THE DECOMPOSITION OF DIAZOBENZENE CHLORIDE IN
WATER SOLUTION¹

BY CECIL J. HAGGERTY AND BARTHOLOMT C. HADLER

RECEIVED SEPTEMBER 5, 1931

PUBLISHED MAY 7, 1932

Introduction

The kinetics of the decomposition of the diazo bodies in water solution have been studied rather extensively by various investigators, *viz.*, Hausser and Muller,² Hantzsch³ and Cain and Nicoll.⁴

More recently Pray,⁵ Yamamoto⁶ and Blumberger⁷ have continued investigations on these same decompositions. An examination of the data of these various individuals will show that the addition of those substances which hydrolyze alkaline give larger velocity constants but that there is a diminished evolution of nitrogen. This is claimed to be due to the so-called coupling reactions which are supposed to take place in the presence of hydroxyl ion in preference to the simple decomposition. Blumberger states that there is a maximum in the curve of reaction rate plotted against hydroxyl ion increase.

It is the purpose of the present paper to show that the decreased evolution of nitrogen is not due to the so-called coupling reactions and that the maximum in the curve of reaction rate against hydroxyl ion is not attributable simply to this ion.

Materials and Apparatus.—Ordinary aniline was redistilled several times; only that portion which boiled constantly at 183.5° was taken for the subsequent experiments. The other chemicals were of C. P. grade and no further attempts at purification were made.

¹ This paper is constructed from a thesis submitted by Bartholdt C. Hadler to the Faculty of Holy Cross College in partial fulfillment of the requirements for the degree of Master of Science.

The reaction vessel consisted of a large test-tube about 15 cm. long and 2.5 cm. in diameter to which had been sealed a capillary side arm. The latter communicated with the water-jacketed gas-measuring buret which was maintained at the same temperature as the thermostat by circulating water from the latter through the former. The aniline hydrochloride was diazotized below 5° and upon completion of this process the solution was placed in the reaction vessel. After adding that substance whose effect we wished to investigate, a mercury-sealed stirrer was fitted into place and rotated at a constant speed. The gas-measuring buret could be adjusted and read accurately to within 0.1 cc., which, in the early stages of the reaction, leads to an error of 3 or 4%. All of the experiments were conducted at $30 \pm 0.01^{\circ}$. The volume of nitrogen evolved was recorded at thirty-minute intervals. These gas volumes were reduced to standard conditions and the reaction velocity constants were calculated according to the graphical method of Guggenheim,⁸ which is supposed to overcome uncertainties in the value of A in the ordinary unimolecular equation.

Experimental

The following experiment is selected as being typical of this decomposition. In this table, as in all following tables, the first column contains the time in minutes; the second column, the corrected amount of nitrogen evolved; the third column, the value of $v-v_0$; the fourth column, the \log_{10} of $v-v_0$; the fifth column, the same value as read from the graph; and the last column gives the value of $0.4343 K \times 10^4$.

TABLE I
EXPERIMENTAL RESULTS

Time	Nitrogen evolved	$v-v_0$	$\log v-v_0$	Calcd.	$0.4343 K \times 10^4$
30	4.0	4.0	0.602	0.607	
60	7.3	3.3	.519	.536	
90	10.4	3.1	.491	.465	
120	13.1	2.7	.431	.393	23.8
150	15.3	2.2	.342	.323	
180	17.0	1.7	.230	.250	
210	18.4	1.4	.146	.178	

The value 23.8 was obtained from the straight-line plot of $\log_{10} v-v_0$ against the time. This value agrees very well with the value 24.0 as found by Pray for this same decomposition.⁹

It has been stated by Pray and others that any substance which exerts a dehydrating effect will retard the velocity of decomposition. He observed this in his study of the effect of sulfuric acid on this decomposition. We give in the following table the effect of sulfuric acid on this decomposition mainly because we will need the constant for subsequent discussion. The sulfuric acid was added to the diazotized aniline hydrochloride in the molar ratio of fifteen to one.

The tabulated data show definitely that there is a decrease in the reaction velocity constant in the presence of sulfuric acid. Blumberger attributes

⁸ Guggenheim, *Phil. Mag.*, 2, 538 (1926).

⁹ Pray, Ref. 5, p. 1481.

TABLE II
RESULTS IN PRESENCE OF SULFURIC ACID

Time	Nitrogen evolved	$v - v_0$	$\log v - v_0$	Calcd.	$0.4343 K \times 10^4$
60	6.6	6.6			
90	9.6	3.0	0.477	0.477	
120	12.1	2.5	.398	.417	
150	14.4	2.3	.362	.357	
180	16.3	1.9	.279	.296	20.1
210	18.1	1.8	.255	.235	
240	19.5	1.4	.146	.175	
270	20.8	1.3	.114	.115	

this decrease to the formation of a $C_6H_5N_2SO_4$ ion. If this is true it seems strange that Pray did not observe the decrease on the addition of potassium sulfate. We cannot, therefore, attribute this decrease simply to the formation of a sulfate ion, and it appears that the dehydrating effect is the proper cause of the decrease.

It is known that the diazonium salt is amphoteric. Consequently there is an equilibrium relation as follows

Also large quantities of the $C_6H_5N_2O$ ion cannot exist in the presence of sodium or potassium ion, for the solubility product is exceeded and precipitation takes place. We should expect, therefore, that if certain salts which hydrolyze alkaline or if alkalies are added to the diazo compound, this precipitate of diazotate will follow with a consequent effect on the decomposition rate of the diazo body. Varying amounts of salts or alkalies added will have differing effects according to the above equilibrium. On the other hand, acid or neutral salts should not affect the reaction rate. This can easily be seen by an examination of the data of Pray.

In the following table we give the effect of monosodium dihydrogen phosphate. Since this substance hydrolyzes acidic, we would not, according to the above argument, expect any effect on the reaction rate. The data show this to be the case.

TABLE III
RESULTS WITH MONOSODIUM PHOSPHATE

Time	Nitrogen evolved	$v - v_0$	$\log v - v_0$	Calcd.	$0.4343 K \times 10^4$
30	3.5	3.5			
60	7.1	3.6	0.556	0.560	
90	10.3	3.2	.505	.492	
120	13.0	2.7	.431	.420	
150	15.2	2.2	.342	.351	23.3
180	17.2	2.0	.301	.279	
210	18.7	1.5	.176	.210	
240	20.1	1.4	.146	.140	

A comparison of this table with Table I will show an almost exact similarity in the amounts of nitrogen liberated at the various points of time. Of necessity then the constants agree with one another very well. Therefore, in spite of the fact that the molar ratio of salt added to the diazo salt is in this case nine to one, there appears no effect on the decomposition rate.

Although secondary sodium phosphate hydrolyzes faintly basic, yet in sufficient quantity (in this case, nine moles of phosphate to one of diazo compound) the P_H of the diazo solution can be changed enough to cause an apparent increase in the reaction rate, as the following table shows.

TABLE IV
RESULTS WITH SECONDARY SODIUM PHOSPHATE

Time	Nitrogen evolved	$v - v_0$	$\log v - v_0$	Calcd.	$0.4343 K \times 10^4$
30	3.8	3.8	0.580	0.575	
60	6.1	2.3	.362	.397	
90	7.9	1.8	.255	.219	59.9
120	9.0	1.1	.041	.040	

The amount of nitrogen liberated in this experiment after a lapse of twenty-four hours was less than half of that obtained in the simple decomposition. This confirms Pray's observation but we do not believe it to be due to the so-called coupling reactions. When the phosphate is added to the diazo solution, a brown precipitate appears. This occurs immediately, and so cannot be attributed to the formation of hydroxyazobenzene, for at the beginning of the reaction there is no phenol present with which the diazo compound might combine. Such behavior is explained according to the previous argument.

Concerning the increase in the reaction rate, for which no one has offered an adequate explanation, may we propose that it is a heterogeneous reaction and so catalyzed by the precipitate of the diazotate. We believe this to be so, for one of us has carried out preliminary experiments on this decomposition in the presence of silica gel and suchar and has found the rate to be approximately tripled in the presence of these substances. These experiments are now in the process of completion and we expect to report them in the future.

The addition of hydrogen ion, according to the above-mentioned equilibrium, should cause a shift to the left and a consequent dissolution of the precipitated diazotate. Normal decomposition would be expected to ensue. This is found to be the case, as the following experiments show. Sodium succinate was added to the diazo solution in the molar ratio of nine to one. Precipitation occurred as with the phosphate. We followed the decomposition of this heterogeneous system for two hours and then added sufficient sulfuric acid to redissolve the precipitate.

TABLE V
RESULTS WITH SODIUM SUCCINATE

Time	Nitrogen evolved	$v - v_0$	$\log v - v_0$	Calcd.	$0.4343 K \times 10$
30	1.3	1.3	0.114		
60	2.7	1.4	.146		
90	3.9	1.2	.079		
120	5.2	1.3	.114		
30	2.5	2.5	.398	0.416	
60	4.9	2.4	.380	.356	
90	6.9	2.0	.301	.296	20.1
120	8.6	1.7	.230	.237	
150	10.1	1.5	.176	.176	
180	11.4	1.3	.114	.114	

The first part of this table shows again decreased nitrogen evolution. The rate appears to be constant within experimental error. The second part of the table shows definitely that the precipitated diazotate will go back into solution and decompose in regular fashion. The constant for this portion of the table is exactly the same as that of Table II.

In the following experiment we added sodium hydroxide in the molar ratio of forty to one in an attempt to reduce the decomposition of the diazo solution to a minimum. After one and one-half hours we added sufficient sulfuric acid to redissolve the precipitate.

TABLE VI
RESULTS OF EXPERIMENT

Time	Nitrogen evolved	$v - v_0$	$\log v - v_0$	Calcd.	$0.4343 K \times 10^4$
90	0.8				
30	5.4	5.4	0.732	0.725	
60	8.4	3.0	.477	.625	
90	11.5	3.1	.491	.521	33.6
120	13.3	2.8	.447	.421	

It will be observed in this experiment that the sodium diazotate decomposes at a very slow rate, for after ninety minutes' time we obtained only 0.8 cc. The constant obtained from these data shows that the reaction is proceeding at a faster rate than the decomposition in Table II. This is due very likely to the large amount of nitrogen liberated in the early stages of the reaction on account of the heat evolved in the neutralization of the alkali. These data show again that the precipitated diazotate can be redissolved and that the resulting decomposition is in order with the simple decomposition.

As a final test the following experiment was performed. In order to overcome the heat effect of the previous experiment, we prepared some solid sodium diazotate by adding sodium hydroxide to the diazo compound around zero degrees. This we filtered off and washed with cold water until it was free from sodium hydroxide. We dried this in a vacuum

desiccator over sulfuric acid. Thirty-two grams of this dried diazotate was suspended in 20 cc. of distilled water and placed in the reaction vessel. We noted the decomposition of this heterogeneous mixture and after two hours' time sufficient dilute hydrochloric acid was added to cause solution.

TABLE VII
EXPERIMENTAL RESULTS

Time	Nitrogen evolved	$v-v_0$	$\log v-v_0$	Calcd.	$0.4343 K \times 10^4$
120	1.9	1.9			
60	10.4	10.4			
90	14.9	4.5	0.653	0.673	
120	18.9	4.0	.602	.578	30.1
150	21.7	2.8	.447	.487	
180	24.4	2.7	.431	.396	

The constant of this experiment is in fair agreement with those of Tables I and III, and the data again show that the diazotate which is precipitated in alkaline solution can be redissolved, forming the diazo salt which decomposes normally.

What the decomposing entity is we do not know. The facts at hand will not admit of any ion as the deciding factor. We do know, however, that in the simple decomposition hydrogen ion is formed. This being so, the equilibrium above will shift to the left as the reaction proceeds, or, what amounts to the same thing, the amount of substance undergoing decomposition in solution is increased. Under these conditions the value of A in the simple unimolecular equation is not known accurately and if sufficient time is allowed to elapse all of the diazo compound would be expected to decompose. The arbitrary method of selecting say twenty-four hours or of taking readings until an apparently constant value occurs cannot give the correct value of A in the presence of alkalies or of substances which hydrolyze alkaline. Consequently the real reaction rates, under these circumstances, can be obtained only by some method which eliminates such an uncertain value. This has been accomplished in the present paper by selecting the method of Guggenheim.

Summary

1. The simple decomposition of diazobenzene has been repeated.
2. The decomposition in the presence of sulfuric acid shows that the rate is decreased. This is not due, however, simply to the formation of a diazosulfate ion.
3. The decomposition has also been studied in the presence of alkali and of substances which hydrolyze alkaline.
4. It has been shown that if the P_H of the solution is in the neighborhood of 7 or greater, a precipitate will form. This precipitate is an alkali diazotate.

5. This precipitate can be redissolved upon the addition of acids and the resulting diazo compound will follow the normal decomposition.

6. The solid diazotate has been prepared and its decomposition noted. The addition of acid to this solid causes it to redissolve and decompose normally.

ABSORPTION SPECTRA IN SOLUTION AT LOW TEMPERATURES

BY L. B. ARNOLD, JR., AND G. B. KISTIAKOWSKY

RECEIVED OCTOBER 5, 1931

PUBLISHED MAY 7, 1932

Introduction

Extended and systematic work on light absorption of carbon compounds in solution has been concerned mainly with the identification and quantitative study of rather broad absorption regions. Each of these can be assigned to a definite electronic transition in the molecule, at least in cases where information on the absorption spectra in the gaseous state is available. The main achievement of this work is the evidence that certain absorption regions, located mostly in the near and middle ultraviolet, can be identified with definite atomic groups like the carbonyl, double bond, benzene ring, etc. Evidence has also been accumulated indicating that, if more than one such light absorbing group is present in a large molecule, the resulting spectrum can be represented in the first approximation as a sum of the component spectra. A more detailed study, by the usual method of quantitative measurement of the light absorption coefficients, has revealed, however, that the summation rule holds only very approximately and that in general the rest of the molecule exerts an influence on the absorption by a given part of it. Such an effect, as has been pointed out frequently, is altogether analogous to the alterations in the chemical properties of a group produced by the rest of the molecule, that are so common in organic chemistry.

The study of the spectral changes in solution is thus of considerable interest, at least in the domain of large and complicated molecules where neither the Raman spectra nor the absorption spectra in the vapor phase are sufficiently simple to offer a promise of a more rapid and direct solution of the problem. An attempt at a closer theoretical treatment of the absorption coefficient data for homologous molecules is complicated, however, by the circumstance that this experimental method records simultaneously the effects of two essentially different phenomena. In addition to alterations in the energy of electronic levels as well as to more or less mechanical changes in vibrational frequencies of an atomic group, resulting in a shift and modification of bands comprising an absorption

region, the light absorption coefficients are affected by changes in electronic transition probabilities. This latter phenomenon is much less accessible to theoretical treatment and so long as the effects of the two are not separated, an uncertainty is attached to speculations based on the study of the absorption coefficients describing only the large scale structure of absorption spectra. The difficulty is removed, in principle at least, by a study, not of the intensity of absorption, but of the locations of the vibrational bands within the absorption region due to the atomic group investigated and their alterations produced by changes in the structure of the rest of the molecule. The scarcity of work in this direction is due undoubtedly to the diffuseness and frequently to the complete absence of any finer structure in the absorption spectra of organic molecules in solution.

The existing literature indicates that the presence or absence of finer structure is typical of large classes of organic compounds and is not "accidental."

Hartley¹ has already pointed out that only aromatic hydrocarbons possess finer structure in their spectra, while aliphatic compounds show only continuous absorption. Stark² denied this conclusion and showed that some aliphatic hydrocarbons had banded spectra. However, the bands which he finds are of an altogether different appearance from those of aromatic hydrocarbons and comprise, judging from their width, many vibrational transitions, each probably representing a definite electronic level. Thus, on the whole, Stark's objections do not disprove the conclusion of Hartley, but show that it needs modification. The present contribution is concerned with this modification and amplification; it also deals with the problem of the mutual influence of two parts of a molecule as a function of their distance apart.

In an attempt to improve experimental conditions use was made of the old and well-known observation that low temperatures tend to sharpen and bring out the finer details in the spectra of solids and liquids.³ Further improvement was expected and obtained by the use of an inert and non-polar solvent, since the influence of the latter on the spectra of solutes is known to be considerable in some cases.⁴

Experimental Details

The experimental set-up consisted of a quartz hydrogen discharge⁵ (E, Fig. 1) as a source of continuous ultraviolet light, a Dewar flask with quartz windows and a small

Hilger quartz spectrograph (F). The construction of the flask will be seen from Fig. 1. (A) are four quartz to Pyrex graded seals, (B) are polished quartz windows sealed to the ends of these and (C) is the absorption cell of quartz, 4 cm. long, placed in line with the windows. Cooling was accomplished by means of liquid nitrogen, whose level was kept somewhat below the absorption cell. A small electric heater (D) placed in the bottom of the flask generated a steady stream of dry nitrogen which kept the absorption cell cool and prevented frost from forming on it and on the inner windows. Exposures were made on Hammer Special plates sensitized with vaseline. The wave length determinations were made by comparison with the copper arc spectrum. Solutions were made by dissolving a weighed amount of the substance in pentane, transparent within the limits of the set-up, and introducing a small known amount of this solution into liquid propane. This procedure was adopted because solutions in the pentane showed a strong tendency to freeze on cooling.

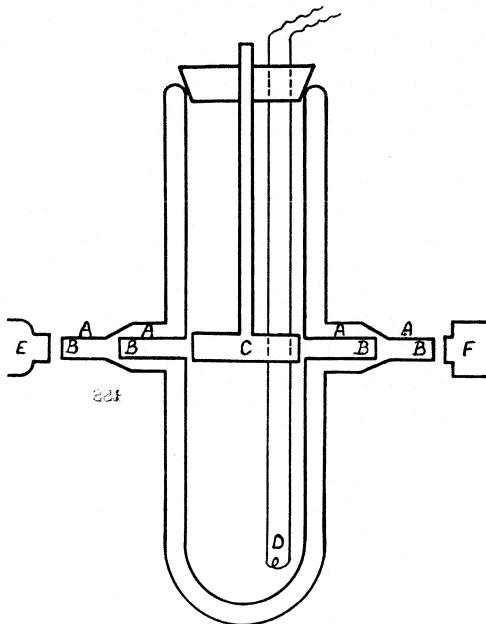

Fig. 1.

In the following a short résumé is given of the more essential points in the preparation and purification of the compounds and solvents used.

Purification of Solvents

Propane.—Gaseous propane from a commercial cylinder was passed successively through spiral wash bottles containing 15% fuming sulfuric acid, concentrated sulfuric acid, saturated permanganate solution containing 10% sodium carbonate, dilute potassium hydroxide solution, and a drying tower filled with sticks of solid potassium hydroxide. It was condensed by solid carbon dioxide.

Pentane.—Shell Pentane Solvent was shaken with saturated potassium permanganate solution containing 10% sodium carbonate until it no longer reduced the permanganate solution. It was then successively washed with water, dilute sulfuric acid and concentrated sulfuric acid. To remove aromatic hydrocarbons the pentane was shaken for four hours with one-fourth its volume of 15% fuming sulfuric acid. After this it was successively washed with concentrated sulfuric acid, dilute sulfuric acid, 10% sodium carbonate solution and finally with distilled water. The pentane was dried over calcium chloride and distilled over sodium. The material all boiled under 34°. It was tested spectrographically for transparency and if any bands persisted the fuming sulfuric acid treatment was repeated. The original material was of such purity that purification was readily obtained. The solvent used was transparent to 2250 Å., which was the limit of the complete apparatus when empty.

Preparation and Purification of Compounds

Benzene.—Eastman thiophene-free benzene was dried over sodium and distilled through a five-foot column. The boiling point was 80.4°.

$\Delta^{1,3}$ -Cyclohexadiene.—This was prepared by removing hydrogen bromide from 1,2-dibromocyclohexane with sodium ethylate according to Hoffmann and Damm.⁶ The product was repeatedly distilled over sodium in a stream of carbon dioxide until the refractive index⁷ was n_D^{20} 1.4740 \pm 0.0002 and the boiling point was 80.25–80.75°.

Cyclohexene.—Eastman cyclohexene was repeatedly distilled over sodium through a silver spiral fractionating column until a constant absorption spectrum was obtained. The spectrum shows no structure.⁸

Dimethylbutadiene.—This compound was prepared from pinacol. The product was redistilled over sodium until its boiling point was 68.8–69.4°.

Benzaldehyde.—Commercial benzaldehyde was purified through the bisulfite derivative. The sample taken boiled at 66° (10 mm.).

Phenylacetaldehyde.—Phenylacetaldehyde diethyl acetal was prepared and hydrolyzed to phenylacetaldehyde after the method of Woods and Comley.⁹ The aldehyde boiled at 195–198° at atmospheric pressure. The semicarbazone melted at 152° and the oxime at 93–95°. The aldehyde was purified through the bisulfite derivative from which it was regenerated by steam distillation from a solution made slightly alkaline with sodium carbonate.

Hydrocinnamic Aldehyde.—Eastman hydrocinnamic aldehyde was purified through the bisulfite derivative. The sample taken boiled at 106–108° (10 mm.).

Chlorobenzene.—C. P. chlorobenzene was redistilled until its boiling point was 132°.

Benzyl Chloride.—Eastman benzyl chloride was redistilled several times. The fraction boiling at 176–179° was filtered through activated charcoal, dried over calcium chloride and distilled again. The sample taken boiled at 178–178.5°.

β -Phenylethyl Chloride, γ -Phenylpropyl Chloride, δ -Phenylbutyl Chloride and ω -Phenylheptyl Chloride.—The preparation of these compounds has been described by Conant and Kirner.¹⁰ The samples were generously loaned by Professor J. B. Conant.

Results and Discussion

It seemed desirable to investigate the relation between the width of absorption bands and molecular structure using the simplest and most similar representatives of the aromatic and aliphatic series. As such, benzene, cyclohexadiene, cyclohexene and dimethylbutadiene were chosen. At room temperature benzene possesses fairly sharp bands while cyclohexadiene has only one wide band according to the work of Stark,¹¹ which we were able to confirm. The other two compounds show only a gradually increasing absorption toward the short wave lengths. Figure 2 presents microphotometer records¹² of the spectra of the first two compounds at

liquid nitrogen temperature. Cyclohexene and dimethylbutadiene are not shown as no significant changes have been obtained on cooling. The reproduction brings out clearly the sharpness of the benzene bands¹³ and also the resolution of the cyclohexadiene absorption into three bands. The half width of the bands in the two spectra is, however, strikingly different, being *ca.* 130 cm^{-1} for benzene and about 700 cm^{-1} for the other compound. This difference seems to be quite general and the literature presents no evidence, which we could locate, of bands observed with aliphatic compounds in solution which even approach the narrowness of benzene bands. The acetaldehyde absorption spectrum, which is resolved into

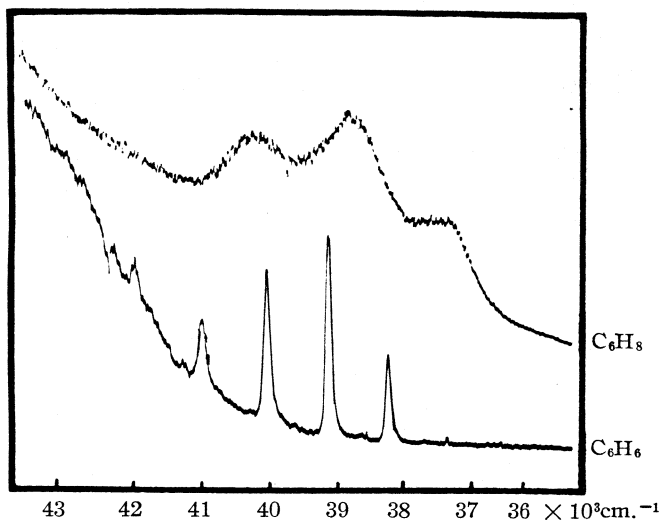

Fig. 2.

seven component bands at liquid air temperature (see Fig. 3, A) has half-widths of about 400 cm^{-1} . About the same half-width persists in the spectra of the carbonyl group attached to the benzene ring (Fig. 3), while the latter retains the narrow bands practically unchanged in their width in all derivatives which we investigated. Various publications dealing with the spectra of aromatic compounds at room temperature indicate that this behavior is typical of other derivatives of benzene and other aromatic carbon rings, showing that a significant difference exists between their spectra and those of aliphatic compounds. This difference, however, is not the absence of bands, as assumed by Hartley, but their different half-width.

At 80°K. the rotational energy of molecules is so small that on this

¹³ Fainter but similarly narrow bands located between the strong ones have been observed visually on our other photographs of the benzene spectrum (see also Kronenberger³).

account alone vibrational bands should all appear at least as sharp as those of benzene, particularly so long as only compounds of approximately the same molecular weight are compared. The unequal width observed is due therefore to other causes. One of these, probably the most important, is that many aliphatic compounds have in the vapor phase only continuous or diffuse spectra owing to photochemical dissociation and predissociation. These spectra, of course, cannot show structure in solution no matter how low the temperature. It is somewhat doubtful, though, whether this explanation suffices for those cases, like cyclohexadiene or the carbonyl group, where vibrational structure is obtained in the liquid state and where at least the long wave length part of the gaseous spectrum is discrete.¹⁴

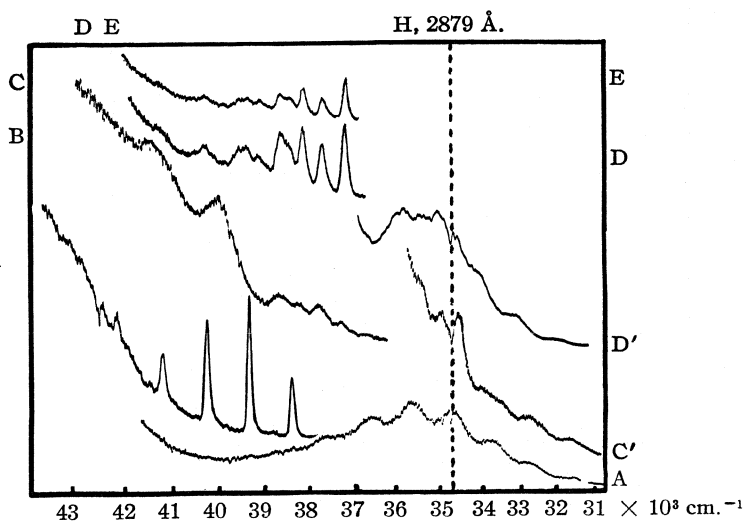

Fig. 3.

It seems more probable that in solution the fields of the surrounding molecules cause considerable broadening of the absorption bands by disturbing the electronic levels. The work of Kronenberger³ also points to this. He found by direct comparison that the bands of benzene in solution are more diffuse than those of benzene crystals. In the latter case, owing to the regular spacing of the molecules, the broadening should be reduced to a minimum. The present work shows that the disturbing influence of the solvent is much greater with aliphatic compounds whether they be small atomic groups or even rings with double bonds. Thus the electronic states in aromatic rings appear to be exceptionally stable against external influences. Perhaps this can be adduced in favor of the central bond theory for such molecules, since neither the ring structure, nor the

¹⁴ V. Henri, "Structure des Molecules," Paris, 1925.

conjugated double bond, both being present in cyclohexadiene, show this phenomenon. At any rate the present experiments indicate that the sharpness of absorption bands in solution can be utilized as a supplementary method in investigating the structure of large molecules and thus completely confirm the conclusions reached in a recent communication by Conant and Kamerling.¹⁵

Although the problem of mutual influence of spectra by two groups in a molecule has already received considerable attention, some new evidence on the subject seemed to be desirable and with this purpose in view a series of aryl aromatic aldehydes has been chosen together with some aryl aromatic monochlorides. The choice was guided by the consideration that the carbonyl group and the benzene ring both have well-defined and not overlapping absorption spectra in an easily accessible spectral region.

The spectra obtained at low temperatures, although considerably sharper and showing more fine structure than those reported previously from the work at room temperature, proved to be insufficiently resolved for an attempt at vibrational analysis. Accordingly in Table I are reported only the wave numbers of the observed bands, while Fig. 3 brings out the salient points and shows the microphotometer records of the spectra of acetaldehyde (A), benzene (B), phenylacetaldehyde (C) and (C'), hydrocinnamic aldehyde (D) and (D'), and phenylheptyl chloride (E). Turning first to the absorption of the benzene ring it will be seen that the substitution of a carbonyl group produces profound changes in the vibra-

Bands for compounds marked with (*) are computed from comparator measurements and in the case of benzaldehyde half-widths are estimated by comparison with bands of known half-width on other plates; benzaldehyde bands marked (**) are from a microphotometer record of this section of the benzaldehyde spectrum. Heptyl aldehyde shows within the limits of experimental error the same absorption spectrum as propionaldehyde. The benzaldehyde band marked (*), judging from the microphotometer record, is comprised of two bands with half-width about 200 cm.⁻¹.

tional structure, as should have been expected from the altered symmetry conditions alone. Further changes are produced by interposing one and two $-\text{CH}_2-$ groups between the carbonyl group and the ring, but at this stage the spectrum has reached its final form, as can be noticed by comparison with phenylheptyl chloride, both being identical in so far as the positions of the bands are concerned.

Similar conclusions are reached with respect to the absorption of the carbonyl group. Considerable alterations in the band positions occur until two CH_2 groups have been introduced between the aldehyde group and the benzene ring (A, C', D' in Fig. 3), or—in case of aliphatic aldehydes—until the carbon chain is two atoms long. With longer chains the carbonyl absorption spectrum remains practically unchanged. Thus the bands belonging to hydrocinnamic, propionic and heptyl aldehydes have identical positions within the experimental errors of their determination, but with benzaldehyde the carbonyl spectrum is shifted to the visible somewhat and the bands are narrower.

Purvis¹⁶ pointed out some time ago that the mutual influence of the groups on their respective spectra decreases as their spacing in the molecule increases. The present work confirms this conclusion and gives it a more precise illustration in the case of the aromatic aldehydes, which show that a very short interposed carbon chain suffices to make the vibrations and the electronic levels of the two groups quite independent of each other. Attention may be called to the fact that this distance of two $-\text{CH}_2-$ groups nearly coincides with the distance at which two such groups as carbonyl and halogens cease to affect appreciably their respective chemical properties in the straight chain compounds. The frequencies of the Raman lines attributed to vibration of certain atomic linkages also cease to be appreciably influenced by the size of the remainder of the molecule when the attached carbon chain is longer than two or three atoms.

In conclusion we wish to express our appreciation for the useful suggestions of Professor J. B. Conant, which have added greatly to the success of this work. We are much indebted to the Cyrus M. Walker Fund of the American Academy of Arts and Sciences for a grant which enabled us to purchase a spectrograph used throughout this work.

Summary

1. An apparatus is described for studying the ultraviolet absorption spectra in solution at low temperatures.
2. It is shown that aromatic rings are characterized by narrow absorption bands in solution at low temperatures, while the spectra of aliphatic groups remain diffuse.

¹⁶ Purvis, *J. Chem. Soc.*, **99**, 2318 (1911); **127**, 9 (1925). This phenomenon was also noticed by Baly and Collie, *ibid.*, **87**, 1332 (1905).

3. The mutual influence of the spectra of two such groups as the carbonyl and benzene rings extends through carbon chains not more than two atoms long. At greater distances in the molecule the spectra become entirely independent of each other.

THE SEPARATION AND DETERMINATION OF THE ALKALI METALS USING PERCHLORIC ACID. IV. THE PERCHLORATO-CHLOROPLATINATE METHOD FOR THE DETERMINATION OF POTASSIUM IN THE PRESENCE OF SODIUM

By G. FREDERICK SMITH AND A. C. SHEAD¹

RECEIVED OCTOBER 22, 1931

PUBLISHED MAY 7, 1932

Introduction

The separation and determination of potassium in the presence of sodium and lithium are most commonly carried out following the semi-extraction process of Fresenius.² Chloroplatinic acid is used to convert the aqueous solution of the mixed chlorides to the corresponding chloroplatinates, followed by the extraction of sodium and lithium chloroplatinates with ethyl alcohol to produce 80–85% of the latter. Many advantages result from the use of lithium chloroplatinate in place of chloroplatinic acid in the separation of potassium from sodium by the Fresenius process as shown by the present authors.³ Very distinct improvements in the perchlorate method in the separation of potassium from sodium have been developed as a result of previously published research from this Laboratory⁴ which seem to justify claims of superiority for the perchloric acid method over the chloroplatinate separation. In addition the use of perchloric acid facilitates the separation of sodium from lithium.⁵

The present paper demonstrates the advantage resulting from the simultaneous application of both perchloric and chloroplatinic acids to the separation and determination of potassium in the presence of sodium. Four distinct advantages result from this method of attack. Only enough chloroplatinic acid is employed to convert the potassium present to potas-

sium chloroplatinate. Following the Fresenius process the sodium must be converted to sodium chloroplatinate to take advantage of its solubility in alcohol. Since the ratio of chloroplatinic acid to sodium chloride, $\text{H}_2\text{PtCl}_6 \cdot 6\text{H}_2\text{O}/2\text{NaCl}$, is approximately 4.8, the saving in platinum is apparent. A second improvement is that the process is completely a precipitation process and not, as with the Fresenius scheme, a semi-extraction method. Occlusion of sodium salts by the precipitated potassium chloroplatinate is therefore minimized. A third improvement results from the weighing of a mixture of potassium and sodium perchlorates in place of the corresponding chlorides. Lastly, as already shown,² the precipitated potassium chloroplatinate is stable after drying at 300–350°. Any error resulting from the occlusion of solvent by the potassium chloroplatinate is thus eliminated and the time required for its drying greatly reduced.

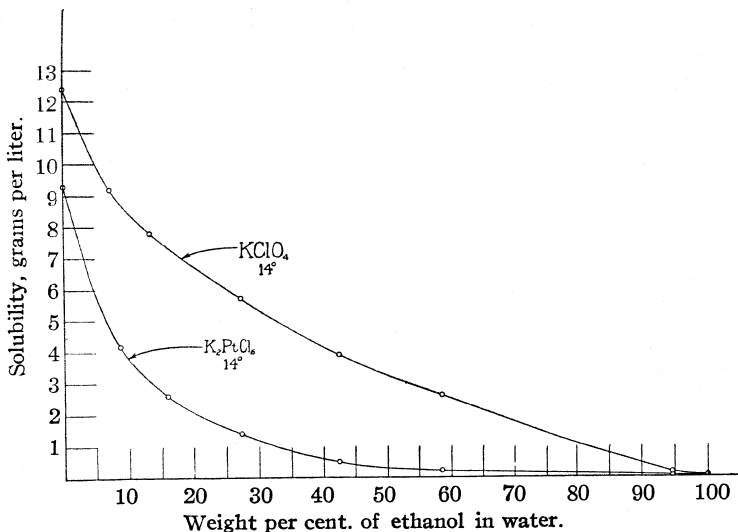

Fig. 1.—The solubility of K_2PtCl_6 and KClO_4 in alcohol–water solutions.

The Method

The process in brief is as follows.

The mixture of potassium and sodium chlorides obtained following the application of the J. Lawrence Smith method for decomposing an insoluble silicate (or a mixture of potassium and sodium nitrates) is converted to perchlorates by evaporation to dryness in a platinum dish or crucible with an excess of 70–72% perchloric acid. A 30-cc. Pyrex beaker may be used for the evaporation. The mixed perchlorates of potassium and sodium are dissolved by heating with a few cubic centimeters of water and again evaporated to dryness and heated for fifteen to thirty minutes at 350°, cooled and weighed. Anhydrous sodium perchlorate is faintly hygroscopic and the container plus the sample should be weighed covered.

The mixture of potassium and sodium perchlorates is dissolved in hot water (5 cc.

is sufficient for all ordinary samples) and 5 cc. of 95% or stronger ethanol is added and the solution warmed to just below the boiling point. Small portions of a 10% solution of chloroplatinic acid dissolved in ethanol are added until potassium chloroplatinate begins to precipitate. After digesting for a minute at just below the boiling point, the slow addition of precipitant is continued until all the potassium present is precipitated and the supernatant liquid is colored slightly yellow. Enough ethanol is added to make an 80–85% concentration of alcohol (not less than 30 cc. of alcohol in case 5 cc. of water was used) and the solution is digested for five minutes on an electric hot-plate with stirring at just below the boiling temperature. The precipitate and solution are cooled to room temperature, filtered, washed with 85% or stronger alcohol and the filtrate set aside for recovery of the slight excess of platinum used or for the direct determination of sodium. The filtering crucible and precipitate are dried for five minutes at 100–130° to remove the alcohol and finally for fifteen minutes at 300–350°, cooled and weighed. The potassium chloride originally present is calculated using the theoretical factor $2KCl/K_2PtCl_6 = 0.3067$.

Solubilities Involved in the Perchlorato-Chloroplatinate Process.—

Five cubic centimeters of water at 25° dissolves more than 10 g. of sodium perchlorate. The addition of alcohol in equal proportion does not greatly diminish this solubility. Lithium perchlorate is less soluble in water (2.98 g. in 5 cc.) but is much more soluble in ethyl alcohol than is sodium perchlorate. The comparative solubilities of potassium perchlorate and potassium chloroplatinate in various strengths of aqueous ethanol are given in Table I taken from the data of M. Pierrot.⁶

^a Solubility determinations in absolute alcohol: KClO₄ by Willard and Smith, *THIS JOURNAL*, **45**, 286 (1923). Solubility of K₂PtCl₆ calculated from accepted solubility data, 1 part of K₂PtCl₆ to 42,600 parts of ethanol.

From an examination of Table I it will be observed that the solubility of potassium chloroplatinate in water is very highly suppressed with increasing addition of ethyl alcohol as compared to the diminution in the solubility of potassium perchlorate under the same conditions. For solutions of equal parts of ethyl alcohol and water, 32.5 mg. of potassium perchlorate dissolves in 10 cc. This amount is increased approximately ten-fold at the boiling point of such solutions.

Potassium chloroplatinate is so slightly soluble in a 50% solution of ethyl alcohol in water (4 mg. in 10 cc.) that this concentration was chosen for the first addition of chloroplatinic acid. It was found that the temperature coefficient of increase in solubility of potassium chloroplatinate

⁶ Pierrot, *Compt. rend.*, **172**, 1041 (1921).

with increase in temperature is very slight. No need for excess of chloroplatinic acid for its common ion effect in reducing the solubility of potassium chloroplatinate is shown by the data. The addition of alcohol serves as an effective substitute when above 80%.

Preparation of Materials for Use in Testing the Accuracy of the Perchlorato-Chloroplatinate Process

Perchloric Acid.—Chemically pure 70-72% material distilled *in vacuo* and supplied by the G. Frederick Smith Chemical Company of Columbus, Ohio.

Potassium Chloride.—A portion of the same stock previously described² and demonstrated to be 100% pure. The fused product only was employed to eliminate the possibility of occluded moisture.

Sodium Chloride.—Samples were taken from a stock used in previous investigations published from this Laboratory. It had been repeatedly crystallized from water solution by the addition of gaseous hydrochloric acid with intermediate filtrations using centrifugal drainage. This preparation had been carried out by Dr. T. R. Ball, at present at Washington University, St. Louis, and was fused before weighings to eliminate the possibility of occluded moisture.

Chloroplatinic Acid.—Purchased from two different laboratory chemical supply houses and used as received.

Ethyl Alcohol.—Anhydrous alcohol as purchased in the market.

The Stability of Chloroplatinic Acid in Hot Alcoholic Solution.—The platinum in a hot alcoholic solution of chloroplatinic acid might be reduced to a lower stage of valence or to metallic platinum especially in the presence of reducing agents such as traces of aldehydes commonly present in alcohol. This possibility in the present method is practically eliminated for two reasons: first, the negligible increase in solubility of potassium chloroplatinate in hot as compared to cold alcohol solutions and second, the use of such a slight excess of chloroplatinic acid the latter being unnecessary either to convert sodium perchlorate to sodium chloroplatinate or for the common ion effect of excess precipitant. Samples of commercial anhydrous ethyl alcohol or the more common 95% alcohol either untreated or dried with lime followed by metallic calcium serve equally as well for this method. No determinations were lost because of the reduction of the chloroplatinic acid. Qualitative tests in all these types of alcohol showed traces of aldehyde or similar reducing agents.

Filtrates from the precipitation of potassium chloroplatinate containing sodium perchlorate, a slight excess of chloroplatinic acid and perchloric acid, when diluted further with water and allowed to digest for periods of thirty to sixty minutes at steam-bath temperature, precipitate their platinum completely as platinum black, a reduction conveniently employed in the direct determination of sodium. The filtrate from the potassium separation is so treated, the platinum filtered and washed and the sodium perchlorate determined by conversion to sulfate or by precipitation as sodium chloride following the method of Willard and Smith,⁵

Smith and Ross⁴ or by direct weight as sodium perchlorate as described in the next section.

The Conversion and Determination of Sodium Chloride as Sodium Perchlorate and its Stability at 350°.—By comparison of the two conversion factors, $\text{Na}_2\text{O}/2\text{NaCl}$ (0.5303) and $\text{Na}_2\text{O}/2\text{NaClO}_4$ (0.2531), weighing sodium as perchlorate instead of chloride is seen to carry a distinct advantage. Conditions for the correct determination of potassium as perchlorate have been clearly demonstrated by Smith and Ross.⁴ To avoid a contamination of potassium perchlorate by either occluded perchloric acid or moisture it must be dried at 350°. If sodium perchlorate can be shown to be stable at 350°, and suitable for weighing in this form, the mixture of sodium and potassium chlorides, frequently weighed after drying at 500°, can be weighed more satisfactorily in the form of perchlorate. This becomes more important since it is recognized that weighing mixtures of sodium and potassium chlorides following drying below their fusion temperature does not eliminate moisture. At the melting point these chlorides are too volatile to permit this treatment without prohibitive loss in weight. It is obvious that an indirect determination of sodium by difference is unsatisfactory for precise work. This practice is, however, commonly applied since the potassium determination is more important than that of sodium. The following experiments in the conversion of sodium chloride to perchlorate for final weighing are, therefore, described.

Weighed samples of pure sodium chloride were placed in a 30-cc. Pyrex beaker, dissolved in water and a small excess of pure 70–72% perchloric acid added. The samples were evaporated dry and the excess perchloric acid expelled. After heating during two and one-half hours in an electric muffle at 350°, the samples were cooled in a desiccator and weighed. In the latter operation a small watch-glass was used as a beaker cover. The results are shown in Table II. Sodium perchlorate crystallized from solution above 30° in the form of the anhydrous salt. A monohydrate is obtained by crystallizing from solution below 25°. The transition point

lies between these limits. It is easy, therefore, to favor the formation of the anhydrous salt and thus avoid its subsequent dehydration. The time of drying at 350° was purposely and unnecessarily extended to completely test the stability of sodium perchlorate. The melting point of sodium perchlorate is 482° .

The Determination of Potassium Chloride Using the Perchlorato-Chloroplatinate Process.—Samples of fused c. p. potassium chloride were weighed and dissolved in a few cc. of hot water in a 150-cc. beaker and converted to perchlorates by evaporation to dryness following the addition of 2 cc. of 70% perchloric acid. The samples were again dissolved by the addition of a few cc. of hot water and a second time evaporated dry and heated finally over a wire gauze to remove the last trace of occluded perchloric acid. The potassium perchlorate was then dissolved in a known volume of 50% ethyl alcohol, warming on the hot-plate nearly to the boiling point to limit the volume of solvent required. The samples were then precipitated as potassium chloroplatinate by the addition of reagent in several portions, with intermediate digestion for a minute on the hot-plate at just below the boiling point. The alcohol used to dissolve the chloroplatinic acid was sufficient to make a final alcohol concentration greater than 80%. Excess of precipitant is easily recognized by the appearance of a yellow color in the solution being precipitated. After five minutes' digestion during precipitation, the solutions and precipitates are cooled to room temperature and filtered using a platinum Monroe filtering crucible or a sintered quartz or glass filtering medium. The precipitates were washed with absolute alcohol and dried for twelve hours at 135° and finally for fifteen minutes at 350° , cooled, dried and weighed after each treatment. The chloroplatinic acid was added in weighed amount calculated to give a 10% excess and the excess platinum finally determined in the filtrates from the potassium separation as previously described. The results of these analyses in the absence of sodium are given in Table III.

It will be seen from the results of Table III that using a perchlorate solution, chloroplatinic acid precipitates potassium chloroplatinate equal in purity to that produced by lithium chloroplatinate in chloride solutions of potassium.³ The precipitated potassium chloroplatinate in the former case differs from the latter only in the formation of free perchloric acid in place of hydrochloric acid. The presence of hydrochloric acid is also thus proved to cause impure precipitates of potassium chloroplatinate by the original Fresenius method. Potassium chloroplatinate is not free from moisture after drying at 135° for twelve hours. Results obtained by dry-

ing for fifteen minutes at 350° , or to constant weight, show that precipitates dried at the lower temperature contain an average of 0.12% occluded solvent. Using chloroplatinic acid as above described, determinations of potassium, sodium and lithium from the same sample can be obtained, which is not true using lithium chloroplatinate. A distinctive feature incorporated in the present method lies in the fact that absolute alcohol can be employed to transfer and wash precipitates of potassium chloroplatinate. This is not possible by the Fresenius method because of the formation of sodium chloride from sodium chloroplatinate. Assuming an average case with 50 cc. of filtrate and washings, only 0.14 mg. of potassium chloride remains unprecipitated, corresponding to 0.08 mg. of potassium oxide. Drying precipitates of K_2PtCl_6 obtained by this method at 135° instead of 350° gives high results almost exactly compensating for the loss of potassium due to solubility.

The Separation of Potassium in Presence of Sodium from Solutions of their Perchlorates Using Chloroplatinic Acid.—Samples of mixtures of weighed portions of potassium and sodium chlorides were converted to perchlorates and prepared for the determination of potassium in exactly the same manner as described in connection with Table III. Potassium chloroplatinate was precipitated in the same manner using a 10% excess of chloroplatinic acid and the precipitates filtered and washed with absolute alcohol and dried for five minutes at 135° and for fifteen minutes at 350° . Results are given in Table IV, calculated from the weight of K_2PtCl_6 using the factor 0.3067 (theoretical).

It is seen from the results of Table IV that the separation of potassium chloroplatinate in the presence of sodium gives as accurate a potassium determination as obtained in Table III in the absence of sodium. The method is accurate to an average of approximately 0.15% in both cases. It is interesting to note that for the combined determinations of Table IV, less than 3 g. of $\text{H}_2\text{PtCl}_6 \cdot 6\text{H}_2\text{O}$ was required, whereas, if the original Fresenius method had been used, approximately 12 g. would have been necessary. The method is very rapid as compared to the original Fresenius process both because of the method of precipitation and the short time (twenty minutes) required to dry the precipitated K_2PtCl_6 . The precipitate is obtained as finely divided, light lemon-yellow colored crystals, which filter with ease and are very easily transferred from precipitating beaker to filtering crucible.

The Determination of Small Amounts of Potassium in Presence of Large Amounts of Sodium.—The present method requiring no conversion of sodium chloride to sodium chloroplatinate immediately suggests its application to the determination of small amounts of potassium in the presence of large amounts of sodium. This determination is generally possibly only in two operations. For example, the potassium present is concentrated by first precipitating as cobaltinitrite, $\text{K}_2\text{NaCo}(\text{NO}_2)_6$, followed by solution in hydrochloric acid and conversion to perchlorate.⁷ The present method was therefore examined in the determination of less than 0.5% of potassium in sodium chloride. The results obtained indicated the need for further investigation of this subject for reasons indicated by the following equation

As the amount of sodium perchlorate increases, the increase of perchlorate ions reaches sufficient magnitude to direct the reaction from right to left rather than the reverse and either the K_2PtCl_6 does not form at all or there is obtained a mixed precipitate of K_2PtCl_6 and KClO_4 . Successful separations of 5 mg. of potassium chloride in the presence of 2000 mg. of sodium chloride were attempted. More data are being collected on this subject. No difficulty in applying the present method is encountered as long as the ratio of potassium chloride to sodium chloride is 1%, using a one-gram sample or less of the mixed chlorides. The attempt to follow out the present procedure (slightly modified in some instances) gave results shown in Table V.

Results given in Table V are seen to be satisfactory only in the case of the first two determinations. The adjustment of the present method to analyses in the range used in this table is now being investigated. No violent reactions were met with in the study of this method. Owing to the relatively high concentration of water present in all solutions of the per-

chlorates in alcohol, no explosion is possible. Converting mixtures of sodium and potassium chlorides or nitrates to perchlorates by evaporation with perchloric acid to dryness is perfectly safe. This method should, therefore, not fail of application because of prejudice from this source.

Summary

1. Potassium and sodium in the form of their perchlorate solution in 50% ethyl alcohol and water mixture may be precipitated by the addition of an alcoholic solution of chloroplatinic acid and the potassium quantitatively separated in the form of potassium chloroplatinate.

2. Since sodium perchlorate is soluble in alcohol, only enough chloroplatinic acid is required to react with the potassium, thus effecting a saving in cost.

3. The method gives precipitates of theoretical composition stable upon drying at 350° .

4. Stronger alcoholic solutions may be used by this method than are possible starting with the mixed alkali chlorides. Anhydrous alcohol can be used to wash the precipitate.

5. Sodium and potassium can be weighed with advantage as mixed perchlorates after heating at 350° .

6. This is a precipitation process, not a semi-extraction method, and, therefore, more efficient.

7. Platinum is recovered from the filtrates by simply digesting for thirty to sixty minutes at $80-90^\circ$. The direct determination of sodium is thus facilitated.

THE HYDROGEN, CHLORINE, HYDROGEN CHLORIDE EQUILIBRIUM AT HIGH TEMPERATURES

BY W. F. GIAUQUE AND ROY OVERSTREET

RECEIVED OCTOBER 28, 1931

PUBLISHED MAY 7, 1932

The experimental investigation of chemical equilibria presents many difficulties. For gaseous equilibria nearly all of these are avoided when spectroscopic data are available for such determinations. Since the energy levels of molecules are independent of temperature the troublesome matters of temperature control and accurate measurements are eliminated. Moreover, even the higher energy levels may be excited for observation under conditions where the gas remains at conservative temperatures. Questions as to whether equilibrium has been reached, or if reached been shifted by quenching, do not enter. The energy levels of gas molecules at moderate pressures are independent of equilibrium conditions and in fact are usually best investigated under conditions where the gases exist separately.

The necessary equations and an example of their application have been given previously.¹

$$\frac{F^\circ - E_0^\circ}{T} = -\frac{3}{2} R \ln M - \frac{5}{2} R \ln T + R \ln P - C - R \ln R - R \ln Q \quad (1)$$

where $F^\circ = H^\circ - TS^\circ$ and the various symbols have their usual significance, the superscript referring to the standard state. E_0° is the energy of the molecules when all are in the lowest level ($T = 0^\circ\text{K.}$). $Q = \sum p e^{-\epsilon/kT}$ the summation being taken over all energy levels that are occupied by appreciable numbers of molecules. p is the *a priori* probability of the level concerned. The values of all constants used are those given by the "International Critical Tables." $R = 1.9869$ calories per mole per degree. $C + R \ln R = -7.267$ calories per mole per degree.

The amount of calculation involved in the evaluation of Q by means of summing the individual Boltzmann terms is very considerable except for the lighter molecules and low temperatures. Thus one of the principal purposes of this paper is to discuss an approximation method by which Q may be evaluated without loss in accuracy.

The rotational levels of a diatomic molecule are usually represented with a high degree of accuracy by the expression

$$\epsilon_r = Bm^2 + Dm^4 + Fm^6 + \dots \quad (2)$$

where $m = j + 1/2$ and j is the rotational quantum number. The terms Dm^4 , Fm^6 , etc., arise from the fact that molecules are not rigid. The effect of these terms becomes considerable at large values of m .

$$p = 2j + 1 = 2m$$

¹ (a) Giauque, *THIS JOURNAL*, **52**, 4808 (1930); (b) *ibid.*, **52**, 4816 (1930).

Then

$$\begin{aligned}
 Q &= \sum 2me[-hc(Bm^2 + Dm^4 + Fm^6 + \dots)]/kT \\
 &= \sum 2me^{-Bhcm^2/kT} \cdot e^{-Dhcm^4/kT} \cdot e^{-Fhcm^6/kT} \dots \\
 &= \sum 2me^{-Bhcm^2/kT} \left[1 - \frac{Dhcm^4}{kT} + \frac{1}{2} \left(\frac{Dhcm^4}{kT} \right)^2 \dots \right] \\
 &\quad \left[1 - \frac{Fhcm^6}{kT} + \frac{1}{2} \left(\frac{Fhcm^6}{kT} \right)^2 \dots \right] \\
 &= \sum 2me^{-Bhcm^2/kT} \left[1 - \frac{Dhcm^4}{kT} - \frac{Fhcm^6}{kT} + \frac{1}{2} \left(\frac{Dhcm^4}{kT} \right)^2 + \right. \\
 &\quad \left. \left(\frac{Dhcm^4}{kT} \right) \left(\frac{Fhcm^6}{kT} \right) + \frac{1}{2} \left(\frac{Fhcm^6}{kT} \right)^2 \dots \right] \quad (3)
 \end{aligned}$$

As a first approximation integration may be substituted for summation, thus

$$\begin{aligned}
 Qe^{-\epsilon_0hc/kT} &= \int_0^\infty 2me^{-Bhcm^2/kT} dm - \int_0^\infty \frac{2Dhc}{kT} m^5 e^{-Bhcm^2/kT} dm - \\
 &\quad \int_0^\infty \frac{2Fhc}{kT} m^7 e^{-Bhcm^2/kT} dm + \int_0^\infty \left(\frac{Dhc}{kT} \right)^2 m^9 e^{-Bhcm^2/kT} dm + \\
 &\quad \int_0^\infty 2DF \left(\frac{hc}{kT} \right)^2 m^{11} e^{-Bhcm^2/kT} dm \dots \quad (4)
 \end{aligned}$$

The factor $e^{-\epsilon_0hc/kT}$ which accompanies Q is due to the fact that the integrals assume zero m as the reference point of energy whereas the reference point which we are to use is one in which $m = 1/2$. This is done since we believe it is preferable to confine our calculations to observable states.

Integrating

$$\begin{aligned}
 Qe^{-\epsilon_0hc/kT} &= \frac{kT}{Bhc} \left[1 - 2! \frac{D}{B^2} \left(\frac{kT}{hc} \right) - 3! \frac{F}{B^3} \left(\frac{kT}{hc} \right)^2 \right. \\
 &\quad \left. + \frac{4!}{2!} \frac{D^2}{B^4} \left(\frac{kT}{hc} \right)^2 + 5! \frac{DF}{B^5} \left(\frac{kT}{hc} \right)^3 \dots \right] \quad (5a)
 \end{aligned}$$

However, as is well known, the substitution of an integral for the summation of discrete terms introduces a small error. A treatment of this problem for the case of rigid diatomic molecules has been given by Mulholland² and by Sutherland.³

They find

$$\sum 2me^{-Bhcm^2/kT} = \frac{kT}{Bhc} \left[1 + \frac{Bhc}{12kT} \dots \right] \quad (6)$$

Investigation of the other integrals which are substituted for summations in Equation 4 shows that no appreciable error is introduced by this procedure. For example, it may be shown that

$$\sum 2m^5 e^{-Bhcm^2/kT} = \int_0^\infty 2m^5 e^{-Bhcm^2/kT} dm + \frac{31}{4032} + = \frac{2}{B^3} \left(\frac{kT}{hc} \right)^3 + \frac{31}{4032} + \quad (7)$$

in which the correction term may be shown to be negligible.

² Mulholland, *Proc. Camb. Philos. Soc.*, **24**, 280 (1928).

³ Sutherland, *ibid.*, **26**, 402 (1930).

The effect of the correction $(B/12) (hc/kT)$ is small compared to the effect of molecular stretching. Applying the above correction to Equation 5a we obtain

$$Qe^{-\epsilon_0 hc/kT} = \frac{kT}{Bhc} \left[1 + \frac{B}{12} \left(\frac{hc}{kT} \right) - 2! \frac{D}{B^2} \left(\frac{kT}{hc} \right) - 3! \frac{F}{B^3} \left(\frac{kT}{hc} \right)^2 + \frac{4! D^2}{2! B^4} \left(\frac{kT}{hc} \right)^2 + 5! \frac{DF}{B^5} \left(\frac{kT}{hc} \right)^3 \dots \right] \quad (5b)$$

This equation leads to values of Q which are more accurate than our requirement of 0.001 calorie per degree per mole in F/T . Equation 5a may be used to obtain the first and second derivatives of Q which are required for the calculation of energy and entropy and for heat capacity, respectively.

Sutherland used Q and its derivative, from Equation 6, to compute the entropy of nitric oxide by a formula which will be mentioned later. His calculation, which was made only for the boiling point temperature where the assumption of rigidity is a fair approximation, gave a result different by 0.03 E. U. from that obtained by Johnston and Giauque,⁴ who used the more accurate summation method. Since we could see no reason why Sutherland's method should not be accurate, a recalculation was made using his method and assumption and we find agreement with the value of Johnston and Giauque.

A comparison of the results of actual summations, which had previously been made, and values from the application of Equation 5a to hydrogen chloride is given in Table I, which also shows the relative importance of the corrections.

TABLE I

COMPARISON OF Q VALUES FOR HCl^{35} BY SUMMATION AND APPROXIMATION METHODS

T	$\frac{hc\epsilon_m - 1/2}{e^{kT}}$	$\times \frac{kT}{Bhc} \times \left(1 + \frac{Bhc}{12 kT} - \frac{D}{B^2} \frac{kT}{hc} - \text{etc.} \right)$	$Q \text{ approx.}$ $n = 1/2$	$Q\Sigma$ $n = 1/2$

Before proceeding to the calculation of the free energy it is necessary to consider the manner in which such calculations are affected by the existence of isotopic molecules. It has long been recognized that the thermodynamic consequences of isotopes affect the reactants and products concerned in a chemical reaction at or above ordinary temperature in such a way as virtually to cancel the free energy effect. Nevertheless, it has seemed worth while to present figures showing the actual magnitude of such effects. Usually, accurate band spectra data apply to the predominant isotopic molecule. However, this is sufficient since the corresponding levels for the others may be easily and accurately calculated from those of the predominant one. The method of making this calculation

⁴ Johnston and Giauque, *THIS JOURNAL*, 51, 3194 (1929).

tion has been carefully considered by Mulliken.⁵ Since the law of force binding the molecule is independent of the particular isotope considered, it may be shown that the constant B in Equation 2 is inversely proportional to the reduced mass μ where $\frac{1}{\mu} = \frac{1}{M_1} + \frac{1}{M_2}$. D varies as μ^{-2} and F as μ^{-3} . In the case of vibrational levels where

$$\epsilon_v = (v + \frac{1}{2})\omega_e + (v + \frac{1}{2})^2 x_e\omega_e + (v + \frac{1}{2})^3 y_e\omega_e \quad (8)$$

$\mu^{-1/2}$ occurs in each term to the same power as $(v + \frac{1}{2})$. Thus the first term varies as $\mu^{-1/2}$, the second as μ^{-1} , etc.

The Free Energy of Diatomic Chlorine.—For the Cl_2 molecule the calculation of the Q function was made for the Cl_2^{35-35} molecule and the values for the Q 's of Cl_2^{35-37} and Cl_2^{37-37} were then obtained by the application of correction factors based on the above equations. We shall not give the details of the above calculation as it should not be necessary to duplicate it for other cases when the negligible extent to which isotopic differences affect the distribution of atoms is made apparent.

The molecular constants of the chlorine molecule are given in Table II. They were taken from the work of Elliott.⁶

B_v and D_v may be represented by the expressions

$$\begin{aligned} B_v &= B_e + \alpha(v + \frac{1}{2}) \\ D_v &= D_e + \beta(v + \frac{1}{2}) \end{aligned}$$

In computing the isotope effect α varies as $\mu^{-1/2}$ and β varies as $\mu^{-1/2}$.

TABLE II

CONSTANTS IN THE ENERGY EQUATION OF THE CHLORINE 35-35 MOLECULE IN CM.^{-1}

Normal State:

$$\begin{aligned} \epsilon_v &= 564.9(v + \frac{1}{2}) - 4.0(v + \frac{1}{2})^2 \\ B_v &= 0.2438 - 1.7 \times 10^{-3}(v + \frac{1}{2}) \\ D_v &= -1.815 \times 10^{-7} - 3.1 \times 10^{-9}(v + \frac{1}{2}) \\ F_0 &= -9.4 \times 10^{-14} \end{aligned}$$

First Electronic Level:

$$\begin{aligned} \epsilon_0 &= 17657.7 \\ \epsilon_v &= 261.1(v + \frac{1}{2}) - 5.42(v + \frac{1}{2})^2 \end{aligned}$$

The values given in heavy type have been observed; the others were calculated.

The electronic level at 17657.7 cm.^{-1} has been classified as a $^3\pi$ level by Mulliken.⁷

With λ type doubling there are six electronic series of rotation-vibration

⁵ Mulliken, *Phys. Rev.*, **25**, 119 (1925).

⁶ Elliott, *Proc. Roy. Soc. (London)*, [A] **127**, 638 (1930).

⁷ Mulliken, *Phys. Rev.*, **36**, 699, 1440 (1930); **37**, 1412 (1931).

levels. Some small doubt remains concerning the $^3\pi$ classification but the matter is of almost negligible importance in the present calculations since at 3000°K. the total contribution to $(F^\circ - E_0^\circ)/T$ is only 0.010 and is but 0.002 calorie per degree per mole at 2500°K. In considering the isotope effect we will make use of the reaction

From Equation 8 the zero point vibrational energy for each of the three molecules can be calculated. They were found to be 800.46, 778.56 and 789.60 cm^{-1} , respectively. While the absolute accuracy of these values is not as great as the figures indicate, the relative accuracy is significant and thus the value of $\Delta E_0^\circ = 0.18 \text{ cm}^{-1}$ is reliable. Similarly, in obtaining the value of $(F^\circ - E_0^\circ)/T$ particular attention was paid to relative accuracy, thus giving a more reliable value of $\Delta(F^\circ - F_0^\circ)/T$ than can be obtained from our tables, to be given later.

The value of $\Delta(F^\circ - E_0^\circ)/T$ for 298.1°K. is -2.7549 . Combining this with $\Delta E_0^\circ/T$ we find

$$K = \frac{[\text{Cl}_2^{35-37}]^2}{[\text{Cl}_2^{35-35}][\text{Cl}_2^{37-37}]}$$

from the equation $\Delta F^\circ/T = -R \ln K = -2.7549 + 0.0006, K_{298.1} = 3.9997$. If the isotopes of chlorine were without preference as to the type of diatomic molecule formed, the value of K would be exactly 4. It may be of interest to note that at the absolute zero all of the chlorine atoms would be combined into molecules of Cl_2^{35-35} and Cl_2^{37-37} type since $R \ln K = -\Delta E_0^\circ/O = -\infty$ for the above reaction. By the methods given above one could readily compute the manner in which the equilibrium would shift with decreasing temperature to approach this interesting condition. However, a knowledge of the nuclear spin of Cl^{37} would be necessary.

Since the calculated value of K agrees with 4 within the limits of accuracy of our tables it is evident that we need not consider the effect further.

In making the above calculation the effect of nuclear spin has been neglected since it has been proved by Gibson and Heitler⁸ that cancellation of this effect occurs in such cases.

In preparing the tables to be given below we have therefore not included in the free energy the effect due to the mixing of isotopes nor the effect due to the nuclear spins which the isotopes may possess. Before proceeding further there is a point which will need special discussion. The Cl_2^{35-37} molecules have twice as many states as the Cl_2^{35-35} or Cl_2^{37-37} molecules and in considering the reaction $\text{Cl}_2^{35-35} + \text{Cl}_2^{37-37} = 2\text{Cl}_2^{35-37}$ we have recognized this fact in computing the $\Delta F/T$ given above. However, in calculating the equilibrium constant we have taken the standard state of each of the three kinds of molecules as that of unit fugacity. While

⁸ Gibson and Heitler, *Z. Physik*, **49**, 465 (1928).

this was desirable for our investigation of the isotope effect, we wish to place the final calculations on the basis of a standard state which consists of the existing mixture of isotopic chlorine molecules in the ideal gas state at a total pressure of one atmosphere. This is in order to be consistent with ordinary thermodynamic procedure. In other words, we are going to agree to ignore the existence of isotopic molecules. Having done this we have imposed the requirement that we must not use any molecular quantum states which owe their origin to the presence of isotopes. We have in mind the fact mentioned above, that Cl_2^{35-37} has twice the number of rotational states possessed by the homopolar chlorine molecules. The Q obtained by summing over all states of the Cl_2^{35-37} molecule must be divided by 2 before computing the contribution which this molecule makes to the total Q of the mixture.

The necessity of the above procedure may be made clearer by considering the reactions

Neglecting the small effects due to the different masses it is evident that the equilibrium constant $K_a = K_c = 2 K_b$, due to the double statistical weight of Cl_2^{35-37} . In this calculation the standard state of each gas is the ideal gas at unit pressure. However, although K_b is but one-half of K_a or K_c , it may be seen that the three chlorine molecules will dissociate to the same extent. If we consider a total pressure of Cl atoms amounting to one atmosphere in each case, the partial pressures of Cl^{35} and Cl^{37} in case b will be one-half atmosphere each. This factor of two just balances the double statistical weight of the Cl_2^{35-37} molecules. In other words, the increased entropy due to the double number of states in Cl_2^{35-37} , namely, $R \ln 2$, is just balanced by the entropy of mixing of the two different species of atoms resulting from its dissociation. Thus if the existence of the isotopic mixture is to be ignored, it is evident that the double weight of Cl_2^{35-37} must also be ignored. Similar consideration shows that in molecules which have a number of equivalent positions occupied by a given element, all statistical weight should be neglected which is created by the presence of two or more isotopes occupying otherwise equivalent positions.

It seems necessary to compare the self-consistent results of the above procedure with those obtained in the ordinary application of the third law of thermodynamics. We may state at once that they are consistent and may be combined with them. In fact, the above method of calculation is practically dictated by this consideration of convenience. As an example let us consider the Cl_2^{35-37} molecule in the solid state. The figure axis of the molecule will point in some direction specified by the crystal structure. However, the crystal will show no appreciable prefer-

ence as to which isotope is on a given end of the figure axis. This factor of two which is ignored by heat capacity measurements to the lowest available temperatures is just that which is concerned in the double statistical weight of the gas molecule which is to be ignored in our calculations. It has previously been pointed out⁹ that in accordance with the third law, the positions of the various isotopes in the crystal become ordered so as to remove the uncertainty referred to above as the absolute zero is approached under equilibrium conditions. However, while this point is of theoretical interest in connection with the exact truth of the third law, it was also pointed out that the required conditions of sufficiently low temperature and attainment of equilibrium are not present in the ordinary application of this law.

The above considerations may be applied with the same results to more complicated molecules in the solid state.

There are, however, two respects in which we shall not ignore the isotope effect. First, the several isotopic molecules have slightly different molecular constants and the value of a given thermodynamic property for the substance as a whole will be obtained by adding the contributions of the several molecules, each in proportion to its abundance. Second, the double statistical weight of the Cl_2^{35-37} molecule is considered in obtaining the relative abundance of these molecules for computing the above average.

In this connection it is very interesting to compare the ordinary method of calculating abundance which assumes that each atom has equal chance with the method of observing the number of molecular states in determining the statistical weight of each kind of molecule. The chance of withdrawing two Cl^{35} atoms in succession from a mixture of the isotopic atoms is equal to $N_{\text{Cl}^{35}}^2$, where $N_{\text{Cl}^{35}}$ is its mole fraction. The chance of obtaining a Cl^{35} and a Cl^{37} atom in two successive draws is $2 \times N_{\text{Cl}^{35}} N_{\text{Cl}^{37}}$ since there is equal chance for each order of drawing Cl^{35} , Cl^{37} or Cl^{37} , Cl^{35} . When the statistical weight is calculated from the number of observed states of the molecules it is seen that the double weight of the Cl_2^{35-37} molecule compared to Cl_2^{35-35} is given by the double number of rotational states. Were it not for the fact that the nuclear spin of chlorine causes all of the energy levels to have some representatives, the Cl_2^{35-35} bands would have only one-half as many lines as the Cl_2^{35-37} bands. This phenomenon has been observed in the case of O_2^{16-16} and O_2^{16-18} .

In the case of chlorine the relative percentages of isotopes 35 and 37 are 75.9 and 24.1%, respectively. These values are obtained from the atomic weight 35.457 combined with the values 34.975 and 36.972 for the individual isotopes. These latter values were obtained from the work of Aston and are corrected on the basis of Mecke and Childs'¹⁰ determination

⁹ Giaque and Johnston, *THIS JOURNAL*, 50, 3221 (1928).

¹⁰ Mecke and Childs, *Z. Physik*, 68, 362 (1931).

of the relative abundance of the oxygen isotopes. From the above figures it is found that chlorine gas is 57.6% Cl_2^{35-35} , 36.6% Cl_2^{35-37} and 5.8% Cl_2^{37-37} .

The values of $(F^\circ - E_0^\circ)/T$ are given in Table IV. As mentioned above, the value of $Q_{\text{Cl}_2^{35-37}}$ has been reduced by a factor of two.

The Free Energy of Hydrogen Chloride

The free energy of hydrogen chloride was calculated in the manner used for chlorine except that the summation method was used to 2000°K. This was done only for comparing the two methods of calculation as previously discussed.

The constants used for hydrogen chloride are those given by Kemble.¹¹ These have been expressed in terms of the more recent nomenclature and are collected in Table III.

TABLE III
CONSTANTS IN THE ENERGY EQUATION OF HCl^{35} IN Cm.^{-1}

$$B_v = 10.6080 - 0.3281(v + \frac{1}{2}) + 0.01195(v + \frac{1}{2})^2$$

$$D_v = -0.000533 + 0.0000121(v + \frac{1}{2})$$

$$F_e = 1.46 \times 10^{-8}$$

$$\epsilon_v = 2994.33(v + \frac{1}{2}) - 53.58(v + \frac{1}{2})^2$$

From the above data the free energy values for hydrogen chloride were calculated. As in the case of chlorine the effects of nuclear spin and isotopic mixing have been neglected but the free energies of the two isotopic molecules were calculated and have been given their proportionate weight in obtaining the final values. The free energy values for the two kinds of hydrogen chloride and the mixture are given in Table IV.

The Reaction $\frac{1}{2} \text{H}_2 + \frac{1}{2} \text{Cl}_2 = \text{HCl}$.—We are now prepared to consider the reaction $\frac{1}{2} \text{H}_2 + \frac{1}{2} \text{Cl}_2 = \text{HCl}$. Combining the free energy values for chlorine and hydrogen chloride given in Table IV with the free energy of hydrogen^{1b} the $\Delta(F^\circ - E_0^\circ)/T$ for the above reaction is found. The $(F^\circ - E_0^\circ)/T$ values used for hydrogen are those obtained when the nuclear spin is ignored since this has also been done in the preparation of the present tables.

In Table V the values of $\Delta(F^\circ - E_0^\circ)/T$ are given along with values of $\Delta F^\circ/T$ and their resulting equilibrium constants.

In making these calculations the ΔE_0° used was obtained by combining the free energy of the reaction at 25° with the value of $\Delta(F^\circ - E_0^\circ)/T$ at this temperature. This free energy has been given by Randall and Young¹² as $\Delta F_{298.1} = -22,741$ calories. Since this value has been obtained from electromotive force measurements, the resulting value of $\Delta E_0^\circ = -21,984$ calories per mole is very reliable.

¹¹ Kemble, *J. Opt. Soc. Am.*, **12**, 1 (1926).

¹² Randall and Young, *THIS JOURNAL*, **50**, 989 (1928).

The equilibrium constants given in Table V are not sufficient to give the extent to which hydrogen chloride will dissociate at high temperatures where the reaction is complicated by the dissociation of chlorine and of hydrogen. The dissociation constant for hydrogen has been previously given^{1b} while that of chlorine may be calculated. For this we shall need the free energy of atomic chlorine which we shall now obtain.

The Free Energy of Atomic Chlorine.—The only electronic levels of the chlorine atom which need be considered for the present calculation are the $^2P_{1/2}$ zero state and the $^2P_{3/2}$ level which Kiess and DeBruin¹³ have found to be 881 cm.⁻¹ above.

In Table V the values of $(F^\circ - E_0^\circ)/T$ are given for the isotopic mixture of atomic chlorine gas. As in the case of molecular chlorine and hydrogen chloride these values do not include the effect of nuclear spin or of isotopic mixing.

The Dissociation of Chlorine.—From the data in Table IV the $\Delta(F^\circ - E_0^\circ)/T$'s for the reaction $\text{Cl}_2 = 2\text{Cl}$ are obtained and given in Table V. These values, when combined with $\Delta E_0^\circ/T$, give $\Delta F^\circ/T$, which is also given in Table V.

The value of ΔE_0° has been taken from Elliott's⁶ revision of Kuhn's¹⁴ determination of this quantity from the band spectrum of chlorine. The value 56,900 calories per mole is in good agreement with the value 57,000 given by Wohl and Kadow¹⁵ on the basis of explosion experiments.

If the accepted value $\Delta E_0^\circ = 56,900$ calories per mole is altered by further investigation a very simple calculation will permit revision of the values given for $\Delta F^\circ/T$ and K in Table V.

Löwenstein¹⁶ has measured the dissociation of hydrogen chloride by passing this gas through a platinum tube and observing the equilibrium pressure of hydrogen which diffused through the wall. His one observation at 1810°K. gave 0.274% dissociation. However, this value was calculated without making a correction for the dissociation of chlorine or of hydrogen. Löwenstein found an equilibrium pressure of 1.03 mm. of hydrogen when the total pressure was 751.2 mm. At 1810°K. and a total pressure of 1.03 mm. of hydrogen, the pressure of diatomic hydrogen is 1.018 mm. and that of atomic hydrogen 0.0115 mm., a very small correction. However, the error made by neglecting the dissociation of chlorine is more serious. Instead of 1.03 mm. pressure of Cl_2 , calculation shows this pressure to be 0.044 mm. and the pressure of monatomic chlorine to be 1.96 mm.

From the above corrections to Löwenstein's values we calculate $K_{1810^\circ} = [\text{HCl}]/[\text{H}_2]^{1/2} [\text{Cl}_2]^{1/2} = 3.54 \times 10^3$, whereas by interpolation in Table IV

The values given in heavy type are calculated by means of Equations 1 and 5b. The others were obtained by interpolating differences between the directly calculated $(F^\circ - E_0^\circ)/T$'s and approximate values calculated by assuming a constant moment of inertia and harmonic oscillation. The values obtained by combination of the interpolated differences with approximate values calculated for the intermediate temperatures gave results of practically the same reliability as those calculated directly.

3000	1.546	8.874	8.702×10	27.956	-8.989

we find the reliable value 1.099×10^3 . The disagreement of the two values is very surprising. In order to bring agreement it would be necessary to assume a value for the heat of dissociation of chlorine which is about 15,000 cal./mole greater than the reliable one which we have used above.

It appears necessary to conclude that Löwenstein's single observation was subject to some very large error.

The Heat of Formation of Hydrogen Chloride.—From the equation^{1a}

$$\Delta H^\circ = \Delta E_0^\circ + \Delta \left[\frac{5}{2} RT + RT^2 \frac{d \ln Q}{dT} \right] = \Delta E_0^\circ + \Delta \left[\frac{5}{2} RT + N \frac{\sum \epsilon p e^{-\epsilon/kT}}{\sum p e^{-\epsilon/kT}} \right] \quad (9)$$

A very reliable value for the heat of formation of gaseous hydrogen chloride from hydrogen and chlorine may be obtained. This calculation could be made for any temperature but we shall obtain only the value for $\Delta H_{298.1}^\circ$ which seems of the greatest utility.

For the equilibrium mixture of ortho and para hydrogen the value of $\frac{5}{2} RT + RT^2 \frac{d \ln Q}{dT}$ is^{1b} 2023.20 calories per mole at 298.1°K. For chlorine the value of $\frac{5}{2} RT + RT^2 \frac{d \ln Q}{dT} = 2193.69$ calories per mole at 298.1°K. This value was obtained by properly weighting the individual contributions of the three isotopic molecules as mentioned above. The effect of ortho and para states could be ignored in this calculation due to the essential establishment of the high temperature limiting equilibrium even at temperatures far below 298.1°K. The corresponding effect in hydrogen^{1b} was only 0.01 calorie per mole at 298.1°K. For hydrogen chloride

$$\frac{5}{2} RT + RT^2 \frac{d \ln Q}{dT} = 2064.30$$

Thus for the reaction $\frac{1}{2} \text{H}_2 + \frac{1}{2} \text{Cl}_2 = \text{HCl}$, $\Delta H = -21,984 - 44 = -22,028$ calories per mole. The only appreciable inaccuracy in this value is the same as that in the free energy change given by Randall and Young.¹² This is probably reliable to ± 10 calories per mole.

It is of interest to note that both Thomsen and Berthelot found $\Delta H = -22,000$ calories per mole for the above reaction.

The Entropy of Hydrogen Chloride and of Chlorine.—From the equation

$$S = \frac{3}{2} R \ln M + \frac{5}{2} R \ln T - R \ln P - 2.300 + R \ln Q + RT \frac{d \ln Q}{dT} \quad (10)$$

the entropies of HCl^{35} and HCl^{37} were calculated.

At 298.1°K. and a pressure of one atmosphere HCl^{35} , $S_{298.1} = 44.619$ calories per degree per mole. HCl^{37} , $S_{298.1} = 44.783$ E. U. Thus for the existing mixture HCl , $S_{298.1} = 44.658$ E. U. This value does not include the entropy of isotopic mixing nor that due to nuclear spin. The value obtained for $S_{298.1}$, HCl from low temperature heat capacity measurements¹⁷ is 44.5 E. U.

For chlorine Cl_2^{35-35} , $S_{298.1} = 53.235$ E. U.; Cl_2^{35-37} , $S_{298.1} = 53.389$ E. U. (one-half of states used on account of isotope effect); Cl_2^{37-37} , $S_{298.1} = 53.543$ E. U. Thus Cl_2 , $S_{298.1} = 53.310$ E. U. This value may be compared with

¹⁷ Giauque and Wiebe, *THIS JOURNAL*, 50, 101 (1928).

one calculated by combining the temperature coefficient of the cell $\text{Ag} + \frac{1}{2}\text{Cl}_2 = \text{AgCl}$, determined by Gerke¹⁸ with the entropies of silver chloride and silver obtained from the third law of thermodynamics. A very accurate value of the entropy of silver chloride has recently been made available through the work of Eastman and Milner¹⁹ soon to be published. AgCl , $S_{298.1} = 22.97 \pm 0.07$ E. U. Combining this with a preliminary determination of the entropy of silver by P. F. Meads and one of us, that is, Ag , $S_{298.1} = 10.01$ E. U. and $\Delta S = -13.73$ E. U., $S_{298.1}$, Cl_2 is found to be 53.38 E. U., which compares very well with the spectroscopic value of 53.310 E. U.

In the above calculations we have gone into considerable detail in investigating the isotope effect. We have had in mind from the beginning that while the presentation of such an example was desirable, the main object was to eliminate the necessity of such detail in future calculations.

It is therefore suggested that in considering the thermodynamic properties of substances which consist of two or more isotopic molecules, the following procedure be adopted. Instead of using the several energy levels of the various isotopic molecules an average set of energy levels may be constructed by giving the proper weight to each isotopic molecule present. When the levels can be represented by equations, the above procedure requires only the computation of an average set of constants.

This procedure assumes that the isotopes have reached their limiting high temperature equilibrium. That this is reached with sufficient accuracy for calculations to 0.001 calorie per degree per mole, far below ordinary temperatures, has been demonstrated above.

Summary

An approximation method which permits the calculation of free energy from the energy levels of diatomic molecules without the necessity of summing the Boltzmann factors for the individual rotational energy levels has been given. The method considers the effects of molecular distortion due to rotation of the non-rigid molecules, without loss in accuracy.

The manner in which the presence of various isotopic molecules affects such calculations is discussed. It is shown that equilibrium in the reaction $\text{Cl}_2^{35-35} + \text{Cl}_2^{37-37} = 2\text{Cl}_2^{35-37}$ is entirely to the left at 0°K.

The values of $(F^\circ - E_0^\circ)/T$ for Cl_2^{35-35} , Cl_2^{35-37} , Cl_2^{37-37} and the equilibrium mixture have been tabulated for ready interpolation from 250°K. to 3000°K.

Similar tables have been prepared for HCl^{35} , HCl^{37} and for Cl^{35} , Cl^{37} and their respective existing mixtures.

The values of $\Delta F^\circ/T$ for the reaction $\frac{1}{2}\text{H}_2 + \frac{1}{2}\text{Cl}_2 = \text{HCl}$ have been

¹⁸ Gerke, *THIS JOURNAL*, **44**, 1684 (1922).

¹⁹ Personal communication.

presented so that values over the range 250 to 3000°K. may be easily obtained by interpolation.

The $\Delta F^\circ/T$ for $\text{Cl}_2 = 2\text{Cl}$ has been tabulated to 3000°K.

The change in heat content for the reaction $\frac{1}{2}\text{H}_2 + \frac{1}{2}\text{Cl}_2 = \text{HCl}$ has been accurately determined from the electromotive force of the hydrogen-chlorine cell and spectroscopic data. The value found was $\Delta H_{298.1} = -22,028$ calories per mole.

The entropies of hydrogen chloride and of chlorine have been calculated.

$$\text{HCl}^{35}, S_{298.1} = 44.619 \text{ E. U.}$$

$$\text{HCl}^{37}, S_{298.1} = 44.783 \text{ E. U.}$$

$$\text{HCl}(\text{mixture}), S_{298.1} = 44.658 \text{ E. U.}$$

$$\text{Cl}_2^{35-35}, S_{298.1} = 53.235 \text{ E. U.}$$

$$\text{Cl}_2^{35-37}, S_{298.1} = 53.389 \text{ E. U.}$$

$$\text{Cl}_2^{37-37}, S_{298.1} = 53.543 \text{ E. U.}$$

$$\text{Cl}_2 (\text{equilibrium mixture}), S_{298.1} = 53.310 \text{ E. U.}$$

The entropy effect of nuclear spin (unknown for Cl^{37}) has purposely been omitted from the above values so that they may be used in combination with those obtained from low temperature heat capacity measurements. The entropy of mixing in the isotopic solutions and the entropy due to the presence of two isotopes in the same molecule have been eliminated for the same reason.

It is suggested that thermodynamic properties of substances which consist of two or more isotopic molecules be based on an average set of energy levels, computed by weighting the several values in proportion to the abundance of the respective molecules. The effect of the reduction in the number of levels by molecular symmetry on the above method has been discussed.

THE RATE OF SOLUTION OF ZINC IN ACIDS

BY CECIL V. KING AND M. M. BRAVERMAN

RECEIVED NOVEMBER 10, 1931

PUBLISHED MAY 7, 1932

The classical theory for the rate of solution of solids in aqueous solutions, developed by Noyes and Whitney,¹ Nernst² and Brunner,³ postulates that the rate of chemical reaction in such cases is very high compared to the rate at which the active component of the solution can reach the solid surface by diffusion; hence the observed rate of dissolution will be that of diffusion to the surface through the products as they diffuse away.

¹ Noyes and Whitney, *Z. physik. Chem.*, **23**, 689 (1897).

² Nernst, *ibid.*, **47**, 52 (1904).

³ Brunner, *ibid.*, **47**, 56 (1904).

This theory can by no means be as generally applicable to heterogeneous reactions as was supposed by the originators. We may assume with Van Name and Hill⁴ that at least three types of heterogeneous reaction will be encountered: (1) the chemical reaction is very much faster than the diffusion rate, and the observed rate will be controlled by the latter; (2) the chemical reaction is very slow compared to the diffusion rate and the observed rate will be controlled by the former; (3) the diffusion rate constant and the reaction velocity constant are comparable in magnitude and the observed rate will be a function of both. In addition to these three types, many complications may appear, as "local elements" in the case of impure metals, solubility of the solid in pure water to an extent comparable to the concentration of the active component in the solution, formation of films at the surface by the reaction, etc.

In the case of metallic oxides, hydroxides and carbonates dissolving in acids, we should expect the chemical reaction to be so fast that the observed rate of solution would be controlled by the diffusion process. In the case of metals dissolving in acids, however, it is possible that the chemical reaction may be slower than the diffusion process. Experiments in such systems could be used advantageously in investigating the nature of acids by determining whether, as heretofore supposed, only the hydrogen ion reacts directly with the metal or whether other acid molecules or ions also enter directly in the reaction.

Brönsted, Lowry, Dawson and their co-workers have shown that in a number of homogeneous reactions not only the H_3O^+ and OH^- ions are active as catalysts, but also other acid and basic molecules. The chief criteria of such a catalysis are: (1) lack of proportionality of the rate to the hydrogen-ion concentration as one goes from strong to weak acids; (2) proportionality of the rate to the concentration of other acid molecules in solutions in which the hydrogen-ion concentration is buffered; (3) for an homologous series of acids, $\log k_A$ (rate constant) shows a linear relation to $\log K_A$ (acid dissociation constant).

The idea that undissociated acids may react with metals is not new; Kahlenberg and his co-workers carried out many experiments designed to show that this as well as other types of reaction can take place in the absence of ions. For example, Patten⁵ found that *N*/10 hydrochloric acid in dry chloroform dissolves zinc faster than *N*/10 hydrochloric acid in water (until the reaction products choke the surface), in spite of the fact that the former solution has an exceedingly low electrical conductivity. However no attempt was made to show that other acids than the H_3O^+ ion react directly with metals in aqueous solution until Kilpatrick and Rushton,⁶

⁴ Van Name and Hill, *Am. J. Sci.*, **42**, 307 (1916).

⁵ Patten, *J. Phys. Chem.*, **7**, 153 (1903).

⁶ Kilpatrick and Rushton, *ibid.*, **34**, 2180 (1930).

in a detailed study of the rate of solution of magnesium in monobasic acids,⁷ applied the criteria of the above theory and showed that they were reasonably well fulfilled. The authors thus imply that the chemical reaction is much slower than the diffusion process and that they have measured the rate of the former. The mechanism is thus represented, for example in acetic acid, by the equations

Brönsted and Kane have applied the same theory to the rate of solution of sodium from sodium amalgam by acids.⁸ This reaction is complicated by the necessity of diffusion of sodium as well as of acid to the amalgam surface, and probably by adsorption of sodium in the amalgam surface.⁹ The authors have, however, carefully considered the possible influence of diffusion on the observed solution rates; and conclude that this factor is all-important with the stronger acids, but that with acids of dissociation constant less than 10^{-7} the chemical reaction rates are sufficiently lower than the diffusion rates to be entirely responsible for the observed velocities.

Five observed facts have, in general, been accepted as criteria of the validity of the diffusion rate theory: (1) a number of different solids dissolve at nearly the same rate, while chemical reaction rates are seldom so nearly the same for such widely different substances; (2) the rate of stirring the solution or rotating the specimen has a very large influence on the observed rates, which is not typical of chemical processes; (3) the rate of solution is usually nearly inversely proportional to the viscosity of the solution; (4) the rates observed with different acids follow, in general, the diffusion coefficients of the acids rather than their acid strengths, although strict proportionality to diffusion coefficients obtained under entirely different experimental conditions cannot be expected; (5) the temperature coefficient of these heterogeneous reactions is usually 1.1 to 1.5 per 10° rise, while chemical reaction rates seldom have temperature coefficients less than 2. Neither Kilpatrick and Rushton nor Brönsted and Kane present experimental work to test the application of these five points in detail, and we feel that detailed study especially of (2), (3) and (5) will be necessary before their point of view can be accepted. Our own work shows that satisfactory formal agreement with the three criteria of the extended acid-base catalysis theory is not sufficient.

Experimental

For the experimental work presented here the rate of solution of zinc in acid solutions containing potassium nitrate as a depolarizer was chosen for

⁷ Kilpatrick, *J. Chem. Ed.*, **8**, 1567 (1931).

⁸ Brönsted and Kane, *THIS JOURNAL*, **53**, 3624 (1931).

⁹ See Meyer, *Z. physik. Chem.*, **70**, 315 (1910), for the peculiar interfacial tension relation of sodium amalgam and solutions.

most of the experiments. It is to be expected that zinc will react chemically more slowly than the more active magnesium and sodium, although just how much effect an efficient depolarizer has on the inherent "activity" is problematical.

