

(7) Bennett, *ibid.*, **121**, 2139 (1922).

soluble in hydrocarbon solvents. This polymer contained the recurring unit $(-CH_2CH_2CH_2S-)_n$.

Preliminary experiments with 2-chloroethyl ether (not sulfide) revealed that its reaction with sodium also liberates ethylene. Reaction was faster than with the sulfur analog. When 0.077 mole of this ether reacted with 0.165 mole of sodium wire in boiling toluene there was formed 0.060 mole of ethylene in two hours. A polymeric substance was formed which was soluble in water, alcohol or acetone.

Experimental Part

Preparation of Chloro Sulfides.—These compounds were prepared as described in the literature: 2-chloroethyl sulfide,[9] ethyl 3-chloropropyl sulfide,[8] butyl chloromethyl sulfide,[11] phenyl 3-chloropropyl sulfide,[14] phenyl 4-chlorobutyl sulfide,[6] 3-chloropropyl sulfide.[12] Supplementary information as shown was obtained for ethyl 2-chloroethyl sulfide[15] (60% yield, b. p. 69–73° (37 mm.)), butyl 2-chloroethyl sulfide[10] (74% yield, b. p. 98–100° (26 mm.)), phenyl 2-chloroethyl sulfide[13] (97% yield, b. p. 127–129° (6 mm.)).

Alkyl Hydroxyalkyl Sulfides.—Sodium was dissolved in a sevenfold weight of absolute alcohol. An equivalent portion of mercaptan (RSH: R = *s*-Bu, *t*-Bu, *n*-Bu) was added, followed by gradual addition of 1.1 equivalents of the chlorohydrin ($ClCH_2CH_2OH$ or $Cl(CH_2)_4OH$). After refluxing up to one hour, the solution was filtered and distilled. These products were obtained:

I. ***s*-Butyl 2-hydroxyethyl sulfide**, yield 44%, b. p. 105–108° (42 mm.).

II. ***t*-Butyl 2-hydroxyethyl sulfide**, yield 85%, b. p. 111–114° (45 mm.).

Anal. Calcd. for $C_6H_{14}OS$: C, 53.50; H, 10.58. Found: C, 53.73; H, 10.46.

III. **Butyl 4-hydroxybutyl sulfide**, yield 60%, b. p. 129–130° (6 mm.).

Anal. Calcd. for $C_8H_{18}OS$: C, 59.26; H, 11.18. Found: C, 60.02; H, 11.15.

Halogenation.—A small excess of thionyl chloride was added to the above hydroxy compounds. It was added directly, dropwise, to I and II. The product from I was distilled after thirty minutes of refluxing; yield 58%, b. p. 98–100° (40 mm.). That from II was allowed to stand overnight, distilled, and redistilled; yield, 30%, b. p. 85–88° (32 mm.). There was much higher boiling residue. Eight grams of *t*-butyl chloride from 39 g. of II was found in the cold trap.

III was diluted with 1.6 volumes each of carbon tetrachloride and dimethylaniline before addition of thionyl chloride; after refluxing the mixture for thirty minutes, it was acidified (hydrochloric acid) and the non-aqueous layer distilled. A 20% yield of crude butyl 4-chlorobutyl sulfide was collected at 120–124° (10 mm.). Purity was only 70% by halogen analysis. This instability compares with that of ethyl 4-chlorobutyl sulfide,[6] which immediately isomerized to the sulfonium chloride and could not be distilled without decomposition. When our hydroxy sulfide was treated with concd. hydrochloric acid as in the synthesis of mustard gas, reaction was rapid. There was formed a water-soluble sulfonium chloride which gave a characteristic yellow precipitate with picric acid.

Anal. Butyl 2-chloroethyl sulfides. *s*-Butyl. Calcd. for $C_6H_{13}ClS$: C, 47.20; H, 8.51. Found: C, 46.26; H, 8.72. *t*-Butyl. Found: C, 47.12; H, 8.95.

Reaction of Chloro Sulfides.—The reaction of the various chloro sulfides with sodium (or zinc) was carried out in a closed system consisting of a reaction flask (100-ml.) attached to a reflux condenser at the top of which was a dropping funnel and a delivery tube leading to a 10-ml. trap at −78°. In turn, this trap was connected to an Orsat gas analyzer. The cold trap was omitted in the experiments involving the 3-chloropropyl and 4-chlorobutyl compounds. The gas evolved was collected over mercury. A controlled rate of heating of the reaction flask by an electrically controlled oil-bath permitted an accurate measurement of the gas evolved. The volume of gas was plotted against time to indicate the speed of the reaction. Whenever the off gas had a volume larger than 100 ml., it was flushed into a collection bulb over water and retained for analytical purposes.

A typical example for the reaction of butyl 2-chloroethyl sulfide with sodium indicates the general technique. A mixture of 50 ml. of dry toluene and 2.3 g. of sodium wire was refluxed until there was no volume change in the gas collection bulb (five minutes). As long as the refluxing was gentle, the sodium remained as a molten wire presenting a large surface. When 7.023 g. of butyl 2-chloroethyl sulfide was drawn into the reaction flask and washed in with three 1-ml. portions of toluene without the admission of air, a reaction started immediately and a gas (ethylene) was evolved at a moderate rate. A faint fleeting blue color developed on the surface of the sodium wire. Over a period of ninety-nine minutes 580 ml. (S. T. P.) of a gas was collected at a measured rate. The last portion of the evolved gas was identified as ethylene by its absorption in 15% fuming sulfuric acid but not in 88%; reaction of 100 cc. of gas with liquid bromine produced 1 ml. of ethylene bromide, b. p. 128–130°, $n^{23}D$ 1.5358 (lit. b. p. 131°, $n^{20}D$ 1.5379).

The toluene in the reaction flask was decanted from the solid as quantitatively as possible, the excess sodium destroyed with ethanol and combined with a water extract of the toluene. This aqueous solution of chloride and mercaptide ion was diluted volumetrically and aliquots titrated for quantitative data. In the chloride analysis an aliquot was warmed for ten minutes with 30% hydrogen peroxide to destroy the mercaptan, the solution acidified with nitric acid, zinc oxide added as a buffer, and the aliquot titrated with standard silver nitrate using dichlorofluorescein as indicator. Another aliquot was acidified with hydrochloric acid and titrated with standard iodine solution to determine the mercaptan content. The toluene layer was evaporated to 10 ml. on a steam-bath then in an oil-bath at 150°. The remaining crude material was shown to be bis-(butylthio)-ethane by its boiling point (160–161° at 20 mm.) and by oxidation in glacial acetic acid with 30% hydrogen peroxide to the disulfone, m. p. 179°; lit. m. p. 180°.

Table I indicates the products isolated by reactions carried out in refluxing toluene with a variety of chloro sulfides.

Identification of Gaseous Products. Ethylene.—This gas was uncondensed in the −78° trap. When diluted with an equal volume of air, it was insoluble in 88% sulfuric acid but dissolved completely after three passes into fuming (15%) sulfuric acid. It dissolved readily in liquid bromine, forming ethylene bromide; b. p. 129–130°, $n^{20}D$ 1.5374.

Cyclopropane.—A molecular weight determination on a sample of the gas gave a value of 42, which corresponds to C_3H_6. That it was cyclopropane and not propylene was confirmed by its reactivity toward sulfuric acid and its sluggishness toward bromine. When the gas was diluted with an equal volume of air, it dissolved rapidly in 88% sulfuric acid. Practically the entire sample dissolved in the first pass. Propylene, in contrast, requires several passes for complete solution. After twelve passes through 76% sulfuric acid, this gas was 92% absorbed, whereas a 1:1 propylene–air mixture was only 56% absorbed.

Cyclopropane also is known to react sluggishly with

TABLE I

CHLOROALKYL SULFIDES AND METALS

Sulfide	Mole	Metal, g.		Time, min.	Products isolated, moles: Gas		RSNa	Cl⁻	RS(CH₂)ₙSR
Ethyl 2-chloroethyl	0.0231	Sodium	1.2	60	Ethylene	0.0135	0.0034	0.0231	0.0047
Butyl 2-chloroethyl	.0460	Sodium	2.3	99	Ethylene	.0258	.0084	.0460	.0204
s-Butyl 2-chloroethyl	.0200	Sodium	1.5	43	Ethylene	.0141	.0084	.0200	.0058
t-Butyl 2-chloroethyl	.0336	Sodium	1.8	90	Ethylene	.0204	.0067	.0336	.0120
Phenyl 2-chloroethyl	.0197	Sodium	2.0	72	Ethylene	.0179	.0175	.0197	....
Phenyl 2-chloroethyl	.0197	Sodium	0.7	105	Ethylene	.0139	.0089	.0196	.0049
Butyl chloromethyl	.0480	Sodium	4.0	30	Ethylene	.0010	.0032	.0483	.016[a]
					Butene	.0025			
					Saturates	.0019			
Ethyl 3-chloropropyl	.0450	Sodium	3.1	35	Cyclopropane	.0293	.023	.044	.012
Phenyl 3-chloropropyl	.0228	Sodium	2.3	63	Cyclopropane	.0135	.0158	.0230	.0038
Phenyl 4-chlorobutyl	.0186	Sodium	2.0	85	Ethylene	.0009	.0089	.0190	.0057
					Butene	.0012			
					Butane	.0039			
Phenyl 2-chloroethyl	.015	Zinc	4.2	300	Ethylene	.0061	None	.0146	....
Phenyl 2-chloroethyl	.0393	Zinc amalgam	10.0	65	Ethylene	.0154	None	.0391	-
2-Chloroethyl	.0035	Sodium	1.8	720	Ethylene	.0052	....	....	[b]
3-Chloropropyl	.0094	Sodium	1.6	30	Cyclopropane	.0093	....	....	[c]

[a] Also found 0.0004 mole of bis-(butylthio)-ethane and 0.2 g. of high boiling hydrocarbon. [b] Mostly bis-(phenylthio)-ethane but also an unidentified solid. [c] Polymers.

bromine. This gas reacted slowly with bromine even when irradiated. The dibromide formed could not have been propylene bromide (b. p. 141°), since it boiled above 150°. 1,3-Dibromopropene boils at 167°. The quantity of dibromide at hand was not purified rigorously.

1-Butene from Butyl Chloromethyl Sulfide.—The gas which collected in the −78° trap boiled at −5.0 to −4.0° (745 mm.). A Siwoloboff micro method[16] was used in this determination, on an 80-cc. sample of material. The gas also was absorbed in 88% sulfuric acid and was absorbed readily by bromine to yield 1,2-dibromobutane.

Butane from Phenyl 4-Chlorobutyl Sulfide.—This gas was unabsorbed in fuming sulfuric acid. Its boiling point was −1.0 to −0.6° by the Siwoloboff micro method. The H:C ratio was determined by combustion analysis to be 0.206. That calculated for C_4H_{10} is 0.208, and for C_4H_8 is 0.166, thus confirming its identity as butane, not cyclobutane.

2-Chloroethyl Sulfide and Sodium.—When 1.8 g. of sodium wire and 40 ml. of toluene was heated to gentle boiling, the sodium formed a pliable, molten wire. A 0.5518-g. sample of 2-chloroethyl sulfide was introduced and rinsed into the flask with two 10-ml. portions of dry toluene. The sodium turned blue. About 115 cc. (S. T. P.) of ethylene was collected in twelve hours.

Similarly, from 18 g. of the sulfide, 10 g. of sodium wire and 150 ml. of butyl ether kept at 80° for eight hours, there was collected 1996 cc. (S. T. P.) of ethylene.

The solid product from these reactions was processed by decanting the solvent, adding alcohol if an excess of sodium was used, then washing with water. Alcohol did not change the blue color, but water decolorized it to pale yellow; m. p. 158–160°.

Several conditions were studied using ether as solvent. A typical run involved refluxing a mixture of 63 g. of 2-chloroethyl sulfide (14 g. recovered), 350 g. of absolute ether, 0.5 g. of ethanol and 20.5 g. of sodium sand for six days. The ethylene was not collected. After decanting the ether, water was added thereby turning the blue solid yellow. It was rinsed thoroughly with acetone, and dried; m. p. 158–160°; yield, 4.2 g. It contained no ash and was insoluble in all the common solvents to less than 0.1% at 100°. These solvents included alcohols, ethers, esters, hydrocarbons, alkyl or aryl chlorides, ketones, nitriles, aniline, nitromethane, nitrobenzene, but was soluble at 170° in aniline, nitrobenzene or camphor.

Anal. Calcd. for $(C_2H_4S)_n$: C, 39.96; H, 6.70; S, 53.33. Found: C, 40.31; H, 6.67; S, 52.35.

Oxidation by Nitric Acid.—A mixture of 3 ml. of concentrated nitric acid and 0.8 g. of this solid was heated on a steam-bath for twenty minutes. Oxides of nitrogen were evolved vigorously at first. Excess nitric acid was removed by adding alcohol. Alcohol caused separation of a yellow precipitate. It was dissolved in 10 ml. of hot water, and reprecipitated by 10 ml. of hot acetone; yield, 0.6 g., m. p. 168–169°. After drying at 100° (30 mm.), it was analyzed.

Anal. Calcd. for $(C_2H_4SO)_n$: C, 31.6; H, 5.28; S, 42.1. Found: C, 31.56; H, 5.27; S, 35.33; neut. equiv., 420, 475, 487.

A terminal sulfonic acid group is suggested by the neutral equivalent. The compound reacted in aqueous solution with aniline to form a salt, m. p. 180–181° dec., precipitated by acetone.

Oxidation by Hydrogen Peroxide.—No solution occurred when 1.17 g. of the solid (m. p. 158–160°), 10 g. of glacial acetic acid and 10 ml. of 30% hydrogen peroxide were heated together for a few minutes but the solid changed to 1.34 g. of a substance of m. p. 312°. It was insoluble in water, alcohol, furfural, acetone or benzene.

Anal. Calcd. for $(C_2H_4SO_2)_n$: C, 26.2; H, 4.35; S, 34.8. Found: C, 26.14; H, 4.94; S, 31.92.

3-Chloropropyl Sulfide.—Butyl ether or toluene were used as solvents. In a typical run, 3.6 g. of sodium wire, 50 ml. of toluene and 4.2 g. of 3-chloropropyl sulfide were heated to gentle refluxing for thirty minutes. The products included 390 cc. (S. T. P.) of cyclopropane, and 0.75 g. of a water-insoluble, benzene-soluble, halogen-free solid of m. p. 55–61°. It was purified by dissolving in chloroform, adding acetone, and partially evaporating; m. p. 56–57°.

Anal. Calcd. for $(C_3H_6S)_x$: C, 48.65; H, 8.10. Found: C, 48.69; H, 8.10; mol. wt. (ebullioscopically in benzene), 2020.

1,2-Bis-(phenylthio)-ethane.—A solution of 0.760 g. of this compound in 10 ml. of toluene was added to a boiling mixture of 50 ml. of toluene and 1.4 g. of sodium wire. The ethylene evolved during three and one-half hours was 41 cc. (S. T. P.). From the reaction flask, 0.21 g. of the

(16) Morton, "Laboratory Technique in Organic Chemistry," McGraw-Hill Book Co., New York, N. Y., 1938, p. 51.

starting material was recovered, and 0.42 g. of thiophenol was identified by titration with iodine. Thus one mole of ethylene was formed for each two of thiophenol.

Acknowledgments.—Combustion microanalyses for C, H or N were performed by Margaret Ledyard, Patricia Craig, Margaret Hines and Jean Gibbs. Assistance given by Lawrence Buckles of the Chemical Corps eased many of the difficulties.

Summary

The reaction of chloroalkyl sulfides with sodium in inert solvents has been shown to be a general reaction. Examples were studied where n in the formula $RS(CH_2)_nCl$ represented 1, 2, 3 and 4. Ethylene is evolved when $n = 2$, cyclopropane when $n = 3$, and n-butane together with ethylene and butene when $n = 4$. Mixed gases were formed also when $n = 1$. Mercaptans and bis-(alkylthio)-alkanes, $RS(CH_2)_nSR$ were formed but practically none of the products which would have been predicted by the Wurtz reaction. 2-Chloroethyl ether also evolves ethylene in reaction with sodium.

Polymers were important products from the reactions involving 2-chloroethyl sulfide and 3-chloropropyl sulfide. The statements in the literature regarding the non-reactivity of mustard gas towards sodium need revision.

Zinc and zinc amalgam also cause liberation of ethylene from the 2-chloroalkyl sulfides.

Dimercaptols of Acetonylacetone. II[1]

BY EDWARD G. RIETZ, JAMES B. FERNANDEZ, LLOYD T. SNIDER AND THOMAS K. TODSEN

With four exceptions, the normal dimercaptols of acetonylacetone, methyl through n-dodecyl, have been recorded.[2,3] The present paper describes the properties of the remaining four: n-amyl, n-heptyl, n-nonyl, and n-undecyl, as well as the preparation and properties of the sulfone and the mercuric chloride addition product derived from each member of the series.

The four dimercaptols were prepared in approximately 75% yield by the interaction of acetonylacetone and the mercaptan under the influence of hydrogen chloride according to the directions previously described.[3] The properties and analyses of the products are shown in Table I, and the melting points of the series are plotted in Fig. 1. Two observations should be made with regard to the series: Lengthening of four chains has the same effect as the lengthening of one chain in an ordinary homologous series, and a reversal of alternation of melting point occurs at the nonyl dimercaptol.

Early attempts at the preparation of the sulfones were directed at the preparation of the sulfoxides as intermediates, but bromine oxidation failed to yield crystalline products. Hence the sulfones were prepared directly by use of permanganate or by acetic anhydride-catalyzed perhydrol oxidation. Yields of the sulfones were uniform and approximated 30%. The melting points and analyses of the sulfones are shown in Table II; the graph of the melting points in Fig. 2.

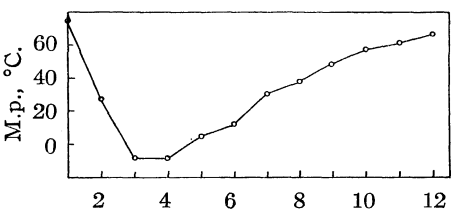

Fig. 1.—Melting points of the mercaptols plotted against the number of carbons in the alkyls.

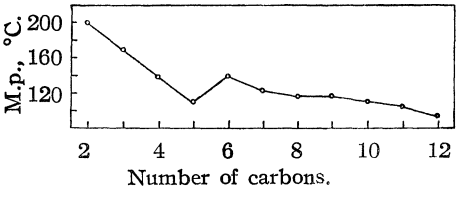

Fig. 2.—Melting points of the sulfones plotted against the number of carbons in the alkyls.

The mercuric chloride addition products were readily obtained by mixing diethylcarbitol solutions of the mercaptol and of mercuric chloride in molecular proportions 1:8, respectively.

The constitution of the mercuric chloride addition product is a function of the chain length. Maximum addition of eight mercuric chloride molecules per molecule of dimercaptol occurs with the

methyl dimercaptol. This value decreases until it reaches the limiting value of four for the heptyl and subsequent dimercaptols.

The products derived from the butyl and hexyl dimercaptols were anomalous. Analysis of the compounds after washing with diethylcarbitol indicated an apparent coördination of 4.5 molecules of mercuric chloride per molecule, but treatment with alcoholic hydrochloric acid caused this value to become intermediate between 4.0 and 4.5. In view of the indefiniteness of the data, the authors can offer only a provisional statement regarding the constitution of these compounds The analyses and melting points of the addition compounds are collected in Table II.

Acknowledgment.—The authors are indebted to Dr. E. Emmet Reid for his advice and to Mr. Max Gergel of the Columbia Organic Chemicals Co., Columbia, S. C., for mercaptans used in the preparation of the dimercaptols.

Experimental

Tetrasulfones.—All tetrasulfones of this article may be prepared in approximately 30% yield by permanganate oxidation or by the use of acetic anhydride-catalyzed perhydrol. If the latter method is to be used, the directions described below should be followed rigorously. Simple addition of the reactants results in a violent reaction after an induction period of about thirty minutes.

2,2,5,5-Tetra-decylsulfonyl Hexane.—A 2.0-g. sample of *n*-decyl dimercaptol was mixed in a separatory funnel with 200 ml. of 4% $KMnO_4$, 3 ml. of 9 *M* H_2SO_4 and 5 ml. of glacial acetic acid. After heating to 60° on a water-bath the mixture was shaken vigorously for five minutes. On cooling, solid sodium bisulfite was added until the solution became clear. The product was extracted with three 50-ml. portions of chloroform and the solvent evaporated on the steam-bath. A repetition of the oxidation, extraction and evaporation followed by crystallization of the residue from ethanol yielded 0.6 g. of the tetrasulfone, m. p. 109–110°, yield, 26%.

2,2,5,5-Tetra-octylsulfonyl Hexane.—A mixture of 15 ml. of 30% perhydrol and 5 ml. of acetic anhydride was allowed to react until the temperature returned to 30°. A 1.8-g. sample of *n*-octyl dimercaptol was added under stirring whereupon the temperature rose gradually to 40°. This temperature was maintained by cooling until the initial reaction was completed. The solution was then warmed to 45° for ten minutes. On cooling, the solid was removed by filtration and crystallized from a 1:1 acetone–methanol solution; yield of product 0.6 g., or 28%; m. p. 117–118°.

This general procedure was modified for the members following the octyl dimercaptol. After the initial reaction had been completed, the mixture was warmed to 55° for completion of the reaction. At ten-minute intervals, the mixture was warmed to melt the products and reactants and was then permitted to cool to 55°. When successive heatings produced no change in melting point, the reaction was complete.

Mercuric Chloride Addition Compounds.—All dimercaptol mercuric chloride salts were prepared by the general method described below.

A 1.5-g. sample of *n*-octyl dimercaptol in 25 ml. of diethylcarbitol was mixed with a solution of 5 g. of mercuric chloride in 20 ml. of diethylcarbitol at 50°. The mixture was heated to effect solution of the initial precipitate and cooled. Filtration, followed by washing with two 5-ml. portions each of diethylcarbitol and ethanol resulted in 2.0 g. of product, m. p. 159–160°. Recrystallization from diethylcarbitol did not alter the melting point.

Great difficulty was encountered in attempts to crystallize the first six dimercaptol salts of the series. In these instances, the elevated temperatures necessary for solution resulted in decomposition. Hence occluded mercuric chloride was removed by washing with 30 ml. of 0.05 *M* hydrochloric acid in ethanol. Such treatment resulted in compounds of composition corresponding to integral numbers of mercuric chloride molecules per molecule of dimercaptol except for the butyl and hexyl dimercaptols.

Summary

1. The acetonylacetone dimercaptols of *n*-amyl, *n*-heptyl, *n*-nonyl and *n*-undecyl mercaptans have been prepared and characterized. These are new to the literature.

2. The tetrasulfones of the normal acetonylacetone dimercaptols, methyl through dodecyl, have been prepared and characterized. With the exception of the ethyl derivative, these are new to the literature.

3. Mercuric chloride forms coördination compounds with acetonylacetone dimercaptols. The extent of such addition is a function of the chain length.

The Structure of Neoprene. III.[1] The Molecular Weight Distribution of Neoprene Type CG

BY W. E. MOCHEL AND J. B. NICHOLS

Neoprene Type CG and Neoprene Type GN are polychloroprenes made in essentially identical emulsion systems at 10 and 40°, respectively. They are both sulfur-modified polymers plasticized with tetraethylthiuram disulfide, but they differ markedly in physical properties, particularly with respect to rate of crystallization.[2] The polymer made at 10°, Neoprene Type CG, on standing at 25° hardens by crystallization in a few hours compared to days required for comparable changes in Neoprene Type GN. Furthermore,[2] Neoprene Type CG has greater plasticity than Neoprene Type GN and its vulcanizates show higher tensile strengths at 25 and 70°. These differences in physical properties have become well known since the introduction of Neoprene Type CG in 1941. It was of particular interest therefore in this study of the structure of neoprene to compare these polymers to obtain information about the structural features responsible for the differences in their properties.

Among the first constants desired in the characterization of any high polymer are the average molecular weight and the molecular weight distribution. That information is available for Neoprene Type GN[3] and the corresponding values are now reported for Neoprene Type CG. The same experimental methods, involving fractional precipitation from dilute benzene solution under controlled temperature conditions, and viscometric and osmometric examination of each fraction, were employed.[3] It is recognized that the fractionation method has certain deficiencies[4] but no clearly satisfactory substitute for general use has appeared.

Experimental

Materials.—A sample (55 g.) of standard, commercial Neoprene Type CG, approximately two months old, was cut into small pieces and dissolved in 500 ml. of thiophene-free, dry benzene. The polychloroprene was precipitated completely with methanol, washed twice with methanol and redissolved immediately in 500 ml. of benzene. After the addition of 0.5 g. of phenyl-α-naphthylamine the solution was diluted to 5 l. and a sample removed for determination of the constants of the original polymer. From the concentration of polymer in this solution it was calculated that 48.8 g. of purified polymer, free from soap residues and other contaminants, had been recovered for the fractionation.

Fractionation.—The fractionation was carried out by fractional precipitation from the approximately 1% solution in benzene, using methanol as the precipitant. Each sample was precipitated at 25° as described previously.[3] The first three fractions were not isolated as dry polymers since it was found that they became cross-linked and insoluble on drying.

Measurements.—Number average molecular weights in benzene solution were measured by means of static type osometers. For each sample, duplicate determinations made at each of four different concentrations were plotted as π/c *vs.* c and extrapolated to zero concentration, assuming a straight line relationship. Representative curves are given in Fig. 1.

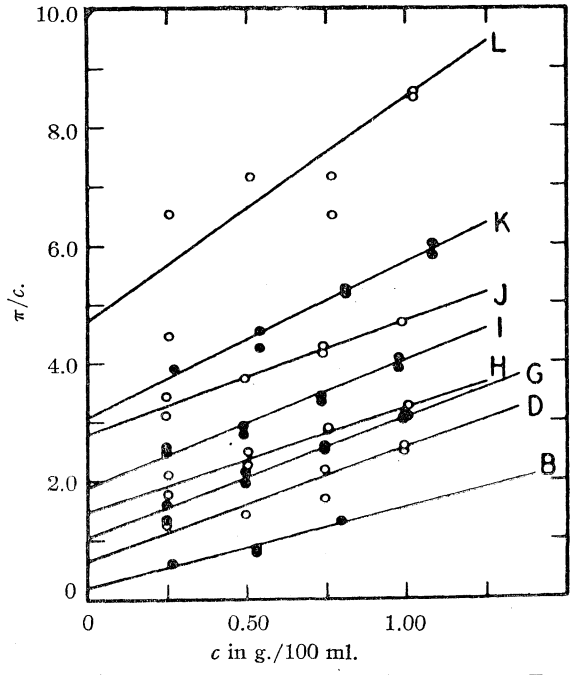

Fig. 1.—π/c *vs.* c curves for representative Neoprene Type CG fractions.

Viscosities were measured in benzene solution using an Ubbelohde suspended-level viscometer which had been modified by the substitution of a 50-ml. reservoir for the usual 5–10-ml. bulb. Dilutions were made directly in the viscometer and the viscosity measured at four different concentra-

tions. The intrinsic viscosity and k' constants were then calculated by plotting reduced viscosity η_{sp}/c *vs.* c and applying the straight line equation, $\eta_{sp}/c = [\eta] + k'[\eta]^2 c$, developed by Huggins and others.[5] The experimental values are shown in Fig. 2. These procedures are described in greater detail in a previous publication.[3]

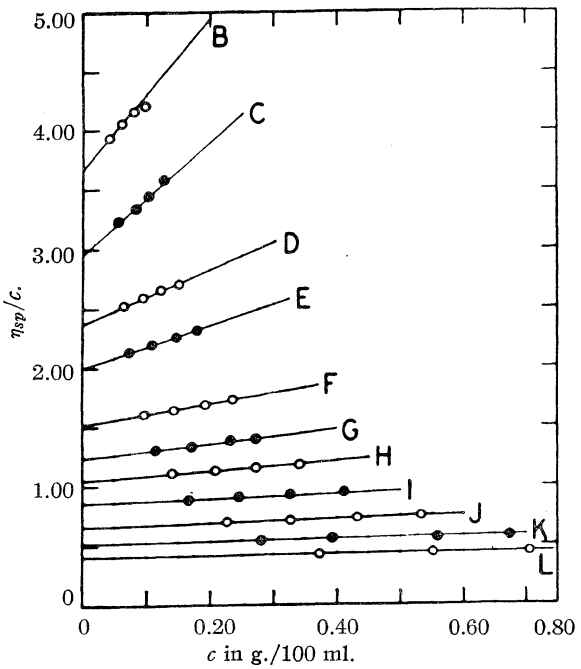

Fig. 2.—η_{sp}/c *vs.* c curves for Neoprene Type CG fractions.

Results and Discussions

The purified Neoprene Type CG was divided into 13 fractions having the properties given in Table I. The total weight of fractions isolated from the 48.8 g. of purified polymer used was 45.3 g. (93% recovery). It was assumed that the 7% loss that occurred had been uniformly distributed over all fractions and therefore the total weight of the isolated fractions was used in calculating that proportion of the whole each fraction constituted.

Fraction A, after precipitation, could not be redissolved in benzene even though the greatest care had been taken to avoid contact with air. Repetition of the experiment led to the same results, indicating that fraction A was probably inherently insoluble or very nearly so. The original whole polymer had been examined for gel content but was found to be completely soluble in benzene when tumbled with benzene and yielded only 0.6% gel when examined by a milder technique using the Baker cell.[6] However, a small amount of "microgel"[6] might well precipitate as a first fraction and carry down with it a small amount of soluble polymer in associated form, giving an insoluble product.

[a] Per cent. of total isolated in fractions. [b] Slope term of osmotic pressure equation.

Fraction B appeared to have a very high molecular weight but unfortunately the osmotic results for this fraction were scattered and a reliable molecular weight value was not obtained. Fraction D was larger than desirable for molecular weight distribution work; judging the amount of precipitant to add each time is one of the major problems of fractionation work. The molecular weight of fraction F or G is probably in error since it would not be expected that successive fractions would be identical. The number of fractions obtained was not as large as would be desired but it is believed that the general conclusions are valid. Reprecipitation of the fractions was not attempted since earlier work[3] had shown that the extra handling required for each fraction led to degradative changes which tended to nullify improvements in homogeneity.

The average molecular weight of whole Neoprene Type CG, 168,000, is considerably higher than that for Neoprene Type GN, 114,000, previously reported.[3] The calculated number average of the molecular weights of the individual fractions was 220,000, leaving out fraction A and the residue. This value is considerably higher than the measured value for the whole polymer due probably to the neglect of the residue. Assuming a reasonable molecular weight of 30,000 for the residue, the calculated number average would be 166,000. The molecular weight of fraction A would be high and would have little effect on the number average.

From the experimental values in Table I there is plotted the cumulative distribution curve of Fig. 3. From the smoothed curve there is calculated the differential molecular weight curve given in Fig. 4. Fifty per cent. of the Neoprene Type CG has a molecular weight above 250,000 compared to 165,000 for Neoprene Type GN. Also the maximum of the Type CG differential curve, *i. e.*, the

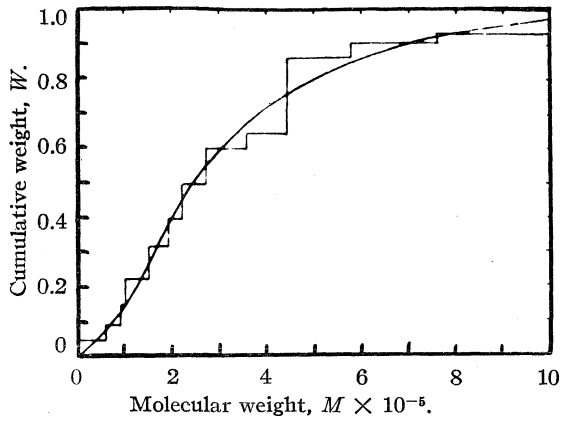

Fig. 3.—Integral molecular weight distribution for Neoprene Type CG.

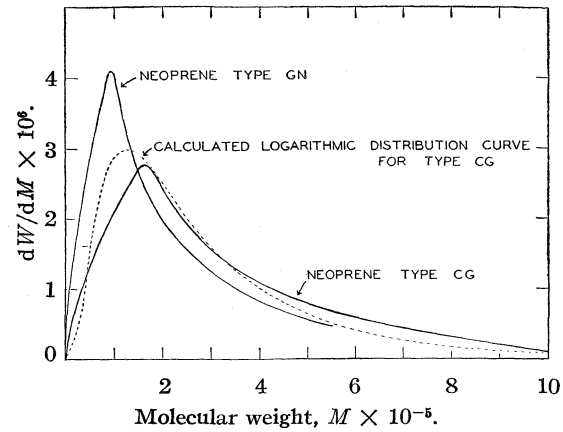

Fig. 4.—Differential molecular weight distribution curves for Neoprene Type CG and Neoprene Type GN. The logarithmic distribution curve (Type CG, calc.) was calculated by the method of Lansing and Kraemer.

most abundant species, is 160,000, compared to about 100,000 for Type GN. The molecular weight distribution curves for both polymers exhibit long extensions at the high molecular weight ends, believed to be due to the presence of soluble, branched and/or cross-linked material.[7] If the gelation of fraction A were due to cross-linking occurring after isolation, this extended tail on the molecular weight distribution curve should be decreased. However, it is believed, as stated before, that fraction A contained microgel and that the distribution curve as drawn is real.

A further difference between Neoprene Type CG and Type GN is that the maximum in the molecular weight distribution curve is not only at higher molecular weight for Type CG but the spread about this point is more uniform than in the case of Type GN. This uniformity is also shown by the lower value, $\beta = 1.12$, for the non-uniformity coefficient of Lansing and Kraemer[8] in contrast to the value, $\beta = 1.27$, reported for Neoprene Type GN[3] (Hevea rubber, $\beta = 0.70$). The logarithmic distribution curve calculated by the Lansing–Kraemer method is shown in Fig. 4 for comparison with the experimental curve. (For CG, $M_w/M_n = 316{,}000/168{,}000 = 1.88$, using the weight average molecular weight calculated from the fractions.)

From Table I it will be noted that the k' constants of the viscosity equations for the fractions of Neoprene Type CG are smaller than the value obtained for the whole polymer, in contrast to the results for Neoprene Type GN, where the fractions exhibited k' values as large or larger than that for the whole polymer.[3] It is believed that the reason for this difference in the case of Neoprene Type CG is that the whole polymer was not completely soluble but contained some microgel. Presumably, k' for fraction A would have been very high had it been possible to measure it. The k' constants for fractions B and C appeared to be slightly higher than average but the difference is not highly significant statistically because of the wide variations in k' constants for the other fractions. Assuming that this difference is real, it appears that fractions A, B and C, which constitute 13.5% of the total, are branched or cross-linked appreciably more than the rest of the polymer. Comparable fractions in Neoprene Type GN made up 25.2% of the total. These figures, however, should not be construed to be the actual percentages of branched or cross-linked material in either polymer. No evidence of micro gel was detected in GN, perhaps because of the lower molecular weight of the latter polymer. It will be noted that B, the osmotic slope term, is lower for fractions B and C than for the remainder. This can be due either to poorer solutions or to higher molecular weights and our evidence cannot distinguish between the two effects. B also shows a definite upward trend with decreasing molecular weight.[9] The k' values for fractions of Neoprene Type CG showed a significant correlation with the intrinsic viscosities (correlation coefficient = 0.787) even when the high values for fractions B and C were omitted. No such correlation was found for Neoprene Type GN.

A straight line relationship between number average molecular weights and intrinsic viscosities for fraction C to L, inclusive, is shown in Fig. 5. The equation for this line is $\log M = 5.2529 + 1.119 \log [\eta]$ or $M = 1.79 \times 10^5 [\eta]^{1.12}$. This may be rearranged into the more usual form $[\eta] = KM^a$ where K is 2.02×10^{-5} and a is 0.89. Agreement of most of the fractions with this relationship is seen to be very good; only B was in serious error and the osmotic value for B was dependent upon only four points in poor agreement. The significance of the high value for the exponent a is not fully understood. Note that the values of K and a for Neoprene Type GN are, respectively, 1.46×10^{-4} and 0.73 when calculated similarly.

(9) *Cf.* Doty and Mark, *Ind. Eng. Chem.*, **38**, 682 (1946).

Statistical analysis has shown that there is less than one chance in a thousand that the exponents for Neoprene Type CG and Type GN are different because of experimental error alone.

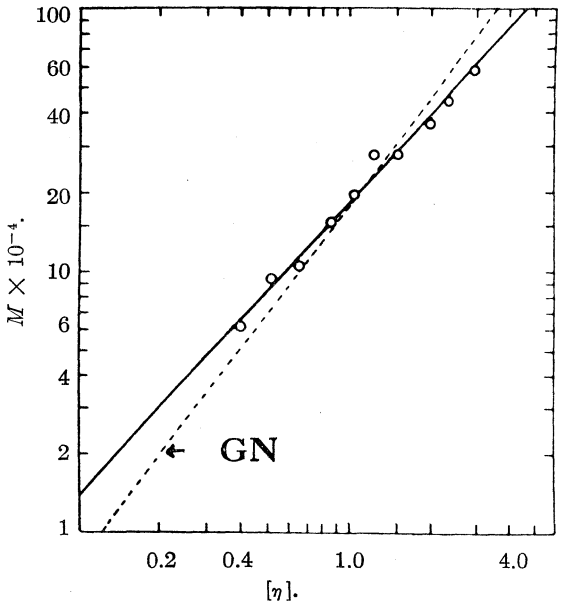

Fig. 5.—Log M_n *vs.* log $[\eta]$ for Neoprene Type CG fractions (GN, neoprene type GN).

The higher value of a for Neoprene Type CG than for Type GN would appear to indicate that the former polymer has less flexible molecules than has GN[10] or that the shielding effect is smaller,[11] due perhaps to greater intermolecular attraction. This exponent a was observed to *increase* with increasing polymerization temperature in the case of styrene,[12] a situation the opposite of that reported here for neoprene, and the results have been interpreted in terms of poorer symmetry, of a stereochemical type, in polystyrene made at high temperatures.[13] The change in a for neoprene may be reversed because of much greater interchain attractive forces, as evidenced by its tendency to crystallize. Certainly poorer symmetry would not be expected in Neoprene Type CG. An attempt to measure association of Neoprene Type CG in benzene solution by determination of intrinsic viscosities at 25 and 50° gave values whose ratio varied from 0.90 to 0.97. These are the same as observed for Type GN and as reported for polychloroprene of a different origin.[14] Whatever the explanation for the difference in values for a, it is evident that there must be a structural difference between Neoprene Type CG and Type GN, quite apart from the differences in molecular weight and molecular weight distribution.

Acknowledgments.—The authors gratefully acknowledge the aid and encouragement of Drs. B. C. Pratt, G. D. Patterson and D. M. McQueen and the assistance of Miss B. L. Price in the osmotic pressure measurements described in this research. Thanks for many helpful discussions go to Professor F. T. Wall, of the University of Illinois, and to Drs. H. W. Walker and M. A. Youker, of the Organic Chemicals Department of this Company.

Summary

The low temperature polychloroprene rubber, Neoprene Type CG, has been fractionated by partial precipitation from dilute solution and the fractions examined both osmotically and viscometrically in benzene solutions. The molecular weight distribution curve for Neoprene Type CG based on osmotic pressure measurements shows a pronounced maximum at 160,000 molecular weight compared to 100,000 for Neoprene Type GN and the curve has a more uniform distribution about the maximum value. Neoprene Type CG whole polymer has a higher number average molecular weight than GN, 168,000 *vs.* 114,000.

Calibration of the intrinsic viscosity–molecular weight relationship by osmotic pressure measurements gave good agreement with the equation $[\eta] = KM^a$ where $K = 2.02 \times 10^{-5}$ and $a = 0.89$. The exponent a, which is generally considered to be related to the flexibility of the molecules in solution, indicates that the molecules of Neoprene Type CG are less flexible or have greater intermolecular attraction than those of GN. It is clear therefore that there is a structural difference between these two polymers in addition to the observed differences in average molecular weight and molecular distribution.

α,β,β-Trifluorostyrene and α-Chloro-β,β-difluorostyrene[1]

BY SAUL G. COHEN, HENRY T. WOLOSINSKI AND PAUL J. SCHEUER[1a]

Consideration of the useful properties of the polymers of tetrafluoroethylene, $CF_2=CF_2$,[1b] and chloro trifluoroethylene, $CF_2=CFCl$,[2] has indicated to us the desirability of preparing and studying the phenyl derivatives of these compounds. There are now in the literature several references to styrenes which contain fluorine or trifluoromethyl substituents in the benzene ring,[3] but apparently only one reference to a phenylperchlorofluoroethylene[4] and that to a monofluorodichlorostyrene with its exact structure unspecified. Recently an unsuccessful attempt to prepare β-fluorostyrene has been reported.[5] In this paper, we are reporting the preparation of α,β,β-trifluorostyrene, $C_6H_5CF=CF_2$ (I) and α-chloro-β,β-difluorostyrene, $C_6H_5CCl=CF_2$ (II).

In the course of this work, chlorodifluoroacetophenone, $C_6H_5COCClF_2$, trifluoroacetophenone, $C_6H_5COCF_3$, and difluoroacetophenone, $C_6H_5COCHF_2$ were prepared by the Friedel–Crafts reactions of the corresponding acid chlorides with benzene in the presence of aluminum chloride.

$$CX_3C(=O)-Cl + C_6H_6 \xrightarrow[CS_2]{AlCl_3} C_6H_5COCX_3 + HCl$$

Trifluoroacetyl chloride[6] and monofluoroacetyl chloride[5,7] have been used in this type of reaction, while treatment of benzene with chlorofluorocarbons and aluminum chloride has been unsuccessful.[8] Optimum conditions for carrying out this Friedel–Crafts reaction are described under the preparation of trifluoroacetophenone. Single attempts to prepare this compound by treatment of diphenylcadmium with trifluoroacetyl chloride[9] and by the Friedel–Crafts reaction of trifluoroacetic acid and benzene failed.

Each of the three ketones was converted to the corresponding dichloride by reaction with phosphorus pentachloride, leading to the compounds $C_6H_5CCl_2CClF_2$, (IV) $C_6H_5CCl_2CF_3$,[6] (V) and $C_6H_5CCl_2CHF_2$.

$$C_6H_5COCX_3 + PCl_5 \longrightarrow C_6H_5CCl_2CX_3 + POCl_3$$

Use of 50 mole per cent.[6] excess phosphorus pentachloride and long heating under reflux was found desirable. Removal of the excess phosphorus pentachloride, whether by filtration or washing,[6] was inconvenient and either was incomplete or led to diminished yields. Treatment of the reaction mixture with a quantity of acetone equivalent to the excess phosphorus pentachloride converted it to phosphorus oxychloride, from which the desired products were readily separated and isolated in 85–90% yield. This greatly facilitated our preparation of compounds IV and V.

The compounds IV and V, $C_6H_5CCl_2CClF_2$ and $C_6H_5CCl_2CF_3$, were each treated with one-third mole of antimony trifluoride and catalytic quantities of bromine at 140–170°.

$$C_6H_5CCl_2CX_3 + {}^1/_3SbF_3 \xrightarrow{Br_2} C_6H_5CClFCX_3 + {}^1/_3SbCl_3$$

The products were mixtures which appeared to contain both starting materials and the products of replacement of two chlorine atoms by fluorine as well as the desired products of replacements of one chlorine atom by fluorine, $C_6H_5CClFCClF_2$ (VI) and $C_6H_5CClFCF_3$[10] (VII). The latter compounds were isolated in about 35% yield.

The desired α,β,β-trifluorostyrene (I) and α-chloro-β,β-difluorostyrene (II) were prepared by the zinc dechlorination of the corresponding pentahaloethylbenzenes.

$$C_6H_5CClFCClF_2 + Zn \xrightarrow[\text{ethanol}]{\text{absolute}} C_6H_5CF=CF_2\ (I) + ZnCl_2$$

$$C_6H_5CCl_2CClF_2 + Zn \xrightarrow[\text{ether}]{\text{anhydrous}} C_6H_5CCl=CF_2\ (II) + ZnCl_2$$

α,β,β-Trifluorostyrene (I) was obtained in 48% yield, b. p. 68–69° (75 mm.), $n^{20}D$ 1.4741, m. p. −23.0 to −22°. Its formation in this way supplies evidence for the assigned structure of the intermediate, $C_6H_5CClFCClF_2$. α-Chloro-β,β-difluorostyrene (II) was obtained in 70% yield, b. p. 100° (100 mm.), $n^{20}D$ 1.5080.

Acknowledgment.—The authors wish to acknowledge helpful discussions with Dr. E. R. Blout.

Experimental

Sodium trifluoroacetate was obtained from the Hooker Electrochemical Company. **Sodium difluoromonochloroacetate** was obtained from Columbia Organic Chemicals, Inc.

Barium difluoroacetate and **sodium difluoroacetate** were prepared in 37% yield and 28% yield, respectively, by oxidation of 1,2-dichloro-3,3-difluoro-1-propene by a procedure similar to that described for the oxidation of the

isomeric 1,1-dichloro-3,3-difluoro-1-propene.[11] 1,2-Dichloro-3,3-difluoro-1-propene was obtained from Halogen Chemicals, Inc.

Chlorodifluoroacetyl chloride was prepared by the interaction of sodium chlorodifluoroacetate (0.65 mole) and phosphorus trichloride (0.59 mole) for 2.5 hours at 100° under reflux. The product was distilled out, 77.5 g., (80% yield) boiling under 40°. A sample was converted to the amide, m. p. 76.5°. This chloride has been prepared by the chlorination of difluoroethanol,[12] b. p. 34°.

Trifluoroacetyl chloride[6] was prepared in 90% yield by the interaction of sodium trifluoroacetate (1.24 mole) and phosphorus oxychloride (1.83 moles) for twenty-one hours at 100° under reflux, the product condensing in a dry ice trap. A sample was converted to the amide, m. p. 74–75°.

Difluoroacetyl chloride was prepared by interaction of sodium difluoroacetate (0.312 mole) and phosphorus trichloride (0.69 mole) under reflux for twenty-one hours. The product boiled at 32–35°, 69% yield. The reported boiling point is 25°.[13]

α,α,α-Trifluoroacetophenone.[6]—Trifluoroacetyl chloride (180 g., 1.35 moles) was distilled over a period of four hours into a well stirred, cooled suspension of aluminum chloride (1.60 moles) in benzene (1.60 moles) and carbon disulfide (490 cc.). The reaction started at 10°, was run at 2–3°, and finally at room temperature for a short time. The complex was decomposed in 335 cc. of concentrated hydrochloric acid and 1900 g. of ice. The organic layer was separated, and the aqueous layer was extracted with ether. The extracts were combined, filtered free from a black precipitate which was then further extracted. The extracts were dried and distilled, leading to trifluoroacetophenone, 150.6 g., 64% yield, b. p. 66–67° (37 mm.), $n^{20}D$ 1.4576.

α,α,α-Difluorochloroacetophenone was prepared similarly, 68% yield, b. p. 95–97° (37 mm.), $n^{20}D$ 1.4954. *Anal.* Calcd. for $C_8H_5OClF_2$: Cl, 18.6. Found: Cl, 18.2. This compound has been obtained in 8% yield in the fluorination of trichloroacetophenone.[10]

α,α-Difluoroacetophenone was prepared, 58% yield, b. p. 84–87° (26–27 mm.), in a standard Friedel–Crafts procedure in carbon disulfide at 10°. This compound has been prepared by the fluorination of acetophenone and the fluorination of dibromoacetophenone.[10]

α,α-Dichloro-β,β,β-trifluoroethylbenzene, $C_6H_5CCl_2CF_3$.[6]—Trifluoroacetophenone (25 g., 0.14 mole) and phosphorus pentachloride (44 g., 0.21 mole) were heated under reflux for twenty-one hours, oil-bath temperature, 175°. Acetone (4.1 g., 0.07 mole) was added to the cooled reaction mixture, and, after the vigor of the ensuing reaction subsided, the product was fractionated and the desired material was obtained, 29 g., 90% yield, b. p. 88–90° (37 mm.), $n^{20}D$ 1.4767. *Anal.* Calcd. for $C_8H_5Cl_2F_3$: Cl, 31.0. Found: Cl, 31.5.

α,α,β-Trichloro-β,β-difluoroethylbenzene, $C_6H_5CCl_2CClF_2$, was prepared similarly from difluorochloroacetophenone, 78% yield, b. p. 98–99° (15 mm.), $n^{20}D$ 1.5106. *Anal.* Calcd. for $C_8H_5Cl_3F_2$: Cl, 43.5. Found: Cl, 42.4.

α,α-Dichloro-β,β-difluoroethylbenzene, $C_6H_5CCl_2CF_2H$, was prepared similarly except that excess phosphorus pentachloride was removed by repeated filtration. The product was obtained in about 70% yield, fuming liquid, b. p. 96–97° (26–27 mm.), $n^{30}D$ 1.5046.

α-Chloro-α,β,β,β-tetrafluoroethylbenzene, $C_6H_5CClFCF_3$.[10]—α,α-Dichloro-β,β,β-trifluoroethylbenzene was treated with one-third mole of antimony trifluoride and 10 mole per cent. of bromine at 150–170° for two hours with stirring. The product was cooled, washed, dried and distilled. Redistillation of the middle fraction, which boiled at 84–109° (100 mm.), led to the product, 35% yield, b. p. 85–86° (100 mm.), $n^{20}D$ 1.4463. *Anal.* Calcd. for $C_8H_5ClF_4$: Cl, 16.7. Found: Cl, 16.0.

α,β-Dichloro-α,β,β-trifluoroethylbenzene, $C_6H_5CFClCF_2Cl$.—α,α,β-Trichloro-β,β-difluoroethylbenzene, $C_6H_5CCl_2CClF_2$ (51 g. 0.21 mole), antimony trifluoride (12.5 g., 0.070 mole) and bromine (0.56 g., 0.0035 mole) were heated under reflux with stirring for one hour at 140°. The product was taken up in ether, washed dried and distilled. The desired product was obtained, 17.8 g., 37% yield, b. p. 92–94° (38 mm.), $n^{20}D$ 1.4766. *Anal.* Calcd. for $C_8H_5Cl_2F_3$: Cl, 30.8. Found: Cl, 30.3. Some starting material was recovered, 10.5 g., b. p. 101° (16–17 mm.), $n^{25.4}D$ 1.5075.

α-Chloro-β,β-difluorostyrene, $C_6H_5CCl{=}CF_2$.—α,α,β-Trichloro-β,β-difluoroethylbenzene (20 g., 0.081 mole) was treated with acid-washed zinc dust (5.55 g., 0.0854 mole) and one crystal of dried zinc chloride in 20 g. of anhydrous ether with stirring, under reflux. The solution was decanted from the residual zinc (0.014 g.), washed with dilute hydrochloric acid and water, dried and distilled through a 36″ wire spiral column at 10/1 reflux ratio. The product was obtained, 9.9 g., 70% yield, b. p. 100–100.5° (100 mm.), $n^{20}D$ 1.5080. *Anal.* Calcd. for $C_8H_5ClF_2$: C, 55.0; H, 2.9; Cl, 20.3; F, 21.7. Found: C, 54.8; H, 3.0; Cl, 20.1; F, 21.8, 22.3.

α,β,β-Trifluorostyrene, $C_2H_5CF{=}CF_2$.—α,β-Dichloro-α,β,β-trifluoroethylbenzene (12.9 g., 0.056 mole), acid washed zinc (3.8 g., 0.059 mole) and a few crystals of dried zinc chloride in 15 cc. of absolute ethanol were boiled under reflux for two hours with occasional shaking. The solution was decanted from residual solid (0.37 g.), washed with 10% hydrochloric acid and water, dried and distilled. The product was obtained, 4.3 g., 48% yield, b. p. 68–70° (75 mm.), m. p. −23 to −22°, $n^{20}D$ 1.4741. *Anal.* Calcd. for $C_8H_5F_3$: C, 60.8; H, 3.2; F, 36.0. Found: C, 60.7; H, 3.2; F, 35.7. This material appeared to contain about 0.4% Cl. Treatment with zinc at 120° for one hour and redistillation from the zinc led to a product which contained less than 0.2% Cl.

Summary

α,β,β-Trifluorostyrene, $C_6H_5CF_2{=}CF_2$, and α-chloro-β,β-difluorostyrene, $C_6H_5CCl{=}CF_2$ have been prepared by the dechlorination of α,β-dichloro-α,β,β-trifluoroethylbenzene, $C_6H_5CClFCClF_2$, and α,α,β-trichloro-β-β-difluoroethylbenzene, $C_6H_5CCl_2CClF_2$, respectively.

The Infrared Spectra of a Number of Isomeric Normal Acetylenic Compounds

BY JOHN H. WOTIZ[1] AND FOIL A. MILLER[2]

This paper presents the infrared spectra of twenty-eight straight chain heptynes, heptynyl alcohols, halides, nitriles and *n*-octynoic methyl esters. Most of these compounds have recently been prepared for the first time.[3] Table I provides a list of the compounds and their numbering.

Measurement of the Spectra.—The spectrum of I is available in the A. P. I. catalog of infrared spectrograms,[7] and is not presented here. The spectra of all the other compounds were measured on a Beckman IR-2 infrared spectrometer in the Spectrographic Laboratory of the Department of Chemistry at The Ohio State University. The range 2–15 μ was covered with a sodium chloride prism. Samples were studied as liquids in cells 0.025, 0.10 or 0.40 mm. thick. The spectra are shown graphically in Figs. 1 and 2.

The Raman spectra of II,[8,9] III[10] and XXXIII[8] have been reported earlier. They provide values for the bands above 2000 cm.$^{-1}$ which are higher than ours by 20–40 cm.$^{-1}$. This is probably due to the poor dispersion of rocksalt in this region, and the Raman values are to be preferred.

TABLE I

A. NUMBERING OF THE COMPOUNDS DISCUSSED IN THIS PAPER; B. POSITION (IN CM.$^{-1}$) AND INTENSITY[a] OF THE C≡C BAND

[a] In estimating intensities, an attempt was made to correct for the effect of the different cell thicknesses. [b] There is a weak or very weak band in the range 2070–2050 cm.$^{-1}$, but this is inordinately low for a C≡C band and probably belongs to a combination tone.

Experimental

Preparation of the Compounds.—The preparation and physical properties of most of these compounds are given in the paper by Newman and Wotiz.[3] The remaining compounds were prepared according to the references cited below. Some physical constants of the infrared-analyzed samples are compared with those in the references: **II**[4]: b. p. 100° (760 mm.), obs. 97° (745 mm.); n^{20}D 1.4088, obs. 1.4038 (25°); **III**[5]: b. p. 107–111° (750 mm.), obs. 109° (721 mm.); n^{25}D 1.4220, obs. 1.4199; **IV**[4]: b. p. 106–107° (?),[6] obs. 104° (748 mm.); n^{25}D 1.415,[6] obs. 1.4165; **V**[3]: The original sample was found to contain the H—C≡ band at 3270 cm.$^{-1}$, indicating some isomerization during its preparation. The impurity was removed by making a mercury complex. **X**[3]: impure; contained Br-$(CH_2)_5$-Br. The curve is included because the spectrum of the impurity will add nothing new to the spectrum of X above 1000 cm.$^{-1}$; **XII**[3]: b. p. 84° (20 mm.), obs. 54° (4 mm.); n^{25}D 1.4878, obs. 1.4844.

Anal. Calcd. for $C_7H_{11}Br$: C, 48.0; H, 6.3; Br, 45.6. Found: C, 48.5; H, 6.2; Br, 45.6.

Discussion of Results

A number of the observed bands can be attributed immediately to various structural groups in the molecule. These bands occur in their expected positions so that no discussion is needed.[11] We shall therefore confine our remarks to two topics: the intensity and position of the C≡C band,

and the presence of some anomalous bands in several of the spectra.

C≡C Band.—One of the interesting features of these spectra is the variable intensity of the C≡C band at 2100–2240 cm.$^{-1}$. In the infrared this intensity is appreciable only if the triple bond is near either end of the chain. As it is moved toward the center of the chain the corresponding band weakens and virtually disappears. This is shown in detail in Table I. The only exceptions occur in the bromide and nitrile series, where the band is more intense for *n*-C_4H_9—C≡C—CH_2— than for *n*-C_5H_{11}—C≡C—. The reason for these two exceptions is not apparent to us, but the explanation of the general behavior seems fairly simple. As the triple bond is moved toward the interior of the molecule, the change in the dipole moment during the valence vibration of the triple bond diminishes. Since (classically) the intensity of infrared absorption is proportional to the square of the rate of change of the dipole moment,[12] the intensity rapidly decreases. It is as though a pseudo center of symmetry were produced at the center of the triple bond. The stretching of the triple bond is symmetric toward this pseudo symmetry center, and so the vibration is inactive in the infrared. It is evident, then, that the infrared spectrum is not an infallible test for the absence

(12) Herzberg, "Infrared and Raman Spectra," D. Van Nostrand Co., Inc., New York, N. Y., 1945, p. 240.

of a triple bond even when the geometric symmetry is so low that there are no formal selection rules.[13]

A similar effect is known in the infrared spectra of olefinic compounds, where the C=C frequency is notorious for its variable intensity. For example, Kletz and Summer[14] have shown that the strength of this band in octenes decreases as the symmetry of substitution about the double bond increases. They explained these results in essentially the same way. It is not unexpected to find that Cl, Br, OH, CN and $COOCH_3$ are all much more effective than alkyl groups in enhancing the intensity of the C≡C band when substituted nearby.

The position of the C≡C band depends upon the number of substituents. For the series H—C≡C—R the band is at 2100–2140 cm.$^{-1}$; for R′—C≡C—R″ it is at 2190–2260 cm^{-1}.[15] This is known, through studies of the Raman spectra, to be a general result for acetylenic compounds.[16,17] It is interesting to note that this holds even when R equals Br (XIII). The Raman work has also shown that the compounds H—C≡C—R have a single line in the C≡C region, whereas in the series R′—C≡C—R″ there are two or more lines in this region, the "extra" ones being due to overtones or combination tones whose intensity has been enhanced by resonance with the fundamental. These same frequencies are observed in the infrared for those disubstituted acetylenes possessing a C≡C band of good intensity. In some cases these satellite bands appear only as weak inflections or shoulders on the C≡C band. Several of these spectra were redetermined on a Baird double-beam spectrometer, and the bands were then clearly resolved.

It is well known that the group ≡C—H has a stretching frequency of about 3270 cm.$^{-1}$. It is therefore simple to distinguish between a monosubstituted and a disubstituted acetylene from the position of either the C—H or the C≡C stretching frequency as follows[18]

	≡C—H	C≡C
H—C≡C—R	3270	2100–2140
R′—C≡C—R″	..	2190–2260 (plus nearby satellites)

Anomalous Bands.—Several of the spectra exhibit unexpected bands that warrant mention. For example, all the esters have some absorption at 3350–3500 cm.$^{-1}$, which may indicate a small amount of free acid. The strong band of XXXII at 1960 cm.$^{-1}$ is probably a combination tone; its intensity is partially illusory because the sample was much too thick.

Some of the nitriles seem to contain a carbonyl impurity. Compound XXI, for example, has a strong band at 1720 cm.$^{-1}$. Another sample was later prepared by an entirely different method—dehydration of the corresponding amide—and the carbonyl band was then much weakened.

The series n-C_4H_9—C≡CH_2— also contains evidence of a carbonyl group in the band at 1650–1710 cm.$^{-1}$, which ranges in intensity from very weak to strong. However, the existence of a carbonyl-containing impurity is open to question. The conversion of XII into XXV was done in the absence of an oxygen-containing reagent and solvent, and yet the "carbonyl" band has maintained its intensity in spite of an appreciable difference in physical properties of the two compounds and the resulting ease of separating them. Furthermore no evidence for an aldehyde or ketone could be found in the ultraviolet spectrum of bromide XII.[19] (This is admittedly not as sensitive a test as the infrared spectrum, however.) One must therefore consider the possibility that this band may be characteristic of compounds where the functional group is removed from the acetylenic linkage by one methylene group. A further investigation of such compounds is under way to determine whether this band is due to an impurity (perhaps an azeotropic mixture), or whether it is indeed characteristic of this type of molecule. If the latter proves to be true, it will be a surprising result.

Acknowledgment.—One of us (J. H. W.) wishes to express his gratitude to Dr. M. S. Newman of The Ohio State University for his aid in the synthesis of the compounds, and for his permission to publish this work in the present form. We are indebted to Mrs. Shirley Forgerson and Dr. Edward Pickett of the Department of Chemistry, The Ohio State University, for determining the infrared spectra.

Summary

The infrared spectra of twenty-eight normal acetylenic compounds and four substituted normal heptanes are presented. The intensity of the C≡C band is observed to vary greatly. The band is most intense when the triple bond is near the end of the chain. If the triple bond is three or more positions from the end, the band is scarcely detectable.

PITTSBURGH, PA. RECEIVED FEBRUARY 11, 1949

(13) By contrast, the C≡C frequency appears with good intensity in the Raman spectra of all acetylenic compounds regardless of where the triple bond is located. References 16 and 17 provide many such examples.

(14) T. A. Kletz and A. Summer, *J. Chem. Soc.*, 1456 (1948).

(15) Compound XXVI is an exception to this, since for it the C≡C band is at 2120 cm.$^{-1}$. However, the C≡C is conjugated with C≡N in this case. Since the "normal" frequencies of these groups are close together, it is probable that Fermi resonance has lowered the C≡C band below its "normal" position.

(16) J. H. Hibben, "The Raman Effect and its Chemical Application," Reinhold Publishing Corp., New York, N. Y., 1939, p. 200 ff.

(17) Reference 9 and earlier papers cited therein.

(18) Hibben states (ref. 16, p. 208) that a Raman line at 1380 cm.$^{-1}$ is quite generally present in the disubstituted acetylenes. This is not a useful criterion in the infrared because this frequency is characteristic of a methyl group.

(19) An isoöctane solution of XII was studied with a Cary spectrophotometer. The only band observed had $\lambda_{max.}$ at 216 mμ, with a molecular extinction coefficient ϵ = 3300.

The Viscosities of Perchloric Acid Solutions

BY L. H. CLARK AND G. L. PUTNAM

Introduction

There is reason to believe that the efficiency of electrolytic cells for the production of ozone[1] may be improved by the study of the anode film temperature in relation to current density and viscosity of the electrolyte. In order to correlate the effect of the viscosity of the electrolyte (aqueous perchloric acid) on anode film temperature, it is necessary to have available the viscosities of the electrolyte at various concentrations for temperatures well below 0°. Since this data could not be found in the literature, experiments were conducted for the purpose of measuring the viscosity of aqueous perchloric acid solutions as a function of temperature and concentration.

In electrolytic cells, such as the one using perchloric acid for the production of ozone, it is believed that the electrode temperature—not the temperature of the electrolyte—is the temperature which controls the primary formation of electrode products. Since the efficiency of the electrolytic cell can be markedly affected by controlling the temperature difference between the anode and electrolyte, it is of great importance to study the variables affecting this temperature.

To correlate the effect of viscosity on the anode film temperature, we have measured the viscosity of 20, 40 and 60% perchloric acid solutions. The temperature range, being limited by the freezing point of the solutions, varies from +50 to −58°. This paper presents the results of these viscosity measurements. A later paper will correlate viscosity to anode film temperature and current efficiency.

Not much work has been done on the viscosity of perchloric acid solutions. Van Wyk[2] and Reyher[3] give values for various concentrations of perchloric acid at 20, 25 and 50° only. As far as could be ascertained from the literature, no authors have previously measured the viscosity of aqueous perchloric acid solutions below 0°.

Experimental

Apparatus.—The viscosity measurements were made using an Ostwald viscometer suspended in a Dewar flask containing the temperature controlled bath. The Dewar flask had a strip of unsilvered glass on the side to permit visual observations of the indices on the viscometer. Uniformity in the temperature of the bath was obtained by an electric stirrer placed in the flask.

The volume of efflux of the viscometer was approximately 1.45 ml. The working volume was 10 ml., this quantity of the desired solution always being pipetted into the viscometer in order to maintain a constant head of solution. The time of efflux was observed by visual observation of the meniscus and was measured to 0.1 of a second using a Waltham type A-8 stopwatch, which on checking against an electric timer showed a negligible difference in one hour. The time of efflux varied from 26 to 1788 seconds for the calibrating liquids and from 24.2 to 710 seconds for the perchloric acid solutions. No kinetic energy corrections were applied as they were less than the experimental error of the work.

In order to measure as accurately as possible the temperature of the solution in the viscometer, a calibrated glass-enclosed copper–constantan thermocouple was inserted directly in the solution in the reservoir of the Ostwald viscometer. Temperatures were read to the nearest 0.1°. The temperature of each run represents an average of several temperatures recorded during the run. The bulb of the viscometer was always kept below the level of the cooling liquid to aid in equalizing temperatures before the liquid passed through the capillary tube.

The viscometer was calibrated by measuring the time of efflux of liquids of known viscosity and density; and subsequently, plotting the computed ratios of kinematic viscosity to time of discharge *versus* the reciprocal of the discharge time squared. This method of calibrating the viscometer is the one described by the Bureau of Standards.[4] The calibrating liquids included distilled water,[5,6] pure ethyl alcohol[5,6] and a 38.6 weight per cent. sulfuric acid solution.[4] The time of efflux for the liquids was measured at temperatures ranging from +45 to −50°, four determinations being made at each temperature.

Since a straight line was obtained for the calibration curve over the range of kinematic viscosities and temperatures measured, the following equation will hold for any unknown over the same range of kinematic viscosities

$$\left(\frac{\eta}{\rho}\right)_T = At - \frac{B}{t}$$

where η/ρ = kinematic viscosity; t = time of flow in seconds; A, B = constants of the instrument, T = temperature of the liquid.

Materials.—Twenty per cent., 40 and 60% weight solutions of C. P. perchloric acid in water were measured at temperatures between −58 and +50°.

The composition of these solutions, expressed as per cent. perchloric acid, was determined by titrating two weighed portions of each solution. The percentages obtained were 20.0, 40.0 and 60.0. As a check on these determinations the specific gravity at 23°/23° of each solution was determined on a Westphal balance. The densities at 23° were then calculated and converted to percentages.[7] The average difference between the measurements by titration and specific gravity was less than 0.1 weight per cent.

In order to calculate the viscosity of these solutions from the kinematic viscosity, it is necessary

to know the density of each solution at each temperature. Data from Perry,[7] from Markham,[8] and our own experimental results at temperatures below 0° have been used as a basis for computing densities needed at the various concentrations and temperatures. By experimentally determining the densities of perchloric acid solutions at several temperatures below 0°, it was found that a linear interpolation of the densities is valid, straight lines being obtained when temperature was plotted *vs.* the combined data of Perry,[7] Markham[8] and our own. Table I gives the densities of perchloric acid interpolated from the combined data of Perry, Markham and the authors.

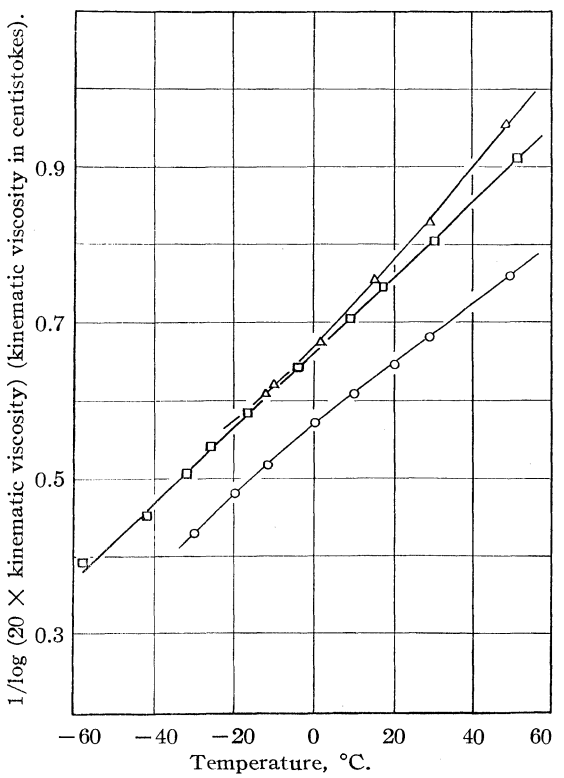

Fig. 1.—Perchloric acid viscosities: O, 60 wt. % $HClO_4$; □, 40 wt. % $HClO_4$; △, 20 wt. % $HClO_4$.

(8) Markham, THIS JOURNAL, **63**, 874–875 (1941).

Results

The experimental results of viscosity measurements are shown in Fig. 1. In plotting these curves, the reciprocal of the log (20 × kinematic viscosity in centistokes) was plotted against temperature as recommended by Vinal.[4] This was done in order to obtain an approximately linear relationship which permits a more accurate interpolation of the curves. The values of the function 1/[log (20 × kinematic viscosity)] were read from Fig. 1 at each 10° of temperature and these values replotted as isothermal lines having per cent. composition of solution as the abscissas. These new working curves facilitated the reading of the kinematic viscosities of perchloric acid at the desired temperatures and compositions.

Table II gives a summary of the numerical values for the absolute viscosity of aqueous perchloric acid solutions at various temperatures. The values for the 10% perchloric acid solution have been obtained by interpolation of the working curves from 20% perchloric to pure water.[9]

Discussion

Accuracy.—Considering sources of error as discussed by Vinal,[4] it is believed that the viscosity values determined in this paper are in error by not more than 1 to 3%. These statements, however, are based on the assumption that the viscosities and densities of the liquids used in calibrating the viscometer, as given in the literature, are sufficiently accurate for the purpose.

Comparison with Accepted Values.—The only values for the viscosity of perchloric acid solutions were taken from the early literature.[2,3,10] Data are available only for 20, 25 and 50° and a comparison of these with our data at 20 and 50° has been made in Table III. Since the 25° values were for very dilute solutions only, they are not shown in the comparison. It is seen that excellent agreement has been obtained for nearly all the

given values. The value at 50° for 60% concentration shows the greatest deviation (about 3%).

Summary

Measurements of the viscosity of perchloric acid solutions containing 20 to 60% acid have been made over a temperature range from +50 to −58°, except as the measurements were limited by the freezing points. The viscosity of these solutions at 0° is about three times as great as at +50°, but at −50° the viscosity is about thirty times as great.

The Density and Transition Points of Solid Hexamethylethane

BY WM. F. SEYER,* R. B. BENNETT AND F. C. WILLIAMS

Numerous studies have been made of the various solid phases of *n*-paraffin hydrocarbons. As a result a considerable amount of knowledge has accumulated concerning their crystal structure, transition points and latent heats. In contrast a corresponding knowledge of the branched hydrocarbons is exceedingly small. The reason for this is undoubtedly the great difficulty encountered in preparing these compounds in the pure state. Calingaert, Soroos, Hnizda and Shapiro prepared recently hexamethylethane in a high state of purity.[1] In a series of measurements dealing with the physical chemical properties of this hydrocarbon, they detected the existence of an unstable solid phase just below the melting point. To establish the nature of these solid phases, the above investigators sent two samples of this material to our laboratory, requesting us to measure its densities and coefficient of expansion by the dilatometer method used previously for some of the *n*-paraffin hydrocarbons.[2]

We were informed that the m. p. of both of the samples was 100.63° and that they had a purity of 99.96 ± 0.04%. One of the characteristics of this hydrocarbon is its small liquid range (5.61°) at normal pressures and another is its high sublimation pressure. It was therefore necessary to develop a special technique for transferring this compound from the glass stoppered ampoule in which it was received to the dilatometer.

Experimental Procedure

Preliminary measurements soon verified the observations of the workers from the chemical research laboratories of the Ethyl Corporation. After several unsuccessful methods were tried for filling the bulb, the following was adopted. The bulb, a funnel with a long drawn out stem and the ampoule containing the hydrocarbon were sealed in a glass tube as shown in Fig. 1. To avoid sublimation during the sealing operation, Dry Ice was placed about the lower end of the containing vessel. The sealing process having been completed, the vessel was then exhausted and refilled with hydrogen several times to remove the air. At the last filling, the hydrogen pressure was brought up to about 2.5 atmospheres. The tube was now inverted and heat applied at the upper end while dry ice was placed about the lower end which contained the bulb. In this manner any amount of hydrocarbon could be melted and run into the bulb. The glass tube was then broken in the center, the bulb removed, stoppered and weighed. The procedure from here on was then the same as with the other hydrocarbons.

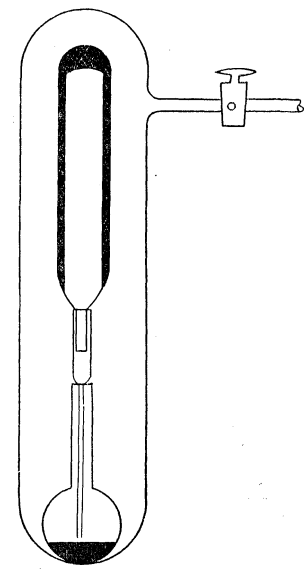

Fig. 1.—Filling the bulb.

A series of density measurements was then made over a temperature range of from 20.69 to 103.50° on the two different lots of materials. Both samples within the limits of accuracy of the measurements gave the same density values. Measurements were first made over intervals of about 2° with both ascending and descending temperatures. In regions near the transition points and rapid density changes the temperature intervals were in the neighborhood of 0.10 to 0.20°, which required an extraordinary amount of bath temperature control. This was found possible with the use of a sensitive thermoregulator and a calibrated Leeds and Northrup platinum resistance thermometer. The absolute density values are considered to be correct to only the third place of decimals while the differential values are within three units of the fourth place. Two phases were found to exist between 20° and the m. p., 100.63°. The density values are given in Table I. The values up to 90° were taken from a large scale plot constructed from the density values obtained in numerous runs. Above 90° to the m. p. actual values of a typical run for phase (1) are given in order to illustrate the manner of approaching a suspected transition or melting point. A similar set of values is given for phase 2.

(2) Seyer, Keays and Patterson, *ibid.*, **66**, 179 (1944).

The phase stable above 20° up to 74.25° is referred to as phase 1 and that stable between 74.25 and 99.65°, as phase 2.

It was found that at the low temperatures equilibrium could be reached in about fifteen minutes, above 80° in over thirty minutes; but near the transition temperatures it required as much as seventy-two hours before the mercury level in the capillary tube became constant.

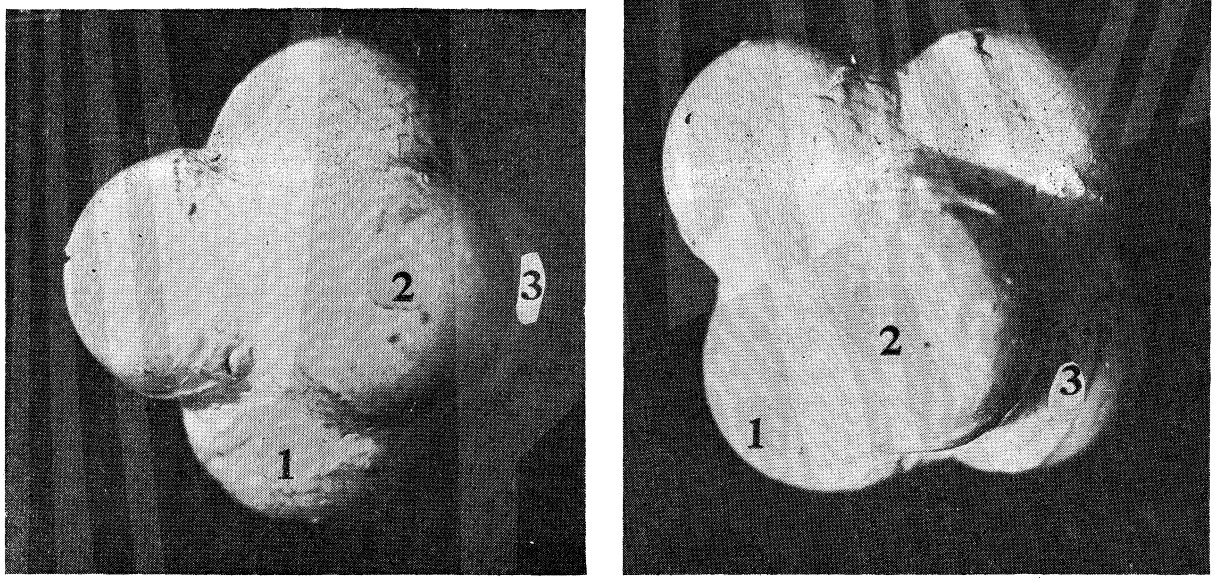
99.65	.7334		

Discussion.—The unusual behavior of this hydrocarbon is shown very clearly when densities are plotted against temperatures (Fig. 2). There is an over-all resemblance to the behavior of the even numbered, C_{18}, C_{20}, C_{22}, hydrocarbons of the normal paraffin series, but there is this difference, that the enclosed region for hexamethylethane does not represent a region in which the possible cooling paths with different cooling rates may lie.[2] Here only two definite paths have been found even though the cooling rates in some cases were as low as 0.5° per day. With ascending temperatures, the path was always along ABCD through the melting point to the liquid. Along ABC the path could be retraced at will to the left of C upon either heating or cooling. In general, once beyond C, along CD such was not the case, for increase of temperature led to D, the m. p. The point C was never actually measured. It was established by drawing a line parallel to the density axis through the point F, which was the first equilibrium point that could be obtained upon cooling the hydrocarbon from the liquid state. As mentioned before, measurements in the neighborhood of C and D were made with temperature intervals of less than a tenth of a degree, with heating and cooling rates from 0.1 to 0.5° per day. Yet no transition point could be detected at 74.25° or at 99.65° with an ascending temperature for phase 1, although Calingaert, Soroos, Hnizda and Shapiro, in their communications with us stated that they had twice observed a break in the density–temperature curve, once at 99.59° and once at 99.63° when proceeding toward the melting point on cooling. In our experience both hydrocarbons samples always behaved in the same way. Reproducible points on a large scale curve could readily be obtained for phase 1 with either ascending or descending temperature runs providing the temperature did not exceed 99.96°. Points beyond this were only obtained when proceeding toward the m. p. Whenever the temperature of 99.96° was exceeded it was not found possible to reverse the path toward B because the mercury level in the dilatometer tube never became steady within a time limit of twenty-four hours. At times the mercury column even began to vibrate and it was necessary to cool it below 70° to again obtain a steady state. Why this was so we are unable to explain except to suggest that the time limit of twenty-four hours was too short.

Starting with the liquid and cooling, the hydrocarbon invariably followed the path EDCFGBA instead of the expected one, EDFGBA. There was at no time mistaking this peculiar behavior of the hydrocarbon of first contracting and then when all the liquid had more or less completely solidified suddenly expanding. Before it was understood what was occurring, the rapidity of the expansion was so great as to force some of the mercury out of the dilatometer. In fact, to make measurements at all over this range, it was necessary to construct a special dilatometer with such tube and bulb dimensions that mercury did not overflow into the reservoir upon re-expansion. The action of the hexamethylethane in detail was somewhat as follows: Upon cooling the liquid to 100.5° solidification began and continued for about a period of from one to two hours. After this time as far as one could observe, all the material had solidified, yet the mercury level in the manometer would still keep falling slowly even after seventy-two hours. Lowering the temperatures by decrements of about 0.1° caused further contraction but no steady state. At 99.65° a sudden expansion occurred, causing a change in the mercury level of from 3 to 5 cm., depending upon the dimensions of the particular dilatomer in use. Simultaneously, the solid changed from being opaque to translucent. Furthermore, the above temperature was the first at which equilibrium



(a) Rotation at right angles to 001 plane possible. (b) No rotation with three methyl groups in 001 plane.

Fig. 2.

could be obtained upon cooling from the liquid phase. The decrease in density between the points C and F was approximately 0.033 or about 4.5%. Further cooling brought about contraction of what is called phase 2 along the line FG until a temperature of 74.25° was reached when transformation into phase 1 took place and the density rose to a value corresponding to point B on the original ABC path.

Once equilibrium had been established just a little to the left of B and the sample then heated, phase 1 did not revert back to phase 2, but persisted in the metastable state along the line BC. Of course it is quite conceivable that had phase been seeded with crystals from phase 2 at the first transformation point (74.25) the latter phase would have formed. However, this was impractical with our present type of apparatus. Furthermore, with all the other hydrocarbons so far investigated this was not necessary to bring about transformation.

Heating phase 2 moved the densities along the line FG. Beyond F to the m. p. no equilibrium states whatever could be obtained. Nor were there any pronounced indications of a contraction equivalent to FC taking place. Thus, as far as could be ascertained with the dilatometer, the path on warming phase 2 was along the path GFD, and not GFCD. In other words, the fusion and solidification processes were not mechanically reversible. A similar situation was recently found when measuring the dielectric constants of *cis* and *trans* decahydronaphthalene, through the melting and freezing regions.[3]

(3) Seyer and Barrow, *ibid.*, **70**, 802 (1948).

Some sort of transformation, about one degree below the melting point, was observed in the case of several long chain normal paraffins by Piper, *et al.*[4] They inferred the existence of a transition point because of a change in optical properties. The dilatometer method used in this Laboratory for measuring the density of these hydrocarbons in the solid phase failed to show any change in volume at this so-called second transition point.

As a result of the X-ray work of Mueller[5a,b] we have a good knowledge of the crystal structure of the *n*-paraffin hydrocarbons in the various solid phases. There appear to be three forms, one of which is stable in a region 5 to 6° below the m. p. In this form the molecules stand upright on a rectangular base, the 001 plane. Another form common to the even numbered *n*-paraffins has the molecules tilted to the base at an angle of about 60°. There is still another form intermediate between the two mentioned in which the angle of tilt is somewhat less than 60° and the base may be more or less of a rectangle. West, from X-ray data, deduced that hexamethylethane at room temperatures has a cubic body centered dodecahedron crystal structure, which is almost spherical.[6]

Any explanation of the unusual behavior of this compound must of necessity be of a tentative nature until X-ray and specific heat measurements have been made. Hence the following attempted explanations must be considered in this light. While the structural formula would indicate that

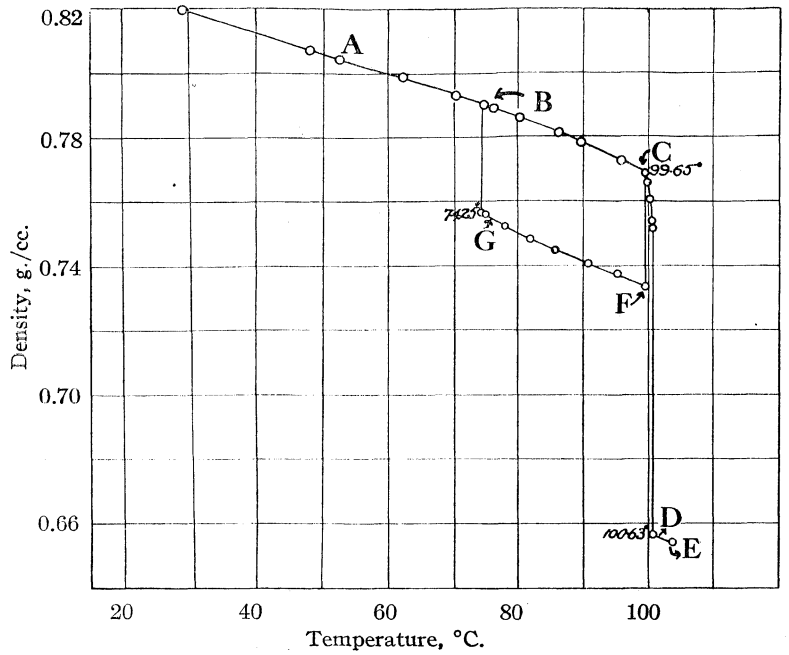

Fig. 3.

hexamethylethane is completely symmetrical, spatial considerations prove that this is not quite so. A geometrical model of the molecule prepared for us by Dr. Robert Delavault with the help of Pauling's data illustrates this clearly in the accompanying photographs. The rounded protuberances represent approximately the volumes swept out by the rotations of the methyl groups attached to the ethane skeleton which is itself buried in the inside of the figure.

West has discussed the crystal modification of C_2X_6 molecules.[6] He reasoned that these derivatives of ethane had not more than one principal axis of rotation. He assumed further that in the cubic modification, there is a large degree of thermal vibration approaching a rotation of the molecules as units, which permits them to simulate a higher degree of symmetry than they actually possess. Consequently, the hexamethylethane molecule might under certain conditions be regarded as a sphere, particularly if it rotated on an axis at right angles to the 001 plane as in Fig. (a) where only one carbon atom of the methyl group lies in this plane.

Unlike the *n*-paraffin hydrocarbons above C_{16} the conditions for the formation of the two solid phases appear to be reversed in the case of this symmetrical octane. Here immediately below the m. p. the stable phase is probably the monoclinic or "tilted form," while at room temperatures the stable one is the cubic form with the long axis at right angles to the 001 plane Fig. 3(a). The former phase could be formed from the latter by merely twisting the molecule through a solid angle of about 30°, so that three of the carbon atoms would lie in the 001 plane (Fig. 3(b)). It is further assumed that in this form no rotation occurs, also that such a form would be anisotropic since that of the cubic form according to West[6] is isotropic.

Hexamethylethane like hexachloroethane appears to be trimorphous. Parks, Huffman and Thomas measured the specific heat of this hydrocarbon from −184.3 to 22.4° and obtained a transition point at −125°.[7] The crystal form below this transition is unknown but from the evidence available, the cubic form is the stable one from this temperature to 74.25°. Let us now assume that the hexamethylethane is heated, that it exists in the form stable above −125.0° which according to West is the cubic form and that rotation of the molecule takes place such as is shown in Fig. 3(a). It is generally considered that the extraordinary stability of solids composed of symmetrical molecules is connected with molecular rotation. Returning again to our Fig. 2, we find that heating causes thermal expansion, only, along the line ABC even beyond the second t. p. 74.25°. Such a belated conversion is not uncommon among the hydrocarbons. At about 99.63° signs of melting appear, the solid becoming soft and more or less plastic in character indicating a loosening up of the polycrystalline mass. This behavior suggests that the melting process is of the type postulated by Mott and Gurney in their discussion on the theory of liquids.[8]

A noteworthy fact was that within the limits of experimental error the amount of expansion at 99.65°, 4.5%, was equal to that found for contraction at 74.25°.

Briefly, the anomalous behavior of hexamethylethane between the temperatures of 101.63 and 99.65° might be regarded as part of the freezing or solid forming process. Were the type of packing in the liquid analogous to that of the GF phase of the solid, this abrupt contraction and re-expansion would probably not take place.

The density of the stable phase at 20° is 0.824. West gave a value of 0.83.[5] The density equation for the liquid phase on the basis of six measurements was established as

$$D_t = 0.6568 - 0.00089\ (t - 100.63)$$

where D_t is density at any temperature t. The extrapolated liquid density at 20° is 0.728 g./cc. Calingaert obtained 0.7219 from solutions of hexamethylethane in *n*-octane.[9]

Their average coefficient $d(D_t)/dt$ for several

branched hydrocarbons is 0.000850, a little lower than that of the symmetrical isomer which is 0.00089.

In conclusion, we wish to acknowledge the helpful suggestions offered by G. Calingaert and his co-workers of the Ethyl Corporation, and also that of R. Delavault, who, as mentioned before, took great pains to prepare a model for us.

Summary

1. The density of hexamethylethane has been measured over a temperature range of from 20° to 103.5°.

2. Two transition points were obtained upon cooling from the liquid, one at 99.65° and the other at 74.25°.

3. The contraction and re-expansion of the hydrocarbon between 100.63 and 99.65° might be considered as part of the freezing process.

4. The existence of the two forms can be explained in a similar manner as that of normal paraffins except that in this case the stable form has a cubic structure with the molecule standing upright in the 001 plane instead of being tilted as are the long hydrocarbon chains.

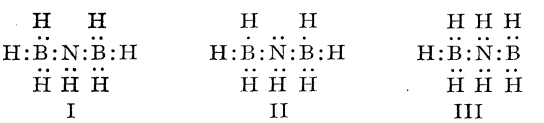
The N-Methyl Derivatives of B_2H_7N[1]

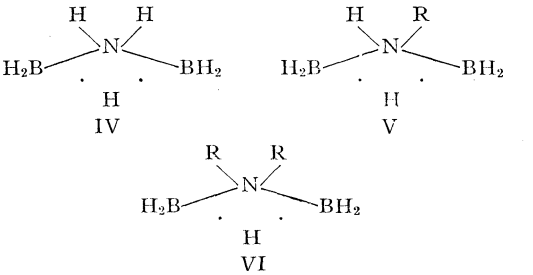
BY ANTON B. BURG AND CARL L. RANDOLPH, JR.

The structure of the aminoboron compound B_2H_7N has not been intelligible in terms of the known chemical facts,[1a] and the application of current theories of electron-deficient bonding has awaited knowledge of the positions of the hydrogen atoms on the B–N–B skeleton. The early electron-diffraction studies[2] suggest an arrangement in which the boron atoms are equivalent, like carbon atoms in dimethylamine. A resonance-structure composed of models such as I and II was suggested but the less symmetrical model III accounts far better for the 1:1 addition compounds formed by B_2H_7N with bases such as ammonia or trimethylamine. On the other hand, the electron-deficiency of the right-hand boron atom in III would demand an irreversible dimerization like that of CH_3BH_2,[3] $(CH_3)_2BH$[4] or $(C_2H_5)_2BH$.[5] Actually B_2H_7N does not dimerize in the least degree.



I II III

The present paper describes the N-methyl derivatives of B_2H_7N, prepared from diborane and methylamine or dimethylamine. Both are more stable and more volatile than B_2H_7N itself, but present the same structural problem. The existence of the N-dimethyl derivative, $(CH_3)_2NB_2H_5$, narrows the problem by eliminating models I and II, but III remains unsatisfactory unless a way can be found to shift electrons toward the tercovalent boron atom. Earlier concepts of the electronic structure of diborane threw no light on this problem, but the recent proposal that each of the two hydrogen atoms of Dilthey's bridge structure[6] is "half-bonded" to two boron atoms without resonance-relation to the other,[7] justifies the replacement of one bridge-hydrogen atom by nitrogen, thus:



IV V VI

These models are like III, except that one hydride unit has moved into a position suitable for sharing electrons equally with the two boron atoms, improving the symmetry and orbital-filling, and achieving a lower energy state by the resonance principle. Base-addition still can occur in terms of structure III, by suppressing one side of the B–H–B bridge linkage in structure IV. Thus structure IV is not only in agreement with the chemical behavior of B_2H_7N, but is also compatible with the suggestion of equivalent boron atoms advanced by Bauer.

The bridge-model for B_2H_7N and its derivatives was suggested by Professor Arthur J. Stosick of this Department in October, 1947.[8] With the as-

sistance of Dr. Kenneth W. Hedberg and Mr. George B. Guthrie at the California Institute of Technology, he has obtained electron-diffraction photographs over a wide range of intensities for B_2H_7N and $(CH_3)_2NB_2H_5$. The results agree with models having BNB angles of 96 and 89°, respectively. Without the postulated hydrogen-bridging the angles should have been nearly tetrahedral. Structures such as IV, V, and VI thus are fully supported by physical and chemical facts.

Aside from the structural problem, the compounds B_2H_7N, $CH_3NHB_2H_5$ and $(CH_3)_2NB_2H_5$ offer interesting series comparisons of both physical and chemical properties. They also imply the existence of many other new compounds based upon the same bonding principle.

The nomenclature of such compounds is difficult, but it seems most satisfactory to follow the convention established by the mono-halogen derivatives of diborane. It seems highly probable that bromodiborane is bridged through bromine and that chlorodiborane is similarly B–Cl–B bonded. Hence $(CH_3)_2NB_2H_5$ may be called dimethylaminodiborane without creating new language.

Dimethylaminodiborane, $(CH_3)_2NB_2H_5$

The preparation of the compound $(CH_3)_2NB_2H_5$ was accomplished by two methods, both dependent upon dimethylaminoborine, $(CH_3)_2NBH_2$, a substance discovered by Wiberg and his co-workers.[9,10] We describe first a procedure for making $(CH_3)_2NBH_2$, a method more adaptable to large-scale operation than the original, and involving less secondary aminolysis.

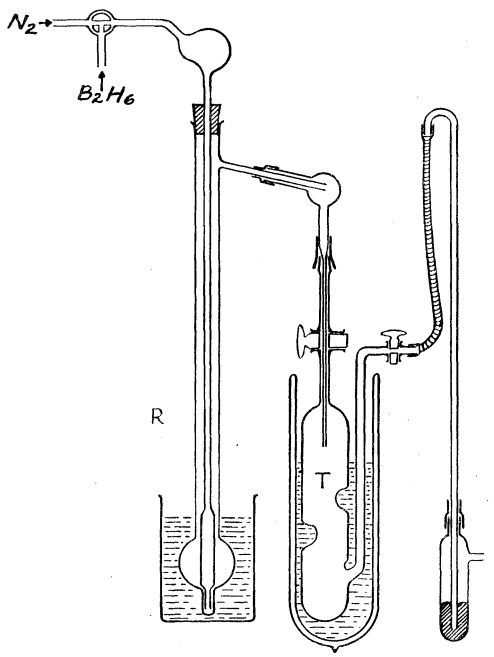

Fig. 1.—Apparatus for preparing $(CH_3)_2NB_2H_5$.

(9) E. Wiberg and A. Bolz, *Ber.*, **73B**, 209 (1940).

(10) E. Wiberg, A. Bolz and P. Buchheit, *Z. anorg. Chem.*, **256**, 285 (1948).

Preparation of $(CH_3)_2NBH_2$.—Diborane is passed into dry liquid dimethylamine at −42°, in the bottom of a 25 × 650 mm. test-tube. This container then is attached through a sealed-on ground joint to the high vacuum system, and the excess amine is pumped off, at room temperature, leaving the liquid compound $B_2H_6 \cdot 2(CH_3)_2NH$ (structure uncertain). Dry nitrogen now is admitted to bring the pressure to 400 mm., and the lower part of the tube is heated to 130° by a tubular electric furnace. Hydrogen is evolved and $(CH_3)_2NBH_2$ sublimes into the cool upper part of the tube, escaping further aminolysis. The yield thus is nearly quantitative. The crude product, containing little of the more volatile bis-dimethylaminoborine[9] and a trace of less volatile liquid, is purified by means of a fractionating column, operating at 98° and 400 mm. pressure (dry nitrogen) and delivering into the vacuum system. The elevated pressure and temperature are necessary to avoid solidification during the process.

A sample produced by this method was purified still further by recrystallization from low-boiling petroleum ether. Its purity was checked by hydrolysis in aqueous hydrochloric acid at 110°: 18.7 mg. yielded 14.78 cc. of hydrogen (gas at S. C.)—theoretical, 14.72. The melting range was determined as 74.5–75° (previous value, 73.5°)[10] and the vapor tension as 9.1 mm. at 23°. Precise measurements of the variation of the vapor density with temperature are in course.

Preparation of $(CH_3)_2NB_2H_5$.—Of two methods of preparing $(CH_3)_2NB_2H_5$ the more direct is the addition-reaction of diborane with dimethylaminoborine, a reaction which can be completed slowly in a sealed bulb at 80°, or very rapidly at 135° in a flow system. By either process, the reaction

$$2(CH_3)_2NBH_2 + B_2H_6 \longrightarrow 2(CH_3)_2NB_2H_5$$

is essentially quantitative, occurring in preference to the thermal decomposition of the diborane. If a large-scale preparation is desired, one proceeds without isolating the $(CH_3)_2NBH_2$, for the small loss of yield (due to secondary reactions) is more than offset by the speed and convenience of this procedure. Diborane is passed into dimethylamine at −42°, in the bottom of the tube R, Fig. 1; then the excess amine is distilled off and the bath temperature slowly raised to 135°. As the resulting $(CH_3)_2NBH_2$ begins to reflux in the upper part of tube R, diborane is bubbled in at the rate of 100–200 cc. per minute. The product is caught at −196° in the trap T, from which it later is distilled into the vacuum system and separated from unused diborane and $(CH_3)_2NBH_2$. About 75–85% of the diborane undergoes reaction and the remainder is recovered. By this process, it is convenient to prepare 25 g. of $(CH_3)_2NB_2H_5$ in the course of two hours, but there is no doubt that a much higher rate would be feasible with larger apparatus.

Small samples of $(CH_3)_2NB_2H_5$ are best purified by a slow high-vacuum distillation from a tube at −78.5° into a trap at −112°, with a second trap at −196° to catch more volatile impurities. The portion condensed at −112° should have a constant vapor tension of 101 mm. (uncor.) at 0°. If a large sample is to be purified by a fractionating column, the reflux temperature should be near −55°. Total elimination of $(CH_3)_2NBH_2$ is difficult.

The second method of preparing $(CH_3)_2NB_2H_5$ was discovered during an attempt to form a boron fluoride addition compound of $(CH_3)_2NBH_2$. The reaction was found to require a temperature of 90°; it was then tried in a sealed bulb (16 hours, 90°), with 142.5 cc. of $(CH_3)_2NBH_2$ (gas at S. C., determined by weight) and 176 cc. of boron trifluoride. Separation of the $(CH_3)_2NB_2H_5$ from diborane and the solid products of low volatility was readily accomplished by fractional condensation in traps at −42, −112 and −196°. The desired product was trapped at −112°. The material balance could be interpreted by the following equations, in which R designates methyl and the coefficients represent cc. of gas at standard conditions (equivalent to molar relationships):

$$19.6R_2NBH_2 + 9.8BF_3 \longrightarrow 9.8(R_2N)_2BH \cdot BF_3 + 4.9B_2H_6$$

TABLE I

VAPOR TENSIONS OF $(CH_3)_2NB_2H_5$

t, °C.	−35.6	−21.0	−17.7	−12.7	−5.5	−1.7	0.0	2.9

$p_{mm.}$ calcd.	157.8	184.2	274.5	346.6	419.8	515.0	652.1	760.4

$$61.8R_2NBH_2 + 41.2BF_3 \longrightarrow 30.9(R_2N)_2BF\cdot BF_3 + 20.6B_2H_6$$

$$13.9R_2NBH_2 + 4.6BF_3 \longrightarrow 4.6(R_2N)_3B\cdot BF_3 + 4.6B_2H_6$$

$$47.2R_2NBH_2 + 23.6B_2H_6 \longrightarrow 47.2\ R_2NB_2H_5 \text{ (obsd. yield)}$$

The reaction actually used 57.5 cc. of boron trifluoride (calcd., 55.6). The resultant diborane was 6.0 cc. (calcd., 6.5). The white solid was treated with trimethylamine to remove boron trifluoride and the resulting inseparable mixture, assumed to be $(R_2N)_2BH$ and $(R_2N)_2BF$, was distilled off and weighed as 201.8 mg. (calcd. 206.4). The mixture, having a vapor tension of 11 mm. at 0°, was hydrolyzed to yield 9.1 cc. of hydrogen (calcd., 9.8). The original white solid was closely similar to $(R_2N)_2BH\cdot BF_3$, which was especially prepared for comparison. The postulated compound $(R_2N)_3B$, which may have resulted from the amine treatment of the solid, was not isolated.

Proof of Formula.—The molecular weight of the new compound was determined from vapor density measurements as 71.8 (calcd., 70.6). Boron-linked hydrogen was determined by acid hydrolysis: an 11.08-cc. sample yielded 56.30 cc. of hydrogen (calcd., 55.40 cc.). Aminoid nitrogen was determined as 11.09 cc. gas (calcd., 11.08), by a modified Kjeldahl-type distillation and titration. Boron was determined on a separate 9.16-cc. sample by hydrolysis, neutralization to the methyl red end-point, and titration of the mannitol spirane to the phenolphthalein end-point. The result was equivalent to 18.28 cc. of gaseous B (calcd., 18.32).

Carbon was converted to carbon dioxide by fuming nitric acid at 200° during forty-eight hours. Gases volatile at −80° were passed over copper at 300°, after which the carbon dioxide was trapped out of the gas stream. A 6.72-cc. sample, treated in this way, gave 13.88 cc. of carbon dioxide (calcd., 13.54 cc.).

That the $(CH_3)_2N$ group is conserved as such in the formation of $(CH_3)_2NB_2H_5$, was confirmed by the recovery of 14.40 cc. of $(CH_3)_2NH$ after hydrolysis of 17.65 cc. of the compound. The non-condensable gas from this hydrolysis was proved to be hydrogen (88.70 cc.) by reaction with hot copper oxide to form only water. These results leave no doubt of the formula $(CH_3)_2NB_2H_5$.

Volatility.—The vapor tensions of a highly purified sample of dimethylaminodiborane, measured over the temperature range −36 to 50° are given in Table I. They determine the equation $\log_{10} P_{mm} = -1727.64/T + 1.75 \log T - 0.004661\ T + 5.3370$, which implies a boiling point of 50.3°. The heat of vaporization at the boiling point is estimated as 6670 cal./mole, and the Trouton constant is 20.6 cal./deg. mole.

Melting Point.—The melting range, determined visually, using the ammonia vapor tension thermometer[11] was −54.7 to −54.4° and −54.8 to −54.4° in two separate determinations.

Liquid Density.—A small capillary-dilatometric pycnometer was used to determine the density equation $d = 0.6456 - 0.001066t$ in the range 0–25°. For comparison, the densities of B_2H_7N were measured in the same range, determining the equation $d = 0.6486 - 0.0075t$.

Thermal Stability.—A relatively high degree of thermal stability sharply differentiates dimethylaminodiborane from the parent compound B_2H_7N: while the latter is appreciably decomposed in the vapor state at 45° during several hours heating, samples of $(CH_3)_2NB_2H_5$ are unaffected over much longer periods of time at temperatures as high as 90°. Vapor or liquid samples standing at room temperature for five months showed no signs of decomposition, whereas B_2H_7N is almost wholly decomposed under similar conditions.

Reaction with Trimethylamine.—Dimethylaminodiborane adds trimethylamine at low temperatures to give the stable product $(CH_3)_2NB_2H_5\cdot N(CH_3)_3$, paralleling the behavior of aminodiborane (B_2H_7N) toward nitrogen bases. Thus when a purified sample of $(CH_3)_2NB_2H_5$ amounting to 7.53 cc. was treated with 17.83 cc. of $(CH_3)_3N$ at −80° and warmed slowly to −42° during two hours, only 9.98 cc. of amine could be regained from the reaction, implying the absorption of 7.8 cc. of $(CH_3)_3N$, and the formation of the compound $(CH_3)_2NB_2H_5\cdot(CH_3)_3N$. This equimolar addition constitutes strong chemical evidence of the structural similarity of $(CH_3)_2NB_2H_5$ and B_2H_7N.[1a]

On warming to room temperature, the addition-product appeared as a white solid, exhibiting a saturation pressure of 4 mm. at room temperature—much more volatile than $B_2H_7N\cdot N(CH_3)_3$. There is no indication that further amine addition occurs, since the $(CH_3)_2NB_2H_5\cdot(CH_3)_3N$ absorbed no more trimethylamine during a two-hour treatment at −42°. Although the material appears to be stable indefinitely at room temperature, heating to 85° causes almost complete decomposition according to the equation

$$(CH_3)_2NB_2H_5\cdot N(CH_3)_3 \longrightarrow (CH_3)_2NBH_2 + (CH_3)_3N\cdot BH_3$$

Thus a homogeneous sample of $(CH_3)_2NB_2H_5\cdot(CH_3)_3N$, amounting to 0.846 mmole, gave 0.724 mmole $(CH_3)_3N\cdot BH_3$ and 0.756 mmole of $(CH_3)_2NBH_2$. These products were effectively separated by repeated fractional condensation through a U-tube at −18°. The $(CH_3)_2NBH_2$ passing this trap was identified by its vapor tension of 9.5 mm. at 18°, while the $(CH_3)_3N\cdot BH_3$, retained at 18°, was recognized by its orthobaric melting point of 92–92.5°.

Reaction with Ammonia and with Sodium in Liquid Ammonia.—Like trimethylamine, ammonia adds in a 1:1 ratio to dimethylaminodiborane, but it is also possible to form a diammoniate. This may be the salt $NH_4^+(CH_3)_2NB_2H_5NH_2^-$, for a 9.86-cc. sample of $(CH_3)_2NB_2H_5$, dissolved in liquid ammonia and allowed to react with 27.9 mg. of sodium at −70°, yielded 4.63 cc. of hydrogen during twenty minutes, increasing to 4.89 cc. (1.01 equiv.) during two hours. In a typical addition experiment, 5.58 cc. of $(CH_3)_2NB_2H_5$, treated with three volumes of ammonia, absorbed 10.4 cc. of ammonia during two and one-half hours at −80°. At −40°, evacuation brought the ratio of ammonia to $(CH_3)_2NB_2H_5$ to 1.47, but no lower. At 0° the compound decomposed, yielding $(CH_3)_2NBH_2$ and a non-volatile solid.

Behavior toward Boron Fluoride.—Dimethylaminodiborane (24.3 cc.) and boron fluoride (22.5 cc.) were heated together in a sealed tube for one hundred and forty hours at 100°, to yield 1.6 cc. of diborane at the expense of 4.0 cc. of boron trifluoride and 3.5 cc. of $(CH_3)_2NB_2H_5$. These results seemed most simply explained by assuming the equilibrium $(CH_3)_2NB_2H_5 + BF_3 \rightleftarrows {}^1/_2B_2H_6 + (CH_3)_2NBH_2\cdot BF_3$—a displacement of a borine group by boron fluoride. On the other hand, there is a possibility that disproportionation reactions, like those observed in the reaction of boron fluoride with $(CH_3)_2NBH_2$, occur.

A Chloro Derivative of Dimethylaminodiborane.—In view of the probable applicability of the structural prin-

(11) A. Stock, *Z. Elektrochem.*, **29**, 354 (1921).

ciple of the aminodiboranes to bromodiborane and chlorodiborane (halogen-bridge instead of N-bridge), it seemed both feasible and theoretically of interest to synthesize a halogenated aminodiborane, involving parallel B–Cl–B and B–N–B linkages in the same molecule. Accordingly, the thermally unstable compound $(CH_3)_2NB_2H_4Cl$ was prepared by the reaction of dimethylaminodiborane with chlorodiborane at 25°.

In a typical experiment, 193 cc. of diborane and 63 cc. of boron trichloride were allowed to react to form the equilibrium amount of B_2H_5Cl during two hours at room temperature. A sample of dimethylaminodiborane amounting to 187 cc., was then condensed into the reaction flask by means of liquid nitrogen. After standing fourteen hours at 25°, the crude product was separated from the more volatile components of the mixture by rapid distillation through a trap cooled to −42°.

Final purification of the product was effected by the use of a micro fractionating column[12] operating at a reflux temperature of −42°. After removal of impurities volatile at this temperature, the reflux temperature was raised to −25° and the chloro compound distilled out. The pure material was kept at −196° except during brief periods of experimentation.

The composition of the material was found by analysis of weighed samples for hydrogen, boron and nitrogen as previously described, and for chlorine by an adsorption-indicator titration of the hydrolysis residue. The resulting empirical formula $[(CH_3)_2N]_{0.97}B_{1.9}H_{4.0}Cl_{1.1}$ indicated the ideal formula to be $(CH_3)_2NB_2H_4Cl$.

This compound, formally named B-chloro-N-dimethylaminodiborane, spontaneously inflames in air. Its vapor tension at 0° is 6.5 mm.; at 20°, 18 mm. Good measurements at higher temperatures proved unfeasible on account of the increased rate of decomposition.

This decomposition was studied by allowing a pure sample of $(CH_3)_2NB_2H_4Cl$ (35.0 cc.) to stand at room temperature for six days, during which the original liquid phase disappeared, leaving a white, semicrystalline solid. The mixture then yielded 7.12 cc. of B_2H_6, 7.21 cc. of $(CH_3)_2NB_2H_5$ and 12.9 cc. of $(CH_3)_2NB_2H_4Cl$, implying the equation

$$3(CH_3)_2NB_2H_4Cl \longrightarrow B_2H_6 + (CH_3)_2NB_2H_5 + (CH_3)_4N_2B_2Cl_3H$$

The solid product was unaffected by a hot solution of hydrochloric acid or sodium hydroxide, and was removed from the apparatus only by boiling nitric acid.

Methylaminodiborane, $CH_3NHB_2H_5$

The high stability and volatility of dimethylaminodiborane, relative to aminodiborane, appears to result from the influence of the two methyl groups bonded to the central nitrogen atom. Hence it was reasonable to expect that methylaminodiborane, possessing a single methyl group, would represent a situation intermediate between that of the parent compound and its N-dimethyl derivative.

The synthesis of this compound has been accomplished by the reaction of methylamine with diborane, and, as expected, the chemical and physical properties of the new material fall between the previously studied extremes.

Preparation.—The formation of methylaminodiborane in good yields required a flow method like that used for aminodiborane,[1a] for closed-bulb heating methods involving diborane with the liquid $B_2H_6{\cdot}2CH_3NH_2$ complex or with its decomposition product $(CH_3NHBH_2)_x$ gave only negligible yields. Evidently $CH_3NHB_2H_5$ is more stable than B_2H_7N, for it forms in better yields under less critical conditions, as indicated in Table II. These yields are based upon the diborane used up in single passages over a larger quantity of methylaminated diborane.

TABLE II

Temp., °C.	Flow rate, cc./min.	Total B_2H_6, cc.	Used B_2H_6, cc.	Product, cc.	Yield, %
92–97	30	337	48	66	69
90–95	40	340	42	75	90

The product was readily purified by passage through a trap at −42° and fractional condensation at −90°; it then showed a constant and reproducible vapor tension of 47.5 mm. at 0°.

Proof of Formula.—The empirical formula of this methyl derivative was established by analysis for hydrolyzable hydrogen, nitrogen, boron and carbon. The methods were as given for $(CH_3)_2NB_2H_5$. A 6.43-cc. sample gave 31.1 cc. of hydrogen, 6.51 cc. of ammonia and 13.3 "cc." of B, while 11.5 cc. of the vapor yielded 11.8 cc. of carbon dioxide. These data are represented by the literal formula $(CH_3)_{1.03}(NH)_{1.01}B_{2.06}H_{4.84}$, or essentially $CH_3NHB_2H_5$.

The molecular weight, calculated from the vapor density, was 56.9 (calcd. 56.73), clearly confirming the formula.

Vapor Tensions.—Intermediate in volatility between B_2H_7N and $(CH_3)_2NB_2H_5$, methylaminodiborane has an extrapolated boiling point of 66.8°, as determined from the vapor pressure equation derived from the data of Table III, namely

$$\log P_{mm} = -2158.56/T + 1.75 \log T - 0.00806T + 7.51883$$

The heat of vaporization thus is estimated to be 6,666 cal./mole, while the Trouton constant is 19.6, a value consistent with this type of equation.

TABLE III

VAPOR TENSIONS OF $CH_3NHB_2H_5$

t °C.	−33.0	−26.3	−19.6	−14.1	0.0	11.4	29.6	39.4
$P_{obs.}$, mm.	5.9	9.4	14.6	20.7	47.6	84.9	195.7	290.6
$P_{calcd.}$, mm.	5.8	9.4	14.7	21.0	47.6	86.2	195.8	288.2

Behavior toward Trimethylamine.—The structural similarity of methylaminodiborane to aminodiborane and dimethylaminodiborane is indicated by the formation of a 1:1 addition compound with trimethylamine. This fact is interpreted, as before, in terms of a B–N–B skeletal pattern. Thus 7.88 cc. of methylaminodiborane absorbed 8.16 cc. of a 17.25-cc. portion of trimethylamine during two hours at −42°. The amine in excess of the 1:1 ratio was removed only with difficulty on warming to room temperature. The white solid product of composition corresponding to the formula $CH_3NHB_2H_5{\cdot}N(CH_3)_3$, showed no detectable vapor tension at room temperature, nor did any increase in volatility occur on standing. It is concluded that the decomposition typical of such compounds, yielding $(CH_3)_3N{\cdot}BH_3$, does not take place at room temperature.

Thermal Stability.—A slow and highly reversible dissociation of methylaminodiborane into diborane and polymeric methylaminoborine places it as expected, between aminodiborane and dimethylaminodiborane in order of increasing thermal stability. Although no deviation from ideal behavior could be detected on heating a gas sample at constant volume to 90° over a five-hour period, a 17.50-cc. sample, held as a liquid at 45° for thirteen days, yielded 2.7 cc. of hydrogen, 3.17 cc. of diborane and solid methylaminoborine polymer. The original sample was 39% decomposed. The mixture appeared to be approaching equilibrium according to the equation

$$2xCH_3NHB_2H_5 \rightleftharpoons (CH_3NHBH_2)_x + xB_2H_6$$

The reversible nature of the reaction was shown by the fact that when solid CH_3NHBH_2[13] was treated with a

(12) A. B. Burg, THIS JOURNAL, **56**, 500 (1934).

(13) Prepared by heating diborane and methylamine at 100° for two hours, and pumping off the volatile products.

17.28-cc. sample of diborane during three days at 40°, 0.8 cc. of diborane was absorbed, producing 1.03 cc. of $CH_3NHB_2H_5$ and 0.7 cc. of hydrogen. Shorter reaction periods, typified by an experiment in which diborane under 100 mm. pressure was passed over polymeric CH_3NHBH_2 at 100°, produced no detectable amount of methylaminodiborane.

Discussion

The observed regular trend toward increased thermal stability as methyl groups are successively substituted for N-bonded hydrogen atoms in the aminodiborane series appears to be inversely related to the stability of the polymeric forms of the aminoborines from which these compounds are formally derived.

Thus it is noteworthy that NH_2BH_2, CH_3NHBH_2 and $(CH_3)_2NBH_2$ show volatility characteristics indicative of a progressively lower degree of polymerization, while the corresponding aminodiboranes exhibit a complementary increase in thermal stability. Formation of a stable polymer withdraws aminoborine units from equilibria such as $B_2H_6 + 2BH_2NH_2 \rightleftarrows 2B_2H_7N$, accounting for the relative instability of B_2H_7N. This effect is lessened in the case of methylaminodiborane, and becomes immeasurable in dimethylaminodiborane, due to the low free energy change in the association of $(CH_3)_2NBH_2$—approximately 1.8 kcal./mole at 100°, according to preliminary experiments in this Laboratory.

The decrease of polymerization energy with N-methylation of the aminoborines might be related to the electron-releasing (+I) effect of the methyl groups, permitting resonance-contribution by structures in which boron has a complete octet. However, steric effects may well be more important.

The regular increase in volatility from B_2H_7N to dimethylaminodiborane is most convincingly attributed to steric factors; thus the reverse trend of boiling points (76.2, 66.8 and 50.3°) with increasing molecular weights, is in harmony with the suggestion that more methyl groups force the molecular dipoles farther apart, sharply lowering the intermolecular attraction.

Acknowledgment.—The generous support of this work by the Office of Naval Research is gratefully acknowledged.

Summary

The new compounds $CH_3NHB_2H_5$ and $(CH_3)_2NB_2H_5$ have been prepared from diborane and methylamine or dimethylamine. These and the parent compound, B_2H_7N, are regarded as derivatives of diborane in which a bridging hydrogen atom is replaced by N. A second hydrogen atom can be replaced by chlorine, yielding the volatile, unstable and self-inflaming $(CH_3)_2NB_2H_4Cl$. Volatility, stability and ease of preparation increase in the order $NH_2B_2H_5$, $CH_3NHB_2H_5$, $(CH_3)_2NB_2H_5$; the last can be stored permanently at ordinary temperatures.

The Molecular Weight of the β-Amylase Limit Dextrin from Corn Starch

BY RALPH W. KERR AND FRANK C. CLEVELAND

Difficulty is experienced in the determination of the molecular weight of starch molecules by physical measurements on dispersions in appropriate solvents owing to the reluctance of these molecules or their derivatives to dissociate, or to become disentangled from each other. It is presumed that this difficulty arises because of the linear or long, thread-like structure of the amyloses, or because of the many linear branches on the large amylopectin molecules. On occasion, some branched starch derivatives are found to be so highly associated that they swell but do not dissolve to any very great extent in any neutral solvent. Accordingly, although molecular weight determinations on the amyloses have been reported frequently,[1-5] examinations of the amylopectins have either been approached with considerable caution, or the results have been given with the qualification that the error may be very large.[1,2,6] However, it appeared that if the linear terminal branches were removed, such as, by hydrolysis with β-amylase, association effects would be minimized when observations were made on the residual portion of the amylopectin molecules. Furthermore, inasmuch as branched starch molecules are thought to be of considerable size and measurements such as osmotic pressure determinations are of a very low order, it is obvious that by removing the end branches which constitute, on the average, nearly half the weight of amylopectin molecules, material would be provided the molecular weight of which could be estimated with very much greater accuracy. Lastly, since it has now generally been concluded that the action of β-amylase on amylopectin stops at a definite end-point, leaving the molecule intact behind points of branching, then it fol-

lows that a determination of the molecular weight of this limit dextrin, divided by the fractional yield of this material from the hydrolysis, should provide a fairly accurate calculation for the molecular weight of the parent molecules.

The principal deterrent to this enzymic approach has been doubt concerning the reliability of β-amylase preparations. The isolation of crystalline β-amylase by Balls, Thompson and Walden[7] which may be highly purified by repeated crystallizations, has served to remove this limitation.

Experimental

Preparation of Corn Limit Dextrin.—Fifty grams, dry basis of corn B-fraction, prepared by the use of Pentasol precipitation on autoclaved, defatted corn starch according to the method of Schoch[8] was dissolved in 1500 ml. of hot water by stirring and bringing to a boil. The solution was cooled to 45° with stirring. The *p*H was 6.0. Then 3 drops of a saturated ammonium sulfate suspension of four times recrystallized β-amylase[9] was added and the hydrolysis mixture held at 45°. The reaction was followed by removal of 5-ml. aliquots (40 ml. in all) from time to time and oxidation with alkaline potassium ferricyanide according to the method of Gore and Steele.[10] Hydrolysis was apparently at an end after three hundred and twenty minutes, at which time 54.4% of the B-fraction had been hydrolyzed to maltose.

It would appear from the method used by Balls and co-workers[7] to prepare the enzyme, wherein the crude β-amylase was pretreated with hydrochloric acid at *p*H 3.25 to 3.30 and wherein the enzyme was exposed for long periods of time to *p*H levels of about 3.5, that freedom from α-amylase activity in the final product was assured. This fact was confirmed by Balls and co-workers. It seems reasonable to assume also that after 4 recrystallizations of the β-amylase, a high degree of chemical purity was attained as well as biochemical purity. However, to test the possibility that this crystalline enzyme sample was not free from traces of α-amylase activity, the limit dextrin which remained in the reaction mixture after three hundred and twenty minutes was treated with another drop of enzyme suspension and the reaction was allowed to proceed for an additional nineteen hours, under toluene. No further increase in reducing value, whatsoever, was observed, the final value being equal to 54.3% conversion to maltose. The solution was brought to a boil, evaporated under reduced pressure to 625 ml. and two volumes of methanol were added with stirring to precipitate the limit dextrin. It was obvious that the dextrin consisted of two fractions of about equal parts by weight. The first precipitated when the concentration of methanol reached about 50% by volume and the second in the region of 60–67%. The entire yield of dextrin was combined and further purified by dissolving in water, adding methanol with stirring until the alcohol content reached 67% and collecting the precipitate. The purification procedure was repeated until the supernatant liquor was substantially free from soluble reducing material. Then the dextrin in a concentrated water solution was poured into absolute methanol, filtered and washed 4 times over a period of four days with 200 ml. of methanol. The methanol was removed *in vacuo* at room temperature. The yield of dextrin was 19.98 g., dry basis, or 41.1%, when allowance is made for the samples removed for analysis during the hydrolysis. This value is 90% of the calculated yield. The ferricyanide reducing value[11] of the limit dextrin is 0.79. For comparison, other ferricyanide reducing values are corn starch, 1.00; corn A-fraction, 1.43; corn B-fraction, 0.46.

Acetylation of Corn Limit Dextrin.—Three grams of the dextrin, dry basis, was ground to a powder and dispersed in 60 ml. of formamide.[12] The mixture was heated with stirring to 85° in about fifteen minutes, cooled to room temperature and diluted with 100 ml. of pyridine. To the clear, limpid solution, 80 ml. of acetic anhydride was added dropwise with stirring and the reaction mixture was allowed to stand at room temperature overnight. The clear solution was added slowly to 1500 ml. of water which was stirred with a circular motion. Unexpectedly, the product showed a very pronounced tendency to precipitate in fibrous form. The acetate was washed three times, each with one liter of water, separated by filtration and dried in the air. The dry material was mixed with 75 ml. of pyridine until dispersed and then heated over a period of about fifteen minutes to 85°. The solution was cooled to room temperature, 60 ml. of acetic anhydride added and the balance of the acetylation procedure completed as in the first phase. The final product, which also was fibrous, was washed with 5 one-liter portions of water and the washing period extended over a period of five days. The yield of acetate was 4.84 g., dry basis, or approximately 90%; acetyl = 44.7%. Polarimeter readings on a 2% solution of the acetate in chloroform gave a value $[\alpha]^{25}D$ 166.5°.

Determination of Osmotic Pressures.—Osmotic pressures were determined at several concentrations in chloroform solution according to general procedures given previously.[11] Solution of the acetate in chloroform appeared to be rapid and complete at room temperature. However, the solutions were held at the boiling point for fifteen minutes and cooled to 30° before use. Static measurements were made at all concentrations, since the experimental error inherent in the dynamic method was considered to be too large in relation to the small actual pressures which were developed in this series of experiments. Moreover, although the actual temperature of the osmotic pressure cell is of some importance in all measurements, it was readily apparent that in the determination of very small pressures, variation in temperature during the period of observation, such as the normal variation, or periodic fluctuation of a well-regulated, thermostatically controlled bath, may set up disturbances which cause very large errors. Accordingly, in addition to using a large metal cell of high heat capacity, the cell was brought to 30° and then heavily insulated in addition to being placed in a cabinet thermostatically held at 30 ± 0.05°. Under these conditions, a thermometer fitted into a metal well on the cell showed a variation of only a few thousandths of a degree during periods of observations.

Permeability of the membrane in the osmometer to small fragments of carbohydrate molecules which might possibly be present in the limit dextrin sample was determined as follows: When the highest concentration of solute used was in the osmometer (2.0349 g. per 100 ml.), it was allowed to stand seventy-two hours, the osmotic pressure was determined as shown and then the liquid in the solvent side was drawn into a weighed evaporating dish. The volume was 12 ml., and the residual weight after evaporation was 0.0003 g. The volume in the solution side was 15 ml. and contained therefore 0.3052 g. Accordingly, less than one part per thousand of the acetate diffused through the membrane.

Several tests at lower concentrations gave residues within the experimental error of weighing.

Discussion

The results of osmotic pressure measurements for the triacetate of the β-amylase limit dextrin from corn B-fraction are shown in Fig. 1 and Table

TABLE I

OSMOTIC PRESSURES OF THE ACETATE OF β-AMYLASE LIMIT DEXTRIN FROM CORN B-FRACTION IN CHLOROFORM

C, concn., g. per 100 ml.	π, g. per square cm.	π/C
0.1021	0.100	0.979
.1924	.147	.765
.3036	.228	.751
.4504	.280	.622
.6075	.426	.701
.8008	.648	.809
1.0130	.825	.815
1.4530	1.604	1.104
2.0349	3.003	1.480

I. It will be observed that the slope of the curve plotting π/C against C is negative at very low concentrations, then changes in slope and at relatively high concentrations assumes a positive slope. A similar shape has been observed by Steurer[13] for high molecular weight ethyl cellulose in toluene. This shape has also been observed by us previously in unreported studies on derivatives of hydrolyzed branched starch molecules although we were unable to observe a similar effect with the acetates of linear starch molecules,[5] at least using concentrations as low as 0.3 g. per 100 ml., which appeared to be the limit for reliable measurements using techniques which were available at that time. In studies on hydrolyzed, branched starch molecules, and using concentrations in the range of 0.2 to 0.8 g. per 100 ml., it was at first assumed that the osmotic pressure curves had very nearly zero slope. More extended observations by improved techniques on branched fractions from acid hydrolyzed starch of the order of DP_n 500–1000 (which will be the subject of a future report) have shown in this case also, that the slope of the curve becomes negative as infinite dilution is approached. This is presumed to be due to residual association between solute molecules; the effect vanishes at low orders of DP_n. At relatively high concentrations, the curve for branched starch molecules shows the usual anomalous osmotic pressure effects given generally by high polymers which has been discussed recently by Bawn.[14]

Extrapolation of curves of the shape shown is difficult and constitutes the principal element of uncertainty of the results reported. It is believed, however, that the extrapolation shown in Fig. 1 indicates at least the correct order of magnitude for the osmotic pressure of the limit dextrin acetate at infinite dilution. The corresponding DP_n value is 810.

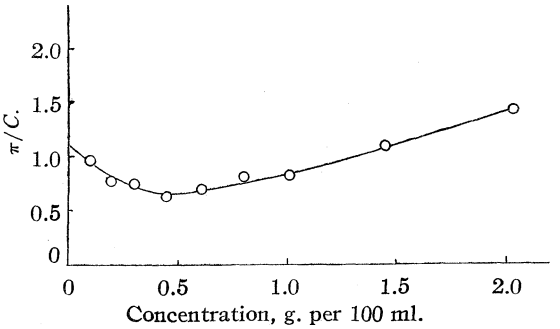

Fig. 1.—Osmotic pressure–concentration relationship for corn limit dextrin acetate in chloroform solution at 30°. The ordinate gives values for π/C as explained in Table I. The abscissa gives values for concentration in grams per 100 ml.

From this value and from the calculated yield of 46% limit dextrin, the indicated DP_n value for the parent amylopectin fraction is of the order of 1800.

In making this computation the assumption is made that each molecular weight group of corn B-fraction is made up of a variety of molecules which give the same average limit of hydrolysis as the total parent fraction. This may not be strictly true since a limited subfractionation of the butanol, non-precipitable fraction of corn starch by Kerr[15] showed that the subfraction of highest apparent molecular weight had a limit of conversion about 10% greater than the subfraction of lowest molecular weight. However, if the difference between various molecular weight groups is not substantially greater than 10%, then the calculation employed would be expected to give the correct order of magnitude for the DP_n of corn amylopectin.

Summary

A limit dextrin has been prepared in 90% of the calculated yield from corn B-fraction using crystalline β-amylase, and its ferricyanide reducing value determined.

The triacetate of the dextrin was found to be readily dispersible in chloroform, have a specific rotation of $[\alpha]^{25}D$ of 166.5° and an osmotic pressure at 30° equivalent to a DP_n of 800.

It was observed that the dextrin acetate tended to precipitate in fibrous form.

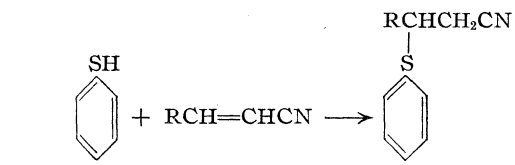
Cyanoalkylation: The Addition of Thiophenol to β-Alkylacrylonitriles

BY ROBERT M. ROSS[1]

Although cyanoethylation has been the subject[2] of considerable work within recent years, no systematic study has been reported anent the relationship of acceptor structure to the reactivity of the conjugate system in alkylated acrylonitriles. Consequently, it became the purpose of this research to investigate the cyanoalkylations of an active hydrogen component by substituted acrylonitriles, wherein alkyl groups were located in the β-position.

The addition of compounds which contain labile hydrogen atoms to acrylonitrile[2] proceeds readily with the formation of excellent yields of adducts. However, substituted acrylonitriles almost invariably react less readily than acrylonitrile with nearly all active hydrogen components. Among the nitriles which have been described in reactions of this type are α-methylacrylonitrile,[2] crotonitrile,[3] cinnamonitrile[4] and 1-cyano-1,3-butadiene.[5] Although the behavior of various addenda with such alkylacrylonitriles has been investigated, thiophenol has seen little or no use in this capacity. Furthermore, since thiophenol has shown especial reactivity[6] in cyanoethylation, it was decided to determine whether β-alkylacrylonitriles would again present difficulties of decreased reactivity even with thiophenol.

Thiophenol was added in the conjugate manner to the following unsaturated nitriles: β-*t*-butylacrylonitrile, β-isopropylacrylonitrile and β-methylacrylonitrile. Triton B[7] was employed as a catalyst, and the reactions were carried out under constant conditions in each of the cyanoalkylations. The poorest yield of adduct was obtained from β-*t*-butylacrylonitrile and thiophenol (21%), whereas crotononitrile afforded the best yield (54%) of the β-phenylmercapto addition compound. It should be noted that these yields are not nearly as satisfactory as those reported[6] for the reaction between thiophenol and acrylonitrile. Apparently, even with the extraordinarily active thiophenol, β-alkylacrylonitriles do not possess the high order of reactivity which is characteristic of acrylonitrile in the presence of a Triton B catalyst.



R = $(CH_3)_3C$—, $(CH_3)_2CH$—, CH_3—

A further study of the thiophenol reaction, however, has brought to light a catalyst which affords high yields even with the alkylated acrylonitriles. It has been found that a mixture of Triton B and piperidine produced β-alkyl-β-phenylmercaptopropionitriles in yields which varied from 87 to 93% of the theoretical value. No significant difference in yields was apparent whether the acceptor molecule was β-*t*-butylacrylonitrile, β-isopropylacrylonitrile or crotononitrile. Reaction conditions for this series of experiments were identical to those employed previously with the Triton B catalyst. Possibly, the mixture of piperidine and Triton B counteracted any adverse equilibrium conditions present when Triton B was the sole catalyst.

A series of similar cyanoalkylations were carried out using piperidine alone as a catalyst. The yields of adducts thus prepared corresponded closely to those obtained with a mixture of piperidine and Triton B; in every instance, however, the yields were slightly less than in the case of the mixed catalyst. Whether or not the diminution of yield was significant is debatable.

All of the adducts were characterized by micro and infrared analyses of the substituted phenylmercaptopropionitriles, hydrogen peroxide oxidation of the adducts to the corresponding sulfonyl derivatives, and microanalyses of the sulfones thus obtained. On the basis of precedent, the addition was assumed to take place in the normal 1,4-manner, since the reactions were not carried out under the influence of peroxides.

It is believed that the true catalyst responsible for the increased yields in those cyanoalkylations carried out with the piperidine and Triton B or piperidine catalysts is a salt or complex of thiophenol and piperidine. This phase of the work is to be investigated further.

Experimental[8]

β-Alkylacrylonitriles.—New methods for the preparation of β-*t*-butylacrylonitrile and β-isopropylacrylonitrile have been described elsewhere.[9] Crotononitrile was prepared by a modification of the method described by Dollfus,[10] which involved acetic anhydride dehydration of crotonaldoxime.[11]

[a] All boiling points and melting points are uncorrected. [b] β-*t*-Butyl-β-phenylsulfonylpropionamide was obtained as a white solid (10% yield) from the fractional crystallization, m. p. 182.2–183.2°. *Anal.* Calcd. for $C_{13}H_{19}NO_3S$: C, 57.96; H, 7.11. Found: C, 57.86; H, 7.30. [c] A small amount (19%) of crude β-isopropyl-β-phenylsulfonylpropionamide was isolated from the hydrogen peroxide oxidation by fractional crystallization, m. p. 145–154°. Further recrystallizations from hot ethyl acetate did not alter its purity sufficiently so that the product could be analyzed. [d] The infrared absorption spectra for these adducts were in complete agreement with the proposed structure. [e] Constants listed are those observed from a middle cut of constant refractive index. [f] A considerable amount (1.6 g.) of unchanged β-*t*-butylacrylonitrile was recovered during the distillation.

Addition of Thiophenol to β-Alkylacrylonitriles

Method A (Triton B and Piperidine Catalyst).—A mixture of 0.02 mole of β-alkylacrylonitrile and 2.20 g. (0.02 mole) of thiophenol[12] was placed in a 10-ml. flask equipped with a reflux condenser. To the contents of the flask was added 5 drops of dry, freshly distilled piperidine. A white precipitate, believed to be the salt of thiophenol and piperidine, formed immediately. After the reaction mixture was allowed to stand for forty-five minutes, 5 drops of Triton B and 2.5 ml. of peroxide-free dioxane[13] were added. The homogeneous contents of the flask were refluxed for twenty-four hours at an oil-bath temperature of 112°. At the end of this time, the source of heat was removed and the amber-colored solution was allowed to stand overnight at room temperature.

The dioxane was removed by distillation under atmospheric pressure, and the residue was extracted with 10 ml. of benzene. The benzene solution was scrubbed successively with 10-ml. portions of water, 5% aqueous sodium hydroxide solution, and finally with water. This procedure was found to be effective in removing any unreacted thiophenol. The benzene extract was dried over anhydrous magnesium sulfate, and the excess benzene removed by distillation. A distillation done under reduced pressure yielded the adduct as a slightly yellow, viscous oil. Redistillation of several combined runs was effected in order to obtain an analytical sample. A middle fraction of colorless β-alkyl-β-phenylmercaptopropionitrile of constant refractive index was obtained.

Method B (Piperidine Catalyst).—Other than the omission of Triton B as a catalyst component, the amounts of reactants and the procedure utilized remained the same as that described under Method A.

Method C (Triton B Catalyst).—The conditions for this method were the same as for Method A with the exception that Triton B alone was employed as the catalyst.

(12) "Organic Syntheses," Coll. Vol. I, second edition, 1946, p. 504.

(13) Fieser, "Experiments in Organic Chemistry," D. C. Heath and Co., Boston, Mass., second edition, 1941, p. 368.

β-Alkyl-β-phenylsulfonylpropionitriles.—A mixture of 1.0 g. of the β-alkyl-β-phenylmercaptopropionitrile and 1.8 ml. of glacial acetic acid was placed in a test-tube and 2.0 g. of 30% hydrogen peroxide was added. The resulting mixture was stoppered, shaken occasionally, and allowed to stand for eight days at room temperature. At the end of two days, shaking was no longer necessary since solution had been effected.

A total of 6 ml. of water was added to the contents of the tube which usually contained some white crystals of oxidation product. These crystals had separated during the eight-day period of standing. Complete crystallization was effected after the tube and contents were chilled at 0° for several hours. The white, crystalline material was removed by filtration, washed with water, and dried in air. The product thus obtained was found to be a mixture of a β-alkyl-β-phenylsulfonylpropionitrile and a β-alkyl-β-phenylsulfonylpropionamide. Six fractional crystallizations using the mixed solvent pair, ethyl acetate and *n*-hexane, were effective in separating the nitrile from the amide. All the amides were found to be less soluble in this solvent pair; thus, the nitrile was isolated in a satisfactory state for elementary analysis by concentrating to dryness the mother liquors from each recrystallization and subjecting the residue to further crystallizations.

Summary

The addition of thiophenol to some *beta*-alkylated acrylonitriles has been studied. It has been found that a catalyst which consists of piperidine and Triton B causes the reaction to proceed with the formation of excellent yields of β-alkyl-β-phenylmercaptoacrylonitriles. Piperidine was also effective in affording high yields, but the use of Triton B as the sole catalyst gave significantly smaller amounts of adduct.

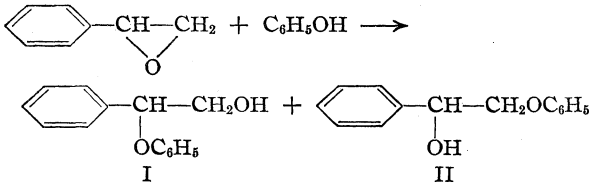
The Reaction of Styrene Oxide with Phenol

BY CYRUS O. GUSS

From the results of previous studies of the alkali-catalyzed reaction of olefin oxides with phenol it was concluded that the products were ether-alcohols. In the case of propylene oxide, an unsymmetrical olefin oxide, the early work[1] indicated that an isomeric mixture of the two possible ether-alcohols was obtained. Recent work[2,3] has shown, however, that the alkali-catalyzed reaction of propylene oxide with phenols produced predominantly or entirely the isomer having a secondary alcohol group. Alcohols were reported[3,4,5] to react with propylene oxide in a similar manner.

In the present investigation it was found that the alkali-catalyzed reaction of styrene oxide with phenol proceeded as shown



Both isomers were isolated and their structures proved by independent synthesis. In most cases the primary alcohol (I) was formed in greater amount, a result in contrast to the analogous reaction of propylene oxide with phenol under similar conditions.

In Table I are summarized some data obtained in this study. The alkali-catalyzed reactions were run in water, or dioxane, and excess phenol. In the presence of water the isomeric mixture was found to consist of approximately three parts of the primary alcohol (I) to one part of the secondary alcohol (II). In dioxane the relatively slower reaction produced the two isomers in more nearly equal amounts. Thus, there was an apparent effect of the reaction medium on the course of the ring-opening reaction. It was also noted, as shown in Table I, that as the concentration of sodium phenoxide was increased, the relative amount of the secondary alcohol (II) formed also increased. This effect of sodium phenoxide concentration was most pronounced in dioxane.

The separation of the two isomers from each other was most easily accomplished by taking advantage of the differences in their rate of reaction with phthalic anhydride.[6] However, since the separation by this method was not attained quantitatively, it was necessary to resort to other means to ascertain the composition of the isomeric mixture more precisely. The use of a phase diagram made it possible to obtain the composition data in Table I.

TABLE I

REACTION OF 0.1 MOLE OF STYRENE OXIDE WITH 0.3 MOLE OF PHENOL[a]

Solvent used	Catalyst	Time, hr.	Yield of mixture, I + II, %	I in mixture, %
15 cc. of water	0.005 mole NaOH	2.5	65.9	78
15 cc. of water	.1 mole NaOH	1.0	85.0	76
15 cc. of water	.3 mole NaOH	1.0	74.8	70
20 cc. of water	.2 mole NaOH	1.0	76.6	75[b]
25 cc. of dioxane	.004 mole Na	3.5	74.8	68
25 cc. of dioxane	.1 mole Na	3.5	89.7	49
25 cc. of dioxane	.25 mole Na	3.0	66.8	39
25 cc. of dioxane	.15 mole Na	3.0	74.7	53[b]
None	None	4.0	32.2[c]	88
15 cc. of water	0.0016 mole HOTs[d]	1.0	14.0[e]	67
None	0.0026 mole HOTs	0.5	..[f]	

[a] All runs in dioxane were at reflux temperature, the uncatalyzed run and those in water at 100°-bath. The last run in the table was at 200°-bath. [b] Styrene bromohydrin (0.1 mole, b. p. 114–115° (3 mm.), $n^{20}D$ 1.5780) was used instead of styrene oxide. [c] A large amount of higher boiling material was also formed. [d] *p*-Toluenesulfonic acid monohydrate. [e] Other products were phenyl glycol (11.6%) and higher boiling material, part of which was alkali soluble. [f] A solid product formed which softened at 80–100° and was alkali soluble. Only 0.1 mole of phenol was used in this run.

Styrene bromohydrin gave the same relative amounts of primary alcohol (I) and secondary alcohol (II) in the isomeric mixture as styrene oxide when it was used instead of styrene oxide in the alkali-catalyzed reaction, showing that the oxide was undoubtedly the species reacting with the phenol. This result excluded the use of the bromohydrin in the reaction as a means for structure proof, and it also seriously jeopardized the validity of the structure proof employed by Emerson[7] in his study of the reaction of styrene oxide with alcohols.

The uncatalyzed reaction of styrene oxide with phenol gave a relatively low yield of the isomeric mixture in which the primary alcohol (I) was present in a ratio of nearly nine to one.

The use of *p*-toluenesulfonic acid to catalyze the reaction of styrene oxide with phenol gave a product that was alkali soluble. When water was present also, as indicated in Table I, a low yield of the isomeric mixture of I and II was formed together with phenyl glycol and higher-boiling materials, part of which was alkali soluble. The alkali-soluble material must have resulted from a reaction of the oxide with the nucleus of the phenol. A study of this latter type of reaction is nearly completed and will be reported upon soon.

The structures of I and II were assigned on the

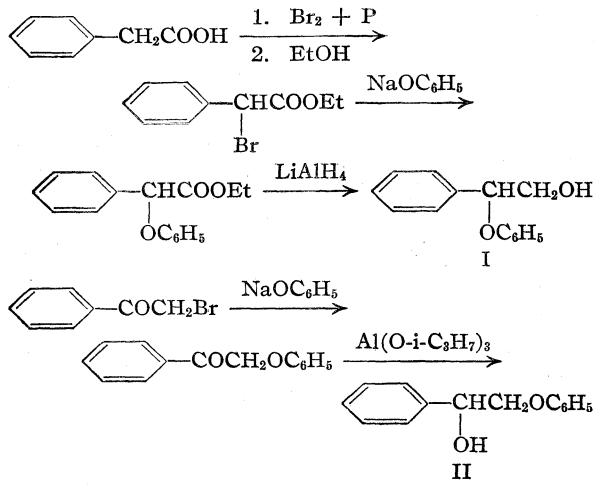
basis of identity with the products from the reaction sequences



I

II

The results from the present study supplement the knowledge of the effect of groups and media on the direction of the ring opening of substituted ethylene oxides. Since propylene oxide is found to give the secondary alcohol in the alkali-catalyzed reaction with alcohols[4,5] or with phenols,[2,3] the course of the reaction is said to be guided by the electron-releasing action of the methyl group.[4,5] In 3,4-epoxy-1-butene, in which the vinyl group is present instead of the methyl group as in propylene oxide, one interpretation that is suggested[5] to account for an observed formation of a primary alcohol exclusively in the reaction of the oxide with sodium alloxide in allyl alcohol is also based on an electron release by the vinyl group. Alternatively, Bartlett and Ross,[8] who find that 3,4-epoxy-1-butene reacts with sodium methoxide in methanol to give the secondary alcohol predominantly but also some primary alcohol, suggest that allylic resonance in a transition state might account for the formation of the primary alcohol. If this concept of resonance in a transition state is applied to the alkali-catalyzed reaction of styrene oxide with alcohols and with phenols, the expected result would be to find the formation of the primary alcohol predominant or exclusive, since the lowering of the energy of the transition state leading to the primary alcohol ought to be greater in the case of styrene oxide than in the case of 3,4-epoxy-1-butene. The present results can be cited in support of this interpretation, as can also the finding by Swern, Billen and Knight[5] that styrene oxide reacts with allyl alcohol and sodium alloxide to give the primary alcohol predominantly. The latter authors explain their results on the basis of an electron-attracting action by the phenyl group. On the other hand, Russell and VanderWerf[9] present the point of view that the phenyl group in styrene oxide is electron releasing in the reaction with sodium diethyl malonate. Perhaps a study of the effect of temperature and other factors of the reaction environment might help to resolve some of the present difficulties in the interpretation of the ring-opening reactions of olefin oxides.

Experimental[10]

Reaction of Styrene Oxide with Phenol.—The runs reported in Table I were all made in a similar manner. The phenol, water or dioxane, and the sodium hydroxide, or sodium, or *p*-toluenesulfonic acid were brought together in a three-necked flask equipped with stirrer, condenser and a dropping funnel. As soon as but one phase existed at the temperature used, the styrene oxide[11] ($n^{20}D$ 1.5352) was added dropwise over a period of five to ten minutes. Heating and stirring were continued for the indicated time. These reactions, except for the first run in Table I, were one-phase. The amber or red reaction mixture was then poured into 200 g. of an ice-water mixture containing sufficient sodium hydroxide to react with the excess free phenol. The insoluble material was then taken up in two 75-cc. portions of ether, and the ether solution was dried over anhydrous potassium carbonate or anhydrous sodium sulfate. After distillation of the ether, the residue was distilled in a 50-cc. modified Claisen flask packed with 3″ of 1/8″ glass helices. A small amount of material boiling in the range 50–60° (0.5 mm.) was usually obtained, after which the temperature rose immediately to 150–160° (0.5 mm.) over which interval the mixture of I and II distilled. A higher-boiling residue that remained was usually not distilled, but it was noted on one occasion to have a boiling point above 200° (0.5 mm.). The fraction boiling at 150–160° (0.5 mm.) rapidly solidified. It was this material whose melting point was now measured to determine the relative amounts of I and II present by the use of the phase diagram.

Determination of Composition of Mixture of Isomers I and II.—The apparatus used was similar to the Beckmann freezing-point depression arrangement, employing a thermometer calibrated in 0.5°. A system of crossed polaroid glasses was used to observe the disappearance of the last crystal. Table II gives the melting points thus obtained for the mixtures of known composition.

TABLE II

MELTING POINTS OF KNOWN MIXTURES OF I AND II

I, %	M. p., °C.	I, %	M. p., °C.
4.88	60.25	40.20	46.00
9.33	58.50	47.68	53.50
16.99	55.50	68.88	65.75
28.97	50.50	86.97	74.50
35.00	47.00		

The graph made from these data was used in the usual manner to determine the composition of the mixture of isomers resulting from the interaction of styrene oxide and phenol.

Separation of I and II.—It was found that isomer I was much more easily esterified than II, and it was this observation that led to the use of the following procedure to separate the two isomers.

A solution of the mixture of isomers (5 g., 0.0234 mole, 76% I), phthalic anhydride (7.4 g., 0.05 mole), and pyridine (4.9 g., 0.062 mole) in dioxane (25 cc.) was allowed to stand at room temperature for five hours. This solution was then dissolved in 100 cc. of ether. The ether solution was shaken with 100 cc. of water containing 10 cc. of concd. hydrochloric acid to remove the pyridine. The half-ester of I and any phthalic acid were removed by shaking the ether solution with 150 cc. of 7.5% sodium carbonate.

(10) Microanalyses reported in this paper were performed by the analyst at the California Institute of Technology, Pasadena, California. All melting points are uncorrected.

(11) Alquist and Guss, U. S. Patent 2,237,284 (April 8, 1941).

The remaining ether solution was then washed with 100 cc. of water, dried over anhydrous potassium carbonate, and the removal of the ether then left a white solid. Two or three recrystallizations from heptane left 0.5 g., m. p. 62–64°, identified as **1-phenyl-2-phenoxyethanol** (II) by mixed melting with an authentic sample.

To the aqueous solution of the half-ester of I was added 4 g. of sodium hydroxide and the solution refluxed for one hour. The insoluble material that separated was taken up in 75 cc. of ether and the ether solution dried over anhydrous potassium carbonate. After removal of the ether and two recrystallizations of the resulting solid from heptane, 3.0 g., m. p. 80–81° was obtained and identified as **2-phenyl-2-phenoxyethanol** (I) by mixed melting point.