When hydrogen is allowed to form on the surface of the metal, undoubtedly the purity of the metal has considerable influence on the rate, especially for metals "whose solution tension is outweighed by the overvoltage of hydrogen."¹⁰ It has been shown that many oxidizing agents greatly hasten the solution of such metals, especially when they eliminate hydrogen evolution entirely, even though they have no specific action on the metals themselves.¹¹ Potassium nitrate was chosen as a depolarizer, since it has no specific action, eliminates hydrogen evolution entirely, forms no insoluble coating on the surface of the metal, has little effect on the rate of solution of magnesium but increases that of zinc to nearly the same value as that of magnesium, and can be replaced by certain other depolarizers with almost identical results. Also it appears to reduce the effect of impurities in the zinc to a minimum.

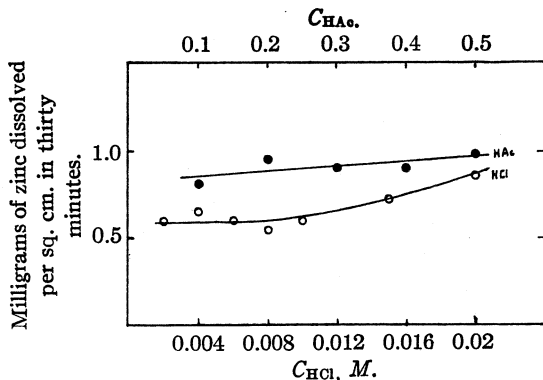

Fig. 1.—Rate of solution of zinc in hydrochloric and acetic acids at 22°, 1600 r. p. m., no oxidizing agent.

Square plates, disks, or cylinders of the c. p. metal were attached to a bakelite shaft with bakelite nuts and rubber washers which prevented the solution from coming in contact with definite areas, in the case of the cylinders the entire end surfaces. Undoubtedly cylinders are most satisfactory for this type of experiment, since all points on the exposed surface will have the same linear speed through the solution; but the other specimens were satisfactory for the comparative experiments in which they were used. With the depolarizers present, there was no induction period and

¹¹ Pullinger, *J. Chem. Soc.*, **57**, 815 (1890); Weeren, *Ber.*, **24**, 1785 (1891); Prins, *Proc. K. Akad. Amsterdam*, **23**, 1449 (1921).

the reactions were unimolecular, or nearly so. The loss in weight of the specimen during four or five minute intervals was taken as a measure of

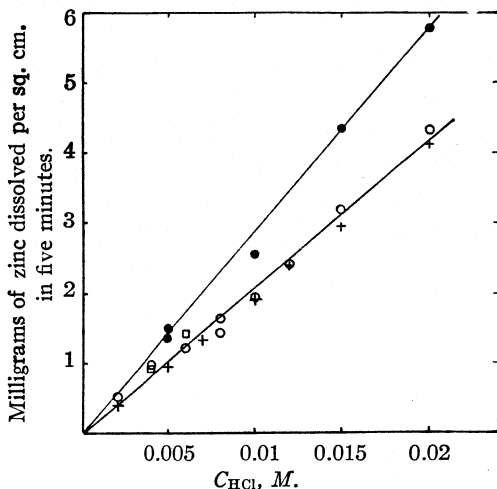

Fig. 2.—Rate of solution of zinc in hydrochloric acid at 23°: upper curve, 2800 r. p. m.; lower curve, 1600 r. p. m. ○, ●, 0.05 M KNO_3 ; □, 0.1 M KNO_3 ; +, 0.04 M H_2O_2 .

constant rate of hydrogen elimination. In a number of dilute acid and buffer solutions, with and without added inert salts, there was no significant dependence of this initial rate on the hydrogen-ion or total acid concentration. There is probably an induction period in such solutions and they have little quantitative significance.

Figure 2 summarizes the experiments with hydrochloric acid with added potassium nitrate and hydrogen peroxide, and compares the rate at two rotational speeds. The rate is, within experimental error, proportional to the acid concentration, inde-

pendent of the particular oxidizing agent and its concentration (of course within limitations), and has little if any inert salt effect in the kinetic sense.

In Fig. 3 are shown similar results for acetic acid. Again the rate is pro-

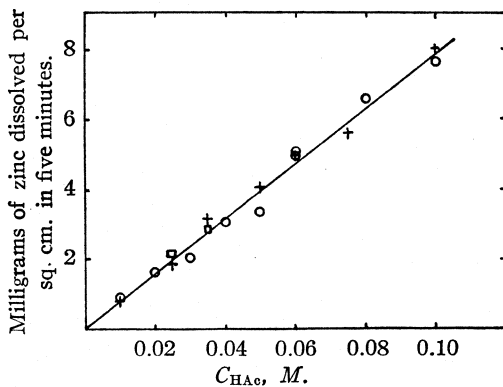

Fig. 3.—Rate of solution of zinc in acetic acid at 23°, 1600 r. p. m.: ○, 0.05 M KNO_3 ; □, 0.10 M KNO_3 ; +, 0.04 M H_2O_2 .

the rate constant; during this time the change in surface area was inappreciable and the decrease in acid concentration was only a few per cent. The volume of acid solution used and the temperatures are given with the tables and figures. The specimens were polished with fine emery paper before each run.

1. Comparison of Different Acids.—Figure 1 shows the results obtained with hydrochloric and acetic acids with no oxidizing agents present. The rate of solution is nearly independent of the acid concentration and probably controlled by a nearly

portional to the total acid concentration and not to the hydrogen-ion concentration; although the hydrogen ion of acetic acid accounts for some 10% of the total rate, the fact that its concentration was not controlled by using buffer solutions does not obscure the conclusions to be reached.

Figure 4 gives the results for formic acid at 1600 and 2800 r. p. m.; this change in rate of rotation increases the rate 38% with hydrochloric acid and 42% with formic acid. These values were used as a basis for estimating the constant at 2800 r. p. m. for acetic acid, as this was not measured directly.

Figures 5 and 6 give measurements with glycolic, tartaric and citric acids. The latter two acids show practically the same rate, greater than the rate with hydrochloric acid at the same molar concentration.

Figure 7 summarizes measurements for boric acid and the ammonium ion (*i. e.*, solutions of ammonium chloride). The rates are very low, but fairly reproducible.

These rates are summarized in Table I and plotted in Fig. 8. The constants given have the dimensions of milligrams of zinc dissolved per square centimeter per five minutes per mole of acid per liter. The values have been calculated roughly for the undissociated acid present only, by assuming that hydrogen ion has the same effect per mole with all acids as with acetic acid (see Fig. 11).

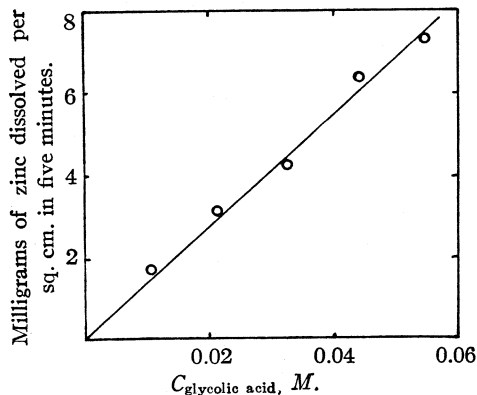

Fig. 5.—Rate of solution of zinc in glycolic acid at 23°, 2800 r. p. m.; 0.05 M KNO_3 present.

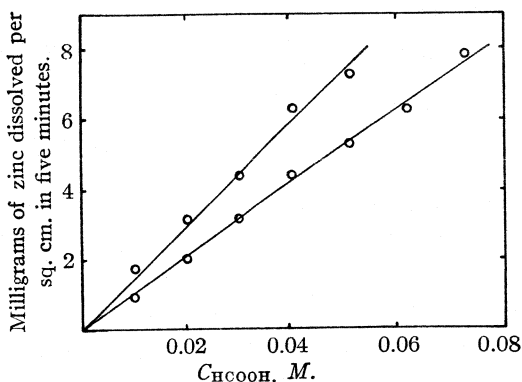

Fig. 4.—Rate of solution of zinc in formic acid at 25°, 0.05 M KNO_3 present; upper curve, 2800 r. p. m.; lower curve, 1600 r. p. m.

This is not strictly valid, but will serve our purpose here.

It is quite unlikely that we can attach any significance to the fact that on this $\log k_A - \log K_A$ plot, the points, with the exception of the polybasic and very weak acids, lie near the straight line indicated. It seems more probable that the rates are determined largely by the diffusion rates, with

TABLE I

SUMMARY OF RATES OF SOLUTION OF ZINC IN ACIDS

Boric	2.0	0.30	10.81
Ammonium ion	1.65	.22	10.75

^a Calculated from experiments with a cylinder at 4000 r. p. m.

the possible exception of those for boric acid and the ammonium ion. In these cases the low values may be due to the slowness of the chemical reaction or more likely to the formation of insoluble reaction products. The high rates with tartaric and citric acids are probably due to the fact

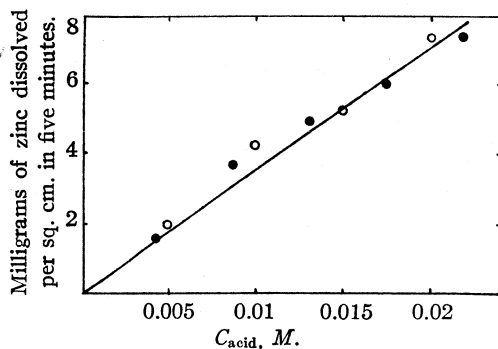

Fig. 6.—Rate of solution of zinc in citric and tartaric acids at 23°, 2800 r. p. m.; 0.05 *M* KNO₃ present: ●, citric acid; ○, tartaric acid.

that when the acid molecules reach the metal surface by diffusion they may furnish two and three hydrogen ions, respectively.

2. Temperature Coefficients.—In Figs. 9 and 10 are shown the temperature coefficients, for hydrochloric and acetic acids. These were measured by rotating zinc disks 4 cm. in diameter, 2 mm. thick, clamped on a shaft with bakelite nuts and rubber washers 2 cm. in diameter, at

a speed of 4000 r. p. m. The coefficients are: for acetic acid, $k_{25}/k_{15} = 1.28$ and $k_{35}/k_{25} = 1.26$; for hydrochloric acid, $k_{25}/k_{15} = 1.29$ and $k_{35}/k_{25} = 1.13$. The last value seems low and may be in error for some reason; our main point is to show that the values are typical of diffusion coefficients and much too low to be considered typical of chemical reaction rates.

3. Effect of a Common Ion with Acetic Acid.—Figure 11 shows the effect of adding comparatively small amounts of sodium acetate to acetic acid. Zinc disks rotating at 4800–5000 r. p. m. were used in these experiments. The effect is similar to that found by Kilpatrick and Rushton with magnesium. In the pure acetic acid we are measuring the rate due to the

combined diffusion of (1) dissociated acetic acid and (2) undissociated acid. In the presence of even 0.02 M sodium acetate, we are practically measuring the rate due to diffusion of undissociated acid alone, and further additions of the salt have a negligible effect. It will be noted that the portion of the rate due to the hydrogen ion (no sodium acetate present) is rather larger than would be expected if the chemical reaction rate were being measured (see Fig. 2). We have no way of deciding from these or any other of the experiments whether undissociated acetic acid or only hydrogen ion can actually react with the zinc. After some sodium acetate has been added, although dissociation is negligible so far as diffusion rates are concerned, the rate of dissociation is undoubtedly so high that all the acid could easily dissociate before reaction with no appreciable effect on the observed rate.

Figure 12 shows the effect of adding hydrochloric acid to a fixed amount of the acetic acid. The first addition of the strong acid represses the

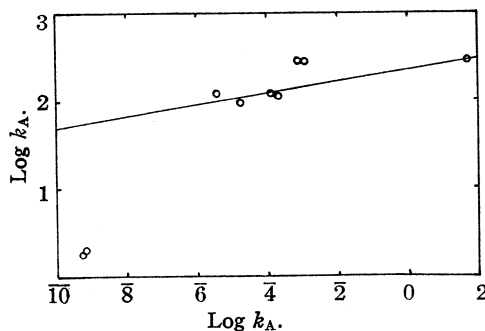

Fig. 8.—The data of Table I.

ionization of the weak one to a value negligible so far as diffusion rates are concerned; and with larger additions the rates are additive.

4. Effect of Rotational Speed.—The effect of increasing the speed of rotation of magnesium and zinc cylinders in hydrochloric and acetic acids is shown in Figs. 13 and 14. The rate increases apparently with some fractional power of the ro-

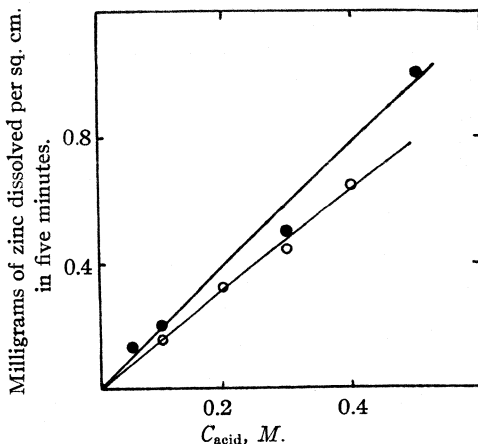

Fig. 7.—Rate of solution of zinc in boric acid and ammonium chloride at 23°, 1600 r. p. m., 0.05 M KNO_3 present: ●, boric acid: ○, ammonium chloride.

stirring the solution or rotating the specimen, although in some cases the relation is linear;¹² but we have seen no results recorded at the higher

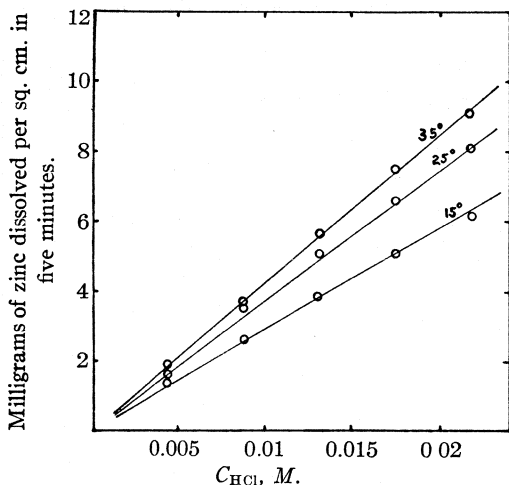

Fig. 9.—Temperature coefficient of rate of solution of zinc in hydrochloric acid, 0.05 M KNO_3 present, 4000 r. p. m.

the chemical reaction is not too fast it may be possible to attain such speeds that diffusion to the surface takes place more rapidly than the

speeds used here. The lack of any tendency for the curves to flatten must indicate that the observed solution rates are still controlled by the diffusion process. If we accept the Nernst picture of a "diffusion layer" surrounding the solid, the thickness of the layer can be calculated from the expression $k = D/\delta$ where k is the observed solution rate, D the diffusion coefficient, and δ the thickness of the layer. It is unlikely that the relation shown in Figs. 13 and 14 can continue until the diffusion layer becomes only a few molecules thick; but if

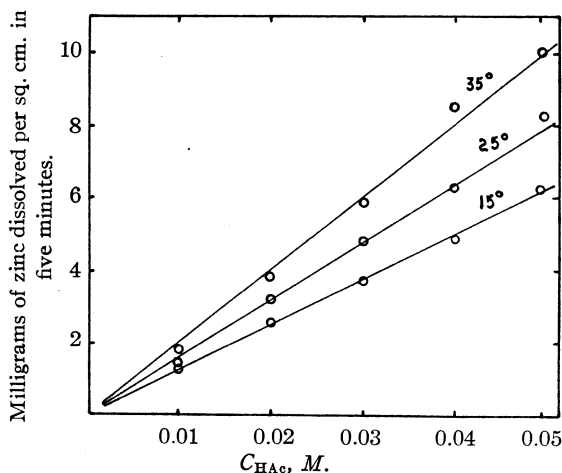

Fig. 10.—Temperature coefficient of rate of solution of zinc in acetic acid, 0.05 M KNO_3 present, 4000 r. p. m.

chemical reaction. However, frictional heating effects and other distur-

¹² Klein, *Z. anorg. allgem. Chem.*, **137**, 56 (1924).

bances apparently unimportant at 5600 r. p. m. with the cylinders used here, may become so at slightly higher speeds.

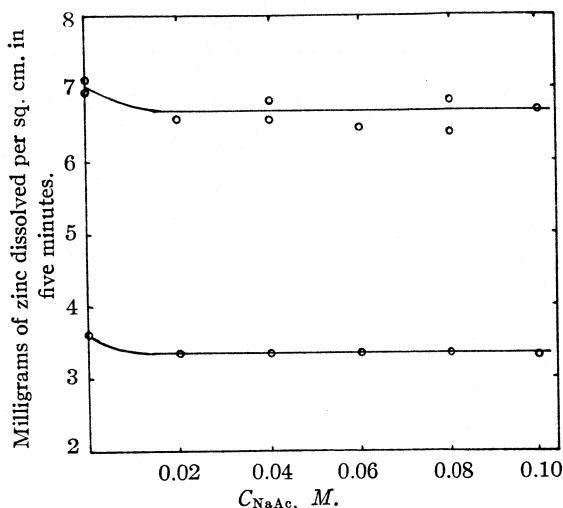

Fig. 11.—Effect of repressing the ionization of acetic acid (0.0122 and 0.0245 M) on its rate of dissolving zinc. 0.05 M KNO_3 present, 25–26°, 4800–5000 r. p. m., 500 cc. solution.

5. Effect of Viscosity Changes.—From the experimental relation between viscosity and diffusion rates $D\eta = \text{constant}$, where η is the viscosity of the medium, and the relation $k = D/\delta$, it is seen that k will be inversely proportional to the viscosity, assuming δ to remain constant. Table II and Fig. 15 show the effect on the rate of solution of zinc obtained by changing the viscosity of a hydrochloric acid solution by adding cane sugar, alcohol and the salts listed. The viscosity values were taken from the

TABLE II

Landolt-Börnstein "Tabellen," in the case of cane sugar by interpolation. The effect of 0.007 *M* hydrochloric acid and 0.05 *M* potassium nitrate on the viscosity was neglected.

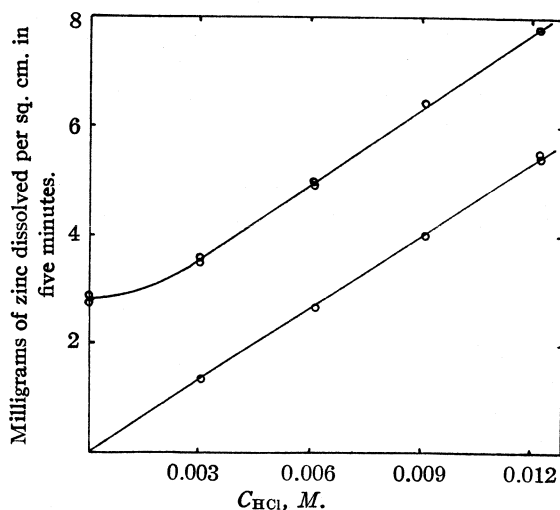

Fig. 12.—Rate of solution of zinc in mixed HCl and acetic acid: lower curve, HCl alone; upper curve, 0.0122 *M* acetic acid + HCl; 0.05 *M* KNO_3 present, 25–26°, 3800–4000 r. p. m., 500 cc. of solution.

That the inverse proportionality holds rather well is shown in Fig. 15. The results with magnesium sulfate may be in error because the solutions

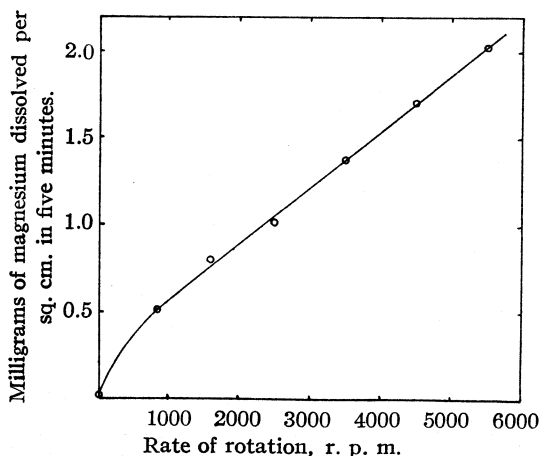

Fig. 13.—Effect of rotational velocity on rate of solution of a magnesium cylinder 2.16 cm. in diameter, 2.50 cm. long, in 0.0071 *M* HCl at 25°, 1 liter of solution.

were not made up very carefully; or possibly HSO_4^- ion may be formed in solutions of these high sulfate ion concentrations (?). The effect of salts is seen to be not a kinetic one, but merely due to the change in the viscosity of the solution.

Van Name and Hill¹³ have measured the effect of alcohol up to 3 *M* and sugar up to 1 *M* on the rate of solution of cadmium in iodine-potassium iodide solutions. The results, when plotted as in Fig. 15, give a similar relation.¹⁴

Brönsted and Kane⁸ mention the experiments of Zecchini¹⁵ on the rate of solution of zinc in hydrochloric acid in a number of different solvents, and find it difficult to explain the rates as those of the chemical reaction. Zecchini's results are rather irregular but, considering the possible errors of the experiments, the rates, when plotted against $1/\eta$ for the pure solvents, do not fall unreasonably far from a straight line passing through the origin. Factors such as the solubility of zinc chloride and the over-voltage of hydrogen in the particular solvent must be important but, whatever the mechanism of the actual chemical reaction, the observed rates must be controlled largely by the diffusion process.

6. Comparison of Different Solids.—Magnesium, zinc and cadmium dissolve at far different rates in acid solutions containing no oxidizing agents, and the rate varies greatly with the purity of the metal. However, with potassium nitrate present, the rates are not widely different, and not far different from the rate of solution of marble. Table III gives quantitative results for these four substances.

¹³ Van Name and Hill, *Am. J. Sci.*, [4] **36**, 543 (1913).

¹⁴ The viscosities of sugar solutions given by Van Name and Hill are apparently somewhat in error.

^a "Spectroscopically pure" zinc furnished by the New Jersey Zinc Co., to whom we wish to express our thanks.

It does not seem plausible that rates so nearly the same can be rates of chemical reaction for substances so widely different in chemical activity and in concentration. More probably the differences are due to differences in the solubility and diffusion rates of the reaction products and their

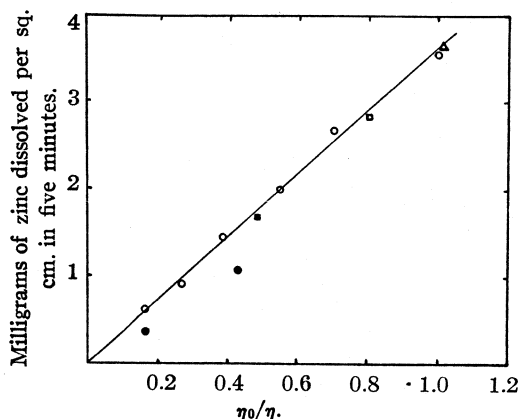

Fig. 15.—Dependence of the rate of solution of zinc in hydrochloric acid on the viscosity of the solution, 25°, 0.05 *M* KNO₃ present, 4000 r. p. m.: O, sugar solutions; ●, 1.22 and 2.44 *M* MgSO₄; □, 2 *M* NaCl; ■, 24.7 volume % ethyl alcohol; Δ, 2 *M* KCl.

effects on the diffusion rates of the acids. The higher values for marble in both acids might be explained by the disruptive effect of carbon dioxide bubbles on the "diffusion layer;"¹⁶ but it is doubtful whether such bubbles were formed during four minutes of rotation in these solutions. Furthermore, the corresponding values for magnesium in similar solutions containing

no potassium nitrate were: in 0.007 *M* HCl, 0.086 milliequivalent, somewhat lower than with nitrate present; in 0.03 *M* HAc, 0.134 milliequivalent, somewhat higher

than with nitrate present. In this case the solutions became cloudy with very small hydrogen bubbles; their formation does not have a pronounced or consistent effect.

Van Name and Hill have proposed another explanation for small differences in the rate of solution of various metals in acid ferric chloride and ferric alum solutions.¹⁷ If the rates of the chemical reactions are not very

¹⁶ See Van Name and Hill, *Am. J. Sci.*, [4] **36**, 543 (1913).

¹⁷ Van Name and Hill, *ibid.*, [4] **42**, 307 (1916).

much higher than the diffusion rates, they may have a noticeable effect on the solution velocities. The rates for marble, magnesium, zinc and cadmium are in the order one should expect if this explanation applies; but, if this were true, the differences would probably be more pronounced at this rotational speed.

A rough calculation from the experiments of Brönsted and Kane indicates that under the conditions described in Table III, $0.03\ M\ H_2PO_4^-$ ion would dissolve approximately 0.1 milliequivalent of sodium from an amalgam containing 0.14 milliequivalent per cc. (above which value the rate of solution is independent of the sodium concentration),¹⁸ which suggests that this rate may likewise be controlled by the diffusion rate of the acid.

Summary

The rate of solution of zinc has been measured in a number of different acids. The simplification of the results obtained in the presence of certain oxidizing agents has been shown, the effect of acid concentration, rate of rotation and the temperature coefficient have been studied; and a comparison of the rate with those for other metals and marble has been made.

The results have been discussed from the viewpoints of the old "diffusion rate" theory and the Brönsted-Kilpatrick theory. While the former theory is not altogether satisfactory without modification, certain results are definitely contradictory to the latter.

It is impossible to decide at present whether other acids than the H_3O^+ ion react directly with magnesium, zinc, cadmium and marble, since previous experiments have measured rates controlled largely or entirely by diffusion rates.

**DIRECT MEASUREMENT OF THE PRIMARY, SECONDARY AND
TOTAL MEDIUM EFFECTS OF ACETIC ACID**

BY BENTON BROOKS OWEN

RECEIVED NOVEMBER 23, 1931

PUBLISHED MAY 7, 1932

Introduction

In calculating the "universal constant" in their equation for the activity coefficient of an electrolyte, Debye and Hückel¹ employ $D^{3/2}$, the $3/2$ power of the dielectric constant of the solvent. This satisfactorily describes the variation of activity coefficients with composition of the solvent so long as all activity coefficients are referred to unity at infinite dilution in their respective solvents. It is well known, however, that variation in solvent is also attended by an *absolute* change in the values of the activity coefficients (referring them all to one particular solvent), and that this absolute change is sometimes 10 to 100 times greater than the relative change accounted for by the term $D^{3/2}$ in the Debye-Hückel equation. In this paper these absolute and relative changes in activity coefficients, hereafter referred to as *primary and secondary medium effects*, will be given careful definition, and a number of fundamentally important equations concerning them will be derived. The direct calculation of the primary and total medium effects from e. m. f. data will be illustrated by the interesting case in which the medium itself, being a weak electrolyte in various concentrations, contributes to the ionic strength and complicates the calculations. The data were derived from cells containing hydrochloric acid, water, and acetic acid in various proportions, and from them a new empirical relation between medium effect and concentration of acetic acid will be derived, and compared with the relation discovered by Harned and Owen.²

Theoretical

The full generality and scope of the term medium effect was not apparent from the definition of Harned and Owen. They were concerned with the primary effect only, and, having found it proportional to the molality of acetic acid, referred to the proportionality constant as "the" medium effect. To secure the greatest generality, the emphasis must be removed from the proportionality constant and directed upon the influence of the medium on the activity coefficients, so that the definition may be free from any dependence upon empirical relationships.³

In a solution of an electrolyte in the presence of neutral (non-aqueous)

¹ Debye and Hückel, *Physik. Z.*, **24**, 185 (1923).

² Harned and Owen, *THIS JOURNAL*, **52**, 5079 (1930).

³ It will be shown later that the proportionality found by Harned and Owen is probably approximate, even in dilute solution, and it was never considered valid for high concentrations.

molecules, the total medium effect is defined as the logarithm of the ratio of the activity coefficient of the electrolyte in the presence of the neutral molecules and in pure water at the same concentration of electrolyte. The primary medium effect is the limit to which the total effect converges as the electrolyte concentration approaches zero. The secondary medium effect is always given by the difference between the total and primary effects.

Throughout this paper all activity coefficients in any medium are referred to unity at infinite dilution in water, unless written with an asterisk (γ^* , γ^* , etc.), in which case they are referred to infinite dilution in the medium itself. Subscripts indicate the electrolyte concentration, but will usually be omitted except in the important case where this is zero. When the medium is pure water, a superscript zero will be used; thus, $\gamma^0 = \gamma_m^0$, $\gamma_0^0 = 1$, etc. For all concentrations we may write

$$\log \gamma = \log \gamma_0 + \log \gamma^* \quad (1)$$

and, by combining it with the identity

$$\log \gamma^0 \equiv \log \gamma_0^0 + \log \gamma^0 \quad (2)$$

obtain a fundamental relation between total, primary and secondary medium effects, thus

$$\log \gamma/\gamma^0 = \log \gamma_0/\gamma_0^0 + \log \gamma^*/\gamma^0 \quad (3)$$

For convenience the primary effect can be written simply $\log \gamma_0$ because $\gamma_0^0 \equiv 1$. $\log \gamma^*/\gamma^0$ is the secondary effect and in dilute solutions is calculable by

$$\log \gamma^*/\gamma^0 = -\alpha\sqrt{c} + \beta c \quad (4)^4$$

where

$$\alpha = 352.6 [(1/D)^{3/2} - (1/D^0)^{3/2}] \quad (4a)^6$$

From the definition of total medium effect, it is obvious that its value may depend upon some or all of the following conditions: (1) nature and (2) concentration of the neutral molecules, (3) nature and (4) concentration of the electrolyte, and (5) the concentration units involved in the definitions of activity coefficient. The effect of varying all of these conditions (except the first) will be considered in this paper. Because Harned and Owen² have already discussed the primary medium effect of acetic acid in terms of "water-molality" units, it was decided to study conditions (2) and (5) simultaneously by making measurements and calculations in different units, and comparing the final results by suitable transformation formulas. Harned and Owen used "molality" for moles per kilo of water, but in the present paper, dealing with mixed solvents, the term "water-molality" is coined for this unit so that "molality" can retain its usual meaning—moles per kilo of solvent.

⁴ It will be shown in a later section that equation 4 is quite accurate for concentrations as high as 0.2 normal; cf. Fig. 3.

⁶ Using 0.357 for the universal constant at 25°, and $D^0 = 78.8$; Noyes, THIS JOURNAL, 46, 1098 (1924); Drude, *Ann. Physik*, 59, 61 (1896).

Thus, for the double cell

the concentrations of hydrochloric acid and acetic acid are in moles per liter of solution. Using the letter "y" to represent activity coefficients when the concentrations are expressed in molarities, the e. m. f. is given at 25° by

$$E^0 - E = 0.05915 \log \frac{y_{\text{H}} y_{\text{Cl}} c_{\text{H}} c}{y_{\text{H}}^0 y_{\text{Cl}}^0 c^0 c^0} \quad (6)$$

Making $c = c^0$ to comply with the definition of medium effect, and writing y^2 for $y_{\text{H}} y_{\text{Cl}}$ and y^{02} for $y_{\text{H}}^0 y_{\text{Cl}}^0$, this equation becomes

$$(E^0 - E)/0.05915 - \log c_{\text{H}}/c = 2 \log y/y^0 \quad (7)$$

The term $\log c_{\text{H}}/c$ would, of course, be zero if the acetic acid were replaced by a non-electrolyte, but it will be shown that the ionization of acetic acid is sufficient to make this term amount to 3 to 10% of the total medium effect for the cells in which c is as low as 0.0296. Such values are, fortunately, still small enough to permit certain simplifying approximations in their calculation without introducing appreciable error into the corresponding medium effects. Their calculation will be taken up in some detail.

The ionization constant of acetic acid may be expressed in several concentration units. Thus, if \bar{M} and C are (total) water-molality and molarity of acetic acid, and \bar{m} and c are water-molality and molarity of hydrochloric acid, or the ions indicated by subscripts

$$K = \bar{\gamma}_A^2 \frac{\bar{m}_{\text{H}} \bar{m}_{\text{Ac}}}{\bar{M} - \bar{m}_{\text{Ac}}} = \gamma_A^2 \frac{c_{\text{H}} c_{\text{Ac}}}{C - c_{\text{Ac}}} \quad (8)$$

and

$$C = \frac{\bar{M}(d - wc)}{1 + W\bar{M}}, \quad c = \frac{\bar{m}(d - wc)}{1 + W\bar{M}} \quad (9)$$

where d is the density of the solution, and w and W are the molecular weights in kilograms of hydrochloric and acetic acids, respectively. Writing the total acetic acid concentration for the concentration of un-ionized acetic acid, equation 8 may be combined with equation 9 to give

$$y_A^2 = \bar{\gamma}_A^2 (1 + W\bar{M})/(d - wc) \quad (10)$$

and

$$c_{\text{H}} = c + KC/(c_{\text{H}} y_A^2) \quad (11)$$

Equation 11 yields c_{H} if y_A^2 is known; but y_A^2 depends upon the medium effect being sought. Fortunately, if the assumption⁶ be made that $\bar{\gamma}_A$ is approximately the same in HCl-HAc and NaCl-HAc solutions of equal ionic strength and HAc concentration, $\bar{\gamma}_A$ (and hence y_A) may be estimated

⁶ This assumption can reasonably be expected to give values of $\bar{\gamma}_A$ less than 10 to 15% in error when c is as low as 0.0296, and such an accuracy is more than is required for this lowest concentration studied. For higher concentrations the error that can be tolerated in $\bar{\gamma}_A$ increases very rapidly with the concentration, as a glance at equations 7 and 11 will show.

from the curves and data published by Harned and Owen. Thus, the empirical equation⁷

$$\log \bar{\gamma}_A^2 = -\sqrt{\mu} + (0.75 + 0.055 \bar{M}) \mu \quad (12)$$

allows the calculation of values of $\log \bar{\gamma}_A^2$ differing from the observed experimental values by less than 5% so long as \bar{M} does not exceed 10, or μ exceed 0.3.

Experimental

The acids used were of the highest purity obtainable commercially. The freezing point of the acetic acid indicated 0.1% water by comparison with the tables of Rudorff.⁸ All solutions were made up by weight (corrected for displaced air) in accurately gaged 500-cc. flasks, and every effort was made to have all concentrations known to better than 0.1%. Fresh electrodes were prepared for each cell from silver oxide⁹ and pure chloroplatinic acid.¹⁰ The cells were the simple H-type. Vacuum technique was not employed in filling them because the acetic acid cells and reference cells were prepared and measured identically, and only the *difference* in their e. m. f.'s enters into medium effect calculations. The hydrogen was electrolytic from sodium hydroxide solution. The cells attained equilibrium in two to four hours, after which their potentials were constant within a few hundredths of a millivolt. The recorded potential is the average of readings taken over two or three hours at equilibrium, and corrected to a partial pressure of one atmosphere of hydrogen. To make these corrections, the excess of each solution not required for filling cells was used for vapor pressure measurements in a 200-cc. isoteniscope. Contrary to the results of earlier investigators,¹¹ who found vapor pressures of the order of 30 mm. for 20 to 75% acetic acid solutions, the results of these measurements were in rough agreement with Raoult's law. The general form of the vapor pressure-composition curves can be represented by the data in Table I to better than the nearest mm. of mercury.

Table II records the experimental data and various calculated functions. To express the concentration of acetic acid, its mole fraction in the solvent

⁷ The family of curves A to F in Fig. 1 of Harned and Owen's paper may be represented by straight lines

$$(\log k' - \sqrt{\mu'}) = \log k^0 - 0.75 + (0.055 \bar{M}) \mu'$$

for small ionic strengths. Their slopes were read from a large plot and found to be a complicated function of \bar{M} , which could, however, be simplified to $0.75 + 0.055 \bar{M}$ as a first approximation. Equation 12 is derived by combining this equation with $\log k^0/K = \log k'/k$ (equation 17, Harned and Owen) and $\log K = \log \bar{\gamma}_A^2 + \log k$ (definitional), and remembering that μ' is not very different from μ in HCl-HAc solutions.

(N, Column 1) was selected because of the straight line relation exhibited in Fig. 1. In Column 3 are recorded the e. m. f. data for the half-cells comprising equation 5. The first e. m. f. in each section of the table is for a

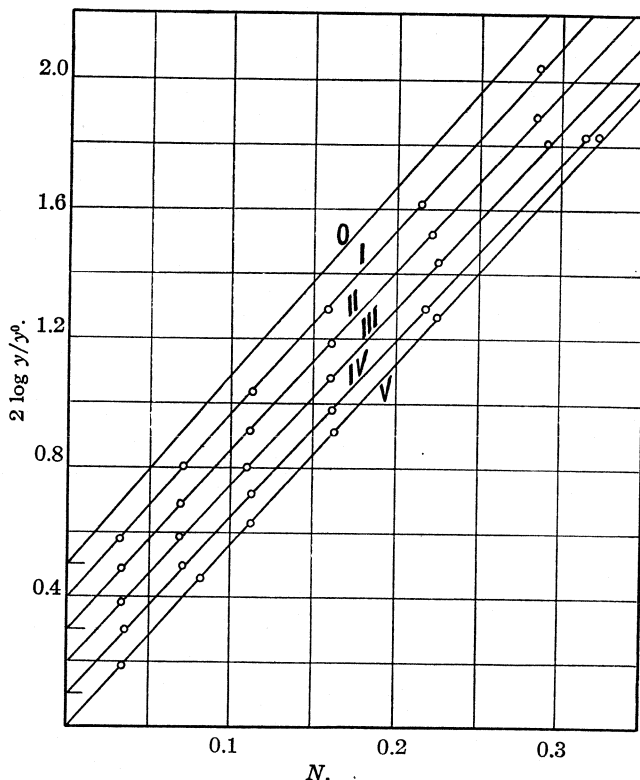

Fig. 1.—Variation of total medium effect with mole fraction of acetic acid. The origins of the five uppermost curves have been shifted. Normality of hydrochloric acid—0; I = 0.0296; II = 0.1112; III = 0.2255; IV = 0.5655; V = 1.1160.

cell containing c -molar hydrochloric acid, but no acetic acid. It is therefore E^0 , the e. m. f. of the reference cell, for that particular section. Of course, c is constant throughout each section and is identical to c_H for the reference cell heading the section. Each e. m. f. is the average for two similar cells, except the reference values, which are each the average for

four cells. The difference between any two e. m. f.'s averaged is given as δE in millivolts. When four e. m. f.'s are averaged, δE is the greatest difference between any two. The values of $\bar{\gamma}_A^2$ were calculated by equation 12, c_H by equation 11, and $2 \log y/y^0$ by equation 7. The densities, d , are included to make possible the transformation of N and c into other concentration units. The quantities NJ in the last column are given to demonstrate the extent of the validity of the empirical equation 13, the values of J being given in parentheses at the top of each section.

Discussion of Results

The family of straight lines obtained by plotting the medium effect against the mole fraction of acetic acid in the solvent is illustrated in Fig. 1, and represented mathematically by

$$2 \log y/y^0 = NJ \quad (13)$$

J is independent of N , but varies with c after the manner of an activity coefficient. The important primary medium effect is equal to the total medium effect at infinite dilution of electrolyte, and can therefore be obtained by extrapolation of $2 \log y/y^0$, or its equivalent NJ . Since $y_0^0 \equiv 1$, equation 13 becomes

$$2 \log y_0 = NJ_0 \quad (14)$$

at infinite dilution, and $\log y_0$ is the primary medium effect. The form of the extrapolation function can be derived by combining equations 3 and 4, transposing, and rewriting in the proper concentration units, thus

$$(2 \log y/y^0 + 2\alpha \sqrt{c}) = 2 \log y_0 + 2\beta c \quad (15)$$

The parameter α varies with N and could be calculated by equation 4a if the dielectric constant of the medium were known. Unfortunately, this is

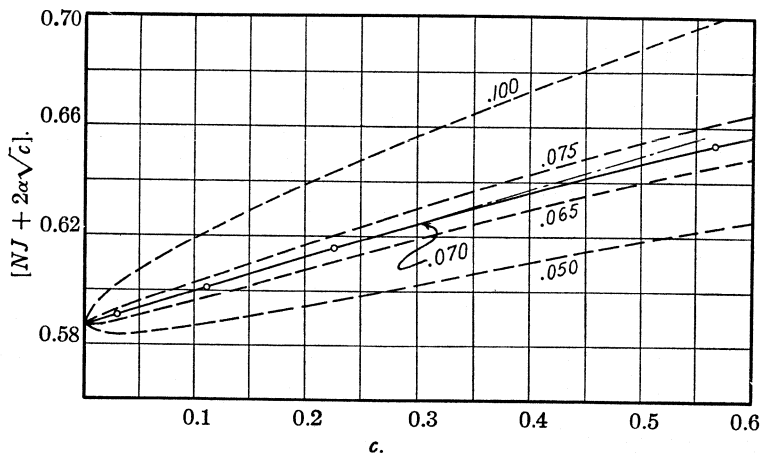

Fig. 2.—Extrapolation to J_0 for the various values of α as indicated, and $N = 0.1$.

not known, but the value of α , giving a straight line (in dilute solution, at least) when the terms in parenthesis are plotted against c , can be determined by trial. In Fig. 2, equation 15 has been plotted for $N = 0.1$ and the several values of α indicated. A straight line is obtained in dilute solution when $\alpha = 0.07$, and it extrapolates to $J_0 = 5.87$. Such a value of α would demand that the dielectric constant of 27% acetic acid solution (mole fraction 0.1) be about 72, which is not unreasonable, but as long as there is no experimental check on this value, α should be regarded as

purely empirical, for it is quite possible that the dielectric constant is much lower and the curvature of the uppermost curves is due to suppression of the "ionic radius" term of the Debye-Hückel formula used in deriving equation 4a.

The secondary medium effect has been defined as the difference between the total and primary medium effects. Since these latter have been shown to be proportional to N (Equations 13, 14), it follows that the *secondary medium effect*, $\log y^*/y^0$, must also be proportional to N ; thus, c being constant

$$\log y^*/y^0 = \frac{1}{2}N(J - J_0) \quad (16)$$

In dilute solutions, the variation of the secondary medium effect with the concentration of electrolyte, is given by equation 4 rewritten in the proper units, thus, N being constant

$$\log y^*/y^0 = -\alpha \sqrt{c} + \beta c \quad (17)$$

In Fig. 3 the experimental values of $\log \theta$, calculated for $N = 0.1$ by equation 16, are indicated by points on the continuous curve. The dashed

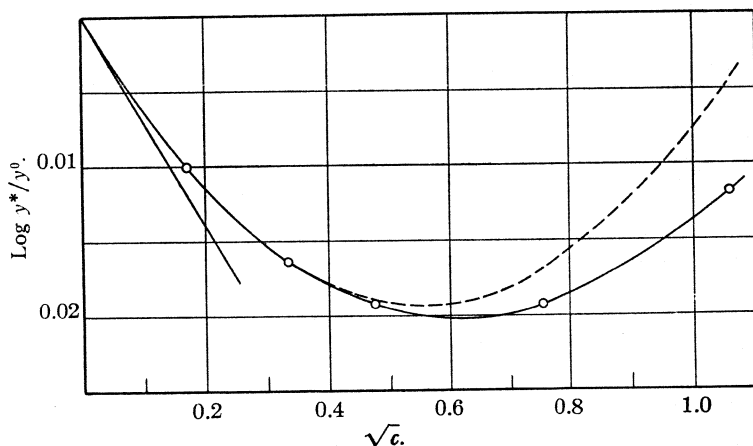

Fig. 3.—Variation of secondary medium effect, N being constant and equal to 0.1: —○—, $\frac{1}{2}N(J_0 - J)$; ---, $0.07 - \sqrt{c} + 0.063c$.

curve represents the values calculated by equation 17, using the values $\alpha = 0.07$ and $\beta = 0.063$ corresponding to the straight line (slope = 2β) in Fig. 2. These curves demonstrate that equations 4 and 17 fit the experimental data quite accurately up to $c = 0.2$.

Complete weight and density data were recorded in making up the cell solutions, so that a study could be made of the effect of different concentration units in plotting the medium effect, in the hope of discovering other relations similar to equations 13 and 14. No other simple relationship was found, although combinations of water-molality, molality and molarity were tried, but the relation of Harned and Owen (equation 17, their paper)

should be derivable from these data if differences in calculation and definition of medium effect be taken into consideration. This involved making the ionic strength (c_H) identical on both sides of the cell (equation 5), thus changing both the value of E^0 and the sign of $\log c_H/c$ in equation 7. The net result of these changes was a series of medium effects almost identical with those calculated by equation 7.¹² The transformation of all of these medium effects into water-molality units proved to be a very complicated proceeding and involved so many graphical interpolations that it was abandoned in view of the fact that transformation of units could not be expected to improve extrapolation by equation 15. The primary medium effect, however, may be studied much more directly.

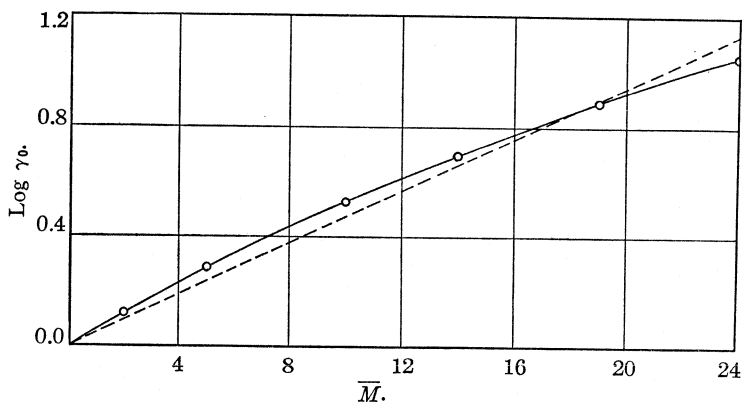

Fig. 4.—Variation of primary medium effect of acetic acid with molality. Broken line from calculations of Harned and Owen.

The primary medium effects in different concentration units are simply interrelated at zero ionic strength.

$$\log y_0 = \log \gamma_0 + \log d^0/d = \log \bar{\gamma}_0 + \log d^0/d + \log (1 + W\bar{M}) \quad (18)$$

γ_0 corresponds to m in moles per kilogram of solvent, \bar{M} is the water-molality of the non-aqueous component of the solvent, and W is its molecular weight in kilograms. The density of water, d^0 , appears because the standard state of y_0 is 1000 cc. of pure water, and not 1000 g., as for $\bar{\gamma}_0$ and γ_0 . This equation is general, being derivable from definitions only. Thus, at infinite dilution of electrolyte, $a_0 = m_0\gamma_0 = \bar{m}_0\bar{\gamma}_0 = c_0y_0(1/d^0)$ and $c_0 = m_0d = \bar{m}_0d/(1 + W\bar{M})$ (cf. equation 9), which give equation 18 by simple combination. Using $J_0 = 5.87$ in equation 14, and combining it with equation 18, $\log \gamma_0$ and $\log \bar{\gamma}_0$ may be calculated for any value of N for which equation 14 is valid (up to about $N = 0.25$). In Fig. 4, $\log \bar{\gamma}_0$ calculated in this way is plotted with the straight line obtained by Harned

¹² All values were identical with those in Column 8, Table II, except those for $c = 0.0296$ and 0.1112 , which were slightly higher, J being 5.695 and 5.545 , respectively.

and Owen.¹³ It will be observed that the numerical agreement is fair, considering the differences involved in the methods of calculation and their complexity, but the form of the two curves brings out the fact that $2 \log \gamma_0 = NJ_0$ and $2 \log \bar{\gamma}_0 = \bar{M}S$ are not compatible. This means that one, or perhaps both, of these relations is not strictly true, but this is not surprising because they are both empirical and deal with fairly concentrated solutions of acetic acid. Furthermore, Harned and Owen's relation could not be expected to hold for very concentrated solutions because it would lead to the absurd result that the activity coefficient of hydrochloric acid is infinite in pure acetic acid.

The results of Åkerlöf's¹⁴ study of hydrochloric acid and the alkali chlorides, in water-methyl alcohol solutions, not only permit the verification of two important equations interrelating the medium effects in terms of different electrolytes, but also can be used to demonstrate the general applicability of equation 15 in the calculation of primary medium effects. In his paper the electrolyte concentrations are expressed in moles per kilogram of solvent, and the composition of the solvent is expressed in per cent. of methyl alcohol by weight. In such units no simplifying relation corresponding to equation 13 is evident, so the determination of the primary medium effect, $\log \gamma_0$ (written $\log \gamma_\infty$ in his notation), necessitated an extrapolation for each concentration of methyl alcohol studied. Equation 15 is readily adapted to this purpose. If E' be the total e. m. f. of the amalgam double cells used by Åkerlöf, or the total e. m. f. ($E^0 - E$), of a hydrochloric acid double cell (similar to equation 5, if the acetic acid be replaced by methyl alcohol, and c by m), then the total medium effect is given by¹⁵

$$E' = (0.05915) 2 \log \gamma / \gamma^0 \quad (19)$$

Combining this equation with equation 15, expressed in appropriate units, and writing α' for 0.05915α and β' for 0.05915β , we obtain a very useful and simple extrapolation function,

$$(E' + 2\alpha'\sqrt{m}) = 0.1183 \log \gamma_0 + 2\beta'm \quad (20)$$

Extrapolation of Åkerlöf's data by this equation leads to two significant results. In the case of hydrochloric acid, the extrapolation is very nearly a straight line when α' is calculated from the known dielectric constants by equation 4a, and the extrapolated values of $\log \gamma_0$ agree closely with $\log \gamma_\infty$ calculated by Åkerlöf. In the case of the alkali chlorides, these theoretical values of α' appear to be too small, for the extrapolation function bends upward as the axis is approached, much after the manner of the

¹³ From their paper (equation 17), $S\bar{M} = 2 \log \bar{\gamma}_{\text{HCl}} / \bar{\gamma}_{\text{HCl}}^0$, which becomes $S\bar{M} = 2 \log \bar{\gamma}_0$ in the present nomenclature at zero ionic strength. Their value of S is 0.047.

¹⁴ Åkerlöf, *THIS JOURNAL*, **52**, 2353 (1930).

¹⁵ Cf. equation 7. The ionization of methyl alcohol is negligible compared with that of the chlorides, or hydrochloric acid.

lowermost curves in Fig. 2. This behavior is in accord with Åkerlöf's findings, for he was unable to fit his data to the Debye-Hückel equation without arbitrarily assigning greater values to the "universal constant" than those calculable from the dielectric constants.

Medium Effect on Different Electrolytes.—Two approximate equations interrelating the primary medium effects of a given solvent upon two similar electrolytes may be derived immediately from equation 20, and applied to Åkerlöf's data¹⁴ to obtain an idea of the concentration range throughout which they may be safely used. Writing equation 20 for each of two electrolytes of the same concentration and medium and subtracting one equation from the other, we obtain an equation in which m appears only in the term $2m(\beta'_{(1)} - \beta'_{(2)})$, which may be neglected when m is small, and we may write

$$E'_{(1)} - E'_{(2)} = 0.1183 (\log \gamma_{0(1)} - \log \gamma_{0(2)}) \quad (21)$$

Åkerlöf's data show that the approximation involved in the use of this equation for concentrations as high as 0.05 in 50% alcohol correspond to an experimental error of 0.2 to 0.3 millivolt.

Rewriting equation 20 for two electrolytes of the same concentration and medium and dividing the two equations one by the other, we obtain two ratios, each containing terms in m . Fortunately, the m -terms appear only as additions to larger terms, and are therefore negligible by comparison when m is small, and the ratios may be simply written

$$\frac{E'_{(1)}}{E'_{(2)}} = \frac{\log \gamma_{0(1)}}{\log \gamma_{0(2)}} = R_{(1,2)} \quad (22)$$

This equation has been tested for all possible combinations of the three alkali chlorides and hydrochloric acid up to $m = 0.5$ and 50% alcohol, and found to describe the data with an average uncertainty of about plus or minus 6%, and individual deviations sometimes twice this figure. Such a high uncertainty¹⁶ is unfortunate, but does not prevent the equation from rendering very important service where complete data are lacking, for *within the same limits of accuracy $R_{(1,2)}$ is independent of both m and the alcohol concentration.* Thus, if complete medium effect data are available for electrolyte (1), only one additional measurement, $E'_{(2)}$, is required for the approximate calculation of complete medium effect data for a similar electrolyte (2) within the limits of concentration and accuracy just specified.

Summary

1. The primary, secondary and total medium effects have been clearly defined, and equations presented for their calculation from electromotive force data.

2. Electromotive force measurements have been made upon hydrochloric acid solutions containing acetic acid. From these data the total

¹⁶ Due in part to a mathematical magnification of experimental errors.

medium effect of acetic acid has been directly determined, and full details of the calculations are included.

3. A simple extrapolation function has been derived, and applied to a determination of the primary medium effect of acetic acid and to the data of Åkerlöf.¹⁴

4. It has been demonstrated experimentally that the primary, secondary, and total medium effects of acetic acid are closely proportional to the mole fraction of acetic acid in the solvent when the concentration of the electrolyte is expressed as molarity.

5. Equations relating the primary medium effects in different concentration units were derived and applied to a comparison of the primary medium effect obtained in this paper, with that calculated by Harned and Owen² from data on sodium chloride solutions containing acetic acid.

6. Two useful approximate equations were derived which interrelated the primary medium effects of a particular medium upon two similar electrolytes. The importance of these equations, in the calculation of approximate medium effects from very limited data, has been pointed out, and the magnitude of the approximations involved has been estimated from Åkerlöf's data.

**THE SPEED OF DECOMPOSITION OF HYDROGEN PEROXIDE
IN THE PRESENCE OF HYDROCHLORIC ACID**

BY E. A. BUDGE

RECEIVED NOVEMBER 23, 1931

PUBLISHED MAY 7, 1932

The decomposition of hydrogen peroxide into oxygen and water in the presence of hydrochloric acid has been studied recently by Livingston and Bray,¹ who measured the concentration of peroxide after various time intervals by titration with permanganate, and also by Maass and Hiebert,² who followed the reaction by measuring the rate of evolution of oxygen. Both pairs of investigators worked mainly at 25° and found the reaction to be unimolecular with respect to the hydrogen peroxide. Maass and Hiebert, however, obtained velocity coefficients which differed from those of Livingston and Bray for (presumably) identical conditions and they also found a well-marked period of acceleration for the more concentrated solutions. In Fig. 1 some of the values obtained by these workers are shown in the one graph, values of $\log k$ being plotted as ordinates and the concentration of hydrochloric acid (in g. moles per liter) as abscissas. Curve I shows some of Livingston and Bray's results and Curve II some

¹ R. S. Livingston and W. C. Bray, *THIS JOURNAL*, **47**, 2069 (1925).

² O. Maass and P. G. Hiebert, *ibid.*, **46**, 290 (1924).

of those of Maass and Hiebert, both at 25°. The other curves will be referred to later.

The present author was prompted to study the same reaction since the inconsistency in these results seemed to be in accord with certain mathematical investigations carried out by him,³ in which it is shown that in the case of consecutive reactions it is possible for experimental reaction velocity coefficients to have different values according as they are based on measurements of reactants or of resultants. The coefficient by resultant may show

an initial acceleration, whereas that by reactant shows no disturbance whatever. Certain types of catalysis, supersaturation of solution with respect to gaseous resultant, and initial changes of temperature due to heat effects on mixing may also cause similar initial disturbances.

Accordingly, experiments were carried out using methods practically the same as those used by Livingston and Bray and by Maass and Hiebert. The two methods were made as comparable as possible by preparing the reaction mixture, bringing it rapidly to the temperature of the bath and dividing it between the two reaction vessels, which were placed side by side in the same bath. In preparing these mixtures commercial 3% hydrogen peroxide and c. p. hydrochloric acid were used. The hydrochloric acid was freed from a trace of impurity (probably iron chloride) by letting

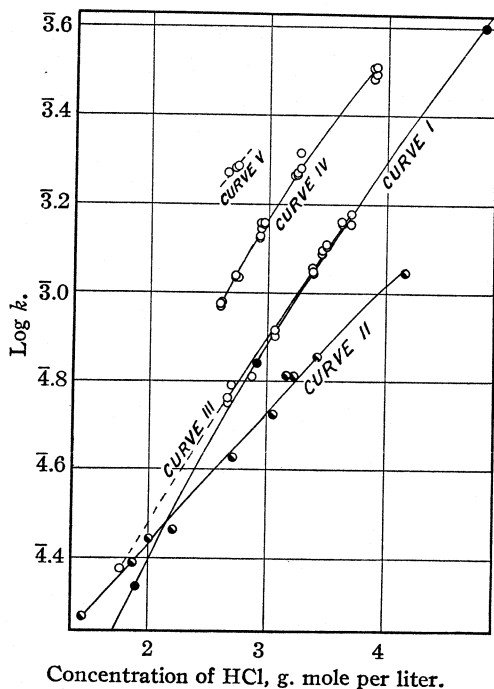

Fig. 1.—Variation of k with temperature and concentration of hydrochloric acid.

it stand for some hours with hydrogen peroxide and then twice distilling, the constant-boiling fraction alone being used. Since the methods were directly compared and the values obtained agreed well with those of Livingston and Bray, further purification of materials was considered unnecessary.

The gas evolution apparatus used by Maass and Hiebert was modified by omitting the tubes of concentrated sulfuric acid and potassium iodide solution and a simpler method of calculating the velocity coefficients was employed. "Instantaneous" values of the unimolecular velocity coefficient were obtained by dividing the rate of evolution of oxygen (in cc. per minute) by the total volume of oxygen (in cc.) yet to be evolved from the instant of the measurement until complete decomposition of the peroxide. This

³ E. A. Budge, "Reports of the Australasian Association for the Advancement of Science," Hobart Meeting, January, 1928, XIX, 147.

necessitated continuing the reaction to near completion and then estimating the residual peroxide. This was done either by heating the reaction mixture to near boiling until the peroxide was decomposed or by titration of an aliquot part of the reaction mixture by permanganate. To render the measurements involved in this method less tedious, an automatic bubble counter⁴ was developed and used. From the readings of this instrument the rate of evolution of oxygen (in bubbles per minute) and also the total volume of oxygen (in bubbles) up to the instant of measurement were easily obtainable.

Throughout the investigation the concentration of hydrochloric acid in the reaction mixtures was measured by the Iceland spar method.⁵ In some cases this was checked by precipitation of silver chloride with concordant results.

The results obtained by the titration method showed a very constant unimolecular coefficient which agreed well with those given by Livingston and Bray for corresponding conditions. The results obtained by the gas evolution method showed a well-marked period of acceleration (lasting from forty to eighty minutes) and thereafter a constant unimolecular coefficient, which was practically identical with that given by the titration method. This period of acceleration has since been shown to be due (at least in part) to supersaturation of the reaction mixture with oxygen.⁶

Accordingly, a new apparatus for the gas evolution method was installed with the object of testing whether there were any irregularity other than that due to supersaturation. A diagram of this apparatus is shown in Fig. 2.

In this apparatus a wide-mouthed bottle A was used as reaction vessel. The mouth of this was closed by a treble-bored rubber stopper B, which was firmly clamped in position (the clamps are not shown in the diagram) and had its lower surface covered with vaseline. The reagents were added to the bottle through tube C, which was closed by a well-fitting rubber stopper.

The middle hole of the rubber stopper carried a mercury seal D and allowed the entrance of the stirrer, which was directly coupled to the shaft of a small motor E. For most of its length the stirrer was of solid glass rod, but, about 5 cm. from the bottom, a T-shaped piece of glass tubing was sealed on and this was provided with a small hole at F. This stirrer, which was rotated at about 1000 r. p. m., proved very efficient in overcoming supersaturation. On account of centrifugal action, gas from the top of the bottle entered

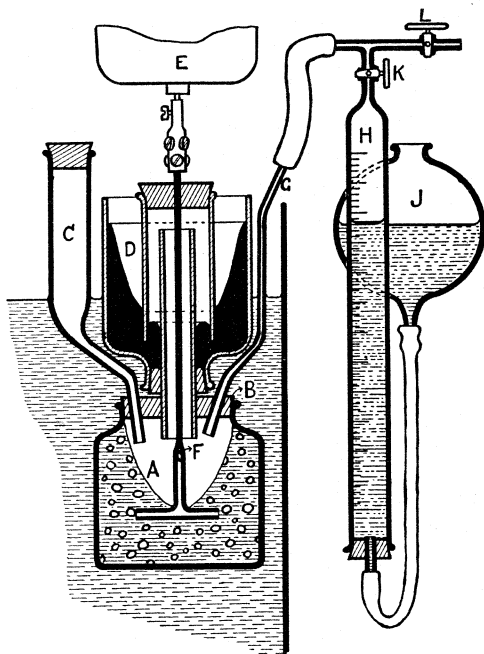

Fig. 2.—Apparatus for measurement of speed of gas evolution (not to scale).

⁶ The author is much indebted to Professor Bray and Mr. B. Makower for suggesting this possibility.

at the hole F and was discharged in a constant stream of bubbles through the open arms of the T-piece. Thus not only was the liquid violently agitated but also it was continually charged with a multitude of small gas bubbles. The third hole in the rubber stopper B carried a tube G leading to the gas buret H, which was filled with water and connected to the counterpoised leveling bulb J. The stopcocks K and L facilitated the manipulation of this part of the apparatus.

The apparatus was used as follows. The charge of peroxide was placed in the vessel A after the stirrer had been adjusted to run steadily without vibration and the apparatus had been placed in position in the bath and proved free from leakage. When this peroxide had reached the temperature of the bath and while the stirrer was running at full speed, the necessary hydrochloric acid was added as rapidly as possible by means of the tube C, which was at once stoppered. On account of the heat of dilution of the acid, it was necessary to determine by previous trial what its temperature must be before addition in order that the temperature of the mixture in the bottle should be the same as that of the bath immediately after the addition. The zero time for the reaction was taken as the instant when half of the acid had been added and measurements of the rate of evolution of oxygen were begun as soon as possible. To make one of these measurements, the stopcocks K and L were opened and J raised until the level of the water was near the top of the buret. After noting the reading of the buret, the stopcock L was closed at a noted instant. As the oxygen accumulated in H, J was lowered to keep the pressure of the gas roughly that of the air outside. When a suitable volume of gas had been collected, K was closed at a noted instant and when the two water menisci were on the same level and the volume of gas was read off. If the readings are taken quickly, several measurements of the rate of gas evolution can be made in quick succession without expelling the gas from the buret. While both K and L are closed, the pressure in the rest of the apparatus rises slightly, but, on opening K again and lowering J, this excess pressure is relieved and a second reading can be taken. The volume of gas collected was corrected for pressure and temperature and divided by the time during which the gas had been collected. This furnished the rate of evolution of oxygen in cc. per minute; this rate of evolution was considered to measure the speed of the reaction at the instant midway between the instants of closing stopcocks L and K. Where several repetitions (usually overlapping one another) were made as described above, the average of the rates was used for further computation. By opening K and L and raising J, the gas collected in the buret was expelled and the apparatus made ready for further rate measurements.

From the values of the speed of reaction at various times thus obtained the unimolecular reaction velocity coefficient was obtained by plotting the logarithm of the speed (in cc. per minute) against the time (in minutes) from the zero of the reaction. The points plotted should lie on a straight line if the reaction is truly unimolecular. The velocity coefficient is obtained by multiplying the slope of the line by -2.303 . This method is especially convenient for studying the early stages of the reaction as it does not necessitate continuing the experiment after sufficient readings have been made to determine the straight line with sufficient accuracy. Also, the method is not affected by what happens to the reaction mixture between readings, provided that its temperature remains constant and that the stirrer has been running for a sufficiently long time before making the reading to overcome supersaturation. This method was subsequently used to recalculate the results of the

previous gas evolution experiments; the results agreed well with those of the former method.

The period of acceleration was now very much shorter (from three to fifteen minutes) and, since it was very variable in duplicate experiments and was reduced by higher speed of stirring, it is considered to be almost entirely, if not entirely, due to supersaturation. In any case, it is too short to enable sufficiently accurate rate measurements to be made to permit its use in determining the mechanism of the reaction. Table I gives the condensed results of one experiment by this method. The number of the reading is given in column 1, the time in minutes from the zero of the reaction

to the middle of the collection period in column 2, the duration in minutes of the collection period in column 3, the volume of the collected oxygen (in cc., corrected for pressure and temperature) in column 4 and the rate

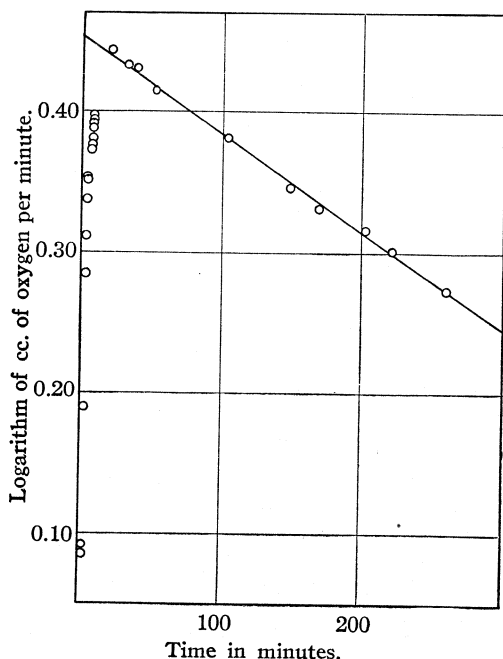

Fig. 3.—Graphical evaluation of k from measured speed of gas evolution.

of evolution of oxygen (in cc. per minute) in the last column. The horizontal lines show when the gas was discharged from the buret. At the beginning of this experiment the stirrer was run at low speed; just before reading number 17 it was speeded up; before 19 it was slowed again; before 22 speeded up; before 24 slowed down again and between 24 and 25 it was stopped altogether for seventeen minutes and then run at full speed. This was to test the efficiency of the stirrer in overcoming supersaturation. The plot of these measurements is shown in Fig. 3, the logarithm of the rate of evolution of gas being plotted as ordinate and the time from zero as abscissa.

The constancy of the velocity coefficient by reactant in the early stages of the reaction was also investigated by a titration method. A measured weight of hydrogen peroxide solution of known titer was placed in a weighing bottle and hung in the bath. At zero time a suitable volume of hydrochloric acid of known concentration was added to the weighing bottle and the weight of acid added was determined by weighing its containing vessel (a stoppered U-tube) before and after the addition of acid. The temperature of the acid was so adjusted before addition that the heat of dilution of the acid just brought the temperature of the mixture to that of the bath. Meanwhile a large beakerful of dilute sulfuric acid had been tinted to a suitable end-point by permanganate. Half of this was reserved for comparison to define the end-point of the titration and to the other half there was added from a weighed weight buret standard permanganate in quantity slightly less than that needed to react with the peroxide in the weighing bottle. At the expiration of the desired reaction period, the weighing bottle was removed from the bath and rapidly washed on the outside with distilled water. The stopper was then removed, the bottle and contents were added to the beaker containing the permanganate solution and the titration then finished so that the tint of the solution matched the blank. From the weight of permanganate solution required and the known titer of the peroxide before addition of acid, the fraction of the peroxide remaining undecomposed could be calculated. Also the concentration of hydrochloric acid in the mixture was calculated. By this means a number of results were obtained for the one reaction period and slightly differing concentrations of acid. The fraction of the peroxide undecomposed at the end of the reaction period was then interpolated graphically for some chosen acid concentration. By a repetition of this process for other reaction periods, ranging from two to forty-five minutes, values were obtained for the fraction of the peroxide undecomposed for a series of times and all for the one acid concentration. The method was very tedious but as far as could be seen the results were exact. On plotting the logarithm of the fraction of peroxide undecomposed against the reaction time, a straight line was obtained in each series of experiments. Hence no measurable irregularity was found in the velocity coefficient as determined by titration of the peroxide, even in the early stages of the reaction.

Table II contains in condensed form the results of all the present experiments in which there are no known sources of gross inaccuracy. In this table the distinguishing number of the experiment is given in column 1. Experiments in which the peroxide was determined by titration are distinguished by T, those in which the rate of evolution of oxygen was measured by G, those in which the rate of evolution of oxygen was measured by bubble counter by B, and two series in which weight titration by permanganate was used are distinguished by W. The concentration of hydrochloric acid in gram molecules per 1000 g. of reaction mixture is given in column 2. The approximate initial concentration of hydrogen peroxide in gram molecules per liter is given in column 3. The total duration of the experiment is given in column 4 and the value of the unimolecular velocity coefficient (k) is given in column 5.

In Fig. 1 these results are shown graphed along with those results of Livingston and Bray¹ and of Maass and Hiebert² which fall within the limits of the graph. In this figure, values of $\log k$ are plotted as ordinates and concentration of hydrochloric acid as abscissas. Curve I shows Livingston and Bray's results at 25°; Curve II shows Maass and Hiebert's

results at 25°; the results of the present investigation are shown in Curves III (25°), IV (30°) and V (35°). It will be seen that the present results are in good agreement with those of Livingston and Bray and quite discordant with those of Maass and Hiebert.

The Temperature Coefficient

Livingston and Bray¹ state that the temperature coefficient of the reaction is 3.60 for a rise of temperature of 10°. This value is based on their measurements at 25 and 40°. The method of calculation used by them appears, however, to be incorrect, in that they have assumed the ratio of velocity coefficients for two temperatures 10° apart to be two-thirds of the ratio of coefficients for temperatures 15° apart. A preferable procedure would seem to be based on the well-known Arrhenius formula

$$\log (k_2/k_1) = A(1/T_1 - 1/T_2)$$

Calculation of the constant A in this expression from Livingston and Bray's data leads to $A = 4500$ and the ratio $k_{35^\circ} : k_{25^\circ}$ derived from this is about 3.1. The results of the present investigation also permit of the calculation of a temperature coefficient. That derived from measurements at 25° and 30° is 3.1, A being 4550. The measurements at 35° are fewer and less reliable than the others but the value of the temperature coefficient derived directly from the measurements at 25 and 35° is 3.25, which leads to $A = 4700$. The value (3.60) given by Livingston and Bray is therefore certainly too high and the true value is in the neighborhood of 3.1.

The author desires to express his sincere thanks to Professor E. J. Hartung for the generous manner in which he has made available facilities for carrying on this work and for his very helpful criticism and advice.

Summary

The decomposition of hydrogen peroxide in the presence of hydrochloric acid has been studied over a moderate range of concentrations at temperatures of 25, 30 and 35°, by methods which have involved measurements of both the residual peroxide and of the rate of evolution of oxygen.

1. The velocity coefficients obtained agree closely with those of Livingston and Bray and disagree with those of Maass and Hiebert.

2. When the concentration of the residual peroxide is measured, the reaction is strictly unimolecular from the first within the limits of measurement.

3. When the rate of evolution of oxygen is measured, the reaction is strictly unimolecular after a very short period of acceleration which is ascribed to supersaturation.

4. The temperature coefficient of the reaction is about 3.1.

5. A method of weight titration of hydrogen peroxide by permanganate is described which enabled reaction velocity measurements to be carried out in the very early stages of the reaction.

6. A graphical method is described which enables unimolecular velocity coefficients to be calculated from measurements of the rate of evolution of gas without any knowledge of the total volume of gas evolved or the exact concentration of the peroxide.

It is believed that both these methods are new.

ABSORPTION SPECTRA AT HIGH PRESSURES AND AT LOW TEMPERATURES. THE TRANSPARENCY OF ARGON AND METHANE¹

By B. J. EISEMAN, JR.

RECEIVED NOVEMBER 24, 1931

PUBLISHED MAY 7, 1932

The purpose of this investigation was to study the absorption spectra of a number of substances whose pressure, volume, and temperature relations suggested the possibility of molecular aggregation as a factor in the attempt to account for the physical properties at high concentration and at low temperature. Since it was not possible to predict the spectral region of the absorption of the supposed associated or aggregated molecular species, the spectral region selected was the visible and the quartz ultra-violet, where absorption may be most readily studied. In this paper we shall describe the design of apparatus found satisfactory for the purpose and the results of the studies with argon and methane.

Method.—The light absorption was determined by the method of photographic spectrophotometry. The relative blackening of the photographic plate served as a measure of the light transmission through the empty absorption tube and through the tube filled with fluid.

An Adam Hilger E 1 spectrograph with glass and quartz optical system was used for photographing the spectra. Exposures were twenty minutes to one hour for slit widths of 0.01 to 0.02 millimeter.

An under-water spark served as a source of continuous light. However, the usual aluminum and copper electrodes were replaced advantageously by magnesium electrodes for the shorter wave lengths. In later work we have used the hydrogen discharge tube as

¹ The results presented here are to be found in greater detail in the Ph.D. Thesis of B. J. Eiseman, Jr., Massachusetts Institute of Technology, 1927.

a source of continuous ultraviolet radiation. For the visible region, a tungsten ribbon heated with 18 amperes at 6 volts in a nitrogen filled glass bulb was very satisfactory.

The iron spark and iron arc spectra were used for obtaining reference lines for determining the wave lengths.

It is doubtful whether a continuous absorption amounting to less than 10% would have been detected with the procedure described.

Absorption Tubes.—A fused quartz Dewar tube of special design was used to contain the refrigerant and absorption tube during loading and for the low temperature absorption measurements. Two tubulations, opposite each other, in the double walls of the Dewar tube permitted the insertion of an absorption tube through the body of the Dewar tube. Figure 1 shows the Dewar tube with the quartz absorption tube (I), used for the low-temperature measurements. Two quartz tubes (T and T'), each with a plane window (W and W') fused on at one end, and the other end open, were fused into another quartz tube (L) of slightly larger diameter to complete the absorption tube, in which all three tubes (T, T' and L) are coaxial. A side tube (C) on the larger tube connected to the vacuum line and loading system by means of a quartz-Pyrex graded seal. The windows (W and W') were 15 millimeters apart and the bore of the larger tube (L) was 10 millimeters. The refrigerant was prevented from escaping through the small clearance space between the tubulations and the absorption tube by packing moistened asbestos fiber (A) in this space. After the asbestos had dried, rubber tape (R) was wound around the ends of the tubulations and the projecting arms of the absorption tube. A stream of dry nitrogen was passed through N at each end of the absorption tube. In an earlier design tubes T and T' were replaced by quartz rods. However, the ultraviolet transmission was not so satisfactory as in the arrangement described above.

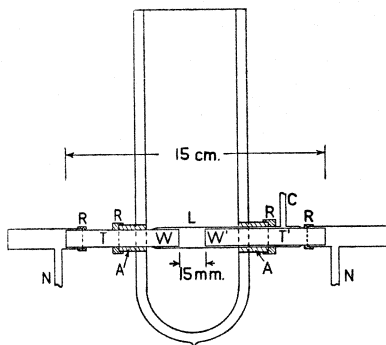

Fig. 1.

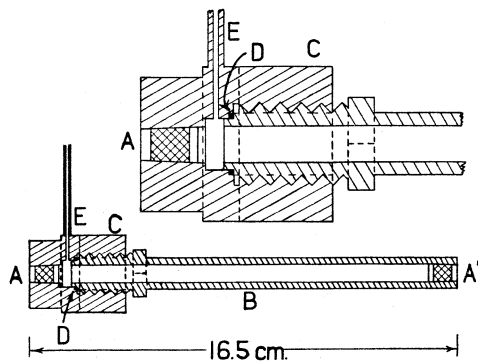

Fig. 2.

Steel absorption tubes with fused-quartz windows were used for the examination of gases at high pressures. In Fig. 2 the tube II was of high tensile strength machine steel. It consisted of two parts (B and C) which could be screwed together. The longer section (B) had an outer diameter of 11 millimeters and a bore of 7.3 millimeters. The bore was tapered at one end to take one of the windows (A'). The other window (A) was in a hexagonal cap (C). An aluminum washer, D, the cross section of which was 1 millimeter square, rendered the tube tight when compressed

between B and C. The assembled tube had a light path of 14.4 centimeters. Connection to the vacuum and loading system was made through E, which was silver soldered to C. The truncated cones (A and A') were of transparent fused quartz, the end faces being polished plane, parallel to each other and perpendicular to the axis of symmetry of the

steel tube. A and A' were carefully ground into their respective tapers in the steel tube by carrying out the preliminary grinding in several replicas of the tapers of the steel tube. The final light grinding was done in the steel tube tapers. The larger faces of the quartz cones were about 8 millimeters in diameter, the taper was about 3° and the height of the truncated cone about 1 centimeter. A number of unsuccessful attempts to produce a tube of this design capable of withstanding a pressure of 500 atmospheres resulted from non-uniform contact between the steel and quartz. In these cases the windows were shattered or so pulverized internally as to become practically opaque upon application of pressure. Inasmuch as the windows are displaced about 0.5 mm. as the pressure is raised to 500 atmospheres, it is very essential that the peripheries of the faces be round chamfered to prevent chipping. The windows were pressed firmly into the steel tapers covered with molten "picein," and tested with an oil injector. During the testing most of the "picein" was extruded, leaving a bright metallic contact surface. The tubes were vacuum tight and could be evacuated so that the pressure rose to only 0.001 millimeter of mercury on standing overnight. The steel absorption tube was of sufficiently small outside diameter to fit into the tubulation of the quartz Dewar tube mentioned above.

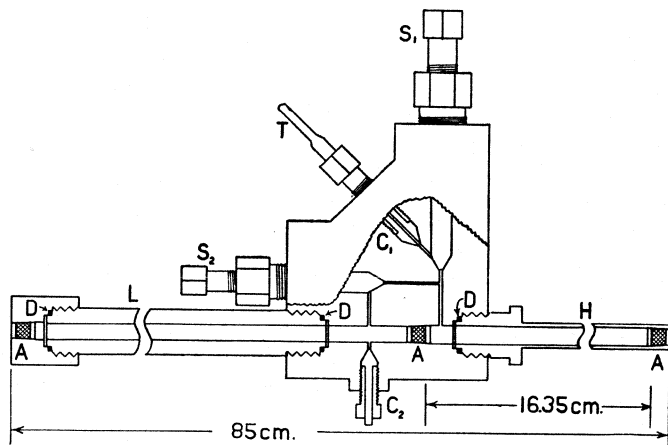

Fig. 3.

A special tube (III) was built for studying Beer's law at high pressures. The general construction was as described for steel tube II. Figure 3 shows a steel absorption tube with three quartz windows (A) affording two absorption chambers of the same internal diameter in tandem. Connection to the vacuum and loading system was made through T, with steel stopcock S_1 . The fluid contained in the shorter tube (H) could be expanded to fill both chambers (H and L) by opening stopcock S_2 . This afforded a considerable change in density of the fluid accompanied by only a slight change in the amount of matter in the light path. The sum of the internal lengths of the absorption chambers was 81.97 centimeters and the internal length of the short absorption chamber was 16.35 centimeters. The ratio of these lengths was 5.013 and the ratio of the corresponding volumes about 3% less. This tube will be referred to as the double steel tube.

Argon

Shaver² found that a column of gas at 140 atmospheres' pressure and 35 centimeters long containing 80% argon and 20% nitrogen was transparent

² W. W. Shaver, *Trans. Roy. Soc. Canada*, **16**, III, 135 (1922).

from 7000 to 2150 Å. E. Meyer³ believed that his measurements showed a slight absorption in the ultraviolet due to gaseous argon at low pressure. Dolezalek,⁴ from a study of the vapor pressures of mixtures of argon and nitrogen, concluded that liquid argon contained a considerable proportion of A_2 .

Liquid argon was examined, since any absorption that might be found would be that of an aggregate and thus of considerable interest.

Procedure.—The argon, supplied in a glass bulb, by the Research Laboratory of the General Electric Company, was specified to be of a high purity. It was manipulated in a glass vacuum line by the use of liquid air at reduced pressure and distilled into the quartz absorption tube (I) in the tubulated Dewar flask containing liquid air.

Results and Discussion.—Liquid argon at about -180° and 135 centimeters of mercury pressure was examined from 6780 to 2450 Å. Argon, as a glassy solid at about -190° and 20 centimeters of mercury pressure, was examined from 2490 to 2130 Å. No absorption was found. Accordingly, argon exercises no sensible selective absorption in the region examined, and if there is a general absorption it must be very small. If aggregates form in appreciable quantity, their absorption does not lie within this spectral region.

Methane

Glockler⁵ found a length of 54 centimeters at atmospheric pressure of methane to be transparent to 2400 Å. Dennison and Ingram⁶ found a length of 10 meters of methane at 70 centimeters pressure of mercury to have one absorption band (8800 to 9000 Å.) in the region from 6500 to 9500 Å.

For this investigation the methane was prepared by the method of Keyes, Smith and Joubert⁷ and loaded into the short steel tube (II). The methane was examined at a pressure of 400 atmospheres at 20° from 6900 to 2150 Å. It was also examined at this concentration, but at a temperature just above that of the disappearance of the liquid phase, from 4500 to 3240 Å. No absorption was found and the conclusions are identical with those for argon.

Acknowledgment.—I wish to thank Professor F. G. Keyes under whose guidance this work was carried out, Dr. R. H. Gerke who suggested the problem, and Professor Louis Harris for his assistance.

THE TRANSMISSION OF LIQUID CARBON DIOXIDE

BY B. J. EISEMAN, JR., AND LOUIS HARRIS

RECEIVED NOVEMBER 24, 1931

PUBLISHED MAY 7, 1932

Preliminary measurements by one of us¹ seemed to indicate a continuous absorption of ultraviolet light by liquid carbon dioxide at room temperature. These measurements were made with the short steel absorption tube.² The double steel tube,² in which the product of length times density was the same through the liquid and gaseous carbon dioxide, gave the same results. When liquid carbon dioxide filled the short arm (16.35 cm.), there was absorption below 3000 Å.; when this liquid was expanded to a gas so that the original mass was distributed over a length of 81.97 cm., no absorption was observed. Upon recondensing this carbon dioxide to a liquid in the short arm, the absorption reappeared. The conclusion seemed inevitable that some molecular species, probably $(\text{CO}_2)_x$, was present in large quantity in the liquid carbon dioxide and absorbed in the ultraviolet. However, after the short arm of the double steel tube had been flushed with liquid carbon dioxide a number of times and the carbon dioxide given more careful purification, the results could not be duplicated. The absorption in the liquid carbon dioxide seemed to be a strange function of the density and eventually disappeared abruptly except perhaps for a slight continuous absorption below 2500 Å. Liquid carbon dioxide containing water (introduced intentionally) showed a slight absorption (beginning around 2650 Å.) which disappeared on vaporizing. (The accuracy of these early measurements was not better than about 10%.) It was necessary to conclude that the absorption in the liquid was due to some dissolved impurity. Whether the impurity causing the absorption was picked up in the absorption tube or was present in the gas originally introduced has not been settled by this work.

Shortly after this phase of the work had been completed, an article by Harig³ appeared on the ultraviolet absorption of liquid carbon dioxide. His results were similar to our early experience except that he found

¹ B. J. Eiseman, Jr., Ph.D. Thesis, M. I. T., 1927.

² B. J. Eiseman, Jr., *THIS JOURNAL*, 54, 1778 (1932).

³ Harig, *Physik. Z.*, 30, 8 (1929).

even more absorption in liquid carbon dioxide. A two-millimeter length of liquid carbon dioxide was sufficient to absorb nearly all radiation below 2600 Å. He found no absorption in a 110-cm. layer of gaseous carbon dioxide at 60 atmospheres. No matter what the conditions of temperature or pressure might be, he found absorption as long as liquid carbon dioxide was present and none through the gaseous carbon dioxide. He concluded that a polymer $(\text{CO}_2)_x$ was present in the liquid carbon dioxide. In the light of our later experience it seemed very certain that Harig was measuring the absorption of some impurity soluble in liquid carbon dioxide. We decided to repeat our measurements in such a way as to avoid all contact of carbon dioxide with grease, oil or any other substances likely to be dissolved by carbon dioxide and thus try to check our later measurements independently.

Preparation of Carbon Dioxide.—Carbon dioxide was prepared by heating sodium bicarbonate. Most of the water was removed by cooling and the last traces of water removed with phosphorus pentoxide. The carbon dioxide was sublimed very slowly three times, first and last portions being discarded each time. The carbon dioxide was stored in large glass bulbs connected to a quartz spiral manometer. Carbon dioxide was introduced from the bulbs into the absorption tube by breaking a tip in a glass valve. (All valves were of this type.) The carbon dioxide was never in contact with grease, cements, or metal.

Apparatus and Manipulation.—The "low temperature" absorption tube² was used for these measurements. Instead of blowing nitrogen on the windows to prevent frost, it was found much more advantageous to add two extra quartz windows to the absorption tube after it had been assembled in the tubulated Dewar tube. The spaces between these extra windows and the windows of the absorption tube were evacuated. There was never any tendency for frost to form on the windows although the body of the absorption tube was kept at -50° for hours. In order to determine the transmission of the absorption tube empty, the lead from the absorption tube was connected to a trap in which the carbon dioxide could be frozen. The absorption tube with this trap attached was sealed off from the pumping system and carbon dioxide reservoir after sufficient (calculated from the known volumes and the change in pressure) carbon dioxide had been loaded into the trap. This arrangement permitted many observations of the transmission, with the tube full or empty, to be made with one sample of carbon dioxide without changing the position of the absorption tube. Solid carbon dioxide-alcohol was the refrigerant used in the tubulated Dewar surrounding the absorption tube, while liquid air was used for freezing out the carbon dioxide in the adjoining trap. At the carbon dioxide triple point (-56.6°) the pressure is 5.2 atmospheres and since it was necessary to make measurements at more elevated temperatures, it was gratifying to find that the absorption tube would withstand pressures up to 10 atmospheres.

The absorption of liquid carbon dioxide was determined at -51° . Although the length of this absorption tube (1.5 cm.) was about one-tenth the length we used previously (ten times the length of the tube used by Harig) the increased density and the lower temperature would certainly favor the formation of carbon dioxide aggregates.

Spectrograms were made with the tube empty and the tube full using a Hilger E 315 spectrograph. A hydrogen discharge tube served as a source

of light. The plates were photometered with the aid of microphotometer lent by Professor G. R. Harrison. The accuracy of the final measurements was within a few per cent. No absorption was observed from 6000 to 2150 Å.

Note.—The last filling of the double steel tube with carbon dioxide was in December, 1928. It was left in January, 1929, with liquid carbon dioxide in the shorter arm. In January, 1931, the amount of liquid was still the same as when it was left two years earlier.

Conclusions

Liquid carbon dioxide (1.5 cm. layer) at -51° has been found to be transparent to the visible and quartz ultraviolet. A 16.35-cm. layer of liquid carbon dioxide at room temperature was also found to be transparent except perhaps for a slight continuous absorption below 2500 Å.

THE KINETICS OF GAS EXPLOSIONS. II. THE THERMAL REACTION BETWEEN OZONE AND HYDROGEN BROMIDE¹

BY BERNARD LEWIS² AND W. FEITKNECHT³

RECEIVED NOVEMBER 30, 1931

PUBLISHED MAY 7, 1932

It was suggested⁴ that the oxygen atom and an active oxygen molecule are the carriers in the reaction chains involved in the thermal decomposition and explosion of ozone sensitized by bromine vapor.^{4,5} In an attempt to detect the presence of free oxygen atoms during this reaction, hydrogen bromide⁶ was added to the mixture, since it is known to react easily with the former.⁷ It was found, however, that ozone reacts with pure hydrogen bromide so rapidly that the chains in the ozone-bromine reaction are dwarfed in comparison with the fast and long chains in this new ozone-hydrogen bromide reaction.

Preliminary experiments indicated that when ozone is added to hydrogen bromide at a pressure of 10 mm. for each gas, an explosion occurs immediately, the hydrogen bromide is oxidized to water vapor and bromine, and any excess ozone is also destroyed. The same action occurs even at temperatures of -77 and -104° at slightly increased pressure. Below the limiting pressure the two gases react at these low temperatures at a fast but measurable rate.

A detailed and comprehensive kinetic study of this reaction disclosed its initial heterogeneity, despite its enormous velocity. The facts leading to the conclusion that the reaction chains start at the walls and then propagate into the gas phase are similar to those given in Part I⁴ of this investigation. In this paper we shall therefore omit detailed experiments but shall point out certain differences and similarities with the ozone-bromine reaction.

Apparatus and Materials.—The apparatus used was the same as described earlier.^{4,8} A Pyrex glass cylindrical reaction vessel 3.5 cm. in diameter and 12 cm. long was used for most experiments. The low-temperature baths used were carbon dioxide-ether (-77°) and boiling ethylene (-104°). Pure hydrogen bromide was prepared from resorcinol and bromine⁹ and was purified by low-temperature distillation. It was kept in the solid state when not in use. Greaseless, non-corrosive needle valves were used in the apparatus to by-pass gases. Pure ozone was prepared as before.^{4,5}

Experimental Procedure.—The reaction could be followed by measuring the decrease in pressure, since the products, water and bromine, have negligible vapor pressures at the low temperatures used. Separate experiments indicated that any reaction between water and hydrogen bromide to form a solid hydrate was negligible.

Usually hydrogen bromide was admitted to the reaction vessel first. At first the pressure increased, and if the initial pressure was above the explosion limit an explosion occurred after a lag of about two seconds. Just below the explosion limit the reaction was complete in ten to twenty seconds after the initial rise in pressure. At considerably lower pressures lag periods varying from three to forty seconds were observed.

For the same pressure and composition the rate of reaction was faster when ozone was admitted first. This probably means that the initial surface adsorption layer, with ozone already adsorbed, favors the initiation of a larger number of chains.

The Non-explosive Reaction.—With an excess of ozone the decrease in pressure in the non-explosive reaction corresponds to the amount of hydrogen bromide used, whereas with excess hydrogen bromide it is approxi-

⁸ Lewis and Schumacher, *Z. Elektrochem.*, **35**, 651 (1929).

⁹ Ephraim and Schärer, *Ber.*, **61**, 2164 (1928).

mately twice as great as the ozone used. This and other data suggest that the reaction follows approximately¹⁰ the formula.

The non-explosive reaction and the lag period preceding it are largely influenced by the activity of the wall. A large increase in activity is obtained when the reaction products of a preceding reaction are left frozen out on the wall.¹¹ The activity increases as the thickness of the layer increases. It reaches a maximum value only after several explosions (compare Fig. 1), but decreases again when this is followed by several non-explosive reactions. The increased activity is due to the increased surface of the frozen reaction products, rather than to a specific chemical effect. An explosion gives rise to more finely divided products.

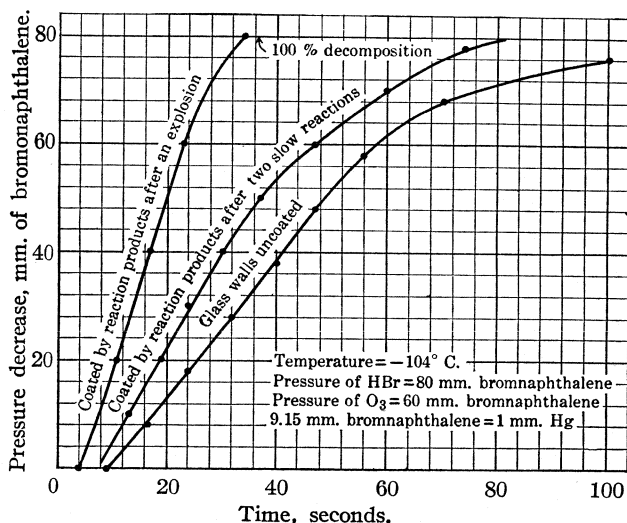

Fig. 1.—Influence of nature of surface on rate of reaction between hydrogen bromide and ozone.

Reaction rates for similar mixtures in a vessel having different activities are shown in Fig. 1. It can be shown that the straight-line portion is due to the lag in freezing out the reaction products and does not represent a zero order reaction. This is evident from Fig. 2, in which the rate is

¹⁰ There are indications that when less ozone than half the hydrogen bromide pressure is used, somewhat more than two molecules of hydrogen bromide may be oxidized by one molecule of ozone but the results obtained so far are not quite conclusive. On the other hand, with excess ozone at higher pressures and especially at the higher temperature (-77°) it is possible that a small amount of ozone is decomposed in addition to that used to oxidize hydrogen bromide in accordance with the above equation.

¹¹ It is impossible to determine whether any or how much of the products are in the form of bromide hydrate.

much smaller for the lower pressures and the curves bend over earlier. If the reaction rates are compared, they are given very well by the relation

$$-\frac{\Delta p}{\Delta t} = k [\text{HBr}]_{\text{init.}} [\text{O}_3]_{\text{init.}} \quad (2)$$

where $[\]_{\text{init.}}$ represents the initial pressures. The k for several experiments is given in the last column of Table I.

TABLE I

THE INITIAL RATE OF THE REACTION BETWEEN HYDROGEN BROMIDE AND OZONE AT DIFFERENT CONCENTRATIONS

Temperature, -104° .	Vessel uncoated.	Pressure in mm. of bromonaphthalene	
Pressure of HBr, mm.	Pressure of O_3 , mm.	$-\frac{\Delta p_{\text{mm.}}}{\Delta t_{\text{sec.}}}$	$k = \frac{\Delta p_{\text{mm.}}}{\Delta t_{\text{sec.}} [\text{HBr}]_{\text{init.}} [\text{O}_3]_{\text{init.}}}$
80	84	1.43	0.021
80	58	1.25	.026
80	38	0.806	.026
60	48	.805	.028
38	44	.52	.031

The small but gradual change in the constants is due to a number of factors which can be shown to decrease the constants at the higher pressures.

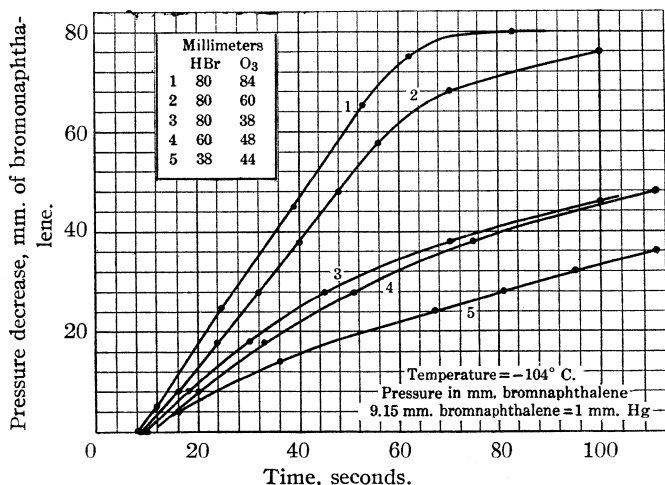

Fig. 2.—Rate of reaction between hydrogen bromide and ozone at different pressures in an uncoated vessel.

Relation (2) is valid in a vessel coated with the reaction products in which the rate of reaction is more than three times as fast as in the uncoated vessel.

From the average of experiments at -77° , k is found to be 0.125, whereas at -104° the average k is 0.026, both in an uncoated vessel. The temperature coefficient is therefore 1.79, which corresponds to a heat of activation of 3800 cal. in this temperature range.

The Effect of Surface and the Influence of Inert Gases on the Non-explosive Reaction.—In a vessel filled with small tubing the reaction was so rapid as to be complete in a few seconds at -104° . In vessels of different sizes with bare or coated walls, the surface, and therefore the activity, was not exactly reproducible. Therefore, no simple relationship could be found between the size of the vessel and the reaction rate. These experiments served, however, to provide additional evidence for the important role played by the surface in starting the reaction.

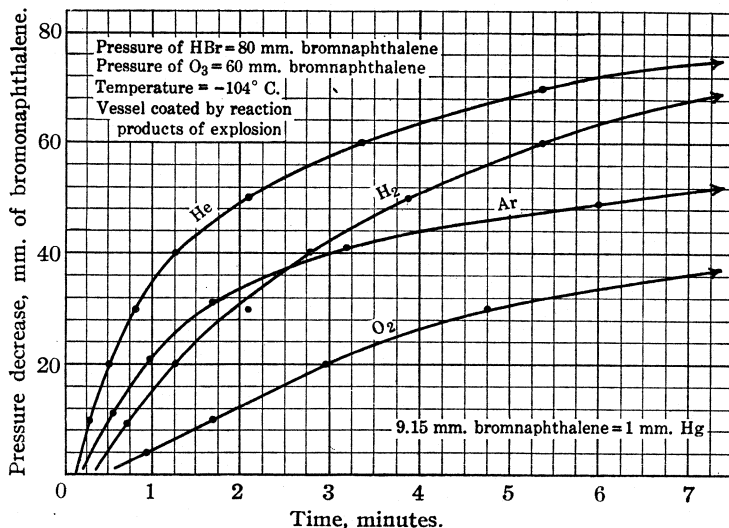

Fig. 3.—Influence of 300 millimeters of inert gas on rate of reaction between hydrogen bromide and ozone.

The rate of reaction decreases markedly with increasing amounts of inert gases. Table II gives the initial rate of pressure decrease for different pressures of four inert gases. The inhibiting influence increases in the order He, A, H_2 ,¹² O_2 . To obtain a more complete picture of the inert gas effects, the curves in Fig. 3 are plotted. It is evident that the curve for argon intersects the curve for hydrogen and that for the latter gas the reaction is completed much earlier. It must be assumed that the inert gases influence only that part of the reaction taking place in the gas phase. It appears that the retarding influence of the inert gases is due to a combined effect of heat capacity and diffusibility. While the monatomic gases can remove less energy from the chain carriers than hydrogen and oxygen, the smaller rate of diffusion in argon begins to impede the reaction, especially at higher pressures, for the reacting gases close to the walls are

¹² Extended experiments with hydrogen indicate that it neither takes part in the reaction nor is acted upon by the reaction products, but that it behaves simply as an inert gas. See reference 6.

quickly used up and fresh gases find it more difficult to diffuse through argon than through hydrogen.

TABLE II

INFLUENCE OF INERT GASES ON THE REACTION BETWEEN HYDROGEN BROMIDE AND OZONE

Temperature, -104° . Vessel coated with reaction products from explosion. Pressure of HBr, 80 mm. of bromonaphthalene. Pressure of O_3 , 60 mm. of bromonaphthalene.

Inert gas	$-\frac{\Delta p_{mm.}}{\Delta t_{sec.}}$ = the initial rate for the following inert gas pressures in mm. of bromonaphthalene			
	0	100	200	300
He	3.2	..	1.16	0.75
A	3.2	1.75	1.00	.58
H ₂	3.2	1.47	0.68	.30
O ₂	3.2	1.52	.50	.12

This marked influence of inert gases is in striking contrast to their slight effect on the ozone-bromine reaction, provided the explosion limit is not approached.⁴

The Explosion Limit.—The explosion limit studied here is what is usually known as the lower explosion limit. If an upper limit exists it cannot be measured conveniently. The transition from non-explosive to explosive reaction is a gradual one. As the pressure is raised, the reaction rate increases, until at the limit the reaction goes over into a general slow inflammation. In contrast with this a sharp detonation occurs if the pressure is raised still more—that is, about 1 mm. It is characterized by a loud click and instantaneous propagation of the explosion through the fine capillaries in the line.

The explosion limit depends on the pressures of both hydrogen bromide and ozone, but the influence of different factors on the explosion limit of equimolecular mixtures only were studied. The results obtained are similar to those found in the ozone-bromine reaction and are listed briefly.

1. The limit depends on the activity of the walls.

TABLE III

Conditions	Temp., $^{\circ}C$.	Explosion limit, mm. of bromonaphthalene total pressure equimolecular mixture
Inactive vessel	-104	400
After several explosions	-104	340
Vessel coated with reaction products from previous explosion	-104	220
Active vessel (uncoated)	-104	340
Active vessel (uncoated)	-77	340
Active vessel (uncoated)	0	160

2. No explosions could be obtained in a vessel filled with small glass tubing.

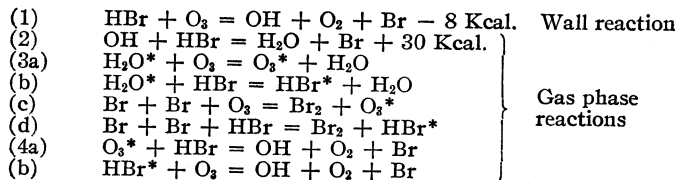

3. A hyperbolic relation was found between the explosion limit and the diameter of cylindrical vessels. Conclusions similar to those in the ozone-

bromine reaction may be drawn: namely, that it is necessary to build up a definite critical concentration of reaction carriers before an explosion results. The results show that the concentration of reaction carriers necessary to bring about an explosion is built up considerably faster in the ozone-hydrogen bromide reaction than in the ozone-bromine reaction.

Effect of Inert Gases on Explosion Limit.—Inert gases increase the explosion limit in the order A, O₂, He, H₂, which is the same order as in the ozone-bromine reaction.

Discussion

The experiments indicate clearly that the initial step in the reaction occurs at the walls between ozone and hydrogen bromide. Some active product, which we believe to be the OH radical, is ejected into the gas phase, where a series of reaction chains develops. The following mechanism is proposed to account for the experimental facts.

where the * indicates an energy-rich molecule.

From the temperature coefficient of the non-explosive reaction a heat of activation of 4000 cal. is found. This probably applies to the wall reaction 1. The calculation of the heat of reaction 1 gives -8000 cal. It is quite reasonable to assume that this value is reduced for the wall reaction to the 4000 cal. found by experiment. Activated O₃* or HBr* formed in 3a and b, c and d, may easily react in the gas phase as in 4a and b. The removal of bromine atoms by the reaction

is improbable, since this reaction takes place with difficulty. A schematic diagram similar to that given in the ozone-bromine reaction¹³ shows clearly how branching as well as straight chains may occur.

There are certain striking differences and similarities between the ozone-bromine and the ozone-hydrogen bromide reactions. The slight influence of inert gases in the non-explosive region on the former reaction and their large influence in the latter reaction, together with the fact that explosions are possible in the hydrogen bromide reaction in vessels of smaller diameter than with the ozone-bromine reaction, indicates that in the ozone-bromine reaction the number of reactions in a chain are relatively fewer and take place with difficulty (see also Ref. 4), whereas in the ozone-hydrogen bromide reaction the chains are long and occur with ease.

¹³ Ref. 4, p. 2930.

The order of inert gases in increasing the explosion limit is exactly the same in the two reactions. On the other hand, the order of inert gases in their effect on the non-explosive reactions is different. For the explosion limits, the effectiveness of inert gases lies in their ability to transport to the wall the heat liberated in the fast reaction—that is, their heat conductivities. The higher the heat conductivity, the higher the explosion limit. However, in the non-explosive reaction the effectiveness of inert gases in decreasing the rate probably lies principally in their ability to deactivate carriers and terminate chains. There is no way of predicting the order, since it depends not only on the heat capacity of the inert gas but also on some specificity involving the transfer of energy from the particular carrier in each reaction to the inert gas molecule.

It is interesting that the non-explosive reaction follows the equation

without further decomposition of ozone when it is present in excess. This is probably due to the fact that the energy taken up by ozone in 3a is insufficient to allow it to react with an ordinary ozone molecule (energy of activation *ca.* 29,000 cal.) but is sufficient for reaction 4a, which has a smaller energy of activation. The occurrence of a detonation at higher pressures and temperatures is probably due to the propagation of ozone chains.

The Effect of Hydrogen Chloride on the Ozone-Bromine Reaction and its Reaction with Ozone.—Since hydrogen chloride reacts readily with oxygen atoms,⁷ this gas was used in an attempt to detect the presence of oxygen atoms in the decomposition of ozone sensitized by bromine. It was found that a very small amount, 0.5 mm., was sufficient to slow down the ozone decomposition very markedly and effectively to prevent an explosion at relatively high ozone pressures. The action of hydrogen chloride is obviously the same as that of water vapor—namely, it covers the walls and prevents the starting of reaction chains therefrom.

Larger amounts of hydrogen chloride undergo a very slow reaction with ozone at 0 and 25° which takes hours to complete itself in contrast to the few seconds necessary for the ozone-hydrogen bromide reaction. Chlorine is one of the products and probably also oxides of chlorine, which very likely react with the water to form acids. The reaction appears to be a wall reaction, but no chains are initiated in the gas phase due to unfavorable energy conditions. An extended study of this reaction was not thought profitable for our immediate purpose.

Summary

The kinetics of the non-explosive and explosive reactions between ozone and hydrogen bromide have been studied from 0 to -104° . *Inflammation and detonation have been observed down to -104° .* The de-

pendence of the rate of reaction and the explosion limit on size of vessel, activity of the wall, inert gases and temperature, have been investigated. The reaction affords another example in which *chains are initiated at the wall and are propagated thence into the gas phase*. In the proposed mechanism the OH radical is believed to be the carrier in these reaction chains.

The effect of hydrogen chloride on the bromine sensitized ozone decomposition and its reaction with ozone have been studied. Very small amounts of hydrogen chloride prevent explosions in the former, while its reaction with ozone seems to be confined to a wall reaction.

THE CATALYTIC DECOMPOSITION OF HYDROGEN PEROXIDE BY THE IODINE-IODIDE COUPLE AT 25°

By HERMAN A. LIEBHAFSKY

RECEIVED DECEMBER 7, 1931

PUBLISHED MAY 7, 1932

Introduction

The reaction system comprising hydrogen peroxide, iodine and iodide ion in neutral and dilute acid solutions has provided the material for a series of investigations extending over some three-fourths of a century, and culminating in the intensive work of Abel.¹ With the last of his papers on the subject, it seemed that these investigations could be regarded as complete, and that this reaction system, while apparently similar to the bromine-bromide system investigated by Bray and Livingston,² was in reality much more complex. In establishing a mechanism for this complex system, Abel deduced for the specific rate of the hydrolysis of iodine (into hypiodous and hydriodic acids) a value which has proved irreconcilable with related experimental results.³ The iodine-iodide reaction system is therefore being re-investigated over a wide range of experimental conditions: that part of the investigation dealing with the pure catalytic decomposition of hydrogen peroxide by the iodine-iodide couple is presented here.

Rate Measurements at the Steady State.—Within a short time after hydrogen peroxide is added to a neutral solution of iodide ion, a *steady state* is reached, in which the main reaction is the catalytic decomposition of hydrogen peroxide

¹ (a) Abel, *Z. physik. Chem.*, **136**, 16 (1928); (b) *ibid.*, **96**, 1 (1920). For a comprehensive historical summary of earlier work by Abel and others, the reader is referred to Ref. 1b.

² Bray and Livingston, *THIS JOURNAL*, **45**, 1251 (1923).

³ (a) Liebhafsky, *Z. physik. Chem.*, **155**, 289 (1931); (b) *THIS JOURNAL*, **53**, 2074 (1931).

The establishing of this steady state is accompanied by an increase in the rate of oxygen evolution, which is initially zero, to the value determined at any temperature by the concentrations of the substances reacting at the steady state. After this rapid initial increase, the rate of oxygen evolution furnishes a convenient measure of the rate at which the catalysis, Reaction 1, proceeds. The results of a series of measurements show that the rate law for this evolution of oxygen⁴ is

$$+\frac{dO_2}{dt} = kH_2O_2 \text{ or } -\frac{d(H_2O_2)}{dt} = k(H_2O_2) \quad (2)$$

that is, the catalytic decomposition of hydrogen peroxide by the iodine-iodide couple is always first order with respect to hydrogen peroxide.

The apparatus in Fig. 1 was patterned after that of Abel.^{1b} The reaction mixture was stirred in a one-liter flask, indentations in which served as baffles. The evolved oxygen was measured in a gas buret attached to B; initial time was taken when the peroxide, added by inverting the cup A, hit the solution.

With a 400-cc. reaction mixture and moderate rates of oxygen evolution, the results depended on the rate of stirring only when this was below 900 r. p. m. When oxygen was evolved faster than 50 cc. per minute, as in experiments at high concentrations of iodide ion, where approximately half the peroxide decomposed in the first minute, accurate results were not obtained even with stirring above 1500 r. p. m.; irregularities in such results (*cf.* the right-hand side of Fig. 3) were attributed to supersaturation. For experiments at low (I^-), the addition of sand effectively prevented supersaturation.

For measurements at (I^-) below $10^{-2} M$ (*cf.* the left-hand side of Fig. 3) an accurate value for the rate of oxygen evolution was obtained before

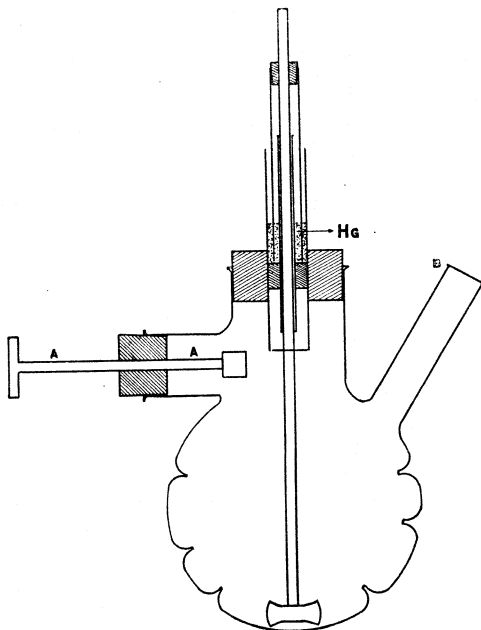

Fig. 1.—Gas evolution apparatus.

were not obtained even with stirring above 1500 r. p. m.; irregularities in such results (*cf.* the right-hand side of Fig. 3) were attributed to supersaturation. For experiments at low (I^-), the addition of sand effectively prevented supersaturation.

For measurements at (I^-) below $10^{-2} M$ (*cf.* the left-hand side of Fig. 3) an accurate value for the rate of oxygen evolution was obtained before

⁴ Since Equation 2 expresses the rate law for a first-order reaction, the value of k is independent of mass units, provided the same unit is employed throughout. k has therefore the same value in both the formulations given above. () denotes "concentration of" in moles/liter; formulas alone denote quantities.

(H_2O_2) had sensibly changed, and k was taken as the quotient of this rate by the concentration of hydrogen peroxide. For experiments at higher (I-) the following integral method was used in evaluating k . If x represents the cc. of oxygen evolved in such an experiment at an arbitrary time, t , and a represents the value of x when the reaction has gone to completion, then $k/2.30$ is the slope of the line obtained by plotting $a - x$ as ordinate on *semi-logarithmic* paper against t as abscissa. To illustrate this method of plotting and to demonstrate that Reaction 1 is first order with respect to hydrogen peroxide, the results of several experiments are given in Fig. 2.⁵ Initial time is placed farther to the right for each experiment in order to prevent crowding.

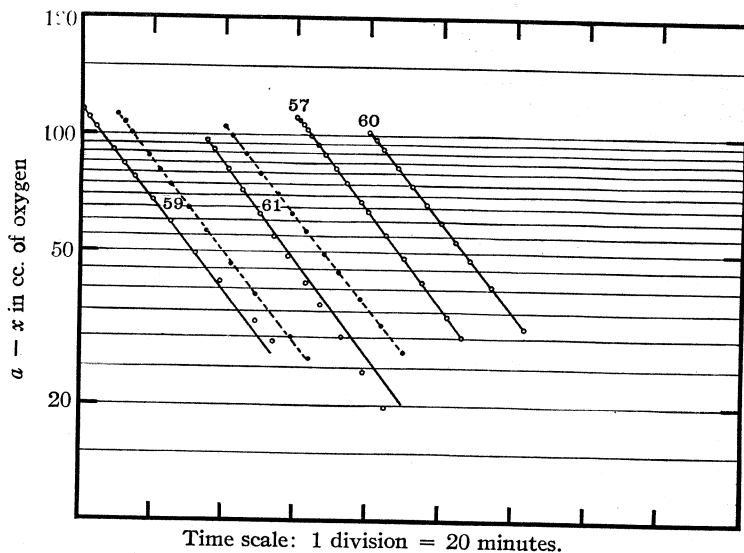

Fig. 2.—Typical rate experiments. (The plot is on semi-logarithmic paper. k values from these experiments are plotted on Curve II, Fig. 4.)

In Fig. 2, two experiments (Nos. 57 and 60) obey perfectly the first order rate law (Equation 2); the points of No. 61 show a downward, and those of No. 59 an upward, trend as the reaction nears completion. When the a values for these two experiments are properly corrected by the number of cc. of oxygen corresponding to the distance of the last point from the solid line, (for No. 61 a is increased by 8 cc., while for No. 59 a is decreased by 3 cc.) these trends disappear entirely as the broken lines,

⁵ It may be pointed out here that the validity of Equation 2 is a sufficient proof that Reaction 1 is the main reaction taking place in the system, for Equation 2 shows that no substance in the system except hydrogen peroxide undergoes a concentration change in the course of the reaction, and it is stoichiometrically impossible to have this condition fulfilled and produce oxygen from hydrogen peroxide except by Reaction 1.

which have been plotted using the corrected a values, show. Such corrections eliminated both positive and negative trends, and, in general, left the value of k practically unaltered. Deviations from Equation 2 were therefore regarded as due only to errors in the experimentally measured value of a caused, for example, by a change in room temperature during the course of an experiment. Measurements were suspended in the slower experiments when these were approximately three-fourths complete, but more rapid experiments often showed Equation 2 to be obeyed within several per cent. of completion.

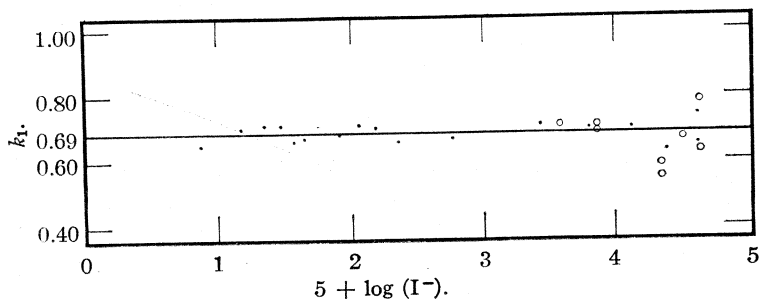

Fig. 3.—Summary of rate measurements in initially neutral iodide solutions:
•, KI solutions; ○, NaI solutions.

From the results of previous investigations^{1b,6} it was expected that in (nearly) neutral solution the complete differential equation for the rate at which hydrogen peroxide is catalytically decomposed would be

$$-\frac{d(\text{H}_2\text{O}_2)}{dt} = k'(\text{H}_2\text{O}_2)(\text{I}^-) \quad (3)$$

corresponding to the reaction

by which hydrogen peroxide is reduced at the steady state. Since one mole of hydrogen peroxide is oxidized for every mole thus reduced, then, for the same concentrations of peroxide and iodide ion, $-(d(\text{H}_2\text{O}_2)/dt)$ in Equation 3 will be twice as great as $-(d(\text{H}_2\text{O}_2)/dt)$ for Reaction 4 at a distance from the steady state. It follows, therefore, that k' will be twice k_1 , the specific rate constant for Reaction 4; or

$$k_1 = \frac{k'}{2} = \frac{k}{2(\text{I}^-)} \quad (5)$$

The rate at which hydrogen peroxide is reduced at the steady state by iodide ion may now be written as

$$-\frac{d(\text{H}_2\text{O}_2)}{dt} = k_1(\text{H}_2\text{O}_2)(\text{I}^-) \quad (6)$$

⁶ (a) Among others, Walton, *Z. physik. Chem.*, **47**, 185 (1904); (b) Noyes, *ibid.*, **18**, 118 (1895).

The k_1 values plotted in Fig. 3 against $\log (I^-) + 5$ as abscissa were obtained at 25° from measurements on a series of initially neutral reaction mixtures; the constancy of k_1 means that Reaction 4 is subject to practically zero salt effect when (I^-) is below 0.1 M and the ionic strength of the reaction system is at a minimum. That this is no longer true when foreign salts are present will be apparent from the k_1 values given in a later section (cf. Fig. 4). The value $k_1 = 0.69$ is in almost perfect agreement with the value $1.34/2 = 0.67$, which was obtained by Walton (Ref. 6a, Table 6) from similar experiments over a much smaller concentration range. The

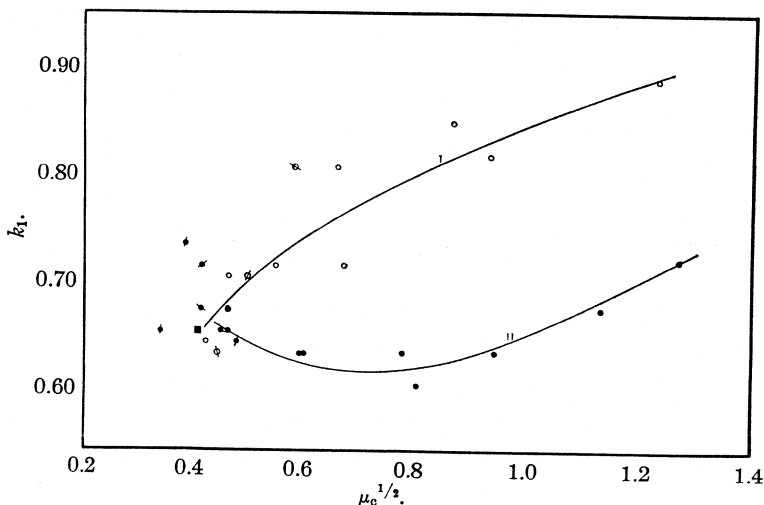

Fig. 4.—Variation of k_1 with ionic strength in the presence of Sørensen phosphate buffer. (Added salt: \circ , NaClO_4 (Curve I); \bullet , Na_2SO_4 (Curve II); ϕ , KI, and \bullet , phosphate buffer only. \blacksquare is the initial point for Curves I and II, and corresponds to a reaction mixture in which $a_{\text{H}^+} = 1.01(10^{-7})$ and $(I^-) = 0.0215$).

value given by Abel for a reaction system containing acetate ion is somewhat higher (Ref. 1b, page 26, has $k_1 = 1.57/2 = 0.78$), probably mainly because the degree of dissociation of potassium iodide as obtained from conductivity measurements was used in its evaluation. Noyes^{6b} finds, by following the rate of iodine formation in solutions of varying acid concentration, that $k_1 = 0.68$ to 0.82 . Since this variation of k_1 is in the form of a trend with (H^+) which may be attributed (as Bray, *Z. physik. Chem.*, **54**, 463 (1906) has shown) to a third-order reaction

negligible in our reaction system, Noyes' value also is in good agreement with the result of the present investigation.

The theory of the hydrogen peroxide catalysis^{1a,2} requires that there be, in addition to Reaction 4, a compensating reaction in which hydrogen per-

oxide is oxidized. The simplest one that has been suggested is the oxidation of H_2O_2 by IO^- , a product in Reaction 4

Hypoiodite ion will exist in the reaction system at an extremely low concentration, always governed at the steady state by the equilibrium

From Equations 7 and 8 it is apparent, therefore, that the absolute rate at which hydrogen peroxide is oxidized at the steady state may be written

$$-\frac{d(\text{H}_2\text{O}_2)}{dt} = k_2(\text{IO}^-)(\text{H}_2\text{O}_2) = k_2' \frac{(\text{I}_2)}{(\text{I}^-)(a_{\text{H}^+})^2 \gamma_{\text{I}^-} \gamma_{\text{IO}^-}} (\text{H}_2\text{O}_2) \quad (9)$$

In this expression k_2' is the product of k_2 , the specific rate constant for Reaction 7, by K' , the equilibrium constant for Reaction 8. Since no suitable values for the activity coefficients γ_{I^-} and γ_{IO^-} are available, Equation 9 will be written in the convenient form

$$-\frac{d(\text{H}_2\text{O}_2)}{dt} = k_2' \frac{(\text{I}_2)}{(\text{I}^-)(a_{\text{H}^+})^2} (\text{H}_2\text{O}_2) \quad (9a)$$

We shall see later that the kinetic interpretation of our results does not depend upon this approximate formulation of Equation 9.

When the steady state has been reached, the rate at which hydrogen peroxide is reduced (Equation 3) is equal to the rate at which it is oxidized according to Equation 9a if *hypoiodite ion alone* oxidizes the peroxide. Subject to this condition, we may write

$$k_1(\text{H}_2\text{O}_2)(\text{I}^-) = k_2' \frac{(\text{I}_2)}{(\text{I}^-)(a_{\text{H}^+})^2} (\text{H}_2\text{O}_2) \quad (10)$$

and

$$\frac{k_2'}{k_1} = \frac{(\text{I}^-)^2 (a_{\text{H}^+})^2}{(\text{I}_2)} = F \quad (11)$$

A sufficient constancy of F over a wide range of experimental conditions may thus serve as a test for the assumption that hydrogen peroxide is oxidized by hypoiodite ion alone. It may be pointed out here that F has the form of the steady state function found by Bray and Livingston for the bromine-bromide catalysis⁷ where the hypohalous acid, and not the corresponding ion, was involved in both compensating reactions.

Concentration Measurements at the Steady State.—When hydrogen peroxide is added to an initially neutral solution of iodide ion, the approach to the steady state is characterized by the oxidation of a small amount of iodide according to the stoichiometric equation

consequently, the solution becomes slightly alkaline. The accurate determination of F is most conveniently accomplished with the use of buffer

⁷ Cf. Ref 2, p. 1262.

solutions, for then the activity of hydrogen ion at the steady state can be calculated with some degree of accuracy. When the initial concentration, $(I^-)_i$, of iodide ion in a reaction mixture at the steady state is known, and the total amount of oxidized iodide, $\Sigma(I_2)$, $\Sigma(I_2) = (I_2) + (I_2^-)$ has been determined by titration, the value of F may be calculated. In making this calculation, the equilibrium

must be considered; $(I_2)(I^-)/(I_3^-) = 0.00140$ at 25° was employed throughout in calculating (I_2) and (I^-) . Any change of buffer in the approach to the steady state is, of course, governed by stoichiometric relations similar to those in Equation 12; the hydrogen ion activity used in the calculation of F was always that corresponding to the buffer solution actually present at the steady state.

For most experiments $\Sigma(I_2)$ was determined by titration with thiosulfate after all of the peroxide had been decomposed. For experiments in which this decomposition was very slow, however, it was often necessary to titrate while peroxide was still present: this could be accomplished satisfactorily when both (H_2O_2) and (I^-) were so low that no appreciable oxidation of iodide ion took place during titration. Such oxidation could always be detected by an "afterbluing" of the solution when the starch end-point had once been reached. At these low concentrations of hydrogen peroxide, blank experiments showed no evidence of reaction between the peroxide and thiosulfate. In general, sufficient (two or more) determinations to ensure a reliable value of $\Sigma(I_2)$ were made for each steady state mixture.

The results of three series of such experiments are listed in Table I in which all data except the initial concentrations of iodide ion, $(I^-)_i$, are for the steady state. The values of a_{H^+} for Table Ia were obtained from the expression

$$P_H = -\log a_{H^+} = 4.73 + \log \frac{\text{acetate ion}}{\text{acetic acid}} + \log \gamma \quad (14)$$

given by Cohn, Heyroth and Menkin;⁹ the γ values given by the authors for buffer solutions M in total acetate and containing no other salt were employed in the calculation. In Table Ib,¹⁰ values of a_{H^+} were calculated

⁸ Jones and Kaplan, *THIS JOURNAL*, **50**, 1485 (1928).

⁹ Cohn, Heyroth and Menkin, (a) *ibid.*, **50**, 696 (1928); (b) *ibid.*, **49**, 173 (1927).

¹⁰ The experiments in Table Ib were carried out after a similar series, which is not published, to conserve space, employing Sørensen's phosphate solutions (see Clark, "The Determination of Hydrogen Ions," Williams and Wilkins Co., Baltimore, 1928, p. 210) had been completed; values of F calculated from the latter varied from 0.8 (10^{-12}) to 1.8 (10^{-12}), and showed a positive trend with increasing (I^-) . These variations were probably due in part to uncertainties in the calculated values of a_{H^+} , for with the Sørensen buffer (in which total phosphate is only $1/15 M$) large changes in a_{H^+} often took place in the approach to the steady state.

from the apparent dissociation constants given by Cohn (Ref. 9b, Table VI); the effect of added salt on the buffer was again neglected. For experiments with a_{H^+} below $10^{-4} M$, the values of F in Table I show no systematic variation with the concentration of any substance; indeed, all these values (except the first two in Table Ib, which are inaccurate)

remain within a two-fold range while the product $(a_{H^+})^2 (I^-)^2$ varies 10^{12} -fold: under these experimental conditions, therefore, the assumption that *hypiodite ion alone* oxidizes hydrogen peroxide appears justified.

In interpreting the experiments for which a_{H^+} is greater than 10^{-4} , we must remember that from No. 89 to No. 123, Table Ia,¹¹ the value $F = 3.5 (10^{-12})$ has been fairly well maintained despite a variation in the ionic strength, μ_c , from 0.81 to 0.20. That the increase in the values of F for the last four experiments might be due to a change in the ionic strength thus seems extremely improbable; consequently this variation will be treated as possessing a kinetic significance. The experimental data in Table Ia may, for the purpose of deducing a mechanism, be represented by the equation

$$F = 3.5(10^{-12}) + 1(10^{-8})(a_{H^+}) \quad (15)$$

which will give the value of F in acetate buffer solution when the concentration of acetate ion is not above 0.8 M and no other electrolyte is present at high concentration. The first term is probably accurate to $\pm 5\%$, but the second must be regarded as an approximate upper limit only. Equation 15 is to be compared with the equation

$$F = 1.4(10^{-12}) + 1.3(10^{-7})(H^+) \text{ at } \mu_o = 0.4 \quad (16)$$

which Abel obtained from similar experimental results in the region of hydrogen-ion concentrations $2(10^{-8})$ – $2(10^{-7})$ M . The first six experiments of Table Ia lie in this region of acid concentrations; the F_A values calculated for these experiments by the substitution of their a_{H^+} values for (H^+) in Equation 16 are in substantial agreement with the F values of Table Ia. For the remaining experiments in the table, however, F_A thus calculated becomes increasingly larger than F as a_{H^+} increases, until for Experiments 112 and 125 F_A is over *six* times as large as the value $F = 4.8(10^{-12})$ experimentally obtained.¹²

¹¹ Certain of the experiments at the three highest values of a_{H^+} in Table I showed a pronounced decrease in $\Sigma(I_2)$ several hours after the steady state had been reached; to determine whether this decrease might be justifiably interpreted as an *increase* in F with increasing a_{H^+} , several reaction mixtures were prepared by adding hydrogen peroxide to the acetate buffer solution in equilibrium with finely divided iodine. For these reaction mixtures $(I_2) = 0.00132$ M , and $(I^-) = (0.00140/0.00132)[\Sigma(I_2) - 0.00132]$. A decrease in $\Sigma(I_2)$ therefore means a decrease in (I^-) ; and, since a_{H^+} and (I_2) are constant, a decrease in F as well. Since such decreases were observed, this disappearance of iodine must be due to a factor not properly a part of the iodine-iodide system. Subsequent analyses proved the iodine to have been oxidized; it would seem, therefore, that the oxidation of iodine to iodate ion by hydrogen peroxide proceeds at lower values of (H^+) and with shorter induction periods when acetic, instead of perchloric (*cf.* Ref. 3b, Table V; these perchloric acid solutions were not buffered) acid is used. It may be worth pointing out, finally, that the occurrence of this oxidation was quite erratic, and that Table I contains for every value of a_{H^+} at least one experiment in which no such oxidation took place.

¹² See Ref. 1a. Abel calculated (H^+) from the dissociation constant for acetic acid; the concentration of acetate ion in his system was for most experiments 0.4 M .

To show, as Abel^{1a} has already done, that the second term of Equation 15 may be attributed to the oxidation of hydrogen peroxide by hypoiodous acid, we need only to trace backward the reasoning by which Equation 11 was obtained. The steady state function corresponding to this term may obviously be written

$$F' = \frac{(a_{H^+})(I^-)^2}{(I_2)} = \frac{\kappa_2}{k_1} = 1(10^{-8}) \quad (17)$$

The concentration of hypoiodous acid at the steady state is governed by the equilibrium

and hence the rate law for the reaction

may be given the form (cf. Equations 9 and 9a)

$$-\frac{d(H_2O_2)}{dt} = \kappa_2(HIO)(H_2O_2) = \kappa_2' \frac{(I_2)}{(a_{H^+})(I^-)} (H_2O_2) \quad (20)$$

κ_2' , thus defined is the product of κ_2 , the specific rate constant for Reaction 19 by K , the equilibrium constant for Reaction 18.

The values $K = 3(10^{-13})$,¹³ $K' = 6(10^{-24})$ ¹⁴ and $k_1 = 0.69$ will now be used to calculate k_2 , the specific rate of Reaction 7, and the order of magnitude of κ_2 . For 25° we obtain

$$k_2 = \frac{Fk_1}{K'} = 4(10^{11})$$

and

$$\kappa_2 = \frac{F'k_1}{K} < 2(10^4)$$

These values of k_2 and κ_2 , deduced from Equation 15, naturally differ from those (10^{11} and $3.3(10^5)$, respectively) similarly deduced by Abel from Equation 16.^{1a} Measurements of Reactions 7 and 19 at a distance from the steady state have been undertaken in this Laboratory in the hope that these may confirm the value of k_2 , and establish more accurately the value of κ_2 .

Effect on the Reaction System of Changing the Ionic Strength.—In Fig. 4 data are given to show the effect on k_1 of changing μ_c , the ionic strength expressed in moles/liter, by adding various salts. Curve I ($NaClO_4$) and Curve II (Na_2SO_4) both embody the results of two independent series of experiments on reaction mixtures of the composition given below Fig. 4, and to which known amounts of the proper salt were suc-

¹³ Bray and Connolly, THIS JOURNAL, 33, 1485 (1911).

¹⁴ K' is obviously the product of K by the dissociation constant of HIO. The value

$$\frac{(H^+)(IO^-)}{(HIO)} = 2(10^{-11}) - 3(10^{-11})$$

is given by Fürth, Z. Elektrochem., 28, 57 (1922). We shall take $K' = 3(10^{-13}) \times 2(10^{-11}) = 6(10^{-24})$.

cessively added. Of the potassium iodide points, only those corresponding to the lower iodide concentrations are thoroughly reliable because of inaccuracies previously mentioned (*cf.* Fig. 3). The points in which only the phosphate buffer was changed (total phosphate is always $1/15\ M$) show a marked salt effect for a relatively small change in μ_c ; in interpreting these data, it is important to remember that the most basic buffer mixture, which is almost pure Na_2HPO_4 solution, has a value of μ_c not very much greater than the most acid mixture, which is almost pure KH_2PO_4 solution. The phosphate points therefore represent the superposition of two salt effects, one for each type of phosphate. All the results of Fig. 4 may be summarized in the statement that the separate addition of various salts to the reaction mixture produces on k_1 effects which are in general small, not "linear" (*cf.* Ref. 16), and quite specific.

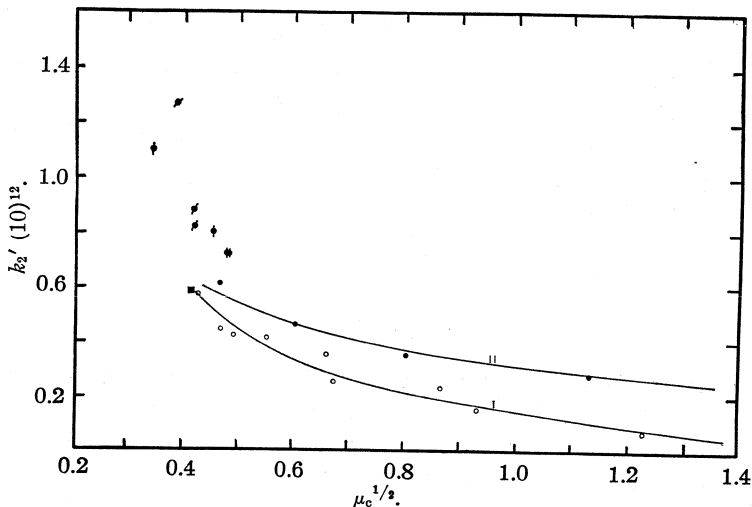

Fig. 5.—Variation of k_2' with ionic strength in the presence of Sørensen phosphate buffer. (Added salt: \circ , NaClO_4 (Curve I); \bullet , Na_2SO_4 (Curve II); and \blacksquare , phosphate buffer only. For composition of reaction mixture designated by \blacksquare , the initial point for the curves, see Fig. 4.)

An examination of Fig. 5 will reveal that addition of sodium perchlorate (Curve I) or sodium sulfate (Curve II) decreases the value of k_2' as calculated from the values of F and k_1 for each reaction mixture. It is apparent from Equation 9, which serves to define k_2' , that this constant is more complex in nature than k_1 , the specific rate of the simple bimolecular Reaction 4. As in Fig. 4, the phosphate points represent the superposition of two salt effects. No matter what salt is added, the effect on k_2' is relatively much greater than the corresponding effect shown in Fig. 4 for k_1 ; this result might have been expected from the fact that the concentra-

tion of hypoiodite ion is governed by the equilibria, Reactions 8 and 13, and by the buffer equilibrium which regulates the activity of hydrogen ion. The salt effect on k_2' is thus the resultant of several equilibrium salt effects,¹⁵ which may be large, and a kinetic salt effect, which is probably small.

Jones and Kaplan have observed $(I^-)(I_2)/(I_3^-)$ to be constant for values of (I^-) below 0.3 *M* in solutions not saturated with iodine, and this constancy may be regarded as evidence that γ_{I^-} and $\gamma_{I_3^-}$ remain proportional to each other over this concentration range. It seems probable that this proportionality will be maintained when other salts are added in moderate amount to dilute solutions of tri-iodide ion—in other words, that our use of the value $(I^-)(I_2)/(I_3^-) = 0.00140$ at varying ionic strength is justified, and that Reaction 13 undergoes no salt effect as large as those in Fig. 5.

To determine whether these effects are due mainly to a salt effect on the equilibrium

measurements were made with a glass electrode of the hydrogen-ion activity in an equimolal Sørensen phosphate buffer solution to which other salts had been added. It was found that a_{H^+} was increased when μ_c was raised to 1 *M* by the addition of sodium perchlorate or sodium sulfate; the increase was greater for the perchlorate, but in both cases it was more than sufficient to explain any decrease in k_2' given by Curves I and II.

Finally, we shall consider how far our main conclusions are dependent on the empirical (and somewhat arbitrary) manner in which we have disposed of activity coefficients in the formulation of *F* (*cf.* Equations 9, 9a and 11). This formulation is convenient for three reasons: it employs the activity of hydrogen ion,¹⁶ which, rather than the concentration, is given by buffer tables; it makes no assumption with regard to γ_{I^-} and γ_{IO^-} ; and it is applicable to both the buffers employed. This formulation does assume, however, that substances present in the reaction system, but not properly a part of the buffer solution, do not affect the value of a_{H^+} given by the buffer tables. We have seen in the case of the phosphate

¹⁵ Brönsted has given the name "secondary kinetic salt effect" to the salt effect on an equilibrium (see, for example, "The Velocity of Ionic Reactions," Contemporary Developments in Chemistry, Columbia University Press, 1927). The use of the term "equilibrium salt effect" might serve to distinguish more clearly between this and a true "kinetic salt effect," such as that on k_1 , which has been called a "primary kinetic salt effect" by Brönsted.

¹⁶ By "activity of hydrogen ion" in a solution is meant the quantity (whose negative logarithm may be regarded as the P_H of the solution) which may be obtained from a hydrogen electrode measurement. (In this connection, *cf.* Ref. 9a.) Whether an individual ion activity has an experimental significance in moderately concentrated solutions if the kinds and concentrations of other ions are left unspecified is another question.

buffer (*cf.* Fig. 5) that this assumption is not valid. In the case of the acetate buffer, however, the added iodide is so small (*cf.* Table Ia) that the value of a_{H^+} is probably unaffected by its addition. The conclusions drawn from Table Ia are therefore uncertain only to the extent to which changing (Ac^-) from 0.1 (Nos. 112, 125) to 0.9 *M* (No. 88) affects γ_{I^-} and γ_{IO^-} .

That this effect cannot be large enough to cause a mistake in the kinetic interpretation of the data is evident from the following considerations. If, in the thermodynamically exact formulation of F , the buffer equilibrium

is included, Equation 11 becomes

$$F_{\text{exact}} = \frac{\gamma_{I^-} - \gamma_{IO^-} - (\gamma_{HAc})^2}{(\gamma_{Ac^-})^2 \gamma_{I_2}} \frac{(I^-)^2 (HAc)^2}{(Ac^-)^2 (I_2)} (K_{HAc})^2 \quad (11a)$$

where K_{HAc} is the dissociation constant of acetic acid. Although the factor involving the activity coefficients is probably not equal to unity even in moderately dilute solutions, it is obvious that its value should change very little when the ionic strength is changed. This consideration leads to the very simple result that the concentration term, which we shall call F_c , in Equation 11a should be constant¹⁷ for all experiments in Table Ia with a_{H^+} below 10^{-4} *M*. In Table II are listed values of F_c calculated for the experiments in Table Ia by use of the value $K'_{HAc} = 2.55 (10^{-5})$ ¹⁸ for the buffer solution employed in Nos. 112 and 125, Table Ia.

TABLE II
RECALCULATION OF MEASUREMENTS IN TABLE Ia^a

Expt.	112	124	123	96	95	87	91	90	89	93	92	88
	125	111	110									
			97									
$\frac{(HAc)}{(Ac^-)}$	90	85	80	70	60	50	40	30	20	15	10	8.8
F_c	5.0	4.2	3.6	3.4	3.6	3.8	3.5	4.0	4.0	3.5	3.1	2.7
F	4.9	4.3	3.6	3.5	3.6	3.7	3.2	3.5	3.2	2.7	2.1	1.8

^a Average values are given for duplicate experiments.

The constancy of the F_c values is all that could be expected; at the higher acetate-ion concentrations they are more constant than the F values themselves. The approximate formulation of F in Equation 11

¹⁷ Abel [*Z. physik. Chem.*, **122**, 49 (1926)] has pointed out that a similar simplification is possible in a study of the oxidation of iodide by iodate ion in acetic acid-acetate ion buffer solutions.

¹⁸ Ref. 9a, Table II. The *apparent* dissociation constant is defined by the equation $K'_{HAc} = a_{H^+}(Ac^-)/(HAc)$; this value, rather than the *absolute* value $K_{HAc} = 1.86 (10^{-5})$, must be used if agreement with F as calculated for Nos. 112 and 125, Table Ia, is to be obtained. The use of the absolute value would not affect the above argument; for this relates only to the trend in F_c , which is unaffected by the value of K_{HAc} chosen.

therefore suffices for purposes of establishing a mechanism. A thermodynamically exact formulation of the steady state function cannot be given, however, until more knowledge is available regarding the activity coefficients concerned.

Conclusion

A re-investigation of the catalytic decomposition of hydrogen peroxide by the iodine-iodide couple has confirmed the mechanism previously assigned to the decomposition at the steady state, and has demonstrated its validity over a much greater concentration range. Although the results obtained differ somewhat from those of Abel, these differences are not great enough to explain why his value for the specific rate of the iodine hydrolysis is smaller by several powers of ten than the lower limit deduced for this constant from related reaction systems. Preliminary experiments indicate that the solution of this difficulty may be found in the investigation of Reactions 7 and 19 at a distance from the steady state.

The author wishes to thank Mr. L. H. Donnally of this Laboratory for making the glass electrode measurements.

Summary

1. Measurements of the rate at which hydrogen peroxide is decomposed at 25° by the iodine-iodide couple yielded the value $k_1 = 0.69 \pm 3\%$ for the specific rate of the reaction

over a 10^3 -fold range of iodide concentrations.

2. Subject to certain restrictions, the steady state function for this decomposition was found to be

$$F = 3.5(10^{-12}) + 1(10^{-8})a_{\text{H}^+} \text{ at } 25^\circ \quad (15)$$

3. By combining rate, steady state, and equilibrium data, the specific rates at 25° for the reactions

and

were computed to be, respectively, $k_2 = 4(10^{11})$ and $\kappa_2 < 2(10^4)$. The value of κ_2 is much less accurate than that of k_2 .

4. The reaction system has been studied over a series of ionic strength values produced by the addition of various salts.

5. For values of a_{H^+} below $10^{-4} M$, only Reactions 4 and 7 need be assumed to explain the decomposition of hydrogen peroxide by the iodine-iodide couple at the steady state. As a_{H^+} is increased, Reaction 19 plays an increasingly important role; at the steady state, however, the absolute rate of Reaction 4 always equals the combined absolute rates of Reactions

7 and 19. This mechanism will explain the catalysis below the value of α_{H^+} at which oxidation of iodine by hydrogen peroxide begins.

THE PHOTOCHEMICAL DECOMPOSITION OF AMMONIA

By EDWIN O. WIIG¹ AND G. B. KISTIAKOWSKY

RECEIVED DECEMBER 9, 1931

PUBLISHED MAY 7, 1932

The mechanism of the apparently simple photochemical decomposition of ammonia by ultraviolet light is still far from being settled. The reaction has been studied by Warburg and by Kuhn in light of wave length 2025–2140 Å. The former² obtained a quantum yield of 0.25, whereas the latter³ found an average of 0.45 molecule of ammonia decomposed per quantum of light energy absorbed. In the far ultraviolet, 1600–1900 Å., the quantum yield reported by Kassel and Noyes⁴ is 0.69 ± 0.24 . These quantum yields have been calculated on the assumption that the photochemical decomposition follows the equation

However, Bates and Taylor⁵ state that the products of decomposition contain 96% hydrogen and 4% nitrogen and express the view that hydrazine is formed, some of which may subsequently decompose. Recently, just as this work was completed, Koenig and Brings⁶ reported hydrazine as a product of the photochemical decomposition of ammonia by ultraviolet light. By repeatedly flowing ammonia gas back and forth through a quartz vessel exposed to the radiation from a zinc spark for fifty hours and by continuously freezing out the hydrazine, a very minute quantity of the latter was condensed, sufficient for a qualitative test. Warburg and Kuhn determined the amount of reaction by measuring the increase in pressure, so that their low quantum yields might be accounted for by assuming that the reaction which occurs is largely

instead of equation (1). Kuhn found that on complete decomposition of ammonia the pressure doubled; this, however, does not prove much since hydrazine would also decompose under such treatment.

It is evident then that the composition of the gas resulting from the photolysis of ammonia should be determined under the same conditions

that obtain during quantum yield measurements. It was the object of the present work to determine the nature of the gas formed when ammonia is exposed to ultraviolet light and to obtain the quantum yields for the reaction at room temperature and at higher temperatures.

Experimental Details

Light Source.—A condensed spark discharge served as the source of ultraviolet light. The spark gap was an adaptation of one described recently by Forbes and Brackett.⁷ It consisted of two metallic disks 8 cm. in diameter and 5 mm. thick with V shaped edges. The disks—made of aluminum, zinc or cadmium—were mounted at right angles one above the other (Fig. 1) and were driven through reduction gears and insulated shafts by two Telechron clock motors. They revolved at the rate of one rotation in forty-five minutes, offering to the spark a steady supply of fresh surface and keeping its location sharply defined. The electrodes were connected, in parallel with a condenser,

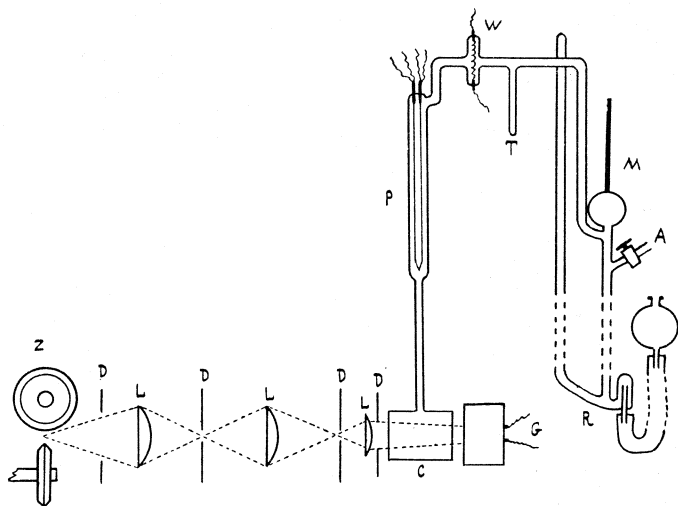

Fig. 1.—Apparatus: Z, spark electrodes; D, diaphragms; L, crystal quartz lenses; C, reaction cell; G, thermopile; P, Pirani gage; W, Pt wire for NH_3 decomposition; T, trap; M, McLeod gage; R, mercury manometer and leveling bulb; A, connection to the pump and gas storage bulbs.

to the poles of a 5 KVA, 10,000 v. transformer. A stream of air was blown across the spark gap. The arrangement worked very satisfactorily and the only source of complication was the home-made condenser, which heated gradually on continuous operation and caused a slow but steady decrease of light intensity.

The difficulty in obtaining large quartz prisms sufficiently transparent to wave lengths in the neighborhood of 2000 Å. led to the use of focal isolation instead of a monochromator in obtaining monochromatic radiation. The arrangement, shown schematically in Fig. 1, gave an approximately monochromatic beam, as shown by the fact that, according to thermopile measurements, as much as 95% of the radiation was ab-

⁷ Forbes and Brackett, *THIS JOURNAL*, 53, 3973 (1931).

sorbed by ammonia when zinc electrodes were used. Spectrograms of the light source confirmed this.

Apparatus and Materials.—The rate of ammonia decomposition was followed by measuring the pressure of hydrogen and nitrogen formed on freezing out ammonia. A McLeod gage and a Pirani gage were incorporated in the apparatus. By calibrating the latter with differently proportioned mixtures of nitrogen and hydrogen and by using both gages in each measurement, the possibility was given to determine not only the pressure but also the composition of the gases resulting from ammonia decomposition. The apparatus is shown schematically in Fig. 1. The quartz cell for the photolysis was of cylindrical shape, 50 mm. long and 25 mm. in diameter, with sealed polished windows. The McLeod gage was of usual construction and had a volume of *ca.* 150 cc. The Pirani gage consisted of 35 cm. of a platinum wire 0.076 mm. in diameter, suspended rigidly in the form of four loops in a 12 mm. tubing and silver soldered to platinum leads. The current through the gage was kept constant and the potential drop was measured by means of a Wolf potentiometer. The temperature of the wire was from 100 to 300° above the temperature of the surrounding constant-temperature (25.0°) water-bath. The gage was calibrated—using the McLeod gage of the system as standard—on carefully purified hydrogen admitted from a storage bulb and on a 1:3 nitrogen-hydrogen mixture prepared *in situ* by decomposing ammonia on the glowing platinum wire (Fig. 1). Tungsten wire was also used for this purpose with identical results.

The volume of the system was corrected for the effect of cooling the trap T (Fig. 1) in freezing out ammonia.

In high temperature experiments the quartz cell was wrapped with resistance wire and asbestos insulation. The temperature in these experiments was measured by a calibrated thermocouple in immediate contact with the quartz cell.

The source of ammonia gas was C. P. ammonium hydroxide solution contained in a storage flask connected with which was a tube of potash sticks and powdered sodium hydroxide, followed by a stopcock and suitable traps for condensing ammonia by cooling with liquid air. After freezing out the desired amount of ammonia with liquid air, the condensation bulb was surrounded with a carbon dioxide-acetone freezing mixture or a hydrochloric acid-ice mixture and the ammonia was allowed to distil into a second bulb surrounded by liquid air. A similar distillation from this bulb allowed the ammonia to expand into the reaction system. The first and last portions were discarded in each distillation.

Hydrogen bromide was prepared by dropping a c. p. 82% solution of hydrobromic acid on phosphorus pentoxide and passing the gas over red phosphorus and phosphorus pentoxide into a condensation bulb surrounded by carbon dioxide-acetone mixture and the hydrogen bromide was allowed to distil into a second bulb surrounded with liquid air. This was followed by a similar distillation into a third bulb from which another distillation sent the hydrogen bromide into a storage bulb connected with the pumping and reaction systems. The liquid hydrogen bromide in the last distillation was colorless.

The light energy was measured by means of a Moll "large surface" thermopile connected with a Leeds and Northrup galvanometer. A fixed diaphragm in front of the reaction cell, slightly smaller than the thermopile surface, aided in focusing the light on the pile. The galvanometer, thermopile and connecting wires were carefully shielded against electrical disturbances from the spark discharge. The calibration of the thermopile against a Bureau of Standards calibrated lamp was carried out exactly as recommended by the Bureau.

A typical experiment was carried out as follows. Ammonia was admitted into the reaction system, frozen in the trap T by means of liquid air and pumped until the pressure of any residual gases (on repeated evaporation and condensation of ammonia)

was less than 1×10^{-4} mm. The mercury leveling bulb was raised to fill the McLeod gage completely and the rubber tubing connecting the leveling bulb to the gage column clamped with a screw pinchcock. The stopcock shown in Fig. 1 prevented mercury from flowing into the main line of the pumping system. The liquid air was removed and the ammonia evaporated into the quartz cell and Pirani gage, its pressure being measured on a manometer sealed into the lower part of the McLeod gage column. After the decomposition, photochemical or thermal, the ammonia was frozen, evaporated and again frozen, the mercury leveling bulb lowered and the gaseous products allowed to expand into the McLeod gage, when the necessary readings on the gages were taken.

Experimental Results

Reaction Products.—The dependence of the quantum yield calculations on the nature of the products formed suggested the advisability of first investigating the composition of the gaseous products. Ammonia at pressures ranging from 13 to 377 mm. was exposed to the radiation of the zinc and aluminum sparks. Various lengths of illumination from one minute upward were employed, giving pressures of the products varying from 0.008 to 0.086 mm. Photochemical decompositions were alternated with thermal decompositions on the glowing wire. Three Pirani and three McLeod gage readings were taken alternately for each point. The results are shown in Fig. 2. Similar results were obtained in other series of experiments in which total radiation of the spark discharge was employed. The results show that the products of thermal and photochemical decompositions are identical. As it has been repeatedly shown that in the thermal decomposition a 1:3 nitrogen-hydrogen mixture is obtained, the same applies to the photochemical reaction. The limits of errors are difficult to estimate but the photochemical products contained certainly not more than 80 and not less than 70% hydrogen and in all probability were much nearer to the stoichiometric ratio.

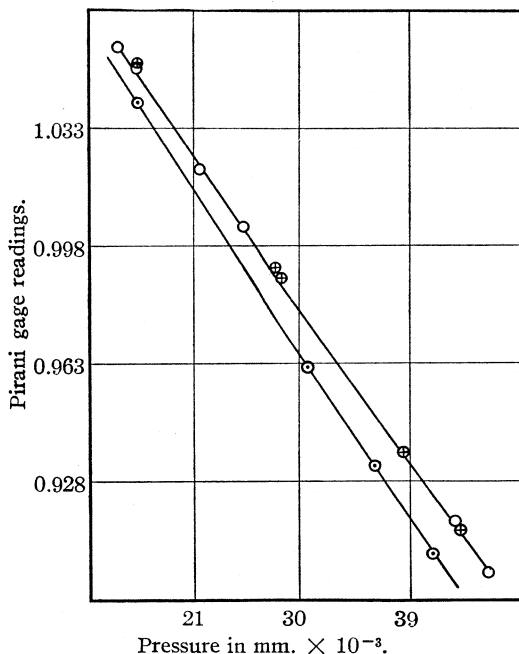

Fig. 2.—Pirani gage readings on the products of the thermal and photochemical decomposition of ammonia: ○, pure hydrogen; ○, products of thermal decomposition; ⊕, products of photochemical decomposition.

In some earlier series of these experiments the procedure in obtaining a 1:3 nitrogen hydrogen mixture was somewhat different. Ammonia was decomposed on the glowing wire to the extent of 0.2–0.3 mm. and the excess of decomposition products, on condensing ammonia, was pumped out until the desired pressure was obtained. Sometimes also a 1:3 mixture was admitted from a storage flask to a pressure of 0.2–0.3 mm. and later reduced by pumping. In all these experiments rather irregular results were obtained and it appeared that the products of photochemical decomposition contained more than 75% hydrogen. These results were

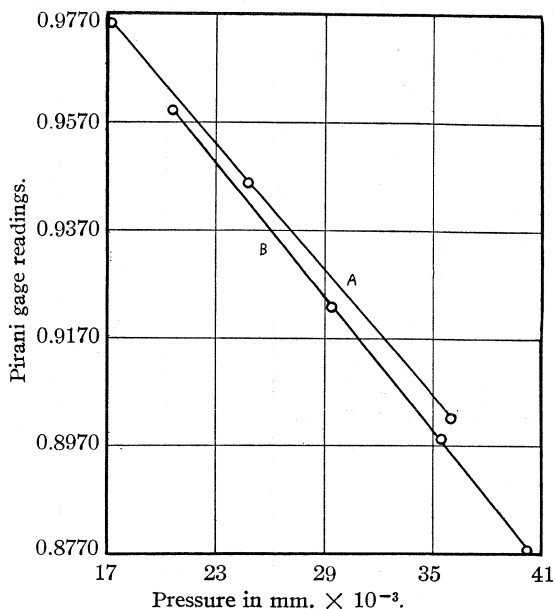

Fig. 3.—Comparison of methods of calibrating Pirani gage on $3\text{H}_2:1\text{N}_2$ mixtures: A, pressures reduced from 0.2 mm.; B, gas pressures produced by decomposition of NH_3 *in situ*.

ultimately traced to a partial separation of nitrogen and hydrogen while reducing their pressure by pumping. At the low pressures employed, hydrogen, due to its higher diffusion rate, is more rapidly removed from the system on opening the stopcock leading to the pumps than is nitrogen. As a result, the remaining mixture contains more than the original 25% nitrogen and a difference in composition is found in comparing the products of photochemical decomposition. The difficulty was avoided by decomposing ammonia on the glowing wire only until the desired pressure of nitrogen and hydrogen was obtained. All final results were obtained by this method. A comparison of the two methods is shown in Fig. 3.

Quantum Yields.—Ammonia was exposed for a period of ten to twenty minutes to the light obtained by focal isolation from the zinc, aluminum and cadmium sparks. The light energy was measured by means of the thermopile before and after the photolysis. Energy measurements were made with the quartz cell empty and filled with ammonia at the desired pressure, the difference giving the energy absorbed by the ammonia. Usually the intensity of the light source slowly decreased during an experiment. All experiments in which the energy absorbed by ammonia changed by more than 20% during the photolysis were discarded. The quantum yields rejected for this reason always agreed very well with those experiments in which the light source was more constant.

Occlusion of nitrogen and hydrogen by the solid ammonia would tend to give a low quantum yield. That no such occlusion occurred was shown in the following way. Ammonia at 25 mm. pressure was decomposed until the pressure of the products was 0.175 mm. Sufficient ammonia at high pressure, which had been carefully pumped until free of residual gases, was rapidly let into the reaction system. The total ammonia pressure was now 280 mm. and when this was frozen out the pressure of the nitrogen and hydrogen was again found to be 0.175 mm. A second experiment with the ammonia at pressures of 10 and 675 mm. gave 0.0239 and 0.0230 mm. of nitrogen and hydrogen, a change of less than 4% for a 67.5-fold increase in ammonia.

After the experiments were all completed, the rear window of the quartz reaction cell was cut away and, using the monochromatized light from the zinc spark, measurements were made of the energy falling on the thermopile without and with the rear window. The ratio of energy without to that with the window was 1.29. A similar quartz window on the thermopile was found to transmit 91.5% of the visible light with which the thermopile was calibrated and only 77.5% of the ultraviolet light falling on it. This gives a factor of 1.18 or a total factor of $1.18 \times 1.29 = 1.52$, by which the energy, as measured by the thermopile, is to be multiplied to obtain that reaching the ammonia within the cell.

Some doubts were felt concerning the accuracy of the absolute value of the quantum yields calculated by means of these corrections. They were based on the observation that the various parts of the thermopile surface differed in light sensitivity. With constant light intensity four equal areas gave mean galvanometer deflections of 2.23, 2.07, 2.68 and 3.32 cm., the first value being that obtained for the center section of the surface. The source of ultraviolet light was not homogeneous but appeared most intense at the center. Thus in our photochemical experiments the energy of the ultraviolet light falling on the thermopile was greater than that indicated by calibration against a uniform light source. Since the quantum yield for the decomposition of hydrogen bromide in the region with which

we are dealing is known to be 2.0,⁸ it was decided to check our system on this substance.

Pure hydrogen bromide was admitted to the quartz cell and its photochemical decomposition followed exactly as in the case of ammonia. It was observed that hydrogen bromide underwent a slight thermal decomposition at room temperature. This slight reaction was determined before and after each photochemical decomposition and corrected for in calculating the quantum yield. In one experiment, for example, a total of 0.1142 mm. of hydrogen was evolved, while the correction amounted to 0.0026 mm. The average of the quantum yields found for hydrogen bromide, as shown in Table I, is 3.33 instead of the value of 2.0 found by Warburg. This latter value cannot be doubted. Not only is it the result of a very careful direct investigation, but it is also supported by numerous independent observations concerning the reactions of hydrogen and bromine atoms. Thus it must be concluded that the quantum yields for ammonia decomposition obtained by means of thermopile measurements must be further divided by 1.66. These corrected values are given in the following tables, II-V.

TABLE I
QUANTUM YIELDS FOR THE DECOMPOSITION OF HYDROGEN BROMIDE AT ROOM TEMPERATURE
Zn spark, mean $\lambda = 2090 \text{ \AA}$.

37	917	.1016	4015	3.40
28	967	.1116	4033	3.53
20	831	.0941	4678	2.99
12	710	.0240	1400	2.98
Mean				3.33

The quantum yields of the ammonia decomposition obtained at room temperatures (21–30°) are given in Tables II, III and IV. A typical experiment showed the following data and calculations:

Mean λ , 2090 \AA .; apparent volume of system, 204 cc.; temp., 26.7°; NH_3 , 110 mm.; galvanometer deflection of 1 cm. = 235.3 ergs/sec.; time of exposure, 1071 sec.; pressure ($\text{N}_2 + 3\text{H}_2$), 0.0692 mm.

At start of experiment { Av. galv. defl. without NH_3 in cell = 13.15 cm.
Av. galv. defl. with NH_3 in cell = 1.54 cm.

At end of experiment { Av. galv. defl. without NH_3 in cell = 12.55 cm.
Av. galv. defl. with NH_3 in cell = 1.31 cm.

Mean energy absorbed by $\text{NH}_3 = \left[\frac{(13.15 - 1.54) + (12.55 - 1.31)}{2} \right] \times 235.3 \times 1.18 \times 1.29 = 4090 \text{ ergs/sec.}$

Total energy absorbed by $\text{NH}_3 = 466 \times 10^{16}$ quanta

⁸ E. Warburg, *Sitzb. preuss. Akad.*, 314 (1916).

$$\text{Molecules NH}_3 \text{ decomposed} = 6.06 \times 10^{23} \times \frac{204}{22,400} \times \frac{0.0692}{2 \times 760} \times \frac{273}{299.7} = \frac{229 \times 10^{15}}{229 \times 10^{15}}$$

$$\text{Apparent quantum yield} = \frac{229 \times 10^{15}}{466 \times 10^{15}} = 0.49 \text{ molecule/quantum}$$

$$\text{Corrected quantum yield} = \frac{0.49}{1.66} = 0.30 \text{ molecule/quantum}$$

Kuhn⁹ reported a nine-fold increase in quantum yield of ammonia decomposition on increasing the temperature from 20 to 500°. As Kuhn has not given any details of his measurements it seemed desirable to repeat his work, particularly since photographs of ammonia absorption spectra taken at high temperatures showed several new bands appearing in the region 2100–2500 Å. and those present at room temperature being enhanced. As measurements of light energy absorbed by ammonia at 500° offered considerable difficulties, the energy measurements were carried out at room temperature. The error thus introduced is negligibly small since with our monochromatizing system about 90% of energy is absorbed and, as photographs showed, absorption in this (2100 Å.) region increases with temperature. After determining the energy absorbed ammonia was frozen out, the cell quickly heated to the desired temperature and ammonia vaporized. After completion of illumination ammonia was frozen out again, the cell quickly cooled and a second measurement of absorbed light energy made. Before each experiment the cell was degassed at 500°.

In calculating the quantum yields given in Table V corrections have been made for ammonia decomposed while energy measurements were performed and for a very slight thermal decomposition in the cell at high temperatures.

The Reaction Mechanism.—The results here obtained may be summed up as follows. The gaseous products of decomposition are very nearly

⁹ W. Kuhn, *Compt. rend.*, **178**, 708 (1924).

a 1:3 nitrogen-hydrogen mixture, irrespective of the time of illumination. The quantum yield is 0.25 at room temperature and about double this value at 500°. It does not depend on ammonia pressure over the range 800 to 1 mm., wave length of radiation from 2150 Å. to 1960 Å., intensity of radiation varied seven-fold and amount of decomposition varied seven-fold.

These results are in partial agreement with the data already recorded in the literature. From the description of Koenig and Brings⁶ it is apparent that hydrazine is present only in traces even in rapidly flowing ammonia. Our results point in the same direction. Moreover, it is possible to show that low, if any, yield of hydrazine is not due to its secondary photochemical decomposition. Experiments of Elgin and Taylor¹⁰ indicate that the photochemical decomposition of hydrazine has a quantum yield not much greater than unity. The absorption spectrum of hydrazine¹¹ is continuous and thus absorption certainly follows Beer's law. A rate of photochemical decomposition of hydrazine sufficiently rapid to explain our failure to detect this substance would require light absorption coefficients at least 10^5 higher than those of ammonia in the region 2150–1970 Å. From Elgin's qualitative description such large values seem to be out of the question.

Bates and Taylor assumed hydrazine formation, finding excess hydrogen in decomposition products of ammonia. Their experimental set-up favored, however, an accumulation of hydrogen, due to its rapid diffusion, in the analytical part of the apparatus. An effect of this type was discussed here on previous pages and Professor H. S. Taylor in a personal discussion suggested it as a possible explanation of his and Bates' results.

The results of Dickinson and Mitchell¹¹ which also indicate an excess of hydrogen in photochemical decomposition of ammonia are somewhat inconclusive as the authors themselves admit.

The value of the quantum yield here obtained agrees excellently with the value given by Warburg. In view of this agreement one may safely conclude that Kuhn's value is erroneous. Possibly the use of a surface thermopile without correcting it for unequal sensitivity caused an error similar to one described on previous pages. The pronounced decrease in the quantum yield, which Kuhn found on improving the monochromacy of radiation, is impossible to explain. It cannot be incorporated in any theory of the reaction which has been set up and we are inclined to attribute it to some unknown experimental error.

Kassel and Noyes⁴ found a quantum yield about 0.69 in the spectral region 1600–1900 Å.

As the authors point out, this value may be somewhat too high. From

¹⁰ Elgin and Taylor, *THIS JOURNAL*, **51**, 2059 (1929).

¹¹ Dickinson and Mitchell, *Proc. Nat. Acad. Sci.*, **12**, 692 (1926).

kinetic considerations (see later) it seems more likely that with these short wave lengths the same quantum yield obtains as in the region above 1950 Å. However, an increase of quantum yield is not impossible from the point of view of the most likely reaction mechanism and only some future experiments can decide the correctness of Kassel and Noyes' value.

Kuhn³ reported a nine-fold increase in quantum yield from 20 to 500°, while here only a doubling has been observed. In absence of any experimental details it is impossible to say whether Kuhn measured the quantum yield or only the reaction velocity at high temperatures and whether some light of wave lengths longer than 2100 Å. was present. In the latter case the change of ammonia absorption with temperature may partly account for Kuhn's results. On the other hand, in the present experiments the quartz cell may have been more opaque to radiation while heated to high temperatures. This is quite in accord with the generally observed shift of absorption to longer wave lengths in liquid and solid systems. Furthermore, some of the gas formed in ammonia decomposition may have been adsorbed on the walls of the quartz cell after cooling. Thus the doubling of quantum yield between room temperature and 500° appears rather as the lower limit of the temperature coefficient of the quantum yield.

As has been pointed out by Lind¹² the temperature coefficient observed by Kuhn is almost identical with the value found by Wourtz¹³ for the ammonia decomposition by α -particles.

This agreement undoubtedly supports Kuhn's value as contrasted with ours. For the following considerations the numerical value of the temperature coefficient is, however, not of paramount importance. Its existence shows the presence of some secondary reactions requiring activation energy and favoring the decomposition.

Further facts to be considered in setting up a mechanism of ammonia decomposition are that neither nitrogen nor hydrogen has any effect on reaction rate at room temperature^{2,14} but that the latter retards the rate at 500°.³

Bonhoeffer and Farkas¹⁵ have shown that ammonia is decomposed photochemically at pressures as low as 10^{-3} mm. This, together with the absence of rotational structure in absorption bands of ammonia and lack of fluorescence, led the authors to suggest that ammonia molecules decompose without intervention of collisions in a predissociation¹⁶ process. The time interval between light absorption and dissociation in such proc-

¹⁶ V. Henri, "Structure des Molecules," Paris, 1925.

esses has been variously estimated as 10^{-10} – 10^{-11} sec., thus a time comparable to average time between molecular collisions at atmospheric pressure. It is, however, necessary to assume that collisions have no effect on dissociation of excited ammonia molecules since otherwise a change of quantum yield with pressure would have been observed. Thus the deficiency of quantum yield must be due to some secondary reactions in which the dissociation products recombine again to form ammonia molecules. There are two energetically possible ways in which ammonia could decompose

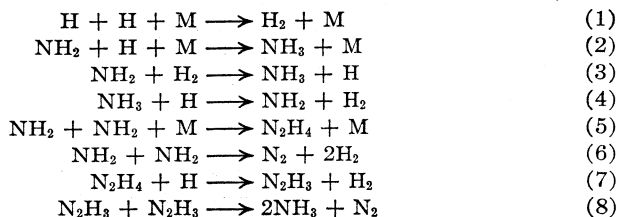

The first scheme leads however to reaction mechanisms which do not agree with experimental facts. The reaction $2\text{NH} \longrightarrow \text{N}_2 + \text{H}_2$ would give a quantum yield unity. The reaction $\text{NH} + \text{H}_2 \longrightarrow \text{NH}_3$ would require retardation by hydrogen. The reaction $\text{NH} + \text{NH}_3 \longrightarrow \text{N}_2\text{H}_4$ would result in a quantitative formation of hydrazine since no mechanism is available for its decomposition (the reaction $\text{N}_2\text{H}_4 + \text{NH} \longrightarrow \text{NH}_3 + \text{N}_2 + \text{H}_2$ would again give a quantum yield unity).

The second mode of decomposition has numerous observations in its favor.

Thus Farkas, Haber and Harteck¹⁷ were able to sensitize hydrogen-oxygen and carbon monoxide-oxygen reactions by decomposing photochemically ammonia added to the gas mixtures. Taylor and Emeléus¹⁸ sensitized in the same manner polymerization and hydrogenation of ethylene, while Hill and Vernon¹⁸ reduced tungstic oxide by decomposing ammonia at low pressures. All these effects are interpreted as indicating the presence of hydrogen atoms.

The secondary reactions to be considered if ammonia decomposes according to the second scheme are

For reactions 2 and 5 the triple collisions are not absolutely necessary on account of a larger number of internal degrees of freedom available, but are rather likely.

In considering the reaction mechanism at room temperature, reactions 3 and 4 may be neglected. The first would require a retardation by

¹⁷ Farkas, Haber and Harteck, *Naturwissenschaften*, **12**, 267 (1930).

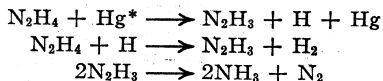

¹⁸ Taylor and Emeléus, *THIS JOURNAL*, **53**, 562 (1931).

hydrogen; the second has been shown to occur extremely slowly by Boehm and Bonhoeffer.¹⁹ For the decomposition at high temperatures, on the other hand, these reactions are probably quite important, the one producing the observed retardation by hydrogen, the other the increase of quantum yield.

The simplest scheme of secondary reactions at room temperature involves processes 1, 2, 6. It leads, however, to a quantum yield dependent on total pressure; since reaction 1 requires triple collisions, reaction 6 certainly does not, while 2 is doubtful. In the more general case, when it is assumed that reaction 2 requires triple collisions at low pressures but does not at high, a pronounced minimum of quantum yield would be obtained in the transition pressure region of reaction 2. This is certainly not the case experimentally since if anything a slight maximum was observed at intermediate pressures with zinc spark.

The remaining possibility involves reactions 1, 2, 5, 7, 8. The quantum yield is now determined by the ratio k_2^2/k_1k_5 which must be equal to eight if the quantum yield is 0.25. Since it is quite possible that all these reactions require triple collisions, the quantum yield may be independent of pressure. It will be also independent of light intensity and amount of decomposition. Reaction 1 needs no further justification and reaction 2 is also quite likely to occur. Reaction 5 is made plausible by the finding of traces of hydrazine in ammonia decomposition experiments by the flow method.

Reactions 7 and 8,²⁰ necessary to explain the absence of larger amounts of hydrazine, may appear somewhat artificial. However, independent evidence can be adduced in their favor. Elgin and Taylor¹⁰ found that in the presence of excited mercury the decomposition of hydrazine was about twice as fast as the rate of water formation. Using an incorrect value of Marshall²¹ for the quantum yield of the latter reaction, they attempted to derive a chain mechanism for hydrazine decomposition. In the meantime Frankenburger and Klinkhard²² have shown that water formation has a quantum yield near unity. Thus two molecules of hydrazine must be decomposed by each excited mercury atom. This finds a most simple explanation in the scheme

The scheme accounts for the quantum yield, the nature of the reaction products and also for the observation of Elgin and Taylor that in presence

¹⁹ Boehm and Bonhoeffer, *Z. physik. Chem.*, **119**, 385 (1926).

²⁰ Reaction 8 could be replaced by $\text{N}_2\text{H}_3 + \text{NH}_2 \longrightarrow \text{N}_2 + \text{H}_2 + \text{NH}_3$. A decision is impossible at present.

²¹ Marshall, *J. Phys. Chem.*, **30**, 1078 (1926).

²² Frankenburger and Klinkhard, *Trans. Faraday Soc.*, **431** (1931).

of excess hydrogen the rate of hydrazine decomposition remains unchanged. In the latter case the primary reaction is $\text{Hg}^* + \text{H}_2 \longrightarrow \text{Hg} + 2\text{H}$ followed by the two last reactions of the preceding scheme. The reactivity of hydrogen atoms toward hydrazine and their inertia toward ammonia are quite analogous to their behavior toward methane and higher saturated hydrocarbons.²³

Results obtained in the extensive work on electric discharges through ammonia and on allied phenomena are somewhat discordant and no binding conclusions can be drawn.

Steiner's²⁴ conclusion that in the reactions of atomic nitrogen and hydrogen hydrazine is formed by the reaction $2\text{NH}_2 + \text{M} \longrightarrow \text{N}_2\text{H}_4 + \text{M}$ agrees with the one proposed here. However, Steiner's conclusions should be reviewed in the light of the unquestionable fact that hydrogen atoms decompose hydrazine.

Koenig and Wagner²⁵ find that by decreasing electric current and increasing ammonia flow through silent discharges, the net reaction $2\text{NH}_3 \longrightarrow \text{N}_2\text{H}_4 + \text{H}_2$ can be made to occur almost quantitatively. A decomposition of ammonia by electron impact in the way suggested by the authors: $\text{NH}_3 \longrightarrow \text{NH} + \text{H}_2$, followed by the reaction $\text{NH} + \text{NH}_3 \longrightarrow \text{N}_2\text{H}_4$, accounts for these results much better than the decomposition $\text{NH}_3 \longrightarrow \text{NH}_2 + \text{H}$. In the latter case a quantitative yield of hydrazine could hardly be expected judging from the photochemical reaction.

Results which do not agree with the mechanism of ammonia decomposition proposed herein are contained in the work of Gedye and Allibone²⁶ on ammonia decomposition by high speed electrons. They find that the hydrazine yield increases with decreasing pressure in the range 700 to 50 mm. If NH_2 radicals are formed here, hydrazine formation is a triple collision process, the decomposition a bimolecular reaction and roughly a proportionality of the yield with pressure should be expected. Formation of NH radicals does not make the explanation simple either. The suggestion of the authors that hydrazine formation is a wall reaction would require an extraordinary chemical inertia of whatever radicals and atoms are formed, so that these have time to diffuse to the walls.

One difficulty of the proposed ammonia decomposition mechanism has not been touched upon yet. Accepting the velocity constant of hydrogen atom recombination as determined by Steiner and Wicke²⁷ or by Senftleben and Riechemeyer²⁸ it is found that reactions 1, 2, 5 must proceed chiefly in the gas phase near the upper limits of ammonia pressures here

investigated. Near the low limit of this pressure however the atoms and radicals have a 1000:1 chance to diffuse to the walls before reaction. Thus it becomes necessary to assume that the ratio $\kappa_2^2/\kappa_1\kappa_5$ is the same for wall and gas reactions.

While this new assumption is not very satisfactory, it offers at any rate new means of testing the theory by studying ammonia decomposition at low pressures in vessels with walls prepared either to accelerate or retard the hydrogen atom recombination. Such experiments are considered for the near future by one of us.

Concluding, we would like to thank Professor G. S. Forbes for his frequent help and the loan of some of the equipment used in this work.

Summary

1. The gaseous products of the photochemical ammonia decomposition are a 1:3 nitrogen-hydrogen mixture even under conditions excluding a photochemical decomposition of hydrazine.
2. The quantum yield of ammonia decomposition at room temperature is 0.25 independent of pressure, light intensity and time of illumination.
3. At 500° the quantum yield is 0.5 or more.
4. The bearing of these results on other work on ammonia decomposition is discussed and a mechanism of ammonia decomposition is developed.

THE SORPTION OF GASES BY IRON

BY ARTHUR F. BENTON AND T. A. WHITE¹

RECEIVED DECEMBER 12, 1931

PUBLISHED MAY 7, 1932

Introduction

As a result of numerous researches in recent years in the field of adsorption of gases by catalytically active solids, three processes, apart from compound formation, have become clearly recognized—physical adsorption, activated adsorption and solution. The characteristics and interrelationships of the two types of adsorption are now reasonably clear.²

In the attempt to distinguish adsorption from solution, it has been customary to assume that the former is always rapid, while the latter is ordinarily slow. However, since it has been shown that activated ad-

sorption may be a slow process,^{2b-f,3} it is clear that rate alone is not a certain criterion. Nevertheless, in the systems copper-hydrogen and copper-carbon monoxide, it was shown^{2f} that by suitable procedures involving both equilibria and rates, activated adsorption and solution could be sharply differentiated, and the contributions of each to the total sorption under any conditions could be separately estimated. In the work here reported, the same methods have been applied in a study of the sorption of nitrogen, hydrogen and carbon monoxide by reduced iron.

No extensive investigations of sorption by iron have previously been reported. Sieverts⁴ found the solubility of hydrogen in iron wire at 400° was very small, but increased with rising temperature; nitrogen dissolved in gamma but not in alpha iron. The "adsorptions" at lower temperatures have been examined by Taylor and Burns⁵ and by Nikitin.⁶

Experimental Details

Since many of the experiments were continued over long periods, it was considered desirable to insure against leaks by substituting mercury seals for stopcocks. The apparatus has already been described.^{2b} The sorption under any given conditions of pressure, temperature and time was determined as the difference between the volume of gas admitted to the bulb containing the iron, and the volume remaining in the free space. The latter was obtained by experiments with helium in the manner previously described.

The sorbent (Iron I, 54.6 g.) was prepared from an 8-14 mesh sample of fused ferro-ferric oxide, containing 0.15% of alumina, for which we are indebted to Dr. P. H. Emmett of the Fixed Nitrogen Research Laboratory, Washington. The oxide was reduced *in situ* in a current of hydrogen for five days at 375° and for fourteen days at 425-450°. Evacuation between runs was carried out at 500° by means of a Töpler pump.

Occasional check runs made at intervals throughout the work revealed no trend in the activity or capacity of the sample. Hence the data obtained for different gases, and for the same gas under different conditions, are directly comparable.

All volumes are given in cc. at 0°, 760 mm., and all pressures in mm. of mercury at 0°.

Results with Nitrogen

The isothermal adsorption of nitrogen at temperatures from -191.5 to 0° is shown in Fig. 1, Curves 1, 2, 3, 4. In this and later figures open circles indicate points obtained from lower pressures, that is, after a fresh addition of gas to the bulb; black circles (and other solid figures) are used for points obtained by the reverse process.

The rate of adsorption at -183, -78.5 and 0° was apparently instantaneous. At -191.5° equilibrium was attained in a few minutes. The fact that the equilibrium was actually reached is shown by the close agreement of points obtained from higher and from lower pressures.

³ Benton and Elgin, *THIS JOURNAL*, **48**, 3027 (1926); **49**, 2426 (1927).

⁴ Sieverts, *Z. physik. Chem.*, **60**, 129 (1907).

⁵ Taylor and Burns, *THIS JOURNAL*, **43**, 1273 (1921).