The above procedure thus gave a 70% yield of the two pure isomers. The separation was not found to be clean-cut, and the remaining 30% consisted of mechanical loss and a mixture of approximately equal parts of the two isomers. An initial mixture containing 49% I gave a 60% yield of pure I and pure II when carried through the above procedure. The reprocessing of the unseparated portion would undoubtedly lead to a higher over-all yield of the two separated isomers.

Preparation of 2-Phenyl-2-phenoxyethanol (I).—Ethyl α-bromophenylacetate (b. p. 102–104° (0.4 mm.), $n^{20}D$ 1.5380) was prepared in 70.7% yield by the procedure of Anschütz[12] from phenylacetic acid, bromine, phosphorus and absolute ethanol. This ester (36.5 g., 0.15 mole) was added dropwise in fifteen minutes to sodium phenoxide (0.15 mole) and phenol (0.15 mole) in dry dioxane (23 cc.) at 100°. After forty-five minutes the reaction mixture was cooled and added to 300 cc. of water. The organic layer was extracted with 200 cc. of ether, dried over anhydrous sodium sulfate, and distilled to give 26.1 g. (68%), b. p. 155–156° (0.8 mm.), $n^{20}D$ 1.5452. That this material was ethyl α-phenoxyphenylacetate was shown by its hydrolysis in refluxing 4% sodium hydroxide to α-phenoxyphenylacetic acid, m. p. 108–109.5°. Meyer and Boner[13] have reported m. p. 108°.

Ethyl α-phenoxyphenylacetate was reduced to 2-phenyl-2-phenoxyethanol (I), needles, m. p. 80–81°, in 84% yield by the use of lithium aluminum hydride according to the usual procedure.[14] Heptane was used for recrystallization. This product mixed with I from the styrene oxide and phenol reaction melted without depression.

Anal. Calcd. for $C_{14}H_{14}O_2$: C, 78.48; H, 6.59. Found: C, 78.50; H, 6.60.

The *p*-nitrobenzoate of this alcohol was prepared in the usual manner[15] with the exception that the reaction mixture was not heated externally but allowed to stand for one hour before working up. The ester was recrystallized from ethanol as platelets, m. p. 86–87°.

Anal. Calcd. for $C_{21}H_{17}NO_5$: C, 69.41; H, 4.72. Found: C, 69.63; H, 4.88.

Preparation of 1-Phenyl-2-phenoxyethanol (II).—Phenacyl bromide was converted into ω-phenoxyacetophenone, m. p. 71–72°, by the procedure of Mohlau[16] in 61% yield; oxime, m. p. 113–114°, as reported by Fritz.[17] The 2,4-dinitrophenylhydrazone was made by the ordinary method,[18] m. p. 183–184°. It was recrystallized from an ethanol–ethyl acetate mixture.

Anal. Calcd. for $C_{20}H_{16}N_4O_5$: C, 61.22; H, 4.11. Found: C, 61.11; H, 4.14.

The ω-phenoxyacetophenone was reduced with aluminum isopropoxide to the corresponding alcohol, 1-phenyl-2-phenoxyethanol (II), needles, m. p. 63–64° in 86.5% yield. The recrystallization solvent was heptane. This product was shown to be identical with II resulting from the reaction of styrene oxide with phenol by the absence of a mixed melting point depression.

Anal. Calcd. for $C_{14}H_{14}O_2$: C, 78.48; H, 6.59. Found: C, 78.75; H, 6.58.

The *p*-nitrobenzoate, prepared in the manner employed for the isomer above, crystallized from ethanol as fine needles, m. p. 83–84°.

Anal. Calcd. for $C_{21}H_{17}NO_5$: C, 69.41; H, 4.72. Found: C, 69.72; H, 4.96.

Summary

1. Styrene oxide was found to undergo an alkali-catalyzed reaction with phenol to give 66–90% yields of an isomeric mixture of 2-phenyl-2-phenoxyethanol (I) and 1-phenyl-2-phenoxyethanol (II) in which the content of I varied from 39 to 78% depending on the conditions used. Resonance stabilization of a transition state is mentioned to explain this difference in the direction of ring opening relative to propylene oxide.

2. The uncatalyzed reaction produced low yields of the isomeric mixture in which I constituted 88% of the total.

3. Acid catalysis of the reaction gave large amounts of an alkali-soluble material presumed to result from the reaction of the oxide with the nucleus of the phenol.

4. Styrene bromohydrin gave the same relative amounts of I and II as styrene oxide in the alkali-catalyzed reaction, indicating intermediate formation of the oxide.

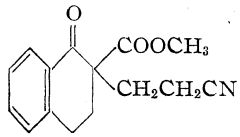
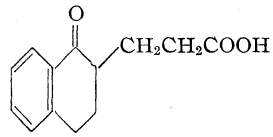
3-Ketohydrophenanthrenes and 2′-Ketohydro-1,2-cyclopentenonaphthalenes

BY W. E. BACHMANN AND G. DANA JOHNSON[1]

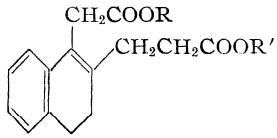
1-Tetralone-2-β-propionic acid (II) was prepared from 2-carbomethoxy-1-tetralone by reaction of its sodio derivative with methyl β-bromopropionate and by cyanoethylation to I followed by hydrolysis and decarboxylation. Reaction of the methyl ester of the acid with zinc and methyl bromoacetate gave the unsaturated acid ester IIIa and not the normal hydroxy ester. The acid ester may have resulted through the intermediate formation of the δ-lactone IV followed by hydrolysis in the isolation process. That the



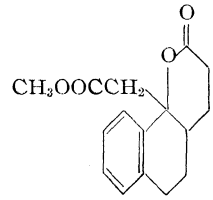
I



II



IIIa, R = CH_3; R′ = H
IIIb, R = R′ = CH_3
IIIc, R = R′ = H



IV

product which was isolated was not the lactone was indicated by its acidic nature and its high absorption maximum (log ε = 4.12) at 264 mμ in the absorption spectrum (Fig. 1). This is to be compared with the spectrum of the γ-lactone VIII (which is similar in structure but more resistant to hydrolysis than the δ-lactone) which absorbs much less strongly (log ε = 2.72) in this region. The double bond appears to be in the ring and not in the exocyclic position in the acetic acid side chain judging from the failure of the corresponding diacid IIIc (which shows the same absorption as the acid ester) to be reduced by sodium amalgam and water. This conclusion is supported by the correspondence of the absorption maximum with the peak of 1,2-dihydronaphthalene at 262 mμ (log ε = 4.01) in hexane.[2]

A Dieckmann cyclization of the dimethyl ester (IIIb) of the unsaturated acid followed by acid hydrolysis and decarboxylation of the resulting β-keto ester yielded 3-keto-1,2,3,9,10,10a-hexahydrophenanthrene (V), which had the same melting point as the ketone prepared from 2-dimethylaminomethyl-1-tetralone and acetoacetic ester in the presence of sodium methoxide.[3] The position of a maximum with log ε = 4.28 at 298 mμ in the absorption spectrum indicated conjugation of the double bond with the aromatic ring and with the carbonyl group.[4] Apparently a shift of the double bond occurs at some stage of the cyclization process.

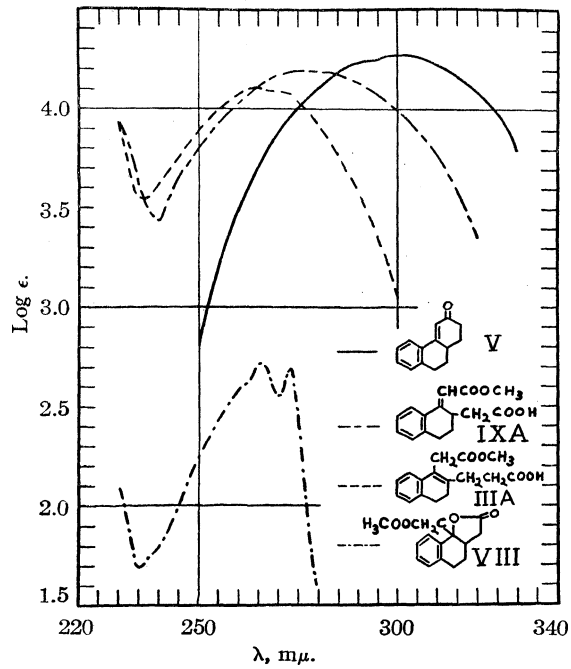


Fig. 1.—Ultraviolet absorption spectra.

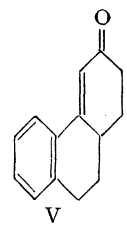
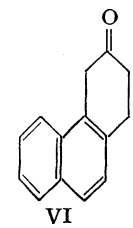
The dimethyl ester IIIb was dehydrogenated smoothly by sulfur to the dimethyl ester of 1-carboxymethylnaphthalene-2-β-propionic acid, which was cyclized to 3-keto-1,2,3,4-tetrahydrophenanthrene (VI), a rather unstable ketone. The position of the keto group was proved by conversion of the ketone into 3-methylphenanthrene by reaction with methylmagnesium iodide, followed by dehydration and dehydrogenation of the carbinol.



V



VI

The saturated diester prepared by hydrogenation of IIIb in the presence of Adams catalyst was cyclized to 3-keto-1,2,3,4,4a,9,10,10a-octahydro-

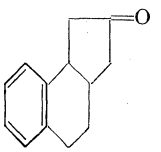
IXb, R = R′ = CH_3
IXc, R = R′ = H



X

A similar series of ketones in which the carbonyl group was part of a five-membered ring was prepared in a similar manner from diesters which contained one less methylene group in the side chain in the 2-position of the naphthalene ring. The starting material was 1-tetralone-2-acetic acid which was prepared from 2-carbomethoxy-1-tetralone and methyl bromoacetate and also from 2-bromo-1-tetralone and malonic ester in the manner of Bergs.[5] The methyl ester of 1-tetralone-2-acetic acid in a Reformatsky reaction with methyl bromoacetate gave the lactone VIII. Hydrolysis of the lactone with one equivalent of alkali yielded the isomeric acid ester IXa. The position of the double bond in the diacid IXc appears to be different from that in the homolog IIIc, since reduction of IXc by sodium amalgam proceeded readily. This indicated the existence of the triple conjugation shown in the formula. Moreover, the maximum in the ultraviolet absorption spectrum of IXa and of IXc is located about 11 mμ higher than in IIIc as would be expected of a completely conjugated system.

The dimethyl ester IXb was cyclized to $\Delta^{1-1'}$-2′-keto-3,4-dihydro-1,2-cyclopentenonaphthalene (like X but with a double bond). The intense absorption (log ϵ = 4.38) at 287 mμ indicated that the double bond was conjugated with the carbonyl group and the benzene ring; the peak is located at a lower wave length than the corresponding maximum in the homologous hexahydrophenanthrene ketone V. As this work was being completed, Wilds and Johnson[6] reported the synthesis of this ketone by a different method. The absorption curve for our compound is identical with that obtained by them.[4a]

(5) Bergs, *Ber.*, **63**, 1285 (1930).

(6) Wilds and Johnson, THIS JOURNAL, **68**, 86 (1946).

Although it was possible to cyclize the dimethyl ester of naphthalene-1,2-diacetic acid (prepared by sulfur dehydrogenation of IXb) to a crystalline cyclic β-keto ester, satisfactory hydrolysis and decarboxylation of the β-keto ester to 2′-keto-1,2-cyclopentenonaphthalene has not yet been accomplished.

Sodium amalgam reduction of the unsaturated acid IXc gave a mixture of the *cis* and *trans* forms of 1,2,3,4-tetrahydronaphthlane-1,2-diacetic acid in about equal amounts, from which the *cis* and *trans* forms of 2′-keto-1,2,3,4-tetrahydro-1,2-cyclopentenonaphthalene (X) were synthesized. Both forms of the cyclic ketone yielded the known 1,2-cyclopentenonaphthalene when subjected to a Wolff–Kishner reduction followed by dehydrogenation of the resulting hydrocarbons.

Experimental[7]

1-Tetralone-2-β-propionic Acid (II). (a) By Cyanoethylation of 2-Carbomethoxy-1-tetralone.—To a stirred solution of 100 g. of 2-carbomethoxy-1-tetralone[8] in 800 ml. of dry, peroxide-free dioxane 4 ml. of Triton B (38% aqueous trimethylbenzylammonium hydroxide) was added in five minutes, followed by a solution of 36 ml. of acrylonitrile[9] in 50 ml. of dioxane in the course of twenty minutes. The reaction failed completely with dioxane which contained peroxide. The temperature rose from room temperature to about 40°. Stirring was continued for an additional two hours; sufficient 10% hydrochloric acid was added to the dark solution to give a clear brownish-yellow solution; and the dioxane was removed in a current of air. Addition of methanol induced crystallization of the product, which was collected by filtration and washed thoroughly with a saturated, ice-cold solution of 60–70° petroleum ether in methanol; yield, 110 g. of nearly colorless needles; m. p. 75–76°. From the filtrates an additional 6 g. of the product was obtained; total yield, 92%. In this manner 293 g. of 2-carbomethoxy-1-tetralone was converted to 338 g. of **2-carbomethoxy-2-(β-cyanoethyl)-1-tetralone** (I). The compound crystallized from a mixture of methanol and 60–70° petroleum ether in colorless needles; yield 331 g. (90%); m. p. 76–77°. Two more recrystallizations of a sample from methanol resulted in no change in the melting point.

Anal. Calcd. for $C_{15}H_{15}O_3N$: C, 70.02; H, 5.88; N, 5.44. Found: C, 69.98; H, 5.62; N, 5.46.

A solution of 51.5 g. of the nitrile in 150 ml. of glacial acetic acid, 300 ml. of concentrated hydrochloric acid, and 20 ml. of water was heated on a steam-bath for four hours, cooled somewhat, and poured with stirring on a mixture of 1000 g. each of ice and water; yield, 42.3 g. (97%); m. p. 105–107°. In this manner 327 g. of the cyanoethyl product gave 270 g. of **1-tetralone-2-β-propionic acid** (II). Recrystallization from acetone gave 264 g. (95%) of colorless rhombs; m. p. 108–110°.

Anal. Calcd. for $C_{13}H_{14}O_3$: C, 71.54; H, 6.47. Found: C, 71.54; H, 6.52.

(b) From 2-Carbomethoxy-1-tetralone and Methyl β-Bromopropionate.—To the solution of sodium methoxide from 1.6 g. of sodium and 80 ml. of absolute methanol was added a solution of 7.1 g. of 2-carbomethoxy-1-tetralone in 80 ml. of dry benzene. The mixture was refluxed on a steam-bath for one hour, cooled, and treated with 11.7 g. of methyl β-bromopropionate. The reaction mixture was allowed to stand for one and one-half hours with oc-

(7) Most of the analyses were performed by the Micro-Tech Laboratories, Skokie, Illinois, and the rest by Mrs. Lea Gafney of the Chemistry Department, Indiana University, Bloomington, Indiana.

(8) Bachmann and Thomas, THIS JOURNAL, **63**, 598 (1941).

(9) Bruson, *ibid.*, **64**, 2457 (1942).

casional shaking; during this time nearly all solid material disappeared. The mixture was then refluxed for one-half hour in a water-bath, cooled, treated with ice-water and extracted with benzene. The product, which was obtained as a liquid by evaporation of the benzene, was heated with 50 ml. of concentrated hydrochloric acid, 50 ml. of glacial acetic acid, and 5 ml. of water for two hours on a steam-bath. The cooled mixture was diluted with 300 ml. of water and extracted with benzene. The benzene solution was extracted with 5% sodium hydroxide and the solution of the sodium salt was treated with Norit, filtered, and acidified; yield 5.4 g. (71%) of crude 1-tetralone-2-β-propionic acid (II); m. p. 99–103°. Upon crystallization of a sample from a mixture of acetone and water, fine colorless needles were obtained exactly as in (a); m. p. 108–110°.

1-Carboxymethyl-3,4-dihydronaphthalene-2-β-propionic Acid (IIIc).—To a solution of 100 g. of 1-tetralone-2-β-propionic acid in 320 ml. of absolute methanol was slowly added with swirling 32 ml. of concentrated sulfuric acid. The solution was refluxed on a steam-bath for one hour, about one-half of the solvent was removed by distillation under reduced pressure on a steam-bath, the residue was diluted with 800 ml. of water, and the mixture was extracted with ether. The ether extracts were washed with saturated sodium bicarbonate solution, dried, and treated with Norit. The liquid dimethyl ester isolated by evaporation of the solution was dried thoroughly in a vacuum desiccator.

To a solution of 20 g. of the methyl ester in 200 ml. of dry benzene was added 20 g. of clean, dry 20-mesh zinc, 14 ml. of methyl bromoacetate, and a small crystal of iodine. The mixture was refluxed on a steam-bath with frequent shaking until the reaction started. At forty-five-minute intervals thereafter 10 g. of zinc was added until a total of three hours reaction time had elapsed. After one hour an additional 6 ml. of methyl bromoacetate was added. After three hours the cooled mixture was treated with 150 ml. of cold 10% hydrochloric acid and shaken vigorously. The solutions were decanted into a separatory funnel and the zinc was washed thoroughly with ether by decantation. The combined extracts were separated and the aqueous layer was extracted with ether. The combined ether–benzene extracts were washed with water and extracted with concentrated aqueous ammonia which had been diluted with an equal volume of water. The ammoniacal extracts were acidified with hydrochloric acid, extracted with ether, and the dried ether solution was treated with Norit. Removal of the ether left **1-carbomethoxymethyl-3,4-dihydronaphthalene-2-β-propionic acid (IIIa)**; yield, 16.8 g.; m. p. 84–88°. A sample after three recrystallizations from methanol formed fine colorless needles; m. p. 94–95°.

Anal. Calcd. for $C_{16}H_{18}O_4$: C, 70.05; H, 6.61. Found: C, 70.22; H, 6.59.

The ultraviolet absorption spectrum (Fig. 1) was obtained on a 0.0011% solution of the acid ester IIIa in methanol by means of a Beckman quartz spectrophotometer.

A solution of 20 g. of the acid ester in 100 ml. of methanol and 300 ml. of 0.5 *N* sodium hydroxide was refluxed for one hour on a steam-bath. After removal of one-half of the solvent in a current of air, the residual solution was acidified with concentrated hydrochloric acid and chilled; yield, 18.2 g. (96%); m. p. 145–148°. A sample of **1-carboxymethyl-3,4-dihydronaphthalene-2-β-propionic acid** after three recrystallizations from benzene formed fine colorless needles; m. p. 147–149°.

Anal. Calcd. for $C_{15}H_{16}O_4$: C, 69.21; H, 6.20. Found: C, 69.33; H, 6.31.

The acid reacted immediately with a solution of bromine in carbon tetrachloride and with potassium permanganate solution.

3-Keto-1,2,3,9,10,10a-hexahydrophenanthrene (V).—The dimethyl ester of 3,4-dihydronaphthalene-1-acetic acid-2-β-propionic acid was obtained readily by esterification of the diacid IIIc and the acid ester IIIa by means of anhydrous methanol and concentrated sulfuric acid. A Dieckmann cyclization was run as for the production of VI with sodium methoxide from 0.5 g. of sodium and 0.93 g. of the dimethyl ester in 10 ml. of dry benzene; yield, 0.65 g.; m. p. 110–121°. After three recrystallizations from methanol–water, a sample of **2(or 4-)-carbomethoxy-3-ketohexahydrophenanthrene** formed fine colorless needles; m. p. 126–128°.

Anal. Calcd. for $C_{16}H_{16}O_3$: C, 74.98; H, 6.29. Found: C, 74.96; H, 6.24.

The compound gave no color with ferric chloride, even on heating. It reacted immediately with bromine in carbon tetrachloride, and with potassium permanganate solution.

Hydrolysis and decarboxylation of 0.95 g. of the β-keto ester was accomplished as for the production of VI; yield, 0.7 g.; m. p. 68–75°. After three recrystallizations from methanol–water the cyclic ketone formed needles with a very pale yellow color; m. p. 79–80° (reported,[2] 80°).

Anal. Calcd. for $C_{14}H_{14}O$: C, 84.81; H, 7.12. Found: C, 84.40; H, 7.24.

The ketone instantly decolorized bromine–carbon tetrachloride solution. The ultraviolet absorption was measured on a 0.0005% solution of the ketone in methanol; a maximum ($\log \epsilon = 4.28$) appears at 298 mμ (Fig. 1).

The 2,4-dinitrophenylhydrazone crystallized from methanol in clusters of crimson prisms; m. p. 204–206° dec.

Anal. Calcd. for $C_{20}H_{18}O_4N_4$: N, 14.81. Found: N, 14.75.

The semicarbazone crystallized from acetic acid in fine colorless needles; m. p. 244–245° dec. It turned yellow in a few hours even when kept in an evacuated desiccator in the dark. This phenomenon has been noted with the semicarbazones of other β-aryl-substituted α,β-unsaturated ketones. A satisfactory analysis was not obtained. A suspension of 0.25 g. of the semicarbazone in ethanolic sodium ethoxide, prepared from 0.5 g. of sodium and 15 ml. of absolute ethanol, was heated in a bomb tube at 170° for twenty hours. Dehydrogenation of the product gave phenanthrene.

3-Keto-1,2,3,4-tetrahydrophenanthrene (VI).—A test-tube containing a mixture of 2 g. of the crude diester IIIb and 0.225 g. of sulfur and fitted with a one-hole stopper bearing a short length of capillary tubing was lowered to the level of the mixture in a metal-bath at 220°. The temperature of the bath was raised to 280° in the course of ten minutes. The cooled mixture was refluxed with 50 ml. of methanol and 20 ml. of 0.5 *N* sodium hydroxide for one hour on a steam-bath. After the solvent had been removed, a solution of the product in 50 ml. of water was heated with Norit; acidification gave 1.56 g. (87%) of the acid; m. p. 178–181°. A sample of **1-carboxymethyl-naphthalene-2-β-propionic acid** after three recrystallizations from a mixture of acetone and water formed fine colorless needles; m. p. 183–184°.

Anal. Calcd. for $C_{15}H_{14}O_4$: C, 69.75; H, 5.46. Found: C, 69.56; H, 5.62.

Dehydrogenation with 10% palladium-on-charcoal gave a poor yield of the acid.

The crude dimethyl ester formed by esterification of the acid with methanol and sulfuric acid was dried thoroughly. A solution of 2 g. of the diester in 25 ml. of dry thiophene-free benzene was added to dry sodium methoxide (made by the reaction of 0.32 g. of sodium with 5 ml. of absolute methanol followed by evaporation under reduced pressure on a steam-bath). The mixture was refluxed in an atmosphere of nitrogen in a water-bath for two hours, the cooled mixture was treated with cold 5% hydrochloric acid and extracted with ether, and the combined ether–benzene extracts were washed with water, dried and treated with Norit. Removal of the solvent under reduced pressure yielded 1.54 g. of **2(or 4-)-carbomethoxy-3-keto-1,2,3,4-tetrahydrophenanthrene**; m. p. 113–120°. A sample crystallized three times from methanol formed colorless leaflets; m. p. 124–125°. It gave a light blue-green color with alcoholic ferric chloride upon heating.

Anal. Calcd. for $C_{16}H_{14}O_3$: C, 75.57; H, 5.55. Found: C, 75.38; H, 5.66.

A solution of 0.25 g. of the β-keto ester in 20 ml. of glacial acetic acid, 10 ml. of concentrated hydrochloric acid, and 1.8 ml. of water was heated on a steam-bath for four hours in an atmosphere of nitrogen, cooled, diluted with 100 ml. of cold water, and extracted with ether. The ether extracts were washed with water and with cold 2% aqueous sodium hydroxide, dried, treated with Norit, and filtered. The solvent was removed under reduced pressure in an atmosphere of carbon dioxide; yield, 0.12 g. (62%); m. p. 54–58°. After evaporative distillation at 0.01 mm., and three recrystallizations from 60–70° petroleum ether, the **3-keto-1,2,3,4-tetrahydrophenanthrene** formed fine colorless needles; m. p. 64–65°. The ketone was unstable in air, being converted to a dark gummy mass in the course of a few hours. A satisfactory analysis was not obtained. The **2,4-dinitrophenylhydrazone**, which was stable, crystallized from a mixture of benzene and methanol in extremely fine red needles; m. p. 246–248° dec.

Anal. Calcd. for $C_{20}H_{16}O_4N_4$: C, 63.82; H, 4.29; N, 14.89. Found: C, 63.66; H, 4.58; N, 14.74.

The oxime crystallized from a mixture of acetic acid and water in clusters of fine colorless needles; m. p. 139–141°.

Anal. Calcd. for $C_{14}H_{13}ON$: C, 79.59; H, 6.20; N, 6.63. Found: C, 79.00; H, 5.84; N, 6.96.

The semicarbazone crystallized in very fine colorless needles upon diluting an acetic acid solution of the substance with water; m. p. 205–207°.

Anal. Calcd. for $C_{15}H_{15}ON_3$: C, 71.12; H, 5.97. Found: C, 71.38; H, 5.95.

A suspension of 0.3 g. of the semicarbazone in ethanolic sodium ethoxide from 0.5 g. of sodium in 15 ml. of absolute ethanol was heated in a bomb tube at 170° for twenty hours, and the product was dehydrogenated with 0.1 g. of 10% palladium–charcoal catalyst at 310–320° for forty-five minutes. The phenanthrene (m. p. 99–100°) and its picrate (m. p. 141–142.5°) were identified through their melting points and by mixed melting points with authentic specimens.

The carbinol formed from 0.5 g. of the ketone and methylmagnesium iodide was heated with 1.7 g. of potassium acid sulfate for one and one-half hours in a bath maintained at 160–165°. The product was heated with 0.2 g. of 10% palladium–charcoal catalyst for forty-five minutes in a bath maintained at 300–320°. The resulting 3-methylphenanthrene after distillation at 0.02 mm. crystallized from alcohol in colorless needles; m. p. 61.5–63° (reported, 61–62°,[10] 62–63°[11]); m. p. picrate, 136–138° (reported,[11] 137–138°).

3-Keto-1,2,3,4,4a,9,10,10a-octahydrophenanthrene (VII).—Numerous attempts to effect a sodium amalgam reduction of 3,4-dihydronaphthalene-1-acetic acid-2-β-propionic acid (IIIc) failed. Catalytic hydrogenation of the diester IIIb was successful. A solution of 5 g. of the diester in 50 ml. of absolute methanol in the presence of 0.2 g. of platinum oxide catalyst was hydrogenated at 30 pounds pressure in four hours. The end of the reaction was indicated by the failure of the solution to decolorize bromine in carbon tetrachloride. Hydrolysis of 2 g. of the crude dimethyl ester in 20 ml. of methanol with 30 ml. of 0.5 *N* sodium hydroxide by one hour of refluxing on a steam-bath gave 1.8 g. (99%) of **1-carboxymethyl-1,2,3,4-tetrahydronaphthalene-2-β-propionic acid**; m. p. 125–129°. A sample after two recrystallizations from acetone–water formed fine colorless needles; m. p. 130–131°. The acid does not decolorize dilute solutions of bromine in carbon tetrachloride or aqueous potassium permanganate.

Anal. Calcd. for $C_{15}H_{18}O_4$: C, 68.68; H, 6.92; neut. equiv., 131. Found: C, 68.34; H, 6.95; neut. equiv., 132.

A Dieckmann cyclization of 2 g. of the crude dimethyl ester of 1,2,3,4-tetrahydronaphthalene-1-acetic acid-2-β-propionic acid carried out as described for VI gave 1.58 g. of **2(or 4-)-carbomethoxy-3-keto-1,2,3,4,4a,9,10,10a-octahydrophenanthrene**; m. p. 76–83°. The compound crystallized from methanol in colorless, broad, flat needles; m. p. 93–95°. No crystalline isomer was found; only a small amount of dark-colored oil which resisted crystallization was found in the filtrate.

Anal. Calcd. for $C_{16}H_{18}O_3$: C, 74.40; H, 7.02. Found: C, 74.37; H, 7.14.

The β-keto ester gave a purple-gray color with alcoholic ferric chloride. It rapidly decolorized bromine in carbon tetrachloride and aqueous potassium permanganate.

Hydrolysis and decarboxylation of 0.3 g. of the β-keto ester by the procedure used for VI gave 0.21 g. of crude **3-keto-1,2,3,4,4a,9,10,10a-octahydrophenanthrene (VII)**; m. p. 53–56°. Three recrystallizations of the material from 60–70° petroleum ether formed colorless prisms; m. p. 73–74°.

Anal. Calcd. for $C_{14}H_{16}O$: C, 83.96; H, 8.05. Found: C, 83.64; H, 8.11.

The 2,4-dinitrophenylhydrazone crystallized from a mixture of chloroform and methanol in globular clusters of fine orange needles; m. p. 175–177°.

Anal. Calcd. for $C_{20}H_{20}O_4N_4$: N, 14.73. Found: N, 15.00.

The semicarbazone crystallized from aqueous acetic acid in clusters of fine colorless needles; m. p. 229–231° dec.

Anal. Calcd. for $C_{15}H_{19}ON_3$: C, 70.01; H, 7.44; N, 16.33. Found: C, 70.49; H, 7.21; N, 16.05.

A Wolff–Kishner reduction of 0.35 g. of the semicarbazone gave 0.15 g. of hydrocarbon which was dehydrogenated with palladium-on-charcoal to phenanthrene.

1-Tetralone-2-acetic Acid. (a) **From 2-Bromo-1-tetralone.**—A solution of the 2-bromo-1-tetralone[5] from 10 g. of 1-tetralone[12] in 50 ml. of benzene was added to a cooled suspension of sodiomalonic ester which had been prepared by refluxing on a steam-bath 21 ml. of diethyl malonate, 2.4 g. of sodium powder and 100 ml. of dry benzene for four to five hours. The mixture was heated on a steam-bath for one and one-half hours. The crude substituted malonic ester was heated with a solution of 17 g. of potassium hydroxide, 50 ml. of ester and 20 ml. of 95% alcohol on a steam-bath for four hours. The cooled solution was extracted with benzene to remove non-acidic materials, treated with Norit, filtered, cooled, and acidified with 50 ml. of cold concentrated hydrochloric acid; yield, 10.4 g. of tan-colored 1-tetralone-2-malonic acid; m. p. 164° with evolution of gas. Extraction of the aqueous filtrates with ether afforded an additional 3.5 g. of somewhat oily material (presumably partially decarboxylated) which on decarboxylation gave the required acid; total yield, 81%. Bergs[5] employed dry ether in the malonic ester condensation and was unable to obtain a satisfactory yield of the malonic acid (m. p. 168° after recrystallization from alcohol). The dried acid was decarboxylated at 160–180° and the solution of the sodium salt was treated with Norit; yield of 1-tetralone-2-acetic acid, 10.9 g. (95%); m. p. 98–102°. A sample recrystallized from a mixture of ether and petroleum ether melted at 105–108° (reported,[5] 109–110°).

(b) **From 2-Carbomethoxy-1-tetralone.**—By the same procedure used to prepare 1-tetralone-2-β-propionic acid (II), the sodio derivative of 6 g. of 2-carbomethoxy-1-tetralone was condensed with 5.9 g. of methyl bromoacetate. The resulting **methyl ester of 2-carbomethoxy-1-tetralone-2-acetic acid** crystallized from methanol in fine colorless needles; m. p. 81.8–82.1°.

Anal. Calcd. for $C_{15}H_{16}O_5$: C, 65.20; H, 5.84. Found: C, 65.06; H, 5.84.

Hydrolysis and decarboxylation of the product gave 5 g. (83%) of 1-tetralone-2-acetic acid; m. p. 100–105°. After two recrystallizations from a mixture of ether and

petroleum ether, a sample had a m. p. 106–108°, alone and when mixed with the product in (a).

Preparation of the Lactone VIII.—The **methyl ester of 1-tetralone-2-acetic acid,** prepared with diazomethane, crystallized in small colorless plates from methanol containing a little water; m. p. 55–56.5°.

Anal. Calcd. for $C_{13}H_{14}O_3$: C, 71.54; H, 6.47. Found: C, 71.35; H, 6.36.

A Reformatsky reaction was carried out with 2.18 g. of the methyl ester, 10 ml. of dry ether, 10 ml. of dry benzene, 10 g. of 20-mesh zinc, 1.5 ml. of methyl bromoacetate and a small crystal of iodine. The mixture was stirred with a wire Hershberg stirrer[13] while it refluxed on a water-bath. The reaction began after fifteen to thirty minutes; it was continued in the manner described for IIIa. The cooled mixture was treated with cold, dilute acetic acid, and extracted with benzene. The benzene extracts were washed with water, dried, treated with Norit, filtered, and the benzene removed under reduced pressure. When the residual oil was treated with a little methanol, the **lactone of 1-hydroxy-1-carbomethoxymethyl-1,2,3,4-tetrahydronaphthalene-2-acetic acid (VIII)** crystallized in colorless prisms; yield, 1.53 g. (59%); m. p. 97–98°. A sample recrystallized from methanol melted at 100–100.5°. The lactone is insoluble in aqueous ammonia and only slowly soluble in aqueous sodium hydroxide.

Anal. Calcd. for $C_{15}H_{16}O_4$: C, 69.21; H, 6.20. Found: C, 69.46; H, 6.49.

The ultraviolet absorption (Fig. 1) was measured on a 0.01% solution of the lactone in methanol.

Hydrolysis of the Lactone to the Unsaturated Acid Ester (IXa).—In one experiment in which 7.5 g. of the lactone (VIII) was refluxed for one hour with only one equivalent of sodium hydroxide (60 ml. of 0.5 *N*) and 100 ml. of methanol, 5.5 g. (74%) of the **methyl ester of 2-carboxymethyl-1-tetrahydronaphthylideneacetic acid (IXa)** was obtained; m. p. 113–116°. A sample crystallized from benzene in fine colorless needles; m. p. 116–117°. A mixture of this compound and the lactone (VIII) melted at 85–88°.

Anal. Calcd. for $C_{15}H_{16}O_4$: C, 69.21; H, 6.20. Found: C, 69.35; H, 6.48.

The ultraviolet absorption spectrum was measured on a 0.001% solution of the acid ester in methanol; log ϵ = 4.19 at 275 mμ (Fig. 1).

Hydrolysis of the Lactone to the Unsaturated Diacid (IXc).—A solution of 1.53 g. of the lactone (VIII) and 8.03 ml. of 0.977 *N* sodium hydroxide in 20 ml. of methanol was refluxed on a steam-bath for one hour. From this solution 1.33 g. (91%) of the unsaturated acid was isolated; m. p. 197–198°. A sample of **1-tetrahydronaphthylidene-1,2-diacetic acid (IXc)** crystallized from a mixture of benzene and acetone in fine, colorless needles; m. p. 204–206°.

Anal. Calcd. for $C_{14}H_{14}O_4$: C, 68.28; H, 5.73. Found: C, 68.28; H, 5.81.

Naphthalene-1,2-diacetic Acid.—The action of ethereal diazomethane on the unsaturated dicarboxylic acid IXc or the monomethyl ester IXa gave a liquid dimethyl ester IXb. Dehydrogenation of 2 g. of the diester by sulfur followed by hydrolysis as described for IIIb gave 1.2 g. of crude naphthalene-1,2-diacetic acid; m. p. 180–190°. A sample after four recrystallizations from a mixture of benzene and acetone formed colorless prisms; m. p. 216–218°.

1′-(or 3′)-Carbomethoxy-2′-keto-1,2-cyclopentenonaphthalene.—Esterification of 2.9 g. of the diacid with methanol and sulfuric acid gave 3 g. (92%) of the **dimethyl ester of naphthalene-1,2-diacetic acid;** m. p. 89–91°. A sample after three recrystallizations from methanol formed colorless leaflets; m. p. 91–92°.

Anal. Calcd. for $C_{16}H_{16}O_4$: C, 70.57; H, 5.92. Found: C, 70.66; H, 5.96.

A Dieckmann cyclization of 1 g. of the dimethyl ester carried out as described for VI gave 0.8 g. of 1′-(or 3′)-carbomethoxy-2′-keto-1,2-cyclopentenonaphthalene; m. p. 130–135°. Crystallization of a sample from a mixture of acetone and methanol formed fine colorless needles; m. p. 145–146.5°. The compound gave a deep blue-green color with alcoholic ferric chloride.

Anal. Calcd. for $C_{15}H_{12}O_3$: C, 74.98; H, 5.04. Found: C, 75.03; H, 5.38.

Heating a solution of 0.4 g. of the β-keto ester in 40 ml. of glacial acetic acid, 20 ml. of concentrated hydrochloric acid and 2 ml. of water for four hours resulted in a nearly black solution from which was isolated only 0.04 g. of an unstable ketone (colorless needles from petroleum ether; m. p. 98–100°) which gave a 2,4-dinitrophenylhydrazone (orange-yellow prisms from chloroform–alcohol; m. p. 214–216° dec.) for which satisfactory analyses were not obtained. Varying the concentrations of acetic acid and water and the time of heating gave the same results or unreacted material.

$\Delta^{1-1'}$-2′-Keto-3,4-dihydro-1,2-cyclopentenonaphthalene.—The Dieckmann cyclization of the dimethyl ester IXb gave a 82% yield of β-keto ester (m. p. 100–108°). Hydrolysis and decarboxylation of 0.88 g. of the keto ester with a mixture of hydrochloric acid and acetic acid gave 0.46 g. of $\Delta^{1-1'}$-2′-keto-3,4-dihydro-1,2-cyclopentenonaphthalene; m. p. 57–68°. After four recrystallizations from 60–75° petroleum ether the ketone formed colorless prisms; m. p. 72–73.5° (reported,[6] 74–75°).

The 2,4-dinitrophenylhydrazone was treated with hot acetic acid. The material soluble in acetic acid precipitated in fine dark red needles on addition of water; m. p. 251–253° dec. The material insoluble in acetic acid formed lighter red prisms; m. p. 252–254° dec. (reported,[6] dark red needles; m. p. 250.5–251° dec., and lighter red plates; m. p. 247.5–248° dec. from a mixture of benzene and toluene). The ultraviolet absorption was measured on a 0.0005% solution of the ketone in methanol; log ϵ = 4.38 at 287 mμ (reported,[4a] log ϵ = 4.38).

1,2,3,4-Tetrahydronaphthalene-1,2-diacetic Acid.—A mixture of 60 g. of 2% sodium amalgam and a solution of 4.47 g. of the unsaturated acid IXc in 40 ml. of *M* sodium hydroxide was shaken vigorously for thirty minutes; excess alkali was neutralized with hydrochloric acid and the mixture was shaken with another 60 g. of amalgam for thirty minutes. The isolated acid (3.61 g., m. p. 134–136°) consisted of a mixture of the *cis* and *trans* forms. By repeated recrystallizations from benzene and from aqueous acetone it was possible to obtain one of the forms (m. p. 145–146°; called the α-form since its configuration is not known) in a pure state in 20% yield. Both forms were isolated by the method used by Drake and McVey[14] on a mixture of different acids. A mixture of the crude isomeric acids (2.44 g.) was shaken with 32.8 ml. of 0.1 *N* sodium hydroxide for twenty-four hours. After the removal of the insoluble acid by filtration, the filtrate was acidified and the acid which precipitated was recrystallized five times from acetone–water and five times from benzene–petroleum ether (60–75°). The **β-1,2,3,4-tetrahydronaphthalene-1,2-diacetic acid** formed colorless needles; m. p. 142–143°.

The insoluble portion from the previous operation was again shaken with 32.8 ml. of the alkali for twenty-four hours and the acid which remained undissolved was recrystallized as above, yielding the **α-1,2,3,4-tetrahydronaphthalene-1,2-diacetic acid** as colorless rods; m. p. 146–147°. A mixture of the pure α- and β-forms of the acid melted at 137–140°.

Anal. Calcd. for $C_{14}H_{16}O_4$: C, 67.72; H, 6.50. Found: (α-acid) C, 67.78; H, 6.86, 6.66; (β-acid) C, 68.20; H, 6.75.

Cyclization of the Stereoisomeric Acids.—A Dieckmann cyclization of the dimethyl ester from 1.53 g. of the α-form

(13) Hershberg, *Ind. Eng. Chem.*, **8**, 313 (1936).

(14) Drake and McVey, *J. Org. Chem.*, **4**, 464 (1939).

of 1,2,3,4-tetrahydronaphthalene-1,2-diacetic acid, carried out as described for VI, yielded 1.24 g. of **α-1′-(or 3′)-carbomethoxy-2′-keto-1,2,3,4-tetrahydro-1,2-cyclopentenonaphthalene**, which after three recrystallizations from methanol formed colorless prisms; m. p. 108–109°.

Similarly from the ester of 1.29 g. of the β-acid 0.98 g. of the **β-form** of the keto ester was obtained, which after three recrystallizations from methanol formed fine colorless needles; m. p. 113–115°. A mixture of the two pure forms melted at 90–95°.

Anal. Calcd. for $C_{15}H_{16}O_3$: C, 73.75; H, 6.60. Found: (α-form) C, 73.94; H, 6.74; (β-form) C, 73.70; H, 6.82.

The cyclic keto esters can be separated from each other more readily and in better yield than can the original acids. Cyclization of the dimethyl esters prepared from 1.66 g. of the mixture of acids yielded 1.48 g. of a mixture of the two forms of the keto esters; m. p. 70–91°. The mixture was dissolved in the minimum of hot methanol and a one-third excess of the solvent was added. On chilling, the β-form of the keto ester precipitated in nearly pure state. When the filtrate was concentrated to one-half its volume and chilled, a small amount of the mixed isomers separated; from the concentrated filtrate the nearly pure α-form of the keto ester separated. Two recrystallizations from methanol yielded the pure compounds. About equal amounts of the two forms were obtained.

Hydrolysis and decarboxylation of 0.7 g. of the α-form of the cyclic keto ester by a mixture of acetic acid and hydrochloric acid gave a quantitative yield of the **α-form of 2′-keto-1,2,3,4-tetrahydro-1,2-cyclopentenonaphthalene (X)**; m. p. 83–85°. It crystallized from methanol in colorless rectangular plates; m. p. 85–86°.

Similarly, the **β-form of X** was obtained in 94% yield (m. p. 48–49°) from the isomeric keto ester; it crystallized from methanol in colorless needles; m. p. 51–52°.

Anal. Calcd. for $C_{13}H_{14}O$: C, 83.83; H, 7.58. Found: (α-form) C, 83.74; H, 6.64; (β-form) C, 83.94; H, 7.71.

The 2,4-dinitrophenylhydrazones were recrystallized from methanol–chloroform; α-form, yellow needles with m. p. 260–261°; β-form, orange-yellow needles with m. p. 240–241° dec.

Anal. Calcd. for $C_{19}H_{18}N_4O_4$: N, 15.29. Found: (α-form) N, 15.11; (β-form) N, 15.12.

The semicarbazones of both forms crystallized in very fine colorless plates; α-form, m. p. 254–256° dec.; β-form, m. p. 220–222° dec.

Anal. Calcd. for $C_{14}H_{17}N_3O$: C, 69.11; H, 7.04; N, 17.27. Found: (α-form) C, 69.43; H, 6.94; N, 17.34; (β-form) C, 69.09; H, 7.34; N, 16.81.

A suspension of 0.25 g. of the semicarbazone (α- or β-form) in ethanolic sodium ethoxide from 0.46 g. of sodium and 13 ml. of absolute alcohol was heated at 170° for twenty hours in a bomb tube. The isolated yellow liquid was heated with 0.2 g. of 10% palladium–charcoal catalyst at 300–320° for forty-five minutes. The product formed a picrate, which after two recrystallizations from ethanol melted at 106–107°, alone and when mixed with an authentic specimen of the picrate of 1,2-cyclopentenonaphthalene.

Summary

Three 3-ketohydrophenanthrenes and two 2′-ketohydro-1,2-cyclopentenonaphthalenes were synthesized by methods involving the Reformatsky and Dieckmann reactions.[15]

(15) A similar series of ketones has been prepared from 2-carbomethoxy-1-keto-1,2,3,4-tetrahydrophenanthrene by L. E. Miller in this Laboratory. These results will be published soon.

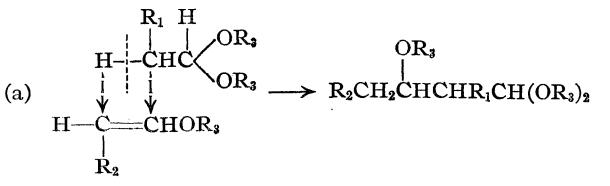
Reaction of Acetals and α,β-Unsaturated Ethers

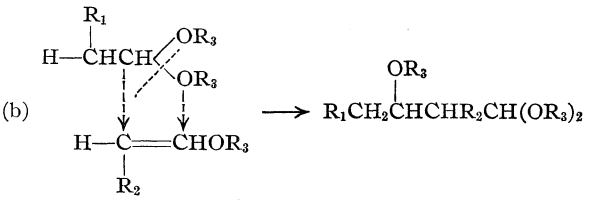
BY R. I. HOAGLIN AND D. H. HIRSH

During the course of an investigation of the chemistry of vinyl ethers the reaction of acetals and α,β-unsaturated ethers was studied. Examples of this reaction were reported by Mueller-Cunradi and Pieroh in a U. S. patent[1] which describes the condensation of acetaldehyde acetals and vinyl ethers in the presence of catalysts capable of effecting the polymerization of vinyl ethers.

A priori the reaction of an acetal with an α,β-unsaturated ether could involve a splitting of either an alpha hydrogen, as suggested by Mueller-Cunradi and Pieroh, or an alkoxy group from the acetal with addition of the corresponding resulting fragments to the double bond of the unsaturated ether as shown in reactions (a) and (b).



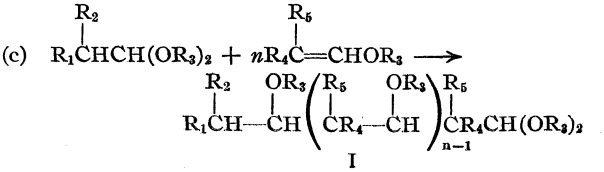
(a)



(b)

R_1 and R_2 may be hydrogen atoms or alkyl radicals; R_3 is an alkyl radical.

The present study showed that an alkoxy group is split from the acetal molecule and that the course of reaction indicated in (b) is correct. The investigation also showed that the reaction could be extended to include acetals of aldehydes other than acetaldehyde and also α,β-unsaturated ethers other than those derived from vinyl alcohol. The results may be generalized by the following equation, where R_1, R_2, R_4 and R_5 may



(c)

I

(1) Mueller-Cunradi and Pieroh, U. S. Patent 2,165,962 (1939).

be hydrogen atoms or alkyl radicals, R_3 is an alkyl radical and n is a whole number.

The manner in which acetals and α,β-unsaturated ethers react was determined by means of two syntheses, the first involving the condensation of diethyl butyral (II) and vinyl ethyl ether (III), reaction (d), while the second entailed the addition of diethyl acetal (IV) to 1-butenyl ethyl ether (V), reaction (f). The product of the first reaction, 1,1,3-triethoxyhexane (VI), was simultaneously hydrolyzed and de-ethanolated with a mineral acid, reaction (e), to give 2-hexenal (VII), a known compound. The product of the second reaction, 1,1,3-triethoxy-2-ethylbutane (VIII), was similarly treated, reaction (g), giving 2-ethyl-2-butenal (IX), also a known compound.

(d) $CH_3CH_2CH_2CH(OC_2H_5)_2$ (II) + $CH_2{=}CHOC_2H_5$ (III) $\xrightarrow{BF_3}$ $CH_3CH_2CH_2\underset{\displaystyle OC_2H_5}{\underset{|}{C}}HCH_2CH(OC_2H_5)_2$ (VI)

(e) VI + $H_2O \underset{}{\overset{H^+}{\rightleftharpoons}}$ $CH_3CH_2CH_2CH{=}CHCHO$ (VII) + $3C_2H_5OH$

(f) $CH_3CH(OC_2H_5)_2$ (IV) + $CH_3CH_2CH{=}CHOC_2H_5$ (V) $\xrightarrow{BF_3}$ $CH_3\underset{\displaystyle OC_2H_5}{\underset{|}{C}}H{-}\underset{\displaystyle C_2H_5}{\underset{|}{C}}HCH(OC_2H_5)_2$ (VIII)

(g) VIII + $H_2O \underset{}{\overset{H^+}{\rightleftharpoons}}$ $CH_3CH{=}\underset{\displaystyle C_2H_5}{\underset{|}{C}}CHO$ (IX) + $3C_2H_5OH$

Had the mechanism indicated by Mueller-Cunradi and Pieroh been correct, the structures of VI and VIII would have been reversed and the products of reactions (e) and (g) would also have been the reverse of those actually observed. Because of the fact that acetals of only acetaldehyde and ethers of only vinyl alcohol were used in the examples of the patent, the error in the mode of reaction was not observed by the inventors.

Examination of the general reaction shown in equation (c) shows that the alkoxy radicals in the acetal and unsaturated ether molecules are identical (OR_3). The reaction occurs with equal ease when reactants are used in which the alkoxy radicals are not identical, although the products are so numerous that isolation of pure compounds is difficult. For example, dibutyl acetal (X) reacted with vinyl ethyl ether (III) to give a mixture of products, two of which, 1-ethoxy-1-butoxyethane (XI) and 1,1,3-tributoxybutane (XII), were isolated. These compounds were assumed to have been formed by an alkoxy interchange between dibutyl acetal and 1,3-dibutoxy-1-ethoxybutane (XIII). These transformations are shown in equations (h) and (i).

(h) $CH_3CH(OC_4H_9)_2$ (X) + $CH_2{=}CHOC_2H_5$ (III) $\xrightarrow{BF_3}$ $CH_3\underset{\displaystyle OC_4H_9}{\underset{|}{C}}HCH_2CH\begin{matrix}OC_2H_5\\OC_4H_9\end{matrix}$ (XIII)

(i) $CH_3\underset{\displaystyle OC_4H_9}{\underset{|}{C}}HCH_2CH\begin{matrix}OC_2H_5\\OC_4H_9\end{matrix}$ (XIII) + $CH_3CH(OC_4H_9)_2$ (X) $\rightleftharpoons$ $CH_3CH\begin{matrix}OC_2H_5\\OC_4H_9\end{matrix}$ (XI) + $CH_3\underset{\displaystyle OC_4H_9}{\underset{|}{C}}HCH_2CH(OC_4H_9)_2$ (XII)

Compound XIII was not isolated but was believed to be present in intermediate fractions obtained in the distillation of the reaction product.

Several new alkoxyacetals were prepared which further illustrate the mechanism of the reaction and its versatility in the synthesis of compounds of specific structure. In Table I are presented yields and some physical properties of several of these alkoxyacetals prepared from acetals and α,β-unsaturated ethers.

The reaction of acetals and α,β-unsaturated ethers is similar to the addition of alcohols to ethylene oxide in that several products are formed, the distribution of which depends primarily on the mole ratio of the reactants. In Fig. 1 are shown graphically the data from several experiments in which the mole ratio of dimethyl acetal (XIV) to vinyl methyl ether (XV) was varied between 1:1 and 5:1. The main products of this reaction are 1,1,3-trimethoxybutane (XVI) and 1,1,3,5-tetramethoxyhexane (XVII) at the mole ratios employed.

(j) $CH_3CH(OCH_3)_2$ (XIV) + $CH_2{=}CHOCH_3$ (XV) $\longrightarrow$ $CH_3\underset{\displaystyle OCH_3}{\underset{|}{C}}HCH_2CH(OCH_3)_2$ (XVI) $\xrightarrow{XV}$ $CH_3\underset{\displaystyle OCH_3}{\underset{|}{C}}HCH_2\underset{\displaystyle OCH_3}{\underset{|}{C}}HCH_2CH(OCH_3)_2$ (XVII)

Because these experiments were carried out batchwise, the mole ratios shown merely indicate a ratio of moles of acetal used to the total moles of vinyl ether added. Actually, the mole ratio varied between infinity and the finite value indicated. The data show, as expected, that the yield, based on vinyl methyl ether, of 1,1,3-trimethoxybutane increases and that of 1,1,3,5-tetramethoxyhexane decreases with an increase in the acetal: vinyl ether mole ratio.

Differences in reactivity between various acetals and vinyl ethers are also illustrated by the

TABLE I

PREPARATION OF ALKOXYACETALS FROM ACETALS AND α,β-UNSATURATED ETHERS

Acetal	Unsaturated ether	Mole ratio of acetal to unsaturated ether	Product isolated	Yield of product based on ether	Physical properties: Boiling point, °C.[a]	Sp. gr., 20/15.6°C.	$n^{20}D$	Molecular refractivity Calcd.	Obs.

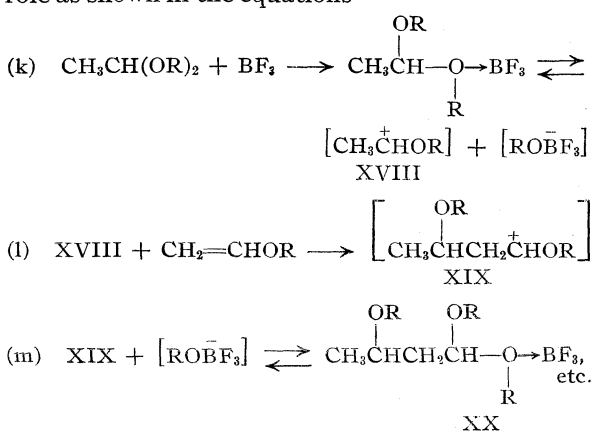
[a] Boiling points uncorrected.

data shown in Fig. 1. These data show a distinct difference in the yields of products obtained when dimethyl acetal and diethyl acetal were treated with vinyl methyl ether and vinyl ethyl ether, respectively. Apparently the difference in reactivity between dimethyl acetal and trimethoxybutane with vinyl methyl ether is greater than the difference in reactivity between diethyl acetal and triethoxybutane with vinyl ethyl ether.

The ease with which boron trifluoride forms complexes suggested that the catalyst plays a role as shown in the equations



The activated forms XVIII and XIX are thus the points attacked by the unsaturated ether and a higher boiling alkoxyacetal is formed when a molecule of unsaturated ether reacts with the active form shown in XIX. In this manner the reaction proceeds indefinitely, resulting in products of the general type indicated in formula I.

A detailed catalyst study was not made for the acetal–α,β-unsaturated ether reaction. However, a single experiment was carried out in which zinc chloride was found to be just as effective as boron trifluoride in the reaction of diethyl acetal and vinyl ethyl ether.

The reaction of acetals and α,β-unsaturated ethers represents a new method of increasing the length of a carbon chain and the products obtained are similar in structure to those obtained by the aldol condensation. For example, for the synthesis of 1-hexanol by the acetal–unsaturated ether reaction, diethyl butyral and vinyl ethyl ether may be used. These intermediates are prepared from butyraldehyde and acetaldehyde, respectively, which raw materials are also involved in the synthesis of 1-hexanol *via* the aldol condensation. The aldol reaction, however, results in the formation of several unsaturated aldehydes because of the ability of each of the raw materials to condense with itself or with

another aldehyde. A complex mixture of aldehydes, consisting of both straight and branched chains, is obtained requiring precise rectification for its resolution. The alkoxyacetals, formed in the acetal–unsaturated ether reaction, are straight- or branched-chained compounds, but both types are not obtained from the same reaction product. The alkoxyacetals are easily separated by distillation because of their difference in molecular weight, this difference being the molecular weight of the unsaturated ether used.

From the alkoxyacetals, obtained by the reaction of acetals and α,β-unsaturated ethers, may be prepared a multitude of chemical intermediates. Although publication of the details of the preparation of these intermediates is not in the scope of this paper the names of a few of the compounds derived from the reaction products of diethyl acetal and vinyl ethyl ether will serve to illustrate the potential utility of these alkoxyacetals. From 1,1,3-triethoxybutane may be obtained by hydrogenolysis 1,3-diethoxybutane (diethyl ether of 1,3-butanediol). Hydrolysis of triethoxybutane with mineral acid gives 3-ethoxybutanal or crotonaldehyde, the product obtained depending on the concentration of acid used.[2] From 3-ethoxybutanal may be obtained, by standard procedures, 3-ethoxybutanol and its esters and 3-ethoxybutanoic acid and its esters. Simultaneous dehydration and de-ethanolation of 3-ethoxybutanol gives butadiene.[1]

By analogous reactions 1,1,3,5-tetraethoxyhexane gives 1,3,5-triethoxyhexane, 3,5-diethoxyhexanal, 3,5-diethoxyhenanol and its esters, 3,5-diethoxyhexanoic acid and its esters, 2,4-hexadienal, hexanal, 1-hexanol, hexanoic acid, sorbic acid, hexyl ether, hexylamine and others. Analogous compounds can be prepared from alkoxyacetals derived from various acetals and α,β-unsaturated ethers.

Experimental[3]

The preparation of a few alkoxyacetals and unsaturated aldehydes is described and will serve to illustrate the experimental procedures employed.

Preparation of Reactants

Acetals used were prepared in the usual way, by the acid-catalyzed reaction of the appropriate aldehydes and alcohols. The unsaturated ethers were obtained by the catalytic vapor-phase decomposition of acetals.

Condensations

(a) **1,1,3-Trimethoxybutane and 1,1,3,5-Tetramethoxyhexane.**—Dimethyl acetal, 1943 g. (21.58 moles), was placed in a 5-l., 3-necked flask equipped with stirrer, brine-cooled condenser, gas diffuser and thermometer. Three and seven-tenths grams of boron trifluoride etherate (25% boron trifluoride in ethyl ether), was added to the acetal solution (0.05% of boron trifluoride based on the weight of acetal). This solution was warmed to 34° and

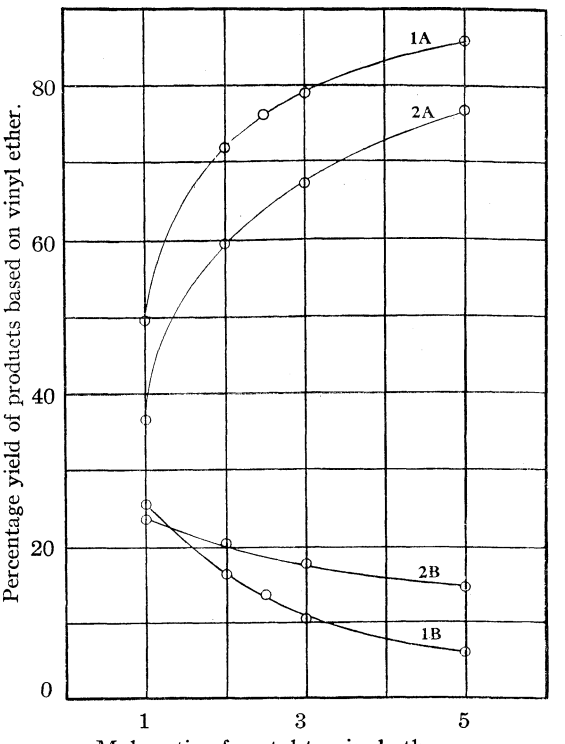


Fig. 1.—Reaction of dimethyl acetal with vinyl methyl ether and diethyl acetal with vinyl ethyl ether. Mole ratio of acetal to vinyl ether *vs.* yield of products based on vinyl ether: 1A, 1,1,3-trimethoxybutane; 2A, 1,1,3-triethoxybutane; 1B, 1,1,3,5-tetramethoxyhexane; 2B, 1,1,3,5-tetraethoxyhexane.

422 g. (7.19 moles) of vinyl methyl ether (99%) was vaporized into the agitated solution. Reaction took place at once with the evolution of heat. The temperature was maintained at 35 to 40° by regulation of the rate of addition of vinyl ether and by external cooling with water. The addition of vinyl methyl ether was completed in one hour and twenty minutes after which the reaction mixture was stirred another hour. The catalyst was then neutralized with 15 g. (400% excess) of anhydrous powdered sodium carbonate. The mixture was agitated four hours and then filtered to remove salts. Fractionation of the filtrate in the presence of a small amount of sodium carbonate gave 1,1,3-trimethoxybutane and 1,1,3,5-tetramethoxyhexane in yields of 79 and 10%, respectively, based on the vinyl methyl ether used. By-products, 1,1-dimethoxy-2-butene and 1,1,3-trimethoxy-4-hexene, were obtained in yields of 0.1 and 0.8%, respectively, although the former compound was not isolated in a pure form. The positions of the methoxy groups and double bond in trimethoxyhexene were indicated by mass spectrometric data. Trimethoxyhexene was obtained in 98% purity by redistillation of intermediate fractions composited from several similar reaction products: b. p. 72–74° (10 mm.); d^{20}_{20} 0.926; $n^{20}D$ 1.4261; *MR*, observed 48.2, calcd. 48.18.

(b) **1,1,3-Triethoxyhexane and 1,1,3,5-Tetraethoxyoctane.**—A mixture of 3070 g. (21 moles) of diethyl butyral and 6 g. of boron trifluoride etherate (25% boron trifluoride in ethyl ether) was stirred and warmed to 49°. To this mixture was added with good agitation 511 g. (7 moles) of vinyl ethyl ether (98.8%). The rate of addition was regulated, so that by cooling the reaction flask with water a reaction temperature of 49 to 50° was maintained. The addition of vinyl ether required forty-five

(2) Halbig and Kaufler, U. S. Patent 1,902,070 (1933).

(3) Boiling points and melting points are uncorrected.

minutes, after which the catalyst was neutralized by agitation with 72 g. of 10% alcoholic sodium hydroxide solution. The reaction product was distilled under vacuum to recover the unreacted diethyl butyral and the products, 1,1,3-triethoxyhexane and 1,1,3,5-tetraethoxyoctane, which were obtained in yields of 72 and 16%, respectively, based on vinyl ethyl ether.

(c) **1,1,3-Triethoxy-2-ethylbutane.**—Three hundred grams (3 moles) of 1-butenyl ethyl ether was added dropwise to 1063 g. (9 moles) of diethyl acetal containing 1 cc. of an ethyl ether solution of boron trifluoride etherate (35% boron trifluoride). The mixture was stirred constantly during the addition of the ether and the temperature was maintained between 45 and 48° with slight cooling of the reaction flask. The addition of the ether was complete in fifteen minutes, although the reaction continued for another fifteen minutes. The catalyst was neutralized by agitation with 5 g. of anhydrous, powdered sodium carbonate for a period of three hours. Distillation of the reaction product gave 1,1,3-triethoxy-2-ethylbutane in 48% yield, based on 1-butenyl ethyl ether.

Hydrolysis and De-alkanolation

(a) **2,4-Hexadienal and 5-Methoxy-2-hexenal.**—One mole (206.2 g.) of 1,1,3,5-tetramethoxyhexane was distilled with 220 g. of 5.0% aqueous sulfuric acid solution. Methanol was removed as fast as formed until the vapor temperature could no longer be maintained at 65°. The removal of methanol (110 g.) required three and one-half hours. Distillation was stopped and the kettle residue was cooled to room temperature. This product consisted of a lower layer containing 5.75% sulfuric acid and 6.0% of aldehyde (as 5-methoxy-2-hexenal), and an upper layer containing essentially 2,4-hexadienal and 5-methoxy-2-hexenal. The upper layer was distilled under vacuum in the presence of 0.5 g. of sodium acetate. The yields of 2,4-hexadienal and 5-methoxy-2-hexenal were 47 and 38%, respectively. Physical properties of 2,4-hexadienal: b. p. 43° (5 mm.); d^{20}_{20} 0.898; $n^{20}D$ 1.5384. Physical properties of 5-methoxy-2-hexenal: b. p. (approx.) 58° (5 mm.); d^{20}_{20} 0.931; $n^{20}D$ 1.4615; *MR*, observed 36.1; calcd. 35.8.

(b) **2-Hexenal and 2-Ethyl-2-butenal.**—1,1,3-Triethoxyhexane, 327 g. (1.5 moles), was distilled with 375 cc. of 2% aqueous hydrochloric acid solution. After refluxing this mixture ten minutes the vapor temperature dropped to 77.5° and an ethanol fraction was removed. After five hours the removal of ethanol was essentially complete, water was added to the kettle and crude 2-hexenal (94% purity) was recovered as the upper layer of the 2-hexenal–water steam distillate. The yield of 2-hexenal was 94%. Physical properties of 2-hexenal: b. p. 50–51° (20 mm.); d^{20}_{20} 0.845; $n^{20}D$ 1.4464. 1-Hexanol was prepared from the aldehyde by hydrogenation; 3,5-dinitrobenzoate, m. p. 58°.

Using the same procedure, 2-ethyl-2-butenal was prepared in 95% yield from 1,1,3-triethoxy-2-ethylbutane. Physical properties of 2-ethyl-2-butenal: b. p. 58° (50 mm.); d^{20}_{20} 0.858; $n^{20}D$ 1.4478. 2-Ethyl-1-butanol was prepared from the aldehyde by hydrogenation; 3,5-dinitrobenzoate, m. p. 50°.

Acknowledgment.—The authors wish to acknowledge the helpful suggestions made by other members of the Process Development Laboratory and Research Laboratory of this Corporation and also the assistance of Dr. Samuel F. Clark who was formerly associated with this project.

Summary

1. The reaction of acetaldehyde acetals and vinyl ethers was extended to include acetals of other aldehydes and α,β-unsaturated ethers of alcohols other than vinyl alcohol.

2. The manner in which acetals and α,β-unsaturated ethers react was shown to be in disagreement with that suggested by Mueller-Cunradi and Pieroh.

3. The utility of the acetal–α,β-unsaturated ether reaction is discussed.

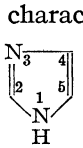
Studies of Imidazole Compounds. II. The Structure of Certain Simple Imidazole Derivatives

BY ROBERT A. TURNER

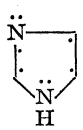
Although the structures of several aromatic nuclei have been discussed extensively in the chemical literature, the structure of the imidazole nucleus has been given scant attention. In this paper we discuss the structure of imidazoles, as revealed by the spectrophotometric data of certain simple derivatives.

Discussion

Imidazole (I) possesses an aromatic sextet (II) and thus satisfies one of the known requirements for aromatic character.



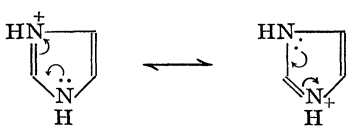
I



II

The nitrogen atom in position 3 has an electron pair, not included in the sextet, and which may be donated to a proton. Imidazole is a basic substance which readily forms salts with acids. Since the two unshared electrons of the nitrogen atom in position 1 are needed to form the sextet, they may not be donated to a proton, and consequently imidazole is a monoacid base.[1]

When the imidazole nucleus has acquired a proton, the charged molecule has the resonance forms III and IV.

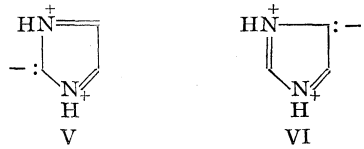


III IV

(1) The structure of pyrrole is, by contrast, enlightening in this connection. It loses its aromatic stability in the presence of hydrogen ions because the sextet is destroyed when the two unshared electrons of the nitrogen atom are donated. Not only is pyrrole a weak base, but it is unstable in the presence of acids.

This resonance is the same as that of an amidine salt and is very similar to that of an imido ester salt. Like amidine salts, imidazole salts are uncolored. The resonance of salts of amidines and of imido esters contributes stability to these substances, but this resonance does not extend through a sufficiently long conjugated system, nor are the resonating forms sufficiently polarized so that the salts are colored.

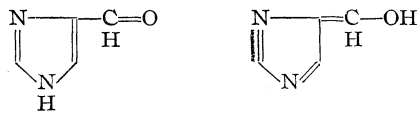
If the electrons of the carbon-to-carbon double bond of III could enter into the resonance between the nitrogen atoms, the resonance of an imidazole salt would not be that of an amidine salt but would be of a more complex kind. However, if the electrons of the carbon-to-carbon double bond do enter into the resonance, structures such as would



V VI

contribute to the total structure of imidazole. These structures would not have much significance, for well substantiated reasons.

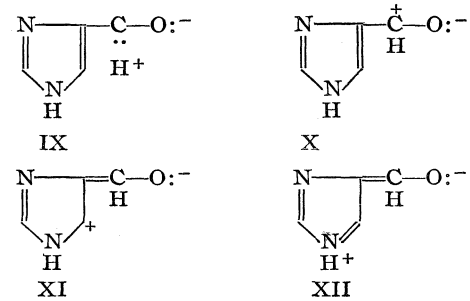
Imidazole-4-aldehyde is a colorless, crystalline substance, of molecular weight 96.09 and m. p. 174°. It is not easily oxidized, contrary to the expected behavior of aldehydes. On the basis of



VII VIII

properties such as these, and others, *e. g.*, the extreme reluctance with which the aldehyde enters into most condensation reactions, Hubball and Pyman[2] postulated that the aldehyde existed chiefly in the enol form VIII rather than in the aldehyde form VII.[3] However, this proposition is simply that VII and VIII are in equilibrium, with the equilibrium shifted so that the enol form VIII preponderates greatly over the aldehyde. It seems unlikely that such a state would effectuate the masking of aldehyde properties in the absence of steric factors, for special steric conditions must usually exist in order to quench the lability which is known to attend the equilibrium between an aldehyde and its enol. In view of this and the evidence to be discussed below we believe the explanation of Hubball and Pyman[2] to be untenable.

Besides the usual structure VII for imidazole-4-aldehyde there are others for which evidence exists if we accept certain premises of modern structure theory. The variable amount of ionic character in the C–H bond makes IX a contributory structure. The strongly electronegative oxygen atom causes the C–O bonding to have considerable ionic character so that X is also a contributory structure. Related to X are structures such as XI and XII. Of these we regard XII as having spe-



IX X

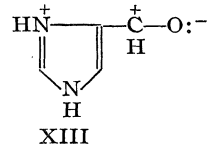
XI XII

cial significance and contributing to a greater degree to the total structure of imidazole-4-aldehyde than any of the corresponding structures for benzaldehyde contribute to its total structure, because of the stability of quadrivalent, positively charged nitrogen.

The structures X, XI and XII are very probably those responsible for the absorption of imidazole-4-aldehyde in the ultraviolet region (Fig. 1). Since imidazole does not absorb light in either the visible or near ultraviolet region, this absorption of imidazole-4-aldehyde is attributable only to the (conjugated) aldehyde group.[4]

An interesting phenomenon appears when acid is added to imidazole-4-aldehyde: the absorption peak at 256 mμ is obliterated. The change occurs immediately, for it does not matter whether the aldehyde is dissolved in acid before its spectrum is measured, or whether a drop is added just prior to the determination of absorption at 256 mμ. We explain the phenomenon as follows.

Addition of a proton to VII causes its stabilization in forms corresponding to III and IV. Either of the nuclear nitrogen atoms has a charge of +1. Thus electrons would be drawn toward the nucleus, and forms corresponding to X, XI and XII would be very improbable. For example, XIII,



XIII

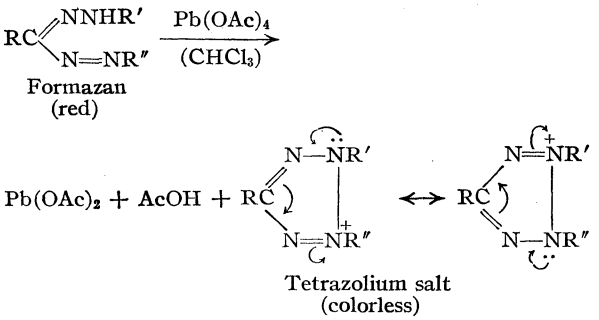
the structure which corresponds to X after the addition of a proton, is very unlikely. We say, then, that the addition of a proton to imidazole-4-aldehyde reduces the contribution of forms such as X, XI and XII to a negligible amount. Since only these forms absorb in the ultraviolet region, absorption *in that region* is eliminated.

(2) Hubball and Pyman, *J. Chem. Soc.*, 21 (1928).

(3) Imidazole-4-aldehyde forms a cyanohydrin, a phenylhydrazone, an anil, an oxime, a sodium bisulfite addition compound and a semicarbazone; it condenses with pyruvic acid and β-naphthylamine to form 2-(imidazol-4-yl)-benzo-f-quinoline-4-carboxylic acid. It does not undergo the Cannizzaro reaction, or the Perkin reaction; it gives a negative Schiff test; it does not form an acetal; and it is not oxidized either by air or by ammoniacal silver nitrate.

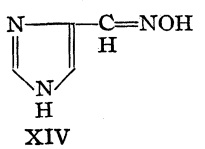
(4) 4-Hydroxymethylimidazole, the alcohol corresponding to imidazole-4-aldehyde, has no absorption peak in the ultraviolet region.

In this connection it is interesting to compare the structure and absorption characteristics of a formazan with those of the tetrazolium salt formed from the formazan by oxidation.[5] It is to

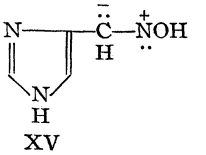


be noted that the tautomerism which is present in the formazan is not present in the tetrazolium salt, which exhibits resonance. Imidazole-4-aldehyde has, like the formazan, a tautomerism in which a hydrogen atom migrates from one nitrogen atom to another; in acid solution imidazole-4-aldehyde is no longer tautomeric but possesses a resonance very similar to that of the tetrazolium salt. A formazan has large absorption peaks in the regions 290 and 420 mμ. Tetrazolium salts have a single, broad peak near 300 mμ, the peak at the longer wave length having been eliminated. Thus the analogy between imidazole-4-aldehyde and a formazan, on one hand, and between imidazole-4-aldehyde hydrochloride and a tetrazolium salt, on the other, is accountable in structure theory and is further supported by the absorption spectra of the several compounds.

The absorption of imidazole-4-aldehyde oxime (Fig. 2) in alcohol solution, and in alcohol solution containing hydrochloric acid, parallels that of the aldehyde. The oxime absorbs strongly, with a peak at 249 mμ; in the presence of hydrochloric acid the peak is shifted to 240 mμ. Thus the effect found to occur in the aldehyde also occurs in the oxime, but to a lesser extent. We account for this as follows. The oxime XIV has a contribution to its structure of the form XV. Data from dipole moment determinations support

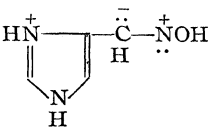


XIV



XV

this view.[6] Structures with a positive nitrogen contribute to the total structure, whereas in the analogous oxygen compound the related form with positive oxygen is unimportant. Furthermore, we may expect that addition of a proton to XV to yield XVI would not depress the absorption at all, but rather augment it, inasmuch as the positive charge in the nucleus would mobilize the electron pair which shifts when XV is formed from XIV.



XVI

We now turn to the evidence derived from infrared spectrometry which bears upon the structure of imidazole-4-aldehyde and related compounds. Generally, aldehydes exhibit a peak, which may be quite broad, in the region 1640 to 1690 cm.$^{-1}$. Aldehydes which are conjugated with a double bond, whether it is part of a chain or in an aromatic ring, have peaks which are shifted toward shorter wave lengths; the peaks of these aldehydes are near 1700 cm.$^{-1}$ and are large. The infrared spectrum of imidazole-4-aldehyde is shown in Fig. 3. It will be noticed that the peak which extends from 1654 to 1696 cm.$^{-1}$ is typical of an aromatic aldehyde. While the spectrometric evidence for the aldehyde group is satisfactory, there is no certain evidence of an alcohol group. We consider that this evidence, which shows that imidazole-4-aldehyde exists as the aldehyde, or that at least a large fraction of it so exists, negates the postulate of Hubball and Pyman[2] that imidazole-4-aldehyde exists chiefly in the enol form VIII.

The comparison of the spectrum of imidazole-4-aldehyde with the spectrum of 4-hydroxymethyl-imidazole (Fig. 4) reveals two easily discernible features. First, the broad band from 1654 to 1696 cm.$^{-1}$, present in the spectrum of the aldehyde, is absent from the spectrum of the alcohol. Second, the spectrum of the alcohol in the region 3000 to 3500 cm.$^{-1}$ (the region of vibrations of hydroxyl groups) shows more absorption than does the spectrum of the aldehyde. Comparison of the spectrum of the aldehyde with those of several blank determinations of mineral oil in the region near 2900 cm.$^{-1}$ has shown that the absorption of the aldehyde is almost identical with the absorption of mineral oil in that region.

If the aldehyde existed in the enol form VIII, either wholly or partly, it would exhibit some absorption in the region 3100 to 3500 cm.$^{-1}$. Thus the evidence from infrared spectrometry shows that the aldehyde is not enolated.[7]

The infrared spectrum of the aldehyde oxime (Fig. 5) now becomes of interest. From what has been stated in the foregoing discussion it might be expected that the oxime would have a peak at

(5) Kuhn and Jerchel, *Ber.*, **74**, 941 (1941).

(6) Hurdis and Smyth, THIS JOURNAL, **65**, 89 (1943), have adduced evidence from dipole moment measurements which strongly indicates a structure with positive nitrogen to be contributory in the case of certain nitriles. It is reasonable to expect the same structure in an oxime, which is a hydrated nitrile.

(7) It may be remarked that both the data from Raman spectra and from polarographic reduction indicate that pyrrole-2-aldehyde exists as the aldehyde and not as the enol, and is slightly more difficult to reduce than benzaldehyde. *Cf.* Bonino and Scaramelli, *Ricerca sci.*, **6**, II, 111–112 (1935); *C. A.*, **30**, 8208 (1936).

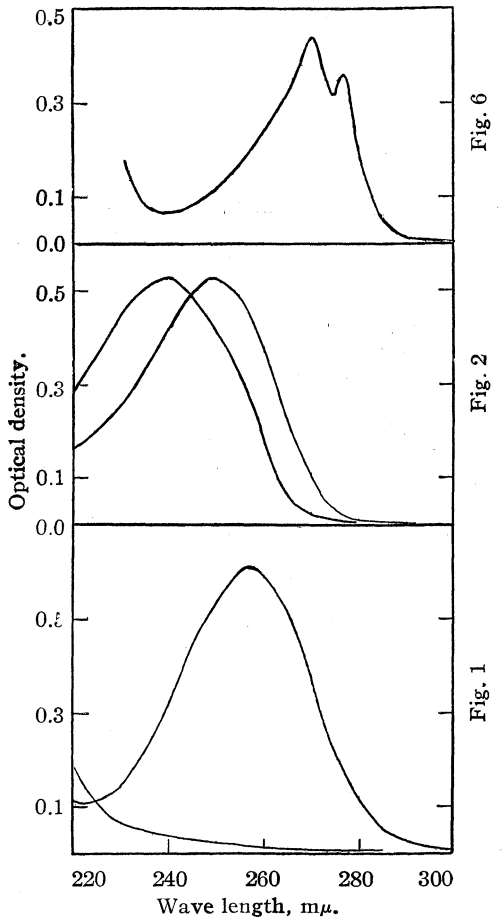


Fig. 1.—Ultraviolet absorption spectra of imidazole-4-aldehyde: upper curve, 0.0050 mg. per ml. in 95% ethanol; peak at 256.5 mμ with ε equal to 11,700. Lower curve, 0.0050 mg. per ml. in 96% ethanol which was 0.040 *N* in hydrochloric acid.

Fig. 2.—Ultraviolet absorption spectra of imidazole-4-aldehyde oxime: right curve, 0.0050 mg. per ml. in 95% ethanol; peak at 249 mμ with ε equal to 11,600. Left curve, 0.0050 mg. per ml. in 95% ethanol which was 0.040 *N* in hydrochloric acid; peak at 240 mμ with ε equal to 11,710.

Fig. 6.—Ultraviolet absorption spectrum of imidazole-4-carboxylic acid: 0.050 mg. per ml. in 95% ethanol; peaks at 270.5 mμ, with ε equal to 980, and at 277 mμ with ε equal to 810.

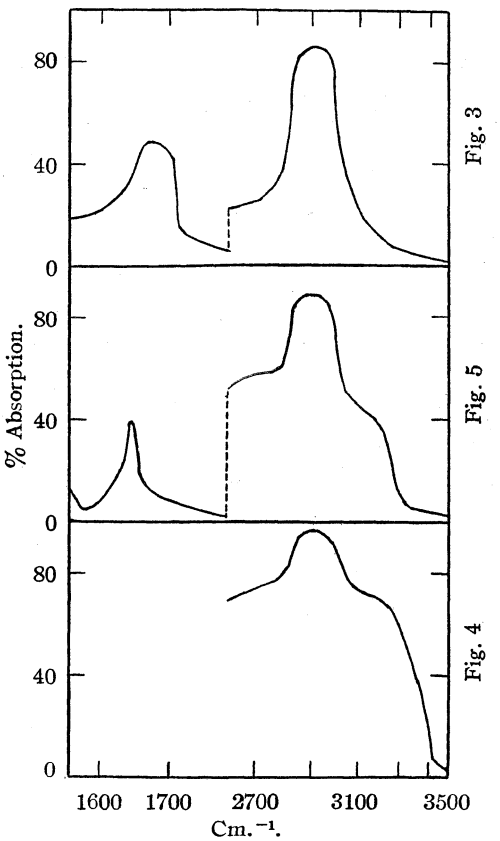

Fig. 3.—Infrared absorption spectrum of imidazole-4-aldehyde: regions 1570 to 1800 cm.$^{-1}$ (left curve) and 2650 to 3350 cm.$^{-1}$ (right curve).

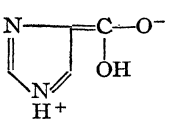
Fig. 4.—Infrared absorption spectrum of 4-hydroxymethyl-imidazole: region 2400 to 3600 cm.$^{-1}$.

Fig. 5.—Infrared absorption spectrum of imidazole-4-aldehyde oxime regions 1570 to 1800 cm.$^{-1}$ (left curve) and 2650 to 3350 (right curve).

the usual place for absorption due to the group C-N of an oxime (1650 cm.$^{-1}$), and also that the spectrum of the oxime would exhibit absorption in the high frequency region on account of the O–H group. The spectrum shows how well these expectations are fulfilled. There is a peak at 1653 cm.$^{-1}$, and there is considerable absorption in the high-frequency region.

Imidazole-4-carboxylic acid presents an absorption spectrum in the ultraviolet (Fig. 6) which has two peaks: at 270.5 mμ, ε = 980; and at 277 mμ, ε = 810. Because the values of these peaks are so much lower than the value for imidazole-4-aldehyde, the electronic transitions to which they are attributable are much less probable. However, there is no certainty that the transitions for both compounds are the same, or even similar. The two peaks must be the result of interaction between the carboxyl group and the imidazole ring since neither moiety alone absorbs radiation in this region. We postulate the structure XVII, corresponding to XII for imidazole-4-aldehyde,



XVII

as the one to which the absorption at 277 mμ is due.[8]

(8) The peak at 270.5 mμ is such a peak, both with respect to position and to intensity, as would be expected for an aromatic acid. Benzoic acid, for example, exhibits a peak at 270 mμ with ε = 800; *cf.* Kumler and Strait, THIS JOURNAL, 66, 2352 (1943).

Experimental

The samples of compounds used in the experiments reported here were prepared as described by Turner and Scholz[9] and had the melting points and properties recorded by them.

Ultraviolet spectrophotometric measurements were made with solutions of the compounds studied, in 95% ethanol. The instrument used was a Beckman Quartz Spectrophotometer, made by the National Technical Laboratories.

Infrared spectrophotometric measurements were made with crystals of the compound, mulled in mineral oil. The mineral oil suspension was held between two sodium chloride plates. A stream of dry nitrogen was allowed to sweep through the carriage holding the salt plates, so that the absorption spectrum of air (due to water and carbon dioxide, chiefly) was greatly diminished. Small absorption bands due to water remained in the spectrophotometric tracings in the region below 1600 cm.$^{-1}$. The instrument used was a Perkin–Elmer Infrared Spectrometer, Model 12A, equipped with a Brown automatically recording potentiometer, and with an adjustable attenuator to oppose and counterbalance the irregularities of emission of infrared radiation from the source (Globar).

The infrared curves are tracings of photographs of the original recording obtained from the spectrometer. The spectra in all cases were determined in the region 650 to 4000 cm.$^{-1}$ but only pertinent regions are shown in the figure. Values of bands given in the discussion were taken from the original recording and are accurate to about ± 5 cm.$^{-1}$ in the region near 1700 cm.$^{-1}$. The per cent. of absorption is only approximate.

Acknowledgment.—The author takes pleasure in expressing his appreciation to Professor Charles P. Smyth of Princeton University, who kindly read and criticized this paper before it was submitted for publication. The author wishes to acknowledge his debt to Professor du Vigneaud for his interest and encouragement in this work. The author also wishes to express his thanks to Dr. Julian R. Rachele for many helpful consultations in relation to the infrared determinations; and to Dr. Caesar R. Scholz of Ciba Pharmaceutical Products, Inc., for samples of imidazole derivatives.

(9) Turner and Scholz, THIS JOURNAL, **71**, 2801 (1949).

Summary

The general properties of imidazoles are discussed, taking into consideration resonance and tautomerism. Comparisons with similar open-chain and ring systems are made.

The structure of imidazole-4-aldehyde is discussed in detail in the light of ultraviolet and infrared spectrophotometric data. These data reveal that, contrary to the postulate of Hubball and Pyman,[2] the aldehyde does not exist as an enol. Its peculiar properties must be explained on the basis of its aldehyde structure.

In connection with the structure theory of the aldehyde related compounds such as the oxime, the corresponding alcohol, and the corresponding acid are discussed.

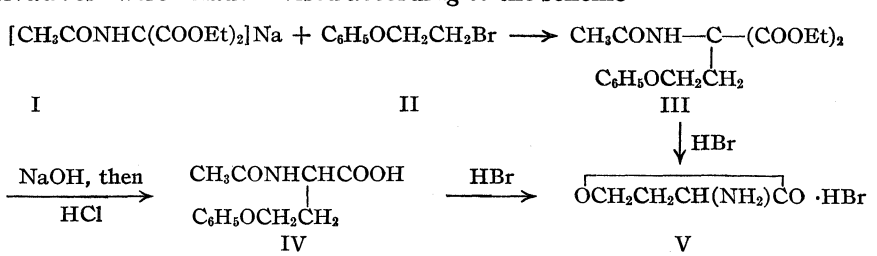
Studies of Imidazole Compounds. III. Synthesis of 4-(2-Chloroethyl)-imidazole

BY ROBERT A. TURNER

In a previous paper of this series[1,2] the synthesis of certain derivatives of 4-methyl-imidazole was described. These derivatives were made from 4-chloromethyl-imidazole, and in order to prepare related derivatives of 4-ethyl-imidazole, 4-(2-chloroethyl)-imidazole was required.

4-(2-Chloroethyl)-imidazole hydrochloride IX has been synthesized in small amounts by Garforth and Pyman[3] through a long series of reaction steps. For our purpose a more practicable and reliable synthesis was needed. In order to achieve this a requisite intermediate was α-amino-γ-butyrolactone hydrobromide V, of which a preparation was recently described.[4] However, this preparation depends on the availability of γ-butyrolactone, and an alternate synthesis of V was devised according to the scheme



Ethyl acetylaminomalonate I and phenoxyethyl bromide II were condensed to the ester III. The latter was not isolated, but was saponified directly to the sodium salt of the corresponding dicarboxylic acid. In aqueous solutions this acid spontaneously released carbon dioxide, and when decarboxylation was complete, the α-acetylamino-γ-phenoxybutyric acid IV was isolated by continuous extraction with chloroform. Conversion of IV into V was performed through long boiling in 48% hydrobromic acid. It was also found

(1) Turner, Huebner and Scholz, THIS JOURNAL, **71**, 2801 (1949).

(2) For the second paper of this series, see Turner, *ibid.*, **71**, 3472 (1949).

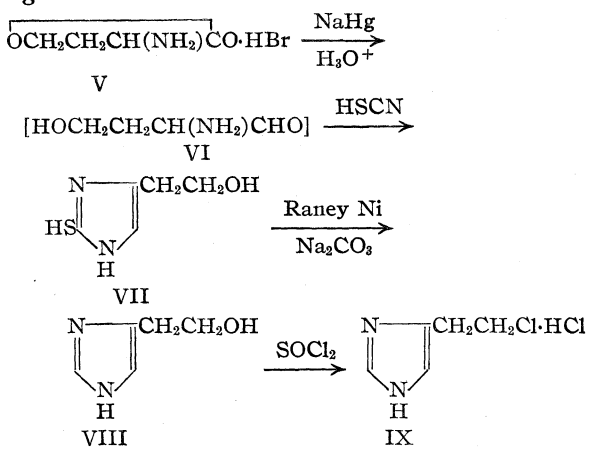
that the malonic ester derivative III could be hydrolyzed directly into V by means of hydrobromic acid; however, the procedure involving separation of the intermediate IV gave a purer product.

The synthesis of the hydrochloride IX from the lactone V was performed according to the following scheme



The Neuberg–Fischer reduction[5] of V has been reported,[3] but the method was found to be unreliable. We have devised a procedure for the Neuberg–Fischer reduction which gives a consistently good yield of the thiol VII (VI was not isolated). It was found that the success of the reduction depended on careful control of several variables, chief among which were the temperature and *p*H. An acidic reaction mixture was necessary in order to prevent the reduction of the amino-aldehyde VI to the corresponding alcohol, as well as the self-condensation of VI to a dihydropyrazine.

Treatment of the acidic solution of VI with ammonium thiocyanate yielded VII, which was isolated in crystalline form. Since VII bears a primary alcohol group, we sought a method of desulfurization differing from the usual[6] addition of a 2-thiolimidazole to boiling 10% nitric acid, and it was found that the desulfurization of VII could be performed smoothly by the action of Raney nickel catalyst suspended in sodium carbonate solution.[7] Attempts to crystallize VIII, either as the base or as the hydrochloride failed.[8] This did not prove to be a serious mischance as the sirupy hydrochloride of VIII was smoothly converted by means of thionyl chloride into 4-(β-chloroethyl)-imidazole IX, which crystallized readily.

Experimental

Condensation of Diethyl Acetylaminomalonate with Phenoxyethyl Bromide.—In a flask equipped with stirrer, dropping funnel, and reflux condenser, was prepared a solution of sodium ethoxide from 10.3 g. of sodium and 250 ml. of anhydrous ethanol. To this solution were added in turn 105 g. of diethyl acetylaminomalonate,[9] 200 ml. of anhydrous ethanol, a solution of 103 g. of phenoxyethyl bromide[10] in 200 ml. of anhydrous ethanol, and 2 g. of potassium iodide. When the reaction mixture had been stirred under reflux for forty-eight hours, the solvent was distilled. A solution of 120 g. of sodium hydroxide in 500 ml. of water was added, and after warming for a time to remove a little ethanol which remained, the mixture was boiled under reflux for two hours, cooled, and made just acid to congo paper with about 250 ml. of concentrated hydrochloric acid. During the acidification the solution seethed as carbon dioxide was evolved, and it was extracted continuously with chloroform for five hours. Following evaporation of the chloroform *in vacuo* a brown sirup remained which was dissolved in a mixture of 250 ml. of benzene and 200 ml. of methanol. The solution was concentrated until crystallization commenced in the hot. After having stood in the cold the crystals were filtered. The filtrate was concentrated to obtain another crop; total yield of **α-acetylamino-γ-phenoxybutyric acid (IV)**, 68 g. (64%); m. p. 131.5–132°.

Anal. Calcd. for $C_{12}H_{15}O_4N$: C, 60.74; H, 6.37; N, 5.90. Found: C, 60.33; H, 6.27; N, 5.74.

Concentration of the aqueous layer after the extraction with chloroform gave a crystallizate which was a mixture of sodium chloride and **α-amino-γ-phenoxybutyric acid.** Recrystallization from water gave 5.30 g. (6.1%) of this acid; m. p. 229°; reported,[11] 233°. After admixture with an authentic specimen of the acid the melting point was not depressed. In preliminary experiments on a small scale IV was isolated as an oil which later crystallized; m. p. 116–120°. After two recrystallizations the melting point was 122.5–123°, unchanged by further recrystallization.

Anal. Found: C, 60.71; H, 6.32; N, 5.72.

After a few experiments in which IV was isolated as a substance of m. p. 122.5° a preparation was performed which yielded IV as a substance of m. p. 131.5–132°. Subsequent to the appearance of this higher-melting, dimorphic modification the other form was never obtained.

α-Amino-γ-phenoxybutyric Acid from IV.—To 2.68 g. of IV was added 17 cc. of concentrated hydrochloric acid and 11 cc. of water. The mixture was heated for fifteen hours on the steam-bath and then distilled *in vacuo* to dryness. The residue was dissolved in 30 cc. of water and again taken to dryness. Solution of the residue in a little water, neutralization with lithium hydroxide solution, and acidification with dilute hydrochloric acid gave a precipitate of the product; yield, approximately quantitative; m. p. 231° (decomposition); after recrystallization, 233° (decomposition).

Anal. Calcd. for $C_{10}H_{13}O_3N$: C, 61.52; H, 6.71; N, 7.18. Found: C, 61.65; H, 6.67; N, 6.95.

α-Amino-γ-butyrolactone Hydrobromide. (V).—A solution of 6.85 g. of IV in 25 g. of 48% hydrobromic acid was boiled under reflux in a stream of nitrogen for four and one-half hours. Then 20 ml. of hydrobromic acid was added, and 20 ml. of solution was distilled (to remove phenol). After two hours more under reflux the solution was distilled *in vacuo* to dryness. The semi-crystalline mass was digested with anhydrous ethanol until the sirup dissolved, then left in the cold, and finally filtered. By reworking the mother liquor a total of 2.70 g. (61%) of the lactone hydrobromide was obtained; m. p. 224–226° (dec.). Five grams of the oily malonic ester III was boiled eight hours with 50 g. of 48% hydrobromic acid. Isolation as described above gave 1.20 g. of lactone; m. p. 227° (decomposition); after recrystallization the melting point was somewhat lower, 224–226°.

Anal. Calcd. for $C_4H_8O_2NBr$: C, 26.39; H, 4.43; N, 7.70; Br, 43.91. Found: C, 26.54; H, 4.34; N, 7.96; Br, 44.45.

α-Amino-γ-butyrolactone Hydrobromide (V) from γ-Butyrolactone.—γ-Butyrolactone was brominated to α-bromo-γ-butyrolactone by the method of Livak, *et al.*[4] Amination of the bromolactone was performed essentially by their procedure, but the isolation of α- and amino-γ-butyrolactone hydrobromide V was greatly facilitated with the use of anhydrous propanol. The mixture of crystalline hydrobromide and brown sirup which was first obtained was partially dried at 100° and 20 mm. and then treated with hot, anhydrous propanol until the sirup dissolved. The first crop of the crystalline hydrobromide, which formed in the cold, was filtered; treatment of the mother liquor in the manner just described gave a second crop; total yield, 64%; m. p. 212–220°.

The lactone hydrobromide was recrystallized by solution in 95% ethanol, addition of an equal volume of benzene, and distillation of ethanol–benzene–water azeotrope through a column. The cooled solution yielded colorless crystals; m. p. 228–231° (dec.), with emollescence at 221°; recovery, 90%.

Anal. Calcd. for $C_4H_8O_2NBr$: N, 7.70; Br, 43.91. Found: N, 7.89; Br, 44.32.

2-Thiol-4-(2-hydroxyethyl)-imidazole (VII).—To a three-necked, 250 ml. flask, equipped with stirrer, dropping funnel and thermometer, and set in a dry ice-cellosolve-bath, were added 18.2 g. (0.10 mole) of α-amino-γ-butyrolactone hydrobromide V and 50 ml. of water. When the lactone had dissolved, 50 ml. of alcohol was poured in, and as soon as the temperature had fallen below −20°, simultaneous addition of 230 g. of 3% sodium amalgam and of 60 ml. of 5 *N* hydrochloric acid from the dropping funnel was begun. The amalgam was added in seven portions at intervals of six minutes, and the acid was allowed to flow in at such a rate that the reaction mixture was maintained just acid to congo paper. After the last portion of amalgam had been introduced the mixture was stirred and kept acid for ten minutes longer. During the whole reaction period the temperature was regulated to the range −16 to −20°.

Following decantation of the supernatant solution and washing of the mercury with 50 ml. of water, the combined solution and washing were filtered, treated with 16.2 g. of ammonium thiocyanate, and, after one-half hour, distilled *in vacuo* to dryness. The yellow, semi-crystalline residue was extracted four times with 50-ml. portions of warm ethanol, and the united extracts were treated with 30 ml. of water and concentrated *in vacuo* until crystallization commenced. After refrigeration overnight the product was filtered; yield, 12.5–14.6 g. (87–100%); m. p. 176° (incomplete). This crude material contained sodium and ammonium halides; after three recrystallizations from water a pure sample was obtained; m. p. 191–192°. After two recrystallizations the melting point was 188–190°; yield, 60–71%. Material of this purity was employed in desulfurization.

Anal. Calcd. for $C_5H_8OSN_2$: C, 41.64; H, 5.59; S, 22.20; N, 19.43. Found: C, 41.67; H, 5.28; S, 21.87; N, 19.32.

4-(2-Chloroethyl)-imidazole Hydrochloride IX. Desulfurization of 2-Thiol-4-(2-hydroxyethyl)-imidazole VII.—A solution of 21.6 g. of VII (m. p. 188° or higher) in 300 ml. of water, containing 23 ml. of saturated aqueous sodium carbonate solution, was distilled to remove traces of ammonia and then added to a suspension of 80 g. of Raney nickel catalyst[12] in 50 cc. of alcohol. The mixture was then stirred and heated under reflux for five and one-half hours.

The nickel was filtered, returned to the flask with 50 ml. of water and stirred and heated for one-half hour. After repetition of the extraction the combined filtrates were acidified with 40 ml. of concentrated hydrochloric acid, and distilled to dryness *in vacuo*. The residue of **4-(2-hydroxyethyl)-imidazole hydrochloride** and inorganic salts was treated with 80 cc. of anhydrous propanol and warmed until the sirup dissolved. After filtration of the salts the solvent was distilled *in vacuo*. The hydrochloride remained as 18.4 g. (83%) of yellow sirup.[13]

The hydrochloride was mixed with 23 ml. of purified thionyl chloride until solution was effected. The mixture was warmed under gentle reflux for one-half hour with exclusion of moisture, treated with an equal volume of benzene, and distilled to dryness *in vacuo*. On cooling, the residue formed a mass of sticky crystals; m. p. 106–110°. Recrystallization from anhydrous propanol–ethyl acetate gave 16.5 g. (79% based on 4-(β-hydroxyethyl)-imidazole hydrochloride) of light yellow platelets; m. p. 118–121, raised to 124° by another recrystallization.

Anal. Calcd. for $C_5H_8N_2Cl_2$: C, 35.95; H, 4.83; Cl, 42.45. Found: C, 35.60; H, 5.02; Cl, 42.03.

Acknowledgment.—We wish to acknowledge the capable assistance of Mrs. Kathryn Oney in these experiments. We are grateful to the Cliffs Dow Chemical Co. for a sample of γ-butyrolactone.

Summary

4-(2-Chloroethyl)-imidazole has been synthesized through this series of steps: α-amino-γ-butyrolactone was reduced to α-amino-γ-hydroxybutyraldehyde, which was converted to 2-thiol-4-(2-hydroxyethyl)-imidazole with ammonium thiocyanate; desulfurization of the thiol led to 4-(2-hydroxyethyl)-imidazole; the latter was converted to 4-(2-chloroethyl)-imidazole hydrochloride with thionyl chloride.

A new synthesis of α-amino-γ-butyrolactone, starting from diethyl acetylaminomalonate has been described.

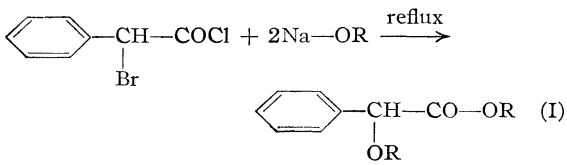
2-Dialkylaminoalkyl α-(2-Dialkylaminoalkoxy)-phenylacetates and Related Amides. II[1]

BY PRICE TRUITT, E. E. RICHARDSON,[2] LOREN M. LONG[3] AND WILLIAM J. MIDDLETON[4]

In the first paper of this series[5] a number of compounds structurally related to 2-dimethylaminoethyl benzhydryl ether hydrochloride, Benadryl,[6] were reported. These compounds were alkyl esters of α-(2-dialkylaminoalkoxy)-phenylacetic acid. Although this substitution of the alkyl carboxyl group for one of the phenyl groups of Benadryl completely eliminated the antihistaminic activity, some antispasmodic activity was noted.[7]

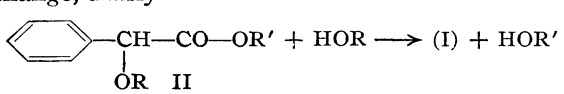
Since numerous reports of physiologically active compounds containing the dialkylaminoalkyl ester linkage have been recorded,[8] we deemed it worthwhile to prepare some 2-dialkylaminoalkyl esters of the α-2-dialkylaminoalkoxy)-phenylacetic acids in order to compare their physiological activity with that of the previously reported alkyl α-(2-dialkylaminoalkoxy)-phenylacetates.[5] Also to obtain a still broader view of the effect of changes in structure on physiological activity, the preparation of several amide derivatives of the α-(2-dialkylamino-alkoxy)-phenylacetic acids was desirable.

The reactions utilized in the preparation of the esters reported in this paper are



R = 2-dialkylaminoalkyl, 2-piperidinoethyl, 2-morpholinoethyl

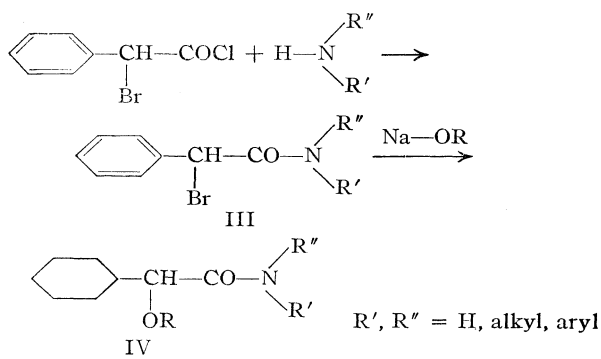
In the preceding paper mention was made of the fact that compound I was formed by ester exchange, thusly



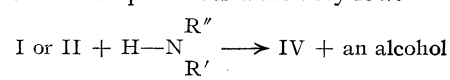
R′ = alkyl, R = as above

The latter method will give a satisfactory yield (60–80%) of I but it is not a useful method of preparation since compound II is obtained in poor yield in two steps from bromophenylacetyl chloride. The method utilized for the synthesis of the esters reported in this paper involves only one step in addition to the preparation of α-bromophenylacetyl chloride.

The amides corresponding to the above esters were obtained via the reactions



Attempts to prepare compound IV by the following reaction were not satisfactory. The yields of desired products were very low.



None of the compounds reported in this paper exhibited anti-histaminic activity; however, all of those tested showed some antispasmodic action.

Experimental

The dialkylaminoalkanols used in these experiments were obtained from Eastman Kodak Company and distilled before use.

The α-bromophenylacetyl chloride was prepared as previously reported.[5]

2-Dialkylaminoalkyl α-(2-Dialkylaminoalkoxy)-phenylacetates (Table I).—Two moles of potassium metal was added to 2.2 moles of dialkylaminoalkanol dissolved in

(7) Recent tests indicate that one of these compounds, benzyl α-(2-diethylaminoethoxy)-phenylacetate had an antispasmodic activity of 200% of papaverine with barium chloride induced spasms and 300% with acetylcholine.

(8) Blicke, *Ann. Rev. Biochem.*, **13**, 549 (1944).

dry toluene. When all of the potassium had reacted, 1 mole of freshly distilled α-bromophenylacetyl chloride dissolved in an equal volume of dry toluene was added dropwise with constant stirring. When the initial reaction had subsided, the mixture was refluxed with continuous stirring for four to ten hours. Apparently little reaction occurred after the four hours heating period but no decrease in yield was noted when the longer reflux time was used.

The reaction mixture was filtered to remove the precipitated sodium salts and the toluene was subsequently distilled under a water-pump vacuum. The residual liquid was distilled *in vacuo* and further purified by two fractional distillations. The hydrochlorides of these esters were too hydroscopic to handle conveniently.

α-Bromophenylacetamide.—A concentrated solution of 2 moles of ammonium hydroxide was cooled to −10°. This solution was stirred vigorously while 1 mole of α-bromophenylacetyl chloride was added dropwise. Care was taken to keep the temperature of the reaction mass below 0°. After stirring for two hours at this temperature the reaction was allowed to warm to room temperature. The crystals which had formed were collected and recrystallized from alcohol to give glistening white crystals of α-bromophenylacetamide.

N,N-Diethyl α-Bromophenylacetamide.—A solution of 1 mole of α-bromophenylacetyl chloride in an equal volume of carbon tetrachloride was cooled to −10° and a solution of 2 moles of diethylamine in carbon tetrachloride added dropwise with constant stirring so as to keep the temperature below 0°. After stirring for two hours at this temperature, water was added to dissolve the diethylamine hydrochloride. The organic layer was separated, dried and the carbon tetrachloride distilled *in vacuo*. The liquid residue was fractionated at reduced pressure to give N,N-diethyl-α-bromophenylacetamide.

The remaining amides were prepared in an analogous manner. Data for all of the amides are given in Table II.

α-(2-Piperidinoethoxy)-phenylacetamide.—One mole of α-bromophenylacetamide was refluxed with 1 mole potassium 2-piperidinoethoxide suspended in xylene for two hours. The product was extracted from the xylene with 5% hydrochloric acid. Neutralization of this acid extract gave a white precipitate. Recrystallization from alcohol gave white flakes of the expected α-(2-piperidinoethoxy)-phenylacetamide.

Other amides were prepared in the same manner and data concerning these are given in Table III. N,N-Diphenyl-α-bromophenylacetamide failed to give the expected product. The yields in all other cases were approximately 50%.

Summary

Six dialkylaminoalkyl α-(2-dialkylaminoalkoxy)-phenylacetates have been prepared and characterized. In addition six N- and N,N-disubstituted α-bromophenylacetamides have been synthesized and four of these converted to the corresponding N- and N,N-substituted α-(2-piperidinoethoxy)-phenylacetamides. A partial evaluation of the physiological properties for some of these compounds is given.

Synthesis of Certain 2-Alkoxyethyl Phenyl Ketones[1]

BY ROBERT EDWARD LESLIE[2] AND HENRY R. HENZE

In connection with another problem, certain alkoxyethyl ketones, especially the 2-propoxyethyl phenyl and 2-(1-methylethoxy)-ethyl phenyl ketones, were needed. Initially, it was visualized that these ketones might be prepared from interaction of Grignard reagents and appropriately substituted alkoxypropionitriles. Attempts to develop this method were not successful, but the desired substances were obtained as a result of reactions between diphenylcadmium and certain β-alkoxypropionyl chlorides. The latter were synthesized through the following sequence: (a) addition of appropriate alcohols to acrylonitrile[3] forming β-alkoxynitriles; (b) hydrolysis of the latter to the corresponding β-alkoxypropionic acids; (c) subsequent conversion into β-alkoxypropionyl chlorides.

Preparation of the ketones was tried first by the method of Cason,[4] namely, addition of the acyl halide to the solution of diphenylcadmium, but the reaction complexes formed very heavy precipitates. Before reaction was complete, agglutination of the suspended matter made stirring practically impossible and thus homogenization of the reaction mixtures was not attained. However, by reversing the sequence of addition of reactants, clumping of the addition products was avoided and

the yields of ketones were increased. It was found preferable, also, to use ether as the solvent and diluent, rather than to employ benzene, as described by Cason. Five β-alkoxyethyl phenyl ketones (alkyl = CH_3, C_2H_5, C_3H_7, $CH(CH_3)_2$ and C_4H_9) were prepared.

Experimental

Preparation of β-Propoxypropionitrile.[4a]—One hundred and seventy grams of acrylonitrile was added dropwise to a solution of 3 g. of sodium methoxide in 120 g. of propanol with maintenance of the temperature below 70°. Two hundred five grams (77% yield) of product was obtained; b. p. 92° (24 mm.), $n^{20}D$ 1.4128, d^{20}_4 0.8969, Σ *MR* 31.30, *MR* calcd. 31.44.

Preparation of β-Alkoxypropionic Acids.—In general, one mole of a β-alkoxypropionitrile was added slowly dropwise with stirring to 50 ml. of 75–80% sulfuric acid, resulting in the formation of a homogeneous solution. The latter, with stirring, was heated for approximately ten minutes at which time a sudden increase in the rate of reflux was observed.[5] Heating was discontinued for twenty minutes, then 60 ml. of water was added and the mixture was subjected to gentle warming, at the reflux temperature, and stirring for ninety minutes longer. The reaction mixture was cooled, the organic layer was removed and added with stirring to a cooled solution of one mole of sodium hydroxide in 300 ml. of water. Upon cooling, the insoluble, upper layer of organic material was removed. The lower layer was acidified, and the additional organic matter which separated was added to the previously collected main fraction of the alkoxy acid. The crude product was dried over anhydrous sulfate before fractionation *in vacuo*. Data obtained for these four acids are listed in Table I.

Preparation of β-Alkoxypropionyl Chlorides.—The acid (1 mole) was added dropwise to the stirred thionyl chloride (1.5 moles) which was warmed since the reaction was notably endothermic. After stirring the mixture for one hour without further heating, the material was fractionated *in vacuo*. Certain data concerning the five acid chlorides prepared are given in Table II.

[a] Weighed sample was warmed with dilute sodium hydroxide solution before completing the gravimetric analysis. [b] The sample of β-methoxypropionic acid was donated by The B. F. Goodrich Co., Akron, Ohio.

Preparation of 2-Alkoxyethyl Phenyl (or Alkyl) Ketones.—One-fourth mole of β-ethoxypropionitrile in 250 ml. of anhydrous ether was added dropwise with stirring to a solution of three-fourths mole of ethylmagnesium bromide in 550 ml. of ether. The evolution of heat was quite noticeable, and a dark green precipitate separated from solution. A small sample of the addition-product was removed and dried to yield a very fine yellow powder which reacted vigorously with water to form a yellow gum. Upon treatment of the small sample with water, ammonia was evolved. Hydrolysis of the main portion was attempted with ice-cold hydrochloric acid; an insoluble, red gum resulted. From the ether solution, upon distillation, there was obtained only a small volume of low-boiling liquid which failed to exhibit typical ketone function. The red gum, also, failed to give a carbonyl test. After fusion of the gummy material with sodium, tests for the presence of magnesium and chlorine were positive, but for nitrogen was negative.

The attempted preparation of a ketone was repeated, except that the solution of ethylmagnesium bromide was added to that of β-ethoxypropionitrile. Similar results were obtained.

A solution of β-methoxypropionitrile in ether was added to a very dilute ether solution of phenylmagnesium bromide (4 equivalents); reaction was vigorous, a viscous gummy mass was formed and was treated with ice-cold, concentrated hydrochloric acid. Again, no identifiable product was isolated.

A similar negative result was obtained when β-ethoxypropionitrile in butyl ether was added to 2.5 equivalents of phenylmagnesium bromide in butyl ether solution.

Attempts were then made to prepare alkoxyethyl phenyl ketones using Cason's procedure.[4] Phenylmagnesium bromide, in 6–7 volumes of absolute ethyl ether, was treated with finely divided, anhydrous cadmium chloride; heat was evolved, the solution darkened in color and suspension of a white precipitate was noted. After addition of the cadmium chloride was complete, usually in five to ten minutes, the reaction mixture was stirred for ninety minutes. Upon discontinuing the stirring, the mixture separated into three layers; the two upper, liquid layers were decanted into a separatory funnel for dropwise addition to the appropriate β-alkoxypropionyl chloride diluted with 5–6 volumes of anhydrous benzene. An approximate ratio of 0.6 mole (estimated) of diphenylcadmium to 1 mole of acyl chloride was employed. As the reactions were exothermic, cooling of the mixture was necessary. A gray precipitate formed and was in such finely divided condition as to offer little resistance to the stirrer. Stirring was continued for one hour.

The mixture was hydrolyzed with ice-cold, concentrated hydrochloric acid. Initially a gray, viscous gum formed, but disappeared after about five minutes, and a clear upper layer formed and was separated. After removal of ether and benzene, the organic material was washed with an aqueous solution of sodium bicarbonate, dried over anhydrous calcium chloride, subjected to a pressure of 4 mm. at room temperature before being distilled at less than 1 mm. pressure. Unless distilled at this low pressure the ketones tended to decompose forming acrylophenone and the corresponding alcohols. Data, secured from characterization of the ketones, have been placed in Table III.

(4a) After completion of all the Experimental and after deposit of the M.A. thesis (March, 1948), Christian and Hixon (THIS JOURNAL, **70**, 1333 (1948)) reported the synthesis in 84% yield of β-propoxypropionitrile; b. p. 84° (19 mm.), $n^{26}D$ 1.4131, d^{20}_{20} 0.9006.

(5) In hydrolysis of β-alkoxypropionitriles by the action of concentrated sulfuric acid, precaution needed to be taken so as to avoid excessive heating in the preliminary course of the reaction. The reaction is so exothermic as to be difficult to control. Overheating resulted in loss of material and possibly could bring about personal injury.

[a] Straus and Berkow (ref. 7, p. 144) reported b. p. 125–126° (16 mm.), d^{15}_4 1.020. [b] Kohler (ref. 6, p. 388), who obtained this ketone as a by-product in the preparation of phenyl vinyl ketone from α,β-dibromopropiophenone, reported b. p. 135° (18 mm.), m. p. about 12°.

These alkoxyethyl phenyl ketones readily formed 2,4-dinitrophenylhydrazones; the melting points of the latter are given in sequence to the appropriate alkyl group: CH_3, 175.5–176.5°; C_2H_5, 161.0–161.5°; C_3H_7, 158.0–158.5°; $CH(CH_3)_2$ 174.5–175.0°; C_4H_9, 152.5–153.0°.

In one instance, the impure 2-(1-methylethoxy)-ethyl phenyl ketone, obtained by distillation as described above, was redistilled through a six-inch column from an oil-bath at 140–155°. Several fractions of constant refractive index were removed at 106–107° (18 mm.)[6,7] and were found to possess the following physical properties: $n^{20}D$ 1.5440; d^{20}_4 1.0350; Σ MR[8] 40.35; MR calcd. 40.31. The product, acrylophenone, formed (a) a 2,4-dinitrophenylhydrazine derivative [or 1-(2,4-dinitrophenyl)-3-phenyl-Δ²-pyrazoline], m. p. 155–156° and (b) a phenylhydrazine derivative [or 1,3-diphenyl-Δ²-pyrazoline],[9,10,11] m. p. 153°.

(6) Kohler, *Am. Chem. J.*, **42**, 375 (1909), reported b. p. 118° (18 mm.).

(7) Straus and Berkow, *Ann.*, **401**, 121 (1913), reported b. p. 115° (18 mm.).

(8) Includes 0.65 correction for exaltation of C_6H_5CO- compounds; *cf.* Auwers, *Ber.*, **45**, 2765 (1912).

Summary

1. Certain β-alkoxypropionitriles, obtained by the interaction of acrylonitrile and various alcohols, were hydrolyzed to yield β-alkoxypropionic acids which, in turn, were converted into the corresponding acid chlorides.

2. The β-alkoxypropionyl chlorides reacted with diphenylcadmium to yield 2-alkoxyethyl phenyl ketones, three of which have not previously been reported. These ketones tend to be unstable upon distillation and decompose to produce acrylophenone.

(9) Straus and Berkow, ref. 7, reported m. p. 152°.

(10) Schafer and Tollens, *Ber.*, **39**, 2181 (1906), reported m. p. 152–153°.

A Proposed Mechanism of the Alkylation of Benzyl Halides with Nitro Paraffin Salts[1]

BY H. B. HASS[2] AND MYRON L. BENDER[3]

It was shown in the preceding paper[4] that, of nine para-substituted benzyl halides, only *p*-nitrobenzyl chloride gave carbon-alkylation with sodium 2-propanenitronate whereas the other eight benzyl halides gave oxygen-alkylation in 68–77% yield as illustrated in the equations

$$p\text{-}NO_2C_6H_4CH_2Cl + (CH_3)_2CNO_2^-Na^+ \longrightarrow p\text{-}NO_2C_6H_4CH_2C(CH_3)_2NO_2$$

$$p\text{-}CH_3C_6H_2CH_2Br + (CH_3)_2CNO_2^-Na^+ \longrightarrow p\text{-}CH_3C_6H_4CHO + (CH_3)_2C{=}NOH$$

These facts led us to seek some explanation for the anomalous behavior of *p*-nitrobenzyl chloride in this reaction.

The anions of nitroparaffin salts have been represented as resonance hybrids involving forms with the negative charge on oxygen or on carbon.[5] Carbon-alkylation may then be considered[6] to involve a nucleophilic displacement by the resonating anion at carbon while oxygen-alkylation may be considered to involve a displacement by the resonating anion at oxygen. The compounds resulting from oxygen-alkylation, nitronic esters, have been isolated in several cases similar to the present work[7] and have been prepared by a different synthesis[8]; they are thermally unstable and decompose spontaneously even at room temperature into carbonyl compounds and oximes. While the mechanisms discussed above account for the possibility of the two modes of alkylation, they furnish no basis of explaining the anomalous behavior of *p*-nitrobenzyl chloride.

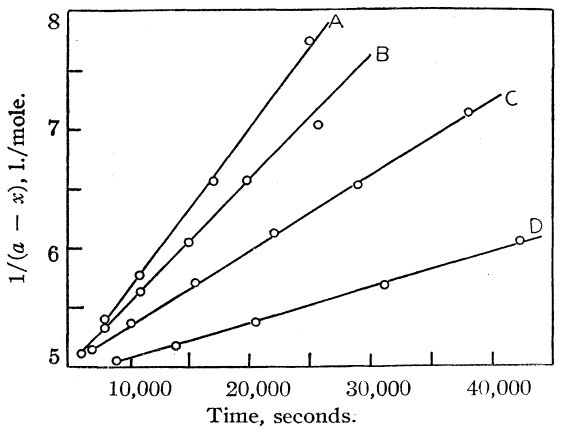

Fig. 1.—Reaction of lithium 2-propanenitronate with benzyl halides at 30 ± 0.3°, $a = a' = 0.200$ *M*: (A) *o*-nitrobenzyl chloride; (B) *p*-nitrobenzyl chloride; (C) *m*-nitrobenzyl chloride; (D) benzyl chloride. Each line represents one run.

step in oxygen-alkylation is the formation of a nitronic ester.[8,7] Since the four halides illustrate both oxygen- and carbon-alkylation, this study leads to the conclusion that the rate-determining step in both oxygen- and carbon-alkylation is the formation of a nitronic ester intermediate.

The reactions of *o*-nitro-, *m*-nitro, *p*-nitro- and 2,4-dinitrobenzyl chlorides with sodium 2-propanenitronate compiled in Table III show that carbon-alkylation occurs with both *o*- and *p*-nitrobenzyl chlorides but not with *m*-nitrobenzyl chloride.

Table II presents a parallelism between those benzyl halides showing carbon-alkylation with sodium 2-propanenitronate and those exhibiting stilbene formation in the Williamson reaction. The mechanism proposed for stilbene formation[10] involves the ready removal of a benzylic hydrogen facilitated by the presence of an ortho- or para-nitro group.

It is therefore proposed that the ease of removal of a benzylic hydrogen is an important factor in the production of carbon-alkylation. The following experiments substantiate this conclusion. The effect of a methyl group on the carbon alpha to the benzene ring would be to reduce the ionization of the benzylic hydrogen and, therefore, to favor oxygen-alkylation. This has been borne out by experiment: 1-(α-bromoethyl)-4-nitrobenzene gave a 60% yield of *p*-nitroacetophenone. The effect of increasing the acidity of the medium would be to hinder the ionization of the benzylic hydrogen and, therefore, to favor oxygen-alkylation. Two parallel runs were made with *p*-nitrobenzyl chloride and sodium 2-propanenitronate except that in one run an additional equivalent amount of 2-nitropropane was added. This increased the acidity of the medium (as

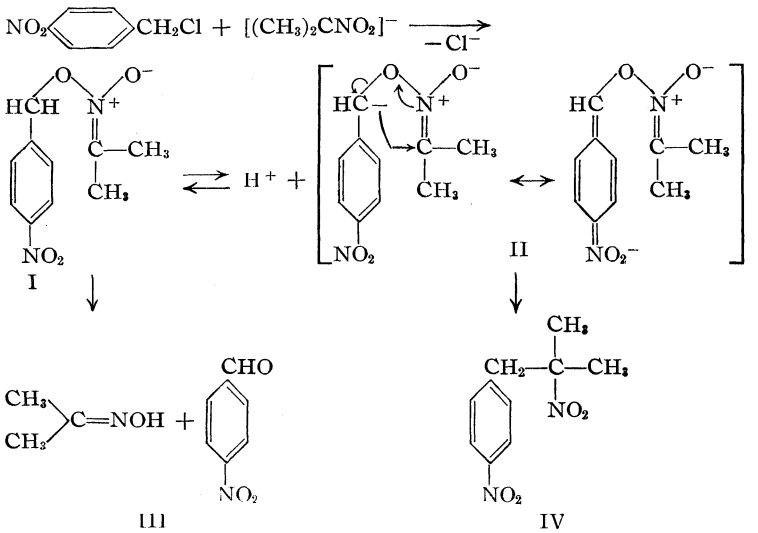
any acid would) and increased the oxygen-alkylation from 1% (no free nitroparaffin) to 6% (with free nitroparaffin).

The mechanism shown is suggested to explain the foregoing experiments.



The first step in both oxygen- and carbon-alkylation is the formation of the nitronic ester, I. When oxygen-alkylation occurs, *p*-nitrobenzaldehyde and acetoxime, III, are produced by thermal cleavage of the nitronic ester, I, at (a) together with a hydrogen shift. When carbon-alkylation occurs, the resonance-stabilized carbanion, II, is formed by the ionization of a benzylic hydrogen of I. Following the ionization, an internal nucleophilic displacement reaction by II occurs, producing the carbon-alkylation product, IV. An examination of the Fischer–Hirschfelder model of II shows that the spatial requirements for this rearrangement are satisfied since the two carbon atoms forming a new bond are adjacent to each other. Thus, there are two competing reactions of a nitronic ester such as I. The relative amounts of the final products are determined by the relative rates of the competing cleavage and ionization reactions. Since the rate of the ionization reaction is a function of the position of the ionization equilibrium, those factors in the structure of the reactants and in the reaction medium which shift the equilibrium of the ionization reaction will shift the direction of alkylation.

That the foregoing mechanism is not the only one possible in the alkylation of nitroparaffin salts is illustrated by the reaction of 1-(β-bromoethyl)-4-nitrobenzene with sodium 2-propanenitronate to produce 3-methyl-3-nitro-1-(*p*-nitrophenyl)-butane. By the preparation of a possible intermediate, *p*-nitrostyrene, and its conversion to the final product under the original reaction conditions, this reaction seems to proceed in two steps. The first step is dehydrobromination effected by the 2-propanenitronate ion acting as a base. The second step is a Michael addition catalyzed by the basic reaction conditions.

Experimental[12]

1-(α-Bromoethyl)-4-nitrobenzene.—Seven-hundreths mole of 1-ethyl-4-nitrobenzene (n^{20}D 1.5454) was brominated in carbon tetrachloride. A procedure of Cumming, Hopper and Wheeler[13] was followed. A 92% yield of 1-(α-bromoethyl)-4-nitrobenzene was obtained; b. p. 152–153° (5 mm.); n^{20}D 1.6028.

Anal. Calcd. for $C_8H_8BrNO_2$: N, 6.09. Found: N, 6.27.

Reaction of Halides and Sodium 2-Propanenitronate.—These alkylations which were run as described in a previous paper[3] are summarized in Table III.

Preparation of *p*-Nitrostyrene.—1-(β-Bromoethyl)-4-nitrobenzene (m. p. 67–68°) was converted to *p*-nitrostyrene according to the method of Strassburg, Gregg and Walling[14]; m. p. 19–20°; lit. m. p. 21°.[14]

Condensation of *p*-Nitrostyrene and 2-Nitropropane.—*p*-Nitrostyrene (2.0 g., 0.013 mole), 2-nitropropane (1.2 g., 0.013 mole), and 10 drops of methanolic sodium methoxide dissolved in 10 ml. of methanol were refluxed for forty hours; after cooling the crystals were filtered. A 72% yield of 3-methyl-3-nitro-1-(*p*-nitrophenyl)-butane was obtained; m. p. 81–82°.

Proof of Structure of 2-Methyl-2-nitro-1-(*o*-nitrophenyl)-propane. a. Reduction.—2-Methyl-2-nitro-1-(*o*-nitrophenyl)-propane was reduced with Raney nickel and hydrogen as described by Hass, Berry and Bender.[15] An 82% yield of 1-(*o*-aminophenyl)-2-methyl-2-propylamine was obtained; b. p. 107–109° (3.5 mm.); n^{20}D 1.5577.

Anal. Calcd. for $C_{10}H_{16}N_2$: N, 17.05. Found: N, 17.11.

(b) **Selective Deamination.**—1-(*o*-Aminophenyl)-2-methyl-2-propylamine was treated with 50% hypophosphorous acid according to the method of Kornblum and Iffland,[16] to produce 2-methyl-1-phenyl-2-propylamine in 85% yield; b. p. 80° (15 mm.); n^{20}D 1.5122; benzoyl derivative, m. p. 112–113°; lit. b. p. 94° (15 mm.); n^{20}D 1.5132; benzoyl derivative, m. p. 112.5–113°.[16]

Proof of Structure of 3-Methyl-3-nitro-1-(*p*-nitrophenyl)-butane. a. Reduction.—3-Methyl-3-nitro-1-(*p*-nitrophenyl)-butane was reduced with Raney nickel and hydrogen as described by Hass, Berry and Bender.[15] A 79% yield of 1-(*p*-aminophenyl)-3-methyl-3-butylamine was obtained; b. p. 120–122° (1 mm.); m. p. 36–37°.

Anal. Calcd. for $C_{11}H_{18}N_2$: N, 15.72. Found: N, 15.7.

(b) **Selective Deamination.**—4-(*p*-Aminophenyl)-2-methyl-2-butylamine was treated with 50% hypophosphorous acid according to Kronblum and Iffland[16] to produce 2-methyl-4-phenyl-2-butylamine in 72% yield; b. p. 98–100° (10 mm.); n^{20}D 1.5061.

Anal. Calcd. for $C_{11}H_{17}N$: C, 80.93; H, 10.50; N, 8.58. Found: C, 80.8; H, 10.8; N, 8.55.

(c) **Exhaustive Methylation.**—2-Methyl-4-phenyl-2-butylamine was converted to the corresponding methiodide with methyl iodide and potassium hydroxide in 73% yield using the directions of Plattner[17]; m. p. 202° dec.

Anal. Calcd. for $C_{14}H_{24}IN$: C, 50.45; H, 7.26; N, 4.20. Found: C, 50.5; H, 7.25; N, 4.28.

The methiodide was converted to 3-methyl-2-phenyl-2-butene according to the procedure of Cope and Overberger[18] in 78% yield; b. p. 85–86° (16 mm.); $n^{20}D$ 1.5060.

(d) **Preparation of Isoamylbenzene.**—3-Methyl-1-phenyl-2-butene in ethanol solution was treated with Raney nickel and hydrogen at 50 p. s. i. and 25° for twenty hours. A 78% yield of isoamylbenzene was obtained; b. p. 83–84° (16 mm.); $n^{20}D$ 1.4862; lit. b. p. 84° (16 mm.); $n^{20}D$ 1.4835.[19] 2,4-Diacetaminoisoamylbenzene was prepared according to method of Ipatieff and Schmerling[19]; m. p. 212–213°. The melting point of a mixture of this sample and an authentic sample showed no depression.

Rate Study. Materials.—Commercial absolute ethanol was used as solvent. 2-Nitropropane ($n^{20}D$ 1.3940) was a re-rectified Commercial Solvents Corp. product. *p*-Nitrobenzyl chloride (m. p. 70–70.5°) was a recrystallized Eastman Kodak Co. product. *m*-Nitrobenzyl chloride (m. p. 45–46°) and *o*-nitrobenzyl chloride (m. p. 47–49°) have been described previously.[3] Benzyl chloride was a Baker C. P. product.

Method.—Fifty ml. of an ethanolic solution containing 0.02 mole of lithium 2-propanenitronate[20] was placed in the reaction vessel and equilibrated in the constant-temperature bath. A fifty-ml. portion of an ethanolic solution containing 0.02 mole of halide was equilibrated in the constant-temperature bath and then pipetted into the reaction vessel. The reaction mixture was shaken and the timer was started.

The rates of reaction were determined by titration of the free chloride ion by the Volhard method. Ten-ml. aliquots were removed from the reaction mixture at intervals and drowned in ice-cold dilute nitric acid in a glass-stoppered bottle. An excess of standard silver nitrate solution and a few ml. of nitrobenzene was added, and the mixture was vigorously shaken. The excess silver nitrate was then titrated against standard potassium thiocyanate solution using ferric alum as indicator. This modification of the Volhard procedure gave reproducible results accurate to within 3% when tested on known synthetic reaction mixtures.[21]

Results.—Figure 1 gives the experimental results of these rate studies. Since the initial concentrations of the reacting substances in these second-order reactions were the same, the rate expression may be written as $k_2t = [1/(a - x)] - (1/a)$ so that the plot of $1/(a - x)$ against t should be linear, the slope being equal to k_2. Table I gives the values of the second-order rate constant calculated in this manner.

Acknowledgment.—Several stimulating discussions with Drs. Herbert C. Brown and Nathan Kornblum on various phases of this theory are gratefully acknowledged.

Summary

A kinetic study of the reactions of four benzyl halides with lithium 2-propanenitronate indicates that the rate-determining step in both oxygen- and carbon-alkylation is the formation of a nitronic ester intermediate. A comparison of the alkylation and Williamson reactions of benzyl halides indicates that the ease of removal of a benzylic hydrogen by a base is an important factor in determining the direction of the alkylation reaction. A mechanism is suggested to explain these results.

A Static Low Temperature Method for Determining Small Residual Fields Accurately in Magnetic Experiments

BY W. F. GIAUQUE AND J. W. STOUT

The technique of adiabatic demagnetization experimentation in this Laboratory has been developed around the iron-free solenoid type of magnet. In this way the complications due to considerable residual fields and hysteresis which interfere with precise measurements, when iron yoke magnets are used, have been largely avoided. However even the earth's field is large enough to interfere with some measurements and the iron in a typical reinforced concrete building will increase the field which remains when the current through a solenoid is reduced to zero.

For example, when a substance has been demagnetized adiabatically to a low temperature, it is desirable to apply some test to determine if any net directed magnetic moment remains. A very simple method of measuring any residual magnetic moment was used by Giauque and MacDougall.[1] They measured the e. m. f. induced in a coil surrounding the sample, while the substance was slowly warmed to temperatures above 1°K., in which region the magnetic properties were comparatively ideal. In such an experiment, the considerable change of magnetic susceptibility with temperature, will, in the presence of a residual field, produce an e. m. f. due to the changing magnetic moment induced by the residual field. The above authors found such an effect with gadolinium phosphomolybdate tridecahydrate and were able to explain it quantitatively by means of residual field measurements made with a flip-coil at a later date. Residual field measurements should be available at the same time as any other measurements which have a field dependence at small fields. It is undesirable to complicate an already complicated measuring system by operating a flip-coil or other rotating device in the proximity of the sample, and we prefer not to use methods which are based on the properties of ferromagnetic materials of high and variable permeability since the presence of such material should be avoided if possible. We have used a simple static method which avoids the above effects.

A convenient and well known method of measuring magnetic field strength at ordinary temperatures is based on the change of electrical resistance of bismuth with field. The ordinary instruments based on this effect are nowhere near sensitive enough for our present purpose. However, measurements of Beckman[2] have shown that the increase of resistance of bismuth with field is greatly enhanced at low temperatures. The bismuth coils used at ordinary temperatures are calibrated and are expected to retain their calibration for considerable periods. It is very improbable that such a coil would retain a low temperature calibration with sufficient accuracy after warming to ordinary temperatures, followed by recooling to the temperature of liquid helium. The following methods avoid the necessity of precalibration.

Some bismuth wire was made by heating the metal and extruding it through a die with a diameter of 0.024 in., under a pressure of 7000 atmospheres. A coil of twelve turns, with a diameter of 2 in. and a length of 1.5 in., was wound non-inductively. It was mounted in a dewar vessel near the center of, and co-axial with, a vertical solenoid magnet.[3] We have supported such coils in grooves cut in micarta, or etched in Pyrex tubing and both leave something to be desired in preventing breakage of the brittle bismuth wire. Potential and current leads were attached to each end of the wire. All measurements were made with the coil immersed in liquid helium at its boiling point 4.22°K.

A steady current of about 2.58×10^{-4} ampere was passed through the coil and the resistance was found to be 21.8645 ohms A small current was then passed through the solenoid magnet and the change in resistance was observed. The current through the magnet was then reversed and the quite different change in resistance of the bismuth was recorded. The procedure was repeated with several other small values of solenoid current. The relationship between field and the current through the solenoid is easily computed from its dimensions.

Since the change of resistance of the bismuth should depend on the magnitude and not the sign of the net magnetic field, a plot of ΔR against applied field should be symmetrical about a line parallel to the ΔR axis, and displaced from it by the amount of the component of the residual field along the axis of the solenoid. Such a plot is shown in Fig. 1. The method is independent of the character of the dependence of ΔR on the applied field.

It is, however, a matter of some interest to inquire concerning the relationship between the change in resistance and the absolute value of the vertical component of the magnetic field. The data are given in Table I. Values of the quantities A and B in Fig. 1 were selected to give a smooth function of $(R_H - R_{H=0})/H^2$ against H.

It is evident that ΔR is proportional to H^2 at fields of the order of 0–20 oersteds and that the rate of change then decreases rapidly and appears to approach a condition in which it depends very little on the applied field.

1210	47.76	.0326
1618	61.33	.0234
3218	90.57	.0088
6206	112.1	.0029
8409[a]	120.5	.0017

[a] Reading at limit of ammeter and thus probably a little low.

The principal source of error in the data in Table I is due to the fact that the applied field was determined by reading an ammeter. ΔR was determined by means of an accurate potentiometer. More accurate results could have been obtained had the magnet current also been determined by a potentiometric method. However the results are such that a residual field of 2.03 oersteds gives considerably better internal consistency of all the data than 2.05 oersteds. Thus we conclude that the vertical component of the residual field was 2.03 ± 0.02 oersteds. This may be compared with the result of Giauque and MacDougall,[1] 2.0 ± 0.1 oersteds, determined with a flip-coil under approximately the same conditions.

During the period of the above experiments all large currents through the magnet produced a field which was in the same direction as the vertical component of the earth's field. In order to find out if the residual field was somewhat greater immediately after the full field of about 8000 oersteds was turned off, an experiment was tried to test this point. It was found that there was no observable change in the resistance of the bismuth coil after a field of about 8400 oersteds had been applied for three-fourths of a minute. In order to improve the sensitivity of the above test an applied field of 16.28 oersteds was used in the direction of the residual field both immediately before and after the large field was applied. This measurement showed that any change in the residual field was less than 0.01 oersted. The magnet was not used for an hour prior to this test.

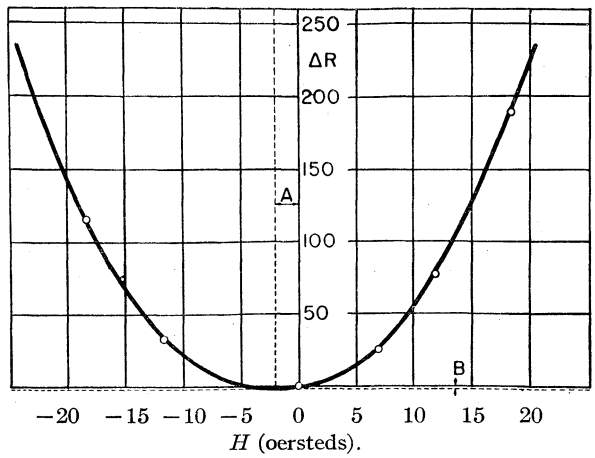

Fig. 1.—Measurement of a small residual magnetic field with a bismuth coil: ΔR = ohms $\times 10^{-3}$; A, residual field along solenoid axis; B, resistance due to the residual field.

Although the above accuracy was sufficient for the investigation of which it was a part, the sensitivity and simplicity of the method could be greatly increased and the result made available in a very short time by the following procedure: Send an accurately measured current through the solenoid and read the potential drop due to the current used in the bismuth coil. Reverse the solenoid current and adjust its value until the potential drop across the bismuth coil returns to the original value, thus restoring its resistance to the initial value. The component of the residual field will be equal to the field produced in the solenoid by one-half the difference in the direct and reverse solenoid currents. We have estimated that with an applied solenoid field of about 20 oersteds, and a current of some 5×10^{-3} ampere through the bismuth coil mentioned above, a potentiometer scale reading of about 1 cm. would be equivalent to 0.001 oersted in the residual field.

For some purposes it will be desirable to know the other components of the residual field. These could be determined with the assistance of auxiliary coils, which, while of necessity must be located at some distance in adiabatic demagnetization experiments, could produce a calculated field, in the desired direction at the location of the bismuth coil.

Summary

A method utilizing the electrical resistance of a bismuth coil at liquid helium temperature to measure accurately a small residual magnetic field has been described.

This static method has been devised to avoid the use of ferromagnetic materials, flip-coils and other rotating or oscillating devices, which are considered to provide undesirable complications during adiabatic demagnetization experiments at temperatures below 1°K.

The Mass Spectrum of Monoisotopic $B_2^{10}H_6$

BY FRANCIS J. NORTON

The dissociation of complex molecules by electron impact presents many features of theoretical and practical interest. This is particularly so in the cases where isotopes occur in the molecular structure. The availability of stable separated isotopes from the Atomic Energy Commission renders possible the construction of molecules with altered isotope ratios. This paper is to report the investigation of one of these, $B_2^{10}H_6$, by the mass spectrometer, and the determination of its molecular fragmentation pattern under electron impact. Normal B_2H_6 with its pattern was also studied.

Normal boron consists of two stable isotopes, about 20% B^{10} and 80% B^{11}. From the Isotopes Division, U. S. Atomic Energy Commission, was obtained the complex $BF_3 \cdot CaF_2$. In this the boron is 96% of the B^{10} isotope and 4% of B^{11}. Through the kindness of Dr. Edith Boldebuck and Dr. J. R. Elliott of our laboratory, $B_2^{10}H_6$ was synthesized from this enriched isotopic material and was used in these experiments.

The mass spectrum of normal polyisotopic diborane has been studied by J. A. Hipple[1] and by Vernon H. Dibeler and Fred L. Mohler.[2] From its mass spectrum they made calculations for the ion distribution of the monoisotopic material. The present work renders possible a comparison between such a calculation and an experimental determination on essentially monoisotopic diborane. Further interest lies in the fact that the mass spectrometers used in references,[1,2] and in the present work were made by three different manufacturers.

Experimental

(a) The synthesis of $B_2^{10}H_6$ was from the complex $B^{10}F_3 \cdot CaF_2$ (the boron consisting of 96% B^{10}). This was heated to 350° in a stream of purified nitrogen. The $B^{10}F_3$ evolved was collected in cooled ether and reacted with lithium hydride. The diborane was separated from the ether and subjected to several low temperature vacuum distillations. It was kept stored at −20°. From mass spectrometer analyses higher boron hydrides and normal B_2H_6, if present at all, were under 0.05%. Diethyl ether was under 0.1%, and a small amount, under 0.1%, of SiH_4, was also found. Normal B_2H_6 was furnished by Dr. L. V. McCarty of our laboratory and was of very high purity.

(b) The mass spectrometer used was the 60° type, single focussing with 6-inch radius of curvature. It is manufactured by the General Electric Company. The accelerating voltage was 2000, ionizing voltage 70. The filament current was 4.5 amperes, total emission current 1.0 ma., trap current (electrons collected at end of ionizing chamber) 0.28 ma. Positive ion currents at the collector were measured by a 954 preamplifier tube in a direct current feedback amplifier circuit. The initial voltage drop to ground was through an IRC resistor of 2×10^9 ohms. The amplifier output was recorded on a General Electric photoelectric recorder with appropriate resistances for selecting sensitivity ranges. The range of masses was covered by sweeping the magnetic field. This could be done either automatically or manually. For precise measurement, the desired peak was selected and held at maximum value on the recorder by manual control. It was focussed to maximum value by manipulating the focussing, drawing out and beam centering voltages.

It should be pointed out that with this type of instrument, to obtain the maximum peak height as is done with these manual measurements reported, refocussing is needed particularly at the lower end of the mass scale, for each mass peak. This means that the scan does not represent the maximum height of peak attainable. The peak heights for a given focus do remain reproducible, and the scans in the lower mass regions especially, should be regarded as recognition patterns. On automatic sweep, changes in focus were made for peaks in the 1, 2, 10–13 and 20–28 mass regions, to give them maximum values possible with fewest focus changes.

The height could be read to ±1% for deflections of the recorder pen from one-half to full scale. For measurements, readings were made in the region of 80 to 100% full scale deflection. This could be chosen by using appropriate, known values of resistance in the measuring circuit.

The gas to be measured was fed into the spectrometer through an orifice type leak. This was so small that 40 mm. gas pressure on the high side gave 2×10^{-7} mm. on the ion gage at the spectrometer tube outlet. The gas used during analysis was minute in amount. With that leak, the change in pressure in a 1 liter reservoir was under 2% per twenty-four hours.

Measurements were made keeping the B_2H_6 on the leak at 25°. I had found in previous work that with very pure, normal diborane handled with good vacuum practice so that the amount of water present is exceedingly small, the following rates of decomposition were observed at an initial pressure of 33 mm. This extrapolated to 25° on a log

°C.	Rate of pressure increase dp/dt (mm./min.)
120	0.045
110	.020
100	.005

rate *vs.* $1/T$ plot gives about 10^{-6} mm./min., or under 0.005% per twenty-four hours.

Before introduction, the hydride was held in a trap at −190° and any traces of gaseous hydrogen pumped away; it was then taken over to the leak reservoir with the trap at −78°. After the mass spectrum was run, the remaining B_2H_6 was taken back into the trap, put at −190° and any hydrogen measured. It was under 0.1%. Hence, it is believed the hydrogen ion peaks found are from B_2H_6 dissociation in the mass spectrometer only.

Results

The isotopic constitution of the gas molecules entering the spectrometer can be calculated very simply from statistical considerations alone. The general expression from simple probability for the abundance distribution of isotopic species of molecules is given by $(a + b)^n(c + d)^m$ where a and b are the relative abundances of the isotopes of one atom, in this case boron isotopes 10 and 11, and c and d are the relative abundances of the stable

TABLE I

ISOTOPIC CONSTITUTION OF THE MOLECULAR GASES USED

Molecular type	Normal B_2H_6 (20% B^{10}) (80% B^{11}) Proportion calculation	Per cent.	"Monoisotopic" B_2H_6 (96% B^{10}) (4% B^{11}) Proportion calculation	Per cent.
$B^{11}B^{11}H_6$	$0.8 \times 0.8 = 0.64$	64.0	$0.04 \times 0.04 = 0.0016$	0.16
$B^{11}B^{10}H_6$	$2(0.2 \times 0.8) = 0.32$	32.0	$2(0.04 \times 0.96) = 0.0768$	7.68
$B^{10}B^{10}H_6$	$0.2 \times 0.2 = 0.04$	4.0	$0.96 \times 0.96 = 0.9216$	92.16

hydrogen isotopes 1 and 2. The exponents n and m represent the number of atoms in the molecule. Taking the relative isotopic abundances as: $B^{10} = 0.2$, $B^{11} = 0.8$, $H^1 = 0.998$, H^2 (deuterium) $= 0.02$, the expression becomes for B_2H_6: $(0.2 + 0.8)^2(0.9998 + 0.02)^6$. For normal deuterium abundances, the second term may be taken as unity. If for the normal B_2H_6 a ratio of $B^{11}/B^{10} = 4.0$ is assumed, the following Table I gives the constitution for the two types of B_2H_6.

In the mass spectrometer these molecules are broken up by the impact of 70 volt electrons, and form positive ion fragments of various masses. The relative abundance of each of these is given by the positive ion current at each mass. This current is recorded as peak height, and the mass spectrum is a record of the peak heights or abundance plotted against mass. No way is known to calculate the theoretical abundance of the ion fragments from complicated molecules.

Figure 1 gives a record of the spectra of the two kinds of B_2H_6 used. Masses are recorded at the bottom, increasing from right to left, and the peak height is the magnitude of the positive ion current.

The measured values of the mass spectra are given in the following Table II. In each case, the dominant peak is taken = 100.

The measured spectrum for $B_2^{10}H_6$ needs correction for the presence of 4% B^{11} with the 96% B^{10} in the starting material. How this is done is illustrated by Table IV. Ions having the same constitution as regards the numbers of hydrogen attached to boron are connected by the slanting ar-

rows. These ions have similar, presumably identical, probabilities of formation by electron impact.

TABLE IV

CONSTITUTION OF MASS SPECTRUM OF B_2H_6

Mass	Constituent positive ions			
28	$B^{11}B^{11}H_6$			
27	$B^{11}B^{11}H_5$	$B^{10}B^{11}H_6$		
26	$B^{11}B^{11}H_4$	$B^{10}B^{11}H_5$	$B^{10}B^{10}H_6$	
25	$B^{11}B^{11}H_3$	$B^{10}B^{11}H_4$	$B^{10}B^{10}H_5$	
24	$B^{11}B^{11}H_2$	$B^{10}B^{11}H_3$	$B^{10}B^{10}H_4$	
23	$B^{11}B^{11}H$	$B^{10}B^{11}H_2$	$B^{10}B^{10}H_3$	
22	$B^{11}B^{11}$	$B^{10}B^{11}H$	$B^{10}B^{10}H_2$	
21	.....	$B^{10}B^{11}$	$B^{10}B^{10}H$	
20	.....	.....	$B^{10}B^{10}$	
14	$B^{11}H_3$			
13	$B^{11}H_2$	$B^{10}H_3$		
12	$B^{11}H$	$B^{10}H_2$		
11	B^{11}	$B^{10}H$		
10	.....	B^{10}		
2	H_2			
1	H_1			

Hence, as we proceed downward along any slanting arrow, say from $B_2^{11}H_5$ mass 27, to $B^{10}B^{11}H_5$ mass 26, to $B_2^{10}H_5$ mass 25, the theoretical distribution of these three similar ions can be calculated directly, if the isotopic abundances of B^{10} and B^{11} are known, in the manner shown in Table I. The probability of $B^{11}B^{11}$ ion formation in the nearly monoisotopic material is only $0.04 \times 0.04 = 0.0016$. This is too low to be of any importance here, and the whole column of ions from $B_2^{11}H_x$ (x from 0 to 6) will be taken as zero for this case.