⁶ Nikitin, *J. Russ. Phys.-Chem. Soc.*, **58**, 1081 (1926); *Z. anorg. allgem. Chem.*, **154**, 130 (1926).

The observed effects of temperature and pressure, together with the practically instantaneous rates, leave no doubt that the sole process occurring here is a surface adsorption of the physical type. Thus, the isotherms show no tendency to reach a saturation limit, and at the higher temperatures the adsorption is very nearly proportional to the pressure.

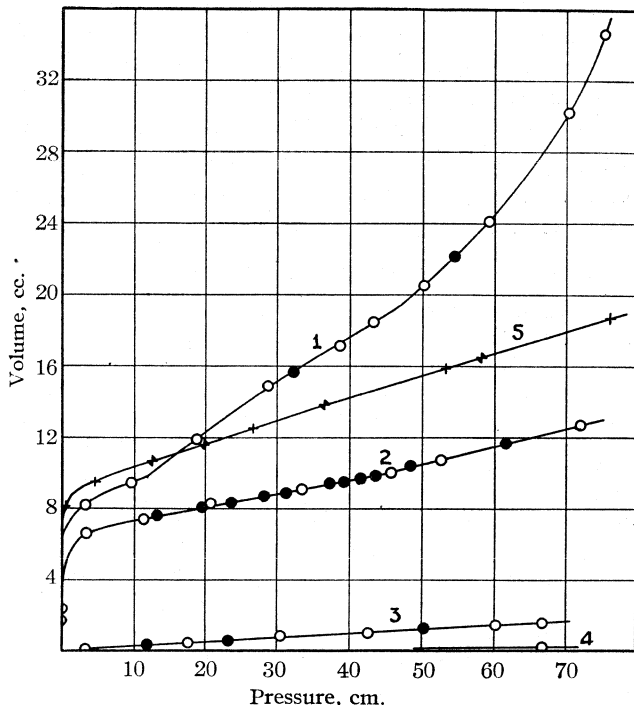

Fig. 1.—Isotherms for nitrogen and carbon monoxide: Curves 1, 2, 3 and 4 are for nitrogen at -191.5° , -183° , -78.5° , and 0° , respectively. Curve 5 is for carbon monoxide at -183° .

Further, at a given pressure the values decrease uniformly with increasing temperature, and the heat of adsorption is relatively small, as shown by the values of Q , in cal. per mole, given in Table I.

TABLE I

HEAT OF PHYSICAL ADSORPTION OF NITROGEN BY IRON I			
Vol. adsorbed	p at -191.5°	p at -183°	Q
8.0	22	190	3700
10.0	117	457	2340
12.0	195	641	2050

These heats cover the same range previously found for nitrogen on copper,^{2f} and exceed the latent heat of vaporization of nitrogen (1380 cal.) by a factor of only 1.5 to 3.

Higher Temperatures.—The data obtained for the sorption of nitrogen at higher temperatures are given in Table II. These results were obtained by introducing a definite amount (5.91 cc.) of gas into the system, and successively determining the apparent equilibria at the temperatures shown.

TABLE II
SORPTION OF NITROGEN AT HIGHER TEMPERATURES

Temp., °C.	Pressure, mm.	Sorption, cc.
321	418.0	0.43
0	195.1	.42
344	425.1	.54
360	435.6	.56
408	469.6	.54
0	195.1	.42

The sorption at these higher temperatures is considerably greater than at 0°. Since here the physical adsorption must be negligibly small, it is evident that these values represent a second type of sorption. The rate of this process at 0° is very slow, so that little, if any, of the gas taken up at high temperatures is evolved on cooling to 0°.

The data obtained are incapable of furnishing a definite decision as to the nature of the high-temperature sorption. On the other hand, since Sieverts' experiments⁴ indicate that gaseous nitrogen at ordinary pressures is insoluble in alpha iron, the evidence points to activated adsorption as responsible for the observed phenomena. This view is rendered still more probable by the fact that at the higher temperatures, iron similar to that here employed is known to activate nitrogen for ammonia synthesis,⁷ and there is now available a large body of evidence to support the hypothesis that activated adsorption is an essential step in contact catalysis.

Results with Carbon Monoxide.—The isotherm for carbon monoxide at -183° is plotted in Fig. 1, Curve 5. Here as with nitrogen the rate was instantaneous. Throughout the whole range of pressure the ratio of the adsorption of carbon monoxide to that of nitrogen at this temperature is 1.44 ± 0.02 . These facts are convincing evidence that in this case also the process is solely one of physical adsorption.

Measurements were also made with carbon monoxide at -78.5 and 0° , but in neither case was equilibrium reached, even after one hundred hours. Nevertheless, the observed rates clearly show the existence of two different processes. A few typical data on rates are given in Table III; the values shown for zero time are the volumes taken up at the last previous point.

At -78.5° a large fraction of the sorption occurred within three minutes (0.05 hour), after which the rate decreased sharply. At 0° relatively little sorption took place during the first three minutes, but after this time

87.2	503.4	8.11	50.2	413.2	9.02

the rate was more rapid than at the lower temperature, and the total sorptions reached after a given time were greater.

These results are precisely what would be expected if the total sorption at these temperatures is a combination of physical adsorption and a second process. Since other surfaces give *physical* adsorptions of carbon monoxide and nitrogen in this range of temperature, which are in the ratio^{2f} of about 1.5, it may be calculated that here the adsorption of this type, at 500 mm. pressure, should amount to about 2 cc. at -78.5°, and about 0.2 cc. at 0°. Thus the first, rapid part of the observed sorption, which is much greater at -78.5° than at 0°, can be largely accounted for as physical adsorption. The nature of the subsequent process, whether activated adsorption, carbonyl formation or solution, or a combination of these, has not been ascertained.

Results with Hydrogen

Low Temperatures.—The adsorptions of hydrogen at -195 and -183° are plotted in Fig. 2, Curves 1 and 2. The striking discontinuities in these curves have previously been considered in detail, in connection with a general discussion of stepwise adsorption.⁸ Neglecting the discontinuities, one observes that the general shape of the isotherms is typical of physical adsorption. There is little or no adsorption at "zero" pressure, and the values continue to increase with increasing pressure without approaching a saturation limit. At both temperatures the rate was apparently instantaneous, and values obtained from the side of higher pressure are in excellent agreement with those approached from lower pressures. The adsorptions decrease with rising temperature, and the heat of adsorp-

⁸ Benton and White, *THIS JOURNAL*, 53, 3301 (1931).

tion calculated from the isotherms by the Clapeyron equation is about 1600 cal. per mole. These observations show that physical adsorption is the sole process occurring.

Curve 3, Fig. 2, represents an isotherm at -78.5° . These results must be considered in the light of the following observations. The first two portions of gas admitted to the iron apparently came to equilibrium immediately at pressures of 50 and 258 mm., respectively, but the adsorption in each case was less than 0.05 cc. The next portion gave an immediate adsorption of 0.30 cc. at 715 mm. In each of these cases the pressure remained constant for the twenty to thirty minutes of observation. Part

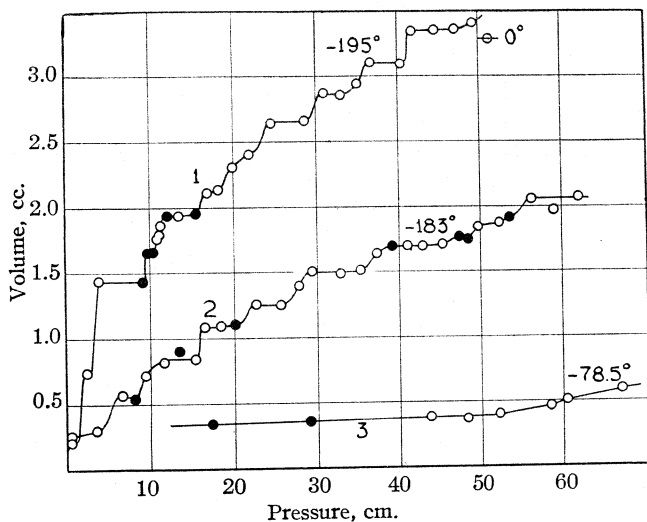

Fig. 2.—Isotherms for hydrogen.

of the gas was then withdrawn from the bulb, with the result that the adsorption at once decreased to 0.05 cc. at 405 mm. However, this volume did not remain constant, but gradually increased until an apparently constant adsorption of 0.28 cc. was reached after sixteen hours. From this point on, the values shown in Curve 3 were successively obtained. At each of these points equilibrium was established very rapidly; even with times of observation as long as twenty-two hours no change in adsorption occurred. A repetition of this experiment gave practically identical results, except that here the slow adsorption (0.24 cc. at 86 mm.) took place at the first point, where the system was kept under observation for thirty-nine hours.

The behavior noted is readily accounted for as follows. At -78.5° there is a small, rapid and readily reversible physical adsorption, which exhibits steps similar to those at lower temperatures, but here the first step

occurs at a pressure of about 600 mm. At one point in the course of following this isotherm, where sufficient time was allowed, a very slow activated adsorption of the order of 0.3 cc. occurred. The isotherm subsequently obtained represents the physical adsorption *plus* the 0.3 cc. adsorbed in the activated form. It is remarkable, however, that the activated adsorption, which reached 0.3 cc. in sixteen hours, showed no further increase in three days.

Higher Temperatures.—At 0° there was an immediate adsorption of 0.2–0.3 cc., followed by an extremely slow process which did not come to equilibrium in 35 days. The value reached at the end of this time, 3.28 cc. at 513 mm., is indicated in Fig. 2. At this point the temperature was quickly raised to 110°. The result was a rapid *decrease* of the sorption to 2.06 cc. at 768 mm., but this decrease was followed by a gradual *increase* over a period of three days to 2.47 cc. at 748 mm., without any sign of an approach to final equilibrium.

It may be concluded from these observations that in the neighborhood of 110° the sorption consists of two distinct processes, one of which is rapid and decreases in extent with increasing temperature, while the second is very slow. This conclusion is confirmed by isothermal measurements conducted wholly at 110°, which showed a rapid initial sorption followed

TABLE IV
RATE OF SORPTION OF HYDROGEN AT 110 AND 210°

24.3	596.4	2.14			

by a very slow process. At 210° also there was a rapid process, which involved smaller quantities of gas than at 110° , and again a slow process ensued. The sorption at these temperatures as a function of time is given in Table IV.

At the conclusion of the measurements at 110° , when a sorption of 2.14 cc. had been reached, the system was rapidly cooled to -78.5° . At this temperature the sorption became constant almost immediately at 2.38 cc. under a pressure of 305.6 mm. It is evident that the gas taken up at 110° was not desorbed on cooling; on the contrary, an increase of about 0.2 cc. occurred, which is undoubtedly physical adsorption and is of the same order as the physical adsorption on the bare surface at -78.5° .

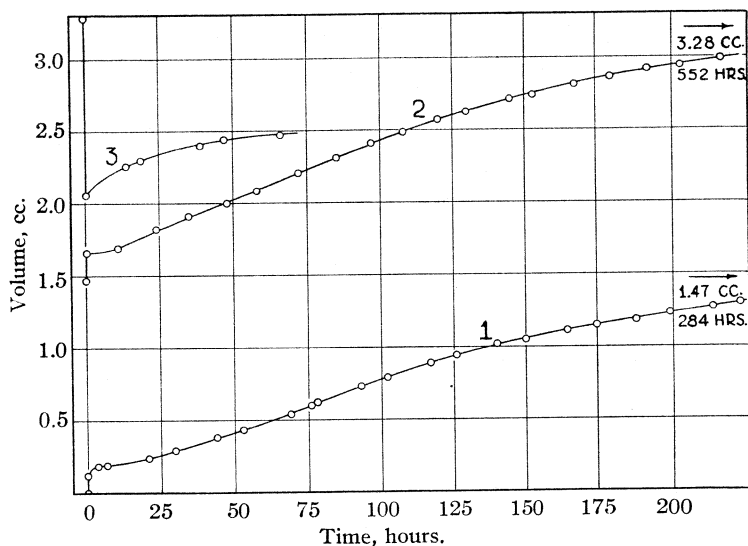

Fig. 3.—Rate of sorption of hydrogen at 0° : Curve 3, after heating to 110° .

The sorption at 0° as a function of time is shown in Fig. 3, Curves 1 and 2. The range of pressure involved here was as follows: for Curve 1, 120.5 to 72.7 mm; for Curve 2, 570.5 to 512.8 mm. In each case, after a rapid initial adsorption of about 0.2 cc., the rate sharply decreased almost to zero, then gradually increased, and finally fell off again. The change of sorption with time after heating to 110° is shown in Curve 3, which brings out clearly the rapid initial decrease of the sorption, followed by a slow increase.

In interpreting these results it is to be noted that the *physical* adsorption, which had already become very small at -78.5° , must be entirely negligible at 0° and above. The two processes which have been distinguished at 110° may provisionally be regarded as activated adsorption and solution.

On this basis the activated adsorption is very slow at 0° , except for the first 0.2–0.3 cc., but rapidly increases in rate with increasing temperature. The final equilibrium, on the other hand, corresponds to a decreasing activated adsorption with increasing temperature. If on a plot of the volumes taken up at 110 and 210° against the time, the slow process at these temperatures is extrapolated back to zero time, a rough estimate may be obtained of the fractions of the total sorption which are due to each individual process. In this manner it was found that (at 500 to 600 mm.) the activated adsorption amounted to about 1.4 cc. at 110° and 1.0 cc. at 210° ; the slow process which has been ascribed to solution amounted to about 0.7 cc. at each temperature, but the time of observation was much longer at 210° , so that equilibrium was doubtless more closely approached. Because of the considerable uncertainty in these values, and because the slow process had certainly not reached equilibrium, the isobars for the different types of sorption will not be given here.

If the above view of the situation is correct, it must be concluded that the process of activated adsorption is *autocatalytic*. Thus at 0° , after about 0.2 cc. had been rapidly adsorbed, an induction period of eight to ten hours occurred, during which there was little further sorption. Subsequently the rate increased, passed through a maximum, and then decreased. This behavior is especially clearly shown by Curve 1 of Fig. 3. At 110° , in spite of the rapid rate of this process, there was some slight evidence of the same phenomenon. It is conceivable that only the few tenths of a cc. which was rapidly taken up at 0° (and slowly at -78.5°) represents activated adsorption, perhaps on the edges of the crystals, and that the autocatalytic process involves the formation of a new solid *phase* of iron hydride. Further data will be necessary before this possibility can be profitably discussed in detail. It may be noted, however, that on this view the rapid decrease in sorption on heating from 0 to 110° would indicate that the hydride is unstable at the latter temperature, even at a pressure of 770 mm.; consequently the rapid process at lower pressures observed in the experiments at 110 and 210° could not be ascribed to the formation of this definite hydride.

Discussion

The results for iron are similar in the main to those previously reported for nickel and copper. At low temperatures all three metals exhibit an apparently instantaneous physical adsorption, which decreases rapidly and uniformly with increasing temperature, corresponding to heats of adsorption which are only about two to four times the latent heat of vaporization of the several gases.

At some point activated adsorption first makes its appearance, and rapidly increases in rate at higher temperatures. On both copper and

iron the rate of this process is considerably greater for carbon monoxide than for hydrogen, and enormously greater than for nitrogen. Comparison of the different metals shows that the rates of activated adsorption of hydrogen were about equal for the particular samples of nickel and copper employed, but were much less in the case of iron. The rate with carbon monoxide was much less for iron than for copper. (The system nickel-carbon monoxide has not been studied from this point of view.) Doubtless the smaller rates with iron are due in part to the fact that the sample of iron was prepared from fused oxide by reduction at a high temperature, while the other two metals were obtained by cautious ignition of their nitrates and reduction at much lower temperatures.

In many of the cases studied, a third process, provisionally ascribed to solution, has been definitely distinguished. Such a process occurs in the system, iron-hydrogen. With nitrogen and carbon monoxide in contact with iron, this third process is not apparent, but it must be noted that in these latter cases the sorptions have been less extensively examined.

Multimolecular Layers at Low Temperatures.—Inspection of Curves 1 and 2 of Fig. 1 reveals the fact that definite "breaks" occur in each case at an adsorption of about 10 cc. This is apparently the volume of nitrogen necessary to form a complete unimolecular layer of molecules over the surface. The sharpness of the breaks is no doubt diminished by the incipient formation of a second layer before the first is entirely completed. At -191.5° there is a second, less definite break at a volume of 19–20 cc., which presumably signifies the completion of the second layer of molecules. From this point on, the adsorption appears to increase in a regular manner, gradually approaching infinity as the pressure increases toward the vapor pressure of liquid nitrogen at this temperature (about 110 cm.).

On this basis the physical adsorptions at the higher temperatures correspond to a very incomplete covering of the surface with a single layer of molecules. It may be of interest to point out also that the activated adsorption of the various gases never amounts to as much as 10 cc. From this fact the conclusion may be drawn that activated adsorption does not exceed a unimolecular layer, although the latter is closely approached in the case of carbon monoxide at 0° .

Summary

The isothermal sorptions of nitrogen, carbon monoxide and hydrogen by reduced iron have been measured at pressures up to one atmosphere and over a range of temperatures down to 78°K . In many cases also the change in sorption with change in temperature has been examined, with a constant volume of gas in the system.

As in the case of copper previously reported, it is found that in general sorption involves three definitely distinguishable processes, (a) *adsorption*

of the physical type, (b) *adsorption* of the activated type and (c) a third process which is probably solution. The contribution of the individual processes to the total observed sorption has been estimated.

The distinguishing characteristics of each process have been further elucidated, particularly in respect to rates, equilibria, heats and thickness of adsorbed layers.

With all three gases at -183° and below, the sorption consists solely of physical adsorption. In each case activated adsorption occurs at higher temperatures. The rate of this process is greatest for carbon monoxide and least for nitrogen. With hydrogen at 110° and above, the third process, ascribed to solution, comes into prominence.

THE REACTION BETWEEN OXYGEN AND PROPYLENE: ACTIVATION, OXIDATION AND POLYMERIZATION

BY SAMUEL LENHER

RECEIVED DECEMBER 14, 1931

PUBLISHED MAY 7, 1932

It was recently shown in a study of the reaction between oxygen and ethylene¹ that activation of ethylene was a primary process in the reaction. This activation led to the formation of polymerization and pyrolysis products from ethylene, as well as oxidation products, under conditions where pure ethylene is not decomposed. The formation of the primary oxidation products, ethylene oxide and acetaldehyde containing one oxygen atom and the elements of ethylene in the molecule, and the formation of the polymerization products, propylene, butylenes and amylenes, without separation of hydrogen or direct formation of saturated hydrocarbons or carbon, showed that the activation of ethylene consisted in an activation of the double bond. Since the primary oxidation and decomposition reactions of ethylene could be interpreted adequately by assuming an activation of the double bond under the influence of heat or of oxygen, it seemed of value to determine whether the next member of the monoolefin series of hydrocarbons, propylene, behaved similarly. The work described in this paper leads to the conclusion that activation of the double bond in propylene is the primary process in the oxidation and polymerization reactions.

The oxidation of propylene has received little attention. In connection with the study of the oxidation of ethylene² some experiments on the oxidation of propylene at 280 – 315° showed that the liquid products of the

reaction were propylene oxide, propionaldehyde, acetic acid, acetaldehyde, formic acid, formaldehyde and a peroxide compound, and that the mechanism of the slow oxidation was very similar to the oxidation of ethylene.

The thermal decomposition of propylene has recently been the subject of several investigations. However, a survey of these researches gives no clear picture of the principal primary reactions involved in the pyrolysis of propylene. Frey and Smith³ concluded from a study of the decomposition of propylene at 575° and 760 mm. in a silica vessel with a time of contact of five minutes that the principal products of the polymerization of propylene (under these conditions) were butylene and higher hydrocarbons, as well as large amounts of methane and ethane. Their results show that the principal products were methane 10.4% ethylene 8.0%, propane 3.0%, butylene 2.8%, C_nH_{2n} ($n = 5$ to 8) 2.6% ethane 1.9% and hydrogen 1.7%. Wheeler and Wood⁴ studied the decomposition of propylene at 650° in silica vessels at times of contact of twenty seconds and longer and reported the principal products to be ethylene, ethane, and butylene with small amounts of aromatic hydrocarbons. Recently Hurd and Meinert⁵ reported on the pyrolysis of propylene in Pyrex glass and quartz at temperatures between 600 and 950° and times of contact of from half a second at 950° to thirty seconds and up to two minutes at the lower temperatures. They found that under their conditions propylene broke down to form simpler gases, the principal products being methane, ethylene, hydrogen, and paraffins higher than methane (principally ethane) in the ratio 3:3:1:1. The mechanism of the pyrolysis of propylene was considered to be the same as that suggested by Hurd and Spence⁶ to explain the pyrolysis of isobutylene involving breaking of C—C and C—H bonds and a possible activation of the C=C bonds. Dunstan, Hague and Wheeler,⁷ in a survey of the pyrolysis of the lower olefins, concluded that the principal primary reaction, common to all, was the formation of either two-carbon or four-carbon atom (or both) members of the mono-olefin series. They considered that the primary reaction in the pyrolysis of propylene was $2C_3H_6 = C_2H_4 + C_4H_8$.

Experimental

The reaction between propylene and oxygen, and the pyrolysis of oxygen-free propylene, were studied in the recirculation apparatus described in detail in a previous communication⁸ using the same experimental procedure. A preheater and reaction vessel of fused silica were used in all the experiments. The only change in the apparatus was the use of a smaller charcoal absorption tube 24 mm. by 30 cm. containing 100 g. of

charcoal, for the recovery of the higher olefins formed. The small amount of charcoal was used because the large volume of propylene absorbed by the charcoal made use of a larger amount impracticable to handle in a recovery system. The oxidation products were determined as outlined in the previous papers on ethylene oxidation.⁹ Propylene was taken from commercial cylinders (Carbide and Carbon Chemicals Corporation). Fractional distillation showed it to be free from other olefins. Analysis showed the gas to be 98.0% propylene, 1.5% propane, 0.13% carbon dioxide and the remainder inerts, probably nitrogen.

Gas analyses were carried out in a Burrell gas analysis apparatus (Precision Type). The procedure of Hurd and Spence,¹⁰ based on the differential absorption of the lower olefins in sulfuric acid of various concentrations, was used for the analysis of the unsaturated hydrocarbons (acetylene hydrocarbons absent). The directions given by Hurd and Spence were checked and found to be entirely satisfactory and dependable for the analysis of a mixture of ethylene, propylene and butylenes, or a complex mixture of these gases with carbon oxides, hydrogen and lower saturated hydrocarbons.

The higher olefins formed in the reaction and absorbed on the charcoal were recovered as liquids by heating the charcoal to 130–140° in a flask and steaming thoroughly. The gases and steam evolved were cooled with a long condenser and a water scrubber. The hydrocarbon products were recovered in a long spiral trap which was cooled in boiling liquid ammonia following the scrubber. As propylene boils at –47° and the temperature of boiling liquid ammonia is –38.5° the excess of propylene from the absorbent charcoal was not condensed with the products. The identity of the hydrocarbon products was established by fractional distillation, giving the boiling point of each constituent, and by chemical tests and analyses. The hydrocarbons boiling below propylene, which were not absorbed by the charcoal saturated with propylene, were allowed to build up together with carbon oxides in the recirculation system, and were determined by gas analysis at the end of a run. The amount of propylene consumed in a run, as calculated from the composition of the oxidation and pyrolysis products, agreed within 10% with the propylene consumption indicated from the observed volume change in the system and the initial and final composition of the gas.

The results of a number of experiments carried out with the recirculation apparatus are summarized in Table I and Table II. The runs were all carried out with high propylene and low oxygen concentrations; the gas at the start of a run was 90% propylene, the remainder being air and carbon dioxide. Oxygen was supplied to the system during the run at approximately its rate of consumption. The average duration of the experiments was four hours.

The experiments in Table I show that under the conditions outlined at temperatures between 500–600° and times of contact of less than eight seconds the oxidation products of propylene are simple in nature. The only oxidation products resulting in amounts sufficient for analysis were acetaldehyde and formaldehyde (grouped as total aldehyde in Table I), formic acid, carbon oxides and water. No evidence was obtained of the presence of propylene oxide or of propionaldehyde which are formed in the oxidation of propylene at lower temperatures.¹¹ It is probable that

they were formed and were rapidly oxidized and decomposed at the high temperatures of the present experiments.

Experiments 1 to 3 show that in addition to oxidation, pyrolysis of propylene takes place, yielding hydrocarbon products. The only hydrocarbons resulting from this decomposition of propylene at temperatures below 530° are higher olefins, butylenes, amylenes and hexylenes. Experiment 5 with pure, oxygen-free, propylene shows that it is unchanged at 510° and times of contact of eight seconds in a silica vessel. A comparison of Expts. 1 to 3 with Expt. 5 shows that pyrolysis of propylene is effected by oxygen under conditions where pure propylene is thermally stable. This activated pyrolysis of propylene is such an important reaction that with small amounts of oxygen (Expts. 2 and 3) more propylene is pyrolyzed or polymerized, than is oxidized. It is noteworthy that in this activated pyrolysis resulting in the formation of higher olefins there was no formation of oil or tar observed below 600°. At higher temperatures of around

600° saturated hydrocarbons are formed both in the pyrolysis of propylene activated by oxygen (Expt. 4) and in the pyrolysis of oxygen-free propylene (Expt. 6). With pure propylene at 590° over two-thirds of the products of pyrolysis are olefins and one-third is saturated hydrocarbons with two carbon atoms in the molecules and with propylene activated by oxygen at 600° of the hydrocarbon products 64.8% is higher olefins, and 35.2% is saturated hydrocarbons with two carbon atoms in the molecule. As higher mono-olefins are the only hydrocarbon products of the pyrolysis of propylene activated by oxygen at 500°, it can be concluded that higher mono-olefins are the primary products of the pyrolysis of propylene and that the saturated hydrocarbons formed at higher temperatures are the result of secondary decompositions of the primary products.

The higher olefin reaction products were dried over solid potassium hydroxide and distilled from fresh potassium hydroxide. They were water-white limpid liquids of density less than 1. They had the characteristic olefinic odor, they absorbed bromine forming liquid bromides, decolorized permanganate solution rapidly in the cold, and were insoluble in water. The dried mixture of hydrocarbons was fractionated in a small still. The fraction boiling from -6 to 0° was assumed to be butylene, after the above chemical tests. In Expts. 1, 2 and 3 sharp fractions at -6° to 0°, 30-38° and 60-65° were the only products. The fraction boiling from 30-38°, where the amylenes boil, was assumed to be amylenes. On microcombustion the composition of this fraction was found to be C = 87.25%, H = 12.71%; theoretical for C_nH_{2n} is C = 85.7%, H = 14.3%. The fraction boiling from 60-65°, where the hexylenes boil, was assumed to be hexylenes. This fraction on microcombustion showed its composition to be: C = 86.71%, H = 12.41%. In Expt. 4 at 600° the dried hydrocarbon products recovered from the absorbent charcoal, after distilling off butylenes (-6 to 0°) boiled over the range 30 to 85° with two main fractions at 30-40° and 60-69°. The 30-40° fraction analyzed C = 87.85%, H = 11.27%, and the 60-69° fraction analyzed C = 87.90%, H = 11.41% by microcombustion. Redistillation of these fractions from solid potassium hydroxide and storing over anhydrous magnesium sulfate did not change the analysis. The boiling ranges of the various fractions together with their physical and chemical properties show that they were olefin hydrocarbons. The fractions probably contained small amounts of dienes, as 1,3-pentadiene b. p. 42°, 2,3-pentadiene b. p. 49-51°, and 1,3-hexadiene b. p. 72-74°, which would change the ratio for carbon to hydrogen from the theoretical for C_nH_{2n} in the direction of the higher carbon and lower hydrogen percentages found by analysis. There was no evidence of the formation of detectable amounts of cycloparaffins.

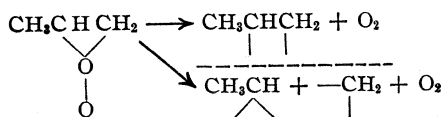

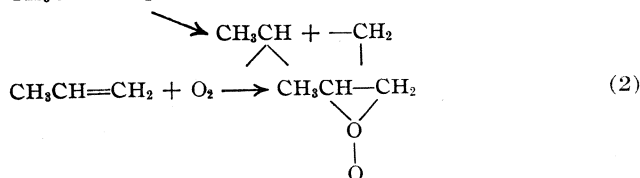

A check on the entire experimental procedure was made by filling the system with propylene, saturating the charcoal and circulating the gas

with the reaction vessel at room temperature. The charcoal was then removed and heated to 140° and steamed. No liquid hydrocarbons, other than propylene, were separated in the recovery system. It is clear that the hydrocarbons recovered after an experiment had been formed in the reaction and had not come from the original propylene as contamination or been formed from propylene in the absorbent charcoal on recovery.

Discussion

These experiments show that propylene containing small amounts of oxygen undergoes a polymerization reaction as well as oxidation and that the primary products of this polymerization are higher mono-olefins. The data show further that oxygen activates this pyrolysis of propylene to take place more rapidly at a lower temperature than is the case in its absence.

Since the pyrolysis of propylene activated by oxygen takes place in its initial stages without separation of carbon or hydrogen or formation of saturated hydrocarbons, the occurrence of mono-olefin products must be due to an activation of the hydrocarbon which will allow it to react with itself without changing the ratio of carbon to hydrogen. This activation consists in an opening up of the double bond by heat, or oxygen. It has been shown in the similar behavior of ethylene that this activation may lead to the formation of activated hydrocarbon molecules by the breaking of one of the carbon double bonds, and to the separation of methylene radicals by a scission of the two carbon double bonds; these considerations¹² may be taken to apply without modification to the oxidation, activation and polymerization of propylene. The first step in the reaction is an activation of the double bond by heat or oxygen

Butylene is formed by a reaction of a methylene radical with propylene

¹² Lenher, Ref. 1, p. 3756.

The amylenes may be formed in a reaction between an ethylidene residue and propylene

As both butylenes and amylenes occur in amounts which are smaller than the amount of hexylene, the formation of hexylene is the most important reaction. Hexylene is formed in the reaction of an activated propylene molecule with a normal propylene molecule, as

This reaction presents certain theoretical difficulties as it is a bimolecular association reaction, but it appears from a recent speculation of Kassel¹³ that such reactions are possible.

This outline of the activation and pyrolysis of propylene explains satisfactorily the observed products and the probable mechanism of the primary processes involved. Recent investigators of the pyrolysis of propylene^{3,4,5} have concluded that the principal primary products are other than those obtained in the present work. These results of other investigators are not actually in conflict with the present findings; they show that these authors were not dealing with the primary products of the pyrolysis of propylene but that the products which they obtained were the result of a more profound decomposition which carried the pyrolysis beyond the primary stage. The present experiments carried out at low temperatures and short times of contact have enabled the isolation of the primary products to be made. Wheeler and Wood's own work⁴ on the pyrolysis of the butylenes shows that when they break down at 600° at longer times of contact than were used in this paper, they yield propylene, ethylene, ethane, methane and hydrogen, and it may be assumed that the C₅ and C₆ olefins yield similar simple products under the same conditions. This pyrolysis of higher mono-olefins formed as the primary products on heating a longer time accounts for the simpler olefin and paraffin hydrocarbon products obtained by Frey and Smith, Wood and Wheeler and Hurd and Meinert. It is evident, therefore, that the primary products of the pyrolysis of propylene are higher mono-olefins and that ethylene, simple paraffins and hydrogen result from secondary reactions. The formation of aromatics occurs only above the temperature range considered in this paper.

The similarity between the behavior of ethylene and of propylene in their oxidation and pyrolysis reactions shows that the mechanism of these reactions which has been outlined above and in a previous paper¹² is general for the mono-olefin series of hydrocarbons.

¹³ Kassel, *THIS JOURNAL*, **53**, 2143 (1931).

Summary

The reaction between propylene and oxygen at high propylene and low oxygen concentrations has been studied in a recirculation apparatus between 500 and 600°. In addition to oxidation of propylene, pyrolysis of propylene takes place.

The oxidation products were acetaldehyde, formaldehyde, formic acid, carbon oxides and water.

The primary products of the pyrolysis were higher mono-olefins, butylenes, amylenes and hexylenes. Secondary products of pyrolysis are olefins, paraffins and hydrogen.

The temperature at which pyrolysis of propylene is appreciable is lowered greatly by the presence of small amounts of oxygen, and the rate of pyrolysis is markedly increased.

A mechanism of the oxidation and pyrolysis of propylene based on the activation of the carbon double bond has been outlined.

THE GAS PHASE EQUILIBRIUM BETWEEN METHYL NITRITE, HYDROGEN CHLORIDE, METHYL ALCOHOL, AND NITROSYL CHLORIDE. THE ABSORPTION SPECTRUM OF NITROSYL CHLORIDE

BY J. A. LEERMAKERS AND H. C. RAMSPERGER

RECEIVED DECEMBER 16, 1931

PUBLISHED MAY 7, 1932

Free energy values of organic substances will probably most often be obtained from heats of combustion and specific heat data by use of the third law of thermodynamics. They may, of course, be obtained with considerable accuracy from equilibrium data, but often a good equilibrium free from side reactions cannot be obtained with organic compounds. It is still more unusual to establish a gas phase equilibrium at room temperature. In the course of an investigation by the junior author to locate a gas phase reaction suitable for reaction rate research it was found that an equilibrium was very rapidly established between the gases listed in the title at room temperature. This was shown by the immediate partial disappearance of the color of nitrosyl chloride gas when added to an excess of methyl alcohol gas, and the appearance of the same color when hydrogen chloride gas was added to methyl nitrite gas. The thermodynamic data for the three gases, methyl alcohol, nitrosyl chloride and hydrogen chloride are quite accurately known so that from equilibrium measurements at two temperatures we are able to calculate the free energy of formation, the heat of formation and entropy of methyl nitrite.

Experimental Method

The equilibrium concentrations were obtained by quantitative measurements of the absorption of light in the spectral region 4000 to 5000 Å., where the absorption of nitrosyl chloride is quite strong. Of the other substances only methyl nitrite absorbs light in this region and then only faintly between 4000 and 4200 Å. From our determination of the absorption of pure nitrosyl chloride and methyl nitrite, the absorption of an equilibrium mixture of the four substances and the initial pressures of two of them it is possible to calculate an equilibrium constant for the reaction

Preparation and Purification of the Compounds.—Nitrosyl chloride was prepared by passing hydrogen chloride into nitrosyl sulfuric acid obtained from sulfur dioxide and fuming nitric acid.¹ The nitrosyl chloride was repeatedly distilled and collected at -20° to remove traces of hydrogen chloride and finally fractionally distilled through a column surrounded by a bath at -25° . The middle fraction boiling at $-6.0 \pm 0.2^\circ$ was used. This was distilled at a low temperature on a high vacuum line into a number of small tubes each drawn down to a capillary and maintained at -78° . When sufficient nitrosyl chloride had collected in a small tube, the supply was also cooled to -78° stopping the distillation and the tube was sealed off.

Methyl nitrite was prepared by dropping sulfuric acid into a stirred and gently heated mixture of sodium nitrite and methyl alcohol. The evolved gas was passed through fused calcium chloride and collected at -78° . The liquid was fractionally distilled through a column surrounded by ether cooled by solid carbon dioxide to about -30° and was collected at -78° . It boiled at a constant temperature of -17.0° and the middle portion was used. It was found necessary to eliminate traces of nitrogen dioxide since the strong characteristic absorption bands of this substance interfered with the measurements. A supply of pure methyl nitrite was obtained by allowing the gas to pass through a long tube containing soda lime into a one-liter storage flask sealed onto the vacuum system and previously evacuated. No bands of nitrogen dioxide were then found in the sample even when a pressure of the gas as high as 40 cm. was in the absorption tube.

The methyl alcohol used was Baker's Analyzed absolute methyl alcohol. This was further dried by refluxing over aluminum amalgam and was then fractionally distilled. It was placed in a small receiver equipped with a stopcock, sealed to the vacuum system, and enough of the vapor pumped off to displace all of the air.

Hydrogen chloride was obtained by dropping c. p. hydrochloric acid on concentrated c. p. sulfuric acid. The hydrogen chloride gas was passed through wash bottles containing concentrated c. p. sulfuric acid, then through a tube filled with c. p. anhydrous calcium chloride, and was collected in a half-liter flask equipped with a stopcock and a tube sealed to the bottom. When gas sufficient to displace the air had passed through the flask the stopcock was closed and the entrance tube sealed off. The flask was sealed to the vacuum system and the hydrogen chloride was frozen down by means of liquid air into the tube at the bottom. Any air left in the flask was then pumped off, the stopcock was closed, and the solid hydrogen chloride allowed to evaporate into the flask. It was used without further treatment.

The Absorption Curve of Nitrosyl Chloride and Methyl Nitrite.—A Pyrex absorption cell 4 cm. in diameter and 40.0 cm. long with plane parallel windows was filled with ni-

¹ Scott and Johnson, *J. Phys. Chem.*, **33**, 1975 (1929).

nitrosyl chloride or methyl nitrite gas as shown in Fig. 1. The absorption cell A was evacuated with a mercury diffusion pump through G. It was filled with nitrosyl chloride by breaking the capillary end of the tube B containing liquid nitrosyl chloride with the magnetic hammer C, or filled with methyl nitrite from the supply D.

The pressure was measured by a "clicker" system. The pressure on the "clicker"² sealed in the bottom of the bulb F was controlled by the variable leaks J or by vacuum through H and was measured by a McLeod gage having a compression of about eight-fold so as to read accurately pressures of several cm.

The absorption cell was then immediately sealed off just above the side tube. Capillary tubing was used to prevent too much reaction of nitrosyl chloride with the grease of the stopcock before sealing off.

Figure 2 shows the apparatus for photographing the absorption spectrum. Light from the 40-watt mazda lamp B operating under constant voltage passes through the diaphragm C which is covered with a ground glass, then through the partition D, the shutter E, the diaphragm F, the absorption cell H containing the absorbing substance, the diaphragm F', and finally into the slit of the spectrograph N. The cell is attached to the galvanized iron thermostat by the large rubber tubes at G and G' which slip over the brass tubes soldered into the ends of the thermostat. The cell has a side tube J (not shown in Fig. 1) used for freezing out the contents of the cell with liquid air. K is a heater and stirrer, L the mercury thermo-regulator and M is a thermometer which was calibrated against a Bureau of Standards thermometer.

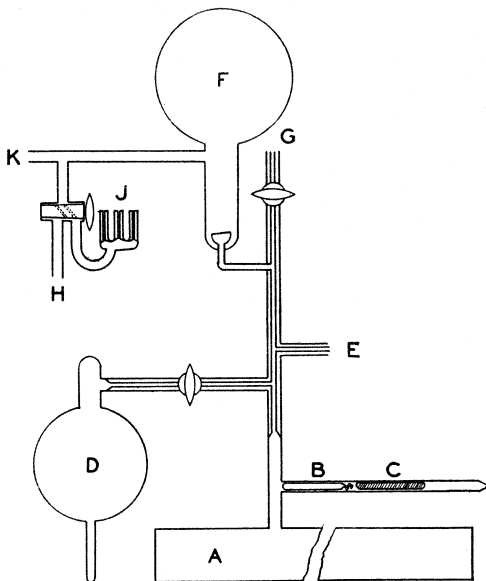

Fig. 1.

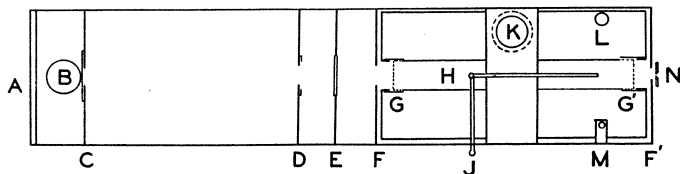

Fig. 2.

A series of spectra are photographed with the absorbing medium in the cell, the cell contents are frozen out, and then a series of photographs are taken on the same plate in between the first exposures. These latter exposures are given the same exposure time but are uniformly reduced in intensity for all wave lengths by placing screens of known absorption in the light path at D. The blackening of the photographic plate on two adjacent spectra is the same for those wave lengths for which the particular screen and the gas in the cell have the same absorption. Positions of equal intensity were deter-

² Smith and Taylor, *THIS JOURNAL*, **46**, 1393 (1924).

mined by a method similar to that used by Ramsperger and Porter.³ The photometer system for this purpose is shown in Fig. 3. The photographic lens D projects an image of the plate in the holder C on the screen L with a magnification of about eight times. A high light intensity is obtained by the 500-watt projection lamp A and the condensing lenses B. A slit in the screen 2 cm. long and 2 mm. wide allows the light from a very narrow region of the spectrum to fall onto a cesium photoelectric cell E. F is a 45-volt battery, G a 10-megohm resistance, H a Leeds and Northrup high-sensitivity galvanometer with critical damping resistance J. With a scale at two meters, deflections of 6 to 20 cm. were obtained. The plate in the holder C could be moved either vertically or horizontally so as to bring the image of the spectra on the slit at any wave length. Points of equal deflection could be located with an accuracy of 2 to 5 Å. An iron arc spectrum served as a wave length reference. We wish to thank Professors Dickinson and Beckman of this Laboratory for the use of the screens which were constructed and calibrated by them. They determined the transmission of the screens by use of a thermopile and a constant light source.

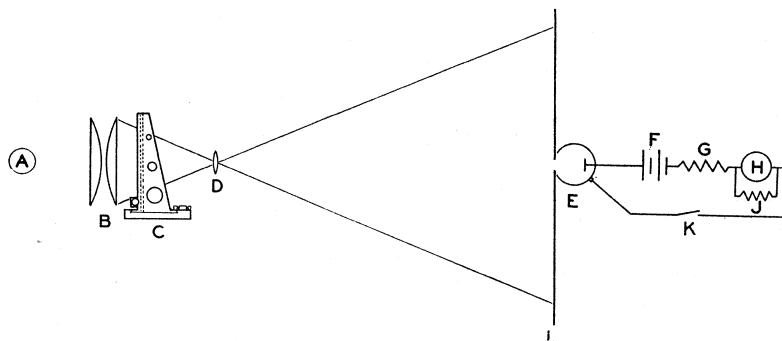

Fig. 3.

Table I gives the data obtained for the absorption of nitrosyl chloride and methyl nitrite at temperatures of 25 and 50°. The pressures are calculated to 25°. The absorption coefficients at the wave lengths listed are then calculated by assuming that Beer's law is obeyed over the range of pressure investigated. The relation used was $I_t/I_0 = 10^{-\epsilon cd}$ where I_t/I_0 is the fraction of light transmitted, c is the concentration expressed in cm. of mercury pressure at 25°, d is the length of the absorption cell (40.0 cm.) and ϵ is the absorption coefficient. Values of ϵ are plotted against the wave length in Fig. 4.

The small circles on the dotted line portion of the curve at 25° were estimated from the difference in galvanometer deflections from the nearest points of equal intensity on one of the plates. This region of the curve was not used in determinations of the equilibrium concentrations of nitrosyl chloride. The coincidence of several points at different pressures indicates that Beer's law is obeyed fairly well in the range studied.

The Partial Pressure of Nitrosyl Chloride at Equilibrium.—When nitrosyl chloride of concentration c and of absorption coefficient ϵ_1 is present

in the same cell with methyl nitrite of concentration c_2 and absorption coefficient ϵ_2 the Beer's law expression becomes $I_t/I_0 = 10^{-(\epsilon_1 c_1 + \epsilon_2 c_2)d}$. If

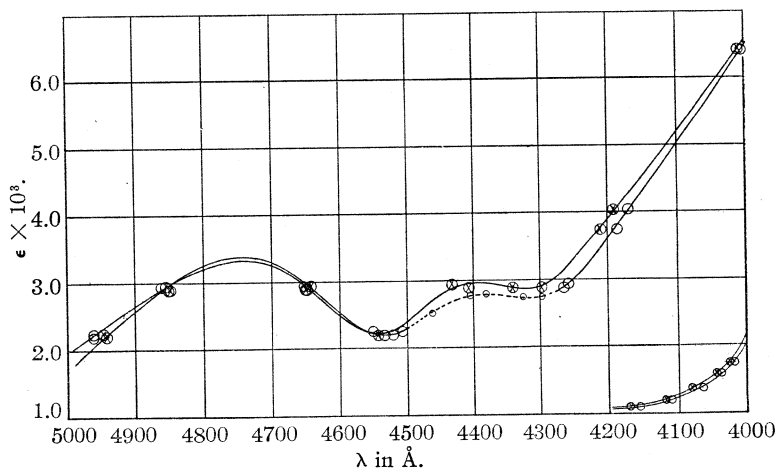

Fig. 4.—Absorption coefficients of nitrosyl chloride and of methyl nitrite plotted against wave lengths. The two upper curves are for nitrosyl chloride; those in the lower right-hand corner are for methyl nitrite. The open circles are for 25°, the circles enclosing crosses are for 50°.

the initial concentration of nitrosyl chloride is a and its equilibrium concentration after adding methyl alcohol is x , the expression becomes $I_t/I_0 = 10^{-\{\epsilon_1 x + \epsilon_2(a-x)\}d}$.

The same expression results if, in starting with methyl nitrite and hydro-

gen chloride, a is the initial concentration of methyl nitrite. The equilibrium concentration x can then be calculated from values of ϵ_1 and ϵ_2 obtained from the absorption curve for the wave length at which I_t/I_0 is measured.

The cell was filled with the two initial substances and their pressures were determined as described before and shown in Fig. 1. Methyl alcohol or hydrogen chloride was attached at E. Capillary tubing was used as indicated so that when the cell was sealed off just above the side tube no appreciable error was made in the partial pressures of gases admitted even though perfect mixing in the tubing had not taken place. The procedure in making the exposures and finding the points of equal intensity was similar to that for determining the absorption curves for the pure gases. Table II gives the complete data of two experiments. Table III gives a summary of all of the experiments.

Experiments 1 and 2 are not included because they were preliminary experiments made before the apparatus was in its final form. In Expts. 3, 9, 10 and 11 the total pressure in the cell was sufficiently high so that there was some evidence of condensation in each case. The equilibrium pressures of nitrosyl chloride are generally the average of four points. The average deviation from the average is shown by the \pm sign in columns 6 and 7. Equilibrium constants have been calculated by assuming the fugacities of the gases equal to their pressures. Experiments 6 and 8 deviate rather badly from the others listed. In these cases the concentration of methyl alcohol at equilibrium is very low, in fact so low that the estimated experimental error in the measurement of the nitrosyl chloride pressure will produce a very large error in the equilibrium constant. These experiments have not been used in obtaining an average equilibrium constant. Experiment 13 at 50° gives a constant which differs widely from the remaining constants at this temperature. No explanation is known for this discrepancy. The probable error of the average constant at 50° , if this value is excluded, is about equal to the probable error introduced by the probable errors in the measured pressures of nitrosyl chloride, while if this value be included the probable error of the average equilibrium constant is increased three-fold. We feel therefore that this value should likewise be excluded in obtaining an average equilibrium constant. When these values are excluded the average value of $K_{298.1} = 0.521$ and $K_{323.1} = 0.753$.

Evidence of a True Equilibrium.—We may present the following evidence that a true equilibrium free from side reactions has been obtained. The data of Table III show that the equilibrium constant is independent of the direction from which the equilibrium is established. It is independent of moderate variations in the partial pressure of the starting materials. No light-absorbing gas other than nitrosyl chloride or methyl nitrite (such as nitrogen dioxide) is likely to be present in appreciable amounts since the calculated concentration of nitrosyl chloride was the same at several wave lengths and any other absorbing gas would not likely have a characteristic absorption curve so very much like nitrosyl chloride. An experiment was carried out in which definite amounts of hydrogen chloride and methyl nitrite were mixed and the calculated pressure was obtained showing that no change in pressure occurred during the reaction. The equilibrium pressure of nitrosyl chloride as determined by its light absorption was found not to be changed on standing in the dark for an hour or on being illuminated for two hours.

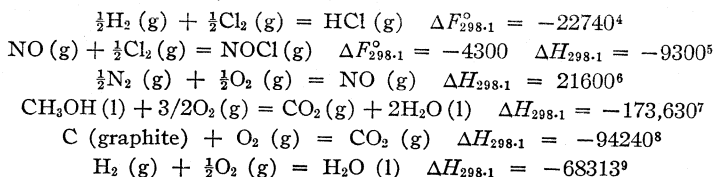

Thermodynamic Calculations.—From the equilibrium constants we find for the reaction

$$\Delta F_{298.1}^\circ = 385 \text{ cal. and } \Delta F_{323.1}^\circ = 182 \text{ cal.}$$

Assuming ΔC_p zero over the range of temperature investigated $\Delta H_{298.1} = 2805$ cal. Then $\Delta S_{298.1}^\circ = 8.12$. The error in ΔF is quite small. The probable error of ΔH may be estimated roughly at 300 to 400 cal. and of ΔS about 1.0 entropy unit.

To calculate $\Delta F_{298.1}^\circ$, $\Delta H_{298.1}$ and $\Delta S_{298.1}^\circ$ for the reaction of formation of methyl nitrite from the elements and the entropy of methyl nitrite it will be necessary to make some choice of the available thermodynamic data of the other three substances occurring in the equilibrium. We have chosen the following data

Vapor pressure of $\text{CH}_3\text{OH}(\text{l})$ at $298.1^\circ = 122.2$ mm.¹⁰

The following values of the molal entropy at $T = 298.1^\circ$ and one atmosphere have been used for third law calculations

$\text{H}_2(\text{g}) = 31.23$	Giauque, <i>THIS JOURNAL</i> , 52 , 4825 (1930)
$\text{C}(\text{graphite}) = 1.3$	Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., Inc., New York, 1923, p. 464
$\text{N}_2(\text{g}) = 45.78$	Giauque, private communication
$\text{O}_2(\text{g}) = 49.03$	Giauque and Johnson, <i>THIS JOURNAL</i> , 51 , 2300 (1929)
$\text{Cl}_2(\text{g}) = 53.3$	McMorris and Yost, <i>ibid.</i> , 53 , 2625 (1931), footnote 2631
$\text{NO}(\text{g}) = 50.43$	Johnson and Giauque, <i>ibid.</i> , 51 , 3194 (1929)
$\text{HCl}(\text{g}) = 44.64$	Giauque and Wiebe, <i>ibid.</i> , 50 , 101 (1928)
$\text{CH}_3\text{OH}(\text{l}) = 30.3$	Kelley, <i>ibid.</i> , 51 , 180 (1929)

The resulting data for the free energy, heat and entropy of formation at 298.1° and one atmosphere and the entropy of the four substances occurring in the equilibrium are listed in Table IV.

Summary

Quantitative measurements of the light absorption of nitrosyl chloride and methyl nitrite have been made. Measurements of the light absorption due to nitrosyl chloride present in the gas phase equilibrium $\text{CH}_3\text{ONO (g)} + \text{HCl (g)} = \text{CH}_3\text{OH (g)} + \text{NOCl (g)}$ have been made and equilibrium constants calculated for the temperatures of 25 and 50° for both the forward and reverse reactions. The equilibrium is instantly established, is independent of the direction from which it is established and is free from side reactions. The equilibrium constants are $K_{298.1} = 0.521$ and $K_{323.1} = 0.753$. From these values and from thermodynamic data in the literature for hydrogen chloride, nitrosyl chloride and methyl alcohol we have calculated the free energy, the heat and the entropy of formation and the entropy of methyl nitrite.

REACTION OF GASES WITH INCANDESCENT TANTALUM

BY MARY R. ANDREWS

RECEIVED DECEMBER 19, 1931

PUBLISHED MAY 7, 1932

It has been known for many years that tantalum, when heated, absorbs actively such gases as nitrogen and hydrogen, but early experimentation was confined to the comparatively low temperatures obtainable in furnaces, and the pressures were the comparatively large ones measurable with a manometer.¹ With modern methods of vacuum technique, it is possible to study reactions at very low pressures and at temperatures up to the melting point of the material under observation. Tantalum offers a particularly interesting subject for such a study.

The following work was done with tantalum filaments mounted in bulbs on an exhaust system. The system contained a reservoir of the particular gas in use and suitable mercury traps for shutting off known volumes. Pressures were read with McLeod gages.

¹ Von Bolton, *Z. Electrochem.*, **11**, 45 (1905); Sieverts and Bergner, *Ber.*, **44**, 2394 (1911); Balke, *Chem. Met. Eng.*, **27**, 1271 (1922); Borelius, *Metallwirtschaft*, **8**, 105-108 (1929)

Nitrogen.—The tantalum filament was given a preliminary degassing in vacuum at $2400\text{--}2500^\circ$ until the cold resistance had decreased to a constant value and no more gas was evolved. A known pressure of nitrogen was then admitted, the filament run at a constant wattage and the pressure was read at known intervals until the gas had been absorbed to an equilibrium pressure.

If, now, another charge of nitrogen was admitted and the filament again run, absorption took place at a somewhat lower rate than before, and the equilibrium pressure was somewhat greater (see Fig. 1). During the first part of any run, the temperature is uncertain, due to the cooling effect of the gas, but for low equilibrium pressures the temperature at the end of the run is accurate within a few degrees.

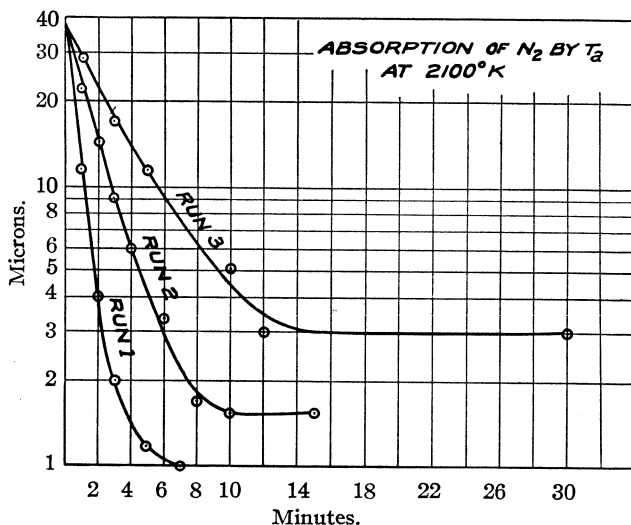

Fig. 1.—Absorption of nitrogen in a volume of 3250 cc. by a 10 mil tantalum filament 20 cm. long at $2100^\circ K$. Pressure in system vs. time of absorption.

If, after absorbing nitrogen, a filament is run in an evacuated bulb, it will evolve gas until an equilibrium pressure is again reached. For a given concentration of gas in the metal, the equilibrium at any given temperature is the same whether obtained by absorption or evolution. If the filament is heated while the gas evolved is steadily pumped away, it will lose all the nitrogen it has absorbed and return to its original degassed condition. In this process there is no loss of tantalum.

These results prove that, at least in low concentrations, nitrogen goes into tantalum by solution, not by the formation of a compound. Were a compound formed, the equilibrium pressure (or decomposition pressure) would be constant during absorption at any given temperature, inde-

pendent of the amount absorbed, until all the metal had been converted to the compound.

Figure 2 shows a composite curve of the logarithm of the equilibrium pressure *versus* the logarithm of the concentration of nitrogen in the filament at 2240°. The concentration is given as the volume (at N. T. P.) of gas absorbed divided by the volume of the filament, that is, the number of times its own volume absorbed by the filament. It should be noted that the slope is about 1:2, or that the pressure varies as the concentration squared. This agrees with results obtained by Sieverts and Bergner on the

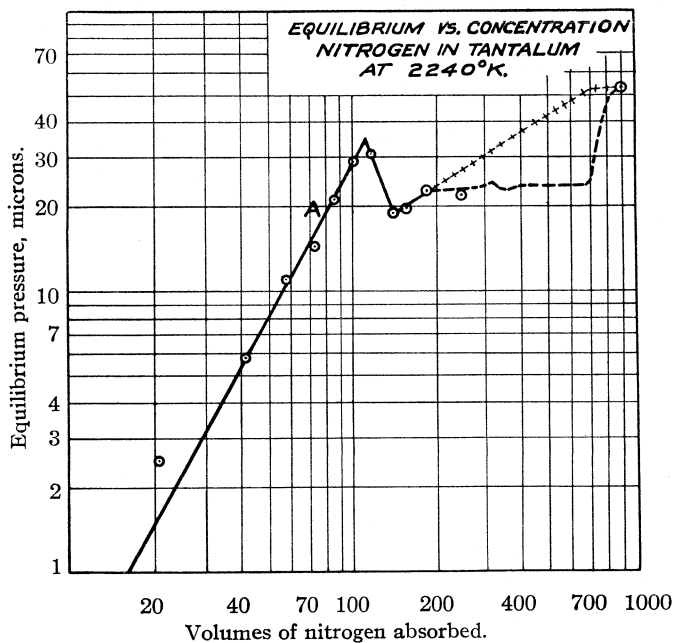

Fig. 2.—Equilibrium pressure *vs.* concentration of nitrogen in tantalum at 2240°K.

solubility of *hydrogen* in tantalum, and indicates that the gas is absorbed in the atomic state. At a concentration of about a hundred volumes, which would give a composition corresponding to $Ta_{10}N$, this curve shows a sudden break in such a direction that by increased concentration of nitrogen in the filament the equilibrium pressure is lowered. Dr. W. P. Davey very kindly took x-ray photographs of two samples of nitrogen-charged tantalum, one of which contained about fifty volumes of nitrogen, the other about two hundred volumes. The first filament showed only the tantalum structure, but the second, more highly charged filament, showed, besides the tantalum structure, an entirely different crystal form. It is not known whether this is the structure for tantalum nitride or whether the

strain produced by the absorbed gas causes the metal to go into a new form in which nitrogen is more soluble. If the change is to the nitride structure, one would assume that the decomposition pressure of the compound was about that at the point A (Fig. 2) and that the metal in absorbing nitrogen became supersaturated and then suddenly reacted to form the nitride with the excess gas, both within and without the metal. This would explain the shape of the curve at higher concentrations quite nicely, the level part at more or less constant equilibrium pressure being the range through which nitride is being formed. There are, however, objections to this theory. First, it is possible to produce this maximum not only through absorption, but also in the opposite direction by evolution of gas from the filament. For instance, a filament which had absorbed 275 volumes of nitrogen was heated at 2200°K. in an evacuated system of known volume so that it evolved gas until an equilibrium pressure was reached. Gas was pumped out and equilibrium again obtained by evolution from the filament. The following shows the maximum pressure obtained at 112 volumes of nitrogen in the filament

Vol. of N ₂ in filament.....	200	175	112	70
Equilibrium pressure, microns.....	23	22	35	26

If the peak were due to supersaturation, it should not appear when the gas is removed. Moreover, the electrical resistance at room temperature, which increases almost linearly with the concentration of nitrogen, shows no break at this critical concentration, such as would be expected if a compound were being formed [see Fig. 4].

As for the shape of the pressure-concentration curve obtained at the higher concentrations (shown as a broken line in Fig. 2), it may have to be altered considerably because above a concentration of about 200 volumes the emissivity of the surface appears to increase gradually, the color going to a dull gray. As no allowance was made for this change, in the wattages used, the filament temperature undoubtedly fell considerably through the range 200 to 700 volumes concentration. Above seven hundred volumes the equilibrium pressure appears to increase rapidly, but because at these high concentrations the filament becomes very brittle, few measurements could be made. A concentration of 900 volumes would correspond to complete conversion of the metal to TaN. It seems probable, therefore, that at about the concentration of 700 volumes this compound begins to form with a resulting sintering of the surface and a rise of the temperature to something much closer to the original value. If this is so the equilibrium curve should follow, at constant temperature, the cross-hatched line shown in Fig. 2.

As the temperature of the metal is increased, the rate of solution increases, but the solubility decreases, *i. e.*, the equilibrium pressure for any

given concentration increases. Absorptions were made from 1600 to 2400°K. Figure 3 shows the equilibrium pressures for constant nitrogen content in the wire, plotted as the logarithm of the pressures against the inverse of the temperature. From the slope of these lines, the heat of solution is calculated to be 102,000 calories. This value may be somewhat in error due to the necessary correction made for the cooling effect of the gas on the filament at the higher temperatures and pressures.

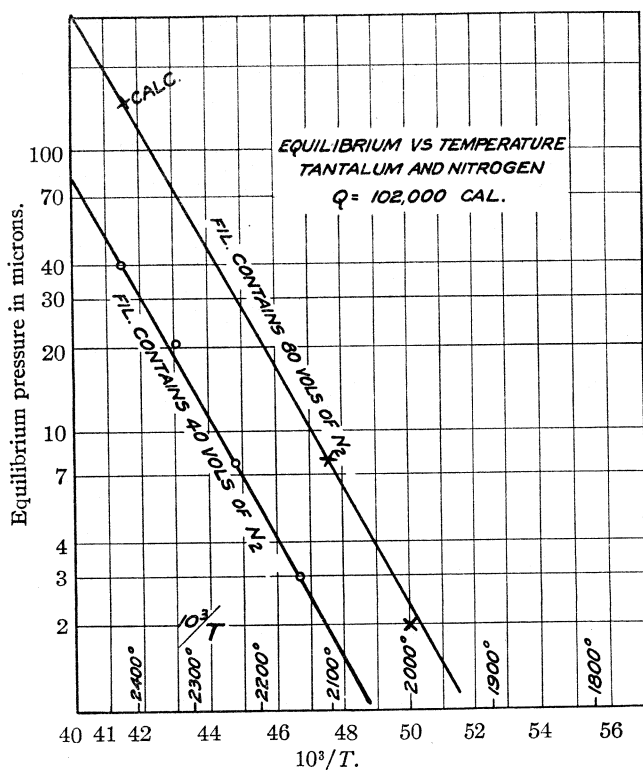

Fig. 3.—Equilibrium pressure vs. temperature at constant concentration of nitrogen. Lower curve: filament contains 40 volumes of nitrogen. Upper curve: filament contains 80 volumes of nitrogen.

Oxygen.—Oxygen is absorbed by tantalum in a somewhat different manner than nitrogen. Whereas nitrogen is taken up very slowly below 1600°, oxygen is absorbed quite readily at 1000°K. and with extreme rapidity at 1800°. Absorption is quite complete up to twenty volumes, the residual pressures being negligible. Further absorption at 1800° (which takes place with great rapidity) leads to the formation of a compound. This is shown by the variation of the resistance with gas content.

(See the oxygen curve in Fig. 4.) The cold resistance increases rapidly with concentration up to twenty volumes and then much more slowly. There appears to be a slight supersaturation just before the oxide begins to form. Not enough work has been done in the absorption of oxygen to show whether the solubility, at the point at which compound formation begins, varies with temperature.

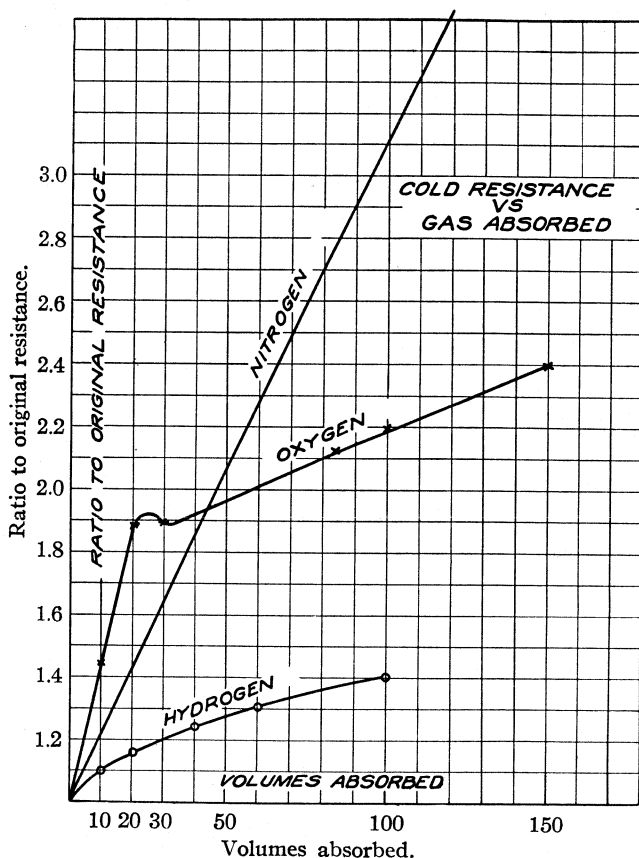

Fig. 4.—Resistance at room temperature *vs.* gas content. Resistance given as the ratio to the resistance of the gas-free filament.

A filament containing twenty volumes of oxygen was examined by Dr. Davey with the x-ray spectrograph. It showed the tantalum structure, but the lattice was stretched, apparently somewhat more in one direction than in the others. This would be exactly what might be expected from a solution of gas in the metal.

Microphotographs were taken of longitudinal sections of a filament that had absorbed 500 volumes of oxygen. The filament was very badly

crinkled and the surface under the microscope looked cracked and scaly (see Fig. 5). The photographs show that penetration takes place most freely along grain boundaries so that the oxide forms in streaks and thin sheets. A concentration of 500 volumes is about one-fifth that necessary to form Ta_2O_5 , and the photographs suggest that nearly this fraction of the metal has reacted.

At the point at which the oxygen compound is first formed, the filament begins to turn dark, so that temperatures were quite uncertain at higher concentrations.

The dissolved oxygen, *i. e.*, the first twenty volumes absorbed can be re-evolved if the filament is run in vacuum at 2200–2300°. There is no appreciable loss of metal in the process. If a filament containing a greater amount of oxygen is heated to such a temperature, some metal is vaporized and deposits as a black film on the bulb wall.

Hydrogen.—The absorption of hydrogen offers an interesting study. At the pressures used, 50 microns or less, no hydrogen was absorbed when the tantalum was heated in the gas; but if an auxiliary filament of tungsten was run in the same bulb at a high temperature so as to dissociate some of the hydrogen and the tantalum filament was run at the same time at 800 to 1200°, hydrogen was absorbed

by the tantalum. Solubility was greater at the lower temperatures. At any given temperature absorption would take place until an equilibrium was established. Addition of more hydrogen caused increased absorption. The action was exactly similar to the absorption of nitrogen except that equilibrium was established between the dissolved hydrogen and the external pressure of *atomic* hydrogen. That is, if equilibrium was established with the tungsten filament running at a constant temperature, say 2400°K., and the tantalum also constant, at say 1000°K., and the temperature of the tungsten filament was then increased, to, say, 2600°, thus increasing the fraction of the hydrogen dissociated, the tantalum absorbed hydrogen further until a new equilibrium was established. If the tungsten filament was lowered in temperature, the tantalum would immediately evolve gas to

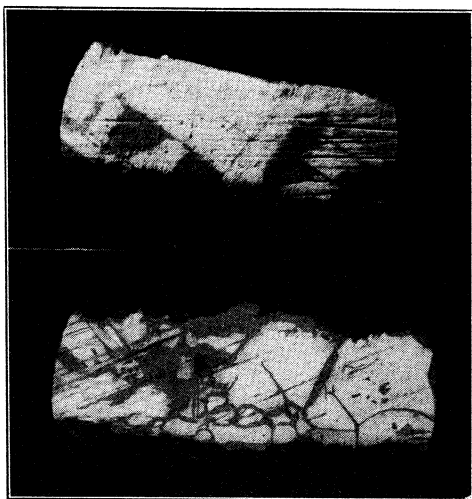

Fig. 5.—Photomicrographs of tantalum filament which has absorbed 500 volumes of oxygen.

establish again an equilibrium, or if the current was taken off the tungsten filament, the tantalum one being left at 1000°K. , gas would be evolved from the tantalum until practically all that had been absorbed had reappeared.

The hydrogen curve in Fig. 4 shows that the resistance at room temperature rises less rapidly with hydrogen concentration than for either oxygen or nitrogen. It can be assumed that this is due to the small atomic volume of the hydrogen, so that a given number of molecules dissolved in the metal would strain the lattice less than larger atoms. There was no evidence of any compound up to the maximum concentrations of hydrogen reached.

Water Vapor.—One or two experiments were made on the reaction between water vapor and hot tantalum. Above 1400°K. the water is decomposed with absorption, by the filament, of the oxygen and evolution of the hydrogen. At 1200° the reaction is negligibly slow.

It was observed in the absorption of both nitrogen and hydrogen that the rate of absorption was much less when a new filament was used than it was after the filament had absorbed gas and had been degassed. Rates were never constant, however. This suggests that diffusion of these two gases as well as of oxygen takes place along grain boundaries and that gassing and degassing helped to open up the structure so that diffusion was more rapid than when the filament was new.

Hydrocarbons.—When heated between 2000 and 2800°K. in low pressures of hydrocarbon vapors, such as benzene or naphthalene, tantalum can form two carbides. The first one to form, *i. e.*, the one of lowest decomposition pressure, is silvery-gray and has a chemical composition of Ta_6C_5 . The electrical resistivity of this carbide is about twelve times that of pure tantalum, or 180×10^{-6} , and the temperature coefficient of resistance is very low. Our measurements do not permit of great accuracy in this determination since by complete conversion to this compound the filament is often warped and sometimes shows longitudinal cracks, but the above figure should be accurate to within 20%. This value agrees with the resistivity and temperature coefficient reported by Friedrich and Sittig,² and copied elsewhere for the compound TaC .

If the filament is heated further in hydrocarbon vapor, the electrical resistance decreases due to the formation of the compound TaC . This has a resistivity about 120% that of pure tantalum, or a specific resistivity of 17 to 18×10^{-6} . TaC has a brilliant golden-yellow color when in the dense crystalline form and shows a metallic luster equal to that of well-crystallized metals. Both carbides have high melting points, certainly above 3800°K. , but no determinations of the two in the pure state have been made here. It would appear, however, from the color and electrical resistivity of their material that Friedrich and Sittig² found the melting point of Ta_6C_5 (rather than TaC as they report) to be 4000 – 4100°K. The

² Friedrich and Sittig, *Z. anorg. allgem. Chem.*, **144**, 169–189 (1925).

material used by Agte,³ which he found to have a melting point of $4150 \pm 150^\circ\text{K.}$, was almost certainly TaC at the start and probably suffered only superficial decarbidization during the melting point determination.

When formed from metal by diffusion of carbon inward, as when a tantalum filament is heated in hydrocarbon vapor, the rate of formation is very much less than is the case when tungsten is carbidized in the same way. The time necessary to convert a 10 mil tantalum filament to the first carbide, Ta_6C_5 at 2600°K. , for instance, is fully ten times as great as that for conversion of a similar filament of tungsten to the carbide W_2C . Like the two carbides of tungsten, both tantalum carbides are brittle. They have been prepared also in powder form by the well-known method of heating mixtures of tantalum oxide and carbon in hydrogen protected by graphite boats. The products agree in composition with those formed by carbidizing metallic filaments. The colors of the powdered materials are, for Ta_6C_5 , a dark gray, and for the TaC a yellowish-brown.

When a filament of the yellow TaC is heated to 2500°K. or more in vacuum or in a neutral gas, such as argon, it loses carbon at a rate depending on the temperature and gas pressure. If the heating is interrupted from time to time to measure the cold resistance, the latter is found to increase very greatly until it has reached the resistance of the compound Ta_6C_5 . On further heating, if this be kept below the temperature at which metallic tantalum melts, the loss of carbon continues and the resistance decreases until that of a pure tantalum filament is reached. If the temperature of the carbidized filament is above the melting point of tantalum, fusion occurs as soon as an appreciable amount of the Ta_6C_5 has lost carbon to form a small amount of tantalum, and the filament burns out immediately. In the decomposition of TaC to Ta_6C_5 even at temperatures of 3000 to 3400°K. there is no appreciable evaporation of the tantalum, or of the carbides.

In conclusion I take this opportunity for thanking Dr. Saul Dushman for his interest and advice and Mrs. Donald McLeod for her assistance in making these investigations.

Summary

A study has been made of the behavior of filaments of tantalum when heated in low pressures of nitrogen, hydrogen, oxygen or hydrocarbons. In nitrogen, absorption increases with increased pressure until about 100 volumes are absorbed. At this point the equilibrium pressure drops as absorption increases. Absorption can take place to the formation of TaN. In hydrogen, the amount absorbed depends on the concentration of atomic hydrogen in the gas. In oxygen, absorption followed by oxide formation

³ Agte, Dissertation, Technische-Hochschule zu Berlin, April 8, 1931. Agte and Alterthum, *Z. anorg. allgem. Chem.*, **144**, 169-189 (1925).

occurs. In hydrocarbons, two carbides may be formed— Ta_5C_3 and TaC . These both have very high melting points. The former has a specific resistance of about 180×10^{-6} , the latter of about 18×10^{-6} .

ELECTRIC MOMENT AND MOLECULAR STRUCTURE. VII. THE CARBON VALENCE ANGLE

BY C. P. SMYTH AND W. S. WALLS

RECEIVED DECEMBER 21, 1932

PUBLISHED MAY 7, 1932

The experimental examination of the angle between the valences of the carbon atom may seem an attempt to prove the obvious, but the calculations of Slater¹ and of Pauling² by means of wave mechanics that the angle is the regular tetrahedral valence angle, 109.5° , and the evidence as to the angle given by x-ray³ and electron scattering⁴ in gases make it desirable to extend the preliminary application of electric moments which has been made in the study of the problem.⁵ This preliminary application was made in the case of the moments of the halogenated methanes. Rough kinetic theory diameters were calculated for chlorine, bromine and iodine by comparison with the dimensions of the corresponding inert gas structures and used as the internuclear distances of the halogens in the methylene halides. The assumption of these distances, when used with the carbon-halogen nuclear separations obtained by Pauling,⁶ necessitated a widening of the angle between the C-X valences to 124° in methylene chloride, 120° in methylene bromide and 135° in methylene iodide. When the C-X dipole moments were resolved at these angles, the resultants agreed so well with the experimentally determined moments of the molecules that the moments were regarded as indicating these values for the angles between the C-X valences. However, it was stated that the disregard of the inductive effects of the dipoles as well as the speculative nature of the treatment of the atomic dimensions rendered the excellence of the agreement between the observed and the calculated values of the moments somewhat fortuitous. As the inductive action of each C-X dipole in the methylene halide lowers the moment of the other C-X dipole in the molecule, it is evident that the angle calculated between the dipoles without regard for this effect is too large, although it is interesting to note that the recent calculation by Bewilogua³ from the results of x-ray scattering also

¹ Slater, *Phys. Rev.*, **37**, 481 (1931); *ibid.*, **38**, 1109 (1931).

² Pauling, *THIS JOURNAL*, **53**, 1367 (1931).

⁶ Pauling, *Z. Krist.*, **67**, 377 (1928).

gives 124° for the angle between the C-Cl valences in methylene chloride. As it appears impossible, at present, to calculate satisfactorily the lowering of the moments by induction, this complication has been avoided by removing the component dipoles so far from one another in the molecule as to render their mutual inductive effects negligible.

In the separation of the dipoles from one another advantage is taken of the fact that the valences directed outward from a benzene ring act in the plane of the ring so that para valences act in the same straight line in opposite directions.⁷ Instead, therefore, of methylene compounds, para-substituted benzyl compounds as represented in Fig. 1 have been measured. In support of this procedure, not only the zero moments of *p*-dinitrobenzene, and *p*-dichloro-, *p*-dibromo- and *p*-diiodobenzene may be cited, but also the excellent agreement of the observed and calculated values when different groups are in the para positions. Thus, the electric moment of nitrobenzene is 3.9×10^{-18} and that of chlorobenzene 1.52×10^{-18} . As the two dipoles should act in opposite directions in the same straight line in *p*-chloronitrobenzene, the resultant moment should be $(3.9 - 1.52) \times 10^{-18} = 2.38 \times 10^{-18}$, in excellent agreement with the observed value 2.45×10^{-18} . If the bromine moment 1.50×10^{-18} is substituted for the chlorine, the calculated value is 2.40×10^{-18} and the observed 2.53×10^{-18} . The results are a little less satisfactory in the case of the cyanides. As the moment of benzonitrile is indistinguishable from that of nitrobenzene, one would expect zero moment for *p*-nitrobenzonitrile, but the observed value is 0.7×10^{-18} .

The moment of *p*-bromobenzonitrile should be $(3.9 - 1.50) \times 10^{-18} = 2.4 \times 10^{-18}$, while the observed value is 2.64×10^{-18} . For *m*-nitrobenzonitrile, in which the two dipoles should make an angle of 120° with each other, the moment should be 3.9×10^{-18} , and the observed value is 3.8×10^{-18} . As the agreement between the observed and calculated values for these two latter compounds is satisfactory and as the small moment apparently observed for *p*-nitrobenzonitrile may be due entirely to the effect of neglected atomic polarization, it seems justifiable to treat the moment

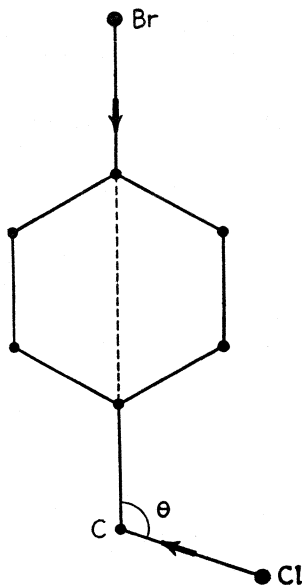

Fig. 1.—The *p*-bromobenzyl chloride molecule.

⁷ Smyth, "Dielectric Constant and Molecular Structure," The Chemical Catalog Company, Inc., New York, 1931, Chap. VI.

⁸ The values of moments, for which the experimental data are not given in this paper, are taken from the appendices of "Dielectric Constant and Molecular Structure."

associated with the cyanide group as acting in the direction of the line joining the group to the rest of the molecule. This implies that the carbon and nitrogen nuclei are in line with the nucleus of the carbon atom to which the group is attached, and is consistent with Pauling's conclusion that the HCN molecule is linear.²

A question may be raised as to the effect of the moments of the two principal dipoles upon each other. It has been shown that carbon-halogen dipoles exert an inductive effect, detectable in the observed moments, through only two carbon atoms of a saturated chain,⁵ while the larger cyanide dipole has a measurable effect upon the third atom of the chain, but would affect the fifth to a hardly detectable extent.⁹ Since, in the para-substituted benzyl compounds, the principal dipoles are separated by five carbon atoms it may be concluded that the moments of these dipoles would little affect one another. This is supported by the values of the moments of *p*-chloro- and *p*-nitrotoluene. As the moment of the toluene molecule, 0.4×10^{-18} , is regarded as acting in the direction of the line joining the methyl carbon to the ring with its positive end toward the former, the moment of *p*-chlorotoluene should be $(0.4 + 1.52) \times 10^{-18} = 1.92 \times 10^{-18}$ and that of *p*-nitrotoluene should be $(0.4 + 3.9) \times 10^{-18} = 4.3 \times 10^{-18}$. As the two dipoles point in the same direction in each of the two molecules, the moment of each should be increased if there were any appreciable inductive action between them, but the observed moment of the one is 1.74×10^{-18} and of the other 4.50×10^{-18} , differing from the calculated values by no more than the possible error. It would thus appear that the moments of the two principal dipoles may be regarded as approximately independent of each other.

A final question may be raised as to whether it is justifiable to treat the moment of a molecule such as benzyl chloride as acting in the C-Cl line, *e. g.*, in the diagram of the *p*-bromobenzyl chloride molecule in Fig. 1, can the dipoles be represented merely by the two arrows shown, the effects of the C-H bonds and of the attachment of the $-\text{CH}_2\text{Cl}$ group to the ring being neglected? Unfortunately, we do not know the small moment, if any, associated with the C-H bond, for the arbitrary calculation of it by Eucken and Meyer¹⁰ as 0.4×10^{-18} , though useful for some purposes, cannot be regarded as establishing its value. The moment of methyl chloride, 1.86×10^{-18} , must act in the line joining the carbon and chlorine nuclei. When one of the hydrogens is replaced by a methyl group to form ethyl chloride, the moment increases by 0.15×10^{-18} because of the moment induced in the added methyl group. It has been seen that, in toluene, a moment of 0.4×10^{-18} acts in the direction of the line joining the methyl carbon to the ring with its positive end toward the methyl carbon.

⁹ Smyth, "Dielectric Constant and Molecular Structure," p. 99.

¹⁰ Eucken and Meyer, *Physik. Z.*, **30**, 397 (1929).

In benzyl chloride a moment of about the same magnitude should occur in about the same location and should oppose the induced moment, as the induced dipole would have its positive end toward the ring. If the carbon valence angle is about 110° , the projection of what may be called the toluene moment, 0.4×10^{-18} , in the direction of the principal moment is 0.14×10^{-18} . In other words, the toluene moment is of such a size as to cancel approximately the increase in induced moment accompanying the replacement of a methyl hydrogen by a phenyl group, which is borne out by the agreement of the moment of benzyl chloride, 1.85×10^{-18} , with that of methyl chloride. The representation of the benzyl chloride moment by a single arrow in the C-Cl line appears, therefore, to be a justifiable approximation, and the similar representation of the moment produced by substitution of the bromine on the ring in Fig. 1 is certainly correct. Identical reasoning should apply to benzyl bromide and its substituted products, but uncertainty in the value for the moment of methyl bromide and the effect of atomic polarization upon the values for the higher alkyl bromides makes the reasoning inconclusive. However, the moment of benzyl bromide, 1.86×10^{-18} , is lower than that calculated for ethyl bromide without taking into account the atomic polarization by an amount identical with the difference between benzyl chloride and ethyl chloride. The moment of benzyl cyanide, 3.52×10^{-18} , is 0.3×10^{-18} higher than that of methyl cyanide, as might be expected from the greater inductive effect of the large cyanide dipole, which the toluene moment is not large enough to cancel. This small induced moment can, as an approximation, be treated as acting in the direction of the C-CN line and is, of course, included in the value 3.52×10^{-18} for the molecule. Evidently it is a justifiable approximation to treat the moment of a $C_6H_5CH_2X$ molecule as acting in the C-X line and Fig. 1 may be regarded as an approximately correct representation of the moments. It is also evident that the larger the moments of the two principal dipoles, the smaller will be the relative effects of the approximations and neglected factors and the greater the accuracy of the value calculated for the valence angle θ .

Preparation of Materials

Benzene.—Merck's c. p. benzene was shaken with concentrated sulfuric acid until no coloration appeared, washed with water, with dilute sodium carbonate solution, and three times with water, dried over calcium chloride, twice fractionally crystallized, refluxed over phosphorus pentoxide and fractionally distilled, refluxed over sodium wire and distilled; b. p. $80.2-80.3^\circ$ (757 mm.); n_D^{20} 1.50135; n_D^{25} 1.49815.

Heptane.—Material from the Ethyl Gasoline Corporation was fractionally distilled from phosphoric anhydride; b. p. $98.2-98.3^\circ$ (757 mm.); n_D^{20} 1.38775; n_D^{25} 1.38530.

All the remaining materials were obtained from the Eastman Kodak Company.

Benzyl Bromide.—Material (b. p. $80-83^\circ$, 10 mm.) was fractionally distilled under reduced pressure, the fraction distilling at $86.8-87.5^\circ$ (19 mm.) being collected. This fraction was redistilled; b. p. $87.0-87.2^\circ$ (19 mm.); d_4^{25} 1.4324.

Benzyl Cyanide.—Material (b. p. 98–100°, 8 mm.) was twice fractionally distilled under reduced pressure; b. p. 115.2–115.4° (19 mm.); n_D^{20} 1.52327; n_D^{25} 1.52086; d_4^{25} 1.0119; d_4^{50} 0.9914. A sample distilled from phosphoric anhydride had the same n_D^{20} .

***p*-Bromobenzyl Chloride.**—Material (m. p. 40–41°) was fractionally distilled under reduced pressure (b. p. 118–119°, 16 mm.), fractionally crystallized from petroleum ether, dried in a vacuum desiccator and twice fractionally crystallized; m. p. 41.3–41.5°.

***p*-Chlorobenzyl Bromide.**—Material (m. p. 48.5–49°) was twice fractionally crystallized from petroleum ether and dried in a vacuum desiccator; m. p. 48.5–48.7°.

***p*-Nitrobenzyl Bromide.**—Material (m. p. 98–99°) was twice fractionally crystallized from a mixture of dry benzene and petroleum ether, washed with petroleum ether and dried in a vacuum desiccator; m. p. 99.4–99.7°.

***p*-Nitrobenzyl Chloride.**—Material (m. p. 70–71°) was fractionally crystallized from carefully dried ether and dried in a vacuum desiccator; m. p. 71.2–71.5°.

***p*-Nitrobenzyl Cyanide.**—Material (m. p. 116°) was twice fractionally crystallized from dry benzene, washed with petroleum ether and dried in a vacuum desiccator; m. p. 116.6–116.8°.

Experimental Results

The densities and dielectric constants of the solutions of the polar substances in the non-polar were measured with the apparatus and methods previously employed,¹¹ a wave length of 1000 meters being used in the dielectric constant determinations. In Table I the first column gives the mole fraction c_2 of the polar substance in the heptane or benzene solution and the succeeding columns give the values at 25 and 50° of the dielectric constants ϵ and the densities d of the solutions and the polarizations P_2 of the polar substance. P_2 is calculated by means of the usual equations

$$P_{12} = \frac{\epsilon - 1}{\epsilon + 2} \frac{c_1 M_1 + c_2 M_2}{d} \text{ and } P_2 = \frac{P_{12} - P_1}{c_2} + P_1$$

in which P_{12} is the polarization of the mixture, and c_1 and c_2 , M_1 and M_2 and P_1 and P_2 are, respectively, the mole fractions, molecular weights and polarizations of the individual components. The molar refraction for the D sodium line, MR_D , of benzyl bromide has been calculated from the atomic refractions given in Landolt-Börnstein (fifth edition), that of benzyl cyanide has been determined directly, and the values for the other substances have been calculated from measurements upon the solutions by means of equations analogous to those for P_{12} and P_2 . These values have been used together with those for P_∞ , the polarization obtained by extrapolating the P_2 - c_2 curve to infinite dilution, and the absolute temperature T to calculate the electric moment μ by means of the equation

$$\mu = 0.0127 \times 10^{-18} \sqrt{(P_\infty - MR_D)T}$$

The absolute values of the moments are a little high because of the neglect of the atomic polarization P_A . The values of the molar refraction and of the orientation polarization $P_\infty - MR_D$ and the moment calculated from the data at 25° and at 50° are listed in Table II, the solvent in which the compound was measured being given in the second column.

Discussion and Interpretation of Results

The moment found for benzyl bromide in heptane is not experimentally distinguishable from that found in benzene solution. In the case of benzyl cyanide, the value found in heptane solution is slightly higher than that in benzene, but, as the low solubility of *p*-nitrobenzyl cyanide in heptane necessitates the use of benzene as solvent, the value for benzyl cyanide found in benzene is used in the calculation of the valence angle, although the mean value 3.52×10^{-18} may be taken for general use as the moment of the molecule. As the moment found for *p*-nitrobenzyl cyanide showed an increase with increase in temperature, a second set of measurements was made upon this substance, the results of which are listed in Tables I and II below those of the first set. The rise with temperature is observed in both sets of measurements, although the agreement is rather unsatisfactory because of the small concentrations of the polar substance necessitated by its low solubility. As no reason for this variation with temperature is apparent in the structure of the molecule,¹² it may possibly arise from incomplete elimination of the effect of intermolecular action by extrapolation of the P_2 - c_2 curve. The considerable variation of P_2 with concentration in the very dilute solutions shows the effect of the large dipoles upon one another's orientation, an effect which would be reduced by rising temperature. In view of these circumstances, a value slightly higher than the mean has been adopted for the moment.

The valence angle θ of carbon has been calculated by means of the equation for the resultant μ of two vectors, m_1 , and m_2 , which make an angle θ with each other. The equation may conveniently be written in the form

$$\cos \theta = \frac{\mu^2 - m_1^2 - m_2^2}{2m_1m_2}$$

In Table III, μ is the moment observed for the molecule of the para-substituted benzyl compound, the formula of which is given in the first column, m_1 is the moment of the unsubstituted benzyl compound, that is, of the C-Cl dipole in Fig. 1, or of one similarly located, and m_2 is the moment of the dipole in the para position. The values are taken from Table II or from the literature.⁸

¹² Cf. Smyth, Dornte and Wilson, THIS JOURNAL, 53, 4242 (1931).