The ion at mass 20 of peak height 1.9 can be due only to B_2^{10}. From its 0.9216 probability, projected back up the arrow we arrive at the similar ion $B^{10}B^{11}$ of 0.0768 probability at mass 21. Its height can then be calculated as $(0.0768/0.9216) \times 1.9 = 0.16$. Then the measured mass 21 peak height minus this 0.16 gives 4.94 as the corrected peak height due to the ion $B_2^{10}H$ only. Proceeding up the table of constitution, Table IV, in this way, we arrive at the corrected values for 100% monoisotopic material, Table II, and put it on the new basis of Peak 25 = 100 = $B_2^{10}H_5$ ion, the most abundant ion.

In a similar manner, the normal B_2H_6 spectrum can be calculated to the monoisotopic spectrum, as did Hipple[1] and Dibeler and Mohler.[2] In agreement with the latter, I found that the best agreement with the observed spectrum, and with the monoisotopic spectrum here reported, was obtained by taking the normal distribution of boron isotopes as $B^{11}/B^{10} = 4.0$.

This is not in agreement with the ratio of 4.311 determined by Inghram[3] using BF_3 and $B(OCH_3)_3$; also Thode,[4] *et al.*, using BF_3 found the B^{11}/B^{10} ratio varied from 4.27 to 4.42 depending on the source of the boron. It is conceivable that either the preparation and repeated vacuum distillation of the B_2H_6 resulted in some enrichment of the light B^{10}, or that the probabilities of ion formation involving B^{10} and B^{11} are not identical as I assumed.

However, a calculation of sensitivities (that is, peak height as a function of the abundance of each type of molecule in terms of its partial pressure on the leak), checks the assumption that the ionization probability is very nearly identical for ions of similar type as $B^{11}B^{11}H_5$, $B^{10}B^{11}H_5$ and $B^{10}B^{10}H_5$, in both the normal and in the monoisotopic material. This is also true for each other ion type, irrespective of its isotopic constitution.

There is one other possibility which could account for the low value of the B^{11}/B^{10} ratio which had to be assumed, compared to the more precise values of Inghram[3] and Thode, *et al.*[4] It may be that the dissociation probability of $B_2^{10}H_6$ is greater than that of the heavier molecules. This would give more B^{10} in the dissociation products than in the original gas, and might explain the low ratio assumed.

In calculating the monoisotopic spectrum from the observed normal spectrum, it seemed best to derive the value for $B_2^{11}H_6$ ion at mass 28, from the $B_2^{10}H_6$ value, in view of the possible contaminations which can accumulate at mass 28. Hence, the value of 1.5 was used for the normal B_2H_6 mass 28 peak height relative to mass 27 = 100.

Using the ratio $B^{11}/B^{10} = 4.0$ for the normal B_2H_6 which I used, a monoisotopic spectrum can be calculated. In Table V are given: (a) the observed monoisotopic spectrum from $B_2^{10}H_6$, corrected for the 4% B^{11} present; (b) the monoisotopic spectrum calculated from my measured normal B_2H_6 spectrum; (c) the monoisotopic spectrum calculated by Hipple[1] from his measured normal spectrum and (d) the monoisotopic spectrum calculated by Dibeler and Mohler[2] from their measured normal spectrum.

TABLE V

MONOISOTOPIC MASS SPECTRUM OF B_2H_6

Ion	(a) Observed spectrum this paper	(b) Calculated this paper	(c) Calculated Hipple[1]	(d) Calculated Dibeler and Mohler[2]
B_2H_6	1.5	1.5	0	0.64
B_2H_5	100.0	100.0	100.0	100.00
B_2H_4	46.5	47.0	44.8	52.6

The concordance, with the exception of H_2 ion, is rather good, considering the determinations were made on three different mass spectrometers, manufactured by different companies. The wide differences in hydrogen mass 2 peak heights are undoubtedly due mainly to thermal decomposition in the source region, where there existed different structures, temperatures and differential pumping rates out of the source region, in the case of the three different types of mass spectrometer.

The use of the monoisotopic material enables the origin of the small peak at mass 11.5 to be identified unambiguously. This peak was noted by both Hipple[1] and Dibeler and Mohler.[2] The constitution of peak 23 is presented in the following Table VI. The figures are relative to the dominant peak = 100 in each spectrum.

It will be seen that peak 11.5 is proportional to the $B^{11}B^{10}H_2$ ion only. Hence, doubly ionized $B^{11}B^{10}H_2$ ion of mass 23 is responsible for this peak. The appearance potential of peak 11.5 was measured as approximately 23 volts (argon calibration), whereas the appearance potential for the singly ionized peaks was about 15 volts. Very small peaks of double ionization also were found at masses 12.5 and 13.5.

TABLE VI

CONSTITUTION OF PEAK 23

Ion	Normal B_2H_6	96% $B_2^{10}H_6$
$B_2{}^{11}H$	4.8	0
$B^{11}B^{10}H_5$	31.4	4.7
$B_2^{10}H_3$	1.4	23.9
Peak 23 height	37.6	28.6
Peak 11.5 height	0.66	0.075
Ratio 11.5 peak to $B^{11}B^{10}H_2$ ion contribution	0.021	0.017

Summary

The mass spectrum of the monoisotopic molecule $B_2^{10}H_6$ was determined. This was compared with the calculated monoisotopic spectrum from measurements on B_2H_6 of normal isotopic boron ratio.

The Kinetics of the Acid-Catalyzed Hydrolysis of Amine Disulfonate Ion; The Third Ionization Constant of Amine Disulfonic Acid[1]

BY GEORGE J. DOYLE[2] AND NORMAN DAVIDSON

Amine disulfonate ion (imidodisulfonate ion) is known to hydrolyze irreversibly and quantitatively in dilute acid at a measurable rate according to the equation[3,4,5]

$$HN(SO_3)_2^{=} + H_2O \xrightarrow{H^+} HSO_4^- + H_2NSO_3^- \quad (1)$$

Wagner[6] in the course of his study of the kinetics of the hydrolytic decomposition of the sulfur–nitrogen acids did one experiment on the hydrolysis of amine disulfonate in dilute hydrochloric acid solution. On the basis of this meager evidence he concluded that the rate of hydrolysis is proportional to the product of the concentrations of hydrogen ion and amine disulfonate ion, and is therefore autocatalytic. Sisler and Audrieth[4] have presented valuable data on the hydrolysis of amine disulfonate and on the two-step hydrolysis of amine trisulfonate ion (nitrilo-sulfonate ion) to amine disulfonate and thence to amine monosulfonate ion (sulfamate ion) at several temperatures. This data is not, however, extensive enough for a kinetic analysis. Because of the lack of quantitative data, we have investigated more thoroughly the kinetics of reaction (1).

Materials.—The distilled water, standard base (0.02 *N* sodium hydroxide) and standard acid (0.02 *N* hydrochloric acid) were prepared and stored so as to be free of carbonate or carbon dioxide. A solution of sodium chloride used to adjust ionic strength was prepared from the C. P. salt which was dried four hours at 200°.[7] A solution of sodium sulfate used as a source of sulfate ion was prepared from the C. P. anhydrous salt which was ignited one and one-half hours at 700–800°.[8]

Potassium amine disulfonate was prepared by hydrolysis of potassium amine trisulfonate

$$N(SO_3)_3^{=} + H_2O \xrightarrow{H^+} HN(SO_3)_2^{=} + HSO_4^- \quad (2)$$

This in turn was prepared by reaction of a large excess of potassium bisulfite with potassium nitrite in hot aqueous solution (Sisler and Audrieth's modification[4,9] of Claus and Koch's[10] method)

$$NO_2^- + 3HSO_3^- \longrightarrow N(SO_3)_3^{=} + H_2O + OH^- \quad (3)$$

A preparation on a scale of about ten times greater than that used by Sisler and Audrieth gave a yield of potassium amine disulfonate, washed free of sulfate, of 64% based on potassium nitrite; Sisler and Audrieth report 51%. The

improvement in the yield is presumably due to the larger scale of operations. A slight modification of the procedure of these authors that was introduced was to wash the trisulfonate prior to hydrolysis with chilled, dilute ammonia (1:100) instead of water.

The salt was analyzed for sulfur, nitrogen and material not volatile on ignition with sulfuric acid (taken as potassium sulfate[8]). The analysis for nitrogen was done by a semi-micro Kjeldahl procedure according to E. C. Wagner,[11] using an apparatus of the type devised by Redemann.[12] Sulfur was determined as barium sulfate after hydrolysis and oxidation of the disulfonate with nitric acid containing a little hydrochloric acid as a catalyst.[13] To avoid coprecipitation of nitrate by barium sulfate, excess nitric acid was removed by repeated evaporation with hydrochloric acid. The results of the analysis, shown in Table I, indicate a purity of 97.6–98.5%.

TABLE I

ANALYSIS OF POTASSIUM AMINE DISULFONATE

K		N		S	
Found	Calcd.	Found	Calcd.	Found	Calcd.
30.43	30.87	5.55	5.53	24.74	25.31
30.38		5.50		24.75	
		5.44			

Another method of analysis was used to check the extent of deterioration, if any, with time. A weighed sample of the salt was dissolved in dilute base in order to neutralize any possible acid impurity and thus prevent premature hydrolysis. The solution was then adjusted to the equivalence point by adding acid. A known excess of acid was added and the disulfonate hydrolyzed completely by heating to 85–95° for an hour, and then titrated with standard base. The hydrolysis of sulfamic acid if it occurs to any extent during the heating will not affect the titer of the solutions. This analytical method indicated a purity of greater than 99% and showed no decomposition of the disulfonate, stored in a vacuum desiccator over anhydrous calcium sulfate, in a period of five months.

The Third Ionization Constant of Amine Disulfonic Acid.—A determination of the equilibrium constant for the reaction

$$HN(SO_3)_2^{=} \rightleftharpoons H^+ + N(SO_3)_2^{\equiv} \qquad (4)$$

is in itself desirable and was necessary in order to select a suitable indicator for the acid titrations in the rate measurements. That the equilibrium constant for the reaction is not negligibly small is suggested by the fact that salts like $K_3N(SO_3)_2$ have been prepared.[5]

The value of the ionization function (classical ionization constant)

$$k_a = [H^+][N(SO_3)_2^{\equiv}]/[HN(SO_3)_2^{=}] \qquad (a)$$

with concentrations expressed in volume molal units, was determined at an ionic strength of 1.00 and 25° by measuring with an electronic (Beckman) *p*H meter and a glass electrode the *p*H's of dilute buffer solutions made by partially neutralizing the imide hydrogen of the disulfonate ion with sodium hydroxide and adjusting the ionic strength to 1.00 with sodium chloride. The *p*H's of dilute hydrochloric acid solutions adjusted to an ionic strength of 1.00 were also measured. In the latter solutions, the hydrogen ion concentration was taken equal to the stoichiometric concentration of hydrochloric acid, and the activity coefficient of hydrogen ion was taken to be the same as in the buffer solutions. The concentrations of hydrogen ion in the buffer solutions are then readily calculated and from this the value of the function (a).

In order to obtain some check on the method, the value of the ionization function $[H^+][HPO_4^{=}]/[H_2PO_4^-]$ was determined by the same method at ionic strengths of 1.00 and 0.15. The results of these measurements are contained in Table II. An average value of the ionization function for the disulfonate ion is about 3.2×10^{-9} at $\mu = 1$.

In order to compare the observed values of the ionization function for the $H_2PO_4^-$ ion with the thermodynamic ionization constant we have used the approximate equation

$$\log f_i = -\frac{Az_i^2\mu^{1/2}}{1+\mu^{1/2}} + \beta_i\mu \qquad (b)$$

In this relation: f_i = activity coefficient of i^{th} ion; A = Debye–Hückel coefficient; z_i = electronic charge of i^{th} ion; μ = "ionic strength" = $\frac{1}{2}\Sigma c_i z_i^2$ where c_i's are in volume molal units[14]; β_i = a constant characteristic of the i^{th} ion and of the medium.

Application of equation (b) to the results for the ionization functions of the $H_2PO_4^-$ ion leads to a value of 6.1×10^{-8} for the ionization constant of the $H_2PO_4^-$ ion, in excellent agreement with the value of 6.226×10^{-8} determined by Nims.[15] Probably equation (b) is not very accurate for ionic strengths as high as 1.0. Therefore, this excellent agreement suggests merely that the method of measurement can be used to obtain values of ionization functions that can be extrapolated to an

(13) Cupery, *Ind. Eng. Chem.*, **30**, 627 (1938).

(14) In this article, all concentrations are expressed in volume molal units. The "ionic strength," μ, is therefore not strictly that originally defined by Lewis and Randall (THIS JOURNAL, **43**, 1140 (1911)) using concentrations in weight-molalities, but is one-half the "ional concentration," Γ, used by Harned and Owen (Ref. 19, p. 33).
(15) Nims, THIS JOURNAL, **55**, 1946 (1933).

ionic strength of zero with some accuracy but it does not prove that the measured ionization functions at ionic strength 1.0 are reliable.

Rate Determination Procedure.—The reaction (1) was followed by titrating samples of the reaction mixture for total strong acid. It may be calculated from the value of the ionization function for the disulfonate ion that an indicator changing in the *p*H range of 5.0–6.0 is desirable for the titration of bisulfate ion in the presence of disulfonate ion. Brom cresol green–methyl red mixed indicator (endpoint 5.1) was used.

A reaction mixture was prepared by rapidly dissolving a known quantity of solid disulfonate in a thermostated solution of the other components in a 250-ml. volumetric flask, adding a small amount of water to adjust the volume and agitating again. The solution was then emptied into a 500-ml. glass-stoppered Erlenmeyer flask immersed in the thermostat. Two 10-ml. samples were taken with calibrated pipets and analyzed to determine the initial hydrogen ion concentration. In some runs, two final samples were hydrolyzed completely by heating to 80–90° for one hour, as a check on the disulfonate concentration. For the rate measurements at 25°, the samples were rapidly titrated with 0.02 *N* base. For the reactions at higher temperature, where the rate of hydrolysis was greater, the samples were run into excess base and back titrated with acid.

Initial Rate Studies at 25.00° at an Ionic Strength of 1.00.—To establish the kinetics of the reaction, a series of experiments was done with the ionic strength[14] fixed at 1.00. An ionic strength of about this magnitude is recommended to minimize the variations due to the salt effect on the rate of an ionic reaction.[16,17]

To establish tentatively the rate law, the average initial rates over the first 10% of hydrolysis for several series of experiments were obtained from graphically smoothed values of the reaction variable (amount of acid produced by the hydrolysis at time $t = x$) and the dependence of initial rates on initial concentrations of reactants determined. The dependence of initial rate on initial hydrochloric acid concentration for two initial disulfonate concentrations (0.0500 and 0.0200 *F*) is shown in Fig. 1. The dependence of initial rate on initial disulfonate concentration for two initial hydrochloric acid concentrations (0.099 and 0.0593 *F*) is exhibited in Fig. 2.

These results suggest the rate equation

$$-\mathrm{d}[\mathrm{HN(SO_3)_2^{=}}]/\mathrm{d}t = k[\mathrm{H^+}][\mathrm{HN(SO_3)_2^{=}}] \quad (c)$$

In an experiment for 34,000 min. at a *p*H of 8 in which $[\mathrm{HN(SO_3)_2^{=}}] = 0.045\ M$ and $[\mathrm{N(SO_3)_2^{\equiv}}] = 0.005\ M$, the observed change in titer of the solution corresponded to hydrolysis of 0.2% of the disulfonate and a calculated average rate of 3×10^{-9} mole/liter × minute. There was therefore no significant uncatalyzed hydrolysis in the experiments at moderate acidities.

In order to establish whether the hydrolysis of disulfonate is specifically catalyzed by hydronium ion (H_3O^+), or is also catalyzed by other acids, in particular by the bisulfate ion formed during the reaction, a series of experiments was performed (at 25.00° and $\mu = 1.00$) at constant initial disulfonate concentration and constant initial hydrochloric acid formality, but with varying initial amounts of added sulfate. In the hydronium ion concentration range with which we are concerned the disulfonate ion is not appreciably converted to $\mathrm{N(SO_3)_2^{\equiv}}$. We assume further that it is not appreciably converted to $\mathrm{HN(SO_3)/(SO_3H)^-}$. Evidence bearing on this point will be discussed more fully in a later section. In addition, the amine monosulfonic acid formed on hydrolysis is completely ionized.[13]

To determine the concentration of hydronium ion [H⁺], in the presence of added sulfate, it was necessary to know the ionization function of

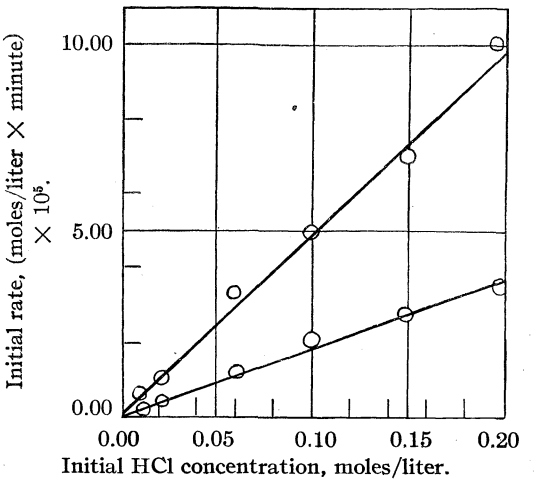

Fig. 1.—The dependence of the initial rate of hydrolysis of amine disulfonate on hydrochloric acid concentration at an ionic strength of 1.00 and at 25.00°; upper curve, $[\mathrm{HN(SO_3)_2^-}] = 0.0500$; lower curve, $[\mathrm{HN(SO_3)_2^-}] = 0.0200$.

(17) Brønsted and Pedersen, *Z. physik. Chem.*, **103**, 307 (1922).

HSO_4^- at an ionic strength of 1.00. This was calculated from the ionization constant[18] of HSO_4^- by multiplying by the ratio of the ionization function of $H_2PO_4^-$ at $\mu = 1.00$ measured by us to the ionization constant[15] of $H_2PO_4^-$

$$K(HSO_4^-, \mu = 1) = \frac{K(H_2PO_4^-, \mu = 1)}{K_0\,(H_2PO_4^-)} K_0\,(HSO_4^-) = \frac{4.67 \times 10^{-7}}{6.23 \times 10^{-8}} \times 1.20 \times 10^{-2} = 0.090$$

This calculation is based on the assumption that the ionic strength effects depend mostly on the charge types of the ions, and the small contributions of specific effects are nearly the same for the two acids. In treating the data, the procedure used above of calculating the average initial rate over the first 10% of hydrolysis was adopted. It is evident from the presentation of the data in Table III that the addition of sulfate decreases the rate of hydrolysis because it converts the hydronium ion to bisulfate. The hydrolysis is specifically catalyzed by hydronium ion.[19]

TABLE III

THE EFFECT OF INITIAL SULFATE CONCENTRATION ON INITIAL RATE AT 25.00° AND $\mu = 1.00$

Initial HCl volume molality, 0.0197; initial $HN(SO_3)_2^=$ volume molality, 0.02000

0.0200	0.860	0.334	0.0166	1.005
.0400	.800	.288	.0143	1.005
.0500	.740	.260	.01250	1.04
.0800	.680	.222	.01107	1.00
.1000	.620	.190	.00985	0.965

The values of k, the specific rate constant at 25.00° and at $\mu = 1.00$, calculated from the slopes of Figs. 1 and 2 and from Table III, that is, from all the initial rate data, are presented in Table IV. Considering the approximate nature of initial rate calculations, the agreement amongst the various series of experiments is good, and tends to confirm the proposed rate equation (c).

The Course of the Reaction at 25.00° and $\mu = 1.00$.—To further confirm the validity of the rate equation (c), analysis of the progress of the reaction with time was carried out. These calculations are rather complicated because one must allow for the varying degree of dissociation of bisulfate (from sulfate added initially and from the hydrolysis of the disulfonate) during the course of the reaction.

(18) Hamer, THIS JOURNAL, **56**, 860 (1934).

(19) After carrying out the calculations outlined here, it was called to our attention that on p. 580 of "The Physical Chemistry of Electrolytic Solutions" (Reinhold Publishing Corp., New York, N. Y., 1943) Harned and Owen recommend the privately communicated value of 0.0101 for the ionization constant of HSO_4^- instead of the 0.0120 we have used. Since the correction to an ionic strength of 1.0 is uncertain, and since a difference of 20% would produce less than a 10% change in the calculated rate constants, we have not recalculated our results using the newer data.

TABLE IV

SPECIFIC RATE CONSTANT AT 25.00° AND AT $\mu = 1.00$ ESTIMATED FROM INITIAL RATE DATA

Description of experiments	k, liter/moles × min. × 10^2
Varying HCl concentration, $[HN(SO_3)_2^=]$ = 0.02000 M	1.00
Varying HCl concentration, $[HN(SO_3)_2^=]$ = 0.05000 M	0.93
Varying $HN(SO_3)_2^=$ concentration, [HCl] = 0.0593 M	1.04
Varying $HN(SO_3)_2^=$ concentration, [HCl] = 0.099 M	1.02
Varying $SO_4^=$ concentration, [HCl] = 0.0197 M, $[HN(SO_3)_2]^=$ = 0.0200 M	1.01

The method chosen to treat most of the data is based on the equation (d)

$$k = \frac{2(x_2 - x_1)}{\int_{t_1}^{t_2} [((s + K - a)^2 + 4K(a + x))^{1/2} - (s + K - a)](d - x)dt} \quad \text{(d)}$$

In this relation: x = increase in acid titer due to the reaction (moles/liter) (reaction variable); K = ionization function of bisulfate ion; a = initial formality of hydrochloric acid (moles/liter); d = initial concentration of disulfonate; s = initial formality of sulfate. The equation (d) is derived in a straightforward manner from the rate equation (c). For the experiments at 25.00° and at $\mu = 1.00$, the integral in the denominator of (d) was evaluated by: (1) smoothing the data (x *vs.* t) graphically, (2) calculating the values of the integrand from the smoothed data, (3) plotting the integrand against time, and (4) evaluating the integral with a polar planimeter.

It should be mentioned that in the form $-d[HN(SO_3)_2^=]/[H^+][HN(SO_3)_2^=] = kdt$, the rate equation may be integrated analytically by applying the method of integration by partial fractions after suitable transformation. The cumbersome expressions resulting therefrom have been used in representative cases to check the method

described above.[1] Table V exhibits the results of representative experiments, analyzed by the graphical integration method.

For the experiments listed in the table and for most of the many other runs that were made, there was a definite downward trend in the calculated rate constants especially after about 50% of the disulfonate initially present had hydrolyzed. It is not known to what this was due. The trend could not be correlated with any of the known variables. In spite of these trends, the calculated constants are so nearly constant under a wide variety of initial conditions that, taken in conjunction with the results of the initial rate study, they indicate that the proposed rate equation (c) is essentially correct.

The fact that the calculated values of the rate constant, as exhibited in Tables IV and V, are constant and independent of the calculated concentrations of hydronium ion and disulfonate ion strongly suggests that no appreciable fraction of these ions reacts to form an acid-disulfonate ion $[H_2N(SO_3)_2^-$ or $HN(SO_3H)(SO_3)^-]$ (that is, an isomer of the activated complex postulated in a later section). If as is indicated in Fig. 1 the rate constant calculated at an H^+ concentration of 0.20 mole/liter is the same within 10% as that at lower acidities so that less than 20% of the disulfonate has been converted to the acid-disulfonate ion in 0.2 M acid, a lower limit for the second ionization function of amine disulfonic acid is $0.2 \times 9 = 1.8$.

Dependence of the Specific Rate Constant on Ionic Strength at 25.00°.—The effect of varying the ionic strength is of interest because the theoretical interpretation gives a clue to the identity of the reacting species in the rate-controlling reaction, that is, it gives the sign and a good idea of the magnitude of the product of the charges of the reacting ions. As is well known, the use of equation (b) for the variation of activity with ionic strength in conjunction with Brønsted's theory yields the equation (e)

$$\log_{10} k = \log_{10} k_0 + \frac{2Az_1z_2\mu^{1/2}}{1 + \mu^{1/2}} + \beta\mu \qquad (e)$$

where z_1 and z_2 are the charges of the reacting ions, k_0 is the limiting specific reaction constant as the ionic strength approaches zero, and β is a constant at constant temperature.

To study this effect, experiments were done at a series of ionic strengths varying from 0.020 to 0.25. The hydrolysis was followed until more than 50% of the disulfonate had hydrolyzed. The data were smoothed and a rate constant calculated by a tabular integration method using the trapezoid rule. The time intervals of the integrals were taken over the first portion of the reaction but they did not include the region about $t = 0$, thus eliminating the effects of the disturbances involved in starting the reaction. The value of the ionization function of bisulfate ion at different ionic strengths, which is involved in the calculation, was estimated by assuming the validity of the equation (b), and that the value of K, 0.090, at $\mu = 1.00$ was accurate. This taken in conjunction with Hamer's value of K_0 at 25.00°[18] gives the equation

$$\log K = \log K_0 + \frac{4A\mu^{1/2}}{1 + \mu^{1/2}} + \gamma\mu \qquad (f)$$

where, at 25.00°, $K_0 = 0.0120$, $A = 0.5065$, and $\gamma = -0.137$ for sodium chloride solutions. The rate constants are shown in Table VI.

TABLE VI

DEPENDENCE OF THE RATE CONSTANT ON IONIC STRENGTH AT 25°

Moles/liter HCl	Moles/liter $HN(SO_3)_2^=$	Moles/liter NaCl	$\left(\frac{\mu}{\text{moles/liter}}\right)^{1/2}$	K, moles/liter	k, liter/moles × min.
0.00479	0.00500	0.00	0.1407	0.0212	0.0478

In order to estimate the value of z_1z_2 in (e), log k was plotted against $0.5065\mu^{1/2}/(1 + \mu^{1/2})$ and a smooth curve drawn through the points as shown in Fig. 3. From smoothed data read from the

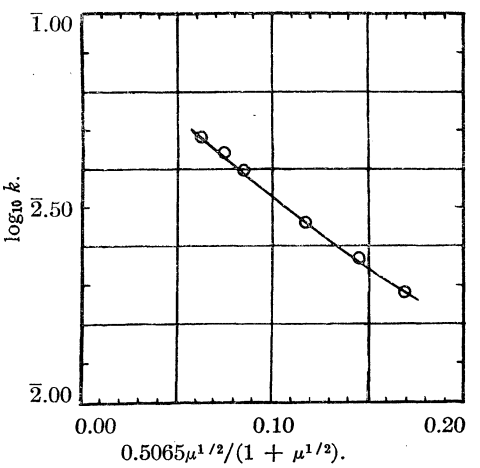

Fig. 3.—The dependence of the reaction constant on ionic strength at 25.00°.

curve, the slope of the curve was calculated, and divided by 2 to give an approximation to z_1z_2. The values thus obtained differed from -2 by about 5–10%. To fit equation (e) to the data, the value of -2 for z_1z_2 was assumed and $\log k + [(4 \times 0.5065\ \mu^{1/2}/(1 + \mu^{1/2})]$ was plotted against μ, as shown in Fig. 4, to evaluate β. It was found that $\beta = +0.092$ and $k_0 = 0.0852$. This value of β is a reasonable one. The conclusion may be drawn that the most probable value of z_1z_2 is -2 which suggests a rate-determining reaction between amine disulfonate ion and hydronium ion. This is consistent with the experimental rate equation.

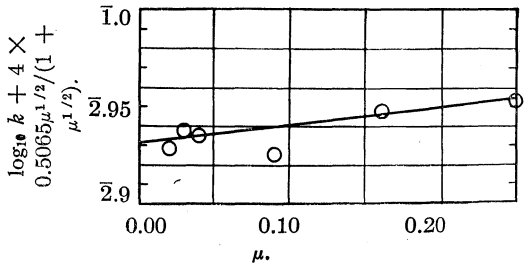

Fig. 4.—Graphical evaluation of k_0 and β of equation (e) at 25.00°.

The Effect of Temperature on the Rate.—To estimate the energy and entropy of activation, two additional series of experiments were done, one at 35°, the other at 45°. Each series consisted of three experiments at decreasing ionic strength to facilitate the extrapolation to μ = 0.00, two experiments to spot check the rate law at constant ionic strength, and one experiment in alkaline medium (added base equivalent to 10% of the disulfonate) to find if an uncatalyzed reaction with water becomes appreciable at the higher temperatures.

The results of these experiments are shown in Table VII. The rate constant was calculated by a tabular integration method utilizing the trapezoid rule over an early time interval which did not include the initial time. No attempt was made in these series to check the rate law by calculating the rate constant over different time intervals for the same experiment as the agreement of the values of the constant calculated for the two spot check experiments was taken as adequately showing the validity of the rate law at the temperature in question. No detectable reaction was found in alkaline media at these temperatures during time intervals comparable with the duration of the other experiments of the same series.

The values of the ionization function of bisulfate ion were estimated by neglecting the term linear in μ in the equation (f) previously derived from equation (b). This approximation is adequate because of the low ionic strengths and the relative intensitivity of the values of the rate constant to the value of the ionization function. Values of K_0 were taken from Hamer's values[18] and the very small corrections to the exact temperature of the experiments made using values of ΔH_i, the enthalpy of ionization, given by Hamer.

To extrapolate to μ = 0, the procedure used in the ionic strength studies at 25° was applied. The graphical evaluation of the constants β and log k_0 of equation (e) is shown in Fig. 5.

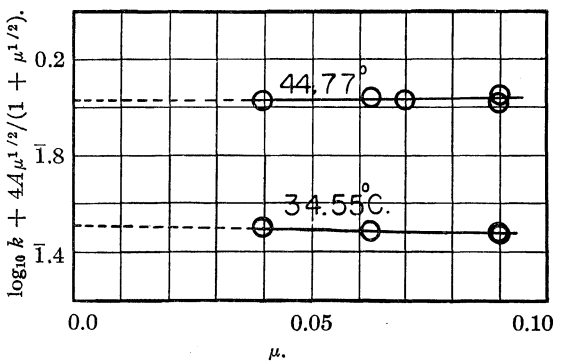

Fig. 5.—Graphical evaluation of k_0 and β at 34.55° and 44.77°.

In Table VIII the behavior of the rate constant with ionic strength and temperature is summarized. The values of A are the theoretical ones calculated from the expression given by the Debye–Hückel theory.

TABLE VIII

SUMMARY OF THE DEPENDENCE OF THE RATE CONSTANT ON IONIC STRENGTH AND TEMPERATURE

Temperature, °C.	A	β	k_0 liters/moles × min.
25.00	0.506	0.092	0.0852
34.55	.517	−.32	0.321
44.77	.528	.13	1.06

The Thermodynamics of the Activated Complex.—The variation of k_0 with temperature was interpreted by the activated complex theory. This theory yields the equation (g)[20]

$$k_0 = (\mathbf{k}T/h) \exp(-E^*/RT)\exp(\Delta S^*/R) \qquad (g)$$

for the specific rate constant of a reaction in solution. In this relation, **k** and h are Boltzmann's and Planck's constants, respectively, and the starred quantities are the internal energy and entropy of activation.

Figure 6 is a plot of log k_0/T *versus* $1/T$. From the slope of the straight line, ΔE^* = 23,500 cal., with an estimated error of the order of ±1000 cal.

Using this value for the activation energy, the values of $(\mathbf{k}T/h)$ exp $(\Delta S^*/R)$ (A in the Arrhenius equation, $k_0 = A \exp(-E^*/RT)$) and of the

entropy of activation listed in Table IX were calculated.

TABLE IX

VALUES OF THE ENTROPY OF ACTIVATION

T	k_0, ml./mole sec.	$(kT/h)\exp(\Delta S^*/R)$	ΔS^*, e. u.
25.00	1.42	2.4×10^{17}	21.2
34.55	5.18	2.67×10^{17}	21.6
44.77	17.66	2.55×10^{17}	21.1
	Av.	2.54×10^{17}	21.3

The frequency factor is about 10^3 times larger than that calculated on the basis of the simple collision theory for a bimolecular reaction.[21] This is to be expected for a reaction between two ions when $z_1z_2 = -2$. For if the results of Scatchard's arguments[22] based on a model of the activated complex consisting of two charged spheres at a distance r apart are used to calculate the contribution (ΔS^*_D) to the entropy of activation due to electrostatic interaction between dielectric medium and charged ion, it is found that

$$\Delta S^*_D = \frac{\epsilon^2 z_1 z_2}{rD}\left(\frac{\partial \ln D}{\partial T}\right)_p$$

Here, ϵ = electronic charge (e. s. u.); z_1,z_2 = charges of reacting ions; D = dielectric constant of medium; T = absolute temperature; p = pressure.[23] For water this yields

$$\Delta S^*_D = -20 z_1 z_2/r \text{ (A) e. u./mole} \qquad \text{(h)}$$

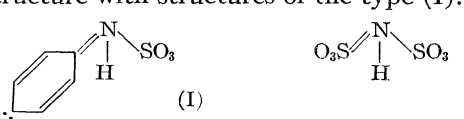
The value of kT/h is 1.7×10^{13} at $T = 298°K.$ Since the collision factor has a value of *ca.* 2.8×10^{14} sec.$^{-1}$ when concentrations are expressed in moles/ml.,[23] a reaction with a "normal" collision factor has an entropy of activation of *ca.* 5.6 e. u. For the reaction in question, we may therefore attribute approximately 15.7 e. u. to the electrostatic interaction, corresponding on the basis of equation (*h*) to a separation of the charges in the activated complex of 2.5 Å. This argument is not presented to prove that in the activated complex, the charges of the reaction ions are separated by exactly 2.5 Å.; it does indicate that it is reasonable to expect a positive entropy of activation of the order of magnitude of that observed.

The Mechanism of the Reaction.—The kinetic evidence indicates that the reaction proceeds via the formation of an activated complex from hydronium ion and amine disulfonate ion which then decomposes to give the reaction products.

$$H_3O^+ + HN(SO_3)_2^- \rightleftarrows (H_3O, HN(SO_3)_2)^-$$

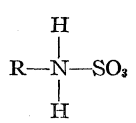
$$H_2O + (H_3O, HN(SO_3)_2)^- \longrightarrow HSO_4^- + H_2NSO_3^- + H_3O^+$$

In speculating about the detailed mechanism of the reaction, it is pertinent to recall that N-alkyl sulfamic acids (*e. g.*, H_3CNHSO_3H) are quite resistant to hydrolysis, but that the N-aryl sulfamic acids (*e. g.*, $C_6H_5NHSO_3H$) have not been prepared because they hydrolyze readily in acid media; salts of the type $C_6H_5NHSO_3Na$ can be prepared.[24] The base strength of the electron pair on the nitrogen in disulfonate or phenylsulfamate is less than that of the corresponding electron pair in methyl sulfamate because the addition of a proton destroys the possibilities of resonance of the normal structure with structures of the type (I).



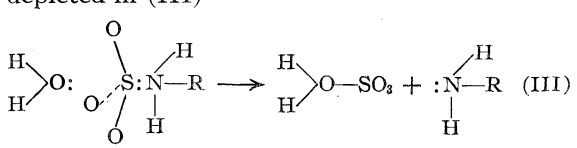
(I)

Consequently an activated complex of the type (II)



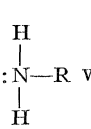
(II)

will exist in smaller concentration for R = C_6H_5 or SO_3 than for R = CH_3. However, in such an activated complex, the attack of a water molecule depicted in (III)



(III)

causes the liberation of



which is stabilized by resonance for R = C_6H_5 or $—SO_3^-$. The experimental evidence indicates that this latter ef-

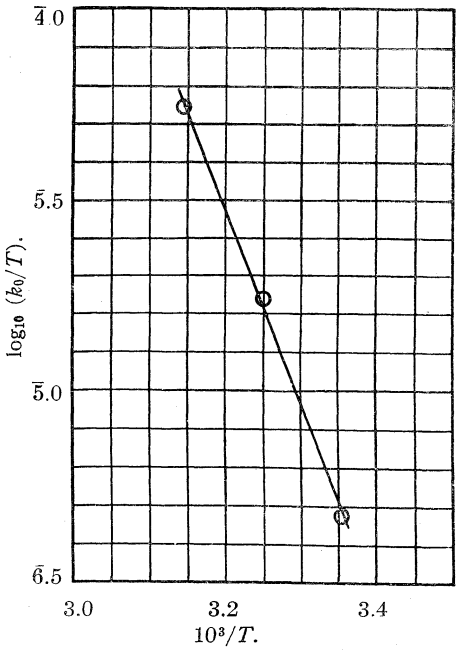


Fig. 6.—The dependence of k_0 on temperature.

(24) Ref. 5, p. 69.

fect is greater than the effect of resonance on the acid strengths of the activated complexes. It is not necessary to think of the addition of a proton and the attack by a water molecule as steps taking place in series; in a single attack by a hydronium ion, the same factors would affect the relative reactivities of disulfonate, N-alkyl and N-aryl sulfamates.

An uncatalyzed reaction with water like (III) would require the liberation of the unstable ion; H |
:N—R and hence does not take place. If the activated complex for the acid catalyzed reaction H

were $HO_3S—\underset{\cdot\cdot}{N}—R$ the same unfavorable factor would affect the reaction.

Acknowledgment.—We are indebted to Professor Don M. Yost for proposing this problem to us. Professors N. Kharasch and S. Winstein of the University of Southern California and The University of California, respectively, have made stimulating suggestions as to the mechanism of the reaction.

Summary

The rate of the acid catalyzed hydrolysis of amine disulfonate ion, $HN(SO_3)_2^=$, in water solution has been studied over the temperature range 25–45°. The results at constant ionic strength conform to the rate equation

$$-d[HN(SO_3)_2^=]/dt = k[H^+][HN(SO_3)_2^=]$$

if the equilibrium between sulfate ion and hydrogen ion is taken into account. The uncatalyzed hydrolysis was found to have an undetectable rate compared to the rate of the acid catalyzed reaction.

The variation of the rate constant with ionic strength implies that the charge product of the ions involved in the rate determining reaction is −2.

The variation of the rate constant at zero ionic strength with temperature is described by the equation

$$k_0(\text{ml./mole} \times \text{sec.}) = 2.54 \times 10^{17} \exp.\ (-23{,}500/RT)$$

The relatively large value of the frequency factor (as compared with that expected on the basis of collision theory for a bimolecular reaction between uncharged molecules) is explained on the basis of a large positive entropy of formation of the activated complex, due to its electrostatic interaction with the solvent.

A mechanism involving an activated complex of amine disulfonate ion and hydronium ion may be invoked to explain these results. A hypothesis to explain the relative stability toward hydrolysis of methyl sulfamic acid as compared with phenyl sulfamic acid or amine disulfonate is advanced.

In addition, the ionization function (classical ionization constant) for the equilibrium: $HN(SO_3)_2^= = H^+ + N(SO_3)_2^{\equiv}$ in a sodium chloride solution at an ionic strength of 1.00 at 25° was measured as 3.2×10^{-9}.

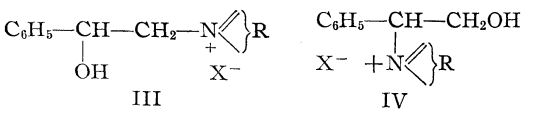
Reactions of 1,2-Epoxides with Salts of Organic Bases. I. Styrene Oxide[1,2]

BY L. CARROLL KING, NEIL W. BERST AND F. N. HAYES

Styrene oxide (I) reacts with strong acid salts of certain organic bases to give a mixture of quaternary salts. For example, I reacted with pyridine hydriodide (II) to give a mixture of 2-phenyl-2-hydroxyethylpyridinium iodide (IIIa) and 1-phenyl-2-hydroxyethylpyridinium iodide (IVa).



III IV

(a) X = I^-; (b) X = Br^-; (c) X = ClO_4^-; (d) X = $^-O_3SC_6H_4CH_3$; R = C_6H_5—

In a series of reactions between I and II the over-all yield of mixed salts was quite constant, with IVa the principal product. The yields of IIIa were consistently low, except in the case where I was in excess. The requisite reaction time was five to ten minutes. Prolonged heating had little effect on the total yield or distribution of isomers except when I was in excess. In this case the products became tarry and the isolable yield of IVa was smaller.

The structure of IIIa was determined by comparison with authentic 2-phenyl-2-hydroxyethylpyridinium iodide, prepared by the method of Krohnke.[3] Further proof was obtained by oxidizing[4] 2-phenyl-2-hydroxyethylpyridinium perchlorate (IIIc), prepared from IIIa, to the known phenacylpyridinium perchlorate.[5] The structure assigned to IVa follows from its non-identity with IIIa and from its formation from the reaction of 2-phenyl-2-iodoethanol[6] with pyridine.

The generality of the reaction was established by allowing I to react with a number of acid salts

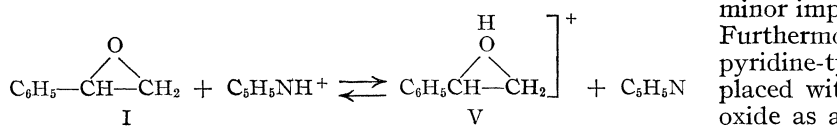
[a] In this table, III and IV refer to the generalized ion as shown in the text. R and X are determined by the salt used in the reaction. [b] Iodide: calcd. 38.9; found, 38.2. [c] This compound was also prepared from 1-phenyl-2-bromoethanol. [d] Iodide: calcd. 38.9; found, 38.4. [e] This compound was also prepared from 2-phenyl-2-iodoethanol. [f] Identical with 1-(2-phenyl-2-hydroxyethyl)-pyridinium perchlorate, synthesized by Krohnke, *Ber.*, **66**, 607 (1933). [g] These salts were not isolated as such. The yields are based on the amount of IVa isolated after metathetical reactions with iodide ion (see experimental). [h] In the first run this compound was obtained in the yield shown by one of us, F. N. H. We were unable to repeat the experiment. The substance is readily obtained by action of β-picoline on 1-phenyl-2-bromoethanol followed by metathetical reaction with iodide ion. [i] Iodide: calcd. 37.2; found, 37.0. [j] When prepared by action of isoquinoline hydriodide on styrene oxide these compounds could not be separated. They were prepared in the yields shown by the reaction of isoquinoline with 1-phenyl-2-bromoethanol followed by metathetical reaction with iodide and from the reaction of isoquinoline with 2-phenyl-2-iodoethanol.

of pyridine and other heterocyclic tertiary amines. The results of these experiments along with the data for the products are listed in Table I. In the reactions employing pyridinium perchlorate and *p*-toluenesulfonate, IIIc and IIId were obtained in much larger yields than IIIa for the analogous reaction using II. Compounds IVc and IVd would not crystallize, but their identity was demonstrated, in each case, by a metathetical conversion to IVa.

Using the pyridinium ion as an example, an initial step in the over-all reaction may be envisioned as an equilibrium partition of a proton between generalized bases.



I V

The ion (V)[7] could then react directly with the base present to form salts of types III and IV, or, V could react with the anion present to form compounds of types VI and VII.[8] Compounds VI and VII could subsequently react with the base to form salts of type III or IV.

VI VII

In connection with this study 2-phenyl-2-iodoethanol (VI, X = I) and 1-phenyl-2-bromoethanol (VII, X = Br) were prepared and their reactions with pyridine type bases were studied. 2-Phenyl-2-iodoethanol reacted with pyridine to give IVa in essentially quantitative yield. No trace of IIIa was observed. Similarly 1-phenyl-2-bromoethanol reacted with pyridine to give IIIb in excellent yield and no IVb could be detected in the reaction mixture. With both halides the time required for complete reaction with pyridine was longer than that required for the formation of the corresponding salts by means of the reaction between styrene oxide and pyridinium salts.

In view of these observations VI and VII are of minor importance in the above reactions. Furthermore when VI or VII react with pyridine-type bases the halogen is displaced without the formation of styrene oxide as an intermediate.

Experimental

Preparation of Starting Materials.—The styrene oxide was a commercial sample; b. p. 66–67° (7 mm.).[9]

The iodide, bromide and perchlorate salts were prepared by mixing the appropriate aqueous acid with a slight excess of the base and evaporating the mixture on the steam-bath. The resulting salt was washed with ether and recrystallized from a suitable solvent. The melting points of the salts and the crystallization solvents were as follows: pyridine hydriodide, m. p. 175–190° (dec.), alcohol; pyridinium bromide, m. p. 215°,[10] alcohol; pyridinium perchlorate, m. p. 289°, water; β-picoline hydriodide, m. p. 87–88°, alcohol; β-picolinium perchlorate, m. p. 40–50°[11]; isoquinolinium perchlorate, m. p. 165–170°, acetone–water.

Pyridinium *p*-toluenesulfonate was prepared directly from pyridine and *p*-toluenesulfonic acid monohydrate. The product was recrystallized from acetone–alcohol, m. p. 117°.[12]

Examples of Styrene Oxide Reactions with Salts. (a) **Pyridine Hydriodide.**—A mixture consisting of 6.0 g.

(7) Kadesch, THIS JOURNAL, **68**, 43 (1946), has suggested that ions such as V undergo ring opening to give carbonium ions. If this should occur the resulting carbonium ions could react with the base present to give products of type III or IV.

(8) The formation of VI or VII, where X is perchlorate, may be assumed to be unimportant because of the poor nucleophilic character of the perchlorate ion. Hammett, "Physical Organic Chemistry," McGraw-Hill Book Company, New York, N. Y., 1940, p. 301. However, because of some known additions of perchloric acid to 1,2-epoxide, an attack by perchlorate ion on V cannot be completely ruled out. Hoffmann, Zedwitz and Wagner, *Ber.*, **42**, 4390 (1909).

(9) We are indebted to the Dow Chemical Company for a generous sample of this substance.

(10) Dehn and Dewey, THIS JOURNAL, **33**, 1596 (1911).

(11) This substance was used without further purification.

(12) Rapoport, THIS JOURNAL, **68**, 341 (1946).

(0.05 mole) of styrene oxide, 8.0 g. (0.1 mole) of pyridine and 10.3 g. (0.05 mole) of pyridine hydriodide was heated on the steam-bath. Within two minutes, the pyridine hydriodide had dissolved and a vigorous reaction began. After the reaction subsided, the mixture was heated ten minutes more, cooled, layered with ether and rubbed with an applicator stick until the entire mass crystallized. The crude mixture of products weighed 13.2 g.

The solid material was leached three times with 75-cc. portions of boiling acetone and the 4.0 g. left was dissolved in 20 cc. of water containing a little alcohol. On cooling, 0.7 g. (4.2%) of a substance melting at 244–252° separated. After recrystallization from water, pure 1-(2-phenyl-2-hydroxyethyl)-pyridinium iodide (IIIa), melting at 252–255°, was obtained.

On cooling the acetone extracts from above, there separated out a compact crystalline product, 8.7 g. (52%),[13] m. p. 125–129°. Recrystallization from acetone gave pure 1-(1-phenyl-2-hydroxyethyl)-pyridinium iodide (IVa), m. p. 128–129°.

(b) **Pyridinium Perchlorate and *p*-Toluenesulfonate.**—As in the previous procedure, high melting acetone-insoluble salts were obtained. However, no crystalline material separated from the acetone extracts, even after concentration. Subsequently, each oil was treated with sodium iodide in acetone. At this point, the pyridinium perchlorate reaction started to deposit crystals. On long cooling of the acetone solution, followed by filtration, a 56% yield of IVa, melting at 128–129° was obtained. The sodium iodide treated acetone solution of the *p*-toluenesulfonate reaction immediately gave a precipitate of sodium *p*-toluenesulfonate. The mixture was heated and filtered. After long cooling, there separated from the filtrate a 52% yield of IVa, melting at 128–129°.

The Oxidation of IIIc to 1-Phenacylpyridinium Perchlorate.—According to the directions of Krohnke,[4] 0.15 g. of 1-(2-phenyl-2-hydroxyethyl)-pyridinium perchlorate (IIIc) in 1 cc. of water was heated under reflux for six hours with 0.5 cc. of 6 *N* sulfuric acid and 0.075 g. of sodium dichromate. On cooling, there separated out long yellow needles, which were filtered off and washed with ice-water. The yellow crystals weighing 0.1 g. (93%), were recrystallized from acetone–water, using norite, yielding white crystals melting at 189°. This material gave no depression in a mixed melting point with an authentic sample of 1-phenacylpyridinium perchlorate prepared in this Laboratory.[5]

Reactions Involving 1-Phenyl-2-bromoethanol.—By heating 1-phenyl-2-bromoethanol[14] with pyridine, on a steam-bath for twenty-four hours, and then washing the product with ether, an essentially quantitative yield of crude 2-phenyl-2-hydroxyethylpyridinium bromide was obtained. An aqueous solution of the bromide on treatment with 48% hydriodic acid gave the corresponding iodide (IIIa); yield 90%; m. p. 252–255°[15] after crystallization from alcohol–water. In a similar manner the following salts were prepared by action of the corresponding bases on 2-phenyl-2-bromoethanol; 1-(2-phenyl-2-hydroxyethyl)-3-picolinium iodide, m. p. 175–177°[15] crystallized from alcohol–water; and 2-(2-phenyl-2-hydroxyethyl)-isoquinolinium iodide, m. p. 173–176° crystallized from alcohol.

No compounds of type IV were observed in any of these reactions.

Reactions Involving 2-Phenyl-2-iodoethanol.—2-Phenyl-2-iodoethanol[6] was heated with pyridine, on a steam-bath for thirteen hours. The resulting reaction mixture was washed with dry ether and the crude crystalline product was recrystallized from acetone; yield, 82%, of 1-(1-phenyl-2-hydroxyethyl)-pyridinium iodide (IVa), m. p. 128–129°[15]; in a similar manner the reaction of 2-phenyl-2-iodoethanol with β-picoline and isoquinoline gave 83% of 1-(1-phenyl-2-hydroxyethyl)-3-picolinium iodide, m. p. 131–132°, and 86% of 2-(1-phenyl-2-hydroxyethyl)-isoquinolinium iodide, m. p. 146–147°.

(13) By reworking all mother liquors including that from which the high melting compound separated, the total yield of IVa, the low melting compound, was 75%.

Summary

1. The reaction of styrene oxide with pyridine hydriodide gives a mixture of salts consisting of 1-phenyl-2-hydroxyethylpyridinium iodide and 2-phenyl-2-hydroxyethylpyridinium iodide.

2. The generality of this reaction was established by allowing styrene oxide to react with a variety of strong acid salts of pyridine and by allowing it to react with salts of a number of pyridine-type bases.

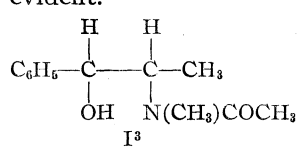
Mechanism and Stereochemical Course of Acyl Migrations in Derivatives of Ephedrine and ψ-Ephedrine

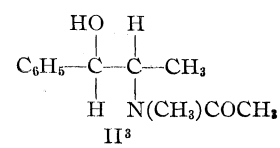
BY LLEWELLYN H. WELSH

It has been reported[1] that treatment of N-acetyl-(−)-ephedrine, I, with hot 5% hydrochloric acid quantitatively yielded a mixture of (−)-ephedrine and its diastereomer, (+)-ψ-ephedrine, in the ratio of 38:62,[2] and that inversion took place at the number one carbon atom during an N → O shift of the acetyl group prior to hydrolysis of the ester salt so formed. Under the same conditions N-acetyl-(+)-ψ-ephedrine, II, gave a product in which complete retention of configuration was evident.



I[3]

erythro configuration



II[3]

threo configuration

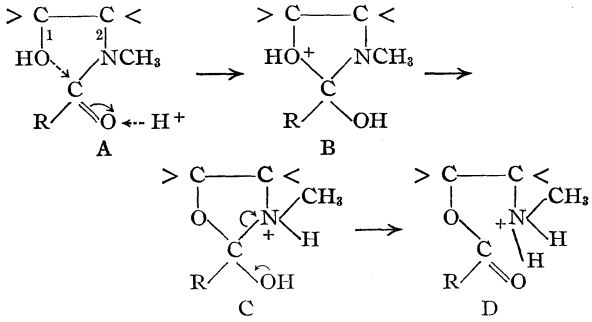
(1) Welsh, THIS JOURNAL, **69**, 128 (1947).

(2) When this reaction is carried out under temperature conditions more closely controlled than those formerly employed, a ratio of 33:67 results

(3) The projection formulas are based on the work of Leithe, *Ber.*, **65**, 660 (1932), and of Freudenberg, *et al.*, THIS JOURNAL, **54**, 234 (1932); *Ann.*, **510**, 223 (1934). Jarowski and Hartung, *J. Org. Chem.*, **8**, 565 (1943), have misinterpreted the publication of Leithe, and are in error when they state that the relative configuration of the methylamino-bearing carbon atom is unsettled.

Stereochemical results similar to these were obtained when the corresponding dry crystalline N-acetyl hydrochlorides[4] were heated at 110°. This similarity of results makes it apparent that hydrolytic cleavage of the amide linkage is not responsible for uninverted material in the product from reactions conducted in aqueous media. It was also reported that the N → O rearrangement of N-acetylephedrine in 90% acetone occurred with predominant retention of configuration.

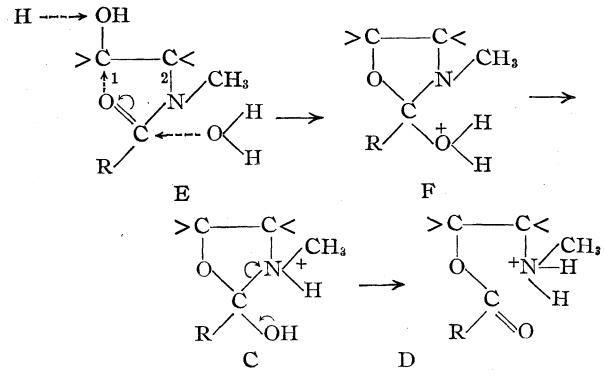
It would seem that two mechanisms are involved in the rearrangements, one leading to inversion, the other to retention of configuration.[5] A mechanism for retention is shown below.[6] Such



Retention (*R*) mechanism

a process would lead to retention of configuration since no bond of the asymmetric center is involved.[7] It is analogous to one used to represent the acid-catalyzed hydrolysis of carboxylic esters.[8] In the rearrangement, the alcoholic hydroxyl, rather than a water molecule, acts as an electron donor to the carbonyl carbon.

A suitable mechanism for inversion, given below, assumes that complete inversion at carbon one would occur as a result of a back-side approach of carbonyl oxygen while a proton attacks the hydroxyl oxygen.[9a,b]



Inversion (*I*) mechanism

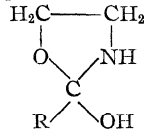
[a] Rotations are in U.S.P. chloroform, $c = 3$ (unless otherwise noted), $l = 2$. [b] Semi-micro Kjeldahl. [c] $c = 4$. [d] Chen, in a review in *J. Am. Pharm. Assoc.*, **15**, 625 (1926), has reported that this compound, m. p. 113°, has been prepared by Nagai. It does not appear to be indexed in the Western literature. [e] $c = 0.9$.

In view of the stereochemical results afforded by rearrangements of the acetylated diastereomers, one must ascribe to the ψ-ephedrine derivatives certain characteristics, inherent in the space relationships in the parent aminoalcohol, which enormously favor rearrangement with retention of configuration, while the relationships in the derivatives of ephedrine must permit rearrangement with either retention or inversion the proportion of which can be influenced relatively easily by variations in experimental conditions.

(4) In these substances the proton is probably linked to the amide oxygen: see Wheland, "The Theory of Resonance," John Wiley & Sons, Inc., New York, N. Y., 1944, p. 181.

(5) At the "Meeting in Miniature" of the Philadelphia Section of the American Chemical Society, January 23, 1948, a paper entitled "Electronic Interpretation of the *p*H-Dependent Acyl Migration in 2-Aminoethanol Systems" was presented by Dr. A. Gero to whom this writer is indebted for a copy of the manuscript. The mechanism proposed for the N → O shift in that paper will not account for rearrangement with inversion of configuration. In some respects it resembles the *R* mechanism presently proposed.

(6) Phillips and Baltzly, THIS JOURNAL, **69**, 200 (1947), have postulated the formation of a hydroxyoxazolidine, corresponding to the cyclic structures in the mechanism presented here.



(7) Retention of configuration may occur in many cases as the result of an even number of inversions as has been explained by Winstein and co-workers in a series of papers which have appeared in THIS JOURNAL since 1942 under the general title of "The Role of Neighboring Groups in Replacement Reactions." It is evident that such an explanation is not applicable to these rearrangements.

(8) Watson, "Modern Theories of Organic Chemistry," second ed., Oxford University Press, London, 1941, p. 130.

(9) (a) Frush and Isbell, *Bur. Standards J. Research*, **27**, 413 (1941), have presented a similar mechanism in explaining the formation of orthoesters, with inversion, from acetohalogen sugars in the Koenigs–Knorr reaction. (b) Fodor, Bruckner, Kiss and Óhegyi, *J. Org. Chem.*, **14**, 337 (1949), in explaining the appearance of O-benzoyl-ψ-ephedrine hydrochloride in some of their experiments on the action of ethanolic hydrogen chloride on racemic N-benzoylephedrine, have assumed that inversion results from the action of the acid on asymmetric center 1 whereby the hydroxyamide of the ψ-ephedrine configuration is formed prior to acyl migration. Such an interpretation cannot be applied to the migrations effected in this Laboratory, since the configuration of ephedrine is almost literally unaffected by the experimental conditions which effect rearrangement and inversion in its N-acyl derivatives[1]; the inversion seems clearly to be the result of a displacement reaction in which a neighboring group, in this case acylamino, participates. See Winstein, *et al.*,[7] also McCasland, Clark and Carter, THIS JOURNAL **71**, 637 (1949).

[a] As one reads down the column, the ortho substituent increases in size; the dissociation constants (K_{th}) $\times 10^5$ of the respective acids are 6.3, 54.1, 8.1, 671, 114, 12.3, 140. [b] Rotations are in U. S. P. chloroform, $c = 3$ (unless otherwise noted), $l = 2$. [c] These percentages are based on the weight of sample and the weight of the hydroxyamide fraction plus the hydroxyamide equivalent of the aminoalcohol hydrochloride fraction. [d] $c = 4$. [e] $c = 0.9$.

To obtain additional information concerning the N → O shift it was decided to investigate reactions in which migrating aroyl groups are involved. For this purpose a series of benzoyl and ortho-substituted benzoyl derivatives were prepared from the diastereomeric aminoalcohols and aroyl chlorides by the Schotten–Baumann reaction. These derivatives, along with analytical data and physical constants, are listed in Table I.

In one series of experiments, the several hydroxyamides were rearranged completely by refluxing with 5% hydrochloric acid. The aminoester salts so formed were rearranged back to hydroxyamides (a process which has not been observed to cause configurational changes[1]) by addition of alkali. Since some hydrolysis of ester salts occurs during the refluxing with acid to yield aromatic acid and parent aminoalcohol, the mixture was subjected to the separation described in the experimental part. The compositions of the hydroxyamide fractions were determined polarimetrically. The proportion of ephedrine and ψ-ephedrine in the basic fractions was determined by thermal analysis. The results of rearrangements conducted thus are summarized in Table II which also includes information on the order of size[10] of the ortho-substituents and dissociation constants[11] of the aromatic acids corresponding to the *o*-substituents.

Consideration of the results in the ephedrine series shows that the presence of an ortho-substituent on the migrating group results in a decided increase in the proportion of molecules rearranging with inversion. In addition, it is evident that among the ortho-derivatives there is no correlation between the electron displacement characteristics of the migrating groups (as measured by the K_{th} of the parent acids) and the per cent. of inversion. On the other hand, although there is a small spread (*ca.* 6%) between the maximum and minimum inversion produced, there is apparently a rough direct relationship between the size of the ortho-substituent and the extent of inversion. The effect of the ortho-substituent can be attributed to its selective steric influence on the elements of the carbonyl group[12] whereby the approach of hydroxyl oxygen to carbonyl carbon in the *R* mechanism is hindered to a much greater degree than is the approach of carbonyl oxygen to carbon one in the *I* mechanism.

From the data in Table II relating to ψ-ephedrine derivatives, one might conclude that the appearance of about 2.5% inversion in rearrangements of the CH_3, Cl and Br derivatives is a result of the proposed *I* mechanism. That the major part, if not all, of this figure is due to another type of reaction is indicated by the appearance of almost 2% inversion as a result of refluxing O-*o*-chlorobenzoyl-ψ-ephedrine hydrochloride with dilute acid for a period of time comparable to that required for rearrangement. How this inversion occurred is not obvious. It is possible that the considerably longer periods of time necessary for complete rearrangement of the CH_3, Cl and Br derivatives are due to their low solubilities or slow rates of solution in the heterogeneous system.

It is evident that the properties peculiar to the ψ-ephedrine configuration which promote rear-

rangement with retention are considerably greater than the ortho-effect which tends to favor rearrangement according to an inversion mechanism.

The reaction velocity of the rearrangement of N-benzoyl-ψ-ephedrine at 30° was investigated by preparing a 95% ethanolic solution approximately 0.1 molar with respect to both hydroxyamide and hydrogen chloride, and following the progress of the reaction by measuring titrimetrically the consumption of acid after various intervals of time. By graphic means (Fig. 1) it was determined that rearrangement proceeds according to second order kinetics over the range studied (0–75%) with a velocity constant of *ca.* 8.2×10^{-1}. The velocity of

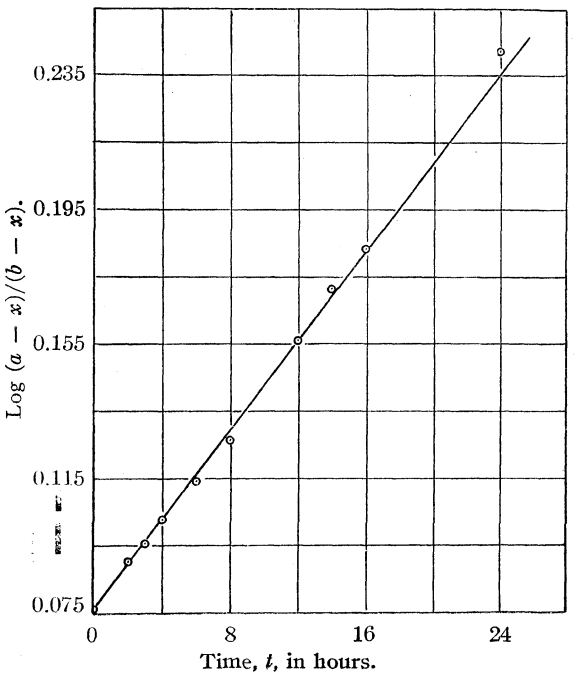

Fig. 1.—Graph showing second order reaction rate for rearrangement of N-benzoyl-(+)-ψ-ephedrine in hydrochloric acid–ethanol: *a* is initial concn. of hydrogen chloride, *b* is initial concn. of hydroxyamide, *x* is concn. of rearrangement product (all in moles per liter).

rearrangement of benzoylephedrine was followed in a similar manner. Although no attempt was made to carry out the rearrangement under controlled temperature conditions (room temperature *ca.* 30–35°) the data are suitable for a rough comparison with those afforded by the ψ-isomer at 30°. Figure 2 graphically illustrates the great difference in speeds of rearrangement of the diastereomers.[13] It was determined that rearrangement proceeds under these conditions with predominant retention of configuration (8–23% inversion).

(13) It is noted that Bruckner, Fodor, Kiss and Kovács, *J. Chem. Soc.*, 885 (1948), report that in the diastereomeric derivatives prepared by them the N → O migration of the acyl group is instantaneous in the nor-ψ-ephedrine compound and does not occur at all in the norephedrine derivative under the same conditions.

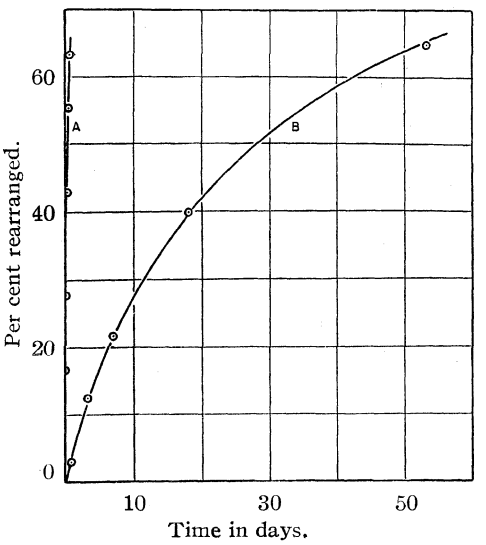

Fig. 2.—Comparison of rearrangement rates of diastereomers in 0.115 *N* ethanolic hydrochloric acid: A, benzoyl-ψ-ephedrine at 30°; B, benzoylephedrine at *ca.* 32°.

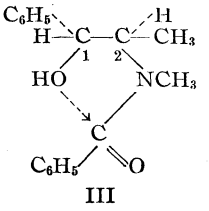
It is not a simple matter to explain the great[14] difference in the velocities of rearrangement of the diastereomers according to a retention mechanism. One would naturally expect the diastereomer having the more basic amide group to show the more rapid reaction rate; if, as has been reported,[15] ψ-ephedrine has about twice the base strength of ephedrine, and this ratio is retained in the amides, then benzoyl-ψ-ephedrine should rearrange at a greater rate than does its diastereomer.

This consideration is believed to be of secondary importance. The major factor responsible for the great difference in rates is attributed to differences in the spatial arrangements of the groups in the diastereomers.[16] Projection formula III, corresponding to structure A of the *R* mechanism, depicts a molecule of benzoyl-ψ-ephedrine at the instant the hydroxyl oxygen and carbonyl carbon atoms are closest to each other prior to actual migration. Formula IV illustrates the same situation in the diastereomer. The two embryonic ring systems are in the plane of the paper and the substituents on carbons 1 and 2 and not in the ring are above this plane where connected to solid lines and below the plane where joined to broken lines. It may be seen that a *trans* relationship exists in

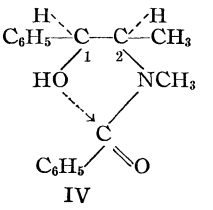
(14) The ratio is of the order of 70:1 if one compares the time required for 50% rearrangement.

(15) Abildgaard and Baggesgaard-Rasmussen, *Dansk. Tids. Farm*, **4**, 30 (1930).

(16) Fodor, *et al.*,[9b] have assumed that for an N → O rearrangement to occur the hydroxyl and methylamido groups must have a *cis* relationship, and that as a result of restricted rotation about the bond between carbons 1 and 2 such a relationship exists in compounds having the ψ-ephedrine configuration, whereas a *trans* relationship of these two groups exists in substances having the configuration of ephedrine. Their conception of restricted rotation obviously is not related to observations on molecular models which correspond to the projection formulas of Leithe and of Freudenberg, *et al.*[3] See also Fodor and Kiss, *Nature*, **163**, 287 (1949).



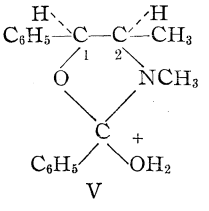
III



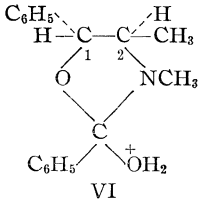
IV

the ψ-ephedrine derivative and a *cis* relationship in the diastereomer. Since a *trans* configuration should be the more equable arrangement of groups under these conditions the ψ-ephedrine configuration might be expected to augment the efforts of the hydroxyl oxygen to approach the carbon atom of the protonated amide group and thus facilitate rearrangement with retention, whereas in the ephedrine series the opposite situation would exist.

In the ψ-ephedrine series, the *R* mechanism would compete with an inversion mechanism in which, by virtue of the displacement occurring at carbon 1, the hydrogen atom and phenyl group must be forced into an orientation which establishes the *cis* relationship shown in formula V which corresponds to cyclic intermediate F in the representation of the *I* mechanism. The virtual absence of inversion in the ψ-ephedrine series may



V

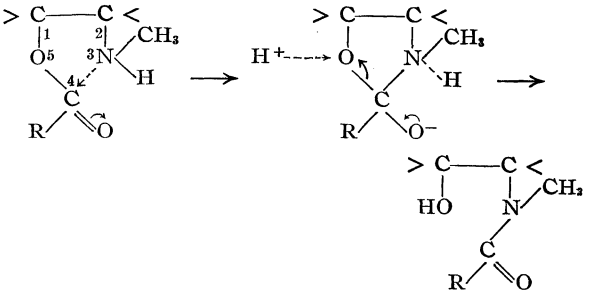


VI

be attributed to the circumstance that the energy required for this phase of the *I* mechanism is relatively high, and that the process must compete with a retention mechanism which is highly favored for reasons previously discussed.

In the ephedrine series, the inversion mechanism requires that a *trans* relationship be established in the intermediate represented by VI and corresponding to F. The displacement leading to this intermediate should be more readily achieved than that which would occur in the ψ-ephedrine series and lead to a *cis* configuration. In the ephedrine series the *I* process is competing with a retention mechanism which is not highly favored according to conclusions which have been presented. If, on this basis, it may be assumed that the two processes do not have widely differing over-all energy requirements, the observed ability of ephedrine derivatives to rearrange with either retention or inversion appears rational.

No additional study has been made in this Laboratory on the influence of various factors on the O → N shift, and no attempt will be made here to correlate the behavior of the numerous esters of aminoalcohols which have been described in the literature and which contain primary or secondary amino groups. This shift, which is not associated with inversion, could occur by the mechanism



The donation of a proton to atom 5 might take place from atom 3 of the same molecule or an adjacent rearranging molecule. In aqueous solution the donation might result from a solvent molecule. The fact that O-acetyl-ψ-ephedrine rearranges at a considerably greater speed than does its diastereomer[1] is attributed to the same factors which have been discussed in connection with the reverse migration.

Investigation of the N → O rearrangement is being continued.

Experimental

Melting points are corrected.

Sources of Aroyl Chlorides.—Benzoyl and *o*-chlorobenzoyl chlorides were obtained from Eastman Kodak Co. The five other halides were prepared from the corresponding ortho-substituted acids and thionyl chloride, and, with the exception of the nitro compound,[17] were purified by vacuum distillation.

o-Fluorobenzoic acid was prepared in 66% yield by substituting the stoichiometric amount of Eastman Kodak Co. *o*-fluorotoluene for *o*-chlorotoluene in the method of preparation of *o*-chlorobenzoic acid described by Clark and Taylor.[18] The *o*-nitrobenzoic acid[19] was Kahlbaum material, and the remainder of the acids were products of the Eastman Kodak Co.

Preparation of the Hydroxyamides.—The aminoalcohol (1.65 g., 10.0 millimoles) was dissolved in 10 cc. of chloroform and acylated by the Schotten–Baumann method with 4 cc. of 20% sodium hydroxide and a solution of 10.0–10.5 millimoles of aroyl halide in 4 cc. of chloroform. The products obtained on removing the solvent were triturated with petroleum ether and filtered off; yields of crude were practically quantitative; twice-recrystallized material averaged 82% of the theoretical. Chlorobenzoyl-ψ-ephedrine was recrystallized from ethylene dichloride. The nitrobenzoyl derivative of the same configuration was dissolved in hot pyridine and precipitated by adding propanol-2. Crude nitrobenzoylephedrine was purified best by dissolving in 10 cc. of hot trichloroethylene and adding 5 cc. of petroleum ether. The rest of the derivatives were first recrystallized by dissolving in hot 95% ethanol (10 cc. was usually used), slowly adding an equal volume of water, and finally chilling the mixture. The derivatives in this group, with the exception of methoxybenzoylephedrine, were given a second recrystallization in which benzene (10–35 cc.) and an equal volume of petroleum ether was used. Methoxybenzoylephedrine is but slightly soluble in benzene, and was therefore recrystallized a second time from ethanol–water.

Rearrangement of Hydroxyamides by Refluxing with Dilute Hydrochloric Acid (Table II).—A sample of the hydroxyamide (2.338–2.415 millimoles) was placed in a 50-cc. standard taper round-bottom flask containing a few

small pieces of carborundum and 5 cc. of water. The mixture was heated under reflux until it gently boiled, then through the condenser 5 cc. of 10% hydrochloric acid (13.7 millimoles) was added from a pipet at such a speed that boiling was not interrupted.[20] The mixture was refluxed until all insoluble matter had disappeared. The time required varied with the hydroxyamide; those which required only a few minutes to form a homogeneous system were refluxed an additional five minutes to ensure complete reaction, whereas the more refractory compounds were refluxed from ten to twenty minutes after solution was complete. Occasionally the ester hydrochlorides crystallized out when rearrangement mixtures were allowed to stand overnight. The condenser and its tip were rinsed with a small amount of water, as was the neck of the flask, and the reaction mixture plus rinsings was made alkaline by adding 3.5 cc. of 20% sodium hydroxide. The heavy oil which precipitated was induced to solidify, and the solid masses were reduced to a coarse powder. The alkaline mixture was allowed to stand at least one hour to ensure that the O → N shift was complete, and was then quantitatively transferred to a separatory funnel by the use of water and U. S. P. chloroform. The system was acidified by the addition of 1.5 cc. of sulfuric acid (50% by weight) and immediately shaken. The separated chloroform layer was washed by shaking with 3 cc. of water in a second separator, and aromatic acid was extracted from the solvent by a subsequent shake-out with 10 cc. of 5% sodium hydroxide in a third funnel. The extract was then filtered through a pledget of cotton wool into a beaker, and the aqueous phases in the three funnels were extracted with an additional five 15- to 20-cc. portions of chloroform which were passed through the train of separators. The combined, filtered chloroform extracts were concentrated to a small volume, transferred to a tared 50-cc. beaker, and evaporated to dryness on the steam-bath in a current of air. Addition of a small quantity of ether to the hydroxyamide residue facilitated the crystallization of any amorphous areas present, and, after removal of this solvent, the vessel was heated one-half hour at 110°, cooled in a desiccator, and weighed. The difference between the weights of sample and recovered hydroxyamide represented the amount of material hydrolyzed. The melting point and specific rotation of the residue were determined.

The aminoalcohol fraction was isolated as the hydrochloride from the aqueous phases in the first and second funnels by a method described elsewhere.[21] After purification by treatment with small amounts of ethylene dichloride–ether, the melting range of the mixture of salts was determined, and the composition was estimated by referring to a temperature–composition diagram. As may be seen in Table II, it was necessary to apply but a slight correction to the inversion found in the hydroxyamide fraction in order to obtain the value for total inversion.

It was not practicable to completely rearrange N-*o*-nitrobenzoyl-ψ-ephedrine under conditions similar to those used on the other compounds probably because of its solubility characteristics. A 370-mg. (1.18 millimoles) sample was refluxed for six hours with about 20 cc. of 5% hydrochloric acid. The unrearranged material was filtered off, and the filtrate was worked up as in the other rearrangements. A hydroxyamide fraction of 43 mg., corresponding to 12% of the sample, was obtained. The melting point (204–205.5°) indicated the presence of a small amount of inverted material.

Originally it was planned to evaluate the stereochemical results of these rearrangements by the procedure used on the acetyl compounds,[1] *i. e.*, after completion of the N → O shift, to effect complete acid hydrolysis of the products by continued refluxing, and determine the composition of the aminoalcohol mixture so obtained. Acid hydrolysis of the mixture of benzoyl ester salts was found to proceed very slowly, however. It was practicable to convert the mixed benzoyl ester salts to hydroxyamides, quantitatively hydrolyze the latter in a 10% solution of sodium hydroxide in 50% ethanol, extract out the mixed aminoalcohols, and ascertain the proportion of inverted material in the mixture of hydrochlorides ultimately obtained. The total inversion figure corresponding to benzoylephedrine in Table II was thus determined; the mixture of hydrochlorides of ephedrine and ψ-ephedrine amounted to 99.1%. Efforts to use alkaline hydrolysis on the *o*-chlorobenzoyl derivatives showed that the substances are resistant to cleavage under these conditions, and no attempts were made to apply the procedure to other ortho-compounds.

Kinetics of Rearrangement of N-Benzoyl-ψ-ephedrine (Fig. 1).—In a 100-cc. volumetric flask was placed 2.598 g. (0.00965 mole) of N-benzoyl-(+)-ψ-ephedrine and 47 cc. of 95% ethanol. After the solid had dissolved, the flask was placed in a constant temperature bath maintained at 29.9 ± 0.2°. After equilibration, 50 cc. of a solution of concentrated hydrochloric acid in 95% ethanol (0.2301 *N* at 30° with respect to hydrogen chloride) was quickly transferred to the flask from another vessel in the bath by means of a pipet; timing of the reaction was started at the beginning of the addition. The mixture was brought up to volume by adding the necessary small amount of ethanol, and was made homogeneous by thorough agitation. As the reaction progressed, 10-cc. aliquots of the solution were pipetted out and transferred to a beaker containing 100 cc. of water which was agitated by a motor-driven stirrer. The time of beginning of addition of the aliquot to the water was taken as the end of a given reaction period. The unconsumed acid in the aqueous dilution was determined by adding standardized 0.1 *N* sodium hydroxide, dropwise and with vigorous stirring, to a methyl red end-point. From these data the concentration of rearrangement product, x, present after each reaction period was calculated. From the figures so obtained for x, and the initial concentration of acid (a, 0.1151 *M*) and of hydroxyamide (b, 0.0965 *M*), the values of the various expressions, $\log a - x/b - x$, were obtained and plotted against the appropriate reaction periods, t (Fig. 1). The best straight line based on the plot corresponded to the equation, $\log (a - x)/(b - x) = 0.006593\ t + 0.0766$, and an average reaction velocity constant of 8.16×10^{-1}. The volume of 0.1 *N* acid theoretically consumed after each reaction period was calculated by use of the equation and may be compared with the experimentally determined consumption in the following sequence in which the first figure is the reaction period in hours and the parenthetical figure is the calculated consumption of acid in cc.: 2, 1.62 (1.55); 3, 2.13 (2.16); 4, 2.68 (2.70); 6, 3.49 (3.58); 8, 4.14 (4.29); 12, 5.34 (5.34); 14, 5.81 (5.74); 16, 6.11 (6.08); 24, 7.16 (7.06). All of the deviations, with the possible exception of that corresponding to the eight-hour period (0.15 cc.), are considered to be within the experimental error of the titrations. The sum of the deviations in the nine determinations equals −0.02 cc.

(20) These are the reaction conditions referred to in footnote (2).

(21) Welsh, *J. Assoc. Official Agric. Chem.*, **30**, 467 (1947); **31**, 528 (1948).

Velocity of Rearrangement of N-Benzoylephedrine.—The progress of the rearrangement of N-benzoyl-(−)-ephedrine was experimentally followed as described above except as regards control of temperature. Facilities were not available for maintaining a regulated temperature over extended periods of time, and the reaction was allowed to proceed at the prevailing temperature of summer heat (within the approximate range of 30–35° and an average of *ca.* 32°). The consumption of acid was calculated in terms of percentage of rearrangement and the results are plotted against time in curve B, Fig. 2. Progress of the rearrangement of N-benzoyl-(+)-ψ-ephedrine is similarly plotted in curve A, Fig. 2.

A 10-cc. aliquot, representing a reaction period of fifty-three and one-third days, was used to determine the stereochemical course of rearrangement of the ephedrine derivative. Titration showed that 168 mg. (64.8%) had rearranged. The titrated solution was taken to dryness at room temperature and dried in a desiccator. The bulk of the residue was transferred to a test-tube, and the remainder was removed by the use of water and a rubber policeman. The rinsings, totaling about 15 cc., were added to the dry material, and the mixture was allowed to stand, with frequent stirring, for one-half hour. It was then filtered, and the undissolved hydroxyamide was washed with an additional 7–8 cc. of water. This fraction of unrearranged material weighed 66 mg., or 25.4% of the sample. The filtrate and washings were acidified with a few drops of hydrochloric acid, and the dissolved unrearranged hydroxyamide was extracted with small portions of ethylene dichloride. The residue of unrearranged benzoylephedrine obtained from the filtered extracts weighed 32.1 mg. (12.3% of the sample). The acidic solution containing aminoester salts was basified with 20% sodium hydroxide (to bring about the O → N shift), allowed to stand one hour, acidified with 50% sulfuric acid, and extracted with chloroform. Each extract was washed with alkali before filtering. The residue of hydroxyamides, representing material which had originally undergone the N → O shift, weighed 143.4 mg., equivalent to 55.2% of the sample or 85.2% of the weight calculated from the titration. It showed $[\alpha]^{20}D$ −31.1° (U. S. P. chloroform, c = 1.2, l = 2) which corresponds to a mixture of diastereomers containing 9.3% of the ψ-ephedrine derivative. The difference between the rearranged material isolated and that calculated from the titration is 24.9 mg., and represents substance lost in one way or another during the various operations. If it represents uninverted hydroxyamide, the minimum inversion produced corresponds to 8% of the rearranged material. If it represents inverted material, the maximum inversion produced is 23%.

O-*o*-Chlorobenzoyl-(+)-ψ-ephedrine Hydrochloride.—This substance was prepared by refluxing *o*-chlorobenzoyl-(−)-ephedrine with 5% hydrochloric acid. The crude product from the chilled reaction mixture was recrystallized from ethyl acetate; the yield of rectangular plates was 83%. The substance is a monohydrate: m. p. (hot stage) 80–85° followed by resolidification and remelting at 131–132°; $[\alpha]^{20}D$ +57.1° (water, c = 3, l = 2).

Anal. Calcd. for $C_{17}H_{18}ClNO_2 \cdot HCl \cdot H_2O$: Cl (ionic), 9.90. Found: Cl (ionic), 9.79.

On undergoing the O → N shift the salt quantitatively yielded the related hydroxyamide, m. p. 162–163°.

A sample was refluxed for six hours with 4.5% hydrochloric acid. Processing the mixture gave a hydroxyamide fraction of 76.9% of the sample weight; $[\alpha]^{20}D$ +101.0° (U. S. P. chloroform, c = 3, l = 2) corresponding to 1.3% inversion in the fraction. The fraction of aminoalcohol hydrochlorides, m. p. 178–182°, was equivalent to 21.3% of the sample; $[\alpha]^{20}D$ + 57.8° (water, c = 0.9, l = 2) representing 4.1% inversion in the fraction. The maximum inversion effected by the hot acid on the ester salt therefore totaled 1.9%.

Acknowledgment.—The author wishes to express his thanks to Dr. G. Forrest Woods of the University of Maryland for his encouraging interest in this work. Helpful discussion with Dr. H. S. Isbell of the National Bureau of Standards also is gratefully acknowledged.

Summary

1. Reaction mechanisms have been proposed to account for the inversion and retention of configuration observed during acyl migrations between nitrogen and oxygen in derivatives of ephedrine and ψ-ephedrine.

2. A series of benzoyl and *o*-substituted benzoyl derivatives of these aminoalcohols has been prepared and subjected to the N → O rearrangement under different conditions. The stereochemical results of the rearrangements have been discussed in terms of the properties of the migrating radicals and the proposed mechanisms.

3. The consistent retention of configuration observed in rearrangements in the ψ-ephedrine series and the ability of ephedrine derivatives to rearrange with either retention or inversion have been interpreted in the light of the different space relationships existing in the diastereomers and on the basis of the proposed mechanisms.

Trifluoromethylated Quinolines

BY ARAM MOORADIAN AND C. M. SUTER

In connection with the study of the antimalarial activity of 7-halo-4-aminoquinolines it seemed of interest to prepare a number of 7-trifluoromethyl-4-dialkylaminoalkylaminoquinolines to determine the effect of replacing the 7-halogen with a trifluoromethyl group. Similar work is described in the patent literature[1] and in a more recent paper[2] wherein 4-(4-diethylamino-1-methylbutylamino)-7-trifluoromethylquinoline and its intermediates are prepared. The present communication describes the preparation and proof of structure for a group of 3-methylquinolines having the trifluoromethyl substituent in the 5- or 7-position and in addition the preparation of 4-(3-diethylamino-2-hydroxypropylamino) - 7 - trifluoromethylquinoline. Furthermore it was confirmed by oxidation of the 4-hydroxy-3-carboxy intermediate to 2-amino-4-trifluoromethylbenzoic acid which was then deaminated to 4-trifluoromethylbenzoic acid, that the trifluoromethyl group is in the 7-position in the compound previously described (I).[1,2] This end-product is a new compound; but since it must be either the 2- or 4-trifluoromethylbenzoic acid, it has been assigned the latter structure, not being similar to the ortho derivative, a previously well characterized compound.[3] Finally the 3-methyl substituted derivatives were prepared by condensing *m*-trifluoromethylaniline with diethyl oxalpropionate and cyclizing the anil to a mixture of 5 and 7-trifluoromethyl-3-methyl substituted quinolines. The compound formed predominantly was the 7-trifluoroquinoline; this was proved by permanganate oxidation to give the 2-amino-4-trifluoromethylbenzoic acid also obtained by oxidation of (I). The structure of the 5-trifluoromethyl derivatives were inferred.

Experimental

4-(4-Diethylamino-1-methylbutylamino)-7-trifluoromethylquinoline (I).—The intermediates used were prepared essentially as described by Snyder.[1] Our poorer yield in the cyclization reaction may be ascribed to the use of mineral oil as a cyclization medium. A mixture of 22.5 g. (1.0 mol) of 4-chloro-7-trifluoromethylquinoline and 31 g. (2.0 mols) of 1-diethylamino-4-aminopentane was heated with stirring for sixteen hours at 150–160°. The reaction mixture was then diluted with four times the theoretically necessary amount of 50% acetic acid. Finally 35% sodium hydroxide solution was added with cooling till the reaction mixture was basic to litmus. The product was extracted thoroughly with a large amount of ether. The ether was evaporated and the residue distilled under high vacuum. Yield was 27.9 g., b. p. 148–154° at 0.01 micron. This sirup soon crystallized to give a non-hygroscopic solid, m. p. 81–83° after trituration with cold Skellysolve A (b. p. 28–38°).

4-(3-Diethylamino-2-hydroxypropylamino)-7-trifluoromethylquinoline (II).—A mixture of 27.4 g. (2 mols) of 3-diethylamino-2-hydroxypropylamine and 21.7 g. (1 mol) of 4-chloro-7-trifluoromethylquinoline was heated on an oil-bath to 140°. At this point heating was stopped but the temperature rose rapidly to 175°. After the temperature had dropped back to 150°, the reaction mixture was kept here for one hour more. The work up was similar to that described with (I). The product distilled at 150° under a pressure of 0.05 micron. The distillate crystallized. It was triturated under Skellysolve A and dried; yield 28.2 g., m. p. 128–129°.

Ethyl 7- and 5-Trifluoromethyl-4-hydroxy-3-methyl-2-quinoline Carboxylates.—To 100 g. (1 mol) of *m*-aminobenzotrifluoride was added 138 g. (1 mol) of diethyloxalpropionate at room temperature. Some heat was evolved. The reaction mixture was kept three days at 40°. It was then washed with 0.5 *N* hydrochloric acid, 0.5 *N* sodium hydroxide solution and finally with water. A yield of 160 g. of red oil which showed some signs of crystallizing resulted. This oil was added over a period of about twenty minutes to 550 cc. of diphenyl ether kept at 260–265° and heating was continued with stirring till no more alcohol was evolved. The reaction mixture was then allowed to cool and the product was filtered off, washed with Skellysolve A and dried; yield 109.5 g., m. p. 172–184°.

The mixture was dissolved in 600 cc. of hot 95% ethanol and cooled. From the alcohol there resulted 87 g., m. p. 199–206°, which upon recrystallization gave 63 g., m. p. 216–217°. Another crystallization did not affect this melting point. This was pure ethyl 4-hydroxy-3-methyl-7-trifluoromethyl-2-quinoline carboxylate.

The alcoholic liquors were diluted with water and the precipitated product filtered and dried. The product was dissolved in 200 cc. of glacial acetic acid and the solution saturated with hydrogen chloride and cooled. This precipitated 16.5 g. of impure 7-isomer. The acetic acid solution was diluted with water and the precipitate filtered and dried to give 23.1 g. of material, melting point 197–201°. After repeated crystallization from toluene 13.3 g. of ethyl 4-hydroxy-3-methyl-5-trifluoromethyl-2-quinoline carboxylate, m. p. 207–209° resulted. A mixed melting point with the 7-isomer gave a 30° depression.

4-(3-Diethylamino-2-hydroxypropylamino)-3-methyl-7-trifluoromethylquinoline (III).—Using the standard procedures of hydrolysis, decarboxylation and chlorination, 4-chloro-3-methyl-7-trifluoromethylquinoline was prepared, and heated with two moles of 3-diethylamino-2-hydroxypropylamine at 150–170° for five hours. The reaction mixture was taken up in 40% acetic acid and brought to a *p*H of 8 with sodium hydroxide. Extraction of this solution with ether gave 28 g. of a solid, m. p. 98–150° after evaporation of the ether. This solid was distilled under a high vacuum and then crystallized from dilute dioxane giving 22.2 g. of product, m. p. 103.5–105.5°.

4-(4-Diethylamino-1-methylbutylamino)-3-methyl-7-trifluoromethylquinoline.—A mixture of 24.5 g. (1 mol) of 4-chloro-3-methyl-7-trifluoromethylquinoline and 31.6 g. (2 mols) of 4-diethylamino-1-methylbutylamine was heated to 160–170° and kept at this temperature for forty-five hours. The reaction mixture was then made alkaline with sodium hydroxide and extracted with ether. Distillation of the ether extract gave 11.0 g. of unreacted chloride and 8.7 g. of product, b. p. 135–140° at two microns, $n^{25}D$ 1.5328.

4-(3-Diethylamino-2-hydroxypropylamino)-3-methyl-5-trifluoromethylquinoline.—The 5-isomer was worked through in a similar manner and the 5-analog of III was prepared. This time the chloride and the base had to be heated together for twenty hours. From 18.3 g. of 4-chloro-3-methyl-5-trifluoromethylquinoline, 11.3 g. of 4-(3-diethylamino-2-hydroxypropylamino)-3-methyl-5-trifluoromethylquinoline resulted as an oil, b. p. 130–135° at 0.1 micron, $n^{25}D$ 1.5522.

2-Amino-4-trifluoromethylbenzoic Acid.—Eleven and four-tenths grams (1 mol) of 4-hydroxy-3-methyl-7-trifluoromethylquinoline was dissolved in 600 cc. of water containing 5 g. of potassium hydroxide at 80°. To this was added a solution of 31.6 g. (4 mols) of potassium permanganate in 800 cc. of water at 65°. The solution was stirred for thirty minutes and then decolorizing charcoal was added and stirring continued for five minutes more. The reaction mixture was filtered through filter-cel and evaporated to 200 cc. This was then made acid to congo with hydrochloric acid to give a product which was filtered off. This product was refluxed with 20 cc. of concentrated hydrochloric acid and 60 cc. of water for three hours and again filtered. The filtrate was acidified with acetic acid and the precipitated product filtered and dried in a desiccator. Recrystallization from benzene gave a product, m. p. 172–174°.

Anal. Calcd. for $C_8H_6F_3NO_2$: C, 46.84; H, 2.95; N, 6.83. Found: C, 46.83; H, 3.40; N, 6.78.

Similarly in the series where the 3-methyl group was lacking 3-carboxy-2-hydroxy-7-trifluoromethylquinoline was oxidized to an acid, m. p. 172–174°, mixed m. p. 172–174°.

4-Trifluoromethylbenzoic Acid.—To a solution of 0.35 g. (1 mol) of sodium nitrite and 0.6 cc. of 35% sodium hydroxide in 10 cc. of water was added 1.06 g. (1 mol) of 2-amino-4-trifluoromethylbenzoic acid. The resulting solution was then added to 2.5 cc. of concentrated hydrochloric acid and 5 g. of ice. This diazo solution was allowed to stand ten minutes and then poured slowly into 7.5 cc. of 95% alcohol containing a small amount of copper sulfate. Soon the reaction mixture became cloudy and crystals were deposited. These were filtered off, dissolved in sodium hydroxide solution, treated with charcoal, and the filtered solution acidified, to precipitate the product which was filtered and dried in vacuum desiccator, m. p. 219–220°.

Anal. Calcd. for $C_8H_5F_3O_2$: C, 50.84; H, 2.65. Found: C, 50.63; H, 2.68.

Summary

A series of 5- and 7-trifluoromethylquinolines have been prepared and their structures proved.

RENSSELAER, NEW YORK RECEIVED MAY 27, 1949

2-Methylcellulose[1]

BY J. M. SUGIHARA[2] AND M. L. WOLFROM

The selective substitution of the hydroxyl group on carbon-2 of carbohydrates has been accomplished by the preparation of 2-methyl-starch by Gaver,[3] of 2-methyl-D-glucose diethyl mercaptal by Lieser,[4] and of 2-methyl-D-glucose and 3-methyl-D-glucose, as derivatives, from a partially methylated cellulose by Heddle and Percival.[5] Lieser[6] has described a methylated cellulose, containing approximately one methoxyl group per two anhydro-D-glucose units, that on hydrolysis yielded 2-methyl-D-glucose, isolated as its phenylhydrazone. Since certain cellulose derivatives of known structure were desired in this Laboratory, the general method described by Gaver[3] was applied to the preparation of a 2-methylcellulose.

It is a commonly accepted fact that hydroxyl groups on carbon atoms α to carbonyl groups are acidic. In the cellulose molecule the hydroxyl group on carbon-2 might be expected to be a stronger acid than the other hydroxyl groups. The reaction of cellulose in an activated form with sodium hydroxide in a near anhydrous medium appeared to justify this assumption. One to 1.2 equivalents of base could be introduced for each anhydro-D-glucose unit. The amount in excess of one was undoubtedly base, not removed by washing and still adsorbed on the cellulose. This appeared probable since the alkali content of those preparations containing more than one equivalent of base per anhydro-D-glucose unit could be reduced to one by suspending at room temperature, the alkali cellulose in anhydrous acetone containing acetyl chloride.

The reaction of the alkali cellulose with methyl iodide occurred with no difficulty. The color of the former, which varied from a light buff to a yellow brown, was in every case removed upon methylation to form colorless, fibrous 2-methylcellulose. The latter had considerable water solubility. This product followed the trend of other methylcelluloses in being less water-soluble at a higher temperature with solubility increasing as the solution was cooled.[7]

To determine the degree of degradation which occurred in the formation of 2-methylcellulose, the cotton linters, the activated cellulose and 2-methylcellulose were nitrated and viscosities were determined by the method of Berl.[8] The calculated degrees of polymerization for the cotton linters, activated cellulose and 2-methylcellulose were 1680, 570 and 88, respectively. The figures are primarily of comparative significance. The nitrate exhibited good film-forming properties.

The structure of 2-methylcellulose was clarified using a degradative procedure. The polymer was methanolyzed in the usual fashion. The methyl D-glucoside mixture obtained was hydrolyzed by acid, and the resultant sugar was converted into the diethyl thioacetal. Crystalline 2-methyl-D-glucose diethyl thioacetal was isolated by a chromatographic technique. No other crystalline compounds were isolable. Control experiments demonstrated that it was possible to detect and to separate small quantities of D-glucose diethyl thioacetal had such been present. Since the methoxyl content of the methylcellulose was 1.03 groups per anhydro-D-glucose unit and since no D-glucose diethyl thioacetal was obtained, the contribution of dimethyl derivatives would not be significant. Therefore, we believe that the cellulose was in all probability uniformly methylated with the methyl group located mainly on C-2 of each anhydro-D-glucose unit.

Experimental

Sodium 2-Cellulosate.—Twenty grams of cotton linters (defatted and bleached) was dissolved in 600 ml. of cuprammonium hydroxide[9] and was regenerated by pouring the viscous solution into 1.5 liters of 6 *N* sulfuric acid. The activated cellulose was filtered and was washed thoroughly with water; yield 192 g. (wet). The water in 96 g. of the wet fibers was replaced by butanol-1. This was accomplished by vigorously stirring the heated suspension while distilling the water–butanol-1 azeotrope, at atmospheric pressure, through a 30-cm. Vigreux column. A solution of 20 g. (8 equivs. per anhydro-D-glucose unit) of sodium hydroxide in 30 ml. of water was added and distillation was continued to remove the additional water. When the temperature at the top of the column reached 100°, distillation was continued for three hours at a rate sufficient to remove any additional water present or formed in the reaction. The alkali cellulose formed was filtered and washed thoroughly with absolute ethanol; yield 10.9 g. (dried in vacuum desiccator over anhydrous calcium chloride).

Anal. Na, 1.08 equivs. per anhydro-D-glucose unit (detd. by suspension in excess standard acid followed by titration with standard base to phenolphthalein endpoint).

2-Methylcellulose.—A suspension of 9.82 g. of the alkali cellulose and 20 ml. of methyl iodide was placed in a bomb tube and heated at 100° for two and one-half hours. The methylated product was treated with sodium hydroxide again as previously described; yield 7.30 g. (dried in vacuum desiccator over anhydrous calcium chloride).

Anal. Na, 0.31 equiv. per anhydro-D-glucose unit (by titer).

An amount of 7.00 g. of the above material was remethylated in a bomb tube with 20 ml. of methyl iodide at 100° for two and one-half hours. The product was

thoroughly washed with acetone and dried (over phosphoric anhydride at 78° *in vacuo*); yield 6.31 g. The fibrous substance showed a significant and reverse solubility in water; it was insoluble in methanol, acetone and chloroform but exhibited some solubility in pyridine.

Anal. Calcd. for $(C_6H_9O_4\text{-}OCH_3)_x$: OCH_3, 17.61. Found: OCH_3, 18.13; Na, 0.04 equiv. per anhydro-D-glucose unit (by titer).

Hydrolysis of 2-Methylcellulose to 2-Methyl-D-glucose Diethyl Thioacetal.—Following the general methanolysis procedure of Irvine and Hirst,[10] 2.3 g. of 2-methylcellulose was methanolyzed for sixty hours at 130° with 50 ml. of methanol containing 0.85% of dry hydrogen chloride. The resultant cooled solution was treated with silver carbonate and activated charcoal and concentrated to dryness under reduced pressure; yield 2.2 g. (85%).

Following the procedure of Haworth, Hirst and Teece,[11] the above glycoside (2.2 g.) was heated in 25 ml. of 2 *N* hydrochloric acid at 85–95° for fourteen hours. The cooled solution was neutralized with silver carbonate, residual silver was removed with hydrogen sulfide and the solution was concentrated to dryness under reduced pressure; yield 1.8 g. (88%).

The above product (1.8 g.) was dissolved at 0° in 2 ml. of concentrated hydrochloric acid (*ca.* 12 *N*) and treated with 2 ml. of ethanethiol. The resultant mixture was maintained at 0° for two hours with stirring. Cold, concentrated ammonium hydroxide (*ca.* 15 *N*) was added at 0° to neutrality and the precipitated solid was removed by filtration. The filtrate was evaporated to dryness under reduced pressure. The residue was repeatedly extracted with chloroform. Solvent removal left a semi-solid product which was combined with the initially precipitated material and treated with activated charcoal in methanol solution; yield 2.1 g. (76%). The ammonium chloride residue contained a negligible amount of organic material as determined by acetylation and extraction of the acetates formed.

An amount of 180 mg. of the above crude thioacetal was dissolved in 25 ml. of warm chloroform (containing 0.5% ethanol), and placed at the top of a column (200 mm. × 35 mm. diam.[12]) of acid-washed Magnesol–Celite.[13]

A mixture of 5 parts (by wt.) of Magnesol and 1 part of Celite was suspended with efficient stirring in a solution composed of 1 part (by vol.) of concentrated hydrochloric acid and 3 parts of water. The amount of Magnesol–Celite added to the diluted acid was regulated so that a very thin paste resulted. After stirring for sixty minutes, the slurry was filtered and washed free of chloride ion (to silver nitrate) with water and the water was displaced with acetone. The material was dried at room temperature overnight and then for two hours at 110°. The adsorbent was cooled, and only that portion which passed a 200-mesh (per linear inch) sieve was used in the chromatography as described. The chromatogram was developed with 350 ml. (5 column lengths) of 30:1 (by vol.) chloroform (containing 0.5% by vol. ethanol)–*t*-butyl alcohol and streaked with alkaline permanganate indicator.[14] The material in the main zone, located about one-third of a column length from the top, was eluted with 50 ml. of methanol; yield 93 mg. (52%), m. p. 115–125°, $[\alpha]^{25}D$ −18° (*c* 1.82, pyridine). This was recrystallized from methanol; yield 69 mg., m. p. 155–156° (unchanged on admixture with an authentic specimen of 2-methyl-D-glucose diethyl thioacetal of m. p. 154.5–155.5°), $[\alpha]^{23}D$ −25° (*c* 1.51, pyridine). The accepted constants[15] for this substance are: m. p. 156–157°, $[\alpha]^{20}D$ −25° (*c* 1.49, pyridine).

A zone appearing at the top of the column was eluted to yield a sirup; yield 24 mg. The effluent also gave a sirup; yield 4.9 mg. Both of the sirups failed to crystallize even when rechromatographed.

In a model experiment, 100 mg. of an equal mixture of D-glucose diethyl thioacetal and 2-methyl-D-glucose diethyl thioacetal was chromatographed as described above. Two zones formed, separated by a distinct though narrow interzone. The upper zone, located about one fourth of a column length from the top, contained the D-glucose diethyl thioacetal.

Action of Acidic Reagents on 2-Sodium Cellulosate.—An amount of 1.023 g. of alkali cellulose (Na, 1.24 equivs. per anhydro-D-glucose unit) was suspended in 4 ml. of acetyl chloride and 50 ml. of anhydrous acetone at 25° for three hours. The fibers were filtered and thoroughly washed with absolute ethanol; yield 1.013 g.

Anal. Na, 1.01 equivs. per anhydro-D-glucose unit (by titer).

An amount of 1.460 g. of alkali cellulose (Na, 1.25 equivs. per anhydro-D-glucose unit) was suspended in 7 ml. of acetic anhydride and 50 ml. of anhydrous acetone under reflux for five hours; yield 1.445 g.

Anal. Na, 1.09 equivs. per anhydro-D-glucose unit (by titer).

Viscosity Determinations.—Cotton linters, the cuprammonium activated cellulose and 2-methylcellulose were nitrated using the method described by Berl.[8] The nitrates were dissolved in *n*-butyl acetate, and the viscosities were measured in an Ostwald viscometer. The nitrate of the 2-methylcellulose could be cast into films. The times of flow in minutes at 25° were as follows: nitrated linters (12.9% N; *c*, 0.025; d^{25}_4, 0.871), 2.923; nitrated activated linters (12.4% N; *c*, 0.250; d^{25}_4, 0.873), 5.130; nitrated 2-methylcellulose (8.4% N; *c*, 0.224; d^{25}_4, 0.872), 2.432; solvent (d^{25}_4, 0.871), 2.001. Employing the formula of Staudinger and Mohr,[16] $K_m = 11 \times 10^{-4}$, the degrees of polymerization found were 1680, 570 and 88, respectively.

Acknowledgment.—This work was supported by the Ordnance Department under contract (W-33-019ord-6279; supervising agency, Ballistic Research Laboratories, Aberdeen Proving Ground, Maryland) with The Ohio State University Research Foundation. We wish to acknowledge the assistance of Mr. E. E. Dickey and Mr. H. C. Prosser.

Summary

Activated cotton linters reacted with sodium hydroxide in a nearly anhydrous medium to form an alkali cellulose, which reacted with methyl iodide to yield a methylcellulose (D. P. *ca.* 100 by nitrate viscosity) containing 1.03 methoxyl groups per anhydro-D-glucose unit. That the methylation was effected largely on C-2 results from the fact that methanolysis of the polymer followed by hydrolysis and mercaptalation yielded 2-methyl-D-glucose diethyl mercaptal as the only chromatographically isolable crystalline product.

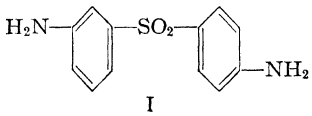
α-(4-Aminophenylsulfonyl)-acetophenone Derivatives[1]

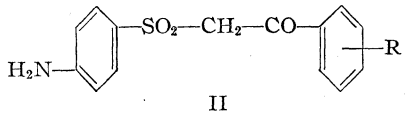
BY PRICE TRUITT, RICHARD STEAD,[2] LOREN M. LONG[3] AND WILLIAM J. MIDDLETON[4]

Numerous attempts have been made to decrease the toxicity of the tuberculostatic compound, 4,4′-diaminodiphenyl sulfone, I.[5-10]

Markees and Burger[11] have reported that the replacement of the sulfone linkage of Promizole with the cyclopropyl group led to a compound active against *M. tuberculosis* in Dubos' medium. Thus, it appears that the $-SO_2-$ linkage in some of the antitubercular sulfones can be replaced by other groups without destroying its activity. However, little work has been carried out to find the effect on the physiological activity that would be produced by replacing this sulfone linkage by other sulfone bearing groups. The present paper is a report of the synthesis of a group of compounds differing from the diaminodiphenyl sulfones in that the $-SO_2-$ group has been replaced by $-SO_2-CH_2-CO-$ as shown by comparing formula I with II.



I



II

Alkaline cleavage of these phenacyl phenyl sulfones has also been studied. It is noted that these keto sulfones could theoretically be hydrolyzed to yield a benzoic acid and a methyl sulfone or an acetophenone and a sulfonic acid. α-Phenylsulfonylacetophenone, gave a 97% yield of benzoic acid; however, only 75% of the methyl phenyl sulfone could be isolated. α-Phenylsulfonyl-4-chloro-acetophenone gave a 90% yield of *p*-chlorobenzoic acid; α-(4-nitrophenylsulfonyl)-acetophenone gave only a 64% yield of benzoic acid; α-phenylsulfonyl-2-acetonaphthone gave 65% yield of 2-naphthoic acid. The kinetics of these hydrolyses are now under investigation in this Laboratory.

Five of the sulfones reported in this paper have been tested for activity against tuberculosis but none showed appreciable activity, as compared to 4,4′-diaminodiphenyl sulfone.

Experimental

4-Nitroacetophenone.—A solution of 3.6 g. (0.087 mole) of diazomethane and 5 g. (0.027 mole) of 4-nitrobenzoyl chloride in dry ether at 0°. The reaction of this diazo ketone with hydriodic acid gave 2.1 g. of product, m. p. 80°. Barkenbus and Clements[12] prepared this compound by another method and reported it to melt at 80–81°.

4-Nitrophenacyl Chloride.—This compound was prepared by the action of concentrated hydrochloric acid on 4-nitrophenyl diazomethyl ketone. The same quantities of reagents as in the previous preparation gave 1.8 g. of 4-nitrophenacyl chloride, m. p. 107°.[13]

α-(4-Nitrophenylmercapto)-acetophenone, Table I. Procedure A.[14]—A solution of 40.1 g. (0.334 mole) of acetophenone in 100 cc. of carbon tetrachloride was added to a solution of 4-nitrophenylsulfenyl chloride,[15] m. p. 94–95°, obtained from 50 g. of 4,4′-dinitrodiphenyl disulfide. After refluxing four hours, a yellow granular solid separated and was filtered. Recrystallization gave the desired mercapto compound.

Procedure B.[16]—A suspension of 0.25 mole of sodium 4-nitrothiophenolate in 300 cc. of dry benzene was cooled to 0° and 38.6 g. (0.25 mole) of phenacyl chloride in dry ether was added dropwise. The temperature was kept below 10° during the addition. After removal of the sodium chloride, concentration of the filtrate gave yellow crystals.

The remaining compounds of this type, were prepared by one of these methods and the pertinent data recorded in Table I.

α-(4-Nitrophenylsulfonyl)-acetophenone, Table II.—To a suspension of 20 g. of α-(4-nitrophenylmercapto)-acetophenone, in 200 cc. of glacial acetic acid and 50 cc. of acetic anhydride at 80° was added dropwise 50 cc. of 30% hydrogen peroxide. The light yellow solid which separated on dilution with water was filtered and recrystallized from a chloroform–hexane solution.

The oxidations of the various sulfides were carried out in the same manner and the data recorded in Table II.

α-(4-Aminophenylsulfonyl)-acetophenone, Table III.—To a suspension of 6.1 g. (0.2 mole) of α-(4-nitrophenylsulfonyl)-acetophenone, in 100 cc. of water was added 15 g. of iron powder and 0.1 cc. of glacial acetic acid and the mixture stirred at 85–90° for ten hours. The product was extracted from the insoluble filter cake by means of hot alcohol or acetone. Recrystallization from ethanol gave very light tan flakes.

The reduction of the other nitro sulfones was fashioned in the same manner, except in one instance (see note *b*, Table III) catalytic reduction was used instead of the iron reduction and the yield from this reduction with hydrogen and Raney Ni catalyst gave almost twice as good a yield and the product had a better appearance. However, the amino compound from each procedure had the same melting point.

The data for all the corresponding compounds are recorded in Table III.

Hydrolysis of α-Phenylsulfonylacetophenone.—A mixture of 2.63 g. (0.01 mole) of α-phenylsulfonylacetophe-

[a] The preparation of this compound was described in a recent patent by F. Bergel, A. Morrison, A. R. Moss and H. Rinderknecht, British Patent 601,329, May 4, 1948. These workers prepared this compound by the method described by Troeger and Beck, *J. prakt. Chem.*, [2] **87**, 299 (1913). The reaction involves the interaction of substituted phenacyl chlorides with substituted sodium benzenesulfenates. This patent states that the above compound melted at 227°. We found that this substance melted at 230° [b] The phenyl ring with the R group is replaced by 2-naphthyl and R is hydrogen. [c] Catalytic reduction with Raney nickel and hydrogen at 40 pounds pressure. Iron reduction gave only 44% yield and the product was slightly reddish and this color could not be removed.

none and 11.51 cc. of 0.877 molar potassium hydroxide (0.01 mole) was refluxed for 100 minutes. The reaction solution was diluted to 200 cc. with water, cooled and extracted four times with 50-cc. portions of ether. Evaporation of this ether extract gave 1.207 g. of ether soluble product, m. p. 85°. Recrystallization raised the melting point to 87°. Acetophenone melts at 88°. This yield represented 74% of the theoretical.

The aqueous solution obtained after ether extraction was acidified and the insoluble precipitate weighed 1.19 g. and melted at 121.5° without recrystallization. Benzoic acid melts at 122°. This represents a yield of 97% of the theoretical of benzoic acid.

Hydrolysis of α-(4-Nitrophenylsulfonyl)-acetophenone.—Hydrolysis of 3.00 g. (0.0098 mole) of α-(4-nitrophenylsulfonyl)-acetophenone gave 0.50 g. of benzoic acid, 62% of theoretical, m. p. 119°.

Hydrolysis of α-(4-Nitrophenylsulfonyl)-2-acetonaphthone.—Hydrolysis of 2.1 g. (0.006 mole) of α-(4-nitrophenylsulfonyl)-2-acetonaphthone according to the pre-

vious procedure gave 0.66 g., 65%, of 2-naphthoic acid, m. p. 183°. 2-Naphthoic acid is recorded as melting at 185°.

Hydrolysis of α-(4-Nitrophenylsulfonyl)-4-chloro-acetophenone.—Hydrolysis of 2.34 g. (0.007 mole) of this compound gave 0.97% g., 90% of 4-chlorobenzoic acid, m. p. 238. The literature gives the melting point of this compound as 243°.

Summary

The synthesis of eight α-(4-nitrophenylmercapto)-acetophenones has been accomplished by one of two procedures and in some instances by both procedures. Each of the mercapto compounds was subsequently oxidized to the sulfone, then followed by reduction to the corresponding α-(4-aminophenylsulfonyl)-acetophenone.

None of the compounds tested were found to be active against tuberculosis.

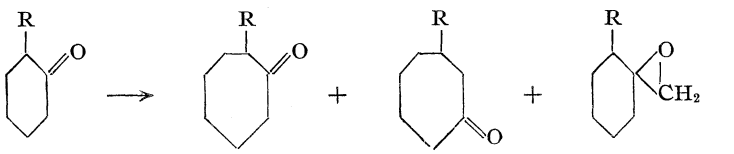
Ring Enlargements. I. The Ring Enlargement of 2-Chlorocyclohexanone and 2-Phenylcyclohexanone

BY C. DAVID GUTSCHE

The ring enlargement of carbocyclic ketones by means of diazomethane has received occasional attention in the two decades since Mosettig and Burger[1] found that cyclohexanone could be smoothly converted to cycloheptanone through the action of this reagent. The synthetic value of these reactions, however, has been largely confined to the ring enlargement of symmetrical ketones, for unsymmetrically substituted ketones often yield mixtures of products.[2] The ratio of isomers present in such mixtures has in no case been accurately ascertained, as a consequence of which considerable confusion exists concerning the course of certain ring enlargements. The present communication discusses the ring enlargement of two 2-substituted cyclohexanones, (Ia) and (Ib), for which the ratio of isomers produced has been determined with fair accuracy.



Ia (R = Cl) IIa (R = Cl) IIIa (R = Cl) IVa (R = Cl)
Ib (R = C_6H_5) IIb (R = C_6H_5) IIIb (R = C_6H_5) IVb (R = C_6H_5)

Ring Enlargement of 2-Chlorocyclohexanone (Ia).—The reaction of Ia with ethereal diazomethane was reported by Giraitis and Bullock[3] in a Communication to the Editor which has not been followed by a fuller exposition of their work. These experimenters claimed that the product from this reaction was pure 2-chlorocycloheptanone (IIa) and that it was obtained in practically quantitative yield. Steadman,[4] using Meerwein's[5] procedure for conducting diazomethane ring enlargements, later showed that chlorocycloheptanone was produced in only 50–60% yield and that the isomeric oxide (IVa) accounted for at least 16% of the product. Steadman sought to prove the structure of the former by the base-catalyzed conversion to cyclohexanecarboxylic acid (VI), a reaction characteristic of cyclic 2-chloroketones.[6] From the chlorocycloheptanone fraction he obtained, upon treatment with alcoholic sodium hydroxide, a 36% yield of "somewhat impure" VI which was identified by conversion to the known amide. The relatively low yield of VI was not rationalized and, as will be shown below, was actually due to the fact that the chlorocycloheptanone fraction consisted of a mixture of the 2- and 3-chloro compounds.

2-Chlorocyclohexanone was treated with nitrosomethylurethan according to the directions of Steadman[4] and his reported yields were duplicated. Two reactions characteristic of the 2-chloroketo grouping were carried out with the chlorocycloheptanone fraction, and the results were compared with the same reactions in which authentic IIa was used as the starting material. In both reactions the material from the ring enlargement resembled the authentic 2-chloroketone qualitatively but not quantitatively. Authentic IIa could be converted by treatment with thiourea to 2-amino-4,5,6,7-tetrahydro-4-cycloheptathiazole, V, in 72% yield whereas the product of ring enlargement produced V in only 17.5% yield. Thus, on the basis of these data, the product of ring enlargement is indicated to consist of 24% of IIa and 76% of IIIa. This ratio of isomers was closely substantiated in the base-catalyzed conversion of the chloroketone to cyclohex-

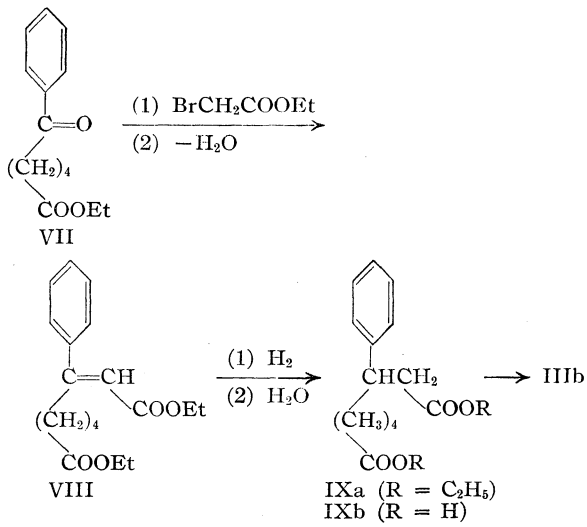
anecarboxylic acid (VI). The authentic material yielded VI in 69% yield whereas the ring enlargement product formed VI in only 15% yield. From these data the product of ring enlargement is indicated to consist of 22% of IIa and 78% of IIIa. That the product resulting from the treatment of IIa with potassium carbonate was indeed VI instead of 2-hydroxycycloheptanone, as previously reported by Kötz and his co-workers,[7] was proved by conversion to the known amide of VI. Meerwein[8] has also cited this inconsistency in Kötz' data.

Steadman[4] subjected the chlorocycloheptanone obtained by ring enlargement of Ia to further reaction with nitrosomethylurethan and obtained a product to which the structure of 2-chlorocyclooctanone was assigned, the proof again depending upon a ring contraction to cycloheptanecarboxylic acid for which no yields were given. In view of the results of the present work it is quite probable that this chlorocycloöctanone was a mixture of the 2-, 3- and 4-chloro isomers containing very little of the 2-chloro isomer.

Ring Enlargement of 2-Phenylcyclohexanone (Ib).—The ring enlargement of Ib, which has not been previously carried out, was effected by two methods but only the diazomethane method was carefully investigated. A smooth reaction took place between Ib and nitrosomethylurethan in the presence of methanol and potassium carbonate, and fractional distillation of the product yielded two main fractions. The lower boiling material, obtained in 21.5% yield, was identified as 4-phenyl-1-oxaspiro[2,5]octane[9] (IVb) from its failure to react with semicarbazide and from its reaction with piperidine to form an amino alcohol. The higher boiling fraction, representing a 49.5% yield, had an analysis compatible with phenylcycloheptanone and formed a semicarbazone in quantitative yield. The semicarbazone, however, melted over a wide range and consisted of a methanol-soluble and a methanol-insoluble component. From the latter there was obtained a pure semicarbazone which was shown to be identical with that of IIIb. The methanol-soluble fraction was difficult to purify but finally yielded a semicarbazone identical with that of IIb. The presence of IIb was also demonstrated by the isolation from the higher boiling fraction of a 2,4-dinitrophenylhydrazone identical with that from IIb.

The most apparent method for the determination of the isomer ratio in the phenylcycloheptanone series depended upon a comparison of the physical characteristics of the mixture with pure IIb and IIIb. 2-Phenylcycloheptanone (IIb) had previously been prepared by Tiffeneau and his co-workers[10] by the isomerization of 1-phenyl-1,2-epoxycycloheptane. However, a less equivocal method, previously employed for the preparation of other 2-substituted cycloheptanones[2,3] appeared to be the ring enlargement of cyclohexanone by means of phenyldiazomethane. Thus, when a mixture of cyclohexanone, methanol and potassium carbonate was treated with nitrosobenzylurethan a smooth reaction took place to yield 26% of IIb. 3-Phenylcycloheptanone, IIIb, hitherto unknown, was synthesized from ethyl δ-benzoylvalerate (VII) in 23% over-all yield according to the method indicated below.



The ratio of the isomers IIb and IIIb in the mixture produced by diazomethane ring enlargement of Ib was most satisfactorily ascertained by infrared analysis.[11] By a quantitative comparison at several wave lengths of the absorptions of IIb, IIIb, and the mixture an average value was obtained (maximum deviation ±3%) which indicated the mixture to contain 81% of IIb and 19% of IIIb. The refractive indices also reflected this isomer ratio. That of the mixture (1.5387) indicated about 75% of IIb (1.5389) and 25% of IIIb (1.5380).

A second method of ring enlargement of Ib was investigated and found to produce a mixture from which the semicarbazone of IIIb could be isolated. 2-Phenylcyclohexanone (Ib) was converted with hydrogen cyanide to 1-cyano-1-hydroxy-2-phenylcyclohexane (X). Hydrogenation to the amino alcohol (XI) followed by treatment

with nitrous acid gave a product containing approximately 84% of ketonic material which was a mixture probably containing IIb and IIIb. The semicarbazone of IIIb was isolated in a pure form but the residual semicarbazone could not be purified.

Acknowledgment.—We gratefully acknowledge a generous Research Corporation grant which has made possible the purchase of certain equipment necessary for this work. We are indebted to Dr. Ralph H. Munch for performing the infrared measurements and quantitatively interpreting the infrared data and to Dorothy Kuenne for performing the micro-analyses.

Experimental[12]

Diazomethane Ring Enlargement of 2-Chlorocyclohexanone (Ia).—The directions of Steadman[4] were precisely followed. From 76.0 g. of freshly distilled 2-chlorocyclohexanone, 57 cc. of methanol, 1.0 g. of finely powdered sodium carbonate and 84 g. of nitrosomethylurethan there was obtained, after fractionation through a thirty-four inch, glass helix-packed column, 12.1 g. (14%) of 4-chloro-1-oxaspiro[2,5]octane (IVa), b. p. 70–75° (14 mm.), 43.1 g. (51%) of chlorocycloheptanone, b. p. 92–95° (14 mm.), and 26.2 g. (32%) of an intermediate fraction, b. p. 75–90° (14 mm.). The major portion of the chlorocycloheptanone fraction had a b. p. of 94–95° (14 mm.), $n^{25}D$ 1.4824, and the following analysis.

Anal. Calcd. for $C_7H_{11}ClO$: C, 57.34; H, 7.56; Cl, 24.18. Found: C, 57.22; H, 7.57; Cl, 23.92.

2-Amino-4,5,6,7-tetrahydro-4-cycloheptathiazole (V). (a) **From Authentic 2-Chlorocycloheptanone.**—Cycloheptanone[13] was converted in 52% yield to 2-chlorocycloheptanone (b. p. 94–96° at 14 mm.; $n^{25}D$ 1.4836) by the method described for the chlorination of cyclohexanone.[14] When a 1.00-g. sample of this material was treated with 0.52 g. of finely powdered thiourea and the mixture heated on the steam-bath for two hours, 1.49 g. (98%) of an almost colorless solid was obtained. This was dissolved in water (completely soluble), the solution made basic with potassium hydroxide, and the thiazole extracted into benzene. Evaporation of the benzene left 0.82 g. (72%) of orange colored material; m. p. 65–70° (previous softening). Sublimation at 95° (0.05 mm.) followed by two recrystallizations from hexane containing a few drops of benzene yielded colorless, glistening prisms; m. p. 76.5–77.5°. Erlenmeyer and Schoenauer[15] prepared the hydrochloride of V but did not convert it to the free base.

Anal. Calcd. for $C_8H_{12}N_2S$: C, 57.10; H, 7.19. Found: C, 57.08; H, 6.98.

(b) **From Chlorocycloheptanone Obtained by Ring Enlargement of 2-Chlorocyclohexanone.**—A 1.00-g. sample of the chlorocycloheptanone obtained by ring enlargement of 2-chlorocyclohexanone was treated with thiourea as described above. The red-brown product failed to solidify upon cooling and was only partially soluble in water. From the water-soluble portion there was obtained 0.20 g. (17.5%) of a material which solidified when seeded with authentic thiazole (V). The water-insoluble, benzene-soluble portion amounted to 0.80 g.

Cyclohexanecarboxylic Acid (VI): (a) **From Authentic 2-Chlorocycloheptanone.**—A 5.00-g. sample of authentic 2-chlorocycloheptanone was treated with 20 cc. of water and 15 g. of potassium carbonate.[7] The mixture was stirred rapidly and heated at reflux for six hours and the product then separated into acidic and neutral fractions in the usual manner. From the acidic fraction there was obtained 3.00 g. (69%) of material melting at 22–26° from which an amide melting at 183–184° was prepared. Cyclohexanecarboxylic acid is reported to melt at 29° and its amide at 184°.[16] The neutral fraction amounted to 0.76 g.

(b) **From Chlorocycloheptanone Obtained by Ring Enlargement of 2-Chlorocyclohexanone.**—A 5.00-g. sample of the chlorocycloheptanone obtained by ring enlargement of 2-chlorocyclohexanone was treated in the same fashion as described above to yield 0.65 g. (15%) of VI and 2.91 g. of a neutral, viscous oil.

Diazomethane Ring Enlargement of 2-Phenylcyclohexanone (Ib).—In a three-necked flask fitted with a stirrer, reflux condenser and dropping funnel was placed 50 g. (0.287 mole) of 2-phenylcyclohexanone,[17] 150 cc. of methanol and 2 g. of finely powdered potassium carbonate. To the rapidly stirred suspension there was added, over a period of two hours, 43 g. (0.296 mole) of nitrosomethylurethan, the reaction temperature being held at 25–30° by means of a water-bath. After the addition of nitrosomethylurethan was completed, stirring was discontinued and the reaction mixture was allowed to stand at room temperature for ten hours. The potassium carbonate was

then removed by filtration, the volatile products evaporated under vacuum on the steam-bath and the residue fractionally distilled through a thirty-four inch, glass helix-packed column. The eight fractions collected were combined as follows: (a) 11.6 g. (21.5%), b. p. 114–117° (2.5 mm.), (b) 1.7 g., b. p. 117–123° (2.5 mm.), (c) 6.7 g., b. p. 123–131° (3 mm.), (d) 26.7 g. (49.5%), b. p. 131–133° (3 mm.).

4-Phenyl-1-oxaspiro[2,5]octane (IVb).—Fraction a from the diazomethane ring enlargement of 2-phenylcyclohexanone solidified after standing several hours, m. p. 53–55° after pressing on a porous plate. Two recrystallizations from petroleum ether (30–60°) gave the oxide (IVb) as colorless, large cubes, m. p. 60.5–62°.

Anal. Calcd. for $C_{13}H_{16}O$: C, 82.93; H, 8.57. Found: C, 82.87; H, 8.39.

The piperidino derivative of IVb was prepared by refluxing a 1.85-g. sample from fraction a with 2.0 cc. of piperidine for two and one-half hours and then allowing the mixture to stand at room temperature for two days. When a benzene extract of this reaction mixture was shaken with dilute hydrochloric acid there precipitated 1.60 g. of a white solid. This was removed by filtration and recrystallized twice from benzene containing a few drops of methanol to yield colorless, fine needles of the hydrochloride of the piperidino derivative of IVb, m. p. 225–226° (some previous softening).

Anal. Calcd. for $C_{18}H_{28}ClNO$: C, 69.76; H, 9.11. Found: C, 69.60; H, 9.06.

The crude free base, obtained by neutralization of the hydrochloride described above, was molecularly distilled at 100° (0.02 mm.) to yield a yellow oil which solidified after standing several hours. Recrystallization from petroleum ether (30–60°) cooled in an acetone–Dry Ice-bath yielded colorless crystals; m. p. 39–40°.

Anal. Calcd. for $C_{18}H_{27}NO$: C, 79.07; H, 9.95. Found: C, 79.09; H, 9.70.

Phenylcycloheptanones (IIb and IIIb) from Diazomethane Ring Enlargement of 2-Phenylcyclohexanone.—Fraction *d* from the diazomethane ring enlargement of 2-phenylcyclohexanone crystallized when it was cooled in an acetone–Dry Ice mixture and seeded with pure, crystalline 2- or 3-phenylcycloheptanone; m. p. 0–17°, $n^{25}D$ 1.5387.

Anal. Calcd. for $C_{13}H_{16}O$: C, 82.93; H, 8.57. Found: C, 82.94; H, 8.30.

A 10.1-g. portion of fraction d was converted to 13.4 g. (101%) of a white, powdery semicarbazone, m. p. approximately 120–140°. After trituration with boiling methanol, a residue of 1.70 g. (13%) remained, m. p. 212–214° (dec., previous softening), which, after several recrystallizations from absolute ethanol, gave colorless, glistening blades melting at 219–220° (dec.) and showing no depression in m. p. when admixed with the semicarbazone of 3-phenylcycloheptanone. Repeated recrystallization of the methanol-soluble fraction from methanol cooled to −5° yielded a compound melting at 155–156° (dec.) and showing no depression in m. p. when admixed with authentic semicarbazone of 2-phenylcycloheptanone.

A 0.500-g. sample of fraction d was converted to a mixture of 2,4-dinitrophenylhydrazones which solidified only after standing for several hours and which was completely soluble in ether. The ether solution, after standing at room temperature for several days, however, deposited 0.10 g. of a yellow solid; m. p. 166–169.5° (dec.). Two recrystallizations from ethanol furnished yellow, fine needles melting at 170.5–172° (dec.) which did not depress the m. p. of authentic 2,4-dinitrophenylhydrazone of 2-phenylcycloheptanone.

The infrared data for the mixture of IIb and IIIb were obtained from a sample of fraction d.

2-Phenylcycloheptanone (IIb).—A stirred mixture of 66 g. (0.675 mole) of cyclohexanone, 100 cc. of methanol, and 2 g. of finely powdered potassium carbonate was treated, over a period of seven hours, with 141 g. (0.675 mole) of nitrosobenzylurethan,[18] the reaction temperature being maintained at 25–30°. The mixture was stirred overnight at room temperature and then worked up as described above. The crude product was fractionated through a thirty-four inch, glass helix-packed column to yield 33.2 g. (26%) of material boiling at 133–137° (4 mm.) and melting at 11–19°. Two recrystallizations from petroleum ether (30–60°), the entire operation performed in a refrigerator, yielded the pure ketone as colorless, very long needles; m. p. 21–23°, $n^{25}D$ 1.5389, μ_{max}^{liquid} cm.$^{-1}$ 700, 717, 756, 795, 840, 867, 934, 967, 1027, 1125, 1154, 1223, 1317, 1450, 1500, 1576, 1688.

Anal. Calcd. for $C_{13}H_{16}O$: C, 82.93; H, 8.57. Found: C, 82.79; H, 8.41.

The **semicarbazone of 2-phenylcycloheptanone**, prepared from 1.00 g. of the oil described above, consisted of 1.17 g. (90%) of slightly tacky, colorless material. Trituration with ether left 0.57 g. (44%) of a white solid, m. p. 133–136°, which, after two recrystallizations from methanol, produced colorless, glistening plates; m. p. 155–156°. Tiffeneau[10] has reported the m. p. as 156°.

Anal. Calcd. for $C_{14}H_{19}N_3O$: C, 68.54; H, 7.81. Found: C, 68.73; H, 7.85.

The **2,4-dinitrophenylhydrazone of 2-phenylcycloheptanone** was obtained in the usual manner and recrystallized from ethanol to yield yellow crystals, m. p. 138.5–142.5°. A second recrystallization from ethanol produced yellow needles, m. p. 171–172° (dec.).

Anal. Calcd. for $C_{19}H_{20}N_4O_4$: C, 61.94; H, 5.47. Found: C, 61.94; H, 5.38.

With both the semicarbazone and the 2,4-dinitrophenylhydrazone of 2-phenylcycloheptanone it appears that a conversion to a higher melting form takes place during recrystallization. This anomalous behavior of derivatives of 2-substituted cyclic ketones has also been observed by other workers.[2]

2-Phenyl-1,6-dicarbethoxyhexene-1 (VIII).—To a three-necked flask fitted with a stirrer, a reflux condenser and a dropping funnel was added 36 g. (0.155 mole) of ethyl δ-benzoylvalerate (VII),[19] 27 g. (0.162 mole) of ethyl α-bromoacetate, 180 cc. of dry, thiophene-free benzene, 10.5 g. (0.162 mole) of granulated, activated[20] zinc and a few crystals of iodine. The reaction mixture was stirred and refluxed for two hours, 12.5 g. (0.075 mole) of ethyl α-bromoacetate and 4.9 g. (0.075 mole) of zinc then added, and stirring and refluxing continued for another hour. The mixture was cooled, treated with 80 cc. of ethanol followed by water, and the organic material was then extracted into benzene. After washing with dilute hydrochloric acid and water, the benzene solution was distilled until no more water appeared in the distillate and the dehydration of the hydroxy ester then carried out with 2.0 cc. of phosphorus oxychloride according to the method of Lipkin and Stewart.[21] The dehydration required five and one-half hours during which time 2.0 cc. (74%) of water was collected. The reaction mixture was then cooled, extracted several times with water, the benzene removed by evaporation under vacuum and the residue fractionally distilled through a ten-inch Vigreux column. The major fraction consisted of 31.7 g. (67.5%) of a yellow oil, b. p. 149–155° (0.1 mm.). A middle fraction taken for analysis had the b. p. 152–153° (0.1 mm.) and $n^{25}D$ 1.5121.

Anal. Calcd. for $C_{18}H_{24}O_4$: C, 71.02; H, 7.95. Found: C, 70.82; H, 7.70

2-Phenyl-1,6-dicarbethoxyhexane (IXa).—A solution of 30.7 g. of 2-phenyl-1,6-dicarbethoxyhexene-1 (b. p. 149–155° at 0.1 mm.) in 100 cc. of ethyl acetate was treated with 2.00 g. of 10% palladium on charcoal (Baker Co.) and submitted to hydrogenation at room temperature and atmospheric pressure. After the required volume of hydrogen had been absorbed (five hours), the catalyst was removed by filtration, the solvent evaporated under vac-

uum and the residue distilled through a ten-inch Vigreux column to yield 26.4 g. (85%) of a colorless oil, b. p. 139–141° (0.08 mm.), $n^{25}D$ 1.4870.

Anal. Calcd. for $C_{18}H_{26}O_4$: C, 70.56; H, 8.55. Found: C, 70.53; H, 8.30.

2-Phenyl-1,6-dicarboxyhexane (IXb).—A 25.4-g. sample of 2-phenyl-1,6-dicarbethoxyhexane (b. p. 139–141° at 0.08 mm.) was refluxed for seven hours with 100 cc. of ethanol and 100 cc. of 30% potassium hydroxide solution. The crude product, obtained in the usual manner, consisted of a slightly sticky, yellow solid. One recrystallization from benzene followed by drying under high vacuum yielded 19.3 g. (93%) of product; m. p. 79–82°. Three recrystallizations from benzene yielded glistening, short blades, m. p. 86–86.5°.

Anal. Calcd. for $C_{14}H_{18}O_4$: C, 67.18; H, 7.25. Found: C, 67.07; H, 7.08.

3-Phenylcycloheptanone (IIIb).—An 18.5-g. sample of 2-phenyl-1,6-dicarboxyhexane (m. p. 79–82°) was dissolved in 100 cc. of ethanol, neutralized to phenolphthalein with 1 *N* sodium hydroxide solution and converted with thorium tetrachloride to 27.5 g. (102%) of the thorium salt.[22] Pyrolysis of the thorium salt at 400° and 0.5 to 2 mm. afforded 8.40 g. (60%) of a dark green oil which, upon fractionation through an eight-inch Vigreux column, yielded 6.10 g. (44%) of a yellow-green oil, b. p. 131–134° (2 mm.). The oil was crystallized twice from petroleum ether (30–60°) (the entire operation carried out in the refrigerator) to produce colorless, long needles, m. p. 17–18°, $n^{25}D$ 1.5380, μ_{max}^{liquid} cm.$^{-1}$ 700, 751, 840, 862, 934, 1027, 1070, 1125, 1141, 1241, 1287, 1338, 1450, 1500, 1576, 1688.

1-Cyano-1-hydroxy-2-phenylcyclohexane (X).—To a stirred, ice-cold mixture of liquid hydrogen cyanide (prepared from 20 g. of potassium cyanide[23]) containing five drops of piperidine was added, over a period of ten minutes, 10.0 g. of 2-phenylcyclohexanone. The reaction mixture was stirred for one hour at ice-bath temperature and the excess hydrogen cyanide then removed to leave 11.4 g. (99%) of a white solid melting at 87–94° (some previous softening) and probably consisting of a mixture of epimeric cyanohydrins. A 10.0-g. portion of the product was dissolved in benzene, the solution washed with dilute hydrochloric acid and water, and then concentrated by boiling. From the cooled solution there precipitated 4.50 g. of colorless cyrstals, m. p. 105–110° (previous softening). A portion of this material was sublimed at 100° (0.01 mm.) and recrystallized twice from benzene to give colorless, felted needles, m. p. 112–113°.

Anal. Calcd. for $C_{13}H_{15}NO$: C, 77.58; H, 7.51. Found: C, 77.48; H, 7.28.

3-Phenylcycloheptanone from Ring Enlargement of 1-Cyano-1-hydroxy-2-phenylcyclohexane.—The reduction of the cyanohydrin (X) to the amino alcohol (XI) and subsequent rearrangement with nitrous acid was carried out by a method patterned after that described by Goldberg and Studer.[24] A 1.52-g. sample of sublimed cyanohydrin (m. p. 105–110° with previous softening) was dissolved in 25 cc. of glacial acetic acid, treated with 0.200 g. of Adams catalyst (Baker Co.) and subjected to hydrogenation at room temperature and atmospheric pressure. When the required amount of hydrogen had been absorbed (twelve hours) the catalyst was removed by filtration and the filtrate diluted to 250 cc. with water. This solution was then cooled to 0° and treated, over a period of ten minutes, with 20 cc. of an aqueous solution containing 1.57 g. of sodium nitrite. The reaction mixture was stirred for four hours at 0° and then allowed to stand for five hours at room temperature. Several extractions of the reaction mixture with ether–benzene yielded, after evaporation of the solvent, 1.07 g. of a yellow oil which was converted to 1.18 g. (84%) of a sticky semicarbazone. Trituration of the crude semicarbazone with ether left 0.25 g. of a white powder melting at 212–217° (dec.) which, after several recrystallizations from ethanol, produced colorless, glistening blades, m. p. 219–220° (dec.). No depression in m. p. was observed when this material was admixed with authentic semicarbazone of 3-phenylcycloheptanone.

Summary

The ratio of the 2- and 3-substituted cycloheptanones formed by diazomethane ring enlargement of 2-substituted cyclohexanones has been investigated for two series. 2-Chlorocyclohexanone yields a mixture containing approximately 23% of the 2-isomer and 77% of the 3-isomer; 2-phenylcyclohexanone yields a mixture containing approximately 81% of the 2-isomer and 19% of the 3-isomer. The ratio of isomers in the chlorocycloheptanone series was determined by chemical means and in the phenylcycloheptanone series by infrared analysis.

Chemical Interactions of Amino Compounds and Sugars. IV.[1] Significance of Furan Derivatives in Color Formation[2]

BY M. L. WOLFROM, R. D. SCHUETZ[3] AND LIEBE F. CAVALIERI[3]

It has long been known that aqueous solutions of the reducing sugars become dark in color on heating with amino acids and that under certain conditions dark-colored, insoluble products are formed. This complex set of reactions is known as the "browning" or Maillard[4] reaction and is believed to play a role, at times beneficial and at times not, in the processing of foods. It is the purpose of this communication to study the possible contributions to these phenomena made by furan derivatives formed from the sugars. That furan derivatives may play a role in these reactions has been suggested by Roxas,[5] Beckley[6] and others.

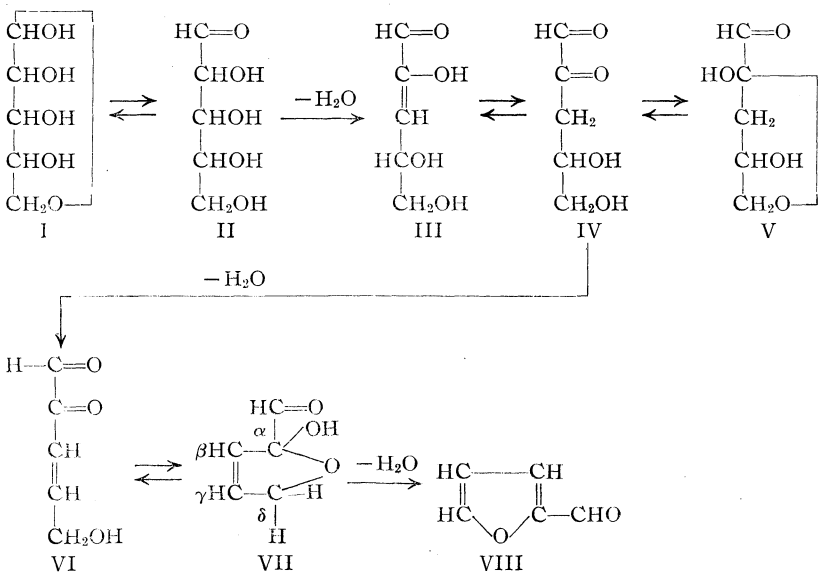

Fig. 1.—Postulated scheme for the conversion of pentoses to 2-furaldehyde.

It is well established that pentoses yield 2-furaldehyde (furfural) on heating with mineral acids. Hurd and Isenhour[7] have shown that this reaction is first order in its early stages if the 2-furaldehyde is removed by steam distillation as fast as formed. Mineral acidity is not required for this conversion, small amounts of 2-furaldehyde being formed when aqueous solutions of the pentoses are refluxed.[8,9]

We believe that the conversion of the pentoses to 2-furaldehyde follows the route outlined in Fig. 1. This scheme is analogous to that previously suggested[1] for the directly related conversion of hexoses to 5-(hydroxymethyl)-2-furaldehyde ("HMF") and is based upon similar evidence.

An aqueous solution of D-xylose was refluxed. After ninety minutes of refluxing, a distinct band with a maximum at 227 mμ (Fig. 3, curve 1) was evident. After three and one-half hours of heating (curve 2) a second band was developing in the region of 277 mμ. At the end of eight hours (curve 3) the maximum at 227 mμ had increased and that at 277 mμ was increasing at an even greater rate. On continued heating for twelve and one-half hours (curve 4) the ratio of the substance producing the band at 277 mμ to the other (producing the band at 227 mμ) became about equal. Further heating for periods of sixteen hours (curve 5) and nineteen hours (curve 6), respectively, greatly increased the ratio of the substance causing absorption at 277 mμ to that producing absorption at 227 mμ. Finally, after a period of heating of twenty-two hours (curve 7), the typical absorption spectrum of 2-furaldehyde (Fig. 4) was developing. The absorption characteristics of 2-furaldehyde as shown in Fig. 4 are in agreement with previously reported[10] data.

It is to be noted first that after one and one-half hours there is absorption only at 227 mμ. That

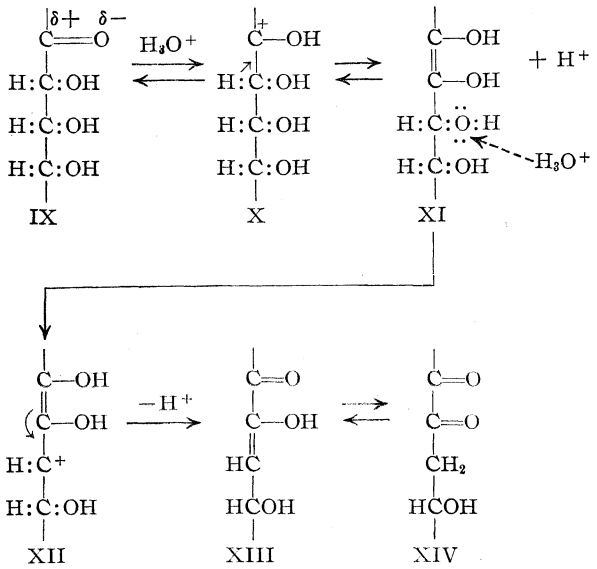

Fig. 2.—Possible mechanism of dehydration.

the substance producing this band is not 2-furaldehyde is evident from the fact that the major peak at 277 mμ is missing. The absorption band at 227 mμ is such as would be given by a conjugated acyclic diene or enal.[1]

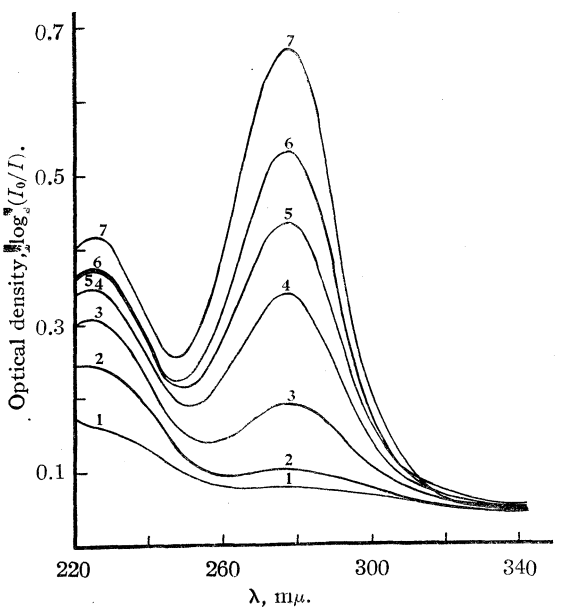

Fig. 3.—Absorption spectra of a 0.0033 molar aqueous D-xylose solution, initial *p*H 6.5, after refluxing for various time intervals. Curve 1, after one and one-half hours; curve 2, after three and one-half hours; curve 3, after eight hours; curve 4, after twelve and one-half hours; curve 5, after sixteen hours; curve 6, after nineteen hours; curve 7, after twenty-two hours. Beckman spectrophotometer (Model DU), 1-cm. cell, slit width 0.19–0.61 mm., optical densities 0.025–1.743.

To explain these absorption curves it is postulated that D-xylose, represented by I (Fig. 1) is transformed first into II or its aldehydrol.[11]

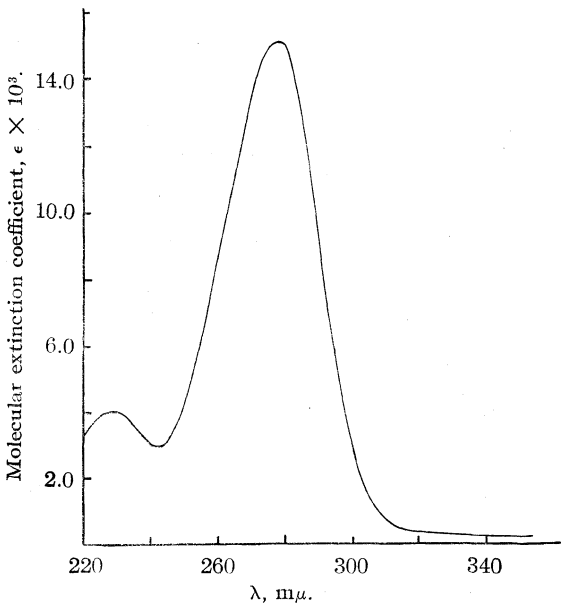

Fig. 4.—Absorption spectrum of pure 2-furaldehyde in water: concentration, 1.155 × 10^{-4} mole per liter; $\epsilon = 1/c \log (100/T)$ wherein c is the molar concentration and T is the percentage transmission; ϵ = 15,100, max. 277 mμ (major peak); ϵ = 4060, max. 227 mμ (minor peak); slit width 0.19–0.61 mm., optical densities 0.025–1.743; Beckman spectrophotometer (Model DU).