The values of the carbon valence angle calculated from the moments of the two para-halogen substituted compounds agree well with one another, as do those calculated from the three para-nitro substituted compounds. The intra-molecular dimensions are such that one would expect little, if any, widening of the valence angle by repulsion between the ring and the side chain. Any such repulsive effect should not be altered by the replacement of a halogen by a nitro group in the para position. It is reasonable to conclude, therefore, that the difference of 5° between the results calculated from the para-halogen substituted compounds and those from the para-nitro is due to the fact that, in the latter, the larger values of the moments render relatively smaller the effects of the approximations necessary in the treatment. As the 4° difference from the theoretical tetrahedral angle may easily arise from these approximations as well as from small errors in μ , m_1 and m_2 , it may be concluded that the carbon valence angle determined in these compounds agrees with the theoretical angle of $109^\circ 28'$ within the limit of the error of experiment and calculation, although, in some cases, the angle may well depart from this value more or less. The results are in excellent agreement with Pauling's estimate of values of 112 and 115° from crystal structure data and with Wierl's calculation from electron scattering that the angle between the C-Cl valences in methylene chloride lies between 110 and 115° . The satisfactory outcome of this treatment establishes the validity of the method, which is now being applied to the determination of the oxygen and sulfur valence angles.

Summary

The electric moments of several benzyl and para-substituted benzyl compounds have been determined and used together with values in the literature to calculate the angle between the valences of the carbon atom. The value obtained, 114° , differs from the theoretical tetrahedral angle by no more than the probable error.

THE DIELECTRIC CONSTANT OF WATER AND ITS TEMPERATURE COEFFICIENT AS DETERMINED BY A RESONANCE METHOD. II

BY E. P. LINTON¹ AND O. MAASS

RECEIVED DECEMBER 26, 1931

PUBLISHED MAY 7, 1932

In the following a new modification of a dielectric cell is described which makes possible a more accurate determination of the dielectric constant of water by the resonance method than the cell previously used for this purpose.²

This cell was also used for the redetermination of the dielectric constants of several liquids and for the measurement of the temperature coefficient of the dielectric constant of water.

New Type of Variable Condenser.—Figure 1 gives a diagrammatic sketch of the new type of cell. It consists of two cylindrical tubes B (closed at each end) and D which are insulated from each other by the glass plates K and C. The outer cylinder D is about 5.2 cm. in diameter and 50 cm. high. By varying the radius of the inner rod a condenser of any desired capacity can be made. In the following measurements two inner tubes were used, one 0.5 cm. and the other 4.4 cm. in diameter.

A maximum of 700 cc. of liquid is necessary to fill the cell. By applying suction or pressure to G the height of the liquid in the cell can be varied as desired, G acting as a reservoir. The position of the liquid in D is measured by means of the glass tube H, which is 2 cm. in diameter. The glass tube F completely filled with liquid is connected through E to D so that the height of the liquid in H is the same as that in D. A, B, E and H are open to the air. A, B, D, G and E are made of pure block tin, and the construction is such that no glass to metal joint is needed in the apparatus.

The purpose of tube A is to drain the liquid from the cell by the application of suction. The cell is dried out by means of a stream of air. As a further precaution the whole apparatus is then rinsed with the liquid whose dielectric constant is to be measured.

¹ Acknowledgment is hereby made of a fellowship granted to one of us by the Research Council of Canada.

² Linton and Maass, *THIS JOURNAL*, 53, 957 (1931).

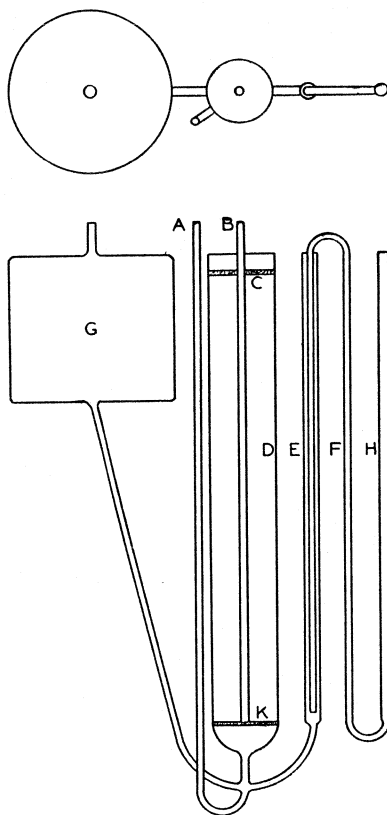

Fig. 1.—The dielectric cell: above, plan; below, elevation,

The apparatus can therefore be cleaned without dismounting or removal from the thermostat. This enables one to measure a series of liquids without removing the inner tube B. The cell is in convenient form for thermostating. An oil- or water-bath can be used in the thermostat, but the outer cylinder of the condenser must be grounded. Since the capacity of the cell is dependent on the ratio of the radii of the inner and outer tubes, a change in temperature does not alter the capacity of the cell for a fixed height. With the procedure used the cell is therefore admirably adapted for the measurement of a temperature coefficient of a dielectric constant of a liquid over a large range of temperature.

Furthermore, in this cell, since the capacity is dependent on the position of the liquid and not on any setting of condenser plates, complete reproducibility is possible. The capacity of the cell was found to vary in a linear manner within the accuracy to which the height of the liquid in the tube could be read, *i. e.*, to within 0.1%.

Then if ϵ_1 and ϵ_2 are the dielectric constants of two liquids and $C_1 - C_1^1$ and $C_2 - C_2^1$ the corresponding changes of capacity for equal changes in position of the liquids in the cell then

$$\frac{\epsilon_1 - 1}{\epsilon_2 - 1} = \frac{C_1 - C_1^1}{C_2 - C_2^1}$$

These changes in capacity are measured by the tuning condenser as previously described.

To eliminate the influence of conductivity in the case of water at the higher temperatures, the power tube described previously was used. With the above cell the "dead space" was found to be negligible and the linear relationship was given by all intermediate settings of the cell.

Experimental Results

In order to determine the dielectric constant of water it was necessary this time to start with a standard liquid, and benzene was chosen. Smyth evaluates the dielectric constant at 25° as 2.273. The authors have found the value of 2.271. It is considered better, however, to use Smyth's value.

Only two stages are required to determine the dielectric constant of water. In the first, benzene and ethylene dichloride and the 4.4-cm. inner tube was used; in the second, ethylene dichloride and water with the 0.5-cm. inner tube.

The average of five determinations, each of which started with benzene, gave 79.2 as the dielectric constant of water at 25°. The greatest deviation from this mean was one in four hundred. The following dielectric constants for carefully purified liquids were found: ether, 4.23; ethylene dichloride, 10.46; nitrobenzene, 34.9.

Temperature Coefficient of the Dielectric Constant of Water.—A large number of determinations of the dielectric constant of water at various temperatures were made. The procedure was as follows. After filling the cell with pure water the capacity height slope at 25° was determined. Then the cell was brought to a different temperature and the new slope

determined. The cell was filled with fresh conductivity water for each measurement. Occasionally the slope at 25° was redetermined after the temperature change and was always found to be the same. From a series of twenty measurements between 0 and 50°, a smooth curve relating temperature and dielectric constant was drawn. The equation to this curve was found to be

$$\epsilon_t = 79.2(1 - 0.00428(t - 25) + 0.0000212(t - 25)^2 - 0.00000041(t - 25)^3)$$

This equation follows the curve from 0 to 25° with an accuracy of one part in one thousand, from 30 to 50° the accuracy is one in five hundred.

Conclusion

The dielectric constant of water now found is the same as that previously determined by the authors, although the dielectric constants of some of the intermediate liquids are not the same. This difference is due to the greater care taken this time in the purification of the liquids. The purity of the liquid, of course, does not alter the absolute value obtained for the dielectric constant of water as long as the first medium in the series of steps (air or benzene) is pure.

The dielectric constant of water as determined by the authors gives good agreement with the Debye-Hückel theory of ions.³

In the Debye-Hückel theory of the heats of dilution of strong electrolytes, the dielectric constant of water and the temperature coefficient of the dielectric constant give much closer agreement with the experimental values found by Lange and Messner⁴ than the values obtained by Kockel and Drude. On the basis of Kockel's values, 41 calories, on the basis of Drude's, 33 calories are the calculated values for the heat of dilution of a potassium chloride solution. The authors' value gives 26 calories, which is in fair agreement with 23 ± 3 found by Lange.

The cell as described can be modified as far as dimensions are concerned so as to be available for much smaller quantities of liquids.

Summary

The new type of variable condenser is described which has a greatly increased accuracy as far as setting is concerned. The dielectric constants of water, nitrobenzene, ethylene dichloride, ether and benzene have been measured at 25°. The dielectric constants of water have been measured over the temperature range 0 to 50°. The new values obtained for water were found to be in better agreement with the calculations involved in Debye's theory.

A STUDY OF THE POTASSIUM DITHIO-OXALATE COLORIMETRIC METHOD FOR THE DETERMINATION OF NICKEL

By JOHN H. YOE AND FLOYD H. WIRSING

RECEIVED DECEMBER 29, 1931

PUBLISHED MAY 7, 1932

Over twenty years ago Jones and Tasker¹ reported a method for making potassium dithio-oxalate, $K_2C_2O_2S_2$. They found that this substance gives intense colors in water solution with certain metallic salts. Among these they discovered that nickel salts give a deep magenta color in dilute solutions. If equal weights of potassium dithio-oxalate and a soluble nickel salt are mixed in concentrated solutions there separate out small black needle-shaped crystals. These crystals color water more intensely than does potassium permanganate.

More recently, Fairhall² has employed potassium dithio-oxalate to determine nickel colorimetrically. The reagent is extremely sensitive and thus permits the determination of very small amounts of nickel. Fairhall made determinations on biological materials which contained small known quantities of nickel and obtained results accurate to a fraction of a milligram. His results indicated that potassium dithio-oxalate possessed advantages over other colorimetric reagents for nickel, such as dimethylglyoxime and α -benzyl-dioxime. These advantages are greater sensitiveness and better formation of color.

The purpose of this investigation was to study the reaction between potassium dithio-oxalate and nickel with reference to its use in the colorimetric determination of nickel. The sensitivity of the reaction, application of Beer's law, effect of various ions and different experimental conditions have been studied.

Apparatus and Reagents.—The apparatus and general technique have been described in a paper by Yoe and Hill.³ A Bausch and Lomb Duboscq colorimeter was used in place of the Kennicott–Campbell–Hurley instrument employed by Yoe and Hill. The Nessler tubes measured 210 mm. to the 50 ml. mark. All weights and volumetric instruments were calibrated.

The potassium dithio-oxalate was obtained from the Eastman Kodak Co. Freshly boiled distilled water was used to make up the reagent solution. A stock solution of nickel nitrate, $Ni(NO_3)_2 \cdot 6H_2O$, was prepared and its concentration determined gravimetrically by the dimethylglyoxime method. The average of three closely agreeing results gave 0.9998 g. of

nickel per liter at 20°. Ten ml. of this solution was diluted to a liter and thoroughly mixed. One ml. of the diluted solution contained 0.01 mg. of nickel and was taken as the standard solution.

Experimental

In the first part of our work a series of eight "unknowns" containing nickel was analyzed. These were checked several times, totaling about 1000 readings for practice in colorimetric measurements with the potassium dithio-oxalate reagent.

The following order of addition of reagents was adopted and observed throughout the investigation. Ten ml. of each of the nickel solutions were pipetted into the colorimeter cups and the required volumes of reagent added according to the concentration of the nickel. The same pipets were always used and they were rinsed out with the solution before the aliquot was taken. One of the cups was marked and it always contained the standard nickel solution, which occupied the left side of the colorimeter. After adding the reagent, the solutions were stirred with separate glass rods. These were bent into a triangle at the end to give more efficient stirring. The solutions were compared immediately.

A measurement required from ten to fifteen minutes. The temperature of the dark room was approximately 25°. The number of readings on the colorimeter for each solution was at least six. These were alternated, one being made as the height of the adjustable column of liquid was increased and the next as the height of the column was decreased. The total number of readings depended on how well they checked, more being taken if they did not agree closely. Usually eight or ten readings were made and the average taken.

To facilitate calculations the "unknown" solutions were set at some easily divisible number as 10, 20 or 30, and the standard adjusted to match this. The calculation was simply

$$\frac{\text{Reading of standard}}{\text{Setting of unknown}} \times \text{concn. of standard} = \text{mg. of nickel per ml. of unknown.}$$

Beer's Law.—Beer's law may be stated as follows. When equal heights or thicknesses of two solutions give the same intensity of color, the concentrations are equal. When equal color intensity is obtained from different heights of two solutions, the concentrations are inversely proportional to the heights, in accordance with Beer's law. This relationship forms the basis for colorimetry. In order for it to hold, the color formation in the two solutions must be perfectly formed, or imperfectly formed to the same extent in both solutions. It is sometimes the case in colorimetric analysis that the color formation is incomplete or unstable. This must be overcome by a calibration or correction curve which can be prepared experimentally from solutions of known concentrations.

The stock solution was used to make nickel solutions of various concentrations. The nickel solution to be diluted and the distilled water used were at $20 \pm 1^\circ$. The concentrations varied from 0.1 to 0.001 mg. of nickel per ml. Ten ml. of each solution was compared with ten ml. of standard nickel solution as explained above. The amount of potassium dithio-oxalate added to each was sufficient for complete color reaction,

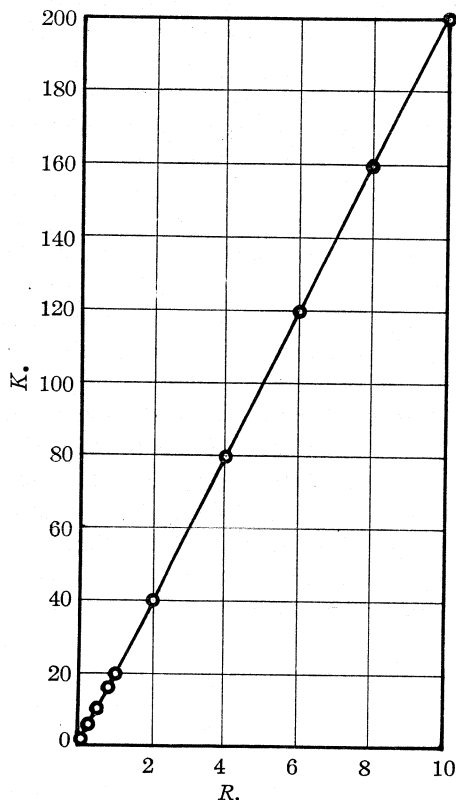

Fig. 1.

because each set of measurements was duplicated with a larger amount of reagent.

According to Beer's law a straight line is obtained by plotting the readings of the standards when the unknown solutions are set at 20.0, against the ratios of the height of standard over the height of unknown. Our results are shown graphically in Fig. 1. It is obvious that Beer's law is valid over the range in concentration studied and hence a correction curve is not required.

Sensitivity.—It is well known that in making color comparisons good results are not obtained with too deeply colored solutions. In practice, dilute solutions are either specified or implied. Horn⁴ pointed out that the sensitiveness of solutions is a variable and that the ease of determination varies with the concentration. In general, it is believed that there is some one concentration at which a

change in the intensity of the color can be more readily detected by the eye than at other concentrations. This concentration is in the range of dilute solutions. The *sensitivity* may be defined as *the reciprocal of the weight in milligrams of the constituent being determined that produces a change in color which can just be differentiated with certainty.*

Comparisons were made in a regular Nessler tube rack having a piece of black cardboard pasted on each side to shield the tubes from light. The solutions were made uniform by stirring. The colored solutions were measured from labeled pipets having 15, 10, 5, 3, 2 and 1 ml. capacity,

⁴ Horn, *Am. Chem. J.*, **35**, 253-9 (1906).

[illegible]

colored solution and 47 ml. of water. Other solutions were made up containing 2.8, 2.9, 3.0, 3.1 and 3.2 ml., respectively. In arranging these, no tube was out of order by more than one place. At this concentration, the amount which produces a perceptible difference is 0.1 ml. Solutions differing by less than a tenth of a ml. were not attempted. In weaker concentrations, say two ml. of colored solution, tubes having 1.8, 1.9, 2.0, 2.1 and 2.2 ml. were always arranged in correct order. Hence a standard

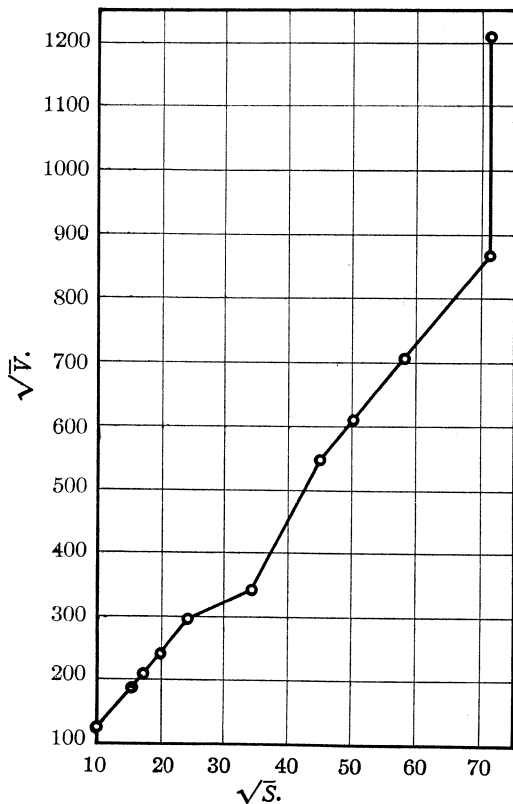

Fig. 2.

nickel solution containing 0.001 mg. per ml. was used for smaller concentrations. This procedure was repeated for a number of concentrations. The measurements and their calculated results are recorded in Table I.

Column 1 gives the volume in liters containing one gram atom of nickel. In the second column B is the total milligrams of nickel in 50 ml. of solution. In column 3 Δ is the mg. of nickel producing a perceptible difference in the color intensity of 50 ml. of solution. $S = 1/\Delta =$ Sensitivity. $B' = B + \Delta$.

Figure 2 shows how the sensitivity varies with the concentration. In plotting the curve the square roots of the volume and of the sensitivity are used to make the graph less extensive. The sensitivity curve obtained for

nickel is very similar to those obtained for other metals. Horn and Blake⁵ made sensitivity curves for Cu^{++} and CrO_4^- ions. Yoe and Hill⁶ obtained sensitivity curves for aluminum by both the Aluminon and Alizarin Red S methods. The sensitivity of the Cu^{++} and CrO_4^- ions increases greatly at a definite concentration, as shown in the curves of Horn and Blake. This is not true in the case of aluminum or nickel. Except for a slight break (maximum sensitivity range) in the curve for nickel and at

⁵ Horn and Blake, *Am. Chem. J.*, **36**, 195-208 (1906).

⁶ Yoe and Hill, *THIS JOURNAL*, **49**, 2395-2408 (1927); **50**, 748-756 (1928).

very dilute solutions, the sensitivity is a straight line function of the concentration. The setting of the standard nickel solution should be made at a point on the colorimeter scale which is within the range of maximum sensitivity.

The data in columns 6 and 7 show that over a wide range in concentration the ratios Δ/B' and B/B' are approximately constant. These ratios are also constant in the work of Horn and Blake and of Yoe and Hill. Δ/B' is the ratio between the amount of nickel which just suffices to produce a distinguishable difference in color, and the total amount of nickel present in 50 ml. of solution. This ratio is a constant except in too dilute solutions and where there is a break in the sensitivity curve. Horn and Blake⁵ have shown that this value multiplied by 100 gives directly the percentage error inherent in the comparison of colors. Other sensitivity data show that the colored solutions may be too dilute, as well as too concentrated, to give the best results.

That the ratio Δ/B' is a constant follows from Weber's⁷ psycho-physical law which states that a sensation is proportional to the natural logarithm of the stimulus, or that the increase of a stimulus necessary to cause an increase in sensation is a constant fraction of the whole stimulus. It is reasonable to assume that the stimulus is proportional to the amount of colored solute (or nickel) present. By definition, the sensitivity of the eye is a small increase in the sensation. From a mathematical consideration, Weber's law becomes

	Sensation	= $k \ln \text{stimulus}$	
Differentiating	d Sensation	= $k d \ln \text{stimulus}$	(1)
From Weber's law	Sensitivity of eye	= d sensation =	
		constant = k_1	(2)
Assumption	Stimulus	= $k' \text{concentration}$	(3)
Substituting (2) and (3) in (1)	Sensitivity of eye = k_1	= $k d \ln k' \text{concentration}$	
		= $K d \ln \text{concentration}$	
Since d concentration = Δ		= $\frac{K\Delta}{\text{concentration}}$	(4)

Equation 4 is the statement of Fig. 2, namely, that the sensitivity, that is, $1/\Delta$, varies inversely as the concentration. Hence it follows that the ratio Δ/B' is a constant fraction of the total weight of nickel present.

B/B' is also constant and is the ratio between the total amounts of nickel in two 50-ml. tubes containing colored solutions that can just be distinguished with certainty. Horn and Blake⁸ obtained for this ratio the average values of 0.92 and 0.95 for Cu^{++} ions and $[\text{Cu}(\text{NH}_3)_4]^{++}$ ions, respectively. They suggest the possibility that B/B' is a constant, independent of the color examined. This seems to be approximately true as indicated by all the known sensitivity work compiled in Table II.

TABLE II

Ion	Method	Color	B/B' , av. values	Observer
Al^{+++}	Aluminon	Red	0.92	Yoe and Hill
Al^{+++}	Alizarin	Red	.89	Yoe and Hill
CrO_4^-	CrO_4^-	Yellow	.96	Horn
Cu^{++}	Cu^{++}	Blue	.92	Horn and Blake
Cu^{++}	$[\text{Cu}(\text{NH}_3)_4]^{++}$	Dark blue	.95	Horn and Blake
Ni^{++}	$\text{K}_2\text{NiC}_4\text{O}_4\text{S}_4$	Magenta	.95	Yoe and Wirsing

In calculating B/B' , values were omitted at each end of a series of measurements where the percentage error inherent in the comparison was large. This constant tends to become unity and its average value is usually above 0.90. In a series of measurements with solutions of any colored ion or molecule, the ratio B/B' approaches unity at the highest sensitivity. It is noted in the case of aluminum, using two different methods, but both giving approximately the same color, that the one with the higher average value of B/B' is the more sensitive.

The potassium dithio-oxalate-nickel reaction is very sensitive. Jones and Tasker¹ detected nickel at a dilution of one part in 40 million parts of solution, when the solution filled a beaker, and one part in 8 millions using a test-tube. Our experiments show that 0.008 mg. of nickel can be detected in a liter of solution, *i. e.*, one part of nickel in 125 million parts of solution, when the observation is made in a 50-ml. (210-mm.) Nessler tube.

Optimum Experimental Conditions

In order to find the optimum experimental conditions, the effect of both the volume and the concentration of the reagent was determined. Ten ml. of standard nickel solution was compared with ten ml. of a nickel solution containing 0.008 mg. per ml. The reagent for the latter solution was added in small amounts and a comparison made after each addition until the intensity remained constant. The amount of reagent just sufficient for complete color formation was 1.2 ml. of a 0.05% $\text{K}_2\text{C}_2\text{O}_2\text{S}_2$ solution. This was repeated using a 0.1% reagent solution and 0.6 ml. was required. The weight of $\text{K}_2\text{C}_2\text{O}_2\text{S}_2$ was the same in both cases, but the volumes were different. Because of this unequal dilution of the nickel solution by the reagent, sufficient distilled water was added to the smaller volume to make the total volume of each the same.

A large excess of reagent causes a different shade or tint of color to develop, which is lighter than the red color of the potassium nickelo-dithio-oxalate. This fading appears more quickly for a large excess of reagent than for a small excess. Table III shows how quickly the fading appears when an excess of 0.1% reagent is used with 10 ml. of standard nickel solution.

TABLE III

Excess reagent, ml.....	1.5	1.0	0.5	0.0
Time before fading, min.....	15	30	75	300

With no excess reagent, fading is not very marked until the end of two days. However, with this concentration fading was never noticed under five hours and satisfactory readings have been made after twelve hours. The order of addition of reagents and nickel appears to make no difference, although it was always the same in this work.

Jones and Tasker represent the reaction of potassium dithio-oxalate with nickel salts by the equation: $2 \text{K}_2\text{C}_2\text{O}_2\text{S}_2 + \text{NiX}_2 = \text{K}_2(\text{C}_2\text{O}_2\text{S}_2)_2\text{Ni} + 2 \text{KX}$. The colored compound is potassium nickelo-dithio-oxalate, as shown by several analyses.

	Per cent. by analysis	Per cent. for $\text{K}_2\text{NiC}_4\text{O}_6\text{S}_4$
C	12.78	12.74
S	34.4	34.0
Ni	16.2	15.8

The theoretical amount of reagent required for a definite amount of nickel may be calculated from the above equation, and is 0.0675 mg. of $\text{K}_2\text{C}_2\text{O}_2\text{S}_2$ for 0.01 mg. of nickel. The amount of $\text{K}_2\text{C}_2\text{O}_2\text{S}_2$ experimentally required for 0.01 mg. of nickel was 0.080 mg. A solution of known nickel content was compared with the nickel standard. The reagent solution was added in small increments, a comparison being made after each addition. When the average reading on the colorimeter indicated the correct amount of nickel for the known solution, an excess of reagent never increased the intensity of the color. This procedure was repeated on a series of solutions of known nickel content.

The heavy line in Fig. 3 shows the amount of potassium dithio-oxalate required for various amounts of nickel as determined experimentally. The theoretical amount of reagent is shown by the

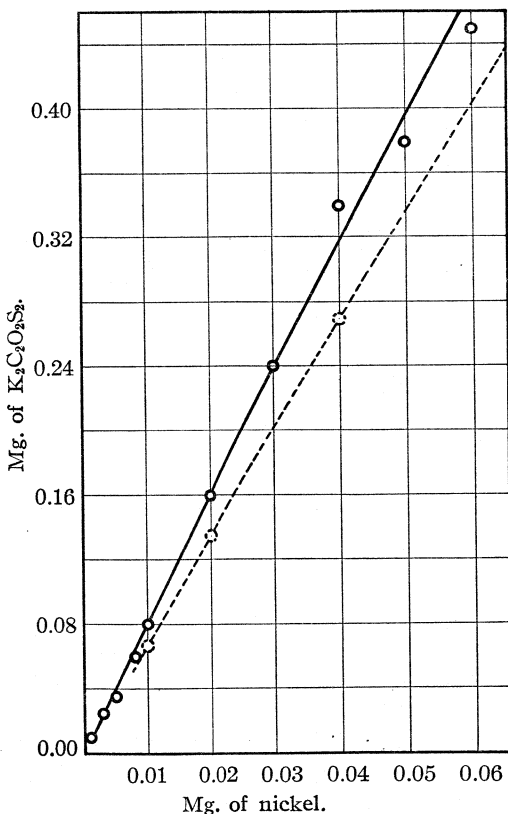

Fig. 3.

broken line. It is evident that all of the reagent is not reacting with the nickel. This is due to a slight decomposition of the reagent.

The instability of the potassium dithio-oxalate was the most troublesome factor in this investigation. The salt was light straw colored when obtained but gradually changed to brown. Dilute solutions are colorless; concentrated ones are yellow. Jones and Tasker reported that evaporation of the reagent solution on the water-bath gives a deposit of large colorless

prisms. The salt is white when recrystallized from alcohol, but on recrystallizing from water it becomes less stable. On keeping, it turns brown. The brown coloration does not seem to be due to the presence of sulfide or free sulfur. Under the microscope particles of different color are visible, but these are very soluble in water.

After a reagent solution has stood for some time, there forms a yellow turbidity which gradually settles out as a yellow precipitate. In the first part of our work measurements indicated that this did not appear so soon if the oxygen dissolved in the distilled water was boiled out before making the reagent up to volume. It so happened that measurements with ordinary distilled water were carried out in the direct sunlight, while those with "oxygen-free" distilled water were not. Later measurements showed that sunlight produces cloudiness more

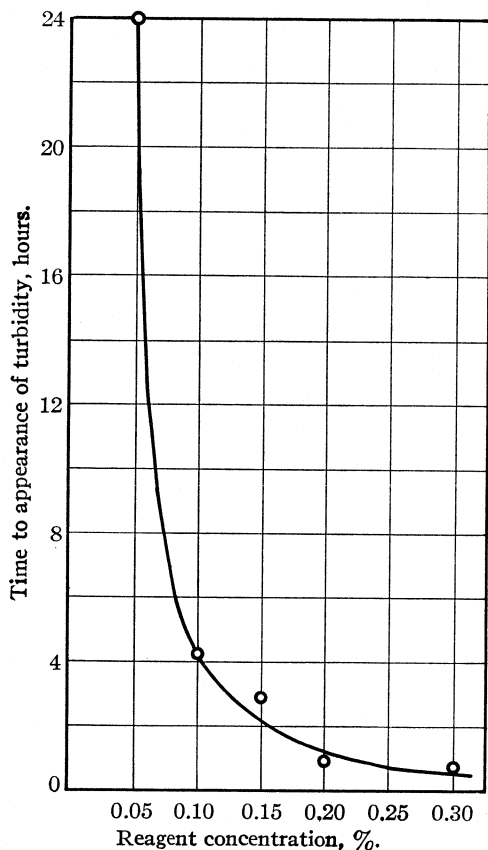

Fig. 4.

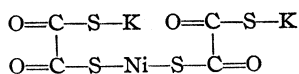

readily than the oxygen in the water. For example, a 0.3% reagent solution made up with "oxygen-free" water showed no noticeable cloudiness in fifty minutes. The same strength reagent made with ordinary distilled water and allowed to stand under the same conditions became noticeably turbid in forty minutes. However, a portion of this same solution kept in the dark room was not cloudy in three days.

The curve in Fig. 4 shows the rate of appearance of turbidity in po-

tassium dithio-oxalate solutions at concentrations ranging from 0.05 to 0.30%. It is obvious that a 0.05% reagent solution is preferable to one more concentrated.

The stability of potassium dithio-oxalate in solution is affected by the hydrogen-ion concentration. An excess of hydrogen ions decomposes the reagent, while an excess of hydroxyl ions prevents it from becoming cloudy. For example, a 0.1% reagent solution in 0.002 *N* potassium hydroxide developed no turbidity upon long standing. In lower concentrations of alkali, turbidity appears more slowly than in neutral solution. Higher alkali concentrations cause the reagent solution gradually to turn yellow on standing for several weeks. Portions of a 0.1% reagent solution made acid with varying amounts of 0.1 *N* sulfuric acid all gave precipitates, the amount increasing with increase in acidity.

Potassium nickelo-dithio-oxalate is relatively stable. Upon standing in solution for several weeks it loses its red color, but no cloudiness or precipitation appears. Its structural formula may be written as

The effect of acidity or alkalinity on the colored potassium nickelo-dithio-oxalate solutions was observed by mixing 10-ml. portions of standard nickel solution with the required quantity of reagent and then adding varying amounts of acid or alkali. Alkali causes a fading of the colored solution. Even as small an amount as 0.2 ml. of 0.0174 *N* potassium hydroxide was sufficient to give incorrect colorimeter readings with 10 ml. of the standard nickel solution. Varying amounts of acid up to 0.8 ml. of 0.0194 *N* sulfuric acid in 10 ml. of standard nickel solution did not seriously affect the colorimeter readings but larger amounts gave a lighter shade of color than the characteristic pink. Hence, the final acidity of the colored nickel solution should not be over 0.002 *N* in sulfuric acid.

Effect of Various Ions.—Many metallic ions react with potassium dithio-oxalate to form colored compounds. Jones and Tasker observed color reactions with the following: Sb, Bi⁺⁺⁺, Cd⁺⁺, Co, Cu⁺⁺, Fe⁺⁺, Fe⁺⁺⁺, Mn, Hg⁺, Hg⁺⁺, Ag⁺, Sn⁺⁺, Sn⁺⁺⁺⁺, Pd, Pt⁺⁺, Zn⁺⁺, Ce⁺⁺⁺⁺, Au, Tl, Ti⁺⁺⁺ and V. It is evident that any of the above ions may interfere with the nickel determination. Ions that give no color reaction are Al⁺⁺⁺, Ca⁺⁺, Ba⁺⁺, Sr⁺⁺ and Mg⁺⁺. Iron and cobalt ions are the ones most likely to interfere with the nickel determination. Their concentration must be under one-hundredth that of the nickel; otherwise, an appreciable error results.

Summary

A study of the reaction between potassium dithio-oxalate and nickel has been made with reference to its use in colorimetry. The reaction obeys

Beer's law over a range in concentration suitable for colorimetric analysis. The sensitivity, optimum experimental conditions and the effect of various ions have been determined. Best results were obtained with a 0.05% reagent solution and a nickel concentration of ten mg. per liter. The reagent will detect one part of nickel in 125 million parts of solution, when the observation is made in a 50-ml. (210-mm.) Nessler tube. The color develops satisfactorily in sulfuric acid solution up to approximately 0.002 normal. Traces of alkali cause fading. Many metallic ions give color reactions with the reagent and hence will interfere with the nickel determination unless they are removed. Iron and cobalt are the ions most likely to interfere and must be removed unless the nickel concentration is at least a hundred times greater than that of these ions.

THE HOMOGENEOUS COMBINATION OF ETHYLENE AND HYDROGEN. A SECOND-ORDER ASSOCIATION REACTION

BY ROBERT N. PEASE

RECEIVED JANUARY 4, 1932

PUBLISHED MAY 7, 1932

It has recently been shown that the polymerization of ethylene at pressures above one atmosphere is a second-order homogeneous gas reaction.¹ The primary action is thus of the association type. In view of the fact that many homogeneous dissociation reactions are known to be first order, it was inevitable that second-order homogeneous association reactions should occur, unless the classical principle of mobile equilibrium is incorrect as ordinarily applied. Nevertheless, a theoretical difficulty has arisen in this connection which makes it especially desirable to investigate other cases. The hydrogenation of ethylene is a particularly suitable example since the reaction is reversible,² and the reverse action (dissociation of ethane) has been rather definitely shown to be first order.³

The theoretical difficulty mentioned above has to do with the accommodation of energy in a single product molecule newly formed by the collision of two reactant molecules. A rather crude analogy on a large scale is the cohesion of two "sticky" masses—say, two balls of tar—which have been directed at each other. In the latter case, any kinetic energy which is lost, and the cohesion energy are converted into internal energy of the resulting mass. Similarly in the case of two associating molecules, the

¹ Pease, *THIS JOURNAL*, **53**, 613 (1931). At lower pressures there is evidence of deviation. See Pease, *ibid.*, **52**, 1158 (1930). The polymerization of acetylene may also be second order. See Pease, *ibid.*, **51**, 3470 (1929).

² Pease and Durgan, *ibid.*, **50**, 2715 (1928).

³ Marek and McCluer, *Ind. Eng. Chem.*, **23**, 878 (1931); Frey and Smith, *ibid.*, **20**, 948 (1928).

product molecule is called upon to accommodate in internal degrees of freedom any loss of kinetic energy due to the inelastic nature of the collision, plus the reaction energy, and the internal energies of the original molecules. However, since internal degrees of freedom are in general quantized, the chance that the product molecule should be able to do this appears to be negligible. The association is, therefore, extremely improbable.

The solution of this apparent difficulty was suggested by Kassel.⁴ The above argument implies that the internal degrees of freedom must be quantized *immediately* the molecule is formed. This cannot be assumed. Rather, the uncertainty principle indicates that the energies of individual states may differ from their final values by as much as $h/\Delta t$, where Δt is the time from the instant of collision. Therefore, if the total energy levels are spaced sufficiently closely, any value of the energy may be temporarily accommodated by the product molecule. Eventually, of course, any excess of energy over that exactly corresponding to some particular set of energy levels must be converted into kinetic energy in another collision, if the product molecule is to be stabilized.

The simplest reaction mechanism appears to be essentially that suggested by Taylor for the ethylene polymerization.⁵ Two molecules whose joint energy exceeds some minimum may unite on collision. The resulting quasimolecule may subsequently either dissociate spontaneously, or it may be dissociated as a result of a collision, or, finally, it may be stabilized as a result of a collision. Which of the last two happens will depend on the state of the molecule at the instant of collision. The rate of association will be

$$\alpha Z_0 e^{-E/RT} c_1 c_2$$

where α is an orientation factor, Z is the total collision rate at unit concentrations and E is the activation energy. If most quasi-molecules of products survive to undergo a collision (instead of decomposing spontaneously), the observed reaction rate will then be given by

$$\alpha \beta Z_0 e^{-E/RT} c_1 c_2$$

where β is the fraction of subsequent collisions in which the quasi-molecule is stabilized, rather than decomposed. In the case of ethylene polymerization the product $\alpha\beta$ was found to be about 1/2000. As will be shown later, it is more nearly unity for the hydrogenation of ethylene.

Apparatus and Method

The apparatus and method were standard. The reaction was followed by measuring the pressure decrease at constant volume in a heated Pyrex reaction vessel of 500 cc. volume. After a measurement was completed, the reaction mixture was collected with a Töpler pump and analyzed.

⁴ Kassel, *THIS JOURNAL*, **53**, 2143 (1931).

⁵ Pease, *ibid.*, **53**, 613 (1931).

The hydrogen was purified by passage over hot platinized asbestos, and through a trap at -79° . The ethylene was purified by fractionation. Both gases were originally better than 99% pure.

Results

The experiments were subject to two limitations. Owing to simultaneous polymerization of ethylene, it was necessary to confine the measurements to mixtures containing a 3:1 excess of hydrogen. Satisfactory results were then obtained when the reaction vessel was unpacked. When, however, the vessel was filled with broken glass, it was found that considerable quantities of hydrogen were absorbed by the latter.⁶ As a result, the observed pressure decrease (at 550°) was about twice that with the empty vessel. Analysis of the gas reaction mixture after exposure showed clearly that the rate of ethane formation was normal. This is the more interesting since it shows that the absorbed hydrogen is not reactive.

The values of k_2 were calculated by means of the equation

$$k_2 = \frac{2.303}{t(a-b)} \log_{10} \frac{b(a-x)}{a(b-x)}$$

where t is the time in seconds, a is the initial pressure of hydrogen, b is the initial pressure of ethylene and x is the pressure of ethane at time t . In calculating values of k_2 , the first measurement ($t = 300$) was taken as the initial state.

Since the reaction is reversible, it was necessary to determine whether the reverse action was interfering to an appreciable extent. It was found that the values of k_2 were not appreciably different when the much more elaborate expression involving the rate of the reverse action was employed. Measurements were only carried up to 50% conversion of the ethylene.

The results of a series of experiments with $3\text{H}_2:1\text{C}_2\text{H}_4$ mixtures carried out in the unpacked reaction vessel are presented in Table I. It will be seen that the values of k_2 are reasonably constant at each temperature. At 550° measurements were made with initial total pressures of one, one-half and one-fourth atmosphere. Although the constants at one-half atmosphere were somewhat lower than the others, there is no reason to doubt that the reaction is second-order.

It has already been mentioned that polymerization of ethylene interfered when the reaction mixture contained more than 25% of this gas. This is shown by the data of Table II. Two runs were made at 550° with mixtures of $2\text{H}_2:1\text{C}_2\text{H}_4$ and $1\text{H}_2:1\text{C}_2\text{H}_4$. In each case the amount of hydrogen reacting was nearly the same as the amount of ethane formed. The amount of ethylene reacting exceeded this latter by 11% with the $2\text{H}_2:1\text{C}_2\text{H}_4$ mixture, and by 33% in the $1\text{H}_2:1\text{C}_2\text{H}_4$ mixture. In consequence it is not possible to calculate a constant for the formation of ethane. Ap-

proximate calculations indicate that the value of k_2 may be somewhat less in these mixtures. Thus, the most favorable view that could be taken would be that the whole pressure drop is due to ethane formation. The corresponding calculation of k_2 gives 11.4×10^{-7} for the 2H₂:1C₂H₄ mixture, and 10.7×10^{-7} for the 1H₂:1C₂H₄ mixture, as compared with 15.1×10^{-7} for the 3H₂:1C₂H₄ mixture.

Experiments with the reaction vessel filled with broken Pyrex glass (4–10 mesh) are recorded in Table III. Analysis showed that in all cases there was a marked loss of hydrogen in excess of ethane formed. In this case also it is not possible to give precise values of k_2 . Assuming that the whole pressure drop represents reaction, the values of k_2 would be 4.15×10^{-7} at 500° and 1 atm. (initial), and 27.4×10^{-7} at 550° and 1 atm. (initial). These are to be compared with 2.37×10^{-7} , and 15.1×10^{-7} , respectively,

in the empty tube. The constants for the packed tube are nearly twice those for the empty tube. Even if this were all due to increased wall reaction in the packed tube, it would still not be serious since the wall surface has been increased by a factor of ten at least. However, the results of analysis show clearly that twice as much hydrogen as ethylene has disappeared, which accounts for the large apparent value of k_2 . In the experiment at 550° the final reaction mixture was fractionated before analysis. The result proved that ethane, rather than a mixture of methane and propane (say), was produced.

TABLE III

Discussion

The results show that the formation of ethane from ethylene and hydrogen is a homogeneous, second-order reaction, at least when hydrogen is in excess. It remains to calculate the reaction rate on the basis of the collision theory.

The values of k_2 for the runs at one atmosphere in the empty bulb with a 3H₂:1C₂H₄ mixture are fitted by the equation

$$\log_{10} k_2 = -\frac{43,150}{2.303RT} + 5.576$$

as shown by the data of Table IV.

TABLE IV
COMPARISON OF CALCULATED AND OBSERVED VALUES OF k_2

Temp., Å.	Obs.	Calcd.
748	1.00	0.97
773	2.37	2.45
797	5.42	5.70
825	15.1	14.5

According to the collision theory, the rate of reaction in terms of molecules of ethane formed per cc. per second should be

$$\alpha\beta 2 \sqrt{\frac{2\pi RT(M_1 + M_2)}{M_1 M_2}} \sigma_{12}^2 n_1 n_2 e^{-43,150/RT}$$

where M_1 is the molecular weight of H_2 , M_2 is the molecular weight of C_2H_4 , σ_{12} is the average diameter of H_2 and C_2H_4 in cm., n_1 is the number of mols. of H_2 per cc. and n_2 is the number of mols. of C_2H_4 per cc. α and β have been already defined. Since σ_{12} can only be approximately estimated in the absence of viscosity determinations at the temperatures of the experiments, it seems best to use the velocity data to calculate $\alpha\beta\sigma_{12}^2$. An estimate of $\alpha\beta$ can then be made by substituting a reasonable value of σ_{12} .

k_2 represents the pressure in mm. of C_2H_6 formed per second when C_2H_4 and H_2 are at 1 mm. pressure each. At 500° (773 \AA.) k_2 is 2.45×10^{-7} . This corresponds to 3.08×10^9 molecules of C_2H_6 formed per cc. per second. At 550° and 1 mm. pressure there will be 1.25×10^{16} molecules each of H_2 and C_2H_4 per cc. Substituting

$$\frac{3.08 \times 10^9}{(1.257 \times 10^{16})^2} = \alpha\beta\sigma_{12}^2 \cdot 2\sqrt{\frac{2\pi \cdot 8.32 \times 10^7 \times 773 \times 28.0}{24.0 \times 4.03}} \cdot e^{-\frac{43,150}{1.985 \times 773}}$$

$$\alpha\beta\sigma_{12}^2 = 4.38 \times 10^{-17}$$

If now we assume that

$$\sigma_{H_2} = 1 \times 10^{-8}$$

$$\sigma_{C_2H_4} = 4 \times 10^{-8}$$

then

$$\sigma_{12}^2 = 4 \times 10^{-16}$$

whence $\alpha\beta = 0.1$, approximately. Thus, of all collisions between H_2 and C_2H_4 molecules having the requisite energy, about 10% lead to formation of C_2H_6 . This is to be compared with 0.05% (1/2000) in the combination of ethylene molecules.

Comparison with Equilibrium Data and Rate of Dissociation of Ethane.—If the velocity constant for the combination of ethylene and hydrogen is k_2 , and the constant for dissociation of ethane is k_1 , the equilibrium constant for the dissociation of ethane

is given by

$$K = \frac{p_{C_2H_4} p_{H_2}}{p_{C_2H_6}} = \frac{k_1}{k_2}$$

The experiments here reported give for k_2 in mm.

$$\log_{10} k_2 = -\frac{43,150}{2.3RT} + 5.576$$

For k_2 in atmospheres, this becomes

$$\log_{10} k_2 = -\frac{43,150}{2.3RT} + 8.457$$

For k_1 , the work of Marek and McCluer³ gives

$$\log_{10} k_1 = -\frac{73,170}{2.3RT} + 15.12$$

Thus

$$\log_{10} K = \log_{10} k_1 - \log_{10} k_2 = -\frac{30,020}{2.3RT} + 6.66$$

Direct measurements of K at 600–700° give²

$$\log_{10} K = -\frac{31,244}{2.3RT} + 6.31$$

The independent determinations thus confirm one another.

Summary

The combination of ethylene and hydrogen in a Pyrex glass vessel at 475–550° and one atmosphere pressure has been shown to be a homogeneous, second-order reaction. A calculation based on the collision theory indicates that about 10% of the collisions between ethylene and hydrogen molecules possessing the requisite energy (43,150 cal. per mole) eventually result in formation of ethane.

Combination of equations for the rates of ethane formation and of ethane dissociation gives an equation for the equilibrium constant of the reaction

in good agreement with that obtained by direct measurement.

THE PREPARATION AND PROPERTIES OF IODINE MONOCHLORIDE¹

BY JACOB CORNOG AND R. A. KARGES

RECEIVED JANUARY 4, 1932

PUBLISHED MAY 7, 1932

I. Preparation

Old Method.—Iodine monochloride has usually been prepared by leading chlorine over solid iodine.² The crude product thus obtained was distilled; the portion of the distillate forming between 100 and 102° was retained. The distillate was far from pure. Stortenbecker³ obtained iodine monochloride of good quality by repeatedly recrystallizing the distillate in its own mother liquor.

Improvement of the Old Method.—The present authors found that passing a slow stream of chlorine through the system during distillation and collecting the distillate formed between 100 and 101.5° increased the yield from about 35 to about 85% and also improved the quality of the

distillate. They also found that analyzing the distillate and adding the quantity of solid iodine required to cause the compositions to correspond to that implied by the formula of iodine monochloride was a profitable expedient. The iodine monochloride was next liquefied and then slowly cooled, whereupon large, black, prism-shaped crystals formed. When about 80% of the iodine monochloride had crystallized, the remaining liquid was removed by decantation. This process was repeated until the freezing point of the crystals was the same as that of the supernatant liquid. Two or three crystallizations were usually required. At best this older method is a tedious, time-consuming process.

A New Method of Preparation.—The statement of Thomas and Dupuis⁴ that solid iodine added to liquid chlorine leads to the formation of iodine trichloride suggested the method for preparing iodine monochloride about to be described. Approximately 300 ml. of liquid chlorine is led directly from a commercially obtained cylinder of chlorine into a tared 500-ml. flask cooled with a mixture of solid carbon dioxide and ether. A weighed quantity of solid iodine, roughly one-half of a molar equivalent of the chlorine in the flask, is next added. The equivalence may vary rather widely but the weight should be accurate. After the addition of iodine the contents of the flask congeal to a solid. The flask is gradually raised from the cooling mixture and allowed to warm to room temperature. During the warming any uncombined chlorine evaporates. The weight of the flask and contents is next determined. Since the weight of the iodine added and the tare weight of the flask are known, the weight of the chlorine is determined by difference. The weight of both chlorine and iodine being known, the quantity of solid iodine that must be added to cause the composition of the impure product to correspond to that implied by the formula ICl is computed and added. The flask is closed with a glass stopper and allowed to stand in a liquid condition for twenty-four hours or longer. The freezing point of the iodine monochloride is usually within 0.1° of that of the pure article. One or two recrystallizations usually suffice to obtain the pure iodine monochloride. The following manipulative observations are helpful. Iodine monochloride vigorously attacks cork, rubber and the human skin, hence contacts with these substances should be avoided. A dilute (6 *M*) solution of hydrochloric acid is an effective antidote for skin burns. While iodine monochloride in bulk is not notably hygroscopic, yet small quantities of moisture from the air or starting materials will noticeably depress the freezing point. Hence exposure to moisture should be at a minimum. Exposure to atmospheric moisture produces a film of iodine pentoxide on the glass of the containing vessel.

By this new method the authors have been able to prepare pure iodine

⁴ Thomas and Dupuis, *Compt. rend.*, **143**, 282 (1906).

monochloride in one or two kilo lots within two or three hours. Preparation of similar quantities by the older methods required a similar number of days. This procedure serves also for the preparation of iodine trichloride but the authors have investigated this only qualitatively.

The iodine monochloride prepared as described had a freezing point of 27.19° as compared with the Stortenbecker value of 27.20° . The thermometer used was marked in 0.1° divisions and had been compared with a similar thermometer calibrated by the United States Bureau of Standards. A second criterion of purity was that afforded by gravimetric analysis. The method was a modification of the one described by Stortenbecker.⁵ Duplicate analyses of the same sample would not vary by more than 0.2%, generally by not more than 0.1%, from each other and from the theoretical composition of iodine monochloride. A third criterion of purity was the similarity of values obtained for the electrical conductivity of iodine monochloride obtained in different runs.

The conjunction of the criteria led to the belief that the iodine monochloride used in these experiments was approximately pure.

II. Vapor Pressure

The vapor pressure was measured by the method of Smith and Menzies.⁶ Iodine monochloride was the confining liquid. When heated above 70° the rate of decomposition of iodine monochloride becomes so rapid that consistent measurements were not obtained. The average of four experimentally determined vapor pressure values at each temperature is recorded in the third column of Table I. The individual measurements did not vary more than 0.25 mm.

TABLE I
VAPOR PRESSURE AND OTHER DATA CONCERNING IODINE MONOCHLORIDE

Temp., $^\circ\text{C}$.	Absolute temp., $^\circ\text{K}$.	Vapor pressure of ICl , mm.	ΔH , molal heat of vaporization, cal.	$\Delta H/T$, boiling entropy of vaporization, cal.
35	308.1	48.0	10,140	27.18
40	313.1	62.5	10,290	27.59
45	318.1	81.0	10,080	27.02
50	323.1	103.6	10,200	27.34
55	328.1	131.9	10,100	27.08
60	333.1	166.0	10,302	27.66
65	338.1	209.0	10,460	28
70	343.1	261.7		

The values for molar heat of vaporization given in column four were computed by the use of the integrated form of the Clausius-Clapeyron equation.

$$2.302 \log \frac{P_2}{P_1} = \frac{\Delta H}{R} \frac{T_2 - T_1}{T_2 T_1}$$

⁵ Stortenbecker, *Z. physik. Chem.*, **10**, 192 (1892).

⁶ Smith and Menzies, *THIS JOURNAL*, **32**, 1427 (1910).

P_2 and P_1 are vapor pressures at temperatures T_2 and T_1 , respectively. ΔH is the molar heat of vaporization.

According to Trouton's rule, the entropy of vaporization for non-associated liquids is 21 calories.

Since iodine monochloride dissociates on boiling at atmospheric pressure, its boiling point is not definite. The literature gives values as low as 94.7 and as high as 102. The value used in the computation of column 4 is 100° or 373.1°K . The values given in column 5 indicate that iodine monochloride is an associated or polar liquid. J. H. Hildebrand⁷ makes the point that, for the application of Trouton's rule, the entropy of vaporization should be taken, not when liquids are boiled under atmospheric pressure, but rather when temperature and pressure are so chosen as to give the same volume of vapor per mole of material in each case.

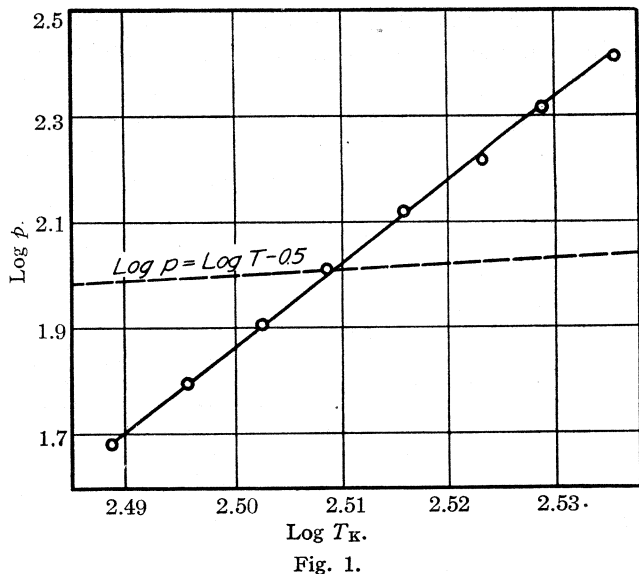

Fig. 1.

By applying a modification of the Clausius-Clapeyron equation to the data given graphically in Fig. 1, the value of the entropy of vaporization of iodine monochloride is computed as 33.4 cal. at the concentration of 0.00507 mole per liter. Hildebrand gives the values of this constant at this concentration as 32.4 cal. for liquid ammonia, 32 cal. for water and 33.4 cal. for ethyl alcohol. For ten known non-associated liquids he gives the average value of 27.4 cal. at this concentration.

Iodine monochloride is an associated or polar liquid.

⁷ J. H. Hildebrand, "Solubility," The Chemical Catalog Co., Inc., New York, 1924, p. 93.

III. The Conductivity of Iodine Monochloride

An ordinary conductivity cell was used to measure the conductivity of iodine monochloride and of solutions of potassium chloride and ammonium chloride in it. The cell constant was obtained in the usual way by measuring the conductivity of a 0.02 *M* solution of potassium chloride in water. The measurements were made in a thermostat at $35 \pm 0.1^\circ$. The specific conductivity of four different samples of iodine monochloride varied from 0.004572 to 0.004589 reciprocal ohms.

Prolonged exposure of iodine monochloride in a wide weighing bottle to the humid air of a June day caused the sides and bottom of the bottle to become heavily coated with iodine pentoxide. This exposure also influenced the conductivity of iodine monochloride. Removing the stopper of the conductivity cell for two minutes produced no measurable change in conductivity; exposure for twenty minutes in the weighing bottle caused the specific conductivity to increase from 0.004589 to 0.00521 and exposure for one hundred minutes increased the conductivity to 0.01327 reciprocal ohms.

The results of vapor pressure measurements indicate that iodine monochloride is an associated liquid; hence it may be expected to act as an ionizing solvent. The validity of this assumption may be put to experimental proof by preparing solutions of potassium chloride and of ammonium chloride and measuring the conductivity at different dilutions. The results are given in Table II.

TABLE II

CONDUCTIVITY OF SOLUTIONS IN IODINE MONOCHLORIDE AT 35°			
Molal concn. of solute	Specific conductivity of cell	K, specific conductivity of solute	Equivalent conductivity
Potassium chloride as solute			
0	4583×10^{-6}
0.5	18,975	$14,387 \times 10^{-6}$	28.76
.25	12,140	7,522	30.21
.125	8,494	3,996	31.20
.0625	6,491	1,903	30.43
.02083	3,230	642	30.81
.00993	4,797	84	31.19
Ammonium chloride as solute			
0	4588
1	24,175	19,650	19.65
0.5	15,770	10,982	21.96
.33 $\frac{1}{3}$	12,100	7,852	22.64
.16 $\frac{2}{3}$	8,558	3,970	23.82
.08 $\frac{1}{3}$	6,642	2,034	24.64

Columns one and four in Table II are graphically represented in Fig. 2. These data indicate that: (1) Potassium chloride dissolved in iodine mono-

chloride increases the conductivity very decidedly. However, after the first dilution the equivalent conductivity shows no regular increase with dilution. (2) Ammonium chloride also shows evidence of dissociation in the solution. While the equivalent conductivity is less than in water, its increase with dilution is entirely analogous to the behavior of a solution of an electrolyte in water.

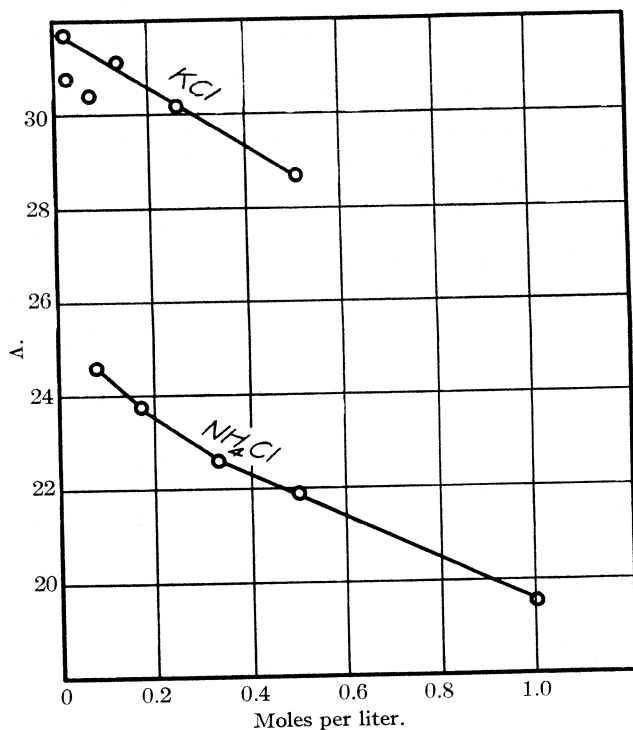

Fig. 2.

Summary

1. Two methods of preparing relatively pure iodine monochloride are described. One is an improvement on traditional methods; the other is a new method.

2. Results of vapor pressure measurements indicate that iodine monochloride is a polar liquid.

3. Conductivity measurements show that iodine monochloride acts as a dissociating solvent on potassium and ammonium chloride.

THE EFFECT OF ADSORBED GASES ON THE PHOTOELECTRIC EMISSIVITY OF IRON AND PLATINUM

By A. KEITH BREWER

RECEIVED JANUARY 8, 1932

PUBLISHED MAY 7, 1932

The present research was undertaken to determine, as far as possible, the physical state of gases adsorbed on metallic surfaces, with the hope in view that this knowledge will contribute to our understanding of surface catalysis. The metals chosen for investigation were iron and platinum, while the gases used were nitrogen, hydrogen, ammonia, helium and oxygen. Thus the study comprises both excellent and poor catalysts for the synthesis of ammonia, as well as reactive and poisonous gases.

Apparatus.—The apparatus, illustrated in Fig. 1, is essentially the same as that described in previous papers,^{1,2} except that a Photron FP 54 four element vacuum tube was used in place of the Compton electrometer. The current sensitivity was 4.35×10^{-16} amp. per cm. galvanometer deflection; it was possible to read currents accurately from 5×10^{-16} to 10^{-11} amp. The sensitivity can be increased considerably beyond this point but it was not necessary in this research.

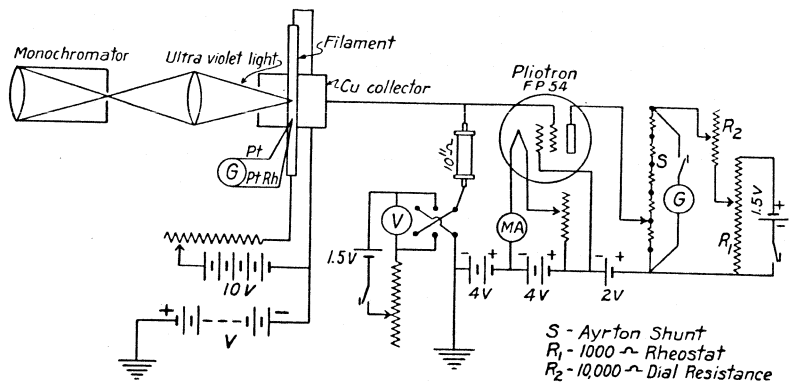

Fig. 1.

Method of Procedure.—It was found necessary to take special precautions for the removal of oxygen and water vapor from the gases. The nitrogen, hydrogen and helium were passed slowly through a tube filled with freshly reduced copper heated to 500°, dried with liquid air, and then stored in a balloon flask containing a tungsten filament. The gases were kept in contact with the incandescent tungsten for a day. The balloon flask was connected to the main system by a stopcock followed by a mercury seal to prevent grease contamination during operation. The gases were again passed through liquid air before entering the photoelectric tube. The ammonia was taken from a tank of liquid ammonia that had stood in contact with metallic potassium for years.

¹ A. Keith Brewer, *Phys. Rev.*, **38**, 401 (1931).

² A. Keith Brewer, *THIS JOURNAL*, **53**, 74 (1931).

The entire system was thoroughly flamed out before starting a series of runs. The filament was then heated to redness in about 2 cm. of hydrogen for an hour, after which the system was again flamed out and the filament heated *in vacuo* until it showed the normal long wave length limit, *i. e.*, a just detectable emission with $\lambda 2536$ for iron and a small emission with $\lambda 2653$ for platinum. An iron surface is readily purified but platinum requires considerable heating at 800° to give anything like a constant threshold, due to the difficulties of removing absorbed hydrogen.

Results with Iron

The factors given special attention in making this study were the effect of the gases on the intensity of emission as well as on the shift in the photoelectric threshold, the character of the wave length *vs.* current curves, and the effect of temperature on the sensitivity.

The data were taken with an accelerating potential of 9 volts plus the contact potential difference between the filament and collector; stopping potential measurements showed the latter to be near +1 volt. This potential was below the ionization potential of any of the gases studied so the possibility of ionization by collision did not exist.

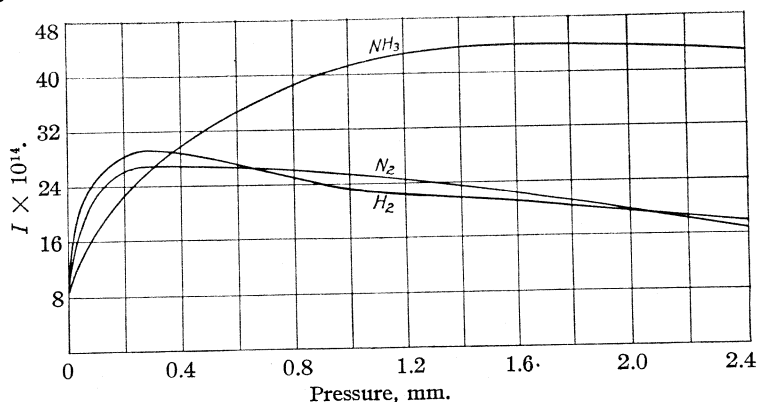

Fig. 2.—The effect of gases on the photoelectric emissivity of iron: V , 9; λ , 2300; temp., 215°C .

Gas	V	λ	Temp.
NH_3	9	2300	215°C .
H_2	9	2300	215°C .
N_2	9	2300	215°C .

The effects of various pressures of hydrogen, nitrogen and ammonia on the emissivity of iron are shown in Fig. 2. The measurements were all extended to 10 cm. pressure; the photoelectric current decreased only slightly with increasing pressure above 2.0 mm.

The emissivity curves for nitrogen and hydrogen are very nearly identical over the entire pressure range; the ammonia curve is distinctive in that the current enhancement for low pressures is less than that for nitrogen or hydrogen, while for high pressures it is materially greater. Oxygen

behaves quite differently in that when present in the most minute traces it materially lowers the emissivity. For instance, nitrogen, when passed slowly through a freshly reduced copper deoxidizer at 500° and thereafter held in contact with glowing tungsten for about fifteen minutes, still contained enough oxygen to give an emissivity definitely lower than nitrogen which had been held in contact with incandescent tungsten for ten hours. The amount of oxygen on the surface necessary to give a lowering of the threshold was too small to be estimated with any degree of precision.

Voltage *vs.* current measurements showed saturation to exist at pressures below the maximum points on the pressure *vs.* current curves; at higher pressures the current increased gradually with the voltage until ionization by collision set in, whereupon rapid increases were observed. At 10 cm. the current increase was but slightly less than linear with respect to voltage. At pressures below 0.4 mm. saturation was obtained for 2.0 volts accelerating potential.

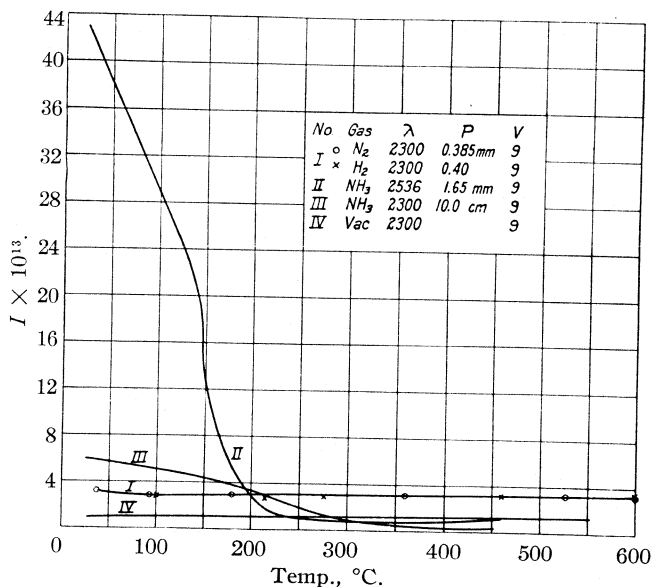

Fig. 3.—The effect of temperature on the photoelectric emissivity of iron in gases.

The effect of temperature on the emissivity is illustrated in Fig. 3. Line 1 shows nitrogen and hydrogen to be almost identical in their behavior, the points for nitrogen being just slightly the higher. Line IV is typical of the results obtained when the pressure becomes too low to read on the McLeod gage, without making any attempt to degas the iron; the curve for degassed iron is similar but somewhat lower. The temperature coefficient for ammonia differs from that for nitrogen and hydrogen, since it ab-

normally increases the emissivity at temperatures below 200° . The curves are all completely reversible when the products of decomposition of ammonia were not allowed to accumulate.

The effect of gases on the long wave length limit is suggested by the character of the lines in Fig. 4. The curves are distinctly different from those obtained in the absence of a gas in that the metal does not have a sharp long wave length limit. Thus the lines in Fig. 4 skirt the wave length axis to no definite limit and do not end sharply at some specific wave length.

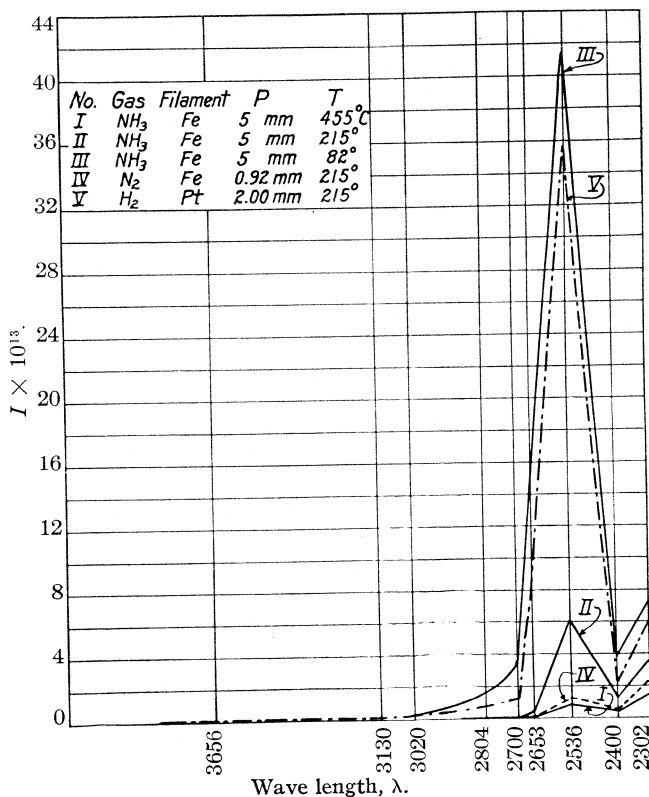

Fig. 4.—Characteristic wave length vs. emissivity curves.

Pure iron in a vacuum showed a just detectable emission for $\lambda 2536^{1,2}$ with a threshold near $\lambda 2575 \text{ \AA}$. In the presence of hydrogen the emissivity became negligible below $\lambda 2750$ and for nitrogen below $\lambda 2802$. Ammonia, however, gave a definite emissivity for $\lambda 3650$, the threshold lying near the limit of the visible, about 4000 \AA . Expressed in equivalent volts the approximate thresholds are: vacuum 4.8 volts, hydrogen 4.5 volts, nitrogen, 4.4 volts and ammonia 3.1 volts. These values are for pressures just

above the maximum point in the curves shown in Fig. 2 and for room temperature.

The long wave length limit in oxygen when present even in small amounts was too low to be measured. One millimeter of nitrogen containing near 0.01% oxygen dropped the threshold to near 2300 Å.; *i. e.*, it raised the work function from 4.8 volts to more than 5.4 volts. Under these conditions there was just about enough oxygen present in the entire system to cover the filament with a monomolecular layer. Since the lowering of the threshold took place immediately upon the introduction of the oxygen and since the system was so designed that the probability of the average oxygen molecule striking the filament surface was very small, the amount of the surface covered by oxygen must have been only a very small fraction of a monomolecular layer. Continued heating in gas of this composition lowered the threshold to a point where an emissivity could no longer be detected.

Results with Platinum

The effect of gas pressure on the emissivity was investigated between 10 cm. and the best vacuum that could be obtained. Characteristic results are plotted in Fig. 5. The emissivity curves given are for $\lambda 2300$ Å. and for $\lambda 2700$ Å.; the temperature of the filament was 215° . The same gas was used throughout each series of runs except for ammonia, where the system was evacuated and refilled between each pressure measurement to prevent the accumulation of any products of decomposition.

The data were all taken starting with high pressures and temperatures working toward the low, though after the filament had once been heated to the maximum temperature used, all points were reproducible when approached from either side.

The curves show that the emissivity increases rapidly with the advent of gas to a maximum in the neighborhood of a few tenths of a millimeter pressure, after which it decreases slowly with pressure over the entire range investigated; the change between 1 and 10 cm. is very slight. The location and sharpness of the maximum depend both on the gas and on the wave length of the light. To illustrate, hydrogen always shows a sharp maximum for wave lengths considerably removed from the threshold, the sharpness gradually disappearing toward longer wave lengths. This is shown in the hydrogen curves for $\lambda 2300$ and $\lambda 2700$.

The emissivity in hydrogen, as is shown by Fig. 5, is large compared to that in nitrogen, ammonia, helium and oxygen. This enhanced emissivity is accompanied by a shift in the long wave length limit toward the red, as is illustrated by magnitude of the currents obtained with $\lambda 2700$ in the various gases. The threshold for oxygen lies near 2225 Å., for helium is near 2650 Å. and for nitrogen and ammonia it is near 2750 Å.

Hydrogen, on the other hand, gives the characteristic curve of a highly composite surface, as will be seen by line V in Fig. 4. Under most advantageous conditions an emission could just be detected with $\lambda 4078$, although $\lambda 3650$ is usually near the limit. The possibility of the observed currents being due to scattered light was removed by placing suitable screens in the path of the ultraviolet light before entering the monochromator.

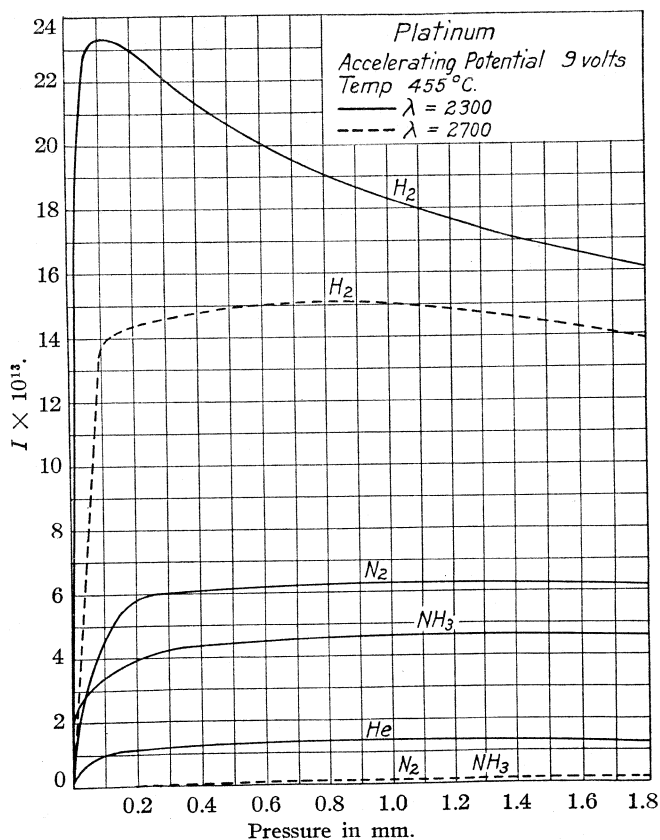

Fig. 5.—The effect of gases on the photoelectric emissivity of platinum.

The decrease in emissivity observed in oxygen is interesting in that it is not due to the normal gas molecules; the effect of oxygen on a cold filament is not materially different from that of nitrogen. As the filament is heated, the photoelectric current rapidly drops, the threshold finally shifting to below 2225 \AA . This rapid shift in threshold is most pronounced when the filament has previously been heated in hydrogen for some time; under such conditions it is accompanied by the formation of water within the tube, even though the filament has been thoroughly glowed in a vacuum

before introducing the oxygen. Apparently the first rapid shift in threshold is due to the removal of hydrogen from the platinum by the oxygen, followed subsequently by a combination between oxygen and platinum, since an appreciable emissivity cannot again be obtained without reducing in hydrogen.

The effect of temperature on the emissivity in various gases is illustrated in Fig. 6. In general, the data were taken while going from higher to lower temperatures, but the effects were all perfectly reversible. Curve 6 for the evacuated system is not for outgassed platinum but represents the condition where the pressure is too low to be read by a McLeod gage and where the filament is being lowered from 600° to room temperature.

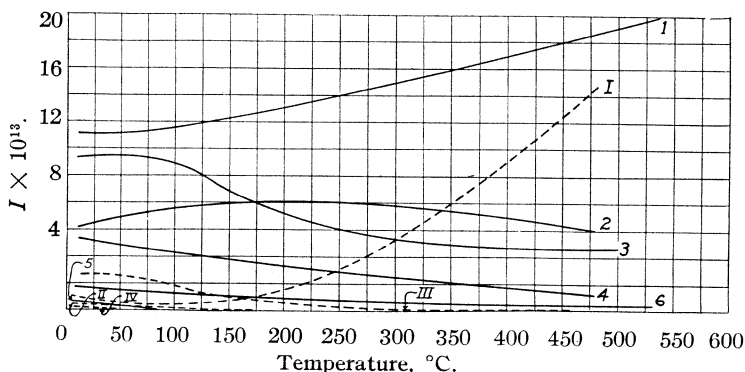

Fig. 6.—The effect of temperature on the photoelectric emission of platinum in gases.

Curve	Gas	λ	P, mm.	Curve	Gas	λ	P, mm.
1	H ₂	2300	0.435	III	NH ₃	2700	0.80
I	H ₂	2700	.435	4	He	2300	.485
2	N ₂	2300	1.7	IV	He	2700	.485
II	N ₂	2700	1.7	5	O ₂	2300	10.00
3	NH ₃	2300	0.80	6	—	2300	vac.

Curves 4 and 6 for helium and for the evacuated system show a small enhancement in emissivity with decreasing temperature, while Curve 1 for hydrogen shows a large positive temperature coefficient. Nitrogen exhibits only a small temperature effect. The ammonia curve is characteristic of this gas in that there is a pronounced increase in emissivity as the temperature drops from 200 to 100°, while above and below these points the temperature coefficient is small; the effect, however, is much less than for iron.

The emissivity in gas mixtures could be analyzed in a few instances. In the case of hydrogen on platinum the addition of nitrogen had no appreciable effect. The addition of nitrogen or hydrogen to ammonia had no effect on the enhancement of the emissivity from iron. For platinum,

on the other hand, the addition of hydrogen to ammonia raised the emissivity to a point corresponding to pure hydrogen.

Discussion of Results

No ambiguity can exist regarding the nature of the wave length *vs.* current curves, as illustrated in Fig. 4. They are distinctly the type of curves obtained only on composite surfaces;^{1,2} indeed, these curves can be exactly duplicated by those previously obtained from pure iron on which various amounts of potassium ions had been deposited. In the neighborhood of 0.5 mm. pressure the wave length characteristic for iron in hydrogen coincides with line 2, Fig. 2, of the previous communication¹ for an iron surface 0.002 covered with potassium ions. The results for nitrogen fall between Curves 2 and 3, and correspond with a surface 0.003 covered, while the maximum effect obtained with iron in ammonia corresponds to line 7 for a surface 0.02 covered with potassium ions.

In continuing the comparison between the photoelectric emission in gases and on composite surfaces it is interesting to note that for low gas pressures the sensitivity of the surface increases almost proportionally to the pressure, while Fig. 3 of the previous article shows the emission to be proportional to the concentration of potassium ions on the iron when the fraction of the surface covered is less than 0.04. The failure of the proportionality between pressure and current to extend over a wider range is doubtless due to three causes. First, saturation cannot be obtained above 0.4 mm. pressure. Second, the sensitivity is lowered by the presence of neutral gas particles, whether atoms or molecules, covering the surface. Third, the presence of space charges in the layers of gas near the surface materially lowers the emission current.

The physical status of the composite surface, capable of giving the observed effect, necessarily entails some degree of speculation. It safely may be said however, that since it affects the work function of the surface for escaping electrons, it is necessarily electrical in nature. Several possibilities may exist: a small percentage of the gas molecule striking the surface may become ionized by the surface forces; the surface may be covered with a highly polar layer of gases, in the "incipient ionization" stage as described by Sir J. J. Thomson;³ or a state of dynamic equilibrium may exist in which the gas is in all degrees of dissociation from normal molecules to complete ions, as prescribed by probability.

Little if anything of a quantitative nature is known regarding the effect of polarized or "incipiently ionized" molecules on the work function, hence it cannot be told whether such a surface state will satisfy the demands of the emissivity curves. Since the curves are identical with those obtained for surfaces sparsely covered with ions, the most probable inter-

³ J. J. Thomson, "The Electron in Chemistry," J. B. Lippincott, Co., 1923.

pretation to adopt is that a fraction of the gas molecule striking the surface is completely dissociated into ions; it is reasonable to assume that the ionized gas is present in various degrees of dissociation in dynamic equilibrium with the ionized and normal molecules. In this connection, Kobosew and Anochin⁴ compute the ionization potential of the average hydrogen molecule on platinum to be of the order of 4 volts.

The ionization of gases at metallic surfaces has long been recognized in thermionics. It was first pointed out by H. A. Wilson⁵ and has been discussed in detail by O. W. Richardson⁶ from the point of view of thermionic emission. Erikson⁷ has shown that the mobilities of the ions from alkali-free platinum in air are identical with air ions and concludes that the ions most probably come from gas molecules dissociated on the platinum.

Schmidt⁸ has calculated the conditions under which hydrogen may be dissociated into ions at metallic surfaces and has shown his deduction to be in agreement with the observed facts found in the catalytic hydrogenation of organic compounds. The writer has shown certain correlations between temperature and work function in thermionic emission in gases,⁹ and has proposed a mechanism for surface catalysis in which the problem is considered as a special case of thermionic emission in gases.¹⁰ The present results furnish another method of attacking the problem of ionization of gases at metallic surfaces wherein it is possible to estimate the degree of ionization over a definite pressure region and also to show the effect of the adsorbed ions (adions) on the work function of the surface.

The condition established by the presence of ions adsorbed on a conducting surface may easily be understood from the following considerations. Becker¹¹ has shown from thermionic studies that barium ions adsorbed on tungsten behave in a manner analogous to that which would result from a grid placed at an atomic diameter from the surface and charged positively with respect to the surface. This same analogy is even more strikingly shown in the recent photoelectric studies. The effect of the adsorbed ions is exactly that of a grid covering the surface where the grid spacings correspond to the distance between the ions; thus for conditions where the fraction of the surface covered by ions is small the *grid spacings* are large compared to the distance between the grid and the surface.

On leaving a conductor an electron must do a certain amount of work

against the image and intrinsic forces of the surface; this work may be expressed in equivalent volts, ϕ , which under ordinary conditions lies between 3 and 6 volts. In thermionics the value of ϕ is obtained directly from the Richardson equation, $I = AT^{3/2} e^{-\phi/kT}$, while in photoelectrics it is given by the relation $\phi = h\nu_0 - \phi_0 e$, where ν_0 is the threshold frequency and $\phi = 12345/\lambda$.

The immediate effect of a positive grid near the surface is to lower ϕ_0 and hence to lower ν_0 by an amount depending on the strength of the field of the grid at the point of exodus of the electron; adsorbed negative ions will tend to raise the work function. In thermionics this point of exodus is where the work function is lowest, *i. e.*, where the grid field is the highest, hence close to the adsorbed positive ion. In photoelectrics, on the other hand, the electron leaves at whatever point the quantum strikes. If the distance between ions is large compared to an atomic diameter, the work function will vary over a wide range depending on whether the electron escapes from a point near the adion or at the maximum point removed. There is little possibility of an electron being emitted from the adion itself, since the second ionization potential of the ion requires more energy than is ordinarily available.

It is this variation in work function from point to point over the surface that is responsible for the shape of the wave length *vs.* current curves obtained for composite surfaces. ϕ_0 no longer has a definite value for the entire surface, but varies from point to point depending upon the nearness of the adsorbed ions. Thus the wave length *vs.* current curves do not have the sharp feet characteristic of pure surfaces but skirt the wave length axis for long distances.

The presence of comparatively few ions adsorbed on the surface has an extremely large effect on the work function of an emitter. When the fraction of the surface covered by K^+ ions is 0.001, the threshold is shifted from 4.8 to about 4.65 volts; a 0.01 fraction shifts ϕ to 3.9 volts, while 0.02 reduces it to 3.1 volts. The values given are derived from the point where the emission becomes detectable; the true threshold doubtless is materially lower, as will be seen from the peculiar shape of the wave length *vs.* current curves. While these values are for K^+ ions, they will not differ markedly for any singly charged ion. From the above it follows that the sphere of influence of an adsorbed ion is strong even at a distance of ten times the ionic radius. The chemical analogy of these considerations is that when the fraction of the surface covered by adsorbed ions is but 1% of the total, the critical increment for electrons is shifted by about 23,000 calories.

The marked inhibiting effect of minute traces of oxygen on the photoelectric emissivity is readily understood in the light of the above considerations. The oxygen, upon combining with the iron, is attached to the

surface in the form of negative ions. It is obviously impossible to apply a lattice structure to an iron surface so sparsely covered with oxygen; however, the linkage most probably resembles that in FeO, which has a sodium chloride structure. If the oxygen is on the surface in the form of O^{--} ions, an abnormally high increase in the work function per ion density would result.

Application to Surface Catalysis.—A quantitative application of these results to surface catalysis cannot be made at this time, since neither the rate of ion formation nor the distribution of ions for mixed gases can be told with certainty. From a qualitative point of view, however, these findings are in accord with the theoretical conclusions of Schmidt,⁸ since the relative ionization of hydrogen appears to be much greater on platinum than on iron. Further, they are in general agreement with the ionic mechanism of catalysis presented by the writer some time ago.¹⁰ This mechanism, which is a direct application of thermionic emission in gases to surface catalysis, has been materially simplified and strengthened by recent studies of chemical action in the glow discharge¹² wherein it has been shown that the reactivity of positive ions is high compared to that of other active states, that the reaction is always initiated by ions of only one of the reactants, and that the number of collisions an ion must make with neutral molecules for reaction to take place is small, being from 10 to 40. Thus it will be seen that a catalyst, on the basis of this mechanism, need produce ions of only the reacting gas to initiate the reaction.

Kunsman¹³ has shown that iron is an excellent catalyst for the decomposition of ammonia while platinum is relatively poor. On the basis of the above mechanism, therefore, ammonia should be highly ionized on iron and only slightly on platinum. The results in general are in agreement with this point of view. The addition of hydrogen to ammonia had no appreciable effect on the emissivity of iron in ammonia, indicating that hydrogen does not replace ammonia at an iron surface. When hydrogen was added to ammonia on platinum, however, the emissivity rose to that for pure hydrogen; apparently it is the hydrogen which is the more dissociated on platinum. It is possible that the preferential adsorption of hydrogen by platinum is responsible for its low catalytic activity.

The glow discharge studies have shown that the synthesis of ammonia is initiated primarily by N_2^+ ions. The relatively high ionization of nitrogen on iron, combined with the fact that nitrogen had no appreciable effect on the emissivity from platinum in the presence of hydrogen, indicates that under the conditions of ammonia synthesis iron is the better source of N_2^+ ions and hence according to the ionic mechanism should

¹² Brewer and Westhaver, *J. Phys. Chem.*, **34**, 153, 2343 (1930); Brewer and Kueck, *ibid.*, **35**, 1281 (1931); Brewer and Miller, *THIS JOURNAL*, **53**, 2968 (1931).

¹³ C. H. Kunsman, *ibid.*, **50**, 2100 (1928); **51**, 688 (1929).

be the better catalyst. Platinum, however, should be the better catalyst for reactions initiated by positive hydrogen ions. The glow discharge studies show the synthesis of water to be initiated by H_2^+ ions. The experimental results in both cases are in apparent conformity with the theory.

The pronounced effect exerted on the work function by the presence of only a sparse distribution of adsorbed ions on the surface, combined with the large sphere of influence about these ions, is of vital importance to any mechanism of catalysis in which electrical forces are involved. In thermionic emission it is generally felt that the electrons escape at the points on the surface having the lowest work function. Since the rate of chemical action is expressed by the same mathematical equations as is the rate of thermionic emission of ions, it seems reasonable to suppose that the reaction takes place primarily at the points of lowest critical increment. The results of Kunsman on the decomposition of ammonia on various catalysts are in qualitative agreement with this contention. These considerations suggest a very simple mechanism for action of promoters and poisons. Ions on the surface that lower the work function serve as promoters while those that raise the work function behave as poisons. An illustration of this may be had from the observed effect of oxygen ions on raising the work function of iron; oxygen is a pronounced poison in the ammonia reaction.

In line with the above point of view it is interesting to note that in every case investigated the thermionic and photoelectric work functions for degassed surfaces have been shown to be identical. Warner¹⁴ has studied tungsten, DuBridge platinum¹⁵ and Cardwell¹⁶ iron, cobalt and tantalum.

Since the thermion escapes at the point of lowest work function while the photoion escapes wherever the quantum strikes, these findings are conclusive proof that the field of force for a degassed surface is uniform over the entire surface. This suggests the possibility that the phenomena generally attributed to active points on catalytic surfaces may in reality be due to the large fields of force about the ions adsorbed on the surface.

The writer is indebted to Dr. C. H. Kunsman for the interest he has taken in this research.

Summary

An investigation of the photoelectric properties of iron and platinum in the presence of various gases shows that the metals do not exhibit the characteristic properties of a pure metal as is found under good vacuum conditions but rather possess the properties of composite surfaces. In-

¹⁴ Warner, *Phys. Rev.*, **38**, 1871 (1931).

¹⁵ DuBridge, *ibid.*, **31**, 263 (1928).

¹⁶ Cardwell, *ibid.*, **38**, 2033 (1931); *Proc. Nat. Acad. Sci.*, **14**, 439 (1928).

deed, it is possible to duplicate exactly the photoelectric characteristics of these metals by curves taken *in vacuo* in which the surface of the metal is partially covered with adsorbed ions. Taking curves of known ion density as a standard, the degree of dissociation of the different gases into ions is estimated.

Threshold measurements on surfaces of known ion density show the field of influence about an ion to extend out to many times its normal radius; at ten times the ion radius the field is of appreciable magnitude. This is true for both positive and negative ions, although the effect is opposite in sign.

It is suggested that the large field of force about the adsorbed ions might account for the phenomena generally attributed to "active centers," and, further, that the large effect of adsorbed ions on the work function of the surface might be responsible for poisoning and promoter action.

The observed ionization of nitrogen, hydrogen and ammonia on iron and platinum surfaces is shown to be in accord with an ionic mechanism for surface catalysis and with the activation results obtained in the glow discharge.

THE HEAT CAPACITY AND ENTROPY OF THALLOUS NITRATE FROM 17 TO 300° ABSOLUTE. THE ENTROPY AND FREE ENERGY OF NITRATE ION

BY WENDELL M. LATIMER AND J. ELSTON AHLBERG¹

RECEIVED JANUARY 11, 1932

PUBLISHED MAY 7, 1932

In a previous investigation² the entropy of nitrate ion was calculated from data on barium nitrate. A similar evaluation of the entropy of nitrate ion has now been made from data on thallos nitrate. A discrepancy of 1.6 entropy units has been found between the two results. As in the previous work in this field the entropy of the solid salt at 25° has been determined from specific heat measurements carried down to the temperatures of liquid hydrogen. The accuracy of these measurements is considerably greater than the discrepancy found in the two calculated values for the entropy of nitrate ion and attention must therefore be directed to a re-examination of the existing data which have been used in the barium nitrate evaluation.

For references to details of theoretical and experimental method, see (b) Latimer and Buffington, *THIS JOURNAL*, **48**, 2297 (1926); (c) Latimer and Greensfelder, *ibid.*, **50**, 2202 (1928); (d) Latimer and Kasper, *ibid.*, **51**, 2293 (1929).

Material.—The thalious nitrate was a mixture of two "c. p." samples from Eimer and Amend and C. A. F. Kahlbaum. This material was filtered and recrystallized four times. It was then dried at 65° for three weeks. The average of six precipitations with potassium iodide gave 100.0% of the theoretical amount of thalious iodide.

Thalious nitrate undergoes a transition at about 75° and the long heating at 65° was carried out to ensure complete transformation into the form stable at low temperatures. The authors are greatly indebted to Professor Linus Pauling and Dr. J. H. Sturdivant of the California Institute of Technology, who have made x-ray examinations of our sample and report that it gives a powder photograph which is identical with that of the low temperature modification.

Heat Capacity Measurements.—The measurements were made with a calorimeter and cryostat similar to that previously described.^{2c} Due apparently to repeated cooling, the bakelite, which cements the gold wire of the resistance thermometer to the walls of the calorimeter, loosened slightly during the course of the measurements and this gave rise to somewhat higher temperature heads during the energy input than had been previously obtained with this calorimeter. The maximum error which might have arisen from this source is less than 1% up to 140°K. and less than 3% from 140 to 300°K.; however, we believe it to be considerably less.

Entropy of Thalious Nitrate.—Figure 1 is the plot of C_p against $\log T$ from which the entropy has been obtained by the graphical integration

$S = \int_0^T C_p d \ln T$. A summary of the entropy calculation is given in Table II.

TABLE II

CALCULATION OF THE MOLAL ENTROPY OF THALLOUS NITRATE	
0–16.45°K. extrapolation	1.16
16.45–298.1°K. graphical from data	36.96
Entropy of thallous nitrate	38.1 E. U.

The maximum error arising from the cooling corrections is less than 0.6 entropy unit. The average deviations of the points on the C_p curve give, however, a calculated error of about 0.1 unit.

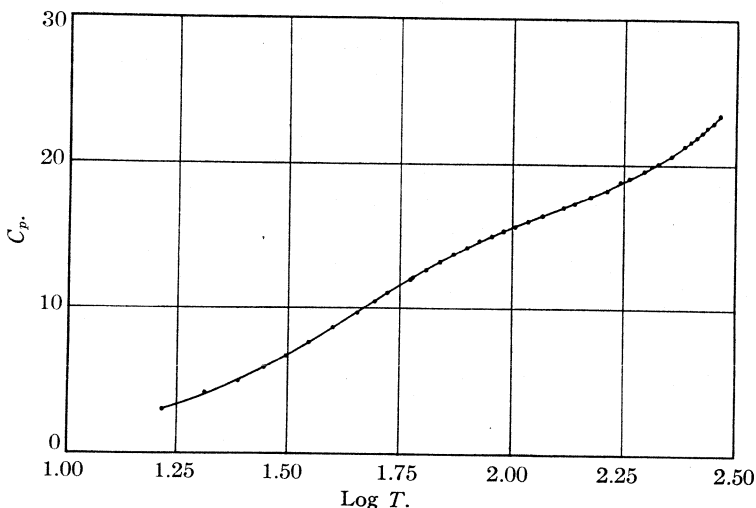

Fig. 1.—Molal heat capacity of thallous nitrate.

Entropy of Nitrate Ion.—The solubility of thallous nitrate at 25° is 0.434 *M*.³ The relative conductivities of solutions of thallous and silver nitrates and also activity data by Lewis and Randall indicate that the activity coefficient of thallous nitrate is slightly lower than that of silver nitrate, for which Lewis and Randall⁴ give 0.55 at 0.434 *M*. Hence we have chosen the value $\gamma = 0.50$ and calculate for the free energy of solution

$$\Delta F^\circ = -RT \ln (\Delta m)^2 = 1790 \text{ cal.}$$

Combining this with Thomsen's value for the heat of solution of thallous nitrate, $\Delta H = 9970$, we obtain for the entropy change, solid to form hypothetical one molal solution

³ Data from Berkeley, *Phil. Trans. Roy. Soc., London*, 203, 89 (1904); and Étard, *Ann. chim. phys.*, 2, 503 (1893).

⁴ Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., Inc., New York, 1923.

$$\Delta S^\circ = \frac{\Delta H^\circ - \Delta F^\circ}{T} = \frac{9970 - 1790}{298.1} = 27.4 \text{ E. U.}$$

This gives for the sum of the entropies of nitrate and thallos ions, using the value obtained for the entropy of the solid, $27.4 + 38.1 = 65.5 \text{ E. U.}$

We now wish to express the entropy of nitrate ion in respect to $\text{H}^+ = 0$ and the most reliable method of carrying out this calculation employs the data for hydrochloric acid and thallos chloride. These have been summarized in Table III.

TABLE III

THE ENTROPY OF HYDROCHLORIC ACID AND THALLOUS CHLORIDE IN AQUEOUS SOLUTIONS

	Entropy of substance 298.1°K.	ΔH of soln., cal.	ΔF of soln., cal.	ΔS of soln., E. U.	Sum of ionic entropies, E. U.
HCl	44.7 ⁵	-17,750 ⁷	-8604 ⁸	-30.5	14.0
TlCl	25.8 ⁶	-10,100 ⁷	5086 ⁸	16.8	42.6

From these values the entropies, referred to $S_{\text{H}^+}^\circ = 0$ are: Cl^- , 14.0 and Tl^+ , 28.6. Using the sum of the entropies of thallos and nitrate ions as given above, we then calculate for the nitrate ion $S_{298.1}^\circ = 65.6 - 28.6 = 36.9 \text{ E. U.}$ In our previous determination² based upon analogous calculations for barium nitrate, we obtained 35.3 E. U. for nitrate ion. We believe that the value from thallos nitrate is accurate to 1 E. U., *i. e.*, to 300 cal. and that the discrepancy probably is due to errors in the data used to calculate the entropy of barium ion. Investigations are under way to check these quantities. It might also be mentioned that the theoretical evaluation of the entropy of aqueous ions by Latimer and Kasper^{2d} has indicated that the experimental value for barium ion is too high.

Free Energy of Nitrate Ion.—For the heat of the reaction

Berthelot gives $\Delta H = -48,800 \text{ cal.}$ and Thomsen $-49,100 \text{ cal.}$ These values are for 18° but may be corrected to 25° since the specific heats of all the substances are known. The average value for $\Delta H_{298.1}$ then becomes $-49,400$. Using the entropies: H_2 , 31.2;⁹ N_2 , 45.8;¹⁰ O_2 , 49.0;¹¹ H^+ , 0 and NO_3^- , 36.9, we calculate $\Delta S = 36.9 - 15.6 - 22.9 - 73.5 = -76.1$. With the value for the heat of the reaction, the free energy then becomes

⁵ Giauque and Overstreet, *THIS JOURNAL*, **54**, 1731 (1932).

⁶ Calculation by Rodebush and Rodebush, "International Critical Tables."

⁷ "International Critical Tables." The value for hydrochloric acid has been corrected to 25° using the heat capacity values given by Rossini, *Bur. Standards J. Research*, **7**, 47 (1931).

⁸ From data in Lewis and Randall, Ref. 4, modified by recent work of Randall and Young, *THIS JOURNAL*, **50**, 989 (1928), and Randall and Vietti, *ibid.*, **50**, 1526 (1928).

⁹ Giauque, *ibid.*, **52**, 4816 (1930).

¹⁰ Giauque and Clayton, to be published.

¹¹ Giauque and Johnston, *THIS JOURNAL*, **55**, 2300 (1929).

$\Delta F^\circ = -49,400 - (298.1 \times -76.1) = -26,700$ cal. This is an excellent agreement with the Lewis and Randall⁴ value $\Delta F^\circ = -26,500$ cal.

Entropy of Nitrite Ion.—We may make use of the values given by Lewis and Randall for ΔF° and ΔH° of the reaction

and the known entropies of the reaction products, to calculate the entropy of solid silver nitrite. This we find to be 27.7. From this value together with the free energy and heat of solution of silver nitrite and the entropy of silver ion we calculate for the entropy of nitrite ion, 24.0 E. U. The direct determination of the entropy of solid silver nitrite will afford an interesting check upon the entropies of both nitrate and nitrite ions.

Entropy of Hydration of Nitrate.—It is of interest to compare the entropy of nitrate, 36.9, with that of carbonate, -14. Since the entropies of the two substances as gases should be very nearly the same, the difference must arise from the effect upon the entropy of the water molecules of the double charge on the carbonate. Latimer and Kasper^{2d} have found for the simple ion that the entropy of hydration is $22 e^2/r$ E. U. where e is the charge on the ion and r the distance in Ångström units from the center of the ion to the center of the water dipoles surrounding the ion. Estimating r as approximately 3 Å. for carbonate and nitrate would lead to a difference of only 30 E. U. between the two ions instead of the 51 units found. It seems probable that part of the discrepancy is due to the dissymmetry of these ions, which permits one or more water molecules to be drawn very much closer to the center of the ion. The calculation also assumes that the effective charge is located at the center of the ion cavity whereas actually the field outside the ion probably corresponds to a more complex distribution.

The authors wish to express their appreciation to Professor Linus Pauling and Dr. J. H. Sturdivant for their x-ray examination of the sample of thallous nitrate.

Summary

The specific heat and entropy of thallous nitrate has been determined from 17 to 300° absolute. These values have been employed in a calculation of the entropy and free energy of nitrate ion.

A GRAVIMETRIC METHOD FOR THE SEPARATION AND DETERMINATION OF TITANIUM¹

BY HAL TRUEMAN BEANS AND DOROTHEA R. MOSSMAN

RECEIVED JANUARY 22, 1932

PUBLISHED MAY 7, 1932

Existing methods for the separation of titanium from its common associates leave much to be desired from the standpoint of accuracy, ease of manipulation and speed. A perusal of the monograph "Titanium" by William M. Thornton is convincing evidence that a method for the determination of titanium in the presence of other elements, which avoids long and tedious separations and does not produce a gelatinous precipitate, is greatly needed.

Under proper conditions, a crystalline salt of titanium is quantitatively precipitated by potassium iodate, no precipitate being produced with aluminum, calcium, magnesium, nickel, phosphorus and chromium, elements which are commonly associated with titanium in ores. With slight modifications the method effects a separation of titanium from zirconium and manganese. It is necessary, however, that iron be removed previous to the determination of titanium. This is readily accomplished without modification of the method in any essential.

Reagents and Solutions

Titanium.—Titanium sulfate solutions were prepared by dissolving twice recrystallized potassium fluotitanate in sulfuric acid and heating to dense fumes of sulfur trioxide. Water was then added to obtain the desired concentration and the solutions were standardized by the precipitation of titanium hydroxide with ammonium hydroxide. The solutions used contained approximately 0.1 g. of TiO_2 in 50 cc. of solution and were 1.2 *N* with respect to sulfuric acid.

Zirconium.—A solution of c. p. zirconium nitrate which was 0.3 *N* with respect to sulfuric acid was prepared and standardized by precipitation with ammonium hydroxide. The solution was tested qualitatively and found to be free from iron and titanium. The hafnium content of this solution is not known and was not investigated.

Other Elements.—Solutions of the following c. p. salts, alum, calcium chloride, magnesium chloride, nickel chloride, iron chloride, manganous sulfate, primary potassium phosphate (recrystallized), ammonium vanadate, sodium chromate, were used as sources of these elements.

Potassium Iodate.—C. p. grade.

Thirty per cent. Hydrogen Peroxide.—Merck's Superoxol.

The Quantitative Determination of Titanium.—The procedure for the determination of titanium, employing the optimum conditions, follows. To 50 cc. of the standard solution, there was added 27 cc. of concentrated nitric acid and the volume made up to 200 cc. The reagent was prepared

¹ From the thesis submitted by Dorothea R. Mossman in partial fulfillment of the requirements for the degree of Doctor of Philosophy in the Faculty of Pure Science, Columbia University, 1930. Original manuscript received August 29, 1931.

by dissolving 10 g. of potassium iodate in 100 cc. of water containing a few drops of nitric acid. This small concentration of nitric acid prevents the precipitation of potassium iodate when the solution cools. The reagent was added to the titanium sulfate solution slowly and with stirring, at room temperature. The precipitate was allowed to stand for about one hour, stirring now and again until the iodate precipitate changed from a flocculent to a dense crystalline form, and then it was washed five times by decantation with 20-cc. portions of a 2% solution of potassium iodate which contained 6 cc. of concentrated nitric acid to every 100 cc. of solution. The filter paper and precipitate were then transferred to the original beaker, 15 cc. of concentrated hydrochloric acid added and the filter paper macerated by the use of a stirring rod. A small volume of water was then added and sulfur dioxide bubbled through the solution until the brown coloration which first formed had completely disappeared. The volume was then adjusted to about 300 cc. and the sulfur dioxide expelled by boiling. The titanium was then precipitated by ammonium hydroxide, filtered, washed, ignited and weighed as titanium dioxide.

Determinations 1 through 20 of Table I show the results obtained when this procedure was followed. Determinations 21 through 35 show the results obtained when acids other than nitric and normalities other than 1.6 were used. Determinations 36 through 41 show the application of this method in determining amounts of titanium dioxide other than 0.1 g.

TABLE I
EXPERIMENTAL DATA

No.	Approx. wt. TiO ₂ , g.	Acid, cc.	Added acid	Total nor- mality acid	KIO ₃ added, g.	Number of analyses	Av. dev., %	Max. dev., %	Dev. of av. from standard, %
1-20	0.12	27	HNO ₃	1.6	10	20	0.1	0.3	+0.01
21-22	.12	13	H ₂ SO ₄	1.7	10	2	.1	.1	+ 2
23-24	.12	27	HCl	1.6	10	2	.05	.05	+ .05
25-26	.12	15	HNO ₃	1.0	10	2	.05	.05	+ .05
27-28	.12	7	H ₂ SO ₄	1.0	10	2	.2	.2	+ .1
29-30	.12	15	HCl	1.0	10	2	.05	.05	+ .15
31-33	.12	5.5	H ₂ SO ₄	0.9	10	3	.03	.1	+ .1
34-35	.12	None	added	.2	10	2	.05	.05	+ .05
36-37	.2	27	HNO ₃	1.6	15	2	.02	.02	- .07
38-39	.05	27	HNO ₃	1.6	10	2	.2	.2	.00
40	.01	27	HNO ₃	1.6	10	1			1.0
41	.01	27	HNO ₃	1.6	15	1			0.00

When the iodate precipitation was performed in solutions of greater acidity than those given in the table, addition of ammonium hydroxide to the filtrate showed the presence of titanium. Hence in solutions whose acid concentration is appreciably greater than 1.7 normal, the precipitation of titanium is incomplete.

It appears advisable when determining amounts of titanium dioxide very much greater or very much less than 0.1 g. to increase the quantity of potassium iodate added, in order to ensure rapid precipitation. Thus, in determination 40 of the above table, the precipitation, while complete, appeared only after standing for several days, whereas in determination 41 the precipitate appeared immediately in the dense very insoluble crystalline form.

Separation from Other Elements

Aluminum, Calcium, Magnesium and Nickel.—Preliminary tests having shown that aluminum, calcium, magnesium and nickel were not precipitated under the conditions of the determination, the maximum weight of the oxides of these elements that could be present without causing interference was then ascertained.

The separation of titanium from these elements using a single precipitation was accomplished by employing the iodate method as outlined above. In those determinations involving a second precipitation, the iodate precipitate was washed back into the original beaker with hot water, 25 cc. of concentrated hydrochloric acid was added and sulfur dioxide bubbled through the solution until the brown coloration disappeared. The sulfur dioxide was then completely expelled by boiling, the volume adjusted to 200 cc. and the titanium reprecipitated by the addition of 10 g. of potassium iodate dissolved in 100 cc. of water. From this point the procedure was similar to that already described. Table II shows the results thus obtained.

TABLE II
EXPERIMENTAL RESULTS

Approx. wt. of TiO ₂ , g.	No. of pptns.	Interfering element, g.	Number of analyses	Av dev., %	Max. dev., %	Dev. of av. from standard, %
0.1	1	0.1–0.2 Al ₂ O ₃	9	0.1	0.3	–0.05
.1	1	.25 Al ₂ O ₃	2	.05	.05	+ .35
.1	2	.35 Al ₂ O ₃	4	.2	.3	+ .2
.1	1	.1 CaO	6	.1	.2	– .1
.1	1	.12–0.15 CaO	2	.15	.15	+ .6
.1	2	.2 CaO	4	.2	.3	+ .2
.1	1	.2–1.0 MgO	6	.1	.2	– .1
.1	1	.4 NiO	4	.15	.2	+ .1

The above results show that an accurate separation of 0.1 g. of TiO₂ from 0.2 g. of Al₂O₃, from 0.1 g. of CaO, from 0.4 g. of NiO and from very large amounts of MgO may be obtained. When a double precipitation is employed, the permissible quantity of Al₂O₃ and of CaO is increased to 0.35 g. and 0.2 g., respectively. The presence of larger quantities of the interfering elements than those shown in the table resulted in adsorption and consequent high results for the titanium oxide content.

Phosphorus, Vanadium and Chromium.—Phosphorus is frequently and vanadium and chromium occasionally are encountered in the analysis of titanic materials. Chromium, equivalent to 0.07 g. of CrO_3 , did not produce a precipitate under the conditions of the determination. Vanadium, equivalent to 0.05 g. of V_2O_5 , produced a bright red precipitate. However, 1 mg. of V_2O_5 , which is as much as is likely to be present in a titanium ore, did not produce a precipitate. The iodate precipitation separated titanium from phosphorus very effectively as the results in Table III show.

TABLE III		
TiO_2 taken, g.	TiO_2 found, g.	P_2O_5 present, g.
0.1023	0.1024	0.025
	.1024	.040
	.1020	.040

Manganese.—Manganese is not precipitated by potassium iodate under the conditions of the experiment but a slight brown deposit, which appears to be manganese dioxide, forms in the course of an hour.

An attempt was made to keep the manganese in solution by observing Blum's precautions when precipitating with ammonium hydroxide, and results 1, 2 and 3 of Table IV were obtained. These results, therefore, corroborate Blum's statement² that oxidation and precipitation of manganese occurs so rapidly as to preclude quantitative separation and are in disagreement with the work of Lundell and Knowles.³

Correct results were obtained when the following procedure was used. The iodate precipitate was washed back into the original beaker by a stream of hot water and its solution effected by means of hydrochloric acid and sulfur dioxide; 1 cc. of a saturated ammonium bisulfite solution was added and the titanium then precipitated by the basic acetate method. Determinations 4 and 5 show the results obtained when 10 milligrams of Mn_3O_4 was present.

3		.1192	.010
4	.1147	.1148	.010
5		.1145	.010

Iron.—Iron, in small quantities, is completely precipitated by potassium iodate under the conditions of the experiment. When larger quantities of iron are present (*e. g.*, 0.1 g. of Fe_2O_3), the iron is incompletely precipitated. It was therefore necessary to remove iron previous to the precipitation of titanium, by Rothe's ether method, the modifications

² W. Blum, "Scientific Papers of the Bureau of Standards," No. 286, 1916.

³ G. E. F. Lundell and H. B. Knowles, *THIS JOURNAL*, 45, 676 (1923).

employed being those described by Barnebey and Isham.⁴ Three ether extractions were performed. The aqueous layer was then transferred to a beaker, warmed to remove ether, and evaporated to 50 cc. to adjust the acid concentration. The volume was then brought to 200 cc. and the titanium precipitated as iodate. After the titanium iodate had changed form, it was washed as in the regular procedure, filtered, and washed back into the original beaker by means of hot water; 15 cc. of hydrochloric acid was added and sulfur dioxide bubbled in to effect the solution of the iodate precipitate. The excess sulfur dioxide was then expelled by boiling and the titanium precipitated by the basic acetate method using ammonium bisulfite to maintain the trace of iron, still remaining, in the reduced condition.⁵ By means of this procedure the results in Table V were obtained.

Zirconium.—Existing methods for the separation of titanium and zirconium were found unsatisfactory. Davis⁶ has given a few results on the use of sodium iodate as a precipitating reagent for zirconium in a nearly neutral solution, claiming that even in the presence of small quantities of acid the precipitation was incomplete. Because of the sensitivity of this reaction to slight changes in acidity, this method has been useless for practical purposes. Since Davis specifies merely an excess of sodium iodate, it was thought that this reaction might be used for quantitative purposes if as much as 10 g. of potassium iodate were used.

Zirconium was found to be partially precipitated by potassium iodate when the regular procedure, using a solution of acid normality 1.6, was employed. However, the precipitation was found to be complete in a solution which was 0.3 normal in respect to sulfuric acid. The iodate precipitate was redissolved by hydrochloric acid and sulfur dioxide and the zirconium reprecipitated by ammonium hydroxide. Determinations 1 through 4 of Table VI show the results obtained when this procedure was followed.

⁵ Wm. M. Thorton, *Am. J. Sci.*, [4] **37**, 173 (1914).

⁶ I. Thomas Davis, *Am. Chem. J.*, **11**, 26 (1889).

Determinations 5 through 10 show analyses of solutions containing both titanium and zirconium. To these solutions 35 cc. of Superoxol was added and the volume made up to 200 cc.; 100 cc. of water containing 10 g. of potassium iodate was added to the solution and the precipitate allowed to stand for about three hours. The slight reaction which occurs between the hydrogen peroxide and the potassium iodate in no way interferes with the determination. After standing for three hours, the zirconium precipitate was filtered through a porcelain filter crucible and washed by decantation with 150 cc. of water containing 3 g. of potassium iodate and 3 cc. of Superoxol. Nine cc. of sulfuric acid was then added to the filtrate and the hydrogen peroxide expelled by boiling. An inverted funnel was suspended over the beaker to prevent loss by effervescence. When the hydrogen peroxide had been expelled the titanium precipitate appeared. The evaporation was continued down to a volume of 300 cc., when the beaker was removed from the flame and allowed to cool with occasional stirring. The remaining operations for the determination of titanium were the same as those already described.

In order to determine the zirconium, the precipitate was dissolved through the porous bottomed crucible by means of concentrated hydrochloric acid, followed by water. Sulfur dioxide was then bubbled through the solution for a minute or two and the excess sulfur dioxide expelled by boiling. Macerated filter paper was then added to the solution, the zirconium precipitated by ammonium hydroxide, washed with hot 2% ammonium nitrate solution, filtered and ignited to the oxide.

When more than 10 milligrams of zirconium dioxide was present it was found that the zirconium precipitate absorbed titanium to a large extent. However, since zirconium occurs only in small quantities in titanium ores, this method will be found applicable.

Determination of the Composition of the Iodate Precipitate.—Since there is no mention in the literature of a compound containing titanium and the iodate radical it was decided to determine, if possible, the composition of the precipitate.

The precipitate was washed about twenty times with pure water, in which it is insoluble. Difficulty was experienced in drying the precipitate as a slight decomposition with simultaneous discoloration of the compound took place very readily. However, one product which was fairly white was obtained by drying over phosphorus pentoxide in a vacuum for several days and another was obtained by drying in the oven at 60° to constant weight.

Weighed portions of the precipitate so prepared were used to determine the titanium and iodate content. Titanium was determined by basic acetate precipitation. Iodate was determined by reduction with potassium iodide and titration of the liberated iodine by sodium thiosulfate solution.

The results, which indicate that the compound is a double salt of formula $\text{Ti}(\text{IO}_3)_4 \cdot 3\text{KIO}_3$, are shown below

% Titanium found	% Iodate found

Summary

A new gravimetric method for the determination of titanium has been described, in which the titanium is precipitated as a double potassium titanium iodate whose probable composition is $\text{Ti}(\text{IO}_3)_4 \cdot 3\text{KIO}_3$. The new method separates titanium quantitatively from a large number of the elements commonly occurring with it in ores, notably aluminum.

A procedure for the separation and determination of small amounts of zirconium from large amounts of titanium has been described.

NEW YORK CITY

NOTE

A Neutral Buffered Standard for Hydrogen Ion Work and Accurate Titrations Which Can be Prepared in One Minute

BY ROGER J. WILLIAMS AND CARL M. LYMAN

Most of the standard buffer solutions recommended in the literature must be prepared with considerable care and one cannot be sure of the result unless all the precautions of quantitative analysis are used. A simply prepared solution that can be relied on for standardizing quinhydrone electrodes, etc., is therefore much to be desired. Standardized buffer mixtures are on the market for this purpose.

Ammonium acetate solution has for a number of years been used by one of us in lecture demonstrations of buffer activity, for which purpose

it is very effective. Since the dissociation constants for ammonium hydroxide and acetic acid are often given in the literature as identical values, we decided to make an accurate determination of the P_{H} value of ammonium acetate solutions. Theoretically they should be neutral.

A quinhydrone electrode of the Cullen¹ type was used and a standard buffer solution (Arthur H. Thomas) $4.63 \pm 0.01 P_{\text{H}}$ at 25° , was checked with it to the second decimal place. The following determinations were then made.

TABLE I
AMMONIUM ACETATE SOLUTION USED

	P_{H} value found
Approx. 0.5 N made with boiled distilled water	7.00
Approx. 0.1 N made with unboiled distilled water	{ 7.01 7.01 7.01
Approx. 0.05 N made with unboiled distilled water	
Approx. 0.5 N soln. (above) through which laboratory air had been bubbled for five minutes	
	6.95

From these results it is apparent that ammonium acetate solutions, through wide limits of concentration, are as nearly neutral as one could hope to get a solution, and are stable toward laboratory conditions. Since such a standard solution can be made in a moment's time there is no occasion, in any event, to store the solutions.

It may be pointed out that whereas buffered solutions, in general, change their P_{H} values only a little by dilution, the P_{H} value of a perfectly neutral buffer such as this one should not change at all on dilution.

The ammonium acetate solution above described is not only valuable as a standardizing solution for quinhydrone electrodes, etc., but may also be used as a standard in titrations when an exactly neutral end-point is desired. If one wishes to bring the color of his indicator exactly to the neutral point it is not necessary to guess at it. Indicator may be introduced into an ammonium acetate solution with assurance that it will assume a neutral tint which can be used for comparison.

THE CATECHIN OF THE CACAO BEAN¹

BY KARL FREUDENBERG,^{1a} RICHARD F. B. COX^{1a} AND EMIL BRAUN

RECEIVED JULY 16, 1931

PUBLISHED MAY 7, 1932

More than twenty years ago A. J. Ultée and W. van Dorssen detected in fresh cacao beans a phenolic crystalline substance which they called "Kakaoöl." They isolated it as a crystalline caffeine compound and suggested the formula $C_{16}H_{16}O_6$. The substance forms a crystalline acetyl compound with the melting point 153–154°.

From the description of this labile material, one of us concluded² that it belonged to the catechin class. When later the various isomeric forms of catechin became better known, the additional suggestion could be made that this substance very probably represented *l*-epicatechin.³

This prediction has now been proved to be correct. We prepared the catechin from a sample of fresh cacao pods procured from Trinidad (collected in January), and another procured from Porto Rico (collected in January). A third sample was kindly sent to us by Dr. A. Frey-Wyssling of Medan, Sumatra, and consisted of fresh beans sterilized in Medan. For the fourth sample we are indebted to Dr. A. J. Ultée, who supplied us with some of his original "caffeine-kakaoöl." From all these samples the same substance was obtained. It was identical in every respect with *l*-epicatechin, which was isolated some years ago from the wood of *Acacia Catechu*.⁴

While our present work was in progress, a paper by W. B. Adam, F. Hardy and M. Nierenstein⁵ appeared in which the view was adopted that cacaoöl belongs to the catechin family. Their experimental results are in sufficient agreement with ours, and they identify it, as we do, with the levorotatory catechin present in the cutch-producing acacias; but they call it *l*-acacatechin and ascribe to it a constitutional formula which we believe is incorrect.

We maintain that catechin and epicatechin are stereoisomeric and that both have the formula I. The tetramethyl ether of each gives rise, after reduction and methylation, to the same pentamethoxy-1,3-diphenylpropane (II).⁶ *dl*-Epicatechin has been obtained from cyanidin⁷ by hydro-

⁷ Ref. 4, page 135.

genation, and its pentamethyl ether from pentamethylcyanidin and pentamethylquercetin⁸ in the same way. As the formulas of cyanidin and quercetin are definitely established, no doubt seems possible concerning the constitution of epicatechin.

Synthetic epicatechin is identical with a mixture of equal parts of natural *l*-epicatechin and *d*-epicatechin obtained by the epimerization of natural *d*-catechin.⁹ *dl*-Epicatechin forms by epimerization *dl*-catechin⁹ which is identical with a mixture of equal parts of natural *d*-catechin and *l*-catechin formed by the epimerization of *l*-epicatechin.¹⁰ *dl*-Catechin in its turn can be converted into *dl*-epicatechin.¹¹ The scheme of these relationships given in 1924,¹² can be completed by an arrow leading from *dl*-epicatechin to *dl*-catechin. Catechin and epicatechin are, therefore, stereoisomers, and their constitution is expressed by the same formula (I). The fact that both yield the same 1,3-diphenylpropane derivative (II) leads to the same conclusion.

It has been deemed necessary to develop a part of the evidence given in favor of formula I for both catechin and epicatechin as M. Nierenstein¹³ has been attempting for many years to establish another formula in which the catechol nucleus is attached to carbon atom 3 or 4 (I). He bases his suggestion on his failure to obtain substance II from either catechin or epicatechin.

As a matter of fact, M. Nierenstein has omitted to carry out, in accordance with our procedure,⁶ this fundamental reaction leading from I to II, in spite of the various suggestions which have been made to him to perform this simple experiment.¹⁴ We, therefore, confine ourselves to a few criticisms of some of his later papers.

¹⁴ Nierenstein, *ibid.*, **56**, 1188, Ref. 6 (1923); *ibid.*, **55**, 1938 (1922); finally K. Freudenberg, some years ago, deposited authentic material in another laboratory and asked Dr. Nierenstein to write to this Laboratory for a part of this substance and carry out

M. Nierenstein and E. O. Hazelton¹⁵ tried to convert *dl*-catechin into *dl*-epicatechin and from their failure concluded that these substances cannot have the same structural formula. They overlooked the fact, mentioned above, that this conversion had been accomplished nine years before.

M. Nierenstein¹⁶ is laboring under a misapprehension in assuming that the work of J. J. Drumm, R. J. P. Carolan and H. Ryan¹⁷ proves a formula of catechin proposed by him and disproves our formula (I). The Irish authors, on the contrary, expressly state that their result is in agreement with our formula.¹⁸

Furthermore, M. Nierenstein¹⁹ refers to a remark made by W. Hückel²⁰ as being a criticism of our formula. Some time ago²¹ one of us suggested that, of the two stereoisomeric formulas derived from formula I, epicatechin has the spacial arrangement Ia and catechin Ib. Evidence for this de-

cision seemed to be given by the fact that tetramethylepicatechin readily loses water, while tetramethylcatechin splits off water only with difficulty, undergoing a rearrangement at the same time. Later²² we again left open the question as to which formula of the two, Ia or Ib, must be ascribed to catechin or epicatechin. Two years later Hückel, who had overlooked the last remark, made the same suggestion. The criticism of Hückel was therefore unnecessary, and did not touch at all upon the question of constitution as might be inferred from Nierenstein's remark.

We state once more that all catechins which K. Freudenberg and his collaborators have had in hand thus far, are stereoisomeric catechins or epicatechins and are all to be expressed by formula I.

Experimental

The beans used in this investigation were heated for an hour at 75° in 95% alcohol, immediately after removal from the pods, in order to kill enzymes. After air-drying the experiment. Cf. R. Robinson's remarks on the question [*Chem. Age* (London), 19, 337 (1928)].

²² Freudenberg and Harder, *ibid.*, **451**, 214 (1927).

they were ground in a mill and the catechin removed by maceration with alcohol at 75°. The alcohol solution contained fat, caffein and catechin. After removal of the alcohol under reduced pressure, the residue, dissolved in a little water, was extracted a few times with petroleum ether for removal of fat, and then exhaustively extracted with chloroform to remove the caffein. The resulting deep red solution was extracted with ether for several days. The solid remaining after evaporation of the ether was taken up in a small quantity of boiling water, treated with talcum to absorb any fat that might be present, and allowed to crystallize. After several days, small rosetts of thick prisms had crystallized from the solution. These were of a slight brownish-pink tinge and had to be purified from an acetone-benzene solution.²³

The material obtained from Trinidad and Porto Rico was sterilized after arrival in Madison, whereas the beans from Sumatra were sterilized there. The meat of the latter beans was light pink, while the meat of the former two samples was dark brown. The yield obtained from the first two samples was only one to two-tenths while the yield from the Sumatra beans was five-tenths of one per cent.

Two and three-tenths grams of the compound sent by Dr. Ultée was dissolved in 25 cc. of hot water, filtered to remove solid impurities and extracted fifteen times in a separatory funnel with 15-cc. portions of chloroform. The water layer was then heated to boiling, filtered and set aside to crystallize. It was seeded with *l*-epicatechin, and the next day a crop of crystals was obtained.

The crystalline form and solubilities of the four samples did not differ from those of *l*-epicatechin. The crystals lost four molecules of water at 100° under reduced pressure (av. 19.5%, calcd. 19.9%).²⁴ The water of crystallization is lost slowly at room temperature.

When heated, following the procedure of E. Fischer,²⁵ the substances decomposed at 237–239° (corr. 245°). *l*-Epicatechin itself and mixtures of the substances with *l*-epicatechin behaved likewise.²⁶

The rotation of the catechin of cacao was measured in acetone-water (1:1 by weight): $[\alpha]_D^{20} - 0.58 \times 100/1 \times 0.998 = -58^\circ$. For *l*-epicatechin in yellow mercury light, -59 – 60° is indicated.²⁷ (M. Nierenstein⁵ used water and found -69° .)

Anal. Subs., 4.368 mg.: CO₂, 9.98; H₂O, 1.99. Calcd. for *l*-epicatechin: C, 62.07; H, 4.82. Found: C, 62.31; H, 5.09.

The acetyl compound was obtained in the usual way.²⁸ The melting point of pentacetyl-*l*-epicatechin was 151–152° (corr. 153–154°).²⁹ When mixed with the original preparation the melting point did not alter.

The acetates of our cacao-catechin as well as the acetate of Dr. Ultée's material had the same rotation in acetylene tetrachloride, varying from -12.1 to -12.3° ; $[\alpha]_D^{20} - 1.09 \times 100/1 \times 8.84 = -12.3$.

Anal. Subs., 4.332 mg.: CO₂, 9.51; H₂O, 1.87. Calcd. for pentacetyl-*l*-epicatechin: C, 59.98; H, 4.83. Found: C, 59.87; H, 4.83.

²³ Ref. 4, page 144.

²⁴ Ref. 10, page 276.

²⁵ Fischer, *Ber.*, **41**, 75 (1908).

²⁶ The point of decomposition of 245° as indicated in *Ann.*, **437**, 276 (1924), is corrected (*cf.* *Ber.*, **56**, 1192 (1923)). M. Nierenstein (ref. 5) indicated a melting point of 229°. When heated slowly, this point of decomposition can also be obtained with our substances.

²⁷ Freudenberg and Purrmann, (a) *Ann.*, **437**, 276 (1924); (b) *Ber.*, **56**, 1192 (1923).

²⁸ Freudenberg, Böhme and Beckendorf, *ibid.*, **54**, 1209 (1921).

²⁹ Freudenberg and Purrmann, *ibid.*, **56**, 1189 (1923); *Ann.*, **437**, 276 (1924).

In a 2-3% solution with mercury light, specific rotations of -14.5 to -15.0° were found for *l*-epicatechin pentacetate. M. Nierenstein reports -12° for sodium light (concentration not indicated).

The melting points reported by M. Nierenstein and his collaborators³⁰ for the acetates of the so-called *dl*-acacatechin (160°), *d*-gambircatechin (137°), *dl*-gambircatechin (156°) do not correspond to those for our pure substances. The acetates of *dl*-epicatechin, *d*-catechin and *dl*-catechin melt at 169° , $131-132^\circ$, $164-165^\circ$, respectively.^{28a}

Summary

1. The catechin present in the cacao bean is shown to be identical with *l*-epicatechin.

2. Recent work of Dr. Nierenstein is criticized.

THE PREPARATION OF 5,7-DI-IDOISATIN

BY WARD C. SUMPTER AND LAWRENCE AMUNDSEN

RECEIVED OCTOBER 19, 1931

PUBLISHED MAY 7, 1932

The preparation of 5,7-di-iodoisatin has been described by Kalb and Berrer.¹ These investigators treated an aqueous solution of the sodium bisulfite addition compound of dehydroindigo with iodine monochloride. 5,7-Di-iodoisatin was obtained by treating the resulting solution with a solution of potassium dichromate in aqueous sulfuric acid.

The writers attempted to repeat the work of Kalb and Berrer but were able to obtain only very poor yields of the compound by this method. A procedure was then developed for preparing 5,7-di-iodoisatin from 5,7,5',7'-tetraiodoindigo. The latter compound was oxidized with an aqueous solution of chromic and nitric acids and more satisfactory yields of the di-iodoisatin were obtained.

It has also been stated that 5,7-di-iodoisatin,² as well as a small amount of tetraiodoisatin, is obtained when a solution of isatin in concentrated hydrochloric acid is treated with iodine monochloride. Hill and Sumpter found that this statement³ is in error, 5-iodoisatin being the sole product even when a large excess of iodine monochloride is used.

The writers have further attempted to prepare 5,7-di-iodoisatin by the action of iodine monochloride on isatin and on iodoisatin in methyl alcohol, ethyl alcohol, concentrated sulfuric acid, fuming sulfuric acid and acetic anhydride without success. It appears that iodine cannot be introduced

¹ Kalb and Berrer, *Ber.*, **57**, 2112 (1924).

³ Sumpter, Ph.D. Dissertation, Yale University, 1930.

directly into the isatin nucleus in position 7. This is in keeping with the observations of Borsche⁴ and of Kalb and Berrer,¹ who also reported that 5,7-di-iodoisatin could not be obtained by the iodination of isatin.

Experimental Part

5,7,5',7'-Tetraiodoindigo.—This compound was prepared according to the directions given by Kalb and Berrer.⁵ The yields averaged 60% of the theoretical.

5,7-Di-iodoisatin. A. By the Method of Kalb and Berrer.¹—Repeated experiments using 10 g. of the sodium bisulfite addition compound gave yields of 1.7–1.8 g. or about 10% of the theoretical. Kalb and Berrer reported 48% yields.

B. By the Oxidation of Tetraiodoindigo.—Ten grams of tetraiodoindigo was suspended in 20 cc. of water and the mixture heated to boiling. A solution of 8.4 g. of chromic acid in 35 cc. of concentrated nitric acid was slowly added to the mixture and the boiling continued for ten minutes; 100 cc. of water was added to the mixture and the insoluble material filtered off. The residue was digested with 150 cc. of hot 10% sodium hydroxide, the whole diluted to a volume of 1500 cc. by the addition of water, boiled for ten minutes and filtered into an excess of dilute hydrochloric acid. The precipitate of 5,7-di-iodoisatin was filtered off and purified by crystallization from glacial acetic acid. It separated in characteristic red plates, m. p. 261–263°. Kalb and Berrer reported decomposition at 240°. The compound is identical with that which was obtained in poorer yields by the procedure of Kalb and Berrer. The yield was 6.3 g. or 60% of the theoretical.

Anal. Calcd. for $C_8H_3O_2NI_2$: N, 3.50; I, 63.66. Found: N, 3.50, 3.46; I, 62.85.

Oxidation of the di-iodoisatin with 3% hydrogen peroxide in alkaline solution gave 2-amino-3,5-di-iodobenzoic acid (m. p. 230°) as stated by Kalb and Berrer.

Summary

5,7-Di-iodoisatin has been prepared by the action of chromic and nitric acids on 5,7,5',7'-tetraiodoindigo.

CONDENSATION BY SODIUM INSTEAD OF BY THE GRIGNARD REACTION. IV. THE PROBABLE EXISTENCE OF A NEW INTERMEDIATE, "METAL HALYL," IN THE REACTION

BY AVERY A. MORTON AND JOSEPH R. STEVENS

RECEIVED NOVEMBER 6, 1931

PRINTED MAY 7, 1932

The action of an alkali metal on a halogenated hydrocarbon has commonly been explained by assuming the intermediate formation of either a metal alkyl or aryl,¹ or a free hydrocarbon radical.^{1e,2} The idea of an earlier stage in which the metal is attached to the organic halide in a complex has received scant attention.³ Having made a study on this point we shall present herein experiments for which a reasonable interpretation lies in the assumption of such an intermediate compound. As examples we have observed the behavior of sodium with chlorobenzene, bromobenzene, and butyl chloride. The complexes assumed to occur may be designated as chlorobenzene sodium,⁴ bromobenzene sodium, and butyl chloride sodium, respectively. Because of certain analogies with the metal ketyls, to be pointed out in the following paragraphs, we shall consider these complexes as belonging to a new class of compounds to be called "Metal halyls."

Evidence for the above is found in the action of sodium on triphenylchloromethane carried out, on the one hand, in the presence of benzophenone or tetraphenylethylene and, on the other, in the presence of chloro- or of bromobenzene. When sodium is allowed to stand with triphenylchloromethane in benzene or ether solution no reaction occurs, but if benzophenone is added, the sodium first combines with the ketone, as shown by the color change, forming the metal ketyl, which in turn reacts with triphenylchloromethane to produce triphenylmethyl, sodium chloride and benzophenone. In other words, the benzophenone has acted as a carrier of sodium to triphenylchloromethane. A similar result is obtained

¹ For example see (a) Acree, *Am. Chem. J.*, **29**, 588 (1903); (b) Schorigin, *Ber.*, **41**, 2717 (1908); (c) Goldschmidt and Schön, *ibid.*, **59**, 948 (1926); (d) Ziegler and Coloni, *Ann.*, **479**, 135 (1930); (e) Schlubach and Goes, *Ber.*, **55**, 2889 (1922).

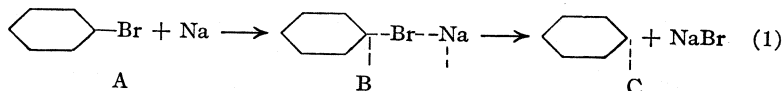

² For example see (a) Marvel, Hager and Coffman, *THIS JOURNAL*, **49**, 2323 (1927); (b) Bachmann and Clarke, *ibid.*, **49**, 2089 (1927).

³ The formation of the blue color in the Wurtz-Fittig reaction has received considerable attention from investigators. Among others Krafft and Göttig, *Ber.*, **21**, 3187 (1888), discuss the formation of a complex. Schlubach and Goes^{1e} find no evidence for organic matter in the blue compound. Wooster, *THIS JOURNAL*, **51**, 1856 (1929), interprets certain statements by Schmidlin in "Das Triphenylmethyl" as referring to the formula C_6H_5NaBr . Staudinger, *Z. Elektrochem.*, **31**, 549 (1925), has advanced the idea of a "Mol-Halogenide" as an intermediate product to account for the explosive nature of mixtures of alkali metals and certain halides.

⁴ In naming the organic metal compounds we have adopted the recent practice of putting the metal last.

when tetraphenylethylene is substituted for benzophenone. The sodium first adds to the ethylenic linkage from which position it reacts with triphenylchloromethane forming triphenylmethyl, and regenerating tetraphenylethylene. It is clear that the initial step in each of these cases has been the addition of sodium to a polar atom, after which the metal is able to act upon the triarylchloromethane.

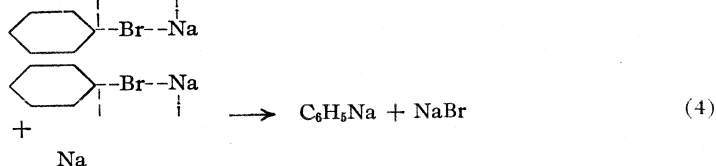

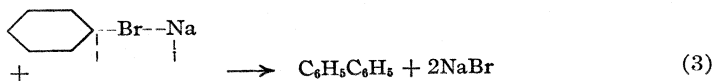

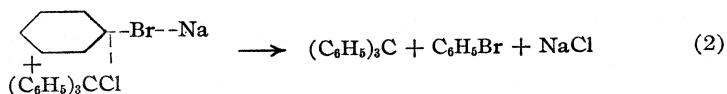

Chloro- or bromobenzene acts similarly to benzophenone or tetraphenylethylene in causing sodium to attack triphenylchloromethane.⁵ We can assume, therefore, that sodium first attaches itself to the polar atom in chlorobenzene, forming a "Sodium Halyl," but before sufficient time has elapsed to remove completely the halogen from the phenyl radical, as in a Fittig synthesis, the complex meets a molecule of triphenylchloromethane and reacts with the latter forming triphenylmethyl. The only difference between benzophenone and tetraphenylethylene on the one hand, and chloro- or bromobenzene on the other, is that the former substances have no atoms which can be removed readily by sodium, whereas the latter will, if given time, lose their halogens completely to the alkali metal. Let us express the action of sodium on bromobenzene as in equation (1). "B" illustrates the complex designated as a "Sodium halyl." The dotted lines

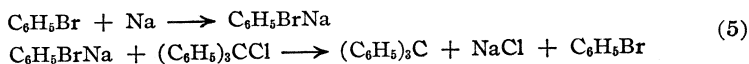

represent partial valences, some of which serve to bind the phenyl radical and the sodium to the polar atom, bromine, and others are unsaturated, representing unused combining power.⁶ These free partial valences enable the complex to react either with a molecule of triphenylchloromethane forming triphenylmethyl, equation (2); or with another complex of the same kind forming diphenyl, equation (3); or with an atom of sodium forming phenylsodium, equation (4). If left to itself the complex will eventually form the free radical, phenyl, and sodium bromide as shown in stage C, equation (1).

⁵ We wish to acknowledge our indebtedness to Professor Norris for calling to our attention the fact that Norris and Sanders, *Am. Chem. J.*, 25, 58 (1901), observed the formation of triphenylmethyl from triphenylchloromethane and bromobenzene in the presence of sodium. This fact has been the basis for the experiments described in this paper.

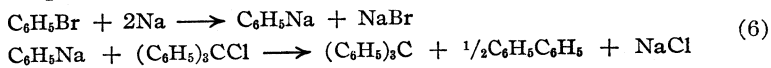

⁶ We recognize that it is possible to picture the complex by an associated molecule, a quinoid compound, or some electronic idea. One might also think of the complex as in a dormant state, awaiting the acquisition of sufficient energy to change to the state C; or as in a continual state of change due to the pulling action of the phenyl radical and the sodium atom for the bromine, as if in a tug of war. These interesting speculations are beyond the scope of this paper. We have adopted a form of writing this complex which expresses in the simplest manner possible the reactions and resemblances to the metal ketyls.

If such a picture of the role of the halide as a carrier of sodium is correct, the chloro- or bromobenzene should be recovered at the end practically unchanged. We have been able to test this hypothesis quantitatively by comparing the amounts of sodium chloride and bromide formed in the reaction of sodium on triphenylchloromethane in the presence of bromobenzene. If the reaction proceeds by the intermediate formation of the "Sodium halyl" which later gives up its sodium as shown in equation (5), sodium chloride will be formed exclusively. If, on the other hand,

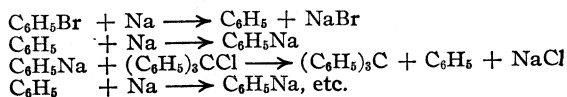

the reaction occurs through the formation of phenylsodium as shown in equation (6), sodium chloride and sodium bromide must be formed in equivalent quantities. Ideal conditions, naturally, will never exist as some

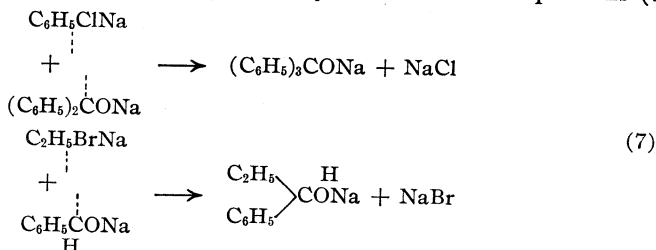

sodium bromide will result from a Fittig reaction. As we increase the concentration of triphenylchloromethane, however, the ratio of chloride to bromide formed will approach 100% sodium chloride if the "Sodium halyl" is the intermediate, and will approach only 50% sodium chloride if phenylsodium is the agent. It is apparent from the analyses of the halides (see Fig. 1), that the quantity of sodium chloride is well above the 50% line demanded by equation (6) and under favorable conditions reaches nearly 88% of the total halides formed. This result shows conclusively that the two are not formed in equivalent quantities and suggests that the probable⁷ course is through the formation of a "Sodium halyl."

⁷ It is still possible, of course, to write the changes using a free phenyl radical as an intermediate. Thus

However, it is exceedingly unlikely that a free phenyl radical would continue such a role

Application of these ideas to some of the reactions which we have discussed in previous papers⁸ of this series may be made as in equations (7).

In drawing conclusions as to the mechanism of reactions in which sodium is involved, it will be necessary in the future to distinguish more closely

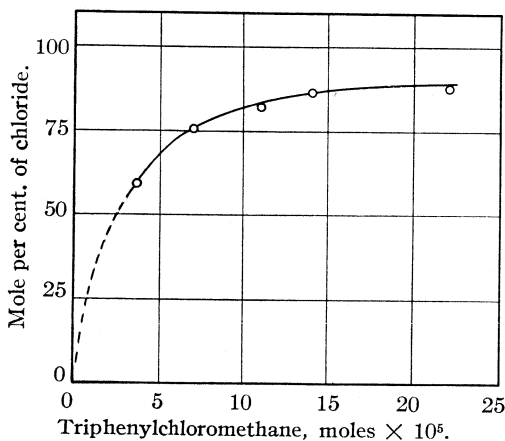

Fig. 1.

form triphenylmethyl. Further studies are being made.

Experiments

The Action of Sodium on Triphenylchloromethane in the Presence of Benzophenone.—Triphenylchloromethane, 2 g., and benzophenone, 1 g., dissolved in 25 cc. of anhydrous ether were put into a closed tube with a small lump of sodium. The surface of the sodium became coated with the blue color of benzophenone ketyl but the solution was yellow from the formation of triphenylmethyl. When air was admitted triphenylmethyl peroxide precipitated. It was identified by means of a mixed melting point. When a similar reaction mixture was allowed to stand for three days it went through the stages of formation of benzophenone sodium ketyl which was blue on the surface of the sodium, triphenylmethyl which was yellow in solution, triphenylmethyl sodium as the solution became red, and finally the blue of benzophenone sodium in solution. All of these changes were clearly evident. After treating the reaction mixture with water as a carrier of sodium when it could even more readily react with triphenylchloromethane and with itself.

⁸ THIS JOURNAL, 53, 2244, 2769, 4028 (1931).

and evaporating the ether, the residue was dissolved in benzene and shaken with concentrated sulfuric acid several times to remove all of the peroxide and carbinol present. A mixture of hydrocarbons was obtained from the benzene layer. This mixture was washed twice with hot acetone to remove any triphenylmethane present. The mixture melted up to 185°. The amount present was very small but it is possible that some hydrocarbon was formed other than triphenylmethane and *p*-benzhydryltetraphenylmethane.

The observation of Schlenk and co-workers,⁹ that benzophenone sodium added to triphenylchloromethane should cause the formation of triphenylmethyl, was confirmed. The blue color of the ketyl was instantly discharged and the yellow color of triphenylmethyl appeared. From the mixture the peroxide was precipitated when air was admitted.

The Action of Sodium on Triphenylchloromethane in the Presence of Tetraphenylethylene.—To a solution of 0.25 g. of triphenylchloromethane in 10 cc. of ether in contact with 0.25 g. of sodium was added 0.25 g. of tetraphenylethylene.¹⁰ The solution became yellow, indicating the formation of triphenylmethyl. When air was admitted triphenylmethyl peroxide was precipitated. It was identified by a melting point and a mixed melting point.

The Action of Sodium on Triphenylchloromethane in the Presence of Chlorobenzene, Bromobenzene or Butyl Chloride.—To a solution of triphenylchloromethane, 0.2 g. in 20 cc. of anhydrous benzene in contact with 1 g. of sodium, was added 5 g. of chlorobenzene. The yellow color of triphenylmethyl formed easily. When air was let into the tube triphenylmethyl peroxide precipitated. Similar experiments with bromobenzene and with *n*-butyl chloride gave the same results. A blank experiment of triphenylchloromethane with sodium in benzene showed that no triphenylmethyl had formed after the mixture had stood for sixty days.

The Action of Phenylsodium on Triphenylchloromethane.—Two grams of triphenylchloromethane in benzene was added to a suspension of phenylsodium in benzene, made from 2 g. of diphenyl mercury and an excess of sodium wire. Heat was evolved and a strongly colored solution of triphenylmethyl was formed. When air was admitted the peroxide precipitated and was identified by means of a mixed melting point. On evaporation of the mother liquors a small amount of a gummy material remained in which no evidence of tetraphenylmethane could be found. Our original purpose in this experiment was to observe if a different product was formed when the metal aryl was an intermediate in the reaction. The failure to find tetraphenylmethane led to an investigation of the relative quantities of chloride and bromide formed when triphenylchloromethane reacts with sodium in the presence of bromobenzene.

The Determination of the Amount of Sodium Bromide and Sodium Chloride Formed in Mixtures of Triphenylchloromethane and Bromobenzene.—A number of experiments were made in which mixtures of triphenylchloromethane and bromobenzene in 10 cc. of benzene were allowed to stand in contact with very nearly enough sodium to combine completely with all of the bromine in bromobenzene. The quantity of triphenylchloromethane was varied. When the sodium had disappeared the tube was opened and the solid material filtered. After washing the solid twice with considerable anhydrous warm benzene to remove any triphenylchloromethane present, it was washed with anhydrous petroleum ether and dried. The halides were then dissolved in water and filtered through the same filter to remove the small quantity of organic insoluble material which was present. After acidification with nitric acid, a portion of the filtrate

⁹ Schlenk and Thal, *Ber.*, **46**, 2854 (1913); Schlenk and Ochs, *ibid.*, **49**, 612 (1916).

¹⁰ Schlenk and Mark [*ibid.*, **55**, 2289 (1922)] added tetraphenylethylene sodium to triphenylchloromethane forming triphenylmethyl.

was treated with an excess of standard silver nitrate solution. The mixture of silver halides was filtered, washed, and weighed. The excess of silver nitrate was titrated with potassium thiocyanate solution using ferric alum as an indicator. From the volumetric results the number of moles of silver halides precipitated could be determined, which value, with the grams of silver halides from the gravimetric analysis of the same sample, enabled one to calculate the moles of chloride and of bromide present. Table I summarizes the results of these calculations.

TABLE I

GRAM ATOMS OF SODIUM, 0.004; MOLES OF BROMOBENZENE, 0.0048; CC. OF BENZENE, 10

Triphenyl- chloro- methane, mole	Silver nitrate equivalent to silver halide precipitated, cc. of 0.0918 <i>N</i> solution	Silver halide, grams	Moles of bromide $\times 10^5$	Moles of chloride $\times 10^5$	Mole per cent. of chloride
0.0036	19.93	0.2951	74.2	108.8	59.4
.007	20.74	.2935	45.5	144.9	76.0
.011	24.38	.3392	40.3	183.5	82.1
.014	23.09	.3166	29.0	183.0	86.3
.022	20.76	.2836	23.2	167.4	87.9

In order to make sure that triphenylchloromethane did not react with the sodium bromide formed during the reaction, a blank test was made by allowing a mixture of 0.0061 mole of triphenylchloromethane to remain in contact with 0.009 mole of sodium bromide under conditions comparable to those in which the action of sodium has been observed. From this mixture the halides obtained by the method given above were found in two separate determinations to be 99.8 and 100.6% sodium bromide.

Conclusions

Chlorobenzene, bromobenzene and butyl chloride have been shown to act as carriers of sodium to triphenylchloromethane, in which respect they are similar to benzophenone and tetraphenylethylene.

Analyses of the halides formed in the reaction of sodium with triphenylchloromethane in the presence of bromobenzene shows that sodium chloride is formed to a greater extent than sodium bromide.

The above facts are interpreted as indicating the formation of a complex between sodium and bromobenzene. Complexes of this type are designated as "Metal halyls" because of their similarity to metal ketyls.

The position of the "Metal halyl" as an intermediate first step in the formation of a free hydrocarbon radical and metal alkyls or aryls is discussed.

THREE NEW DERIVATIVES OF *d*-GLUCOHEPTULOSE¹

By W. C. AUSTIN

RECEIVED NOVEMBER 9, 1931

PUBLISHED MAY 7, 1932

In 1930 the writer,² in association with Hudson, described the preparation of a new crystalline ketoheptose, *d*-glucoheptulose, from *d*- α -glucoheptose following rearrangement of the latter with dilute alkali. The *d*-glucoheptulose was reported to have a rotation of $[\alpha]_D^{20} + 67.5^\circ$, without mutarotation. In order to determine whether the *d*-glucoheptulose exists in the alpha or beta form it became necessary to prepare the methyl-*d*-glucoheptuloside from it. By heating *d*-glucoheptulose in methyl alcohol containing 1% of dry hydrogen chloride there was formed the crystalline α -methyl-*d*-glucoheptuloside, of $[\alpha]_D^{20-25} + 108.5^\circ$ in water, melting at $138-140^\circ$. It will be shown later in this article that the rotation of this derivative proves that the *d*-glucoheptulose exists in the alpha form.

By acetylating the α -methyl-*d*-glucoheptuloside with acetic anhydride and sodium acetate, the α -methyl-*d*-glucoheptuloside pentaacetate has been prepared in crystalline form. This second new derivative of *d*-glucoheptulose has been recrystallized to constant specific rotation, $[\alpha]_D^{20-25} + 78.5^\circ$, in chloroform, with m. p. 110° .

The acetylation of *d*-glucoheptulose with acetic anhydride and sodium acetate has given the crystalline *d*-glucoheptulose α -hexaacetate, which has been purified to constant specific rotation, $[\alpha]_D^{20-25} + 87.0^\circ$, in chloroform, with m. p. 112° .

Calculation of the Rotations of the Beta Forms of the above Derivatives of *d*-Glucoheptulose.—The rotations of the above alpha forms of the three derivatives of *d*-glucoheptulose will now be examined in connection with those of α -methyl-*d*-fructoside and its tetraacetate, recently described by Schlubach and Schröter.³ These workers have called attention to the fact that the values of the rotations of the end asymmetric carbon atoms may now be calculated for these derivatives of *d*-fructose by the application of the rule of Hudson,⁴ taking one-half the difference between the molecular rotations of the alpha and beta isomers. The β -methyl-*d*-fructoside and its tetraacetate, beta isomers of the two alpha compounds recently prepared by Schlubach and Schröter, were made in 1916 by Hudson and Brauns.^{5a} The alpha and beta forms of *d*-fructose penta-

¹ Announced, in part, on the program of the meeting of the American Chemical Society in Minneapolis, Minn., Sept. 9-13, 1929. The author desires to thank Mr. B. J. Gregory for valuable technical assistance.

acetate were also prepared by Hudson and Brauns^{5b} and furnish values of rotations for determining the value of the end asymmetric carbon atom in the *d*-fructose pentaacetate. The determinations on the three pairs of isomers are shown in Table I for these fructose derivatives. For purposes of comparison the corresponding values given by Hudson⁶ for the aldoses are also given in the tabulation.

TABLE I
VALUES OF THE COEFFICIENT a_{Me} , A_{Me} AND A_{Ac} IN THE FRUCTOSE SERIES

Substance	Mol. wt.	$[\alpha]_D^{20}$ in water	$[M]_D$	Rotation of end Carbon, A	A for correspond- ing derivatives of aldoses
α -Methyl- <i>d</i> -fructoside	194	+ 46.0°	+ 8,900	$a_{Me} = 21,200$	$a_{Me} = 18,700$
β -Methyl- <i>d</i> -fructoside	194	-172.7°	-33,500		
Tetraacetates of		$[\alpha]_D^{20}$ in $CHCl_3$			
α -Methyl- <i>d</i> -fructoside	362	+ 45.5°	+16,850	$A_{Me} = 31,050$	$A_{Me} = 26,900$
β -Methyl- <i>d</i> -fructoside	362	-125.0°	-45,250		
Pentaacetates of					
α - <i>d</i> -Fructose	390	+ 34.7°	+13,533	$A_{Ac} = 30,458$	$A_{Ac} = 19,100$
β - <i>d</i> -Fructose	390	-121.5°	-47,384		

Schlubach and Schröter have called attention to the fact that the values of a_{Me} and A_{Me} are greater for the derivatives of fructose than for the corresponding derivatives of aldoses. Differences of the same nature are observed in comparison of the value A_{Ac} from derivatives of fructose with that from derivatives of aldoses. The reason for these differences between the corresponding coefficients of fructose and the aldoses is not definitely known. The differences may be due to the fact that the end asymmetric carbon atom in fructose is attached to $-CH_2OH$ or to $-CH_2OR$ instead of to $-H$, as in the aldoses and their derivatives. The attachment of additional weight to the end asymmetric carbon in the fructose series may cause its rotation to be larger than in the aldose series; this explanation would lead one to expect that the rotation coefficients of the fructose series will be found to apply in other 2-ketose series. For the present it is assumed that the values of a_{Me} , A_{Me} and A_{Ac} are the same in the fructose and glucoheptulose series on account of the like groups attached to carbon 2 in these ketoses.⁷ The values of the rotations of the unknown beta isomers of the three known alpha derivatives of *d*-glucoheptulose may now be calculated by deducting from the molecular rotation of the alpha isomer twice the value of the rotation of the end asymmetric carbon atom for the corresponding derivative of fructose and dividing the difference so obtained by the molecular weight of the beta isomer.

The value of the $[M]_D$ of α -methyl-*d*-glucoheptuloside is (+108.5°)

⁶ Hudson, THIS JOURNAL, 48, 1428 (1926).

⁷ I am indebted to Dr. C. S. Hudson for the suggestion that the coefficients of the fructose series may apply to the series of the 2-ketose sugars in general.

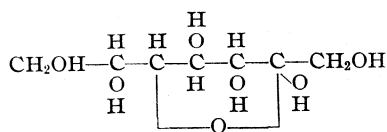

(224) = +24,300. The value of $2a_{Me}$ from the fructose series is +42,400, and the difference is -18,100, which is the calculated $[M]_D$ for β -methyl-*d*-glucoheptuloside. The corresponding specific rotation is $[\alpha]_D = -18,100/224 = -81.0^\circ$.

The value of the $[M]_D$ of α -methyl-*d*-glucoheptuloside pentaacetate is (+78.5°) (434) = +34,069. The value of $2A_{Me}$ from the fructose series is +62,100, and the difference is -28,031, which is the calculated $[M]_D$ for β -methyl-*d*-glucoheptuloside pentaacetate. The corresponding specific rotation is $[\alpha]_D = -28,031/434 = -64.6^\circ$.

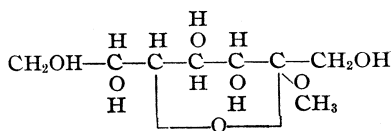

The value of the $[M]_D$ of *d*-glucoheptulose α -hexaacetate is (+87.5°) (462) = +40,424. The value of $2A_{Ac}$ from the fructose series is +60,917, and the difference is -20,493, which is the calculated $[M]_D$ for *d*-glucoheptulose β -hexaacetate. The corresponding specific rotation is $-20,493/-462 = -44.3^\circ$.

On page 1928 the rotation of the unknown beta form of *d*-glucoheptulose is calculated by a slightly different method.

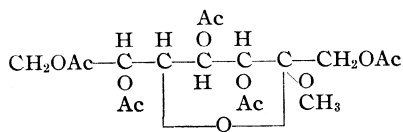

The Ring Structure of the Derivatives of *d*-Glucoheptulose.—In the article describing the preparation of *d*-glucoheptulose, shown as structure I, evidence was given that the new sugar contained the 2,5 ring. Proof may now be advanced that the ring structure of the derivatives of *d*-glucoheptulose is also 2,5, and that the structures of the new derivatives are those represented in II, III and IV.

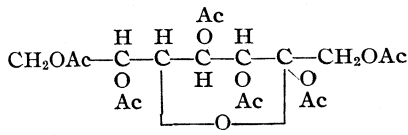

I
d-Glucoheptulose(2,5)

II
 α -Methyl-*d*-glucoheptuloside(2,5)

III
 α -Methyl-*d*-glucoheptuloside
pentaacetate(2,5)

IV
d-Glucoheptulose α -hexaacetate(2,5)

In each of the structures shown the asymmetric carbon atoms (Nos. 3, 4, 5 and 6) have the same configurations as the corresponding asymmetric carbon atoms (Nos. 2, 3, 4 and 5) of *d*-glucose, or the corresponding derivative of this sugar with the 1,4 ring. The rotations of *d*-glucose and its derivatives with this ring have not been measured because the substances are not known, but the values of the rotations have been calculated by Hudson.⁸ Using the values for the corresponding derivatives of *d*-glucose-

⁸ Hudson, THIS JOURNAL, 48, 1434 (1926); 52, 1680 (1930).

(1,4) it should be possible to calculate the rotations of the derivatives of *d*-glucoheptulose, with the same type of ring(2,5).

Hudson has calculated for the α -methyl-*d*-glucoside(1,4) the rotation $[\alpha]_D +114^\circ$, or $[M]_D (+114^\circ) (194) = +22,120$. By subtracting from the $[M]_D$ of this compound the value of a_{Me} for aldoses, $+18,700$, there is obtained the value of $B_{d\text{-glucose}(1,4)} = +3420$. The $[M]_D$ for α -methyl-*d*-glucoheptuloside(2,5) should be the value $B_{d\text{-glucose}(1,4)}$ plus a_{Me} from the fructose series, $+21,200$, giving $+24,620$. The corresponding $[\alpha]_D$ value is $+24,620/224 = +110^\circ$. This calculated value is so near the observed value of $+108.5^\circ$ that it may be safely concluded that the α -methyl-*d*-glucoheptuloside is an alpha form and has the 2,5 ring.

Haworth and Porter⁹ have prepared α -ethyl-*d*-glucoside(1,4) and β -ethyl-*d*-glucoside(1,4), with $[\alpha]_D$ values of $+98$ and -86° , respectively. By taking one-half the sum of the values of the $[M]_D$ of these compounds, $+20,384$ and $-17,888$, the value of $B_{d\text{-glucose}(1,4)}$ is obtained $= +1248$. The $[M]_D$ of α -methyl-*d*-glucoheptuloside(2,5) should be the value of $B_{d\text{-glucose}(1,4)}$ plus a_{Me} from the fructose series, $+21,200$, giving $+22,448$, which corresponds to the $[\alpha]_D$ value of $+100^\circ$. By subtracting from the value of $B_{d\text{-glucose}(1,4)}$ the value of a_{Me} from the fructose series the $[M]_D$ of β -methyl-*d*-glucoheptuloside(2,5) is found to be $-19,952$, corresponding to the $[\alpha]_D$ value of -89° . The differences of 8° between the values calculated by this method and the values found for the α -methyl-*d*-glucoheptuloside(2,5), or calculated for the β -methyl-*d*-glucoheptuloside(2,5) by the method on page 1926, are not in conflict with the conclusions from the calculations in the preceding paragraph and are due to the slight differences in the values of $B_{d\text{-glucose}(1,4)}$ as calculated from the data of Hudson or from the observations of Haworth and Porter.

The specific rotation of the α -methyl-*d*-glucoheptuloside pentaacetate(2,5) may be calculated similarly. The $[M]_D$ of the corresponding compound of *d*-glucose(1,4) is $(+83^\circ) (362) = +30,046$. From this value of $+30,046$ the value of A_{Me} for aldoses, $+26,900$, is subtracted to give the value $B_{d\text{-glucose}(1,4), Ac} = +3146$. By adding the value of A_{Me} for ketoses, $+31,050$, to the value of $+3146$ there is obtained the $[M]_D$ value for the α -methyl-*d*-glucoheptuloside pentaacetate(2,5) $= +34,196$. The corresponding $[\alpha]_D$ value is $+34,196/434 = +78.8^\circ$. This calculated value for the derivative with the 2,5 ring is so near the observed value of $+78.5^\circ$ that the 2,5 ring is also assigned to the α -methyl-*d*-glucoheptuloside pentaacetate.

The specific rotation of the *d*-glucoheptulose α -hexaacetate(2,5) may be calculated in the following manner. The $[M]_D$ of *d*-glucose pentaacetate is obtained, $(+55^\circ) (390) = +21,450$. From this value of $+21,450$ is subtracted the value of A_{Ac} for aldoses, $+19,100$, giving the value of $B_{d\text{-glucose}(1,4), Ac} = +2350$. Adding to the value of $+2350$ the value

⁹ Haworth and Porter, *J. Chem. Soc.*, 2796 (1929).

of A_{Ac} from the fructose series, +30,458, there is obtained the value of +32,808, the calculated $[M]_D$ for *D*-glucoheptulose α -hexaacetate-2,5. The corresponding $[\alpha]_D$ value is $+32,808/462 = +71^\circ$. This value of $+71^\circ$ is lower than the observed value of $+87.5^\circ$, but not sufficiently different to indicate any ring but the 2,5 type in the hexaacetate. In consideration of the values of the rotations of the basal acetylated chains in derivatives of *D*-fructose and of *D*-glucoheptulose the observation has been made that the values are larger in the pentaacetates of fructose and in the hexaacetates of *D*-glucoheptulose than in the methylfructoside tetraacetates and methyl-*D*-glucoheptuloside pentaacetates by 2725 and 6896. At present no valid explanation can be given for the abnormally large value calculated for $B'_{d\text{-glucoheptulose}(2,5), Ac}$ from the hexaacetates. The question of the differences in the values of the basal acetylated chains is one peculiar to the 2-ketose sugars and can only be solved by the preparation and study of corresponding derivatives of other 2-ketoses. It is interesting to note that, using the value $B_{d\text{-glucoheptulose}(2,5), Ac} = +3019$ (one-half the sum of the values of $[M]_D$ from the methyl-*D*-glucoheptuloside pentaacetates), one may calculate the value of the specific rotation of the α -*D*-glucose pentaacetate(1,4) by adding the value of A_{Ac} for aldoses and dividing by the molecular weight, 390, of the compound of *D*-glucose. The value calculated is $[\alpha]_D +56.1^\circ$, which is so near the value of $+55^\circ$ calculated for this substance by Hudson, from other rotations, as to warrant the suggestion that the normal value of $B_{d\text{-glucoheptulose}(2,5), Ac}$ is found by consideration of the methyl-*D*-glucoheptuloside pentaacetates rather than the hexaacetates of the ketose. The use of the value $B'_{d\text{-glucoheptulose}(2,5), Ac} = +9915$ in a similar calculation leads to the value $[\alpha]_D +74.4^\circ$ for the α -*D*-glucose pentaacetate(1,4). As there is no other evidence for the existence of an acetate of *D*-glucose of such rotation, the value of $B'_{d\text{-glucoheptulose}(2,5), Ac}$ must be considered abnormal, pending the preparation of similar acetates of other ketoses.

The above methods of allocation of ring structure in the derivatives of *D*-glucoheptulose may be applied to a determination of the ring in *D*-glucoheptulose itself. From one-half the sum of the $[M]_D$ values of the two forms of methyl-*D*-fructoside the value of $B_{d\text{-fructose}}$ is obtained, -12,300. If this value is subtracted from the $[M]_D$ value of β -*D*-fructose, -24,000, there is obtained the value A_{OH} for fructose, -11,700. The $[M]_D$ value of α -*D*-glucose(1,4), calculated by Hudson, is $(+66^\circ)(180) = +11,880$. From this value of +11,880 the value of $B_{d\text{-glucose}(1,4)} = +3380$ is obtained by subtraction of the value of A_{OH} for aldoses, +8500. Adding the values of +3380 and +11,700 there is obtained the calculated $[M]_D$ of α -*D*-glucoheptulose(2,5) = +15,080. The corresponding $[\alpha]_D$ value is $+15,080/210 = +72^\circ$. This is so near the observed rotation, $[\alpha]_D^{20} +67.5^\circ$, as to constitute further proof, independent of

that in the previous paper by the writer, that the *d*-glucoheptulose which has been synthesized is of the alpha form and contains the 2,5 ring.

The specific rotation of the β -*d*-glucoheptulose may now be calculated. The value of the $[M]_D$ of α -*d*-glucoheptulose(2,5) is $(+67.5^\circ)$ (210) = +14,175. The value of $2A_{OH}$ from the fructose series, as derived in the preceding paragraph, is +23,400, and the difference is -9225, which is the calculated $[M]_D$ for β -*d*-glucoheptulose(2,5). The corresponding specific rotation is $[\alpha]_D = -9225/210 = -44.0^\circ$.

Experimental Part

Preparation of α -Methyl-*d*-glucoheptuloside.—This substance was prepared by the method used by Fischer¹⁰ in the preparation of α -methyl-*d*-glucoheptoside. *d*-Glucoheptulose, 8.4 g. of $[\alpha]_D^{20} +67.3^\circ$, was finely powdered and dissolved, with heating, in 100 cc. of methyl alcohol containing 1 g. of dry hydrogen chloride. The solution of the sugar was accomplished in twenty minutes of heating on the steam-bath. The reaction mixture was allowed to stand at room temperature for twelve to fourteen hours and was then freed of hydrogen chloride by warming with an excess of silver carbonate and filtering. The filtrate was diluted to 150 cc. with methyl alcohol. A quantitative copper reduction test on a 5-cc. portion of this solution showed that only 3.2% of the used ketose remained uncombined. The remaining 145 cc. of solution was concentrated to a thin sirup by evaporation under reduced pressure. After holding this sirup for several days in a desiccator over calcium chloride crystal tufts appeared. On stirring these into the sirup the entire mass became semi-crystalline. This mass was dissolved in 35 cc. of warm methyl alcohol and 500 cc. of warm acetone was added. The solution was cooled to zero, decanted from an impurity of sirup and refrigerated overnight. The next day the crop of crystals, which formed as tufts of prisms, was filtered out and dried at 37° . The precipitated sirup was worked over twice by solution in methyl alcohol and dilution with acetone, followed by cooling to zero, decantation of the cleared solution, and crystallization of more of the substance by refrigeration. The three crops of material were united to give 5.5 g., 63% of the theoretical yield. This fraction was found to have $[\alpha]_D^{20-25} +109.38^\circ$ (0.6342 g. of substance in water to 25.0 cc. read $\alpha = +5.55^\circ$, using a 2-dm. tube). The material softened at 135° and melted at $138-140^\circ$. The remaining 4.9 g. was recrystallized from 20 cc. of warm methyl alcohol by the addition of 250 cc. of acetone, followed by refrigeration overnight. No sirup separated and the next day the mother liquor was decanted and the crystals washed with acetone by decantation and dried at 37° to 4.2 g. of substance, melting at $138-140^\circ$ of $[\alpha]_D^{20-25} +108.78^\circ$ (0.5890 g. substance in solution with water to 25.0 cc. read $\alpha = +5.13^\circ$, using a 2-dm. tube). These values did not change on further recrystallization and the $[\alpha]_D^{20-25} +108.5 \pm 0.5^\circ$, with melting point $138-140^\circ$, are accepted as constants for the pure substance.

Anal. Estimations of OCH_3 were made on 0.3089 and 0.2160 g. samples of the substance and gave 0.3216 and 0.2295 g. of AgI , corresponding to 13.76 and 14.04% OCH_3 . Calcd. for $C_8H_{16}O_7$: mol. wt., 224.12; OCH_3 13.84%.

The combustions¹¹ of 0.15 to 0.23 g. samples showed C, 42.93, 42.30; H, 7.57, 7.17; calcd.: C, 42.83; H, 7.19.

¹⁰ Fischer, *Ber.*, **28**, 1157 (1895).

¹¹ All of the combustions reported herein were made by the writer in the Chemical Laboratory of the College of Liberal Arts, Northwestern University, by the kind permission of Dr. C. D. Hurd.

Preparation of α -Methyl-*D*-glucoheptuloside Pentaacetate.—A mixture of 2.3 g. of pure α -methyl-*D*-glucoheptuloside, 15 cc. of acetic anhydride, and 1.5 g. of anhydrous sodium acetate was heated for one and one-half hours on the steam-bath with frequent shaking. The solution was then poured into a mixture of ice and water, 100 g. of each. The acidity of the mixture was reduced with additions of solid sodium bicarbonate. The sirup which immediately separated hardened and crystallized in thirty minutes. The next day the crystalline material was filtered out and dried at 37° to 3.5 g. Extraction of the filtrate with chloroform resulted in the recovery of 0.2 g. more of the substance, making a yield of 87% of the theoretical. The 3.5 g. of substance was recrystallized three times from solution in 10–15 cc. of absolute alcohol by the addition of 5 volumes of water to give 2 g. of substance with a melting point of 110° and a rotation of $[\alpha]_D^{20-25} +78.44^\circ$ (0.5466 g. substance in chloroform to 25.0 cc. read $\alpha = +3.43^\circ$, using a 2-dm. tube). A fourth recrystallization did not alter the value of the rotation or the melting point. Accordingly, the constants, $[\alpha]_D^{20-25} +78.5 \pm 0.5^\circ$, and m. p. 110°, are accepted for the pure α -methyl-*D*-glucoheptuloside pentaacetate.

Anal. Estimations of OCH_3 were made on 0.4120 and 0.3103 g. samples of the substance, and gave 0.2337 and 0.1749 g. AgI, corresponding to 7.50 and 7.45% OCH_3 . Calcd. for $\text{C}_{18}\text{H}_{26}\text{O}_{12}$: mol. wt., 434.2; OCH_3 , 7.14. The combustions¹¹ of 0.15 g. samples of the substance showed C, 49.67, 49.58; H, 6.12, 6.30; calcd.: C, 49.75; H, 6.04. By the directions of Kunz¹² 0.3840 and 0.4081 g. samples of the substance were equivalent to 44.04 and 46.74 cc. of 0.1 N KOH. Calcd., 44.23, 46.99 cc.

Preparation of *D*-Glucoheptulose α -Hexaacetate.—A mixture of 10 g. of finely powdered *D*-glucoheptulose with 70 cc. of acetic anhydride and 6 g. of anhydrous sodium acetate was heated for one and one-half hours on the steam-bath with frequent shaking. The dark colored reaction mixture was then poured into a mixture of ice and water, 200 g. of each. The acidity of the mixture was reduced with additions of solid sodium bicarbonate. The dark sirup which separated slowly crystallized overnight. The soft dark mass was then filtered out and dried at 50° to 10 g. This crude product was recrystallized from solution in 15 cc. of alcohol by the addition of 7 cc. of water to give 5.5 g. of material. This material was combined with 16.0 g. of similar material made from 30 g. more of the *D*-glucoheptulose. The average yield of recrystallized acetate was approximately 25% of the theoretical, much lower than the customary yield of 60% in acetylating *D*- α -glucoheptose. Extraction of all mother liquors with chloroform and carbon tetrachloride has given no evidence of the formation of isomeric acetates. The continued darkening during the acetylation by heating the reaction mixture is indicative of decomposition of the acetate. In future preparations it is hoped that shortening the period of heating will result in a larger yield of pure product. The 21.5 g. of material was recrystallized twice from solution in three times its weight of alcohol by the addition of its weight of water, and gave 20.0 g. of hexaacetate, of $[\alpha]_D^{20-25} +87.8^\circ$ (0.4907 g. substance in chloroform to 25.0 cc. read $\alpha = +3.45^\circ$, using a 2-dm. tube). The substance melted at 112°. A third recrystallization gave 17.5 g. of substance of $[\alpha]_D^{20-25} +87.08^\circ$ (0.4923 g. of substance in chloroform to 25.0 cc. read $\alpha = 3.43^\circ$, using a 2-dm. tube). The melting point was unchanged, at 112°. The values $[\alpha]_D^{20-25} +87.0 \pm 0.5^\circ$, m. p. 112°, are accepted for the pure crystalline *D*-glucoheptulose α -hexaacetate. The substance crystallizes from alcohol by the addition of water in very slender, interlaced and silky prisms. It was found that recrystallized preparations must be dried in vacuum over calcium chloride at room temperature to avoid decomposition, which is slight but detectable at 50°.

Anal. The combustions¹¹ of 0.15 to 0.22 g. samples of the substance showed C,

¹² Kunz and Hudson, THIS JOURNAL, 48, 1982 (1926).

48.94, 48.99; H, 5.72, 5.77; calcd.: C, 49.32; H, 5.67. By the directions of Kunz¹² 0.5285 and 0.4592 g. samples of the substance were equivalent to 70.18 and 61.01 cc. of 0.1 *N* KOH. Calcd., 70.20 and 61.00 cc.

The author desires to thank Dr. C. S. Hudson for his helpful interest and many valuable suggestions in connection with the above contribution.

Summary

The following three new crystalline derivatives of the ketoheptose, *d*-glucoheptulose, have been prepared and purified to constant rotation and melting point: α -methyl-*d*-glucoheptuloside, $[\alpha]_D^{20-25} +108.5^\circ$, in water, m. p. 138–140°; α -methyl-*d*-glucoheptuloside pentaacetate, $[\alpha]_D^{20-25} +78.5^\circ$, in chloroform, m. p. 110°; and *d*-glucoheptulose α -hexaacetate, $[\alpha]_D^{20-25} +87.0^\circ$, in chloroform, m. p. 112°.

d-Glucoheptulose and *d*-fructose are alike in configuration about carbon atoms No. 1 and 2, and *d*-glucoheptulose contains about carbon atoms 3, 4, 5 and 6 the same configurations as carbon atoms 2, 3, 4 and 5 of *d*-glucose. By applying to the above-mentioned rotations and those of the corresponding derivatives of *d*-glucose the rotation coefficients of the 2-ketose series (given in large part by Schlubach and Schröter from the fructose series) and of aldoses (given by Hudson) it has been shown that the new derivatives of *d*-glucoheptulose are alpha forms and contain the 2,5 ring.

The rotations of the corresponding unknown beta forms of this sugar and its derivatives have been calculated from those of the known alpha forms by applying the rotation coefficients of the 2-ketose series.

By the use of the above rotation coefficients in connection with the rotation of *d*-glucose (1,4 ring), predicted by Hudson, the rotation of the alpha form of *d*-glucoheptulose has been calculated; the fair agreement with the observed value lends further support to the conclusion in the previous paper that the ring in the known form of this ketoheptose is 2,5. Conversely, the rotations of *d*-glucoheptulose and its derivatives, containing the 2,5 ring, lend added support to the values given by Hudson for *d*-glucose and its corresponding derivatives of the 1,4 ring.

The rotations of the alpha and beta forms of methyl-*d*-glucoheptuloside-(2,5) have also been calculated by considering the rotation coefficients of the 2-ketose series in connection with the rotations of the alpha and beta forms of ethyl-*d*-glucoside(1,4), recently prepared by Haworth and Porter. These calculated rotations agree so closely with the values found, or calculated by the other methods, that they are accepted as added confirmation that the ring in these derivatives of *d*-glucoheptulose is 2,5 and corresponds to the 1,4 ring in the new ethyl glucosides of Haworth and Porter.

THE ACTION OF DILUTE ALKALI ON *d*-XYLOSE, *d*- AND *l*-ARABINOSE, *d*- α -GLUCOHEPTOSE AND *d*-GLUCOHEPTULOSE¹

BY W. C. AUSTIN, C. J. SMALLEY AND M. I. SANKSTONE

RECEIVED NOVEMBER 9, 1931

PUBLISHED MAY 7, 1932

The recent investigations of Lewis² and co-workers have aroused new interest in the Lobry de Bruyn³ conversion. Wolfrom and Lewis^{2b} found that saturated calcium hydroxide induces rearrangements in sugar structures with minimal formation of caramel and saccharinic acids. Advantage was taken of this finding by Montgomery and Hudson⁴ in the conversion of lactose to lactulose and by Austin⁵ in the conversion of *d*- α -glucoheptose to *d*-glucoheptulose. The more widely accepted theory of the mechanism of the conversion is that the reducing sugar, when dissolved in alkali, forms a common enol which then rearranges to form new reducing sugars. The new reducing sugars so formed are predominantly those differing from the starting sugar only with respect to the configurations about the first and second carbon atoms.⁶ The general structures shown in the formulas illustrate the extent and mechanism of the predominating interconversions between reducing sugars under the influence of alkali. The arrows indicate that the reactions are reversible and that the three remaining substances are formed from any one in solution with alkali.

With *d*-xylose as the starting sugar it would be expected from the above theory that a common enol would be formed by the action of the alkali and from it *d*-lyxose and *d*-xyloketose would next form to constitute an equilibrated system.

In like manner *l*-arabinose in solution with alkali would be expected to form a common enol which would form *l*-ribose and *l*-araboketose and constitute another equilibrated system. Also *d*- α -glucoheptose would be expected to form a common enol which in turn would give rise to *d*- β -glucoheptose and *d*-glucoheptulose and constitute a third equilibrated system.

Before beginning experiments with the purpose of isolating products of rearrangement of *d*-xylose and of *l*-arabinose, it was thought advisable to follow quantitatively the changes which these sugars undergo when dissolved in saturated calcium hydroxide. It was found that the rotation of a solution of *d*-xylose in this medium changed from $[\alpha]_D^{20-35} + 18.2^\circ$ to the constant value of $[\alpha]_D^{20-35} + 10^\circ$ in twenty-four hours at 30–35°. The *P_H* changed in a month of observation from 10.19 to 6.01. During this longer period the percentage of reducing pentose fell from 99.73 to 91.53% of the used *d*-xylose, while the aldose concentration decreased from 97.5 to 88.2% of the used *d*-xylose. These concentrations of reducing pentose and aldopentose indicated that at no time was more than 5% of reducing ketose evident. Solutions of *d*-xylose which have attained such equilibrium values have been freed of unchanged *d*-xylose by evaporation and crystallization, leaving sirupy residues from which as yet no *d*-lyxose or *d*-xyloketose has crystallized. One such sirup showed a rotation of $[\alpha]_D^{20-35} - 0.26^\circ$, with 118% apparent aldose pentose, with only 70% reducing pentose. When a portion of this sirup was dissolved in saturated calcium hydroxide, it changed from $[\alpha]_D^{20-35} - 0.26$ to $+2.07^\circ$ in rotation in one hundred forty-four hours.

It was found that the solution of *l*-arabinose in calcium hydroxide changed in rotation from $[\alpha]_D^{20-35} + 99.6^\circ$ to the constant value of $+62.2^\circ$ in seventy-two hours. The *P_H* changed in two months from 10.8 to 5.28. During this longer period of observation the percentage of reducing pentose fell from 94.5 to 86.4% of the used *l*-arabinose, while the aldose concentration decreased from 95.02 to 82.0% of the used *l*-arabinose. These concentrations of reducing pentose and aldopentose indicated that at no time was more than 5% of reducing ketose present. Solutions of *l*-arabinose which have attained equilibrium values have been freed of unchanged *l*-arabinose by evaporation and crystallization, leaving sirupy residues from which no *l*-ribose or *l*-araboketose has crystallized. A sirup so prepared has shown $[\alpha]_D^{20} + 4.73^\circ$ with 78.36% reducing pentose and 75.7% aldose pentose. Attempts to form the known *p*-bromophenylhydrazone of *l*-ribose from such sirups have met with uniform failure. Portions of the

sirups have been oxidized with bromine and the reaction products used in futile attempts to form the known phenylhydrazide and the cadmium salt of *l*-ribonic acid.

By solution of *d*-arabinose in saturated calcium hydroxide, the initial value of $[\alpha]_D^{20-35} - 100.4^\circ$ changed in ninety-six hours to $[\alpha]_D^{20-35} - 54.4^\circ$. Evaporation of this solution and removal of unchanged *d*-arabinose by crystallization left a sirup with the value of $[\alpha]_D^{20-35} - 7.4^\circ$. This sirup showed 74.04% of reducing pentose and 60.32% of aldopentose. A portion of this sirup was dissolved in saturated calcium hydroxide and the rotation changed very slightly in one hundred twenty hours to the constant value of $[\alpha]_D^{20-35} - 4.9^\circ$. Another portion of this sirup was seeded with *d*-ribose without any crystallization of this pentose resulting.