Substance II is a β-hydroxy carbonyl compound and undergoes dehydration to yield the conjugated enal III. The keto tautomer IV again loses water by dehydration from a β-hydroxy carbonyl system and produces VI. Both IV and VI can be in equilibrium with their ring structures V and VII, respectively. A final dehydration with bond adjustment then yields 2-furaldehyde (VIII). Such a bond adjustment may possibly involve a proton shift from the δ carbon of VII subsequent to a dehydration between its α and β carbons. Support for this reaction sequence is found in the work of Wolfrom, Wallace and Metcalf.[12] These workers isolated, in the form of its phenylosazone, the analog of VI as an intermediate in the action of mineral acid upon a hexose derivative. Isbell[13] assumes the same intermediates as involved in a series of successive electron displacements, the driving force for which is the combination of hydroxyl groups with hydrogen ions to form water.

The ease of acid dehydration of β-hydroxy carbonyl compounds may be interpreted electronically in the following fashion (Fig. 2). The polarization (IX) of the carbonyl group as enhanced by acid catalysis (X) allows the release of a proton

to form the enediol XI. These reactions are reversible and all of the hydroxyls present are under attack by the hydronium ions present in the solution. That hydroxyl will be released which is the most basic. Of the hydroxyl groups present, the several secondary hydroxyls are more basic than either the enolic hydroxyls or the terminal primary hydroxyl. The secondary hydroxyl which is removed, however, is that one adjacent to the enolic hydroxyl, the extra impetus for its release being provided by the electron pair of the endiolic function tending to produce the resonating system of conjugated double bonds shown in XIII (its tautomer is XIV). The essentially irreversible change from XI to XIII is represented as passing through the intermediate XII which is stabilized by the ejection of a proton and the shift of the electron pair down the carbon chain.

A dilute solution (0.05 *M*) of D-xylose was refluxed for one thousand minutes in the presence and absence of significant amounts of glycine. At the end of this period the amount of 2-furaldehyde formed was determined spectroscopically in the solution. The data are recorded in Table I and it is seen that the total conversion to furan bodies is small and is enhanced by the presence of glycine. Similar conclusions were expressed by Rice[9] on employing somewhat different experimental conditions. It is believed that the main aldehydic substance determined spectroscopically is 2-furaldehyde but it is not excluded that other carbonyl-containing compounds might have been present and caused absorption in the same band. The dilute solutions were adopted in order to yield sharp spectroscopic data. The presence of 2-furaldehyde in these solutions is established by its isolation in this Laboratory and in others.[8,9]

TABLE I

Conversion of 0.0500 *M* Aqueous Solutions of D-Glucose and D-Xylose to Furan Bodies on Heating under Reflux (101°) for 1000 Minutes in the Presence and Absence of Glycine

[a] Per cent. transmission at 285 mμ ($\epsilon_{max.} = 1/[HMF] \log 100/T = 16{,}500$) for D-glucose and at 277 mμ ($\epsilon_{max.} = 1/[F] \log 100/T = 15{,}000$) for D-xylose; 1 cm. cell; Beckman spectrophotometer, Model DU; all solutions made from triply distilled water. [b] Conversion to 5-(hydroxymethyl)-2-furaldehyde (HMF) for D-glucose and 2-furaldehyde (F) for D-xylose. [c] Diluted five times for absorption measurements.

We next sought to determine whether this small amount of 2-furaldehyde, produced on heating aqueous solutions of pentoses, could be a factor in the "browning" of such solutions on heating with glycine. To this end equimolar (0.25 *M*) solutions of the pertinent substances were refluxed and the degree of coloration at various time intervals was measured at a selected wave length (490 mμ). Highly purified materials were employed and the results were reproducible to within approximately 5%. Curve F of Fig. 5 shows that 2-furaldehyde and glycine "brown" at a high rate of speed in accordance with the findings of Kertesz and coworkers.[14] No initial induction period was present. The upturn of the curve at the end, indicating a decreased rate of color formation, may be due at least in part to the formation of a colloidal solution containing suspended particles removed from the reaction sphere; particles actually separated at the last point measured. Thus 2-furaldehyde seems to be a real and powerful color precurser for glycine solutions. D-Xylose and pure 2-furaldehyde, alone or in admixture (curves A, B and C), do not produce significant colorations in the time intervals measured; with longer time these incipient colorations would become significant. The inverted S or sigmoid curve E is that of an admixed equimolar D-xylose and glycine solution. The slow rate of initial color development gives indication of an initial induction period. It is reasonable that this may be due to the time required for the formation of color precursors. The nature of the colored bodies formed is presently unknown but it is believed that they are formed by polymerization reactions in which glycine plays a part. It is possible that the furan ring may be an integral constituent of these polymers. It is not excluded that there may be an initial carbonyl-amino reaction followed by dehydrations to furan or other derivatives.

Since D-galacturonic acid is a constituent of pectins and is an established 2-furaldehyde precursor, its behavior under our selected "browning" conditions was of interest; curve D (0.25 *M* in D-galacturonic acid and glycine) of Fig. 5 is the result. A longer induction period was present. Seaver and Kertesz[15] have shown that D-galacturonic acid is a potent color producer with amino acids and it has been demonstrated[16] that furan intermediates are involved in the browning of dried apricots.

While the pentoses are convertible to 2-furaldehyde, the hexoses are convertible to 5-(hydroxymethyl)-2-furaldehyde and finally to levulinic acid. This reaction is enhanced by acidity but

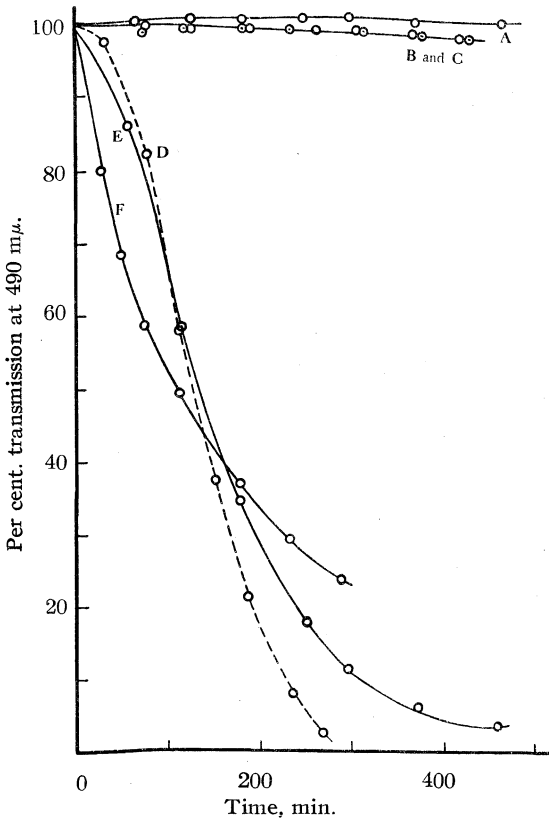

Fig. 5.—Rate of change in the percentage transmission at 490 mμ of D-xylose, D-galacturonic acid and 2-furaldehyde in the presence and absence of glycine; 0.2500 molar (in each constituent) aqueous solutions at reflux temperature (102°): Curve A, D-xylose alone; B, O, 2-furaldehyde alone; C, ⊙, D-xylose and 2-furaldehyde; D, D-galacturonic acid and glycine; E, D-xylose and glycine; F, 2-furaldehyde and glycine; Lumetron (Mod. 402E) photoelectric colorimeter.

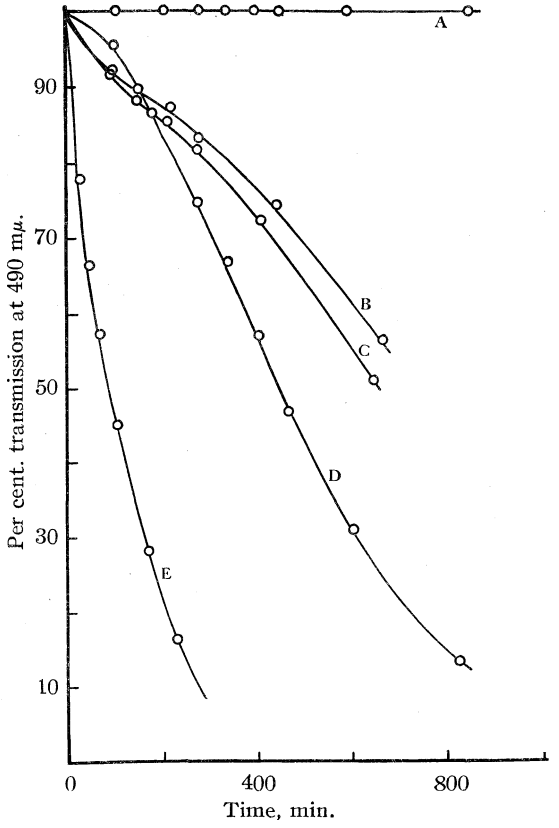

Fig. 6.—Rate of change in the percentage transmission at 490 mμ of D-glucose and 5-(hydroxymethyl)-2-furaldehyde in the presence and absence of glycine; 0.2500 molar (in each constituent) aqueous solutions at reflux temperature (102°): Curve A, D-glucose alone; B, D-glucose and 5-(hydroxymethyl)-2-furaldehyde; C, 5-(hydroxymethyl)-2-furaldehyde alone; D, D-glucose and glycine; E, 5-(hydroxymethyl)-2-furaldehyde and glycine; Lumetron (Mod. 402E) photoelectric colorimeter.

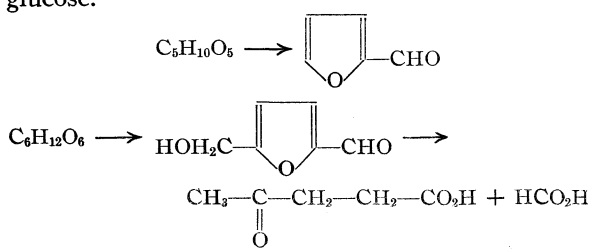
takes place in a refluxing aqueous solution of D-glucose.[17]



The data of Table I show the conversion of D-glucose to 5-(hydroxymethyl)-2-furaldehyde as measured spectroscopically directly in the heated (refluxed for one thousand minutes) solution. It is believed that the main component of the analyzing band is 5-(hydroxymethyl)-2-furaldehyde but the presence of other contributing carbonyl compounds is not excluded. It is noted that the presence of significant amounts of glycine has a promoting effect upon the furan bodies formed. The conversion of the hexose to furan bodies is apparently lower than with the pentose D-xylose but this may be more apparent than real since the 5-(hydroxymethyl)-2-furaldehyde produced is subject to further conversion to levulinic acid. The *p*H of both the hexose and pentose solutions (Table I) drifts downward with time. That 5-(hydroxymethyl)-2-furaldehyde is formed from D-glucose in the presence of glycine was established by isolation from such a mixture.

The degree of conversion of hexoses and pentoses to furan bodies (Table I) is small but the measured figure represents only the amount of substance actually exhibiting the absorption at the wave length employed. This is undoubtedly an intermediate value and the total quantity of hexose or pentose passing through this stage may be much greater.

Singh, Dean and Cantor[18] have shown that the 5-(hydroxymethyl)-2-furaldehyde formed in acid

(17) B. I. Scallet with J. H. Gardner, THIS JOURNAL, **67**, 1934 (1945).

(18) B. Singh, G. R. Dean and S. M. Cantor, *ibid.*, **70**, 517 (1948).

solutions of D-glucose is the prime cause of color development in them. We are then presently concerned with attempting to determine whether this same intermediate is a probable factor in the "browning" of aqueous solutions of D-glucose by glycine. To this end we employed the same color-forming conditions as we used for the pentoses. The results are diagrammed in Fig. 6. D-Glucose alone (Fig. 6, curve A) did not form colored substances as readily as did our sample of D-xylose (Fig. 5, curve A). 5-(Hydroxymethyl)-2-furaldehyde alone is a good source of color (curve C), much more than is 2-furaldehyde. Admixture with D-glucose (curve B) has little effect upon this property. Refluxing of 5-(hydroxymethyl)-2-furaldehyde with glycine (curve E) produces a very rapid color formation. The curve (D) of D-glucose and glycine is similar in general characteristics to that of D-xylose and glycine (curve E of Fig. 5); it exhibits even a more pronounced initial induction period. Thus the behavior of D-glucose is similar to that of D-xylose.

On heating in dilute aqueous solution an equimolar mixture of D-glucose and glycine ethyl ester, the *p*H falls gradually (curve A of Fig. 7).

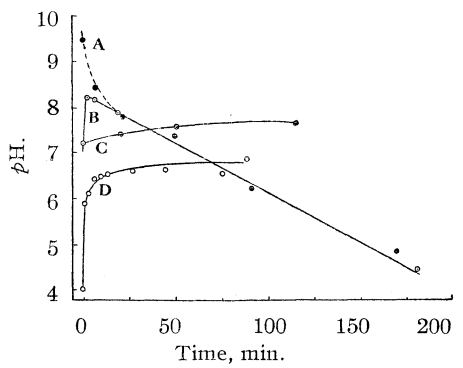


Fig. 7.—Change in *p*H of a 0.001 molar solution of N-D-glucosylglycine ethyl ester: at room temperature (20–25°), curve C; at 90–92°, curve B; in 0.02 *N* hydrochloric acid at room temperature (20–25°), curve D. Change in *p*H of a mixture of D-glucose and glycine ethyl ester at an equivalent concentration, 90–92°, curve A. Measurements of *p*H on the heated solutions were made by rapidly cooling an aliquot to room temperature.

When an equivalent amount of crystalline N-D-glucosylglycine ethyl ester is heated under the same conditions (curve B, Fig. 7), a very rapid initial increase in *p*H occurs followed by a slower drop in *p*H which merges into the *p*H-time curve of the D-glucose–glycine ester system. These data are those predictable should the N-D-glucosylglycine ethyl ester have hydrolyzed largely to D-glucose and glycine ethyl ester with the latter substance then undergoing a slower hydrolysis to glycine. N-D-Glucosylglycine ethyl ester undergoes hydrolysis at room temperature (curve C, Fig. 7) and its instability toward water is shown also by the rapid and essentially quantitative release of the amino group (ninhydrin colorimetric assay) on heating in aqueous solution for only a few minutes. Toward mineral acid, the substance is very unstable at room temperature (curve D, Fig. 7). This hydrolytic behavior shows that only a small amount of N-D-glucosylglycine could possibly be formed by the interaction of D-glucose and glycine in aqueous solution. It is not excluded, however, that this small amount may be a significant factor in a complex equilibrium.

Finally we may state that our findings stand contrary to the statement of Enders[19] that these furan derivatives do not brown with sufficient rapidity to be of significance in the Maillard reaction. When present in sufficient concentration, both 2-furaldehyde and 5-(hydroxymethyl)-2-furaldehyde form deeply colored products with glycine and do so at a high rate of speed.

Experimental

Materials.—The colorless 2-furaldehyde required in this investigation was obtained from a commercial sample that had been freshly triply distilled under reduced pressure. 5-(Hydroxymethyl)-2-furaldehyde was prepared according to the procedure of Middendorp[20] with some modification. An amount of 180 g. (0.527 mole) of sucrose was dissolved in 600 ml. of water. To this was added 0.180 g. (0.00143 mole) of oxalic acid. The resulting solution was refluxed for twenty hours, after which it was cooled to room temperature and the black, insoluble material was removed by filtration. The filtrate was neutralized with 11.0 g. (0.110 mole) of calcium carbonate with mild heating. To the neutralized filtrate was added 2 g. of basic lead acetate and after standing for ninety minutes the solution was again filtered. The 5-(hydroxymethyl)-2-furaldehyde was extracted with a 100-ml. portion of ethyl acetate and then with four 50-ml. quantities. The solvent was removed under reduced pressure from the dried extract and the 5-(hydroxymethyl)-2-furaldehyde was purified by molecular distillation at 2×10^{-3} mm.; m. p. 33.3–33.5° (cor.).

The glycine and the carbohydrates employed were highly purified materials recrystallized in our own laboratories. The D-galacturonic acid used was the α-monohydrate. All aqueous solutions were made with triply distilled water.

Isolation and Characterization of 2-Furaldehyde from the Decomposition of D-Xylose in the Presence of Glycine.—An aqueous solution (100 ml.) of D-xylose and glycine (2.5 molar in each constituent) was refluxed for two hours. It was then steam-distilled, the distillate being led directly into a heated solution of 2 *N* hydrochloric acid saturated with 2,4-dinitrophenylhydrazine. The resulting 2,4-dinitrophenylhydrazone was filtered and recrystallized from pyridine; m. p. 229° (dec., Fisher–Johns apparatus), accepted value 229° (dec., cor.).[21] In an identical manner, a 2,4-dinitrophenylhydrazone of like melting point was isolated from a 2.5 *M* solution of D-xylose alone after refluxing for sixteen hours. Mixed melting points of these two products with an authentic reference compound were unchanged.

Isolation and Characterization of 5-(Hydroxymethyl)-2-furaldehyde from the Decomposition of D-Glucose in the Presence of Glycine.—An aqueous solution (400 ml.) of D-glucose and glycine (2.5 molar in each constituent) was refluxed for twenty hours and then extracted with ethyl acetate for eight to ten hours in a continuous extractor. Crude 5-(hydroxymethyl)-2-furaldehyde was obtained as a light brown oil on solvent removal under diminished

pressure; yield 1–2 g. Identification was effected by ultraviolet absorption[1,18] and by the preparation of two crystalline derivatives: the 2,4-dinitrophenylhydrazone of m. p. 198–200° (dec., Fisher–Johns apparatus) (after recrystallization from 95% ethanol; in agreement with accepted value[21]) and the condensation product with β-naphthylamine of m. p. 130–131° (after recrystallization from benzene; accepted value[22] 131–132°). These two derivatives showed no depression in melting point on admixture with authentic samples of like melting point.

Preparation of N-D-Glucosylglycine Ethyl Ester.—This compound was first recorded by Euler and Zeile.[23] The following is an improved method of preparation which makes this substance readily available. An amount (66 g.) of freshly prepared glycine ethyl ester was added to a suspension of 115 g. of anhydrous D-glucose in 200 ml. of absolute ethanol and the mixture was mechanically stirred and heated under reflux on a water-bath while protected from moisture by a guard tube. The heating was continued until all of the D-glucose had dissolved, about seventy-five minutes of heating time generally being required. The resultant solution was tea-colored. Approximately 125 ml. of ethanol was then removed under diminished pressure and *ca.* 150 ml. of acetone added to the residual sirup. The resultant solution was nucleated and allowed to stand at room temperature until crystallization was complete (overnight). The crude product was removed by filtration and washed with absolute ethanol; yield 110 g. (64%), m. p. 80°. Quite pure material was obtained on three recrystallizations from equal parts of hot absolute ethanol; yield 50 g. (30%), m. p. 108°, $[\alpha]^{25}D$ −5° (*c* 3, absolute ethanol). A significant purification could be obtained by making a slurry of the crude product with absolute ethanol, filtering and washing with a small amount of ethanol. The filtrate was discarded and the filtered material was crystallized from hot absolute ethanol.

Hydrolytic Breakdown of N-D-Glucosylglycine Ethyl Ester in Water; Ninhydrin Reaction.—An amount (0.26 g.) of D-glucosylglycine ethyl ester was heated on a water-bath in 10 ml. of water containing ninhydrin. The characteristic color developed in a few minutes and heating was continued for a total of thirty minutes. Comparison of this solution (cooled rapidly to room temperature) with a solution containing an equivalent amount of glycine by means of a photoelectric colorimeter revealed that both solutions absorbed to the same extent.

Summary

1. Aqueous solutions of D-xylose form small amounts of 2-furaldehyde on being heated. The presence of a relatively large amount of glycine promotes this conversion as it does the analogous conversion of hexoses to 5-(hydroxymethyl)-2-furaldehyde.

2. The course of the formation of 2-furaldehyde from D-xylose has been followed spectroscopically and on this basis structures are postulated for several intermediates.

3. It is demonstrated that 5-(hydroxymethyl)-2-furaldehyde, in the case of D-glucose, and 2-furaldehyde, in the case of the pentoses and D-galacturonic acid, are important precursors in the formation of the brown colors developed when aqueous solutions of these substances are heated with glycine.

4. Evidence is presented which shows that the carbonyl-amino reaction could occur to only a slight extent if at all in dilute aqueous solutions of D-glucose and glycine.

A Synthesis for 4-Bromo-7-methoxyhydrindene

BY RODERICK A. BARNES, ELISE R. KRAFT[1] AND LOUIS GORDON[2]

In a previous paper[3] the use of 4-substituted hydrindenes as starting materials for preparation of cyclopentanophenanthrene derivatives has been illustrated. The present work was undertaken in order to extend the scope of this method by making available a new 4-substituted hydrindene (IV).

The method which finally proved successful for the synthesis of IV and which was most readily applicable to large-scale preparation was based on the hydrindone synthesis of von Auwers.[4] Although halogen substituted hydrindones have not previously been prepared by this procedure, we have found that it can be used to synthesize 4-bromo-7-hydroxy-1-hydrindone (II) in 40–50% yield. The Clemmensen reduction (80% yield) to 4-bromo-7-hydroxyhydrindene (III) and methylation of III with diazomethane complete the synthesis.

The von Auwers preparation of hydrindones takes place in two steps, first a Fries rearrangement of the phenol ester of an α- or β-halopropionic acid, and second a cyclization of the intermediate haloketone. In harmony with this conception of the reaction we have found that the best yields of II were obtained when I was heated with aluminum chloride at 95–100° for five to six hours to complete the Fries rearrangement and then at 170° for one hour to cause cyclization. Extended heating at the higher temperature results in de-

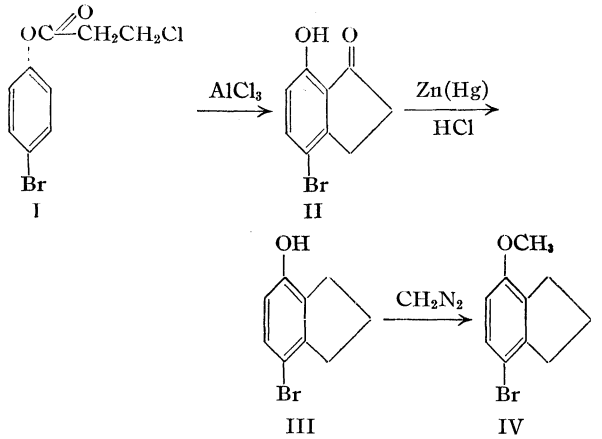
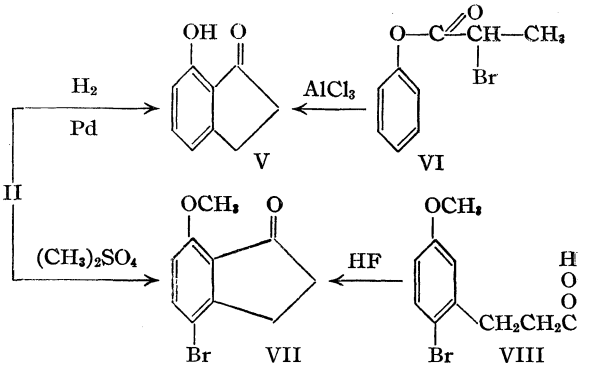
(4) von Auwers, *Ann.*, **439**, 132 (1924).





struction of II; however, cyclization is very slow at the lower temperature.

The yield of II was less than has been reported[5] for *p*-cresyl β-chloropropionate (60%); however, this may be explained by a comparison of the inductive effect of the bromine atom and the methyl group. Thus, the lower electron density at the cyclization position in our case requires that a higher temperature be used for this step of the reaction with a resultant increase in destructive side reactions. The more readily available *p*-bromophenyl α-chloropropionate gave only a trace of II in spite of the fact that 7-hydroxy-1-hydrindone (V) can be prepared in small yield from phenyl α-bromopropionate (VI).[6]

In view of the rather drastic reaction conditions necessary to produce the hydrindone II, it was important to prove its structure.[7] To show that II had the desired carbon skeleton it was reduced over palladium until no more hydrogen was absorbed. It was anticipated that the known 4-hydroxyhydrindene would be formed; however, the product was 7-hydroxy-1-hydrindone (V).[6] The failure of the carbonyl group to undergo catalytic reduction is believed to be due to chelation.[8]

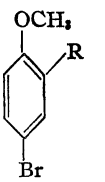
The position of the bromine atom in II was confirmed by an alternate synthesis of 4-bromo-7-methoxy-1-hydrindone from β-(2-bromo-5-methoxyphenyl)-propionic acid (VIII) which was prepared by direct bromination of β-(*m*-methoxyphenyl)-propionic acid in carbon tetrachloride at −5°.

The location of the bromine atom in VIII was determined by oxidation to the known 2-bromo-5-methoxybenzoic acid.[9] The synthesis of IV from acid VIII was not seriously considered as a preparative method because of the greater number of steps and more expensive reagents necessary to prepare VIII from *m*-hydroxybenzaldehyde. The preparation of I from acrylonitrile and *p*-bromophenol requires only two steps.

Additional proof for the position of the bromine atom was furnished by the nitration of III to produce a steam-volatile nitration product whose methyl ether did not react with a boiling alcoholic solution of silver nitrate. The steam volatility of this product indicates that the nitro group must be ortho to the phenolic hydroxyl, and the inactivity of the bromine atom indicates it to be meta to the nitro group. The indicated structure for III, with the bromine atom in the 4-position, is the only one in accord with these facts. Chromic acid oxidation of III produced a small amount of 4,7-hydrindenequinone; the bromine atom would not have been eliminated during oxidation to this product if it were in any but the 4-position.

The first approach to the preparation of IV had been based on the observation of Johnson and Shelberg[10] that β-(*p*-methoxyphenyl)-propionic acid could be cyclized in 85% yield to 5-methoxy-1-hydrindone. To this end β-(2-methoxy-5-bromophenyl)-propionic acid XII was prepared. The condensation of ethyl cyanoacetate with 2-methoxy-5-bromobenzaldehyde produced the cyanoester IX in good yield, but prolonged acid hydrolysis of IX produced only cyanoacid X. The condensation of the aldehyde with malonic acid produced the desired cinnamic acid XI but the reduction with hydrogen and Raney nickel removed the bromine atom.

IX, R = —CH=C(CN)COOEt
X, R = —CH=C(CN)COOH
XI, R = —CH=CH—COOH
XII, R = —CH_2CH_2COOH
XIII, R = —CH_2Cl



The desired acid XII was prepared in an over-all yield of 63% from *p*-bromoanisole by chlorometh-

(5) Krollpfeiffer and Schultze, *Ber.*, **57**, 600 (1924).

(6) von Auwers and Hilliger, *ibid.*, **49**, 2410 (1916).

(7) The migration of the bromine atom during the cyclization was the possibility which seemed most likely to produce a substance isomeric with the desired hydrindone. A discussion of the rearrangement of bromo compounds under acid conditions is presented by Moyle and Smith, *J. Org. Chem.*, **2**, 112 (1937).

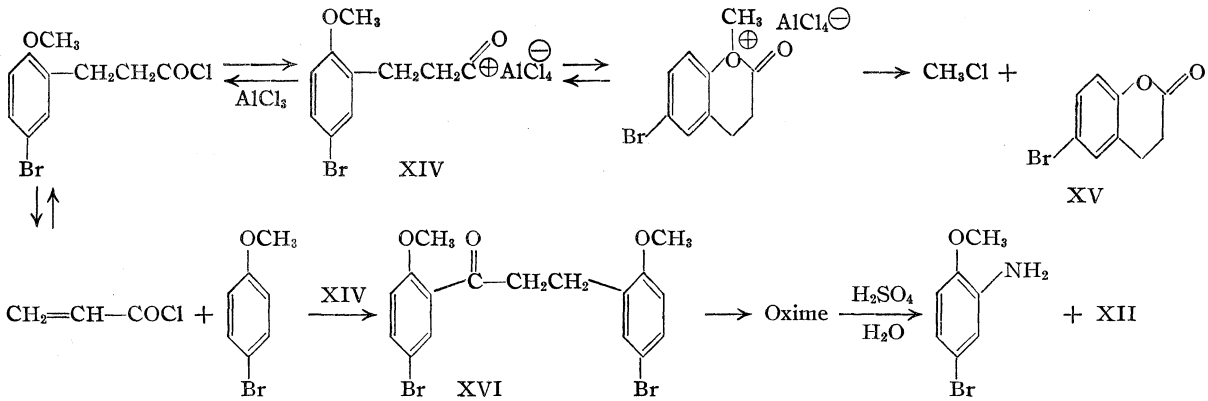
(8) Jarowski and Cramer (Washington A.C.S. Meeting, September, 1948) have observed that the carbonyl group of 2-carbethoxy-5-hydroxy-γ-chromenone is not reduced by hydrogen in the presence of Raney nickel. In this case chelation is also possible.

(9) We are indebted to Dr. Domenick Papa for a generous sample of β-(*m*-hydroxyphenyl)-propionic acid and a melting point sample of 2-bromo-5-methoxybenzoic acid. Schwenk and Papa have reported (Chicago A. C. S. meeting, September, 1948) that bromination of the silver salt of β-(*m*-methoxyphenyl)-propionic acid also produces VIII.

(10) Johnson and Shelberg, THIS JOURNAL, **67**, 1853 (1945).

ylation to 2-methoxy-5-bromobenzyl chloride (XIII) followed by alkylation of malonic ester with XIII.

Using a variety of reaction conditions we have been completely unable to cyclize either β-(2-methoxy-5-bromophenyl)-propionic acid XII or β-(*o*-methoxyphenyl)-propionic acid.[11] Neither stannic chloride nor anhydrous hydrogen fluoride caused any reaction of acid XII. With aluminum chloride in benzene or nitrobenzene the main product was 6-bromo-3,4-dihydrocoumarin (XV). When nitrobenzene was used as a solvent there was also obtained in 18% yield a ketone m. p. 93–94° (XVI). The structure assigned to this ketone is based on the analysis, molecular weight, oxidation by potassium permanganate to 2-methoxy-5-bromobenzoic acid and the Beckmann rearrangement of the oxime.



The results obtained in this attempted cyclization of the acid XII would indicate that the failure of β-(*o*-methoxyphenyl)-propionic acids to cyclize is due to preferential reaction of the positive carbon of the complex XIV with the oxygen of the methoxyl group rather than with the ring carbon meta to the methoxyl group. The relative yield of the dihydrocoumarin XV and the ketone XVI were not materially changed by the addition of a mole of *p*-bromoanisole to the cyclization mixture; this would indicate that the intramolecular reaction with oxygen was faster also than reaction with the ortho position of *p*-bromoanisole.

Acknowledgment.—The authors wish to express their appreciation for a Frederick Gardner Cottrell Research Grant which made possible the successful completion of this work.

Experimental[12]

β-Chloropropionic Acid.—Acrylonitrile (250 g.) was added to concentrated hydrochloric acid (2 liters), and the mixture refluxed for six hours. After cooling the precipitated ammonium chloride was filtered and the filtrate concentrated *in vacuo*. The residue was distilled to yield 384 g. (75%) of acid which boiled at 115–117° (32 mm.) and which solidified on standing for a short time.

***p*-Bromophenyl β-Chloropropionate.**—Phosphorus trichloride (90 ml.) was added dropwise to β-chloropropionic acid (332 g.) and the mixture heated at 110–120° for three hours. Then, a solution of *p*-bromophenol (533 g.) in toluene (500 ml.) was added and the mixture refluxed for an additional three hours. The cool reaction mixture was washed with dilute potassium hydroxide solution, dried and distilled. There was obtained 567 g. (65%) of the ester which boiled at 106–117° (0.4–0.6 mm.).

Anal. Calcd. for $C_9H_8O_2ClBr$: C, 41.02; H, 3.06. Found: C, 41.05; H, 3.11.

***p*-Bromophenyl α-Chloropropionate.**—α-Chloropropionyl chloride[13] (50.9 g.) and *p*-bromophenol (60.5 g.) were refluxed for two hours and the reaction mixture processed as for the previous ester. There was obtained 33.8 g. (53%) of the ester which boiled at 160–167° (26 mm.). This substance crystallized on standing and after recrystallization from ligroin (b. p. 90–110°) melted at 56.2–56.8°.

Anal. Calcd. for $C_9H_8O_2ClBr$: C, 41.02; H, 3.06. Found: C, 40.88; H, 3.20.

4-Bromo-7-hydroxy-1-hydrindone.—A mixture of *p*-bromophenyl β-chloropropionate (131.5 g.) and aluminum chloride (250 g.) was stirred while the temperature was maintained at 95–100° for six hours; the temperature was then raised to 170° and the reaction mixture was heated at this temperature for one hour. After cooling, the mixture was treated with ice water and then steam distilled. The steam distillate was chilled and filtered to yield 70.2 g. of yellow crystals. After drying and recrystallization from ligroin (b. p. 90–110°) there was obtained 49.8 g. (44%) of the hydrindone which melted at 142–145°.[14] This substance was obtained analytically pure by alternate recrystallization from methyl ethyl ketone and ligroin, m. p. 146.2–146.9°.

Anal. Calcd. for $C_9H_7O_2Br$: C, 47.60; H, 3.11; Br, 35.19. Found: C, 47.37; H, 3.18; Br, 35.32.

This compound can be preserved pure only if kept in a sealed evacuated container. Without this precaution surface oxidation of the crystals takes place; however, on standing in air only a small percentage of the compound is oxidized by this process. Thus, a sample left exposed to air for two weeks had the following analysis: C, 46.82; H, 3.20; Br, 33.97.

p-Bromophenyl α-chloropropionate was allowed to react with aluminum chloride at temperatures from 140–185° for periods of time varying from one-half hour to five hours, but the main steam volatile product was an oil.

(11) Heinzelmann, Kolloff and Hunter, THIS JOURNAL, **70**, 1386 (1948), have reported that β-(*o*-methoxyphenyl)-propionic acid could not be cyclized by anhydrous hydrogen fluoride, aluminum chloride or phosphorus pentoxide.

(12) All melting points are corrected. Microanalyses are by W. Manser and Lois E. May.

(13) Prepared by the method of Henry, *Compt. rend.*, **100**, 116 (1885).

(14) These conditions, which produce a maximum yield of the hydrindone, were worked out by Dr. G. L. Shoemaker, Cottrell Grant Research Fellow.

By extraction of an ether solution of the oil with sodium hydroxide and subsequent neutralization of the aqueous solution a very small amount of hydrindone II could be isolated.

4-Bromo-7-hydroxyhydrindene.—4-Bromo-7-hydroxy-1-hydrindone (65 g.) was refluxed with amalgamated zinc (75 g.) and alcohol (200 ml.) while hydrochloric acid (250 ml.) was added in portions during eight hours. After filtration and dilution with water the product was extracted with ether. Recrystallization from ligroin produced 49.6 g. (81%) of product which melted at 106–107°. The pure substance melts at 108–108.8°.

Anal. Calcd. for C_9H_9OBr: C, 50.73; H, 4.26. Found: C, 50.46: H, 4.39.

4-Bromo-7-methoxyhydrindene.—4-Bromo-7-hydroxyhydrindene (15 g.) was allowed to stand with a solution of diazomethane in ether (prepared from 16 g. of nitrosomethylurea) for twenty-four hours. The ether solution was washed with dilute sodium hydroxide (0.2 g. of the phenol was recovered) and the solvent was removed on the water pump. The crystalline residue was recrystallized from petroleum ether (30–60°). There was obtained 13.2 g. (82%) of product which melted at 66–66.5°.

Anal. Calcd. for $C_{10}H_{11}OBr$: C, 52.88; H, 4.88. Found: C, 52.47; H, 4.85.

β-(2-Bromo-5-methoxyphenyl)-propionic Acid.—β-(*m*-Methoxyphenyl)-propionic acid (5.0 g.) prepared by methylation of β-(*m*-hydroxyphenyl)-propionic acid[9] with dimethyl sulfate, was dissolved in carbon tetrachloride (100 ml.) and cooled to −10° while a solution of bromine (4.8 g.) in carbon tetrachloride (15 ml.) was added dropwise with mechanical stirring. On processing of the reaction mixture there was obtained 5.4 g. (75%) of product which melted at 81–83°. The purified acid melted at 83.7–84.4°.[15]

Oxidation of 0.5 g. of this substance by boiling with potassium permanganate solution produced 2-bromo-5-methoxybenzoic acid, melting point and mixed melting point with an authentic sample[9] 160–160.8°.

4-Bromo-7-methoxy-1-hydrindone.—**A.** β-(2-Bromo-5-methoxyphenyl)-propionic acid (4 g.) was dissolved in anhydrous hydrogen fluoride (100 ml.) contained in a copper reaction bottle and allowed to stand at room temperature until all of the hydrogen fluoride had evaporated. Recrystallization of the residual solid from alcohol produced 2.2 g. (60%) of product which melted at 133.6–134.2°.

B. The methylation of 4-bromo-7-hydroxy-1-hydrindone (1.8 g.) by reaction with dimethyl sulfate (2.9 ml.) and a slight excess of sodium hydroxide in methanol solution produced 1 g. of material which melted at 134.5–135°. The melting point of a mixture of this substance and the product obtained in part A was 133.5–134.5°.

Anal. Calcd. for $C_{10}H_9O_2Br$: C, 49.81; H, 3.84. Found: C, 49.67; H, 3.78.

7-Hydroxy-1-hydrindone.—**A.** 4-Bromo-7-hydroxy-1-hydrindone (5 g.) was shaken with hydrogen in the presence of palladium on barium sulfate (1 g.) at atmospheric pressure until no more hydrogen was absorbed (twenty hours). The catalyst was filtered off, the filtrate evaporated and the residue crystallized from petroleum ether. The product melted at 112–113°.[16]

B. Phenyl α-bromopropionate (20 g.) was treated with aluminum chloride (40 g.) according to the procedure of von Auwers.[6] There was obtained 1.55 g. (12%) of the steam-volatile 7-hydroxy-1-hydrindone. The melting point of this substance and also of a mixture of it and the product from part A was 112–113°.

4-Bromo-6-nitro-7-hydroxyhydrindene.—Fuming nitric acid (1 ml.) dissolved in acetic acid (10 ml.) was added dropwise to a solution of 4-bromo-7-hydroxyhydrindene (2.4 g.) in acetic acid (25 ml.) at 5°. When the addition was complete the reaction mixture was allowed to stand fifteen minutes and then poured into cold water. The crude product was filtered and purified first by steam distillation and then by recrystallization from ethanol. There was obtained 2.3 g. (80%) of the bright yellow nitrophenol which melted at 101.8–102.6°.

Anal. Calcd. for $C_9H_8O_3NBr$: C, 41.88; H, 3.12; N, 5.43. Found: C, 41.99; H, 3.23; N, 5.32.

The methyl ether was prepared by allowing the nitrophenol to stand for twenty-four hours with a solution of diazomethane. After recrystallization from ethanol the nearly colorless product melted at 81.7–82.2°.

Anal. Calcd. for $C_{10}H_{10}O_3NBr$: C, 44.14; H, 3.70; N, 5.15. Found: C, 44.16; H, 3.82; N, 5.03.

There was no reaction when this methyl ether was boiled with an alcoholic solution of silver nitrate.

4,7-Dihydroxyhydrindene.—4-Bromo-7-hydroxyhydrindene (1 g.) dissolved in 70% acetic acid (100 ml.) was treated with chromic anhydride (6 g.) for ten minutes at 70–75°. The product was isolated by dilution of the reaction mixture with cold water and ether extraction. The ether extract was concentrated and the quinone sublimed *in vacuo*. The oily sublimate was shaken with ether and aqueous sodium hydrosulfite. Evaporation of the ether left the crystalline hydroquinone (28 mg.) which was purified by crystallization from methyl ethyl ketone and ligroin. When heated under a microscope the product began to melt at 155–160°; however, at this temperature a new crystalline form appeared which melted sharply at 186–187°.

This same behavior was noted with an authentic sample prepared by the method of Arnold and Zaugg[17] and there was no lowering of the melting point when the two samples were mixed and heated.

Ethyl α-Cyano-2-methoxy-5-bromocinnamate.—2-Methoxy-5-bromobenzaldehyde[18] (50 g.) was treated with ethyl cyanoacetate (30 g.), ammonium acetate (3.9 g.), acetic acid (12 g.) and benzene (50 ml.) according to the directions of Cope, *et al.*[19] After recrystallization from ethanol there was obtained 65 g. (91%) of product which melted at 103–104°.

Anal. Calcd. for $C_{13}H_{12}O_3NBr$: C, 50.34; H, 3.90. Found: C, 50.60; H, 4.04.

α-Cyano-2-methoxy-5-bromocinnamic Acid.—Ethyl α-cyano-2-methoxy-5-bromocinnamate (31 g.) was refluxed for thirty hours with a mixture of hydrochloric acid (150 ml.) and acetic acid (300 ml.). After filtration of the cold reaction mixture there was obtained 27 g. (96%) of the acid which crystallized as yellow needles from alcohol, m. p. 240–242° (dec.).

Anal. Calcd. for $C_{11}H_8O_3NBr$: C, 46.83; H, 2.86; N, 4.97; Br, 28.33. Found: C, 46.91; H, 2.79; N, 4.53; Br, 28.16.

A repetition of the treatment with acid produced no further change in this substance. When a solution of this acid in potassium hydroxide was allowed to stand at room temperature, crystals of 2-bromo-5-methoxybenzaldehyde (m. p. and mixed m. p. with an authentic sample 117–118°) were slowly deposited.

2-Methoxy-5-bromocinnamic Acid.—The condensation of 2-methoxy-5-bromobenzaldehyde (13.6 g.) with malonic acid (6.5 g.) produced only 2.1 g. (13%) of the desired acid, m. p. 223–226°.[20] The starting aldehyde was recovered in 62% yield (8.5 g.).

The reduction of 2-methoxy-5-bromocinnamic acid (1 g.) in alkaline solution with hydrogen (40 lb.) and Raney nickel produced β-(*o*-methoxyphenyl)-propionic acid, m. p. and mixed m. p. with an authentic sample 87–88°.

(15) Schwenk and Papa (ref. 9) report a melting point of 83–84° for this substance.

(16) von Auwers and Hilliger, ref. 6, report the melting point of this substance to be 111–112°.

(17) Arnold and Zaugg, THIS JOURNAL, **63**, 1317 (1941), report the melting point to be 184–185°.

(18) Graebe, *Ann.*, **340**, 210 (1905).

(19) Cope, Hoffman, Wyckoff and Hardenbergh, *ibid.*, **63**, 3452 (1941).

(20) Billmann and Rimbert, *Bull. soc. chim.*, **33**, 1473 (1923), report the melting point of this substance as 222–223°.

β-(2-Methoxy-5-bromophenyl)-propionic Acid.—A. 2-Methoxy-5-bromobenzyl chloride[21] (250 g.) was slowly added to a cold (5–10°) solution of sodium (25 g.) and malonic ester (250 g.) in absolute ethanol (800 ml.). The mixture was stirred for twelve hours at room temperature and then refluxed for an additional three hours. The crude alkylated malonic ester was isolated by pouring the reaction mixture into water (3 liters) and extracting with ether. The ether and excess malonic ester were removed by distillation until the vapor temperature of the distillate reached 95° (6 mm.). The residue (371 g.) was refluxed for twenty hours with potassium hydroxide (145 g.) water (100 ml.) and methanol (400 ml.). The mixture was poured into water and extracted with ether. The aqueous solution was acidified and the solid malonic acid filtered and decarboxylated by heating to 180°. The crude acid was purified by dissolving in dilute potassium hydroxide, washing the aqueous solution with ether, reprecipitating with hydrochloric acid and finally recrystallizing from benzene and petroleum ether. There was obtained 226 g. (82%), of the acid which melted at 117–118°.

Anal. Calcd. for $C_{10}H_{11}O_3Br$: C, 46.35; H, 4.28. Found: C, 45.74; H, 4.37.

B. β-(*o*-Methoxyphenyl)-propionic acid was brominated by the same procedure as for the meta isomer. The product from this reaction melted at 117–118° and when mixed with the acid obtained in part A caused no depression of the melting point. The oxidation of this acid with aqueous potassium permanganate produced 2-methoxy-5-bromobenzoic acid, m. p. 119°. A mixture of this oxidation product (m. p. 119°) and β-(2-methoxy-5-bromophenyl)-propionic acid (m. p. 117–118°) melted at 84–95°.

Cyclization Attempts with *o*-Methoxyphenylpropionic Acid.—Seven experiments using variations of the procedure developed by Johnson and Shelberg[10] for the para isomer, were carried out but in each case there was obtained either recovered acid or an amorphous precipitate (m. p. *ca.* 230–280°) which was insoluble in both organic and inorganic reagents (presumably a polymer). In three experiments small amounts (0.5–5%) of an oil were isolated which reacted with 2,4-dinitrophenylhydrazone. The small amounts of partially purified 2,4-dinitrophenylhydrazones obtained (m. p. 113–118°, 153–156° and 245–250°) were not further investigated.

Cyclization Attempts with β-(2-Methoxy-5-bromophenyl)-propionic Acid.—This acid (24 g.) was recovered quantitatively after standing for thirty hours at room temperature with anhydrous hydrogen fluoride (200 g.).

The acid chloride when treated with stannic chloride in benzene solution at room temperature did not undergo any reaction.

The acid chloride (prepared from 79 g. of acid and thionyl chloride) was dissolved in benzene (400 ml.) and aluminum chloride (40 g.) was added slowly to the cold solution. The mixture was stirred for six hours at room temperature, then after washing with water the organic layer was extracted with dilute potassium hydroxide. Acidification of this alkaline solution liberated 21 g. of β-(2-hydroxy-5-bromophenyl)-propionic acid which melted at 139–140°.[22] Evaporation of the benzene and recrystallization of the residue from ethanol produced 18 g. of 6-bromo-3,4-dihydrocoumarin, m. p. 106–106.5°.[23] It was subsequently observed that the dihydrocoumarin can be completely extracted from an organic layer by warm potassium hydroxide solution. Both the dihydrocoumarin and the hydroxy acid were reconverted to β-(2-methoxy-5-bromophenyl)-propionic acid (m. p. and mixed m. p. 117–118°) by reaction with dimethyl sulfate and potassium hydroxide.

The acid chloride (60 g., b. p. 152–155° (3 mm.)) was dissolved in nitrobenzene (200 ml.) and treated with a solution of aluminum chloride (29 g.) in nitrobenzene (100 ml.) at room temperature for nine hours. The dihydrocoumarin was removed by shaking with warm potassium hydroxide solution to yield 37 g. (70%) of β-(2-hydroxy-5-bromophenyl)-propionic acid. After removing solvents and recrystallizing from ethanol there was obtained 9 g. (18%) of a substance melting at 93–94°.

Anal. Calcd. for $C_{17}H_{16}O_3Br_2$: C, 47.69; H, 3.77; Br, 37.33. Found: C, 47.18, 47.72; H, 3.76, 3.79; Br, 36.87.

In an attempt to prepare larger quantities of the above substance β-(2-methoxy-5-bromophenyl)-propionic acid (14 g.) was treated with aluminum chloride in nitrobenzene as above except that one equivalent of *p*-bromoanisole (10 g.) was added. By extraction of the reaction mixture with sodium bicarbonate solution 0.89 g. (6%) of the starting acid was recovered. Most of the dihydrocoumarin was removed by recrystallization from alcohol (7.3 g., 60%), the remainder by washing with warm potassium hydroxide solution (acidification liberated 0.9 g. of crude hydroxy acid). The residual ketone (2.2 g., 9%) was contaminated with a small amount of another substance (0.09 g., m. p. 149–151°) which was obtained by concentration of the mother liquors after most of the ketone (m. p. 92–94°) had been removed.

Structure Proof for β-(2-Methoxy-5-bromophenyl)-ethyl 2′-Methoxy-5′-bromophenyl Ketone.—The molecular weight determined by the depression of the freezing point of benzene was 412 (calcd. 428). Oxidation with aqueous potassium permanganate produced only 2-methoxy-5-bromobenzoic acid, m. p. and mixed m. p. 118–119° (the authentic sample was prepared by oxidation of 2-methoxy-5-bromobenzaldehyde). The following derivatives were prepared by standard procedures; oxime, m. p. 141–142°.

Anal. Calcd. for $C_{17}H_{17}O_3NBr$: C, 46.07; H, 3.87. Found: C, 46.10; H, 4.18.

Phenylhydrazone, m. p. 159–161°.

Anal. Calcd. for $C_{23}H_{22}O_2N_2Br_2$: C, 53.30; H, 4.28. Found: C, 53.07; H, 4.00.

p-Nitrophenylhydrazone, m. p. 187–188°.

Anal. Calcd. for $C_{23}H_{21}O_4N_3Br_2$: C, 49.04; H, 3.76. Found: C, 49.22; H, 3.96.

The oxime (0.4 g.) was mixed with 85% sulfuric acid (10 ml.) and heated to 180° during five minutes. After dilution with water (100 ml.) the solution was boiled for five hours. The cool hydrolysis mixture was extracted with ether and the aqueous layer made alkaline and extracted with ether to remove the amine. There was obtained 0.13 g. of amine which after recrystallization from petroleum ether melted at 94.8–95.6°. The melting point of a mixture of this substance and an authentic sample of 2-amino-4-bromoanisole was 95–96.2°. The 2-amino-4-bromoanisole was prepared by reduction with iron and acetic acid of 2-nitro-4-bromoanisole (m. p. 84–85°) which had been prepared by the method of Reverdin and Düring.[24] The ether extract of the original hydrolysis mixture was shaken with sodium bicarbonate solution to remove the acid. Acidification of the aqueous solution followed by ether extraction and evaporation of the ether yielded 0.04 g. of crude acid. After purification by sublimation and recrystallization from petroleum ether this substance melted at 116–118° and was found by mixed melting to be identical with β-(2-methoxy-5-bromophenyl)-propionic acid.

Summary

A satisfactory method for the preparation of 4-bromo-7-methoxyhydrindene has been worked out using the von Auwers hydrindone synthesis.

The structure of the intermediate 4-bromo-7-hydroxy-1-hydrindone has been proven by an alternate synthesis.

(21) Prepared in 78% yield by the method of Quelet, *Bull. soc. chim.*, [5] **1**, 539 (1934).

(22) Lasch, *Monatsh.*, **34**, 1662 (1913), reports the melting point as 142°.

(23) Fittig and Hochstetter, *Ann.*, **226**, 362 (1884), report the melting point as 106°.

(24) Reverdin and Düring, *Ber.*, **32**, 161 (1899).

It has been established that attempted cyclization of β-(2-methoxy-5-bromophenyl)-propionic acid produces 6-bromo-3,4-dihydrocoumarin as the main product.

The structure of a minor product (β-(2-methoxy-5-bromophenyl)-ethyl 2′-methoxy-5′-bromophenyl ketone) of the cyclization has been proved. This substance must have been formed by the elimination of a propionic side chain in the presence of aluminum chloride.

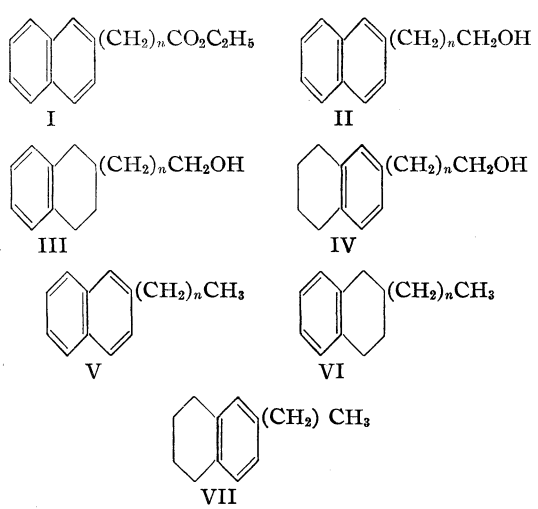
NEW BRUNSWICK, N. J., AND NEW YORK, N. Y. RECEIVED MAY 14, 1949

[A COMMUNICATION FROM THE LABORATORY OF ORGANIC CHEMISTRY OF THE UNIVERSITY OF WISCONSIN]

Selective Hydrogenation of Esters Containing a Naphthalene Nucleus

BY HOMER ADKINS AND EDWARD E. BURGOYNE[1]

The selective hydrogenation of a carbethoxy to a carbinol group, in an ester containing a naphthalene nucleus, has not seemed a feasible process. This was true because the naphthalene nucleus is rather rapidly and quantitatively hydrogenated to a tetralin over the copper chromium oxide catalyst at 150–190°. A further complication arises from the fact that the unsaturation of the rings labilizes an attached carbinol group toward hydrogenolysis. Thus the hydrogenation of esters of the type shown in I may give one or all of the three types of alcohols II, III and IV, and the hydrocarbons V, VI and VII resulting from hydrogenolysis.



Ethyl and methyl esters where "*n*" has a value of 0, 1, 2 and 3, and the chain is in the 1- or the 2-position of the nucleus, have been subjected to hydrogenation over a copper chromium oxide catalyst.[2] A summary of the numerical results of several of the more significant hydrogenations is given in Table I. The extent of hydrogenation is indicated in the fourth column of the table by stating the percentage to which the carbethoxy group reacted, as well as the moles of hydrogen absorbed during the period of reaction. A hydrogenation of ethyl benzoate to benzyl alcohol is also listed in the table. The result at 125° was similar to that reported at 165° by Mozingo and Folkers, who were the first to hydrogenate a carbethoxy group on a benzenoid nucleus to a carbinol group.[3]

The experimental conditions, as well as the structure of the ester, make important differences in the rates and relative rates of the various types of hydrogenation and hydrogenolysis. The compounds, where *n* equals 1, 2 or 3 in formula I, underwent hydrogenation to alcohols smoothly at 190–200°. The yield of alcohols when *n* equals 1 was lower (77%) than where *n* equals 2 or 3 (90%). There was no significant difference in behavior between the esters containing the 1- as compared with the 2-naphthyl group. However, in all the four esters just mentioned, four moles of hydrogen per mole of ester were absorbed so that the alcohol produced contained a tetrahydronaphthyl, rather than a naphthyl, group. That is to say, the naphthalene nucleus is sufficiently labile toward hydrogenation in the presence of the copper oxide–chromite catalyst so that hydrogenation of the ring took place under the same conditions required for the hydrogenation of the carbethoxy to a carbinol group. The relative distribution of hydrogen between the substituted and unsubstituted rings during catalytic hydrogenation, will be considered in more detail below, but it will suffice for the present to state that the tetrahydronaphthyl alcohols of structure IV predominate with lesser amounts of alcohols of type III.

In compounds where *n* equals zero in I, hydrocarbons are almost the only products resulting when the esters are hydrogenated at 190–200°. Fortunately, the esters where *n* equals 0 or 1, can be hydrogenated under milder conditions than when *n* equals 2 or 3. The naphthoates and naphthylacetates may be hydrogenated at tempera-

(1) Wisconsin Alumni Research Foundation Research Assistant 1946–1948.

(2) The catalyst was prepared as described by Adkins, "Reactions of Hydrogen," University of Wisconsin Press, Madison, 1937, p. 13, except the decomposition step was carried out by a procedure recommended by Dr. Ralph Mozingo. This consisted of decomposing 2 g. of copper ammonium chromate, stirring in another 2 g. and carefully decomposing, then adding 4 g., etc., each time doubling the amount added and carrying out the decomposition at the minimum temperature with constant stirring until a total of 60–100 g. of material was used.

tures as low as 80° with an activated catalyst. At temperatures in the range 90–110°, with a high ratio of catalyst to ester, alcohols containing the unhydrogenated naphthalene nucleus were obtained. The best yields, so far obtained, are 35–40% for 2-(1-naphthyl)-ethanol and 2-naphthylcarbinol and only 6% for 1-naphthylcarbinol although the percentage yield of the naphthylethanol would be increased to almost 100% and the others by 50%, if allowance were made for the amount of ester not reacting.

In order to obtain the best yields it is necessary to carefully control the extent of hydrogenation and to stop the reaction after about 70% of the ester has been hydrogenated. If the reaction is allowed to proceed, then the carbinol is destroyed more rapidly than it is produced. Hydrogenolysis of the carbinols and hydrogenation of the naphthalene nucleus do take place over the catalyst even at temperatures below 100°. In fact, if too low a temperature is used in attempting to convert esters to alcohols, the reaction proceeds so slowly that hydrocarbons are produced just as they are at too high a temperature.

Since the hydrogenation of esters of formula I, when n was 3 or 4, gave only alcohols of formulas III and IV rather than of II, it became of interest to attempt to prepare the latter from III and IV through dehydrogenation. Two general methods were used with a palladium on activated carbon catalyst. In one method the dehydrogenation was carried out under pressure of ethylene in a steel reaction vessel at 200–225° for 8–13 hours, with benzene or cymene as the medium.[13] In the other the compound to be dehydrogenated was heated with a palladium catalyst under reflux at 180–185° for 18–29 hours in cymene. The extents of dehydrogenation obtained in both methods seemed to be about 65–80%. However, the yields of naphthyl alcohols were quite poor, both with respect to amount and quality of product. In every case hydrocarbons were produced, even when the dehydrogenations were far from complete. These results are similar to those reported by Newman and Zahm[14] and by others.

The relative rates of hydrogenation of the substituted and unsubstituted rings in esters of the structure of I has apparently not been determined. The isomeric tetrahydro esters or the corresponding alcohols (III and IV), or hydrocarbons (VI and VII) are not readily separated nor the proportions of the isomers in a mixture estimated. Several esters have been hydrogenated over W-6 Raney nickel at room temperature and low pressures, *i.e.*, ethyl γ-(1-naphthyl)-butyrate, ethyl γ-(2-naphthyl)-butyrate, methyl β-(1-naphthyl)-propionate, ethyl 1-naphthoate, and methyl 2-naphthoate. The corresponding tetrahydronaphthyl esters were produced almost quantitatively, four moles of hydrogen per mole of ester being taken up within a few hours.

The saponification of the esters and the separation of the acids showed that the tetrahydro esters from ethyl γ-(1-naphthyl)-butyrate and ethyl γ-(2-naphthyl)-butyrate gave good yields of the 5,6,7,8-tetrahydro (III) acids. The isomeric 1,2,3,4-tetrahydro (IV) acids were not found. The tetrahydro ester from methyl β-(1-naphthyl)-propionate gave both acids, the

yield of the 5,6,7,8-tetrahydro acid being three times as large as that of the 1,2,3,4-tetrahydro acid. Similarly ethyl 1-naphthoate gave the 5,6,7,8-tetrahydro acid and the 1,2,3,4-tetrahydro acid in a ratio of 5:3. Methyl 2-naphthoate gave the 5,6,7,8- and the 1,2,3,4-tetrahydro acids in a ratio of 15:1.

The distribution of hydrogen between the rings of an ester or alcohol over a copper chromium oxide catalyst under 300 atm. would not necessarily be the same as over a nickel catalyst at 2–3 atm. However, the evidence available is that the proportion of 1,2,3,4- and 5,6,7,8-tetrahydroalcohols is similar in the two cases. The 2-(1-tetrahydronaphthyl)-ethanol obtained (Table I) gave the 3,5-dinitrobenzoate of 2-(1-(5,6,7,8-tetrahydronaphthyl))-ethanol[15] in good purity and yield.

Saponification of the residual ester in an incomplete hydrogenation of methyl β-(1-naphthyl)-propionate over copper chromium oxide gave 3-(1-tetrahydronaphthyl)-propanol-1 and after saponification of the residual esters, β-[1-(5,6,7,8-Tetrahydronaphthyl)]-propionic acid. This acid constituted at least 70% of the mixture of acids, a proportion in harmony with that obtained in the low pressure hydrogenation over W-6 Raney nickel. Thus the 5,6,7,8 isomers probably predominate in the tetrahydronaphthyl alcohols listed in Table I, although significant amounts of the 1,2,3,4 isomer are no doubt present.

Experimental Part

The esters used were distilled from Raney nickel before they were submitted to hydrogenation. They had the properties indicated in the footnotes to Table I. The ethyl γ-naphthylbutyrates were prepared from naphthalene (154 g.) through the reaction of succinic anhydride with naphthalene[7,9,16,17,18,19]; separation of the isomeric acids (m. p. 120–125° and m. p. 167–172°); their reduction to γ-(1-naphthyl)-butyric acid (m. p. 104–107°) and γ-(2-naphthyl)-butyric acid (m. p. 95–97°); and esterification of the acids. The over-all yield of the esters from naphthalene was approximately 50% of the theoretical, the two esters being obtained in a ratio of 4 parts of 1-naphthyl to 3 parts of the 2-naphthyl ester.

The catalyst was separated by centrifugation; solid potassium hydroxide (5 g.) added to the methanol solution; the solvent distilled off during a period of 3–4 hours; water added to the residue; the alcohols and hydrocarbons extracted with ether; the products dried and distilled; and the acids recovered from their salts. The products were crystallized where possible, or fractionated through a Vigreux column (12 mm. × 15 cm.). The alcohol from ethyl 1-naphthylacetate was characterized as the 3,5-dinitrobenzoate, m. p. 126–127°, of 2-1-(5,6,7,8-tetrahydronaphthyl)-ethanol.[6] The 2-(1-naphthyl)-ethanol from the methyl 1-naphthylacetate (20 g.) was obtained in a yield of crude product of 6.9 g., b. p. 115–121° (0.12 mm.), $n^{25}D$ 1.6105–1.6180. Purification by distillation and crystallization from petroleum ether gave 3.8 g., m. p. 55–58° and recrystallization 3.3 g., m. p. 60.5–61.5°. The phenylurethan had a m. p. 116–116.5°.[20] 1-Naphthylacetic acid (11.0 g.) was recovered after saponification of the residual ester, indicating that the hydrogenation had not been more than 41% complete. Ethyl 1-naphthoate at 80° gave 1-methylnaphthalene (7.3 g., b. p. 97–99° (6.5 mm.), $n^{25}D$ 1.6140, Z 35.0. Ethyl 1-naphthoate at 88° gave products which after several recrystallizations gave 0.6 g. of 2-(1-naphthyl)-ethanol, m. p. 58–59°, and 0.3 g., m. p. 60–61°, with a phenylurethan m. p. 89–89.5°.[21,22] There was also obtained in the usual way 1-naphthoic acid (9.5 g.) and 1-methylnaphthalene (4.9 g.) b. p. about 100° (7 mm.), $n^{25}D$ 1.6120–1.6132.

Methyl 2-naphthoate gave 2-naphthylcarbinol (5.7 g., m. p. 80–81°),[23] 2-methylnaphthalene (0.8 g., m. p.

31–32°), and 2-naphthoic acid (5.8 g.) after saponification of the residual ester. The material not accounted for above was apparently a mixture of hydrocarbons which did not crystallize. When the hydrogenation was carried out at 166° the chief product was a hydrocarbon (10.2 g., b. p. 75–85° (6.5 mm.), $n^{25}D$ 1.5335, Z 23.2). The product was apparently predominantly 2-methyl-5,6,7,8-tetrahydronaphthalene.[24]

Hydrogenation of Esters at 2–3 atm. Pressure.—The esters (0.05 mole) in 50–75 ml. of methanol or ethanol, depending upon whether a methyl or ethyl ester was used, were hydrogenated at room temperature, in a pyrex glass centrifuge bottle of 235 ml. capacity, with 5 g. of W-6 Raney nickel,[25] under a pressure of 45 to 30 p. s. i. The esters absorbed 2 moles of hydrogen per mole of ester during a period varying from 1.2 hours for ethyl 1-naphthoate to eight hours for ethyl γ-(2-naphthyl)-butyrate. The other esters ethyl γ-(1-naphthyl)-butyrate, methyl β-(1-naphthyl)-propionate and methyl 2-naphthoate required two to four hours for hydrogenation. The hydrogenations went quantitatively with the formation of the tetrahydro esters. The products were distilled and showed the properties and analyses given in Table II.

Samples of each of the six tetrahydro esters were saponified in the usual way and the acids isolated. The γ-[1-(5,6,7,8-tetrahydronaphthyl)]-butyric acid, 3.5 g., m. p. 96–97°,[26] was obtained by recrystallization from 5.2 g. of acid obtained from the saponification. None of the isomeric 1,2,3,4-tetrahydro acid could be found in the mother liquors. Similarly γ-[2-(5,6,7,8-tetrahydronaphthyl)]-butyric acid, 3.6 g., m. p. 46.5–47.5°,[27] was obtained in turn from 10.8 g. of the acid. The amide, m. p. 135–136°, was prepared.[28] None of the isomeric 1,2,3,4-tetrahydro acid could be found in the mother liquors from which the 5,6,7,8-tetrahydro acid had been obtained.

The saponification of ethyl β-(1-tetrahydronaphthyl)-propionate gave a mixture of acids. From the mixture of acids (3.5 g.) there was obtained by recrystallizations from petroleum ether, β-[1-(5,6,7,8-tetrahydronaphthyl)]-propionic acid, 2.5 g., m. p. 136–137°.[29] The isomeric β-[1-(1,2,3,4-tetrahydronaphthyl)]-propionic acid, 0.5 g., m. p. 75–76°, was also obtained.[30] The ratio of the two isomeric acids was calculated to be about 3:1.

Two acids were obtained by the saponification of a sample of methyl 1-tetrahydronaphthoate. Through the usual procedures 1-(5,6,7,8-tetrahydro)-naphthoic acid, 1.7 g., m. p. 148–150°, was obtained from 2.2 g., m. p. 140–145°, which was in turn obtained from 4.7 g. of the mixture of acids from a saponification. The amide m. p. 185° was prepared.[31,32] There was also obtained from the mixture of acids (4.7 g.) the 1-(1,2,3,4-tetrahydro)-naphthoic acid, 1.3 g., m. p. 74–80°. The amide m. p. 141–143° was prepared.[33]

The chief component of the mixture of acids (8.6 g.) from methyl 2-naphthoate was 5,6,7,8-tetrahydro-2-naphthoic acid, 6.8 g., m. p. 148–151°, 5.8 g., m. p. 152–153.5°. The amide m. p. 137–138° was prepared.[34,35] There was also obtained 0.3 g. of somewhat impure 1,2,3,4-tetrahydro-2-naphthoic acid, m. p. 85–87°, and after recrystallization m. p. 86–88°.[36,37]

Dehydrogenation of Tetrahydronaphthyl Alcohols.—A sample (10.2 g.) of 4-[2-(tetrahydronaphthyl)]-butanol-1 in 50 ml. of *p*-cymene was dehydrogenated with 2 g. of a 5% palladium on activated carbon catalyst,[38] by heating it in a bath held at 185–190°. The apparatus was equipped with ground glass connections and a mechanical stirrer. About 2.5 liters of hydrogen was evolved during a period of 28.5 hours. When the products of the reaction were worked up a hydrocarbon fraction 2.6 g., b. p. 83–116° (0.3 mm.), $n^{25}D$ 1.5718, Z 29.0, d^{25}_4 0.9647; and an alcohol fraction 4.2 g., b. p. 135–137° (0.3 mm.), $n^{25}D$ 1.5664, Z 25.6 were obtained. Upon the basis of the Z values, the mixture of alcohols was estimated to contain 60% of 4-(2-naphthyl)-butanol-1 mixed with 40% of the tetrahydro alcohol. A picrate m. p. 77–78° prepared from the hydrocarbon fraction indicated 2-(*n*-butyl)-naphthalene.[39] 3-[1-(Tetrahydronaphthyl)]-propanol-1 (9.5 g.) was dehydrogenated as described for the butanol above. Similar results were obtained, 2140 ml. of hydrogen was evolved and 5 g. crude γ-(1-naphthyl)-propanol-1, b. p. 131–133° (0.7 mm.), $n^{25}D$ 1.5917, Z 28.5, d^{25}_4 1.0719[10] was obtained. Analysis for carbon and hydrogen as well as the Z values indicated that the product was not more than 80% pure. Hydrocarbons (2 g.) were also produced in the dehydrogenation.

Summary

Esters of formula I where *n* is 0, 1, 2 or 3, and the substituent is in the 1 or 2 position of the naphthalene nucleus, have been submitted to hydrogenation over the copper chromium oxide catalyst at temperatures from 80 to 200°. Through the use of a high ratio of catalyst to ester at 80–120° and by controlling the extent of hydrogenation, alcohols of formula II have been obtained where *n* is 0 or 1. Where *n* has a value of 2 or 3 the temperature required for the hydrogenation of the carbethoxy group was sufficiently high so that tetrahydronaphthyl alcohols of formula III and IV were obtained.

Esters of formula I have been quantitatively hydrogenated to the corresponding tetrahydronaphthyl esters, over W-6 Raney nickel at 2-3 atm. and room temperature. The unsubstituted ring is more susceptible to hydrogenation than the substituted ring in these esters.

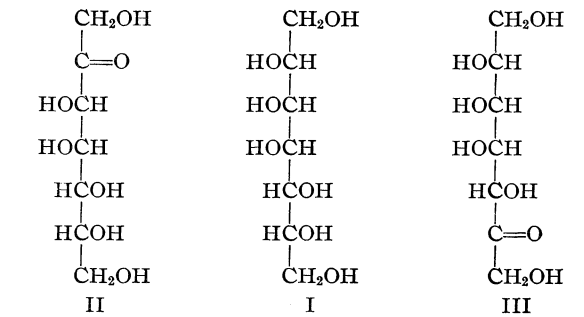
The Oxidation of Volemitol by Acetobacter suboxydans and by Acetobacter xylinum

BY LAURA C. STEWART, NELSON K. RICHTMYER AND C. S. HUDSON

Volemitol (I) was discovered by Bourquelot[1] in the mushroom *Lactarius volemus* Fr., by Bougault and Allard[2] in the roots of several species of *Primula*, and more recently by Asahina and Kagitani[3] in the lichen *Dermatocarpon miniatum* (L.) Mann. From the synthetic side this same heptitol has been described by Peirce[4] who called it D-β-mannoheptitol because he had obtained it from D-β-mannoheptose by reduction with sodium amalgam; by LaForge,[5] who isolated it as one of the reduction products of naturally occurring D-mannoheptulose; and by LaForge and Hudson,[6] who called it α-sedoheptitol when they found it to be one of the reduction products of naturally occurring sedoheptulose. LaForge[7] showed that α-sedoheptitol was identical with volemitol, and Ettel[8] later proved the identity of volemitol with D-β-mannoheptitol of known configuration.[4] By our present system of nomenclature, volemitol (I) may be named either D-manno-D-*talo*-heptitol or D-altro-D-*manno*-heptitol.

In a recent contribution from this Laboratory[9] it was established that the "phenyl-volemosazone" which Fischer[10] obtained from the products of oxidation of volemitol by sodium hypobromite was D-mannoheptose phenylosazone, and it was suggested accordingly that the name "volemose" might well be discarded or used only in a historical way. In accord with a previously announced intention,[9] we have now repeated Bertrand's[11] biochemical oxidation of volemitol with *Acetobacter xylinum* and have identified "volemulose," the sirupy ketone sugar formed. Very recently, Ettel and Liebster[12] showed that *A. suboxydans* oxidized volemitol to a mixture of D-mannoheptulose and D-altroheptulose (= sedoheptulose) and estimated that the two sugars were produced in equal amounts. The present independently conceived experiments agree with these results, but they disprove Ettel and Liebster's inference that *A. xylinum* and *A. suboxydans* give the same products from volemitol.

Because *Acetobacter suboxydans*, in contrast to *A. xylinum*, had previously been found to give excellent yields of ketone sugars from most of the polyhydric alcohols which it attacks, we decided to study first the behavior of *A. suboxydans* toward volemitol. According to the specificity rule of Bertrand[13] for *A. xylinum*, as extended by Hann, Tilden and Hudson[14] to *A. suboxydans*, we should expect that the latter organism would oxidize volemitol (I) to D-mannoheptulose (II), D-altroheptulose (=sedoheptulose) (III), or to a mixture of these two ketoses. Experiments showed that volemitol was indeed oxidized readily by *A. suboxydans*, and reducing sugar was produced in nearly theoretical yield. The resulting solution, from 9 g. of volemitol, was deproteinized, deionized, and concentrated to a sirup from which we were able to isolate 3.8 g. of crystalline D-mannoheptulose. The mother liquor was heated with dilute sulfuric acid to convert any sedoheptulose to its anhydride, and we could then obtain 2.2 g. of crystalline sedoheptulosan. Thus, as might be expected from the presence of the favorable grouping  at each end of the volemitol molecule, both D-mannoheptulose and D-altroheptulose were formed by the action of *A. suboxydans*.



On the other hand, the oxidation of 4 g. of volemitol by *A. xylinum* proceeded very slowly. A heavy pellicle of cellulosic material was formed, and titration of the solution showed that only 29% of the expected reducing sugar was formed even after fifty-five days. The solution, freed from

protein, ionizable material, and 2.2 g. of unchanged volemitol, was concentrated to a sirup which showed no tendency to crystallize when inoculated with D-mannoheptulose. It was heated with dilute sulfuric acid, with a resulting change in rotation from positive to negative, and 0.22 g. of crystalline sedoheptulosan was isolated. The mother liquor was acetylated and chromatographed, but no evidence could be found to indicate the presence of D-mannoheptulose.[14a] The conclusion is that *A. xylinum* appears to attack only one end of the volemitol molecule to produce a ketoheptose, and that Bertrand's sirupy "volemulose" was in reality the first description of the sugar we now know as D-altroheptulose (=sedoheptulose). The phenylosazone of "volemulose," reported by Bertrand[11a,b] to melt at 205–207° is to be identified as D-altroheptose phenylosazone, even though the melting point of the latter is known to be somewhat lower, namely, 197°[6] or 194–195°.[15]

Experimental

Volemitol.—The material used in these experiments was prepared by Dr. Raymond M. Hann and Mr. John T. Sipes, of this Laboratory, by the reduction of sedoheptulose sirups with sodium amalgam.[16] The recrystallized product melted at 152°.

Oxidation of Volemitol by Acetobacter suboxydans.—After some preliminary experiments had been completed, the following procedure was adopted for the oxidation of the 10-g. sample. A medium was prepared to contain 0.5% of Difco yeast extract, 0.3% of potassium dihydrogen phosphate, 0.05% of D-glucose and 2% of volemitol after dilution to 500 ml. with distilled water. This solution was distributed among five 500-ml. Erlenmeyer flasks, sterilized, and each flask was inoculated with 0.3 ml. of a three-day-old culture of *A. suboxydans*[17] grown on a yeast extract and D-glucose medium. The mixture was incubated in an oven at 30°. The progress of the reaction was followed by deproteinizing 1-cc. aliquots with zinc sulfate and barium hydroxide according to Somogyi,[18] and determining reducing sugar in the filtrate by the method of Hagedorn and Jensen[19] as modified by Hanes.[20] After one hundred and sixty-two hours a reducing value equivalent to 18.1 mg. of mannoheptulose per ml. had been reached, and was unchanged after another twenty-four hours.

The remainder of the material in the five flasks was combined and deproteinized by the addition of 250 ml. of 5% aqueous zinc sulfate solution followed by an equivalent amount of aqueous barium hydroxide solution, so that the resulting reaction mixture was neutral to phenolphthalein. The clear, colorless filtrate was deionized by passage through columns of Amberlite IR-100 and IR-4B, and then concentrated *in vacuo* to 280 ml. At this point, 28 ml. of the solution, corresponding to about 1 g. of reducing sugars, was heated with 2 ml. of phenylhydrazine and 1 ml. of glacial acetic acid for two hours on the steam-bath. The resulting phenylosazone was filtered from the cooled solution, and washed successively with 10% acetic acid, water, ethanol and ether. The yellow, finely crystalline powder weighed 1.1 g. and melted at 180–187° with decomposition. Upon recrystallization from 75 ml. of ethanol the clusters of tiny, yellow needles (0.4 g.) melted at 177–185° with decomposition. The material is evidently a mixture of the phenylosazones[9] of D-altroheptose (194–195°) and D-mannoheptose (199–200°), and no further attempts were made to separate the components.

The main portion of the solution was concentrated *in vacuo* to a dry sirup which was taken up in methanol and allowed to concentrate in a desiccator. Upon inoculation at the thin-sirup stage, D-mannoheptulose separated in a yield of 2.8 g., with an additional 1.0 g. being obtained later. The product, after one recrystallization as prisms from methanol, weighed 2.2 g., melted at 151–152° and showed no depression of melting point when mixed with an authentic sample. The rotation, $[\alpha]^{20}D$ +29.1° in water (c, 2.5), was in agreement with the values +29.0 and +29.4° reported by LaForge.[5]

The filtrate from the D-mannoheptulose crystals was concentrated to a sirup which was dissolved in 30 ml. of N sulfuric acid and heated on the steam-bath for three hours. The solution was neutralized with excess barium carbonate, filtered, and concentrated *in vacuo* to a thick sirup. By dissolving the sirup in methanol and again concentrating we obtained a total of 2.2 g. of the characteristic prisms of sedoheptulosan.[21] After one recrystallization from hot methanol the product had a rotation, $[\alpha]^{20}D$ −143° in water (c, 2), and melting point, 154–155°, in good agreement with the values −146° and 155–156° reported by LaForge and Hudson.[6] A mixture of our product with sedoheptulosan from *Sedum spectabile* showed no depression of melting point.

Oxidation of Volemitol by Acetobacter xylinum.—In view of the experience of Tarr and Hibbert,[22] preliminary studies were made to determine optimal cultural conditions for the growth of *A. xylinum* upon mannitol and perseitol as substrates. A small concentration of ethanol appeared to stimulate the oxidation to some extent, whereas D-glucose and sodium lactate had little or no stimulatory effect. The medium finally selected contained 0.5% of Difco yeast extract, 0.3% of potassium dihydrogen phosphate and 2% of volemitol after dilution to 200 ml. with distilled water. The solution was divided between two 500-ml. Erlenmeyer flasks, sterilized, and to each flask was added 0.7 ml. of ethanol; this was followed by an inoculum of five drops of a twenty-four-hour culture of *Acetobacter xylinum*[23] which had been grown on a yeast extract and D-glucose broth containing 10% of canned cherry juice. After thirty days' incubation at 30° the mixture contained the equivalent of 5.2 mg. of mannoheptulose per ml.; after forty days the value had risen to 5.8 mg./ml., and was unchanged after another fifteen days. The solution was separated from the pellicle of cellulosic material, deproteinized, deionized, and concentrated *in vacuo* to dryness. The solid residue was extracted several times with warm methanol, leaving 2.2 g. of unchanged volemitol. The concentrated methanol solution would not crystallize when inoculated with D-mannoheptulose. Accordingly, the sirup was heated on the steam-bath for three hours with 50 ml. of N sulfuric acid; the levorotatory solution was neutralized with excess barium carbonate, filtered, and concentrated to a dry sirup. A methanol extract then yielded 0.22 g. of crystalline sedoheptulosan which was identified, after one recrystallization from methanol, by its rotation of $[\alpha]^{20}D$ −146° in water

(14a) **Note added Sept. 29, 1949.**—In order to eliminate the possibility that D-mannoheptulose was formed and then oxidized further by *A. xylinum*, it has now been shown in a separate experiment that a 0.5% solution of this ketose was unaffected even by seven weeks' incubation with *A. xylinum* in the usual culture medium.

(15) The melting point reported by Bertrand may have been observed on the Maquenne block.

(*c*, 1.2), and its melting point and mixed melting point of 154–155°.

The mother liquor from the sedoheptulosan still would not crystallize when concentrated and inoculated with D-mannoheptulose. The 0.38 g. of sirup was acetylated with acetic anhydride and pyridine, to yield 0.57 g. of sirupy acetate. Using the technique of flowing chromatography which we had already found could be applied to the acetylated mother liquor of the *A. suboxydans* experiment, we dissolved the 570 mg. of this acetate in ether, poured it on a column containing 10 g. of alumina, and eluted it exhaustively with absolute ether to remove 363 mg. of levorotatory material. Further elution with mixtures of ether and ethyl acetate produced 152 mg., in five fractions, all of which were dextrorotatory, but none could be induced to crystallize when inoculated with hexaacetyl-α-D-mannoheptulose as did certain of the corresponding fractions from the *A. suboxydans* experiment. In this case the dextrorotatory material presumably consists of acetylated sedoheptulose which has not yet been obtained in crystalline form. The combined five fractions were deacetylated, but the small amount of sirup still would not crystallize when inoculated with mannoheptulose.

Summary

The action of *Acetobacter suboxydans* upon volemitol proceeds readily and nearly quantitatively to produce both D-mannoheptulose and D-altroheptulose (=sedoheptulose). This result is in agreement with the specificity rule of Hann, Tilden and Hudson for the action of *A. suboxydans*.

The action of *Acetobacter xylinum* upon volemitol is slow and incomplete; only one end of the molecule appears to be oxidized, and the sirupy ketose, which was first obtained by Bertrand and named "volemulose," has been identified as D-altroheptulose (=sedoheptulose).

BETHESDA, MARYLAND RECEIVED MAY 31, 1949

Hydrogen Transfer. III.[1] Reaction of *p*-Ethyltoluene and *p*-Propyltoluene with Methylcyclohexene. Synthesis of Diarylalkanes

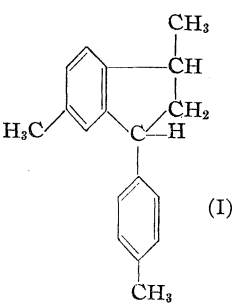
BY HERMAN PINES, D. R. STREHLAU[2] AND V. N. IPATIEFF

In a previous paper it has been shown that an abnormal reaction occurs when *p*-cymene is contacted with methylcyclohexene in the presence of either sulfuric acid or hydrogen fluoride.[3] Instead of the expected cycloalkylation of *p*-cymene, a hydrogen transfer was the main reaction; the methylcyclohexene acted as a hydrogen acceptor, forming methylcyclohexane, while *p*-cymene acted as a hydrogen donor yielding as the main product 1,3,3,6-tetramethyl-1-*p*-tolylindan.

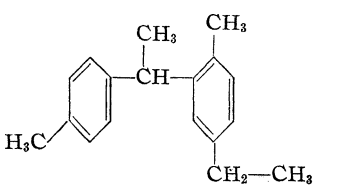
It was of interest to determine whether a para disubstituted benzene ring having an alkyl group containing more than one hydrogen atom on the carbon attached to the benzene ring would also yield products resulting from a hydrogen transfer reaction. For that reason *p*-xylene, *p*-ethyl- and *p*-propyltoluene reacted with methylcyclohexene in the presence of hydrogen fluoride and/or sulfuric acid.

p-Xylene, on reacting with methylcyclohexene in the presence of hydrogen fluoride, yielded only methylcyclohexyl-*p*-xylene. The formation of methylcyclohexane which serves as an indicator of a hydrogen transfer reaction was not observed.

Hydrogen transfer was the main reaction when *p*-ethyltoluene and methylcyclohexene in the molal ratio of two to one reacted in the presence of hydrogen fluoride. Forty-five per cent. of the methylcyclohexene was converted to methylcyclohexane and 20% to a compound corresponding to dimethyldicyclohexyl. Of the converted *p*-ethyltoluene 65% underwent a hydrogen transfer reaction to form a compound (Y) containing 18 carbon atoms boiling at 157° (6 mm.), $n^{20}D$ 1.5540; and 23% underwent condensation with methylcyclohexene, yielding probably 2-(1-methylcyclohexyl)-4-ethyltoluene[3a]; and remainder of the reacted *p*-ethyltoluene corresponded to a condensation product of methylcyclohexene with compound (Y). It was thought at first that *p*-ethyltoluene reacted with methylcyclohexene in a manner similar to the reaction of *p*-cymene and methylcyclohexene, and that 3,6-dimethyl-1-*p*-tolylindan (I), would be formed.



(I)



(II)

It was found however that the physical constants, solid derivatives and infrared absorption spectra (Graph I) of synthetic (I) did not correspond to the compound (Y) (Graph II).

In line with the mechanism proposed for the hydrogen transfer reactions described previously,[1] it

(1) For paper II of this series see H. Pines, A. Weizmann and V. N. Ipatieff, THIS JOURNAL, **70**, 3859 (1948).

(2) Universal Oil Products Company Predoctorate Fellow (1945–1947).

(3) V. N. Ipatieff, H. Pines and R. C. Olberg, THIS JOURNAL, **70**, 2123 (1948)

(3a) This conclusion is based on the observation that during the reaction of *p*-cymene with cyclohexene the carbon atom ortho to the methyl group is substituted[1] and that the reaction between benzene and isomeric methylcyclohexenes, including 4-methylcyclohexene results in the formation of 1-methyl-1-phenylcyclohexane (V. N. Ipatieff, E. E. Meisinger and H. Pines, unpublished work).

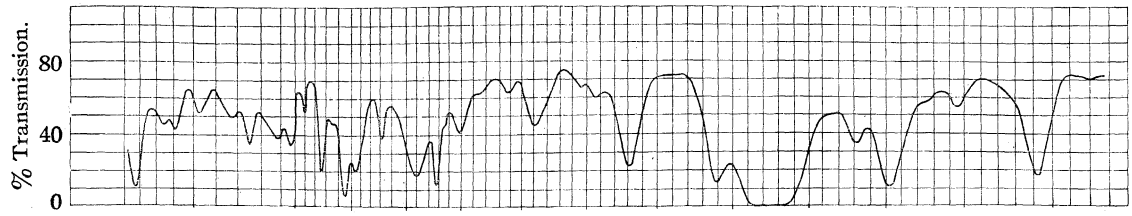


Fig. 1.—Synthetic 3,6-dimethyl-1-*p*-tolylindan.

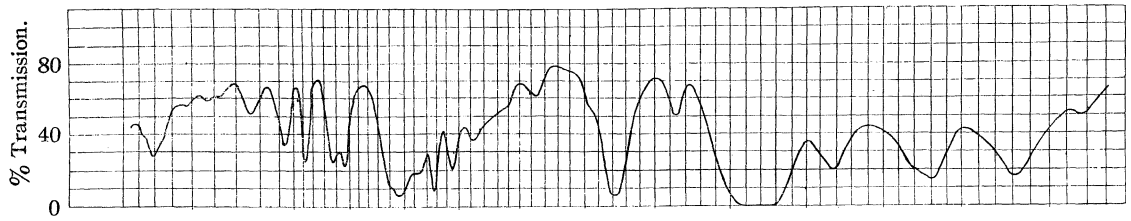

Fig. 2.—1-*p*-Tolyl-1-(2-methyl-ethylphenyl)-ethane obtained from hydrogen transfer reaction.

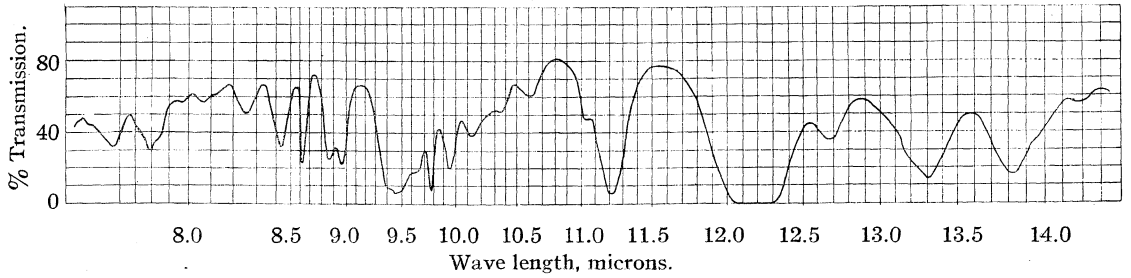

Fig. 3.—Synthetic 1-*p*-tolyl-1-(2-methyl-5-ethylphenyl)-ethane.

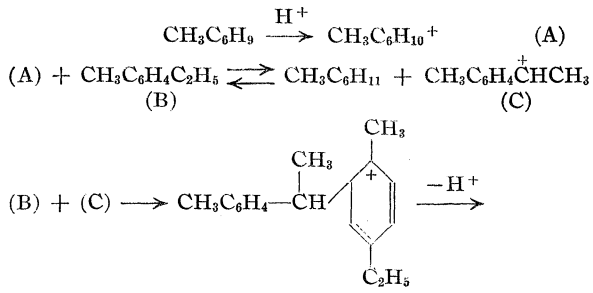
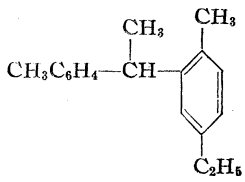
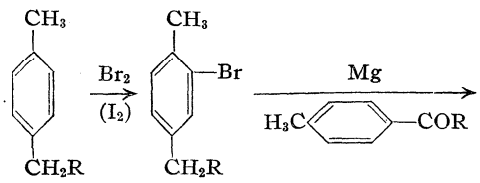
was reasoned that the reaction between *p*-ethyltoluene and methylcyclohexene might have yielded 1-*p*-tolyl-1-(2-methyl-5-ethylphenyl)-ethane (II). Compound II was synthesized, and it was found to be identical with the compound (Y) obtained from the hydrogen transfer reaction (Graphs I and III). Sulfuric acid used as the catalyst caused a similar type of reaction to occur as did hydrogen fluoride; 60% of the olefins used was converted to methylcyclohexane. The higher boiling hydrocarbons obtained from the reaction catalyzed by sulfuric acid were identical with the corresponding fraction obtained from the reaction in the presence of hydrogen fluoride.

To explain these findings, it is assumed that the proton from sulfuric acid or hydrogen fluoride adds to the methylcyclohexene to form a carbonium ion which then acts with *p*-ethyltoluene

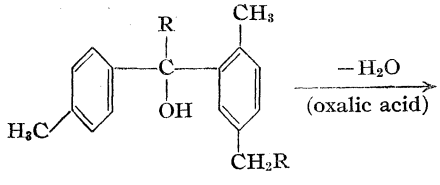




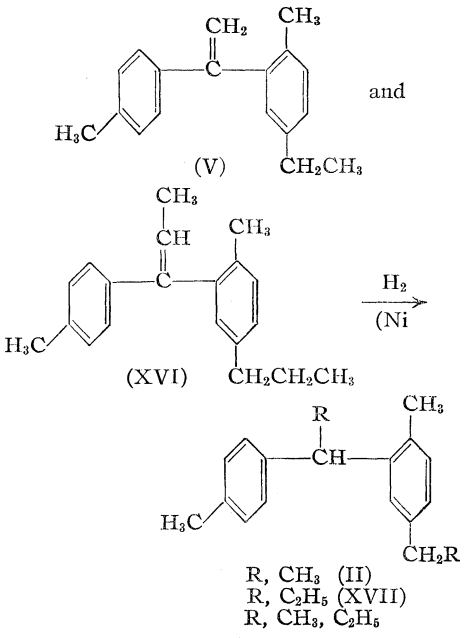
The synthesis of compound II and of a similar compound XVII was carried out according to the equations



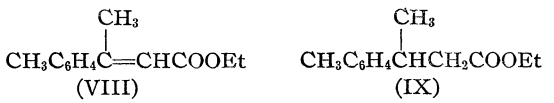
R, CH_3 (III)
R, C_2H_5 (XIV)



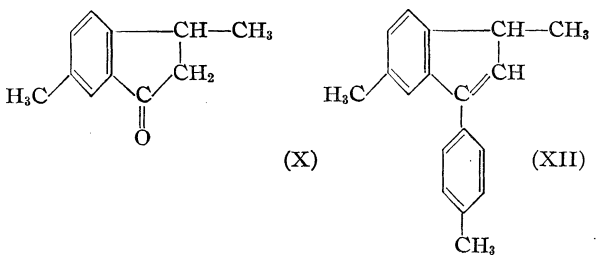
R, CH_3 (IV)
R, C_2H_5 (XV)



To synthesize (I) these steps were followed: *p*-methylacetophenone and ethyl bromoacetate were condensed in a Reformatsky reaction into ethyl 3-*p*-tolyl-3-hydroxybutyrate (VII); after dehydration of this compound to VIII, hydrogenation to IX and ring closure to 3,6-dimethyl-1-indanone



(X) using hydrogen fluoride, the indanone was treated with *p*-tolylmagnesium bromide; the intermediary tertiary alcohol (XI) was not isolated but was dehydrated to the substituted indene (XII) which was hydrogenated to (I).



p-Propyltoluene on treatment with 4-methylcyclohexene in the presence of hydrogen fluoride under experimental conditions indicated for *p*-ethyltoluene, yielded also as main reaction products compounds resulting from a hydrogen transfer reaction. Of the methylcyclohexene reacted, 40% was converted to methylcyclohexane and 15% to a compound corresponding to a dimethyldicyclohexyl and only 24% was condensed with *p*-propyltoluene to form methylcyclohexyl-*p*-propyltoluene. Of the *p*-propyltoluene reacted, 50% was converted to 1-*p*-tolyl-1-(2-methyl-5-propylphenyl)-propane; the structure of this compound was proved by comparing its infrared spectra (Graph IV) with that of the corresponding compound prepared by synthesis (Graph V).

The synthesis of 1-*p*-tolyl-1-(2-methyl-5-propylphenyl)-propane was made according to the outline presented above.

The *p*-ethyl- and *p*-propyltoluene used in this reaction were prepared by hydrogenation of the appropriate ketones.[4]

In attempting to prepare acetyl derivatives of compounds II and XVII which could be converted to solid 2,4-dinitrophenylhydrazones, it was found that acetylation causes a split at the aliphatic bridge at the para position of the tolyl and gives rise to *p*-methylacetophenone and tarry products from either II or XVII.

Experimental Part

I. Synthesis of *p*-Ethyltoluene

(a) ***p*-Acetyltoluene (VI).**—This compound was prepared from 275 g. (3.5 moles) of acetyl chloride, 276 g. (3 moles) toluene and 467 g. (3.5 moles) of aluminum chloride in 1800 ml. of carbon disulfide; yield 88%, b. p. 108° (18 mm.), $n^{20}D$ 1.5348. The oxime of this ketone melted at 87–88°.[5]

(b) ***p*-Ethyltoluene.**—*p*-Acetyltoluene was hydrogenated under 100 atmospheres of initial hydrogen pressure and at 180° in the presence of a copper oxide–alumina catalyst[4] (94% CuO, 6% Al_2O_3). The *p*-ethyltoluene which was obtained in a yield of 95% distilled at 161–162°, $n^{20}D$ 1.4943.[6]

II. Reaction of *p*-Ethyltoluene with 4-Methylcyclohexene in the Presence of Hydrogen Fluoride

The reaction was carried out according to a procedure described previously.[3] The following reagents were used: 240 g. (2 moles) of *p*-ethyltoluene, 96 g. (1 mole) of 4-methylcyclohexene and 250 g. of hydrogen fluoride. The hydrocarbon, 310 g. obtained from this reaction, was distilled through a 20–25 plate column at a reflux ratio of 10 to 1 and the following fractions were separated: (1) b. p. 102° (752 mm.), $n^{20}D$ 1.4250, 43 g. (methylcyclohexane); (2) b. p. 160–161° (752 mm.), $n^{20}D$ 1.4944, 99 g. (*p*-ethyltoluene); (3) b. p. 96–98° (5 mm.), $n^{20}D$ 1.4860, 19 g.; (4) b. p. 114–115° (4 mm.), $n^{20}D$ 1.5310, 21 g.; (5) b. p. 142–143° (4 mm.), $n^{20}D$ 1.5560, 100 g.; (6) b. p. 150–230° (4 mm.), $n^{20}D$ 1.5505, 16 g.; (7) residue 10 g.

Fraction 3 was stable toward a nitrating mixture; it corresponds to dimethyldicyclohexyl, d^{20}_4 0.8858; MR_D calcd. 62.4, obsd. 62.8.

Anal. Calcd. for $C_{14}H_{26}$: C, 86.51; H, 13.49. Found: C, 86.23; H, 13.17.

Fraction 4 corresponds to a (methylcyclohexyl)-*p*-ethyltoluene, d^{20}_4 0.9478; MR_D calcd. 70.3; obsd. 70.5.

Anal. Calcd. for $C_{16}H_{24}$: C, 88.82; H, 11.18. Found: C, 88.91; H, 10.70.

Acetyl derivative was prepared according to the method described previously.[1] The 2,4-dinitrophenylhydrazone of the ketone melted at 179–181°.

Anal. Calcd. for $C_{24}H_{30}N_4O_4$: C, 65.72; H, 6.57; N, 12.77. Found: C, 65.75; H, 6.42; N, 12.99.

Fraction 5 corresponds to 1-*p*-tolyl-1-(2-methyl-5-ethylphenyl)-ethane, d^{20}_4 0.9617; MR_D calcd. 78.1, obsd. 79.5.

Anal. Calcd. for $C_{18}H_{22}$: C, 90.75; H, 9.25. Found: C, 91.23; H, 9.19.

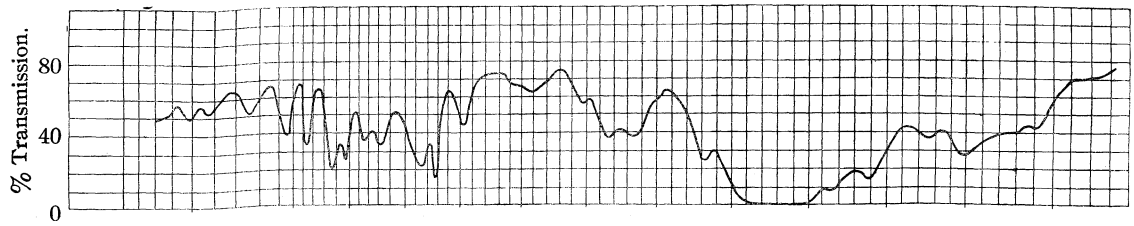

Fig. 4.—1-*p*-Tolyl-1-(2-methyl-5-propylphenyl)-propane obtained from hydrogen transfer reaction.

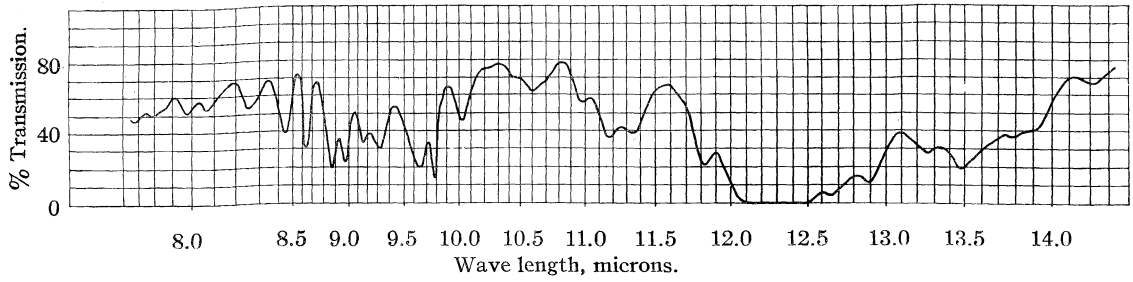

Fig. 5.—Synthetic 1-*p*-tolyl-1-(2-methyl-5-propylphenyl)-propane.

Infrared absorption spectra are given in Graph II.

Nitro Derivative.—Nitration with a nitrating mixture composed of 2 volumes of 96% sulfuric acid and 1 volume of 72% nitric acid gave a tetranitro derivative, m. p. 160–163°.

Anal. Calcd. for $C_{18}H_{18}N_4O_4$: C, 51.67; H, 4.36; N, 13.46. Found: C, 51.80; H, 4.25; N, 13.65.

Acetylation followed by the preparation of the 2,4-dinitrophenylhydrazone resulted in a small yield of solid product, m. p. 263–265°. A mixed melting point with the 2,4-dinitrophenylhydrazone of an authentic sample of *p*-methylacetophenone showed no depression.

Anal. Calcd. for $C_{15}H_{13}N_4O_4$: N, 17.9. Found: N, 17.5.

III. Reaction of *p*-Ethyltoluene with 4-Methylcyclohexene in the Presence of Sulfuric Acid

The reaction was made according to the procedure described previously[3]; 48 g. (0.4 mole) of *p*-ethyltoluene, 20 g. (0.2 mole) of 4-methylcyclohexene and 35 g. of 96% sulfuric acid were used. Fifty-seven grams of product was obtained from which the following cuts were separated: (1) b. p. 102° (751 mm.), $n^{20}D$ 1.4230, 11.8 g., methylcyclohexane; (2) b. p. 159–160° (751 mm.), $n^{20}D$ 1.4943, 16.7 g., *p*-ethyltoluene; (3) b. p. 114–115° (4 mm.), $n^{20}D$ 1.5330, 2-(1-methylcyclohexyl)-4-ethyltoluene; (4) b. p. 136–137° (3 mm.), $n^{20}D$ 1.5562, 11 g. (compound II); (5) residue 10 g.

Cut 3 was identified by the dinitrophenylhydrazone of the acetyl derivative and cut 4 by the infrared absorption spectra and nitro derivative.

IV. Synthesis of 1-*p*-Tolyl-1-(2-methyl-5-ethylphenyl)-ethane

(a) 1-Bromo-2-methyl-5-ethylbenzene (III).—Prepared by the bromination of *p*-ethyltoluene at 0° with bromine in the presence of a small amount of iodine,[7,8] 49 g. of the bromo-compound (83% yield), b. p. 99–101° (14 mm.), $n^{20}D$ 1.5440, was realized from 40 g. of the hydrocarbon.

Compound III on oxidation with a solution of chromic acid, sulfuric acid and water yielded 3-bromo-*p*-toluic acid melting at 203–204°; this agrees with the published data.[7]

(b) 1-*p*-Tolyl-1-(2-methyl-5-ethylphenyl)-ethanol (IV).—This was prepared by the Grignard method using 40 g. of 2-methyl-5-ethylbromobenzene, 4.8 g. of magnesium and 26.8 g. of *p*-methylacetophenone. The carbinol which was obtained and which amounted to 20.6 g. boiled at 162–164° (5 mm.), (64% yield), $n^{20}D$ 1.5655, d^{20}_4 1.0307; MR_D calcd. 79.6, obsd. 79.8.

Anal. Calcd. for $C_{18}H_{22}O$: C, 85.04; H, 8.66. Found: C, 84.88; H, 8.43.

(c) 1-*p*-Tolyl-1-(2-methyl-5-ethylphenyl)-ethane (V).—A solution of 13 g. of compound (IV) in 40 cc. of benzene was refluxed for one hour with 2 g. of oxalic acid to effect the dehydration. The olefins, 12 g., had the following physical constants: b. p. 146–146.5° (4 mm.), $n^{20}D$ 1.5770, d^{20}_4 0.9745; MR_D calcd. 77.7, obsd. 80.2.

Anal. Calcd. for $C_{18}H_{20}$: C, 91.50; H, 8.50. Found: C, 91.20; H, 8.52.

(d) 1-*p*-Tolyl-1-(2-methyl-5-ethylphenyl)-ethane (II) which was prepared by the hydrogenation of compound V in the presence of a nickel–kieselguhr catalyst at 100 atm. and 45° distilled at 148–150° (4 mm.), $n^{20}D$ 1.5540, d^{20}_4 0.9625; MR_D calcd. 78.1, obsd. 79.2. Infrared absorption spectra are given in Graph III. A tetranitro derivative, m. p. 160–162° was obtained by treating compound II with a nitrating mixture consisting of 2 volumes of 96% sulfuric acid and 1 volume of 72% nitric acid.

Anal. Calcd. for $C_{18}H_{18}N_4O_8$: C, 51.67; H, 4.36, N, 13.46. Found: C, 51.80; H, 4.31; N, 13.55.

The nitro compound did not show any depression in melting point when mixed with the corresponding nitro compound obtained from the hydrogen transfer reaction.

VI. Synthesis of 3,6-Dimethyl-1-*p*-tolylindan

(a) 3-*p*-Tolyl-3-hydroxybutyrate (VII) was prepared in 61% yield from 84 g. of *p*-methylacetophenone according to the procedure of Lindenbaum.[9] Compound VII thus prepared was colorless, boiling at 116–117° (4 mm.), $n^{20}D$ 1.5000, d^{20}_4 0.9381; the same compound was reported[7] as being a light yellow oil, boiling at 156–157° (16 mm.).

Anal. Calcd. for $C_{13}H_{18}O_3$: C, 70.22; H, 8.17. Found: C, 69.82; H, 7.91.

(b) Ethyl *β*-*p*-Tolylcrotonate (VIII).—Sixty-seven grams of compound (VII) was dehydrated in the presence of 12 g. of oxalic acid and 150 ml. of benzene. The following main two fractions were separated: (1) b. p. 116.5–120° (3–4 mm.), 39.6 g., $n^{20}D$ 1.5335; (2) b. p. 120–125° (3–4 mm.), 15.8 g., $n^{20}D$ 1.5455. The yield of VIII amounted to 89%. The dehydrated ester corresponded to a mixture of the two expected isomers.[9]

(7) H. N. Morse and I. Remsen, *Ber.*, **11**, 225 (1878).

(8) G. Defren, *ibid.*, **28**, 2651 (1895).

(9) S. Lindenbaum, *Berg-tech.*, **50**, 1270 (1917).

(c) **β-*p*-Tolylbutyric Acid (IX).**—Compound VIII, 55 g. was hydrogenated in the presence of 69 g. of *n*-pentane and 6 g. of a nickel–kieselguhr catalyst at 48° and under 115 atm. of hydrogen pressure.

The saturated ester was saponified by heating it at a reflux temperature with a solution of alcoholic potassium hydroxide. An 82% yield of the acid was obtained, m. p. 91–92°. It yielded the known *p*-toluidide[10] m. p. 112–113°.

(d) **3,6-Dimethylindanone (X).**—Twenty grams of compound IX was stirred into 200 g. of anhydrous hydrogen fluoride in a copper beaker at 0°. After standing two hours at 0° the hydrogen fluoride was evaporated and the remaining oil was washed with 2% potassium hydroxide. Distillation yielded 15 g. (88.5%) of the cyclic ketone b. p. at 100–102° (5 mm.), $n^{20}D$ 1.5518. The semicarbazone melted at 225° with decomposition.[11]

The following data on the ketone were not previously published: d^{20}_4 1.0454; dinitrophenylhydrazone m. p. 271–273°.

Anal. Calcd. for $C_{17}H_{17}O_4N_4$: C, 59.82; H, 4.99; N, 16.42. Found: C, 59.80; H, 4.92; N, 16.20.

A study of the various methods for cyclization was made with the following results:

Cyclization agent	Yield of ketone, %
Hydrogen fluoride	88.5 (Acid was used directly)
Aluminum chloride	67.0 (Acid chloride was used)
Stannic chloride	48.0 (Acid chloride was used)

(e) **3,6-Dimethyl-1-*p*-tolylindene (XII).**—3,6-Dimethyl-1-*p*-tolyl-1-indanol (XI) was prepared by the Grignard reaction using 2.68 g. of magnesium, 18.8 g. (0.11 mole) of *p*-bromotoluene and 13.0 g. (0.1 mole) of the 3,6-dimethyl-1-indanone (X). Because tertiary alcohol tends to dehydrate, it could not be isolated; 12.6 g. of the olefin (54% yield) was obtained distilling at 157° (5 mm.), $n^{20}D$ 1.6022, d^{20}_4 1.0307; MR_D calcd. 74.7, obsd. 74.4.

Anal. Calcd. for $C_{18}H_{18}$: C, 92.31; H, 7.67. Found: C, 91.75; H, 7.97.

(f) **3,6-Dimethyl-1-*p*-tolylindan (I).**—Twelve grams of the compound XII was hydrogenated under pressure in the presence of a nickel–kieselguhr catalyst at 50°. Distillation gave a colorless fluorescent oil boiling at 144–146° (5 mm.), $n^{20}D$ 1.5700, d^{20}_4 0.9998; MR_D calcd. 75.2, obsd. 77.4.

Anal. Calcd. for $C_{18}H_{20}$: C, 91.53; H, 8.47. Found: C, 91.37; H, 8.46.

The infrared absorption spectra of this compound are given in Graph I.

VII. Synthesis of *p*-Propyltoluene (XIII)

(a) ***p*-Methylpropiophenone.**—This ketone boiled at 114.5° (18 mm.), $n^{20}D$ 1.5287. The semicarbazone of this ketone melted at 187–188° and the oxime melted at 87.5–88° which is identical with the data given in the literature.[12,13] A dinitrophenylhydrazone (not previously reported) melted at 200–202°

Anal. Calcd. for $C_{16}H_{16}N_4O_4$: N, 17.1. Found: N, 17.0.

(b) ***p*-Propyltoluene,** which was obtained by hydrogenation[4] of *p*-methylpropiophenone distilled at 179–180° (750 mm.), $n^{20}D$ 1.4934, d^{20}_4 0.8588; the physical constants agree with those reported in the literature.[13a] A sulfonamide derivative[14] (not previously reported) melted at 79–80°.

Anal. Calcd. for $C_{10}H_{15}O_2NS$: C, 56.34; H, 7.04; N, 6.57. Found: C, 56.53; H, 7.14; N, 6.48.

VIII. Reaction of *n*-Propyltoluene with 4-Methylcyclohexene in the Presence of Hydrogen Fluoride

The reaction was carried out as described above, using the following reagents: *p*-propyltoluene, 240 g. (1.86 moles), 89 g. (0.93 mole) of 4-methylcyclohexene and 250 g. of hydrogen fluoride. The product resulting from this reaction weighed 304 g. The following fractions were separated by distillation: (1) b. p. 102° (750 mm.), $n^{20}D$ 1.4260, 40.5 g., methylcyclohexane; (2) b. p. 179–180° (750 mm.), $n^{20}D$ 1.4930, 109 g., *n*-propyltoluene; (3) b. p. 84–87° (3 mm.), $n^{20}D$ 1.4833, 13 g.; (4) b. p. 116–120° (3 mm.), $n^{20}D$ 1.5300, 34 g.; (5) b. p. 151–153° (3 mm.), $n^{20}D$ 1.5450, 86 g.; (6) b. p. 155–180° (3 mm.), $n^{20}D$ 1.5418, 10.0 g.; (7) residue 9.6 g.

Fraction 3 corresponds to a dimethyldicyclohexyl; it was stable toward a nitrating mixture consisting of 2 volumes of 96% sulfuric acid and 1 volume of 72% nitric acid; d^{20}_4 0.8850; MR_D calcd. 62.4, obsd., 62.6.

Anal. Calcd. for $C_{14}H_{26}$: C, 86.51; H, 13.49. Found: C, 86.19; H, 13.13.

Fraction 4 corresponds to 2-(1-methylcyclohexyl)-4-propyltoluene d^{20}_4 0.9502; MR_D calcd. 74.9; obsd. 74.8.

Anal. Calcd. for $C_{17}H_{26}$: C, 88.63; H, 11.37. Found: C, 89.12; H, 10.90.

The 2,4-dinitrophenylhydrazone of the acetyl derivative melted at 230–233°.

Anal. Calcd. for $C_{25}H_{32}N_4O_4$: C, 66.30; H, 7.13; N, 12.38. Found: C, 66.35; H, 7.05; N, 12.50.

Fraction 5 corresponds to 1-*p*-tolyl-1-(2-methyl-5-propylphenyl)-propane, d^{20}_4 0.9478; MR_D calcd. 89.1, obsd. 88.7.

Anal. Calcd. for $C_{20}H_{26}$: C, 90.16; H, 9.84. Found: C, 90.31; H, 9.93.

The infrared absorption spectra are given in Graph IV.

Nitration yielded a gummy product which could not be crystallized.

Acetylation followed by treatment with 2,4-dinitrophenylhydrazone gave a solid derivative, m. p. 263–265°. A mixed melting point with the dinitrophenylhydrazone of synthetic *p*-methylacetophenone showed no depression.

Anal. Calcd. for $C_{15}H_{14}N_4O_4$: C, 57.32; H, 4.46; N, 17.83. Found: C, 57.50; H, 4.89; N, 17.40.

IX. Reaction of *n*-Propyltoluene with 4-Methylcyclohexene in the Presence of Sulfuric Acid

p-Propyltoluene, 26.8 g. (0.2 mole), 4-methylcyclohexene, 10 g. (0.1 mole) and 10 g. of 96% sulfuric acid were used for the reaction. The following cuts were separated from 33.6 g. of the hydrocarbon layer: (1) b. p. 103° (750 mm.), $n^{20}D$ 1.4215, 3.6 g., (2) b. p. 179° (750 mm.), $n^{20}D$ 1.4938, 15.8 g.; (3) b. p. 122–129° (5 mm.), $n^{20}D$ 1.5318, 6.5 g.; (4) b. p. 144–150° (5 mm.), $n^{20}D$ 1.5440, 4.2 g.; (5) residue 2 g.

The distillation data and the physical constants show that the results obtained from sulfuric acid catalyzed reaction are comparable to the hydrogen fluoride catalyzed reaction except that no dimethyldicyclohexyl fraction is detectable and more cycloalkylation seems to occur.

X. Synthesis of 1-*p*-Tolyl-1-(2-methyl-5-propylphenyl)-propane

(a) **1-Bromo-2-methyl-5-propylbenzene (XIV).**—The same procedure was used as for bromination of *p*-ethyltoluene. Forty-eight grams (95% yield) of compound XIV was obtained (not previously reported), boiling at 119–120° (20 mm.), $n^{20}D$ 1.5388, d^{20}_4 1.2470; MR_D calcd. 52.4, obsd. 53.5.

Anal. Calcd. for $C_{10}H_{13}Br$: Br, 37.52. Found: Br, 37.48.

The position of the entering bromine atom was proved to be ortho to the methyl group by oxidation with dilute nitric acid to 3-bromo-*p*-toluic acid, m. p. 203–204°, which agrees with the data reported.[7]

(b) **1-*p*-Tolyl-1-(2-methyl-5-propylphenyl)-1-propanol (XV).**—Prepared by means of a Grignard reaction using

4.1 g. of magnesium, 40 g. of the bromide XIV and 28 g. of *p*-propionyltoluene. Distillation gave 26.2 g. of the tertiary alcohol boiling at 160–163° (3 mm.), $n^{20}D$ 1.5540, d^{20}_4 1.0025; MR_D calcd. 88.9, obsd. 90.2.

Anal. Calcd. for $C_{20}H_{26}O$: C, 85.1; H, 9.2. Found: C, 84.3; H, 9.4.

(c) **1-*p*-Tolyl-1-(2-methyl-5-propylphenyl)-propene (XVI).**—Prepared by dehydration of compound XV in benzene solution in presence of oxalic acid. The olefin was obtained in 87% yield, b. p. 149–150° (3 mm.), $n^{20}D$ 1.5695, d^{20}_4 0.9616; MR_D calcd. 86.9, obsd. 89.9.

Anal. Calcd. for $C_{20}H_{24}$: C, 90.84; H, 9.16. Found: C, 90.80; H, 9.20.

(d) **1-*p*-Tolyl-1-(2-methyl-5-propylphenyl)-propane (XVII).**—The olefin, compound XVI, was hydrogenated under pressure in the presence of a nickel–kieselguhr catalyst at 45°. The hydrocarbon obtained (XVII) boiled at 143–144° (3 mm.), $n^{20}D$ 1.5455, d^{20}_4 0.9480; MR_D calcd. 87.3, obsd. 86.6.

Anal. Calcd. for $C_{20}H_{26}$: C, 90.16; H, 9.84. Found: C, 90.29; H, 9.80.

The infrared absorption spectra are given in Graph V.

Acetylation followed by treatment with 2,4-dinitrophenylhydrazone gave a solid derivative m. p. 263–265°. A mixed melting point with the dinitrophenylhydrazone of synthetic *p*-methylacetophenone showed no depression.

XI. Reaction of *p*-Xylene with 4-Methylcyclohexene

Forty-two grams (0.4 mole) of *p*-xylene was treated with 19.2 g. (0.2 mole) of 4-methylcyclohexene in the presence of 50 g. of hydrogen fluoride by the usual procedure described above. The hydrocarbon layer after washing and drying weighed 52 g. The following products were separated by fractional distillation through a 20-plate column: (1) 135–137° (750 mm.), 22 g., $n^{20}D$ 1.4960 (*p*-xylene); (2) 131–134° (10 mm.), 18 g., $n^{20}D$ 1.5260; (3) > 135° (4 mm.), 9 g., $n^{20}D$ 1.5310.

Fraction 2 corresponded to (1-methylcyclohexyl)-*p*-xylene, d^{20}_4 0.9363; MR_D calcd. 65.7, obsd. 66.2 (new compound).

Anal. Calcd. for $C_{15}H_{22}$: C, 89.11; H, 10.89. Found: C, 89.05; H, 10.77.

Acetylation yielded a ketone from which 2,4-dinitrophenylhydrazone was prepared. Crystallization from the chloroform–ethanol solution produced orange needles m. p. 172–174° (new compound).

Anal. Calcd. for $C_{23}H_{28}N_4O_4$: N, 13.21. Found: N, 13.70.

Nitration of the hydrocarbon with a solution of 2 volumes of 96% sulfuric acid gave a sirupy product which could not be crystallized.

Acknowledgment.—The authors wish to thank Dr. W. S. Gallaway, Universal Oil Products Company, for the infrared absorption spectra, and Miss Patricia Craig, Northwestern University, for microanalyses.

Summary

When *p*-ethyltoluene and *p*-propyltoluene react with methylcyclohexene in the presence of hydrogen fluoride and sulfuric acid, the main products formed result from a hydrogen transfer in which the aromatic hydrocarbons acted as a hydrogen donor and methylcyclohexene as a hydrogen acceptor.

The products obtained from the respective aromatic hydrocarbons through a hydrogen transfer were: 1-*p*-tolyl-1-(2-methyl-5-ethylphenyl)-ethane and 1-*p*-tolyl-1-(2-methyl-5-propylphenyl)-propane.

A mechanism for the hydrogen transfer reaction has been proposed; *p*-xylene on reaction with methylcyclohexene yields the expected cycloalkylation products.

The following new compounds and their derivatives were prepared; 1-*p*-tolyl-1-(2-methyl-5-ethylphenyl)-ethanol, 1-*p*-tolyl-1-(2-methyl-5-ethylphenyl)-ethene, 1-*p*-tolyl-1-(2-methyl-5-ethylphenyl)-ethane, 3,6-dimethyl-1-*p*-tolylindene, 3,6-dimethyl-1-*p*-tolylindan, 1-bromo-2-methyl-5-propylbenzene, 1-*p*-tolyl-1-(2-methyl-5-propylphenyl)-propanol, 1-*p*-tolyl-1-(2-methyl-5-propylphenyl)-propene, 1-*p*-tolyl-1-(2-methyl-5-propylphenyl)-propane and (1-methylcyclohexyl)-*p*-xylene.

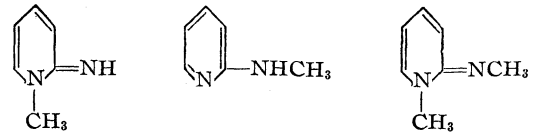
NOTES

2-Triphenylmethylaminopyridine

BY ROGER ADAMS AND JOHN B. CAMPBELL

The direct interaction of 2-aminopyridine and methyl iodide yields almost entirely the hydroiodide of N-methyl-2-pyridoneimide (I).[1] The reaction of the sodio derivative of 2-aminopyridine and methyl iodide yields principally 2-methylaminopyridine (II). The reaction of I or II with methyl iodide gives the dimethyl derivative (III). The same general behavior occurs when benzyl chloride is used rather than methyl iodide.

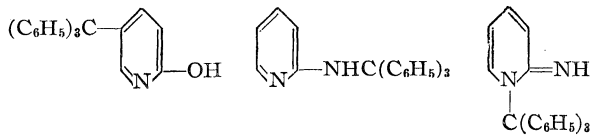


I II III

Triphenylcarbinol was condensed with 2-aminopyridine in the presence of a trace of acid in an attempt to obtain 5-triphenylmethyl-2-aminopyridine. Diazotization of the product in an effort to get the known 5-triphenylmethyl-2-hydroxypyridine (IV) resulted in cleavage of the molecule to yield triphenylcarbinol. Cleavage was also readily effected by means of concentrated

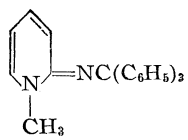
(1) Chichibabin, Konovalova and Konovalova, *Ber.*, **54**, 814 (1921).

sulfuric acid. This behavior indicated that N-alkylation had occurred to produce V or VI. The attempted condensation of triphenylcarbinol with 2-aminopyridine using larger amounts of acidic catalyst gave only dark tarry products which could not be crystallized.



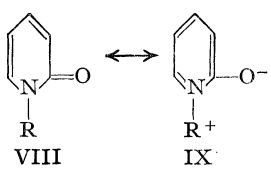
IV V VI

The product obtained was shown to be 2-triphenylmethylaminopyridine (V) by reaction with methyl iodide to yield N-methyl-2-pyridonetriphenylmethylimide(VII), the latter also being obtained in low yield by the reaction of N-methyl-2-pyridoneimide(I) with triphenylchloromethane. Thus, triphenylcarbinol reacts differently than do the methyl and benzyl halides.



VII

It is noteworthy that the free bases having the quinoid structure, as shown by I, III and VII, have a yellow color. The color is lost upon preparing the hydrochlorides. Since color is lacking in N-alkyl-2-pyridones (VIII), the color in the imide-type structures may be because the latter do not have as great a tendency to exist in a "zwitterion" structure as do the N-alkyl-2-pyridones as shown by IX. The zwitterion structure results in the loss of the quinoid structure and the attendant color.



VIII IX

Experimental

2-Triphenylmethylaminopyridine.—A mixture of 40 g. of 2-aminopyridine, 26 g. of triphenylcarbinol and 0.1 g. of *p*-toluenesulfonic acid was refluxed gently for two hours, steam being passed through the condenser to remove the water formed. The cooled mixture was recrystallized from 90% ethanol to yield 18.2 g. (54%) of light cream-colored crystals. Recrystallization from 95% ethanol gave glistening white crystals, m. p. 152–153° (cor.).

Anal. Calcd. for $C_{24}H_{20}N_2$: C, 85.68; H, 5.99; N, 8.33. Found: C, 85.57; H, 6.02; N, 8.18.

Cleavage of 2-Triphenylmethylaminopyridine. (A) By Nitrous Acid.—A suspension of 4.97 g. of powdered 2-triphenylmethylaminopyridine in 25 ml. of concd. hydrochloric acid was stirred at room temperature as a solution of 1.1 g. of sodium nitrite in 15 ml. of water was dropped in over a period of fifteen minutes. The mixture was stirred for one hour after the addition was complete. The white product was then collected on a filter and washed well with water. The yield was 3.50 g. (91%). Two recrystallizations from 95% ethanol gave pure triphenylcarbinol, m. p. 162°, as shown by the melting point of a mixture with an authentic sample.

(B) By Sulfuric Acid.—Upon dissolving 2-triphenylmethylaminopyridine in concd. sulfuric acid and pouring the solution into water, a nearly quantitative yield of triphenylcarbinol resulted.

N-Methyl-2-pyridonetriphenylmethylimide. (A) From 2-Triphenylmethylaminopyridine.—A solution of 1 g. of 2-triphenylmethylaminopyridine and 5 ml. of methyl iodide in 20 ml. of absolute ethanol was refluxed for five hours and then diluted with 50 ml. of petroleum ether. The precipitate of hydroiodide was collected on a filter and washed well with petroleum ether. It was then dissolved in 50 ml. of a 3:2 mixture of hot ethanol and water and the solution made basic with dilute aqueous sodium hydroxide. The mixture was warmed and stirred a few minutes and then cooled overnight in the ice-box. The yellow crystalline precipitate was collected on a filter and washed well with 50% ethanol. The yield was 0.52 g. (50%). Two recrystallizations from 95% ethanol gave yellow crystals, m. p. 151–152° (cor.). A melting point of this compound mixed with 2-triphenylmethylaminopyridine gave a large depression.

Anal. Calcd. for $C_{25}H_{22}N_2$: C, 85.67; H, 6.33; N, 8.00. Found: C, 85.84; H, 6.46; N, 7.98.

(B) From N-Methyl-2-pyridoneimide.—To a suspension of 2.36 g. of the hydroiodide of N-methyl-2-pyridoneimide[1] in 50 ml. of hot benzene was added 5 ml. of 10% aqueous sodium hydroxide and the mixture quickly shaken. The benzene layer was separated, dried over anhydrous sodium sulfate and the benzene removed on the steam-cone. To the green residual oil was added 2.8 g. of triphenylchloromethane and the mixture heated on the steam-cone one hour. Then 30 ml. of benzene was added and the mixture boiled a few minutes. After cooling overnight in the ice-box, the precipitate of hydrochloride was collected on a filter, washed well with benzene and dried. It was then taken up in 10 ml. of boiling ethanol and the solution made basic with the addition of 10% aqueous sodium hydroxide. After cooling in the ice-box, 0.20 g. of dark yellow crystalline material was collected on a filter. Recrystallization from 95% ethanol gave yellow crystals, m. p. 151–152° (cor.), identical with the product obtained above, as shown by a melting point of the mixture.

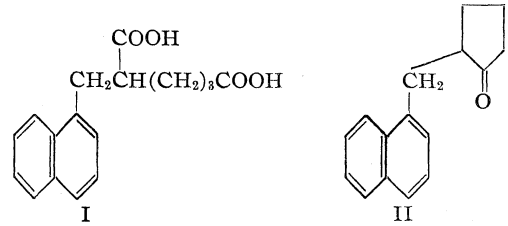
Preparation of the Isomeric 2-(Naphthylmethyl)-cyclopentanones

BY W. E. BACHMANN AND N. C. DENO[1]

Condensation of α-chloromethylnaphthalene with the sodio derivative of 2-carbethoxycyclopentanone gave the substituted cyclic keto ester, which was hydrolyzed by alkali with ring cleavage to α-(1′-naphthylmethyl)-adipic acid (I). Cyclization of the diacid with the aid of acetic anhy-



I II

(1) Present address: Department of Chemistry, The Ohio State University, Columbus, Ohio.

dride or by dry distillation with calcium oxide yielded 2-(1′-naphthylmethyl)-cyclopentanone (II). The ultraviolet absorption spectrum of II was similar to that of 1-methylnaphthalene.

2-(2′-Naphthylmethyl)-cyclopentanone was prepared in a similar manner from β-chloromethylnaphthalene. An excellent yield of the crystalline ketone was obtained by cyclization of the intermediate α-(2′-naphthylmethyl)-adipic acid with acetic anhydride. The ketone was obtained also by acid hydrolysis of 2-carbethoxy-2-(2′-naphthylmethyl)-cyclopentanone.

Experimental[2]

α-(1′-Naphthylmethyl)-adipic Acid (I).—A mixture of 15.6 g. (0.1 mole) of 2-carbethoxycyclopentanone, sodium methoxide (prepared from 2.3 g. of sodium and dried at 100° and 20 mm.), and 150 cc. of dry benzene was refluxed for five minutes; any lumps present were crushed with a spatula. After the addition of 17.6 g. (0.1 mole) of α-chloromethylnaphthalene, the mixture was refluxed for six hours. After the removal of the benzene under reduced pressure, 40 cc. of 40% aqueous potassium hydroxide and 60 cc. of methanol were added and the solution was refluxed for eighteen hours. After being cooled and diluted with water to 300 cc., the solution was washed twice with ether and then acidified with hydrochloric acid. The substituted adipic acid, which was isolated by extraction with two 200-cc. portions of ether and removal of the ether, was triturated with 30 cc. of benzene; yield of colorless granular crystals, 15 g., m. p. 116–121°. An additional 1.17 g. of the acid (m. p. 110–118°) was obtained by further treatment of the non-crystalline portion with 40 cc. of 20% aqueous potassium hydroxide at 100° for twenty-four hours; total yield, 56%. After several recrystallizations from benzene the acid melted at 126–127.4°.

Anal. Calcd. for $C_{17}H_{18}O_4$: C, 71.30, H, 6.33; neut. equiv., 143. Found: C, 71.42; H, 6.37; neut. equiv., 144.

2-(1′-Naphthylmethyl)-cyclopentanone (II).—The acetic anhydride was distilled slowly from a solution of 0.5 g. of the aforementioned acid in 1.5 cc. of acetic anhydride. After the apparatus had been filled with nitrogen, the temperature was raised to 300° in the course of five minutes; the pressure was then lowered to 30 mm. in order to complete the distillation; yield of colorless liquid, 71%. **The 2,4-dinitrophenylhydrazone** (m. p. 232.2–233.2°), which was prepared in 76% yield by addition of 1 cc. of concentrated hydrochloric acid to a refluxing solution of 100 mg. of the ketone and 150 mg. of 2,4-dinitrophenylhydrazine in ethanol, crystallized in fine, yellow needles.

Anal. Calcd. for $C_{22}H_{20}N_4O_4$: C, 65.33; H, 4.99. Found: C, 65.47; H, 5.16.

When the diacid alone was distilled, the yield of ketone was low and much acid was recovered. By dry distillation of an intimate mixture of 2 g. of the diacid and 0.4 g. of powdered calcium oxide under nitrogen and redistillation of the dark distillate at 130–170° and 0.1 mm., 1.02 g. of the ketone was obtained.

2-(2′-Naphthylmethyl)-cyclopentanone.—The cyclic keto ester prepared from 11.2 g. of β-chloromethylnaphthalene and an equivalent amount of 2-carbethoxycyclopentanone was completely hydrolyzed and cleaved by refluxing with aqueous methanolic alkali for eighteen hours. Recrystallization of the crude diacid from acetone–benzene gave two crops: 12.8 g., m. p. 149–150°, and 2 g., m. p. 144–146°; total yield, 81%. The highest m. p. obtained for α-(2′-naphthylmethyl)-adipic acid was 152.3–152.8°.

Anal. Calcd. for $C_{17}H_{18}O_4$: C, 71.30; H, 6.33; neut. equiv., 143. Found: C, 71.50; H, 6.50; neut. equiv., 142.5.

(2) All melting points are corrected.

By the procedure described for the isomer, 3.63 g. (93%) of the cyclic ketone (m. p. 57–63°) was obtained from 5 g. of the diacid and 15 cc. of acetic anhydride. The **2-(2′-naphthylmethyl)-cyclopentanone** crystallized from ether–petroleum ether in colorless glistening flakes; weight, 2.9 g. (75%), m. p. 70.3–71.3°.

Anal. Calcd. for $C_{16}H_{16}O$: C, 85.66; H, 7.19. Found: C, 85.78; H, 7.45.

A 38% yield of the ketone (m. p. 65.5–67°) was obtained when the diacid was distilled from calcium oxide and a 53% yield of ketone (m. p. 57–65°) resulted from refluxing a solution of 3.6 g. of the 2-carbethoxy-2-(2′-naphthylmethyl)-cyclopentanone in 10 cc. of acetic acid and 10 cc. of concentrated hydrochloric acid for twelve hours and evaporatively distilling the neutral product up to 180° at 0.1 mm.

The 2,4-dinitrophenylhydrazone (prepared in quantitative yield as described for the isomer except that the mixture was refluxed for five minutes and then allowed to stand for several days) crystallized in fine, short yellow needles; m. p. 138–139°, raised to 144.2–145° by recrystallization from ethanol.

Anal. Calcd. for $C_{22}H_{20}N_4O_4$: C, 65.33; H, 4.99. Found: C, 65.48; H, 4.95.

Derivatives of Indole-2-carboxylic Acid

BY WARREN J. BREHM

This report of work originally aimed at a synthesis of lysergic acid, but now discontinued, is prompted by Uhle's successful synthesis of 5-keto-1,3,4,5-tetrahydrobenz[cd]indole.[1] It was hoped that an abrine suitably protected at the 2-position to permit closure of the (α-methylamino)-propionic acid side-chain into the 4-position could be prepared by following the tryptophan syntheses developed by Snyder[2] or Robson.[3] The choice of the carboxypiperidide as the protective group made subsequent decarboxylation or its equivalent a necessary step. In an attempt to avoid the difficulties often attendant upon decarboxylation of indole-2-acids, 2-hydroxymethylindole was prepared. When this compound did not lose formaldehyde on treatment with base this alternate scheme had to be abandoned.

Experimental

Ethyl Indole-2-carboxylate.—Crude ethyl *o*-nitrophenylpyruvate, obtained as an oil by the method of Wislicenus and Thoma,[4] was dissolved in glacial acetic acid (35 g. of ester in 225 cc. of solvent). It was reduced with hydrogen at a pressure of 3 atm. over Adams catalyst (0.2 g.). At the end of the very rapid reduction the catalyst was filtered off and the solution diluted with water. This gave 22 g. (80%) of ethyl indole-2-carboxylate, m. p. 121–123°.

2-Hydroxymethylindole.—Lithium aluminum hydride (4.75 g.) was dissolved in 180 cc. of dry ether. With mechanical stirring a solution of 18.9 g. of ethyl indole-2-carboxylate in 250 cc. of dry ether was added dropwise at a rate sufficient to keep the solution boiling. When the addition was complete, stirring was continued for fifteen minutes, and then 100 cc. of water added slowly to decompose the excess reducing agent. The ether layer was

(4) Wislicenus and Thoma, *Ann.*, **436**, 45 (1924).

separated, washed with water and dried over magnesium sulfate. The ether was boiled off and the residue twice recrystallized from benzene–hexane; 10.0 g. (68%) of colorless plates, m. p. 74–77°. Analytical sample sublimed *in vacuo*, m. p. 75–77°. *Anal.* Calcd. for C_9H_9NO: C, 73.45; H, 6.16; N, 9.52. Found: C, 73.79; H, 6.24; N, 9.52.

A solution of 1.0 g. of 2-hydroxymethylindole in 60 cc. of alcohol was treated with 3.0 g. of barium hydroxide in 60 cc. of water. The solution was heated on the steam-bath for three hours, diluted with 400 cc. of water and extracted with ether. The ether was dried over sodium sulfate. After removal of the ether and recrystallization from hexane the residue weighed 0.7 g., m. p. 76–77°. This melting point was not depressed when the sample was mixed with starting material.

2-Carboxypiperidinoindole.—(a) Ethyl indole-2-carboxylate (3.8 g.) was suspended in 50 cc. of 1 *N* sodium hydroxide and the mixture was heated on the steam-bath for one hour when complete solution had been attained. The solution was treated with charcoal, filtered and acidified with hydrochloric acid. The precipitated indole-2-carboxylic acid was filtered off, 2.9 g. (90%), m. p. 206–208°. A solution of 2.85 g. of this acid in 100 cc. of dry ether was treated with 3.0 cc. of thionyl chloride. After standing at room temperature for one hour the solvents were removed *in vacuo*. The residue was twice treated with 60 cc. of dry ether and taken to dryness to remove traces of hydrogen chloride. Finally it was dissolved in 90 cc. of dry ether, filtered and treated with 3.5 cc. of piperidine. There was an immediate precipitation of a gum which gradually crystallized. After recrystallization from ethanol–water, 0.4 g. of 2-carboxypiperidinoindole, m. p. 161–164° separated. After three recrystallizations from hexane the white needles melted at 165–166°. *Anal.* Calcd. for $C_{14}H_{16}N_2O$: C, 73.65; H, 7.07; N, 12.27. Found: C, 73.63; H, 6.86; N, 12.45.

(b) Ethyl indole-2-carboxylate (36 g.) was suspended in 480 cc. of piperidine, and the mixture was treated with 90 cc. of glacial acetic acid. The mixture was heated to boiling, giving a complete solution, and maintained at reflux for two days. The hot solution was diluted with 200 cc. of water and filtered. The filtrate was treated with 2 liters of water to precipitate the 2-carboxypiperidinoindole, 36 g. (83%), m. p. 163–166°.

3-Dimethylaminomethylindole-2-carboxypiperidide.—A suspension of 10.0 g. of 2-carboxypiperidinoindole in 65 cc. of glacial acetic acid, 24 cc. of 25% aqueous dimethylamine and 14 cc. of 40% aqueous formaldehyde was heated on the steam-bath for one hour and then kept at room temperature overnight. After diluting the solution with 700 cc. of water it was extracted with 100 cc. of benzene. The aqueous layer was made basic with concentrated ammonium hydroxide, and the oily product was extracted into ether (one 400-cc. and three 250-cc. portions of solvent). The combined extracts were washed twice with 150 cc. of water and dried over sodium sulfate. After removal of the ether on the steam-bath the oily residue weighed 17 g. Since the theoretical yield was only 12 g. there was considerable contamination, but the material was suitable for further work as it stood.

When a small amount of this oil was heated with 10% chloroplatinic acid a crystalline chloroplatinate precipitated which contained two organic residues per atom of platinum. After recrystallization from water this melted at 208° (dec.). *Anal.* Calcd. for $C_{34}H_{46}N_6O_2$–H_2PtCl_6: C, 41.63; H, 4.93; N, 8.57; Cl, 21.69. Found: Cl, 41.60; H, 4.97; N, 8.53; Cl, 20.83.

2-Carboxypiperidinoskatylacetylaminomalonic Ester.—The 17 g. of crude 3-dimethylaminomethylindole-2-carboxypiperidide (see above) was treated with 150 cc. of xylene and the solution distilled until the distillate was no longer cloudy. The volume of the solvent was replenished, and there was added 9.6 g. of acetylaminomalonic ester (prepared according to the method of Snyder and Smith[2]) and 0.6 g. of powdered sodium hydroxide. With stirring, the mixture was heated to its boiling point while dry nitrogen was passed over the system. Bubbles appeared in the reaction mixture as soon as it became warm, and the exhaust gases became basic. This was presumably due to the evolution of dimethylamine. After twenty hours the evolution of amine had ceased, and the reaction mixture was filtered, washed with 50 cc. of water, twice with 50 cc. of 10% hydrochloric acid and again with 50 cc. of water. The xylene solution was dried over sodium sulfate. After removing the xylene *in vacuo* the residue was crystallized by boiling with ether. The insoluble crystalline residue of 2-carboxypiperidinoskatylacetylaminomalonic ester weighed 10.0 g., m. p. 146–149°; after recrystallizations from ethyl acetate–hexane, ethanol–water and ethyl acetate–isopropyl ether, m. p. 149–152°. *Anal.* Calcd. for $C_{24}H_{31}N_3O_6$: C, 63.00; H, 6.83; N, 9.18. Found: C, 63.22; H, 6.88; N, 8.77.

When this preparation was repeated the ether-insoluble residue melted at 197–200°. It was recrystallized from acetic acid–water, acetone–water and ethanol–water, m. p. 200.2–201.6°. *Anal.* Calcd. for $C_{24}H_{31}N_3O_6$: C, 63.00; H, 6.83; N, 9.18. Found: C, 63.11; H, 6.92; N, 9.17. A sample of the lower melting material, m. p. 149–152°, was recrystallized from ethanol–water and seeded with a crystal of this latter form. The product melted at 200–202°.

2-Carboxypiperidinoindole-3-aldehyde.—To a cold solution of 5.4 g. of N-methylformanilide and 3.66 cc. of phosphorus oxychloride in 35 cc. of *o*-dichlorobenzene there was added gradually 9.1 g. of 2-carboxypiperidinoindole. The resulting suspension was kept at room temperature for forty-three hours although solution was complete after fifteen hours. The solution was poured into a slurry of 30 g. of ice and 20 g. of 35% sodium hydroxide solution. The organic layer was separated, washed with 20 cc. of water and dried over sodium sulfate. The solvent was removed *in vacuo*, the residue dissolved in ethanol, and the solution diluted with water. The precipitated product was recrystallized from benzene–hexane; 6.6 g. (65%), m. p. 149–155°. Five recrystallizations from benzene–hexane gave white needles, m. p. 155.5–156.5°. *Anal.* Calcd. for $C_{15}H_{16}N_2O_2$: C, 70.29; H, 6.29; N, 10.93. Found: C, 70.38; H, 6.09; N, 11.20.

The compound gave a red-orange 2,4-dinitrophenylhydrazone; recrystallized from dioxane, m. p. 310° (dec.). *Anal.* Calcd. for $C_{21}H_{20}N_6O_5$: C, 57.79; H, 4.62; N, 19.26. Found: C, 57.98; H, 4.48; N, 18.68.

5-(3′-α-Carboxypiperidinoindolal)-1-methylhydantoin.—A solution of 1.8 g. of 1-methylhydantoin (prepared according to the method of Miller and Robson[3]) and 2.86 g. of 2-carboxypiperidinoindole-3-aldehyde in 5 cc. of piperidine was heated under reflux for one hour. Some solid yellow material had precipitated during this period. The reaction mixture was treated with 30 cc. of hot water, made slightly acidic with acetic acid, cooled and the solid product filtered off; 3.0 g. (76%), m. p. 289–295°. After seven recrystallizations from pyridine–water the light yellow plates melted at 306–307.5° (dec.). *Anal.* Calcd. for $C_{19}H_{20}N_4O_3$: C, 64.76; H, 5.72; N, 15.90. Found: C, 65.08; H, 5.81; N, 16.03.

Acylation of Some Thiophenes with Crotonyl Chloride[1]

BY CHARLES K. BRADSHER, FRANCES C. BROWN AND R. J. GRANTHAM

Recently Hartough, Kosak and Sardella[2] have shown that thiophene in the presence of activated montmorillonite clay may be acylated with crotonyl chloride to yield 2-crotonylthiophene.

(1) This note consists of a report of work done under contract with the Medical Division, Chemical Corps, U. S. Army.

(2) Hartough, Kosak and Sardella, THIS JOURNAL, 69, 1014 (1947).

[a] Constants are for analytical sample. [b] Yields based on product obtained in first fractionation; average boiling range seven degrees. [c] Analyses by Clark Microanalytical Laboratory. [d] Previously reported b. p. 109–116° (5 mm.); yield 22% (ref. 2). [e] The 2-butylthiophene used was obtained by refractionation of a sample obtained from the Midland Chemical Company. On the basis of the work of Appleby, Sartor, Lee and Kapranos (THIS JOURNAL, **70**, 1552 (1948)) this starting material, $n^{20}D$ 1.4981, may have contained 6 ± 3% of 3-*t*-butylthiophene. [f] M. p. 72–73°.

In a similar reaction, using stannic chloride as the catalyst we have produced the crotonylthiophene in a somewhat better yield. Acylation of the 2-chloro-, 2-*t*-butyl- and 3-methylthiophenes with crotonyl chloride was likewise effected successfully, but 2,5-dichlorothiophene appeared unreactive.[3]

General Procedure.—A solution containing 0.15 mole of the thiophene and an equimolecular quantity of crotonyl chloride in 200 ml. of dry benzene was cooled to 0°, and 18 ml. (about 0.15 mole) of anhydrous stannic chloride was added dropwise over a period of one hour. The temperature was allowed to rise slowly to room temperature and stirring continued for an additional hour. The reaction mixture was decomposed with one molar hydrochloric acid and the benzene layer was separated, washed, dried and concentrated. The residue was fractionated under reduced pressure. The results are summarized in Table I.

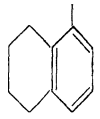
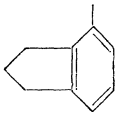
The Rate of Dissociation of 1,1,1,2-Tetraphenyl-2-(4′-hydrindenyl)-ethane

BY ROBERT G. CHRISTIANSEN[1] AND REUBEN B. SANDIN

In an attempt to relate the ease of preparation and properties of certain polynuclear hydrocarbons to a possible steric effect, the rate of dissociation of 1,1,1,2-tetraphenyl-2-(4′-hydrindenyl)-ethane has been determined. This has been done following the very convenient method of Bachmann and co-workers.[2] The rate constant and half-life period in the reaction with iodine at 80° have been found to be 0.0246 and 28.3 minutes, respectively. Recently Bachmann and Brockway[3] have determined the dissociation rate of 1,1,1,2-tetraphenyl-2-(1′-tetralyl)-ethane. For this hydrocarbon k = 0.0728 and $t^{1/2}$ = 9.5 minutes.[4] It is evident that the 1-tetralyl group (I) shows a somewhat greater effect than the 4-hydrindenyl group (II).



I



II

This is in agreement with the interesting work of Arnold and co-workers[5] wherein they have presented evidence to prove that the steric effect of the methylene groups in five membered rings (*i. e.*, hydrindene) is smaller than that in the corresponding six-membered rings (*i. e.*, tetralin).

Experimental

4-Benzoylhydrindene.—This ketone prepared in 65% yield by the reaction of the Grignard reagent from bromobenzene and 4-cyanohydrindene[6] was obtained as a viscous oil which did not solidify on long standing; b. p. 177–180° at 2 mm.

Anal. Calcd. for $C_{16}H_{14}O$: C, 86.44; H, 6.35. Found: C, 86.76; H, 6.47.

Phenyl-4-hydrindenylcarbinol.—The carbinol prepared in 53% yield by the aluminum isopropoxide reduction of the ketone, was obtained as a viscous liquid; b. p. 180° at 4 mm.

Anal. Calcd. for $C_{16}H_{16}O$: C, 85.69; H, 7.19. Found: C, 85.84; H, 7.17.

1,1,1,2-Tetraphenyl-2-(4′-hydrindenyl)-ethane.—The phenyl-4-hydrindenylmethyl bromide from 9.0 g. of the carbinol and acetyl bromide was coupled at once with triphenylmethylsodium by the standard procedure. The resulting hydrocarbon crystallized from benzene–methanol as colorless crystals; yield, 60%; m. p. in air, 185–190°.

Anal. Calcd. for $C_{35}H_{30}$: C, 93.29; H, 6.71. Found: C, 93.44; H, 6.90.

Rate Measurements.—These were carried out according to the procedure of Bachmann and Osborn.[2b] Methanol was used in the place of ethanol in the *o*-dichlorobenzene, iodine and pyridine mixture.

Acknowledgment.—The authors express their appreciation to the Canadian Cancer Society for a grant which made this work possible.