In contrast with the apparent lack of reversibility between *d*-xylose and its products, and between *d*-arabinose and its products, it has been found that alkali forms *d*- α -glucoheptose from *d*-glucoheptulose in a reversible manner. With either of these heptoses as the starting material in solution with alkali the final equilibrium value of $[\alpha]_D^{20-35} + 40$ to $+45^\circ$ is attained. In the equilibrium mixture from the *d*-glucoheptulose there is about 23% aldose and 77% ketose. Resaturation of such an equilibrated solution with calcium hydroxide caused the value of the $[\alpha]_D^{20-35} + 45^\circ$ to decrease further to the constant value of $[\alpha]_D^{20-35} + 36^\circ$, when the solution contained 42% aldose and 58% ketose.

Experimental Part

The Action of Dilute Alkali on *d*-Xylose.—*d*-Xylose (37.5 g. with $[\alpha]_D^{20} + 19.9^\circ$) was dissolved in calcium hydroxide solution, previously saturated at $30-35^\circ$ and filtered, to make 500 cc. of solution, half-molar in concentration of the sugar. Before the sugar was dissolved the P_H of the solution of calcium hydroxide was 12.3, determined potentiometrically with the hydrogen electrode. Five minutes after solution of the *d*-xylose in this medium the P_H was 10.19. A portion of the solution was used to fill a 2-dm. tube and found to have the value of $[\alpha]_D^{20-35} + 18.19^\circ$, five minutes after the solution of the sugar. A second portion of the solution was diluted and used for the iodine titration by the directions of Goebel,⁷ employing a fifteen-minute oxidation time. This estimation accounted for 97.56% of the used *d*-xylose, five minutes after solution. At the same time interval a portion of the diluted solution was used to estimate the total reducing pentose by the directions of Bertrand,⁸ and showed the value of 99.73% of the used *d*-xylose. The solution was preserved with xylene and kept at $30-35^\circ$. From time to time other portions of this stock solution were withdrawn for repetition of the analyses, with the addition of iodine oxidations on portions of the solution which had been denolized by the directions of Wolfrom and Lewis,^{2b} holding the sample in 2 *N* sulfuric acid for twenty-four hours before neutralization and oxidation with iodine in the usual manner. The changes in the solution are shown in Table I, and graphically in Fig. 1.

Further Studies of the Products from *d*-Xylose.—A solution, containing in 1180 cc. the products of the action of calcium hydroxide on 88.5 g. of *d*-xylose, was clarified and

evaporated to a thick sirup under reduced pressure. The sirup was diluted with 20 cc. of water and 480 cc. of hot methyl alcohol, filtered from an amorphous precipitate, and again reduced by evaporation to a sirup under reduced pressure. This sirup was thinned with 90-95% ethyl alcohol and allowed to crystallize overnight. Eighteen g. of

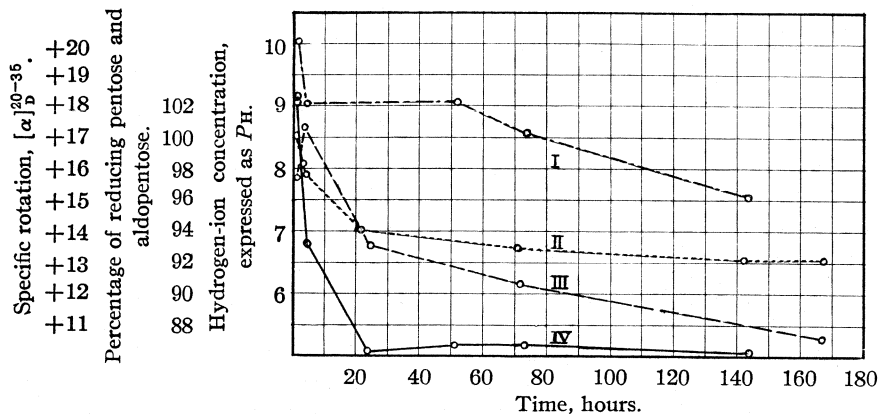

Fig. 1.—Changes in a solution of 37.5 g. of *d*-xylose in 0.04 *N* calcium hydroxide to 500 cc., at 30-35°: I, change in *P_H*; II, change in percentage of reducing pentose; III, change in percentage of aldopentose; IV, change in specific rotation, $[\alpha]_D^{20-35}$.

crude *d*-xylose was then removed by filtration. Concentration of the filtrate gave 6.0 g. more of crystalline *d*-xylose in three crops. The mother liquor of the last crop was dissolved in 50 cc. of methyl alcohol and the solution then diluted with 200 cc. of anhydrous ether. After one hour the supernatant solution was decanted from the hygroscopic brown precipitate and evaporated to a very clear and lightly colored sirup, from which 1.0 g. more of *d*-xylose was crystallized and removed. The sirup was then dried in a vacuum desiccator to 11.2 g. A sample of 1.9316 g. of the purified sirup was dissolved in water to 50 cc. A portion of this solution was saturated with calcium hydroxide and filtered into a 2-dm. tube for the reading $\alpha = -0.03^\circ$, corresponding to $[\alpha]_D^{20-35}$

-0.26° . Seventy-two hours later the value was $[\alpha]_D^{20-35} +1.67^\circ$, and in 144 hours $+2.07^\circ$. Before the solution was saturated with calcium hydroxide, the apparent aldopentose was 118.1%, with 69.37% reducing pentose. At the end of the one hundred and forty-four hour period the apparent aldopentose was 46.79%, with 45.72% reducing pentose.

The Action of Dilute Alkali on *l*-Arabinose.—*l*-Arabinose (37.5 g., $[\alpha]_D^{20} +101.5^\circ$) was dissolved in calcium hydroxide solution, previously saturated at $30-35^\circ$ and filtered, to make 500 cc. of solution, half-molar in concentration of *l*-arabinose. Before the sugar was dissolved the P_H of the calcium hydroxide was 12.3, determined potentiometrically by the hydrogen electrode method. Twenty-five minutes after solution of the sugar the P_H was 10.80. A portion of the solution was used to fill a 2-dm. tube and found to have the value of $[\alpha]_D^{20-35} +99.6^\circ$. At the same time interval a second portion of the solution was used for the iodine titration by the method of Goebel,⁷ employing fifteen minutes' time for oxidation. This estimation accounted for 95.02% of the used *l*-arabinose as aldopentose. A portion of the diluted solution was held for twenty-four hours in 2 *N* sulfuric acid, the solution then neutralized and oxidized with iodine in the usual manner. This estimation on the de-enolized sample accounted for 96.43% of the used *l*-arabinose as aldopentose. At the same time interval, twenty-five minutes after solution of the sugar, another portion of the diluted solution showed 94.56% of the used *l*-arabinose as reducing pentose, using the directions of Bertrand.⁸ The remaining solution was preserved with xylene and kept at $30-35^\circ$. From time to time portions of this stock solution were withdrawn for repetition of the mentioned examinations. The changes in the *l*-arabinose are shown in Table II, and graphically in Fig. 2.

^a $C = M/2$ solution of *l*-arabinose in 0.04 *N* calcium hydroxide. ^b Before de-enolization. ^c After de-enolization.

Further Studies of the Products from *l*-Arabinose.—Sixty grams of *l*-arabinose of $[\alpha]_D^{20} +101.8^\circ$ was dissolved in saturated calcium hydroxide solution and allowed to change to the final constant value $[\alpha]_D^{20-35} +56.7^\circ$ in seven days. The solution was then evaporated to a sirup under reduced pressure, diluted with 400 cc. of methyl alcohol, and filtered from an amorphous precipitate of 7 g. The filtrate was concentrated to a sirup again and allowed to crystallize overnight. Twenty grams of crude sugar was filtered out and recrystallized to 15.6 g. of crude *l*-arabinose of $[\alpha]_D^{20} +97.7^\circ$. From the sirup

5.2 g. more of *l*-arabinose was crystallized in three crops. The sirup was no longer crystallizable and showed the rotation of $[\alpha]_D^{20} +5.34^\circ$ (0.6544 g. in water to 25 cc. to read $\alpha = +0.28^\circ$, using a 2-dm. tube). The sirup was diluted with 300 cc. of methyl alcohol and 300 cc. of anhydrous ether and the solution then filtered with carbon from an amorphous colored precipitate of 3 to 5 g. The solution was again reduced to a sirup from which 0.6 g. more of *l*-arabinose was removed after crystallization. The residual sirup showed $[\alpha]_D^{20} +4.73^\circ$ (0.8455 g. in water to 25 cc. for reading $\alpha = +0.32^\circ$, using a 2-dm. tube). The sirup showed 78.36% of reducing pentose and 75.7% of aldopentose. The remaining 7.5 g. of the sirup was mixed with 5 g. of *p*-bromophenylhydrazine and 35 cc. of absolute alcohol. The mixture did not form any *l*-ribose *p*-bromophenylhydrazone crystals in forty-eight hours at 30–35°, as described by Fischer and Piloty.⁹ The solution was freed of alcohol by evaporation and diluted with 300 cc. of water containing 19 cc. of 50% acetic acid, 20 g. more of *p*-bromophenylhydrazine hydrochloride and 15.0 g. of sodium acetate. No *l*-ribose *p*-bromophenylhydrazone formed in one hour of

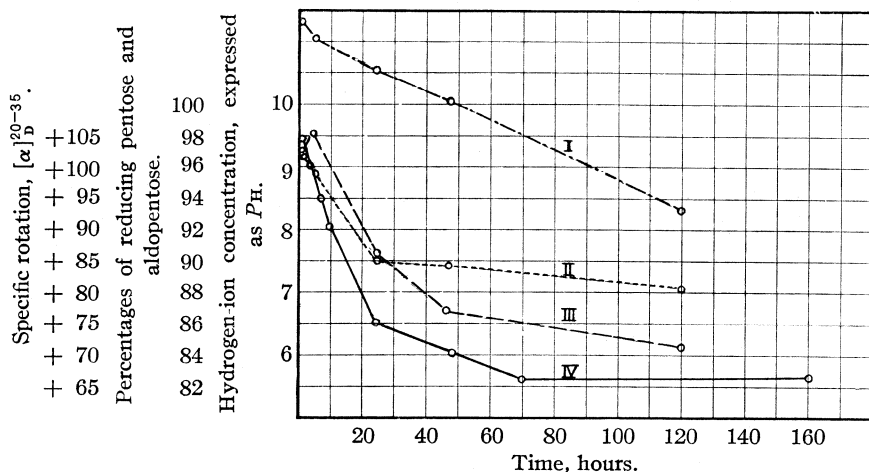

Fig. 2.—Changes in a solution of 37.5 g. of *l*-arabinose in 0.04 *N* calcium hydroxide to 500 cc. at 30–35°: I, change in P_H ; II, change in percentage of reducing pentose; III, change in aldopentose; IV, change in specific rotation, $[\alpha]_D^{20-35}$.

standing as described by van Ekenstein and Blanksma¹⁰ so 20 g. of *l*-arabinose in 30 cc. of water was added. The *l*-arabinose *p*-bromophenylhydrazone began to crystallize in two minutes. After one and one-half hours this insoluble hydrazone was filtered off and dried to 30 g., the customary yield from *l*-arabinose.

By the action of calcium hydroxide solution on 80 g. of *l*-arabinose, followed by removal of 26 g. of unchanged *l*-arabinose by crystallization, and purification of residual sirup, there was prepared 16 g. of sirup of $[\alpha]_D^{20} +10.1^\circ$. This sirup was oxidized by the directions of Hudson and Isbell¹¹ to form sugar acids of any remaining aldose and the solution freed from benzoate, bromide and silver ions. The solution of about 80 cc. was divided into two equal parts, each containing 3 to 4 g. of aldonic acids by estimate.

One portion was heated with an excess of cadmium hydroxide suspension, according to the directions of Fischer and Piloty,⁹ who have described the crystalline cadmium salt of *l*-ribonic acid. The solution was filtered from the excess of base and evaporated to a brown sirup which contained dissolved cadmium, but which has deposited no crystalline salt of *l*-ribonic acid. The second portion of the solution suspected of containing *l*-ribonic acid was evaporated on the steam-bath, after the addition of 5 g. of phenylhydrazine, to a sirup which was heated for one hour longer in an attempt to form the *l*-ribonic acid phenylhydrazide described by Fischer and Piloty.⁹ The mass deposited only a brown tarry residue on dilution with water. Attempts to crystallize material from this mass with the use of various solvents have resulted in uniform failure.

The Action of Dilute Alkali on *d*-Arabinose.—By the process of Clark¹² and Ruff,¹³ degradation of calcium gluconate with 3% hydrogen peroxide and ferric acetate, 267 g. of pure *d*-arabinose was made with a yield of 11%. The *d*-arabinose showed $[\alpha]_D^{20} -103.7^\circ$, with m. p. 154–156°. The 267 g. of the sugar was dissolved in saturated calcium hydroxide to the volume of 3780 cc. Readings on a portion of the solution, kept at 30–35°, were $[\alpha]_D^{20-35} -100.4^\circ$ after fifteen minutes, -68.2° after twenty-two hours, -55.1° after seventy hours, and constant at -54.4° after ninety-four hours. The solution was then clarified with carbon and concentrated to 170 cc. of sirup under reduced pressure. This sirup was diluted with 220 cc. of methyl alcohol and, after three days of refrigeration, filtered from 133 g. of *d*-arabinose of $[\alpha]_D^{20} -99.5^\circ$, m. p. 148–149°. The mother liquor and washes were concentrated to 75 cc., diluted with 250 cc. of methyl alcohol and saturated with 60 cc. of absolute alcohol. Two grams more of *d*-arabinose was crystallized and removed. The filtrate was seeded with *d*-ribose¹⁴ without any crystallization being induced. The solution was held in the refrigerator for several days and did not crystallize. It was then diluted to 500 cc. with methyl alcohol and a 25-cc. portion evaporated under reduced pressure in a tared beaker to a residue of 5.1804 g., indicating that 100 to 105 g. of sirup was produced from the 267 g. of *d*-arabinose by rearrangement. The 5.1804 g. of sirup was dissolved in water to 50 cc. for reading ($[\alpha]_D^{20} -6.99^\circ$, $\alpha = -1.45^\circ$, using a 2-dm. tube). Analyses of this solution showed that the sirup contained 74.04% of reducing pentose and 60.32% of aldopentose. A solution of 1.2951 g. of this sample of sirup in 25 cc. of water was saturated with calcium hydroxide and showed $[\alpha]_D^{20-35} -7.42^\circ$ fifteen minutes after saturation, -6.17° twenty-four hours later, and -4.91° , constant, one hundred and forty-four hours after saturation. The reducing pentose had decreased to 67.72% of the sample and the aldopentose to 56.49%.

The remaining larger portion of the solution of 95 to 100 g. of the sirup was evaporated under reduced pressure to a thick sirup of 90 cc. This was thinned with 35 cc. of methyl alcohol and 10 cc. of absolute alcohol and again seeded with *d*-ribose. Beyond the formation of 6 g. more of crystalline *d*-arabinose, no crystallization has occurred in three months.

The Action of Dilute Alkali on *d*- α -Glucoheptose and α -Glucoheptulose.—In order to determine whether the reaction *d*- α -glucoheptose \longleftrightarrow *d*-glucoheptulose is reversible in dilute alkali, a 10% solution of *d*-glucoheptulose in saturated calcium hydroxide was made at 30–35°. The $[\alpha]_D^{20-35}$ changed from an initial rotation of $[\alpha]_D^{20} +67.4^\circ$, the value of the ketose, to $+66.9^\circ$ in three hours, $+64.7^\circ$ in five hours, $+55.9^\circ$ in twenty-two hours, and became constant in one hundred and twenty hours at $+45.4^\circ$. An iodine estimation of aldoses in this solution showed 23% aldoses, with 77% ketoses. The remainder of the solution was resaturated with alkali and the $[\alpha]_D^{20-35}$ value decreased

¹² Clark, *J. Biol. Chem.*, **31**, 605 (1921).

¹³ Ruff, *Ber.*, **32**, 554 (1899).

¹⁴ We are indebted to Mr. F. P. Phelps, U. S. Bureau of Standards, who kindly supplied crystalline *d*-ribose for this use.

further over six days to a new equilibrium rotation of $+35.0^\circ$. The solution now showed that 42% of the ketose had been transformed to aldose capable of iodine consumption. The balance of 58% of unchanged ketose was shown by difference. These results are compared graphically in Fig. 3 with those published by Austin⁵ on the extent of change of *d*- α -glucoheptose in dilute alkali. Taken together the results indicate reversibility of the interconversion between *d*- α -glucoheptose and *d*-glucoheptulose.

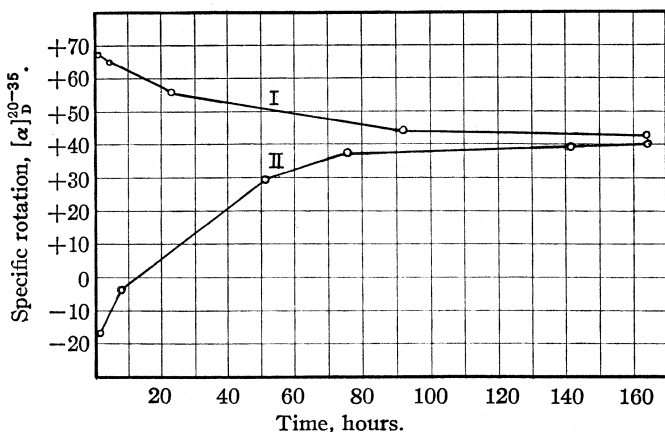

Fig. 3.—Changes in specific rotations of half-molar solutions of *d*-glucoheptulose and *d*- α -glucoheptose in 0.04 *N* calcium hydroxide, at 30–35°: I, *d*-glucoheptulose; II, *d*- α -glucoheptose.

In Table III is shown a summary of the changes observed in these sugars and their products by solution in saturated calcium hydroxide.

TABLE III
SUMMARY OF CHANGES CAUSED BY DILUTE ALKALI AT 30–35°

Substance	$[\alpha]_D^{30-35}$		Percentages of Aldose			
	Initial	Final	Reducing sugar Initial	Final	Initial	Final

<i>d</i> - α -Glucoheptose	– 20.0	+40.0			99.0	40.0
<i>d</i> -Glucoheptulose	+ 67.5	+45.0 (35) ^a			0.0	23.0 (42.0) ^a

^a The values shown in parentheses represent further changes observed after re-saturation of the equilibrated solution with calcium hydroxide.

Discussion

Assuming that *d*-xylose formed only *d*-lyxose in alkali, it was calculated that the equilibrium mixture contained about 24% of the used *d*-xylose as *d*-lyxose, from a consideration of the rotation of the system and those of the two sugars. By similar assumptions the equilibrium mixture from

l-arabinose was calculated to contain about 37% of the used *l*-arabinose as *l*-ribose. These calculations are proved to be unwarranted by the behavior of the sirups from the two pentoses and by the findings of Gross and Lewis^{2d} that polymerized xyloketose is present in the equilibrium mixture from *d*-xylose. A polymerized ketose of the nature described by Gross and Lewis would not be fully detected by the Bertrand copper reduction procedure, calculating results in terms of percentage of used *d*-xylose. The iodine titrations and copper reduction values are subject to the criticism that it is possible that still other substances than aldopentoses and reducing pentoses may have been present in small quantity to react with the reagents and introduce error. Thus Gross and Lewis have isolated the xyloketose in yield of 9.8% of the used *d*-xylose, while our results indicate that only about 5% of the used *d*-xylose was transformed into reducing ketose. Gross and Lewis have confirmed the findings of van Ekenstein and Blanksma¹⁵ that *d*-lyxose is also formed from *d*-xylose by the action of dilute alkali, although the *d*-lyxose was not crystallized as such by either group of investigators. Although Gross and Lewis have employed molar solutions of *d*-xylose for rearrangement as compared with half molar in our experiments, the final rotations and quantitative studies on each system indicate formation of mixtures of the same nature.

The apparently slight degree of reversibility between the pentoses and the sirups produced from them by the action of alkali, and the apparently large degree of reversibility between the *d*- α -glucoheptose and *d*-glucoheptulose, are indications that the composition of the equilibrium mixture is determined to a large extent by the nature of the sugar dissolved in the alkali. Spoehr and Strain¹⁶ have observed that *d*-glucose, *d*-mannose, and *d*-fructose are mutually interconvertible by the action of a weakly alkaline disodium phosphate solution. They have found, however, that the compositions of the equilibrium mixtures are determined by the nature of the sugar dissolved in the weak alkali.

Before it can be concluded that the systems *l*-arabinose \longleftrightarrow *l*-ribose and *d*-xylose \longleftrightarrow *d*-lyxose are not reversible by the action of the solution of calcium hydroxide, further experiments with *l*-ribose and *d*-lyxose as starting sugars are desirable. It is quite possible that these crystalline sugars would exhibit greater reversibility than the sirups made from *d*-arabinose and *d*-xylose have shown.

We have been unable to confirm the findings of van Ekenstein and Blanksma¹⁷ that *l*-arabinose is partially transformed into *l*-ribose in alkaline solution. These workers have heated the *l*-arabinose in normal sodium hydroxide and then oxidized the mixture to *l*-arabonic and *l*-ribonic acids.

¹⁵ Van Ekenstein and Blanksma, *Chem. Weekblad*, **11**, 182 (1914).

¹⁶ Spoehr and Strain, *J. Biol. Chem.*, **85**, 370 (1929).

¹⁷ Van Ekenstein and Blanksma, *Chem. Weekblad*, **10**, 213-214 (1913).

The *l*-ribonic acid was separated from the *l*-arabonic acid by fractional crystallization of the mixed phenylhydrazides. We have employed 0.04 *N* calcium hydroxide, removed unchanged *l*-arabinose, oxidized the remaining sirup and attempted to form by their directions the phenylhydrazide of *l*-ribonic acid without success. In the light of our further negative experiments of seeding with *d*-ribose the sirups from the rearrangement of *d*-arabinose, the different findings can at present be best explained as due to differences in the temperatures, nature of the alkali and concentrations.

The authors are pleased to note here the recent findings of Neher and Lewis¹⁸ on changes of a solution of *l*-arabinose in calcium hydroxide. Although they have studied changes in a molar solution of this sugar with respect to rotation and content of aldopentose, while we have measured changes of a half-molar solution with regard to rotation, contents of aldopentose and reducing pentose, and P_H , the results given by the two independent studies are close agreement.

The authors desire to thank Dr. C. S. Hudson for his helpful interest and valuable suggestions in connection with the above studies.

Summary

1. When a half molal solution of *d*-xylose was made in saturated calcium hydroxide at 30–35° the value of the $[\alpha]_D^{20-35}$ changed in twenty-four hours from +18.2° to the constant value of +10.2°. The P_H of the solution decreased more slowly from 10.19 to 6.01 during one month. The percentages of the reducing pentoses and of the aldopentoses decreased slowly from initial values of 99.73 and 97.5 to 91.53 and 88.20 during the month. The sirup prepared from *d*-xylose by the action of the alkali was dissolved again in calcium hydroxide solution and changed slightly from $[\alpha]_D^{20} - 0.26^\circ$ to +2.0° in one hundred forty-four hours, indicating very little reversibility toward the equilibrium value obtained from *d*-xylose.

2. When a half-molal solution of *l*-arabinose was made in saturated calcium hydroxide at 30–35°, the value of $[\alpha]_D^{20-35}$ changed in seventy-two hours from +100.0° to the constant value of +62.0°. The P_H of the solution decreased more slowly from the initial value of 10.8 to 5.28 during seventy days. The percentages of the reducing pentoses and of the aldopentoses decreased from beginning values of 94.5 and 95.0 to 86.4 and 82.0 during the seventy days. Sirups prepared from *d*- and *l*-arabinose by the action of the alkali have not been convertible to crystalline ribose, ribose *p*-bromophenylhydrazone, or to crystalline derivatives of ribonic acid (phenylhydrazide or cadmium salt). A sirup prepared from *d*-arabinose by the action of the alkali was dissolved again in calcium hydroxide solution. The $[\alpha]_D^{20-35}$ changed slightly from the initial value of

¹⁸ Neher and Lewis, *THIS JOURNAL*, **53**, 4411 (1931).

—7.5° to —5.0° during five days, indicating very little reversibility toward the equilibrium value obtained from *d*-arabinose.

3. In contrast to the very small reversibility in the pentose systems, *d*- α -glucoheptose and *d*-glucoheptulose are mutually interconvertible by the action of saturated calcium hydroxide solution to give a common equilibrium value of $[\alpha]_D^{20-35}$ of approximately 45.0°.

CHICAGO, ILLINOIS

[A COMMUNICATION FROM THE LABORATORY OF ORGANIC CHEMISTRY OF THE UNIVERSITY OF WISCONSIN]

CERTAIN FACTORS INFLUENCING THE YIELD OF GRIGNARD REAGENTS AND THE RATIO OF R_2Mg TO $RMgX$

BY GEORGE O. JOHNSON AND HOMER ADKINS

RECEIVED NOVEMBER 16, 1931

PUBLISHED MAY 7, 1932

The ratio of Grignard reagent to hydrocarbon formed in the reaction of magnesium with alkyl halides is in part determined by the presence of compounds other than the two essential components of the reaction mixture. Metallic chlorides have long been known to modify this ratio of Grignard to Wurtz reactions and more recently copper has been shown to exert a similar influence.^{1,2} It has sometimes been assumed that the hydrocarbon formation was dependent upon the reaction of the Grignard reagent with some of the alkyl halide which had not yet reacted with magnesium as illustrated in equation 1.

Equation 1 represents a reaction known to occur, for example, between allylmagnesium bromide and allyl bromide.³

It has become increasingly evident that the Grignard reagent in many cases is not exclusively or even predominantly in the form $RMgX$ but rather as R_2Mg , these compounds being in more or less stable combination with MgX_2 and the solvent.^{4,5,6,7} Therefore, a possible explanation of the effect of copper in modifying the ratio of the Grignard and Wurtz reactions is that it modifies the ratio of $RMgX$ and R_2Mg , thus increasing the amount of the former available for the reaction represented in equation 1. This explanation of the effect of copper upon the proportion of products would rest on the further assumption that R_2Mg does not react as rapidly, if at all, with RX . The foregoing hypothesis has now been tested.

The yields of active Grignard reagent and of R_2Mg for sixteen alkyl halides with pure magnesium and with magnesium-copper alloy have been determined. It has been ascertained previously that the only reactions of any consequence occurring under the experimental conditions used in this work are the Grignard reagent formation and the Wurtz reaction, so that the extent of the latter is given by the difference between 100% and the figures given for the yield of Grignard reagent, except in the case of the more inactive chlorides. The determination of the effect of various experimental conditions upon the ratio of the Grignard and Wurtz reactions was made as previously described.¹ The amount of R_2Mg in the Grignard reagent was determined in general according to the method of Schlenk as modified by Noller. A summary of the experimental data is presented in Table I. The alkyl halides have been arranged in the order of the magnitude of the effect of copper in modifying the yield of Grignard reagent.

TABLE I
THE EFFECT OF COPPER UPON THE FORMATION OF THE GRIGNARD REAGENT

Alkyl halide	Yield of Grignard reagent, %		Grignard reagent as R_2Mg , %		Effect of Cu	
	Mg (pure)	Mg-Cu	Mg (pure)	Mg-Cu	Upon total	Upon R_2Mg
Allyl bromide	72.3 \pm 0.2 (2)	5.7 \pm 2.0 (6)	49.4 \pm 3.6 (2)	-67	...
Benzyl bromide	83.8 \pm 0.2 (2)	49.4 \pm 1.9 (3)	70.5 \pm 2.5 (3)	49.2 \pm 6.6 (4)	-34	-21
Ethyl bromide	93.1 \pm 0.8 (2)	62.4 \pm 1.0 (2)	42.2 \pm 1.8 (3)	30.2 \pm 0.4 (2)	-31	-12
β -Phenylethyl bromide	91.6 \pm 0.1 (2)	73.4 \pm 1.0 (2)	76.0 \pm 2.2 (4)	75.4 \pm 2.8 (4)	-18	0
Cyclohexyl bromide	79.8 \pm 0.4 (2)	64.4 \pm 3.2 (2)	81.6 \pm 1.7 (2)	72.9 \pm 1.2 (2)	-15	-8
Isobutyl bromide	87.5 \pm 0.9 (5)	73.6 \pm 2.1 (2)	79.7 \pm 1.8 (6)	76.0 \pm 3.3 (2)	-14	-4
<i>n</i> -Butyl bromide	91.8 \pm 0.4 (2)	74.9 (1)	81.6 \pm 1.7 (2)	76.9 (1)	-17	-5
Benzyl chloride	93.6 \pm 0.7 (2)	76.5 \pm 4.0 (3)	73.4 \pm 2.5 (2)	72.8 \pm 6.1 (3)	-17	0
Ethyl iodide	86.6 \pm 2.3 (3)	72.5 \pm 1.7 (2)	6.9 \pm 2.7 (3)	5.9 \pm 1.9 (2)	-14	-1
<i>n</i> -Butyl chloride	91.3 \pm 1.0 (2)	79.5 \pm 0.5 (2)	84.2 \pm 1.5 (2)	81.6 \pm 1.6 (3)	-12	-2
<i>n</i> -Butyl iodide	82.1 \pm 0 (2)	74.3 \pm 1.1 (2)	76.7 \pm 1.4 (3)	62.6 \pm 7.9 (2)	-8	-14
<i>n</i> -Heptyl bromide	80.6 \pm 1.0 (2)	72.8 \pm 1.3 (2)	66.8 \pm 9.1 (2)	72.8 \pm 6.8 (2)	-8	+6
Phenyl bromide	94.7 \pm 0.5 (3)	92.3 \pm 1.5 (2)	75.8 \pm 2.7 (3)	81.5 \pm 3.2 (2)	-2	+6
<i>Tert.</i> -butyl bromide	23.7 \pm 1.5 (2)	27.1 \pm 1.1 (2)	39.4 \pm 2.6 (2)	39.3 \pm 2.8 (3)	+3	0
<i>Tert.</i> -butyl chloride	28.1 \pm 0.5 (2)	43.4 \pm 1.7 (2)	62.2 \pm 2.8 (3)	74.9 \pm 0.5 (2)	+15	+13
<i>Tert.</i> -amyl chloride	25.3 \pm 0.3 (2)	38.6 \pm 0 (2)	67.7 \pm 1.2 (3)	71.1 \pm 1.1 (2)	+13	+3

The effect of copper upon the course of the reaction of magnesium with the halides may be summarized as follows. The presence of copper in the magnesium decreased the yield of the Grignard reagent in the case of all of the primary and secondary halides, the depression of the yield varying from 66.6% in the case of allyl bromide to 2.4% in the case of phenyl bromide. The depressing effect of the copper was more marked with the bromides than for the chlorides, and more for the chlorides than for the iodides. Copper very definitely raised the yield of Grignard reagent from the three tertiary halides, the effect being more in the case of tertiary butyl chloride than it was in the case of the bromide. The potency of copper in depressing the Grignard reaction decreased with increasing length of chain in the alkyl halide.

The proportion of active Grignard reagent existing as R_2Mg was in nine cases very definitely modified when copper was added to the magnesium. The magnitude of the effect of copper upon the proportion of R_2Mg (column 7 of table) was in general less than it was upon the yield of Grignard reagent (column 6 of table). However, the sign of the effect, except for heptyl and phenyl bromide, was the same for both phenomena, *i. e.*, when copper brought about a considerable decrease in the yield of Grignard reagent it also brought about a decrease in the proportion of R_2Mg , and when copper increased the Grignard reaction it also increased the proportion of R_2Mg .⁸

The question now arises as to the rate at which alkyl halides react with the Grignard reagents prepared from them, and also with the corresponding solution of R_2Mg . In order to test this point Grignard reagents were prepared from twelve halides. Four aliquots were removed from each reaction mixture. The first two were analyzed for total Grignard reagent and R_2Mg , respectively. The third aliquot was treated with a small excess of the corresponding alkyl halide. An excess of alkyl halide was also added to the solution of R_2Mg from the fourth aliquot, from which the $RMgX$ had been precipitated with dioxane. The two solutions containing the allyl halide were then refluxed for ten minutes and the residual active Grignard reagent in each determined in the usual manner, *i. e.*, by hydrolyzing and titrating the basicity so developed.

TABLE II

THE EFFECT OF ADDED RX ON SOLUTIONS OF GRIGNARD REAGENTS AND OF DIALKYL MAGNESIUM

Halide	Change in amount	
	Of Grignard reagent	Of R_2Mg
Allyl bromide	-50.0 ± 3.5 (2)	-7.8 (1)
Allyl bromide ^a	-31.9 ± 3.1 (3)	-8.0 ± 1.4 (3)
Ethyl bromide	-0.7 ± 0.7 (2)	-3.9 (1)
Ethyl iodide	$+2.0 \pm 3.0$ (3)	$+3.5 \pm 3.0$ (3)
<i>n</i> -Butyl bromide	-0.2 (1)	$+1.5$ (1)
Isobutyl bromide	$+1.3 \pm 1.0$ (6)	$+1.7 \pm 1.6$ (4)
<i>n</i> -Butyl chloride	0	-4.3 (1)
<i>n</i> -Butyl iodide	$+1.8 \pm 2.0$ (4)	$+5.0 \pm 5.0$ (4)
<i>n</i> -Heptyl bromide	-1.0 (1)	...
Cyclohexyl bromide	-2.5 ± 2.0 (5)	-2.8 ± 2.2 (3)
Phenyl bromide	-0.4 ± 0.1 (2)	-3.5 ± 3.1 (2)
Benzyl bromide	-0.4 ± 0.6 (2)	...
Benzyl chloride	-5.5 ± 2.0 (6)	-3.5 ± 6.5 (5)

^a Zinc dust was added to the reaction mixture.

The data so obtained are summarized in Table II. These data show: (1) that allyl bromide reacted to a considerable extent with the Grignard

⁸ Data are not available to show what effect, if any, the concentration of the Grignard reagent in the ether has upon the ratio of R_2Mg to $RMgX$.

reagent prepared from it under the conditions under which the latter is formed; (2) that diallyl magnesium reacted very slowly, if at all, with allyl bromide; (3) that in the case of the other halides there was little if any reaction of either the Grignard reagent or R_2Mg with the corresponding alkyl halide. It is true that for certain pairs of reactants there was a decrease in the amount of R_2Mg or Grignard reagent. However, the magnitude of the changes and the variations in duplicate analyses rob these changes of any significance.

There are recorded in Table III data which indicate the effect of zinc and mercuric chloride upon the yield of Grignard reagent and the proportion of it which is in the form R_2Mg . These data show that the addition of zinc to the reaction mixture increased the yield of the Grignard reagent in the case of allyl bromide, but was without effect upon the other halides. Mer-

TABLE III
EFFECT OF VARIOUS METALLIC CHLORIDES AND ZINC UPON THE FORMATION OF THE GRIGNARD REAGENT^a

Alkyl halide	Yield of reagent, %	Reagent as R_2Mg , %	Change in yield of reagent, ^b %	Change in R_2Mg , ^b %
Allyl bromide ^d	80+2.1 (8)	46+1.2 (3)	+ 8	- 3
Ethyl iodide ^d	90	...	- 1	..
Isobutyl bromide ^e	88+0.6 (2)	76+1.0 (2)	+ 1	- 4
<i>n</i> -Butyl iodide ^e	83	61	+ 1	-15
Cyclohexyl bromide ^f	82+0.1 (2)	68	- 1	..
Cyclohexyl bromide ^g	41	53	-37	-28
Cyclohexyl bromide ^h	44	...	-20	..
<i>Tert.</i> -butyl bromide ^g	15	20	- 9	-19
Benzyl bromide ^g	90	70	+ 6	0
Benzyl bromide ^h	64	63	+14	+13
Benzyl chloride ^g	94	70 ^c	+ 1	+ 5
Benzyl chloride ^h	91+0.5 (4)	81	+12	+ 9

^a The following changes in the yield of Grignard reagents were obtained by adding approximately 0.01 g. of various chlorides to a reaction mixture containing 0.06 mole of the alkyl halide and 1.7 g. of a 12% copper-magnesium alloy: cyclohexyl bromide with ferric chloride, -29%; with aluminum chloride, -13%; with mercuric bromide, -17%; with zinc chloride, -32%; benzyl chloride with ferric chloride, -25%; *n*-butyl bromide with aluminum chloride, -1%; with magnesium bromide, +1%; with zinc chloride, -21%. ^b These figures represent the differences in percentage between the values given in columns 2 and 3 of this table, and the values given in Table I for the yield of Grignard reagent and R_2Mg obtained in the absence of mercuric chloride or zinc.

^c There is a change of several per cent. in the value when the solution is allowed to stand for from one to twenty-three hours. The percentage of R_2Mg increases and the amount of halogen in the solution decreases, due no doubt to the precipitation of $MgCl_2$. This is in agreement with Schlenk, *Ber.*, **64**, 734 (1931). ^d 0.2-0.4 g. of zinc, 6.5 g. of magnesium, 0.06 mole of alkyl halide. ^e 0.2 g. of zinc, 1.53 g. of magnesium and 0.06 mole of alkyl halide. ^f 0.2 g. of zinc, 4.0 g. of magnesium, 0.06 mole of alkyl halide. ^g 0.04 g. of mercuric chloride, 1.53 g. of magnesium and 0.06 mole of alkyl halide. ^h 0.04 g. of mercuric chloride, 1.53 g. of magnesium in an 88% magnesium-12% copper alloy, and 0.06 mole of alkyl halide.

curic chloride in some cases markedly increased the yield of Grignard reagent while with other halides the effect was the more normal one for metallic chlorides, *i. e.*, it decreased the yield. Both copper and mercuric chloride affected the proportion of Grignard reagent existing as R_2Mg . With mercuric chloride the effect upon the yield of Grignard reagent for a given alkyl halide was the same as it was upon the proportion of R_2Mg , *i. e.*, both were increased or both were decreased.

Conclusions and Summary

The yields of Grignard reagent and the proportion of dialkyl magnesium (R_2Mg) contained in each of them, as conditioned by the presence of copper, mercuric chloride, etc., have been ascertained for sixteen alkyl halides. The results so obtained and other data on certain related reactions seem to lead to the following conclusions.

1. The proportion of Wurtz and Grignard reactions which occur when an alkyl halide reacts with magnesium varies with the particular alkyl group and the halogen involved. It is also modified by the presence in the reaction mixture of small amounts of the metals copper and zinc and of mercuric and other metallic halides. The effect of copper, for example, upon the proportion of the two competitive reactions is not fixed but varies both in amount and in direction of change. For example, copper *decreased* the Grignard reaction from 72 to 6% for allyl bromide and *increased* the same reaction with *tert.*-butyl chloride from 28 to 43%.

2. The proportion of the active Grignard reagent existing as R_2Mg varies with the alkyl halide from which it is prepared, the variation being from 6% for ethyl iodide to 84% with *n*-butyl chloride. The proportion of R_2Mg is also modified by the presence of copper, mercuric chloride, etc., the variation being from a decrease of 21% in R_2Mg for benzyl bromide to an increase of 13% of R_2Mg from *tert.*-butyl chloride.

3. Those added reagents which for a given alkyl halide decrease the yield of Grignard reagent also in general decrease the proportion of the reagent existing as R_2Mg , and those reagents which for a given alkyl halide increase the yield of Grignard reagent also increase the proportion of R_2Mg in that reagent.

4. The alkyl halides except allyl bromide were quite inactive toward the Grignard reagent made from them (and also toward the R_2Mg component of that reagent) under the conditions under which the reagent is formed. It seems very improbable, therefore, that the formation of hydrocarbons (Wurtz reaction) during the reaction of magnesium with alkyl halides is dependent upon the reaction of the Grignard reagent with the alkyl halide.

THE CONSTITUTION OF ABNORMAL AMMONIUM SALTS¹

BY W. H. HUNTER AND GORDON D. BYRKIT

RECEIVED NOVEMBER 23, 1931

PUBLISHED MAY 7, 1932

Investigations of the systems in which abnormal ammonium salts are reported to exist are far from numerous. Kuriloff² studied the system, ammonium nitrate-hydrogen nitrate, and showed that the only abnormal compound was $\text{HNO}_3 \cdot 4\text{NH}_3$. Kendall and Davidson³ investigated the systems of ammonia with halogen hydrides, and demonstrated the existence of the compounds $\text{HX} \cdot 4\text{NH}_3$ in which X is chlorine, bromine and iodine and also the compound $\text{HI} \cdot 5\text{NH}_3$. These authors state that the compounds of the types $\text{HX} \cdot 2\text{NH}_3$ and $\text{HX} \cdot 7\text{NH}_3$ reported by Troost⁴ do not exist. They found no abnormal compounds in the hydrogen fluoride system and no compounds in any of these systems in which the ratio of acid to base was greater than one.

While there are, apparently, no investigations of the systems of amines with halogen hydrides,⁵ there are numerous compounds in the literature which belong to these systems. The compounds reported by Berliner and Hann⁶ of the type $\text{Base} \cdot 4\text{HF}$ are especially interesting. The bases were aromatic amines of the most diverse sorts. Three of the hydrogen fluoride molecules were "titratable with alkali" while the last was combined as the normal salt of the base. These compounds are all solids and are well characterized by elementary analysis for carbon, nitrogen and fluorine.

Most of the other compounds which are reported in the literature⁷ have been reported on the basis of absorption experiments. In general, the method was to pass the anhydrous halogen hydride over the dry normal salt until no further absorption took place at the particular temperature chosen. Kaufler and Kunz,⁸ using this method, reported a dihydrochloride

¹ The work described in this paper constituted part of a thesis submitted to the Graduate Faculty of the University of Minnesota by Gordon D. Byrkit in partial fulfilment of the requirements for the degree of Doctor of Philosophy, September, 1929. This paper was prepared by the junior author after the death of Dr. W. H. Hunter, which occurred on August 19, 1931. [L. I. SMITH.]

⁵ Except that of Leopold [*Z. physik. Chem.*, **71**, 59 (1910)] on the system aniline-hydrogen chloride. This investigation, however, is incomplete in the range 19.6 to 49.7 mole per cent. of aniline, in which abnormal compounds of the type $\text{C}_6\text{H}_5\text{NH}_2 \cdot n\text{HCl}$ ($n = 2, 3$ or 4) would occur.

of dimethylamine, liquid di- and trihydrochlorides of trimethylamine and also reported that methylammonium chloride absorbed no hydrogen chloride. This is a series of abnormal compounds in which the maximum number of halogen hydride molecules added is equal to the number of alkyl groups in the amine. The influence of alkyl groups in this case would constitute an exception to the usual view, since the effect of the type and number of alkyl (and aryl) groups on the character of the ammonium salts formed is usually very small with respect to all other properties. Except for the work of Wieland⁹ and Rheinboldt,¹⁰ who showed that the number of molecules of desoxycholic and other bile acids¹¹ which added to one molecule of fatty acids, esters, etc., was directly dependent on the number of methyl and methylene groups in the molecule, there seems to be no work indicating a relation between the size and character of alkyl groups and the additive power of the molecule.

Experimental Method

The purposes of the present investigation were two: first, to determine whether or not the compounds reported by Kaufler and Kunz exist, and, second, to investigate further the systems obtained from amines and halogen hydrides, in order to ascertain whether there is a discoverable relation between the number and nature of the groups in a substituted ammonia and the amount of halogen hydride which may be added to it. Two types of measurements accordingly were made. We determined the amounts of halogen hydride absorbed by the amines at various temperatures, and also investigated the thermal behaviors of the systems thus formed.

Preparation of Materials

Dimethylammonium Chloride.—Kahlbaum's liquid dimethylamine was dissolved in ice cold toluene and dry hydrogen chloride passed into the cold solution until precipitation was complete. The crystals were filtered off, washed with dry benzene and dried; m. p. 167°.

Trimethylammonium Chloride.—This was prepared by students from ammonium chloride and paraformaldehyde. A solution of this material was made strongly alkaline, the base distilled into concentrated hydrochloric acid and the salt crystallized out. The process was repeated and the salt recrystallized several times from water, finally being dried over anhydrous calcium chloride in a desiccator; m. p. 273–275°, with decomposition.

Tetramethylammonium Chloride.—This was prepared by dissolving dry trimethylamine in purified methanol and saturating this solution with methyl chloride. The solution was concentrated to crystallization and the product recrystallized from methanol. The salt was treated with silver oxide in aqueous solution and, on crystallizing it

from methanol, a product was obtained which gave no odor of trimethylamine with aqueous alkali.

Methylphenylammonium Chloride.—Vacuum distilled methylaniline was dissolved in dry toluene and dry hydrogen chloride passed in to complete precipitation. The salt was filtered off, washed with dry benzene, dried and recrystallized from purified acetonitrile; m. p. 123.7–124.2°.

Absorption Experiments

Dry hydrogen chloride was passed over a weighed quantity of the normal salt in a weighed absorption bulb placed in a constant temperature bath until no more absorption took place. The increase in weight is the amount of hydrogen chloride absorbed by the salt. Results, expressed as the ratio of moles of hydrogen chloride to moles of base in the saturated mixture at various temperatures, are given in Table I. In most cases the resulting product was liquid.

^a It was difficult to maintain these low temperatures constant, hence the variation in results.

Discussion of the Absorption Experiments

The data in Table I show that the amount of absorption of hydrogen chloride by the normal salts depends on the temperature; as this is lowered, the amount of absorption increases. It is true as Kaufler and Kunz state that trimethylammonium chloride absorbs two additional moles of the gas at 0°. However, since the amount of absorption shows a continuous change, so that any ratio whatever may be obtained by a proper choice of temperature, it appears that the report of the compound $(\text{CH}_3)_3\text{N} \cdot 3\text{HCl}$ is erroneous. The same authors report a dihydrochloride of dimethylamine on the basis of the amount of hydrogen chloride absorbed by the normal salt at ordinary temperatures.¹² This again seems to be a fortuitous choice

¹² Their statement⁸ “0.1624 g. Dimethylaminhydrochlorid nahmen bei gewöhnlicher Temperatur 0.971g. Chlorwasserstoff auf = 1.00 Mol HCl,” however, is erroneous either in data or calculation. The data given correspond to the absorption of 13.26 moles of hydrogen chloride by the normal salt.

of temperature since at -3.6° the normal salt absorbs 1.45 moles of hydrogen chloride or a total of 2.45 moles per mole of base.

Other salts as well show a non-stoichiometric absorption of hydrogen chloride at various temperatures. In such experiments as these we seem to be determining the solubility of hydrogen chloride in the liquid phase present, and this changes gradually with the temperature without reference to the stoichiometric relation between the two components. *At the same time, there is a strong force acting between many of these normal salts and hydrogen chloride.* Trimethylammonium chloride, especially, absorbs the gas with an avidity which is comparable only with the absorption of water vapor by potassium hydroxide.

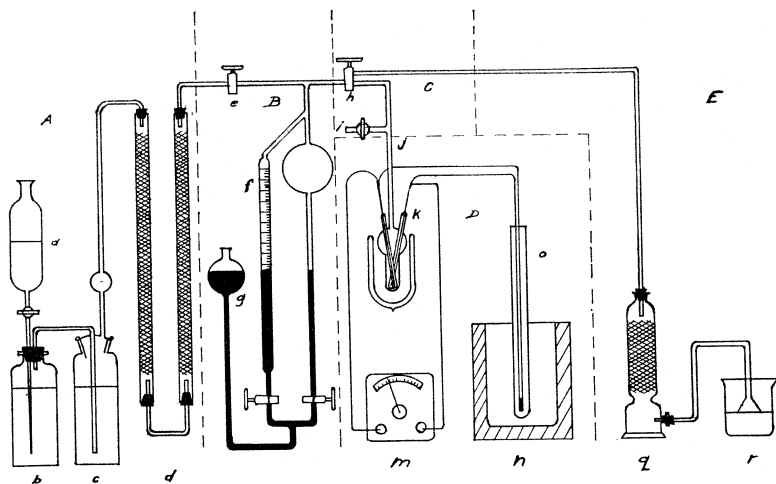

Fig. 1.

Thermal Investigation

Preparation of the Mixture.—The apparatus shown in Fig. 1 was used. The thermocouple tube, *k*, was first weighed, filled with pure normal salt,¹³ reweighed and sealed to the apparatus at *j*. Hydrogen chloride was generated in *b*. After passing through the bubbler of concentrated sulfuric acid, *c*, the gas continued through two long tubes, *d*, packed with anhydrous calcium chloride to remove oxides of sulfur. With both the buret and bulb filled with mercury and stopcock *h* opened to *E*, the system was flushed with hydrogen chloride until all the air was removed, while a water pump attached at *i* removed the air from the thermocouple tube. With *h* closed and the buret, *f*, filled with mercury, the calibrated bulb of five hundred cubic centimeters' capacity was filled with hydrogen chloride to the lower mark. With stopcocks *e* and *i* closed, *h* was opened to the bulb, *k*, which was surrounded by a Dewar flask of liquid air. Hydrogen chloride was condensed into *k* until when the stopcock, *h*, was closed and the mercury leveled, it stood at the upper mark of the calibrated bulb. The temperature and pressure were noted during this process. By using the bulb and/or buret (for quantities less than 500

¹³ On account of the great hygroscopicity of these salts, this operation was accomplished in a desiccator box.

cubic centimeters) any desired quantity of hydrogen chloride could be condensed into k, resulting in a mixture of any desired composition.

Melting Point Determination.—With stopcock h closed, the tube k was surrounded by liquid air until all of the hydrogen chloride had been condensed (five minutes was sufficient). Stopcock i was opened to the air,¹⁴ and the tube sealed off at j. The tube was then warmed until the contents were melted and thoroughly mixed. The thermocouple tube was air jacketed and fitted with the wires of the cold junction of the thermocouple while the hot junction was placed in a stirred bath of ice and water. The jacketed tube was surrounded by a cooling bath about 20° below the approximate freezing point of the mixture, and the millivoltmeter (calibrated at the freezing point of several highly purified organic liquids) was read at regular intervals. The horizontal portion of the cooling curve thus obtained represented the freezing (melting) point of the mixture and the corresponding temperature was read from the calibration chart of the thermocouple.

In cases in which the melting point of the mixture was near or above 0°, a tube without provision for the thermocouple junctions replaced k. The procedure for the preparation of the sample was precisely the same. The melting points were determined by placing the sealed tube in a stirred glycerin bath which was warmed very slowly. Several determinations, at twenty-four hour intervals, were made on each tube. The necessity for the long interval between determinations is, of course, the fact that as the temperature is raised to the melting point, hydrogen chloride passes into the vapor phase, which changes the melting point. More consistent results were therefore obtained if the contents of the tubes were allowed to return to equilibrium before a second determination was made.

The systems trimethylamine- and methylphenylamine-hydrogen chloride were investigated in this way. The results are given in Tables II and III and the corresponding Figs. 2 and 3.

¹⁴ When a tube prepared as described and surrounded by liquid air for five minutes was broken off at j and held at the mouth of a bottle of 28% ammonia, no fumes were formed; hence there was no loss of hydrogen chloride.

Investigations in the systems methylamine- and dimethylphenylamine-hydrogen chloride offered considerable difficulty and were finally laid aside. In the first case, the normal salt seemed to have no tendency to absorb hydrogen chloride and the pressures developed on warming were almost invariably greater than the glass tubes would stand. In the second case, the normal salt was too hygroscopic to be handled even in the desiccator box. Attempts to use the free base were also unsuccessful because of the high melting point of dimethylaniline (2°) which prevented the base from reacting with the hydrogen chloride as it was condensed into the bulb. Before the base was warm enough to react, the pressure of the hydrogen chloride was always sufficient to break the tube.

Discussion of Thermal Investigations

That di- and trihydrochlorides of trimethylamine do not exist is evident from the thermal diagram of the system (Fig. 2), since there are no maxima at either $66\frac{2}{3}\%$ or 75 mole per cent. of hydrogen chloride. On the other hand, it is equally evident from Fig. 3 that a dihydrochloride of methylaniline is formed. That the high point of the curve is at 69 mole per cent. hydrogen chloride rather than at $66\frac{2}{3}\%$ is to be expected because at the temperatures at which these mixtures melted, much of the hydrogen chloride was in the vapor phase. Thus, while sufficient gas had been placed in the tube to give a mixture of the composition 69% hydrogen chloride, enough was probably in the vapor phase and therefore without effect on the melting point, to reduce the amount in the solid and liquid phases to $66\frac{2}{3}\%$.¹⁵

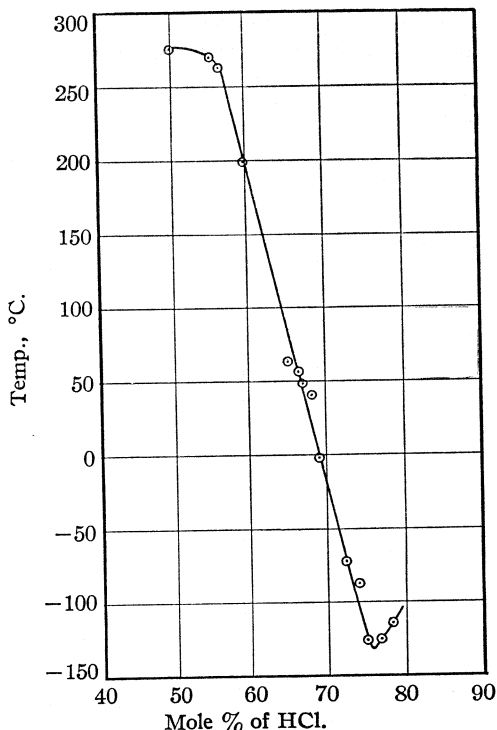

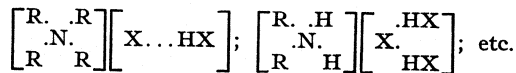

Fig. 2.—Trimethylamine-hydrogen chloride.

¹⁵ In general, the melting points below -83° (the boiling point of hydrogen chloride) are the most accurate. As the temperature of fusion rises, the observed melting points become higher and higher than they would be were all the hydrogen chloride in the solid and liquid phases. This accounts for the extreme flatness of the curves in the neighborhood of the normal salt.

A General System of Molecular Compounds of Higher Order

Werner's¹⁶ formulation of normal and abnormal ammonium salts as $[H_3N \dots H]X$ and $[H_3N \dots H \dots NH_3]X$, respectively, is usually extended in the case of abnormal salts with extra ("exo")¹⁷ acid molecules by assuming the addition of the exo molecules to the anion of the salt, thus

However, these formulas do not express experimental facts in that, while ammonium chloride does not add hydrogen chloride,¹⁸ many substituted

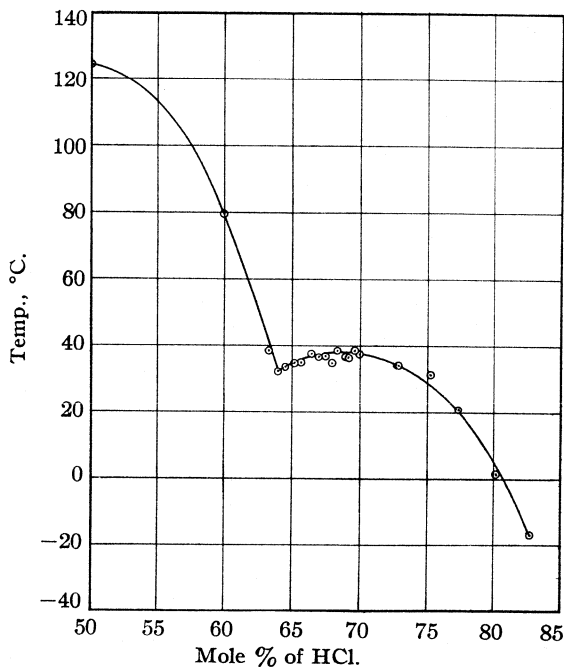

Fig. 3.—Methylphenylamine—hydrogen chloride.

ammonium chlorides do. Since the difference here is in the character of the cation of the salt, formulas for dihydrochlorides, etc., must be based on the cation of the salt, and must not involve the anionic chlorine, which is identical in both cases.

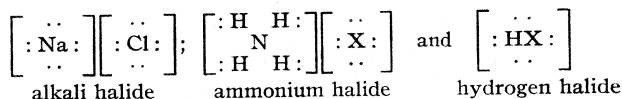

The attempt to correlate the additive properties with the change in character of the cation depends on a development of the conception of

¹⁸ Kendall and Davidson, *THIS JOURNAL*, **42**, 1141 (1920).

"pseudo atoms" of Grimm¹⁹ and Glockler.²⁰ According to these authors, the well-known similarity of the ammonium and potassium ions, the former a pseudo atom of neon and the latter of argon, lies in that the L electrons of the nitrogen atom are so altered by the sphere of four protons (which are *inside* their respective electron pairs in the ammonium ion) that they behave almost as the M electrons of the potassium ion. That neither the alkali halides nor ammonium halides add halogen hydrides, as Kendall and Davidson³ observed, is not surprising when their electronic structure is considered

In the terminology of Sidgwick,²¹ these are all donors.

However, substituted ammonium halides do absorb halogen hydride even when there is no formation of definite compounds. It is conceivable that in these the alkyl and aryl groups are of such size that in replacing the protons they so distort the electronic arrangement of the atom that some or all of the remaining protons lie without the L shell, thus

With such a configuration as this, it is possible that the protons so "extrapolated" may possess the power of coördination in quite a weakened sense. It is possible to account on this basis for the absorption of hydrogen chloride, for example, by trimethylammonium chloride, even though the additive power of the extrapolated proton is insufficient to cause the formation of a definite compound. With methylphenylammonium chloride, on the other hand, the comparatively great size of the phenyl group, together with the methyl group, makes this extrapolation so pronounced that a definite compound, $\text{CH}_3(\text{C}_6\text{H}_5)\text{NH}\cdot 2\text{HCl}$, is formed. The exo molecule is bound in the "second sphere" of Werner,²² the substituted ammonium ion acting as the center of the complex. It is possible to conceive of a third zone in which the forces available to bind additional molecules are much weaker than those of the second sphere, and may even attract molecules without binding them in a stoichiometric way.

No matter how they may be written in a Werner type formula, it seems of great importance that these compounds with exo molecules form a transition from the coördination compounds of Werner, in which groups of definite number are geometrically arranged about a central atom, to the "ion atmosphere" of Debye and Hückel, in which there is an indefinite

²² Werner-Pfeiffer, *Ref. 16*, p. 234.

"cloud" of electrostatically attracted dipole molecules or ions about another ion or about another strongly dipolar molecule. These forces are often considered to be all of the same nature, that is, electrostatic,²³ and it is on this basis that an organization of our knowledge is possible with the aid of Table IV. In the compounds of the first and second orders, the groups about the central atom, which are definite in number and position in the molecule, are held by the strong forces of primary valence in the first-order compounds and by the weaker forces of secondary valence in the second-order compounds. Intermediate between these two types are the compounds in which, while the number and position of the groups about the central atom are definite, it is difficult to say whether the groups are held by primary or secondary valence. The nitroprussides, metal carbonyls, etc., are examples.

Compounds of the third order are those in which, while the number of added molecules is stoichiometric, it is at present impossible to determine the exact arrangement of the constituents of the molecule, as in many dihydrochlorides of monacid ammonium bases. Between the second and third orders are those compounds formed by addition to molecules already coördinatively saturated, as, for example, $\text{NiCl}_2 \cdot 8\text{NH}_3$.

Those compounds in which the number of bound molecules is indefinite even though there is marked affinity between the two components (for example, trimethylammonium chloride and hydrogen chloride) lie between the compounds of the third order and the class of Debye and Hückel. In the latter there is an indefinite cloud of dipoles, which may be either oppositely charged ions or neutral molecules, about a central dipole, which again may be either an ion or a molecule. The exo compounds in which we have been especially interested include compounds of the third order and the intermediate types on both sides.

AN IMPROVED PROCEDURE FOR THE PREPARATION OF ORGANOLITHIUM COMPOUNDS

BY HENRY GILMAN, E. A. ZOELLNER AND W. M. SELBY

RECEIVED DECEMBER 4, 1931

PUBLISHED MAY 7, 1932

Introduction

The chief and outstanding chemical difference between organometallic compounds containing alkali metals and those prepared from alkaline earth metals is the general tendency of the former to add to some ethylenic linkages and the absence of such addition with organometallic compounds like the Grignard reagent. There are, of course, occasional differences in a series of organolithium compounds, for example, just as there are differences between RMgX compounds. It is reasonable to expect that, in general, the mechanisms of reaction of these two groups of organometallic compounds with a given reactant would be similar and, in many cases, identical. However, the literature contains numerous cases where the mechanism proposed with organoalkali compounds does not agree with that established with organomagnesium compounds. It was in connection with such studies, as they concern terminal cumulated unsaturated linkages and allylic systems, that we needed phenyl-lithium in quantity.

Organolithium compounds were first prepared by Schlenk and Holtz¹ by the reaction of lithium with an R_2Hg compound in accordance with this general reaction, which has recently been shown to be reversible²

The technique in this operation was subsequently improved and excellent

¹ Schlenk and Holtz, *Ber.*, 50, 272 (1917). See, also, Groll, *THIS JOURNAL*, 52, 2998 (1930).

² Ziegler and Colonius, *Ann.*, 479, 135 (1930). For other studies on the reaction between RX compounds and lithium, see Spencer and Price, *J. Chem. Soc.*, 97, 385 (1910), and Wittig and Leo, *Ber.*, 64, 2395, 2405 (1930).

yields of alkyl-lithium compounds were obtained more conveniently.³ More recently, the elegant studies by Ziegler and Colonius² have shown that it is possible to prepare many organolithium compounds by the direct interaction of lithium with an RX compound in ether or benzene, the latter solvent being preferred with alkyl-lithium compounds because they react much more rapidly with ether than do aryl-lithium compounds.

An essential and long-practiced difference in manipulation of organo-alkali compounds and compounds like Grignard reagents lies in the use of glass-sealed containers of various modifications for the preparation and subsequent reactions of the organoalkali compounds. The purpose of the sealed containers is to exclude rigidly the deleterious effects of the atmosphere and moisture. However, because RMgX compounds are also sensitive to moisture, oxygen and carbon dioxide and yet can be prepared and manipulated very satisfactorily with a minimum of refinements to diminish the destructive action of moist atmosphere, it occurred to us that a corresponding simpler technique might be used with organoalkali compounds like phenyl-lithium, etc.

This finds support in experiment. Phenyl-lithium, for example, can be prepared very readily and in excellent yields from lithium and bromobenzene in ether. The general manipulation is that used in the preparation of Grignard reagents. Actually, the 95% yield of phenyl-lithium, obtained about as rapidly as the usual 95% yield of phenylmagnesium bromide, is 15–25% in excess of that reported recently.² The yields were determined by the acid-titration method of analysis used in studies on organomagnesium compounds. As a check on this analytical procedure, the phenyl-lithium was treated with an equivalent of benzophenone and the yield of triphenylcarbinol obtained in this manner was essentially that expected. For this reason, it was considered unnecessary to use also the *n*-butyl bromide–dibenzylmercury indirect method of analysis.²

The yield of phenyl-lithium from iodobenzene, lithium and ether was 80%. The yield of phenylmagnesium iodide prepared under corresponding conditions is 85.6%. There is then a resemblance in the effect of various phenyl halides on the yields of phenyl-lithium, and of phenylmagnesium bromide and phenylmagnesium iodide. However, this correlation breaks down apparently when the yields are compared in corresponding experiments where the phenyl halide is added very rapidly to the metal in ether. When bromobenzene is added rapidly to magnesium in ether the yield is 89.8%, or a drop of 4.9% from that obtained under "normal" conditions. With phenyl-lithium prepared by the rapid addition of bromobenzene the drop in yield is of the same order, namely, 3.9%. But with phenyl-

³ Hager with Marvel, *THIS JOURNAL*, **48**, 2689 (1926). The latest paper by Marvel and co-workers with organolithium compounds is *ibid.*, **52**, 376 (1930).

lithium prepared by the rapid addition of iodobenzene, there is no drop in yield, whereas the rapid addition of iodobenzene to magnesium in ether gives a 71.8% yield of phenylmagnesium iodide, or a drop of 13.8%.

It might have been predicted that the rapid addition of *n*-butyl chloride to lithium would not decrease the yield, because the 91.9% yield of *n*-butylmagnesium chloride obtained under so-called normal conditions is not decreased by a rapid addition of the halide. This prediction is supported by experiment, and there is no essential drop in yield with the rapid addition of *n*-butyl chloride to lithium in ether. The reaction between lithium and *n*-butyl chloride in benzene is slow,² and under our conditions the yield of *n*-butyl-lithium after six hours is 70%. However, the formation of *n*-butyl-lithium in ether is more rapid and yields of 75–80% are readily obtained. No study was made of the optimal conditions for the preparation of *n*-butyl-lithium since our prime need was phenyl-lithium.

The practical significance of the observation that there is no appreciable drop in yields in the preparation of phenyl-lithium and *n*-butyl-lithium lies in the fact that these organolithium compounds can be prepared conveniently without regard to the rate of addition of halide. If analogies between organometallic compounds prepared from alkali metals and alkaline earth metals have any significance, then it is probable that the yields of other organolithium compounds will vary with the rate of addition.⁴ This is based on published studies on the preparation of such Grignard reagents as allylmagnesium bromide, *tert*-butylmagnesium chloride, cinnamylmagnesium chloride, etc.

The advantages of manipulating organolithium compounds in either open containers, or with a slow stream of nitrogen in essentially open containers, provided with the conventional mercury-sealed stirrers, will undoubtedly apply with other organoalkali compounds. A case in point is the addition of sodium to benzophenone-anil and the subsequent carbonation of the di-sodium compound, $(C_6H_5)_2C(Na)N(Na)C_6H_5$, to give ultimately diphenylanilinoacetic acid, $(C_6H_5)_2C(NHC_6H_5)COOH$, in practically quantitative yields.⁵ It is significant that carbon dioxide, one of the atmospheric constituents that has a deleterious effect on reactive organometallic compounds, reacts with phenyl-lithium to give a very poor yield² of benzoic acid. This is in striking contrast with $RMgX$ compounds which generally give very high yields of carboxylic acids.⁶ Oxygen with phenyl-

⁴ Another important factor is the excess of lithium used. An excess of lithium has no effect² on the yields of organolithium compounds mentioned in this paper. An excess of magnesium is very helpful in obtaining high yields of $RMgX$ compounds like allylmagnesium bromide, etc.

⁵ Studies by Mr. R. H. Kirby. The original reaction was carried out by Schlenk and Michael, *Ber.*, **47**, 483 (1914).

⁶ The only two exceptions in our experience are with the carbonation of allylmagnesium bromide and β -styrylmagnesium bromide.

lithium, as with phenylmagnesium halides, induces chemiluminescence. In these incidental studies the color test for reactive organometallic compounds has been found to be highly useful to determine whether an organolithium compound was formed, and when it was used up in a given reaction. In reactions with ketones, it appears that any unused lithium might act as an indicator by developing distinctive colors (possibly those of ketyls) when the ketone is used up in its reaction with the organolithium compound. For example, in a preparation of triphenylcarbinol from benzophenone and phenyl-lithium, when the phenyl-lithium was used up (as indicated by a negative color test), a violet color developed near some small pieces of unused lithium which had not been removed. Characteristic colors were also observed when the ether solution of *n*-butyl-lithium was treated with α -naphthyl isocyanate in the preparation of *n*-valero- α -naphthalide as a derivative.

Experimental Part

The apparatus and general procedure were those used in related studies on organomagnesium compounds. Some modifications, concerned largely with the cutting of lithium, used in the small quantitative studies are unnecessary in the preparation of phenyl-lithium and *n*-butyl-lithium in large quantities. A few details of the small-sized quantitative experiments are given because they serve to correlate the present procedure with that of organomagnesium halides, and because they may prove of assistance to others in not only determining optimal conditions for some organolithium compounds which cannot now be prepared satisfactorily, but also in determining the relative labilities of halogens in RX compounds toward various metals.

The small quantitative studies were all carried out in a nitrogen atmosphere for two reasons. First, organolithium compounds undergo ready reaction with oxygen. Second, the purity of RX compounds appears to have a greater influence on initiating reaction with lithium than with magnesium. In larger runs it may be unnecessary to use a nitrogen atmosphere with most aryl halides. Such an atmosphere is necessary with a slow reacting compound like chlorobenzene and with the alkyl halides, in order to reduce appreciable decomposition due to the diffusion of atmospheric oxygen.

The metal was cut by means of a chisel and hammer into pieces measuring about 7×7 mm. in cross section and 30 mm. in length. These were shaped into prisms of about the above-mentioned dimensions by means of pliers having smooth-faced jaws, and this operation apparently served to press out most of the kerosene under which the original metal was kept. Incidentally, the lithium prisms were shaped fairly uniformly to ensure an approximately constant thin oxide layer. These prisms were readily scraped and cut so that they weighed 0.76 g. (1.1 atoms), the quantity used in the 0.05 mole experiments, allowing a 10% excess. They were then kept, for a few minutes prior to use, under dry ether in an inverted test-tube arrangement provided with a small hole near its upper end to permit escape of any entrapped air. The ether level was over this orifice in the test-tube, and a handle made it convenient to remove the tube from the Erlenmeyer flask in which it was contained.

The simplified, analytical reaction flask used in organomagnesium studies was heated in an oven at 110° , and swept out with pure, dry nitrogen which was admitted through the side neck. After adding 15 cc. of ether, the prism of lithium was cut transversely (by means of a scissors) into about thirty pieces which were allowed to drop into the flask through the main neck, from which issued a stream of nitrogen.

The flask was then attached to the mercury-sealed stirrer (fitting the main neck) and dropping funnel which entered the main neck through a second boring in the rubber stopper holding the stirrer, and a spiral condenser (fitting the side neck). The top of the spiral condenser and the top of the dropping funnel were connected by tubes provided with pinchcocks which made it possible to admit nitrogen through the condenser or (and) through the dropping funnel. The nitrogen now left the system through a U-tube having a 2-3 mm. head of mercury pressure. This gage permitted the subsequent operations with a minimum actual flow of nitrogen, and very little loss of ether.⁷

Then 40 drops of the halide was added to the lithium and ether. Gentle warming by means of a micro-burner was sufficient to induce prompt reaction. Reaction having set in, the remainder of the halide in 15 cc. of ether was added either over a period of thirty to thirty-five minutes in a so-called normal run or all at once in those experiments concerned with the effect of rapid addition on the yield. Stirring was used throughout the preparation.

When the preparation was completed, the flask containing nitrogen was detached from the rest of the apparatus, stoppered and allowed to stand for thirty minutes, at the end of which time any precipitate settled. The visible unused lithium was readily removed by long-handled tweezers, and aliquots were taken for analysis.⁸ As in related quantitative studies with organomagnesium compounds, each of the experiments was checked at least twice and the degree of accuracy for aliquots from a given preparation is that obtained with Grignard reagents.

Miscellaneous Observations

Size of Lithium.—When the 0.76 g. prism of lithium was cut lengthwise into two pieces, the yield of phenyl-lithium from bromobenzene was 93.1%. In this experiment, the apparent reaction continued for fifty to fifty-five minutes; whereas under standard conditions with smaller pieces of lithium the apparent reaction continued for ten to twenty minutes. The mixture was then refluxed for an additional forty-five minutes. For practical purposes it is, therefore, unnecessary to cut the lithium into small pieces if the slightly greater time required for completion of the reaction is of secondary consequence.

Tarnishing of Lithium.—In one experiment with lithium and bromobenzene, the 30-33 pieces of metal (totaling 0.76 g.) were exposed to moist air for one minute, which was sufficient to coat them entirely with a black film. Reaction set in at once, probably because the sharp-winged small stirrer removed some of the oxide, as was evidenced by the clean, silvery patches on the metal after stirring for a few minutes. The yield of phenyl-lithium was 86.8%. It is possible that an adequate excess of tarnished metal may prevent a decrease in yield. When one piece (0.76 g.) of tarnished lithium was used, the yield was 88.6%, and about five minutes of stirring with the application of heat was required for the starting of reaction. Stirring was obviously less effective with the single piece of lithium in the small flask.

Time of Reaction.—In every case it appears desirable to apply heat and to use stirring in initiating reaction. With Grignard reagents it is generally better not to use stirring until after the reaction has commenced. The time of apparent reaction, after all of the halide had been added very rapidly (in so-called drop runs) to the lithium in ether, varies with the RX compound and is probably a measure of the lability of the halogen toward a given metal. With iodobenzene this time is ten to fifteen minutes;

⁷ In large-sized runs, particularly with slow acting RX compounds, it may be sufficient to use a trap to exclude the atmosphere subsequent to sweeping out the apparatus with nitrogen.

⁸ During these operations, nitrogen was admitted through the side neck.

with bromobenzene, thirty-five to forty minutes; and with *n*-butyl chloride, forty to forty-five minutes. The corresponding times when these halides are added separately to magnesium in ether are: ten to fifteen minutes; ten to fifteen minutes; and forty-five to fifty minutes, respectively.

When the apparent reaction is ended, refluxing with stirring should be continued for forty-five minutes. There is no improvement in yield of phenyl-lithium from bromobenzene when this period of refluxing exceeds thirty minutes; and with a fifteen minute period of refluxing the yield was 92%.

Yields of Some Other Aryl-lithium Compounds.—Under corresponding conditions the following yields were determined from RBr compounds, the number in parentheses being the percentage yield when the RBr compound was added rapidly to the lithium: *o*-tolyl-lithium, 93.3 (85.6); *m*-tolyl-lithium, 86.4 (80.0); *p*-tolyl-lithium, 94.9 (95); *o*-anisyl-lithium, 85 (85); *p*-anisyl-lithium, 66.1 (65.3); α -naphthyl-lithium, 79 (80); and β -naphthyl-lithium 75.3 (47.8).

***n*-Butyl-lithium.**—The time of apparent reaction when all of the *n*-butyl chloride is added to the lithium in ether is forty to forty-five minutes. Gentle refluxing is continued for about two hours, and the yield is 75–80%. In one experiment when the time of refluxing was one-half hour the yield was 67%. When twelve instead of the customary six molecular equivalents of ether were used the yield was 68%. As previously mentioned, the reaction in benzene is much slower than in ether. Because the very high yields of *n*-butyl-lithium in benzene were obtained in twenty-four hours,² it may be desirable to prepare *n*-butyl-lithium in benzene in sealed containers; however, effective stirring would probably reduce the time required for complete reaction. The *n*-butyl-lithium was characterized by the preparation of *n*-valero- α -naphthalide from α -naphthyl isocyanate in accordance with the general directions suggested for this reaction in the preparation of derivatives of reactive organometallic compounds. The preparation of *n*-butyl-lithium in ether can be simplified by adding the freshly cut lithium to all of the halide in ether and thereby dispensing with the use of a dropping funnel.

The authors are grateful to Dr. F. Breuer, Dr. B. Barrett Gilman, Mr. E. B. Towne and Mr. P. Van Ess for valuable suggestions and assistance.

Summary

Directions are given for the preparation of aryl-lithiums and *n*-butyl-lithium, from lithium and the corresponding halides. Excellent yields are readily obtainable under conditions essentially like those used with the related Grignard reagents.

Attention is directed to some simplifications in procedure which make it possible to prepare and to manipulate some organoalkali compounds in readily available apparatus and without the use of glass sealed containers.

FURTHER STUDIES IN KETO-ENOL DETERMINATION

BY GLADYS A. MICHALEK AND HOWARD W. POST

RECEIVED DECEMBER 9, 1931

PUBLISHED MAY 7, 1932

Previous work of ours¹ included evidence that ethyl α -phenylacetoacetate exists in the enol form to the extent of about 28.6% at room temperatures. Later work by K. von Auwers² presented values of approximately 39.2% for the same property.

We did not find in our first contribution sufficient agreement between bromine titration values representing the enol content of ethyl α -phenylacetoacetate and like figures derived from refractive indices by von Auwers, Brühl or anyone else, in spite of the existence of corrections which might be applied to the latter. It should be noted also that this ester required several days to reach equilibrium after distillation even when the same type of Pyrex glass was used for all operations and for all containers throughout the work.

We have accordingly repeated our work in the hope of being able to reconcile our values with those of von Auwers.

Preparation of the Ester.—Ethyl α -phenylacetoacetate was prepared by the same method outlined in our first paper on this subject. The hydrolysis of acetobenzyl cyanide was, however, modified in that the solution was kept at room temperature instead of at zero degrees during the addition of hydrochloric acid and later was poured into water at room temperature instead of ice water. As in earlier work fractionation was carried out under vacuum using a flask with fractionating column attached. The ester was first collected over a range of fifteen degrees and refractionated to boil at 145–147° under 11 mm. pressure. Two batches of crude ester were purified separately in order to have a check on the index of refraction. Both showed an index of refraction of 1.5130 at 20° when given time to reach equilibrium. Freshly distilled material always showed a high index.

Bromine Titration.—Titration of the enol content was carried out as before. The sample, which was weighed by difference, was introduced into 30 cc. of alcohol at –7° and sufficient freshly prepared alcoholic bromine solution added quickly to give a slight color, which was immediately discharged with alcoholic β -naphthol solution. To this was added 10 cc. of 5% potassium iodide solution and the whole heated on the steam-bath for twenty minutes in the dark, then titrated with *N*/10 sodium thiosulfate solution. The latter had a factor of 1.1227 at 20°. The buret was calibrated and found to be correct at 20° within the accuracy of the titration.

Some trouble was experienced in obtaining β -naphthol sufficiently pure that it could effectively remove the excess of bromine. Distillation of β -naphthol followed by two recrystallizations from water gave a product requiring not more than 0.3 cc. of thiosulfate solution to discharge the color

¹ Post and Michalek, *THIS JOURNAL*, **52**, 4358 (1930).

² Von Auwers, *ibid.*, **53**, 1496 (1931).

of the blank. Calculations were made with and without this correction, however; in the actual titration the amount of thiosulfate accounted for in this way is probably much smaller since the excess of bromine is much less. We know of no way of calculating the actual excess of thiosulfate used in the titration due to the impurity of the β -naphthol. In the previous work a correction of 0.5 cc. was made in the results.

DATA				
Temp., °C.	Na ₂ S ₂ O ₃ , cc.	Sample, g.	Titrated % Enol	Corrected
21.5	19.8	0.7353	31.15	30.68
22.0	16.0	.6213	29.76	29.18
22.0	17.9	.6911	29.93	29.44
22.0	13.9	.5256	30.59	29.93
Average			30.36	29.81

Conclusions.—Our results agree within the limits of experimental error with those of our former paper. In view of the discrepancy still existing between these values and those of von Auwers, we are forced to conclude that the only further light which can be thrown on the question should come from an isolation of enol and keto in the pure state, followed by a determination of the refractive index and the bromine titration value of each.

Summary

The enol content of ethyl α -phenylacetoacetate has been redetermined both by bromine titration and by the determination of the refractive index. The values so obtained check within the limits of experimental error with those previously published by the authors.

BENZENESULFONYLGUANIDINES¹

BY H. T. CLARKE AND H. B. GILLESPIE

RECEIVED DECEMBER 10, 1931

PUBLISHED MAY 7, 1932

In the course of an investigation, now in progress, of the benzenesulfonyl derivatives of proteins and peptides, it became necessary to ascertain the effect of benzenesulfonyl chloride upon guanidine and its derivatives under various conditions. Ackermann² treated guanidine carbonate with benzenesulfonyl chloride in the presence of excess sodium hydroxide, thereby obtaining the sparingly soluble benzenesulfonylguanidine. He also reported failure to produce a sparingly soluble derivative of arginine under analogous conditions. The corresponding β -naphthalenesulfonyl

¹ Work supported by a research grant from The Chemical Foundation.

² Ackermann, *Z. physiol. Chem.*, **47**, 366 (1906).

derivatives of certain guanidines have recently³ been employed for their characterization in urine.

We have been able to confirm Ackermann's observation with guanidine, but find that the yield of benzenesulfonylguanidine depends upon the amount and the concentration of the sodium hydroxide, as well as upon the amount of benzenesulfonyl chloride employed. The reason for this is not far to seek. Guanidine is a strong base which furnishes a titration curve⁴ almost indistinguishable from that obtained with sodium hydroxide, and replacement of a hydrogen atom apparently takes place with guanidine only in its undissociated form.

This view is borne out by the behavior of guanidine carbonate toward benzenesulfonyl chloride in the presence of potassium carbonate, under which conditions the sole product is a well crystalline benzenesulfonate of guanidine.

Analogous results are obtained with methylguanidine, asymmetrical dimethylguanidine and piperidoguanidine, which are bases as strong as guanidine.⁴ The resulting benzenesulfonyl derivatives display weakly basic properties, forming crystalline hydrochlorides which appear to be readily hydrolyzed in aqueous solution. Benzenesulfonylguanidine also forms an acetyl derivative and an unstable picrate. It shows no tendency to form salts with alkalis, thereby differing from the majority of primary sulfonamides. This may be interpreted as being due either to the preponderance of the benzenesulfonimino form or, more plausibly, to the inability of the single benzenesulfonyl group entirely to suppress the basic properties of the guanidine molecule. Guanidine nevertheless shows no tendency to form derivatives containing more than one benzenesulfonyl group, nor do the benzenesulfonyl guanidines yield nitrogen by the action of sodium nitrite in presence of acetic acid, therein resembling guanidine.⁵

The guanidine group in arginine appears, from the dissociation curve of arginine⁶ and from the fact that benzylidenearginine is incapable of forming a sodium salt,⁷ to be as strongly dissociated as guanidine itself. It should therefore be possible, by treating arginine with benzenesulfonyl chloride in the presence of sodium carbonate, to attach a benzenesulfonyl group to the α -nitrogen atom, while leaving the terminal guanidine group untouched. This appears to be the case; monobenzenesulfonylarginine, isolated in the form of its picrate, yields very little nitrogen under the conditions adopted by Van Slyke⁵ and must, in consequence, possess the anticipated structure. This is confirmed by the regeneration of the amino group on acid hydrolysis.

On the other hand, when the benzenesulfonylation is carried out in presence of a large excess of concentrated sodium hydroxide, benzenesulfonyl groups attach themselves to the guanidine group as well. While it was not found possible to isolate the resulting product in crystalline condition, analysis showed it unquestionably to consist of dibenzenesulfonylarginine.

Attempts to prepare benzenesulfonyl derivatives of acetamidine were unsuccessful, benzenesulfonamide being the only product isolated; analogous experiments with creatine also failed.

Experimental

Guanidine Benzenesulfonate.—To a solution of 18 g. of guanidine carbonate (0.2 m. of guanidine) in 125 cc. of water were added 26 cc. (0.2 m.) of benzenesulfonyl chloride and 14 g. (0.2 m.) of potassium carbonate. The mixture was stirred vigorously; the temperature rose to 43°. The crystals which formed on cooling were collected (22 g.) and recrystallized from 50 cc. of water from which they separated in diamond-shaped plates melting at 209–210° (corr.). The product was soluble in nine parts of water at 26°; it was readily soluble in alcohol and insoluble in ether. It could be recrystallized unchanged from dilute sodium hydroxide solution.

Anal. Calcd. for $C_7H_{11}O_3N_3S$: C, 38.7; H, 5.07; N, 19.4; S, 14.8. Found: C, 38.7; H, 5.01; N, 19.0; S, 15.1.

On adding a hot concentrated solution of picric acid to a solution of the salt, guanidine picrate melting at 330° (uncorr.) separated; this picrate contained no sulfur.

Benzenesulfonylguanidine.—Solutions of 3 g. of guanidine carbonate in 35 cc. of water were treated with varying amounts of sodium hydroxide and 6-cc. quantities of benzenesulfonyl chloride. After stirring mechanically until the odor of benzenesulfonyl chloride had disappeared (thirty to sixty minutes), the resulting precipitate was collected, washed with cold water and weighed. The crude product so obtained was recrystallized from the minimum quantity of 95% alcohol, when it separated in leaflets melting at 212° (corr.). The maximum yield (42%) of recrystallized product was obtained with 6.4 g. of sodium hydroxide; with 3.2 g. of alkali the yield was 17%; intermediate yields were obtained with intermediate quantities of alkali. With 8.6 g. the yield was only 30%. Decreasing the amount of benzenesulfonyl chloride to 4 cc. had only slight effect on the yield.

The pure product is no more readily soluble in cold aqueous alkali than in cold water; on boiling 0.250 g. with 200 cc. of *N* sodium hydroxide for twenty-four hours, 94.6% of the total amount of nitrogen was recovered as ammonia.

Benzenesulfonylguanidine hydrochloride was prepared by dissolving 0.5 g. of benzenesulfonylguanidine in 10 cc. of concentrated hydrochloric acid and evaporating the excess acid at room temperature in a current of air under reduced pressure. It melted at 160–163° (corr.).

Anal. Calcd. for $C_7H_{10}O_2N_3SCl$: Cl, 15.1. Found: Cl, 14.9.

The picrate separated in yellow needles, melting at 190–191° (corr.), on adding picric acid to a solution of benzenesulfonylguanidine in hot alcohol. On attempting to recrystallize from alcohol or ethyl acetate, dissociation took place with loss of picric acid.

The acetyl derivative was prepared by boiling benzenesulfonylguanidine for fifteen to thirty minutes with eight parts of acetic anhydride; m. p. 197–197.5° (corr.) from ethyl acetate.

Anal. Calcd. for $C_9H_{11}O_3N_3S$: S, 13.3. Found: S, 13.4.

The benzenesulfonyl derivatives of alkyl guanidines were prepared by the procedure which had been found to give the best yields with guanidine.

Benzenesulfonylmethylguanidine.—M. p. 180.5–181° (corr.).

Anal. Calcd. for $C_8H_{11}O_2N_3S$: C, 45.1; H, 5.20; N, 19.7; S, 15.0. Found: C, 45.2; H, 5.26; N, 19.2; S, 15.1.

Hydrochloride: M. p. 123–126° (corr.).

Anal. Calcd. for $C_8H_{12}O_2N_3SCl$: Cl, 14.2. Found: Cl, 14.0.

Benzenesulfonyl-*as*-dimethylguanidine.—M. p. 164.5–165.5° (corr.).

Anal. Calcd. for $C_9H_{13}O_2N_3S$: C, 47.6; H, 5.75; N, 18.4; S, 14.1. Found: C, 47.8; H, 5.65; N, 17.2; S, 14.1.

Benzenesulfonylpiperidoguanidine.—Three and one-half grams of a pure product, m. p. 168.5–169° (corr.), was obtained from 4 g. of piperidoguanidine sulfate.⁴

Anal. Calcd. for $C_{12}H_{17}O_2N_3S$: C, 53.9; H, 6.36; N, 15.7; S, 12.0. Found: C, 53.7; H, 6.28; N, 15.1; S, 11.7.

Monobenzenesulfonylarginine.—To a solution of 6 g. of arginine nitrate (0.025 m.) in 30 cc. of water were added 11 g. (0.08 m.) of potassium carbonate and 5 cc. of benzenesulfonyl chloride (0.039 m.). After stirring mechanically for a half hour at room temperature the clear solution was weakly acidified with 7 cc. of concentrated hydrochloric acid and evaporated to dryness under reduced pressure. The residue was extracted with ethyl alcohol; the alcoholic solution was again evaporated to dryness and taken up in the minimum quantity of alcohol. The glassy sirup left on evaporation was dissolved in 100 cc. of water and treated with 6 g. of picric acid in hot concentrated aqueous solution. The oily precipitate became crystalline on standing. On recrystallization from alcohol, 9.5 g. of yellow needles, melting at 161–162° (corr.), was obtained.

Anal. Calcd. for $C_{18}H_{21}O_{11}N_7S$: C, 39.8; H, 3.87; N, 18.0; S, 5.89; picric acid, 42.2. Found: C, 38.9; H, 4.02; N, 16.9; S, 5.60; picric acid, 41.9.

A 3% solution of the picrate in *N*/10 sodium hydroxide when treated by Van Slyke's method gave 4.2% of the amount of amino nitrogen theoretically obtainable from a corresponding quantity of arginine. This solution was mixed with an equal volume of concentrated hydrochloric acid, freed of precipitated picric acid by filtration, and boiled under reflux; 2-cc. portions removed at intervals were analyzed for amino nitrogen, the hydrochloric acid being neutralized by first adding 1.5 cc. of 25% sodium hydroxide and 0.5 cc. of acetic acid to the reaction mixture.