Proportions of Cymenes from Propylation of Toluene

BY FRANCIS E. CONDON

A mechanism advanced to explain the formation of considerable *m*-dialkylbenzene in the aluminum chloride-catalyzed alkylation of a monoalkylbenzene, in apparent opposition to the well-known ortho–para directing influence of an alkyl group, is alkylation to 1,2,4-trialkylbenzene, followed by dealkylation.[1] In an experimental test of this hypothesis, as part of the present investigation of the proportions of cymenes produced by propylation of toluene under homogeneous liquid-phase conditions, pure *p*-cymene was alkylated with propylene at 65° in the presence of aluminum chloride and of benzene and nitromethane[2] as solvents, in order to determine whether any *m*-cymene would result from *p*-cymene under conditions that produced considerable *m*-cymene from toluene. The experimental data are presented in Table I.

No *o*-cymene and no *m*-cymene were produced when *p*-cymene was alkylated with propylene, whereas 38% *o*-cymene, 27% *m*-cymene, and 35% *p*-cymene were produced from toluene under the same conditions. These results show that all the isomeric cymenes were produced by direct alkylation of toluene at the available positions, rather than by isomerization or by alkylation-dealkylation of *p*-cymene. The considerable proportion of *m*-cymene means that a methyl group exerts a relatively feeble ortho–para orienting influence during propylation. (During nitration of toluene, only about 4% of *m*-nitrotoluene is produced.[3])

The proportions of cymenes produced at 5 and at 65° are slightly different. These differences appear real, and probably should not be considered within the experimental error (*cf.* ref. 3).

The proportions of cymenes appear to be independent of whether the catalyst is aluminum chloride or boron fluoride. Noteworthy, too, is their apparent independence of the extent of conversion (measured by the mole ratio of propylene to aromatics given in Table I). Some dependence at high conversions would be expected from inequalities in the rates of further propylation of the different isomers.

The Dissociation Constant of Dimethylaniline Hydrochloride in Chloroform

BY MARION MACLEAN DAVIS

Recently Moede and Curran[1] described the determination of the dissociation constant, K_c, for

(1) J. A. Moede and C. Curran, THIS JOURNAL, **71**, 852 (1949).

the sulfur dioxide addition compounds of several amines in benzene, *n*-butyl chloride or chloroform, by measurement of dielectric properties or ultraviolet absorption spectra. The reaction assumed was

$$\text{C (addition compound)} \rightleftharpoons \text{A (amine)} + \text{B (sulfur dioxide)}$$

The correctness of this assumption was supported by the good agreement of values for K_c at various concentrations.

In the same paper, data and calculations were presented for the dissociation of dimethylaniline hydrochloride in chloroform. The equilibrium postulated in this case was

$$C_8H_{11}NH^+ + Cl^- \rightleftharpoons C_8H_{11}N + HCl \quad (1)$$

Values obtained for K_c showed a progressive increase with dilution, varying from 0.38×10^{-6} for 0.008442 molar solution to 31×10^{-6} for 0.001203 molar solution. The salt effect of the hydrochloride was suggested as a possible explanation of the trend toward higher values of K_c as the solutions became more dilute. This interpretation of the reaction seemed erroneous to the writer, because spectrophotometric data obtained at the National Bureau of Standards for various acid–base reactions in benzene[2] and measurements of the effect of dilution on the dielectric polarization of tribenzylammonium picrate in benzene[3] have been interpreted satisfactorily on the assumption of *negligible* ionic dissociation, and the dielectric constant of chloroform (~4.7) is nearly as low as that of benzene (~2.3). Provisional calculations of the dissociation constant for dimethylaniline hydrochloride, using the data in Moede and Curran's Table V and interpolating in their Fig. 6 to obtain ϵ_C (169) and ϵ_A (11,000), but considering the reaction to be

$$C_8H_{11}NHCl \rightleftharpoons C_8H_{11}N + HCl \quad (2)$$

gave nearly constant values with the mean value 6.0×10^{-8} for K_c at all concentrations. These provisional values for K_c were reported to Professor Curran, who graciously furnished the experimental values at 255 mμ for ϵ_C (192) and ϵ_A (10,530), and also stated that the same equilibrium (2) had originally been considered by him and Dr. Moede but that because the resulting values for K_c showed a decrease with increasing concentration, the alternative equation (1) was adopted. However, when the values for K_c computed according to both equations are compared (see Table I), it is evident that the data are more consistent with equation (2). According to either formulation, the dissociation of the salt into dimethylaniline and hydrogen chloride occurs to so slight an extent, in the range of concentrations concerned, that a small experimental error will have a large effect on the constancy of K_c. Therefore, the slight trend in the values shown in column 3 of Table I does not appear significant, particularly since the first two values correspond to transmittancies outside the range recommended by Mellon for reliable measurement.[4] The correct value for K_c thus appears to be $\sim 1.5 \times 10^{-8}$.

[a] Computed by Moede and Curran according to equation (1); see ref. (1), Table V. [b] Computed by M. M. Davis, according to equation (2).

To consider that dimethylaniline hydrochloride exists mainly as an addition compound in chloroform is contrary to the rather common belief that salts are largely dissociated into the free ions in all non-aqueous solvents as well as in water. However, Kraus and his associates have found that the ionic dissociation of a salt drops off rapidly as the dielectric constant of the solvent approaches very low values.[5] Moreover, both Walden[6] and Kraus[7] have pointed out that salts which appear equally strong in water may exhibit pronounced differences in strength when dissolved in solvents of low dielectric constant and that, for example, incompletely substituted ammonium salts are distinctly weaker than quaternary ammonium salts in such solvents. This decrease in strength appears to be caused in part by the presence of a hydrogen bridge in salts of the former type.[7]

Moede and Curran report that the conductance of a 0.1 molar solution of dimethylaniline hydrochloride was observed to be about a thousand times that of hydrogen chloride in chloroform.[1] This does not necessarily imply a significant concentration of dimethylanilinium and chloride ions. Kraus has stated that hydrogen chloride in nitrobenzene, of dielectric constant ~35, is a very weak electrolyte.[7] In chloroform, therefore, the

ionic dissociation of hydrogen chloride must be practically negligible. The approximately linear relationship between $-\log K_c$ and $\sqrt{c} \times 10^2$ shown in Moede and Curran's Fig. 8 is probably fortuitous and is somewhat uncertain because of the scattering of the experimental points. A nearly linear relationship also appears to hold if $-\log K_c$ is plotted against $c \times 10^3$ or $\sqrt[3]{c}$. Moreover, these authors found that $k = 14$ in the relationship $-\log K_c = -\log K_a + 2k\sqrt{\mu}$, instead of the expected value, 32.8, and stated that the "low value appears to be due in part to the presence of a large number of $C_8H_{11}NH^+$–Cl^- ion pairs, which reduces the ionic strength below the calculated value." However, in view of the considerations outlined above, it seems more probable that in the chloroform solutions of dimethylaniline hydrochloride under discussion less than 0.6% of the salt was dissociated into $C_8H_{11}N$ and HCl, that the extent of dissociation into $C_8H_{11}NH^+$ and Cl^- was practically negligible, and that the salt existed almost entirely as hydrogen-bonded ion pairs, $C_8H_{11}NH^+$–Cl^-, in effect analogous to the amine–sulfur dioxide addition compounds. The importance of this interpretation is apparent when one observes that equilibrium (2) represents an association as well as a dissociation. More explicitly, I believe the results of Moede and Curran provide new evidence that the product of the reaction of a base with either a "Lewis" acid or a "Brønsted" acid is essentially the same thing, namely, a highly polar addition compound, when the solvent has a low dielectric constant and solvation is not a factor.

WASHINGTON, D. C. RECEIVED MAY 13, 1949

An Improvement on the Process for Making Amidone

BY JOHN W. CUSIC

One of the difficult steps in the synthesis of Amidone is the preparation of the intermediate 4-dimethylamino-2,2-diphenylvaleronitrile.

This has usually involved the use of a hazardous chemical such as sodium amide.[1] Cheney[2] has used lithium amide which, however, is a fairly expensive chemical.

I have found that the condensation of 1-dimethylamino-2-chloropropane hydrochloride with diphenylacetonitrile can be carried out with sodium hydroxide, which is both cheap and safe.

Experimental

Sixty grams (1.5 moles) of commercial sodium hydroxide flake, 77.2 g. (0.4 mole) of diphenylacetonitrile and 79.0 g. (0.5 mole) of 1-dimethylamino-2-chloropropane hydrochloride were mixed in an erlenmeyer flask and heated with occasional stirring for six to seven hours on the steam-bath.

The reaction mixture was extracted with ether and the ether in turn extracted with dilute hydrochloric acid. The acid solution was made strongly alkaline with sodium hydroxide and the liberated base extracted with ether. The ether solution was dried over anhydrous potassium carbonate, filtered and after removal of the ether the product was distilled to yield 89 g. of product, b. p. 173–174° at 1 mm. It was then crystallized from petroleum ether (60–71°) to give 49 g. (45.7%) melting at 89–90°.

Anal. Calcd. for $C_{19}H_{22}N_2$: N, 10.3. Found: N, 9.91.

Some 1,2-Dialkylcyclohexanes[1,2]

BY J. R. DICE, L. E. LOVELESS, JR., AND H. L. CATES, JR.[3]

There is a surprising paucity of data concerning 1,2-dialkylcyclohexanes where neither substituent group is methyl. Our original intention was to synthesize an extensive series of these compounds, but the poor yields encountered in many of the steps limited the number prepared.

The crucial intermediates 2-ethyl- and 2-propylcyclohexanone were prepared by the interaction of 2-chlorocyclohexanone and the appropriate Grignard reagent.[4] Propyllithium was used in one experiment. The improvement in yield was more than offset by the increased difficulty of preparation. Attempts to prepare 2-(1-methylethyl)-cyclohexanone by the Grignard method were unsuccessful, although this preparation (without any experimental details) is reported by Bouveault and Chereau.[4] Addition of cobaltous chloride did not affect the yield of 2-propylcyclohexanone. Direct alkylation of cyclohexanone using sodium amide or sodium in liquid ammonia as catalysts gave a complex mixture of products.

The addition of various Grignard reagents to 2-ethyl- and 2-propylcyclohexanone gave a series of 1,2-dialkylcyclohexanols which were dehydrated to the corresponding 1,2-dialkylcyclohexenes by distillation from iodine. The double bond was believed to be in the ring because of the difficulty of hydrogenating the unsaturated products.[5] It also has been proved[6] that the dehydration of 1,2-dimethylcyclohexanol by this method yields 1,2-dimethylcyclohexene. Hydrogenation of the dialkylcyclohexenes using Raney nickel as a catalyst gave the desired 1,2-dialkylcyclohexanes.

Experimental

2-Ethylcyclohexanone.[7]—To the Grignard reagent prepared from 25.6 g. of magnesium, 114 g. of ethyl bromide and 600 ml. of dry ether was added 122 g. of 2-chlorocyclo-

[a] Difficulties were encountered in adapting the semi-micro analytical procedure outlined by Horning and Horning, *Ind. Eng. Chem., Anal. Ed.*, **19**, 688 (1947), to the analysis of these compounds. The use of small glass bulbs consistently led to rather vigorous "flashing" and low results. Open platinum boats were impractical due to the volatility of the compounds. Reasonably satisfactory results were finally obtained by increasing the size of the sample to approximately 40 mg. and adding 75 mg. of potassium chlorate to the open boat. [b] Ruzicka and Peyer, ref. 7c, prepared but did not isolate this compound. [c] Vavon and Barbier, *Bull. soc. chim.*, [4] **49**, 4567 (1931), report a *cis-cis*-dipropylcyclohexanol. The positions occupied by the alkyl groups are not indicated, nor is the method of synthesis given.

hexanone[8] over a period of two hours. Most of the ether was replaced by 500 ml. of dry benzene and the mixture was refluxed for five hours. After hydrolysis the product was distilled through a 60-cm. fractionation column to yield 52 g. (41%) of a colorless liquid boiling at 42° (2 mm.) (reported[4] 67° (13 mm.)); $n^{16}D$ 1.4530 (reported[4] 1.4528); semicarbazone, m. p. 161–162° (reported,[4,7b] 161, 165°).

2-Propylcyclohexanone[9] using Propylmagnesium Bromide.—Using the method described previously 2-propylcyclohexanone was prepared from 13.4 g. of magnesium, 67.5 g. of 1-bromopropane and 66.7 g. of 2-chlorocyclohexanone. The colorless distillate (14 g., 20%) boiled at 80–81° (12 mm.) (reported[9a,9c] 83–84° (13 mm.) and 94–95° (25 mm.)), semicarbazone m. p. 119–120° (reported[9a] 133.5–134.0°), semicarbazide m. p. 101–103° (reported[9a] 103–104°), semicarbazide hydrochloride m. p. 146–148° (reported[9a] 146–148°).

2-Propylcyclohexanone Using Propyllithium.—To a stirred mixture of 7.6 g. of freshly-cut lithium and 300 ml. of dry ether was added a solution of 67.5 g. of 1-bromopropane in 200 ml. of dry ether over a three-hour period. The mixture turned black and was refluxed for twelve hours. To the stirred propyllithium reagent was added 61.5 g. of 2-chlorocyclohexanone over a two-hour period; a green color formed. After standing eight hours the mixture was filtered from excess lithium and the filtrate was hydrolyzed by means of an ice–hydrochloric acid slurry. The mixture was extracted with ether and the organic layer was washed with dilute sodium hydroxide and dilute hydrochloric acid and dried over sodium sulfate. The ether was removed by means of a current of air and the residue was distilled at 86–88° (16–17 mm.), yield 22.2 g. (30%), semicarbazone m. p. 119–120°, mixture m. p. with semicarbazone from Grignard method, 119–120°.

Preparation of 1,2-Dialkylcyclohexanols.—To the Grignard reagent prepared from 0.23 mole of magnesium and 0.23 mole of the appropriate alkyl halide in 200–300 ml. of dry ether was added 0.20 mole of the desired 2-alkylcyclohexanone over a period of two hours. The mixture was refluxed with stirring for twelve hours and then poured on an ice–hydrochloric acid slurry. The combined ether extracts were washed with saturated sodium bisulfite solution and twice with water. After drying over sodium sulfate and evaporation of the solvent the alcohols were distilled *in vacuo*. Yields, physical constants and other pertinent data are given in Table I.

Preparation of 1,2-Dialkylcyclohexenes.—Two to 25 g. batches of the various 1,2-dialkylcyclohexanones were distilled from 0.05 to 0.20 g. of iodine. The distillate was washed with sodium thiosulfate solution, dried over calcium chloride and then refluxed with sodium from ten to sixty minutes. Distillation from the sodium gave colorless liquids. Table II contains the data relative to these compounds.

(9) For other preparations of 2-propylcyclohexanone see (a) Vavon and Aziani, *Bull. soc. chim.*, [4] **41**, 1642 (1927); (b) ref. 4; (c) Cornubert and Marvel, *Bull. soc. chim.*, **49**, 1498 (1931).

Preparation of 1,2-Dialkylcyclohexanes.—Preliminary tests showed that the 1,2-dialkylcyclohexenes were resistant to hydrogenation at room temperature and 1–2 atmospheres of hydrogen using platinum as catalyst. Hydrogenation occurred smoothly in a bomb at 150° and a starting hydrogen pressure of 2400 p. s. i. using 0.5–1.0 g. of Raney nickel catalyst for 2–5 g. of cyclohexene. Absolute ethanol (30–50 ml.) was used as solvent in all cases. After filtration the solution was evaporated to approximately 10 ml. and poured into water. The mixture was extracted with benzene and the combined extracts dried over sodium sulfate. After evaporation of the solvent the residue was treated with concentrated sulfuric acid to remove any cyclohexenes. The mixture was diluted with water and was extracted with benzene which was washed with dilute sodium hydroxide and water and dried over sodium sulfate. On distillation colorless liquids were obtained. Data on the cyclohexenes prepared are given in Table III.

Preparation of 2-Pyridylmethanol[1]

BY WALTER M. EDWARDS[2] AND PEYTON C. TEAGUE[3]

Harries and Lenart[4] and Graf, *et al.*,[5] have reported the preparation of 2-pyridylmethanol by methods which require several steps beginning with readily obtainable derivatives of pyridine. This report describes a simple method of preparation of 2-pyridylmethanol from 2-picoline, which does not involve the isolation of any intermediate product. 2-Picolyllithium was prepared by the hydrogen–metal interchange reaction between 2-picoline and phenyllithium. The picolyllithium was oxidized with a slow current of air to form the desired 2-pyridylmethanol.

A compound, $C_{12}H_{12}N_2$, was obtained as a by-product of the reaction. This compound was not identified but is probably 1,2-dipyridylethane, which would be expected[6] as the coupling product of two pyridyl radicals.

Experimental[7]

2-Picolyllithium was prepared by the procedure of Finkelstein and Elderfield[8] from 46.5 g. of 2-picoline. When the reaction was complete, the source of nitrogen was removed. Dry, carbon dioxide-free air was drawn at the rate of 2 cc. per minute into the flask and over the surface of the solution. The oxidation was carried out with stirring and without heating or cooling for eight hours, at which time the bright red color had disappeared and the mixture was light yellow. From time to time, more anhydrous ether was added to replace that lost by evaporation.

For the separation of the product, 6 *N* hydrochloric acid was added until the solution was acid to congo red. The aqueous layer was separated, made alkaline with sodium carbonate, saturated with sodium chloride, and extracted several times with chloroform. After the chloroform layer had been dried over anhydrous calcium sulfate for twenty-four hours, the chloroform and 2-picoline was distilled from the mixture at atmospheric pressure. The picoline boiled at 128° and was identified by the melting point of its picrate (168°). It weighed 11.3 g. or 24% of the original amount added.

The mixture of free bases was then fractionally distilled under reduced pressure. The following fractions were obtained: Fract. 1 (70–103° at 3–4 mm.), 11.2 g.; fract. 2 (103–136° at 3–4 mm.), 8.0 g., fract. 3 (138–170° at 1–2 mm.), 0.9 g.; residue, 16 g.

Identification of 2-Pyridylmethanol.—Fraction 1 on redistillation boiled completely at 111–115° at 16 mm. *Anal.* Calcd. for C_6H_7NO: N, 12.84. Found: N, 12.64. The picrate melted at 150° and the chloroplatinate at 179°. These data are in agreement with the values of Harries and Lenart.[4]

The yield of 11.2 g. was 20.5% based on the 2-picoline added or 27.0% on the basis of 2-picoline consumed in the reaction.

Compound $C_{12}H_{12}N_2$.—Fraction 2 redistilled at 112–114° at 1–2 mm. The distillate solidified on standing. After recrystallization from ligroin, its melting point was 49°. *Anal.* Calcd. for $C_{12}H_{12}N_2$: C, 78.23; H, 6.57; N, 15.21. Found: C, 77.98; H, 6.67; N, 15.05. Molecular weight determination by the Rast camphor method. Calcd.: 184. Found: 197, 196, 193; av. 195. This product was not further characterized.

Polyvinyl Bromide[1]

BY DAVID EDELSON AND RAYMOND M. FUOSS

In connection with our work on polyelectrolytes,[2] we attempted to prepare a polymeric quaternary compound by the addition of tertiary amines to polyvinyl bromide. The desired product was not obtained, but the results of some of our experiments seem worth reporting. Vinyl bromide is one of the earliest known vinyl compounds; Regnault[3] prepared it by treating ethylene dibromide with alkali. Staudinger[4] studied its polymerization and noted that the polymer readily loses hydrogen bromide.

We heated 0.5 cc. of 30% hydrogen peroxide and 10 g. of vinyl bromide[4a] in a bomb at 47° for twenty-four hours and obtained no polymer, although Güyer and Schütze[5] report complete conversion in twenty hours at 60°. About 30% conversion was obtained in two days at 60° from a (deoxygenated) solution of vinyl bromide (10 g.) in toluene (8 g.) saturated with benzoyl peroxide. The product was white, but darkened on drying under vacuum at 30°; Parr bomb bromine averaged to 70.2% (theoretical 74.77%). Fair results were obtained by photochemical

polymerization[6] in ether solution in a sealed quartz tube placed in front of a 100-watt quartz mercury arc, but the product darkened in the tube unless precautions were taken to shield the polymer from the ultraviolet radiation.

Oxidation-reduction polymerization[7] using the recipe: 75 cc. of deoxygenated water, 2 g. of Cetab, 10 cc. of 1.0 *N* sulfuric acid, 13 g. of vinyl bromide, 1 cc. of 0.01 *N* ferrous sulfate in *N*/10 sulfuric acid and 1 cc. of 0.01 *N* hydrogen peroxide gave no yield, possibly as a consequence of the difficulty of deoxygenating a monomer which boils at 15.8°. Some conversion was obtained with potassium persulfate as catalyst, using the procedure described by Kolthoff and Dale.[8]

The polyvinyl bromide obtained by solution polymerization was insoluble in Bu_3N (cohesive energy density 44), petroleum ether (52), carbon tetrachloride (73), nitromethane (143), ethyl alcohol (260), and methyl alcohol (346); swelled in toluene (75), benzene (81) and acetone (91); and dissolved in methyl ethyl ketone (80), dioxane (91), $C_6H_5NO_2$ (102) and C_5H_5N (105). From these data, we estimate that the cohesive energy density[9] of polyvinyl bromide is about 90, approximately the same as that of polyvinyl chloride.[10]

Addition of polyvinyl bromide to pyridine in a conductance cell at 25° produced electrolyte, as shown by a rapid increase in conductance. Reaction with triethylamine and with trimethyl amine in methanol also lead to electrolyte formation. No polyelectrolyte was produced, however; in every case, an insoluble red-to-dark-brown precipitate was obtained, and tertiary amine hydrobromide was found in the supernatant liquid. This result shows that tertiary amines dehydrohalogenate polyvinyl bromide[11] in preference to adding to it to form a polymeric quaternary salt. Two facts favor the elimination of hydrogen bromide: first, steric hindrance militates against the insertion of an R_3N group at every other carbon of the polymer chain; and, second, any single elimination of hydrobromic acid produces labile allylic bromines (—CHBr·CH=CH—) in the chain, which are more reactive than the original bromine atoms of the polymer. The tendency thus is to produce conjugated segments in the polymer chain. If the elimination of hydrogen bromide is purely statistical,[12] occasional methylene groups will be isolated, which will break the conjugation. From the deep color and the insolubility of the product, however, we conclude that the conjugated segments must be quite long, in analogy to the higher members[13] of the $R(CH{=}CH)_nR'$ series.

Inhibition of Growth of *Escherichia coli* by 4-Aminopteroylglutamic Acid and its Reversal

BY A. L. FRANKLIN, E. L. R. STOKSTAD, C. E. HOFFMANN, M. BELT AND T. H. JUKES

Recent investigations[1-5] have shown that thymidine and certain other desoxyribosides can replace vitamin B_{12} as a growth factor for various lactic acid bacteria. In the present study, the relation of these desoxyribosides to the reversal of the inhibitory effect of 4-aminopteroylglutamic acid[6] (4-amino PGA), a potent antagonist of PGA, was measured. It was found that the growth of *Escherichia coli* was inhibited by high levels of 4-amino PGA in spite of the fact that the organism does not need PGA for growth. The inhibition was found to be reversed by liver extract or thymidine but not by PGA, *p*-aminobenzoic acid, vitamin B_{12}, thymine, guanine, hypoxanthine, adenosine, adenylic acid, cytidylic acid or the desoxyribosides of guanidine and hypoxanthine (Table I).

It was also found that *Lactobacillus leichmannii* 313, which needs both PGA (or *p*-aminobenzoic acid) and vitamin B_{12} for growth, was inhibited by 4-amino PGA. This inhibition was reversible by PGA at low levels of 4-amino PGA, up to 5 γ per ml., but at high levels of 4-amino PGA, 25 γ per ml., PGA was ineffective while thymidine produced a reversal. The desoxyribosides of guanine and hypoxanthine were ineffective as reversing agents, although these two compounds produced approximately maximum growth in the presence of PGA if 4-amino PGA and B_{12} were omitted. In the absence of 4-amino PGA, thymidine produced an incomplete growth response, about 50% of maximum, if PGA and *p*-aminobenzoic acid were omitted, with or without the addition of vitamin B_{12}. The response to guanine desoxyriboside or hypoxanthine desoxyriboside under these conditions was 25 to 33% of maximum.

Experimental

The liver extract was a commercial antipernicious-anemia preparation, 10 units per ml. The medium used

with *Lactobacillus leichmannii* was similar to that of Snell and co-workers[2] but with thioglycolic acid, 0.2 mg. per ml.[7] When 25 γ of 4-amino PGA per ml. and 0.2 γ of PGA were added, the following are typical of optical densities obtained at 18 hours: no supplement, 0.02; 200 γ PGA, 0.04; 0.01 γ B_{12}, 0.05; 2 γ thymidine, 0.58; 2 γ guanine desoxyriboside, 0.08; 2 γ hypoxanthine desoxyriboside, 0.04; 100 γ thymine, 0.10; 100 γ thymine *plus* 2 mγ vitamin B_{12}, 0.29. The addition of 2 mγ of vitamin B_{12} did not augment the growth obtained with the desoxyribosides. When 4-amino PGA, PGA and *p*-aminobenzoic acid were omitted from the basal medium the following optical densities were obtained: no supplement, 0.03; 2 mγ B_{12}, 0.27; 2 γ guanine desoxyriboside, 0.37; 2 γ hypoxanthine desoxyriboside, 0.37; 2 γ thymidine, 0.52; 2 mγ B_{12} *plus* 0.2 γ PGA, 1.5; 2 γ guanine desoxyriboside *plus* 0.2 γ PGA, 1.1; 2 γ hypoxanthine desoxyriboside *plus* 0.2 γ PGA, 1.1; 2 γ thymidine *plus* 0.2 γ PGA, 1.2.

Discussion.—The inhibitory effects of low levels of 4-amino PGA for certain organisms are reversible by PGA but high levels of the antagonist produce toxic effects which are not so reverse.[8,9,10] The present investigation shows that these toxic effects may in certain instances be reversed by thymidine, which may indicate that PGA has a role in the formation of thymidine. The inhibitory effect of 4-amino PGA on the growth of *E. coli* conceivably may be due to the entrance of this substance into the cell to displace endogenously-formed PGA from this role. The inhibitory effect of "x-methyl-PGA" upon *Leuconostoc mesenteroides* 8293 was found by Shive and co-workers[11] to be reversed by either PGA or thymidine. After the present experiments were completed, Sauberlich[12] reported inhibition of the growth of *Leuconostoc citrovorum* 8081 by 4-amino PGA and reversal by thymidine. We are indebted to Dr. J. O. Lampen for thymidine, to Dr. H. M. Kalckar for guanine desoxyriboside and to Dr. E. E. Snell for hypoxanthine desoxyriboside.

The Reduction of 2-Acetylpyridine to 2-Ethylpyridine

BY ARTHUR FURST

Recently Gregg and Craig[1] reported that the melting point of the picrate of 2-ethylpyridine made by two different methods—hydrogenation of 2-vinylpyridine and the action of methyl iodide on lithium picoline—did not agree with that obtained by Bergstrom and McAllister[2] who made it by the addition of ethylmagnesium bromide to pyridine. In confirmation of the work of the former authors 2-acetylpyridine was reduced to 2-ethylpyridine by three different methods, namely, Clemmensen, Wolff–Kishner, and Huang-Minlon. The results of the boiling points, melting points, mixed melting points, and fusion analysis[3] show that these reduction products agree in all respects with each other and with the compound obtained by Gregg and Craig by hydrogenation of 2-vinylpyridine.

Experimental

The 2-acetylpyridine, from Dougherty Chemical Co., was redistilled: picrate m. p. 131°; lit. 131°.[4]

Clemmensen Reduction.—A solution of 2-acetylpyridine (0.12 mole) in 70 ml. of concentrated hydrochloric acid was vigorously refluxed in contact with amalgamated zinc (0.77 mole).[5] After ten hours 50 ml. more acid was added, and refluxing was continued an additional five hours. The solution was made basic with solid hydroxide, filtered through a stainless steel funnel, extracted with benzene, dried and fractionated. The colorless distillate that came over at 144° was caught in a 50% alcoholic solution

of picric acid. The solid was isolated as described below (yields).

Anal. Calcd. for $C_{13}H_{12}O_7N_4$: N, 16.7. Found: N, 16.7.

Wolff-Kishner.—A yield of 7.8 g. (83.5%) of the semicarbazide hydrochloride of 2-acetylpyridine was obtained by the method of Woodward, *et al.*,[6] using ten equivalents of hydrochloric acid, m. p. 202° (uncor.).

Anal. Calcd. for $C_8H_{10}ON_4 \cdot HCl$: N, 26.2; Cl, 16.6. Found: N, 26.6; Cl, 17.0, 16.9.

The reduction was carried out by heating the semicarbazide hydrochloride with eight equivalents of sodium ethylate in an oil-bath at 180°. The distillate was caught in a 50% alcoholic solution of picric acid.

Huang-Minlon.[7]—A mixture of 2-acetylpyridine (0.06 mole), 5 ml. of 85% hydrazine hydrate, 5 g. of sodium hydroxide, and 80 ml. of diethylene glycol was heated for six hours. No attempt was made to remove the water. The solution was cooled, extracted with benzene, and converted into the picrate.

Yields.—No attempt was made to obtain maximum yields. The solid picrates were isolated from the alcoholic solution, dissolved in hot acetone, treated with decolorizing carbon, crystallized by cooling and finally recrystallized from alcohol. From the weights of the crude products, and the purified picrates the following estimates of yields were made: Clemmensen 80%, Wolff-Kishner 50% and Huang-Minlon 65%.

Melting Points and Fusion Analysis.—Using a copper block[8] and raising the temperature at a rate no faster than 1–2° per minute each picrate, and all possible combinations of picrate mixtures melted at 107–107.5° (uncor.). When the picrate of the Clemmensen reduction product was mixed with (a) the picrate of 2-acetylpyridine a depression of 20° in the melting point was noted; (b) the picrate of the hydrogenation product of Gregg and Craig the melting point was 107.5°. A fusion analysis showed these last pair to be identical also, for no eutectic melt was noted at the boundary. This in contrast with the eutectic melt shown in the fusion analysis of the first pair.

Acknowledgments.—I should like to acknowledge thanks to Robert Seiwald for the analytical data, and Dr. Luthy for a sample of the picrate of the hydrogenation product of 2-vinylpyridine and for the fusion analysis.

The Reaction of Propyl Disulfide with Decyl Mercaptan

BY GEORGE GORIN,[1] GREGG DOUGHERTY AND ARTHUR V. TOBOLSKY

It is known that thioglycolic acid reacts with cystine in solution to give cysteine[2]; indeed, a quantitative study of the reaction has been made.[3] We wish to report some results which indicate that a similar reaction occurs between simple alkyl disulfides and mercaptans.

Mixtures of propyl disulfide and decyl mercaptan were heated in sealed Pyrex glass tubes for varying lengths of time. The samples were then cooled, the mercaptans were titrated with standard silver nitrate solution to an amperometric end-point, and the precipitated silver mercaptides weighed.[4] It was found that the number of moles of total mercaptan did not change during the reaction, but that the weight of the precipitate decreased continuously to an equilibrium value. It was thus indicated that there had taken place a mole per mole exchange of propyl for decyl mercaptan. The data obtained in a run at 138–139° are given in Table I.

TABLE I

MIXTURES OF PROPYL DISULFIDE AND DECYL MERCAPTAN HEATED AT 138–139°

Time, hr.	Moles SH found	Av. mol. wt. of AgSR	% PrSH
0		280	1
3	275	268	13
6	282	260	21
9	276	253	29
12	278	248	34
36	277	243	39
62	277	226	56

At 180° the reaction proceeded more quickly, and after a few hours heating considerable amounts of propyl mercaptan could be isolated directly by distillation of the cooled reaction mixture.

We believe the reaction proceeds by a stepwise exchange which at first gives rise to a mixed disulfide. We made no attempt to isolate this compound but hope to obtain evidence on this question in future work.

Experimental

Material.—The propyl disulfide was an Eastman Kodak Co. "white label" product which had been redistilled at least once, b. p. 93.3–94.6° at 30 mm. The decyl mercaptan was a Connecticut Hard Rubber Co. product, which had been redistilled at least once; b. p. 102–106° at 15 mm., $n^{30}D$ 1.4534, molecular weight[4] 171 (calculated 174).

Approximate Rate Measurements.—Equal volumes (1.00 ml.) of a mixture of one mole of propyl disulfide and one mole decyl mercaptan were sealed in several tubes of nearly equal volumes (1.5 ml.) and heated in a vapor bath for some time (*p*-xylene used at 138–139°; *p*-cymene at 176°). At the end of the appropriate period each tube was withdrawn and cooled, and the contents washed into 375 ml. of 95% alcohol containing 25 ml. of 0.2 *M* alcoholic ammonium acetate as supporting electrolyte. The solution was then titrated with standard 0.1 *N* alcoholic silver nitrate to an amperometric end-point. The precipitate was transferred to Gooch-type filters consisting of a layer of asbestos placed over a medium Pyrex glass fritted filter disk, and dried *in vacuo* at 60–70° to constant weight.

Acknowledgments.—The authors are indebted to Dr. F. O. Davis and Mr. E. M. Fettes of the Thiokol Corporation for their active interest and valuable advice.

Measurement of Ion Hydration by the Diffusion Method

BY A. HUNYAR

C. H. Hale and T. de Vries have recently reported[1] that the hydration of quaternary ammonium salts cannot be determined by the Nernst–Washburn method[2] because the reference substance as well as water is transported during electrolysis. This fact was previously demonstrated by T. Erdey-Gruz and A. Hunyar[3] using a modified form of the diffusion method developed by J. W. McBain and T. H. Liu.[4] They usually employed allyl alcohol of various concentrations as a reference substance and hydrochloric acid, potassium bromide, potassium chloride, lithium chloride, lithium acetate and tetramethylammonium chloride as electrolytes. They found that the concentration of the reference substance decreased, with one exception, in that part of the apparatus from which the electrolyte diffused and increased in that part into which it diffused.[5] The remarkable fact concerning these experiments was that the amount of allyl alcohol transported increased nearly linearly with the concentration of alcohol in the range 0.2 to 25% from 0.003 to 0.31 mole of allyl alcohol per mole of potassium chloride. The amount of alcohol transported decreased from 0.033 mole of allyl alcohol per mole of potassium chloride on the first day to 0.023 on the fourth day which was mathematically shown to be due to the back diffusion of the alcohol. The following results were obtained.

Electrolyte	Hydration numbers by Remy[6]	Mole of allyl alcohol per mole electrolyte
$LiC_2H_3O_2$	22.0	0.041
LiCl	15.6	.033
$N(CH_3)_4Cl$	7.6	.015
KCl	7.1	.031
KBr	6.2	.025
HCl	4.0	.005

Pogány[7] also observed that the electrolytes carried more reference substance than water, using the diffusion method. In the electrolysis of a solution of silver nitrate with pyridine as reference substance, Morgan and Kanolt[8] reported that a large proportion of the pyridine was combined with silver ions.

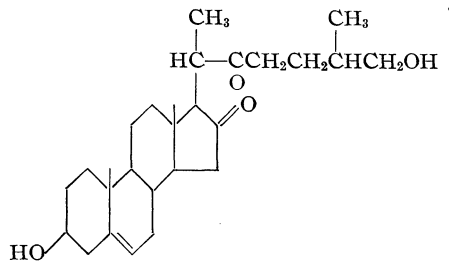
Steroidal Sapogenins. III. 16-Alkylsapogenins[1]

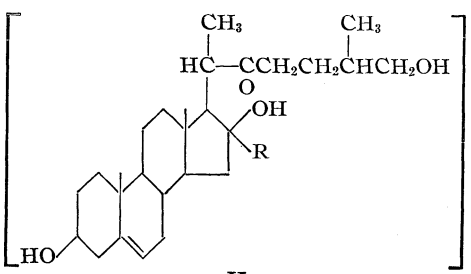
BY ST. KAUFMANN AND G. ROSENKRANZ

Through our recent work[1] it became evident that the two keto groups of the open-side-chain sapogenin, kryptogenin, possess different reactivity and that the conversion into sapogenins of the spiroketal form can easily be achieved as soon as the hydroxy group is introduced in the 16-position: we prepared[2] the 16-dihydrokryptogenin, a very unstable compound which can easily be transformed into diosgenin.

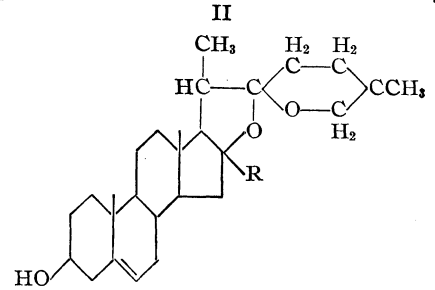
Based on this selective behavior of the 16-keto group we now reacted kryptogenin (I) with alkylmagnesium halides and obtained the respective 16-alkyldiosgenins (III) in good yield. The intermediate compound is very probably a 16-alkyl derivative of 16-dihydrokryptogenin (II)



I



II



III

The same reaction occurs with the esters of kryptogenin. If an excess of alkylmagnesium halide is used, the ester groups also react, thus yielding the free compounds.

In analogous manner, 5,6-dihydrokryptogenin or its esters can be transformed into the 16-alkyltigogenins. These latter compounds can be obtained also from the respective 16-alkyldiosgenins

(1) For Paper II in this series see Rosenkranz, Kaufmann, Landa, Corona and Olalde, THIS JOURNAL, **70**, 3518 (1948).

(2) Kaufmann and Rosenkranz, *ibid.*, **70**, 3502 (1948).

by catalytical hydrogenation with platinum oxide as catalyst.

Since it is known that the neosapogenins can be converted by acids into the corresponding normal side-chain sapogenins, while the compounds obtained with alkylmagnesium halide are stable against acids, we suggest that the normal side chain should be ascribed to the 16-alkylsapogenins described above.

The unsaturated 16-alkylsapogenins behave like diosgenin and the saturated like tigogenin inasmuch as they form mono-esters and as the 3-hydroxy group can easily be converted into a keto-group. The transformation and degradation of the side chain, as well as the resulting 16-alkylpregnane and androstane derivatives shall be dealt with in a forthcoming paper.

Experimental[3,4]

16-Methyldiosgenin.—To a solution of 10 g. (about 0.02 mole) of kryptogenin diacetate in 200 cc. of dry benzene, a diluted solution of 0.2 mole of methylmagnesium bromide in ether was added. The mixture was refluxed for three hours under anhydrous conditions, then poured into water and ice containing hydrochloric acid, and subsequently extracted with ether. After washing the ether solution with water until neutral it was dried and evaporated. After recrystallization from ether–methanol, about 7 g. of 16-methyldiosgenin was obtained m. p. 174–175°, $[\alpha]^{20}D$ −105° (in chloroform). *Anal.* Calcd. for $C_{28}H_{44}O_3$: C, 78.45; H, 10.34. Found: C, 78.46; H, 10.39.

The same product can be obtained from free kryptogenin, utilizing anhydrous dioxane instead of benzene as a solvent. After refluxing 16-methyldiosgenin with hydrochloric acid in alcoholic solution for ten hours, it can be recovered unaltered.

Acetate.—M. p. 171–172°, $[\alpha]^{20}D$ −100° (in chloroform). *Anal.* Calcd. for $C_{30}H_{46}O_4$: C, 76.55; H, 9.85. Found: C, 76.74; H, 9.75.

Benzoate.—M. p. 218–218.5°, $[\alpha]^{20}D$ −70° (in chloroform). *Anal.* Calcd. for $C_{35}H_{48}O_4$: C, 78.94; H, 9.02. Found: C, 78.89; H, 9.30.

16-Methyl-4,5-dehydrotigogenone.—16-Methyldiosgenin was oxidized with cyclohexanone and aluminum *t*-butylate to 16-methyl-4,5-dehydrotigogenone; m. p. 182.5–186°, $[\alpha]^{20}D$ −8° (in chloroform). *Anal.* Calcd. for $C_{28}H_{42}O_3$: C, 78.82; H, 9.92. Found: C, 78.78; H, 9.98.

16-Ethyldiosgenin.—The Grignard reaction with ethylmagnesium bromide led to 16-ethyldiosgenin; m. p. 171–172°, $[\alpha]^{20}D$ −107° (in chloroform). *Anal.* Calcd. for $C_{29}H_{46}O_3$: C, 78.68; H, 10.47. Found: C, 78.59; H, 10.51.

Acetate.—M. p. 176.5–177.5°, $[\alpha]^{20}D$ −105° (in chloroform). *Anal.* Calcd. for $C_{31}H_{48}O_4$: C, 76.81; H, 9.98. Found: C, 76.81; H, 9.91.

Benzoate.—M. p. 208–211°, $[\alpha]^{20}D$ −72° (in chloroform). *Anal.* Calcd. for $C_{36}H_{50}O_4$: C, 79.07; H, 9.21. Found: C, 79.12; H, 9.14.

16-Ethyl-4,5-dehydrotigogenone.—Prepared as the lower homolog, m. p. 171–173°, $[\alpha]^{20}D$ −7° (in chloroform). *Anal.* Calcd. for $C_{29}H_{44}O_3$: C, 78.86; H, 10.04. Found: C, 79.12; H, 10.01.

16-Methyltigogenin.—(a) This saturated compound was prepared from 5,6-dihydrokryptogenin-diacetate and methylmagnesium bromide under analogous conditions as described for 16-methyldiosgenin; m. p. 215–216.5°, $[\alpha]^{20}D$ −56° (in chloroform). *Anal.* Calcd. for $C_{28}H_{46}O_3$: C, 78.07; H, 10.76. Found: C, 78.08; H, 10.75.

(3) The microanalyses were carried out by Dr. Carl Tiedcke, New York, N. Y., and in our microanalytical laboratory under the direction of Miss Amparo Barba.

(4) All the melting points were determined on the Kofler micro-melting point apparatus.

(b) The same product was obtained by catalytical hydrogenation of 16-methyldiosgenin in glacial acetic acid with platinum oxide as catalyst; m. p. 215–216.5°. The mixed m. p. with the 16-methyltigogenin obtained by method (a) showed no depression.

Acetate.—M. p. 186.5–189.5°, $[\alpha]^{20}D$ −65° (in chloroform). *Anal.* Calcd. for $C_{30}H_{48}O_4$: C, 76.22; H, 10.23. Found: C, 76.28; H, 9.98.

Benzoate.—M. p. 207–212°, $[\alpha]^{20}D$ −50° (in chloroform). *Anal.* Calcd. for $C_{35}H_{50}O_4$: C, 78.60; H, 9.42. Found: C, 78.50; H, 9.47.

16-Methyltigogenone.—It was prepared by oxidation of 16-methyltigogenin with chromic anhydride in glacial acetic acid; m. p. 175–178°, $[\alpha]^{20}D$ −45° (in chloroform). *Anal.* Calcd. for $C_{28}H_{44}O_3$: C, 78.45; H, 10.34. Found: C, 78.43; H, 10.52.

16-Ethyltigogenin.—The Grignard reaction of 5,6-dihydrokryptogenin with ethylmagnesium bromide led to 16-ethyltigogenin. The catalytical hydrogenation of 16-ethyldiosgenin with platinum oxide gave the same product; m. p. 194.5–197°, $[\alpha]^{20}D$ −60° (in chloroform). *Anal.* Calcd. for $C_{29}H_{48}O_3$: C, 78.32; H, 10.88. Found: C, 78.32; H, 10.86.

Acetate.—M. p. 197–199°, $[\alpha]^{20}D$ −62° (in chloroform). *Anal.* Calcd. for $C_{31}H_{50}O_4$: C, 76.47; H, 10.35. Found: C, 76.66; H, 10.29.

Benzoate.—M. p. 178.5–181°, $[\alpha]^{20}D$ −49° (in chloroform). *Anal.* Calcd. for $C_{36}H_{52}O_4$: C, 78.78; H, 9.55. Found: C, 78.59; H, 9.66.

16-Ethyltigogenone.—Prepared as the lower homolog; m. p. 169–173°, $[\alpha]^{20}D$ −44° (in chloroform). *Anal.* Calcd. for $C_{29}H_{46}O_3$: C, 76.68; H, 10.47. Found: C, 76.58; H, 10.59.

The Exchange of Mercury(I) and Mercury(II) Ions

BY EDWARD L. KING

The exchange of mercury(I) and mercury(II) ions in solution is of interest because this involves breaking the bond in dimeric mercury(I) ion. Unpublished work[1a,b] indicates that this exchange proceeds rapidly at room temperature. It seemed desirable to carry out further experimental studies on this reaction using several techniques for separation of the two oxidation studies of mercury.

The separation of the two oxidation states has been effected by the precipitation of mercury(I) chloride, mercury(I) chromate and mercury(I) sulfate. In addition a partial separation has been effected by the diffusion technique[2] although no exchange experiments were run using this technique.

Experiments of three types were run using the precipitation of mercury(I) chloride and mercury(I) chromate. These differed in the order of addition of reagents: (a) the precipitating agent was added to a solution containing mercury(I) and mercury (II) perchlorates immediately after the two valence states had been brought together, (b) a solution containing mercury(II) perchlorate and the precipitating reagent was added to the solu-

tion of mercury(I) perchlorate, and (c) the solution containing mercury(II) perchlorate was added to a slurry of the freshly precipitated mercury(I) compound. Using mercury(I) sulfate precipitation, the procedure corresponding to (a) was the only type experiment performed.

The results of experiments of type a and b are reported in Table I. It is seen that the exchange is essentially complete even in experiments of type (b).

TABLE I

EXCHANGE OF MERCURY(I) AND MERCURY(II) IONS

Exp. type	Ppt.	Composition (moles/liter) (Hg^{++})	(Hg_2^{++})	(H^+)	Extent of exchange
a	Hg_2Cl_2	0.0031	$0.0016^{\otimes a}$	0.5[b]	94, 98
a	Hg_2Cl_2	$10^{-5\otimes a}$	10^{-3}	0.5[b]	>98
b	Hg_2Cl_2	$10^{-5\otimes a}$	10^{-3}	0.5[b]	97[c], 98[d]
b	Hg_2Cl_2	$10^{-5\otimes a}$	10^{-3}	3	97–98[e]
a	Hg_2CrO_4[f]	0.0044	$0.0069^{\otimes a}$	0.1	94, 98
b	Hg_2CrO_4[f]	$0.0048^{\otimes a}$	0.0067	0.1	92, 102

a	Hg_2SO_4[g]	$0.0136^{\otimes a}$	0.0064	0.16[h]	

[a] ⊗ at concentration indicates activity started here. [b] Solutions also contain 3 *M* sodium perchlorate. [c] Two experiments. [d] Two experiments at 0°. [e] Three experiments; Cl^- concentration 0.04–0.06 *M*. [f] Composition of solid not established. [g] Precipitation incomplete; results of two experiments coupled lead to listed conclusion. [h] Not corrected for HSO_4^- formation.

The results of the experiments of type b involving mercury(I) chromate are consistent with a mechanism involving rapid homogeneous exchange and a rapid rate of recrystallization of the freshly precipitated solid. The concentration conditions in the chloride experiments are such that no conclusions may be drawn in this regard.

Experiments of type c are relevant to this question. The extent to which mercury(II) ion exchanges with precipitated mercury(I) chloride varies. The extent of exchange is approximately 30% if the mercury(II) is added within a few seconds after precipitation and then stirred with the precipitate for 2.5 minutes; it is 10% if the mercury(II) is added 7.5 minutes after precipitation and then stirred for 2.5 minutes. These represent extremes in the results of the seven experiments of this type performed. Contrasted with this are the results of this type experiment involving mercury(I) chromate. It was found that mercury(II), added in an amount comparable to the mercury(I), present as long as one minute after the precipitation of the mercury(I) chromate, exchanges completely with the precipitate upon stirring an additional two minutes. If, however, six minutes elapse between the time of precipitation and the addition of the mercury(II), essentially no exchange occurs upon stirring two minutes. This behavior, too, is consistent with a mechanism involving a rapid homogeneous exchange coupled with a relatively high recrystallization rate for freshly precipitated mercury(I) chromate and a much lower recrystallization rate for the coagulated solid. Visual observations reveal the change in the nature of the precipitate at times approximately one minute after precipitation. It was found that mercury(I) chromate precipitated under these conditions would dissolve completely in approximately thirty seconds upon treatment with excess iron(II) if only thirty seconds elapsed between the time of precipitation and addition of iron(II), while many minutes were required if this time interval was increased to three minutes.

This work doesn't discount the possibility that the exchange observed is in reality being induced during the precipitation. Under the conditions of these experiments it appears that the bond in dimeric mercury(I) is readily broken.

It has been shown that mercury(I) ion diffuses approximately 10% more rapidly than mercury(II) under certain concentration conditions. This observation is consistent with the relative diffusion coefficients determined by Kolthoff and Miller.[3] The condition under which this separation is achieved $((Hg_2^{++})_0/(Hg^{++})_0 = 0.5)$ is such that the counting rate of the diffusate would vary by only 5% depending upon whether the extent of exchange is 0% or 100%. The analytical and counting rate uncertainties are such that it does not appear worthwhile to use this technique in the exchange study.

Experimental

The radioactive mercury was prepared by the $Hg(n, \gamma)$ reaction in the Oak Ridge pile and allocated by the United States Atomic Energy Commission. The work was all performed after the Hg^{197} had decayed; thus the mercury isotope present was $Hg^{205,203}$. Solutions of active mercury(II) perchlorate were prepared by dissolving active mercury(II) oxide in perchloric acid. Solutions of active mercury(I) perchlorate were prepared by allowing a solution of mercury(I) perchlorate to exchange for several days with a small amount of active mercury(II) perchlorate. Other reagents were all analytical reagent grade and all solutions were prepared using doubly distilled water.

The mercury(I) fraction was generally counted in the form precipitated while the mercury(II) was counted as the oxide or a basic salt. The samples were mounted for counting on filter paper by suction filtering.

pounds reported here are new. The general method involved the treatment of an α,β-unsaturated ketone with the appropriate mercaptan in the presence of catalytic amounts of sodium ethoxide. Yields were excellent, ranging from 85 to 100%, and all the compounds studied were crystalline.

Experimental

β-Ketosulfides.—Directions are given for the preparation of one compound only. Others may be synthesized in a similar manner.

Benzylacetophenone β-*n*-Dodecylsulfide.—In a 125-ml. erlenmeyer flask were mixed 10.4 g. (0.05 mole) of benzylideneacetophenone, 10.1 g. (0.05 mole) of *n*-dodecyl mercaptan and 40 ml. of benzene. One-half ml. of 2 *N* sodium ethoxide was added and the mixture was vigorously shaken, a considerable amount of heat developing. After standing for twelve hours, glacial acetic acid was added dropwise until the solution was acid to phenolphthalein, and the solvent was removed under reduced pressure, leaving a crystalline residue which was recrystallized from methanol, giving a product melting at 52°[3] in 95% yield. The properties and analyses of the new compounds are listed in Table I.

(3) All melting points were taken with a Fisher–Johns apparatus.

2-Substituted-1,3-oxathiolanes

BY FRANK KIPNIS[1] AND JOHN ORNFELT

A search of the literature has indicated that surprisingly little information is available relating to the preparation and properties of 1,3-oxathiolanes. Sjoberg[2] discussed the preparation of 2,2,5-trimethyl-1,3-oxathiolane from acetone and 1-sulfhydryl-2-hydroxypropane in the presence of phosphorus pentoxide and sand. Other information[3] has indicated the possibility of the formation of oxathiolanes from the interaction of aldehydes or ketones with 2-mercaptoethanol in the presence of hydrochloric acid, but no specific data were given.

A method for the preparation of a number of hitherto unreported oxathiolanes is given here. These compounds are liquids with fresh, aromatic aromas, insoluble in water and soluble in most organic solvents, fairly stable to bases, but completely decomposed into the starting materials by very dilute acid. Table I summarizes the properties of three new oxathiolanes.

TABLE I

[a] Analyses by Oakwold Laboratories, Alexandria, Virginia.

Experimental

All the oxathiolanes were prepared by the same method. Directions are given for one compound only.

2-Isopropyl-1,3-oxathiolane.—In a 1000-ml. 3-neck interjoint flask fitted with a sealed Hershberg stirrer, dropping funnel and Dean–Stark adapter and condenser, was placed 39 g. (0.5 mole) of 2-mercaptoethanol, 36 g. (0.5 mole) of isobutyraldehyde and 250 ml. of dry benzene. The stirrer was started and a solution of 250 mg. of hydrogen chloride in 10 ml. of anhydrous ether was added from the dropping funnel during five minutes. A considerable amount of heat was produced and water was evolved. The mixture was refluxed for ninety minutes, and at the end of which time the theoretical amount of water (9 ml.) had been removed. The solution was cooled, washed thoroughly with 10% potassium carbonate, dried over calcium sulfate, filtered and the solvent stripped from the filtrate. The residue was fractionated at 29–31° (2.5 mm.) through a 35-cm. Vigreux column to give 39.6 g. (60%) of a colorless oil with a pleasant aroma.

A Method for Reduction of Steroid Oxides

BY L. CARROLL KING AND J. ALLAN CAMPBELL

Recent interest in the reduction of steroid oxides[1] impels us to record a method for reduction of these substances which has been under investigation in this Laboratory.

(α)-Cholesteryl oxide (I) reacts with thiourea and *p*-toluenesulfonic acid in alcoholic solution to give 3(β),5(α)-dihydroxycholestanyl-6-isothiuronium tosylate (II) in 73–92% yield. An alcoholic solution of II on shaking with an equivalent amount of sodium hydroxide and an excess of standard nickel catalyst[2] was reduced to 3(β),5(α)-dihydroxycholestane (III), yield 88–95%. The identity of III was established by conversion to 3(β)-acetoxy-5(α)-hydroxycholestane.

The application of this method of reduction to the preparation of 17-hydroxysteroids from the corresponding 16,17- or 17,20-oxido compounds is in progress.

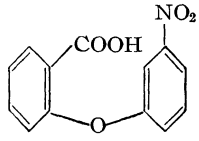
Camps Reaction with 1-Xanthonamine[1]

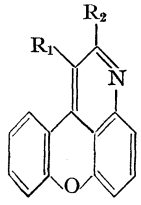
BY C. F. KOELSCH AND F. J. LUCHT

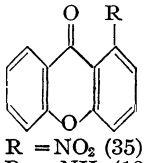
This paper describes a synthesis of [1]benzopyrano[4,2,de]quinoline (IX) and some reactions designed to yield its 6-methoxy derivative. It is planned to use these substances in experiments which it is hoped will furnish 4-*o*-hydroxyphenylquinolinic acid and ultimately morphine analogs.[2]

The synthesis involved intermediates I–VIII, formulated below. The route from VI to IX through X and XI instead of VII and VIII gave poorer yields. Yield of each substance is indicated by the figure in parentheses.



I (85)





II, R = NO_2 (35)
III, R = NH_2 (100)
IV, R = $NHCOCH_2$-$COOC_2H_5$ (86)

	R_1	R_2
V	$COOC_2H_5$	OH (90)
VI	COOH	OH (94)
VII	H	OH (98)
VIII	H	Cl (89)
IX	H	H (28 from VIII; good from XI
X	COOH	Cl (25)
XI	COOH	H (59)

Experimental

***o*-(*m*-Nitrophenoxy)-benzoic Acid, I.**—The substance has been prepared but not isolated by Dhar.[3] In the present work it was obtained by heating and stirring a mixture of 62 g. of *o*-chlorobenzoic acid, 63 g. of *m*-nitrophenol, 50 g. of sodium carbonate, 5 g. of copper filings, 0.2 g. of cuprous chloride, and 150 ml. of *n*-amyl alcohol for three hours in an oil-bath at 160–170°. The crude crystalline product (55 g.) was suitable for cyclization. Crystallization from benzene gave pale yellow prisms, m. p. 138–139°.

Anal. Calcd. for $C_{13}H_9NO_5$: C, 60.2; H, 3.5. Found: C, 60.2; H, 3.8.

Xanthone Ring Closure.—A solution of 55 g. of crude nitrophenoxybenzoic acid in 300 ml. of sulfuric acid was heated on a steam-bath for thirty minutes and then poured into water. Acidic materials were removed, and the crude neutral residue (25 g., m. p. 160–170°) was separated by crystallization from acetic acid into 18 g. of 1-nitroxanthone (II), pale yellow prisms m. p. 206–207° (reported[3] 210°), and 7 g. of brown crystalline material, m. p. 155–160°. The latter contained the still unknown 3-nitroxanthane, for by reducing it with stannous chloride and alcoholic hydrochloric acid, and fractionally crystallizing the product from alcohol, there was obtained 3.7 g. of 3-xanthonamine, m. p. 231–232° (reported[4] 232°).

Anal. Calcd. for $C_{13}H_9NO_2$: C, 73.9; H, 4.3. Found: C, 74.0; H, 4.4.

1-Xanthonamine, III.—Reduction of 11.5 g. of 1-nitroxanthone with 45 g. of stannous chloride in 115 ml. of alcohol containing 50 ml. of hydrochloric acid and crystallization of the product from alcohol gave 9.5 g. of yellow prisms, m. p. 150–151°.

Anal. Calcd. for $C_{13}H_9NO_2$: C, 73.9; H, 4.3. Found: C, 73.9; H, 4.5.

All the isomeric xanthonamines are now known: 2 (m. p. 205°),[5] 3 (m. p. 232°),[4] and 4 (m. p. 201°).[6] The structure of the substance, m. p. 175°, formerly thought to be a xanthonamine of uncertain orientation,[7] is thus rendered still more uncertain.

1-(Carbethoxyacetamido)-xanthone, IV.—A solution of 12.5 g. of 1-xanthonamine in 125 ml. of ethyl malonate was boiled for twenty minutes, then most of the ester was removed by rapid distillation. Crystallization of the residue from alcohol gave 16.5 g. of pale tan powder, m. p. 122–123°.

Anal. Calcd. for $C_{18}H_{15}NO_5$: C, 66.4; H, 4.7. Found: C, 66.5; H, 4.7.

Pyridone Ring Closure.[8]—A solution of sodium ethoxide from 3 g. of sodium in 100 ml. of alcohol was added during fifteen minutes to a boiling suspension of 16 g. of IV in 300 ml. of alcohol. The mixture was boiled for an additional fifteen minutes and then cooled. The solid product was stirred for some time with dilute hydrochloric acid, then washed and dried, giving 13.5 g. of ethyl 2-hydroxy[1]benzopyrano[4,2-de]quinoline-1-carboxylate (V), m. p. 279–282°. Recrystallization from acetic acid gave fine pale yellow plates, m. p. 285–287°.

Anal. Calcd. for $C_{18}H_{13}NO_4$: C, 70.3; H, 4.3. Found: C, 70.3; H, 4.2.

2-Hydroxy[1]benzopyrano[4,2-de]quinoline-1-carboxylic Acid, VI.—The ester (3.4 g.) was saponified by boiling it six hours with excess 5% aqueous sodium hydroxide. The solution was then poured into excess hot dilute hydrochloric acid and the product was crystallized from acetic acid, giving 2.9 g. of small yellow plates. It began to lose carbon dioxide and change its appearance at 270°; the residue melted at 350–352° without effervescence.

Anal. Calcd. for $C_{16}H_9NO_4$: C, 68.8; H, 3.2. Found: C, 68.6; H, 3.4.

2-Hydroxy[1]benzopyrano[4,2-de]quinoline, VII.—The acid VI (2.9 g.) left a residue of nearly pure decarboxylation product (2.4 g.) when it was heated at 360°. Sublimation gave long yellow needles, m. p. 350–352°.

Anal. Calcd. for $C_{15}H_9NO_2$: C, 76.6; H, 3.9. Found: C, 76.8; H, 3.8.

2-Chloro[1]benzopyrano[4,2-de]quinoline, VIII.—A solution of 2.4 g. of VII in 10 ml. of phosphorus oxychloride was heated on a boiling water-bath for thirty minutes, then cooled and poured on ice. The mixture was neutralized and the product was crystallized from benzene, giving 2.3 g. of yellow crystals, m. p. 179–180°.

Anal. Calcd. for $C_{15}H_8ClNO$: C, 71.0; H, 3.2. Found: C, 70.9; H, 3.2.

[1]Benzopyrano[4,2-de]quinoline, IX.—A solution of 2 g. of VIII and 1 g. of sodium acetate in 100 ml. of acetic acid was shaken with 0.1 g. of platinum oxide and hydrogen at two atmospheres for twenty minutes. Treatment of the product with hydrochloric acid left 0.54 g. of unchanged chloro compound and dissolved the desired dehalogenated substance. The latter formed fine yellow needles (0.5 g.) from ligroin; m. p. 138–140°.

Anal. Calcd. for $C_{15}H_9NO$: C, 82.2; H, 4.1. Found: C, 82.2; H, 4.2.

2-Chloro[1]benzopyrano[4,2-de]quinoline-1-carboxylic Acid, X.—A solution of 0.9 g. of VI in 5 ml. of phosphorus oxychloride was heated for thirty minutes, then poured into water and allowed to stand overnight. The bicarbonate soluble product crystallized from alcohol in the form of a bright yellow powder (0.25 g.), m. p. 221–222° with decomposition.

Anal. Calcd. for $C_{16}H_8ClNO_3$: C, 64.5; H, 2.7. Found: C, 64.6; H, 2.7.

The corresponding **ethyl ester**, yellow crystals from benzene–ligroin, m. p. 177–179°, was obtained in a yield of 80% from 3.3 g. of V, with 10 g. of phosphorus oxychloride.

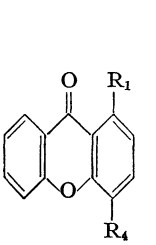
Anal. Calcd. for $C_{18}H_{12}ClNO_3$: C, 66.3; H, 3.7. Found: C, 66.6; H, 3.8.

[1]Benzopyrano[4,2-de]quinoline-1-carboxylic Acid, XI.—Dehalogenation of 0.24 g. of X was accomplished by shaking its solution in dilute alkali with Raney nickel and hydrogen at three atmospheres for ninety minutes. The product formed yellow crystals from alcohol, m. p. 265° dec., yield, 0.125 g.

Anal. Calcd. for $C_{16}H_9NO_3$: C, 73.0; H, 3.4. Found: C, 72.8; H, 3.6.

The residue left from the melting of the acid was nearly pure decarboxylation product (IX), yellow needles from alcohol, m. p. 138–139° alone or mixed with the previously described substance.

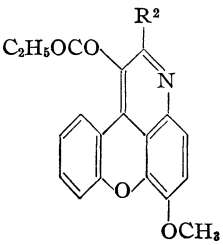
Preceding the work described above, experiments designed to furnish the 6-methoxy derivative of IX and involving compounds XII–XVI, were undertaken. Because of poor yields of intermediates, the objective was not reached. These experiments are outlined in the following paragraphs.



XII, R_1 = H, R_4 = OH

XIII, R_1 = NH_2, R_4 = OCH_3

XIV, R_1 = $NHCOCH_2COOC_2H_5$, R_4 = OCH_3



XV, R_2 = OH

XVI, R_2 = Cl

4-Hydroxyxanthone, XII.—The Ullmann reaction between guaiacol and *o*-chlorobenzoic acid gave *o*-(*o*-methoxy)-phenoxybenzoic acid in yields of 36% when no solvent was used, and 43% when *n*-amyl alcohol was used.[6]

Cyclization by sulfuric acid in acetyl chloride[9] and subsequent demethylation using aluminum chloride[4] in benzene gave nearly quantitative yields.

4-Methoxy-1-xanthonamine, XIII.—4-Hydroxyxanthone (23.4 g.) suspended in cold aqueous soda coupled with diazotized sulfanilic acid to give an azo compound in nearly quantitative yield. This dye was dried and mixed with 100 ml. of methyl sulfate. The mixture was treated with 300 g. of 20% aqueous sodium hydroxide, added with shaking and cooling (70°) during thirty minutes. The resulting material was diluted, treated with more sodium hydroxide and boiled to destroy excess methyl sulfate, and then treated with excess sodium hydrosulfite. The part of the product soluble in hydrochloric acid was crystallized from methanol, giving 14 g. (52%) of yellow prisms, m. p. 169–169.5°. In most preparations the yields were much smaller (5–20%), but the reason was never found.

Anal. Calcd. for $C_{14}H_{11}NO_3$: C, 69.7; H, 4.6. Found: C, 69.9; H, 4.4.

The acetyl derivative, from the amine and acetic anhydride in 90% yield, formed yellow crystals from benzene, m. p. 234–234.5°. No pyridone ring closure[8] could be effected using sodium hydroxide in water, or sodium alkoxide in butyl or ethyl alcohol; from these experiments, the acetyl derivative was recovered largely unchanged.

Anal. Calcd. for $C_{16}H_{13}NO_4$: C, 67.8; H, 4.6. Found: C, 67.8; H, 4.6.

1-(Carbethoxyacetamido)-4-methoxyxanthone, XIV.—From 4 g. of XIII and 100 ml. of malonic ester, there was

Chemical Degradation of Isotopic Succinic Acid[1]

BY MORTON KUSHNER AND SIDNEY WEINHOUSE

In connection with biochemical studies it was necessary to determine the distribution of isotopic carbon in samples of succinic acid isolated from biological sources. It has been found that pyrolysis of the barium salt in a high vacuum at 500° results in a satisfactory conversion of the carboxyl carbon of succinic acid to barium carbonate. The course of this reaction is uncertain. In addition to barium carbonate and some carbon, products such as carbon dioxide, carbon monoxide, methane, ethane, ethylene and hydrogen were identified by mass-spectrometric analysis.

The accompanying table, giving the results of the pyrolysis of carboxyl- and methylene-labeled succinates, shows that the barium carbonate satisfactorily represents the carboxyl carbon. Evidently there is some contamination of the carboxyl carbon by methylene carbon, but this is so small as to introduce only a negligible error. This slight enrichment of C^{13} in the non-labeled carboxyl position was not an artifact, since non-isotopic barium succinate invariably yielded barium carbonate with the normal C^{13} abundance. This enrichment may be due to oxidation of the methylene carbon by traces of oxygen; or possibly, to transfer of oxygen between barium carbonate and the accompanying residual carbon.

TABLE I

C^{13} DISTRIBUTION IN SYNTHETIC LABELED SUCCINIC ACIDS

Atom % C^{13} excess

	Over-all	Carboxyl carbon—Calcd.	Carboxyl carbon—Found
Carboxyl-labeled	2.41	4.82	4.80
Methylene-labeled	3.10	0.00	0.04 ± 0.02
Unlabeled	0.00	.00	.00 ± .01

(1) This work was sponsored by the Sun Oil Company and aided by a grant from the National Cancer Institute, U. S. Public Health Service.

Experimental

Preparation of Isotopic Succinic Acids.—Carboxyl-labeled succinic acid was prepared by refluxing ethylene dibromide with isotopic potassium cyanide, according to the procedure of Vanino.[2] The dinitrile was saponified with alkali without isolation, and after removal of neutral substances by extraction with ether, the succinic acid was isolated by acidification and continuous ether extraction. Yields ranged between 85 and 95%.

The methylene-labeled acid was prepared by a 4-step process giving an over-all yield of about 40%. Barium carbonate was reduced to the carbide according to the procedure of Cramer and Kistiakowsky[3] and the acetylene obtained therefrom reduced to ethylene by a modification of the method of Patterson and du Vigneaud.[4] This was converted to ethylene dibromide by addition of bromine and the former converted to succinic acid by the same procedure used for the carboxyl-labeled acid.

Preparation and Pyrolysis of Barium Salts.—About 20 mg. of the acid is dissolved in 1 ml. of water, 1 ml. of 20% barium chloride is added, and the solution brought to neutrality with dilute ammonia. Two volumes of 95% ethanol are added and the precipitated barium salt centrifuged, washed successively with alcohol and ether, and dried thoroughly in a vacuum.

The barium salt is transferred to a small glass tube, which is then sealed to the vacuum line or attached by means of a standard taper joint. After evacuation to a low pressure the salt is heated to 500° in an electric furnace. After about an hour the tube is cooled, the dark-colored residue is treated with dilute sulfuric acid and the evolved carbon dioxide collected for mass-spectrographic analysis.[5] It is important to avoid even traces of oxygen in this degradation since in its presence some of the methylene carbon will be oxidized to carbon dioxide and contaminate the carboxyl carbon.

Acknowledgment.—The authors express their appreciation to the Sun Oil Company for its support and interest, and to Mr. Arthur Kent for the C^{13} analyses.

Methoxyacetone

BY RAYMOND P. MARIELLA AND JOHN L. LEECH

In continuing our investigations of unsymmetrical ketones, it became necessary to prepare a large quantity of methoxyacetone.

It was found that the wet oxidation of the inexpensive and easily-available 1-methoxy-2-propanol (Dowanol 33B) with chromic acid at room temperature goes conveniently in one step to give methoxyacetone. The present method is adapted from that of Petrov[1] and gives methoxyacetone in much shorter time than other published methods[2–5] although in a somewhat lower yield.

(5) Traetta, Masca and Preti, *ibid.*, **51**, II, 275 (1921).

The dry catalytic dehydrogenation of 1-methoxy-2-propanol was also investigated, but no ketone could be isolated. Various attempts to prepare methoxyacetone from chloroacetone using a non-polar solvent also failed.

Two derivatives of methoxyacetone were easily obtained; the 2,4-dinitrophenylhydrazone and the *p*-nitrophenylhydrazone, but the semicarbazone did not form. Attempts to prepare the semicarbazone gave a very insoluble substance, which was proved to be the disemicarbazone of *pyruwaldehyde*. In addition, the osazone of pyruvaldehyde was prepared from phenylhydrazine and methoxyacetone.

Methoxyacetone gave a positive Benedict test (basic medium),[6] a positive Schiff test (acid medium) and a positive test with Tollens reagent (basic medium). Apparently then, methoxyacetone is not too stable in either acid or basic media in the presence of oxidizing agents. This accounts for the rather low yield (28%) in its preparation from Dowanol 33B.

It is probably the rapidity of the reaction of methoxyacetone with 2,4-dinitrophenylhydrazine and *p*-nitrophenylhydrazine, and the insolubility of the resulting derivatives that make their isolation feasible. It is interesting to note that methoxyacetaldehyde also did not give the expected semicarbazone.[7] The product obtained was probably the disemicarbazone of glyoxal.

The authors wish to express their thanks to the Graduate School for providing some funds, to Misses Guy, Hines and Hobbs, for the microanalyses, and to the Dow Chemical Company for a generous sample of Dowanol 33B.

Experimental

Methoxyacetone from 1-Methoxy-2-propanol.—To a solution of 375 g. of sodium dichromate and 202 g. of 1-methoxy-2-propanol (b. p. 118–120° at 745 mm.) in 200 cc. of water was added dropwise over a period of six hours, a solution of 450 g. of sulfuric acid in 115 g. of water. The reaction mixture was stirred during the addition and the temperature kept between 20–25°. After standing at room temperature all night, the green mixture was extracted four times with 200-cc. portions of ether. The ether extract was dried with anhydrous potassium carbonate, the ether removed, and the product fractionated; b. p. 112–116° at 750 mm.; yield 55.5 g. There was also isolated 10 g. of unreacted alcohol. The ketone was carefully refractionated, and the liquid, b. p. 114.5–115.0° at 756 mm., collected; $n^{20}D$ 1.3982, d^{20}_4 0.9494.

The *p*-nitrophenylhydrazone[5] was isolated as yellow-orange plates from alcohol, m. p. 110–111°.

Anal. Calcd. for $C_{10}H_{13}N_3O_3$: N, 18.9. Found: N, 19.2.

The 2,4-dinitrophenylhydrazone was easily formed as yellow-orange needles from alcohol, m. p. 162.5–163°.

Anal. Calcd. for $C_{10}H_{13}N_4O_5$: N, 20.9. Found: N, 20.6.

When 1.0 g. of methoxyacetone, 1.2 g. of semicarbazide hydrochloride and 0.9 g. of sodium acetate were refluxed in 10 cc. of water for three hours, on cooling, 0.6 g. of a white solid was formed. It was insoluble in all common solvents. A sample was recrystallized with great difficulty from a very large volume of water, m. p. 250–254° (dec.). Wohl and Lange[8] noted the insolubility of the disemicarbazone of pyruvaldehyde, and reported a m. p. of 254°, which was not sharp.

Anal. Calcd. for $C_5H_{11}N_3O_2$ (monosemicarbazone of methoxyacetone): N, 29.2. Calcd. for $C_5H_{10}N_6O_2$ (disemicarbazone of pyruvaldehyde): N, 45.1. Found: N, 45.3.

When 1.0 g. of methoxyacetone, 5.0 g. of phenylhydrazine hydrochloride and 7.0 g. of sodium acetate in 40 cc. of water were refluxed for three hours, on cooling, a very viscous dark liquid was formed. This material was easily separated from the water layer by decantation. Crystallization of this liquid from alcohol–water slowly deposited 0.6 g. of an orange solid. Several recrystallizations produced an orange-brown solid, m. p. 147°.[9]

Anal. Calcd. for $C_{10}H_{14}N_2O$ (phenylhydrazone of methoxyacetone): N, 15.7. Calcd. for $C_{15}H_{16}N_4$ (osazone of pyruvaldehyde): N, 22.2. Found: N, 21.7.

Methoxyacetone turned Benedict solution green in ten minutes and a small red precipitate was visible in one-half hour. When a few drops of methoxyacetone were added to 2 cc. of Schiff reagent, a deep purple color was produced immediately. With Tollens reagent, methoxyacetone developed a faint turbidity at room temperature in fifteen minutes, and gave a visible silver mirror in five minutes when heated on a steam-bath.

Attempted Catalytic Dehydrogenation of 1-Methoxy-2-propanol.—1-Methoxy-2-propanol (110 cc.) was passed over brass turnings at a rate of 1.2 cc. per minute. The gas evolution was almost negligible at 400°, increased slightly at 450°, and at 500° the evolution was rapid at first, but then decreased after the first fifteen minutes. At 500°, for instance, 3100 cc. of gas was collected. The product was fractionated and was for the most part unreacted starting material. No 2,4-dinitrophenylhydrazone of methoxyacetone could be isolated from any of the material.

Reactions with Chloroacetone.—Freshly distilled chloroacetone was added to sodium methoxide in benzene and, in another experiment, sodium methoxide was added to chloroacetone in benzene. In both cases, a brown sticky mass was obtained and no methoxyacetone could be isolated.

(6) This result is similar to that obtained with α,α'-diethoxyacetone, which also gave a positive Fehling test; Grimaux and LeFèvre, *Bull. soc. chim.*, [3] **1**, 12 (1889).

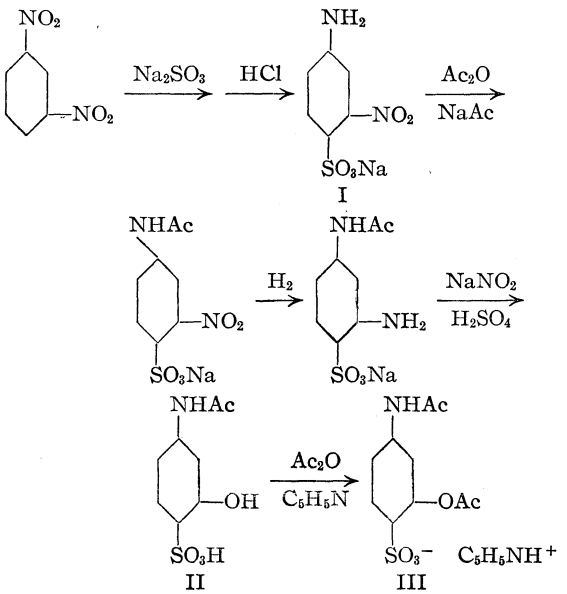
cedure have reported this latter structure for the product. To the best of our knowledge no structure proof for the product from the sulfonation of *m*-aminophenol has been reported.

In connection with some of our work in the field of synthetic drugs we have determined the structure of this amino-hydroxybenzenesulfonic acid by synthesis through another route as indicated in the series of reactions given. The structure of the intermediate 4-amino-2-nitrobenzenesulfonic acid (I) has been previously established beyond reasonable doubt.[8] Since neither 4-



amino-2-hydroxybenzenesulfonic acid nor the acetyl derivative (II) have definite melting points, comparison was made of the pyridinium-4-acetylamino-2-acetoxybenzenesulfonate (III) derivatives. The products made by the above method and that obtained from the sulfonation of *m*-aminophenol followed by the action of acetic anhydride and pyridine were shown to be identical by a mixed melting point study. This clearly indicates that the structure reported in the Oehler patent is in error and that the stable sulfonation product of *m*-aminophenol is 4-amino-2-hydroxybenzenesulfonic acid as assumed in the other reports.[5,6,7]

Experimental

The Sulfonation of *m*-Aminophenol.—The Oehler procedure[4] consists in heating a solution of one part of *m*-aminophenol in three parts of concentrated sulfuric acid on the water-bath for one hour. The product is obtained by dilution with water. It was converted into the pyridinium acetylaminoacetoxybenzenesulfonate (III) by the method of Thorpe and Williams.[7] After recrystallization from absolute ethanol and ether, it melted at 164–166°.

4-Amino-2-nitrobenzenesulfonic Acid.—A slurry of 86 g. of *m*-dinitrobenzene in 800 ml. of a saturated sodium sulfite solution was prepared and heated until solution was complete. To the hot solution, 250 ml. of concentrated hydrochloric acid was added and the resulting mixture heated at boiling for thirty minutes. The precipitate that formed on cooling was purified by solution and reprecipitation; yellow powder, 50 g.[8,9]

Sodium 4-Acetylamino-2-nitrobenzenesulfonate.—To a slurry of 10.5 g. of 4-amino-2-nitrobenzenesulfonic acid in 30 ml. of glacial acetic acid, sufficient sodium acetate was added to effect solution. After the addition of 30 ml. of acetic anhydride, the acetylation mixture was heated at reflux overnight. One-half of the acetic acid was evaporated and sufficient ether added to cause precipitation. The product was recrystallized from absolute ethanol; 14 g.

Sodium 4-Acetylamino-2-aminobenzenesulfonate.—A solution of 14 g. of sodium 4-acetylamino-2-nitrobenzenesulfonate in 300 ml. of absolute ethanol was shaken with hydrogen in the presence of Adams catalyst at three atmospheres pressure. The reduction was not complete. The precipitate which formed was filtered and purified, 2.5 g. It gave a positive test for an aromatic amine.

4-Acetylamino-2-hydroxybenzenesulfonic Acid.—A solution of 3.5 g. of sodium 4-acetylamino-2-aminobenzenesulfonate in 50 ml. of 3% sulfuric acid was prepared and cooled to 3°. Upon completion of the slow addition of a sodium nitrite solution (1.2 g. of sodium nitrite in 15 ml. of water), 100 ml. of a 1% copper sulfate solution was added and the resulting solution refluxed for one hour. After cooling for several days at 0°, approximately 1 g. of a light brown solid was isolated which gave a negative test for a free amine group and which had no definite melting point.

Pyridinium-4-acetylamino-2-acetoxybenzenesulfonate.—To a pyridine solution of the 1 g. of crude 4-acetylamino-2-hydroxybenzenesulfonic acid was added 1 ml. of acetic anhydride and the resulting precipitate was recrystallized from absolute ethanol and ether, m. p. 164–166°. A mixed melting point with the previously prepared pyridinium salt gave no depression.

We gratefully acknowledge the financial assistance of Parke, Davis and Company in this work.

The Willgerodt Reaction with Acetylphenylacetylene and Benzalacetone

BY DOROTHY NIGHTINGALE AND RICHARD A. CARPENTER[1,2]

The Willgerodt reaction with acetylphenylacetylene and benzalacetone appeared to offer a method for the synthesis of γ-phenylethynylacetic acid and γ-phenylvinylacetic acid. Initial experiments with acetylphenylacetylene and ammonium polysulfide at 190°[3] yielded a product, m. p. 54–56°, containing nitrogen and sulfur which decomposed on standing and was too unstable for consistent analyses. When the reaction was repeated by the procedure of Schwenk and Bloch[4] using morpholine and sulfur, the γ-phenylethynylthioacetomorpholide (I) was obtained in 51% yield. Ozonolysis of (I) followed by oxidative cleavage yielded benzoic acid. All efforts to hydrolyze the thioacetomorpholide to γ-phenylethynylacetic acid were fruitless. Propionylphenylacetylene, morpholine and sulfur yielded an intractable tar.

(1) From the Master's thesis of Richard A. Carpenter.

(2) Present address: Wood River Refinery, Shell Oil Company, Wood River, Illinois.

(3) Wadsworth, Ph.D. Dissertation, University of Missouri (1948).

(4) Schwenk and Bloch, THIS JOURNAL, **64**, 3051 (1942).

Benzalacetone reacted with morpholine and sulfur under the same conditions to form γ-phenylvinylthioacetomorpholide (II) in 35% yield. Ozonolysis of (II) followed by reductive cleavage yielded benzaldehyde which was identified by its dimethone derivative. Hydrolysis of (II) with alcoholic potassium hydroxide yielded only unchanged starting material, but long refluxing with hydrochloric acid and acetic acid yielded a product (III) melting at 112–114°, soluble in base and containing neither nitrogen halogen nor sulfur. Analyses of (III) approximated an empirical formula of $C_7H_7O_2$, but a neutral equivalent of 189–195 and a mixed melting point indicated that the product was not benzoic acid.

Experimental[5]

γ-Phenylethynylthioacetomorpholide.—Acetylphenylacetylene (29 g., 0.2 mole), 26 g. (0.3 mole) of morpholine and 9.6 g. of sulfur were heated gently for one hour and then refluxed vigorously for three hours more. The reaction mixture was cooled, taken up in 200 cc. of benzene, washed with dilute hydrochloric acid and finally with water. The benzene solution was dried, the benzene removed and the residue recrystallized first from aqueous alcohol and finally from Skellysolve A. The thioacetomorpholide (I) crystallized in pale yellow amorphous knobs, m. p. 79–80°; yield 25 g. (51%).

Anal. Calcd. for $C_{14}H_{15}ONS$: C, 68.53, H, 6.16. Found: C, 68.34; H, 6.52.

Ozonolysis of 0.1 g. of (I) in carbon tetrachloride at 0° followed by oxidative cleavage yielded benzoic acid, melting point and mixed melting point, 121°.

When 2 g. of (I) was refluxed for ten hours with 20% alcoholic potassium hydroxide or with a solution of 2 cc. of concentrated hydrochloric acid in 15 cc. of glacial acetic acid, only starting material was recovered.

γ-Phenylvinylthioacetomorpholide (II).—Benzalacetone (30 g., 0.2 mole), 26 g. (0.3 mole) of morpholine and 9.6 g. (0.3 mole) of sulfur were heated gently for one hour and then refluxed vigorously for four hours. The product was worked up as described above except that the tarry residue was recrystallized from aqueous alcohol and finally treated with boneblack to remove the color. The thioacetomorpholide (II) crystallized in white plates, m. p. 133–134°; yield, 17 g. (35%).

Anal. Calcd. for $C_{14}H_{17}ONS$: C, 67.98; H, 6.93; N, 5.67. Found: C, 67.93; H, 6.57; N, 5.85.

The thioacetomorpholide (II) (80 mg.) dissolved in ethyl bromide was ozonized at 0°. The solvent was removed and the solid ozonide was decomposed reductively in the usual manner. The benzaldehyde was isolated as the dimethone derivative, melting point and mixed melting point 194–195°.

Hydrolysis of (II).—The thioacetomorpholide (II) (2 g.), 2 cc. of hydrochloric acid and 15 cc. of acetic acid were refluxed vigorously for ten hours. The reaction mixture was poured into water and after standing overnight the solution and suspended solid were extracted with ether. The ether extract was dried, the ether removed and the gummy residue was sublimed. A white solid (III) was obtained which melted at 112–114°[6] and contained no nitrogen or sulfur. The product was soluble in base but the melting point of the recovered acid was unchanged. A mixture of benzoic acid and (III) melted at 100–105°.

Anal. Calcd. for γ-phenylvinylacetic acid, $C_{10}H_{10}O_2$: C, 74.04; H, 6.21; neut. equiv., 162. Found: C, 67.10; H, 5.95; neut. equiv., 189, 195.

(5) The semimicro carbon–hydrogen analyses were done by R. A. Carpenter.

(6) The recorded melting point of γ-phenylvinylacetic acid is 86°. Fittig and Jayne, *Ann.*, **216**, 98 (1883).

When (II) was refluxed with 20% alcoholic potassium hydroxide for ten hours, only unchanged starting material was isolated.

N-(*p*-Chlorophenyl)-diamidophosphoric Acid

BY KURT RORIG

A compound considered to be N-(*p*-chlorophenyl)-amidophosphoric acid, *p*-$ClC_6H_4NHPO(OH)_2$, on the basis of an elemental analysis for carbon and hydrogen was first prepared by Otto[1] in 1895. Recently it has been prepared by Otto's method for use as an enzymatic substrate in histochemical experiments.[2]

This compound was also prepared according to Otto in our laboratory and was found to have the melting point reported by him. A complete elemental analysis, however, showed it to be N-(*p*-chlorophenyl)-diamidophosphoric acid, *p*-$ClC_6H_4NHPO(OH)(NH_2)$, rather than the monoamidophosphoric acid postulated by Otto. In accordance with the diamidophosphoric acid structure, the titration curve of our compound showed only the one break characteristic of a monobasic acid. A mixed melting point determination has shown that Gomori's compound[2] is the same as ours. However, our N-(*p*-chlorophenyl)-diamidophosphoric acid, melting at 156–157°, is insoluble both in hot water and in hot ethanol; whereas Otto reported that his compound, melting at 155°, was soluble in these solvents. Since Otto has also reported the existence of a di-silver salt of his compound, it is prudent to say only that by following his somewhat incomplete instructions as closely as possible, N-(*p*-chlorophenyl)-diamidophosphoric acid was obtained by Gomori and ourselves.

Furthermore, the formation of the diamidophosphoric acid is in harmony with the experience of Caven,[3] who found that anilidophosphoryl-dichloride, when dissolved in aqueous ammonia, formed N-phenyl-diamidophosphoric acid rather than the monoamidophosphoric acid as surmised by Michaelis and Schulze.[4]

Experimental

A mixture of 163.5 g. (1 mole) of *p*-chloroaniline hydrochloride and 307 g. (2 moles) of phosphorus oxychloride was refluxed for two and one-half hours. The cooled, solidified reaction mixture was filtered and washed with petroleum ether (b. p. 60–71°) to give 202 g. of crude *p*-chloroanilidophosphoryl-dichloride, *p*-$ClC_6H_4NHPOCl_2$, melting at 97–104°. A small sample melted at 105–107° when recrystallized from benzene.

Thirty grams of crude *p*-chloroanilidophosphoryl dichloride was added slowly to 60 ml. of aqueous ammonium hydroxide (28%) while keeping the temperature below 10°. The turbid solution was immediately filtered and acidified with a slight excess of hydrochloric acid to precipitate the

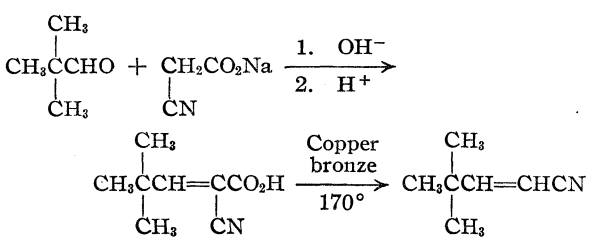
The Preparation of Some β-Alkylated Acrylonitriles

BY ROBERT M. ROSS[1] AND MARY LOUISE BURNETT

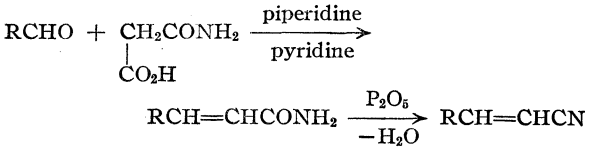
Certain nitriles, namely, β-*t*-butylacrylonitrile, β-isopropylacrylonitrile and β-ethylacrylonitrile were needed for studies which were in progress in this Laboratory. No method for the synthesis of β-*t*-butylacrylonitrile could be found in the literature and, although preparative methods exist for β-isopropylacrylonitrile and β-ethylacrylonitrile,[2] they appeared unnecessarily arduous. Accordingly, new routes for the syntheses of the desired nitriles have been investigated.

β-*t*-Butylacrylonitrile has been prepared by the condensation of pivalaldehyde with sodium cyanoacetate[3] in an aqueous, alkaline medium and subsequent decarboxylation of the cyano acid thus obtained.



The over-all yield for the method is about 45%.

Galat[4] reported a novel synthesis of α,β-unsaturated amides which involved the condensation of aromatic aldehydes with malonmonoamide. We have extended the use of malonmonoamide to include condensations with some aliphatic aldehydes. β-Isopropylacrylamide and β-ethylacrylamide were prepared in this manner. The amides were then dehydrated by the usual method using phosphorus pentoxide.



This synthesis affords over-all yields of about 56 and 20% for the β-isopropyl- and β-ethylacrylonitriles, respectively. A previously reported[2] method for the preparation of these nitriles consisted of a relatively tedious four-step synthesis and furnished β-isopropylacrylonitrile in about 18% yield; no over-all yield was reported for β-ethylacrylonitrile. Thus, the use of malonmonoamide eliminates two reaction steps and affords significantly greater yields at least in the preparation of β-isopropylacrylonitrile.

Experimental

Pivalaldehyde.—Trimethylpyruvic acid[5] was decarboxylated in the presence of diphenylamine to yield pivalaldehyde according to the directions of Trister and Hibbert.[6]

Malonmonoamide.—Galat's[4] procedure for the synthesis was employed.

α-Cyano-β-*t*-butylacrylic Acid.—A mixture of 126 ml. of 2.65 *M* sodium cyanoacetate solution,[7] 1.63 g. of sodium hydroxide pellets and 85 ml. of water were placed in a 500-ml., three-necked, round-bottomed flask equipped with a rubber-sealed Hershberg stirrer, condenser and thermometer. To the contents of the flask was added 19.0 g. (0.24 mole) of pivalaldehyde and vigorous stirring was commenced. The contents of the flask were heated to 50° for fifteen minutes by a warm water-bath. At the end of this time, the bath was removed and stirring was continued for two hours. Then an additional 40 ml. of 2.65 *M* sodium cyanoacetate solution and 0.51 g. of sodium hydroxide pellets were added to the reaction mixture. The contents of the flask were reheated to 50° for fifteen minutes and stirring was continued for three hours longer. At the end of this time, the solution was made neutral to litmus by the careful addition of concentrated hydrochloric acid. A 20-ml. excess of hydrochloric acid was added to the neutral solution. The brown oil which formed was induced to crystallize by scratching the flask sides with a glass rod. After thorough chilling at 0°, the tan-colored crystals of α-cyano-β-*t*-butylacrylic acid were removed by filtration, suction dried on the filter funnel, and washed with 30 ml. of cold benzene. A total of 26 g. (71%) of crude α-cyano-β-*t*-butylacrylic acid was isolated, m. p.[8] 115–119° (dec.). Recrystallization was effected from about 150 ml. of dilute ethanol (10%) with Norit. Long, white needles were obtained, m. p. 123.5–125° (slight dec.).

Anal.[9] Calcd. for $C_8H_{11}O_2N$: C, 62.72; H, 7.24; N, 9.15; neut. equiv., 153. Found: C, 62.70; H, 7.30; N, 8.99; neut. equiv., 157.

β-*t*-Butylacrylonitrile.—In a 50-ml., round-bottomed flask, equipped with mechanical stirrer and condenser, were placed 6.5 g. (0.042 mole) of α-cyano-β-*t*-butylacrylic acid and 1.5 g. of fine copper-bronze powder. The contents of the flask were heated by an electrically controlled oil-bath. The temperature of the oil-bath was raised rapidly to 170°. When the cyano acid melted (about 125°), stirring was started and the evolution of carbon dioxide was noted by leading an exit tube from the condenser top into a test-tube of water. The evolution of carbon dioxide became rapid when the bath temperature was 140°, and at 160°

(8) All melting points reported herein are uncorrected.

(9) The analyses reported were done by the Clark Microanalytical Laboratories, Urbana, Illinois.

it was vigorous. After twenty-five minutes of heating at 170°, carbon dioxide was no longer evolved. Heating was stopped and the melt was allowed to cool. The copper–bronze powder was removed by filtration with the aid of a small amount of ether. The powder was washed thoroughly with 25 ml. of ether which was combined with the filtrate. Ether was removed by distillation, and the residue was distilled under reduced pressure. A colorless and pungent smelling liquid, boiling between 59 and 60° (28 mm.) was obtained; $n^{20}D$ 1.4344. The yield was 3.2 g. (70%).

Anal.[9] Calcd. for $C_7H_{11}N$: C, 77.01; H, 10.16. Found: C, 77.16; H, 10.16.

β-Isopropylacrylamide.—In a 100-ml., round-bottomed flask were placed 10.8 g. (0.15 mole) of freshly distilled isobutyraldehyde, 30.9 g. (0.30 mole) of malonmonoamide, 25 ml. of dry pyridine and eight drops of dry piperidine. The mixture was heated under reflux (oil-bath temperature was 82°) for twenty-four hours. At the outset of the heating, there was a vigorous evolution of carbon dioxide, which gradually subsided over the twenty-four-hour period. At the end of this time, the mixture was concentrated to dryness under reduced pressure. The residue was diluted with 10 ml. of water and extracted with 250 ml. of ether in five 50-ml. portions. The ether extract was dried over anhydrous magnesium sulfate. Ether was removed by distillation whereupon the residue solidified. The crude, nearly white β-isopropylacrylamide was dried under a reduced pressure of less than 1 mm. overnight. The yield was 11.9 g. (70%), m. p. 79–84°. Recrystallization from 15 ml. of hot benzene gave 9.0 g. of white crystals which melted between 83 and 86° (lit.[2] 82–86°).

β-Isopropylacrylonitrile.—A mixture of 4.4 g. (0.039 mole) of β-isopropylacrylamide and 6.5 g. of phosphorus pentoxide was placed in a 100-ml., round-bottomed flask. The contents were mixed thoroughly. The flask was equipped with a small take-off head for downward distillation and the contents were heated gradually by an oil-bath. The temperature of the bath was brought to and maintained at 200°. At the end of thirty minutes the system was placed under a reduced pressure of about 50 mm. The distillate was collected in a tube immersed in a Dry Ice–acetone-bath. Heating was continued for about two hours and during this time the pressure was lowered gradually to 15 mm. The black residue frothed considerably during this period. At the end of this time, no further distillation took place and heating was stopped. A total of 3.0 g. of colorless β-isopropylacrylonitrile was obtained; $n^{20}D$ 1.4316. Redistillation yielded a product which possessed the following physical constants: $n^{20}D$ 1.4329, b. p. 68° (34 mm.). Reported[10] values for the *trans* compound are: $n^{20}D$ 1.4342, b. p. 48.5° (13.5 mm.).

β-Ethylacrylamide.—Essentially the same conditions were employed for the preparation of β-ethylacrylamide as those described for β-isopropylacrylamide. Crude β-isopropylacrylamide was isolated in the amount of 7.2 g. from 8.7 g. of freshly distilled propionaldehyde and 30.9 g. of malonmonoamide. Subsequent recrystallization from acetone afforded 3.4 g. of glistening, white needles, m. p. 148–148.5° (lit.[2] 148°).

β-Ethylacrylonitrile.—β-Ethylacrylamide was dehydrated with phosphorus pentoxide under essentially the conditions described for the preparation of β-isopropylacrylonitrile. A mixture of 6.28 g. (0.06 mole) of β-ethylacrylamide and 9.2 g. of phosphorus pentoxide yielded 2.3 g. (45%) of colorless β-ethylacrylonitrile, b. p. 72° (72 mm.), $n^{20}D$ 1.4301 (lit.,[11] b. p. 73° (72 mm.), $n^{20}D$ 1.4298 (for the *trans* compound)).

Equilibria of the Boric Acid–Mannitol Complexes

BY SIDNEY D. ROSS AND ARTHUR J. CATOTTI

The recent publication by Deutsch and Osoling[1] on the stoichiometry and equilibria of boric acid–mannitol complexes prompts us to report some related results obtained in these laboratories. We have focused our attention on determining the equilibrium constant for the reaction

$$HB + 2M \rightleftarrows BM_2^- + H^+$$

In determining this constant, we have consciously selected concentrations of both boric acid and mannitol which would permit us to make the simplifying assumption that the concentrations of both B^- and BM^- are negligible in comparison with the concentrations of both H^+ and BM_2^-. For the equilibrium constant, we may write

$$K = \frac{[H^+][BM_2^-]}{[HB][M]^2} \cong \frac{[H^+]^2}{[HB_0 - H^+][M_0 - 2H^+]^2}$$

and K can be calculated from a single pH measurement. The justification for this assumption will be discussed later.

The reagents were C.P. boric acid and mannitol and freshly boiled distilled water. All solutions were thermostatted at 25°, and the ionic strength was kept at 0.10–0.12 M by addition of C.P. potassium chloride. The pH's were measured with a Beckman pH meter. The results are summarized in Table I.

TABLE I

CALCULATED VALUES OF K

[HB]	[M]	[M]/[HB]	[KCl]	pH	$K \times 10^4$
0.0141	0.0534	3.78	0.117	4.20	1.01
.0166	.0985	5.94	.104	3.88	1.09
.0141	.0865	6.16	.117	3.99	0.955
.00532	.0370	6.95	.104	4.56	1.05
.00350	.0257	7.30	.114	4.81	1.05
.00350	.0292	8.30	.114	4.79	0.892
.00851	.0737	8.70	.104	4.17	1.00
.00350	.0374	10.7	.114	4.66	0.990

The average of these values is 1.00×10^{-4} and the maximum deviation from this average value is less than 11%. This agreement is as good as can be expected, since the uncertainty in the pH measurement is 0.02 unit, and a change of 0.02 in pH will change K by as much as 11%.

To check our accuracy, we determined the dissociation constant of boric acid in 0.104 M potassium chloride at 25.0°. The determined values ranged from 6.77×10^{-10} to 8.24×10^{-10}, with the average value being 7.40×10^{-10}. Again, all of the deviations from the average value can be accounted for by an uncertainty of 0.02 unit in the pH measurement. The accepted value for the dissociation constant in pure water is 6.4×10^{-10}, and a higher value is to be expected in our medium of higher ionic strength.[2]

(1) Deutsch and Osoling, THIS JOURNAL, **71**, 1637 (1949).

(2) Hammett, "Physical Organic Chemistry," McGraw-Hill Book Company, Inc., New York, N. Y., 1940, p. 89.

Böeseken, Vermaas and Küchlin[3] have also determined the equilibrium constant for this complex formation from data on the potentiometric titration of boric acid in the presence of mannitol. They do not specify the temperature at which the measurements were made but report a value of 1.7×10^{-4} for K. Neither this result nor the result obtained by us are in agreement with that reported by Deutsch and Osoling.[1] The latter workers have defined K differently, but their K can be made equivalent to ours by multiplying it by the dissociation constant for boric acid. This gives for K, 0.33×10^{-4}, a value only one-third that obtained by us. Part but certainly not all of this difference can be attributed to the fact that our measurements were made in solutions of much higher ionic strength.

In making our calculations we have assumed that both B^- and BM^- are negligible compared to H^+ and BM_2. We have chosen concentrations of both boric acid and mannitol such that the hydrogen ion concentration is in every case at least ten times what it would be in the absence of the mannitol. Moreover, by using our determined value for the dissociation constant of boric acid and the Deutsch and Osoling value for the equilibrium constant, K_1, of the reaction

$$B^- + M \rightleftarrows BM^-$$

we can calculate the concentrations of B^- and BM^- and correct our equilibrium constant accordingly. We have not reported these revised values, since we strongly question the validity of the value of K_1 as determined by Deutsch and Osoling, and since these corrections would change our values by no more than 10% which is within our known experimental uncertainty.

Boron Trifluoride Catalyzed Esterification of *p*-Aminosalicylic Acid

BY JOSEPH J. SCHAEFER AND LEONARD DOUB

The effectiveness of *p*-aminosalicylic acid (4-amino-2-hydroxybenzoic acid) in experimental tuberculosis chemotherapy[1,2] led us to prepare a number of its esters. These compounds have been prepared by reduction of the corresponding nitro esters,[3] but since *p*-aminosalicylic acid has become commercially available, it was desirable to investigate direct esterification. Conventional methods of esterification under various conditions led to very low yields,[4] the primary product being *m*-aminophenol.

Boron trifluoride as an esterification catalyst, following the work of Sowa and Nieuwland,[5] was tried and found to give excellent results. Approximately 70% yields were obtained with several alcohols. In general we used 4.5 moles of boron trifluoride for each mole of *p*-aminosalicyclic acid. In accord with the procedures of Sowa and Nieuwland, this provides one-half mole excess of boron trifluoride over that necessary for complex formation with the functional groups.

Experimental

Preparation of the Esters of 4-Amino-2-hydroxybenzoic Acid.—To a suspension of 153 g. (1.0 mole) of 4-amino-2-hydroxybenzoic acid in 1000 ml. of the anhydrous alcohol, 565 ml. (4.5 moles) of boron trifluoride–ethyl ether complex was added slowly, keeping below 40°. The resulting clear solution, after standing at room temperature for several days, was evaporated under reduced pressure to a thick slurry, and 500 ml. of water was introduced. Solution was effected by adding 10 *N* sodium hydroxide with cooling until alkaline to phenolphthalein. After charcoaling and filtering, solid carbon dioxide was added with agitation to precipitate the ester. This precipitate was removed by filtration and dissolved in dilute hydrochloric acid, charcoaled and filtered. The filtrate was neutralized with potassium bicarbonate. The ester precipitated, was filtered off and crystallized from ethyl alcohol.

ESTERS OF 4-AMINO-2-HYDROXYBENZOIC ACID

Ester	Reaction time, days	Yield, %	M. p., °C.	Empirical formula	Nitrogen, % Calcd.	Found
Methyl	10	74	121–122[4]	$C_8H_9NO_3$	7.73	7.88
Ethyl	10	71	114–115[3]	$C_9H_{11}NO_3$	8.38	8.27
Isopropyl	30	75	73–75[3]	$C_{10}H_{13}NO_3$	7.18	7.43 7.40

(4) Rosdahl, *Svensk Kem. Tid.*, **60**, 12 (1948), reports the preparation of the methyl ester with sulfuric acid in methyl alcohol. In our hands this procedure gave less than 10% yield.

The Melting Point of Potassium Hydroxide

BY RALPH P. SEWARD AND KENNETH E. MARTIN

The melting point of potassium hydroxide has been reported as 360° by Hevesy[1] and 380° by Scarpa.[2] A determination of the melting point of potassium hydroxide was suggested by the observation that a sample which had been heated several hours to remove water was found to remain solid above 400°. The observations which are recorded below indicate the melting point to be 410 ± 1°.

The "reagent" quality potassium hydroxide employed, from titration with standard acid, was found to be 86.5% potassium hydroxide and 1.0% potassium carbonate, which agreed with the maker's analysis. On heating to constant weight at a

(1) Hevesy, *Z. physik. Chem.*, **73**, 667 (1910).

(2) Scarpa, *Atti Acad. Lincei*, [5] **24**, 745 (1915); *C. A.*, **9**, 2828 (1915).

dull red heat, a weight loss of 12.5% was found. It was assumed that the only impurity present in significant amount after dehydration was the 1% of carbonate. To estimate the effect of the carbonate, freezing points were determined with known amounts of additional potassium carbonate.

About 50 g. of the hydroxide was melted in a nickel container brought gradually to 475–500°, and kept at this temperature ten to twelve hours to remove water. Further heating did not change the freezing point. The freezing points were obtained from cooling curves. Temperatures were measured with a chromel–alumel thermocouple which was calibrated at the freezing points of tin, lead and zinc, using Bureau of Standards samples. The same freezing point was found with and without a monel metal protecting tube around the couple. When a stream of dry nitrogen was passed over the hydroxide during dehydration and cooling, the freezing point did not differ from the freezing point of the hydroxide in contact with air. The observations are summarized in the accompanying table. The carbonate concentrations are not known with great precision because of the tendency of the molten hydroxide to creep up the walls of the container.

FREEZING POINTS OF KOH–K_2CO_3 MIXTURES

K_2CO_3, wt. %	1.0	4.9	7.0	12.2	16.2
F. p., °C.	408.0	400.0	394.5	384.2	373.5
Eutectic, °C.	358.7	365.0	365.0	366.9	366.5

By extrapolation, the freezing point of potassium hydroxide with no carbonate present was estimated to be 410°. A transition which Hevesy found at 248° and Scarpa at 360° was found at 249°. The heat of fusion calculated from the effect of carbonate on the freezing point was 1830 cal. per mole. Kelley[3] has calculated a value of 1980 cal. per mole from the data of Scarpa on the potassium hydroxide–potassium iodide system.

STATE COLLEGE, PENNSYLVANIA RECEIVED JUNE 3, 1949

Comparison of Some Properties of Thiolsulfonates and Thiolsulfinates

BY LAVERNE D. SMALL,[1] JOHN HAYS BAILEY AND C. J. CAVALLITO

The thiolsulfinates, R–SO–SR, have been shown to be active antibacterial and antifungal agents.[2] Although these oxides were previously unknown, the dioxides frequently have been described. These are now generally believed to have the thiolsulfonate structure, $R–SO_2–SR$. No record could be found of antibacterial tests with these compounds and it was of interest to compare the effect of the thiolsulfonate with that of the thiolsulfinate group in this respect.

The compounds used in this comparison were those where R was ethyl in the preceding structures. The thiolsulfonate was only 1.2% soluble in water compared with approximately 11% for the thiolsulfinate. This reduced interest in the higher alkyl thiolsulfonates. Both compounds react quickly with dilute alkalies.

Tests conducted by methods previously described[2] showed that the two thiol esters are of comparable antimicrobial activity, the thiolsulfonate being more effective against *S. aureus* and *K. pneumoniae*.

The antibiotic activity of thiolsulfinates has been attributed to the ability of the compounds to react with biologically essential –SH groups as exemplified by the reaction with cysteine to yield derivatives of type I, $R–S–S–CH_2–CH(NH_2)–COOH$.[3] With the thiolsulfinates one mole of compound yielded, nearly quantitatively, two moles of I. Under similar conditions the thiolsulfonate gave only one equivalent of I and an acid, presumably ethanesulfinic acid. This in harmony with the observations of Smiles and coworkers[4] who found that thiolsulfonates reacted with mercaptans to yield one mole of disulfide and one of the sulfinic acid. The ability of thiolsulfinates to react rapidly with cysteine (thiols) to yield two moles of I is further support of Smiles' evidence that "disulfoxides" have a thiolsulfonate structure. A disulfoxide presumably would yield two moles of sulfenic acid as an intermediate (plus one cystine) and reaction with more cysteine would give two moles of I. As it is, only one mole of I and one of the sulfinic acid are formed under the conditions.

$$R–SO_2–SR + HS–CH_2–CH(NH_2)–COOH \longrightarrow I + RSO_2H$$

$$R–SO–SR + HS–CH_2–CH(NH_2)–COOH \longrightarrow I + RSOH$$

$$RSOH + HS–CH_2–CH(NH_2)–COOH \longrightarrow I + H_2O$$

The observation of Toennies and Lavine[5] that cystine "disulfoxide" reacts with cysteine to yield a mole of cystine and one of cysteine sulfinic acid favors the thiolsulfonate structure for this compound. Tests in our Laboratories show that cystine dioxide also is inhibitory to bacterial growth. Such compounds may have an *in vivo* biological growth-control function if oxidation of

–S–S– groups to the mono- or dioxide stage is demonstrated to occur in an organism.

Experimental

Ethyl Ethanethiolsulfonate. Method A.—One liter of ethyl acetate and 24.5 g. (0.2 mole) of ethyl disulfide were placed in a three-liter, three-neck flask. The solution was cooled with an ice-bath and while stirring there was added, during fifteen minutes, a solution of 5 moles of 40% peracetic acid in 500 cc. of ethyl acetate. After stirring and cooling for an additional hour the solution was allowed to stand at room temperature overnight. The reaction mixture was stirred with a solution of 30 g. of ferrous sulfate heptahydrate in 150 cc. of water to decompose excess per-acid. The ethyl acetate layer was separated and shaken with sufficient saturated aqueous sodium bicarbonate solution to remove acids. The ethyl acetate extract was dried over anhydrous sodium sulfate and then evaporated under reduced pressure to remove solvent. The liquid residue was distilled, yielding the thiolsulfonate, b. p. 56° at 0.2 mm.; $n^{25}D$ 1.4972; yield 3.7 g. or 12%.

Anal. Calcd. for $C_4H_{10}O_2S_2$: C, 31.15; H, 6.54. Found: C, 31.42; H, 6.41.

Method B.—Ethyl ethanethiolsulfonate was first prepared by Otto by reaction of an ethyl halide with sodium ethanethiolsulfonate, but few details were given and the compound was poorly characterized.[6,7]

An alcoholic solution of potassium sulfide was prepared by dissolving 0.5 mole of potassium hydroxide in 250 cc. of absolute ethanol, saturating the solution with hydrogen sulfide and adding a second 0.5 mole of alkali to the solution.

Ethanesulfonyl chloride ($n^{25}D$ 1.4515) was prepared by the method of Lee and Dougherty.[8] To the potassium sulfide solution was added dropwise, during four hours of stirring under anhydrous conditions, a solution of 0.5 mole of ethanesulfonyl chloride in 250 cc. of ethanol. The mixture was cooled with an ice-bath during this period. The mixture was then made alkaline to litmus with alcoholic potassium hydroxide and allowed to stand for fifteen hours at 25° and then heated to 50° for ten minutes. The solution was filtered and the filtrate refluxed for four hours with 0.75 mole of ethyl bromide. After cooling, the solution was filtered, the filtrate concentrated under reduced pressure and the residual thiolsulfonate distilled: yield 23.2 g. or 30%.

Anal. Found: C, 31.07; H, 6.23; $n^{25}D$ 1.4977.

Reaction with Cysteine.—Unbuffered aqueous solutions of cysteine hydrochloride and the thiolester adjusted to *p*H 6.5 with sodium hydroxide solution were mixed[3] and within a few seconds there appeared a white crystalline precipitate of I where R is ethyl, m. p. 196° dec. The thiosulfinate yielded nearly two moles of I (compare where R is allyl[3]) with no change in *p*H; the thiolsulfonate gave 90% yield for one mole of I and the *p*H dropped to 3.0.

Anal. Calcd. for I, $C_5H_{11}O_2NS_2$: N, 7.75. Found: N, 7.79.

Further Studies on Oxythiamine

BY MORRIS SOODAK[1] AND LEOPOLD R. CERECEDO

The preparation of oxythiamine from thiamine by deamination with gaseous nitrogen oxides has been previously reported from this Laboratory.[2] In the present communication, we wish to report additional information on this compound.

During the course of this work the thiochrome method was used in following the fate of thiamine, and the Prebluda–McCollum reagent as modified by Melnick and Field[3] served in tracing both the thiamine and oxythiamine, since both compounds give a positive reaction with equal color production. We have found that Melnick and Field[3] and also Rosenberg[4] are incorrect in assuming that the amino group in position 4 of the pyrimidine moiety is necessary for the production of color. Todd and Bergel,[5] and Prebluda and McCollum[6] had already shown that the essential features required for the production of color are the β-hydroxyethyl group on position 5 and a free hydrogen on position 2 of the thiazole moiety. In fact, Bergel and Todd[7] were able to synthesize oxythiamine and showed that it gave a positive formaldehyde–azo reaction. Thus, whereas thiamine gives both positive thiochrome and Prebluda–McCollum reactions, oxythiamine reacts only with the Prebluda–McCollum reagent, and the chloroxy- and bromoxythiamine give neither reaction. Our findings, therefore, confirm those of Todd and Bergel.

Oxythiamine is very similar to thiamine in its chemical properties. Both substances form chloride–hydrochloride salts, picrates and picrolonates, and they can be adsorbed on and eluted from Decalso under similar conditions.[8] Neither compound is attacked by sodium in the presence of glacial acetic acid[9] and both are split by the sulfite treatment of Williams.[10] Thus, by treatment of oxythiamine with sulfite, we have obtained 2-methyl-4-oxypyrimidine-5-methylsulfonic acid.

The ultraviolet absorption spectrum of oxythiamine chloride–hydrochloride was determined for aqueous solutions at neutral and acid reactions, by means of a Model DU Beckman spectrophotometer. Oxythiamine shows two maxima at 223 and 266 mμ, respectively, at *p*H 7.2 (phosphate buffer, 0.02 *M*), and at 221.5 and 265 mμ in 0.02 *M* phosphoric acid. The spectrum is very similar to that of oxychlorothiamine.[11]

Experimental[12]

Picrate and Picrolonate of Oxythiamine.—These compounds were prepared in the usual manner. They were recrystallized several times from an ethanol–water (1:1) mixture.

(12) All melting points are uncorrected. The analyses were performed by Mr. M. Bier.

Oxythiamine picrolonate, m. p. 130–133°. *Anal.* Calcd. for $C_{12}H_{16}O_2N_3S(C_{10}H_8O_5N_4)_2$: C, 48.36; H, 4.03. Found: C, 48.00; H, 4.15.

2-Methyl-4-oxypyrimidine-5-methylsulfonic Acid.—Oxythiamine hydrochloride was treated with sulfite according to the method of Williams and co-workers.[10] After standing with the sulfite for two days (faint Prebluda–McCollum reaction), the solution was adjusted to *p*H 10, the thiazole fragment removed by extraction with chloroform, and the oxysulfonic acid isolated according to the method used by Cline, *et al.*,[13] in their synthesis of this compound.

Anal. Calcd. for $C_6H_8N_2SO_4$: C, 35.29; H, 3.92. Found: C, 35.70; H, 3.84.

The substance was also prepared as follows: The aminosulfonic acid, obtained by treatment of thiamine with sulfite,[10] was treated with the nitrogen oxide gases. The deamination could be easily followed, since the aminosulfonic acid is insoluble, whereas the oxysulfonic acid is rather soluble. The solution was evaporated to dryness *in vacuo*, and recrystallized by solution in water and precipitation with alcohol.[13]

Anal. Found: C, 35.54; H, 4.03.

Bromoxythiamine Bromide Hydrobromide.—One gram of thiamine hydrochloride was dissolved in 20 ml. of glacial acetic acid saturated with dry hydrogen bromide, and sealed in a bomb tube. The mixture was heated at 150–160° for three hours. After removal from the tube, the solution was concentrated *in vacuo* to dryness. The residue was recrystallized several times by solution in methanol and precipitation with absolute ether.[14] The resulting material was washed with ether and dried. It melted at 206–208° with decomposition. The compound does not form thiochrome and does not react with the Prebluda–McCollum reagent.

Anal. Calcd. for $C_{12}H_{16}N_3SOBr_3$: C, 29.38; H, 3.26; Br, 49.00. Found: C, 29.51; H, 3.87; Br, 49.05.

Dichlorovinyltrichlorosilanes

BY G. H. WAGNER AND A. N. PINES

In a recent publication,[1] Agre has described the preparation of "α,β-dichlorovinyltrichlorosilane." In the interest of clarifying the structure of his compound, we would like to record the properties and reactions of two dichlorovinyltrichlorosilanes prepared in this Laboratory. Our data indicate that his compound is β,β-dichlorovinyltrichlorosilane. The properties of our dichlorovinyltrichlorosilanes, I and II, are compared below with Agre's compound.

		Compound I	Compound II	Agre's compound
Boiling point	°C.	163.5–164	162.5–163	159
	Mm.	750	750	729
Density, g./cc. at 25°C.		1.56	1.54	....
$n^{20}D$		1.4958	1.4942	1.4942

Compound I on treatment with concentrated potassium hydroxide gave 1,2-dichloroethylene by fission of the carbon–silicon bond similar to that observed[2] for chloromethyl groups attached to silicon. An explosive gas, probably chloroacetylene, was also formed during this treatment. Compound II, which compares well in its properties with Agre's compound, gave 1,1-dichloroethylene on similar treatment with concentrated potassium hydroxide solution. These reactions indicate that compound I is α,β-dichlorovinyltrichlorosilane and compound II is β,β-dichlorovinyltrichlorosilane. Since the properties of these compounds are almost identical, within experimental error, the part of Agre's proof of structure which is based on a comparison of the physical properties of the compounds obtained from the reaction of trichlorosilane with trichloroethylene and with 1,2-dichloroacetylene is questionable.

Experimental

Treatment of Compound I with Concentrated Potassium Hydroxide.—A three-liter flask was fitted with a dropping funnel and a small water condenser. The water condenser was vented to the atmosphere through two traps, one cooled in ice-water and one in Dry Ice and acetone. A solution of 200 g. of potassium hydroxide in 1500 cc. of water was added to the flask. Seventy-seven grams of compound I was added rapidly through the dropping funnel to the potassium hydroxide solution. After heating the mixture for a few minutes at reflux, a water-insoluble liquid formed. This was steam distilled into the traps after shutting off the cooling water to the water condenser. Upon cooling, a violent explosion occurred in the vent lines but 6 g. of material with the following properties was recovered from the traps.

		Unknown	Reported for 1,2-dichloroethylene *cis*	*trans*
Boiling point, °C.		56	48.4	60.3
Density	g./cc.	1.245	1.265	1.29
	°C.	25	15	15
$n^{20}D$		1.4501	1.4490, 15°	1.4519, 15°

Treatment of Compound II with Concentrated Potassium Hydroxide.—Using the same equipment and technique described above, 114 g. of compound II was added to a solution of 300 g. of potassium hydroxide in 700 cc. of water. Upon cooling, a small flash occurred in the vent line; 27.4 g. of material with the following properties was recovered from the traps.

		Unknown	Reported for 1,1-dichloroethylene
Boiling point, °C.		30.5	31.6
Density	g./cc.	1.168	1.218
	°C.	25	20
$n^{20}D$		1.4253	1.4270

The reactions observed here may be formulated in steps as exemplified below for the reaction of β,β-dichlorovinyltrichlorosilane.

$$OH^- + \text{SiCH=CCl}_2 \longrightarrow \text{HOSi} + {}^-\text{CH=CCl}_2 \quad (1)$$

$${}^-\text{CH=CCl}_2 + H_2O \longrightarrow CH_2\text{=CCl}_2 + OH^- \quad (2)$$

$${}^-\text{CH=CCl}_2 \longrightarrow \text{CH}\equiv\text{CCl} + Cl^- \quad (3)$$

The first step is an attack of hydroxyl ion on silicon to give the carbanion, $^-CH=CCl_2$, which may stabilize itself by reaction with the solvent, reac-

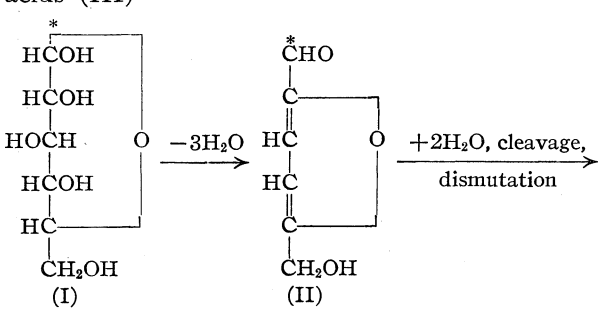
TONAWANDA, NEW YORK RECEIVED JUNE 29, 1949

The Action of Hydrobromic Acid on 1-C^{14}-D-Glucose

BY JOHN C. SOWDEN

The dehydration and cleavage of D-glucose by vigorous treatment with mineral acids was first studied by Grote and Tollens[1] who recognized the principal products of the reaction as levulinic acid and formic acid, which are formed along with varying amounts of highly colored polymeric "humins." Earlier, Mulder[2] had obtained formic acid from the action of sulfuric acid on sucrose and undoubtedly the other product he obtained, "glucinic acid," was in reality levulinic acid, later purified, characterized and renamed by Grote and Tollens.[3]

The mechanism of the reaction remained obscure until comparatively recent times: 5-Hydroxymethyl-2-furaldehyde was recognized as a probable intermediate by Kiermayer[4] and by van Ekenstein and Blanksma.[5] Following a critical study of the reaction, Pummerer and co-workers[6] concluded that 5-hydroxymethyl-2-furaldehyde (II) is first formed from the hexose (I) with the loss of three molecules of water and that this intermediate then undergoes hydration, cleavage and dismutation to produce levulinic and formic acids (III)



According to this proposed mechanism, the aldehyde carbon of the hexose eventually becomes the carbon of the resultant formic acid. This latter assumption has now been substantiated by an examination of the products from 1-C^{14}-D-glucose[7] and hydrobromic acid: The levulinic acid produced was devoid of radioactivity whereas the formic acid showed quantitatively the radioactivity previously possessed by the aldehyde carbon of the glucose.

(7) Sowden, *Science*, **109**, 229 (1949).

Experimental

One gram of 1-C^{14}-D-glucose, showing radioactivity of 860 ± 20 c.p.m./mg., was heated with 10.0 cc. of 10% hydrobromic acid in a sealed tube at 130° for twenty-four hours.[8] The resulting slight precipitate of "humins" was filtered off and washed. Sufficient sodium hydroxide solution was then added to the filtrate to exactly neutralize the hydrobromic acid. The resulting solution was distilled to dryness, using an oil-bath, and water was added and the distillation repeated twice.

The residue was extracted with anhydrous ether and the extract concentrated. The residual liquid, on treatment with phenylhydrazine, yielded 0.55 g. (48%) of *non-radioactive* levulinic acid phenylhydrazone, m. p. after recrystallization 109–110°.[9]

The distillate from the reaction mixture was titrated with 0.1 *N* sodium hydroxide solution to neutralize the distilled formic acid, requiring 44.7 cc. (80%) to the methyl red end-point. The resulting sodium formate was converted to *p*-phenylphenacyl formate, m. p. after recrystallization 74–75°.[10] This product when counted in the same manner[7] as the original 1-C^{14}-D-glucose showed radioactivity of 650 ± 20 c.p.m./mg. On the assumption that the formic acid was produced from the aldehyde carbon of the D-glucose the predicted radioactivity was 645 ± 20 c. p. m./mg.

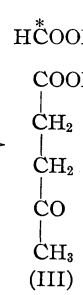
An Antistine Intermediate

BY ARTHUR J. TOMISEK[1]

This synthesis of (N-phenyl-N-benzylglycyl)-2′-aminoethylamide, $Ph(PhCH_2)NCH_2CONHCH_2CH_2NH_2$, represents an abandoned project in which it was desired to test a synthetic route leading to compounds of antistine-like structure.



Ethyl N-Benzyl-N-phenylglycinate.—Twenty-one and two-tenths grams (0.116 mole) of benzylaniline[2] and 6.42 ml. (0.058 mole) of ethyl bromoacetate in a stoppered flask were heated in a 45° oven for twenty hours. The pasty product was churned for two hours with 585 ml. of 0.3 *N* hydrochloric acid (0.174 mole) in order to extract unreacted benzylaniline. The viscous, semi-crystalline phase was crude ethyl N-benzyl-N-phenylglycinate hydrochloride. This was an unstable product, and was therefore dried in a desiccator and used directly in the next step.

(N-Phenyl-N-benzylglycyl)-2′-aminoethylamide.—The crude ethyl N-phenyl-N-benzylglycinate and 35 ml. of ethylenediamine (95–100%) were refluxed for five hours, cooled and poured into water. The oily phase was extracted with methylene chloride, washed with water and dried over sodium sulfate. Solvent was removed on a steam-bath and the residue was crystallized and recrystallized from anhydrous butanol–ethanol–hydrogen chloride. The white powder separated very slowly. It was characterized by the benzaldehyde odor and the intense red color which result from its contact with strong nitric

acid.[3,4] The yield of crude, pale blue dihydrochloride was 6.8 g. (33% based on ethyl bromoacetate). For purposes of analysis a sample was purified by chromatography of an absolute alcoholic solution over hydrochloric acid-washed alumina. Pure samples of the monohydrochloride were readily obtained by diluting the first few fractions with dry acetone, then adding dry ether to incipient turbidity. The white leaflets melted at 189° (microblock). *Anal.* Calcd. for $C_{17}H_{21}N_3O\cdot HCl$: C, 63.84; H, 6.93; N, 13.14; Cl, 11.09. Found: C, 63.68; H, 6.85; N, 13.13; Cl, 11.17.

(N-Phenyl-N-benzylglycyl)-2′-benzamidoethylamide.—This was prepared in excellent yield from the preceding compound by the Schotten–Baumann method and recrystallized from pyridine–water and from alcohol; m. p. 165–166° (microblock). *Anal.* Calcd. for $C_{24}H_{25}N_3O_2$: C, 74.40; H, 6.50; N, 10.85. Found: C, 74.36; H, 6.65; N, 10.64.

(3) The color test is negative for the ethyl phenylbenzylglycinate.

(4) Bischoff, *Ber.*, **31**, 2675 (1898), reports the benzaldehyde test as characteristic of N-phenyl-N-benzylglycine.

NEW COMPOUNDS

Symmetrical Morpholinium and Thiamorpholinium Alkyl Sulfates[1]

The previously reported studies in "Symmetrical Morpholinium Alkyl Sulfates"[2] dealt with the reaction of dimethyl, diethyl, di-*n*-butyl, di-*n*-hexyl and di-*n*-hexadecyl sulfates with N-*n*-dodecyl, N-*n*-tetradecyl, N-*n*-hexadecyl and N-*n*-octadecyl morpholines. The purpose of the present communication is to report the extension of these reactions to include di-*n*-octyl, di-*n*-decyl and di-*n*-dodecyl sulfates and the reaction of di-*n*-hexadecyl sulfate with the corresponding previously described thiamorpholines, oxides and dioxides.[3]

N,N-Dialkylmorpholinium alkyl sulfates were obtained by the reaction of equimolecular quantities (approximately 0.003 mole) of the N-alkylmorpholine and the appropriate dialkyl sulfate in a tightly stoppered Pyrex test-tube. The reaction mixture was heated to 115° (external temperature) by means of an oil-bath, held at this temperature for six hours and then allowed to remain at room temperature overnight. The reactions employing di-*n*-dodecyl and di-*n*-hexadecyl sulfates were heated at 150° for five hours. The resultant products were washed with 3 cc. of ether at 33°, cooled and centrifuged. The ether layer containing the more soluble unreacted starting materials was decanted. The washed products were crystallized three times from ethyl acetate and dried on a porous tile. Yields by this method varied from 25 to 47%, in most cases from 40 to 45%.

It was found that carrying out the reaction by refluxing the reactants in toluene for eight hours gave somewhat lower yields.

N,N-Dialkylthiamorpholinium Alkyl Sulfates.—Equimolecular quantities (approximately 0.003 mole) of the N-alkylthiamorpholine, oxide or dioxide and di-*n*-hexadecyl sulfate were added to 5 cc. of toluene which had been dried over sodium. The solution was refluxed for four hours, using an oil-bath, with an external temperature of 160–170°. Lower temperatures were found to give incomplete reaction. The toluene was distilled off *in vacuo* a little alcohol was added and distilled *in vacuo* to remove the last traces of toluene. The residue was taken up in ethyl acetate and crystallized from this solvent. In cases where decolorization was necessary, this was done with Darco in alcohol solution. The compounds were recrystallized three times from ethyl acetate or from ethyl acetate containing a little ethyl alcohol.

Some New Chalcones[1]

In connection with the study of the antifungal activity of organic compounds, we have prepared fourteen new chalcones. Except as noted, these were made by the condensation of substituted benzaldehydes and acetophenones at 0–10° in ethanol–water mixture using sodium hydroxide as a catalyst,[2] the duration of the reaction being about eighteen hours.

Mercaptomethylthiazole Derivatives

2-Methyl-4-mercaptomethylthiazole.—In a 250-ml. three-neck flask fitted with a sealed stirrer, reflux condenser and drying tube, and dropping funnel was placed 16 g. (0.11 mole) of 2-methyl-4-chloromethylthiazole,[1] 10.5 g. (0.14 mole) of thiourea and 32 ml. of anhydrous ethanol. The solution was refluxed with stirring for two hours, cooled, treated with a solution of 8 g. (0.2 mole) of sodium hydroxide in 75 ml. of water and refluxed for an additional hour. To the cooled mixture was added enough 10% hydrochloric acid to show slight acidity to litmus and then 10% sodium carbonate solution to slight basicity. The mixture was extracted four times with 100 ml. of ether, and the solvent phase was dried with anhydrous calcium sulfate. The desiccant was removed by filtration, the volatiles removed from the filtrate by distillation, finally at reduced pressure and the residue distilled at 89–91° (3 mm.) to give 10.3 g. (64% yield) of a colorless oil.

Anal.[2] Calcd. for $C_5H_7NS_2$: N, 9.64. Found: N, 9.34.

2-Methyl-4-benzylthiomethylthiazole.—In a 250-ml. three-neck flask fitted with a sealed stirrer, reflux condenser and drying tube, dropping funnel and thermometer, was placed 4.6 g. (0.08 mole) of potassium hydroxide and 100 ml. of anhydrous ethanol. Stirring and refluxing was initiated and continued until solution was complete, after which time the heater was replaced by an ice-bath until the temperature dropped to 5°, when 8.7 g. (0.07 mole) of benzyl mercaptan in 20 ml. of absolute ethanol was added dropwise (fifteen minutes) at that temperature. At the end of that time, 10 g. (0.07 mole) of freshly prepared 2-methyl-4-chloromethylthiazole in 20 ml. of ethanol was added during ten minutes, causing an immediate precipitation of potassium chloride. The mixture was stirred and refluxed for one hour, cooled, diluted with 700 ml. of water and extracted four times with 200 ml. of ether. The ethereal solution was washed with a total of 200 ml. of water and then dried with calcium sulfate. After separation of the desiccant, the solvent was removed by distillation and the residue distilled at 131–135° (0.75 mm.) to give 12.1 g. (75% yield) of a colorless oil.

Anal. Calcd. for $C_{12}H_{13}NS_2$: N, 5.86. Found: N, 5.35.

Thiol Esters

During work on compounds containing the thiophene-2-methyl group, it became desirable to prepare a series of thiol esters derived from thiophene-2-methyl mercaptan.[1] It was found that the mercaptan reacted in the usual manner with acyl halides and with acid anhydrides to give the desired esters in acceptable yields. The new products and their properties are tabulated in Table I.

Experimental

All of the compounds were prepared by the interaction of molar quantities of the appropriate acyl halide or anhydride with the mercaptan in excess pyridine, and worked up in the usual manner.

(1) Prepared *via* the isothiouronium salt from thienyl chloride.

2-Thenyl Sulfides

During work on compounds containing the 2-thenyl grouping, it became desirable to prepare a series of sulfides bearing that loading. Certain of these compounds were obtained in good yields from the interaction of 2-thenyl chloride and the appropriate potassium mercaptide, while 2-(2′-thenylmercapto)-ethyl cyanide and the corresponding mercaptopropionic ester were synthesized by the addition of 2-thenyl mercaptan to the respective acylic compounds in the presence of a trace of alkaline catalyst.[1] The new compounds are listed in Table I.

***i*-Butyl-2-thenyl Sulfide.**—In a 250-ml. 3-neck flask fitted with a sealed Hershberg stirrer, reflux condenser, thermometer and dropping funnel, was dissolved 6.6 g. (0.1 mole) of 85% potassium hydroxide in 100 ml. of absolute ethanol with stirring and heating. After solution was complete, the temperature was allowed to drop to about 25° and 10 g. (0.11 mole) of *i*-butyl mercaptan was added from the dropping funnel during ten minutes, the temperature being maintained constant. At the end of this time, 13.2 g. (0.1 mole) of 2-thenyl chloride[2] was added dropwise at the same temperature (fifteen minutes). The precipitation of potassium chloride began almost immediately, and the mixture was stirred and refluxed for three hours, after which time further heating did not increase the yield. The cooled mixture was poured into 900 ml. of water, causing separation of an oil which was removed by extraction with a total of 400 ml. of ether. The solvent layer was dried with calcium sulfate, filtered from the desiccant, stripped (finally at reduced pressure) and then fractionated through a 30-cm. Vigreux column to give 13 g. (70% yield) of a colorless oil boiling at 89–91° (3.5 mm.).

2-(2′-Thenylmercapto)-ethyl Cyanide.—In a 250-ml. 3-neck flask fitted as above was placed 26 g. (0.2 mole) of 2-thenyl mercaptan,[3] 0.05 g. (0.0022 mole) of sodium and 100 ml. of anhydrous benzene. The mixture was stirred and refluxed until the sodium had reacted completely. The mixture was cooled to 5° and 11.1 g. (0.21 mole) of freshly distilled acrylonitrile in 50 ml. of benzene was added dropwise during five minutes, the temperature rising to 40°.[4] The solution was refluxed for one hour, cooled, acidified with glacial acetic acid and the volatiles removed from the steam-bath at reduced pressure. The residue was fractionated at 127–130° (2.5 mm.) to give 17.3 g. (47% yield) of a colorless oil.

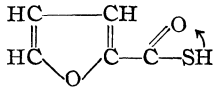
Thiofuroic Acid

Sixteen and four-tenths grams of furoyl chloride was added with agitation to 75 ml. of 10% aqueous sodium hydrosulfide. The reaction proceeded smoothly in the cold (4°). The reaction mixture was acidified to liberate the thioacid and then extracted with ether. The ether solution was dried with anhydrous sodium sulfate and the solvent

removed by distillation. Vacuum distillation of the residue yielded 10.4 g. of a yellow oil boiling 101–103° at 16 mm. *Anal.* Calcd. for $C_5H_4O_2S$: C, 46.9; H, 3.1; S, 25.4. Found: C, 46.5; H, 3.1; S, 23.9. This oil upon hydrolysis with dilute alkali yielded furoic acid and hydrogen sulfide.

Some of the physical and chemical characteristics of this compound are as follows: m. p. −9°; $n^{24}D$ 1.589; it has a disagreeable sulfide-like odor; it is heavier than and insoluble in water, miscible with alcohol and ether; its sodium salt is yellow and water soluble; it gives a green-yellow precipitate with dilute copper sulfate solution and no color reaction with sodium nitroprusside. Earlier attempts to distil the compound at atmospheric pressure were unsuccessful. On standing, the thioacid gives rise to colorless needles m. p. 107–108° which have been identified as difuroyl disulfide (see below). The following structure seems indicated for thiofuroic acid.



A by-product was isolated from the distillation residue, as colorless needles, m. p. 107–108°, by recrystallization from an acetone–water mixture. Hydrolysis of this compound with dilute alkali yielded furoic acid and hydrogen sulfide. A mixed melting point with difuroyl disulfide prepared by Frank, *et al.*,[1] showed no depression (106–108°). *Anal.* Calcd. for $C_{10}H_6O_4S_2$: C, 47.2; H, 2.4; S, 25.2. Found: C, 47.1; H, 2.8; S, 25.6.

The disulfide has a disagreeable odor resembling that of biphenyl. It is insoluble in water and dilute alkali, soluble in alcohol and ether.

The reaction, used in these experiments to synthesize thiofuroic acid, appears to be virtually quantitative when the yield of disulfide is also considered.

The author is indebted to A. P. Dunlop of the Quaker Oats Co. for helpful suggestions concerning this research.

Alkyl Quinolyl Sulfides

The formation of the hydrochlorides of several aromatic quinolyl sulfides[1] took place readily when 4-chloroquinoline was refluxed with the mercaptan in a solvent such as chloroform. However, when certain aliphatic sulfides of quinoline were desired, reaction failed to take place even at a higher reflux temperature. Alkyl quinoline sulfides were prepared from 2- and 4-chloroquinolines by refluxing with the mercaptan in alcohol in the presence of sodium ethylate, as reported by Clinton and Suter,[2] and as described by Hannan, *et al.*[3]

6-Methoxy-4-*n*-butylthio-2-methylquinoline.—A 0.05-mole run was refluxed in 8 volumes of absolute ethanol for six hours. Sodium chloride separated in the theoretical yield and alcohol was removed under reduced pressure. A chloroform solution of the crude product was washed with normal sodium hydroxide. The oily solid recovered from chloroform was suspended in hexane, filtered, and crystallized from 1.5 volumes of ligroin (90–100°); yield, about 50% of theory. Three crystallizations from ligroin gave a colorless solid melting at 67.3–68°. This sulfide was slightly soluble in pentane and readily soluble in benzene, acetone, methanol and ethanol. *Anal.* Calcd. for $C_{15}H_{19}ONS$: N, 5.36; S, 12.26. Found: N, 5.34; S, 12.33.

6-Methoxy-4-*n*-tetradecylthio-2-methylquinoline.—The alcoholic solution of sodium ethylate, tetradecylthiol[4] (myristyl mercaptan) and 6-methoxy-4-chloro-2-methylquinoline was refluxed for fifteen hours. After treatment with chloroform and alkali, the colorless sulfide was crystallized from 1.2 and from 6 volumes of acetone, m. p. 64–64.5°. Little loss occurred in recrystallizing this product from 10 volumes of methanol; the sulfide is fairly soluble in benzene. *Anal.* Calcd. for $C_{25}H_{39}ONS$: N, 3.49; S, 7.98. Found: N, 3.40; S, 8.16.

4-Chloro-4′-*t*-butylbenzophenone and 4-Chloro-4′-*t*-butyldiphenylmethane

4-Chloro-4′-*t*-butyl-benzophenone.—A mixture of 20.4 g. of *t*-butylbenzene, 29.1 g. of *p*-chlorobenzoyl chloride and 115 ml. of anhydrous nitrobenzene was cooled to about 5°. The mixture was stirred and 22.3 g. of powdered aluminum chloride was added slowly. After all the aluminum chloride had been added, the ice-bath was removed and the mixture was stirred overnight at room temperature. The mixture was now cooled to about 5° and small pieces of ice were dropped in. The decomposition was completed with concentrated sulfuric acid. The nitrobenzene was removed by steam distillation and the residue was taken up in ether, washed with water and dried over "Drierite." When the ether was distilled off, the residue crystallized. Recrystallization from 95% ethanol gave white crystals, m. p. 79–81°; yield 34 g. (82%).

Anal. Calcd. for $C_{17}H_{17}OCl$: C, 74.85; H, 6.28; Cl, 13.00. Found: C, 75.11; H, 6.40; Cl, 13.41.

4-Chloro-4′-*t*-butyldiphenylmethane.—A mixture of 50 g. of the above ketone, 50 g. of 47% hydriodic acid and 50 g. of red phosphorus was refluxed for forty hours with mechanical stirring. The mixture was cooled and made basic with 10% sodium hydroxide solution. The mixture was then extracted with ether, the red phosphorus was filtered off, and the ethereal solution was washed with 10% sodium hydroxide solution and then with water. Finally the ethereal solution was dried over "Drierite" and concentrated. The residue was fractionated under reduced pressure. The entire residue distilled at 176–177° (5 mm.), yield 39.5 g. (84%).

Anal. Calcd. for $C_{17}H_{19}Cl$: C, 78.90; H, 7.40. Found: C, 79.05; H, 7.45.

COMMUNICATIONS TO THE EDITOR

THE SOLUBILITY OF HYDROGEN CHLORIDE AT LOW TEMPERATURES—A MEASURE OF THE BASIC PROPERTIES OF AROMATIC NUCLEI

Sir:

There is now considerable evidence that aromatic nuclei possess basic properties. Klatt[1] observed that aromatic compounds dissolve in liquid hydrogen fluoride, whereas saturated hydrocarbons do not. Winstein and Lucas[2] and, more recently, Keefer and Andrews[3] attribute complex formation between silver ion and aromatic hydrocarbons to the basic properties of the aromatic nuclei. Fairbrother[4] correlated changes in the apparent dipole moments of iodine in several hydrocarbon solvents with changes in the probable donor character of the π electrons in the hydrocarbon. Finally, the absorption spectra of solutions of iodine in aromatic hydrocarbons show changes which can also be correlated with the basic properties of the solvent.[5]

In the course of studies of the action of the catalyst couple, aluminum chloride–hydrogen chloride, on aromatic hydrocarbons at low temperatures, we have observed that the solubility of hydrogen chloride varies considerably with different aromatic hydrocarbons. The variation in solubility cannot be correlated with any of the usual physical properties of the solvent, but it can be correlated with the predicted variation in the basic properties of the compounds.

In order to investigate this phenomenon more carefully, we developed a method for measuring Henry's law constant with a precision of approximately 1 part in 500. Toluene is used as solvent. A solution of 10 moles of toluene and 1 mole of aromatic hydrocarbon is prepared. The solution is maintained at $-78.51°$ and small quantities of hydrogen chloride are introduced. Henry's law is followed over a wide range of concentration. From the observed pressures, the constant is calculated from the usual expression, $p = kx$, where p is the pressure of hydrogen chloride, x is its mole fraction and k is the desired constant.

The following values for k (in mm.) have been obtained: (1) trifluoromethylbenzene, 332; (2) chlorobenzene, 318; (3) benzene, 308; (4) toluene, 299; (5) *p*-xylene, 294; (6) *o*-xylene, 286; (7) *m*-xylene, 278; (8) pseudocumene, 272; (9) hemimellitene, 265; (10) mesitylene, 254.

(5) Benesi and Hildebrand, THIS JOURNAL, **70**, 2832 (1948); **71**, 2703 (1949).

It is apparent that the order of increasing solubility is identical with the order of increasing reactivity toward the usual electrophilic substituting agents. Therefore, Henry's law constant may be taken as a measure of the relative basicity of the ring. It is particularly interesting that the method is sufficiently sensitive to differentiate between the isomeric xylenes and trimethylbenzenes.

We are now applying the procedure to other benzenoid derivatives, polynuclear hydrocarbons, heterocyclics and olefins. The data should be useful in giving a quantitative measure of the effect of structure on the relative basicities of these compounds.

PROPARGYLGLYCINE: AN ACETYLENIC AMINO ACID ANTAGONIST[1,2]

Sir:

As part of a research program designed to get information concerning the basis for the preparation of specific metabolite antagonists, we prepared and studied the vinylene-type unsaturated amino acids, allylglycine, methallylglycine, crotylglycine and 2-amino-5-heptenoic acid.[3] Since allylglycine was a potent inhibitor of the growth of bacteria and yeast, we deemed it desirable to prepare the corresponding acetylenic amino acid, propargylglycine. In this communication we wish to report the synthesis and preliminary microbial-growth inhibitory properties of propargylglycine.

Diethyl Propargylformamidomalonate.—To a solution containing 0.92 g. (0.04 g. atom) of sodium dissolved in 75 ml. of absolute alcohol was added 8.12 g. (0.04 mole) of diethyl formamidomalonate.[4] Five grams (0.042 mole) of propargyl bromide[5] in 20 ml. of ethanol was added and refluxed for eighteen hours. After concentration to dryness, the residue was taken up in a mixture of chloroform and water. The residue from the chloroform was recrystallized from water. The diethyl propargylformamidomalonate melted at 69–70°, and the yield was 90%. An analytical sample was obtained from di-*n*-butyl ether, m. p. 71–72°.

Anal. Calcd. for $C_{11}H_{15}NO_5$: C, 54.77; H, 6.22; N, 5.81. Found: C, 54.85; H, 6.34; N, 5.59.

(1) This work was supported in part by a research contract with the Office of Naval Research.

(2) The authors gratefully acknowledge the technical assistance of Mrs. Ann E. Johnson and Mr. Robert P. Martin.

(3) (a) Dittmer, Goering, Goodman and Cristol, THIS JOURNAL, **70**, 2499 (1948); (b) Goering, Cristol and Dittmer, *ibid.*, **70**, 3310, 3314 (1948).

(4) A. Galat, *ibid.*, **69**, 965 (1947).

(5) A. Kirrmann, *Bull. soc. chim.*, IV, **39**, 698 (1926).

Propargylglycine.—The diethyl propargylformamidomalonate was hydrolyzed by refluxing 2.4 g. (0.01 mole) of the ester with 24 ml. of 8% sodium hydroxide for four hours. The mixture was diluted to 100 ml. with water and passed through a column of Duolite C-10H which removed all the base. The effluent was subsequently passed through a column of Duolite A-2 which removed the formic acid produced. The resulting solution was concentrated *in vacuo*, decolorized with Darco G-60, and on addition of acetone, the amino acid crystallized. The yield was 88.5%. An analytical sample of propargylglycine was obtained from water and acetone, m. p. 243° with decomposition.

Anal. Calcd. for $C_5H_7O_2N$: C, 53.09; H, 6.24; N, 12.39. Found: C, 53.24; H, 6.20; N, 12.47.

Norvaline.—Hydrogenation of 113 mg. (0.001 mole) of propargylglycine in the presence of Adams catalyst, at 28° and 1 atmosphere, required 0.00207 mole (104% of theoretical) of hydrogen and produced 100 mg. of norvaline, which melted with decomposition at 297° in a sealed tube; the benzoyl derivative prepared as above, m. p. 150–151°.

Microbiological Tests.—Propargylglycine was tested as an inhibitor of the growth of *Escherichia coli*, strain 9723 and *Saccharomyces cerevisiae*, strain 139.[6] To inhibit the growth of these microörganisms, to 50% of normal growth, required 4 micrograms per 7.5 ml. of medium for *S. cerevisiae* and 65 micrograms for *E. coli*. According to these data propargylglycine is more active than allylglycine for yeast but less active for the inhibition of *E. coli*.

(6) The methods employed and the test organisms were the same as those previously described.[3a]

N[10]-NITROSOPTEROYLGLUTAMIC ACID

Sir:

The action of nitrous acid upon 2-aminopteridines has led to destruction of the ring system,[1] desamination in the 2-position,[2] and simultaneous desamination of the 2-position and nitrosation on the nitrogen atom in the 10-position of pteroic acid.[3] "Folic acid" concentrates from natural sources[4] were inactivated by nitrous acid under the conditions of the Van Slyke determination.[5] These experiments involved the use of excess nitrous acid and temperatures ranging from "room temperature" to 100° or higher.

We wish to report that pteroylglutamic acid in cold hydrochloric acid solution reacts quantitatively with one mole of nitrous acid to form N[10]-nitrosopteroylglutamic acid, which precipitates from the reaction mixture as a white solid.

N[10]-Nitrosopteroylglutamic acid gives a positive Liebermann nitroso reaction. The nitroso group can be removed by treatment with phenol and hydrochloric acid, and pteroylglutamic acid thus regenerated.

Under substantially the same conditions, the following give N[10]-nitroso compounds: pteroyl-α-glutamylglutamic acid[6]; pteroyl-γ-glutamyl-γ-glutamylglutamic acid,[7] 9-methylpteroylglutamic acid,[8] 4-aminopteroylglutamic acid,[9] 2-dimethylaminopteroylglutamic acid,[10] and 4-(1-piperidyl)-pteroylglutamic acid.[10]

Neither 2-amino-4-hydroxy-6-methylpteridine,[11] 2,4-diamino-6-methylpteridine,[9b] nor N[10]-methylpteroylglutamic acid[12] react appreciably with nitrous acid under these conditions.

In a typical experiment, 4.4 g. of pteroylglutamic acid (90% purity,[13] 0.5% *p*-aminobenzoylglutamic acid, 8% H_2O) was dissolved in 50 ml. of concentrated hydrochloric acid, and cooled to 5–10° by the addition of ice. Then 0.7 g. of sodium nitrite dissolved in a little water was added slowly. A white precipitate formed, which was filtered, washed, and dried to give 3.2 g. of N[10]-nitrosopteroylglutamic acid. One gram of this dissolved in 25 ml. of 5 *N* sodium hydroxide was clarified with activated charcoal. On standing the sodium salt crystallized. It was collected, dissolved in water and precipitated with acid, filtered, washed, and dried two hours at 100° (2 mm.). *Anal.* Calcd. for $C_{19}H_{18}N_8O_7$: C, 48.5; H, 3.83; N, 23.8. Found: C, 48.9; H, 4.77; N, 24.05 (corrected for 3.8% ash).

Through the courtesy of our colleagues, Dr. B. L. Hutchings, and Dr. J. J. Oleson, of the Lederle Laboratories Division, American Cyanamid Company, N[10]-nitrosopteroylglutamic acid has been tested in a preliminary way in the nutrition of *S. faecalis* R and the chick, and in both cases appears to be equivalent to pteroylglutamic acid.

STEROLS. VIII.[1] 17α-HYDROXYPROGESTERONE AND 17α-HYDROXY-11-DESOXYCORTICOSTERONE

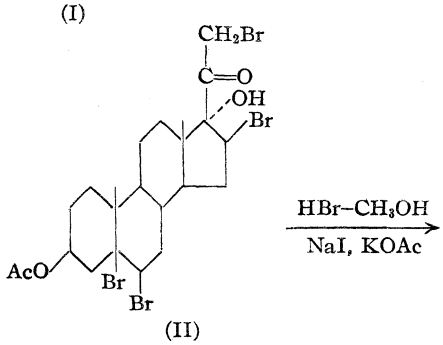
Sir:

Recently we reported[1] the facile preparation of 16,17-oxidoprogesterone from 16,17-oxido-5-pregnene-3β-ol-20-one acetate (I). We now wish to record the use of I as an intermediate for a new and very simple partial synthesis of both 17α-hydroxyprogesterone and 17α-hydroxy-11-desoxycorticosterone acetate (V) (acetate of Reichstein's Compound S). The reactions as applied to the latter are schematically presented by formulas I → V. A treatment of 16,17-oxidoprogesterone

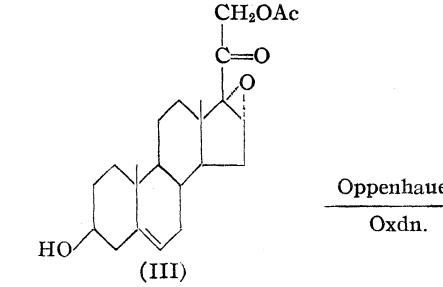
(1) For paper VII in this series see THIS JOURNAL, **71**, 756 (1949)

similar to that given IV produced 17α-hydroxyprogesterone.

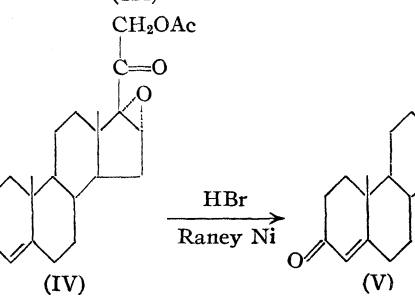
16,17-Oxido-5-pregnene-3β-ol-20-one acetate (I) —Br_2, HBr / Br_2→ (I)



(I) —HBr–CH_3OH / NaI, KOAc→ (II)



(II) —Oppenhauer Oxdn.→ (III)



(III) —HBr / Raney Ni→ (IV) and (V)

The smooth cleavage of the oxido compounds by hydrogen bromide, the clean reductive removal of bromine from the resulting bromohydrins by Raney nickel, and the good yields encountered at every step make these hitherto difficultly accessible cortical hormones readily available.

16,17-Oxido-5-pregnene-3β,21-diol-20-one 21-Acetate (III).—From 16,17-oxido-5-pregnene-3β-ol-20-one acetate by treating first with one molar equivalent of bromine in acetic acid–carbon tetrachloride, then with hydrogen bromide in acetic acid followed by a second molar equivalent of bromine. Then hydrolysis with hydrogen bromide in methanol–benzene, treatment with sodium iodide in benzene–ethanol and finally with potassium acetate in acetone gave needles from acetone–petroleum ether, m. p. 190–192°; $[\alpha]^{24}D$ +15° (chloroform). *Anal.* Calcd. for $C_{23}H_{32}O_5$: C, 71.11; H, 8.30. Found: C, 70.86; H, 8.33.

16,17-Oxido-4-pregnene-21-ol-3,20-dione Acetate (IV).—By the Oppenauer oxidation of III; prisms from ether–petroleum ether, m. p. 170–172°; $[\alpha]^{25}D$ +167° (chloroform). *Anal.* Calcd. for $C_{23}H_{30}O_5$: C, 71.48; H, 7.82. Found: C, 71.82; H, 8.23.

17α-Hydroxy-11-desoxycorticosterone Acetate (V).—From IV with hydrogen bromide in acetic acid, followed by reduction with Raney nickel in ethanol; needles from methanol, m. p. 235–238° (sinters 230°), no depression with material isolated from a natural source[2]; $[\alpha]^{24}D$ +114° (acetone). *Anal.* Calcd. for $C_{23}H_{32}O_5$: C, 71.11; H, 8.30. ELECTRON DEFICIENT COMPOUNDS. IV. THE STRUCTURE OF HEXAMETHYLDIPLATINUM

Sir:

The reaction $(CH_3)_3PtI + K$ was presumed to yield $(CH_3)_3Pt—Pt(CH_3)_3$.[1] A recent explanation of electron deficient bonding[2] suggests that since Pt^{IV} has six low energy orbitals, d^2sp^3, the configuration about platinum should be octahedral, requiring polymerization through electron deficient bonds.

"Hexamethyldiplatinum" is monoclinic, $a_0 = 17.35$, $b_0 = 18.99$, $c_0 = 17.79$ kX., $\beta = 116°$, space group from Weissenberg diagrams, $P2_1/c$. The observed density, 3.65, requires 48 $Pt(CH_3)_3$ per unit cell. There can be only 2 or 4 crystallographically equivalent atomic aggregates per unit cell. In molecular crystals these aggregates are almost invariably the molecules, so that the unit cell and density data indicate a minimum molecular size of $[(CH_3)_3Pt]_{12}$. Our data do not exclude continuous chains.

Patterson functions, $P(x,z)$ and $P(x,y)$, have been calculated, each involving about 125 reflections. All important peaks of $P(x,z)$ (Fig. 1) are interpreted, even as to heights, in terms of 16 platinum positions. Since h is even except for 13 weak reflections, there is a pseudo eightfold set of positions: x,z; $\bar{x},\bar{z}$; $x,{}^1/_2+z$; $\bar{x},{}^1/_2-z$; ${}^1/_2+x,z$; ${}^1/_2-x,\bar{z}$; ${}^1/_2+x,{}^1/_2+z$; ${}^1/_2-x,{}^1/_2-$

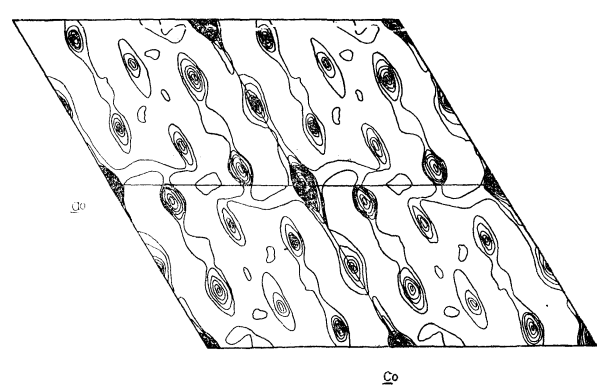

Fig. 1.—Patterson projection, $P(xz)$ for "Hexamethyldiplatinum."

(1) H. Gilman and W. Lichtenwalter, THIS JOURNAL, **61**, 957 (1939).

(2) R. Rundle, *ibid.*, **69**, 1327 (1947); *J. Chem. Phys.*, **17**, 671 (1949).

z. There are two such sets with $x_1 = 0.313$, $z_1 = 0.125$; $x_2 = 0.138$, $z_2 = 0.008$. These parameters lead to satisfactory $(h0l)$ intensities.

The sixteen platinum positions projected onto (010) form four, well-separated squares per unit with Pt–Pt = 2.84 kX. Each point must represent three platinum atoms. $P(xy)$ gives 2.82 kX. for one important Pt–Pt distance along b_0. There are four molecules, or possibly four continuous chains, per unit cell. The square projection on $P(x,z)$ suggests that platinum is octahedral, as expected. The complete structure has not yet been determined.

"Hexamethyldiplatinum" is quite soluble in benzene, but negligibly soluble in non-aromatic hydrocarbons. The pronounced difference suggests that benzene may depolymerize the molecule. It is noteworthy that benzene leaves the tetramethylplatinum tetramer unaltered.[3]

Thanks are due Prof. Henry Gilman for advice and encouragement.

NEW BOOKS

Aquametry. Application of the Karl Fischer Reagent to Quantitative Analyses Involving Water. By JOHN MITCHELL, JR., M.S., and DONALD MILTON SMITH, Ph.D., Ammonia Department, E. I. du Pont de Nemours and Co., Inc., Wilmington, Delaware. (Chemical Analysis. Vol. V. A Series of Monographs on Analytical Chemistry and Its Applications. Editors: Beverly L. Clarke and I. M. Kolthoff) Interscience Publishers, Inc., 215 Fourth Avenue, New York 3, N. Y. 1948. xi + 444 pp. 51 figures. 15.5 × 23.5 cm. Price, $8.00.

The monograph "Aquametry" by John Mitchell, Jr., and Donald Milton Smith is the fifth of a series dealing with topics in Analytical Chemistry. The present work is primarily concerned with "the application of the Karl Fischer reagent to quantitative analyses involving water" but the authors have done much more than is indicated in this sub-title. The book is written in two parts; the first and longer section deals with considerations of a general nature as well as with specific quantitative determinations using the Karl Fischer reagent; the latter part deals with the determination of organic functional groups.

Contained in the first part is a brief survey of the classical methods used for the determination of water. It is shown later that in most cases the Karl Fischer Reagent yields better results and for this reason the older methods are not discussed in detail. There follows a chapter which presents almost in outline form a summary of the most important procedures which utilize the Karl Fischer Reagent. The presentation of this laboratory manual so early in the running text is a departure from the usual practise. It is placed in its particular position so that persons who have studied the pertinent portions of the book will be able to work in the laboratory more efficiently. The authors then present a discussion of possible alternative compositions of the reagent and give what they consider to be the best of those studied. After an investigation of the stoichiometry of the reactions involved, there is given a series of general discussions which deal with the determination of water on the macro and micro scales. This includes an excellent review of the important instrumental as well as the usual visual methods. Then actual working procedures are given for many common organic and inorganic materials. In each of these latter cases there are outlined alternative methods when such exist but these are necessarily brief. Extensive references are given in all cases. The first section is closed with examples of reactions with inorganic compounds which lead to apparent anomalies. These include redox couples which react with the iodine liberated in the titration to give false end-points. The second part of the book will probably be of great use to organic chemists. In this section there are detailed instructions for the determination of various functional groups such as the alcoholic hydroxyl, the amino and the carbonyl radicals. These are not direct titration methods but include some intermediate water producing step. The frequent reference to interfering substances will be of great help to future workers. The book closes with a chapter on work which is as yet not done.

The volume as a whole is formulated in a concise, accurate and readable manner. The lack of serious errors is commendable and is probably due in large part to the care with which practically every entry was checked in the laboratory of the authors. If all future volumes in the Analytical Chemistry series are up to the standards set by Mitchell and Smith, one can easily visualize a set of these treatises in every complete chemical library.

EDWARD H. DE BUTTS

Natural Products Related to Phenanthrene. By LOUIS F. FIESER and MARY FIESER, Department of Chemistry, Harvard University. Third Edition of the Monograph Previously Entitled "Chemistry of Natural Products Related to Phenanthrene" by L. F. Fieser. A. C. S. Monograph No. 70. Reinhold Publishing Corporation, 330 West 42nd Street, New York 18, N. Y., 1949. xii + 704 pp. Price, $10.00.

More than a decade has passed since the scientific world greeted with unanimous acclaim the first edition of Fieser's treatise which Butenandt has called a model *par excellence* for chemical monographs. The first edition arrived at a time when steroid chemistry had just firmly established itself as a special branch of organic chemistry, when most of the important hormones and related products had been discovered and the rough outlines of their structures had been drawn. Since then, in a bewildering multitude of papers, the more intimate structural details have been furnished with which to complete the picture. Once again Fieser, now in coöperation with Mrs. Fieser and Dr. Turner, has summarized the significant developments and has presented them in an eminently lucid and readable manner. The book is much more than a mere review of the subject. It abounds in original ideas concerning the revision of nomenclature, the relations between physical properties and structure of steroids, the course of certain

reactions and other points, ideas which might well have been the subject of separate publications. Like its predecessor the present edition is bound to become the most significant treatise, the standard reference book on the subject.

It appears futile to the reviewer to recommend this volume to the specialists in the field. They have been waiting impatiently for its appearance and they have probably enjoyed reading it by the time this review is published. The reviewer strongly recommends study of this book to organic chemists in general and to graduate students in particular. Not only does it present a very important subject in a most captivating manner, but it also acquaints the reader with a multitude of reactions and syntheses, and with the significance of physical properties in form of a story rather than as isolated facts. In short, the monograph is recommended as an outstanding, advanced textbook of organic chemistry.

WERNER BERGMANN

The Theory of Solutions of High Polymers. By A. R. MILLER, Imperial Chemical Industries, Research Fellow at the Royal Society Mond Laboratory in the University of Cambridge. Oxford University Press, 114 Fifth Avenue, New York 11, N. Y., 1949. vi + 117 pp. Illustrated. 14.5 × 23 cm. Price, $3.25.

The aim of this brief monograph is "to give an account of the [recent] mathematical advances in the treatment of solutions of high polymers," a subject to which its author has made significant contributions. The introductory chapter discusses models for solutions of simple molecules and the formulation of partition functions for them. The extension of the quasi-lattice model to polymer solutions is dealt with briefly in the second chapter. Chapter III begins with an account of Bethe's method and its grand partition function analog presents the fairly obvious extension to monomer-dimer mixtures and ultimately leads to the formulation of a partition function for monomer-polymer systems of zero mixing energy. The comparison of the theory with experiment in Chapter IV is partially satisfactory, but a rather large discrepancy occurs in dilute solutions. The refinement of the theory (Chapter V), after the manner of the late Dr. W. J. C. Orr, to allow for non-randomness brought about by non-zero energies of mixing fails to remove the discrepancy. The final chapter (VI) presents a non-mathematical discussion of limitations of the theory and concludes with a statement to which this reviewer subscribes completely: "Further advances . . . are probably to be sought in a physical model which represents an actual liquid more faithfully than does the quasi-crystalline model, rather than in refinements of the mathematical and statistical techniques."

The subject is approached primarily from the viewpoint of the contributions of its author supplemented in part by those of Guggenheim and of Orr. This preference is excusable and may in part be justified, but the casual disposal of the alternate method of direct evaluation of the combinatory factor because it "introduces unwanted algebraic complications" is not realistic and may be quite misleading. The emphasis on mathematical rigor is commendable, but it is disappointing to see that it carries one substantially no further than the obviously simpler procedures. In the opinion of this reviewer, the book's most serious weakness occurs in the discussion of the failure of the theory as applied to dilute solutions. This failure has been shown to result from the certain inapplicability of the assumption of randomness in dilute solutions, and separate theories have been advanced which are successful at sufficient dilutions. These are either misrepresented or ignored altogher. The author prefers to attribute the state of affairs in dilute solutions to aggregation of molecules which in some unexplained fashion is favored by dilution!

The book contains a number of minor errors, few of which are troublesome. It is disconcerting to see Raoult's law misstated on p. 3 and again in the figures appearing on pp. 70, 71 and 72, where the activity is equated to volume fraction in the name of Raoult. Research workers interested in polymers or in the statistical mechanics of solutions will welcome this monograph. It will not be digested easily, however, without a well developed feeling for the methods of statistical mechanics.

P. J. FLORY

The Basis of Chemotherapy. By THOMAS S. WORK B.Sc., Ph.D., Research Staff, National Institute for Medical Research, London, and ELIZABETH WORK, B.A., Ph.D., Research Staff, Department of Chemical Pathology, University College Hospital Medical School, London. Interscience Publishers, Inc., 215 Fourth Ave., New York, N. Y., 1948. xx + 435 pp. 14.5 × 22.5 cm. Price, $6.50.

The authors present the subject of the drug therapy of infectious diseases from the point of view of the biochemist and microbiologist. Principal exposition is given to bacterial and protozoal diseases, less attention (due no doubt to our lesser knowledge) to virus infections, and scanty attention to parasitic and mycotic diseases. Throughout the book is emphasized the place of enzyme inhibition and metabolite antagonism in mechanisms of drug action. The first half of the book consists of an orientation in these subjects through excellent chapters on cell metabolism, essential metabolites, and enzyme inhibition, along with a historical introduction as fascinating as some popular expositions, but far more penetrating. The second half of the book consists of chapters on "Drug Antagonism," covering substances that diminish or modify the action of drugs, "Drug Resistance," or the tendencies toward adaptation or selection of resistant strains of organisms, and a brief chapter on "The Relation of Structure to Activity." This arrangement may inconvenience somewhat readers seeking information on particular groups of drugs or organisms, but serves well the authors' purpose of seeking logical bases for chemotherapeutic action. The book shows strongly the influence of Wood, Fildes, Woolley, Lwoff, and Sevag.

The book seems to be addressed mainly to advanced students of chemistry, microbiology and medicine; it should be extremely useful to these groups. More advanced research workers may also find in it convenient summaries of work in fields related to their specialties, and references that might otherwise be overlooked. The style is direct and readable, the explanations usually clear, printing legible, and formulas carefully drawn.

WALTON B. GEIGER

Fourier Technique in X-Ray Organic Structure Analysis. By A. D. BOOTH, PH.D., Fellow and Lecturer at Birkbeck College, London. (The Cambridge Series of Physical Chemistry. General Editor, E. K. Rideal.) Cambridge University Press, The Macmillan Company, 60 Fifth Avenue, New York 11, N. Y., 1948. vii + 106 pp. Illustrated. 14.5 × 22 cm. Price, $2.75.

This little book comprises an extremely condensed, but rather complete, presentation of the methods currently being used to discover the atomic arrangements in complex crystals. As the author writes in his preface, this subject is developing so rapidly that one or two important methods inevitably were not included, because they had not been discovered when the book was written two years ago. This detracts in no way from the book's value.

There are seven concise chapters, entitled, respectively: I. The interaction of X-rays with matter; II. The representation of electron density by Fourier series; III. Methods of obtaining approximate structures; IV. The refinement of atomic coördinates; V. Methods of computation; VI. Mechanical computation; VII. The results of Fourier synthesis. These titles show the scope and character of the book: it is intended as a handbook for those actively engaged in the determination of crystal structures. Such workers will find here many valuable de-

tails not conveniently available elsewhere. In particular, the author has included many of his own important contributions to the art of crystal structure analysis by means of Fourier series. For beginning students of X-ray diffraction methods, however, this book may well prove too concise.

DAVID HARKER

Rhenium. DVI-Manganese. The Element of Atomic Number 75. By J. G. F. DRUCE, M.A., M.Sc. (Lond.) R.Nat.Dr.(Prague), F.R.I.C., Fellow of the Chemical Society, Member of the Masaryk Academy of Work, Corresponding Member of the Royal Bohemian Scientific Society, Member of the Netherlands Chemical Society, etc. Cambridge University Press, The Macmillan Company, 60 Fifth Avenue, New York 11, New York. 1948. viii + 89 pp. 14.5 × 22 cm. Price, $2.50.

This book is the first published summary of the studies of rhenium since the appearance of "Das Rhenium" by I. and W. Noddack in 1933. In the fifteen-year interval between the writing of these two books knowledge concerning rhenium has increased materially through the efforts of numerous investigators in many countries. These advances are briefly and clearly reviewed in this newest publication, and the present status of the element is shown in concise manner.

The subject matter is divided into eight chapters. In the Introduction there is a brief and impartial summary of the search for both eka-manganese and dvi-manganese. This is followed by chapters devoted to (2) The Isolation and Properties of Rhenium, (3) The Oxides of Rhenium, (4) Perrhenic Acid and Its Salts, (5) The Halogen Compounds of Rhenium, (6) The Sulfides, Selenides and Thio-Salts of Rhenium, (7) Some Organic Rhenium Derivatives, and (8) Applications and Patents Related to Rhenium. Possibly the most valuable feature of the book is the complete and useful bibliography, of which there are over 300 references, arranged both topically and chronologically.

That the author is eminently qualified to give authoritative information about rhenium is indicated by the fact that at least 36 of these references are to his own articles, those of his late colleague, F. H. Loring, and their collaborators. Few first edition errors are apparent. There is an adequate index.

In this book Dr. Druce has made an outstanding contribution to the literature of the less familiar elements. It will be welcomed by all who are interested in rhenium.

B. S. HOPKINS

Radioactive Measurements with Nuclear Emulsions. By HERMAN YAGODA, Senior Physical Chemist, National Institute of Health. John Wiley and Sons, Inc., 440 Fourth Ave., New York, N. Y., 1949. ix + 356 pp. 75 figs. 22 × 14 cm. Price, $5.00.

The first phenomenon utilized for the detection of radioactivity was the fogging of photographic emulsions. Methods based on the use of sensitized halide emulsions were quickly supplanted by procedures based on ionization measurements. In the last few years, however, emulsions have been staging a strong comeback, owing particularly to the development of thick, fine-grained emulsions astonishingly well suited to the study of densely ionizing particles. These emulsions may be designated as "nuclear" to distinguish them from ordinary photographic emulsions. Studies such as the now classic researches of Powell and his collaborators on the detection of meson components in cosmic radiation illustrate the refinements in techniques employing nuclear emulsions which have reached a point hardly conceivable ten years ago. No comprehensive treatment of radioactive measurements using nuclear emulsions appears to have been available until the publication of this book.

It has been the author's purpose to present a volume which provides sufficient coverage of the field so that "any scientist who owns a microscope can make quantitative measurements." There seems to be little doubt that this objective has been achieved remarkably well and that the reader will find a well integrated description of theory and practice in the use of nuclear emulsions. The material is organized into 12 chapters, the first two of which afford a succinct account of basic principles. Probably one of the most useful sections is the third chapter on laboratory manipulations in which the reader will find a number of recipes for the preparation of various types of samples as well as useful material on exposure and processing of emulsions. In other chapters there are included numerous instances of applications to radiochemistry, biology, crystallography, metallurgy and nuclear physics. A bibliography containing some 700 references is included.

The text is enlivened by many historical references and quotations. Some readers will be interested in the author's use of the word "serendipical." This is an adjectival construction from the word "serendipity" coined by Walpole in the 18th century to indicate the gift of finding agreeable or valuable things not sought for. It is to be hoped that this word comes into more common use because it is a convenient descriptive term for one of the most characteristic aspects of scientific research.

The format employed is one with small margins on a convenient page size. However, the glossy finish renders the print somewhat less legible than would have been the case on a rougher stock.

MARTIN D. KAMEN

Silicones and Other Organic Silicon Compounds. By HOWARD W. POST, Department of Chemistry, University of Buffalo. Reinhold Publishing Corporation, 330 West 42nd St., New York 18, N. Y., 1949. 230 pp. 15.5 × 23.5 cm. Price, $5.00.

The author has set himself the task of abstracting every published article on organosilicon compounds. He has succeeded in making a complete search of the literature through 1947—no small achievement in view of his bibliography of over 700 references. The present extent of organosilicon chemistry has created a need for a handy, up-to-date reference book on the subject. This book could have admirably filled that need, but it has several faults which have somewhat reduced its usefulness.

In the first place the organization of the book is on a historical rather than a chemical basis, which makes it difficult to look up material under a given subject. The first two chapters are introductory, and deal with the inorganic chemistry of silicon. Chapter 3 covers the work of Kipping and others prior to about 1935. Kipping's work is taken up in a more or less chronological order, rather than subject by subject; as it is all in one place, however, it is easy to look through it. Chapter 4 covers the more recent scientific literature on the preparation of organosilicon compounds at moderate temperatures and Chapter 5 covers the patent literature on the same subject. Included here are preparations involving Grignard reagents, hydrolysis, dehydration and other metathetical reactions. The accompanying tables of compounds classified according to the method of preparation may be of value. The physical chemistry of organosilicon compounds is given a rather inadequate treatment, 35 articles being abstracted in 30 sentences near the end of Chapter 4.

Chapter 6 covers reactions carried out at temperatures over about 250°. This includes some of the interesting new industrial methods. Chapter 7, "The Uses of Polymerized Oxosilanes," would have been more valuable if the distinction between silicone resins, oils, rubbers and other products had been made clear. It does, however, give a good idea of the extraordinary versatility of the silicones. Chapter 8 purports to be an extension of the author's previous book, "The Chemistry of the Aliphatic Orthoesters." It is actually a jumble of unrelated material on alkoxy and amino silanes and other derivatives, many of which have no carbon–silicon bonds and are therefore not true organosilicon compounds.

In Chapter 9 on nomenclature Dr. Post has reprinted articles by Sauer and by the A. C. S. Committee on Nomenclature in their entirety. He has thus done justice to the present rules of nomenclature, but he does not follow them himself. Thus the silyl radical is frequently called "silicyl," a term which he also uses for multivalent radicals as in "dichlorosilicyl diisocyanate." His resurrection of the "oxosilanes" seems unnecessary. The strange combination of Greek and Latin roots as in "quadradecamethylhexasiloxane" is not in accord with general usage.

Chapter 10 consists of a table of physical properties of compounds. It appears to be reasonably complete, although there are a few omissions, pentamethylphenyldisiloxane, for instance. The boiling point given for tetraphenylsilane is low by 68°.

The haste with which this book has apparently been prepared is regrettable. The organization within each chapter is generally bad. There are innumerable misprints and misspelled words and some of the tables appear without proper explanation or reference in the text.

The serious student will find "Silicones" of some value, despite its shortcomings; he will have to search a little for his information, but it is all here.

RICHARD N. LEWIS

Elsevier's Encyclopedia of Organic Chemistry, Volume 13A, Bicyclic Compounds (Except Naphthalene) Series III, Carboisocyclic Condensed Compounds. E. JOSEPHY AND F. RADT, Editors. Elsevier Publishing Company, Inc., 215 Fourth Avenue, New York 3, N. Y., 1948. xxvii + 1262 pp. 17.5 × 26 cm. Subscription Price, $78.00; Serial Price, $91.00; Single Volume Price, $104.00.

The general remarks on this new encyclopedia made by L. F. Fieser (THIS JOURNAL, **70**, 1294, (1948)) are equally pertinent to the volume here under consideration; these remarks have the whole-hearted approval of the present reviewer. Although the work may eventually assume something of the function of Beilstein, the two should be considered supplementary. Because of different publishing schedules, Elsevier will dominate certain fields and Beilstein others.

Elsevier is in clear English. It has the advantage of a viewpoint some forty years more mature than Beilstein. The wide use of the charts and tables is not only superb from the encyclopedic standpoint, but also makes the work of greater utility as a general reference. Because of these charts the advanced student can study from Elsevier, something which could hardly be done from Beilstein. There is a general criticalness in Elsevier which is lacking in Beilstein, but it is not used to obscure or to evade references, but rather to point out the existence of doubts and controversies.

Specifically, Volume 12 A contains bicyclic compounds, except naphthalene and its derivatives. The bicyclic terpenes, bicyclic sesquiterpenes, indene and its derivatives make up most of the book. The literature has been covered completely through 1941 and references bearing on structure through 1947. No errors of omission were apparent in the terpene fields, and there are surprisingly few typographical errors. The lack of patent references is not a serious handicap in the chemistry here covered; however, this may prove a serious objection in fields of greater industrial activity.

From the standpoint of topography, system, indices and binding, the volume is indeed of very high standard.

Larger libraries should maintain both Beilstein's Handbuch and Elsevier's Encyclopedia. Collections operating on smaller budgets will probably find Beilstein more essential because of its present completeness in the organic field in comparison with Elsevier. Single volumes of Elsevier should certainly find their way into specialized collections and to the desks of practicing chemists, especially those working in fields which have been very active in the last thirty years.

We American organic chemists must be eternally appreciative of our foreign colleagues who undertake these monumental tasks so successfully.

W. A. MOSHER

Fundamental Processes of Dye Chemistry. By HANS EDUARD FIERZ-DAVID AND LOUIS BLANGEY, Eidgenössische Technische Hochschule, Zürich. Translated from the Fifth Austrian Edition by Paul W. Vittum, Eastman Kodak Company, Rochester, New York. Interscience Publishers, Inc., 215 Fourth Avenue, New York 3, N. Y., 1949. xxix + 479 pp. 57 figs. 15.5 × 23.5 cm. Price $9.50.

This book is an excellent translation of the fifth Austrian edition of "Grundlegende Operationen der Farbenchemie" (1943) which constitutes a revision and extension of the earlier Austrian editions. Its primary object, as stated by the authors, is to teach the fundamental principles of dye chemistry to the student and to serve primarily as a laboratory manual; they point out specifically that this book is not intended to compete with the more comprehensive books such as that of P. H. Groggins, "Unit Processes in Organic Synthesis" (1947). To this end, the material has been presented in a most successful manner so that it may be employed either as a text for systematic reading or as a laboratory reference manual.

The major portion of the book (279 of the 479 pages) is devoted to detailed procedures with discussion for the laboratory preparation of dye intermediates and the finished dyes. Many of the examples are taken from industrial practice and much of the descriptive material will be of immediate value not only to the student of dye chemistry but to those chemists interested in unit operations. This includes a discussion, with examples, of the numerous available methods for introducing into the aromatic nucleus the sulfonic acid, nitro, hydroxyl, amino, alkoxy and halogen groups; also a brief treatment of oxidation and reduction reactions with procedures. It provides the student with an excellent appreciation of the many possible routes leading to a single dye intermediate, and furthermore alerts him to the fact that the most direct or the least expensive process from the chemical standpoint is often not the best one when all factors are taken into consideration. The established process may, for example, employ less direct methods in order to avoid producing isomeric or other undesirable products; or excessive corrosion or expensive equipment may rule out what otherwise might be considered a good laboratory process. In this respect the authors are very prone to weigh and compare the laboratory procedures with the industrial operations, and, in fact, one complete chapter (III) is devoted to technical details covering such subjects as vacuum distillation in the laboratory and in the plant, the construction and use of autoclaves, factory management and methods for computing cost calculations for production of a simple dyestuff.

The analytical section provides a treatment of methods employed in dye chemistry and is followed by a most instructive discussion dealing with the determination of the constitution of unknown commercial dyes; also references to published works which have become accepted as basic standards in the dye industry.

One of the main features of this book is the schematic arrangement of approximately six hundred compounds in twenty-one tables. A genetic system is used and clearly presents the general steps involved for the production of dyes and their intermediates from the basic coal tar products. The usefulness of these tables is further increased by cross references to one another and to details of the reactions described in the text, and in some instances to the original literature. In the reviewer's opinion the scope of the book would have been increased appreciably had many more references, especially to patents, been included.

Chapter VI dealing with light fastness of dyes is not so thoroughly treated as the other sections of the book. It seems unfortunate also that less than two pages are devoted to the phthalocyanin class of dyes which have proved so valuable because of their excellent stability to light and

washing. However, the broad scope of the book and the clear manner in which the material is presented makes it most valuable to the beginner whose primary concern is that of learning the basic principles of dye chemistry.

WILLARD D. PETERSON

Colloid Science. Volumes I and II. By A. E. ALEXANDER AND P. JOHNSON. Oxford University Press, 114 Fifth Avenue, New York 11, N. Y. (Oxford at the Clarendon Press.) April 14, 1949. xx and viii + 837 pp. Illustrated. 15.5 × 24.5 cm. Price, $15.00 the set.

This book aims to be intermediate in level between the elementary textbook and the specialized monograph and to give especially the newer methods. A review of the topics discussed will indicate what the book is about and what two young workers in one of the most active centers of colloid research think colloid science is now and is about to become.

The book is divided into three parts. Part I gives in five chapters a general survey with a history of colloids, a review of the present status, thermodynamics with some applications to colloid problems, and the theory of the electrostatic interaction of ions. In Part II, fourteen chapters are devoted to experimental methods: determination of composition and solvation in particular, osmotic equilibria, sedimentation equilibria, translational diffusion, sedimentation, velocity, electrophoresis, viscosity, rotational diffusion, scattering of light, X-rays and electrons, plasticity and elasticity, insoluble monolayers, adsorbed films at fluid interfaces and liquid–solid interfaces. Part III, with nine chapters in a separate volume, discusses the specific colloidal systems: dilute suspensions and sols, gels and pastes, foams, emulsions, colloidal electrolytes, clays and zeolites, proteins, polymers, and membranes.

The index at the end of Volume II is only a third as long as the Table of Contents at the beginning of Volume I. References are given at the end of each chapter. There are about seven hundred, but many of these are duplications, especially among the forty references to books.

As a result of this division and of the disregard of any shortage of paper, a topic may be discussed in any part or in all three of them, and the index is quite inadequate to follow the discussion. For example, the Flory–Huggins theory comes up under thermodynamics, osmotic pressure and high polymers, but I could not find it in the index.

Very few errors have caught my eye, none of them typographical. One glaring error is in equations 4.81 to 4.83 which appear to violate the law of conservation of mass as well as those of thermodynamics.

The use of this book for teaching will be greatly restricted by the authors' decision to pass lightly over surface chemistry since it is well treated elsewhere. There are other omissions which seem important to this reviewer. The treatment of adsorption stops before Brunauer–Emmett–Teller. The discussion of X-rays gives most space to single crystals although they are not of great importance to colloid science. The treatment of the osmotic pressure of proteins overemphasizes the importance of membrane potential at the expense of both the empirical extrapolation of P/C as for non-aqueous solutions and the exact thermodynamic treatment. The electrostatic treatment makes no mention of Kirkwood's treatment of ions which lack spherical symmetry.

One of the important contributions of a book of this kind is to consider many diverse phenomena from a uniform and consistent point of view. In this book we find none of the occultism or of the inferiority complex of many of the older colloidal chemists. Colloid Science does not claim to be an isolated system, but is a branch of Physical Chemistry which merges gradually with the many other branches.

The authors have not always succeeded in carrying their treatment back to fundamentals. For example, there is no indication in the electrostatic theory that the treatment is limited to spherical symmetry; and the treatment of surface omits the fundamental relation upon which the measurement of surface tension depends. However, it is clear that the authors have tried hard to unify Colloid Science as a true science, and they have succeeded much better than most writers on colloids. The book will be a very useful addition to any reference shelf.

GEORGE SCATCHARD

The Chemical Arts of Old China. By LI CH'IAOP'ING. Professor of Chemistry, National Northeastern University, Mukden, China, with a Foreword by Tenney L. Davis. Published by Journal of Chemical Education, Easton, Pennsylvania, 1948. viii + 215 pp. Illustrated. 15.5 × 23.5 cm. Price, $5.00.

It is probably safe to say that the knowledge of the average American chemist of the chemical arts of China is limited to the discovery of gunpowder and the manufacture of porcelain. It is therefore of especial interest to find so extended and detailed a record of the Chemical Arts of Old China as recorded by the author in this book.

Following quite an extended account of the alchemy of ancient China wherein the desire to acquire the "Elixir of Life" or Immortality seemed to predominate over the desire to produce gold and silver, called the "Art of Yellow and White," the author reviews the following topics: METALS AND ALLOYS.—Here is discussed the smelting and refining of silver, copper, zinc, iron, including steel, tin and lead. SALT.—The driving of wells, the evaporation of the recovered brines and that of sea-water. CERAMICS.—The author naturally gives much space to the description of the porcelains of the various Dynasties, and to the reviewer, unacquainted with the different porcelains of old China, this chapter makes most interesting reading. The porcelains of the Sung Dynasty (960–1126) and the Ming Dynasty (1368–1544) seem to be regarded as outstanding. LACQUER AND LACQUERING.—This work is done with the sap of *Rhus vernicifera*. The processes of both the flat and carved work is described. GUNPOWDER.—The author makes out a good case for China as the originator of gunpowder and places it at the time of the Sung Dynasty (960–1126). Still earlier in various internal revolutions fire weapons called "thunder caps," "fire-arrows" and "fire-balls" had been used. The author states that the gunpowder used at the battle of Crëcy (1346) and Augsburg (1353) were later than the time of the Chinese invention in the 12th century. COLORS AND DYES.—This chapter includes the processes of making Chinese ink, lamp-black, vermilon, white and red-lead, stamp-ink, indigo and sufflower. VEGETABLE OILS AND FATS.—The author tells of methods of extraction of essential oils, the production of rouge and face-powders dating back to 1100 B. C.! Other chapters discuss Sugar, Paper, Leather and Glue, Soybean Products and Alcoholic Beverages and Vinegar.

The book is illustrated by many fine line drawings in the Chinese style depicting the processes described; it is unique in subject and style, well printed and will be an addition to the History of Chemistry.

H. MONMOUTH SMITH

The Problem of Reducing Vulnerability to Atomic Bombs. (A Report Prepared for the Committee on the Social and Economic Aspects of Atomic Energy of the Social Science Research Council.) By ANSLEY J. COALE. Princeton University Press, Princeton, N. J., 1947. 116 pp. 14 × 21 cm. Price, $2.00.

In the present plethora of works on the atomic bomb, this sound and solid study of the Committee amounts to a valuable touchstone with which may be tested the validity of many of the statements now being made and the speculations offered as to the employment of the bomb. Often

it seems to elude writers that proposing defenses against the hurtful effects of nuclear fission is analogous to proposing defenses against the operation of gravity. The bomb admits of no genuine defense and restricts all such efforts to what Mr. Coale calls "the problem of reducing vulnerability." Under this proper description, Mr. Coale, with the collaboration of Committee members, canvasses the possibilities of political agreement and of attack prevention. He discusses measures which may be taken before and after bombs are exploded. In extremely small compass this book covers a vast range of material. Its striking and useful purpose lies in its careful organization. It raises far more questions than it offers to solve and in so doing makes clear that all glib and over-simplified atomic bomb "defense" proposals must be regarded with high suspicion.

RUSS SYMONTOWNE

Surface Active Agents. Their Chemistry and Technology. By ANTHONY M. SCHWARTZ, Harris Research Laboratories, Washington, D. C., and JAMES W. PERRY, Massachusetts Institute of Technology, Cambridge, Massachusetts. Interscience Publishers, Inc., 215 Fourth Avenue, New York 3, New York. 1949. xi + 579 pp. Illustrated. 15.5 × 23.5 cm. Price, $10.00.

Surface active (S. A.) agents are those which, in the authors' words, "have the startling property of altering the surface energy of their solvents to an extreme degree," even when present at low concentrations. The oldest, most familiar and still the most important is soap, but many hundreds of synthetic S.A. compounds have been described within the past twenty years and, to the reviewer's knowledge, this is the first book adequately to cover the subject. The authors have done a splendid job with a difficult assignment.

This book has been limited in scope to S.A. compounds other than soap (soap is discussed very briefly) and their behavior in dilute solutions. Aqueous solutions are, naturally, emphasized almost to the exclusion of others. The book is divided into an introduction and three major parts which cover, respectively, general considerations and classification, synthesis and manufacture, physical properties of solutions and industrial applications.

In the introductory part (18 pp.), S.A. compounds are classified as far as possible on the basis of the ionic character of the hydrophylic group, which leads to the three familiar and logical designations of anionic, cationic and non-ionic compounds. In addition, the authors have quite logically put ampholytes in a fourth class and have included two others which do not fit into the general scheme: water-insoluble emulsifiers (*e. g.*, monoglycerides) and compounds useful in non-aqueous systems (*e. g.*, lubricant additives). Further breakdown is, first, on the basis of the "connecting link," *i. e.*, the atom or group(s) which connect the hydrophylic to the lipophylic portion of the molecule. For example, we have: I. Anionics, B. Sulfuric Esters (Sulfates). 1. Sulfate joined direct to hydrophobic group, a (Simple types such as alkyl sulfates).

Part I (212 pp.) covers the organic chemistry of S.A. compounds—preparation, properties and manufacture—the discussion being arranged as far as practicable to conform to the order of the classification outline in the introduction. Coverage is adequate and complete, and is conspicuously well done when one considers that, except for patents, there is next to nothing in the way of pertinent original literature. In such a situation, it is almost impossible to avoid endowing some types, which have been described but never used, with unwarranted importance, but on the whole the commercially successful types have been singled out for especial mention and others thereby relegated to their proper perspective. For example, the table on page 126 lists 15 aromatic nuclei and 23 alkyl side-chain sources without pointing out that the keryl and tetrapropenyl benzenes probably account for more production than all the rest put together. On the other hand, the inclusion in the text of trade names and their identification for the most part with the proper active ingredient types (Oronite detergent, p. 123 is one conspicuous exception) tends to emphasize the commercially important compounds and to make the discussion correspondingly more useful. Other features of this section illustrate the careful job the authors have done. For example (p. 153), it is emphasized that cationics have been developed largely for applications where their surface activity is of only secondary importance. Again, description of the important fatty monoglyceride sulfate manufacturing process (p. 71) serves to emphasize this ingenious procedure over the usual sulfation methods theoretically applicable to monoglycerides.

Part II (153 pp.) deals with the physical chemistry of aqueous solutions of S.A. compounds in discussions which are lucid and readable. Here the authors have access to a considerable body of original literature and their coverage is remarkably complete. The collection and coördination of published work on detergency, foaming and other interfacial effects serves a very useful purpose, especially since it is handled in such a realistic manner. For instance, it is repeatedly emphasized that, even though our knowledge of S.A. solution properties has increased enormously in recent years, our understanding of the many complex factors involved in detergency is still far too limited to allow us to make useful performance tests out of any measurements short of actual washing experiments.

Part III (120 pp.) is an interesting discourse on industrial applications of S.A. agents. By the authors' own statement, application patents are not covered completely, but this is a recommendation rather than a criticism and the section is on the whole well done.

Even with the authors' careful handling of their material, some inaccuracies have inevitably crept in, but for the most part they are of minor importance. Mono- and diethanolamines are said to give predominantly amides in reacting with F.A. (p. 182); actually their behavior should be contrasted, since diethanolamine gives mostly ester. The statement that soap shampoos are still the most widely used (p. 444) is misleading, since certainly of products sold as shampoos, synthetic-base products make up the large volume. This reviewer will emphatically take issue with the statement (p. 444) that ". . .such irritating effect (of coconut oil soap) has been traced, *with a high degree of certainty*, to the presence of C_8 and C_{10} fatty acids. . . ." Nonyl naphthalene sulfonate (p. 124) is hardly in a class with the good alkyl benzene sulfonates as a detergent. Isobutene polymers have not proved very suitable for alkylating benzene (p. 125) to form good surface-active compounds. On the other hand, certain other reports from the literature are handled with discrimination. For instance (p. 373) "rosin soap is by itself a poor detergent, but up to 50% can be incorporated into fatty acid soaps without seriously impairing the detergency of the latter"—a very good summary of the situation.

The book as a whole is well set-up, printing is good and no typographical errors have been noted. Indexing is good, which enhances the volume's value as a reference. In short, it is a pleasure to recommend this volume to anyone interested in the subject.

N. B. TUCKER

The Structure of Matter. By FRANCIS OWEN RICE, Professor of Chemistry, The Catholic University of America, and EDWARD TELLER, Professor of Physics, The University of Chicago. John Wiley and Sons, Inc., 440 Fourth Avenue, New York 16, N. Y. (Chapman and Hall, Ltd., London) 1949. xiii + 361 pp. 15.5 × 23.5 cm. Price, $5.00.

In this book the distinguished authors have boldly attempted to describe in words a very extensive range of applications of quantum mechanics with only the barest recourse to mathematics. The topics covered include atomic structure, chemical binding, the solid state, mag-

netic and dielectric properties of matter, molecular vibrations, electronic spectra, nuclear chemistry and even the state of matter in stars. All of these topics are treated in a very original manner, using qualitative statements based on various quantum-mechanical generalizations.

This reviewer found the book profitable reading and believes that there are few who would not likewise at least acquire useful new viewpoints from it. The attack on the subject is tremendously ambitious and the scope covered is very great.

Nevertheless, it is a little difficult to decide upon a class of reader for whom it can be recommended without qualification. It is obviously intended for readers not prepared to undertake the study of the mathematical basis of quantum mechanics. This is a hard task and one should not expect perfection in any such enterprise. It must be reluctantly confessed, however, that this reviewer does not like the general approach which was used. It seems too dogmatic, too ready to jump into rather glib word-explanations of complicated phenomena without a proper discussion of fundamentals, too lacking in clear definitions of concepts or precise statements of basic hypotheses. The reader is not, for the most part, presented with evidence in support of statements made. Although it is not always feasible to present a clean-cut mathematical derivation from definitely stated hypothesis to carefully worded conclusions, it would seem that the basic hypotheses, the results and the experimental comparisons should be given.

It appears doubtful that the reader who cannot even be exposed to the Schrödinger equation is going to be able to grasp the concepts of "coulomb and exchange integrals" introduced on p. 73 without any real explanation, to pick just one example. These are likely to remain mere words, perhaps memorized and repeated back to the teacher, but carrying no useful meaning.

It can be argued that the proper way to introduce the non-mathematical reader to the results of quantum mechanics is the conventional one of using the experimental approach. The observed facts of electron diffraction, spectroscopy, chemical valence, etc., provide a credible framework upon which to hang underived statements of the results of quantum mechanical calculations, but even then much discussion of the nature of the fundamental postulates is desirable and a very definite distinction between those conclusions which follow rigorously from the postulates and those which involve approximations of untested validity.

It is unfortunate that these criticisms seem necessary, because the authors have carried out a really remarkable translation of a vast variety of deductions into word pictures. It is certainly highly desirable for theoretical scientists to uncover the physical meaning of each stage of their mathematical derivations.

In summary, it may well be that this book will be most useful for those who have previously been exposed to some mathematical treatment of quantum mechanics and can, therefore, view the word pictures in the proper perspective. Such readers are sure to learn something new from this challenging work.

The Low Temperature Heat Capacity of Columbium Nitride[1,2]

BY GEORGE T. ARMSTRONG[3]

Measurements of the thermodynamic properties of superconducting materials and of the effect of magnetic field upon them have provided a valuable tool for the study of the nature of the superconducting state. Heat capacity measurements have previously been made at low temperatures on the elements tin,[4] thallium[5] and tantalum,[6] alloys of tin with bismuth,[7] lead with bismuth[8] and of lead with thallium.[9] No measurements have been reported on any superconducting compound. The existence of columbium nitride with a transition temperature near 15°K. provides an opportunity for the study of the heat capacity of such a compound in a region which can be reached with liquid hydrogen. The only previous heat capacity measurements on this substance were reported by Sato and Sogabe[10] above 0°. On the basis of their work Milton[11] estimated the low temperature heat capacity. This is a report of the measurement of the heat capacity of columbium nitride between 11 and 21°K. in the absence of magnetic fields and in the presence of fields up to 1000 gausses.

Materials

The columbium nitride, CbN, which was used in the measurements was prepared by roasting columbium metal powder of 400-mesh size or finer in an atmosphere of nitrogen for twelve hours at 1300°. The time was somewhat longer than that used by Horn and Ziegler[12] and this may account for the fact that the product has a somewhat higher nitrogen content than was reported by them. The columbium metal was obtained from the Fansteel Metallurgical Corporation and was reported to have impurities present only as traces of less than 0.1%. The nitrogen used was a prepurified grade containing not more than 0.002% each of oxygen and hydrogen. The product of the reaction was gray with a distinct yellowish tinge. X-Ray examination showed only the sodium chloride lattice, with no evidence of any other structure. The gain in weight in preparation indicated 48.1 mole per cent. nitrogen, while an analysis by the Dumas method performed by a commercial analyst indicated 49.1 mole per cent. nitrogen.

Apparatus and Methods

The Cryostat.—The general plan of the cryostat is conventional in most respects. The calorimeter is shielded from the influences of room temperature by being immersed in a liquid hydrogen-bath which in turn is contained in a dewar of nitrogen. Figure 1 shows a cross section view of the hydrogen chamber and its contents and the location of the magnetic field solenoid (j). The hydrogen can (e) is suspended from a circular brass plate bolted to the lid of the german silver nitrogen dewar. It consists of a supernickel tube two inches in diameter fitted with spun metal top and bottom. Supernickel tubes from above are hard soldered to the top. These tubes are: (a) a half-inch filling tube, which is also the pump line for reducing the pressure of hydrogen vapor, (b) a quarter-inch tube which goes through the top and extends to the calorimeter shield below, used for high vacuum pumping, (c) an eighth-inch tube extending to the manometer for

(12) Horn and Ziegler, THIS JOURNAL, **69**, 2762 (1947).

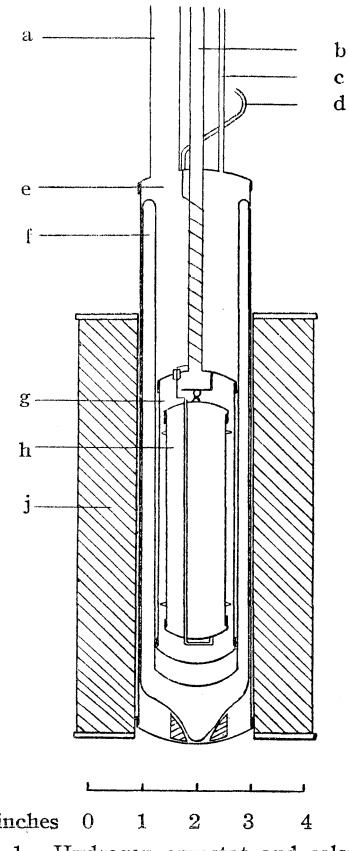

Fig. 1.—Hydrogen cryostat and solenoid.

hydrogen vapor pressure measurement, (d) a sixteenth-inch tube carrying six no. 40 copper wires for the calorimeter. The cover with its attached tubes is removable to permit access to the calorimeter.

Inside the hydrogen can is the glass hydrogen dewar (f). Its diameters are such that there is little clearance between it and the can outside or the calorimeter chamber inside. The dewar contains about sixty cubic centimeters of hydrogen above the calorimeter chamber and this is sufficient to permit operation for approximately four hours before refilling is required. The only advantage of the small volume is that it permits rapid passage through the triple point of hydrogen.

Suspended from the hydrogen can cover by the quarter-inch supernickel tube is the calorimeter chamber (g). This is of 1.25-inch supernickel tubing with spun covers. Access to the interior is obtained by unsoldering the upper cover, to which all attachments are made. To prevent radiation leakage from above striking the calorimeter inside, a baffle of copper is placed so as to cover the opening of the high vacuum line. This baffle provides a convenient point from which to suspend the calorimeter (h). Because the calorimeter chamber must be capable of evacuation to 10^{-6} mm. of mercury, all necessary precautions must be taken to ensure tightness when it is assembled. The electrical leads are brought in through glass buttons sealed in kovar and having a kovar center conductor. The tube carrying the wires ends at the top of the hydrogen can, and the wires are then wrapped on the high vacuum tube to provide additional length in the hydrogen-bath before passing into the calorimeter chamber.

The Calorimeter.—The calorimeter consists of a tube of supernickel of 0.020-inch wall thickness, one inch in diameter and four inches long, with top and bottom spun from sheet metal. The top is silver-soldered in place, but the bottom is soft soldered and is removable. The calorimeter is wound non-inductively with 300 feet of no. 38 gold wire lacquered carefully in place, which is used both as a resistance thermometer and as a heater. Two copper leads are soldered to each end of the resistance element. In order to get increased length in spite of the very small space available, the wires are led once around the long dimension of the calorimeter before going to the glass insulators. In circling the calorimeter the wires are contained in a very thin wall capillary tube of glass to prevent them from touching either calorimeter or shield. The glass is mounted on small drops of a cement made of water glass and talc. Additional tiny pyramids of this same cement are used as spacers to keep the calorimeter from touching the shield. As a result of the precautions described here, the heat leak into the calorimeter was found to be approximately 0.004 calorie per minute per degree difference in temperature. The completed calorimeter weighs 58 g. and has a volume of 50.5 cc.

The choice of supernickel for construction of the calorimeter was in part suggested by factors of convenience and compactness of assembly made possible by its use. It should be noted that although supernickel is not ferromagnetic, its composition is rather close to that for which ferromagnetism occurs among copper nickel alloys at low temperature, and so it should be used with caution where small magnetic effects are to be observed. This fact does not appear to have had any effect upon the present work, but should be borne in mind in considering other applications of the material.

Temperature Control and Measurement.—For control of the hydrogen-bath temperature a Cenco Megavac pump is used, the pumping speed being regulated by means of valves. Approximately constant hydrogen pressure is secured by the use of a regulator similar in design to one described by O'Gorman.[13] This does not provide absolutely constant pressure, nor does it have sufficient flexibility to permit control at all hydrogen pressures, so that other valves must be used with it. The pressure regulation is sufficiently good to permit heat capacity measurements for periods up to an hour without adjustment.

The vapor pressure of the hydrogen-bath was used as the temperature standard. The vapor pressure equation of Simon[14] was used for temperatures below the triple point and that of Henning and Otto[15] was used from the triple point to 21°K. The vapor pressure was calculated from these equations for every tenth of a degree and observed temperatures were calculated from observed pressures by linear interpolation between these values. For the purpose of calibration of the gold resistance thermometer the hydrogen vapor pressure is indicated by a large bore manometer from which a small tube runs directly to the hydrogen chamber. The absence of any pumped gases in this line ensures that there is no pressure gradient due to flow of hydrogen. A value of $g = 980.103$ cm. sec.$^{-2}$ for Baltimore was used and corrections were made for temperature changes in the glass and the brass scale in all measurements of pressure. The calibration data of the resistance thermometer was smoothed according to well-known procedures and the value of dR/dT was evaluated at intervals of one-tenth degree by numerical differentiation of the smoothed data. Values of T and dR/dT corresponding to observed values of resistance were obtained by linear interpolation between the tabulated values.

Measurements of thermometer resistance were made using the White potentiometer arrangement described by Ahlberg, Blanchard and Lundberg.[16] The thermometer resistance is 18.084 ohms at 20.40° and 15.667 ohms at 11.00°K. The value of dR/dT is 0.450 ohm deg.$^{-1}$ at 20.40° and diminishes nearly linearly to 0.0800 ohm deg.$^{-1}$ at 11.00°K. Although no special calibration of the resistance thermometer was made in magnetic field, sufficient evidence is contained in the original measurements to show

that any change produced by a field of 1000 gausses is not larger than the order of magnitude of 0.01°K.; so that there is little possibility that an appreciable error has resulted from this source.

Time Measurement.—In order to minimize the number of operations to be performed in each experimental heat capacity determination, so that one person could handle them all, and to increase the accuracy of time measurement, the heating intervals were mechanically controlled. The time standard was a General Radio precision 100 cycle per second tuning fork, the output of which was used to activate a two-decade electronic counter. The electronic counter operated a stepping relay at one-second intervals. The stepping relay was connected to the heating circuit in such a way that it would close the heating circuit on one count and open it an integral number of seconds later. The length of the heating period could be adjusted to multiples of 10 seconds, with an error not greater than 0.01 second.

Magnetic Field.—The magnetic field was generated by a solenoid in which size and weight were reduced to a minimum by designing it to fit in the annular space around the hydrogen can, within the nitrogen chamber. In order to give a reasonably uniform field over the length of the calorimeter the solenoid was made nearly twice the length of the calorimeter. Twenty thousand turns of no. 25 B. and S. gage enamelled wire were used. The resistance was 640 ohms at room temperature, but diminished to 80 ohms when cooled in nitrogen. A field of 1000 gausses could be achieved with a power dissipation of 50 watts which resulted in the boiling away of nitrogen at the rate of about a liter per hour. The strength of the field was measured with a search coil calibrated by the U. S. Bureau of Standards. Calibration of the field strength was made under conditions as nearly resembling the actual experimental conditions as possible. Because of the possibility of ferromagnetism at low temperatures in the copper–nickel alloys used in the construction of the cryostat, the field was measured with the search coil enclosed within two supernickel cans at 11°K. The calibration under these conditions was the same as in the absence of any supernickel containers, so it may be concluded that the materials used in the cryostat do not shield the contents of the calorimeter from the magnetic field. The uniformity of the field was such that at the ends of the calorimeter the field was 5% less than at the center. The values of magnetic field listed in the experimental work are those measured at the center of the calorimeter.

Heat Capacity Measurement.—A heat-capacity determination was made in the following way. The temperature of the calorimeter was recorded at one-minute intervals during a fore-period of about six minutes to determine its rate of drift. The heating period was then begun and amounted generally to one hundred and fifty seconds. After the heating current was shut off the temperature drift of the calorimeter was observed during an after-period of eight or ten minutes. The time elapsed between the last point of the fore-period and the first point of the after-period was three minutes. The resistances during the fore- and after-periods were extrapolated to the center of the heating period. The change in temperature caused by the heating was taken from the difference between the resistances at this point, and the heat input was computed using their mean value as the resistance of the heater.

For measurement of the heat capacity of the columbium nitride, the calorimeter was filled with 182.21 g. of material. In order to secure rapid thermal equilibrium throughout the sample, the interstices were filled with helium gas to a pressure of one atmosphere at room temperature. A small correction was added to the heat capacity of the calorimeter because of the heat capacity of this gas.

Experimental Results

The heat capacity of columbium nitride in the absence of magnetic fields was determined principally on two different days. Table I shows smoothed values for this data at intervals of 1°K. Measurements in magnetic fields were made with slight variations in procedure during different runs. The first series was made in the following way. The calorimeter was brought to the desired temperature and then the field was applied only during the course of the measurements. In this way one set of measurements was made in which the temperature was varied but the magnetic field was 500 gausses for each point. Another set of measurements was made in which for each of several magnetic fields the initial temperature of the calorimeter was the same or nearly so. A group of measurements of this type was made at a number of temperatures both below and above the superconducting transition temperature, including magnetic fields of 250, 750 and 1000 gausses. In some cases a point at 0 field and at 500 gausses was taken to provide a check on the consistency of data taken on different days. The purpose of taking measurements in this way was to provide information about the behavior of the heat capacity at constant temperature as a function of magnetic field strength. One particularly complete group of measurements of this type was made near 11° including ten values of the field between 0 and 1200 gausses.

TABLE I

HEAT CAPACITY OF COLUMBIUM NITRIDE IN THE ABSENCE OF MAGNETIC FIELDS

T, °K.	C_p (cal. deg.$^{-1}$ mole^{-1})	T, °K.	C_p (cal. deg.$^{-1}$ mole^{-1})
11.00	0.0390	16.00	0.0848
12.00	.0468	17.00	.0983
13.00	.0612	18.00	.1123
14.00	.0791	19.00	.1300
15.00	.0874	20.00	.1535

In order to satisfy certain questions concerning the interpretation of the data obtained in the presence of a magnetic field, an additional series of measurements was made on July 9 in a field of 1000 gausses, in which the field was applied before the calorimeter was cooled below the transition temperature. The field was not turned off during the whole series of measurements.

Discussion of the Results

The experimental data are plotted in Fig. 2. A smooth curve has been drawn through the points determined in the absence of magnetic fields. These points have a mean deviation of 0.7% from the curve. This curve shows an anomaly between 14.7 and 15.3°K., in which the heat capacity decreases as the temperature rises. This anomaly is in the region in which the transition to superconductivity of columbium nitride is commonly found. Although all previous work on the heat capacities of superconductors has shown a sharp discontinuity at the transition temperature, the present work indicates that the anomaly of columbium nitride is spread over a range of 0.6° and is a smoothly rounded hump. It has been observed

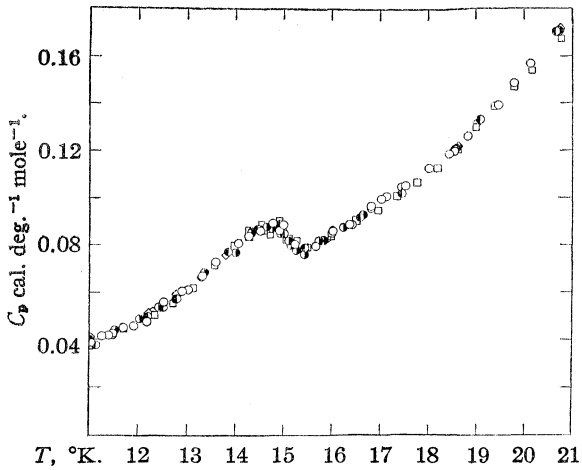

Fig. 2.—Field 0, O; 250, ◐; 500, □; 750, ◇; 1000, ◑.

in this Laboratory that powdered samples of columbium nitride prepared in different batches show slightly different transition temperatures, and that for a single batch the transition studied by an induction method occupies several tenths of a degree. A reasonable explanation of the rounding of the anomaly and its width is a variation of transition temperature in various parts of the sample; the possibility that the width of the anomaly would be characteristic of even the most homogeneous sample may not be completely ignored.

If the curves above and below the anomaly are extrapolated to 15°K., their difference at this point is 0.023 cal. mole^{-1}. If this difference be interpreted in terms of the Rutgers formula

$$\Delta C = (VT/4\pi)(dH/dT)^2$$

a value of the slope (dH/dT), of the critical magnetic field needed for quenching superconductivity is found to be 257 gausses per degree.

No true measurements of the critical magnetic field have been reported for columbium nitride.[17] The only comparison which can be made is with some unpublished data of S. J. Socolar which merely indicates that fields less than 300 gausses per degree below the transition temperature were insufficient to produce resistance in a superconducting ribbon. The near agreement of these two figures appears to be quite accidental on the basis of the measurements of heat capacity in the presence of a magnetic field.

A graph of C_p/T *versus* T^2 for points below the transition temperature in the absence of fields gives a straight line passing through the origin, (Fig. 3), from which the Debye θ may be calculated to be 253° from the approximate equation

$$C_p/T = 464T^2/\theta^3$$

(17) It has just come to the writer's attention that Ascherman, Friedrich, Justi and Kramer [*Physik. Z.*, **42**, 349 (1941)], measured the magnetic threshold field slope for restoration of resistance of columbium nitride to be approximately 6500 gausses per degree, near the normal transition temperature. This value is not inconsistent with the calorimetrically observed changes in transition temperature herein reported.

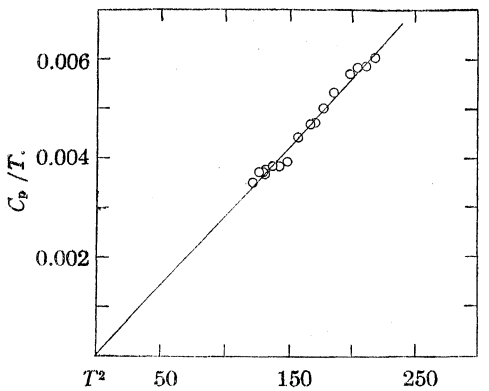

Fig. 3.

The striking fact about the measurements in magnetic fields is the close similarity of the data in every case. The changes in heat capacity either above or below the anomaly are so small that one cannot with certainty say they are greater than would be produced by experimental errors. A graph (Fig. 4) of the data in Table II for 11° shows a slight trend of the heat capacity upward with increasing magnetic field. The change in heat

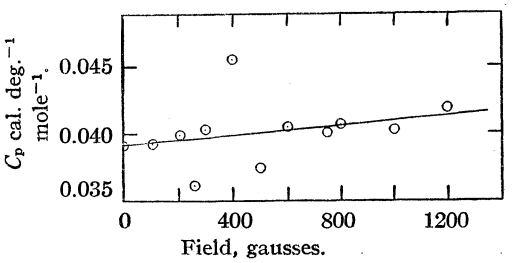

Fig. 4.

capacity between 0 and 1200 gausses is less than the fluctuations between separate points, so that only a qualitative statement of the direction of the change is justified.

TABLE II

HEAT CAPACITY AT 11°K.

H (gausses)	C_p (cal. deg.$^{-1}$ mole^{-1})	H (gausses)	C_p (cal. deg.$^{-1}$ mole^{-1})
0	0.0391	500	0.0374
100	.0392	600	.0405
200	.0399	750	.0400
250	.0361	800	.0406
300	.0403	1000	.0398
400	.0455	1200	.0418

The temperature of the anomaly is only slightly shifted, although according to the simple thermodynamic treatment of the transition in superconductors one would expect from the magnitude of the anomaly that the transition would be about 4° lower in a field of 1000 gausses. The observed change in the transition temperature appears not to exceed 0.20°, corresponding to a critical magnetic field slope of 5000 gausses per degree. This should be considered only as an order of magnitude in view of the fact that the experimental er-

ror in the points near the transition, as indicated by their spread, is not much smaller in magnitude than the change described.

No positive indication of any latent heat of transition in the magnetic field was found. An irregularity in the data in a field of 500 gausses might be attributed to this source, but since it does not appear again at higher fields, the possibility diminishes that it is evidence of a latent heat.

Investigations of tin[4] and thallium[5] bear out the validity of Rutgers' formula for predicting the discontinuity of specific heat of soft superconductors, for which the magnetic field which first penetrates the body of the material also restores the resistance. Studies of metals for which penetration begins at a much lower field than that required to restore resistance have also been made. Mendelssohn and Moore[9] observed that the heat capacity of an alloy of lead and thallium does not show such a large jump as that predicted on the basis of the field needed to restore resistance. Their measurements were not precise enough to indicate whether a smaller discontinuity existed. Shubnikov and Chotkevitch[8] made a similar observation on an alloy of lead and bismuth. Keesom and Desirant[6] observed that the change in heat capacity of tantalum at its transition temperature corresponds to a much lower critical field slope than is indicated by the depression of the temperature of the calorimetrically observed transition in a magnetic field. They found that the calculated dH/dT corresponds nearly to the threshold field which first penetrates the specimen, while the temperature of the anomaly is more nearly that at which resistance is restored by a given magnetic field.

The powdered columbium nitride used in these measurements has a behavior similar to tantalum in that the lowering of the transition temperature in magnetic field cannot be predicted from the magnitude of the anomaly. Unfortunately, the strength of magnetic field necessary to penetrate CbN has not been measured as a function of temperature, so that it is not possible to compare the slope of this function with that calculated from the calorimetric data by Rutgers' equation.

Because of the resemblance of the thermal properties of CbN to those of alloys and of tantalum, the possibility was considered that some hysteresis phenomenon might cause a difference in the heat capacity observed when the sample is cooled through the transition in the presence of a magnetic field from that observed when the field is applied only below the transition temperature. The data of July 9 were taken with this in mind. No difference is observable in the heat capacity measurements using the different procedure.

In view of the lack of data on the penetration of columbium nitride and the restoration of its resistance by magnetic fields, it is not possible to say whether this compound may behave in other ways like a hard superconductor or an alloy. In any attempt to account for its observed behavior it is reasonable to question whether this behavior is due to the lack of stoichiometric proportions in the sample of the compound used here, or to the small size and irregular shape of the particles, or whether the observed behavior is characteristic of the pure compound in bulk.

Summary

The heat capacity of columbium nitride has been determined in the temperature range from 11 to 21°K. An anomaly of 0.023 cal. mole^{-1} occurs at 15°K., and may be associated with the transition to superconductivity. The effect of magnetic fields of 250, 500, 750 and 1000 gausses is very small both on the magnitude of the heat capacity and the change in temperature of the anomaly. No latent heat of transition was observed.

Kinetics of the Decomposition of Ethyl Xanthic Acid

BY ALFRED CHATENEVER AND CECIL V. KING

The rate of decomposition of various xanthic acids was first studied in detail by V. Halban and Kirsch,[1] who tried to correlate the rates with dielectric constant and other properties of the solvents used. Later V. Halban and Hecht[2] studied the decomposition rates of potassium methyl and ethyl xanthates in aqueous hydrochloric acid at 0°. They found that these xanthic acids are not fully ionized, and assumed the reaction to be a unimolecular decomposition of the undissociated acid, though recognizing this to be kinetically identical with a bimolecular reaction between hydrogen and xanthate ions.

The decomposition of ethyl xanthic acid in dilute aqueous buffers has been studied by King and Dublon.[3] It was shown that there is little or no salt effect on the rate in acetic acid–sodium acetate buffers of low ionic strength, since primary and secondary effects cancel; in aniline–anilinium ion buffers, on the other hand, there is a large primary salt effect.

The rate of decomposition of various xanthic acids in non-aqueous solvents has been studied in

(1) V. Halban and Kirsch, *Z. physik. Chem.*, **82**, 325 (1913).

(2) V. Halban and Hecht, *Z. Elektrochem.*, **24**, 65 (1918).

(3) King and Dublon, THIS JOURNAL, **54**, 2177 (1932).

this Laboratory by F. M. Lewis.[4] Free ethyl xanthic acid is quite stable in anhydrous benzene, and the catalytic effect of added substances is roughly proportional to their strength as bases.

In the present work the decomposition rate was studied with potassium ethyl xanthate in dilute acetic acid–sodium acetate buffers, with added dioxane from 0 to 60% by volume, at temperatures from 15 to 35°. The purpose of the work was to obtain the energy and other thermodynamic quantities of activation, to attempt to learn more about the mechanism of the reaction, and to test the applicability of the theories dealing with electrostatic effects on ionic reaction rates.

Experimental

In all the experiments reported here small weighed samples of solid potassium ethyl xanthate were dissolved in 60 ml. of solution containing 0.0848 *M* acetic acid and 0.0106 *M* sodium acetate. Rates were measured by following the evolution of carbon disulfide in an apparatus similar to that used previously.[3] Ground caps with mercury seals and no lubrication were used on the flasks, and a solenoid release mechanism served to drop glass capsules containing the xanthate. Measurements were made at 15, 20, 25, 30 and 35°, and the thermostat temperature was maintained constant to ±0.02°. The thermometer used was compared, at each temperature, with one calibrated at the Bureau of Standards.

Potassium ethyl xanthate was prepared by recrystallizing a commercial sample from alcohol until an aqueous solution of the dried salt was neutral to litmus. A sample synthesized in the laboratory gave identical rates.

Acetic Acid.—Sodium acetate buffers were made by partial neutralization of an appropriate solution of the acid with carbonate-free sodium hydroxide (standardized with potassium acid phthalate). The mixture was then diluted to volume with water or dioxane and water.

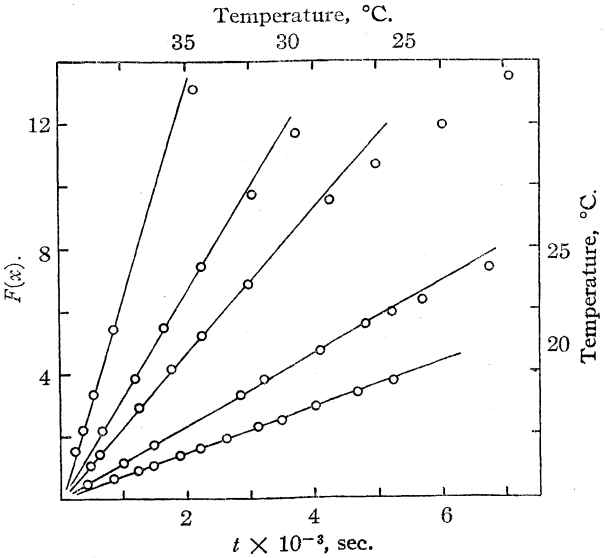

Fig. 1.—Time *vs.* $F(x) = (a + c) \log a/a - x - (b + c) \log b/b - x$; solvent 30% dioxane by volume.

Dioxane (dioxane-1,4) was purified by refluxing a commercial product with sodium until a fresh surface of the metal remained untarnished for several hours; a portion was then distilled just prior to use. The boiling point was 101.2°, in agreement with the data of Kraus and Vingee.[5] Some determinations were made using dioxane prepared by the more exacting method of Harned and Morrison,[6] with no appreciable difference in rate. Solutions were made with 10, 20, 30, 40, 50 and 60 ml. of dioxane per 100 ml. of solution, and weight per cent. values were obtained by interpolation using densities in the literature.[7]

Specific Rate Constants.—In acetic acid buffers the over-all reaction is essentially

$$\left[S{=}C\begin{matrix}OC_2H_5\\ S\end{matrix}\right]^- + HAc \longrightarrow CS_2 + C_2H_5OH + Ac^- \quad (1)$$

and the rate equation derived previously[3] may be written

$$k(\text{expt.}) = kK_0 = \frac{2.3}{(b-a)t}\left[(a+c)\log\frac{a}{a-x} - (b+c)\log\frac{b}{b-x}\right] \quad (2)$$

In this equation a, b and c are the initial molar concentrations of xanthate ion, acetic acid and acetate ion, respectively; $a - x$ and $b - x$ are values at the time t (in minutes), and the value of K_0 depends on the mechanism of the reaction (see below). The quantity in brackets (called $F(x)$ in Fig. 1) was plotted *vs.* time for each experiment and k(expt.) was evaluated from the slope. Typical plots are shown in Fig. 1, and while it is seen that there is some deviation as the reaction progresses, the linear relation is satisfactory over about 70% of the reaction.

Up to 30% dioxane the precision of k(expt.) is about ±3%. At higher dioxane concentrations the solubility of carbon disulfide increases, the pressure rise in each experiment becomes less, and the possible error in k becomes as high as ±10% in 60% dioxane. The concentration of potassium xanthate varied from one experiment to another, averaging about 0.009 *M*. Limitations of the apparatus made it difficult to use higher concentrations in order to increase the pressure rise in the apparatus.

The rate constants are summarized in Table I, each value being the average from two or more experiments. The dielectric constants D were interpolated from large plots of the data of Åkerlöf and Short.[8] The columns headed K_0 and k will be referred to later.

Several experiments were carried out with the addition of 0.025 *M* and 0.05 *M* sodium chloride to the solutions. Only at the highest dioxane concentrations was the effect on the rate greater than 3%, and it may be concluded that the constants given in Table I are essentially valid for zero ionic strength.

TABLE I

THE RATE CONSTANTS IN DIOXANE–WATER MIXTURES

[a] *k* in (moles/liter)$^{-1}$ (min.)$^{-1}$

Analysis of Results.—As seen in Table I, the addition of dioxane, changing the dielectric constant as much as from 82 to 28, has very little effect on the observed rate or on values of *k* (expt.). While the variation at each temperature is outside the precision of individual experiments, it is probably within the over-all experimental error, at least to 50% dioxane. The small effect of changing the solvent is not unexpected if activity coefficients involved in the rate expression cancel, although the dielectric constant effect on a reaction between an ion and a neutral molecule is probably usually somewhat greater.

Average values of *k*(expt.) at each temperature, up to 40% dioxane, may be expressed with a maximum deviation of about 5% by the equation

$$\log k(\text{expt.}) = 11.56 - 19{,}050/2.3RT \qquad (3)$$

where 11.56 is the Arrhenius frequency factor and 19,050 cal. is the activation energy.

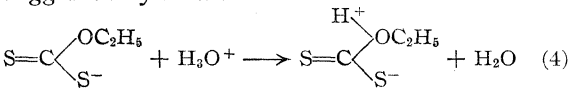
Mechanism of Reaction.—While the stoichiometric reaction is closely approximated by equation (1), it is evident that the rate-determining step is not between xanthate ion and molecular acetic acid, which would not be in accord with the rate equation (2). As postulated by V. Halban, the reaction could be a unimolecular decomposition of undissociated xanthic acid or a bimolecular reaction with hydrogen ion. In the first case K_0 of equation (2) would be the equilibrium constant of the reaction

$$X^- + HAc \rightleftharpoons HX + Ac^-$$

where X^- indicates the xanthate ion; then $K_0 = K_{HAc}/K_{HX}$, the ratio of the two ionization constants.

This mechanism does not appear plausible for two reasons: since molecular xanthic acid is stable in aprotic solvents, there is no reason why it should decompose spontaneously in water; such decomposition would have to be pseudo-unimolecular, actually reaction with some basic component of the solution, as water or acetate ion, and this has not been detected.

The rate-determining step must then be a bimolecular reaction with hydrogen ion, but this could not be the rapid equilibrium reaction which maintains a very small concentration of undissociated xanthic acid. It is probably an attack on the oxygen bridge in the xanthate molecule, as suggested by Lewis[4]



critical complex

In this case K_0 in equation (2) is the ionization constant of acetic acid, at zero ionic strength in each solvent and at each temperature; and *k* is the constant for the bimolecular, rate-determining step.

Evaluation and Analysis of the Rate Constant *k*.—Since accurate values of K_0 for the ionization of acetic acid in the solutions used are available, it is possible to evaluate $k = k(\text{expt.})/K_0$ on the assumption that the mechanism is correct. The ionization constant of acetic acid has been measured in dioxane–water mixtures over a wide temperature range by Harned and Kazanjian,[9] and Harned and Fallon[10] have shown that accurate interpolation is possible. Values of log K_0 and log *k* are given in Table I for each experimental condition.

The rate constants for a reaction between two ions are related with dielectric constant, ionic strength and size of the interacting ions by the Christiansen–Scatchard equation.[11] In the absence of salt effects this equation becomes

$$\log k = \log k_\infty - \frac{Z_A Z_B \epsilon^2 N}{2.3DRT} \frac{1}{r_A + r_B} \qquad (5)$$

(9) Harned and Kazanjian, THIS JOURNAL, **58**, 1912 (1936).
(10) Harned and Fallon, *ibid.*, **61**, 2377 (1939).
(11) Scatchard, *ibid.*, **52**, 52 (1930); *Chem. Revs.*, **10**, 229 (1932).

In this expression k_∞ refers to the rate constant extrapolated to infinite dielectric constant ($D = \infty$), where coulombic forces between ions should vanish. A plot of log k *vs.* $1/D$ at constant temperature should give a straight line from whose slope the sum of the radii of the interacting ions ($r_A + r_B$), or the radius of the critical complex, may be calculated. Figure 2 gives such a plot for the five temperatures used. Values of ($r_A + r_B$) obtained from the slopes of the linear portions of these curves vary between 1.77 and 1.81 Å., with an average of 1.79 Å. Points at lower dielectric constants deviate from the linear relation, as has often been found in similar cases.[12,13,14]

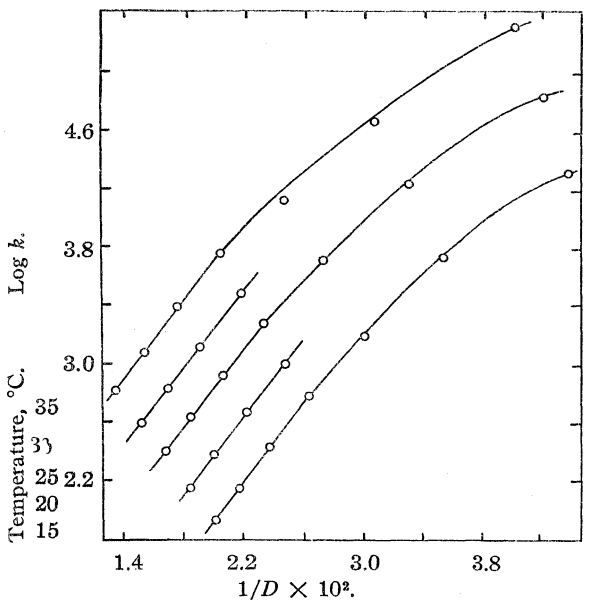


Fig. 2.—Log k *vs.* reciprocal of dielectric constant. Subtract 0.02 from abscissa values for 30°, 0.04 for 25°, etc.

The Arrhenius frequency factor (log A) and activation energy (E) were calculated by the method of least squares and are given in Table II. The equations implied fit the data of Table I with a maximum deviation of 0.05 log unit and an average deviation of <0.02 log unit. The "maximum error" of E is then about ±400 calories, the "probable error" about ±250 cal. There is no indication of variation of E with temperature over this short range.

TABLE II

EXPERIMENTAL ENERGY, FREE ENERGY AND ENTROPY OF ACTIVATION

Dioxane, %	log A	E	ΔF^*, 25°	ΔS^*, 25°
0	15.83	18380	16640	3.76
10	16.60	19100	16310	7.28
20	17.31	19670	15930	10.56
30	17.73	19750	15420	12.45
40	17.72	19150	14820	12.41
50	17.08	17530	14100	9.48
60	20.22	20960	13250	23.86

(12) Amis and LaMer, THIS JOURNAL, **61**, 905 (1939).
(13) Davis and LaMer, *J. Chem. Phys.*, **10**, 585 (1942).
(14) King and Josephs, THIS JOURNAL, **66**, 767 (1944).

The free energy and entropy of activation were calculated using the equations[15]

$$\Delta F^* = 2.3RT\,(\log RT/Nh - \log k) \quad (6)$$
$$\Delta S^* = 2.3R\,(\log A - \log eRT/Nh) \quad (7)$$

These values are given in Table II.[16] Since log A, E, ΔF^* and ΔS^* vary considerably with dielectric constant, they cannot be compared directly with similar quantities for a reaction in an ideal (gaseous) state. It was suggested by Svirbely and Warner[17] that rate constants obtained in mixed, iso-dielectric media (as temperature is varied), would be more nearly comparable to rate constants for ideal gas reactions. While this method frees ΔS^* from electrostatic effects, it still leaves log A, E and ΔF^* as variables with dielectric constant.

Probably a more satisfactory treatment is to calculate log k_∞, E_0, ΔF_0^* and ΔS_0^*, values of these quantities at infinite dielectric constant. Following the suggestion of LaMer,[18] equation (5) may be written as

$$\Delta F^* = \Delta F_0^* + \Delta F_D^* \quad (8)$$

Analogous equations for energy and entropy are $E = E_0 - E_D$ and $\Delta S^* = \Delta S_0^* - \Delta S_D^*$. The dielectric contributions are given by

$$\Delta F_D^* = \frac{Z_A Z_B \epsilon^2 N}{D(r_A + r_B)} \quad (9)$$

$$E_D = \Delta F_D^* + T\,\Delta S_D^* + RT \quad (10)$$

$$\Delta S_D^* = \frac{\Delta F_D^*}{D} \cdot \frac{\partial D}{\partial T} \quad (11)$$

The values of E_0, ΔF_0^* and ΔS_0^* should be independent of solution composition in the range of validity of equation (5), and ΔS_0^* should be the same as ΔS^* obtained from isodielectric media.

These quantities are given in Table III up to 30% dioxane, and are seen to be constant within the experimental error. The calculation is useless when D <50, since equation (5) is not valid, as shown by Fig. 2.

TABLE III

ACTIVATION ENERGY AND ENTROPY AT $D = \infty$, 25°

% Dioxane	ΔF_0^*	E_0	ΔS_0^*
0	19000	16840	−7.4
10	18970	17180	−6.1
20	19000	17310	−5.7
30	19010	17000	−7.0

Comparison with the Collision Theory.—The fundamental collision theory equation, applied

(15) Glasstone, Laidler and Eyring, "The Theory of Rate Processes," McGraw-Hill Book Co., Inc., New York, N. Y., 1941, pp. 195–199.
(16) The Arrhenius or experimental energy of activation is designated as E and differs by RT from the internal energy of activation ΔE^*.
(17) Svirbely and Warner, THIS JOURNAL, **57**, 1883 (1935); Warner, *Ann. N. Y. Acad. Sci.*, **39**, 345 (1940).
(18) LaMer, *J. Franklin Inst.*, **225**, 709 (1938).

to an ionic reaction, may take the form

$$k_\infty = Z_0 e^{-E_0/RT} \quad (12)$$

Use of k_∞ and E_0 should be most nearly comparable with a reaction between uncharged gas molecules, if calculation of the collision frequency is to take the simplest form. This frequency, Z_0, in terms of moles, liters and minutes, is given by

$$Z_0 = \frac{60N}{1000}\sigma^2\left[\frac{8\pi RT}{\mu}\right]^{1/2} \quad (13)$$

where σ is the average collision diameter and μ is the reduced molecular weight, taken in this case to equal $19 \times 121/140$.

On combining equations (12) and (13) there is obtained

$$\log \sigma = {}^1/_2 \log k_\infty - 13.92 + E_0/2730 \quad (14)$$

Table IV gives log k_∞ (equation (5), using $(r_A + r_B) = 1.79$ Å.) and the corresponding values of σ. It is evident that there is reasonable agreement with the collision theory in its simplest form.

TABLE IV

COLLISION DIAMETERS FOR $D = \infty$, 25°

% Dioxane	log k_∞	σ, Å.
0	0.65	3.72
10	.63	2.09
20	.65	1.66
30	.64	1.25

Similar calculations were made by Amis and LaMer[12] for the reaction of brom phenol blue and hydroxyl ion, and similar results were obtained.

Summary

The rate of reaction of potassium ethyl xanthate in dilute acetic acid–sodium acetate buffers has been measured, at five temperatures from 15 to 35°, in dioxane–water mixtures from 0 to 60% dioxane. The effect of added dioxane, or changed dielectric constant, on the over-all reaction, has been shown to be small. Also, in agreement with previous work, the effect of low concentrations of inert salt has been found negligibly small.

The possible mechanism of the reaction has been discussed, and the formation of a critical complex by bimolecular reaction of xanthate and hydrogen ions has been proposed as most probable. Since the ionization constant of acetic acid in dioxane–water mixtures is known, it was possible to calculate the bimolecular rate constants for the postulated rate determining step.

The variation of rate constants with dielectric constant was found to follow the predictions of electrostatic theory (the Christiansen–Scatchard equation) over the range found usable in other cases (D = 80 to 50), and reasonable values for the radius of the critical complex or $(r_A + r_B)$ were obtained.

The experimental energy, free energy and entropy of activation have been calculated, and the electrostatic contribution to these quantities has been evaluated. Constancy of the values calculated for $D = \infty$ has been found satisfactory.

It has been shown that reasonably good agreement with the simple collision theory is obtained when rate constants and activation energies extrapolated to $D = \infty$ are used in the calculations.

It is believed that these factors support the suggested reaction mechanism.

Molecular Freedom and Proton Transfer in Solid Long-Chain Amines[1]

BY JOHN D. HOFFMAN AND CHARLES P. SMYTH

In the course of investigations of solid long-chain alcohols[1a] a direct current conductivity effect probably attributable to proton transfer[2] was found almost uniquely associated with the solid rotator state, often called the "α phase." The term "rotator" was not meant to imply actual dynamic rotation of all the molecules, but merely their possession of sufficient energy of rotational vibration to permit of frequent passage over restricting potential barriers. The effect also appeared to a smaller extent below the transition point. No such phenomenon appeared in long-chain bromides,[3] ketones[4] or esters.[5] It was thus thought advisable to look for proton transfer and transitions in the amines. If the molecules rotated about their long axes, direct current proton transfer conductivity giving rise to Maxwell–Wagner polarization would be expected to appear.

Purification of Substances

The samples of *n*-dodecyl, *n*-tetradecyl, *n*-hexadecyl and *n*-octadecyl amines obtained from the Paragon Chemical Company were purified by a single vacuum distillation.

n-Octylamine, also from Paragon, was distilled at atmospheric pressure, b. p. 179°. Carbon dioxide, which forms the carbamates, was carefully excluded in the distillations and handling. The melting points of the purified compounds are given in the second column of Table I with literature values for comparison. Refractive indices for the D sodium line are given in the last column.

Experimental Results

The experimental method used to make dielectric constant–temperature runs at 0.5, 5.0 and 50 kc. has been described previously.[1a] In addition to the usual precautions regarding moisture entering the dielectric cell, a tube containing Ascarite was attached to the air vent on the cell to prevent contamination by carbon dioxide. The dielectric constants for the amines studied are given in Table II as a function of temperature. Only the cooling curves are given since the warming curves were very similar. The melting points were higher than the freezing points by 0.2 to 1.3°. The dielectric data are plotted in Figs. 1–5. *n*-Dodecylamine was cooled from 100 to 0° as rapidly as possible in the dielectric cell, and the dielectric constant at 0.5, 5.0 and 50 kc. plotted as a

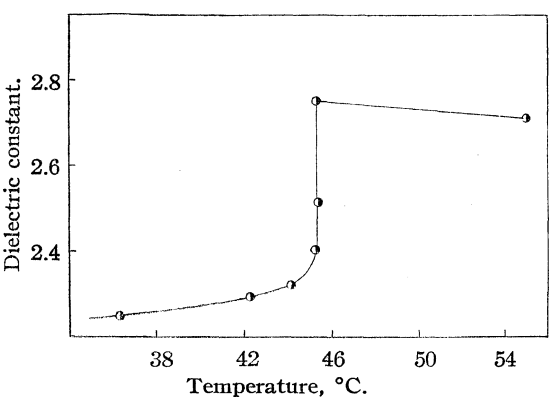

Fig. 4.—Temperature dependence of dielectric constant of *n*-hexadecylamine at 5.0 kc.

Discussion of Results

No transitions in the solid are evident in any of the compounds studied, and all of the materials appear to freeze predominantly into the stable non-rotator form. Thus the large direct current conductivity effect originally sought in this research cannot appear in full force since no α phase producing sheets of rotating $-NH_2$ groups appears. Proton transfer demands molecular rotation and a convenient path such as a sheet of $-NH_2$ or $-OH$ groups.[1a,2] A small conductivity effect appears in the two shorter amines even though few of the molecules are rotating. The effect is thus analogous to the conductivity observed in *n*-tetradecyl, *n*-octadecyl and *n*-docosyl alcohol below the transition point. The conductance is manifested as Maxwell–Wagner polarization as shown in Figs. 1, 2 and 5. The dispersion should not be confused with anomalous dispersion, since, at low frequency, the dielectric constant exceeds the extrapolated liquid value (Fig. 5) and the loss factor, ϵ'', was observed to exceed $(\epsilon_0 - \epsilon_\infty)/2$, where ϵ_0 is the static dielectric constant and ϵ_∞, the so-called optical dielectric constant. It is thus clear that, as in the alcohols, the high dielectric constant is not due to orientation polarization. When $\epsilon'' \geqq \epsilon'$ and when two phases of different conductivity are present, large dielectric constants exceeding those possible by orientation polarization are commonly observed.[1a] In *n*-octylamine and *n*-dodecylamine the high conductivity observed for some distance below the freezing point makes $\epsilon'' \geqq \epsilon'$, and causes the dielectric constant to be abnormally high, suggesting the possible coexistence of two phases with proton transfer occurring in one of them. In Fig. 5 it is shown that the dielectric constant of *n*-dodecylamine at 0° at low frequency drops with time, just as was found for *n*-octadecyl alcohol. This indicates that a slow change of condition perhaps, a trace of vertical phase transforming to tilted, often called a β_1–β_2 transition, is taking place, wherein molecules capable of molecular freedom and proton transfer are reorienting into more stable positions in the lattice. It should be emphasized that the combination of proton transfer and Maxwell–Wagner effect greatly magnifies the effect of what is undoubtedly a rather small amount of molecular freedom in the solid state.

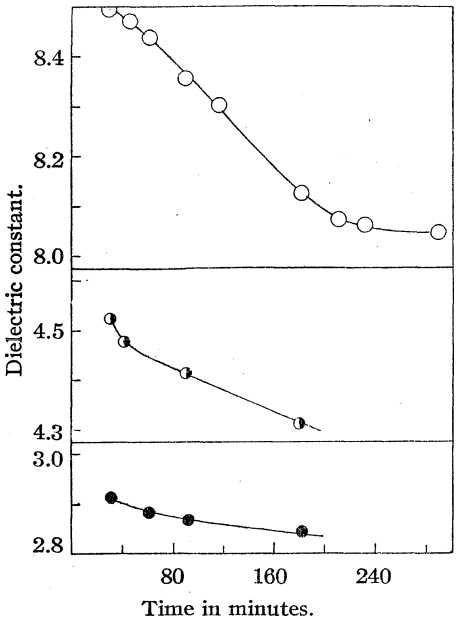

Fig. 5.—Dependence of dielectric constant of *n*-dodecylamine at 0° on time. Sample was cooled rapidly from 100 to 0°. Hollow circles represent values at 0.5 kc., half-filled circles values at 5.0 kc., and filled circles values at 50 kc.

The pronounced maximum in the low frequency dielectric constant which occurs at about 20° below the freezing point in *n*-octylamine and *n*-dodecylamine has no analog in the alcohols. The maximum would seem to suggest a second order transition, but this view must be regarded with

caution. It has been shown that the observed dielectric constant due to Maxwell–Wagner effect depends on the ratios of the conductivities of the two phases.[1a,8] It is much more likely that the ratio of the conductivities of the two phases varies in such a way as to produce a maximum of the type shown in Figs. 1 and 2.

Molecular freedom in the solid state may have several origins. Impurities may cause the formation of small amounts of liquid with corresponding molecular freedom. Premelting[9] has been attributed by Oldham and Ubbelohde to the effect of a network of coöperative flaws which breaks up a crystal into a mosaic producing a sort of unsharp melting and molecular freedom. The flaws may stem from impurities or thermal fluctuations. Premelting is generally considered to be operative only near the melting point. Another cause of molecular freedom in the solid state is the rotation of a molecule from one equilibrium position to another due to coöperative loosening of the lattice. The term "prerotation" has been used to describe this effect below the transition point.[10] This effect will also occur if no transition point is present. Operationally, prerotation differs from premelting in that it covers a much wider temperature range, and its onset is more gradual. Prerotation will be used henceforth in this paper to describe the occasional rotation or reorientation of molecules in a solid at any temperature, probably due to cooperative loosening of the lattice. Finally, molecular freedom may result in a solid from the presence of a stable or unstable rotator phase, or a substance which contains a portion of such a rotator phase. A rotator phase will yield a liquid-like dielectric constant.

In the present case, impurities and premelting may be ruled out as the cause of the molecular freedom in the lattice 20° below the freezing point in the two shorter amines, so the effect must be due to prerotation or the presence of a small amount of a rotator phase which is unstable. Inasmuch as prerotation is an equilibrium phenomenon, it would appear, in view of the drop in dielectric constant with time observed in *n*-dodecylamine, that the major part of the molecular freedom may be due to the presence of a small amount of unstable rotator phase. The longer amines show a definite decrease of dielectric constant with temperature far below the freezing point with no Maxwell–Wagner effect. This is characteristic of prerotation. The decrease of conductivity in the longer amines may be ascribed, in part, to the fact that fewer dipoles are present per cc. and, in part, to a lower cooling rate used in the measurements.

The amines differ from the corresponding alcohols in that they have no rotational transitions in the solid in the range studied. This may be connected with the fact that hydrogen-bonding in the amines is weaker than in alcohols or acids. The differing degree of hydrogen-bonding may be seen by comparison of the boiling points of the eight-carbon acid, alcohol and amine. *n*-Octanoic acid boils at 237°, *n*-octyl alcohol at 195°, and *n*-octylamine at 179°. An unassociated long-chain molecule will generally exhibit rotation about the long axis, as manifested by solid transitions, if it is at least eighteen to twenty-four carbon atoms long. Thus, *n*-docosyl bromide and *n*-docosane show monotropic transitions, while *n*-octadecyl bromide and *n*-hexadecane do not. Since hydrogen-bonding will change the effective chain length, we might expect the compounds with the strongest hydrogen-bonding (*e. g.*, acid dimers) to have transitions at shorter formula weight chain length than weakly bonded substances. In accordance with this, acids show transitions when the chain length is eleven carbons,[11] and alcohols at thirteen carbons,[11] while amines do not show transitions at eighteen or shorter. Thus, the eleven-carbon acid dimer, which has an effective chain length of about twenty-four atoms behaves like a hydrocarbon of that length. It should be pointed out that, in addition to increasing the effective length of a molecule, hydrogen-bonding may stabilize the tilted form, which does not rotate, and thus alter the chain length at which transitions are observed. It is likely that a solid rotator state will be found in amines of twenty-two to twenty-six carbon atoms in length.

The evidence for proton transfer rests mainly on the appearance of direct current conductivity accompanied by strong Maxwell–Wagner polarization below the freezing point in *n*-octylamine and *n*-dodecylamine, and the similarity of this phenomenon to that found below the transition points in the alcohols. The dielectric constant showed time dependence in these materials, which strengthened the correlation with the alcohols. Since molecular rotation is a requirement for proton transfer, some molecular freedom was indicated. It has been pointed out that the failure of any rotational transitions to appear in the amines may be due to the different degree of hydrogen bonding in the amines as compared to the alcohols. Prerotation was observed in the higher members of the series.

Summary

The dielectric constants of *n*-octyl, *n*-dodecyl, *n*-tetradecyl, *n*-hexadecyl, and *n*-octadecyl amines have been investigated in the vicinity of the melting point. No solid phase corresponding to all the molecules rotating about their long axes was detected, so that the large apparent direct current conductivity due to proton transfer associated with the rotator state could not be investigated. In *n*-octylamine and *n*-dodecylamine the dielectric data indicated the presence of a small conductivity in the solid state attributable to proton transfer. The dielectric data for the longer mem-

bers indicate some molecular freedom below the freezing point, but no Maxwell–Wagner polarization due to conductivity was encountered in the cases of the three longer molecules. The dielectric properties of the alcohols and amines have been compared, and tentative reasons advanced for the absence of the rotator state in the amines.

A Synthesis of Vinylcyclopropane[1]

BY ROSS VAN VOLKENBURGH, K. W. GREENLEE, J. M. DERFER AND C. E. BOORD

The hydrocarbon vinylcyclopropane is interesting from both the synthetic and theoretical points of view. In 1922, Demjanov and Dojarenko[2] prepared it by exhaustive methylation of the amine obtained from the oxime of methyl cyclopropyl ketone, and they stated that this hydrocarbon could not be prepared by the dehydration of methylcyclopropylcarbinol. It has sometimes been assumed that vinylcyclopropane is "*incapable of existence.*"[3] Recently there has been speculation concerning the possible utility of the hydrocarbon in the manufacture of synthetic rubber.[4] In the present work methylcyclopropylcarbinol was successfully dehydrated to vinylcyclopropane, and some of the hydrocarbon's properties were observed.

The methylcyclopropylcarbinol was prepared by reduction of methyl cyclopropyl ketone; four different methods were tried. Catalytic hydrogenation gave the desired carbinol along with a nearly equal amount of the close-boiling 2-pentanol. Reduction by sodium and ammonium sulfate in liquid ammonia gave ring-opening products exclusively. The Meerwein–Ponndorf method gave the desired carbinol in low yield along with large amounts of condensation products. The only method which gave methylcyclopropylcarbinol exclusively and in high yield was reduction with lithium aluminum hydride.

The dehydration of methylcyclopropylcarbinol was accomplished by refluxing it with a catalytic amount of sulfuric acid, giving 39% yield of vinylcyclopropane with 0.8° boiling range (Fig. 1). The dehydration was extremely slow, apparently because of the influence of the cyclopropane ring adjacent to the carbinol group; this may explain the failure of previous workers to observe it. The structure of the hydrocarbon was proved by an ozonolysis experiment from which both formaldehyde and cyclopropanecarboxaldehyde were identified. The physical properties listed in Table I were determined on a sample of vinylcyclopropane, estimated from a time–temperature freezing curve to be 96 ± 2 mole % pure.

Evidence for conjugation between the double bond and the cyclopropane ring of vinylcyclopropane is seen in the boiling point which is 4.5° higher than that of ethylcyclopropane; by contrast, the double bond produces a 7.8° lowering when the related 2-methylbutane is converted to 3-methyl-1-butene. Similarly, the refractive index of vinylcyclopropane shows an elevation of 0.0264 (at 20°) which approaches the elevation of 0.0332 exhibited by 2-methyl-1,3-butadiene.

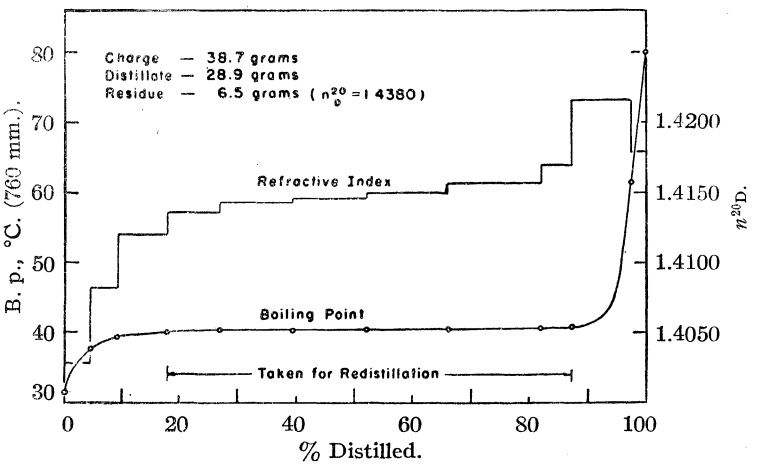

Fig. 1.—Distillation of crude vinylcyclopropane.

fied spectroscopically as ethylcyclopropane containing *n*-pentane as impurity (about 30 mole % on the basis of refractive index). The *n*-pentane was formed by hydrogenolysis of the cyclopropane ring through "1,4-addition" of hydrogen as in the case of a conjugated diene.[5] Other reactions in which the cyclopropane ring appears to possess many of the attributes of a double bond have been observed.[6]

The infrared absorption spectrogram of the vinylcyclopropane on which physical properties were determined is given in Fig. 2. The band at 9.9 μ, believed to be characteristic of the cyclopropane ring,[7] appears to be present, although obscured by strong olefin absorption in this region (type I olefins characteristically show absorption at 9.5 and 10.1 μ).

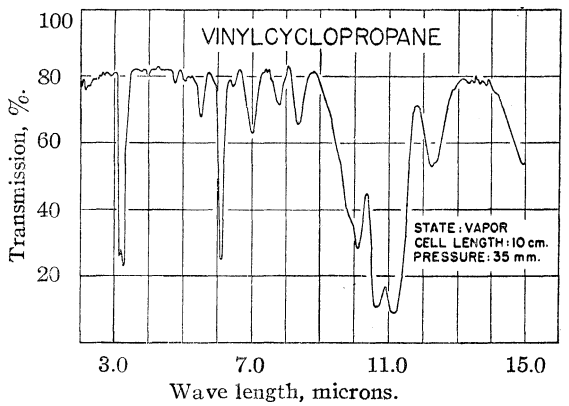

Fig. 2.—Infrared absorption spectrogram of vinylcyclopropane.

Unlike typical conjugated diolefins, vinylcyclopropane does not react with maleic anhydride at temperatures up to 100°. However, preliminary experiments indicate that it does polymerize rapidly in the presence of benzoyl peroxide when exposed to ultraviolet light.

Experimental

Reduction of Methyl Cyclopropyl Ketone

By Catalytic Hydrogenation.—Hydrogenation of methyl cyclopropyl ketone[8] over nickel-on-kieselguhr at 50 to 60° and 600–1100 p. s. i. gave a mixture of 2-pentanol (b. p. 119.85°) and methylcyclopropylcarbinol in the ratio of 2:3; distillation at about 20-plate efficiency indicated the composition but was not nearly adequate for a quantitative separation.

By Sodium and Ammonium Sulfate in Liquid Ammonia.—It has been found previously in this Laboratory that certain ketones are reduced to the corresponding carbinols by sodium in liquid ammonia in the presence of ammonium sulfate. The details of this type of reaction will be published later. When the method was applied to methyl cyclopropyl ketone, distillation of the reaction product gave no evidence for methylcyclopropylcarbinol, the desired product; only 2-pentanone and 2-pentanol were isolated. It is believed that "1,4-addition" of hydrogen first occurs, yielding 2-pentanone in its enolic form; further reduction of this ketone would then yield 2-pentanol.

By Aluminum Isopropoxide.—This reaction was carried out on methyl cyclopropyl ketone by essentially the same procedure given by Wilds[9] for the reduction of crotonaldehyde. Crude methylcyclopropylcarbinol (b. p. 119.2 to 124.1°, $n^{20}D$ 1.4394 to 1.4323) was obtained in 23% yield, along with higher boiling by-products, believed to be carbinols of higher molecular weight.

By Lithium Aluminum Hydride.—The procedure followed was essentially that described by Nystrom and Brown.[10] Distillation of the reaction product gave an 80% yield of methylcyclopropylcarbinol (b. p. 121.8 to 123.7°, $n^{20}D$ 1.4283 to 1.4317). Of this carbinol, about three-fourths had a constant boiling point and refractive index; the physical properties of this material are listed in Table II.

TABLE II

METHYLCYCLOPROPYLCARBINOL

	This work	Henry[11]

M. p., °C.	−32.1	.....
d^{20}_4	0.8893	0.88778
$n^{20}D$	1.4316	1.42966

From a sample of this material, the phenyl urethan derivative was prepared by the method of Shriner and Fuson.[12] After two recrystallizations from "Skellysolve C," the melting point of the derivative was 69.6–70.5° (cor.).

Vinylcyclopropane

Preparation.—Methylcyclopropylcarbinol (65.8 g., 0.76 mole), along with 12 drops of concentrated sulfuric acid, was placed in a flask attached to a small fractionating column packed with glass helices. The olefin material distilled as it formed, and the dehydration proceeded steadily but very slowly, yielding only 45 ml. of crude product during two days at reflux temperature (about 120°). Addition of 12 drops of *p*-toluenesulfonic acid gave no noticeable increase in rate, but slow dehydration continued for another day. A considerable amount of carbonaceous material remained in the flask.

After percolation through a 10-cm. column of silica gel, Dry-Ice-cold, the crude product (38.7 g.) was distilled at about 20-plate efficiency to obtain 20.0 g. (a 39% yield from carbinol) of good vinylcyclopropane (b. p. 40.0 to 40.8°, $n^{20}D$ 1.4136 to 1.4170); the curves describing this distillation are given in Fig. 1.

Several differences are to be noted between the dehydration of methylcyclopropylcarbinol and dimethylcyclopropylcarbinol.[6a] The latter, a tertiary alcohol, dehydrated easily over sulfuric acid, giving nearly pure isopropenylcyclopropane in 80% yield. By contrast, methylcyclopropylcarbinol appears to dehydrate very slowly and to give a mixture containing a number of components. The impurity which caused the low initial boiling point in the distillation may have been 1,4-pentadiene, isoprene or fragmentation products. The higher boiling impurity probably was 1,3-pentadiene (*cis* and/or *trans*), causing a gradual rise in refractive index.

(5) Hydrogenolysis of the cyclopropane ring in such pseudoconjugated systems can apparently be avoided by the use of a barium-promoted copper chromite catalyst. See Slabey, Wise and Gibbons, THIS JOURNAL, **71**, 1518 (1949).

The good fractions from the distillation described above (Fig. 1) were combined with similar material from an identical run, and the composite was redistilled at about 20-plate efficiency to obtain the 16 g. of material on which the physical properties in Table I were determined.

Ozonolysis.—Vinylcyclopropane, 3.6 g. (0.053 mole), was ozonized in the apparatus described by Henne and Perilstein.[13] *n*-Pentane was used as the solvent, and the solution was immersed in a Dry Ice-cooled medium.

The ozonide solution was decomposed by the method of Cook and Whitmore[14] in which the ozonide solution is added dropwise to Raney nickel in *n*-pentane with stirring. The pentane was stripped off through a short Vigreux column, and the residue, after heating one and one-half hours on a steam-bath to assure complete decomposition of the ozonide, was extracted with *n*-pentane. The filtered extract was fractionated to remove the pentane but the residue failed to give a derivative with 2,4-dinitrophenylhydrazine, though it should have contained the bulk of the expected cyclopropanecarboxaldehyde. Presumably the aldehyde was hydrogenated or decarbonylated by contact with the hot Raney nickel.

The pentane stripped from the ozonide decomposition was fractionated at about 20-plate efficiency giving a distillate rich in formaldehyde and a residue from which cyclopropanecarboxaldehyde was isolated as the 2,4-dinitrophenylhydrazone (8% yield). This derivative, after recrystallization, melted at 182–185°, and there was no depression when it was mixed with an authentic sample.[15]

(14) Cook and Whitmore, *ibid.*, **63**, 3540 (1941).

(15) Kindly furnished by Christopher L. Wilson, The Ohio State University.

Formaldehyde was identified by extracting it from the pentane distillates with small amounts of water, and preparing the dimedone derivative. The crude derivative (3.3 g. or 21% yield) was leached with 10 ml. of hot methyl alcohol, filtered and dried to yield 2.8 g. of crystals with a melting point of 187.5–189.5° (cor.). A mixed melting point with an authentic sample (m. p. 188–189°) showed no depression.

Hydrogenation.—A portion (7.3 g., 0.11 mole) of the vinylcyclopropane on which physical properties were determined was hydrogenated over 0.5 g. of Raney nickel in absolute ethanol at 65 p. s. i. g. and 10 to 20°. Absorption of hydrogen ceased after about six hours. The hydrogenate was steam distilled, washed thoroughly with water and dried by percolation through a small column of silica gel to obtain a 64% yield of material with a refractive index of 1.3724. The infrared absorption spectrum of this product corresponded closely to that of an authentic sample of ethylcyclopropane,[7] but showed minor bands indicating the presence of *n*-pentane (about 30% on the basis of refractive index). Similar results had been obtained in the hydrogenation of isopropenylcyclopropane.[6a]

Infrared Absorption Spectra.—The spectra determined in the course of this work were measured on the Beckman IR-2 Spectrophotometer of the Department of Chemistry at The Ohio State University.

Summary

Vinylcyclopropane has been prepared from methyl cyclopropyl ketone. Additional evidence for the double bond character of the cyclopropane ring has been presented.

Polynitro Paraffins

BY CARL T. BAHNER AND HARVEY T. KITE[1]

Dinitro paraffins in which the nitro groups are in a 1,3-position to each other and the middle carbon atom carries no hydrogen atom have been prepared by Fraser and Kon,[2] Hass and Bourland,[3] and Larrison and Hass[4] by reaction of nitromethane with ketones. Hass[5] has found evidence that the reaction of nitromethane with acetone takes place through the formation of 1-nitro-2-methylpropene which adds nitromethane to form dinitroneopentane. Lambert and Piggott[6] have reported the preparation of dinitro compounds by "heating a primary or secondary nitroparaffin or nitroether or nitrothioether .... with a Δ^{α}-nitroolefin .... in the presence of a basic substance." Prior to the publications by Hass and Lambert and their associates we had undertaken the preparation of polynitro paraffins by the addition of alkali salts of nitro paraffins to nitro olefins. Our experiments throw light on matters not investigated by them.

Using nitro olefins of the type $R^1C(NO_2)=CHR^2$, where R^1 and R^2 represent H or an alkyl radical, and nitro paraffins containing two or more carbon atoms we have succeeded in obtaining a type of compound which it is inherently impossible to prepare from ketones by the methods of Fraser and Kon, Hass, Larrison and Bourland. We have found that the alkali metal salts of the nitro paraffins give much better results than the use of nitro paraffins together with a basic catalyst. For example, the gradual addition of 2-nitro-1-butene to an alcoholic solution of an equivalent quantity of potassium salt of *aci*-2-nitropropane gave about 90% of the theoretical yield of crude potassium salt of 3,5-dinitro-3-methylhexane, from which the free dinitro compound was recovered readily by treatment with acetic acid. On the other hand, no 3,5-dinitro-3-methylhexane was isolated from a reaction mixture of equimolecular quantities of 2-nitropropane, diethylamine and 2-nitro-1-butene. The use of a quantity of potassium hydroxide sufficient to convert only one-fourth of the 2-nitropropane into the potassium salt resulted in the formation of a viscous high molecular weight product instead of the dinitro paraffin, while the use of a large excess of so-

dium ethylate over the amount necessary to produce the sodium salt of the 2-nitropropane led to the conversion of a large portion of the nitro olefin into a nitro ether.[7] Metallic sodium added to an equimolecular mixture of 2-nitro-1-butene and 2-nitropropane at 8° did not appear to react immediately, but within a few minutes produced a violent reaction terminating in a mild explosion. For best yields it is desirable that the nitro olefin be added in small quantities with vigorous stirring to a solution of the alkali salt of the nitro paraffin at near or below room temperature and that the reaction mixture be acidified with a weak acid as soon as the addition reaction is complete.

Distillation of the dinitro compounds which we prepared was made more difficult by a tendency toward decomposition at high temperature. However we succeeded in purifying 3,5-dinitroheptane, 3,5-dinitro-3-methylhexane and 1,3-dinitro-2,2-ethyl-3-methylbutane by crystallization from methanol solution at Dry-Ice temperature.

Our chemical process is not limited to the preparation of dinitro paraffins, since the alkali metal salt of the dinitro compound obtained in the first step can be allowed to react in the same manner with one or more additional molecules of nitro olefin to form high molecular weight polynitro compounds.

Experimental

Nitro Paraffins.—The nitro paraffins used in these experiments were supplied by the Commercial Solvents Corporation.

Nitro Olefins.—The nitro olefins used were prepared by heating the acetates of the corresponding nitro alcohols with sodium acetate, by a modification of the method of Schwarz and Nelles.[8] The nitro ester mixed with about 5% by weight of anhydrous sodium acetate in a flask attached to a Vigreux column and condenser was heated in an oil-bath at 110–135° at a pressure of 20–50 mm., thus distilling off the decomposition products as they were formed. This procedure prevented the violent decomposition sometimes encountered when the heating was done at a higher pressure. The distillate was treated with a saturated solution of sodium carbonate to remove the acetic acid, washed with water, dried over calcium chloride, and used at once to avoid polymerization.

3,5-Dinitro-3-methylhexane.—Forty-five grams (0.5 mole) of 2-nitropropane was added to 221 ml. of 2.259 *N* alcoholic potassium hydroxide (0.5 mole) to form the potassium salt. This solution was chilled in an ice-bath and 50.2 g. (0.497 mole) of fresh 2-nitro-1-butene added in small portions with vigorous stirring over a period of thirty minutes, keeping the temperature at 18–20°. At the end of this time the reaction mixture suddenly deposited a large quantity of white crystals of the potassium salt of *aci*-3,5-dinitro-3-methylhexane. After dilution with water to approximately 500 ml. the salt was converted to 3,5-dinitro-3-methylhexane by acidifying with acetic acid, a 90% yield of crude product being obtained. Repeated recrystallization from chilled methanol yielded an analytically pure product in the form of white crystals which could be kept indefinitely in an ice-chest at 4° but melted below 21° to a liquid $n^{25}D$ 1.451. *Anal.* Calcd. for $C_7H_{14}N_2O_4$: C, 44.20; H, 7.42. Found: C, 43.93; H, 7.22.[9]

1,3-Dinitro-2-ethyl-3-methylbutane.—An 85% yield of crude 1,3-dinitro-2-ethyl-3-methylbutane was obtained from 1-nitro-1-butene and potassium 2-nitropropane. A sample was crystallized repeatedly from redistilled methanol by chilling with Dry Ice–acetone mixture and the white needle-shaped crystals were washed quickly with chilled methanol. Since the moist crystals melted below 5°, the operation was carried out in a cold storage room. After removal of remaining traces of solvent by warming the melted crystalline material to 50° at 1 mm. it had the following properties: $n^{25}D$ 1.463; d^{25}_4 1.152. MR_D predicted: 45.77. Found: 45.49. *Anal.* Calcd. for $C_7H_{14}N_2O_4$: C, 44.20; H, 7.42. Found: C, 43.99; H, 7.34.

3,5-Dinitroheptane.—This compound was prepared from potassium 1-nitropropane and 2-nitro-1-butene in a similar manner, but the yield was not as good as the yields of the two compounds described above, possibly because of its structure. The symmetrical structure resulted in its melting point being above room temperature. The long white needle-shaped crystals, m. p. 33°, have a mild menthol like odor and can be kept for years. *Anal.* Calcd. for $C_7H_{14}N_2O_4$: C, 44.20; H, 7.42. Found: C, 44.53; H, 7.26.

Acknowledgments.—The authors wish to express their appreciation to Mrs. Lucia Zachert Stumpe and Mr. William K. Easley for assistance in carrying out laboratory operations and to the Commercial Solvents Corporation for supplying nitro paraffins and 2-nitro-1-butanol.

Summary

New polynitro compounds having the nitro groups in a beta position to one another have been synthesized by the addition of an alkali salt of a nitro paraffin to a nitro olefin and treatment of the resulting salt with a weak acid.

Lignin. III. Fractional Precipitation of Barium Lignin Sulfonates from Water by Ethanol

BY AARON E. MARKHAM, QUINTIN P. PENISTON AND JOSEPH L. MCCARTHY

Introduction

Several investigations of the empirical composition of lignin sulfonic acids have been carried out by separating the acids or their salts into fractions which were then analyzed. Fractionation was conducted by Erdtman[1] with organic bases, by Racky[2] with hydrofluosilicic acid, by Lautsch and Piazolo[3] with benzacridine and by Schwabe and Hahn[4] with propanol. In all these cases, fractions were precipitated directly from sulfite waste liquor, and considerable departures from uniformity in composition within a particular series of fractions are apparent. Also there seems to be no clear evidence of fractionation on a basis of molecular size of lignin sulfonates. Since these departures might have resulted from the presence of non-lignin substances, it seemed that they might be eliminated by study of lignin sulfonates previously purified by dialysis.[5] Thus the present investigation has been carried out to effect a fractionation of non-dialyzable lignin sulfonates in order to study the uniformity of composition and the range of diffusion coefficients manifested by the several fractions.

Experimental

Preparation of Barium Lignin Sulfonate Solution.—Calcium sulfite waste liquor (from about 85% western hemlock and 15% white fir woods) from a commercial source was subjected to continuous countercurrent dialysis[5] against distilled water to yield an aqueous solution of purified non-dialyzable lignin sulfonates containing about 65% of the methoxyl originally present in the liquor. This calcium lignin sulfonate solution was evaporated under reduced pressure to a concentration of about 130 g. of total solids per liter. Calcium and other metallic ions were removed by cation exchange resin treatment (Ionex No. 2),[6] and the ash-free solution of lignin sulfonic acids was treated with barium carbonate in quantity just sufficient to neutralize the strong acids, as determined by conductometric analysis. A small precipitate of barium sulfate, probably resulting from cleavage and oxidation of small amounts of loosely combined sulfur dioxide, was removed by centrifugation. The aqueous solution of barium lignin sulfonates (121.9 g. of total solids per liter) was fractionally precipitated.

Fractionation Technique.—Fractionation was conducted in triplicate. Into each of three 250-ml. centrifuge flasks was placed 75 ml. of the solution of barium lignin sulfonate. With the flasks in a water-bath at 20.5 ± 0.1°, increments of absolute ethanol (*n*-propyl and isopropyl alcohols were found to be effective as precipitants at lower concentrations than ethanol, but yielded systems of two phases that were not easily separated) were added dropwise to each, with continuous stirring. The addition of each increment required about an hour, and stirring was continued for three hours more. The first increments were of 10 ml. each, this volume being increased to secure the later fractions. After a total of twenty-four hours in the thermostat for each precipitation, the solids were centrifuged from the solution, the solution decanted off, and the solids washed from the flasks with water. The weights of the flasks and contents at each step in the operations were taken. From these data the ethanol content of the solution as each fraction was precipitated was calculated. The final composition of the solution so estimated agreed within 0.1% with the figure obtained by analysis of the final solution by distillation and density determination.

Treatment of Fractions.—The solution of each fraction was evaporated under reduced pressure (about 40°) nearly to dryness, then redissolved in water, and again taken to dryness in a vacuum desiccator over calcium chloride. This repeated evaporation served to remove completely the ethanol, which if present would give rise to erroneously high results in the methoxyl determination. Drying was continued to constant weight in a vacuum oven at 60° and 15 mm. pressure (about four hours). The weights of the corresponding fractions from the triplicate experiments were nearly identical. Corresponding fractions were combined.

Characterization of Fractions.—Methods used for chemical analyses have been previously described.[5] Of the original total solids, methoxyl, sulfur and sulfated ash, 99.9, 97.4, 100.3 and 101.9%, respectively, were accounted for in the several fractions.

Extinction coefficients were calculated from absorption data secured from 3500 to 2400 Å, using a Beckman Quartz Spectrophotometer at minimum slit width. Silica cells with a 10-mm. light path were used. Absorption was measured at 50-Å. intervals for aqueous solutions of the barium lignin sulfonate fractions at two concentrations (1.00 and 5.00 mg. methoxyl per liter) buffered at *p*H 5.0 with 0.001 *M* acetate buffer.

Diffusion coefficients were determined by the solution-to-gel method of Felicetta, Markham, Peniston and McCarthy.[7]

Water Content of Fractions.—The water content of several fractions was estimated by measurement of the volume of water vapor evolved from a sample on heating at low pressure. The apparatus was a modification of that used by Browne and Houlehan,[8] and was so constructed that the evolved vapor could be condensed in an attached capillary tube, and its saturated vapor pressure, melting point and vapor density determined.

Discussion

A purified barium lignin sulfonate preparation has been fractionated by precipitation from aqueous solution by addition of increments of ethanol. Ten fractions were obtained at characteristic ethanol concentrations and the last was recovered from the remaining solution. Sufficient time was allowed at each solvent composition so that equilibrium in precipitation is believed to have been approximated. The several fractions were precipitated from solutions containing lignin sulfonates in rather high concentration in order to

[a] Duplicate analyses for methoxyl, S, ash, C and H departed from the averages not more than 0.06, 0.05, 0.5, 0.10 and 0.06%, respectively, except fract. 6, methoxyl, 0.08%; fract. 2, S, 0.13%; and fract. 8, ash, 0.9%. Diffusion coefficient departed from the averages not more than 0.45 mm.²/day. [b] Microanalyses by Microchemical Specialties Co., Berkeley, Calif.

provide adequate material for careful characterization, although sharpness of fractionation was probably thereby sacrificed.[9]

The analytical characteristics of the several barium lignin sulfonate fractions are found to be quite similar (Table I). These quantities, taken with the weights of the fractions, yield satisfactory material balances. Considering the precipitated fractions in order obtained, there is observed a trend of decrease in content of carbon and methoxyl, and of increase in content of sulfur and sulfated ash. These differences are not large and, while possibly affecting the precipitability of the barium lignin sulfonates, they are not believed to be controlling factors.

Before analysis, the fractions were dried to constant weight in a vacuum oven at 60° and 15 mm. pressure. These mild drying conditions were employed to avoid degradation of the material used for later characterization. To determine how much water might still be contained in the fractions, and if possible to differentiate between water of adsorption and of hydration, measurements of the vapor evolved on heating at reduced pressure were made on fractions 2, 4, 7 and N. The saturated vapor pressures of the condensed vapors from fractions 2 and 7 were determined at 0, 10 and 20° and found to be very close to those of water; the frozen condensate melted around −4 to −5°; and the vapor density, determined from the volume of evolved vapor and the weight of condensate, indicated molecular weights of the vapors from fractions 2 and 7 to be 16 and 17, respectively.

Similar measurements of vapor evolution from sodium tetradecane sulfonate hemihydrate supplied by Dr. E. C. Lingafelter, and from copper sulfate pentahydrate, showed stepwise evolution in four and one steps, respectively, characteristic of hydrates. The evolution of vapor from the barium lignin sulfonate fractions, however, proceeded without discrete steps. Instead, a more or less smooth curve was observed which may indicate evolution of water held by adsorption, or as a rather large number of hydrates, or both. The amount of vapor so liberated at 10 mm. was: at 117°, 3.08, 3.5, 3.67 and 3.8% from fractions 2, 4, 7 and N, respectively; and at 129°, 3.48, 3.9 and 4.1 from fractions 2, 4 and N, respectively. The amount of water evolved is nearly proportional to the number of sulfonate groups present. Thus, from 1.14 to 1.20 moles of water per sulfonate group was driven off at 117°, and from 1.29 to 1.32 moles at 129°. At 150° the amount is about 1.6 moles which appears to be nearly a limiting value. There is evidence of some decomposition at higher temperatures but over 80% of the gas evolved at 175° was re-adsorbed on cooling. From the known tendency of metal sulfonates to form hydrates and from the close proportionality between the water evolved and the amount of sulfonate present, it seems probable that the water is combined in a numb er of hydrates of differing dissociation characteristics.

For those fractions for which carbon and hydrogen analyses were available, the analytical data have been recalculated after subtraction of the indicated 1.6 moles of water per sulfonate group. A basis of nine carbon atoms was chosen because there now exists extensive evidence from degradation experiments[10] indicating that the structural units of gymnosperm lignins consist, in large proportion at least, of phenyl propane skeletons. The data when so calculated show that each fraction contains nearly an identical number of equivalents of barium and sulfur as expected for barium sulfonates, and that the degree of sulfonation of

Can.*, **43**, 253 (1942); (d) Percival, *Ann. Repts. Progress Chem. (Chem. Soc. London)*, **39**, 142 (1942); (e) Lewis and Pearl, U. S. Patent 2,433,227 (Dec. 23, 1947).

the several lignins is not quite the same. The first precipitated fraction is sulfonated to the extent of 0.37 mole per C_9 unit and the degree of sulfonation increases, reaching 0.52 in fraction 10. The difference in degree of sulfonation makes desirable a further recalculation of the data to a sulfur-free basis. This has been done by assuming that barium is exactly equivalent to sulfur and, for calculation purposes only, that each sulfonate group replaced a hydrogen atom in the original lignin.

The empirical composition of the several lignin fractions on an anhydrous, and also sulfur-free and ash-free basis is found to be nearly uniform (Table II) in spite of the accumulation of error in the hydrogen and oxygen data.[11] This composition is in general agreement with that reported by Wald, Ritchie and Purves[12] for pine lignin *in situ*, by Brauns[13] for "native" spruce lignin and by Racky[2] for some of his fractions of lignin sulfonic acids from spruce (Table II).

TABLE II

ESTIMATED EMPIRICAL COMPOSITION OF LIGNINS

Lignin	Composition
Fr. 1	C_9 $(OCH_3)_{0.85}$ $H_{7.9}$ $O_{2.4}$
2	C_9 $(OCH_3)_{0.91}$ $H_{8.4}$ $O_{2.7}$
4	C_9 $(OCH_3)_{0.92}$ $H_{8.8}$ $O_{2.7}$
7	C_9 $(OCH_3)_{0.93}$ $H_{9.1}$ $O_{2.5}$
10	C_9 $(OCH_3)_{0.93}$ $H_{7.9}$ $O_{2.2}$
N	C_9 $(OCH_3)_{0.91}$ $H_{8.4}$ $O_{2.6}$
Pine,[12] *in situ*	C_9 $(OCH_3)_{0.91}$ $H_{7.8}$ $O_{2.0}$
Spruce,[13] "native"	C_9 $(OCH_3)_{0.89}$ $H_{8.7}$ $O_{2.6}$
Spruce,[a] from LSA	C_9 $(OCH_3)_{0.93}$ $H_{8.4}$ $O_{2.2}$

[a] Calculated by us to a nine-carbon atom basis from data on lignin sulfonic acids (LSA) given by Racky[2] in his Table 2 using the average composition of his fractions 2, 3, 7 and 9 which were very similar.

The similarity of ultraviolet absorption spectra found for the fractions is in agreement with the uniformity of chemical composition. Extinction coefficients (cm.$^{-1}$ per mg. of methoxyl per liter) obtained in aqueous solutions containing 5.00 mg. of methoxyl per liter were 0.259, 0.243, 0.241, 0.231, 0.227 and 0.241 at 2800 Å., and 0.222, 0.210, 0.205, 0.192, 0.187 and 0.194 at 2650 Å. for fractions 1, 2, 4, 7, 10 and N, respectively.

Diffusion coefficients are found to increase markedly throughout the series of fractions. If molecular weights are calculated on the basis of spherical particles, a range from 100,000 to 4,000 is indicated although the actual molecular weights are probably somewhat lower judging from the few frictional ratios for lignins which have been reported.[14] It thus appears probable that the molecular size of the lignin sulfonates controls the order of precipitation although the latter may be influenced by degree of sulfonation. The characteristics manifested by the lignin sulfonate fractions seem to be in accord with those expected for fractions secured from a polymeric series.

The authors gratefully acknowledge the aid of Mr. Vincent F. Felicetta and of Mrs. H. D. Agar in performance of analyses.

Summary

1. A lignin sulfonate preparation purified by dialysis has been precipitated as a barium salt from aqueous solution by ethanol to yield a number of fractions which have been characterized by chemical analyses, ultraviolet extinction coefficients and diffusion coefficients.

2. When results of the chemical analyses are calculated to an anhydrous, sulfur-free and ash-free basis, the fractions are found to be of nearly uniform composition.

3. Diffusion coefficients of the several fractions are found to increase progressively in order of precipitation and indicate a corresponding decrease in molecular weights over a wide range.

4. The uniformity of chemical composition and of ultraviolet absorption spectrum and the regular trend in diffusion coefficients indicate the polymeric character of lignin sulfonic acids.

SEATTLE, WASHINGTON RECEIVED JUNE 22, 1949

(11) The analytical margins of error in Table I, increased by the assignment of hydrogen and oxygen to methoxyl, sulfonate and hydration groups may amount to as much as 0.75 atom of hydrogen and 0.4 atom of oxygen in the C_9 formulas of Table II.

Coumarins. I. Derivatives of Coumarin-3- and 4-Carboxylic Acids

BY R. O. CLINTON AND S. C. LASKOWSKI

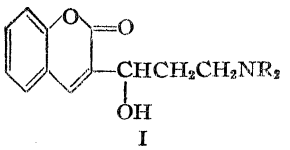
With the exception of a brief publication by Werder,[1] no pharmacological or chemical investigations appear to have been made of the basic esters and amides derivable from coumarins. Werder[1a,c] found that N,N-dialkyl-coumarin-3-carboxamides[2] exhibited remarkable sedative properties, and it is of considerable significance that they also had but slight toxicity. Furthermore, the favorable toxicity indices of coumarin-3-carboxylic acid were also apparent in salts of this acid with certain physiologically active bases such as ephedrine.[1b] These results are striking, since although coumarin itself has a slight narcotic activity, its toxic action is predominant.

In the same publication, Werder[1a] described 2-diethylaminoethyl coumarin-3-carboxylate hydrochloride and N-(2-diethylaminoethyl)-coumarin-3-carboxamide hydrochloride. The therapeutic properties of these compounds were not described; in particular no mention is made of observed local anesthetic activity. Local anesthetic activity in the coumarin-3-carboxylic acid esters and amides is of interest, since the compounds may be regarded as cinnamic acid types (*i. e.*, vinylogs of benzoic acid). In general, the basic esters of cinnamic acid show considerably greater activity than do the corresponding benzoates,[3] although toxicity has been found to increase proportionally.[4]

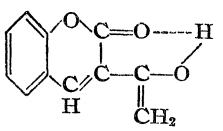
In the present work we have investigated a series of basic esters and amides derived from coumarin-3-carboxylic and coumarin-4-carboxylic acids. A subsequent communication will cover related compounds in the coumarin-3-acetic and coumarin-4-acetic acid series.

The substituted coumarin-3-carboxylic acids used in the present work were prepared by the conventional Knoevenagel method,[5] from a substituted salicylaldehyde and malonic ester. Modifications necessary in certain cases are detailed in the Experimental section. Only a single example of the coumarin-4-carboxylic acid type was investigated, due to the very low yields obtainable in the synthesis of these types.

An attempt was made to extend the investigation to the preparation of compounds of type I, through use of the Mannich reaction with 3-acetylcoumarin[6] followed by reduction (*e. g.*, by aluminum isopropylate). However, in spite of numerous experiments, under a variety of conditions, we were unable to isolate any reaction product when 3-acetylcoumarin was subjected to the Mannich reaction with diethylamine hydrochloride; in all cases only starting materials were recovered. This lack of reactivity may be due to stabilization of the hydrogen bonded structure II under the conditions of the Mannich reaction, for it is known that 3-acetylcoumarin readily forms an oxime[6] under normal conditions.



I



II

Werder[1c] prepared N,N-dimethylcoumarin-3-carboxamide from salicylaldehyde and malonic acid bis-dimethylamide at 145–150°. We were able to extend this method to the preparation of 2-diethylaminoethyl coumarin-3-carboxylate from salicylaldehyde and bis-(2-diethylaminoethyl) malonate, in high yield. It is interesting in this connection that reaction between the two components takes place only slowly at elevated temperature, even though tertiary amino groups are present, whereas the addition of catalytic amounts of piperidine or other secondary amine brought about an exothermic reaction at room temperature.

Among the coumarin-3-carboxylic acid derivatives prepared were a number of *bz*-nitro types. It was hoped that there could thus be prepared a series of *bz*-amino-substituted-coumarin-3-carboxylic acid derivatives, which would be vinylogs of aminobenzoic acid derivatives. The relative inaccessibility of 4-nitrosalicylaldehyde[7] precluded the preparation of 7-aminocoumarin derivatives, although the 6-nitro types are readily available.

In contrast to the easily manipulated reduction of 6-nitrocoumarin to 6-aminocoumarin either by iron–acetic acid[8] or electrolytically,[9] we were unable to prepare basic esters or amides of *bz*-aminocoumarin-3-carboxylic acids by either chemical or catalytic reduction. Part of the difficulty can be

ascribed to the ease with which the pyrone ring is opened in the presence of the new amino group or the basic group in the ester or amide linkage[10]; further, from the properties of the highly colored products which we have isolated from chemical reduction experiments it can be assumed that in this case reduction was incomplete. Catalytic reduction, with a variety of catalysts and under varying conditions, gave only the corresponding *bz*-amino dihydrocoumarins.[11] Judging from hydrogenation experiments there was no perceptible difference in the rate of reduction between the nitro group and the double bond.

Therapeutic assay of the coumarin-3-carboxylic acid derivatives for local anesthetic activity has been carried out by Drs. T. J. Becker and F. P. Luduena of these laboratories. A complete report will be published by these authors at a later date.

Experimental[12]

Salicylaldehydes.—The nitration of salicylaldehyde with fuming nitric acid (d. 1.49–1.50) in glacial acetic acid, and separation of the mixture of 3-nitro- and 5-nitrosalicylaldehydes, was carried out essentially by the method of Miller.[13] Bromination of the 3-nitro isomer according to the method of Auwers and Bürger,[14] or the nitration of 5-bromosalicylaldehyde,[14,15] gave high yields of 3-nitro-5-bromosalicylaldehyde. 2-Hydroxy-3-methoxy-5-nitrobenzaldehyde was prepared by the method of Dey and Kutti.[16] The bromination of 5-nitrosalicylaldehyde with bromine in glacial acetic acid solution at 30–40° gave a 70% yield of **3-bromo-5-nitrosalicylaldehyde,** long slender white needles from dilute acetic acid or from alcohol, m. p. 149–150°.

Anal. Calcd. for $C_7H_4BrNO_4$: C, 34.17; H, 1.64; N, 5.69. Found: C, 34.17; H, 1.87; N, 5.85.

The oxime formed pale yellow needles from dilute alcohol, m. p. 222.1–223.0°.

Anal. Calcd. for $C_7H_5BrN_2O_4$: N, 10.73. Found: N, 10.60.

The position of the bromine was proven by oxidation of the aldehyde to the known 3-bromo-5-nitrosalicylic acid with potassium permanganate in acetone. The product crystallized from 4% hydrochloric acid in long slender white needles, m. p. 225–226° (lit.,[17] m. p. 223–224° uncor.).

Ethyl Coumarin-3-carboxylates.—In general, the usual Knoevenagel procedure[5] was used to prepare the intermediate coumarin-3-carboxylates. However, in certain cases the salicylaldehydes (*e. g.*, 2-hydroxy-3-methoxy-5-nitrobenzaldehyde, 3-bromo-5-nitrosalicylaldehyde, etc.) were relatively slow in condensing by this method, and it was found necessary to force the reaction by heating and through use of increased amounts of the piperidine catalyst. A typical example follows:

A mixture of 25.0 g. (0.126 mole) of 2-hydroxy-3-methoxy-5-nitrobenzaldehyde, 25.0 g. (0.156 mole) of ethyl malonate, 30 ml. of absolute alcohol and 2 ml. of piperidine was refluxed for six hours. The orange colored reaction mixture was diluted with 400 ml. of alcohol, filtered, and the crystalline material was washed well with alcohol. Recrystallization from ethyl acetate gave 31.5 g. (85%) of ethyl 8-methoxy-6-nitrocoumarin-3-carboxylate as pale yellow needles.

The difficulty of preparing 2-hydroxy-3-methoxy-6-nitrobenzaldehyde[18] precluded the possibility of preparing 8-methoxy-5-nitrocoumarin-3-carboxylic acid in this manner. Dey and Kutti[16] have reported that the nitration of 8-methoxycoumarin-3-carboxylic acid takes place exclusively in the 5-position; in our hands, however, the method did not prove adaptable to large-scale preparations. We have found that nitration of the ethyl ester gives fair results, although the yields are low:

To 100 ml. of concentrated nitric acid (d. 1.42) at 25° was slowly added 24.8 g. (0.10 mole) of ethyl 8-methoxycoumarin-3-carboxylate[18] with stirring. The resulting solution was slowly heated to 40–45° and maintained at this temperature (the reaction becomes uncontrollable above 55°) by alternate cooling and heating for one hour. The solution was poured into one liter of ice-water with stirring, and the resulting precipitate was filtered and washed thoroughly with water. After two recrystallizations of the air-dried material from ethyl acetate with decolorization there was obtained a 22% yield of ethyl 8-methoxy-5-nitrocoumarin-3-carboxylate as pale yellow needles, m. p. 184–186°.

Anal. Calcd. for $C_{13}H_{11}NO_7$: N, 4.78. Found: N, 4.75.

Saponification of the ethyl ester gave a 92% yield of 8-methoxy-5-nitrocoumarin-3-carboxylic acid, m. p. 215–217° (lit.,[16] m. p. 203° uncor.).

Anal. Calcd. for $C_{11}H_7NO_7$: C, 49.81; H, 2.64. Found: C, 50.04; H, 2.73.

Coumarin-3-carboxylic Acids.—The ethyl esters were saponified by refluxing with an excess of dilute sodium hydroxide solution for several hours, followed by acidification with hydrochloric acid. It was generally preferable to pour the solution of the sodium salt into an excess of strong hot hydrochloric acid, since by the reverse process there was sometimes obtained a substantial amount of the coumaric acid.

Coumarin-3-carbonyl Chlorides.—The acid chlorides were prepared by the action of thionyl chloride on the acid, without solvent[19]:

A mixture of 20 g. (0.075 mole) of 8-methoxy-6-nitrocoumarin-3-carboxylic acid and 119 g. (1.0 mole) of pure thionyl chloride[20] was refluxed under anhydrous conditions for two hours. Solution was complete after twenty minutes. The excess thionyl chloride was distilled under reduced pressure, and the crystalline residue was taken down twice with 250-ml. portions of dry benzene. Recrystallization of the residual solid from dry benzene gave 21.2 g. (97%) of 8-methoxy-6-nitrocoumarin-3-carbonyl chloride.

Coumarin-3-carboxylates, -thiolcarboxylates and -carboxamides.—The coumarin-3-carboxylates were prepared by several methods. Reaction between the basic alcohol and a coumarin-3-carbonyl chloride in dry benzene gave high yields, as did the reaction between a coumarin-3-carboxylic acid and an ω-dialkylaminoalkyl halide in iso-

(10) Both Clayton and Morgan, ref. 8, have pointed out the intense yellow and orange colors of the pure *bz*-aminocoumarins. On structural grounds it is apparent from these observations and from the observed high melting points that the *bz*-aminocoumarins must exist at least partially in the open (cinnamic acid salt) forms.

(19) *Cf.* Boehm and Schumann, *Arch. Pharm.*, **271**, 490 (1933).

(20) The high ratio of thionyl chloride to acid was used to increase the rate of reaction through increased solubility.

propyl alcohol.[21] A third method consisted of the trans-esterification of the ethyl coumarin-3-carboxylate with a basic alcohol, in certain cases using toluene as a diluent. The yields by this latter method were quite good, but purification of the product from traces of starting materials often proved difficult. A further method was the direct synthesis from suitable malonic esters, although this method gave low over-all yields because of the difficulty of preparing the required basic esters of malonic acid:

A mixture of 160 g. (1.0 mole) of redistilled diethyl malonate, 250 g. (2.14 moles) of redistilled 2-diethylaminoethanol and 400 ml. of dry toluene was distilled slowly during eight hours through a 14″ vacuum-jacketed Vigreux column surmounted by a total reflux, variable take-off distillation head. A total of 435 ml. of distillate was collected, and the final internal temperature was 152°. Fractionation of the pale yellow-colored still residue gave 95.2 g. of a colorless liquid, b. p. 91–102° at 0.2–0.5 mm. (with slight decomposition).[22]

A mixture of 12.2 g. of salicylaldehyde and 30.2 g. of the above crude bis-(2-diethylaminoethyl) malonate gave no evidence of reaction, either when heated at 100° or when treated with, *e. g.*, pyridine. However, the addition of 10 drops of piperidine brought about an immediate coloration and an exothermic reaction. After heating on the steam-bath at 100° for three hours, the product was recrystallized from alcohol and converted to the hydrochloride with alcoholic hydrogen chloride. The yield of 2-diethylaminoethyl coumarin-3-carboxylate hydrochloride, m. p. 211–212°,[1a] was excellent.

The thiolcarboxylates were prepared by the direct reaction between a coumarin-3-carboxyl chloride and an ω-dialkylaminoalkanethiol in dry benzene.[23] The yields were essentially quantitative, and the products were easily purified.

The preparation of the coumarin-3-carboxamides was most conveniently carried out by direct interaction between a coumarin-3-carbonyl chloride and the dialkylaminoalkylamine in cold dry benzene. In certain cases (*e. g.*, with 4-diethylamino-1-methylbutylamine) a purer product was obtained by amination in a mixture of chloroform, water and sodium bicarbonate.[24] Amination by reaction between the ethyl ester and an amine gave unworkable mixtures (ring opening was very extensive under these conditions).

The properties and yields of the coumarin-3-carboxylates, -thiolcarboxylates, -carboxamides, and intermediates in their preparation, are given in Table I.

7-Hydroxycoumarin-4-carboxylic Acid.—The method of v. Pechman and Graeger[25] was modified through substitution of commercial sodio-oxalacetic ester for the oxalacetic ester–sodium ethylate mixture used by these workers. The yield (on one-mole runs) was 46%. Saponification of the ethyl ester according to v. Pechman and Graeger[25,26] gave 98% yields of purified acid, m. p. 245–246° (reported,[25] m. p. 247–248° uncor.).

2-Diethylaminoethyl 7-Hydroxycoumarin-4-carboxylate Hydrochloride.—A mixture of 5 g. of 7-hydroxycoumarin-4-carboxylic acid, 3 g. of 2-diethylaminoethyl chloride and 50 ml. of isopropyl alcohol was refluxed for one hour. A yellow crystalline precipitate appeared after twenty minutes. The reaction mixture was cooled, filtered, and the product was washed with cold isopropyl alcohol. Two recrystallizations from a large volume of ethanol gave 7.0 g. of long slender yellow needles, m. p. 192.7–193.9°.

Anal. Calcd. for $C_{16}H_{20}ClNO_5$: C, 56.22; H, 5.90; Cl, 10.38. Found: C, 56.31; H, 5.65; Cl, 10.30.

The following compounds were prepared by a similar method:

2-(1-Piperidyl)-ethyl 7-hydroxycoumarin-4-carboxylate hydrochloride, yellow leaflets from hot water, m. p. 213.4–215.0°.

Anal. Calcd. for $C_{17}H_{20}ClNO_5$: C, 57.72; H, 5.70; N, 3.96; Cl, 10.02. Found: C, 57.81; H, 5.49; N, 3.92; Cl, 9.90.

3-(4-Morpholinyl)-propyl 7-hydroxycoumarin-4-carboxylate hydrochloride, pale yellow prisms from dilute hydrochloric acid, m. p. 233.0–233.8°.

Anal. Calcd. for $C_{17}H_{20}ClNO_6$: C, 55.21; H, 5.45; N, 3.79; Cl, 9.59. Found: C, 55.44; H, 5.46; N, 3.67; Cl, 9.53.

The reaction failed with 2-dimethylaminoethyl chloride. The trans-esterification of ethyl 7-hydroxycoumarin-4-carboxylate by means of a basic alcohol in toluene gave good results, although purification proved difficult. Attempts to aminate the ethyl ester by means of an ω-dialkylaminoalkylamine failed.

The Reduction of Nitrocoumarin-3-carboxylic Acid Derivatives.—Both chemical and catalytic reductions were tried as means of securing *bz*-aminocoumarin-3-carboxylic acid derivatives; both methods failed.

Catalytic Reductions.—Hydrogenation of the nitrocoumarin derivatives was carried out in a modified[27] Parr–Burgess apparatus. No difference was observed in products obtained when the catalyst was varied between platinum, palladium or Raney nickel. Plots of hydrogen uptake *versus* time showed no definite change in slope ascribable to a difference in the rates of reduction between a nitro group and a double bond. A typical reduction follows:

A solution of 3.0 g. of ethyl 6-nitrocoumarin-3-carboxylate in 100 ml. of ethyl acetate was mixed with 5 g. of neutral Raney nickel catalyst and shaken with hydrogen at 2.5–3 atmospheres. Only a slow hydrogen uptake was evident at room temperature (ninety-six hours for completion) but reduction was initially rapid at 50°. During the latter stages of the reduction an orange precipitate appeared in the mixture (*vide infra*), and the reduction rate slowed while this precipitate gradually redissolved. At completion of the reduction (twelve to forty-eight hours at 50°) the solution was clear and colorless. After filtration of catalyst, the filtrate was diluted with a large volume of Skellysolve A. The resulting precipitate was filtered and recrystallized from a warm ethyl acetate–Skellysolve A mixture. **Ethyl 6-amino-3,4-dihydrocoumarin-3-carboxylate** crystallized in clusters of white cottony needles, m. p. 90–91° (dec.). The yield was 90%.

Anal. Calcd. for $C_{12}H_{13}NO_4$: C, 61.23; H, 5.53; N, 5.96. Found: C, 61.33; H, 5.45; N, 6.02.

The hydrochloride precipitated as white needles when an ethyl acetate solution of the base was treated with ethereal hydrogen chloride, m. p. 211–212° (dec.).

Anal. Calcd. for $C_{12}H_{14}ClNO_4$: C, 53.04; H, 5.16; N, 5.16. Found: C, 53.08; H, 4.96; N, 5.10.

The use of platinum or palladium catalysts increased the rate of reduction but did not affect the phenomena observed. In a manner similar to the above, there were prepared:

Ethyl 5-amino-8-methoxy-3,4-dihydrocoumarin-3-carboxylate, *via* an intermediate insoluble red-brown precipitate (*vide infra*); cottony white needles from ethyl acetate–Skellysolve A, m. p. 126–128°, yield 92%.

Anal. Calcd. for $C_{13}H_{15}NO_5$: C, 58.87; H, 5.66; N, 5.28. Found: C, 58.52; H, 5.64; N, 5.22.

The hydrochloride crystallized from absolute alcohol–ethyl acetate in white needles, m. p. 185–186°.

Anal. Calcd. for $C_{13}H_{16}ClNO_5$: N, 4.64. Found: N, 4.56.

(21) Hörenstein and Pählicke, *Ber.*, **71**, 1644 (1938). In the special case of nitrosubstituted coumarin-3-carboxylic acids the yields were lowered.

(22) Gilman and Johnson, THIS JOURNAL, **50**, 3346 (1928), prepared the compound from malonyl chloride and 2-diethylaminoethanol. They record a b. p. of 163° at 4.5 mm.

Ethyl 6-amino-8-methoxy-3,4-dihydrocoumarin-3-carboxylate, *via* an intermediate insoluble red-orange precipitate (*vide infra*); rosets of white needles from ethyl acetate–Skellysolve B, m. p. 81–82°, yield 93%.

Anal. Calcd. for $C_{13}H_{15}NO_5$: N, 5.28. Found: N, 5.32.

The hydrochloride formed white needles from absolute alcohol–ether, m. p. 185–190° (dec.).

Anal. Calcd. for $C_{13}H_{16}ClNO_5$: N, 4.64; Cl, 11.77. Found: N, 4.66; Cl, 11.65.

In solution the 3,4-dihydrocoumarin-3-carboxylates were very unstable to heat and to air. This phenomenon has been observed in a similar case by Smith and Byers.[11]

Chemical Reductions.—Application of the iron–acetic acid method of Clayton[8] to ethyl 8-methoxy-6-nitrocoumarin-3-carboxylate gave no reduction. Use of the general reduction procedure of West[28] afforded a high yield of a product which crystallized in red-orange needles from dilute alcohol, m. p. 149–150°. This material, of unknown constitution, proved to be identical (mixed

(28) West, *J. Chem. Soc.*, **127**, 494 (1925).

m. p.) with the intermediate colored insoluble reduction product observed during the catalytic reduction of ethyl 8-methoxy-6-nitrocoumarin-3-carboxylate (*vide supra*).

Anal. Found: C, 57.75; H, 4.98; N, 5.95.

A similar reduction of 2-diethylaminoethyl 8-methoxy-6-nitrocoumarin-3-carboxylate hydrochloride gave, as the only isolatable reduction product, a solid crystallizing from absolute alcohol–Skellysolve A in white needles, m. p. 134–135°.

Anal. Found: C, 46.06; H, 9.09.

The reduction of ethyl 6-nitrocoumarin-3-carboxylate by West's method gave a brown solid, crystallizing from dilute alcohol in bright yellow needles, m. p. 161–163°. This solid was identical (mixed m. p.) with the intermediate insoluble precipitate observed during catalytic reduction of the same compound (*vide supra*).

Anal. Found: C, 58.47; H, 4.73.

Similarly, the chemical reduction of N,N-diethyl-6-nitrocoumarin-3-carboxamide gave a bright yellow unstable solid, m. p. 110–115° (from benzene–Skellysolve A).

Anal. Found: C, 68.97; H, 5.83; N, 10.41.

Summary

There has been described the preparation of a series of substituted coumarin-3- and coumarin-4-carboxylic acid derivatives. Attempts to prepare *bz*-amino members of this series resulted either in 3,4-dihydrocoumarins or in highly colored compounds of unknown constitution.

A Crystalline Compound of β-Lactoglobulin with Dodecyl Sulfate[2]

By T. L. McMeekin, B. D. Polis, E. S. DellaMonica and J. H. Custer

Previous studies[3,4,5,6] have shown that proteins are precipitated from solution by synthetic detergents. Anionic detergents such as dodecyl sulfate precipitate proteins from acid solutions, whereas cationic detergents precipitate proteins from alkaline solutions. In the *p*H region close to the isoelectric point, neither cationic nor anionic detergents form precipitates with proteins.[6] Precipitated protein detergent complexes are soluble in an excess of detergent, accompanied by the denaturation of the protein and the liberation of free sulfhydryl groups.[3] The interaction of proteins with synthetic detergents has been extensively reviewed by Putnam.[7]

The work reported here deals with the preparation and properties of a crystalline complex of β-lactoglobulin combined with small quantities of dodecyl sulfate.

Experimental

Preparation of β-Lactoglobulin.—Crystalline β-lactoglobulin was prepared from unpasteurized milk by the method of Palmer.[8] The β-lactoglobulin contained 15.6% nitrogen and was electrophoretically homogeneous at *p*H 8.4 but inhomogeneous at *p*H 4.7, as was demonstrated by Li.[9]

Purified sodium dodecyl sulfate was used. A 0.01 molar aqueous solution, made to *p*H 4.2 with acetic acid, was used in precipitating β-lactoglobulin.

Preparation of Crystalline β-Lactoglobulin-dodecyl Sulfate.—β-Lactoglobulin-dodecyl sulfate was prepared by several procedures, in which the proportion of dodecyl sulfate to protein ranged from 4.2 to 14.0 cc. of 0.01 molar dodecyl sulfate per gram of protein. In every case, the crystalline protein prepared by dialysis at *p*H 5.1–5.2 after the removal of dodecyl sulfate with barium chloride, as described by Putnam and Neurath,[6] differed from β-lactoglobulin in solubility and mobility. Figure 1 gives a comparison of normal and dodecyl sulfate β-lactoglobulin electrophoretic patterns and mobilities in acetate buffer at *p*H 4.8 and veronal buffer at *p*H 8.4.

By adding 4.4 cc. of 0.01 *M* dodecyl sulfate to 50 cc. of a 2.1% solution of protein at *p*H 4.8, it was possible to crystallize the modified β-lactoglobulin directly, without the preliminary formation of a precipitate or the use of barium chloride to remove dodecyl sulfate. On standing for several hours, characteristic crystals appeared which had the electrophoretic mobility of modified β-lactoglobulin, demonstrating that only a small amount of dodecyl sulfate is necessary to modify the properties of β-lactoglobulin and that barium ions or barium sulfate do not produce the modification. The preparation which has been analyzed most completely was made as follows: approximately 10 g. of crystalline β-lactoglobulin suspended in 250 cc. of water was dissolved in dilute acetic acid and made to *p*H 4.2. Then 70 cc. of 0.1 *N* dodecyl sulfate at *p*H 4.2 was added with stirring. The small amount of precipitate formed was ignored. The solution then was made to *p*H 6.0 by adding dilute ammonia. The excess dodecyl sulfate was precipitated by adding 5 cc. of a 5% solution of barium chloride. After thirty minutes, the precipitated barium dodecyl sulfate was removed by centrifugation, and the supernatant was adjusted to *p*H 5.1. On dialysis, a yield of about 8 g. of crystalline protein was obtained. This material had a mobility u(sq. cm. volt^{-1} sec.$^{-1}$ $\times 10^5$) of 1 $u \times 10^5$ at *p*H 4.7 in acetate buffer and a mobility of $-5.9\ u \times 10^5$ at *p*H 8.4 in veronal buffer of 0.1 ionic strength. After several recrystallizations of the protein by dialysis from salt solutions, the properties were unchanged.

Table I shows the total nitrogen, α-amino nitrogen and total sulfur contents.

Properties of β-Lactoglobulin Dodecyl Sulfate

The analytical data in Table I indicate that two molecules of dodecyl sulfate are bound to one molecule of β-lactoglobulin. The method of preparation involving dialysis and treatment with barium to remove the insoluble barium salt of do-

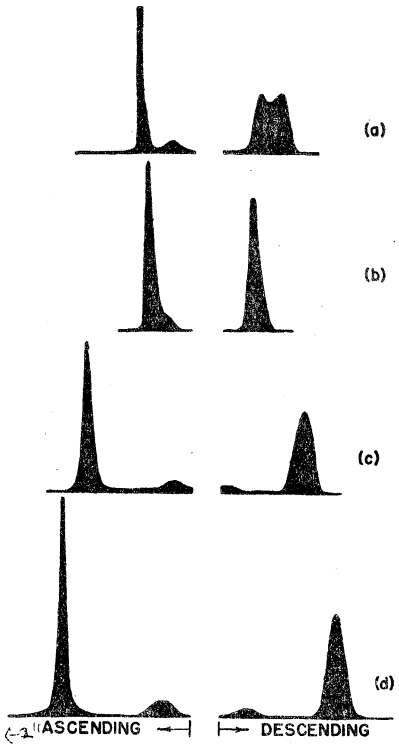

Fig. 1.—Comparison of electrophoretic patterns of normal β-lactoglobulin with those of its dodecyl sulfate derivative. In acetate buffer at *p*H 4.8, ionic strength 0.1: (a) β-lactoglobulin after 10,800 sec. at 4.37 volts/cm., (b) β-lactoglobulin dodecyl sulfate derivative after 10,800 sec. at 4.0 volts/cm. In veronal buffer at *p*H 8.4: (c) β-lactoglobulin after 10,800 sec. at 4.7 volts/cm., (d) β-lactoglobulin dodecyl sulfate derivative after 10,800 sec. at 4.6 volts/cm. Mobilities (a) 1.3, 2.5 *u*, (b) 1.0 *u*, (c) −5.1 *u*, (d) −5.9 *u*.

decyl sulfate indicates that the dodecyl sulfate is firmly held by the protein. It would be of great interest to locate the position of attachment of the dodecyl sulfate to the protein. It was thought that some information on the place of attachment between β-lactoglobulin and dodecyl sulfate might be obtained from a comparison of the properties of the normal and the modified protein.

TABLE I

COMPOSITION OF β-LACTOGLOBULIN AND ITS DODECYL DERIVATIVE

	Weight percentages		
	Total N	α-Amino N	Total S
β-Lactoglobulin	15.67	1.26	1.58
β-Lactoglobulin dodecyl sulfate	15.39	1.24	1.76
Calculated for:			
1 *M* β-lactoglobulin (mol. wt. 35000)			
2 *M* dodecyl sulfate (mol. wt. 265)			
	15.43	1.24	1.74

Titration Curve.—The combination of β-lactoglobulin–dodecyl sulfate with acid and alkali was compared with that of untreated β-lactoglobulin in potassium chloride solutions of 0.1 ionic strength, according to the method described by Cannan, *et al.*[10] Figure 2 shows the results. The combining capacity is consistent with the electrophoretic mobilities, in that at *p*H 4.7 the β-lactoglobulin–dodecyl sulfate with the smaller mobility combines with less acid than does β-lactoglobulin, whereas at *p*H 8.4 the alkali-combining capacity of the β-lactoglobulin–dodecyl sulfate is about two equivalents greater than that of β-lactoglobulin and the mobility is also greater. The two titration curves for solutions more acid than *p*H 4 are essentially the same; apparently the change in dissociation takes place between *p*H 4 and 6, which could not be that of the sulfate group, since it is a very strong acid and does not give a measurable *pK*.

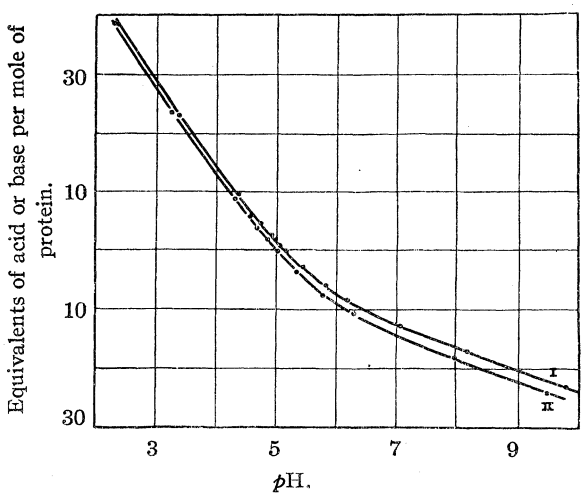

Fig. 2.—Titration curve of β-lactoglobulin (I), mol. wt. 35,000, and of β-lactoglobulin–dodecyl sulfate (II), mol. wt., 35,530.

Solubility.—There is a striking difference in the solubility of β-lactoglobulin and its dodecyl sulfate derivative. With the technique used by Gronwall,[11] the solubility of β-lactoglobulin at 25° was found to be 0.16 mg. of nitrogen per cubic centimeter in water and 1.7 mg. per cubic centimeter in 0.02 *M* sodium chloride. The solubility of dodecyl sulfate derivative was 0.08 mg. of nitrogen per cubic centimeter in water and 0.5 mg. of nitrogen per cubic centimeter in 0.02 *M* sodium chloride. Figure 3 shows the influence of *p*H on the solubility in water in 0.02 *M* sodium chloride.

Temperature of Coagulation.—Luck and his associates[12] have determined the effect of a variety of substances on temperature of coagulation or cloud point of serum albumin. These investigators have reported that small amounts of sodium dodecyl sulfate are particularly effective in preventing urea denaturation of serum albumin.

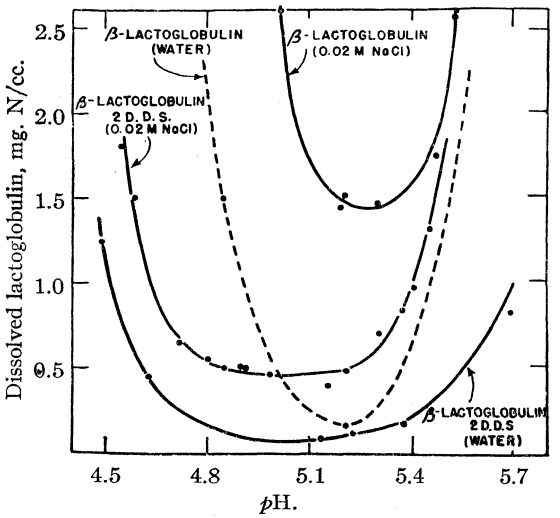

Fig. 3.—Comparison of the solubility of β-lactoglobulin with that of its dodecyl sulfate (D. D. S.) derivative.

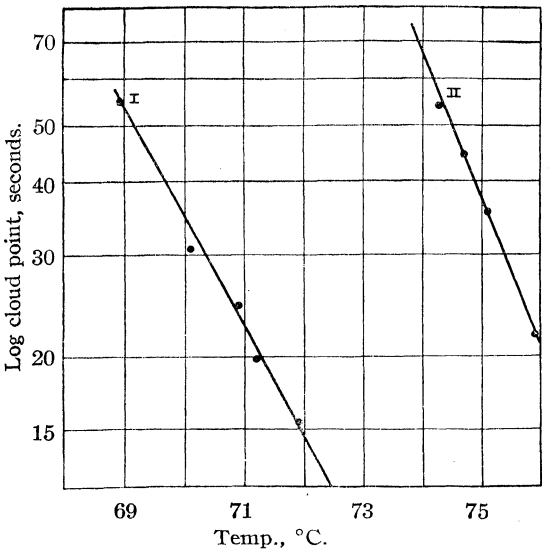

Fig. 4.—Comparison of log cloud point of β-lactoglobulin (I) with that of β-lactoglobulin–dodecyl sulfate (II) (1% solutions in 0.05 *M* sodium chloride, *p*H 5.2).

Cloud points of a 1% solution of β-lactoglobulin and its dodecyl sulfate derivative were determined in 0.05 *M* sodium chloride at *p*H 5.2. These are illustrated in Fig. 4. The presence of combined dodecyl sulfate increases the cloud point of β-lactoglobulin approximately 5°.

Optical Activity.—When dissolved in 0.1 *M* acetate buffer at *p*H 4.8, the β-lactoglobulin-dodecyl sulfate derivative had a specific rotation of $[\alpha]^{25}D$ −23.6°, as compared with a specific rotation of −30.5 for the untreated β-lactoglobulin.

Discussion

Exploratory studies with substances other than dodecyl sulfate, such as the dioctyl ester of sulfosuccinic acid and orange II, indicate that the combination of β-lactoglobulin with small amounts of large anions is rather general. Davis and Dubos[13] have found th t β-lactoglobulin combines with fatty acids, but to a smaller extent than does serum albumin.

Efforts to remove the two equivalents of dodecyl sulfate from β-lactoglobulin have not been successful. Long dialysis at *p*H 8.4 or treatment with barium hydroxide at *p*H 9.0 did not remove the dodecyl sulfate. Modification of the mobility of β-lactoglobulin by the presence of two molecules of unremovable dodecyl sulfate appears to be analogous to the difference in mobility between serum albumin and regenerated detergent-treated serum albumin,[6] indicating that barium chloride does not remove all the detergent from serum albumin.

The electrophoretic results of Li[9] indicate that β-lactoglobulin is heterogeneous. A partial separation of the electrophoretic components has been attained by fractionation,[14] giving crystalline fractions differing in solubility in water and salt solutions. It was hoped that dodecyl sulfate would be a useful substance for separating the components of β-lactoglobulin. However, all the fractions obtained by means of dodecyl sulfate had the same electrophoretic composition and behavior, indicating that the component proteins of β-lactoglobulin were all modified in a similar manner by the addition of dodecyl sulfate.

It is possible that the electrophoretic heterogeneity of β-lactoglobulin is due to the presence of non-amino acid groups combined with a portion of the β-lactoglobulin molecules in a manner similar to the combination of dodecyl sulfate. Electrophoretic determinations made on mixtures of equal parts of β-lactoglobulin and its dodecyl sulfate derivative are consistent with this hypothesis. In veronal buffer at *p*H 8.4, the normal β-lactoglobulin and the dodecyl sulfate derivative have markedly different mobilities, −5.1 and −5.9 *u*, respectively. The mixture moved as a single component with a mobility of −5.7 *u*. At *p*H 4.8 in acetate buffer, the electrophoretic pattern of the normal β-lactoglobulin indicated two components, with 60% of the protein in the faster component. The dodecyl sulfate derivative gave an electrophoretic pattern which was almost homogeneous, being composed largely of a component moving with a mobility of the slowest of the two β-lactoglobulin components. Mixtures of the normal protein and dodecyl derivative had a composite electrophoretic pattern. It will be necessary, however, to await the separation and analysis of the electrophoretic components of β-lactoglobulin before this hypothesis gains further credence.

Acknowledgment.—We are indebted to Dr. S. Lenher of E. I. du Pont de Nemours Company for the purified and analyzed sodium dodecyl

sulfate; and also to Dr. S. R. Hoover for the α-amino nitrogen determinations and Dr. C. L. Ogg for the sulfur determinations.

Summary

Preparation of a crystalline derivative of β-lactoglobulin containing two equivalents of firmly bound dodecyl sulfate is described. The solubility, mobility, titration curve and denaturation temperatures of the derivative are compared with the corresponding properties of β-lactoglobulin.

Synthesis of Naphthoquinones for Studies of the Inhibition of Enzyme Systems[1]

BY LOUIS F. FIESER AND RUSSELL H. BROWN[2]

Bueding, Peters and Waite[3] have reported the interesting finding that 2-methyl-1,4-naphthoquinone has the power to inhibit the anaerobic glycolysis of *Schistosoma mansoni* in *in vitro* tests at low concentrations, and that in experimental schistosomiasis in mice the quinone potentiates the action of subcurative doses of fuadin; the effect apparently vanishes when the dose is increased to the limit of tolerance. In coöperation with the program of pharmacological testing conducted by Dr. E. Bueding and Dr. L. Peters, we synthesized a number of additional naphthoquinones in the search for compounds of value in the chemotherapy of schistosomiasis. The assay data to be reported elsewhere show that, although several of the hydroxyl-free 2,3- and 2,6-disubstituted naphthoquinones described in this paper are considerably more potent than 2-methyl-1,4-naphthoquinone in the inhibition of the glycolytic enzyme concerned; the effect invariably is subject to strong antagonism by plasma proteins and the *in vivo* efficacy is in no instance appreciably greater than that of the simpler quinone.[4] A few of the compounds were tested against *Trichinella spiralis* in rats with completely negative results.[5]

Nachmansohn and Berman[6] observed that 2-methyl-1,4-naphthoquinone effects half-inhibition of choline esterase at dilutions in the order of 5×10^{-4} *M*, and Dr. Nachmansohn has found several of the new quinones here described to be distinctly more potent than methylnaphthoquinone against this enzyme system. The compounds are being studied for antitubercular activity at the Merck Institute for Therapeutic Research, following an observation by Dr. R. Dubos that some of the antimalarial 2-hydroxy-3-alkyl-1,4-naphthoquinones[7] show considerable *in vitro* potency, although the effect is greatly diminished in the presence of plasma proteins. 2-Methyl-6-valeryl-1,4-naphthoquinone appeared particularly promising in the *in vitro* assays but proved to be too toxic for *in vivo* evaluation in infected mice.

Specific naphthoquinones are recognized to influence the synthesis of prothrombin and the respiratory enzymes of malaria parasites, as well as enzymes associated with glycolysis, esterification, and the functioning of the *tubercle bacillus*. The present assay data indicate considerable specificity of action: a naphthoquinone showing high potency against one of the systems is not necessarily active against the others.

One route to compounds possessing enzyme-inhibiting activity was addition of an alkyl or aryl mercaptan to 1,4-naphthoquinone or its 2-methyl (Ia, b) derivative in methanol and oxidation of the resulting substituted hydroquinone by pouring the reaction mixture onto dichromate solution. Quinones of Type II are thus obtained more conveniently and in higher yield than by earlier procedures[8,9]; a similar method has recently been reported for the preparation of 2-thiomethyl-1,4-naphthoquinone, which was found to have high antifungicidal activity.[10] The

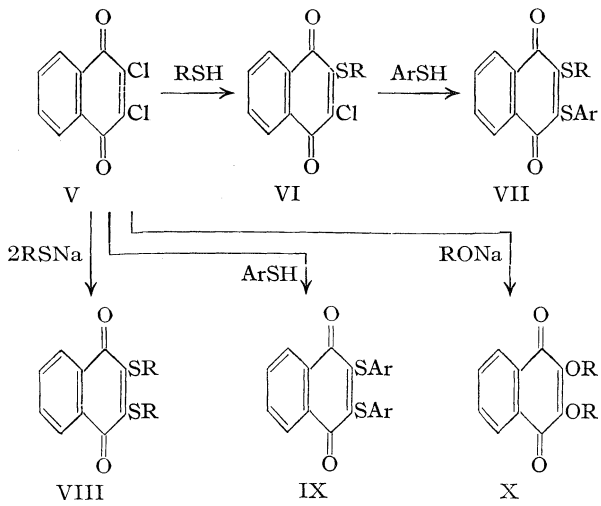
method served well for the preparation of 2-thioalkyl derivatives containing 1–12 carbon atoms in the alkyl group, 2-thioaryl derivatives, 2-methyl-3-thioalkyl and 2-methyl-3-thioaryl derivatives. 2-Chloro-1,4-naphthoquinone (Ic) is known to react with alkali[11] and with aniline[12] not by halogen displacement but by hydroxylation or arylamination at the 3-position, probably through an addition–oxidation mechanism. The reaction with mercaptans follows a similar course and leads to 2-chloro-3-thioalkyl-1,4-naphthoquinones (III). We have found, however, that treatment of the chloroquinone with a sodium mercaptide results in smooth displacement of chlorine to give the 2-thioalkyl derivative (IV). By the same method the chlorine atom of 2-chloro-3-anilino-1,4-naphthoquinone can be replaced by the thioalkyl group; 2-anilino-3-thiomethyl-1,4-naphthoquinone has been prepared previously by a lengthier method.[13] A related observation is that 2-chloro-1,4-naphthoquinone can be converted in good yield into 2-methoxy-1,4-naphthoquinone by reaction with sodium methoxide under anhydrous conditions; the reaction is in contrast to that occurring in aqueous alkali.

Further thio-derivatives were obtained from 2,3-dichloro-1,4-naphthoquinone.[14] When this substance (V) is refluxed in alcoholic solution with an aliphatic mercaptan only one of the chlorine atoms is replaced and the product (VI) is not affected by an excess of reagent. Aryl mercaptans react readily with replacement of both chlorine atoms (IX), and we were unable to isolate a monosubstitution product in experiments utilizing excess dichloronaphthoquinone.[15] Furthermore the chlorine atom of the 2-chloro-3-thioalkyl-1,4-naphthoquinones, although inert to alkyl mercaptans, is easily displaced by reaction with an aryl mercaptan to give VII. As in the examples cited above, the greater reactivity of the sodium salts of the alkyl mercaptans is manifested in the ability of these salts to replace both chlorine atoms of V and afford the 2,3-dithioalkyl derivatives (VIII). 2,3-Dimethoxy-1,4-naphthoquinone (X) was similarly obtained by treatment of dichloronaphthoquinone with sodium methoxide in methanol. The 2,3-diphenoxy derivative has previously been prepared by reaction with potassium phenolate in phenol solution,[16] and the condensation of dichloronaphthoquinone with β-naphthol in pyridine has been shown to proceed with closure of a furan ring.[17] We obtained the isomeric *brazanquinone* by reaction with α-naphthol. An attempt to prepare the thiophene analog led only to 2,3-dithio-β-naphthyl-1,4-naphthoquinone.



Other workers in this Laboratory have attempted without success to introduce the benzyl group into 2-methyl- or 2-hydroxy-1,4-naphthoquinone by peroxide alkylation,[18] but in the present work conditions were found for the satisfactory peroxide benzylation of these compounds and of the 2-chloro derivative by diphenacetyl peroxide. Whereas 2-methyl-3-benzyl-1,4-naphthoquinone was difficultly accessible by previous methods,[19] a 7-g. sample for *in vivo* assay was readily prepared by the present procedure.

A series of 6-acyl-2-methyl-1,4-naphthoquinones (XII) were prepared by oxidation of the 6-acyl-2-methylnaphthalenes (XI) available by Friedel–Crafts acylation of β-methylnaphthalene in nitrobenzene solution according to Haworth.[20] 3-Alkyl and 3-thioalkyl derivatives (XIII) of the 6-acyl quinones were obtained by the methods described above.

Experimental[21]

2-Thioalkyl-(aryl)-1,4-naphthoquinones (Table I). Example: R = CH_3.[10]—A suspension of 15.8 g. (0.1 mole) of α-naphthoquinone in 140 cc. of methanol was treated at 0° with a cold solution of 5.06 g. (0.125 mole) of methyl mercaptan in 20 cc. of methanol and the mixture allowed to stand at room temperature for two hours, when considerable solid reaction product had separated. The mixture was then poured into a vigorously stirred mixture of 20 g. of sodium dichromate dihydrate, 10 cc. of concentrated sulfuric acid, ice and water. The crude product collected by filtration weighed 17.7 g., m. p. 105–145°. Crystallization from 200 cc. of 95% ethanol and 100 cc. of benzene gave 10.22 g. (51%) of 2-thiomethyl-1,4-naphthoquinone, m. p. 180–184°; the fully purified quinone melted at 185–186° (No. 1).

Other Examples.—A similar preparation conducted with 7.91 g. (0.05 mole) of α-naphthoquinone and 3.10 g. (0.05 mole) of ethyl mercaptan yielded 8.72 g. of crude material, m. p. 97–115°; crystallization from 100 cc. of methanol and 75 cc. of 95% ethanol gave 4.45 g. (41%) of 2-thioethyl-1,4-naphthoquinone (no. 2), m. p. 139–142°. The yield was substantially the same when the amount of ethyl mercaptan was increased to 4.65 g. (0.075 mole): 4.87 g. (45%), m. p. 138–142°. 2-Thioisoamyl-1,4-naphthoquinone was prepared from a mixture of 3.16 g. (0.02 mole) of α-naphthoquinone and 2.08 g. (0.02 mole) of isoamyl mercaptan in 50 cc. of methanol. After standing for eighteen hours at room temperature long colorless needles of the substituted hydroquinone had separated. Oxidation as above and crystallization from 40 cc. of methanol gave 2.15 g. (41%) of large yellow leaves of nearly pure quinone (no. 9).

2-Thioisoamyl-1,4-naphthoquinone was also obtained by adding a solution of 1.04 g. of isoamyl mercaptan and 0.4 g. of sodium hydroxide in 10 cc. of methanol and 1 cc. of water to a solution of 1.93 g. of 2-chloro-1,4-naphthoquinone in 25 cc. of acetone at room temperature. After one hour the solution was diluted and the precipitated material crystallized from methanol (charcoal). A second crystallization from 40 cc. of methanol gave 0.9 g. (35%) of pure no. 9, identical with that of the above synthesis.

2-Thioalkyl-(aryl)-3-methyl-1,4-naphthoquinone (Table II). Example: R = $CH_2C_6H_5$.—A mixture of 3.44 g. (0.02 mole) of 2-methyl-1,4-naphthoquinone and 2.48 g. (0.02 mole) of benzyl mercaptan in 40 cc. of methanol was allowed to stand at room temperature for twenty-four hours and poured with stirring into a mixture of 5 g. of sodium dichromate dihydrate, 5 cc. of 96% sulfuric acid, 50 cc. of water and 150 g. of ice. The crude

(21) All melting points are corrected.

[a] Fieser, THIS JOURNAL, **48**, 2922 (1926). [b] Madinaveitia, *Ann. Soc. Expan. Quim. Fis.*, **31**, 750 (1933).

product (5.33 g.) on crystallization from 40 cc. of methanol yielded 4.11 g. (70%) of 2-methyl-3-thiobenzyl-1,4-naphthoquinone (no. 26), m. p. 68–70°. One more crystallization gave 3.74 g. of product m. p. 71–72°. The compound was obtained previously (Table II, Note *a*) in only 28% yield.

The same procedure was applied to the preparation of the other compounds listed, usually with substantially the same results: 70% yield of once crystallized product. The reaction of 2-methyl-1,4-naphthoquinone (17.2 g.) with *t*-butyl mercaptan (9 g.) in methanol (200 cc.) proceeded less smoothly. After standing for eight days the mixture was refluxed for twenty-four hours and on cooling deposited 3 g. of 2-methyl-3-thio-*t*-butyl-1,4-naphthoquinone.

Derivatives. (a) **Ethyl-(2-methyl-1,4-naphthoquinonyl-3)-sulfoxide.**—2-Methyl-3-thioethyl-1,4-naphthoquinone (2 g.) was covered with 5 cc. of fuming nitric acid and the mixture kept at room temperature for ten minutes and poured into 25 cc. of cold water. Crystallization of the precipitated material from 20 cc. of methanol yielded 1.55 g. (72%) of well-formed red-orange needles, m. p. 140–142°. A recrystallized sample melted at 143–144°.

Anal. Calcd. for $C_{13}H_{12}O_3S$: S, 62.87; H, 4.87. Found: C, 62.99; H, 5.12.

(b) ***n*-Dodecyl-(2-methyl-1,4-naphthoquinonyl-3)-sulfoxide** was obtained by the same method in 70% yield. The compound formed small tan balls from ethanol, m. p. 105–106°.

Anal. Calcd. for $C_{23}H_{32}O_3S$: C, 71.10; H, 8.30. Found: C, 71.46; H, 7.99.

2-Methyl-3-thioethyl-1,4-naphthohydroquinone dibenzoate was prepared in 78% yield (m. p. 138–140°) by the action of benzoyl chloride on the hydroquinone in pyridine. The pure material formed tiny white needles from ethanol–acetone, m. p. 143–145°.

Anal. Calcd. for $C_{27}H_{22}O_4S$: C, 73.26; H, 5.01. Found: C, 73.01; H, 5.28.

2-Halo-3-thioalkyl-1,4-naphthoquinones (Table III). (a) **From 2,3-Dichloro-1,4-naphthoquinone.**—Treatment of the dichloroquinone in alcoholic suspension with as much as two moles of an aliphatic mercaptan results in replacement of only one of the chlorine atoms. Thus 2-chloro-3-thio-*n*-octyl-1,4-naphthoquinone (No. 35) was prepared by heating a mixture of 6.81 g. (0.03 mole) of 2,3-dichloro-1,4-naphthoquinone and 8.76 g. (0.06 mole) of *n*-octyl mercaptan in 100 cc. of 95% ethanol under reflux for two hours. The resulting clear solution when cooled deposited a solid product that when recrystallized from 100 cc. of 95% ethanol afforded 6.30 g. (62%) of the substituted quinone, m. p. 61–65°. Further crystallizations from ligroin and from methanol gave material melting at 73–74°.

(b) **From 2-Chloro-1,4-naphthoquinone.**—2-Chloro-3-thio-*n*-dodecyl-1,4-naphthoquinone was prepared from a suspension of 1.93 g. (0.01 mole) of the monochloroquinone in 50 cc. of methanol, treated with a solution of 2.02 g. (0.01 mole) of *n*-dodecyl mercaptan in 25 cc. of 95% ethanol. After six hours at room temperature a solid reaction product that had separated was collected and recrystallized from 20 cc. of ethanol and afforded 1.0 g. (51%) of the 2-chloro-3-thio-*n*-dodecyl compound (no. 36), m. p. 83–84°.

(c) **By Halogenation.**—A mixture of 0.7 g. of 2-*n*-thiobutyl-1,4-naphthoquinone, 1 g. of fused sodium acetate, and 5 cc. of acetic acid was treated with 15 cc. of a solution of 1 cc. of bromine in 100 cc. of acetic acid. After standing for three hours at room temperature, the mixture was poured into 50 cc. of cold water and the precipitated solid collected, washed and dried: 0.83 g. (90%), m. p. 72–76°. Crystallization from 20 cc. of methanol gave 0.52 g. of 2-bromo-3-thio-*n*-butyl-1,4-naphthoquinone (No. 37), m. p. 82–84°.

2-Halo-3-alkoxy-1,4-naphthoquinones (Table III). (a) **By Halogenation.**—For the preparation of 2-bromo-3-methoxy-1,4-naphthoquinone (no. 38), a mixture of 0.51 g. of 2-methoxy-1,4-naphthoquinone and 1 g. of fused sodium acetate was treated with 15 cc. of a solution of 3.12 g. of bromine in 100 cc. of acetic acid at room temperature. There resulted a clear solution from which a yellow solid separated. Precipitation with 50 cc. of water after eight hours gave 0.68 g. (94%) of crude product, m. p. about 150°. This was crystallized to constant m. p. (163–164°) from methanol. The bromoethoxy and bromobutoxy derivatives (nos. 39–41) were prepared by the same method in comparable high yield. 2-Chloro-3-ethoxy-1,4-naphthoquinone (no. 40, known) was prepared by chlorination of 2.02 g. of 2-ethoxy-1,4-naphthoquinone in 25 cc. of acetic acid in the presence of 3.6 g. of fused sodium acetate with 15 cc. of an acetic acid solution containing 0.48 g. of chlorine for sixteen hours at room temperature. The precipitated product (1.96 g., 83%) melted at 80–85° and afforded pure material, m. p. 97–98°, on one crystallization.

(b) **From 2,3-Dichloro-1,4-naphthoquinone.**—A mixture of 2.27 g. of the dichloroquinone and 0.9 g. of sodium acetate in 60 cc. of absolute ethanol was refluxed for two hours, water was added, and the solid product was crystallized from methanol (charcoal). The resulting 2-chloro-

3-ethoxy-1,4-naphthoquinone (1.38 g., 58%) melted at 96–98°.

2-Methyl-3-alkoxy-1,4-naphthoquinones (Table III).—For preparation of the 3-methoxy compound (no. 42), 3 g. of the powdered silver salt of phthiocol was covered with 10 cc. of methyl iodide and allowed to stand at room temperature with occasional agitation for one hour. The product was extracted with 100 cc. of ether, the solution was washed three times with 3% ammonia solution, dried and evaporated. Crystallization of the residue from 15 cc. of methanol gave 0.93 g. (45%) of product, m. p. 93–94°.

The ethoxy compound was prepared in the same way in 47% yield (m. p. 72–74°); the silver salt failed to react with ethyl chloride. The alloxy, *n*-propoxy, *n*-butoxy, and benzyloxy derivatives (nos. 44–47) were obtained with use of allyl bromide, *n*-propyl iodide, *n*-butyl iodide and benzyl chloride in yields of 37, 53, 52 and 10%, respectively; the reaction of the silver salt with benzyl chloride was conducted for one-half hour on the steam-bath.

2,3-Dithioalkyl-1,4-naphthoquinones (Table IV).—The dithiomethyl derivative (no. 48) was prepared by treating a suspension of 5.7 g. of 2,3-dichloro-1,4-naphthoquinone in 20 cc. of methanol with a solution prepared from 2 g. of sodium hydroxide, 20 cc. of methanol, and 12 cc. of a solution of 25.3 g. of methyl mercaptan in 100 cc. of methanol. The mixture was refluxed for one-half hour and the resulting clear solution when cooled to 0° deposited 1.55 g. of yellow crystalline product, m. p. 90–100°. The solid was ground to a powder, shaken with 25 cc. of water, dried (1.33 g.) and crystallized from 95% ethanol (charcoal); the yield of long orange-red needles, m. p. 114–117°, was 0.74 g. (12%). 2,3-Dithioethyl-1,4-naphthoquinone (no. 49) was obtained similarly in 19% yield; the substance forms as an orange solution in ethanol, but the crystals that separate are extraordinary for their deep, almost black, purple color.

2,3-Dithioaryl-1,4-naphthoquinones (Table IV).—In a typical case a mixture of 2.27 g. of 2,3-dichloro-1,4-naphthoquinone and 2.48 g. of *p*-thiocresol in 100 cc. of 95% ethanol was refluxed for one hour and the solution cooled to 0°, when 3.68 g. (89%) of red crystals, m. p. 170–172°, separated. Two crystallizations from ethanol (80 cc./g.) gave pure 2,3-di-*p*-thiocresyl-1,4-naphthoquinone (no. 52), m. p. 173–174°. 2,3-Di-β-thionaphthyl-1,4-naphthoquinone was obtained in the same way in 95% yield (m. p. 192–195°).

2,3-Dithiophenyl-5-nitro-1,4-naphthoquinone was prepared by refluxing for one-half hour a mixture of 0.68 g. of 2,3-dichloro-5-nitro-1,4-naphthoquinone[22] in 25 cc. of 95% ethanol with 1.10 g. of thiophenol in 25 cc. of ethanol. A crystalline orange product separated (1.09 g., quantitative; m. p. 130–132°) and when crystallized from 75 cc. of ethanol formed red needles, m. p. 134–135°. A polymorphic form melts at 152°.

Anal. Calcd. for $C_{22}H_{13}O_4S_2N$: C, 63.00; H, 3.13. Found: C, 63.01; H, 3.28.

2-Thioalkyl-3-thioaryl-1,4-naphthoquinones (Table IV).—A solution of 0.25 g. of 2-thioethyl-3-chloro-1,4-naphthoquinone in 10 cc. of 95% ethanol was treated with 0.124 g. of *p*-thiocresol in 5 cc. of 95% ethanol and the mixture was heated gently for fifteen minutes and cooled to 80°, when 0.30 g. (89%) of long needles separated, m. p. 115–117° (no. 54). The homolog no. 55 was prepared similarly in 88% yield (m. p. 105–106°). The less soluble derivative no. 56 was prepared from 1.57 g. of the chloro compound in 20 cc. of 95% ethanol, treated with 0.162 g. of *p*-thiocresol in 25 cc. of 95% ethanol and 15 cc. of benzene; the yield of product, m. p. 98–100°, was 1.60 g. (80%).

2-Anilino-3-thio-*n*-amyl-1,4-naphthoquinone (no. 58) was prepared from a solution of 1.35 g. of 2-anilino-3-chloro-1,4-naphthoquinone[13] in 50 cc. of 95% ethanol mixed with a solution of 0.86 g. of *n*-amyl mercaptan and 0.2 g. of sodium hydroxide in methanol. The mixture was refluxed for two hours, diluted with 50 cc. of water, and the product that separated was crystallized from 20 cc. of methanol to give 1.44 g. (82%) of long, deep-red needles, m. p. 113–115°.

2,3-Disubstituted Naphthoquinones by Peroxide Alkylation

Diphenacetyl Peroxide.—Phenacetyl chloride (5.2 g. 0.0336 mole) was cooled well below 0° in Dry Ice–acetone and treated with 7.5 cc. of 30% hydrogen peroxide, cooled to 0° and added in one portion. The resulting semi-solid mass was treated with a solution of 7 g. of sodium hydroxide in 50 cc. of water that had been cooled almost to its freezing point and the mixture was shaken for ten minutes with intermittent cooling in Dry Ice–acetone, when the peroxide separated as a granular white solid. This was extracted with 100 cc. of ice-cold ether and the ether layer washed with cold saturated sodium chloride solution and used at once.

2-Methyl-3-benzyl-1,4-naphthoquinone.[19]—The above ethereal solution of peroxide was added to a solution of

0.0167 mole of 2-methyl-1,4-naphthoquinone in 50 cc. of acetic acid and the mixture heated very gently on the steam-bath for one-half-hour and then heated more vigorously for an equal period. The resulting acetic acid solution was diluted and the precipitated product collected and dissolved in 100 cc. of ether. The solution was extracted repeatedly with 2% alkali, shaken for ten minutes with hydrosulfite solution, and starting material was removed by extraction of the ethereal hydroquinone solution with dilute alkali containing hydrosulfite. The solution was washed with brine, shaken for five minutes with 5 g. each of silver oxide and magnesium sulfate, filtered and evaporated. Crystallization of the residue from 20 cc. of methanol gave 0.7 g. (16% based on the acid chloride) of the substituted quinone, m. p. 106–108°, identical with an authentic sample.

Other Examples.—**2-Hydroxy-3-benzyl-1,4-naphthoquinone**[23] was prepared by the same method and the unchanged 2-hydroxy-1,4-naphthoquinone removed by extraction of an ethereal solution of the product with bicarbonate solution; the yield of material m. p. 175–176° was 31%, based on the acid chloride. **2-Chloro-3-methyl-1,4-naphthoquinone**[24] was obtained in 50% yield (m. p. 152–153°) by alkylation of the chloroquinone with diacetyl peroxide. The **ethyl** and ***n*-undecyl** and **benzyl** derivatives (Nos. 60–62) were prepared similarly in yields of 45, 37 and 36%, respectively.

Ethers from Chloroquinones

2,3-Dimethoxy-1,4-naphthoquinone[25] was prepared by refluxing a suspension of 2.27 g. of the dichloro compound and 1.08 g. of sodium methoxide in 50 cc. of absolute methanol for one-half hour. The bright yellow product that separated on cooling (1.8 g., 83%; m. p. 100–105°) on crystallization from methanol gave material m. p. 114–115°. **2-Methoxy-1,4-naphthoquinone** was obtained similarly from the 2-chloroquinone in 37% yield (recrystallized, m. p. 182–183°).

3,4-Benzo-8,11-β-brazanquinone.—A mixture of 9 g. of 2,3-dichloro-1,4-naphthoquinone and 6 g. of α-naphthol in 50 cc. of pyridine was refluxed for five hours and the sparingly soluble product was precipitated with alcohol and crystallized from benzene–alcohol; yield 6.8 g. (58%). The pure substance formed tiny orange needles, m. p. 229–230°.

Anal. Calcd. for $C_{20}H_{10}O_3$: C, 80.54; H, 3.35. Found: C, 80.28; H, 3.30.

6-Acyl-2-methyl-1,4-naphthoquinones (Table V)

The 6-acyl-2-methylnaphthalenes employed as starting materials were prepared by Friedel–Crafts acylation in nitrobenzene solution by the method of Haworth.[20] 6-Acyl derivatives purified to a condition suitable for oxidation have the following melting points: *n*-butyryl, 43–44°; *n*-valeryl, 53–55°; *n*-capryl, 66–68°; γ-cyclohexylbutyryl, 75–76°. Oxidation to the naphthoquinones listed in Table V was conducted with chromic acid in approximately 90% acetic acid solution[26]; the yields varied to 10–40%, depending upon the purity of the starting material. The 3-alkyl derivative No. 68 was prepared by peroxide alkylation; the 3-thioalkyl derivatives were prepared by mercaptan addition and oxidation.

Summary

The preparation of over seventy new naphthoquinones was undertaken in coöperation with investigators who have observed that 2-methyl-1,4-naphthoquinone possesses some power to inhibit the glycolytic enzyme of the schistosome and to inhibit choline esterase. A number of 3-thioalkyl and 6-acyl derivatives of the parent quinone are described, as well as various 2,3-disubstituted-1,4-naphthoquinones and related compounds. The results of assays will be reported elsewhere.

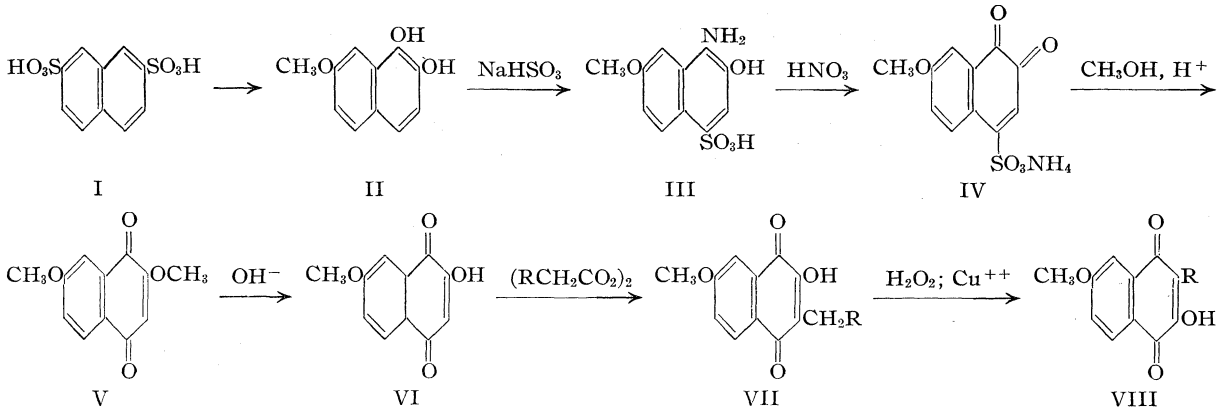
Naphthoquinone Antimalarials. XXIII. Bz-Substituted Derivatives[1]

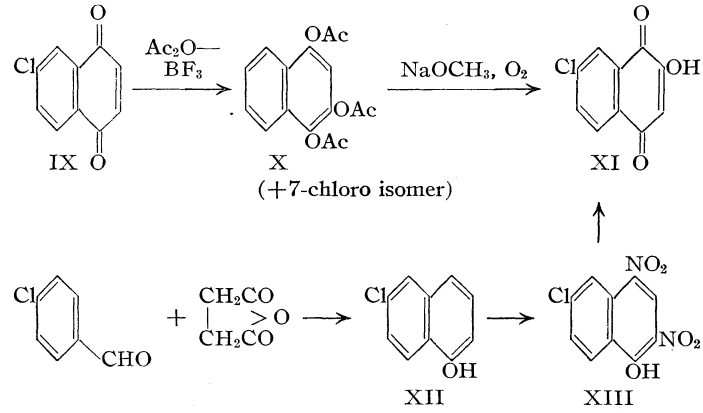
BY LOUIS F. FIESER AND RUSSELL H. BROWN[2]

In the few instances previously investigated the substitution of alkyl or hydroxyl groups in the benzenoid ring of a 2-hydroxy-3-alkyl-1,4-naphthoquinone has been found to practically obliterate antimalarial activity.[3] Since the case of atabrine would suggest the possibility of a more favorable result from the introduction of β-methoxy or β-chloro substituents into the aromatic ring, several new compounds of this type have been examined.



Two series of β-bz-methoxyquinones were prepared starting with 7-methoxy-1-nitroso-2-naphthol (II), available from naphthalene-2,7-disulfonic acid in three known steps. By procedures worked out for 1-nitroso-2-naphthol, II was converted through the aminonaphtholsulfonic acid III, the quinone sulfonate IV, and the dimethoxy quinone V into 2-hydroxy-7-methoxy-1,4-naphthoquinone (VI). By the peroxide alkylation reaction this was converted into 3-alkyl derivatives having from seven to eleven carbon atoms in the side-chain. These were converted by the modified Hooker oxidation[4] reaction into the next lower homologs in which, in consequence of the opening and reclosing of the quinone ring, the methoxy group is transposed to the 6-position (VIII). None of the compounds tested showed any antirespiratory activity,[5] whereas the corresponding methoxyl-free compounds are all active, even though the methoxyl substitution produces little change in the extraction constants.[6]

Related compounds carrying a chlorine atom at the 6- or 7-position were prepared starting with 6-chloro-1,4-naphthoquinone (IX), available from chloroprene and benzoquinone. The Thiele reaction afforded a separable mixture of the two hydroquinone triacetates, each of which was converted into the corresponding hydroxychloronaphthoquinone. One of these was identified as



the 2-hydroxy-6-chloro isomer by synthesis from the known 6-chloro-1-naphthol (XII) through the dinitro derivative XIII; this on reduction and oxidation afforded 6-chloro-2-amino-1,4-naphthoquinone-4-imine, which yielded XI on hydrolysis. The two hydroxychloroquinones were then alkylated with the peroxide from γ-cyclohexylbutyric acid, but neither product showed appreciable antirespiratory activity.

Experimental[7]

2-Hydroxy-3-alkyl-7(6)-methoxy-1,4-naphthoquinones

1-Nitroso-2-hydroxy-7-methoxynaphthalene.—Additional data on previously described procedures are as follows. Naphthalene (128 g.) was sulfonated with 95%

sulfuric acid (350 cc.) for four hours at 160°[8,9] and the cooled solution poured onto 500 g. of ice and 1.5 l. of water and neutralized with 450 g. of powdered calcium carbonate or 300 g. of quicklime. The mixture was filtered at 40° and the residual calcium sulfate extracted twice with 500-cc. portions of boiling water. The combined filtrates were evaporated to dryness and the mixture of 2,6- and 2,7-sulfonates was dried to constant weight at 200°; yield 263–285 g. Three parts of the crude calcium salt was treated with 5 parts of boiling water and the mixture was filtered by suction at the boiling point and the solid washed with a little hot water. Evaporation of the filtrate and dehydration as above gave 190 g. (58%) of **calcium 2,7-disulfonate.** Conversion to **2,7-dihydroxynaphthalene**[8] was effected by fusing 100 g. of calcium salt with 200 g. of crude potassium hydroxide flakes and 50 cc. of water for four hours at 250°. The granular mixture was added while hot in small portions with stirring to 800 cc. each of 36% hydrochloric acid and water and the granular 2,7-dihydroxynaphthalene that separated after cooling at 0° overnight was crystallized twice from water (100 cc.); yield 21.8–24.0 g. (44–49%), m. p. 189–190°.

2-Hydroxy-7-methoxynaphthalene[10] was prepared as outlined by Fischer and Hammerschmidt[11] by slowly adding 5.6 g. of potassium hydroxide in 100 cc. of water to a stirred mixture of 16 g. of 2,7-dihydroxynaphthalene; 150 cc. of water, and 20 cc. of dimethyl sulfate at 40°. After fifteen minutes 10% alkali was added to the point of distinct alkalinity, the solution was filtered by suction into dilute hydrochloric acid containing sodium sulfite and the residual diether washed repeatedly with warm alkali. The monomethyl ether separated as large white leaflets and was crystallized from ligroin; yield 9.76 g. (56%), m. p. 116–117°.

The 1-nitroso derivative[11] was prepared by slowly adding 20.3 g. of sodium nitrite in 150 cc. of water to a stirred solution at 0° of 51 g. of 2-hydroxy-7-methoxynaphthalene in 300 cc. of acetic acid containing 30 cc. of water. The resulting slurry was allowed to stand at room temperature for several hours, diluted with water, and the solid collected, washed, dried, and crystallized from 400 cc. of methanol. The yield of bright red needles, m. p. 124–125°, was 41 g. (69%).

7-Methoxy-1,2-naphthoquinone was obtained from the nitroso derivative by reduction and oxidation; it formed crimson microprisms from ethanol, m. p. 143–145°.

Anal. Calcd. for $C_{11}H_8O_3$: C, 70.20; H, 4.28. Found: C, 70.01; H, 4.18.

2,7-Dimethoxy-1,4-naphthoquinone (Table I).—By reaction with sodium bisulfite and acidification by a procedure worked out for the methoxyl-free compound,[12,13] 67 g. of 1-nitroso-2-hydroxy-7-methoxynaphthalene yielded 74 g. (84%) of 1-amino-7-methoxy-2-naphthol-4-sulfonic acid as a light gray granular solid. Oxidation of 83 g. of this material with nitric acid by the procedure of Fieser and Martin[14] gave 73 g. (83%) of ammonium 7-methoxy-1,2-naphthoquinone-4-sulfonate. Treatment of this substance with methanol and sulfuric acid according to Fieser and Martin afforded satisfactory 2,7-dimethoxy-1,4-naphthoquinone in 72% yield (No. 1, Table I).

The dimethoxy compound dissolved rapidly in hot dilute alkali, and acidification of the red solution gave **2-hydroxy-7-methoxy-1,4-naphthoquinone** in 82.5% yield (No. 2).

Alkyl Derivatives.—The 2-hydroxy-7-methoxy-3-cyclohexylpropyl and 3-undecyl derivatives Nos. 3 and 5 were prepared by peroxide alkylation in the usual manner.[15] A succession of Hooker oxidations[3] then gave, alternately, members of the 6-methoxy and the 7-methoxy series; thus: 3 → 7 → 4 → 8, and 5 → 9 → 6.

2-Hydroxy-3-alkyl-6(7)-chloro-1,4-naphthoquinones

6-Chloro-1,4-naphthoquinone[16] was prepared by the procedure described by Fieser for the parent quinone.[17] *p*-Benzoquinone (108 g.) was condensed with chloroprene[18] (89 g.) in acetic acid (500 cc.) at room temperature

(18) Obtained by fractionation of a stabilized chloroprene–xylene solution kindly supplied by the du Pont Company.

for forty-eight hours. Isomerization with hydrochloric acid–stannous chloride resulted in crystallization of 149 g. (76%) of light gray 6-chloro-5,8-dihydro-1,4-naphthoquinone (recrystallized sample, m. p. 197–198°). Oxidation in acetic acid with nitrous acid and then dichromate mixture gave bright yellow 6-chloro-1,4-naphthoquinone, m. p. 102–105°, in 77% yield from the dihydronaphthohydroquinone. Crystallization from ether raised the m. p. to 106–107°.

6- and 7-Chloro-1,2,4-triacetoxynaphthalene.—A suspension of 58 g. of 6-chloro-1,4-naphthoquinone in 120 cc. of acetic anhydride was cooled to 0° and treated with 6 cc. of boron fluoride etherate. After standing at room temperature for several hours, the mixture was warmed briefly on the steam-bath and again let stand. The suspension of crystals in dark brown liquor was poured into water and the product collected as a tan solid, m. p. 120–135°; yield 65 g. (63%). Fractionation from methanol was tedious but afforded substantial amounts of the less soluble 7-chloro compound, m. p. 163–164°, and of the more soluble 6-chloro isomer, m. p. 143–144°.

Anal. Calcd. for $C_{16}H_{13}O_6Cl$: C, 57.08; H, 3.89. Found: (164°) C, 57.34; H, 3.88; (144°) C, 57.31; H, 3.95.

6- and 7-Chloro-2-hydroxy-1,4-naphthoquinone (Table I) was prepared by the hydrolysis procedure of Fieser.[17] Thus 8.4 g. of 7-chloro-1,2,4-triacetoxynaphthalene was added in ten minutes to a suspension of 7 g. of sodium methoxide in 70 cc. of methanol, stirred in an ice-bath. After one hour the red salt was collected (more from mother liquor with air), dissolved in hot water, and the filtered solution acidified; yield of bright yellow microcrystalline product 4.5 g. (91%). The isomer was obtained in 81% yield.

The properties and analyses of the products of peroxide alkylation are listed in Table I.

Synthesis of 2-Hydroxy-7-chloro-1,4-naphthoquinone

7-Chloro-1-naphthol.—In the preparation of this substance according to Erdmann and Kirchhoff[19] the reaction mixture from 70 g. of *p*-chlorobenzaldehyde, 41 g. of fused sodium acetate and 50 g. of succinic anhydride was treated with water and 10 g. of the unchanged aldehyde was removed by steam distillation. The residue was diluted with water to about 2 liters, filtered, and acidified with hydrochloric acid. The crude precipitated *p*-chlorophenylparaconic acid [containing *p*-chlorobenzoic acid and β-(*p*-chlorobenzal)-propionic acid] weighing 40 g. was heated in a distilling flask until the evolution of carbon dioxide had subsided and distilled; the yellow, solidified distillate was dissolved in dilute alkali. The solution was extracted with ether to remove oily material and neutralized with carbon dioxide, when the 7-chloro-1-naphthol separated as almost colorless, fine needles, m. p. 125–130°; yield 8 g. (22%). One crystallization from water raised the m. p. to 130–131°.

2,4-Dinitro-7-chloro-1-naphthol was prepared by the exact procedure described for the chlorine-free substance[20] and obtained as the ammonium salt in 67% yield. The free phenol after several crystallizations from alcohol melted at 169–170°, dec.

Anal. Calcd. for $C_{10}H_5O_5N_2Cl$: C, 44.71; H, 1.88. Found: C, 44.70; H, 1.75.

2-Hydroxy-7-chloro-1,4-naphthoquinone.—By the procedure indicated,[20] 4 g. of the ammonium salt of the dinitro phenol yielded 2.0 g. (59%) of 2-amino-7-chloro-1,4-naphthoquinone-4-imine hydrochloride as deep red crystals. A suspension of 1.5 g. of this salt in 50 cc. of 5% aqueous potassium hydroxide solution was boiled for fifteen minutes and the resulting deep red solution was acidified. The amorphous precipitate of the hydroxyquinone (0.72 g.) was purified in the form of the hydroquinone triacetate, which crystallized from 40 cc. of methanol in the form of colorless needles, m. p. 140–143°. After five recrystallizations the analytical sample melted at 143–144° and gave no depression when mixed with the **7-chloro-1,2,4-triacetoxynaphthalene** described above.

Anal. Calcd. for $C_{16}H_{13}O_6Cl$: C, 57.08; H, 3.89. Found: C, 57.14; H, 3.73.

Other Observations

The **2-hydroxy-3-Δ$^{\omega}$-alkenyl-1,4-naphthoquinones** listed as Nos. 14–19 in Table I were all prepared from 2-hydroxy-3-Δ^{9}-decenyl-1,4-naphthoquinone[21] by the modified Hooker oxidation procedure.[4] We attempted to determine the nature of the water-soluble products obtainable[22] by the action of acetyl sulfuric acid in acetic acid solution on the homologs having 8, 7 and 6 methylene groups in the side-chain. The results were not fully conclusive but suggested that the products have the side-chain structure: $-(CH_2)_nCHOHCH_2SO_3H$. Thus the product from No. 7 yielded an aniline salt, m. p. 152–154°, and a *p*-toluidine salt, m. p. 163–165° (from alcohol–water) of the following analyses.

Anal. **Aniline salt.** Calcd. for $C_{25}H_{31}O_7NS$: C, 61.33; H, 6.38. Found: C, 61.61; H, 6.38. ***p*-Toluidine salt.** Calcd. for $C_{26}H_{33}O_7NS$: C, 62.00; H, 6.61. Found: C, 62.54; H, 6.67.

These substances were completely devoid of antirespiratory activity, as was a sulfonation product obtained in crude form from an oil resulting from alkylation of hydroxynaphthoquinone with the peroxide from oleic acid.

Oxidation of 3-Alkyl-1-tetralones with Selenium Dioxide.—The method of Weygand and Schröder[23] for the synthesis of 2-hydroxy-3-alkyl-1,4-naphthoquinones was briefly investigated with the following results. 3-Ethyl-1-tetralone, b. p. 112–114° at 2 mm., on reaction with selenium dioxide in ethanol afforded 2-hydroxy-3-ethyl-1,4-naphthoquinone, m. p. 137–138°, in 35% yield; the substance was compared with an authentic sample from the Hooker collection.[24]

2-Hydroxy-3-methyl-1,4-phenanthrenequinone was obtained by the same method in comparable yield; it formed bright orange needles from benzene, m. p. 215–217°.

Anal. Calcd. for $C_{15}H_{10}O_3$: C, 75.61; H, 4.23. Found: C, 75.44; H, 4.25.

Summary

Substances related to actively antimalarial 2-hydroxy-3-alkyl-1,4-naphthoquinones but having methoxyl or chloro substituents in the β-positions of the benzenoid ring were synthesized and found to be devoid of activity.

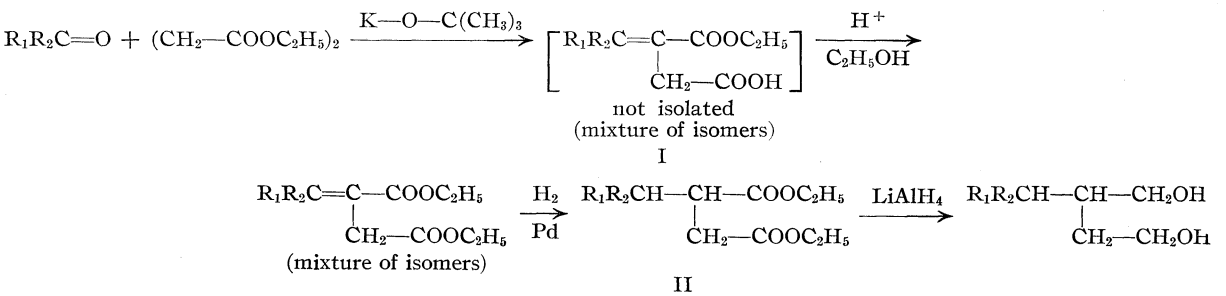
CONTRIBUTION FROM THE INSTITUTE OF POLYMER RESEARCH, POLYTECHNIC INSTITUTE OF BROOKLYN]

The Preparation of 2-Alkyl-1,4-butanediols[1]

BY C. G. OVERBERGER AND CARLETON W. ROBERTS

We have undertaken the preparation of a series of 2-alkylbutadienes in order to determine the reactivities of such dienes in the copolymerization reaction,[2] and to study the effects of side-chain alkyl groups, both straight and branched, upon the physical properties of diene polymers. Crystallization of the polymeric backbone and of the side chain are of special interest. Thus, the long alkyl side chains in a polymer of hexadecyl acrylate[3] results in crystallite formation in the side chain. Likewise, a branched alkyl group[4] or a long alkyl group may increase the amount of the 1,4-addition of the diene when forming the polymer, increasing the homogeneity and thus increasing the crystalline properties of the main polymer chain when the chains are oriented by stretching.

This paper will describe the preparation of some 2-alkyl-1,4-butanediols (II, also Table III), intermediates in the preparation of 2-alkylbutadienes. The synthetic route for preparing these diols was similar to that used by Wojcik and Adkins[5] and by Marvel, Myers and Saunders[6] to prepare 2-isopropyl-1,4-butanediol. Our improved procedure is experimentally different, and furnishes a good general method for the preparation of the 2-alkyl-1,4-butanediols. The procedure is outlined below.



The crude half-esters (I) obtained by the general procedure of Johnson and co-workers[7] were not isolated by us but were esterified to give high yields of a mixture of isomeric unsaturated 2 alkyl succinate esters (Table I). The yield reported for the condensation of acetone and diethyl succinate to the unsaturated diester according to the original conditions of the Stobbe condensation with sodium ethoxide was 53%[6]; compare 92%, Table I. The unsaturated alkyl diesters were further characterized by saponification to the unsaturated 2-alkylsuccinic acids (Table I).

Hydrogenation of the unsaturated diethyl esters over palladium at low pressures gave the 2-alkylsuccinic esters (Table II), which were similarly characterized by conversion to the 2-alkylsuccinic acids (Table II). Reduction of the diethyl 2-alkylsuccinates to the 2-alkyl-1,4-butanediols (Table III) was accomplished in almost quantitative yields by means of lithium aluminum hydride.[8] The diacetates of these diols are described in Table IV. The preparation and characterization of the dienes will be described in a later paper.

Discussion of the Structure of the Unsaturated 2-Alkylsuccinate Diesters and Diacids.—On the assumption that the extinction coefficient of an α,β-unsaturated ester is similar to that of an α,β-unsaturated acid[9] and is between 11,000 and 13,000 depending on the solvent, between 2200 and 2100 Å., some of the compounds in Table I have the double bond largely in the α,β-position: R_1 = iso-C_3H_7, n-C_9H_{19}, n-$C_{11}H_{23}$ and n-C_6H_{13}; R_2 = H. Those that have a lower extinction coefficient between 2200 and 2100 Å. are the esterified conden-

sates from methyl ethyl ketone (R_1 = CH_3, R_2 = C_2H_5) cyclohexanone, (R_1R_2 = C_5H_{10}), and methyl isopropyl ketone (R_1 = iso-C_3H_7, R_2 = CH_3). The condensate from acetone (R_1 = CH_3, R_2 = CH_3) has an extinction coefficient at the indicated range between the above two groups.

Separation of the unsaturated alkyl esters from unsymmetrical ketones or from aldehydes into possible *cis–trans* isomers has not been attempted. In general, there would only be slight displacements in the intensity and position of the absorption maxima for *cis* and *trans* forms in compounds of this type.

From the close agreement of the absorption spectra of the unsaturated alkyl diacids resulting from the diesters derived from aldehydes (R_1 = iso-C_3H_7, n-C_9H_{19} and n-C_6H_{13}; R_2 = H) it would appear that under the mild conditions of the saponification, no isomerization took place. The maximum absorption compares favorably with other α,β-unsaturated acids.[9b] Small increases of the extinction coefficients are noted, but this may be due to the small increase in resonance through a carboxyl group over the carbalkoxy group.[9e] Here again no attempt has been made to distinguish between *cis* and *trans* forms from aldehydes and unsymmetrical ketones.

The melting points of the diacids reported in

[a] From cyclohexanone. [b] B. p. also 119° (6.9 mm.), 87%. Ref. 6 reported b. p. 96° (1.5 mm.), $n^{20}D$ 1.4349, d^{20}_4 1.0055. [c] B. p. also 132–133° (8.5 mm.), 82%. [d] B. p. also 88–90° (1.1 mm.). [e] Analysis by H. S. Clark.

Table I are dependent on the rate of heating. A sample of the diacid from the cyclohexanone condensate obtained from Professor W. S. Johnson[10] was identical with our acid, mixed m. p. 179–180°, if the rate of heating was 3° per minute whether immersion of the sample was at low temperature or 170°. Heating at the rate of one degree per minute gave a m. p. 164.5-166° dec., mixed m. p. 164–166° dec. This depression may be due to lactone formation or to other decomposition. We used a heating rate of a 2 or 3° rise per minute to obtain our melting points.

Experimental

Preparation of Diethyl 2-Alkyl Unsaturated Succinates. Procedure A.—The compounds listed in Table I were prepared according to modifications of the procedure described by Johnson and co-workers.[7a,7b] We have extended the preparative scheme to the direct preparation of the diethyl esters of 2-substituted unsaturated succinic acids. The following procedure was employed for the compounds in Table I indicated by superscript b.

A mixture of 0.8 mole of the carbonyl compound and 1.0 mole of diethyl succinate was added over fifteen minutes to a refluxing solution of 0.88 mole of potassium in 800 ml. of anhydrous *t*-butyl alcohol. The stirred reaction mixture was heated under reflux for a time depending upon the reactivity of the carbonyl compound (see Table I). The solvent was removed from the reaction mixture under reduced pressure, the residue was made slightly acid to litmus with dilute hydrochloric acid and the remainder of the solvent was removed. The organic layer was dissolved in 200 ml. of ethyl ether and the aqueous layer was separated and extracted with three 200-ml. portions of ether. The combined ether solutions were washed with water and then extracted completely with 10% aqueous carbonate. The ether washing of combined alkaline extracts was added to the original ether layer and the ether solution was dried over anhydrous magnesium sulfate. From this residue it was possible to recover unreacted and excess diethyl succinate.

The alkaline solution was made strongly acid with concentrated hydrochloric acid and chilled. The organic layer was separated, and the aqueous layer was extracted with four 150-ml. portions of ethyl ether. The ether layers were combined with the separated organic layer, washed with water, and dried over anhydrous magnesium sulfate. After removal of the ether from the "half-acid," a chilled solution of the residue in 10 volumes of anhydrous ethyl alcohol was treated with dry hydrogen chloride to give a 5% solution by weight. After twenty-four hours at room temperature, the alcohol was removed under reduced pressure. The residue was poured into an ice–ice-water mixture, and the ester layer was taken up in ethyl ether. The aqueous layer was extracted with four 200-ml. portions of ethyl ether, and the extracts, after combining with the original separation, were neutralized by washing with aqueous sodium bicarbonate and dried over anhydrous magnesium sulfate. The alkaline washes were saved and on subsequent saponification gave a small quantity of 2-alkenesuccinic acid. The residual diester was fractionated through a 30-cm., helices-packed column. The yields of the diesters and physical constants are found in Table I.

(10) We are indebted to Professor W. S. Johnson for a sample of the half-acid derived from the cyclohexanone condensate and the diacid from its saponification, m. p. 179–180°. Evidence was presented to show that this was the α,β-acid.

Procedure B.—The compounds listed in Table I (superscript c) were prepared by this modified procedure since by-products obtained in the initial condensation and difficulties due to emulsification made it impossible to completely separate the "half-acid" by the usual carbonate extraction. Therefore, the initially acidified reaction mixture was extracted with ether in the usual manner and dried over anhydrous magnesium sulfate. The entire ether-soluble reaction product was esterified as in the previous procedure, and the residue fractionated through a similar column. A typical experiment gave in the case of diethyl 2-*n*-decylidenesuccinate the following fractions: Fraction 1, 25 g., b. p. 80–90° (0.7 mm.); fraction 2, 75 g., b. p. 155–160° (0.6 mm.); fraction 3, 75 g., b. p. 210–220° (0.6 mm.). Fraction 2 was refractionated through the same column to give 60 g. (35%) of pure product.

Saponification of Unsaturated Diesters.—Five grams of the pure diethyl unsaturated 2-alkylsuccinates were saponified in 50 ml. of a refluxing 10% aqueous sodium hydroxide. Acidification of the decolorized and filtered reaction mixtures with concentrated hydrochloric acid gave crystalline succinic acids. The products were air-dried and recrystallized from the appropriate solvent as noted in Table I.

Preparation of Diethyl 2-Alkylsuccinates.—One-tenth mole of our initial condensation product (Table I) was dissolved in 50 ml. of 95% ethyl alcohol containing 0.5 g. of suspended 5% palladium-on-charcoal catalyst, and the mixture shaken in an atmosphere of hydrogen at 55–60 p. s. i. pressure. In all experiments between 95 and 100% of the theoretical quantity of hydrogen was absorbed. The reaction mixture was filtered to remove the catalyst, and the solvent was removed by distillation at atmospheric pressure. The residual ester was distilled under reduced pressure. The data are summarized in Table II.

Preparation of 2-Alkylsuccinic Acids.—Five grams of the diethyl 2-alkylsuccinates was saponified as described for the treatment of the unsaturated esters. The data are summarized in Table II.

Preparation of 2-Alkyl-1,4-butanediols.—Following the general procedure of Nystrom and Brown,[8] 0.1 mole of the diethyl 2-alkylsuccinate was added dropwise to a chilled, stirred anhydrous ether solution of 0.12 mole of lithium aluminum hydride. The reaction mixture was stirred for one hour after the addition was completed and the excess hydride was decomposed by the careful addition of the required amount of water. The reaction mixture was then poured into a mixture of ice and water containing 10% sulfuric acid. The ether layer was separated after the complex had been completely decomposed and the aqueous layer was extracted with five 100-ml. portions of ethyl ether. The combined ether layers were washed with a minimum of water containing bicarbonate and dried over anhydrous magnesium sulfate. The residual diol was fractionated through a 30-cm., helices-packed column. There was usually a forerun of lower boiling material. The data on each of the diols are summarized in Table III.

Preparation of the 2-Alkyl-1,4-butanediol Diacetate.—Each diol was suspended in a threefold excess by weight of acetic anhydride and boiled under reflux for from six to ten hours. The excess anhydride was removed by distillation under reduced pressures, the residue taken up in ethyl ether and the ether solution washed with bicarbonate solution until neutral. The ether solution was dried over anhydrous magnesium sulfate, and the residue was fractionated through a 30-mm., helices-packed column. The data are summarized in Table IV.

Ultraviolet Absorption Spectra.—Ultraviolet absorption spectra were determined with a Beckman quartz ultraviolet spectrophotometer in purified cyclohexane[11] and 95% ethanol as solvents. The cell length used in all experiments was 1 cm. Figure 1 describes the spectra for the esterified condensation product of diethyl succinate and *n*-decylaldehyde and the analogous diacid.

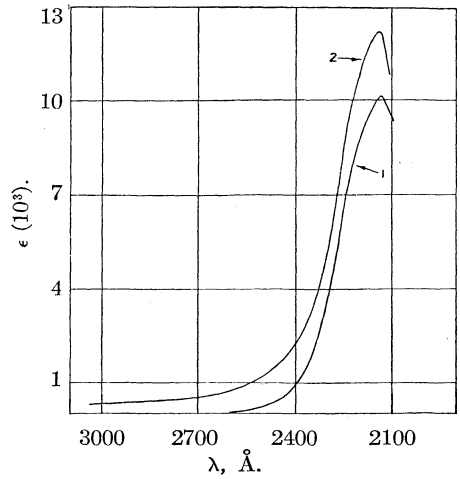

Fig. 1.—Ultraviolet absorption spectrum of: (1) diethyl-2-decylidenesuccinate in cyclohexane; (2) 2-decylidenesuccinic acid in 95% ethanol.

Summary

1. A convenient preparation of 2-alkyl-1,4-butanediols, intermediates in the synthesis of 2-alkyl-1,3-butadienes has been described.

2. Seven new 2-alkyl-1,4-butanediols have been prepared and characterized [OH–CH_2–$CH(CHR_1R_2)$–CH_2–CH_2OH] R_1 = CH_3, R_2 = C_2H_5; R_1R_2CH = C_5H_{10}; R_1 = iso-C_3H_7, R_2 = H; R_1 = *n*-C_9H_{19}, R_2 = H; R_1 = *n*-$C_{11}H_{23}$, R_2 = H; R_1 = *n*-C_6H_{13}, R_2 = H; R_1 = iso-C_3H_7, R_2 = CH_3. The diacetates of these diols have likewise been prepared and characterized.

3. Seven new diethyl 2-alkylsuccinates intermediate in the diol synthesis have been prepared and characterized [EtOOCCH(CHR_1R_2)CH_2–COOEt]. Likewise the diacid (R_1 = iso-C_3H_7, R_2 = CH_3) derived from the corresponding diester is described.

4. The absorption spectra of eight unsaturated 2-alkylsuccinates (see above R_1R_2, also R_1 = CH_3, R_2 = CH_3) have been measured. The isomeric structures surmised from these data are briefly discussed. Likewise, absorption spectra have been obtained for four new unsaturated 2-alkylsuccinic acids. On the basis of existing data for the absorption spectrum of an α,β-unsaturated acid, the results indicate that the double bond is in the α,β-position.

The Oxidation Potentials of Aldehydes and Ketones

BY HOMER ADKINS, RICHARD M. ELOFSON,[1a] A. G. ROSSOW[1b] AND COWIN C. ROBINSON

The relative strengths of ninety carbonyl compounds as oxidizing agents have been ascertained by determining the concentrations at equilibrium in systems of the type

$$R_2CO + R'_2CHOH \underset{}{\overset{Al(OC_4H_9\text{-}t)_3}{\rightleftharpoons}} R_2CHOH + R_2'CO.$$

The experimental observations on which the data in the table are based were made by F. W. Cox,[2] Robert H. Baker,[3,4] A. G. Rossow,[5] C. C. Robinson[6] and Richard M. Elofson.[7] The last named has calculated all the values given herewith, and has concluded[7] that except for benzaldehyde, the values previously published are high by 33 m.v.

The oxidation potentials were calculated on the basis of the oxidation potentials of certain quinones. Three quinones of known oxidation potentials[8] were included in the series, *i. e.*, 9,10-anthraquinone, 154 mv., 1-chloroanthraquinone, 174 mv. and isopropyl 9,10-anthraquinone-2-carboxylate, 222 mv. One ketone, 2,7-dichlorofluorenone, was equilibrated against each of the three quinones. The oxidation potential, E_0, of 2,7-dichlorofluorenone was calculated from the oxidation potential of a quinone E_0' using the expression $E_0 = E_0' + RT/NF \ln K$ where K is the equilibrium constant for the reaction given above. For 25° the expression becomes $E_0 = E_0' + 0.0296 \log K$.

The oxidation potential of the ketone was found to be 157, 156 or 160 mv. depending upon the quinone used in comparison. Fluorenone and benzophenone have also been equilibrated against each other and against 9,10-anthraquinone. These ketones were in turn equilibrated against cyclohexanone and the latter against 2,7-dichlorofluorenone. The values of E_0 for 2,7-dichlorofluorenone, calculated from these series of comparisons, were 154 and 159 mv. The average of the five values for 2,7-dichlorofluorenone is 157 mv. This figure has been used as the basis for calculating the oxidation potential of most of the carbonyl compounds listed in the Table I, since 2,7-dichlorofluorenone was equilibrated directly or indirectly against all the other ketones and aldehydes except chloral and the alpha-keto esters. These keto esters and chloral were equilibrated against isopropyl benzoylformate and the latter against isopropyl 9,10-anthraquinone-2-carboxylate.

Limitations and Reliability of Data

There are several factors which determine and limit the reliability of the procedures on which the data in Table I are based. The method for the determination of the concentration of the reactants at equilibrium depends upon at least one of the two carbonyl compounds in a reaction mixture showing a depolarization potential on a polarograph. Thus direct comparisons must include an aldehyde, or a quinone, or a ketone with unsaturation in the 2,3-position. The concentration of such carbonyl compounds can be determined so accurately with a polarograph[4] that if the analytical determination were the only source of error the calculated oxidation potential would in general be reliable within 1 or 2 mv.

The greater the difference in oxidation potential between the two carbonyl compounds in the reaction mixture, the less accurate is the calculated oxidation potential. Small errors in the analytical determination will cause relatively large errors in the calculated oxidation potential when the difference between E_0 and E_0' is more than about 50 mv. This follows from the fact that if two carbonyl compounds A and B differ in potential by 100 mv. then at equilibrium there will be only 2% of the ketone A having the higher potential and 98% of B. If the difference in potential is 80 mv. there will be 4.2% of A, for 60 mv. 8.8% A, for 50 mv. 12.5% A, for 30 mv. 23.5% A, for 20 mv. 31.5% A and for 10 mv. 40.5% A. In order to minimize errors arising from this source, fluorenone, 119 mv., 2,7-dichlorofluorenone, 157 mv., and isopropyl benzoylformate, 282 mv., were preferred for the measurement of carbonyl compounds having potentials in the three ranges. Cyclohexanone, 162 mv., has been used in equilibrations where the polarographic curve for 2,7-dichlorofluorenone was obscured by that of the other carbonyl compound in the reaction mixture. Benzaldehyde, 192 mv., and trimethylacetaldehyde, 211 mv., were also useful in determining the oxidation potential of other aldehydes in the range of 186 to 270 mv.

The most serious limitation upon the accurate determination of the oxidation potential of a carbonyl compound, by the procedures described herewith, is imposed by side reactions. These are particularly serious with carbonyl compounds which react slowly as oxidizing agents and yet are capable of undergoing the aldol or Tischenko types of condensation. The more rapid the oxidation by the reference compound the less

TABLE I

[a] The carbonyl compound against which Cox (C), Baker (B), Rossow (Rs), Robinson (Rb), or Elofson (E) equilibrated a given compound is indicated in the fifth column of the table, by using the number of the carbonyl compound as given for the compound in the first column of the table. The values for the methoxyacetophenones, given by Baker and Schafer,[4b] are in agreement with the potentials listed in the table for these compounds, if they are based upon a potential for fluorenone of 117 mv., rather than upon the value 150 mv. reported earlier.[4a] [b] These depolarization potentials were observed in a 0.1 *N* ammonium chloride solution, while the others reported were in a 0.05 *N* tetramethylammonium hydroxide solution. [c], [d] and [e] These ketones were reduced to the corresponding alcohols with aluminum isopropoxide[c] or by catalytic hydrogenation over Raney nickel[d] or copper chromium oxide[e]. [f] Boiling points. [g] This is a minimum value.

chance there is for a significant amount of a side reaction. Fluorenone is outstanding in giving rapid reactions. 2,7-Dichlorofluorenone is less reactive while isopropyl benzoylformate reacts quite slowly. Cyclohexanone reacts rapidly but is itself subject to condensation.

The determination of the oxidation potentials of Δ^4-cholestenone-3, Δ^5-cholestenone-3, Δ^2-cyclohexenone and Δ^3-cyclohexenone involves certain peculiar difficulties and uncertainties. In the classical Oppenauer oxidation of cholesterol by acetone to Δ^4-cholestenone-3 there is an intramolecular as well as an intermolecular oxidation–reduction. The latter ketone may be isolated in a yield of about 80% from such a reaction mixture. The reactions may be represented by the scheme

$$\begin{array}{ccc} \Delta^5\text{-cholestenol-3} + \text{K} & \rightleftharpoons & \Delta^5\text{-cholestenone-3} + \text{A} \\ \uparrow\downarrow & & \uparrow\downarrow \\ \Delta^4\text{-cholestenol-3} + \text{K} & \rightleftharpoons & \Delta^4\text{-cholestenone-3} + \text{A} \end{array}$$

where K represents a ketone and A the alcohol corresponding to it.

Cholesterol (Δ^5-cholestenol-3) is oxidized by

fluorenone, under our standard conditions of reaction, until at equilibrium the concentration of fluorenone is 80%. The conversion at equilibrium corresponds to a value of 153 mv. for Δ^5-cholestenone-3. The concentration of fluorenone at equilibrium with Δ^4-cholestenone-3, *i. e.*, 11%, corresponds with an oxidation potential of 63 mv. for the Δ^4-cholestenone-3, but the equilibrium then shifts in the direction of increasing fluorenone concentration. These facts are compatible with the hypothesis that in the oxidation of cholesterol to Δ^4-cholestenone-3 by ketones such as acetone and fluorenone, the Δ^5-cholestenone-3 is first formed and then undergoes intramolecular oxidation–reduction and the formation of the isomeric Δ^4-cholestenone-3.

Δ^2-Cyclohexenone and fluorenol or Δ^2-cyclohexenol and fluorenone give a similar series of changes which presumably involved the formation of Δ^3-cyclohexenol and Δ^3-cyclohexenone, *i. e.*

$$\Delta^3\text{-cyclohexenol} + K \rightleftharpoons \Delta^3\text{-cyclohexenone} + A$$

$$\Delta^2\text{-cyclohexenol} + K \rightleftharpoons \Delta^2\text{-cyclohexenone} + A$$

These intramolecular changes will be discussed in a subsequent paper; however, it should be pointed out that the conclusions as to the potential of the four ketones just discussed did not involve the isolation of Δ^5-cholestenone-3, Δ^3-cyclohexenone nor Δ^3-cyclohexenol.

Many of the ketones react so slowly that it was necessary to approach equilibrium concentrations by a series of approximations. After the probable ratio of the two ketones at equilibrium had been estimated, several reaction mixtures of the two ketones, R_2CO and $R_2'CO$, and the corresponding alcohols were made up. The ratios of reactants were varied so that in some mixtures there was slightly more and in some slightly less of R_2CO than at equilibrium. Determination of the direction and extent of shift could then be made after relatively short periods of reaction that minimized the effect of any side reactions.

Due to uncertainty as to the precise concentrations at equilibrium, the oxidation potentials given for formaldehyde, Δ^3-cyclohexenone, cinnamaldehyde, the α-methoxy ketones, ω-piperidinoacetophenone, *t*-butylglyoxal, chloral, isopropyl and ethyl pyruvates, Δ^4- and Δ^5-cholestenone-3 and ethyl oxomalonate may be in error by as much as ± 10 mv. Only a minimum value can be given for 1,3-dimethoxyacetone. The values for other equilibria, except as noted below, may be considered as accurate to within ±5 mv. Relative to each other, the potentials of most of the ketones having values from about 110 to 170 mv. are probably reliable to within ±3 mv. All equilibria except as noted were approached from both directions.

The equilibrium between formaldehyde and benzaldehyde could only be approached from one direction, *i. e.*, through the reaction of methanol and benzaldehyde. However, the value determined, 270 mv., is in fair agreement with the value of 257 mv. calculated from thermal data.[9] The earlier data in Parks and Huffman[10] indicate an oxidation potential of 277 mv.

The oxidation potentials of acetaldehyde, acetone and pyruvic acid have been reported, or may be calculated from data in the literature, and so compared with the potentials determined in this Laboratory. The oxidation potential of acetone, calculated from the data of Parks and Huffman,[10] is 126 mv. Later measurements by Dolliver, Gresham, Kistiakowsky and Vaughan[11] indicate that the value should be lower, *i. e.*, 121 mv. From Conant's[12] work it can be concluded that the oxidation potential of 9,10-anthraquinone in the gas phase is not more than 10–20 mv. lower than in solution. Thus the value of 129 mv. reported here for acetone is in agreement with those calculated from thermal data.

The free energy of reduction of acetaldehyde in the gas phase reported by Parks and Huffman is only 7,320 calories. However, they state that this value leads to an inconsistency of 2,230 calories in the free energy of formation, calculated for gaseous acetaldehyde. If such a correction is made, we find that $\Delta F^\circ_{298} = -9550$ cal., and $E_0 = 207$ mv. for acetaldehyde. The data given by Kistiakowsky and associates indicate that $\Delta F^\circ_{298} \approx -9400$ cal., assuming an entropy of 60 e. u. for acetaldehyde. However, until the entropy of gaseous acetaldehyde is measured, an accurate estimate of the free energy of reduction of gaseous acetaldehyde is not available. The oxidation potential measured by equilibration is 226 mv., which is in satisfactory agreement with the approximate values calculated above, since the values in solution are presumably 10 or 20 mv. higher than in the gas phase reaction.[12]

Three groups of investigators[13,14,15] have reported the oxidation potential of pyruvic acid in solution to be 288 mv. while two other groups[16,17] give higher values of 316 and 325 mv. The value reported here is 297–299 mv. for two esters of pyruvic acid. Conant and Fieser[8] have shown that in the quinone series the potential of an acid is about 10 mv. lower than for the ester. Thus the value for pyruvic acid would be 287–289 mv. which is in perfect agreement with that reported by three groups of investigators.

Attention should be called to two assumptions made in the calculations of the potentials given in the table. The oxidation potentials for the quinones used for reference were determined in an alcohol–water solution,[8] while the equilibria were measured in toluene solution in the presence of aluminum alkoxides. The equilibria were in most instances established at 60 to 70°. In the calculations it is assumed that the value of K is the same at these temperatures as at 25°. The heat of the oxidation–reduction reaction is small and measurements with the aldehydes showed that the concentrations at equilibrium at 25° were the same as at 60°. Neither of these assumptions would affect the relative values of the oxidation potentials given herewith, but might distort the absolute values. However, the agreement between the values of E_0 calculated from physical chemical data and those from our experimental results supports the thesis that the absolute as well as the relative values of E_0 as given are reliable for the carbonyl compounds reported.

Relations of Structure and Oxidation Potential

There is a wide difference in oxidation potentials of carbonyl compounds depending upon the associated structures. The oxidation potential, or the free energy of reduction, is approximately five times as large for the highest as for the lowest member of the group of compounds reported here. The magnitude of this variation from a practical standpoint may be illustrated by a comparison of Δ^4-cholestenone-3 63 mv., cyclohexanone 162 mv., formaldehyde 270 mv., and dimethoxyacetone 350 mv. *Each* of these compounds would oxidize the alcohol corresponding to the *preceding* member of the series in a conversion of about 98%.

However, the potentials of the majority of ketones apparently lie within the range of 110 to 160 mv. The potentials of about half the ketones determined lie within this range despite the fact that compounds of lower and particularly of higher potentials were being sought. The potentials of the aldehydes lie somewhat higher, *i. e.*, in the range 220 to 270 mv.

Replacement of Hydrogen by Alkyl or Aryl Groups.—The replacement of hydrogen on a carbonyl by an alkyl or aryl group lowers the oxidation potential of a carbonyl compound. This is illustrated by the series H_2CO 260 mv., CH_3CHO 226 mv. and $(CH_3)_2CO$ 129 mv. Replacement of a hydrogen on a carbon adjacent to the carbonyl has a similar but much less marked effect, *e. g.*, CH_3CHO 226 mv., $(CH_3)_2CHCHO$ 220 mv. and $(CH_3)_3CCHO$ 211 mv. There is a similar effect in a series of open-chain ketones, which may be considered as related to acetone.

There are many alkyl and aryl groups which compared with methyl manifest little difference in effect upon the potential of the carbonyl group. There are perhaps twenty-five ketones listed in the table which show relatively little difference in potential as compared with acetone. Yet among this group of ketones are such diverse structures as in acetophenone, cyclopentanone, xanthone, benzophenone, fluorenone and the acetylnaphthalenes. No doubt there are among this group of ketones counterbalancing effects where one group tends to raise while another tends to lower the potential of the carbonyl group.

Four ketones have surprisingly high potentials, *i. e.*, cyclohexanone 162 mv., *t*-butyl phenyl ketone 169 mv., benzhydryl methyl ketone 182 mv. and dibenzyl ketone 216 mv. The high oxidation potentials of at least two of the ketones just mentioned, as well as many other observations reported in this paper, have been rationalized in the electronic terms of the English school.[7]

Effect of Unsaturation.—The presence of carbon-to-carbon double bonds in the 2,3-position with respect to a carbonyl brings about a distinct lowering of the oxidation potential. A comparison of benzaldehyde 197 mv., crotonaldehyde 194 mv. and cinnamaldehyde 186 mv., with a saturated aldehyde, acetaldehyde 226 mv. or isobutyraldehyde 220 mv., shows a lowering of 20 to 40 mv. An even more marked lowering of potential as compared with acetone 129 mv., is shown by Δ^4-cholestenone 63 mv., α-hydrindone 73 mv., α-tetralone 80 mv. and Δ^2-cyclohexenone 85 mv. α-Furyl methyl ketone 122 mv., is 73 mv. lower than the corresponding saturated ketone.

Carbon-to-carbon unsaturation in the 3,4-position with respect to the carbonyl has little or no effect upon the potential. Apparently Δ^3-cyclohexenone and cyclohexanone have the same potential of 162 mv. β-Tetralone 155 mv., and β-hydrindone 139 mv., have potentials similar to the corresponding alkyl aryl ketones. Δ^5-Cholestenone has a potential 90 mv. higher than the Δ^4-isomer. The unsaturation of the phenyl group does not in many instances have any marked effect on the potential when it replaces a methyl group in a methyl ketone. Acetone, benzophenone and acetophenone all have potentials in the range of 118–129 mv. However, in α-tetralone and benzaldehyde the potentials are considerably lower than for similar saturated cyclic compounds.

Effect of Ring Structures.—The very low oxidation potentials of certain cyclic ketones such as camphor, Δ^4-cholestenone, α-hydrindone and α-tetralone would not be anticipated from a knowledge of open-chain and aryl ketones. The high oxidation potential of cyclohexanone must result from the ring structure. However, the potential of cyclopentanone is in accord with that of open-chain compounds.

Effect of Alkoxy, Carbonyl and Carbalkoxy Groups.—The replacement of hydrogen by oxygen in the alpha position in a ketone results in a marked increase in the oxidation potential of the

carbonyl. This is shown by a comparison of acetone 129 mv., methoxyacetone 189 mv. and dimethoxyacetone of more than 350 mv. The ω-mono- and dimethoxyacetophenones, $C_6H_5COCH_2OCH_3$ and $C_6H_5COCH(OCH_3)_2$ show potentials of 212–213 mv., about 95 mv. higher than the corresponding non-oxygenated ketone acetophenone. α-Tetrahydrofuryl methyl ketone 195 mv., is 60–70 mv. higher than ketones without oxygen α to the carbonyl.

The α-methoxy ketone $C_6H_5CH(OCH_3)COC_6H_5$ 199 mv. is 59 mv. higher than the corresponding benzyl phenyl ketone 140 mv. 2-Methoxycyclohexanone 218 mv. is 56 mv. higher than cyclohexanone.

If the series of compounds $C_6H_5COCH_3$ 118 mv., $C_6H_5COCH_2OCH_3$ 213 mv., $C_6H_5COCH(OCH_3)_2$ 212 mv. and $C_6H_5COCO_2C_3H_7$ 282 mv. be considered to involve a progressive oxidation of the carbon atom α to the carbonyl to the alcohol, aldehyde and carboxylic acid stages, then it may be considered that the first step in oxidation of methylene increases the potential of the ketone by 95 mv. The second step in oxidation to the aldehyde or ketone is without effect, while the third step of oxidation to the acid raises the potential of the ketone group almost as much as the first. A similar effect is evident in the series CH_3COCH_3 129 mv., $CH_3COCH_2OCH_3$ 189 mv., and $CH_3COCO_2C_3H_7$ 299 mv. although in this series the third step in oxidation is more effective than the first. In both series the difference in potential between the simple ketone and the α-keto ester is quite large, *i. e.*, 164–170 mv.

Alkoxy and carbalkoxy groups more distant from a carbonyl than in the α-substituted compounds just considered, are considerably less effective in raising the oxidation potential. *m*-Methoxyacetophenone had a potential almost identical with acetophenone, while *o*-methoxyacetophenone was 22 mv. higher and *p*-methoxyacetophenone 19 mv. lower than acetophenone. The 3- and 4-methoxycyclohexanones had potentials little different from cyclohexanone. The carbalkoxy substituted ketones such as items 42, 45, 48, 49, 51, 52 and 53 in the table show potentials 18 to 29 mv. higher than the corresponding unsubstituted ketones.

The potential of an α-keto aldehyde was found to be considerably higher than for an aldehyde of somewhat similar structure but without an α-carbonyl group, *i. e.*, *t*-butylglyoxal was 34 mv. higher than trimethylacetaldehyde. The effect of free hydroxyl or carbonyl groups on the oxidation potential of a carbonyl group cannot in general be determined because of the multiplicity of equilibria which would be involved. However, the potential of *t*-butylglyoxal could be evaluated since the *t*-butyl group served to inactivate the adjacent carbonyl toward reduction.

Effect of Amino and Nitro Groups and of Halogens.—The substitution of a nitrogen for hydrogen α to carbonyl, like the substitution of an oxygen, gave a marked increase in potential. ω-Piperidinoacetophenone with a potential of 203 mv. is 85 mv. higher than acetophenone. Nitrogen in the β-position with respect to the carbonyl also enhances the potential. β-Pyridyl phenyl ketone with a potential of 167 mv. is about 40 mv. above benzophenone. The introduction of a nitro group in the meta position of acetophenone and in the para position in benzophenone also raised the potentials by 34 and 42 mv., respectively.

The substitution of a chlorine for a hydrogen in a ketone has given in certain instances a marked increase in oxidation potential. The 2-chlorofluorenone and 2,7-dichlorofluorenone were prepared and tested because Conant and Fieser[8] had noted that certain chloroquinones had higher oxidation potentials than the parent compounds. The discovery[5] of the relatively high potential of the dichlorofluorenone, 157 mv., as compared to 117 mv. for fluorenone, was one of the important steps in making possible the determination of the potential of ketones high in the series. The effectiveness of chlorine substitution in raising the oxidation potential is very evident in a comparison of chloral 277 mv., with acetaldehyde 226 mv.

Rate of Reaction.—There is a very considerable difference in the rate with which equilibrium is established with different carbonyl compounds. Quantitative data on the rates of reaction are not available and in many cases significant numerical values are not obtainable because of side reactions. However, it may be significant to note some of the facts encountered.

Aldehydes such as acetaldehyde, trimethylacetaldehyde, isobutyraldehyde, furfural and benzaldehyde reach equilibrium within an hour or less at 60°. Certain ketones such as cyclohexanone and acetone react with fluorenol almost as rapidly as the aldehydes mentioned. The cyclic ketones β-hydrindone, the two tetralones and the 3- and 4-methoxy cyclohexanones react rather rapidly, only a few hours being required for the attainment of equilibrium. Many ketones such as acetophenone, furyl methyl ketone and benzophenone require twelve to forty-eight hours to reach equilibrium even with fluorenol. The α-oxygenated ketones and aldehydes, chloral, β-pyridyl phenyl ketone, ω-piperidinoacetophenone, tetrahydrofuryl methyl ketone and the carbethoxy ketones react very slowly indeed so that one hundred to one thousand hours would be required for the attainment of equilibrium.

Depolarization Potentials of Carbonyl Compounds.—The oxidation potential of a quinone may be calculated from its depolarization potential at a dropping mercury electrode.[18,19,20]

TABLE II

ANALYSES OF COMPOUNDS

Name of compound	B. p. °C.	Mm.	Formula	Calcd., % Carbon	Calcd., % Hydrogen	Found, % Carbon	Found, % Hydrogen
Mandelaldehyde dimethyl acetal	126.5–127.5	10	$C_{10}H_{14}O_3$	65.9	7.7	65.7	7.8
3-Methoxycyclohexanone	76.5–77	9	$C_7H_{12}O_2$	65.6	9.4	65.3	9.3
Isopropyl 9-fluorenol-2-carboxylate	M. 118–119.5		$C_{17}H_{16}O_3$	76.1	6.0	75.9	5.9
Isopropyl *p*-benzoylbenzoate	190–192	2	$C_{17}H_{16}O_3$	76.1	6.0	76.1	5.9
t-Butyl *p*-benzoylbenzoate	190–192	2	$C_{18}H_{18}O_3$	76.6	6.4	76.7	6.2
4-Carbisopropoxy benzhydrol	209	4	$C_{17}H_{18}O_3$	75.5	6.7	75.2	6.8
Isopropyl benzoylformate	153.5–154.4	12	$C_{11}H_{12}O_3$	68.6	6.2	68.5	6.1
Isopropyl pyruvate	50.5–51	13	$C_6H_{10}O_3$	55.4	7.7	55.5	7.6
β-Pyridylphenylcarbinol	M. 67.5–69		$C_{12}H_{11}ON$	77.8	5.9	77.7	5.9
1-Chloro-10-oxanthrol	M. 135–137		$C_{14}H_9O_2Cl$	68.7	3.7	69.0	3.7
Isopropyl anthraquinone-2-carboxylate	M. 138–139		$C_{18}H_{14}O_4$	73.6	4.8	73.5	4.7
Methyl-*p*-carbethoxyphenylcarbinol	131	2	$C_{11}H_{14}O_3$	68.0	7.3	68.4	7.4
3-Carbisopropoxybenzohydrol	180–181	2	$C_{17}H_{18}O_3$	75.5	6.7	75.7	6.6

There has been no similar correlation observed between the oxidation potentials of aldehydes and ketones and their depolarization potentials.[4] The depolarization potential of many carbonyl compounds was determined at the dropping mercury electrode, incidental to the analytical procedure used in determining the concentration of carbonyl compounds at equilibrium. These values are given in the last column of Table I. The potential recorded is that applied between the falling droplets of mercury and the quiet pool of mercury at the bottom of the polarograph cell, when the diffusion current had attained one-half of its limiting value. A comparison of the depolarization potentials with the oxidation potentials of the carbonyl compounds in column three of Table I lends further support to the conclusion expressed above as to the lack of correlation between the two characteristics of a carbonyl compound. For example Δ^4-cholestenone-3 and ethyl pyruvate have similar depolarization potentials yet the oxidation potentials of the two carbonyl compounds lie almost at the extremes of the compounds listed in the table.

Procedures and Preparations of Reactants.—The procedures followed in equilibrating a quartet of carbonyl compounds and alcohols, and in determining the relative concentration of the compounds at equilibrium, were essentially those described earlier.[4] Since many of the sets of reactants reacted very slowly and gave side reactions it was usually necessary to make up many mixtures and carefully bracket the equilibrium mixture before drawing the final conclusion as to the true concentration at equilibrium. These data, even in abstract form, are so voluminous that they are not submitted for publication.

A few minor improvements in the procedures were introduced in order to avoid difficulties encountered from time to time. The addition of a drop of 0.25 *N* ammonium chloride solution facilitated the complete precipitation of aluminum hydroxide in the hydrolysis step. Care was taken to avoid the exposure of the alcohols or the reaction mixtures to strong sunlight at any stage of the procedure. An electrode of the type described by Kolthoff and Lingane[21] is more satisfactory than that used in earlier work. A stopcock without grease was inserted just above the flat-bottom capillary. The intervals between droplets of mercury were 2 ± 0.5 seconds.

Most of the carbonyl and carbinol compounds used in this investigation have been prepared earlier by others. Space was not available for publication of references to the earlier papers, however the references have been assembled.[5,6,7] Analytical data for compounds not previously described are given in Table II. The melting points or refractive indices of the alcohols and ketones used in the determinations, reported for the first time in this paper, are given in Table I. Several of the alcohols were prepared for the first time through the reduction of a ketone to the corresponding alcohol with aluminum isopropoxide or by catalytic hydrogenation over Raney nickel or copper-chromium oxide. These cases have been noted in Table I. Procedures for the preparation of a few compounds are given below.

2,7-Dichlorofluorenone and 2,7-Dichlorofluorenol.—Ten grams of pure, white, distilled fluorene, m. p. 110–112°, was chlorinated in 90 ml. of chloroform during one and one-half hours. The temperature of the mixture rose somewhat above room temperature due to heat of reaction but fell again to room temperature during the period of reaction. The solvent was blown off on a steam-bath and the residue recrystallized two or three times from petroleum ether (b. p. 90–100°). The yield was 5.4 g. (38%) of 2,7-dichlorofluorene, m. p. 123–124.5°. The compound (21 g.) was dissolved in 100 ml. of hot acetic acid and 65 g. of sodium dichromate in 100 ml. of acetic acid added slowly. The mixture was refluxed for thirty minutes and then poured into cold water. The product was separated by filtration and crystallized from a 1:4 mixture of benzene and petroleum ether (b. p. 90–100°). The yield of 2,7-dichlorofluorenone, m. p. 190–191° was 17.5 g. The ketone (9 g.) was reduced with zinc in an ammoniacal solution[22] to give 2,7-dichlorofluorenol (7.4 g.), m. p. 161–162°.

(21) Kolthoff and Lingane, *Chem. Revs.*, **24**, 1 (1939).

(22) Courtot, *Ann. chim.*, **14**, 5 (1930).

2-Chlorofluorenone and 2-Chlorofluorenol.—2-Aminofluorene[23] (15.8 g., m. p. 127–128°) was made into a paste on a steam-bath with 90 ml. of water. Concd. hydrochloric acid (16.5 ml.) in 185 ml. of water was added to the paste and the mixture allowed to cool to room temperature. The amine was diazotized with a solution of 6.1 g. of sodium nitrite in 45 ml. of water. The mixture, in which the diazonium salt had crystallized out, was poured with shaking into a solution of 25 g. of cuprous chloride in 125 ml. of concd. hydrochloric acid and refluxed for thirty minutes. After cooling, the solid material was filtered off, dried, pulverized and extracted with 500 ml. of ether. The ether solution was washed with a 5% solution of sodium hydroxide and dried over potassium carbonate. The ether was distilled off and the residue distilled 140–150° (2 mm.). The white solid product (10.5 g.) was recrystallized from 30 ml. of hot 95% alcohol giving 8.7 g. white 2-chlorofluorene m. p. 93–94°. The product was converted to 2-chlorofluorenone (8.0 g., m. p. 113–116° or 6.3 g., m. p. 122–123°) by oxidation as described for 2,7-dichlorofluorenone. The ketone (3.5 g.) was reduced to 2-chlorofluorenol (3.2 g., m. p. 142–143°) as by Courtot.

sym-Dimethoxyacetone.—Methyl methoxyacetate (101 g., b. p. 128–130° (740 mm.), $n^{25}D$ 1.3940) was prepared from methanol and chloroacetic acid (157 g.) as by Schreiner.[24] The ester was added to sodium methoxide (from 17 g. of sodium) and stirred for four hours on a steam-bath. The reaction mixture was then cooled, diluted with water and neutralized with acetic acid. The solution was extracted twice with ether and the latter washed with a sodium carbonate solution and dried over sodium sulfate. After removing the ether the desired dimethoxy keto ester was distilled at 114–115° (10 mm.). The yield was 31.8 g. having $n^{25}D$ of 1.4358. The ester was hydrolyzed in 200 ml. of a 5% sodium hydroxide solution for three hours on the steam-bath. The reaction mixture was acidified with sulfuric acid in the cold. About three-fourths of the solution was distilled; the distillate was saturated with potassium carbonate. The solution and oil was extracted with ether and dried over sodium sulfate. After removal of the ether the product was distilled through a short column giving 2.2 g. of crude ketone b. p. 58–65° (10 mm.). Redistillation gave 1.6 g. of 1,3-dimethoxyacetone b. p. 62.5–63° (10 mm.).

3-Methoxycyclohexanol.—Resorcinol (110 g.) was methylated at room temperature during two hours with dimethyl sulfate (100 ml.) in 600 ml. of water containing 100 g. of potassium hydroxide. The solution was acidified and extracted three times with benzene. The benzene solution was washed with 40 g. of sodium hydroxide in 600 ml. of water in three equal portions, in order to separate the desired product from the dimethylated material. The alkaline extract was acidified with hydrochloric acid, extracted with benzene, the solution dried, and the benzene distilled. Resorcinol monomethyl ether (59 g.) was distilled 115–119° (7.5 mm.). The product was hydrogenated over 5 g. of Raney nickel at 150° during forty-five minutes under 3000 p. s. i. of hydrogen. 3-Methoxycyclohexanol (36 g.) was obtained by fractionation of the product at 88–89° (8 mm.).

2- and 3-Methoxycyclohexanones.—These ketones were prepared by the oxidation of the corresponding alcohols, which had been prepared by hydrogenation of the corresponding phenols over Raney nickel as described for 3-methoxycyclohexanol. For example, 2-methoxycyclohexanol (28 g.) was added to a cool solution of 43 g. of potassium dichromate in 31 ml. of concentrated sulfuric acid and 190 ml. of water. The temperature rose from 12 to 65° and then slowly dropped to room temperature. The solution was extracted with 600 ml. of ether in three portions. The ether solution was washed with a carbonate solution and dried over sodium sulfate. Fractionation of the product gave 13 g. of 2-methoxycyclohexanone b. p. 58–59° (8 mm.), $n^{25}D$ 1.4519. The yield of 3-methoxycyclohexanone (3.8 g.) b. p. 76.5–77° (9 mm.), from 3-methoxycyclohexanol (22 g.) was rather low.

Dibenzyl Ketone.—A solution of 155 g. of benzyl cyanide in 200 ml. of ether was added to a solution of benzylmagnesium chloride, prepared from 37.7 g. of magnesium and 196 g. of benzyl chloride in 750 ml. of ether. The mixture was refluxed for two hours and the addition product hydrolyzed in ice-water and then with dilute sulfuric acid. The crude ketone (48 g.) was distilled at 138–140° (3 mm.). The ketone solidified and was crystallized from petroleum ether (b. p. 40–60°) to give 32 g., m. p. 32.5–34°, and 25 g., m. p. 35° after recrystallization.

α-Tetrahydrofuryl Methyl Ketone.—Ethyl tetrahydrofuroate (b. p. 73–74° (11 mm.), $n^{25}D$ 1.4328) was prepared by the hydrogenation of ethyl furoate (220 g.) over Raney nickel at 100° in 88% yield. Ethyl α-tetrahydrofuroylacetate was prepared through the reaction of the sodium salt of ethyl acetoacetate (0.63 mole) with ethyl tetrahydrofuroate (1.25 moles) at 150–155°, for four hours by the method of McElvain and Weber.[25] The desired keto ester 15.5 g., b. p. 115–116° (8 mm.), $n^{25}D$ 1.4530 was obtained by fractionation of the crude distillate. The keto ester (15 g.) was hydrolyzed in a 5% sodium hydroxide solution during four hours on a steam-bath. The cold solution was acidified with dilute sulfuric acid and two-thirds of the solution distilled. The distillate was made slightly alkaline and two-thirds of it again distilled. The distillate was saturated with potassium carbonate and extracted twice with ether. The ether solution was dried and the desired ketone (4.9 g., b. p. 160.5–161.5° (740 mm.)) distilled through a short Vigreux column.

Benzhydryl Methyl Ketone.—Lead diphenylacetate was prepared by the reaction of lead nitrate in a slightly acid water solution of sodium diphenylacetate. Dry lead diphenylacetate (31 g.) was intimately mixed with dry lead acetate (62 g.) in a mortar and the mixture heated under reduced pressure in a 250-ml. distilling flask held in a Woods metal bath at 280°. A yellow distillate (6 g.) was obtained and redistilled at 155–157° (8 mm.) to give 3.7 g. of crude ketone. The product solidified when kept overnight in a refrigerator, and was then crystallized from 40 ml. of petroleum ether (b. p. 40–60°). In different experiments both the stable form m. p. 58–60° and the unstable form m. p. 45–46° of the ketone were obtained in beautiful white crystals.[26,27]

Summary

The oxidation potentials of eighty-seven ketones and aldehydes have been determined by equilibrating them against each other and against three quinones of known oxidation potentials. The data are summarized in Table I. The limitations and reliability of the data and some of the relationships of structure to oxidation potentials have been discussed.

A Spectrophotometric Study of Three Zirconium Lakes

BY JOHN F. FLAGG, HERMAN A. LIEBHAFSKY AND EARL H. WINSLOW

Surprisingly enough, Beer's law holds over a considerable concentration range in the complex systems of alcohol–hydroxyanthraquinone–suspended zirconium (or hafnium) lake, and this fact forms the basis for a spectrophotometric determination of either metal in microgram amounts.[1] Furthermore, spectrophotometric evidence[2] has indicated that the hafnium–alizarin lake is a definite chemical compound, the combining ratio being unity. Similar evidence is given here for the lakes that zirconium forms with alizarin, with purpurin and with quinalizarin.

As for hafnium, lake formation was studied with zirconium in excess, and with zirconium and dye in stoichiometrically comparable amounts. In the former (limiting) case, all the dye is assumed to be combined so that the lake is the only colored substance present; in the latter (intermediate) case, there is free dye also. The experimental results are interpreted with the aid of data for the other limit, where dye is in excess and zirconium can be determined spectrophotometrically. The procedures for all cases have been fully described, and detailed references will consequently make repetition unnecessary.

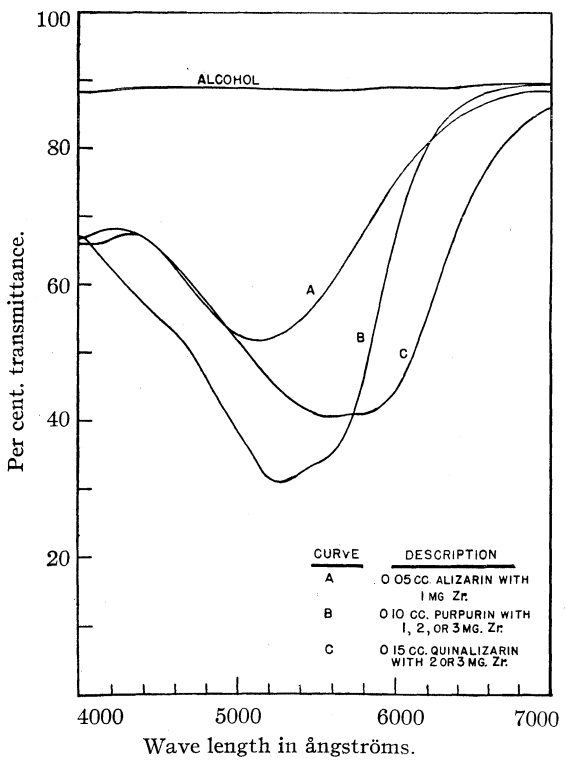

Fig. 1.—Transmittance curves for the three lakes, zirconium being in excess.

Experimental Results

Zirconium in Excess.—Transmittancies[3] were measured on a General Electric recording spectrophotometer for a series of suspensions prepared in the standard way by adding varying excess amounts of standard zirconium solution each to the same amount of dye. When increasing the excess of zirconium did not further increase the transmittance at the minimum in the curve for the dye (near 4360 Å. for alizarin; *cf.* ref. 2, Fig. 1), it was assumed that all the dye had combined to form a lake of formula $Zr_m(Dye)_n$. From the number of moles of dye added and the number of moles of zirconium combined (as obtained from Beer's law plots[1b]), values of the combining ratio n/m (Table I) were calculated (see ref. 2, Fig. 4, and the second paragraph beginning on p. 1131). Typical transmittance curves for the lakes are given in Fig. 1.

TABLE I

RATIO OF DYE TO ZIRCONIUM IN LAKES

Dye	Moles of dye taken × 10^7	Moles of Zr taken × 10^7	Moles of Zr combined × 10^7	n/m
Alizarin	2.88	37.2	2.58	1.1
Alizarin	4.03	37.2	3.77	1.1
Alizarin	5.75	74.4	5.06	1.1
Alizarin	5.32	74.4	5.14	1.0
Alizarin	7.83	330	5.72	1.4
Alizarin	7.87	55.8	8.10	1.0
Alizarin	8.62	37.2	7.73	1.1
Quinalizarin	1.81	330	1.26	1.4
Purpurin	2.94	330	2.68	1.1

Within the range of concentrations chosen, the combining ratio is essentially one for the alizarin lakes. As in the case of the hafnium lake, these ratios tend to exceed unity, perhaps owing to experimental error or to the incomplete realization of a fundamental assumption; *e. g.*, the absorption of dye by the lake may explain the value 1.4 found for the quinalizarin lake.

(1a) The Knolls Atomic Power Laboratory is operated by the General Electric Research Laboratory for the Atomic Energy Commission. Part of the work reported here was carried out under Contract No. W-31-109 Eng.-52.

(1b) Liebhafsky and Winslow, THIS JOURNAL, **60**, 1776 (1938); (c) see also Green, *Anal. Chem.*, **20**, 370 (1948).

(2) Liebhafsky and Winslow, THIS JOURNAL, **69**, 1130 (1947).

(3) National Bureau of Standards Letter Circular LC857 attempts to standardize the confused nomenclature in the field of absorptometry. The recommendations given there will be followed so far as is possible without complicating the references to previous work. Let I_1 and I_2 represent the radiant energy incident upon, and that leaving the filled cell. Then $T = I_2/I_1$ is the (over-all) *transmittance*. The transmittancy, T_S, is the ratio Tsoln./Tsolv., where "soln." in our case refers to a colored system and "solv." to alcohol. $A_S = \log 1/T_S$ is the *absorbancy*.

Zirconium and Dye in Comparable Amounts.—Lake and uncombined dye are both present, so that the absorbancy for a cell of unit length is given by

$$A_S = \epsilon_1(\Sigma[\text{Dye}] - n[\text{L}]) + \epsilon_2[\text{L}] \qquad (1)$$

in which ϵ_1 and ϵ_2 are, respectively, the molar absorbancy indexes of dye and lake, the brackets denote moles/l., Σ[Dye] represents dye added, and L the lake. Given a series of transmittance curves (*cf.* ref. 2, Fig. 2) for suspensions each prepared from a constant amount of dye and a different, comparable amount of zirconium, n/m at a suitable wave length can be obtained graphically from a plot of absorbancy against *combined* zirconium provided ϵ_2/m and ϵ_1 are known; see ref. 2, eq. 2 and 3, Fig. 5, and the neighboring text. The values of ϵ_2/m required for this evaluation were calculated from curves like those of Fig. 1 and are listed in Table II along with the molar absorbancy indexes (ϵ_1's) for the dyes.

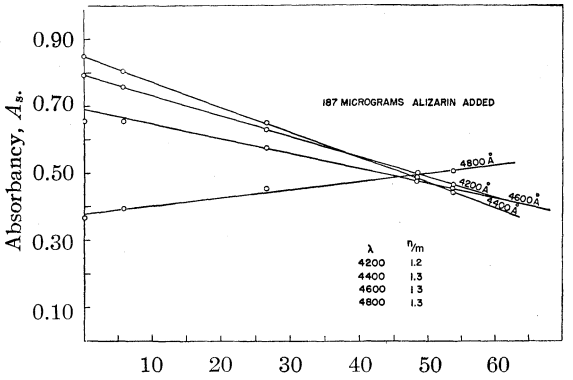

Fig. 2.—Determination of combining ratio, n/m, for the zirconium–alizarin lake at a higher amount of added alizarin.

TABLE II

1. MOLAR ABSORBANCY INDEXES OF THE DYES IN ETHYL ALCOHOL

Wave length, Å.	ϵ_1 of dye: Alizarin	Quinalizarin	Purpurin
4060	4350	3595	2360
4200	5170	4610	3260
4400	5420	6240	5180
4600	4270	7720	7070
4800	2410	8880	8020
5000	960	8760	6070

2. ABSORBANCY INDEXES OF THE LAKES[a]

Wave length, Å.	ϵ_2/m of lake prepared from: Alizarin[b]	Quinalizarin[c]	Purpurin[c]
4060	3280	4950	2350
4200	3260	4725	2890
4400	3190	5170	3630
4600	3580	6270	4300
4800	4310	7990	5460
5000	5030	9930	6910

[a] If m is (plausibly) taken as unity, then ϵ_2/m values are the molar absorbancy indexes. [b] Averaged values from seven curves. [c] Values from a single curve.

The results of the graphical evaluation of the combining ratios are given in Figs. 2–5. As in the case of the hafnium–alizarin lake, n/m tends to increase with wave length; possible reasons for this have been considered previously.[2] In general, these data support the conclusion drawn from the experiments with zirconium in excess—namely, that $n/m = 1$.

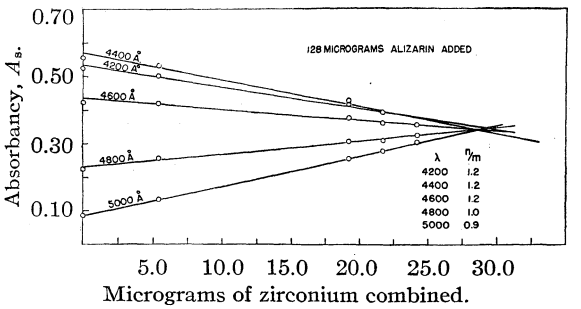

Fig. 3.—Determination of combining ratio, n/m, for the zirconium–alizarin lake at a lower amount of added alizarin.

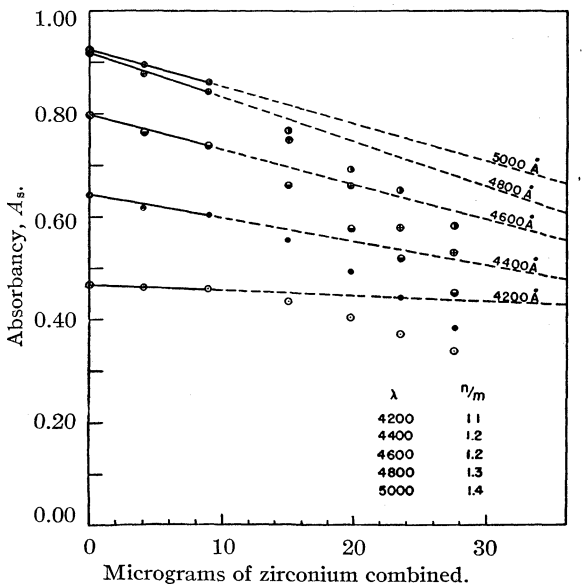

Fig. 4.—Determination of combining ratio, n/m, for the zirconium–quinalizarin lake.

Incomplete Lake Formation.—When a lake was formed from comparable amounts of zirconium and dye, the zirconium combined was less in each case than the zirconium added. Some of the complex situations that could lead to this result have been mentioned for the hafnium–alizarin case, where lake formation was incomplete also (see ref. 2, especially p. 1132). Of these situations, the following seems the most likely. When the lakes are formed in alkaline solution, equilibrium is reached (or at least approached) although the time allowed (two minutes) is short. Because acidification and dilution follow rapidly, these equilibria are "frozen" so that the concen-

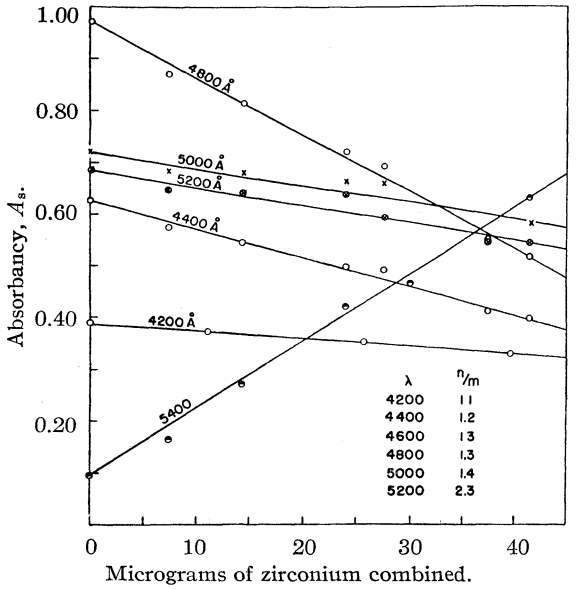

Fig. 5.—Determination of combining ratio, n/m, for the zirconium–purpurin lake.

trations of lake, dye and zirconium remain at the equilibrium values for the alkaline medium. To test this explanation, the "equilibrium quotients" (Q = moles of lake divided by the product of moles uncombined zirconium and moles free alizarin) in Table III were calculated, $n/m = 1$ being assumed. The constancy of the Q's, especially of those for the alizarin lake, makes the explanation seem reasonable.

In parallel experiments at different temperatures, lake formation from comparable amounts of zirconium and alizarin was found to be 67% complete at room temperature and 83% complete at 75°.

Summary

Spectrophotometric evidence indicates that the lakes formed by zirconium with each of the dyes, alizarin, purpurin and quinalizarin, are definite compounds, the two constituents being combined in equimolal amounts.

The spectrophotometric behavior, and the incomplete lake formation observed under some conditions, resemble closely experimental results obtained on the hafnium–alizarin lake. On this basis, it is logical to assign the three lakes studied here a chelate-ring formula analogous to that given the lake formed by hafnium and alizarin.

The Partial Pressure of Hydrogen Chloride from Its Solutions in Aprotic Solvents: Comparison of Solubility and Infrared Absorption Studies[1]

BY S. JAMES O'BRIEN[2] AND CECIL V. KING

Data were presented in previous papers[3] which indicated that the entropy of solution of hydrogen chloride in aprotic solvents is related linearly to the shift produced by the various solvents in the position of the 3.46 μ absorption band as measured by Gordy and co-workers.[4] In further work along these lines, measurements have been made at two or more temperatures of the partial pressure of hydrogen chloride above its solutions in four more aprotic solvents for which infrared absorption values are available. These determinations provide additional facts pertinent to the relationships between the entropy of solution of hydrogen chloride and the shift of its 3.46 μ absorption band. It is the purpose of this paper to

report the new measurements which were made in phenetole, *n*-butyl phenyl ether, diphenyl ether and *m*-nitrotoluene and to consider them in connection with the relationship between the partial molal entropy of solution and the shift of the infrared absorption band of the solute.

Experimental

The apparatus and procedure used were the same as in the earlier work.[3,5] The phenetole, *n*-butyl phenyl ether, diphenyl ether and *m*-nitrotoluene were all Eastman Kodak Co. products which were carefully dried and redistilled before using. The index of refraction, or in the case of *m*-nitrotoluene the melting point, was taken as the criterion of purity.

Results

As in the earlier studies, it was found that hydrogen chloride agreed with the law of Henry in the four solvents employed in the present work. The results of the partial pressure measurements are summarized in Table I.

TABLE I

HENRY LAW CONSTANTS AND THE MOLE FRACTION SOLUBILITY OF HYDROGEN CHLORIDE AT 1 ATM.

Solvent	Temp., °C.	Detns.	k	Dev. ±	N
Phenetole	25	6	1.02	0.04	0.107
Phenetole	20	2	0.90	.01	.120
Phenetole	10	2	0.70	.03	.151
n-Butyl phenyl ether	25	4	1.37	.05	.100
n-Butyl phenyl ether	20	4	1.21	.04	.110
Diphenyl ether	30	4	3.52	.01	.0442
Diphenyl ether	25	4	3.33	.07	.0494
m-Nitrotoluene	35	4	2.08	.04	.0614
m-Nitroltoluene	25[a]	7	1.65	.05	.0768

[a] Reported previously: S. J. O'Brien and C. L. Kenny, THIS JOURNAL, **62**, 1189 (1940).

In Table I, the first column gives the solvent; the second, the temperature at which the measurements were made; the third, the number of individual determinations; the fourth column gives the Henry law constant, k, in the form

$$k = p/m$$

where p is the partial pressure in atmospheres and m is the molal concentration of hydrogen chloride in the solution; the fifth column contains the average deviation from the mean of the individual Henry law constants; the last column gives the mole fraction solubility of hydrogen chloride at a partial pressure of 1 atmosphere calculated by means of the equation

$$N = 1/(1 + km_s)$$

N being the mole fraction solubility and m_s the number of moles of solvent in 1000 g.

Discussion

In the earlier work,[3] it was found that the change of mole fraction solubility of hydrogen chloride with temperature could be represented by an equation of the form

$$\log N = A/T + B \quad (1)$$

where T is the absolute temperature and A and B are constants which may be identified with the heat and entropy of solution.[6] That is

$$A = \Delta H/2.303R \quad (2)$$
$$B = \Delta S/2.303R \quad (3)$$

where ΔH is the partial molal heat of solution of the solute, ΔS is the partial molal entropy of solution and R is the molar gas constant. The data presented above for phenetole solutions also fit an equation of this type, and it has been assumed that a similar relationship between the temperatures and the solubility of hydrogen chloride is valid in the other solvents. On this basis, the heats and entropies of solution were derived from the mole fraction solubilities given in Table I. These calculated thermodynamic values are shown in the second and third columns of Table II.

TABLE II

THE HEAT AND ENTROPY OF SOLUTION

Solvent	$-\Delta H$, cal.	$-\Delta S$, eq. 3, e. u.	$-\Delta S$, eq. 4, e. u.
Phenetole	3950	17.6	17.7
n-Butyl phenyl ether	3780	17.2	17.3
Diphenyl ether	3800	18.9	19.0
m-Nitrotoluene	3900	18.8	18.7

The connection between the entropy of solution of hydrogen chloride and the shift of its 3.46 μ absorption band in solution, which was suggested by the data given in a prior paper,[3] could be expressed by the linear equation

$$\Delta S = 10.0\,\Delta\mu - 21.1 \quad (4)$$

in which ΔS is the partial molal entropy of solution of hydrogen chloride and $\Delta\mu$ is the shift of the infrared absorption band. The data reported in this paper are also in agreement with this equation. This is demonstrated in Table II where the last column contains entropy values calculated by means of equation (4) using the infrared absorption data of Gordy.[4] All of the available data relative to this proportionality between the entropy of solution and the shift of the absorption band are summarized graphically in Fig. 1. The line drawn in this diagram is a plot of equation (4); the circles define values obtained from the experimental data as presented in this and the earlier papers.[3] The agreement between the experimental points with equation (4) is quite good; the values assigned to the slope and intercept are adequate. This linear correlation of the shift of the infrared absorption band with the entropy of solution makes it evident that a good straight line connection is not to be expected between the shift of the infrared band

(6) Compare J. H. de Boer, *Chem. Weekblad*, **35**, 839 (1938), and V. A. Kireev, *Acta Physicochim. (U. R. S. S.)*, **13**, 531 (1940).

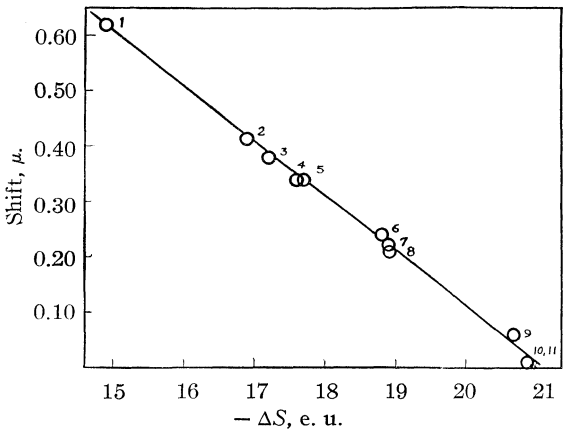

Fig. 1.—A plot of the shift of the 3.46μ absorption band of hydrogen chloride against its entropy of solution in: (1) diethyl ether, (2) β,β'-dichlorodiethyl ether, (3) *n*-butyl phenyl ether, (4) phenetole, (5) anisole, (6) *m*-nitrotoluene, (7) nitrobenzene, (8) diphenyl ether, (9) chlorobenzene, (10) bromobenzene and (11) benzene. The spectroscopic data are taken from the papers of Gordy[4] except those for chlorobenzene and bromobenzene [W. West and P. Arthur, *J. Chem. Phys.*, **2**, 215 (1934)] and for benzene [E. K. Plyler and D. Williams, *Phys. Rev.*, **49**, 215 (1936)]. The entropy values not presented in Table II were taken from the earlier papers.[3]

and the deviation of hydrogen chloride from the law of Raoult.[7] Differences in the heat of solution in the various solvents would lead to deviations from such a relationship. It is, of course, interesting that the increase in the partial molal entropy of the solute is greatest in the more basic solvents in which the infrared absorption band is shifted to the greatest extent.

Summary

1. The partial pressure of hydrogen chloride from its solutions in phenetole, *n*-butyl phenyl ether, diphenyl ether and *m*-nitrotoluene have been determined at two or more temperatures. From these data, the mole fraction solubilities at 1 atm., the partial molal heats and the partial molal entropies of solution of hydrogen chloride have been calculated.

2. A linear relationship between the entropy of solution and the shift of the 3.46 μ absorption band of hydrogen chloride reported previously is further substantiated by a comparison of the calculated entropies of solution with the spectroscopic data available in the literature.

The Importance of Interatomic Spacing in Catalysis. A Correlation between Hydrogen Overvoltage on Metals and the Distance between Atoms[1]

BY HENRY LEIDHEISER, JR.

Introduction

It is of great importance to the theories of surface phenomena to understand the importance of the distance between surface atoms in controlling the rates of reactions. A few studies indicate the importance of this distance in catalytic reactions.[2] Recent measurements of the hydrogen overvoltage offer a series of values which may be utilized to compare the relative catalytic activities of a number of metals under similar experimental conditions. Hydrogen overvoltage may be considered as a numerical value representing the ability relative to platinized platinum with which a material catalyzes the over-all reaction, $2H^+ + 2e = H_2(gas)$, in an acid solution. The greater the numerical value of the hydrogen overvoltage, the greater the difficulty with which the reaction occurs.

Correlations of the results of hydrogen overvoltage studies on different metals have been made previously with position in the periodic table, melting point, catalytic activity for the combination of hydrogen atoms, and thermionic work functions,[3] but no one has pointed out the interesting correlation between hydrogen overvoltage and the distance between atoms in the surface.

Results

In Fig. 1 values for the hydrogen overvoltage at 10^{-3} amp./sq. cm. are plotted *versus* the distance of closest approach of atoms for all the body-centered cubic and face-centered cubic metals for which reliable values are available. The values for nickel, copper, molybdenum, tantalum and columbium were taken from Bokris,[4] the values for lead, aluminum, silver, chromium (estimated from the value at 10^{-1} amp./sq. cm.), iron, tungsten, plati-

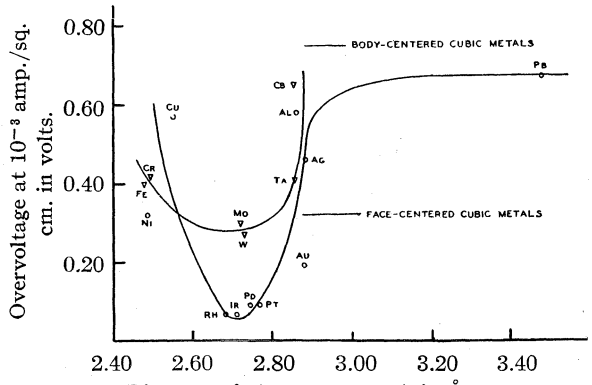

Fig. 1.—The relation between the hydrogen overvoltage at 10^{-3} amp./sq. cm. and the distance of closest approach of atoms for sixteen metals of the body-centered cubic and face-centered cubic structures.

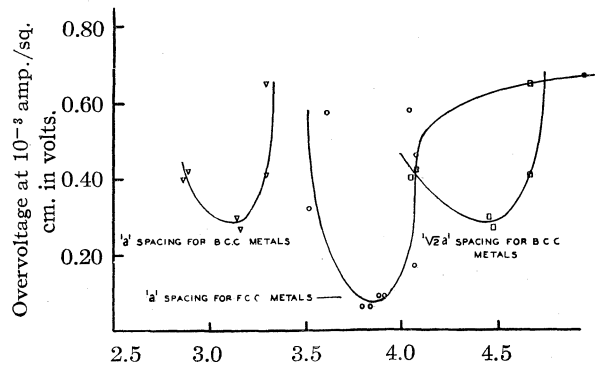

Fig. 2.—The relation between the hydrogen overvoltage at 10^{-3} amp./sq. cm. and the a and $\sqrt{2}a$ spacings for sixteen metals of the body-centered cubic and face-centered cubic structures.

num, gold and rhodium from Hickling and Salt,[5] and values comparative to these were estimated for palladium and iridium from the combined data of Newbery,[6] Volmer and Wick,[7] and Frumkin and Aladzhalova.[8] It should be pointed out that Bokris and Hickling and Salt obtained similar values for the hydrogen overvoltage using different methods for nickel, copper and lead, the only metals that were studied in common. The choice of values obtained at 10^{-3} amp./sq. cm. for plotting is purely arbitrary but curves of comparable shape would be obtained if the hydrogen overvoltage at 10^{-2} or 10^{-1} amp./sq. cm. were plotted. These three current densities are the only ones that have been extensively studied with a number of different metals.

With the exception of vanadium and barium, for which no data are available, and the alkali metals, which cannot be studied in aqueous solution because of their reactivity, all the metals of body-centered cubic structure that are stable at room temperature are included. In the case of the face-centered cubic metals ten different metals are included. It can be seen that the interatomic spacing of approximately 2.7 Å. in the case of both body-centered cubic and face-centered cubic metals corresponds to the minimum overvoltage. The hydrogen overvoltage values for the hexagonal close-packed metals are not complete enough to prepare a similar plot for metals of this structure. However, the values at 10^{-3} amp./sq. cm. for beryllium, cadmium and thallium, the only hexagonal close-packed metals for which reliable values are available, are not inconsistent with a plot of the same general shape as those for the body-centered cubic and face-centered cubic metals.

As shown in Fig. 2 equally good curves can be drawn for the a spacing of the face-centered cubic metals and for the a and $\sqrt{2}a$[9] spacing of the body-centered cubic metals. However, as can readily be seen from Fig. 2 the minimum overvoltage does not occur at the same spacing for these two different metallic structures when plotted in this manner. It is felt that the approximate coincidence of the minima for both types of structure at 2.7 Å. is evidence that this spacing is the important one in hydrogen overvoltage phenomena.

The exact manner in which the curves are drawn in Figs. 1 and 2 is subject to considerable latitude. In the case of the body-centered cubic metals it is impossible to decide on the exact position of the minimum. The reason for this is the small number of body-centered cubic metals which are stable at room temperature. In the case of the face-centered cubic metals the exact position of the minimum depends on a more critical determination of the relative values for the hydrogen overvoltage of rhodium, iridium, palladium and platinum. However, the presence of minima at approximately 2.7 Å. is very definite. Two points occur to the left of the minimum and two occur to the right of the minimum for the body-centered cubic metals. For the face-centered cubic metals two points occur to the left of the minimum and 4 points occur to the right of the minimum. The fact that all of the 16 points plotted are consistent with minima at the 2.7 Å. spacing is strong statistical evidence that the effect is a valid one.

Discussion

The results reported herein furnish evidence that the spacing between atoms in the surface is an important consideration in the rates of catalytic reactions. An interesting observation which shows up in Fig. 1 is the fact that not only is spacing important but also the crystal structure in which the metal crystallizes. The face-centered

(9) The a spacing refers to the distance along the cube edge and the $\sqrt{2}a$ spacing refers to the distance along the diagonal of the cube face.

cubic metals and body-centered cubic metals fall in two distinct classes. Although the data are incomplete for the hexagonal close-packed metals it also appears that these metals fall into a third class. The structure can play a part in the geometry of the surface and in the frequency with which a certain type of spacing occurs in the surface. It is impossible at present to decide between the relative importance of these two possibilities. Figure 3 represents a schematic drawing of the arrangement of atoms on the 3 major faces, (100), (110) and (111), of the body-centered and face-centered cubic metals. The solid lines represent the distance of closest approach of the atoms. It will be noticed that the arrangement of atoms, or geometry, is different on each of these 6 faces and that the distance of closest approach occurs more often in the face-centered cubic structure than in the body-centered cubic structure.

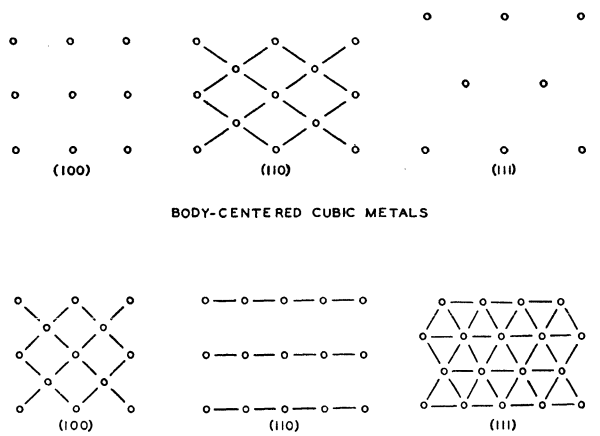

Fig. 3.—The arrangement of atoms and the frequency with which the distance of closest approach of atoms occurs on the major faces of the body-centered cubic and face-centered cubic metals. The solid lines represent the distance of closest approach.

It is of interest in terms of the correlation between hydrogen overvoltage and thermionic work function[4] that there is no relation similar to that of Fig. 1 for thermionic work function and interatomic distances. Thermionic work function is very roughly a linear function of interatomic distance in the case of the high-melting body-centered cubic metals, the low-melting body-centered cubic metals, and the face-centered cubic metals (the linear relation here is very poor—platinum is a bad exception).

Weeks[10] has previously pointed out the qualitative correlation between hydrogen overvoltage and the melting point of metals. As shown in Fig. 4 there is also a correlation between melting point and the distance of closest approach of atoms in the case of the face-centered cubic and body-centered cubic metals. A comparison of Figs. 1 and 4 indicates that the maximum in melting point and the minimum in hydrogen overvoltage occur at approximately 2.7 Å. Although the shapes of the curves are drawn slightly differently in Figs. 1 and 4, it can be seen that there is a semi-quantitative similarity of the relative positions of the metals in both figures.

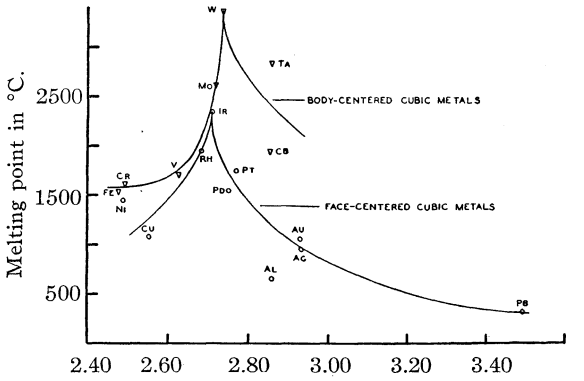

Fig. 4.—The relation between the melting point and the distance of closest approach of atoms for seventeen metals of the body-centered cubic and face-centered cubic structures.

The correlation between hydrogen overvoltage and the spacing between atoms in the surface as reported in this paper does not in itself enable one to choose between the numerous theories developed to account for the phenomenon of hydrogen overvoltage. It is hoped, however, that these results will stimulate theoretical investigations of the significance of the 2.7 Å. spacing in hydrogen overvoltage.

Summary

Evidence was presented which indicated that the spacing between atoms is an important factor in catalysis. Values of the hydrogen overvoltage were shown to be a minimum at a distance of closest approach of atoms of approximately 2.7 Å. for both the body-centered cubic and face-centered cubic metals.

The Surface Area and Catalytic Activity of Aluminum Oxide[1]

BY WALLACE S. BREY, JR.,[2] AND K. A. KRIEGER

The ability of a solid catalyst to promote a gaseous reaction depends upon the amount of surface which the solid possesses as well as upon the specific activity of the surface. Methods of surface area measurement, such as that based on the theory of Brunauer, Emmett and Teller,[3] afford a means of distinguishing between changes in quality and in extent of a catalyst surface. Aluminum oxide is known to undergo changes on thermal treatment, and the purpose of this investigation was the determination of how the resulting variations in its effectiveness as a catalyst for the dehydration of ethanol are related to the two aspects of surface alteration.

Experimental

Alumina catalysts were prepared from $^{8}/_{14}$ mesh Alorco Activated Alumina by heating at temperatures between 500 and 1000°, both in vacuum and in the presence of water vapor. Surface areas of the catalysts before use were measured by the BET method using nitrogen,[3] following outgassing of the samples at 400°.

The catalytic reaction was carried out at 350 and 400° in an electrically heated, vertical tube, of 25 mm. inside diameter. The 200-proof ethanol was pumped at constant rate into an electrically heated evaporator and then passed as vapor into the reactor. The upper part of the reactor tube contained a preheater section packed with quartz chips and provided with manual temperature control; the middle section of the tube contained the catalyst bed of 49 cc. volume, and the temperature of this part was controlled to about ±1° by means of a Micromax potentiometer controller. The liquid products of the reaction were condensed in receivers cooled in ice and in dry ice and were analyzed by distillation. The uncondensed gas was measured in a wet-test meter and analyzed for ethylene by absorption in $HgSO_4$–H_2SO_4 solution.[4] Before the reaction was begun the catalyst tube was brought up to temperature under vacuum and then filled with nitrogen; the first portion of the products was discarded while the system was reaching a steady state.

Results and Discussion

Surface Areas.—Catalysts prepared by evacuation at 600 to 900° show an approximately linear decrease of area with increasing temperature (Table I). The areas of aluminas treated with water vapor are always lower than are those of the aluminas vacuum-treated at corresponding temperatures; the magnitude of the difference depends somewhat upon the pressure of water vapor as well as upon the duration of vapor treatment.

All materials prepared by heating at temperatures between 500 and 900°, either in vacuum or in the presence of water vapor, were shown by X-ray diffraction powder photographs to consist of gamma alumina. Increasing treatment temperature, as well as the presence of water, caused the sharpening of the gamma alumina lines, indicating growth of the crystallites composing the solid. A parallel increase in particle size[5] would, of course, explain the reduction in area. Between 900 and 1000° a sharp decrease in area was found as the result of both methods of treatment; the diffraction patterns indicated that the 1000° samples had been partially converted to corundum.

The surface area values here cited may be compared with the measurements made earlier in this laboratory on portions of the same large quantity of alumina.[6] For samples outgassed between 400 and 500°, the present area values are about 15% larger than the previous results, while areas of samples evacuated at 600° and above are closely coincident in the two sets of measurements. We interpret these facts as evidence that interaction with water took place during the intervening period in a manner so that removal of water by heating disrupted the crystal; this effect was eliminated by higher evacuation temperatures at which crystallite growth and sintering occurred, and where, in the absence of water vapor, the area is a function of temperature of preparation only.

Changes of Catalyst Activity with Use.—Runs employing one catalyst under similar conditions in general gave results which were in satisfactory agreement; ethylene conversion at a reaction temperature of 400° was reproducible within 3%. For certain catalysts, however, there was a consistent trend in activity with use for the first few runs: catalysts heated in vacuum at 800 and 900° became more active, while those heated at 600° in vacuum or in steam were deactivated.

That these changes were not due to changes in surface area is evidenced by the complete restoration, after use, of the activity of catalyst D, originally steam-treated at 600°, by heating in vacuum at 525°, and by the observed lack of increase in area with use of catalyst K, originally heated in vacuum at 900°. Rather, they are associated with the existence of an optimum surface water content for the reaction, and with the slow activated adsorption of water by the catalyst during use. The 600° catalysts thus have at the outset a water content in excess of the optimum; as they are used, adsorption of more water reduces activity. The 800 and 900° vacuum-treated catalysts have initially less than the optimum water

[a] Following several runs in which it was used with aqueous feed, catalyst batch A was designated A-2; the area cited for A-2 was determined after use. [b] In flowing stream of water vapor at 1 atm. pressure. [c] Water vapor pressure about 25 mm. [d] Catalyst D, after use, was evacuated to produce this batch. [e] Activity not determined. [f] Estimated from relatively few runs.

content; adsorption of more water causes the surface to become more efficient as a catalyst.[7]

Reaction Products and Mechanism.—In Figs. 1 and 2 are plotted representative conversion curves for the formation of ether and ethylene in runs using several of the catalysts. The reaction rate is given by the slope of these curves.[8] The trend of the curves with increasing extent of reaction is similar to the results of earlier workers.[9] For every catalyst studied at a reaction temperature of 400° and for the more active catalysts at 350° the ether conversion passes through a maximum while the ethylene conversion steadily increases. For the less active catalysts at 350° the alcohol feed rate was not in all cases sufficiently reduced for the ether maximum to be reached but there seems no doubt that it could have been observed.

In order to evaluate quantitatively the catalyst activity, it is necessary to relate the observed rates of ethylene formation to a velocity constant of the rate-determining step in the reaction. Diffusion is not rate-controlling, in view of the large temperature coefficient of the reaction and the dependence of rate upon surface area. The problem of establishing the rate constant is thus that of the choice of the direct precursor or precursors of ethylene.

If alcohol is assumed to be the sole immediate source of ethylene, then, since ether is produced initially quite rapidly and subsequently disappears, the ether must be formed from alcohol and then reconverted to alcohol to maintain equilibrium with the latter as it is converted to ethylene

$$C_2H_5OH \longrightarrow CH_2{=}CH_2 + H_2O$$
$$\uparrow\downarrow$$
$$H_2O + C_2H_5OC_2H_5$$

This mechanism, with the assumptions that the surface reaction is rate-determining, that ethanol and water are strongly adsorbed while ethylene and ether are not, that only one active site is involved in the reaction and that the reverse reaction may be neglected because of the magnitude of the equilibrium constant, leads to the equation

$$22{,}400R = \frac{kLK_aP_a}{K_aP_a + K_wP_w} = \frac{k_1P_a}{P_a + k_1'P_w} \quad (1)$$

where R is the rate in moles ethylene formed per cc. of catalyst bed per sec., k is the rate constant, L is the number of active sites per cc., the K's are adsorption equilibrium constants, the P's are partial pressures, and the subscripts a and w refer to alcohol and water, respectively.[8] Equation (1) fits the experimental data, while similar equations for the cases in which adsorption or desorption are rate-determining do not. The curves of conversion to ethylene in Figs. 1 and 2 have been calculated from equation (1), employing the values of the constants shown in Table I, while the points shown represent experimental results. The constants in equation (1) were evaluated by the method described in reference (8), pages 958–959.

If, on the other hand, ether is formed from alcohol and is the sole source of ethylene, the initial

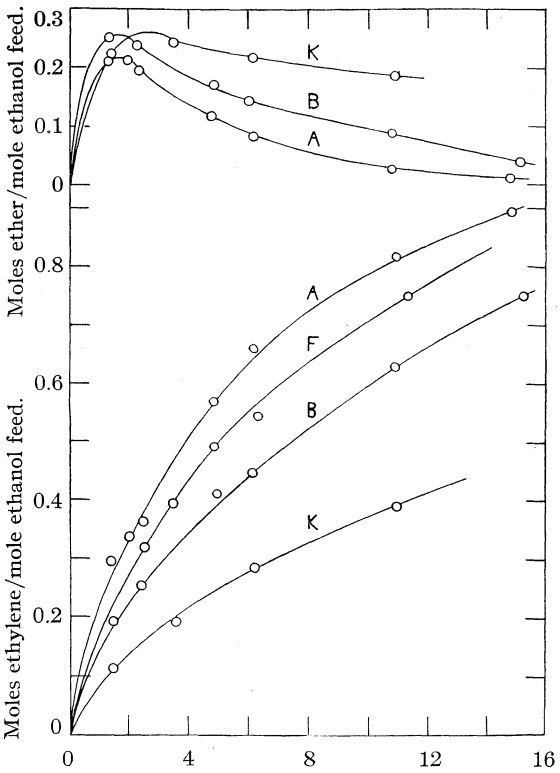

Fig. 1.—Conversion of ethanol to ethylene and ether at 400° reaction temperature for representative catalyst batches.

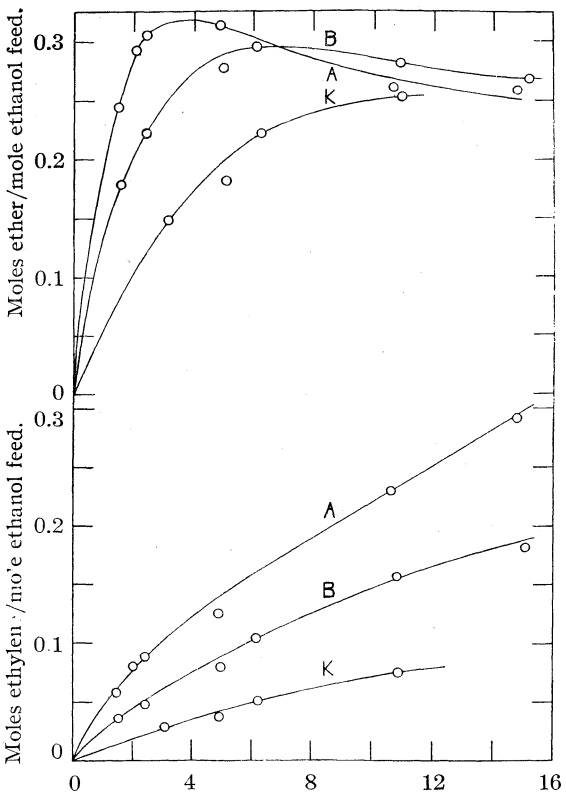

Fig. 2.—Conversion of ethanol to ethylene and ether at 350° reaction temperature.

rate of ethylene production should be zero, since the initial ether concentration is zero. There is no indication of this in the present work or in the results reported by others, except in those of Alvarado.[9d]

It is possible that ethylene is produced by parallel paths, with a fraction coming directly from alcohol and the remainder from ether. In fact, ethylene is formed quite rapidly when ether is passed over the catalyst. From 0.52 mole of ether fed during sixty minutes, 0.39 mole of ethylene and 0.05 mole of alcohol were obtained, at a reaction temperature of 400°. This is roughly 50% more ethylene than would have been obtained from one mole of alcohol under the same conditions. However, the circumstance that the rate of ethylene formation is given satisfactorily by equation (1) and seems, on examination of the conversion curves, not to be directly affected by the changing ether pressure during the course of the reaction, indicates that if ethylene is produced by two paths, the effect of the presence of ether is not exerted independently of the alcohol concentration.

To account for this situation, it seems necessary to assume that a common intermediate such as a carbonium ion may be formed from either alcohol or ether and can then react to form either ethylene or ether

$$C_2H_5OH \underset{+OH^-}{\overset{-OH^-}{\rightleftharpoons}} C_2H_5^+ \xrightarrow{-H^+} C_2H_4$$

$$-C_2H_5O^- \uparrow\downarrow +C_2H_5O^-$$

$$C_2H_5OC_2H_5$$

The appearance of this type of intermediate is indicated by the products formed when higher alcohols are dehydrated over alumina.[10] This mechanism also explains the important role of a water molecule in the reaction as the result of its ability to supply a hydrogen atom to form a hydrogen bridge between the catalyst and an alcohol or ether oxygen atom, thus weakening a carbon to oxygen bond in the organic molecule and creating a favorable situation for carbonium ion formation.[7a] If the carbonium ion concentration is proportional to the surface concentration of alcohol, and the rate-determining step is the conversion of the ion to ethylene, then the rate of ethylene production is proportional to the surface concentration of alcohol and the use of equation (1) is justified.

Specific Activity of the Catalyst.—In Table I are given the values of k_1 and k_1', from equation (1), for the reaction temperatures of 350° and 400°, as well as the ratio of k_1 at 400° to the total

(10) Henne and Matuszak, THIS JOURNAL, **66**, 1649 (1944).

surface area of the catalyst batch. This ratio represents the activity of unit area of surface. For catalysts for which activity changed with use, the values are for the final, stable level of activity.

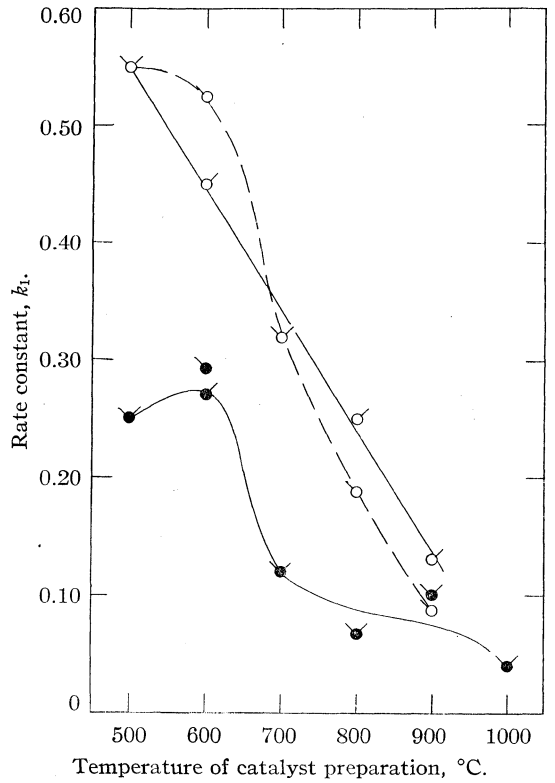

Fig. 3.—Rate constants at 400°: ◔, initial activity of vacuum-treated alumina; ◑, stable (final) activity, vacuum-treated; ◔, initial activity, steam-treated; ◕, stable (final) activity, steam-treated.

In Fig 3 are plotted the values of k_1 at 400°, along with estimates of the original activities for the catalysts showing changing activity. It is clear from Fig. 3 that the effect of steam treatment is markedly to reduce total activity below that resulting from vacuum activation at the same temperature, except perhaps at the highest temperatures where all catalysts show very small activities. That this decrease in activity is not, however, a matter of quality, but only of quantity of surface is illustrated in the plot of specific activity presented in Fig. 4, which demonstrates that the activity per unit area of remaining surface is substantially independent of method of treatment except at 800°, where the vacuum activated surface is distinguished by ability to improve its activity upon use. Further evidence that the effect of water vapor is exercised largely through a change in surface area is given by the data in Table I for catalyst A. Following reaction runs with pure alcohol, this catalyst was employed several times with a feed containing approximately 75 mole per cent. water, at a temperature of 350°. When the catalyst was then again used with pure alcohol feed, the total activity had been reduced, during the runs with high water content, by 33%, while the specific activity had decreased only 10%.

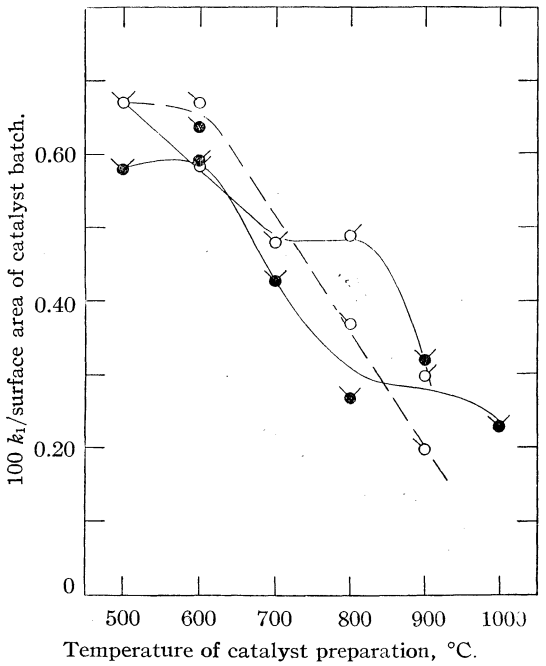

Fig. 4.—Specific activity of catalysts for 400° reaction temperature: ◔, initial activity, vacuum-treated; ◑, stable activity, vacuum-treated; ◔, initial activity, steam-treated; ◕, stable activity, steam-treated.

The specific activity of the catalyst decreases as the temperature of preparation is increased above 600°. This is probably a consequence of increased perfection of the crystal lattice, leading to a decrease in the number of sites at which there exist unsatisfied valence forces. However, it appears from the values of k_1 for 350° and for 400° in Table I that the temperature coefficient of the reaction is very nearly constant, within the experimental error, for all the catalysts studied, and consequently the active sites have approximately the same nature in all the materials.

Summary

1. The catalytic activity of samples of aluminum oxide prepared by heating in vacuum and in water vapor at temperatures between 500 and 1000° has been measured for the dehydration of ethanol at reaction temperatures of 350 and 400°.

2. Both total activity and specific activity decrease as the preparation temperature increases above 600°. Heating with water vapor induces an additional loss of area and activity as compared with heating in vacuum, but the specific activity of the surface is nearly independent of the presence of water.

3. Crystallite growth is a concomitant of the reduction in area produced by high temperatures

and by the presence of water vapor; under the more severe conditions of treatment, this change is accompanied by a decrease in the number of catalytic centers without substantial change in their nature.

4. Some possible mechanisms for the formation of ethylene have been considered in the light of the reaction kinetics, and the ether intermediate theory in its simplest form has been shown to be inapplicable.

5. Changes of activity with use have been explained as the result of changes in the water content of the surface, rather than in surface area.

Copper(II) and Nickel(II) Complex Ions of Hydroxyethylethylenediamine

BY JEAN L. HARVEY,[1] CHARLES I. TEWKSBURY AND HELMUT M. HAENDLER

Complex ions formed by the action of multidentate amines on metal ions are of considerable interest structurally. In a previous article Haendler[2] reported the formation of copper(II) and nickel(II) complex ions with diethylenetriamine, $H_2N(CH_2)_2NH(CH_2)_2NH_2$. Subsequently, Breckenridge[3] isolated specific complexes of this amine and of hydroxyethylethylenediamine (2-(2-aminoethylamine)-ethanol), $H_2N(CH_2)_2NH(CH_2)_2OH$ (abbreviated "hn"). The work on diethylenetriamine led to the conclusion that it probably behaved as a tridentate ligand, a conclusion supported by polarographic studies by Laitinen, *et al.*,[3a] and that the copper and nickel complexes were structurally similar.

Using hydroxyethylethylenediamine, however, Breckenridge was able to isolate copper complexes with a copper:hn ratio of 1:1 and 1:2 from 95% ethanol and a single nickel complex with a nickel:hn ratio of 1:3 from absolute ethanol. Spectrophotometric methods have now been applied to the study of the ions formed in water solution by copper(II) and nickel(II) ions and this amine. It has been found that copper forms the complex ions $[Cu(hn)]^{++}$, $[Cu(hn)_2]^{++}$ and $[Cu(hn)_4]^{++}$, and that nickel forms the ions $[Ni(hn)]^{++}$ and $[Ni(hn)_2]^{++}$.

The results for copper are compatible with the structures suggested by Breckenridge. In $[Cu(hn)]^{++}$ and $[Cu(hn)_2]^{++}$, the amine probably acts as a bidentate ligand, the coördinating power of the hydroxyl group being slight. The shape of the spectral curves for $[Cu(hn)_4]^{++}$ indicates low stability of the ion, consistent with a non-chelated structure involving four primary amine groups. The complex is apparently stable only in solution.

Attempts to identify the ions formed between copper(II) and diethanolamine (2,2′-dihydroxydiethylamine), $HO(CH_2)_2NH(CH_2)_2OH$ (abbreviated "den"), indicate that there are ions with copper:den ratios of both less than 1:3 and greater than 1:3. If the amine were coördinated through both the amine and hydroxyl groups, a ratio of 1:2 would be the maximum expected. No ratio greater than 1:3 could be expected if coördination were through the hydroxyl groups only. It is thus probable that the diethanolamine is coordinated only through the secondary amine group. The ions are stable only in the presence of excess amine, indicating lower coördinating power than with primary amine groups. This supports the proposal that only primary amine groups are involved in the 1:4 ion of hydroxyethylethylenediamine and that both amine groups participate in the formation of 1:1 and 1:2 ions.

The $[Ni(hn)]^{++}$ and $[Ni(hn)_2]^{++}$ are assumed to be similar in structure. No evidence could be found of an ion corresponding to $[Ni(hn)_3]Cl_2$ isolated by Breckenridge. There is evidence, however, that the solvent affects the coördinating power of the amine. Mann[4] reported that only two moles of diaminopropanol would coördinate to nickel in water solution. The compound $[Ni(hn)_2]HgI_4$ has been prepared by reaction in

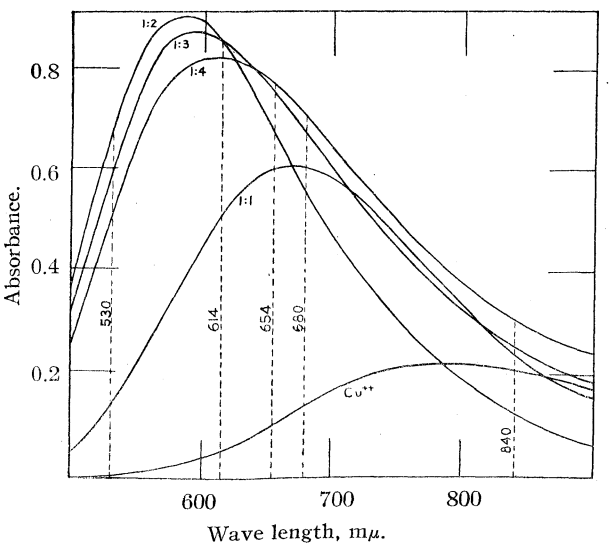

Fig. 1.—The absorption spectra of solutions of Cu^{++} and hn.

water solution, using an amount of amine in excess of that needed for the 1:3 compound.

Experimental

Determination of composition was made by the method of continuous variations, as described by Vosburgh and Cooper.[5] Maxima of curves obtained by plotting the amount of ligand solution (x) against the difference (Y) between observed absorbance and that calculated for no reaction give directly the compositions of the ions present, if both components are in solutions of equimolar concentration.

All absorption spectra were measured with the Beckman DU Spectrophotometer, using 1-cm. Corex cells. Measurements were made directly in terms of absorbance.[6]

Hydroxyethylethylenediamine was purified by vacuum distillation, b. p. 130.5° at 11 mm. Solutions of the amine were standardized against hydrochloric acid, using brom thymol blue. Diethanolamine was also distilled, b. p. 155–157° at 12 mm.

Copper(II) Complex Ions.—A 0.100 M copper(II) ion solution was prepared from copper(II) acetate monohydrate, used without further purification. Five drops of 6 M acetic acid per liter was added to prevent hydrolysis. The absorption spectra were measured for solutions 0.010 M in copper ion and, in addition, 0.010, 0.020, 0.030, 0.040 and 0.060 M in hydroxyethylethylenediamine, corresponding to molar ratios of 1:1, 1:2, 1:3, 1:4 and 1:6. The spectra are shown in Fig. 1. The 1:6 curve closely resembled the 1:4 curve.

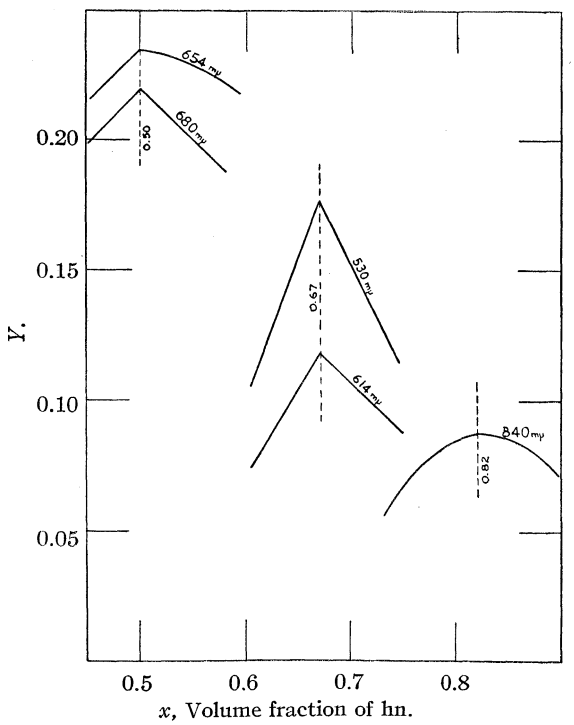

Fig. 2.—Y curves for mixtures of $(1 - x)$ volumes of 0.010 M Cu^{++} and x volumes of 0.010 M hn solutions.

(6) Mellon, *Anal. Chem.*, **21**, 3 (1949).

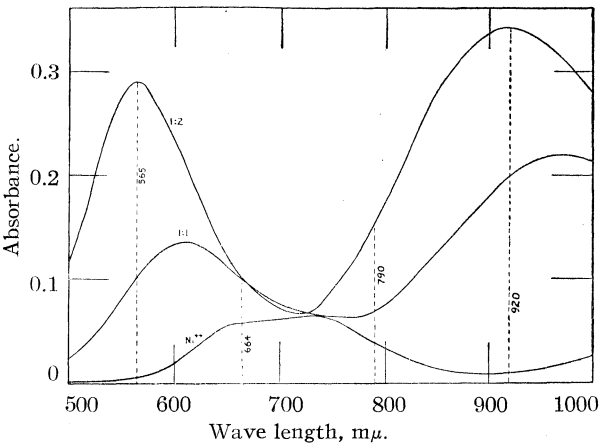

Fig. 3.—The absorption spectra of solutions of Ni^{++} and hn.

Further measurements were made at 530, 614, 654, 668, 680 and 840 mμ, using variable amounts of 0.010 M solutions. The Y curves are shown in Fig. 2. The maxima indicate the presence of the ions $[Cu(hn)]^{++}$, $[Cu(hn)_2]^{++}$ and $[Cu(hn)_4]^{++}$.

Nickel(II) Complex Ions.—A 0.667 M nickel (II) sulfate solution was prepared from the hexahydrate, which had been treated for removal of cobalt.[7] Five drops of 3 M sulfuric acid per

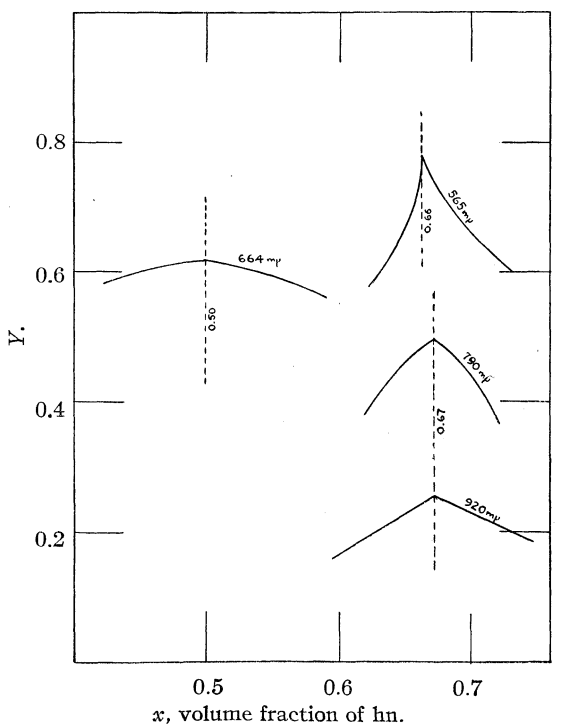

Fig. 4.—Y curves for mixtures of $(1 - x)$ volumes of 0.334 M Ni^{++} and x volumes of 0.334 M hn solutions.

(7) Deakin, Scott and Steele, *Z. physik. Chem.*, **69**, 126 (1909).

liter was added. A 0.667 *M* amine solution was used. By dilution, solutions 0.067 *M* in nickel ion and of the proper amine concentration for ratios of 1:1, 1:2, 1:3, 1:4 and 1:6 were prepared. The absorption spectra of these solutions are shown in Fig. 3. The spectra of the 1:3, 1:4 and 1:6 ratios are almost identical to the 1:2 curve.

The *Y* curves were obtained from measurements at 565, 664, 790 and 920 mμ, using 0.334 *M* solutions. These curves, Fig. 4, show the presence of the ions $[Ni(hn)]^{++}$ and $[Ni(hn)_2]^{++}$.

The compound $[Ni(hn)_2]HgI_4$ was prepared by adding an excess of a solution of mercury(II) iodide in excess potassium iodide to a mixture of nickel sulfate and hydroxyethylethylenediamine. The pale blue-violet precipitate was washed with dilute amine solution and with ethanol. Nickel was determined as anthranilate, after removal of mercury with hydrogen sulfide, and mercury was determined as $[Cu(en)_2]HgI_4$.[8]

Anal. Calcd. for $[Ni(hn)_2]HgI_4$: Ni, 6.02; Hg, 20.6. Found: Ni, 6.09, 5.92; Hg, 20.1, 20.2.

Copper(II) Complex Ions of Diethanolamine.—The absorption spectra were measured for solutions 0.010 *M* in copper ion and containing diethanolamine in ratios of 1:3, 1:4, 1:6 and 1:8. The spectra are shown in Fig. 5. The 1:8 curve resembled the 1:6. Solutions of lower ratio could not be prepared because of precipitation of hydroxide. The 1:3 solution hydrolyzed slowly. Uncorrected *Y* curves for the higher values of *x* are shown in Fig. 6. The maximum at 0.82 suggests the 1:4 ion for the measurement at 530 mμ. At the other wave lengths the absence of maxima indicate that the ions formed are less than 1:3.

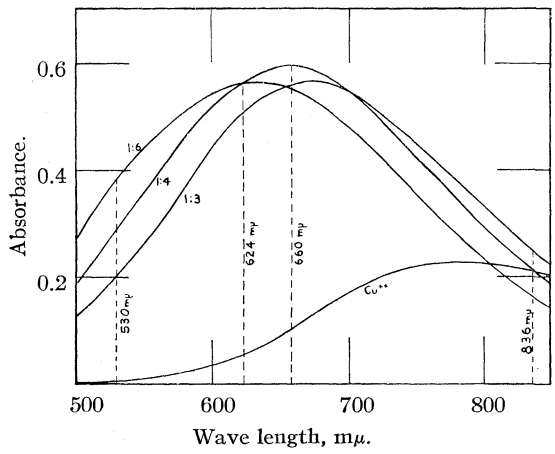

Fig. 5.—Absorption spectra of solution of Cu^{++} and diethanolamine.

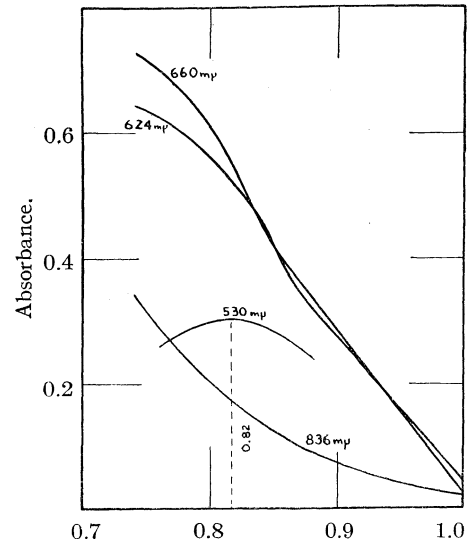

Fig. 6.—Absorption spectra for mixtures of $(1 - x)$ volumes of 0.010 *M* Cu^{++} and *x* volumes of 0.010 *M* diethanolamine.

Summary

Complex formation between copper(II) and nickel(II) ions and hydroxyethylethylenediamine has been studied spectrophotometrically.

The presence of the ions $[Cu(hn)]^{++}$, $[Cu(hn)_2]^{++}$, $[Cu(hn)_4]^{++}$, $[Ni(hn)]^{++}$ and $[Ni(hn)_2]^{++}$ has been shown.

Cation Complexes of Compounds Containing Carbon–Carbon Double Bonds. IV. The Argentation of Aromatic Hydrocarbons[1]

BY L. J. ANDREWS AND R. M. KEEFER

Detailed information concerning the argentation of aromatic hydrocarbons is lacking. The results of studies of the phase relationships in the systems silver perchlorate–benzene–water and silver perchlorate–toluene–water[2] suggest that the tendency for such complex formation is appreciable.

In the present investigation, which represents an extension of the work reported previously,[3] the solubilities of several aromatic hydrocarbons in aqueous silver nitrate solutions have been measured. The data have been interpreted on the assumption that from each hydrocarbon two water-soluble complexes, $AgAr^+$ and Ag_2Ar^{++}, are formed.[4] Equilibrium constants for reactions leading to their formation have been calculated.

Experimental

The Aromatic Hydrocarbons.—All of the hydrocarbons used were of the best grade obtainable from Eastman Kodak Co. The benzene and toluene were washed successively with concentrated sulfuric acid, water and dilute sodium hydroxide and, after drying, were fractionated. Cuts of b. p. 80.1° (benzene) and 110.4° (toluene) were used in the solubility experiments. The xylenes were fractionated and samples of the following b. p. used: *o*-xylene (144.3–144.5°), *m*-xylene (139.5°), *p*-xylene (138.5°). The naphthalene was recrystallized from ethanol, m. p. 80.5°. The biphenyl was used directly, m. p. 70.0–70.5°. The diphenylmethane was purified by fractional freezing,[5] m. p. 25.0°. Phenanthrene was recrystallized twice from ethanol, m. p. 101.0°.

The Solubility Measurements.—To aqueous silver nitrate solutions of varying silver ion concentration contained in glass-stoppered Erlenmeyer flasks were added 0.1–1.0-g. samples of aromatic hydrocarbon. In all cases sufficient potassium nitrate was contained in the aqueous solution to maintain an ionic strength of unity. The mixtures were rotated twenty hours in a constant temperature bath at 25.0° to saturate the aqueous phase with hydrocarbon.

Pipet samples (5–20 ml.) of the aqueous phase were then removed and extracted with measured volumes of hexane (10–50 ml.) by shaking in glass-stoppered Erlenmeyer flasks. The optical density of the hexane phase was measured against a hexane blank on the Beckman spectrophotometer at a wave length and slit width setting for each particular hydrocarbon for which values of the molecular extinction coefficient of such solutions had previously been determined. In all cases investigated one extraction with hexane removed all of the hydrocarbon, both free and complexed, from the aqueous phase, as was indicated by the fact that hexane samples used in a second extraction of the aqueous phase gave negligible optical density readings. The volumes of the aqueous and hexane phases were adjusted insofar as possible to obtain optical density readings between 0.200 and 0.800. Thus the data were available to calculate the aromatic hydrocarbon content of the saturated aqueous solutions.

Samples of aqueous silver nitrate and potassium nitrate were extracted with hexane. The hexane phase contained no light absorbing materials as evidenced by measurement of its spectrum against a hexane blank.

The hexane was Skellysolve B rendered optically pure for purposes of the experiments by two washings with fuming sulfuric acid, followed by washings with water and dilute sodium hydroxide solution, drying and distillation.

The wave lengths and slit width settings used in the optical density measurements of the hexane solutions of the hydrocarbons with corresponding values of the molecular extinction coefficients are given in Table I. In each case the solutions obeyed Beer's law. Included in this table are values of the water solubilities of the hydrocarbons at 25.0°, determined by the method described above as a check on the extraction procedure, with corresponding data from the literature.

Attempts at a determination of the argentation constants for anthracene by this method were unsuccessful. Reproducible results were not obtainable, since difficulty was encountered with contamination during sampling of the saturated solutions.

To check on the possibility that silver nitrate may have distributed to the aromatic hydrocarbon phase in the solubility experiments, equal volumes of benzene and 1 *N* silver nitrate solution were shaken for several hours. Samples of the benzene were removed and shaken with dilute aqueous potassium chloride. No silver chloride was formed.

Results

The solubility of the several hydrocarbons in aqueous solutions increased with increasing silver ion concentration to a greater degree than was consistent with the supposition that only a 1–1 complex, $AgAr^+$, was formed. Accordingly the data were interpreted on the assumption that equilibria (1) and (2) were established in these solutions.

$$Ag^+ + Ar = AgAr^+ \quad K_1 = (AgAr^+)/(Ag^+)(Ar) \quad (1)$$

$$Ag^+ + AgAr^+ = Ag_2Ar^{++} \quad K_2 = (Ag_2Ar^{++})/(Ag^+)(AgAr^+) \quad (2)$$

An additional constant K was defined in terms of the several species postulated as present in the saturated aqueous solutions as follows

$$K = \frac{(Ar_c)}{[(Ag_t^+) - (Ar_c) - (Ag_2Ar^{++})](Ar)} = \frac{(AgAr^+) + (Ag_2Ar^{++})}{[(Ag_t^+) - (AgAr^+) - 2(Ag_2Ar^{++})](Ar)} = K_1 + K_1K_2(Ag^+) \quad (3)$$

where

- (Ar_c) = the molar concentration of complexed hydrocarbon = $(Ar_t) - (Ar)$
- (Ar_t) = the molar concentration of all hydrocarbon-containing species
- (Ar) = the molar concentration of free hydrocarbon = the concentration of hydrocarbon in its saturated solution in 1 *N* potassium nitrate
- (Ag^+_t) = the molar concentration of silver ion in free and complexed form

Biphenyl	252	.48	1.58×10^4	5.94×10^{-4}	.....
Diphenylmethane	222	1.10	7.69×10^3	1.41×10^{-4}	.....
Phenanthrene	252	0.42	7.16×10^4	9.94×10^{-5}	1.6×10^{-4} (27°)[c]

[a] Values, except as noted, from Seidell, "Solubilities of Organic Compounds," Third Edition, Volume II. [b] For a xylene mixture of unrecorded composition. [c] Results of Davis, Krake and Clowes, THIS JOURNAL, 64, 108 (1942), as based on the nephelometric method.

To calculate K the concentrations of substances as defined above were substituted in the left-hand expression of equation (3). It was assumed that (Ag_2Ar^{++}) was sufficiently small as compared to the concentration of uncomplexed silver ion so that it could be neglected in calculating K. In every case the K_2 values obtained as described below indicated that (Ag_2Ar^{++}) was very small as compared to uncomplexed silver ion concentration, so that the values of K needed no correction.

Values of K calculated from the data recorded for each compound are summarized in Table II.

If reaction (1) were the only one contributing appreciably to complex formation, K should equal K_1 and values of K for any particular hydrocarbon should be independent of silver ion concentration of the medium. The marked increase in K values observed indicates an appreciable contribution of reaction (2). As would be expected, if equations (1) and (2) account for all complexes formed, plots of K against the silver ion concentration in the saturated solutions should give straight lines. This was found to be true for all the compounds investigated. In such plots the ordinate intercept is K_1, and K_2 may be obtained from the slope of the lines which is equal to K_1K_2. The values of K_1 and K_2 obtained are given in Table III.

TABLE III

THE EQUILIBRIUM CONSTANTS FOR ARGENTATION OF THE HYDROCARBONS AT 25.0°

Hydrocarbon	K_1	K_2
Benzene	2.41	0.212
Toluene	2.95	.214
o-Xylene	2.89	.315
m-Xylene	3.03	.320
p-Xylene	2.63	.331
Naphthalene	3.08	.909
Biphenyl	3.94	1.01
Diphenylmethane	3.46	1.04
Phenanthrene	3.67	1.80

The Structures of the Complexes.—The complex formed between silver ion and a molecule containing an unconjugated double bond has been described[6] in terms of resonance formulas

$$>C-\overset{+}{C}< \qquad >\overset{+}{C}-C< \qquad >C=C<$$
$$\diagdown\ Ag \qquad Ag\ \diagup \qquad Ag^+$$

A similar structure in which silver ion is bonded to one particular double bond of a ring might be postulated for aromatic systems. This seems unattractive since such a structure would entail the loss of considerable ring resonance energy within the aromatic system itself. An attractive

(6) Winstein and Lucas, THIS JOURNAL, 60, 836 (1938).

modification of the above structure, as applied to the singly argentated benzene molecule, pictures the silver ion as being located above the plane of the ring at a position equidistant from the six-ring carbon atoms. This silver ion would be in a position to utilize the π-electrons of the ring to form covalent bonds of the type indicated above with any of the six ring carbons. The structure of the complex would then be represented by eighteen equivalent single-bonded structures in addition to two no-bond structures as contributors to a resonance hybrid.[6,7] The loss of ring-resonance energy when such a complex is formed would be compensated to a large degree by the resonance energy associated with the complex itself. In the doubly argentated benzene complex the second silver ion could bond to the plane of the ring from the side opposite to which the first silver ion is attached. A synchronized resonance[8] in which two silver–carbon bonds resonate among six equivalent positions might then exist. One can calculate, using the tetrahedral covalent radii for the ring-carbon atoms and for silver,[9] that the silver ion in the complex would not penetrate the plane of the ring, thus eliminating the possibility of steric interference between two silver ions in the doubly argentated complex. It is interesting to note that the covalent radius of silver is sufficiently large so that the silver ion would overlap the perimeter of the carbon–carbon bond skeleton of the ring. With these postulates as to structure in mind it is interesting to consider the tendencies for complex formation of the several hydrocarbons.

It appears that a methyl substituent enhances slightly the basic strength of the benzene ring, as reflected in the values of the equilibrium constants for benzene and toluene. The presence of two methyl groups on the ring (see the data for the xylenes) apparently causes no marked increases in basicity over that for toluene, which suggests that a steric effect opposing complex formation may be present in these molecules.[10]

In the case of the multiple ring systems the K_1 values are higher than those for benzene. One might expect for biphenyl, in which the two phenyl groups are on the average in the same plane,[11] a K_1 value approximately double that for benzene. The interaction between rings in biphenyl is at least partially responsible for the fact that K_1 observed is less than the predicted value.

For diphenylmethane, in which the two rings are not coplanar, steric influences should effectively eliminate one of the four positions of attack available to silver ion. On this basis K_1 should be approximately $^3/_2$ K_1 for benzene, and the observed value is only slightly less than the predicted value.

A lower value of K_1 is obtained for naphthalene than for biphenyl. Since there are only five double bonds in naphthalene as compared to six in biphenyl, naphthalene might be expected to be less basic than biphenyl.

The K_1 value for phenanthrene is greater than that for naphthalene but less than that for biphenyl. In addition to the possibility that silver ion may coördinate with any of the three rings in this molecule, the possibility that it may coördinate with the carbon–carbon bond at the 9,10-position should be considered. This bond has a high degree of double bond character, and in other reactions preferential substitution or addition occurs at this point.[12]

The K_2 values for the single ring compounds are small as compared to those for multiple-ring systems. This seems reasonable since the presence of a silver ion in $AgAr^+$ must considerably reduce the basicity of the ring with respect to addition of a second silver ion. This effect would be much less pronounced in the multiple-ring systems since the second silver may bond to a ring other than that to which the first silver ion is attached.

Assuming that the first silver ion attached to benzene does not alter the ability of a molecule to coördinate a second silver ion, the predicted value of K_2 for benzene (on a statistical basis) would be $^1/_4$ K_1. The observed value is about $^1/_3$ the predicted value.

There are three positions at which a silver ion might add to the $AgAr^+$ complex of biphenyl. The position on the side of the ring opposite to that at which the first silver ion is attached might be expected to be roughly equivalent in base strength to the $AgAr^+$ complex of benzene. Two alternate bonding positions are available on the other ring, each of which should be roughly equivalent in basicity to one of the four positions available when silver ion coördinates with biphenyl. The ease of loss of a silver ion should be twice as great from Ag_2Ar^{++} as from $AgAr^+$. Combining the above observations one might predict that K_2 for biphenyl would be $^1/_4$ K_1 for biphenyl plus K_2 for benzene. The observed value of 1.01 is less than the value of 1.2 predicted on the above basis.[13]

(8) Pauling, *J. Chem. Soc.*, 1461 (1948).

(9) Pauling, "Nature of the Chemical Bond," Cornell University Press, Ithaca, New York, 1940.

(10) Benesi and Hildebrand, THIS JOURNAL, **70**, 2832 (1948), have described a 1–1 complex for certain aromatic hydrocarbons and iodine and report evidence that increasing methyl substitution on the benzene ring appears to result in an increased tendency for complex formation. Undoubtedly these iodine complexes are closely associated structurally with those under consideration in this report. It is further interesting in this connection to note that if benzene solutions of iodine are treated with anhydrous silver salts, reaction occurs to yield iodobenzene and silver iodide; *cf.* Birckenbach and Goubeau, *Ber.*, **66B**, 1280 (1933). One cannot overlook the possibility that these silver complexes may be very closely related structurally to the transition state intermediates in certain aromatic substitution reactions; *cf.* Dewar, *J. Chem. Soc.*, 777 (1946); 463 (1949).

(11) Wheland, "The Theory of Resonance," John Wiley and Sons, Inc., New York, N. Y., 1944, p. 160.

(12) Price, THIS JOURNAL, **58**, 2101 (1936).

(13) This treatment assumes that the front and rear faces of the free ring in the $AgAr^+$ complex of biphenyl offer equivalent bonding positions for the second silver ion. Considering the coplanarity of biphenyl this assumption is open to question insofar as the silver–silver repulsions would be different for the two possible forms of

A maximum value of K_2 for diphenylmethane of $^1/_3$ K_1 (for diphenylmethane) is predicted if it is assumed that the position sterically prohibited is the other side of the ring containing the first silver ion. The observed value of K_2 is 1.04 as compared to a maximum calculated value of 1.15.

In attempting to predict K_2 values for the fused ring systems, as represented by naphthalene and phenanthrene one cannot overlook the possibility that structures for Ag_2Ar^{++} in which two silver ions are coördinated with adjacent rings on the same side of the plane of the molecule are sterically unfavorable. Neglecting such structures values of K_2 may be calculated which are considerably less than the observed values. For fused ring systems, the structural nature of the Ag_2Ar^{++} complex may be somewhat different from those suggested for non-fused ring molecules.

Ag_2Ar^{++} in which one silver ion is coördinated with each ring. The method used in predicting a value for K_2 is similar to that used in approximating dissociation constants for dibasic acids; *cf.* Branch and Calvin, "The Theory of Organic Chemistry," Prentice-Hall Inc., New York, N. Y., 1945, p. 200.

Summary

By measurement of the solubilities of several aromatic hydrocarbons in aqueous silver nitrate solutions, evidence has been obtained for the formation of two water-soluble complexes, $AgAr^+$ and Ag_2Ar^{++}. Equilibrium constants for the reactions to form these complexes at 25° have been calculated. Structures for the complexes are suggested, and the tendencies for the various hydrocarbons to undergo argentation have been considered in terms of these structures.

A method of analysis for the aromatic hydrocarbon content of aqueous solutions is described in which the hydrocarbon is extracted from the solution with hexane, and its concentration in the hexane phase determined by spectrophotometric measurement.

Absorption Spectra of ortho-Substituted Aldehydes. I. The o-Hydroxynaphthaldehydes[1]

BY NORTEN C. MELCHIOR[2]

The difficulties encountered in attempts to correlate the molecular structures of compounds with their absorption spectra makes careful comparisons of the spectra of closely related compounds important. During an investigation[3] of some of the metal derivatives of the *o*-hydroxynaphthaldehydes, the absorption spectra of these aldehydes and their negative ions was measured in methanol–water solutions. The striking differences in these spectra led to this extension of the measurements.

Experimental

Absorption Measurements.—All measurements were made with a Beckman model DU spectrophotometer in silica cells having a 10-mm. light path. The temperature of the cells was controlled by hollow metal plates, pierced by a small opening for the light beam, which were placed on opposite sides of the cell compartment. Water from a controlled temperature bath was circulated through these plates. A slow stream of dry air passed into the cell compartment prevented fogging of the cell windows at temperatures below the dew point of the laboratory air. Small differences in the measurements due to the volume change of the solvent were eliminated by making final dilutions at the temperature at which the spectrum was run, or by calculation from the measured temperature–volume coefficient of the solvent. Measurements at a given wave length were made with the same slit width, which was kept as small as possible.

Solvents.—Methanol was reagent grade, octane and heptane mixtures were purified by standard procedures. In all cases blanks were prepared from the same sample of solvent used for dissolving the compound studied.

Aldehydes.—The preparation of these compounds has been reported.[3,4] Each sample was sublimed several times at pressures below 0.001 mm., once immediately before use.

Results.—The more pertinent results are shown in Figs. 1 to 5. It is evident in Fig. 1 that the first band of the negative ion of 3-hydroxy-2-naphthaldehyde appears at a lower frequency but with considerably lower intensity, than do those of its isomers. It is easily seen by comparing Figs. 2, 3 and 4 that this is also the case in the neutral molecule, regardless of solvent. It is also apparent that solvent change has a greater effect on the spectrum of the 3-2-compound than upon that of either of its isomers. In addition, Fig. 5 shows the striking effect of temperature change on the absorption spectrum of the 3-2-compound in 80 mole per cent. methanol.

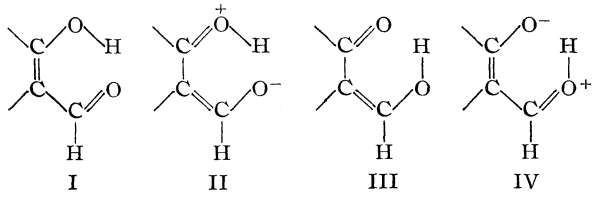
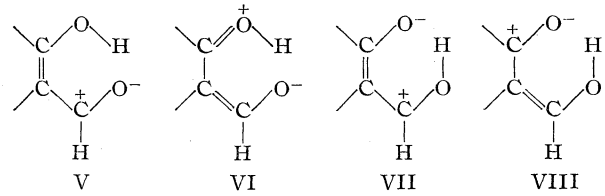
Discussion

It should be possible to account for some of the observed differences in the spectra of these compounds on the basis of reasonable assumptions concerning the nature of the ground and excited states of the molecules. If we consider their common naphthalene nucleus, we find that its major resonance forms are such that the bond between carbon atoms 1 and 2 has about $^2/_3$ double bond character while that between carbon atoms 2 and 3 has only about $^1/_3$ double bond character. In the molecules considered, hydrogen bonding will be an important additional factor, so that we may expect structures such as the following to make contributions to the ground state of the molecule[5]:



Structures I and IV do not require a double bond between the carbon atoms holding the functional groups, but structures II and III require that a double bond be available there. Therefore, as a first approximation, we would expect the contribution of forms II and III to the resonance hybrid to be less in the case of 2-hydroxy-3-naphthaldehyde than in either of its ortho-isomers, and that therefore its ground state would be of higher energy than those of its isomers.

It is reasonable to assume that the low energy absorption band (low frequency, long wave length) is associated with absorption by the carbonyl group and that the corresponding upper state may be the hybrid with important contributions from



It is reasonable to assume that structures VI and VIII are so much more important in the upper state than their analogs in the lower state, that, although one would still expect the upper state of the 3-2 compound to be of somewhat higher energy than that of either of its isomers, due in part to differences in the nuclear resonance forms, this energy difference will be reduced.

From this it follows that the energy difference between the upper and lower states of the 3-2 compound will be less than in its isomers; therefore its absorption maximum for this band should appear at a lower frequency, as observed. This postulated energy diagram is given in Fig. 6.

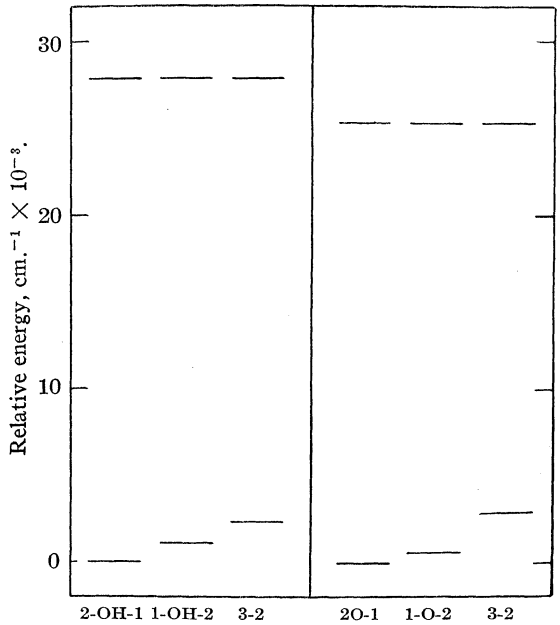


Fig. 6.—Energy diagram for the first absorption bands of hydroxynaphthaldehydes: left, in hydrocarbon solvents; right, in 0.1 *N* sodium hydroxide.

Second, from the author's assumption concerning the nature of the upper state of the low energy band of these compounds, it follows from resonance theory that the shape (*i. e.*, the bond distances and angles) of the ground state of the 1-2-

(5) Regardless of the fine structure of the hydrogen bond, its presence must decrease the energy of the molecule and this discussion does not postulate or depend on the fine structure.

and 2-1-compounds more closely approaches that of the upper state than does that of the 3-2-compound. From the Franck–Condon principle that the absorption of light occurs in a fraction of time much shorter than that required for atom vibrations, it follows that, other factors being equal, the more completely the shape of the molecule in the lower state corresponds to the shape of its upper state, the higher is the probability of light absorption. Thus one would predict that the probability of light absorption would be lower *for this band* in the 3-2 compound than for its isomers. This lowered probability would be reflected directly in the extinction coefficient if, as in this case, the bands are approximately the same shape.

This argument is applicable in its entirety to the corresponding absorption band of the negative ions of these compounds, with the resultant prediction that the first band of the negative ion of the 3-2 compound will appear at a lower frequency but with a lower extinction coefficient than those of its isomers. Both predictions are in agreement with the experimental results in Fig. 1. This relatively lower resonance interaction of the ground state of the ion of the 3-2 compound as compared with its isomers is in harmony with the results of Arnold and Sprung,[4] who found that it was a much weaker acid than its isomers, and with observations made on metal derivatives of these compounds.[3]

Extension of this reasoning to the closely related compounds, salicylaldehyde and the enol form of acetylacetone, leads to the prediction that the absorption probability for the low frequency bands of these compounds should increase in the order: 3-2, salicylaldehyde, [1-2, 2-1], acetylacetone; and that the same order should hold for the absorption probability of their negative ions. We are not, however, able to predict the energy of this transition. Table I indicates that the predictions of the order of the extinction coefficients is confirmed by experiment. The fact that the intensity of absorption in the first band of a series of diphenylpolyenes increases with the number of double bonded units in the chain[6] is in agreement with this idea. Table II shows some additional examples of variations in extinction coefficients of corresponding absorption bands in closely related compounds for which the idea of corresponding shapes may provide an explanation. In the absorption of light by a carbonyl group, the excited state is a hybrid which presumably has a single bond between the carbon and oxygen atoms. Thus any change in the molecule which would increase the C^+-O^- contribution in the ground state should, according to the idea of corresponding shapes, increase the absorption probability. The electron donating effects of the alkyl groups and their steric effects would both increase the C^+-O^- contribution in hexaethylacetone over that in acetone itself, and the expected increase in extrinction coefficient is found.

The data in Table II for the conjugated dienes may be interpreted similarly if we assume that the upper state of the absorption considered involves an oscillation of electrons over the four-carbon conjugated system. The preferred configuration approaches a line in this case, therefore the closer the lower state is to a linear system the higher should be its absorption probability. The straight chain dienes, it is seen, have similar extinction coefficients, while in the dienes where ring formation restricts the approach to linearity, the values are considerably lower. Moreover, the values decrease with decrease in ring size as expected.

It should be emphasized that the shape factor is only one of the factors which affect absorption probability, but these data indicate that it is important and might be used with due caution in drawing conclusions about the actual shapes of molecules.

Temperature Effects.—With the exception of the 3-2 compound, the temperature effects over the small range used (25°) are too small to be shown on these figures. The expected effect is a slight broadening of each band and a shift of the band toward the red. However, when two bands are sufficiently close together, these effects add on the low frequency band and oppose on the higher frequency band with the result that the low frequency peak will increase with temperature, while the higher frequency peak decreases. These effects, however, are slight. In the case of the 3-2 compound in 80 mole per cent. methanol–water solution (Fig. 5) an effect of a far different order

(6) Hauser, R. Kuhn and E. Kuhn, *Z. phy ik. Chem.*, **B29**, 391 (1935).

of magnitude is observed. This effect is attributed to the reversible formation of the acetal and will be discussed in paper II of this series.

Summary

The absorption spectra of the three *o*-hydroxynaphthaldehydes and their negative ions has been determined in a variety of solvents. A theory, based on resonance possibilities in the ground and excited states, accounts for the striking differences in the low frequency absorption bands of these compounds.

Absorption Spectra of *o*-Substituted Aldehydes. II. Aldehyde–Acetal Equilibrium in Methanol–Water Solutions[1]

BY NORTEN C. MELCHIOR[2]

The striking effect of temperature change upon the absorption spectrum of 3-hydroxy-2-naphthaldehyde in acidified 80 mole per cent. methanol–water,[3] and the fact that temperature change had no such effect on the spectra of either 1-hydroxy-2-naphthaldehyde or 2-hydroxy-1-naphthaldehyde under identical conditions led to the extension of these studies to related compounds. Under the same conditions it was found that the spectrum of salicylaldehyde was somewhat affected by temperature, while that of *o*-methoxybenzaldehyde showed a pronounced temperature effect. Further experiments showed that the temperature dependence vanished when *neutral* methanol or methanol–water was used as solvent, and that temperature dependence appeared when acidified 98 mole per cent methanol was used as solvent for either 1-hydroxy-2-naphthaldehyde or 2-hydroxy-1-naphthaldehyde. These experiments suggested that the changes observed were caused by acid catalyzed formation of acetals or hemiacetals. To distinguish between these possibilities, and to define the differences existing among these related compounds, their spectra were determined in neutral and acid methanol–water solutions over a range of temperature and methanol concentration.

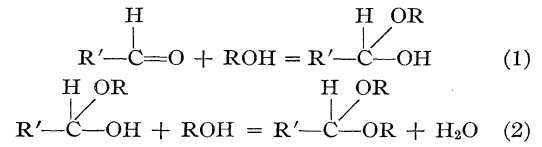
Experimental

Absorption Measurements.—A Beckman model D. U. spectrophotometer was used in all measurements. One-cm. fused silica cells with standard taper stoppers prevented solvent loss by evaporation. The temperature of the cells was controlled as previously described.[3] As a precaution, the previously purified aldehydes were distilled or sublimed immediately before use and were handled in nitrogen. Methanol was reagent grade, and blanks were prepared from the same sample of solvent in all cases.

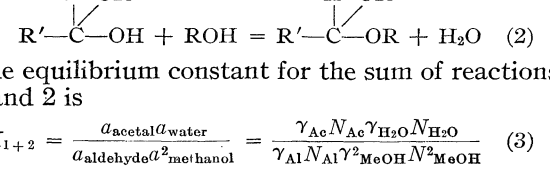
Preparation of Salicylaldehyde Methyl Acetal.—Twenty-five ml. (29 g.) of salicylaldehyde was dissolved in 100 ml. of methanol which contained 0.002 mole of hydrochloric acid. The solution was cooled in stages to Dry-Ice temperature and stored in Dry Ice for one week. It was then neutralized at that temperature with 1 *N* sodium hydroxide, and the methanol and water removed below 0.1 mm. as the mixture warmed to room temperature. The precipitated salt was filtered off with the aid of an anhydrous ether wash, and the product distilled at less than 0.01 mm. after removal of the ether below 25°. After the lapse of a week, this fraction was redistilled, and after preliminary evolution of a low-boiling liquid (possibly methanol), a 9-g. fraction (b. p. 64.5–65.0°, 0.01 mm.; d^{25}_4 1.107, $n^{25}D$ 1.5119) was obtained. The colorless residue weighed 9 g. Analysis of the distillate gave C, 64.8, 64.8; H, 7.2, 7.3. Calculated for $C_9H_{12}O_3$: C, 64.27; H, 7.19. This is apparently the same substance prepared by Pauley and v. Buttlar,[4] but these authors report only the boiling point.

Calculations and Results

The equilibria considered are



$$R'-\underset{H}{\overset{|}{C}}=O + ROH = R'-\underset{H}{\overset{|}{C}}(OR)-OH \quad (1)$$



$$R'-\underset{H}{\overset{|}{C}}(OR)-OH + ROH = R'-\underset{H}{\overset{|}{C}}(OR)-OR + H_2O \quad (2)$$

The equilibrium constant for the sum of reactions 1 and 2 is

$$K_{1+2} = \frac{a_{\text{acetal}}a_{\text{water}}}{a_{\text{aldehyde}}a^2_{\text{methanol}}} = \frac{\gamma_{Ac}N_{Ac}\gamma_{H_2O}N_{H_2O}}{\gamma_{Al}N_{Al}\gamma^2_{MeOH}N^2_{MeOH}} \quad (3)$$

If we assume that hemiacetal formation is small, the ratio N_{Ac}/N_{Al} can be obtained from the measured absorption spectra as

$$\frac{N_{Ac}}{N_{Al}} = \frac{\epsilon_0 - \epsilon}{\epsilon - \epsilon_1} \quad (4)$$

where, at a given wave length,[5] ϵ_0 is the measured extinction coefficient of the aldehyde in neutral methanol, ϵ_1 is that of the acetal in neutral methanol and ϵ is the apparent extinction coefficient of the aldehyde in a given acidified methanol–water solution. If ϵ_1 is zero or small compared to ϵ_0 and ϵ, the equation reduces to (1)

$$N_{Ac}/N_{Al} = \epsilon_0 - \epsilon/\epsilon \quad (5)$$

Measurements of the spectra of the acetals of salicylaldehyde and *o*-methoxybenzaldehyde showed that ϵ_1 was small at the wave lengths chosen in each case, and consideration of the spectra of α- and β-naphthol indicated that this

(1) Presented at the meeting of the American Chemical Society in San Francisco, March, 1949.

(2) Present address: Stritch School of Medicine, Loyola University, Chicago 12, Illinois.

(3) Paper I, THIS JOURNAL, **71**, 3647 (1949).

(4) H. Pauley and R. v. Buttlar, *Ann.*, **383**, 283 (1911).

(5) The preferred wave length is that of an absorption maximum which can be ascribed to the carbonyl group.

was also the case at the rather long wave lengths chosen for the naphthaldehyde calculations.

Preliminary calculations of K_{1+2} (equation 3) assuming that $\gamma_{Ac} = \gamma_{Al}$ and using values from the literature[6] for the activities of methanol and water gave only fair agreement between values calculated from measurements at different methanol–water ratios. Examination of the published data revealed that no measurements had been made in the range of concentration which is of interest here, although in some cases data from smoothed curves had been tabulated in this range.

It was, therefore, necessary to obtain some assurance as to the meaning of the numbers which could so easily be obtained from laboratory measurements. Rearrangement of equation (3) and combination with (5) gives

$$\frac{\epsilon_0 - \epsilon}{\epsilon} = \frac{N_{Ac}}{N_{Al}} = K_{1+2}\frac{\gamma_{Al}\gamma^2_{MeOH}N^2_{MeOH}}{\gamma_{Ac}\gamma_{H_2O}N_{H_2O}} \quad (6)$$

If the plot of $(\epsilon_0 - \epsilon)/\epsilon$ against N^2_{MeOH}/N_{H_2O} is a straight line, the quantity $(\gamma_{Al}\gamma^2_{MeOH})/(\gamma_{Ac}\gamma_{H_2O})$ is a constant over the range considered, and if that constant is unity, the slope of the line is K_{1+2}. Figure 1 shows typical measurements from which these data can be obtained, and Fig. 2 shows this test applied to the data for salicylaldehyde.[7] The linear relationship found is confirmed by the data on *o*-methoxybenzaldehyde and 3-hydroxy-2-naphthaldehyde. This test simultaneously verifies the assumption that hemiacetal formation is small, since any appreciable hemiacetal formation would cause a deviation from the straight line observed.

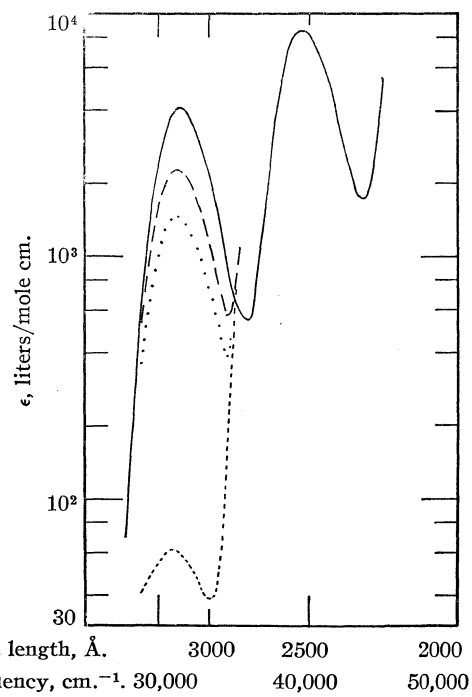


Fig. 1.—Absorption spectra of *o*-methoxybenzaldehyde in methanol–water solutions: — neutral methanol, 25°; — — eighty mole % methanol, 0.01 *M* HCl, 25°; . . . . . eighty mole % methanol, 0.01 *M* HCl, 2°; - - - - methanol, 99.8 mole %, 0.01 *M* HCl, 25°.

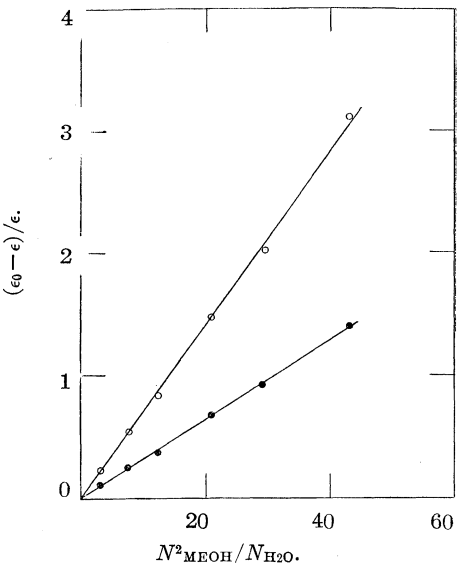

Fig. 2.—Extinction coefficients of salicyaldehyde in acidified methanol–water solutions, λ = 3250 Å.: filled circles, 25°, open circles, 2°.

One can then calculate equilibrium constants on a comparative basis. The values obtained will be subject to a constant correction when the activity coefficient of water in these solutions is available, but are useful for comparative purposes and can be used in calculation of comparative values for ΔH and ΔS without ambiguity. The data obtained are given in Table I and the calculated thermodynamic values are collected in Table II.

Discussion

The data in Table I show clearly the reason temperature has so much less effect on the spectra of 2-hydroxy-1-naphthaldehyde and 1-hydroxy-2-naphthaldehyde than on those of the other aldehydes studied. In most methanol–water solutions so little acetal is formed from either of these aldehydes that the spectrum is only slightly affected, and in 80 mole per cent. methanol even a 100% change in the amount of acetal would scarcely be measurable.

The values obtained for the equilibrium constants cannot, unfortunately, be compared with

(6) (a) Ferguson and Funnell, *J. Phys. Chem.*, **33**, 1 (1929); (b) M. Ewert, *Bull. soc. chim. Belg.*, **45**, 493 (1936); (c) Butler, Thomsen and Maclennan, *J. Chem. Soc.*, 674 (1933); (d) Dulitkaya, *J. Gen. Chem.* (*U. S. S. R.*), **15**, 9 (1945).

(7) Although the straight line relationship is found, it has not been shown that $\gamma_{Al}/\gamma_{Ac} = 1$, nor that $\gamma^2_{MeOH}/\gamma_{H_2O} = 1$. The first is probably correct, since the solutions of aldehyde were very dilute and the standard state chosen is the infinitely dilute solution. The second relation is probably not correct. In this range γ_{MeOH} is probably unity, while γ_{H_2O} is somewhat greater than unity. Over the range of interest, however, both appear to be constant.

1-Hydroxy-2-naphthaldehyde	+3300	−2800	−20.5

[a] For comparative purposes, see note (7) and the text.

those obtained by Adkins and co-workers,[8] since, as these workers recognized, one cannot estimate the activities of any of the substances in their reaction mixtures. The only advantage the spectroscopic measurement can claim is the use of very dilute solutions of aldehyde and acetal; so that the problem is reduced to the estimation of the activities of water and the alcohol concerned. For the first time we are able to examine the separate factors which influence the formation of acetals from different aldehydes with some degree of assurance.[9]

The driving force of the reaction is found in ΔH, and is comparable to that for the formation of ethers from alcohols. The entropy of the system decreases in all cases. A portion of this decrease can be ascribed to the decrease in the number of particles, while some of the remainder may be due to differences in hydrogen bonding of water molecules as compared to alcohol molecules. These factors are constant in all the cases considered. The *differences* observed must be due to differences in the aldehydes and their corresponding acetals and their respective solvent envelopes. Comment on these differences is restricted because of the lack of a common plane of reference, but cautious analysis may yield some information.

In comparing the equilibrium formation of acetal from salicylaldehyde with that from *o*-methoxybenzaldehyde one might reason that, since a chelated hydrogen bond must be broken in the case of the salicylaldehyde but not in *o*-methoxybenzaldehyde, the formation of acetal from the latter should be favored over that from the former. This is exactly what is observed. However, the data in Table II show that this argument, based on energy considerations, has substantially nothing to do with the result, and that differences in ΔS are the basis of the observed changes. The values for ΔH, which is closely related to energy change, indicate that energy required to replace that of the chelated hydrogen bond is supplied, most probably by the formation of several new hydrogen bonds with the solvent. If, then, we accept the values for ΔH as evidence that the *increase* in the number of solvent molecules bound is greater in the formation of salicylaldehyde methyl acetal than in the formation of *o*-methoxybenzaldehyde methyl acetal, we are prepared for the experimental result that the increase in order (decrease in entropy) is greater in the former reaction. It may be noted that the values of ΔS for the sterically similar compounds salicylaldehyde and 3-hydroxy-2-naphthaldehyde are more nearly alike. This same small but, the author believes, real difference is observed in the values of ΔS in the reactions of 3-hydroxy-2-naphthaldehyde and 2-hydroxy-1-naphthaldehyde, both of which yield substituted β-naphthols with the hydroxyl group sterically available to the solvent. This is not the case with 1-hydroxy-2-naphthaldehyde, and we find definitely different values for both ΔH and ΔS, a result which is consistent with a much smaller change in solvation in the reaction than in those of the isomeric compounds considered. There are two qualitative indications that the hydroxyl group is a solvation site even when the chelate ring is presumably intact. One is the almost negligible effect of the solvent

(8) For leading references to the work of Adkins, Adams, Hartung, Street, Broderick, Minne and Dunbar, see THIS JOURNAL, **56**, 442 (1934).

(9) Parks and Huffman have calculated some standard free energies from the equilibrium data of Adkins and co-workers ("The Free Energies of Some Organic Compounds," The Chemical Catalog Co., New York, N. Y., 1932, pp. 169–170). These authors estimate the uncertainty in these free energies to be of the order of 100 calories. Since this corresponds to values of the ratio of the activity coefficients in the range 0.8 to 1.2, this author believes that their estimate of the uncertainty is too low.

change hydrocarbon to water on the spectrum[3] of 1-hydroxy-2-naphthaldehyde, while its isomers show a real, albeit small, effect which is not due to acetal formation. The second is the fact that this compound steam distils with ease, its isomers with considerable difficulty.

Further, if we assume the energies of the acetals which are substituted β-naphthols to be the same, we find that the values for ΔH indicate that the ground state of 3-hydroxy-2-naphthaldehyde is some 2,000 calories above that of 2-hydroxy-1-naphthaldehyde. This is the order deduced in the previous paper,[3] but the numerical difference is less than half that expected. It seems probable that this is due to differences in solvent interaction which were much less important in the measurements made in hydrocarbon solvents.

Summary

The differences observed in the spectra of certain aldehydes in neutral methanol as compared to solutions in acidified methanol have been shown to be due to the reversible formation of the corresponding acetal in the acid solutions. The equilibrium constants for these reactions have been determined at 25 and 2°, and from these data comparative values for ΔH and ΔS have been calculated. Comparison of these data suggests the importance of solvation in interpreting the differences observed. The spectroscopic method offers a tool for the study of this reaction which is capable of separating to some extent energy factors from orientation factors.

Ferrous Mono-α,α′-dipyridyl

BY P. KRUMHOLZ

It has been assumed until recently, that only one type of complexes between ferrous ion and α-α′-dipyridyl (D) or *o*-phenanthroline (Ph) exists in solution and that the 6-coördinated ions FeD_3^{++} and $FePh_3^{++}$ are present.[1]

The formation of lower Fe^{++}–D complexes as intermediates in the formation of FeD_3^{++} has been recently assumed and confirmed by the observation that the formation of FeD_3^{++} is less complete with an excess of Fe^{++} than with equivalent concentrations.[2]

Analogous yellow-colored complexes exist in the system Fe^{++}–Ph, and it seems that both complexes $FePh_2^{++}$ and $FePh^{++}$ may be formed under favorable conditions.[3]

We found strong evidence for the existence of the complex ion FeD^{++} studying the kinetics of formation of FeD_3^{++},[4] by the observation, that the reaction velocity, initially proportional to the Fe^{++} concentration, is retarded by a large excess of Fe^{++}. The kinetics could be correctly interpreted, assuming the very rapid formation of FeD^{++} with an equilibrium constant $K_{FeD} = 2.7 \times 10^4$ at 25° and $\mu = 0.33$.

In the present paper we confirm this indirect finding by an entirely different and direct method. We found that acid solutions of α,α′-dipyridyl, containing only a small amount of free D, form with a large excess of Fe^{++} yellow solutions which turn reddish more or less rapidly, due to the formation of FeD_3^{++}. Under suitable conditions such solutions are stable enough to determinate their extinction in dependence on the concentrations of the reactants, and thus the composition and equilibrium constant of the yellow compound. Solutions containing a very large excess of Fe^{++} are stable enough to measure the absorption spectrum of the yellow compound. As the calculation of the equilibrium constants involves the acid constant of the α,α′-dipyridylium ion (HD^+), this constant has been determined.

Experimental

Material Used.—α,α′-Dipyridyl was purified by vacuum distillation and recrystallized from diluted alcohol and hexane; m. p. 70°. Ferrous chloride solutions were prepared by dilution of a filtered 0.5 *M* solution, kept over iron powder with 0.005 *N* hydrochloric acid.

Determination of the Acid Constant of α,α′-Dipyridylium Ion.—The acid constant of HD^+ was computed from *p*H values of solutions of D and its hydrochloride, the ionic strength being adjusted with potassium chloride. The *p*H values were determined with a glass electrode, calibrated with standard biphthalate and acetate buffers at the same temperature as the sample. Temperatures were kept constant to within ±0.3°. The potential readings could be reproduced within ±0.5 m. v. Even accounting for possible errors due to diffusion potentials between the saturated potassium chloride bridge and the measured solution and for the uncertainty in the *p*H values of the buffer, the error of the absolute values of the constants should be less than 10%.

Determination of the Extinction of Fe^{++}–D Solutions.—To obtain reproducible extinction values of solutions of the yellow complex, it is necessary to establish very rapidly a high concentration of Fe^{++}, because at low Fe^{++} concentrations there appears almost immediately the red color of FeD_3^{++}. The mixing set up consisted of a 250-ml. beaker provided with two propeller stirrers rotating with the maximum speed, not yet introducing air bubbles into the liquid. About 125 ml. of the HD^+ solution, containing various amounts of hydrochloric acid and potassium

(4) P. Krumholz, *Nature*, **163**, 724 (1949). The formulation FeD^{++} does not exclude that other groups, as water or Cl^- are coördinated to Fe^{++}.

chloride, were placed in the beaker and the Fe^{++} solution introduced by means of a 25-ml. pipet with a large opening. The time of complete mixing is less than one second. A parallel light-beam was directed across the beaker, between the shafts of the stirrers, the light intensity being measured by a photronic cell and a spotlight galvanometer of 5×10^{-9} amp./mm. sensitivity, calibrated, within 0.1%. The light-beam was filtered with an interference filter in combination with a blue glass, with a transmission maximum of 438 mμ, very closely to the absorption maximum of the yellow complex. As the isolated spectral band is very narrow and the absorption curve flat, it may be taken for granted that the measured extinctions are proportional to the concentration of the yellow complex.

As ferrous chloride solutions in the concentrations used show a marked absorption, slightly dependent on the amount of free acid present, the extinction values were referred to the extinction of a blank solution containing all components except α,α'-dipyridyl.

The final galvanometer reading could be made within about two seconds after the introduction of the Fe^{++} solution. If the reading did not persist at least for a few seconds, the absorptions were read at different times and the zero time value determined by extrapolation.

The photometric accuracy was about 1% at extinctions > 0.1, decreasing to about 3% at $E = 0.03$.

Due to the large volume of the solution and the short time of measurement, the temperature could be kept constant within $\pm 0.5°$ without thermostatic device.

Determination of Absorption Spectra.—Solutions containing a very large excess of Fe^{++} were prepared in the mixing device already described, rapidly transferred in a 50-mm. Korex cell, and the extinctions determinated in intervals of 5 mμ using a Beckman spectrophotometer. The extinctions were referred as above to a α,α'-dipyridyl free blank. Readings remained constant within 2% during about two minutes.

Results

Acid Constant of α,α'-Dipyridylium Ion.—Tables I and II show pH values of 1:1 mixtures of α,α'-dipyridyl and α,α'-dipyridylium hydrochloride in 4×10^{-3} M solution at different ionic strengths and temperatures, as the corresponding values of the concentration dissociation constant K_c.

TABLE I

μ	pH	γ_{H^+}	K_c[a] $\times 10^{-5}$
4.7×10^{-3}	4.38	0.92	4.6
2.4×10^{-2}	4.41	.86	4.6
4.2×10^{-2}	4.43	.84	4.5
7.8×10^{-2}	4.45	.82	4.4
1.1×10^{-1}	4.47	.81	4.3
1.8×10^{-1}	4.50	.80	4.0
3.3×10^{-1}	4.53	.81	3.7
5.5×10^{-1}	4.59	.87	3.0

[a] $T = 25°$.

TABLE II

T, °C.[a]	pH	K_c $\times 10^{-5}$
15	4.61	3.1
20	4.57	3.4
25	4.53	3.7
30	4.49	4.1
35	4.45	4.5
40	4.40	5.0
45	4.36	5.5
50	4.32	6.1

[a] $\mu = 0.33$.

K_c was calculated by means of

$$K_c = \frac{(H^+)(D)}{(HD^+)} = \frac{(H^+)\{(D)_0 + (H^+)\}}{(HD^+)_0 - (H^+)} = K_a \frac{\gamma_{HD^+}}{\gamma_{H^+}\gamma_D} \quad (1)$$

where γ represents the activity coefficient and $(HO)_0$ the initial analytical concentrations. (H^+) was calculated from the pH values, using the values of γ_{H^+} indicated in Table I computed by the method of individual activity coefficients from the known mean activities of potassium chloride and hydrochloric acid. At low ionic strengths K_c approaches, as shown in Table I, the steady value of the thermodynamic constant K_a, which may be taken as $K_a = 4.6 \times 10^{-5}$ at 25°.[5]

From the temperature dependence of K_c, the mean heat of formation of the α,α'-dipyridylium ion may be calculated as 3.5 ± 0.5 kcal.[6]

Elucidation of the Nature of the Yellow Complex.—To establish the composition and the dissociation constant of the yellow complex, we determined the extinctions of solutions containing various amounts of Fe^{++}, HD^+ and H^+ (at 25° and $\mu = 0.33$). As the extinction coefficient of the yellow compound was unknown, we calculated first of all the concentration of the yellow complex, *supposed to be* FeD^{++}, using the previously reported "kinetic" value of the stability constant

$$K_{FeD} = \frac{(FeD^{++})}{(Fe^{++})(D)} = 2.7 \times 10^4 \quad (2)$$

To calculate (FeD^{++}) from (2), (D) has to be expressed as function of $(HD)_0$ and $(H^+)_0$, $(HD)_0$ representing the total initial concentration of α,α'-dipyridyl. In Fe^{++} free solutions this relation is given by

$$(D) = K_c \frac{(HD^+)}{(H^+)} = K_c \frac{(HD)_0 - (D)}{(H^+)_0 + (D)} \sim K_c \frac{(HD)_0}{(H^+)_0 + K_c} \quad (3)$$

Because in our experiments always $(H^+)_0 \gg (D)$, we used the last approximation throughout. Due to the formation of FeD^{++}, (HD) and (Fe^{++}) decrease by the amount of (FeD^{++}) formed, (H^+) increasing by the same amount. (FeD^{++}) may then be calculated from

$$(FeD^{++}) = K_c \times K_{FeD} \times \{(Fe^{++})_0 - (FeD^{++})\} \frac{(HD)_0 - (FeD^{++})}{(H^+)_0 + (FeD^{++}) + K_c} \quad (4)$$

The mean value of the relation of the thus calculated concentrations to the measured extinctions was used as proportionality factor (f) in the calculation of the experimental values of (FeD^{++}).

As shown in Table III, theoretical and experimental values of (FeD^{++}), calculated from E with $f = 4.95 \times 10^{-4}$, are in excellent numerical agreement. As easily may be shown, this agreement does not hold with values of K_{FeD}, differing more than 5% from the "kinetic" value, confirming thus the numerical value of this constant previously obtained by an entirely different method.

It is, of course, impossible to correlate theoretical and experimental values on the assumption that the yellow complex is FeD_2^{++}, using any value of K_{FeD_2}. Our experiments, however, do not disprove the possible existence of this complex, which hardly could be detected, if $K_{FeD_2} \leqslant K_{FeD}$ (and $\epsilon_{FeD_2} \sim \epsilon_{FeD}$).

(5) Baxendale and George, ref. 2, found $K_a = 4.2 \times 10^{-5}$ at 17° and $\mu = 0.025$ in close agreement with our corresponding value (4×10^{-5}). A. Albert, R. Goldacker and J. Philips, *J. Chem. Soc.*, 2247 (1948), indicate the rather high value of about 6×10^{-5} at 25°.

(6) Baxendale and George, ref. 2, found the lower value of about 2 kcal.

TABLE III

$(Fe^{++})_0 \times 10^3$	$(HD)_0 \times 10^5$	$(H^+)_0 \times 10^3$	$E \times 10^3$	$(FeD^{++}) \times 10^6$ Found	Calcd.

Table IV shows the dependence of K_{FeD}, calculated by means of (4) from $(FeD^{++})_{expt.}$, on the ionic strength.

TABLE IV

$(Fe^{++})_0 = 3.75 \times 10^{-3}$, $(HD)_0 = 1.33 \times 10^{-4}$, $(H^+)_0 = 1.46 \times 10^{-2}$, $T = 25°$

μ	$E \times 10^3$	$(FeD^{++})_{expt.} \times 10^6$	$K_{FeD} \times 10^{-4}$
0.03	56.5	28	2.3
.10	56	27.7	2.4
.20	55	27.2	2.6
.33	54	26.7	2.7

K_{FeD} decreases slowly with the decrease in μ, approaching the value of the thermodynamic constant, which may be taken to $2.3 \pm 0.3 \times 10^4$ at 25°, accounting for the possible error introduced with K_c.

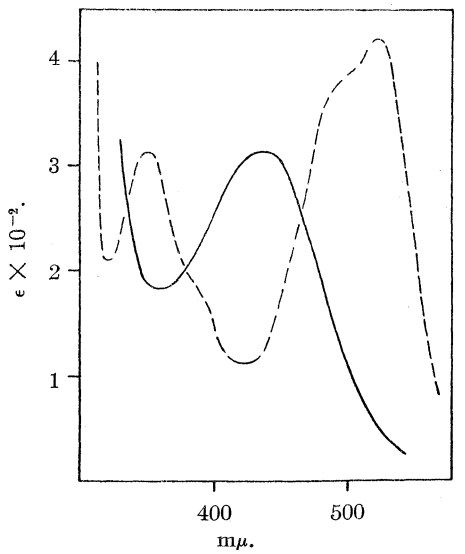

Fig. 1.———FeD^{++}, - - - FeD_3^{++}. Values of ϵ for FeD_3^{++} to be multiplied by 20.

We tried furthermore to determine the dependence of K_{FeD} on the temperature. As shown in Table V the values of K_{FeD} at 45° vary considerably with the composition of the solution, if (FeD^{++}) is calculated from E with the mean proportionality factor f, obtained at 25°.

TABLE V[a]

$(Fe^{++})_0 \times 10^3$	$(HD)_0 \times 10^4$	$(H^+)_0 \times 10^3$	$E_{25°} \times 10^3$	$E_{45°} \times 10^3$	$K_{25°}$	$K_{45°} \times 10^{-4}$	$\bar{K}_{45°}$
74	1.33	8.0	242	220	2.65	0.9	1.45
30	1.33	3.8	236	215	2.6	0.95	1.45
30	1.33	7.15	216.5	190.5	2.75	1.1	1.4
30	1.33	13.8	183	157	2.7	1.2	1.4
30	1.33	34	126.5	102	2.75	1.25	1.4
30	1.33	67	83	65	2.7	1.3	1.4
3.75	1.33	14.6	54.5	42.5	2.7	1.35	1.45

[a] $\mu = 0.33$.

Using however the proportionality factor $f_1 = 5.3 \times 10^{-4}$, that is assuming that the extinction coefficient decreases by about 7% from 25 to 45°, the values of $\bar{K}_{45°}$ agree perfectly.

If this assumption is valid, the heat of formation of FeD^{++} may be calculated to approximately 6 kcal.

We measured finally the absorption spectrum of FeD^{++} in the visible and near ultraviolet, shown in Fig. 1, in comparison with the spectrum of FeD_3^{++}. The extinctions were determined in a solution of the composition: $(Fe^{++})_0 = 7 \times 10^{-2}$, $(HD)_0 = 1.33 \times 10^{-4}$, $(H^+)_0 = 1.4 \times 10^{-2}$ at 25°, corresponding to a concentration of FeD^{++} of 1.1×10^{-4}. The extinction coefficient at the absorption maximum $\lambda = 435$ mμ is 3.1×10^2, and thus about 25 times less than the extinction coefficient of FeD_3^{++} at $\lambda = 523$ mμ ($\epsilon = 8.5 \times 10^3$).

Summary

The acid constant of α,α'-dipyridylium ion has been determinated at various ionic strengths and temperatures. The value of the thermodynamic constant at 25° was found to be 4.6×10^{-5}. The heat of formation was calculated to about 3.5 kcal.

The previously assumed existence of a ferrous mono α,α'-dipyridyl complex has been confirmed and its thermodynamic equilibrium constant determinated as 2.3×10^4 at 25°. An approximative value of 6 kcal. for the heat of formation of this complex has been calculated.

The absorption spectrum of the ferrous mono-α,α'-dipyridyl complex has been measured in the visible and near ultraviolet.

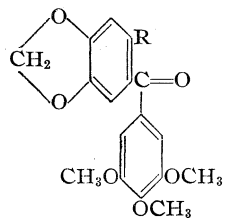
Synthesis of Some Compounds Related to Podophyllotoxin[1]

BY WILKINS REEVE AND JOHN D. STERLING, JR.[2]

The synthesis of a number of compounds related to podophyllotoxin has been studied. Podophyllotoxin[3] has previously been shown to have tumor-damaging activity.[4,5]

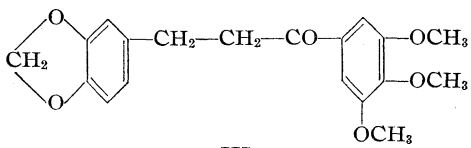


I, R = CH_3
II, R = COOH

3′,4′,5′-Trimethoxy-2-methyl-4,5-methylenedioxybenzophenone (I) was prepared by the reaction of trimethylgalloyl chloride with 3,4-methylenedioxytoluene in carbon disulfide solution using stannic chloride catalyst. Attempts to use aluminum chloride as the catalyst for this type of reaction have proven unsatisfactory presumably because of cleavage of the methoxy and methylenedioxy groups.[6] Attempts to convert I to the corresponding acid II by oxidation were not successful. The stannic chloride-catalyzed condensation of trimethylgalloyl chloride with a number of 4-substituted-methylenedioxybenzenes was tried to determine the limitations of this reaction. It was found that safrole, 3,4-methylenedioxybenzyl acetate, ethyl piperonylate, piperonal diethyl acetal, and piperonal would not react.

The 3,4-methylenedioxytoluene for the above reaction was prepared by the hydrogenation over copper–chromium–barium oxide catalyst at 160° of piperonal in dioxane solution to piperonyl alcohol, and the hydrogenolysis of this in dioxane solution over the same catalyst at 280° and 210 atmospheres starting pressure. This method has not previously been used to prepare 3,4-methylenedioxytoluene. It is of interest that the hydrogenolysis occurs under much more difficult conditions than does the hydrogenolysis of benzyl alcohol. The latter undergoes hydrogenolysis readily at 150–200° and 250 atmospheres starting pressure over this catalyst.[7]

Attempts to prepare I by condensing trimethylgallic acid with 3,4-methylenedioxytoluene in the presence of phosphorus pentoxide by Kosolapoff's procedure[8] yielded a tan colored solid, m. p. 112–120°, believed to be a mixture of compounds containing no isolatable amounts of I.



III

3,4,5 - Trimethoxy - α - piperonylacetophenone (III) was prepared by the reaction of piperonyl bromide with ethyl 3,4,5-trimethoxybenzoylacetate in alcohol solution using sodium ethoxide catalyst followed by hydrolysis and decarboxylation with barium hydroxide solution. This compound had been previously reported by Bargellini and Monti,[9] but the reported melting point was not in agreement with ours. They reported the preparation of the compound by the reduction of piperonylidene-3,4,5-trimethoxyacetophenone, but the reported melting point of this intermediate did not agree with that of other workers.[10] In view of the doubt concerning the starting compound, the uncontrolled nature of the hydrogenation reaction, and the lack of evidence that the ketone was properly characterized, it seems certain that they did not obtain ketone III.

Experimental

All melting points are "corrected."

Piperonyl Alcohol.—Ninety grams of freshly distilled piperonal in 70 ml. of dioxane (purified by refluxing over odium) was hydrogenated under 4500 lb. pressure (300 atm.) of hydrogen at 160–175° over 5 g. of copper chromite catalyst.[11] The reduction was nearly complete at 160° in fifteen minutes but was continued at 175° for another hour. Distillation gave 90 g. of piperonyl alcohol (98% yield), m. p. 51°, b. p. 125–128° at 6 mm. pressure. Reported[12]: m. p. 51°, b. p. 161° at 20 mm. pressure.

3,4-Methylenedioxytoluene.—Seventy-six grams of piperonyl alcohol in 60 ml. of purified dioxane was hydrogenated under 5500 lb. pressure (375 atm.) hydrogen at 280° over 4 g. of copper chromite catalyst.[11] The theoretical amount of hydrogen was absorbed in approximately two hours. The reaction mixture, after filtering and drying over calcium chloride, gave 58 g. of 3,4-methylenedioxytoluene (84.5% yield), b. p. 78–81° at 12–14 mm. pressure; reported[13] b. p. 81–83° at 11 mm.

Trimethylgalloyl Chloride.—This was prepared in 84% yield by stirring 191 g. of trimethylgallic acid with 175 ml. of thionyl chloride and 400 ml. of benzene at 60° for five

hours,[14] b. p. 130° at 2 mm.; m. p. after crystallization from cyclohexane, 77–78°; reported[14] b. p. 168–170° at 14 mm., m. p. 77–78°.

3′,4′,5′-Trimethoxy-2-methyl-4,5-methylenedioxybenzophenone (I).—In a 250-ml. three-necked flask were placed 10 ml. (0.084 mole) of 3,4-methylenedioxytoluene, 50 ml. of anhydrous carbon disulfide and 4.5 ml. (0.037 mole) of anhydrous stannic chloride. To this was added slowly with cooling and stirring 10 g. (0.043 mole) of freshly distilled trimethylgalloyl chloride dissolved in 50 ml. of carbon disulfide. The reaction mixture was stirred at ice-bath temperature for six hours; during this time, the product separated as a red complex. The reaction mixture was decomposed with ice-cold 7% hydrochloric acid, extracted with ether, and the ether extract washed with dilute hydrochloric acid, water, dilute sodium hydroxide and with water. The ether solution was dried with calcium chloride, the ether distilled off, and the residue refluxed with a solution of potassium hydroxide in methyl alcohol for twenty minutes. The resulting mixture was diluted with water and extracted with ether. The ether solution was washed with water, dried with calcium chloride, and the ether removed by distillation. The residue was crystallized from methyl alcohol or cyclohexane giving 6.2 g. (43% yield) of product, m. p. 108–110°. The product gave a positive test for the methylenedioxy bridge when warmed with sulfuric acid and a trace of gallic acid.[15]

Anal. Calcd. for $C_{18}H_{18}O_6$: C, 65.45; H, 5.45; OCH_3, 28.15. Found: C, 65.60; H, 5.61; OCH_3, 27.94.

3,4,5-Trimethoxy-α-piperonylacetophenone (III).—In a 100-ml. flask fitted with a condenser and drying tube were placed 50 ml. of absolute alcohol and 0.46 g. (0.02 mole) of sodium. The sodium ethoxide solution thus prepared was cooled in an ice-bath and 5.6 g. (0.02 mole) of ethyl 3,4,5-trimethoxybenzoylacetate[16] was added. Four and one-half grams (0.029 mole) of piperonyl bromide,[17] dissolved in 10 ml. of absolute ether was then added to the cold alcohol solution. Sodium bromide began to precipitate. After ten minutes, the ice-bath was removed, and the reaction allowed to proceed for half an hour while warming up to room temperature. The reaction mixture was then acid. It was diluted with water and extracted with ether. The ether solution was dried, the ether distilled off, and a viscous residual oil obtained. This was hydrolyzed by dissolving in 400 ml. of methanol and adding a solution of 45 g. of barium hydroxide octahydrate in 800 ml. of water at room temperature. A white solid soon formed; after twelve hours, it was removed by filtration. The organic material was separated from inorganic salts by dissolving in chloroform, the chloroform solution dried with anhydrous magnesium sulfate, and the chloroform removed by distillation. There remained 3.8 g. (55% yield for the two steps) of a white crystalline mass which after recrystallization from methanol gave 3.4 g. of product, m. p. 146–147°; reported[9] 96–98°.

Anal. Calcd. for $C_{19}H_{20}O_6$: C, 66.27; H, 5.83; OCH_3, 27.03. Found: C, 66.14; H, 5.95; OCH_3, 26.87.

Dinitrophenylhydrazone of III.—Accurately weighed samples of III dissolved in alcohol reacted with excess dinitrophenylhydrazine in 2 *N* hydrochloric acid to give the 2,4-dinitrophenylhydrazone according to the quantitative procedure of Iddles, *et al.*[18] Quantitative yields were obtained. After two recrystallizations from benzene, approximately half the material remained, m. p. 188.5–189°.

Anal. Calcd. for $C_{25}H_{24}O_9N_4$: C, 57.25; H, 4.61; N, 10.68. Found: C, 57.47; H, 4.62; N, 10.84.

Acknowledgment.—The authors wish to express their appreciation to the National Institute of Health for the financial assistance which made this work possible, and to Mrs. Mary H. Aldridge and Mr. Byron Baer for carrying out the microanalyses.

Summary

1. 3′,4′,5′-Trimethoxy-2-methyl-4,5-methylenedioxybenzophenone (I) has been prepared by the stannic chloride catalyzed condensation of 3,4-methylenedioxytoluene with trimethylgalloyl chloride.

2. 3,4,5-Trimethoxy-α-piperonylacetophenone (III) has been prepared by an acetoacetic ester type of synthesis.

3. 3,4-Methylenedioxytoluene has been prepared by the hydrogenolysis of piperonyl alcohol. The latter is more resistant to hydrogenolysis over a copper–chromium–barium oxide catalyst than is benzyl alcohol.

Spirobarbituric Acids Containing a Six-membered Carbocyclic Ring

BY ARTHUR C. COPE, PETER KOVACIC[1] AND MARION BURG[1]

Several spirobarbituric acids have been described by Dox and Yoder[2] in which the 5-carbon atom of the barbituric acid nucleus forms part of an unsubstituted cyclobutane or cyclohexane ring, but no pharmacological data were reported for these compounds. The spirobarbituric acids present points of structural similarity and dissimilarity to the 5,5-dialkylbarbituric acids which have led us to prepare a number of such compounds for pharmacological evaluation. In both classes the two acidic hydrogen atoms in the 5-position of the barbituric acid nucleus have been replaced by establishment of carbon-to-carbon linkages, but the spiro compounds differ uniquely from the 5,5-dialkylbarbituric acids in the spatial arrangement of the two rings in perpendicular planes. Since the pharmacological characteristics of 5,5-dialkylbarbituric acids vary widely according to the size and structure of the alkyl substituents, properties of the spiro compounds could not be predicted.

The intermediate esters required for the synthesis of spirobarbituric acids were prepared by the addition of butadiene to diethyl methylene-

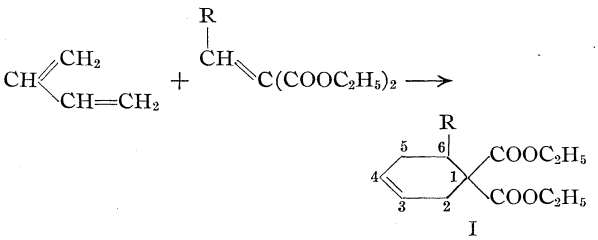
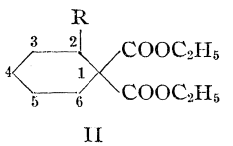
[a] The preparation by a different method is described by Dox and Yoder, THIS JOURNAL, **43**, 1366 (1921). [b] Described in ref. 4 and by Freer and Perkin, *J. Chem. Soc.*, **53**, 206 (1888).

malonate[3] or higher molecular weight diethyl alkylidenemalonates[4] to give esters of type I. Similar adducts were prepared by reaction of 2,3-dimethyl-1,3-butadiene and cyclopentadiene with diethyl ethylidenemalonate.

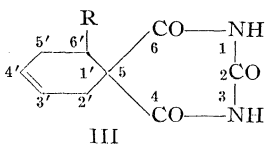


I

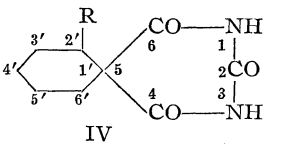
Catalytic hydrogenation of the unsaturated esters yielded corresponding saturated esters (II). Condensation of both classes of esters with urea and thiourea furnished spirobarbituric and thiobarbituric acids (III, IV, V and VI).[5]



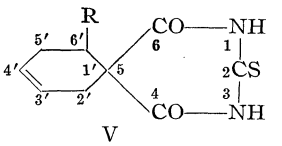
II



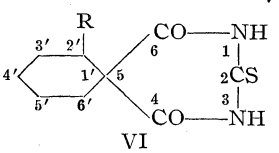
III



IV



V



VI

Unsaturated esters (I) prepared by the diene synthesis are listed in Table I. The butadiene additions proceeded fairly well at 170–180° except in the case of diethyl isobutylidenemalonate, which gave a low yield of adduct. Diethyl isopropylidenemalonate and ethyl isopropylidenecyanoacetate failed to react with butadiene under the conditions investigated. Butadiene reacted with diethyl (2-methylmercaptoethylidene)-malonate to give an adduct (I, R = CH_3SCH_2–), but failed to add to diethyl (3-methylmercaptopropylidene)-malonate, which polymerized when the addition was attempted at 220°. The adduct formed from cyclopentadiene and diethyl ethylidenemalonate decomposed on distillation, except at low pressures, presumably by disproportionation into the original diene and ester. In one case (I, R = *n*-C_3H_7) the unsaturated ester was prepared by heating together the aldehyde (butyraldehyde), diethyl malonate, acetic anhydride and butadiene. The product was isolated in a yield equiva-

[a] Prepared by Procedure D. [b] Tested by intraperitoneal injection in Carworth Farms strain F′ female mice weighing 16–18 g. Solutions were freshly prepared from the sodium salts for each test. Calculations are based on the equivalent weights of the free acids. Five mice were used at each dose level. The test for narcosis was performed by placing the mice on their left sides on a flat surface and striking their tails with a forefinger, then placing them on their right sides and repeating the process. A mouse which failed to right itself under these conditions was considered to be narcotized. ND^{50} is the dose at which 50% of the mice were narcotized; ND^{100} is the dose at which all were narcotized. LD^{50} signifies the dose at which 50% of the mice were killed.

lent to that obtained if the condensation and diene addition reactions were carried out separately.

The catalytic hydrogenations of the unsaturated esters (I) to saturated esters II (Table II) proceeded rapidly and in good yield in the presence of Adams platinum catalyst.

The spirobarbituric acids (III and IV, Tables III and IV) were prepared by condensing the corresponding esters with urea in the presence of sodium isopropoxide in isopropyl alcohol. Isolation of the spirothiobarbituric acids (Tables V and VI) required a modification of the usual procedure because of the ease with which they were hydrolyzed to dicarboxylic acids. For example, acidification of a cold alkaline solution of 6′-methyl-2-thiospiro-[barbituric acid-5,1′-3′-cyclohexene] by

[a] Procedure C gave a crude product, m. p. 150–156.5° (dec.), which contained the corresponding dicarboxylic acid.

the addition of hydrochloric acid gave a mixture of the thiobarbituric acid derivative (V, R = CH_3) and 6-methyl-3-cyclohexene-1,1-dicarboxylic acid. This hydrolysis could be minimized by isolating the crude, dry sodium salt of the thiobarbituric acid derivative and adding it to an excess of cold hydrochloric acid (procedure D). The sodium salts of the spirothiobarbituric acids proved to be sufficiently stable in aqueous solution for pharmacological testing.

Pharmacological

Preliminary pharmacological data which were obtained for the spirobarbituric acid derivatives by Dr. Karl H. Beyer and Mr. S. E. McKinney of Sharp and Dohme, Inc., are included in Tables III–VI. Among the spirobarbituric acid (Tables III and IV) both narcotic activity and toxicity increased with increasing molecular weight, and the compounds with the highest therapeutic ratios were the 6′-isopropyl and *n*-propyl derivatives (formula III) and the 2′-isopropyl and *n*-propyl derivatives (formula IV). Both unsaturated and saturated spirothiobarbituric acids (formulas V and VI) were less active, longer acting and had poorer therapeutic ratios than the corresponding spirobarbituric acids.

Experimental[6]

Diethyl methylenemalonate was prepared from paraformaldehyde and diethyl malonate by the method of Bachmann and Tanner.[3] The crude reaction mixture was distilled through a 20-cm. Widmer column until the distillation temperature reached 116° (43 mm.). Some decomposition occurred at 105–116° (43 mm.). The pale green viscous residue was distilled through a 20 × 1.3 cm. Vigreux column with a heated jacket and the diethyl methylenemalonate fraction which collected at 124–128° (35 mm.) was treated with butadiene at once to prepare diethyl 3-cyclohexene-1,2-dicarboxylate.[3] Other diethyl alkylidenemalonates were prepared by procedures described previously.[7]

Diethyl 6-Alkyl-3-cyclohexene-1,1-dicarboxylates (I). Procedure A.—Conditions similar to those used by Alder and Rickert[4] were employed, which can be illustrated by description of the procedure followed for preparing diethyl 6-*n*-propyl-3-cyclohexene-1,1-dicarboxylate. Diethyl *n*-butylidenemalonate (112.7 g., 0.53 mole) was placed in a 500-ml. steel hydrogenation bomb which had been cooled with Dry Ice. After the ester was cooled to −15°, 115 g. (2.1 moles) of butadiene (previously collected in a Dry-Ice-cooled tube from a commercial cylinder) was added. The mixture was stirred, the bomb closed, and allowed to stand until it reached room temperature, It was then heated for twelve to fourteen hours at 170–180° without shaking. The product was distilled through a 20-cm. Widmer column. About 80 g. of vinylcyclohexene was collected at 20–60 mm., followed by 50 g. of recovered diethyl *n*-butylidenemalonate, b. p. 99–109° (3 mm.). The crude adduct (70 g., b. p. 109–125° at 2.8 mm.) was redistilled through the same column and yielded 52 g. (39%) of diethyl 6-*n*-propyl-3-cyclohexene-1,1-dicarboxylate, b. p. 114–116° (1.3 mm.). The properties of other esters prepared by this procedure are listed in Table I.

Procedure B.—Diethyl malonate (80.1 g., 0.5 mole), freshly distilled butyraldehyde (36.1 g., 0.5 mole), acetic anhydride (51.1 g., 0.5 mole) and butadiene (108 g., 2.0 moles) were mixed in a Dry-Ice-cooled 500-ml. steel hydrogenation bomb. The mixture was heated at 182–195° for twelve and one-half hours without shaking, and the product was isolated by the method described under Procedure A. The yield of diethyl 6-*n*-propyl-3-cyclohexene-1,1-dicarboxylate, b. p. 99–101.8° (0.8 mm.), (32 g., 20.3%) was equivalent to the yield obtained by carrying out the condensation and addition reactions as separate preparations.

Diethyl (2-Methylmercaptoethylidene)-malonate. (a) Methylmercaptoacetaldehyde Diethyl Acetal.—Diethyl bromoacetal[8] was treated with sodium methylmercaptide by an adaptation of the procedure of Barger and Coyne[9] suitable for a larger scale preparation. Absolute ethanol (1.3 l.) was placed in a 3-l. three-necked flask fitted with a reflux condenser and a motor-driven slip-sealed stirrer. Sodium ethoxide was prepared by the addition of 79 g. (3.44 g. atoms) of clean sodium. The solution was cooled in an ice-bath and the reflux condenser was replaced by a spiral condenser cooled with ice-water. A T-tube was attached to the top of condenser which led to a safety trap which was connected to a water aspirator. A screw clamp attached to the open end of the T-tube was used to regulate the aspiration. Methyl mercaptan (100 g., 2.08 moles) was introduced gradually through a gas inlet tube by aspiration during one hour, in an assembly of apparatus similar to that used for introducing bromine in the preparation of bromoacetal,[8] except that the methyl mercaptan was placed in a 200-ml. round-bottom flask (fitted with inlet and outlet tubes) which initially was cooled and subsequently was warmed to control the rate of addition. The inlet tube was replaced by a 500-ml. dropping funnel and 296 g. (1.5 moles) of freshly distilled diethyl bromoacetal was added during twenty-five minutes with stirring. Sodium bromide separated during the addition. The reaction mixture was allowed to stand overnight, filtered,

(6) Melting points are corrected and boiling points are uncorrected. We are indebted to Mr. S. M. Nagy, Mrs. Louise W. Spencer and Mr. Philip H. Towle for analyses.

(8) McElvain and Kundiger, "Organic Syntheses," Vol. 23, John Wiley and Sons, Inc., New York, N. Y., 1943, p. 8.

(9) Barger and Coyne, *Biochem. J.*, 22, 1417 (1929).

and the filtrate added to 2 l. of water. The oily layer was removed and the aqueous layer saturated with sodium chloride and extracted with five 100-ml. portions of benzene. The combined oil and extracts were distilled through a 20-cm. Widmer column and yielded 164 g. (67%) of methylmercaptoacetaldehyde diethyl acetal, b. p. 72.5–73.5° (11 mm.).

(b) **Methylmercaptoacetaldehyde.**—Methylmercaptoacetaldehyde diethyl acetal (86.1 g., 0.52 mole) was heated under reflux with 200 ml. of water and 2 ml. of concd. hydrochloric acid for one-half hour. The mixture became homogeneous after five minutes at the reflux temperature. The solution was cooled, extracted with 150 ml. of ether, partially saturated with sodium chloride and again extracted with 150 ml. of ether. The combined extracts were washed with two 100-ml. portions of 10% sodium bicarbonate solution, three times with 250-ml. portions of water, dried over magnesium sulfate and distilled through a 20-cm. Widmer column. The yield of methylmercaptoacetaldehyde, b. p. 93–95° (235 mm.), was 25 g. (53%).

(c) **Diethyl (2-Methylmercaptoethylidene)-malonate.**—Diethyl malonate (62.5 g., 0.39 mole), methylmercaptoacetaldehyde (70 g., 0.78 mole) and acetic anhydride (62.5 g., 0.61 mole) were heated under reflux in an oil-bath at 130° for twenty-four hours. The mixture was fractionated through a 20-cm. Widmer column at atmospheric pressure until the distillation temperature reached 113°. Continuation of the fractionation under reduced pressure yielded a crude product (42 g., b. p. 121–135° at 3 mm.) which was fractionated through a 220 × 8 mm. glass helix-packed, total condensation, variable take-off type column. The yield of diethyl (2-methylmercaptoethylidene)-malonate was 33.5 g. (37%) b. p. 123.5–125.5° (1.5 mm.), $n^{25}D$ 1.4882, d^{25}_4 1.1057; M_D calcd. 59.19, found 60.55 (exaltation 1.36).

Anal. Calcd. for $C_{10}H_{16}O_4S$: C, 51.70; H, 6.94. Found: C, 51.59; H, 6.92.

Diethyl (3-Methylmercaptopropylidene)-malonate.—Diethyl malonate (40 g., 0.25 mole), β-methylmercaptopropionaldehyde[10] (57 g., 0.55 mole) and acetic anhydride (40 g., 0.39 mole) were allowed to react under the conditions described above. Redistillation of the crude product through a 220 × 8 mm. glass helix-packed, total condensation, variable take-off type column yielded 43.8 g. (70.6%) of diethyl (3-methylmercaptopropylidene)-malonate, b. p. 143–145° (2.5 mm.), $n^{25}D$ 1.4885; d^{25}_4 1.0877; M_D calcd. 63.81, found 65.31 (exaltation 1.50).

Anal. Calcd. for $C_{11}H_{18}O_4S$: C, 53.64; H, 7.53. Found: C, 53.70; H, 7.35.

Diethyl 6-(Methylmercaptomethyl)-3-cyclohexene-1,1-dicarboxylate.—Diethyl (2-methylmercaptoethylidene)-malonate (22.5 g., 0.097 mole) was placed in a 60 × 2 cm. Pyrex bomb-tube and cooled in a chloroform–carbon tetrachloride–Dry Ice-bath. Butadiene (27 g., 0.5 mole) was added and the tube was sealed and heated in a bomb furnace at 160–170° for fourteen hours. Distillation yielded 19.4 g. of a crude product, b. p. 123–134.5° (1 mm.) which was redistilled through the helix-packed column described above. The yield of diethyl 6-(methylmercaptomethyl)-3-cyclohexene-1,1-dicarboxylate was 12.5 g. (44%), b. p. 133–133.5° (less than 1 mm.), $n^{25}D$ 1.4905, d^{25}_4 1.1069; M_D calcd. 75.46, found 74.86.

Anal. Calcd. for $C_{14}H_{22}O_4S$: C, 58.71; H, 7.74. Found: C, 58.58; H, 7.89.

Under these conditions no adduct was obtained from butadiene and diethyl (3-methylmercaptopropylidene)-malonate, and most of the ester was recovered. At 220° partial polymerization occurred and the recovery of the ester was reduced to 50%, but no adduct was isolated.

(10) Supplied by U. S. Industrial Chemicals, Inc., through the courtesy of Harry L. Fisher. Described by Hurd and Gershbein, THIS JOURNAL, **69**, 2334 (1947); Catch, Cook, Graham and Heilbron, *Nature*, **159**, 578 (1947); ref. 9.

Diethyl 2-Alkylcyclohexane-1,1-dicarboxylates (II).—Solutions of the unsaturated esters (I) (approximately 50 g.) in dry ethyl acetate (about 50 ml.) were hydrogenated in the presence of 0.5 g. of prereduced Adams platinum catalyst at room temperature and about 25 p. s. i. during one-half to two hours. The properties and yields of the saturated esters (II) which were obtained are listed in Table II.

Barbituric Acid Condensations.—The barbituric acid derivatives described in Tables III and IV were prepared by a modification of a procedure described previously,[11] which is illustrated by the synthesis of 2′-*n*-propylspiro-[barbituric acid-5,1′-cyclohexane] (IV, R = *n*-C_3H_7) (procedure C).

Diethyl 2-*n*-propylcyclohexane-1,1-dicarboxylate (14.8 g., 0.055 mole) and urea (6.6 g., 0.11 mole) were added to the sodium isopropoxide prepared from 2.3 g. (0.1 g. atom) of sodium and 95 ml. of dry isopropyl alcohol, and the mixture was heated under reflux for fifteen hours in an oil-bath at 105°. The isopropyl alcohol was removed under reduced pressure and the solid residue cooled in an ice-bath and dissolved in 100 ml. of cold water. The solution was extracted with three 30-ml. portions of ether, and the combined extracts were washed with water. The combined water washes and aqueous solution were cooled in ice and acidified by dropwise addition of a 50% excess of 20% hydrochloric acid, with stirring. The solid barbituric acid derivative was separated by filtration, washed with water and recrystallized to constant melting point from dilute alcohol. Distillation of the ether extracts resulted in recovery of 4.6 g. of diethyl 2-*n*-propylcyclohexane-1,1-dicarboxylate, b. p. 108° (0.8 mm.), $n^{25}D$ 1.4478.

Thiobarbituric Acid Derivatives.—The thiobarbituric acid derivatives described in Tables V and VI were prepared by a method (procedure D) which may be illustrated by details of the synthesis of 6′-*n*-propyl-2-thiospiro-[barbituric acid-5,1′-3′-cyclohexene] (V, R = *n*-C_3H_7).

Procedure C (above) was followed with 24.3 g. (0.088 mole) of diethyl 6-*n*-propyl-3-cyclohexene-1,1-dicarboxylate, 10.5 g. (0.14 mole) of thiourea and the sodium isopropoxide prepared from 4.0 g. (0.17 g. atom) of sodium and 200 ml. of dry isopropyl alcohol as the reactants. After the period of reflux, distillation of the isopropyl alcohol under reduced pressure left a crude solid mixture containing the sodium salt of 6′-*n*-propyl-2-thiospiro-[barbituric acid-5,1′-3′-cyclohexene]. This solid was washed with ether, collected on a filter, and added in portions with stirring to 250 ml. of 20% hydrochloric acid cooled in an ice-bath. The solid product was separated by filtration and recrystallized to constant melting point from dilute alcohol. No appreciable amount of a carboxylic acid was isolated when this procedure was followed. A similar preparation (I, R = CH_3–) according to procedure C gave a crude product which was in part soluble in aqueous sodium bicarbonate solution. Acidification of the sodium bicarbonate solution precipitated 6-methyl-3-cyclohexene-1,1-dicarboxylic acid, which after recrystallization from acetone–benzene had m. p. 175–176° (dec.).

Anal. Calcd. for $C_9H_{12}O_4$: C, 58.68; H, 6.56; neut. equiv., 92.09. Found: C, 58.60; H, 6.54; neut. equiv., 92.49.

Summary

The preparation, properties and pharmacological assay of a number of spirobarbituric and thiobarbituric acids derived from diethyl 6-alkyl-3-cyclohexene-1,1-dicarboxylates and diethyl 2-alkylcyclohexane-1,1-dicarboxylates and the preparation and properties of these intermediate esters are described.

Chemical Constitution and the Tanning Effect. III. Polyhydroxybenzophenones[1]

BY ALFRED RUSSELL[2] AND GEORGE B. BUTLER[3]

Previous communications from this laboratory have described the tanning properties of the gallic acid esters of certain sugars.[4,5] From an observation of the type compounds that the natural tannins are believed to be, as well as these synthetic materials, there seems to be in every case a pattern consisting of at least two benzene nuclei joined by some type of bridge, and having a sufficient number of water solubilizing groups to import to the compound a moderate degree of water solubility. This pattern may be only a part of the molecule in some cases, but it always appears to be present. Also of the fission products of all the natural tannins, the polyhydroxybenzenes and the polyhydroxybenzoic acids are the main constituents.

The present investigation describes the preparation of a series of polyhydroxybenzophenones which conform to the above molecular pattern, and evaluation of these materials as tannins. A literature investigation of known compounds of this series revealed the fact that 3′,4′,2,4,6-pentahydroxybenzophenone,[6] commonly known as maclurin, which was isolated from the wood of *Chlorophora tinctoria*, precipitates gelatin from solution, an indication that this polyhydroxy compound might have tanning properties. Therefore, this compound was included in the series which was prepared and tested. In no case, however, did these substances exhibit tanning properties as described in detail below.

Experimental

Preparation of Materials.—The methyl ethers of vanillin, catechol, resorcinol, hydroquinone, pyrogallol and phloroglucinol were prepared by the procedure described in "Organic Syntheses," Coll. Vol. II, p. 619. Veratroyl chloride was prepared by the action of thionyl chloride on veratric acid which was obtained by the oxidation of veratraldehyde. Anisoyl chloride was obtained from anisic acid by the action of thionyl chloride.

Synthesis of the Polyhydroxybenzophenones.—Method I, a Friedel–Crafts reaction between the methoxybenzoyl chloride and the methoxybenzene followed by demethylation, gave better yields in the first step but the demethylation was unsatisfactory when the number of hydroxyl groups exceeded three. Method II, a dehydration reaction between the hydroxybenzoic acid and the hydroxybenzene in the presence of zinc chloride,[7] was used when the acid chloride was not available or when Method I did not give good results.

(7) Blueler and Perkin, *J. Chem. Soc.*, **109**, 541 (1916).

A. Method I.—A solution of one-half mole of the methoxybenzoyl chloride and one-half mole of the methoxybenzene in dry carbon disulfide was added slowly to one mole of anhydrous aluminum chloride and 200 g. of dry carbon disulfide maintained at 15–20° and contained in a one-liter, three-necked flask equipped with stirrer, reflux condenser, dropping funnel and thermometer. The solution was allowed to warm up to room temperature and stirring was continued for three hours. The mixture was then let stand overnight, refluxed for three and one-half hours, cooled, poured onto ice and extracted with ether. The extract was washed with sodium carbonate solution and with water, then dried over calcium chloride. The product, isolated from the ether, was recrystallized from 50% alcohol.

The methoxybenzophenone was converted to the hydroxybenzophenone by heating with an equal weight of anhydrous aluminum chloride in anhydrous toluene for one hour at 120°. The mixture was poured into iced dilute hydrochloric acid and the toluene layer was washed with water. The hydroxybenzophenone was extracted with sodium carbonate solution and precipitated from this solution by the addition of carbon dioxide or dilute hydrochloric acid. The lower members were recrystallized from dilute ethanol, the higher members from very dilute hydrochloric acid. Over-all yields up to 65% were realized.

B. Method II.—Equal parts of the hydroxybenzoic acid and the hydroxybenzene were heated together with three parts of freshly fused and powdered zinc chloride for forty-five minutes at 125–140°. The reaction mass was taken up in dilute hydrochloric acid, filtered, the solid product washed thoroughly with sodium bicarbonate solution and finally crystallized from dilute ethanol or very dilute hydrochloric acid.

Tanning Procedure

The standard gelatin test was used as a preliminary indication of the tanning properties of these compounds. In all cases, the solutions resulting from the first crystallization of the hydroxy ketones caused gelatin precipitation, however these solutions always contained either aluminum or zinc salts, as well as other impurities. After a second crystallization, the resulting saturated solutions of the hydroxy ketones would in no case cause gelatin precipitation. Pure synthetic maclurin behaved as described above. It is probable that the sample of natural maclurin which was reported to have the property of precipitating gelatin contained some tannin material as an impurity, since the original source of maclurin is known to contain tannins also.

The standard procedure previously described[4] for conducting tannage tests could not be used since the polyhydroxybenzophenones were not soluble enough in 4% aqueous sodium chloride. The following modified procedure was therefore employed:

A standard size test piece of calfskin was dehydrated by agitation with several portions of absolute ethanol. It was then covered with three times its weight of absolute ethanol, treated with 25% of its weight of the pure material to be tested, and the whole agitated for twenty-four hours. A comparison was then made between the

[a] Melting points recorded in literature are enclosed in parentheses. [b] Reported to crystallize with one molecule of water of crystallization.[8] The monobenzoate of pyrogallol is also reported to have a melting point of 140°. [c] Reported to crystallize with 1.5 molecules of water of crystallization.[9] [d] Controversial melting points reported.[10] [e] Heilbron[11] lists this compound as having been reported by Korczynski and Nowakowski,[12] m. p. 242°. These authors reported 3',4',2,4,5-pentahydroxybenzophenone prepared by the Hoesch reaction between protocatechunitrile and 1,2,4-trihydroxybenzene, m. p. 242°.

test piece of skin and a similar piece of skin treated with mimosa tannin under the same conditions. While the piece of skin treated with mimosa tannin was converted to leather, in no case did the samples treated with the polyhydroxybenzophenones show any change. After thorough washing with cold water, and drying in air, these samples were converted to an inflexible, horn-like material characteristic of untreated skin. On storing samples of these test pieces in aqueous media, apparently normal putrefaction occurred.

The data concerning the polyhydroxybenzophenones are presented in tabular form.

Summary

Fifteen polyhydroxybenzophenones have been prepared and tested for tanning properties. None were found to have the property of converting hide to leather as judged by color, feel, texture, flexibility and fullness, even though one naturally occurring polyhydroxybenzophenone is reported in the literature to cause precipitation of gelatin, a preliminary test for tanning materials.

Four of these compounds have not previously been reported, while physical properties of four others reported in the literature are either controversial or fail to agree with those obtained in this investigation. Analyses are reported for these compounds.

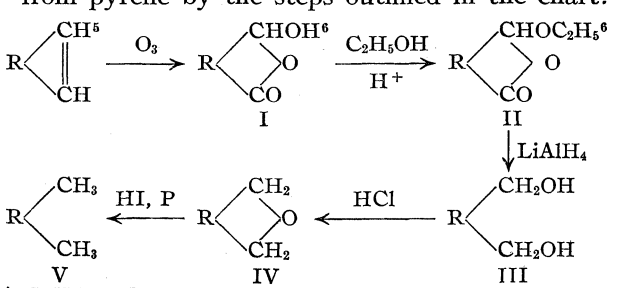
The Preparation of 4,5-Dimethylphenanthrene[1]

BY MELVIN S. NEWMAN AND HARRY S. WHITEHOUSE[2]

Considerable interest is associated with 4,5-dimethylphenanthrene (V) because of (1) its possible identity with the hydrocarbon,[3] $C_{16}H_{14}$, isolated from the dehydrogenation products of strophanthidin, and (2) its position as the parent hydrocarbon of compounds containing methyl groups in the so-called "impossible" positions.[4] In this paper we describe the preparation of V from pyrene by the steps outlined in the chart.



(1) The material herein presented is taken from the Ph.D. thesis of H. S. W., Ohio State University, December, 1948.
(2) Present address, Procter and Gamble Company, Chemical Division, Ivorydale, Ohio.

(4) See discussion in Newman, THIS JOURNAL, **62**, 2295 (1940), and Newman and Hussey, *ibid.*, **69**, 3023 (1947).
(5) R, $C_{14}H_8$, represents the phenanthrene nucleus carrying the substituents indicated in positions 4 and 5.
(6) Our reasons for preferring the cyclic structure for these compounds will be set forth in a forthcoming paper.

The ozonization of pyrene was carried out essentially as described previously.[7] The aldehydo acid[6] (I) thus obtained was converted into the ethyl ester[6,8] which was subsequently reduced with lithium aluminum hydride[9] to the diol (III). This diol was converted quantitatively to the cyclic ether (IV) by a variety of acidic reagents. Reduction of IV with hydriodic acid and red phosphorus under very carefully controlled conditions afforded a hydrocarbon, m. p. 76.3–76.9°, which is assigned the structure of 4,5-dimethylphenanthrene (V) on the following counts: (1) analysis of the hydrocarbon, its picrate, and its 2,4,7-trinitrofluorenone[10] (TNF) derivative; (2) cyclodehydrogenation to pyrene; (3) the ultraviolet absorption spectrum and (4) the non-identity of V with any of the fifteen previously described 9,10-unsubstituted dimethylphenanthrenes (there are only sixteen 9,10-unsubstituted dimethylphenanthrenes).

It is interesting to note that V forms a picrate which dissociates very easily in alcohol. This picrate is also lower melting than that of any of the other above mentioned fifteen dimethylphenanthrenes. This behavior is found in other compounds having the same or a similar structural feature.[11]

The ultraviolet absorption spectrum proved similar to that of 1,4,5-trimethylphenanthrene.[11c] The intensity of the absorption, expressed in log units, at the maxima and minima are as follows[12]: 224, 3.91; 230, 3.98; 235, 3.84; 255, 4.56; 285, 3.73; 301, 3.91; 307, 3.82 and 313, 3.92.

One attempt to oxidize V to a quinone was made. As no crystalline quinone was readily isolated, an alcoholic solution of the oxidation product was treated with *o*-phenylenediamine whereupon a yellow crystalline quinoxaline derivative was obtained.

A consideration of the properties of the known dimethylphenanthrenes not containing a substituent in the 9 or 10 position indicates that 4,5-dimethylphenanthrene (V) herein reported is different from any of the others[13] and from the hydrocarbon, $C_{16}H_{14}$, obtained from strophanthidin by Lewis and Elderfield.[3]

Attempts to reduce the aldehyde group of the aldehydo acid (I) to a methyl group are of interest. On Clemmensen reduction 1,2-dihydropyrene[14] was obtained. This ready formation of a carbon–carbon bond between the carbons in the aldehydo acid (I) recalls the fact that on reaction of I with phenylhydrazine 2-phenylazo-1-pyrenol is formed.[7] Treatment of I with alkali and Raney nickel alloy[15] yielded a small amount of the lactone of 5-hydroxymethyl-9,10-dihydro-4-phenanthrenecarboxylic acid, but no acidic material was found. This is surprising in view of the ready hydrogenolysis of carbon–oxygen bonds of the benzyl type usually noted with this reductive system.[15] The lactone ring in VI could be reductively cleaved by refluxing with 47% hydriodic acid, red phosphorus, and 85% phosphoric acid but no pure acid was isolated from the reaction products. The dihydrolactone (VI) was converted into the fully aromatic lactone of 5-hydroxymethyl-4-phenanthrenecarboxylic acid (VII) by heating with sulfur. This lactone (VII) was also formed by refluxing II with toluene and aluminum isopropylate.[16] An attempt to reduce VII with hydriodic acid as with VI failed, VII being recovered quantitatively. Prior to a proposed thioacetal hydrogenolysis,[17] the aldehydo-acid (I) was treated with ethyl mercaptan. Since a compound which we believe to be the CH_3CH_2S-analog of II was obtained further work along this path was discontinued.

The extraordinary ease of cyclization of the dimethanol (III) to the seven-membered cyclic ether (IV) and the resistance of IV to cleavage are noteworthy. Any acidic reagent readily caused the cyclization of III to IV. On passing anhydrous hydrogen bromide through a refluxing solution of IV in toluene, no cleavage was observed, as was also the case on refluxing III with benzene and aluminum bromide. Reaction between hydrogen bromide and fused IV did not set in rapidly until a temperature of 150° was reached, and then a dark tar was formed.

Experimental[18]

Pseudo Ethyl 5-Formyl-4-phenanthrenecarboxylate (II).—A suspension of 8.5 g. of 5-formyl-4-phenanthrenecarboxylic acid,[19] (I) in 50 ml. of alcohol and 100 ml. of benzene containing 5 drops of concentrated sulfuric acid was refluxed on a column with a phase separating head until no further water was obtained. The ester was crystallized from benzene to yield 7.2 g. (76%) of fine silky colorless needles as a first crop, m. p. 177.2–179.2°. The analytical sample melted at 178.8–179.5°. *Anal.* Calcd. for $C_{18}H_{14}O_3$: C, 77.7; H, 5.1. Found[a]: C, 78.0, 77.7; H, 5.5, 5.1.

The same ester was prepared in quantitative yield by treatment of the acid chloride[6] with alcohol in pyridine.

(19) Prepared as described on p. 148 of ref. 7.

4,5-Phenanthrenedimethanol (III).—A warm solution of 5.0 g. of II in 250 ml. of dry sulfur-free benzene was added to a stirred solution containing 0.5 g. of lithium aluminum hydride in 100 ml. of ether. After careful hydrolysis at 0° with water and then dilute sulfuric acid, III was isolated in 90% yield as colorless crystals, m. p. 156–162°. It proved quite tedious to purify this product to its maximum melting point, 164.4–168.8°, by recrystallization from benzene as small amounts of an impurity, evidently the cyclic ether (IV) persisted. III crystallized in rosettes of stout faintly straw-colored elongated prisms. The dibenzoate, dense colorless prisms, m. p. 152.8–154.2°, was prepared in pyridine at 0° using benzoyl chloride and was recrystallized from petroleum ether, b. p. 90–97° (Skellysolve C). *Anal.* Calcd. for $C_{16}H_{14}O_2$: C, 80.7; H, 5.9. Found[a]: C, 80.4, 80.6; H, 6.0, 6.0. Active hydrogen: 2.0. Found (Zerewitinow): 1.8, 1.9. Calcd. for $C_{30}H_{22}O_4$: C, 80.7; H, 5.0. Found[k]: C, 81.3, 80.8; H, 5.1, 5.1.

Cyclic Ether of 4,5-Phenanthrenedimethanol (IV).—Anhydrous hydrogen chloride was passed into a suspension of 2.87 g. of III in 20 cc. of benzene at room temperature for fifteen minutes, during which the glycol disappeared, heat was evolved, and droplets of water were formed. The crude product was vacuum distilled to yield 2.41 g. (90%) of colorless IV, m. p. 72.8–76.2°, b. p. 168–169° at 1 mm. An analytical sample, recrystallized from methanol, melted at 78.5–78.8°. This ether was the main product when the glycol was treated under the following conditions: thionyl chloride in benzene–pyridine; phosphorus pentasulfide in refluxing benzene (on fusion with this reagent a violent reaction took place and no pure product was isolated); anhydrous hydrogen bromide in boiling benzene or with molten III; and *p*-toluenesulfonyl chloride in pyridine at 0°. The TNF[10] complex of IV formed orange elongated prisms, m. p. 194–195° after recrystallization from alcohol–benzene. *Anal.* Calcd. for $C_{16}H_{12}O$: C, 87.3; H, 5.5. Found[p]; C, 87.2, 87.2; H, 5.7, 5.6. Calcd. for $C_{29}H_{17}O_8N_3$: C, 65.1; H, 3.2; N, 7.9. Found[e]: C, 64.9, 65.1; H, 3.3, 3.1; N, 8.1, 8.1.

4,5-Dimethylphenanthrene (V).—In one of the better of many runs a mixture of 3.0 g. of IV, 1.5 g. of red phosphorus, and 30 ml. of 47% hydriodic acid was sealed in a tube and heated at 165° for twelve hours. Vacuum distillation at 1 mm. of the organic reaction product afforded 0.73 g. (26%) of crude V, m. p. 66–72°. There remained a large quantity of viscous non-volatile residue in the distilling flask. The crude product was converted to the TNF derivative[10] which was recrystallized once from ethanol. By chromatography over alumina the TNF derivative was decomposed and the resulting hydrocarbon was recrystallized from methanol to yield 0.47 g. (17%) of V, m. p. 76.0–76.8°. Further recrystallization from methanol yielded the analytical sample, m. p. 76.3–76.9°, as small colorless crystals. The recrystallized TNF derivative formed glistening scarlet needle-shaped crystals, m. p. 120.4–121.4° after several recrystallizations from alcohol. *Anal.* Calcd. for $C_{16}H_{14}$: C, 93.2; H, 6.8. Found[c]: C, 92.9, 92.8; H, 6.8, 6.8. Calcd. for $C_{29}H_{19}O_7N_3$: C, 66.8; H, 3.7; N, 8.1. Found[c]: C, 66.7; H, 3.6; N, 8.2.

The picrate was best formed by dissolving 0.103 g. of V and 0.115 g. of pure picric acid in alcohol. On standing at room temperature orange-red elongated prisms separated. These were collected on a small suction funnel and rinsed with small amounts of ice-cold alcohol. They melted sharply at 109.6–110.2°. *Anal.* Calcd. for $C_{22}H_{17}O_7N_3$: C, 60.7; H, 3.9; N, 9.7. Found[c]: C, 60.6, 60.7; H, 3.9, 3.9; N, 9.8, 10.0.

The separation of unreacted ether (IV) from V was effected most easily by conversion to the TNF derivatives, that of the ether (IV) being much less soluble. Considerable amounts of IV were present in hydriodic reductions which were run at lower temperatures than 165° or at this temperature for less than twelve hours. When reductions were attempted at 180–190° less V and more non-volatile residue were produced.

Conversion of V to Pyrene.—A mixture of 0.20 g. of V and 2 g. of selenium was heated for 18 hours at 300–310°. The mixture was extracted with boiling toluene. After removing the toluene the residue was sublimed and the sublimate treated with TNF to yield 20 mg. of the TNF derivative of pyrene, m. p. 228–234° (4.2%). Recrystallization from 95% alcohol yielded 12 mg. of the TNF derivative of pyrene, m. p., alone and mixed with authentic material,[10] 239–240°.

Oxidation of V.—To a warm (about 40°) solution of 0.5 g. of V in 5 cc. of acetic acid was added dropwise a solution of 1.0 g. of chromic anhydride in 5 cc. of acetic acid. After shaking as long as an exothermic reaction was noticed the reaction mixture was poured on ice. The organic oxidation product was taken into ether–benzene. Removal of the solvent yielded an oil which could not be crystallized. When dissolved in a small amount of alcohol and treated with alcoholic *o*-phenylenediamine, a yellow precipitate separated. After three recrystallizations from alcohol there was obtained 30 mg. of the quinoxaline derivative as yellow crystals, m. p. 171.8–172.8°. *Anal.* Calcd. for $C_{22}H_{16}N_2$: C, 85.7; H, 5.2; N, 9.1. Found[s]: C, 85.4, 85.6; H, 5.1, 5.3; N, 8.6, 8.7.

Reduction of I.—A mixture of 8.0 g. of I, 50 ml. of acetic acid, 50 ml. of concentrated hydrochloric acid, 25 ml. of toluene and 20 g. of amalgamated zinc was heated to reflux for seventy-two hours during which time an additional 36 ml. of hydrochloric acid was added. From the reaction products was obtained 3.8 g. (58%) of 1,2-dihydropyrene, m. p. 127–131°. On recrystallization from alcohol there was obtained pure 1,2-dihydropyrene, m. p. 131.0–132.0°, which formed a picrate melting at 145–147°. These constants agree with those previously reported.[14]

The unchanged starting material was recovered after attempts at high pressure hydrogenation of I or II over copper chromite (37 KAF[20]) in absolute alcohol at 130° and 2000 p. s. i. Similarly, I was recovered unchanged after refluxing with 47% hydriodic acid and 85% phosphoric acid for three days.

When 15.0 g. of Raney nickel–aluminum was added in small portions during one hour to a stirred solution at 90° of 5 g. of I in 200 ml. of 10% sodium hydroxide there was obtained from the neutral product (4.54 g.) 1.59 g. (34%) of the lactone of 9,10-dihydro-5-(hydroxymethyl)-4-phenanthrenecarboxylic acid (VI), m. p. 156.0–156.8°. Attempts at further reduction of VI using the Raney alloy method[15] or the hydriodic–phosphoric acid procedure above described failed to yield crystalline material. *Anal.* Calcd. for $C_{16}H_{12}O_2$: C, 81.3; H, 5.1. Found[p]: C, 81.4, 81.5; H, 4.8, 5.0.

Lactone of 5-(Hydroxymethyl)-4-phenanthrenecarboxylic Acid (VII).—Heating 0.23 g. of VI with 0.03 g. of sulfur at 230–235° for one hour afforded crude VII, m. p. 167–175°, in 66% yield. The analytical sample, purified by alkaline hydrolysis, acidification and recrystallization from alcohol, melted at 177.2–178.0°. The same lactone was obtained in 56% yield on slow distillation of a mixture of 2.78 g. of II, 2.04 g. of aluminum isopropoxide and 150 ml. of toluene until a test[16] for acetone in the distillate was negative. VII was recovered quantitatively from an attempted reduction with hydriodic–phosphoric acids as above described. *Anal.* Calcd. for $C_{16}H_{10}O_2$: C, 82.1; H, 4.3. Found[k]: C, 82.1, 82.1; H, 4.2, 4.3.

Pseudo Ethyl 5-Formyl-4-phenanthrenecarbothiolate.—To a stirred mixture at 0° of 10 ml. of ethyl mercaptan, 1.0 g. of freshly fused zinc chloride and 1 g. of anhydrous sodium sulfate was added, in portions, 0.5 g. of powdered I. After stirring for 14 hours at room temperature the mixture was diluted with ether–benzene and the organic layer washed well with 10% sodium hydroxide, water and saturated salt solution. No acidic material was recovered from the alkaline extract. After removal of the solvent and recrystallization of the residue from alcohol there was obtained a small amount (24%) of the crystalline thioester, m. p. 150.8–152.4°. The analytical sample melted at 152.2–153.0°. No further experiments were carried out on the compound. An attempt to prepare the butyl thio-

(20) R. Connor, K. A. Folkers and H. Adkins, THIS JOURNAL, **54**, 1138 (1932).

ester in a similar manner failed. *Anal.* Calcd. for $C_{18}H_{14}O_2S$: C, 73.4; H, 4.8. Found: C, 73.6, 74.0; H, 5.0, 4.9.

Summary

The preparation of 4,5-dimethylphenanthrene from pyrene is described. The steps involved are: (1) ozonization to 5-formyl-4-phenanthrenecarboxylic acid, (2) esterification, (3) reduction to 4,5-phenanthrenedimethanol, (4) cyclization to the corresponding cyclic ether and (5) reduction to 4,5-dimethylphenanthrene.

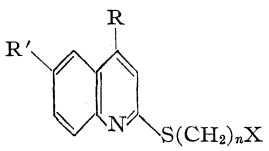
Some Dialkylaminoalkylmercaptoquinolines

BY HENRY GILMAN AND MARY ALYS PLUNKETT[1]

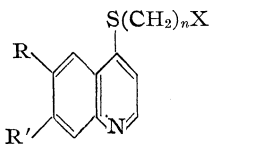
In connection with some studies on the pharmacological activity of certain mercapto quinolines, a series of dialkylaminoalkylmercaptoquinolines has been prepared. It seemed of interest to introduce into nuclei which have chemotherapeutic potentialities certain alkylamino groupings connected directly to the nuclei by a sulfur atom. The quinoline derivatives are of types I and II. Compounds of these types are reported by Bachman, *et al.*,[2] and by Clinton and Suter.[3]

(I)



Where R is methyl, hydrogen or carboxy; R′ is methoxy or hydrogen; X is diethylamino, N-piperidyl or N-morpholyl; *n* is 2 or 3.

(II)



Where R is methoxy or hydrogen; R′ is chloro or hydrogen; X is diethylamino, N-piperidyl or N-morpholyl; *n* is 2 or 3.

The compounds reported were prepared by condensation of the appropriate chloroquinoline with the sodium alkyl mercaptide or by condensation of the sodium quinolyl mercaptide with the appropriate alkyl chloride. In general, absolute ethanol was used as solvent for the condensations involving chloroquinolines. In the case of 2-chloro-4-methyl-6-methoxyquinoline it was found that the reflux temperature of methyl cellosolve was necessary for condensation. Reactions using the quinolyl mercaptides were carried out in a 1:1 mixture of ethylene glycol and methyl cellosolve.

In the preparation of 6-methoxy-2-(β-diethylaminoethylmercapto)-quinoline both the quinolyl and the alkyl mercaptides were used. Similar yields were obtained in the two cases. 6-Methoxy-4-methyl-2-(γ-diethylaminopropylmercapto)-quinoline was prepared by treating a mixture of γ-diethylaminopropylisothiouronium chloride hydrochloride and 2-chloro-4-methyl-6-methoxyquinoline in methyl cellosolve with excess sodium ethoxide. The same compound was obtained from the alkyl mercaptide and the chloroquinoline.

(1) Present address: Vassar College, Poughkeepsie, New York.

(2) Bachman, Welton, Jenkins and Christian, THIS JOURNAL, **69**, 366 (1947).

(3) Clinton and Suter, *ibid.*, **70**, 491 (1948).

In general, the mercaptoquinolines were isolated as the hydrochlorides in yields varying from 23–75%. The compounds prepared are listed in Table I. Details of the preparation of typical compounds are given in the experimental section. The sodium alkyl mercaptides were prepared in accordance with procedures described earlier from the corresponding alkyl chloride[4] or by the isothiouronium salt synthesis.[5]

Most of these compounds have been tested for their pharmacological activity toward malaria-causing plasmodia. Results of these tests will be reported elsewhere.

The authors are grateful to William Meikle for assistance and to Parke Davis and Co. for arranging for the tests.

Experimental

6-Methoxy-2-(β-diethylaminoethylmercapto)-quinoline.—A solution of 5 g. (0.04 mole) of β-diethylaminoethyl chloride and 0.02 mole of the sodium salt of 2-mercapto-6-methoxyquinoline in absolute ethanol was refluxed for four hours. After removal of the solvent the residue was dissolved in ether, dried over anhydrous sodium sulfate and treated with ethereal hydrogen chloride. Recrystallization of the dihydrochloride from absolute ethanol gave a product melting at 168–170° which was identical with that obtained from the reaction of sodium β-diethylaminoethyl mercaptide and 2-chloro-6-methoxyquinoline.[6]

4-Methyl-2-[β-(N-piperidyl)-ethylmercapto]-quinoline.—This compound was prepared by a method analogous to the above procedure from N-β-chloroethylpiperidine[7] and 2-mercapto-4-methylquinoline[8] using a 1:1 mixture of ethylene glycol and methyl cellosolve as solvent. The free base deposited from an ether solution as crystals melting at 75–76°.

The corresponding N-morpholyl compound, as well as the intermediates[9] for the reaction, were prepared in a similar manner.

2-Mercapto-6-methoxyquinoline.—This compound was prepared with some modification, according to the directions of John[10] for the preparation of 4-mercapto-6-methoxyquinoline.

[a] NC_5H_{10} refers to the N-piperidyl radical; NC_4H_8O refers to the N-morpholyl radical. [b] M. p. of free base. [c] Starting materials for this compound were made according to references 11–12. [d] Reported by Clinton and Suter.[2]

A mixture of 14 g. (0.08 mole) of 2-chloro-6-methoxyquinoline, 11 g. of potassium hydrosulfide and 56 ml. of absolute ethanol was heated at reflux temperature for fifteen hours. The solid material which formed was washed well with water and neutralized with acetic acid. After recrystallization from absolute ethanol 5 g. (33%) of product melting at 185–187° was obtained.

Anal. Calcd. for $C_{10}H_9ONS$: N, 7.33. Found: N, 7.40.

6-Methoxy-4-methyl-2-(γ-diethylaminopropylmercapto)-quinoline.—To a solution of 7.8 g. (0.03 mole) of γ-diethylaminopropylisothiouronium chloride hydrochloride[4] in 50 ml. of methyl cellosolve was added 6.2 g. (0.03 mole) of 2-chloro-4-methyl-6-methoxyquinoline[11] dissolved in a minimum of methyl cellosolve. The mixture was heated under reflux with stirring and treated with a solution of 3.2 g. (0.14 g. atom) of sodium in absolute ethanol, added in a thin stream over a period of one hour. The reaction mixture was refluxed for seven hours, filtered and freed from solvent by distillation under reduced pressure. The residue was dissolved in ether, washed with water and dried over anhydrous sodium sulfate. Treatment with ethereal hydrogen chloride gave 46% of product which, after recrystallization from absolute ethanol, melted at 200–201°.

This compound was also prepared in 50% yield according to the usual method using sodium γ-diethylaminopropyl mercaptide and 2-chloro-4-methyl-6-methoxyquinoline.[12,13]

(11) Kindly furnished by S. P. Massie.

Summary

The preparation of a series of dialkylaminoalkylmercapto quinolines is described. The compounds were isolated and identified as the hydrochlorides.

The Synthesis of Derivatives of Glucose-4-phosphoric Acid[1]

BY F. J. REITHEL AND C. K. CLAYCOMB[2]

During the course of an investigation of biochemical mechanisms forming glucosidic linkages it became desirable to secure glucose-4-phosphoric acid for use as a substrate. In our hands Raymond's[3] synthesis resulted in very poor yields. The synthesis described by the present authors utilizes a novel rearrangement first described by Helferich and Klein[4] and the convenient phosphorylating agent diphenylchlorophosphonate.[5]

Experimental

1,2,3,6-Tetraacetyl-β-D-glucopyranose.—Pure β-D-glucose-1,2,3,4-tetraacetate[6] was prepared utilizing the crystallization procedure of Lardy and Fischer.[7] In accordance with the method of Helferich and Klein[4] 11.2 g. of the above compound was dissolved in 110 ml. of 95% ethanol, the specific rotation of the solution being $[\alpha]^{25}D$ +4.49°. The addition of 2.8 ml. of 0.1 *M* aqueous potassium hydroxide catalyzed a change in rotation in one minute to $[\alpha]^{25}D$ −1.03°. The alcohol solution was acidified with 0.5 *N* acetic acid, concentrated to one-half the original volume, seeded and cooled.[8] The crystal crop, filtered cold, was recrystallized from ether containing 10% pyridine and then from 95% ethanol. This procedure yielded 3.9 g. of pyridine-free 1,2,3,6-tetraacetyl-β-D-glucose, m. p. 131.5–132.5°; $[\alpha]^{22}D$ −28.6° (chloroform).[9]

1,2,3,6-Tetraacetyl-4-diphenylphosphono-β-D-glucose.—A solution of 2.0 g. of purified 1,2,3,6-tetraacetyl-β-D-glucose in 25 ml. of pure dry pyridine was warmed to 35° until clear and then cooled to 10°. To it was added 1.7 g. (1.33 ml.) of pure diphenylchlorophosphonate.[5] If turbidity developed during the first half hour after addition of the reagent the solution was warmed until it became clear, and again cooled. After a half hour reaction time the temperature of the reaction mixture was allowed to rise to 20° and was maintained at that figure for about twenty-four hours. Any solid material which had deposited was redissolved by the addition of a few drops of water and the whole was poured, with vigorous agitation, into 170 ml. of ice water. The white granular precipitate thus produced was dissolved in 10 ml. of chloroform, washed with dilute hydrochloric acid and water, and dried over anhydrous sodium sulfate. When the chloroform solution was evaporated *in vacuo* there was obtained a flaky white product soluble in acetone, alcohol and benzene, and insoluble in water or petroleum ether. Recrystallization from hot alcohol or aqueous acetone yielded 1.5 g. of silky needles, m. p. 146.5–147.5°; $[\alpha]^{25}D$ −34.4° (chloroform).

Anal. Calcd. for $C_{26}H_{29}O_{13}P$: C, 53.80; H, 5.04; P, 5.34; 4 acetyl,[10] 6.47. Found: C, 53.77, 54.00; H, 5.27, 5.23; P,[11] 5.34; acetyl, 6.35, 6.40.

1,2,3,6-Tetraacetyl-4-phosphono-β-D-glucose.—An 850-mg. sample of pure 1,2,3,6-tetraacetyl-4-diphenylphosphono-β-D-glucose was dissolved in 15–20 ml. of absolute ethyl acetate, 0.1 g. of Adams catalyst added, and hydrogenated at a pressure of 2–3 cm. After two and one-half hours reaction ceased; hydrogen used, 270 ml.; calcd., 262 ml. (8 moles). The catalyst was removed by filtration and the solution evaporated to a volume of about 5 ml. Cooling to −10° caused the deposition of 550 mg. of a crystalline compound, m. p. 168°; $[\alpha]^{20}D$ −0.42° (*c*, 1.2, H_2O).

Anal. Calcd. for $C_{14}H_{21}O_{13}P$: C, 39.2; H, 4.90; P, 7.24. Found: C, 39.04, 39.16; H, 4.81, 4.93; P, 7.26.

Di-sodium Salt of Glucose-4-phosphoric Acid.—Pure crystalline 1,2,3,6-tetraacetyl-4-phosphono-β-D-glucose was neutralized (phenolphthalein end-point) with aqueous sodium hydroxide. Water was removed *in vacuo*, the residue was dissolved in pure anhydrous methanol, and a catalytic amount of potassium methylate in methanol was added. The deacetylated di-sodium salt began to precipitate at once. After twelve hours at 0° the precipitate was centrifuged down, washed with anhydrous methanol and with ether and dried *in vacuo*. A white hygroscopic solid was obtained which decomposed at about 155° and reduced alkaline copper solutions; $[\alpha]^{20}D$ +51.5° (*c*, 2.1, H_2O).[12]

Anal. Calcd. for $C_6H_{11}O_9PNa_2$: P, 10.2. Found: P, 10.2.

1.00 ml. of an aqueous solution containing 20.7 mg. of the disodium salt was added to 1.00 ml. of 2 *N* hydrochloric acid and the mixture heated at 100° for three hours. At the beginning 0.0325 mg. of inorganic phosphorus was present. During hydrolysis an additional 0.262 mg. of inorganic phosphorus was produced. This increase corresponds to 12% hydrolysis.

Dibrucine Salt of Glucose-4-phosphoric Acid.—Pure crystalline 1,2,3,6-tetraacetyl-4-phosphono-β-D-glucose was dissolved in pure dry methanol. To this solution 0.4 *N* barium methylate in methanol was added until a drop of the solution, when added to water, turned phenolphthalein a deep pink. A voluminous white precipitate of the barium salt appeared. After standing twelve hours at 0° the mixture was again tested for excess barium methylate. If an excess was still present the barium salt was centrifuged down, washed with dry methanol and with ether and dried *in vacuo* briefly.

The barium salt of glucose-4-phosphoric acid thus obtained was dissolved in a minimum amount of water and the barium precipitated as barium sulfate by adding the proper amount of sulfuric acid. The resulting solution of glucose-4-phosphoric acid was neutralized (brom thymol blue) with a solution of brucine in methanol. After concentration *in vacuo* to about one-third of the original volume, an amount of acetone equal to the final volume was added, and the mixture cooled to −10°. Crystals slowly appeared forming clusters of rosettes. Several recrystallizations from 50% acetone–water followed by thorough drying *in vacuo* yielded a product which reduced alkaline copper solutions, m. p. 173–

Discussion

In an effort to prove that the phosphate group was actually attached to carbon number four of the glucose, Raymond[3] compared the osazones and the rate of glucoside formation of his product with those of glucose-3- and glucose-6-phosphoric acids and found marked differences.

Steric considerations point to interaction between groups on carbons four and six as the most likely to be involved in rearrangement. The following data, when compared with values for analogous compounds to be found in the present paper, indicate that there has not been a shift of the phosphate group to carbon number six. Lardy and Fischer[7] report 1,2,3,4-tetraacetyl-6-diphenylphosphono-β-D-glucopyranose, m. p. 64–66°, $[\alpha]^{22}D$ 16.5° (*c*, 1.37, pyridine) and 1,2,3,4-tetraacetyl-β-D-glucose-6-phosphoric acid, m. p. 126–128° $[\alpha]^{25}D$ 18.7° (*c*, 1, pyridine). Robison and King[14] report the dibrucine salt of glucose-6-phosphoric acid, $[\alpha]^{20}D$ 20.6° (*c*, 0.84, water).

Both physical properties and presence of reducing power rule out a transfer of the phosphate group to carbon number one. Presumably the pyranose ring would remain intact in such a synthesis as the one presented and it would seem unlikely that carbon number five would be involved. However, until such time as glucose-5-phosphate can be studied this possibility cannot be ruled out and the nomenclature in this paper avoids specifying ring structure.