Hours boiling.....	0	1	3	8	16	24	44
Amino nitrogen, % of theoretical.....	4.2	17.0	24.1	43.8	68.6	79.7	106.0

Dibenzenesulfonylarginine.—To a solution of 4 g. of arginine monohydrochloride in 8 cc. of water was added 20 cc. of 25% sodium hydroxide solution; 6 cc. of benzenesulfochloride was added in two equal portions, the mixture being shaken vigorously after each addition. The temperature was not allowed to rise above 25°. After standing for half an hour, the mixture was freed of crystals (about 6 g., largely sodium benzenesulfonate), and the filtrate shaken with a further 3-cc. portion of benzenesulfochloride. After standing overnight, the mixture was rendered strongly acid with concentrated hydrochloric acid; the gummy precipitate was taken up by shaking with a mixture of butyl alcohol (75%) and ethyl acetate (25%). Undissolved salts were removed and the solution concentrated to a sirup. This was taken up in dioxane; the filtered solution was evaporated to a sirup and treated with excess of ethyl ether. The

sticky insoluble product was washed with ether, treated with 60 cc. of boiling water until free of steam-volatile and water-soluble impurities, and finally dried at 100°. On cooling, it formed a colorless resin, soluble in acetic acid, acetone, chloroform, ethyl acetate and ethyl alcohol, but insoluble in benzene, carbon tetrachloride, ethyl ether and water. A sample gradually dissolved in boiling sodium hydroxide solution, giving off the odor of butyl alcohol; it thus appeared to consist principally of the butyl ester of dibenzenesulfonylarginine.

Anal. Calcd. for $C_{22}H_{35}O_6N_4S_2$: C, 51.34; H, 6.79; N, 10.87; S, 12.42. Found: C, 50.4; H, 5.97; N, 10.43; S, 11.45.

Hydrolysis was effected by warming on the steam-bath a solution in ethyl alcohol to which small quantities of concentrated ammonia were added from time to time. After twelve hours no precipitation occurred on diluting with water; the solution was evaporated to dryness, and the residue taken up in boiling water, filtered hot and allowed to cool. The clear resin which separated was rinsed with water and dried at 100°; it appeared to consist of the ammonium salt.

Anal. Calcd. for $C_{18}H_{25}O_6N_6S_2$: N, 14.85; S, 13.59; acid equiv., 471. Found: N, 15.25; S, 11.9; acid equiv., 465.

The free acid was thrown out as an oil on adding a slight excess of mineral acid to a saturated solution of the ammonium salt in cold water. After rinsing with cold water and drying at 100° it solidified to a colorless resin, soluble in acetone, acetic acid, ethyl alcohol and hot water, but insoluble or sparingly soluble in benzene, carbon tetrachloride, chloroform, ethyl acetate and ethyl ether.

Anal. Calcd. for $C_{18}H_{25}O_6N_6S_2$: N, 12.34; S, 13.84. Found: N, 12.39; S, 13.07.

The authors wish to express their indebtedness to Mr. William Saschek for carrying out the microanalyses recorded in this paper.

Summary

The introduction of the benzenesulfonyl group into guanidine and its derivatives takes place only in the presence of strong alkalis, and not with alkali carbonates. Similarly, with arginine, the benzenesulfonyl group attaches itself only to the α -nitrogen atom in the presence of carbonate, but when alkali hydroxide is present in excess, the guanidine group is acylated as well.

Benzenesulfonyl guanidine is a weak base, and exhibits no tendency to form a sodium derivative analogous to that formed by benzenesulfonamide. It yields an acetyl derivative on treatment with acetic anhydride.

THE REARRANGEMENT OF 9,10-DIARYLDIHYDROPHENANTHRENE DIOLS

By W. E. BACHMANN

RECEIVED DECEMBER 14, 1931

PUBLISHED MAY 7, 1932

In continuing the study of the pinacol-pinacolin rearrangement,¹ we have investigated the rearrangement of a number of 9,10-diaryldihydrophenanthrenediols. These glycols correspond to pinacols and it appeared that they would be formed by the reduction of 2,2'-diacylbiphenyls by a mixture of magnesium and magnesium iodide in the same manner that ketones are reduced to pinacols.²

It was found that 2,2'-dibenzoylbiphenyl ($R = C_6H_5$) reacts with the binary mixture and is reduced to a mixture of stereoisomeric 9,10-diphenyldihydrophenanthrenediols. The product formed in the largest proportion is a pinacol which melts at 179–180°; a small amount of a pinacol melting at 202° is produced. Our products were found to be identical with the two stereoisomeric forms of diphenyldihydrophenanthrenediol that had been obtained by Werner and Grob³ and by Acree⁴ by other methods. These investigators prepared the low-melting pinacol by the action of phenylmagnesium bromide on phenanthrenequinone; the high-melting isomer was obtained by the reduction of dibenzoylbiphenyl by zinc and potassium hydroxide. On repeating the latter reaction we actually obtained a mixture of the two isomers and not a single compound.

Werner and Grob reported that the two isomeric diphenyldihydrophenanthrenediols when treated with a mixture of sulfuric acid and hydrochloric acid at 200° gave the same pinacolin, 10,10-diphenylphenanthrone (9). We have repeated the rearrangement reaction using acetyl chloride at a lower temperature and also acetic acid containing a small amount of iodine² in order to be certain that the product was not the result of a secondary action⁵ but was the initial product of rearrangement.

⁴ Acree, *Am. Chem. J.*, **33**, 186 (1905).

⁵ "Annual Reports," 1930, Vol. 27, p. 120; also Bergmann and Schuchardt, *Ann.*,

Under these conditions each pinacol gave diphenylphenanthrone, showing that of the two possible rearrangements, I and II, only the mechanism I, involving the migration of the phenyl group, takes place.

Since in symmetrical mixed pinacols the relative migration aptitudes of the *p*-tolyl and the anisyl groups were found to be greater than that of the phenyl group, it was predicted¹ that in the rearrangement of di-*p*-tolylldihydrophenanthrenediol and of dianisylldihydrophenanthrenediol the *p*-tolyl group and the anisyl group, respectively, would migrate practically exclusively. These new pinacols were synthesized and subjected to rearrangement. It is found that the predictions are confirmed. Rearrangement of di-*p*-tolylldihydrophenanthrenediol gives 10,10-di-*p*-tolylphenanthrone(9); dianisylldihydrophenanthrenediol gives 10,10-dianisylphenanthrone(9).

It was possible to prepare two stereoisomeric di-*p*-tolylldihydrophenanthrenediols and two stereoisomeric dianisylldihydrophenanthrenediols. A high-melting compound was obtained by reduction of the corresponding 2,2'-diacylbiphenyl by magnesium and magnesium iodide or by zinc and potassium hydroxide; a low-melting isomer resulted from the action of a Grignard reagent on phenanthrenequinone. The two stereoisomeric di-*p*-tolylldihydrophenanthrenediols were rearranged to the same pinacolin; in like manner the pair of dianisylldihydrophenanthrenediols gave the same compound on rearrangement. All of the pinacols are oxidized by chromic acid to the corresponding 2,2'-diacylbiphenyls.

The investigation of the rearrangement of substituted dihydrophenanthrenediols is being continued.

Experimental

Reduction of 2,2'-Dibenzoylbiphenyl by Mg + MgI₂.—Two grams of 2,2'-dibenzoylbiphenyl was added to a mixture of magnesium and magnesium iodide prepared from 2 g. of iodine and 1 g. of magnesium powder in 15 cc. of ether and 30 cc. of benzene; an insoluble oily complex of ketone and magnesium iodide precipitated. The mixture was refluxed until the oily complex had disappeared. The pinacol which was obtained on hydrolysis of the filtered solution was recrystallized from *n*-propyl alcohol. In this way there was obtained 1.1 g. of needle-like crystals of 9,10-diphenylldihydrophenanthrenediol melting at 202°; from the alcoholic filtrate 0.65 g. of the low-melting pinacol was isolated. When this latter product was recrystallized from acetic acid, it was obtained in the form of prisms melting at 179–180°. These prisms were found to be identical with the pinacol which was prepared by the action of phenylmagnesium bromide on phenanthrenequinone according to the directions of Acree.⁴ Acree ob-

tained 25 g. of product from 20 g. of phenanthrenequinone. Recently, Schlenk and Bergmann⁶ reported that they obtained only one-half of this yield. We obtained, in agreement with Acree, a yield of 26 g. of recrystallized pinacol from 20 g. of phenanthrenequinone.

When dibenzoylbiphenyl was treated with zinc and potassium hydroxide according to the directions of Werner and Grob, there was obtained a 76% yield of the high-melting pinacol and a 13% yield of the low-melting compound. Reduction of dibenzoylbiphenyl by zinc and acetic acid at room temperature gave the high-melting pinacol as the principal product; when the reaction was carried out in a warm solution the product was not pinacol but the pinacolin, diphenylphenanthrone.

Rearrangement of 9,10-Diphenyldihydrophenanthrenediol.—The product obtained by heating 1 g. of pinacol of m. p. 179–180° with a mixture of 10 cc. of acetyl chloride, 5 cc. of acetic acid and 20 cc. of benzene was practically pure 10,10-diphenylphenanthrone-(9). The same compound was obtained by rearrangement under the same conditions of the pinacol melting at 202°; from 0.5 g. of pinacol there was obtained 0.44 g. (92%) of pure diphenylphenanthrone.

2,2'-Di-*p*-toluylbiphenyl, $\text{CH}_3\text{C}_6\text{H}_4\text{COC}_6\text{H}_4\text{C}_6\text{H}_4\text{COC}_6\text{H}_4\text{CH}_3$.—This compound was prepared from 2-bromo-4'-methylbenzophenone by the Ullmann reaction. The substituted benzophenone was obtained by the action of the Grignard reagent from 17 g. of *p*-bromotoluene in 35 cc. of ether on 12 g. of *o*-bromocyanobenzene in 35 cc. of benzene. After twelve hours of refluxing, the reaction mixture was treated with water and the ketone-imine was hydrolyzed in the usual manner. The ketone was recrystallized from alcohol; yield, 15 g. (83%). Heidenreich⁷ obtained this ketone from *o*-bromobenzoyl chloride and toluene. Our method of synthesis proves that it was the *p*-methyl derivative that was formed in the Friedel and Crafts reaction carried out by him.

A mixture of 2 g. of 2-bromo-4'-methylbenzophenone and 5 g. of copper powder was heated with stirring at 200° for one-half hour. The mass was cooled and extracted with acetone. Evaporation of the acetone gave 2,2'-di-*p*-toluylbiphenyl. Recrystallization from acetic acid gave needle-like prisms melting at 137°; yield, 0.95 g. (68%).

Anal. Calcd. for $\text{C}_{28}\text{H}_{22}\text{O}_2$: C, 86.1; H, 5.7. Found: C, 85.9; H, 5.6.

Reduction of 2,2'-Di-*p*-toluylbiphenyl. (a) **By Mg + MgI_2 .**—Two grams of 2,2'-di-*p*-toluylbiphenyl was added to a mixture of magnesium and magnesium iodide prepared from 2 g. of iodine and 1 g. of magnesium powder in 15 cc. of ether and 30 cc. of benzene. The mixture was refluxed until the insoluble oily complex of ketone and magnesium iodide had disappeared. The pinacol which was obtained by hydrolysis of the filtered solution was recrystallized from a mixture of benzene and alcohol. The product (1.8 g.) appeared to be a mixture of pinacols. When it was recrystallized from *n*-propyl alcohol, there was obtained 1.0 g. of di-*p*-tolylidihydrophenanthrenediol in the form of transparent prisms; m. p. 213°.

Anal. Calcd. for $\text{C}_{28}\text{H}_{24}\text{O}_2$: C, 85.7; H, 6.2. Found: C, 85.9; H, 6.2.

(b) **By Zn + KOH.**—One gram of 2,2'-di-*p*-toluylbiphenyl was dissolved in 40 cc. of 95% alcohol, several grams of zinc dust and 5 cc. of 40% potassium hydroxide solution were added and the resulting mixture was refluxed for eight hours. The solution was filtered and the filtrate was poured into water. The solid which precipitated was filtered off and recrystallized from *n*-propyl alcohol; m. p. 213°; yield, 0.6 g. (60%). This compound was identical with the product obtained by means of magnesium and magnesium iodide. From the filtrate 0.1 g. of pinacol melting at 136° was isolated.

⁶ Schlenk and Bergmann, *Ann.*, **463**, 209 (1928).

⁷ Heidenreich, *Ber.*, **27**, 1452 (1894).

9,10-Di-*p*-tolylldihydrophenanthrenediol (Low-melting Isomer).—To the Grignard reagent which had been prepared from 42 g. of *p*-bromotoluene in 80 cc. of ether was added 50 cc. of benzene and then 17 g. of phenanthrenequinone in portions. The mixture was refluxed for five hours, cooled and hydrolyzed. The crude ditolylldihydrophenanthrenediol which was obtained by evaporation of the ether-benzene solution was digested with cold alcohol in order to remove oily impurities and it was then recrystallized from a mixture of benzene and alcohol; m. p. 103°; yield, 18 g. (57%). When the product was recrystallized again from *n*-propyl alcohol the melting point remained unchanged. When, however, a small amount was recrystallized from ethyl alcohol, the melting point was changed to 136°. This represents a second modification of the compounds, for both behaved alike on oxidation and rearrangement. The low-melting form is very soluble in hot organic solvents; it crystallizes from acetic acid in needle-like prisms containing solvent of crystallization which melt at 84°. The 136° modification is not very soluble in cold or in hot alcohol but is readily soluble in hot acetone; it crystallizes from acetic acid without solvent.

Anal. Calcd. for $C_{28}H_{24}O_2$: C, 85.7; H, 6.2. Found: C, 85.3; H, 6.1.

Oxidation of 9,10-Di-*p*-tolylldihydrophenanthrenediol.—Eight grams of pinacol (m. p. 103°) was added to a solution of 1.6 g. of chromic anhydride in 4 cc. of water and 100 cc. of acetic acid. The mixture was warmed on a steam-bath for one-half hour and was then poured into water. The colorless solid which precipitated was filtered off and was recrystallized from acetic acid; yield of 2,2'-di-*p*-toluylbiphenyl, 6 g. (75%); m. p. 137°. The product was identical with 2,2'-di-*p*-toluylbiphenyl which was synthesized from 2-bromo-4'-methylbenzophenone by the Ullmann reaction.

In another run, oxidation of 1 g. of pinacol gave needles melting at 125.5–126.0°. This product proved to be a second form of di-*p*-toluylbiphenyl. This low-melting form can be converted to the modification melting at 137° by inoculation of an acetic acid solution of the low-melting form or of the melted compound with a crystal of the high-melting form.

Oxidation of 1 g. of pinacol of m. p. 136° gave 0.80 g. (80%) of 2,2'-di-*p*-toluylbiphenyl. In like manner oxidation of the pinacol of m. p. 213° gave an 80% yield of the diketone.

Rearrangement of 9,10-Di-*p*-tolylldihydrophenanthrenediol.—One-half gram of pinacol (m. p. 213°) was heated for five minutes with 3 cc. of acetic acid to which a crystal of iodine² had been added. Two cc. of alcohol saturated with sulfur dioxide was added in order to remove the iodine. On cooling, 0.41 g. of 10,10-di-*p*-tolylphenanthrone (9) melting at 159° crystallized out. From the filtrate an additional 0.04 g. of the same product was isolated, making a total yield of 95% of that theoretically possible. Bergmann and Schuchardt³ report 158° for the melting point of di-*p*-tolylphenanthrone which they obtained by rearrangement of di-*p*-tolylbiphenylene ethylene glycol.

One-half gram of the pinacol of m. p. 103° was heated with acetic acid and iodine in the same manner; again the product was ditolylphenanthrone. Rearrangement by means of acetyl chloride gave the same product. Finally, the same compound resulted on rearrangement of the second modification (m. p. 136°) of this stereoisomeric pinacol.

2,2'-Dianisoylbiphenyl, $CH_3OC_6H_4COC_6H_4C_6H_4COC_6H_4OCH_3$.—The ketone, 2-bromo-4'-methoxybenzophenone,⁷ was prepared by the action of anisylmagnesium bromide from 19 g. of *p*-bromoanisole on 12 g. of *o*-bromocyanobenzene; yield, 13 g. (69%). A mixture of 4.4 g. of this ketone and 10 g. of copper powder was heated at 200° for thirty minutes. Extraction of the cooled mass with acetone gave 2,2'-di-

² Bergmann and Schuchardt, *Ann.*, 487, 225 (1931).

anisoylbiphenyl. The compound was recrystallized from acetic acid and was obtained in the form of needle-like prisms; yield, 1.6 g. (50%). The compound melted at 147°, then solidified and melted at 152–153°. The low-melting modification can be changed to the high-melting form by inoculation of a solution of the former with a crystal of the latter.

Anal. Calcd. for $C_{28}H_{22}O_4$: C, 79.6; H, 5.2. Found: C, 80.0; H, 5.4.

Reduction of 2,2'-Dianisoylbiphenyl.—Reduction of 1 g. of 2,2-dianisoylbiphenyl by a mixture of magnesium and magnesium iodide gave 0.62 g. of 9,10-dianisylldihydrophenanthrenediol. After two recrystallizations from *n*-propyl alcohol it was obtained in the form of prisms (0.43 g.); m. p. 188–190°. The pinacol is not very soluble in cold or in hot alcohol; it is somewhat more soluble in hot propyl alcohol.

Anal. Calcd. for $C_{28}H_{24}O_4$: C, 79.2; H, 5.7. Found: C, 79.3; H, 5.7.

By refluxing a mixture of 2.5 g. of 2,2'-dianisoylbiphenyl, 10 g. of zinc dust, 100 cc. of alcohol and 10 cc. of 40% potassium hydroxide for six hours, there was obtained 9,10-dianisylldihydrophenanthrenediol. From hot *n*-propyl alcohol there crystallized 1.3 g. of pinacol of m. p. 188–190°; from the filtrate a 10% yield of the stereoisomer melting at 154–155° was isolated.

Oxidation of the dianisylldihydrophenanthrenediol (m. p. 188–190°) by a solution of chromic anhydride in acetic acid gave an 80% yield of 2,2'-dianisoylbiphenyl; m. p. 152–153°.

9,10-Dianisylldihydrophenanthrenediol (Low-melting Isomer).—Seventeen grams of phenanthrenequinone was added in portions to the Grignard reagent which had been prepared from 46 g. of *p*-bromoanisole in 80 cc. of ether and 50 cc. of benzene. After being refluxed for six hours, the mixture was hydrolyzed. A viscous oil was obtained which partly crystallized after three weeks. The mass was digested with a cold mixture of benzene and alcohol; this dissolved the oil but not the crystals. By recrystallization from *n*-propyl alcohol the dianisylldihydrophenanthrenediol was obtained as heavy diamond-shaped plates; m. p. 154–155°; yield, 8 g.

Anal. Calcd. for $C_{28}H_{24}O_4$: C, 79.2; H, 5.7. Found: C, 78.9; H, 5.7.

Oxidation of 3.0 g. of this pinacol by a solution of 0.6 g. of chromic anhydride in 36 cc. of acetic acid and 2 cc. of water at 100° gave 2.52 g. (83%) of 2,2'-dianisoylbiphenyl.

Rearrangement of 9,10-Dianisylldihydrophenanthrenediol.—By heating 0.5 g. of dianisylldihydrophenanthrenediol (m. p. 154–155°) with 3 cc. of acetic acid containing a small amount of iodine, there was obtained 0.46 g. (95%) of 10,10-dianisylphenanthrene(9) melting at 151–152°. This product was found to be identical with dianisylphenanthrene which was synthesized in a yield of 80% by the action of dimethyl sulfate on bis-(*p*-hydroxyphenyl)-phenanthrene.⁹

The dianisylldihydrophenanthrenediol of m. p. 188–190° gave a quantitative yield of dianisylphenanthrene when it was treated with acetic acid and iodine.

Summary

The binary system $Mg + MgI_2$ reduces 2,2'-dibenzoylbiphenyl to a mixture of stereoisomeric diphenyldihydrophenanthrenediols. 2,2'-Di-*p*-toluylbiphenyl and 2,2'-dianisoylbiphenyl are reduced in the same manner to the corresponding substituted diaryldihydrophenanthrenediols.

The three pairs of stereoisomeric diaryldihydrophenanthrenediols readily undergo the pinacol-pinacolin rearrangement; in these rearrangements

⁹ Goldschmidt, Vogel and Bredig, *Ann.*, **445**, 123 (1925).

migration of the phenyl, *p*-tolyl and anisyl groups occurs practically exclusively.

THE INTERACTION OF AMIDES WITH ANILINE

BY CHARLES D. HURD, MALCOLM F. DULL AND K. E. MARTIN

RECEIVED DECEMBER 14, 1931

PUBLISHED MAY 7, 1932

Very little information is to be found in the literature regarding the interaction of amides with aniline. To study this question, two methods were chosen: (1) to leave the amides in contact with aniline for varying periods at several temperatures, and (2) to conduct the amide vapors through a hot tube, discharging them into cold aniline.

Except for a catalytic transformation of acetamide into methylamine (or $\text{HCN} + \text{H}_2$) and carbon monoxide using nickel¹ at 400°, the only recorded course of pyrolysis of acetamide is the one into acetonitrile² and water. In our high temperature experiments there was the possibility of deammonation into ketene. With acetamide the equation would be $\text{CH}_3\text{CONH}_2 \rightarrow \text{CH}_2\text{CO} + \text{NH}_3$. If so, the acetanilide might originate either from acetamide or ketene.

Actually, aniline was found to be quite non-reactive at 100° with such amides as acetamide, propionamide or isobutyramide. In fact, a mixture of the amide and aniline could be distilled (to 240°) without giving rise to anilide in the residue. Continued refluxing, however, was found to generate small yields of anilide, the best yields coming from propionamide. It was found that isobutyramide was exceedingly sluggish.

When the amides were passed through a tube which was maintained at 500–700°, some pyrolysis undoubtedly occurred because of nitrile formation. By passing the hot, effluent gases directly into cold aniline, fairly good yields of propionanilide or acetanilide, but no isobutyranilide, were obtained. The data for a few representative runs out of seventy-five which were performed are collected in Table I. The percentage yield of anilide is based on the amide which was not recovered. Examination of the data shows the best yields of acetanilide and propionanilide at tube temperatures of about 500° and contact times of but a few seconds. As high as 45–49% yields of propionanilide resulted, as compared with a 28% yield of acetanilide and no yield of isobutyranilide. Somewhat higher yields of acetanilide were obtained on a few occasions, but the selected runs seem more characteristic.

² Boehner and Andrews, *THIS JOURNAL*, **38**, 2503 (1916); Boehner and Ward, *ibid.*, p. 2505.

Whether or not ketene and methyl ketene were pyrolytic products cannot be answered. If they were, they never persisted in the gases when a condenser (to remove amide, etc.) was inserted between the hot tube and the cold aniline. To establish whether or not an amide as such could react with aniline, benzamide was passed through the hot tube and thence into cold aniline. In this case there exists no possibility of deammonation into a ketene, yet a 33% yield of benzanilide was obtained. While this does not eliminate the possibility of ketenes as intermediates in the case of acetamide and propionamide, certainly they are not essential intermediates for anilide formation.

Experimental Part

Liquid Phase Experiments.—When 15 cc. of aniline was left for four hours with 5 g. of either acetamide, propionamide or isobutyramide³ and then distilled at 20 mm. until the aniline and amide were removed, no residue of the anilide remained. Heating

³ By stirring a mixture of ethyl isobutyrate (250 g.) and concd. ammonium hydroxide (1 liter), an 80% yield of isobutyramide resulted in fifty days, whereas the yield was negligible in five days.

the mixtures for an hour at 100° prior to distillation gave no acetanilide or isobutyranilide but yielded a minute quantity of propionanilide. Reaction was produced by refluxing. When equal weights (20 g. each) of aniline and the three amides (three separate experiments) were refluxed for forty minutes, ammonia was evolved. Distillation at atmospheric pressure to 240° revealed a 13.7% yield of acetanilide, a 17% yield of propionanilide and a 5% yield of isobutyranilide: $\text{RCONH}_2 + \text{C}_6\text{H}_5\text{NH}_2 \longrightarrow \text{RCONHC}_6\text{H}_5 + \text{NH}_3$.

Reaction of Cold Aniline with Hot Amide Vapors.—Each amide was distilled in turn into a quartz or Pyrex combustion tube, packed with porcelain chips, which was heated by an electric furnace. A slow stream of nitrogen was blown through the system to maintain a uniform flow of the vapors. Experiments were performed at temperatures varying from 400 to 800°, the temperature being measured by a thermocouple placed inside of the tube. The thermocouple wires were encased in a sealed-off piece of Pyrex tubing. The vapors passed from the hot tube into a flask containing an excess of ice-cold aniline. Any carbon which formed was burned from the tube at the end of each run.

Distillation methods were used in working up the contents of the aniline solution. The nitrile and water were taken off below 105°. Aniline was then collected to 200° and the original amide between 200–240°. For the most part, the residue was the anilide, which was recrystallized from water.

The details of seventeen out of seventy-five experiments have been collected in Table I. Less than a liter of gases, collected over water, was formed in the 500° experiments. At 800°, the volume was 5 to 6 liters. Carbon monoxide was present, together with lesser amounts of carbon dioxide and methane.

Summary

Amides do not react with aniline at room temperature or at 100° but refluxing for an extended period gives rise to small yields of anilides. Amide vapors issuing from hot tubes were found to react with cold aniline to give fair yields of anilides. These results were obtained with acetamide, propionamide and benzamide, but isobutyramide gave almost negligible yields in all cases. The possibility of ketene formation from amides was discussed.

STEREOCHEMISTRY OF DIPYRIDYLS. PREPARATION AND RESOLUTION OF 2,4,2',4'-TETRACARBOXY-6,6'-DIPHENYL-3,3'-DIPYRIDYL. XX^{1,2}

BY E. H. WOODRUFF AND ROGER ADAMS

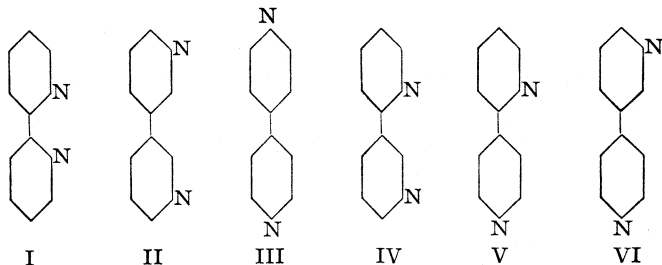

RECEIVED DECEMBER 19, 1931

PUBLISHED MAY 7, 1932

The extension of the study of optical isomerism in certain substituted diphenyls to other binuclear ring systems has already been accomplished in certain cases, notably the N-phenylpyrroles, the N,N'-dipyrrolys, and the phenylquinones. However, attempts to obtain optically active compounds with a phenyl and a heterocyclic ring linked through a —C—C— linkage have thus far met with failure.

Steele and Adams³ and Lions⁴ have reported several unsuccessful attempts to resolve a —C—C— linked phenylpyridine. In spite of this fact it still seemed probable that with correctly selected groups in the *o*-positions, especially if all four positions are substituted, compounds might be found which could be resolved.

In this communication the study of a substituted dipyridyl is reported. There are six types of dipyridyls containing —C—C— linkage. The unsubstituted compounds are all known.⁵

If such molecules are analogous to diphenyl compounds, it might be anticipated that resolvable compounds of Type I and possibly of Types IV and V might not exist unless, perhaps, the nitrogen atoms were converted to quaternary ammonium groups.

A compound of the general type (II) has been prepared and resolved into optically active isomers. It is 2,4,2',4'-tetracarboxy-6,6'-diphenyl-

¹ This communication is an abstract of a thesis submitted by E. H. Woodruff in partial fulfilment of the requirements for the Degree of Doctor of Philosophy in Chemistry at the University of Illinois.

3,3'-dipyridyl (VII). The active forms have rotations, $[\alpha]_D +6.1^\circ$, $[\alpha]_D -5.9^\circ$, and readily racemize upon warming in alcohol solution. It would appear, then, that the resistance to free rotation between the rings is very slight. It is probable that the interfering effect of two of the carboxyl groups is partially diminished due either to the smaller size of the ions found because of the presence of the basic nitrogen, or to the electrical characteristics of the ions or to the distortion of the forces on account of the internal neutralization of the carboxyl and the nitrogens. It is quite probable, moreover, that the character of a pyridine ring as regards conditions necessary for resolution of phenylpyridines and dipyridyls is different from that of benzene. Such a dipyridyl as has been described in this communication is quite analogous to a diphenyl of the formula 2,6,2',6'-tetracarboxy-3,3'-diaminodiphenyl (VIII) which has not yet been prepared. By past

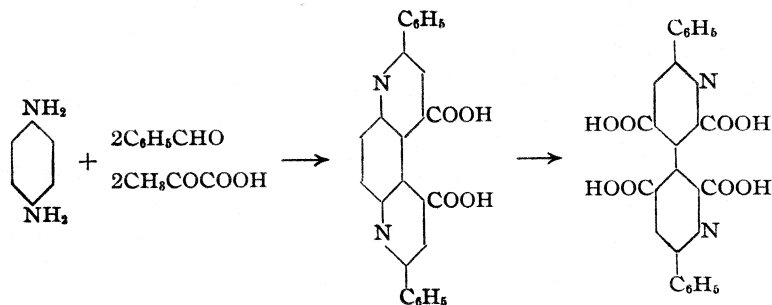

experience it would be expected that any ortho-tetracarboxydiphenyl with the two rings asymmetrically substituted but without other complicating factors should be relatively stable to racemization. However, in the diamino derivative the interfering effect of the two carboxyls adjacent to the two amines might be lessened to such an extent that the active compound would racemize readily.

The 2,4,2',4'-tetracarboxy-6,6'-diphenyl-3,3'-dipyridyl was synthesized by the following reactions. *p*-Phenylenediamine was condensed with benzaldehyde and pyruvic acid to 1,10-dicarboxy-3,8-diphenyl-4,7-phenanthroline. Although the exact structure of this compound was not determined, the conclusion that both nitrogen rings closed toward each other in the position indicated is supported by the results of previous investigators,⁶ who have proved that the unsubstituted phenanthroline made from *p*-phenylenediamine by the Skraup synthesis has the pyridine rings closed on the same side of the benzene ring. Moreover, the other isomeric phenanthroline could hardly be expected to oxidize to a tetrabasic acid.

Upon oxidation of the phenanthroline with potassium permanganate, the tetracarboxydipyridyl was obtained and resolved through the di-

⁶ Döbner and Ferber, *Ann.*, **281**, 16 (1894).

brucine salt. The chief difficulty involved was the isolation of the product due to the fact that the phenanthroline and tetracarboxydipyridyl are both acidic in character and rather similar in solubility.

Experimental

1,10-Dicarboxy-3,8-diphenyl-4,7-phenanthroline.—To 55 g. of *p*-phenylenediamine dissolved in 1 liter of boiling 95% alcohol in a 2-liter beaker was added 106 g. of benzaldehyde. The solution was then allowed to cool slightly until the Schiff base started to separate in the form of green-golden plates. The solution was then reheated to boiling and 88 g. of freshly prepared pyruvic acid was added with stirring over a period of five minutes in 10-cc. amounts. The reaction mixture boils violently so that the addition of pyruvic acid should not be too rapid. The solution, now deep red in color, was evaporated on a hot-plate to a total volume of 300–400 cc., when it was poured into a hot solution consisting of 60 g. of potassium hydroxide in 1500 cc. of distilled water. The solution was further evaporated until the volume reached about 1000 cc. in order that all of the alcohol would be removed. Then 1 liter of water was added and the solution was allowed to cool and stand. The by-product separated as a tar which solidified when cool. The solution was then filtered through norite. (This solution can now be used without further purification for the oxidation subsequently described.)

The isolation of the substituted phenanthroline was accomplished by heating the solution to 80–90° and acidifying with dilute hydrochloric acid. The product separated immediately in a crystalline condition and was filtered. If the solution was acidified when cold, the phenanthroline precipitated in an amorphous condition and was filtered and dried only with difficulty. The yield was 90–110 g. (42–50%).

Purification was accomplished by redissolving in a liter of hot potassium hydroxide solution (containing 40 g. of solid potassium hydroxide), filtering and reprecipitating with hydrochloric acid while hot. After cooling and filtering, the product could be crystallized from alcohol as follows. The dried material was dissolved in 300 cc. of hot 95% alcohol and filtered. It was then cooled in ice and salt and a small amount of material separated. The major portion did not appear until cooled to the temperature of a carbon dioxide–ether mixture. The product from alcohol is a deep brick red after it is dried and finely divided; yield 42 g. It may also be recrystallized from water, from which it separates as a bright scarlet material. The melting point is 250.5–251.5°, with decomposition.

Anal. Calcd. for $C_{26}H_{16}O_4N_2$: C, 74.26; H, 3.84; N, 6.66. Found: C, 74.20; H, 4.13; N, 6.68.

The di-silver salt of this compound was also prepared. A small amount of the acid (0.5–1.0 g.) was dissolved in 25 cc. of water containing a few drops of concentrated aqueous ammonia. The solution was then boiled to expel the excess ammonia and fil-

tered into a hot aqueous solution of silver nitrate. The di-silver salt separated as a yellow flocculent precipitate which was filtered with suction, washed with hot water and then with hot acetone.

Anal. Calcd. for $C_{26}H_{14}O_4N_2Ag_2$: Ag, 34.04. Found: Ag, 33.60.

2,4,2',4'-Tetracarboxy-6,6'-diphenyl-3,3'-dipyridyl.⁷—A solution of 21 g. of 1,10-dicarboxy-5,8-diphenyl-4,7-phenanthroline in 6 g. of potassium hydroxide, dissolved in 1 liter of water, was placed in a 2-liter beaker. Cracked ice was added to cool the solution to 10–15°, at which point a solution of 30 g. of potassium permanganate in 400 cc. of hot water was added with rapid stirring. This caused the temperature of the solution to rise to 20–25°. If the oxidation was carried out below this temperature, the manganese oxides formed did not coagulate properly and made filtration difficult. The solution was allowed to stand for one hour, after which time it was heated on a steam cone to coagulate further the oxides of manganese. After standing, the oxides settled and about one-half of the liquid could be decanted before filtration.

The filtered solution was placed in a large porcelain evaporating dish and was acidified with concentrated nitric acid to Congo red paper. The solution was then evaporated to dryness on a steam cone and the crude acids were extracted from the salt with acetone. The acetone solution, after filtration, was evaporated to dryness and the last traces of solvent removed in a vacuum desiccator. The dry product was boiled with 300 cc. of ethyl acetate and the hot solution filtered into 900 cc. of petroleum ether (b. p. 65–110°).

The precipitate was filtered with suction and partially dried by allowing the air to pass through for about fifteen minutes. This solid was then redissolved in 100 cc. of boiling ethyl acetate and the procedure repeated. This was again done, using about 50 cc. of ethyl acetate. This series of precipitations serves to remove the phenanthroline, which is only slightly soluble in ethyl acetate.

The removal of the last traces of solvent can be accomplished by a final drying in an Abderhalden dryer over phosphorus pentoxide at a temperature of 100° (water). About 7.5 g. of product was obtained as a light yellow powder, which decomposes without melting at 181°.

Anal. (Micro). Calcd. for $C_{26}H_{16}O_8N_2$: C, 64.44; H, 3.33; N, 5.78. Found: C, 64.13, 64.24; H, 3.51, 3.41; N, 5.16.

Resolution of 2,2',4,4'-Tetracarboxy-6,6'-diphenyl-3,3'-dipyridyl.—Two methods of resolution were used. The first was more extensively studied but the second proved much the simpler of the two.

First Method.—A solution of 4.84 g. (0.01 mole) of the tetracarboxydipyridyl in 200 cc. of ethyl acetate and a solution of 7.88 g. (0.02 mole) of brucine in 200 cc. of ethyl acetate were mixed together in a 2-liter beaker. Sufficient ethyl acetate was then added to dissolve almost completely the brucine salt. The hot solution was filtered, cooled and the precipitated salt filtered out by means of a Gooch crucible. About 0.5 g. was usually obtained.

Rotation. 0.2205 g. made up to 50 cc. with chloroform at 20° gave $\alpha_D -0.02 \pm 0.01^\circ$; $l = 1$; $[\alpha]_D^{25} -4.9^\circ$.

This precipitate was extracted several times with 100-cc. portions of hot ethyl acetate, but neither the residue nor the salt which separated on cooling showed any change in rotation.

The filtrate from the 0.5 g. of salt from the original solution was then concentrated and various fractions as they precipitated were filtered. This was continued until a volume of 50 cc. was reached when no more salt could be obtained in a solid condition

⁷ Skraup and Vortmann, *Monatsh.*, **4**, 583 (1883).

upon cooling the solution. These intermediate fractions were worked up for less soluble and more soluble salt by the process just discussed.

Upon evaporating the 50 cc. to dryness and removing the last traces of solvent by suction, the more soluble salt was obtained in a dry powdery form. Generally less than a gram was obtained.

Rotation. 0.1136 g. made up to 20 cc. with chloroform at 20° gave $\alpha_D -0.20 \pm 0.01^\circ$; $l = 1$; $[\alpha]_D^{25} -35.8^\circ$.

Second Method.—To a solution of 9.682 g. (0.02 mole) of the acid in 200 cc. of ethyl acetate was added 7.88 g. (0.02 mole) of brucine in 100 cc. of ethyl acetate. A precipitate (8.7 g.) was obtained which decomposed without melting at 202–207°. It was purified by boiling with ethyl acetate to dissolve any more soluble salt which had adhered.

Rotation. 0.1400 g. made up to 50 cc. with chloroform at 20° gave $\alpha_D -0.01 \pm 0.01^\circ$; $l = 1$; $[\alpha]_D^{25} -3.5^\circ$.

Upon the addition of another 7.88 g. (0.02 mole) of brucine in 100 cc. of ethyl acetate, 1.9 g. more of precipitate was obtained which apparently was a less soluble form.

Rotation. 0.1623 g. made up to 50 cc. with chloroform at 20° gave $\alpha_D -0.046 \pm 0.01^\circ$; $l = 1$; $[\alpha]_D^{25} -5.6^\circ$.

The solution was then evaporated to 50 cc., whereupon 14 g. of salt had precipitated.

Rotation. 0.1916 g. made up to 20 cc. with chloroform at 20° gave $\alpha_D -0.19 \pm 0.01^\circ$; $l = 1$; $[\alpha]_D^{25} -19.8^\circ$.

The last 50 cc. was evaporated to dryness and 3 g. of more soluble salt was obtained. It turns brown at 155–160° and melts with decomposition at 180–184°.

Rotation. 0.1500 g. made up to 20 cc. with chloroform at 20° gave $\alpha_D -0.26 \pm 0.01^\circ$; $l = 1$; $[\alpha]_D^{25} -34.7^\circ$.

By extracting the 14 g. of intermediate fraction with 50-cc. portions of the ethyl acetate, 1.5 g. of the more soluble salt was readily obtained having $[\alpha]_D^{25} -35^\circ$.

Anal. Calcd. for $C_{72}H_{48}N_8O_{16}$: N, 6.69. Found: for less soluble salt, N, 6.61; for more soluble salt, N, 6.66.

d and *l*-2,2'-4,4'-tetracarboxy-6,6'-diphenyl-3,3'-dipyridyl.—Three grams of the salt $[\alpha]_D^{25} -5.0^\circ$ was triturated in a small porcelain mortar with ice-cold, 5% hydrochloric acid, filtered and washed with distilled water. After partially drying, the procedure was repeated. The acid was then taken up in ice-cold, very dilute sodium hydroxide and shaken three times with 100-cc. portions of chloroform. The solution was filtered into cold dilute hydrochloric acid. (The procedure occupied about twenty minutes up to this point.) The free acid separated and was filtered and washed with distilled water and dried over phosphorus pentoxide *in vacuo* at room temperature. About 0.8 g. of the acid (entirely free from brucine) was recovered from the 3 g. of salt.

Rotation. 0.0896 g. made up to 20 cc. with acetone at 20° gave $\alpha_D +0.035 \pm 0.01^\circ$; $l = 1$; $[\alpha]_D^{25} +7.8^\circ$. 0.1628 g. made up to 20 cc. with 95% alcohol at 20° gave $\alpha_D +0.05 \pm 0.01^\circ$; $l = 1$; $[\alpha]_D^{25} +6.1^\circ$.

The same procedure was followed with the more soluble salt. The yield of free acid was less from this fraction.

Rotation. 0.0677 g. made up to 20 cc. with 95% alcohol at 20° gave $\alpha_D -0.04 \pm 0.01^\circ$; $l = 2$; $[\alpha]_D^{25} -5.9^\circ$.

Anal. Calcd. for $C_{26}H_{16}N_2O_8$: N, 5.78. Found: for +6.1° acid, N, 5.16; for -5.9° acid, N, 5.08.

Racemization Tests.—0.3705 g. made up to 50 cc. with 95% alcohol at 20° gave $\alpha_D +0.04 \pm 0.01^\circ$; $l = 1$; $[\alpha]_D^{25} +5.4^\circ$. The solution was allowed to stand at room temperature for twenty hours ($T = 33-35^\circ$). $\alpha_D +0.02 \pm 0.01^\circ$; $[\alpha]_D^{25} +2.7^\circ$.

The solution was then boiled for fifteen minutes, after which the rotation was 0. Due to the deep color of the sodium salt, no rotation could be observed on account of the extreme dilution which was necessary before light would pass through the tube.

Summary

1. 2,4,2',4'-Tetracarboxy-6,6'-diphenyl-3,3'-dipyridyl has been prepared by the oxidation of 1,10-dicarboxy-3,8-diphenyl-4,7-phenanthroline. This in turn was prepared by the condensation of *p*-phenylenediamine with benzaldehyde and pyruvic acid.

2. The dipyridyl was resolved through the brucine salt. The active acid was readily racemized by warming for a short time in ethyl alcohol.

THE PREPARATION OF VARIOUS OMEGA-CYCLOHEXYL ALKYL AMINES AND THEIR BACTERICIDAL ACTION TO MYCOBACTERIUM LEPRAE. XXII¹

BY GERALD H. COLEMAN AND ROGER ADAMS

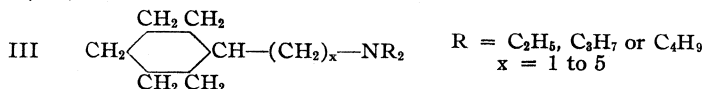

RECEIVED DECEMBER 21, 1931

PUBLISHED MAY 7, 1932

In one of the earlier papers² describing the preparation and bactericidal properties of various aliphatic acids, it was demonstrated in the case of chaulmoogric acid (I) that the carboxyl group could be replaced by a $-\text{CH}_2\text{N}(\text{C}_2\text{H}_5)_2$ group and the product (II) still had bactericidal properties.

The present investigation involved the synthesis of a series of ω -cyclohexyl-alkyl tertiary amines of varying molecular weight and of the general formula (III).

These compounds correspond essentially to the series of acids described in earlier papers.

The bacteriological study was made with the same strain of *Mycobacterium leprae* used with the acids. The amines were made into the hydrochloride salts and tested in the same manner as the sodium salts of the acids.^{1b} The table (I) of results is given below.

The conclusions are very definite. The bactericidal value is dependent, in part at least, on molecular weight just as in the acids. It is obvious

from the table that the molecules containing fifteen to eighteen carbon atoms show marked bactericidal action, but the action is insignificant or nil in the smaller molecules. The distribution of the carbon atoms in the cyclohexylalkyl residue or in the alkyl groups has, apparently, very little effect.

Presumably the proper combination of physical properties exists in these amine salts as in the salts of the acids. From these results it would appear that the carboxyl group and the amine group in bactericidal compounds of equal molecular weight may be interchangeable, though the bactericidal value of the amines is less than in the corresponding acids.

The amines were prepared by condensing the proper bromide with the secondary amines and the hydrochlorides were formed by precipitation with dry hydrogen chloride from a dry ether solution of the bases. The intermediate bromides were the same as those used in the synthesis of ω -cyclohexylalkyl aliphatic acids.³

Experimental

Cyclohexylamine was prepared according to the method of Hiers and Adams,⁴ b. p. 132–133°; hydrochloride salt, after crystallization from chloroform and petroleum ether, m. p. 202°.

Cyclohexylmethylamine,⁵ b. p. 159.5–160°; hydrochloride salt after crystallization from chloroform and petroleum ether, m. p. 252–253°.

β -Cyclohexylethylamine⁵ was prepared from cyclohexylethyl bromide. A mixture of 10 g. of cyclohexylethyl bromide and 9.8 g. of potassium phthalimide was refluxed in a 100-cc., round-bottomed flask at 230–250° for seven hours. The mixture was cooled and extracted with 125 cc. of absolute alcohol. After evaporating the alcohol, the product was refluxed for one-half hour with 50 cc. of 10% potassium hydroxide solution and then for one-half hour after the addition of 10 cc. of concentrated hydrochloric acid.

³ Hiers and Adams, *THIS JOURNAL*, **48**, 2385 (1926).

⁴ Hiers and Adams, *Ber.*, **59**, 162 (1926).

⁵ Wallach, *Ann.*, **353**, 297 (1907).

The solution was cooled, made alkaline, and ether extracted. The base was dried and distilled and converted to the hydrochloride; hydrochloride salt, m. p. 245–246°.

Cyclohexyldiethylamine was prepared by the method of Sabatier and Senderens:⁶ b. p. 56–57° at 5 mm.; n_D^{25} 1.4560; d_{25}^{25} 0.8445; hydrochloride from benzene and petroleum ether, m. p. 152–153°.

General Method of Preparation of Amines and their Salts.—About 20 g. of bromide was mixed with three molecular equivalents of dialkyl amine and allowed to stand at room temperature. Crystals of hydrobromide separated. About 100 cc. of water was added and the solution, after acidification with hydrochloric acid, was ether extracted to remove unreacted bromide, then made alkaline and again ether extracted to remove the product. The base was dried with solid potassium hydroxide, then with metallic sodium and fractionated.

The hydrochlorides were prepared by dissolving the amines in dry ether, precipitating by passing in dry hydrogen chloride and recrystallizing the crude products from a suitable solvent. Excess of hydrogen chloride should be avoided; otherwise the hydrochlorides may separate as oils. These oils may be converted into crystalline products by evaporating the solvent, adding chloroform, re-evaporating, and recrystallizing with or without the addition of a second solvent such as petroleum ether.

Summary

It has been shown that ω -cyclohexylalkyl amines of the general formula $C_6H_{11}(CH_2)_xNR_2$ are bactericidal to *B. leprae* providing the molecules have the proper molecular weight. The compounds should contain fifteen to eighteen carbon atoms just as found necessary in the various acids already tested, distribution of the carbon atoms having very little effect.

THE IDENTIFICATION OF MERCAPTANS WITH 2,4-DINITROCHLOROBENZENE

BY R. W. BOST, J. O. TURNER AND R. D. NORTON

RECEIVED DECEMBER 21, 1931

PUBLISHED MAY 7, 1932

Due to the increasing interest shown in mercaptans and due to the paucity of good reagents whereby they may be identified, it seemed desirable to study methods for their identification. Numerous mercaptides^{1,2,3} have been prepared. Purification of these is not always easy and certain of the mercaptides are frequently unstable.⁴ Wertheim¹ has proposed 3,5-dinitrobenzoyl chloride and also 3-nitrophthalic anhydride as reagents for mercaptan identification. The use of these reagents is restricted, due to the close proximity of the melting points of certain of their derivatives. Reid⁵ and his co-workers have suggested the use of sodium anthraquinone α -sulfonate and also sodium anthraquinone 1,5- and 1,8- disulfonates, although the sulfonic group could not be replaced with phenyl mercaptan. The time required for these reactions to go to completion varies from a few minutes to several hours, while in certain cases several products are obtained.

In this paper the authors propose 2,4-dinitrochlorobenzene as a new reagent for the identification of mercaptans. It rapidly forms solids with all mercaptans thus far studied. The reagent is inexpensive, it is stable, and gives excellent yields of stable derivatives which are easily purified, having sharp melting points and definite crystalline structure. In no case was it necessary to heat the reactants for over ten minutes. The reagent is unique in that it forms solid sulfides that can be rapidly oxidized to the corresponding sulfones, thus ensuring complete identification in a remarkably short time.

⁵ Reid, Mackall and Miller, *ibid.*, **43**, 2108 (1921).

Experimental

Preparation of Sulfide.—The general procedure used to make the condensation products with 2,4-dinitrochlorobenzene was carried out as follows. 0.01 Mole of the mercaptan was added to 30 ml. of absolute alcohol in the case of liquid mercaptans; in the case of solid mercaptans, the smallest amount of hot alcohol necessary to dissolve it was used. The sodium mercaptide was made by adding 0.01 Mole of sodium hydroxide dissolved in 3 ml. of water to the mercaptan solution. 0.01 Mole of 2,4-dinitrochlorobenzene was dissolved in 10 ml. of absolute alcohol in a 100-ml. balloon flask and the alcoholic solution of the sodium mercaptide added to the flask containing the reagent. At this point many mercaptans react almost instantly, as shown by the generation of heat and the precipitation of the sulfide. To ensure complete reaction the mixture was refluxed on the steam-bath for ten minutes. The hot solution was quickly filtered, whereupon the sulfide crystallized in beautiful golden-yellow needles from the filtrate on cooling. The product was recrystallized from absolute alcohol until a constant melting point was obtained. As a general rule the melting point was not raised after one recrystallization except in the case of iso-mercaptans. It has been found best to use a slight excess of mercaptan. This prevents the formation of a reddish-brown solution caused by an excess of sodium hydroxide which might affect the purity of the final product.

The melting points of the sulfides are given in Table I. In certain cases the melting points of the sulfides are not far enough separated to ensure complete identification. Thus further to ensure the identity of the mercaptan, the sulfide was converted into the sulfone by oxidation with potassium permanganate in acid solution at room temperature.

TABLE I
DERIVATIVES OF MERCAPTANS WITH 2,4-DINITROCHLOROBENZENE

Mercaptan	M. p., °C. (corrected)	Analysis for sulfur, %		Mercaptan	M. p., °C. (corrected)	Analysis for sulfur, %

<i>n</i> -Propyl	81	13.25	13.36	Cetyl	91	7.60	7.50
Isopropyl	94.5	13.25	13.47	Thiophenol	121	11.57	11.71
<i>n</i> -Butyl	66	12.51	12.54	<i>p</i> -Thiocresol	103	11.05	11.05
Isobutyl	76	12.51	12.76	Benzyl	130	11.05	11.08
<i>n</i> -Amyl	80	11.87	11.76	Phenylethyl	89.5	10.54	10.51
Isoamyl	59	11.87	11.88	Thienyl	119	22.61	22.72
Hexyl	74	11.28	11.02	Furfural	130	11.43	11.68
Heptyl	82	10.75	10.88	Biphenyl	146	9.09	9.21

Preparation of Sulfone.—0.01 mole of the sulfide was dissolved in just enough glacial acetic acid to put it into solution. In cases of difficultly soluble sulfides, solution may be facilitated by gentle warming. The solution was treated with 50% excess of the calculated amount of potassium permanganate dissolved in thirty times its weight of water to form the sulfone. The permanganate was added, with shaking, as fast as it was decolorized. Some of the less soluble sulfides have a tendency to precipitate on addition of the aqueous solution of the permanganate. In such cases, a slight excess of acid should be added to keep it in solution and ensure complete oxidation. When all the permanganate had been added, the excess was removed by treating with a solution of sulfurous acid at room temperature, avoiding an excess of the reagent. In most cases the sulfone occurs in the form of a colorless precipitate at this point. In cases where it is only incompletely precipitated at this point, two or three volumes of cracked ice is added.

The sulfone is filtered, dried and recrystallized from absolute alcohol. In a few cases purification was facilitated by the use of charcoal. Usually one recrystallization is sufficient. The sulfones are colorless needles having sharp melting points. Data on these compounds are found in Table II.

TABLE II
SULFONES OF 2,4-DINITROPHENYL THIOETHERS

Sulfone	M. p., °C. (corrected)	Analysis for sulfur, %		Sulfone	M. p., °C. (corrected)	Analysis for sulfur, %	
		Calcd.	Found			Calcd.	Found
Methyl	189.5	13.00	12.87	Heptyl	101	9.69	9.81
Ethyl	160	12.30	12.67	Octyl	98	9.30	9.31
<i>n</i> -Propyl	127.5	11.68	11.78	Nonyl	92	8.93	8.86
Isopropyl	140.5	11.68	11.55	Phenyl	161	10.38	10.40
<i>n</i> -Butyl	92	11.11	11.05	<i>p</i> -Cresyl	189.5	9.93	9.89
Isobutyl	105.5	11.11	11.04	Benzyl	182.5	9.93	9.90
<i>n</i> -Amyl	83	10.59	10.70	Phenylethyl	133.4	9.52	9.56
Isoamyl	95	10.59	10.69	Thienyl	143	20.38	20.14
Hexyl	97	10.12	10.22	Biphenyl	170	8.33	8.61

The above sulfides and sulfones may be prepared on a much smaller scale using 0.001 molar quantities of the reactants in the proportionate amounts of solvent and carrying out the reactions in test-tubes. Where only enough of the sulfide or sulfone is desired for a melting point, this procedure may be followed with gratifying results. Under ordinary conditions, the conversion of the mercaptan into the sulfide and thence into the sulfone may be accomplished in twenty to twenty-five minutes, although with a higher degree of technique it is possible to carry out the reactions in even shorter time.

Summary

1. 2,4-Dinitrochlorobenzene readily reacts with sodium mercaptides to form alkyl and aryl dinitrophenyl thioethers.
2. The dinitrophenyl thioethers are easily oxidized to the corresponding sulfones by potassium permanganate in acetic acid solution.
3. 2,4-Dinitrochlorobenzene is strongly recommended as a reagent for mercaptans.

ROTENONE. XX. THE STRUCTURE OF TUBAIC ACID

BY H. L. HALLER AND F. B. LAFORGE

RECEIVED DECEMBER 24, 1931

PUBLISHED MAY 7, 1932

In a brief note recently published in THIS JOURNAL¹ it was reported that on catalytic hydrogenation tubaic acid ($C_{12}H_{12}O_4$) yields a mixture of dihydrotubaic ($C_{12}H_{14}O_4$) and tetrahydrotubaic ($C_{12}H_{16}O_4$) acids. The latter was stated to be 2,4-dihydroxy-3-isoamylbenzoic acid, and its relation to tubaic acid was indicated. The present paper presents the experimental evidence for these statements.

Tetrahydrotubaic acid is practically insoluble in cold chloroform, in alcoholic solution it gives a violet color with ferric chloride, and it is optically inactive. It readily forms a diacetyl derivative ($C_{16}H_{20}O_6$) and a monomethoxy acid ($C_{13}H_{18}O_4$). The monomethoxy acid resists further methylation. When heated to its melting point the tetrahydro acid loses carbon dioxide, forming an alkyl resorcinol.

The fact that tetrahydrotubaic acid is practically insoluble in cold chloroform, in contrast to tubaic and dihydrotubaic acids, which are soluble in this solvent, suggests that tetrahydrotubaic acid contains an hydroxyl group para to the carboxyl group, as para hydroxy acids are insoluble in cold chloroform.²

Tubaic acid is optically active, but isotubaic acid ($C_{12}H_{12}O_4$), which differs from tubaic acid in the position of a double bond, is optically inactive. The resolution of dihydroisotubaic acid,³ the levo form of which is identical with dihydrotubaic acid, proves that the isomerization of tubaic acid to isotubaic acid is due to the migration of a hydrogen atom originally attached to an asymmetric carbon atom. It follows, therefore, that the asymmetric carbon atom in tubaic acid possesses one hydrogen atom.

Tetrahydrotubaic acid also is optically inactive, indicating that one of its hydroxyl groups is formed by the opening of a ring containing an indifferent oxygen atom which is attached on one side to an asymmetric carbon atom. The disappearance of the optical activity of tubaic acid on drastic hydrogenation, as well as in the isomerization of tubaic to isotubaic acid, is proof that tubaic acid has but one asymmetric center.

Diacetyltetrahydrotubaic acid, which is easily obtained from the tetrahydro acid by the action of acetic anhydride and sodium acetate, is converted into a monoacetyltetrahydrotubaic acid when it is refluxed in a

¹ Haller and LaForge, THIS JOURNAL, 53, 4460 (1931).

² Meyer, "Analyse und Konstitutionsermittlung organischen Verbindungen," 5th ed., 1931, p. 418.

³ Butenandt and Hildebrandt, *Ann.*, 477, 245 (1930); Takei, Koide and Miyajima, *Ber.*, 63, 1369 (1930).

solution of potassium acetate in absolute alcohol. In alcoholic solution this monoacetyl derivative gives a violet color with ferric chloride.

On methylation of tetrahydrotubaic acid with dimethyl sulfate and dilute alkali, its monomethoxymethyl ester is obtained, which is readily saponified, to the monomethoxy acid ($C_{13}H_{18}O_4$).

Attempts to methylate the second hydroxyl group were unsuccessful.

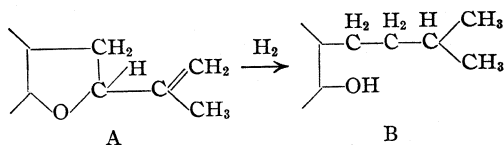

The fact that one of the hydroxyl groups in tetrahydrotubaic acid resists methylation, and the corresponding acetyl derivative is easily saponified, indicates that the hydroxyl group involved is di-ortho substituted.

When heated to its melting point the tetrahydro acid loses carbon dioxide and is converted into a crystalline substance ($C_{11}H_{16}O_2$) which gives the characteristic reactions of resorcinol.

That only one alkyl group is present in the diphenol and that this group is an isoamyl group is shown by the following facts: on oxidation with potassium permanganate tubaica acid yields only acetic acid, whereas under the same conditions isotubaica and dihydrotubaica acids give isobutyric acid.

Takei⁴ isolated isovaleric acid by alkali fusion of isotubanol ($C_{11}H_{12}O_2$), (decarboxylated isotubaica acid), and he also demonstrated the presence of the isoallyl group in tubaica acid. On ozonization of tubanol methyl ether, he obtained a methyl ether methyl ketone, which on oxidation with hypiodide yielded an iodine-containing carboxylic acid that had one carbon atom less than the methyl ketone. We have ozonized the acetyl derivative of tubaica acid ($C_{14}H_{14}O_5$) and obtained from the ozonide a product which analyzes for a compound of formula $C_{13}H_{12}O_6$ and gives the reactions of a methyl ketone.

From the foregoing facts it follows that grouping A is present in tubaica acid and that on drastic hydrogenation it is changed to grouping B.

Tubaica acid and all rotenone derivatives which are converted by hydrogenation into phenolic compounds therefore contain the grouping —O—CH—C=CH_2 . This grouping is comparable with that of a conjugated system, and hydrogenation takes place with the opening of the ether ring.⁵ This reaction is explained by the assumption that a 1,4-addition of hydrogen (at —O— and C_4) first takes place, followed by the formation of the double linkage at 2,3. This double linkage is further reduced in the formation of

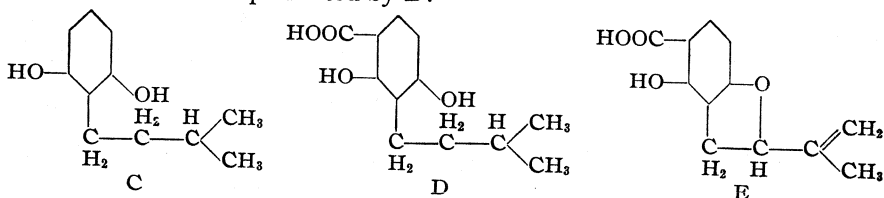

⁴ Takei, Koide and Miyajima, *Ber.*, **63**, 1369 (1930).

⁵ Schöpf, *Ann.*, **452**, 237 (1927); **483**, 157 (1930).

tetrahydrotubaic and dihydrotentenonic acids, but remains unsaturated in rotenonic acid, which therefore contains the grouping $\text{—}\overset{\text{H}_2}{\text{C}}\text{—}\overset{\text{H}}{\text{C}}\text{=C}(\text{CH}_3)_2$. This reaction is analogous to the formation of β -tetrahydrodesoxycodeine from desoxycodeine-C.⁶

The position of the alkyl group in the resorcinol derivative is either 2, 4 or 5 (formula C). Position 4 is excluded because this alkyl resorcinol is known. Its melting point is 62–62.5°, while the compound obtained from tetrahydrotubaic acid melts at 85°. Position 5 is excluded because alkyl groups meta to the hydroxyl groups in resorcinol do not give a fluorescein reaction. Also it is more probable that the two linkages on the benzene nucleus of the original oxide ring of tubaic acid are ortho to each other rather than meta, and therefore the alkyl group and the hydroxyl group in tetrahydrotubaic acid are also ortho to each other rather than meta. It follows, therefore, that the alkyl group occupies position 2.

The behavior of the tetrahydro acid indicates that the carboxyl group is ortho to one of the hydroxyl groups and para to the other. Tetrahydrotubaic acid is best represented by D.

Structure E, which satisfactorily accounts for all the known facts, is now proposed for tubaic acid.

The relation of tubaic acid to rotenone has been discussed in a previous paper.⁷

Tubaic acid was considered to be a secondary decomposition product because at that time⁸ the rotenone molecule was supposed to contain a lactone group and also because it was difficult to account otherwise for the failure to obtain tubaic acid when rotenone derivatives were oxidized with hydrogen peroxide, as tubaic acid is stable to this oxidizing agent. The fact that no tubaic acid is obtained is satisfactorily accounted for, however, with consideration of the observation of Dakin⁹ on the oxidation of hydroxy aromatic aldehydes and ketones with hydrogen peroxide. Dakin has shown that hydroxy aromatic aldehydes and ketones in which the free hydroxyl group is in the ortho or para position to the aldehyde or ketone group, are oxidized by hydrogen peroxide with the formation of polyphenols. *No substituted benzoic acid is formed in the reaction.*

Most of the rotenone derivatives which are cleaved by hydrogen peroxide possess an hydroxyl group ortho to the carbonyl group, and in some cases an hydroxyl group is present in both the ortho and para positions.

Derrisic acid has an hydroxyl group ortho to the carbonyl group. In this case, on oxidation with hydrogen peroxide, cleavage takes place between the carbonyl group and the benzene ring with the formation of derric acid and probably a catechol derivative, which is for the most part oxidized further by the excess of peroxide. No tubaic acid is formed in the process.

Dehydrodihydrotentenonic acid possesses an hydroxyl group para to the carbonyl group. In the oxidation of this compound hydrolysis of the ortho (ether) oxygen linkage probably takes place first, and oxidation then proceeds with the formation of risic acid.

Methyl derritolic and dihydrotentenolic acids have a hydroxyl group in the ortho position as well as in the para position, and oxidation takes place without the formation of tubaic acid. On the other hand such compounds as rotenone itself and rotenonic acid are not cleaved by hydrogen peroxide. These reactions are illustrated as follows

Experimental

Tetrahydrotubaic Acid (2,4-Dihydroxy-3-isoamylbenzoic Acid).—One gram of tubaic acid dissolved in 25 cc. of ethyl acetate was reduced with hydrogen at 48 lb. pressure, with 0.5 g. of freshly prepared reduced platinum oxide as catalyst. The reduction was allowed to proceed for two hours. The solution was filtered and concentrated to dryness on the steam-bath. The mixture of dihydro and tetrahydrotubaic acid was dissolved in 95% alcohol. The solution, heated to boiling, was diluted with an equal volume of hot water and filtered through charcoal.

The crystals which deposited on cooling were found to be pure dihydrotubaic acid. On concentration of the filtrate a second crop of crystals was obtained. This was filtered off, dried and then washed several times with cold chloroform. The remaining substance was crystallized from 20% alcohol. It can also be recrystallized from benzene, chloroform or toluene. It melted at 206° with decomposition, and was optically inactive. The yield was about 0.1 g.

Anal. Subs., 0.0822, 0.0806: CO_2 , 0.1931, 0.1903; H_2O , 0.0529, 0.0526. Calcd. for $C_{12}H_{16}O_4$: C, 64.25; H, 7.20. Found: C, 64.07, 64.40; H, 7.20, 7.30. *Titration.* Subs., 0.0297: 1.34 cc. of $N/10$ KOH. Calcd. mol. wt., 224.13. Found: acid equivalent, 222.

Attempts were made to increase the yield of tetrahydrotubaic acid by the use of different solvents as well as by the addition of pinene to the ethyl acetate solution. Ethyl alcohol (95%) and glacial acetic acid were employed as solvents, but in all cases there was no appreciable increase in the amount of tetrahydrotubaic acid formed.

Diacyltetrahydrotubaic Acid.—Two-tenths gram of tetrahydrotubaic acid was

refluxed in 5 cc. of acetic anhydride and 0.2 g. of anhydrous sodium acetate for one hour. After most of the solvent had been removed by distillation, water was added. The precipitated oil soon crystallized. The substance was filtered off and dissolved in 10 cc. of 95% alcohol. After the solution had been refluxed for one hour, it was diluted with an equal volume of hot water, filtered through charcoal and allowed to crystallize. The diacetate which separated melted at 143° . The yield was 0.18 g.

*Anal.*¹⁰ Subs. (mg.), 3.052, 3.997: CO_2 , 7.020, 9.151; H_2O , 1.750, 2.335. Calcd. for $\text{C}_{16}\text{H}_{20}\text{O}_6$: C, 62.31; H, 6.52. Found: C, 62.73, 62.44; H, 6.42, 6.54. *Titration.* Subs., 0.0338: 2.15 cc. of *N*/20 KOH. Calcd. mol. wt., 308.16. Found: acid equivalent, 314.

To 0.0338 g. of the diacetyltetrahydrotubaic acid was added 8.75 cc. of *N*/20 KOH. The solution was heated on the steam-bath for one-half hour, cooled and the excess of alkali was titrated with *N*/10 hydrochloric acid. The reaction required 3.28 cc. of *N*/20 potassium hydroxide; calcd. for 2 acetyl: 3.28 cc. of *N*/20 KOH.

Monoacetyltetrahydrotubaic Acid.—Two-tenths gram of diacetyltetrahydrotubaic acid was dissolved in 2 cc. of absolute alcohol containing 0.2 g. of potassium acetate. The solution was refluxed for one hour and then diluted with an equal volume of water. After the solution had cooled, 0.5 cc. of 20% sulfuric acid was added carefully. The substance, which separated immediately, was crystalline. It was filtered off, washed with water and dried. The yield was 0.08 g. It melted at 156° . In alcoholic solution it gave a purple color with ferric chloride.

Anal. Subs. (mg.), 3.223, 3.406: CO_2 , 7.452, 7.869; H_2O , 1.991, 2.068. Calcd. for $\text{C}_{14}\text{H}_{18}\text{O}_5$: C, 63.13; H, 6.82. Found: C, 63.07, 63.01; H, 6.91, 6.79. *Titration.* Subs., 0.0270: 2.05 cc. of *N*/20 KOH. Calcd. mol. wt., 266.14. Found: acid equivalent, 264.

To 0.0270 g. of monoacetyl tetrahydrotubaic acid was added 5.20 cc. of *N*/20 potassium hydroxide. The solution was heated on the steam-bath for one-half hour. It was then cooled, and the excess alkali was titrated with *N*/10 hydrochloric acid. The reaction required 4.07 cc. of *N*/20 potassium hydroxide. Calcd. for 1 acetyl, 4.07 cc. of *N*/20 KOH. On addition of excess acid to the solution obtained above, tetrahydrotubaic acid separated. It was identified by its melting point.

Methyltetrahydrotubaic Acid (2-Hydroxy-4-methoxy-3-isoamylbenzoic Acid).—To 0.2 g. of tetrahydrotubaic acid dissolved in 5 cc. of 5% potassium hydroxide solution was added 0.5 cc. of dimethyl sulfate. The solution was frequently shaken and was kept alkaline by further addition of alkali. After two hours, it was acidified with dilute sulfuric acid. The precipitate was filtered off, washed with water and then refluxed in 95% alcohol to which had been added 1 cc. of 5% potassium hydroxide in order to saponify any ester that had formed. The solution was concentrated, diluted with an equal volume of water, filtered through charcoal and acidified with dilute sulfuric acid. On cooling, the methoxy acid separated. The yield was 0.18 g. The acid was recrystallized from dilute alcohol. It can also be crystallized from benzene. It melted at 156° . In alcoholic solution it gave a purple color with ferric chloride.

Anal. Subs. (mg.), 3.387, 4.300: CO_2 , 8.110, 10.357; H_2O , 2.300, 2.939. Calcd. for $\text{C}_{15}\text{H}_{18}\text{O}_4$: C, 65.51; H, 7.62. Found: C, 65.30, 65.69; H, 7.60, 7.65.

An attempt was made to methylate the second hydroxyl group by using a large excess of methyl iodide and silver oxide and also with methyl iodide and potassium carbonate, but in each case unchanged starting material was recovered.

¹⁰ We are indebted to Mr. J. R. Spies of this Division for the microcombustions reported in this paper.

Tetrahydrotubanol (2-Isoamylresorcinol).—Five-tenths gram of tetrahydrotubaic acid was heated in a Wood's metal bath at 215–225° for about five minutes. When the evolution of carbon dioxide, which took place vigorously at first, had ceased, the remaining reddish liquid was distilled under reduced pressure. On cooling it readily crystallized. The substance was recrystallized from chloroform–petroleum ether. It can also be recrystallized from benzene–petroleum ether (b. p. 37–75°). It melted at 85°.

Anal. Subs. (mg.), 3.560, 3.936: CO₂, 9.504, 10.521; H₂O, 2.807, 3.115. Calcd. for C₁₁H₁₆O₂: C, 73.28; H, 8.95. Found: C, 72.81, 72.90; H, 8.82, 8.86.

The compound gave a precipitate with bromine water, and a cherry red color with Millon's reagent. With Lieberman's reagent, an intense blue color was obtained. This soon turned quite dark and on dilution with water the color practically disappeared. There was no change on addition of alkali. When the substance was dissolved in chloroform, and a small piece of potassium hydroxide was added a rose-red color was slowly produced around the edges of the potassium hydroxide (Guareschi–Lustgarten reagent).¹¹ In alcoholic solution no color test was obtained with ferric chloride, but in aqueous solution a purplish-blue color was formed with this reagent. The color disappeared on addition of sodium bicarbonate.

With formaldehyde and sulfuric acid a red ring slightly tinged with violet was obtained.¹² After fusion with phthalic anhydride and a drop of concentrated sulfuric acid, the diluted solution became red with a green fluorescence when excess alkali was added.

Ozonization of Acetyltubaic Acid.—A stream of ozonized oxygen was passed into a solution of 1 g. of acetyltubaic acid in 15 cc. of chloroform for four hours. Most of the chloroform was then removed by distillation. Water was added to the remaining sirup, and the solution was boiled for fifteen minutes. It was then cooled, and extracted with ether. The ether extract was dried over sodium sulfate. On removal of the ether, the substance readily crystallized. It was washed with isopropyl ether and recrystallized from a solution of 20% acetic acid—80% butyl ether. The yield was 0.2 g. It melted at 145°.

Anal. Subs., 0.0832, 0.0845: CO₂, 0.1784, 0.1834; H₂O, 0.0356, 0.0358. Calcd. for C₁₃H₁₂O₆: C, 59.07; H, 4.58. Found: C, 58.48, 59.19; H, 4.79, 4.74. Subs., 0.0475: cc. of N/10 KOH, 1.87. Calcd. mol. wt., 264.1. Found: acid equivalent, 254.

The substance reduced Fehling's solution, and with sodium hydroxide and iodine it gave iodoform. The same compound was obtained when acetyltubaic acid was ozonized in glacial acetic acid.

Conversion of Tetrahydrotubanol to Tetrahydrotubaic Acid.—Two-tenths gram of tetrahydrotubanol was refluxed in 50 cc. of a saturated solution of sodium bicarbonate for half an hour. The solution was cooled, filtered and acidified with dilute sulfuric acid. The precipitate was filtered off, washed with water and dried. It was then twice recrystallized from benzene. It melted at 206° and was identified as tetrahydrotubaic acid.

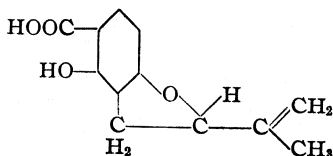

Summary

Tubaic acid is reduced by hydrogenation with platinum oxide catalyst to a mixture of dihydro and tetrahydrotubaic acid.

Tetrahydrotubaic acid is 2,4-dihydroxy-3-isoamylbenzoic acid, and tubaia acid is represented by the formula

¹¹ Rosenthaler, "Der Nachweis organischen Verbindungen," 1923, p. 240.

¹² Mulliken, "Identification of Pure Organic Compounds," 1908, Vol. I, p. 24.

An explanation of the mechanism of the oxidation of rotenone derivatives by hydrogen peroxide is given.

The behavior of tubaic acid on hydrogenation is analogous to that of desoxycodeine-C. Both contain the same groupings and both give tetrahydrophenols under the same conditions.

QUINAZOLINES. III. THE INTERACTION OF ANILINE WITH 2-CHLORO-4-ALKOXYQUINAZOLINES AND 2-CHLORO-4-KETODIHYDROQUINAZOLINE

BY N. A. LANGE AND F. E. SHEIBLEY

RECEIVED DECEMBER 26, 1931

PUBLISHED MAY 7, 1932

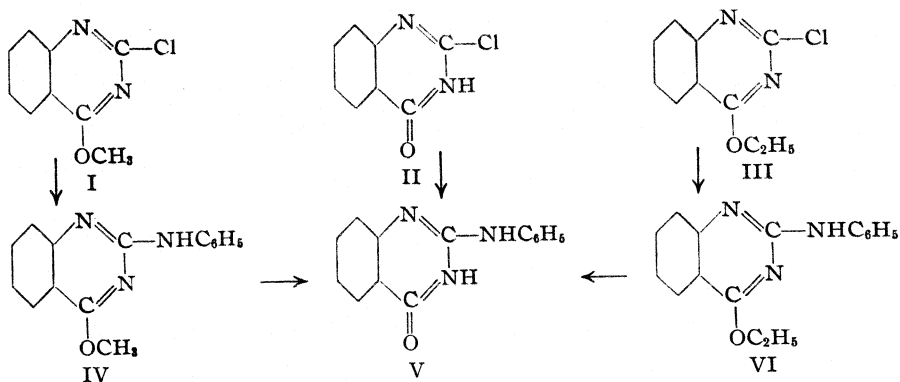

When 2,4-dichloroquinazoline in alcohol is boiled with sodium acetate, a compound with properties and a composition corresponding to a chloro-ketodihydroquinazoline is always found among the reaction products. In an earlier communication it was stated that by analogy with the similarly formed 2-chloro-4-alkoxyquinazolines this substance was most likely 2-chloro-4-ketodihydroquinazoline but that attempts to confirm this view by converting it into the known 4-ketodihydroquinazoline and 2-ethoxy-4-ketodihydroquinazoline were unsuccessful.¹

The ease with which aniline replaces both of the chlorine atoms of 2,4-dichloroquinazoline with phenylamino groups suggested the possibility of transforming 2-chloro-4-alkoxyquinazolines into 2-anilino derivatives. By treating 2-chloro-4-methoxyquinazoline (I) and 2-chloro-4-ethoxyquinazoline (III) with aniline in alcohol, hydrochlorides of 2-anilino-4-methoxyquinazoline (IV) and 2-anilino-4-ethoxyquinazoline (VI), respectively, are obtained. These last, on hydrolysis with dilute hydrochloric acid in the presence of aniline, or simply on heating, when the elements of an alkyl chloride are evolved, revert to the known 2-anilino-4-ketodihydroquinazoline (V), a compound which results directly when the previously mentioned chloroketo compound is treated with an alcoholic solution of aniline, and thus identifies the latter as 2-chloro-4-ketodihydroquinazoline (II).

A confirmation of the orientation of the halogen and alkoxy groups in the chloro-alkoxy derivatives arrived at in a previous paper² is afforded

¹ Lange and Sheibley, *THIS JOURNAL*, **53**, 3871 (1931).

² Lange, Roush and Asbeck, *ibid.*, **52**, 3696 (1930).

by the identity of (V) with a specimen of 2-anilino-4-ketodihydroquinazoline prepared according to the method of previous investigators.³ When phenylpseudomethylthiourea in ethereal solution was treated with anthranilic acid, what appeared to be an anthranilate of the base was precipitated. This product on fusion evolved methyl mercaptan, and the residue, treated with sodium hydroxide, yielded a product identical with (V) in every respect.

The free bases, 2-anilino-4-methoxyquinazoline (IV) and 2-anilino-4-ethoxyquinazoline (VI), are readily obtained from their hydrochlorides by treatment with sodium alcoholates. They are colorless, easily soluble substances, crystallizing in plates rather than the usual needles common to this class of compounds, and form characteristic salts.

All melting points given in this paper are corrected.

Experimental Part

Preparation of $\text{N}=\text{COCH}_3\text{C}_6\text{H}_4\text{N}=\text{CNHC}_6\text{H}_5\cdot\text{HCl}$, 2-Anilino-4-methoxyquinazoline Hydrochloride.—A mixture of 2.2 g. of 2-chloro-4-methoxyquinazoline and 1.2 g. of aniline was dissolved in 30 cc. of alcohol and the solution boiled under a reflux condenser on a steam-bath for one hour. The condenser was then removed and the alcohol allowed to evaporate until the total volume of the reaction mixture was about 10 cc. This was cooled slightly, or till crystallization just began, and diluted with 40 cc. of ether; the precipitated mass was disintegrated with a glass rod, filtered and washed with ether, and weighed 3.1 g. A crystallization from alcohol yielded 1.8 g. of slightly yellow needles (m. p. 152°); further purification was effected by recrystallizing from methyl alcohol containing a few drops of concentrated hydrochloric acid, when colorless needles of 2-anilino-4-methoxyquinazoline hydrochloride, melting around 160° (decomp.), were obtained.

Similarly when 1.5 g. of chloromethoxyquinazoline and 0.9 g. of aniline in 25 cc. of methyl alcohol were heated, 0.75 g. of a precipitate (m. p. 295°, and probably impure benzoylene urea) separated after the first half hour of heating and was removed by filtration. Concentration of the filtrate and precipitation with ether as outlined above yielded 1.6 g. of crude 2-anilino-4-methoxyquinazoline hydrochloride.

³ Wheeler, Johnson and McFarland, *THIS JOURNAL*, 25, 797 (1903).

This compound is soluble in alcohol, methyl alcohol or acetone, and insoluble in water, concentrated hydrochloric acid or ether. Its melting point was found to vary slightly but in general pure specimens melted within the range 158–161° (decomp. and foaming with loss of methyl chloride), the melts then solidifying and remelting within a range of 255–260°, the latter melting points being identical with those of impure specimens of 2-anilino-4-ketodihydroquinazoline (V). Recrystallization from ethyl alcohol gave blunt needles or prisms somewhat shorter than the crystals from methyl alcoholic solutions but of identical melting point.

A platinichloride was immediately precipitated on mixing hot methyl alcoholic solutions of the hydrochloride and platinic chloride. Washed with hot methyl alcohol and dried, it formed a granular, light orange, micro-crystalline mass, softening with decomposition at 225–230°, and soluble only in chlorohydrin. It ignites without melting.

Anal. Calcd. for $C_{16}H_{14}ON_3Cl$: C, 62.59; H, 4.91; N, 14.61; Cl, 12.33. Found: C, 62.94; H, 5.00; N, 14.51; Cl, 12.21. Calcd. for $(C_{16}H_{14}ON_3Cl)_2PtCl_4 \cdot H_2O$: Pt, 20.99. Found: Pt, 20.89, 20.98.

Preparation of $N=COC_6H_5C_6H_4N=CNHC_6H_5 \cdot HCl$, 2-Anilino-4-ethoxyquinazoline Hydrochloride.—This compound was obtained in the same manner as the anilino-methoxy derivative just described: 1.5 g. of 2-chloro-4-ethoxyquinazoline and 0.75 g. of aniline in 25 cc. of alcohol yielded 2.0 g. of crude precipitated product. A crystallization from alcohol gave 1.2 g. of fine needles (m. p. 161°); further recrystallizations from alcohol containing a few drops of hydrochloric acid resulted in colorless needles melting around 170°. The solubilities of this substance are the same as those of the analogous anilinomethoxy salt. Its melting point was also variable, pure specimens fusing within the range 168–171° with evolution of ethyl chloride and consequent solidifying and remelting around 259° due to the formation of 2-anilino-4-ketodihydroquinazoline (V). When kept at 40° for a day or so, these hydrochlorides often acquire a yellow color without any apparent change in composition.

Anal. Calcd. for $C_{16}H_{16}ON_3Cl$: C, 63.66; H, 5.35; Cl, 11.76. Found: C, 64.32; H, 5.27; Cl, 12.00.

Hydrolysis of the Hydrochlorides of 2-Anilino-4-methoxyquinazoline (IV) and 2-Anilino-4-ethoxyquinazoline (VI) to 2-Anilino-4-ketodihydroquinazoline (V).—Originally, instead of precipitating it with ether as described above, 2-anilino-4-ethoxyquinazoline hydrochloride was isolated by pouring the alcoholic reaction mixture into water, adding sufficient hydrochloric acid to dissolve the droplets of excess aniline, and removing the precipitated product by filtration. This method was later found to promote an appreciable hydrolysis; moreover, when it was attempted to prepare the anilino-methoxyquinazoline hydrochloride in the same way, the precipitation of the product was incomplete and on warming hydrolysis ensued. However, when pure specimens of these hydrochlorides were boiled with alcoholic hydrochloric acid and even with concentrated aqueous hydrochloric acid, aniline being absent, no appreciable hydrolysis was observed; this stability toward hydrolysis is in contrast to the non-basic and easily hydrolyzed 2-chloro-4-alkoxyquinazolines which even on standing soon decompose into benzoylene urea. Because of this property, the following procedure was finally adopted. One-half gram of 2-anilino-4-methoxyquinazoline hydrochloride with 5 cc. of alcohol, 10 drops of hydrochloric acid, 2 drops of aniline and 10 cc. of water was slowly taken to dryness on a steam-bath over a period of three hours or longer. The residue was washed with hot water and dissolved in normal sodium hydroxide, the solution diluted, filtered and precipitated from the hot solution by the addition of acetic acid. The white precipitate of 2-anilino-4-ketodihydroquinazoline thus obtained was washed with hot water

and dried, m. p. 261°. A similar treatment of 2-anilino-4-ethoxyquinazoline hydrochloride gave the same product, also in a practically theoretical yield, m. p. 261°.

Preparation of 2-Anilino-4-ketodihydroquinazoline (V) from 2-Chloro-4-ketodihydroquinazoline (II).—One and seventy-five hundredths grams of chloroketodihydroquinazoline and 1.0 g. of aniline were dissolved in 50 cc. of alcohol and the solution warmed on a steam-bath. A precipitate began to separate after the first few minutes of heating; at the end of two and one-half hours the mixture was cooled, diluted with 60 cc. of ether, and the precipitate filtered, washed with ether and dried. The 1.9 g. of material thus obtained was dissolved in hot normal sodium hydroxide and precipitated from the hot solution with acetic acid in the usual manner; this precipitate was filtered, washed with hot water and dried. It crystallized from an alcoholic solution to which water had been added in the form of tiny snow white rosetts of minute needles, m. p. 261°. The compound is sparingly soluble in alcohol, acetone or methyl alcohol, and crystallizes in the same minute needles from all three solvents. It is insoluble in ether or ammonia but soluble in sodium hydroxide or concentrated sulfuric acid. For analysis, drying at temperatures above 100° was necessary in order to remove 2-3% of moisture which adhered to the material crystallized from dilute alcohol.

Anal. Calcd. for $C_{14}H_{11}ON_2$: C, 70.85; H, 4.68. Found: C, 70.80; H, 4.84.

Preparation of 2-Anilino-4-ketodihydroquinazoline (V) from Phenylpseudo-methylthiourea.³—Ten grams of the hydriodide of phenylpseudomethylthiourea⁴ was dissolved in ether and converted into the free base by shaking with an aqueous solution of sodium carbonate. The ethereal layer, washed three times with water, was treated with 5 g. of anthranilic acid, when a slight evolution of heat occurred and 8.5 g. of a precipitate, m. p. 118°, and evidently an anthranilate of the base, soon separated. This product after filtering from the ether and drying was heated in an oil-bath at 120-130° for three hours; methyl mercaptan was evolved and a red glassy melt remained. Several extractions of this with boiling alcohol removed the viscous red material; the residue was dissolved in twice normal sodium hydroxide, filtered and precipitated with acetic acid as before. The dried precipitate was dissolved by prolonged boiling in alcohol and crystallization effected by diluting with water; m. p. 261°.

Melting points of mixtures of this product with the same compound obtained by the other three methods of preparation (*i. e.*, hydrolysis of the two anilino-alkoxy derivatives and the product of condensation of chloroketodihydroquinazoline with aniline) showed no depression. A mixture composed of samples from each of the products from the four methods of preparation melted at 261°.

Anal. Calcd. for $C_{14}H_{11}ON_2$: C, 70.85; H, 4.68. Found: C, 70.70; H, 4.78.

Preparation of 2-Anilino-4-methoxyquinazoline (IV).—To 0.4 g. of sodium dissolved in 40 cc. of methyl alcohol was added 1.9 g. of 2-anilino-4-methoxyquinazoline hydrochloride and the solution warmed slightly until a considerable quantity of sodium chloride began to separate. After standing overnight the mixture was poured into 100 cc. of water, when a white opaque suspension resulted. This began to crystallize immediately and within three hours the separation was complete. The crystalline product was filtered, dried and amounted to 1.53 g. of the crude base. Recrystallization was effected from either methyl alcohol or a hot methyl alcoholic solution to which a little water was added, the separation being more nearly complete when the latter method was employed.

The compound forms small colorless glistening plates, m. p. 113°. It is soluble in alcohol, methyl alcohol, petroleum ether, acetone or ether and insoluble in water. Treatment with hydrochloric acid in methyl alcohol regenerated the hydrochloride salt

⁴ Bertram, *Ber.*, 25, 49 (1892).

described above. When hot alcoholic solutions of the base and picric acid were mixed, a flocculent yellow precipitate consisting of fine needles of the picrate separated. This was washed with water and recrystallized from alcohol, from which it slowly separates as fine, light yellow, feathery needles, m. p. 210°.

Anal. Calcd. for $C_{15}H_{13}ON_3$: C, 71.68; H, 5.22. Found: C, 72.08; H, 5.15.

Preparation of 2-Anilino-4-ethoxyquinazoline (VI).—This compound was prepared in essentially the same way as the methoxy derivative just described. Ethyl alcohol was employed and the coagulation of the precipitate obtained on pouring the mixture into water was a matter of days rather than hours. One gram of 2-anilino-4-ethoxyquinazoline hydrochloride and 0.3 g. of sodium in 25 cc. of alcohol gave 0.85 g. of the crude precipitated base, which was recrystallized from 50% alcohol.

This compound separates as colorless glistening plates, m. p. 110–111°, somewhat larger than the crystals of 2-anilino-4-methoxyquinazoline. Its solubilities are the same as those given for the last-named substance. Addition of hydrochloric acid regenerated the hydrochloride but attempts to form an addition product with methyl iodide were unsuccessful. The picrate, prepared in the manner outlined above, crystallized from alcohol in rosetts of coarse yellow needles, m. p. 183°; glossy needles were obtained on slow evaporation of the solvent.

Anal. Calcd. for $C_{16}H_{15}ON_3$: C, 72.41; H, 5.70. Found: C, 72.67; H, 5.81.

Summary

Aniline has been found to react with 2-chloro-4-ketodihydroquinazoline and with 2-chloro-4-alkoxyquinazolines to yield 2-anilino-4-ketodihydroquinazoline and hydrochlorides of 2-anilino-4-alkoxyquinazolines, respectively. The constitutions of 2-chloro-4-alkoxyquinazolines and of 2-chloro-4-ketodihydroquinazoline are demonstrated by their conversion into the known 2-anilino-4-ketodihydroquinazoline. The following new compounds have been prepared: 2-anilino-4-methoxyquinazoline, 2-anilino-4-ethoxyquinazoline and their picrates and hydrochlorides.

BETA-SULFHYDRYL-BETA-PHENYLPROPIOPHENONE

BY BEN H. NICOLET

RECEIVED DECEMBER 26, 1931

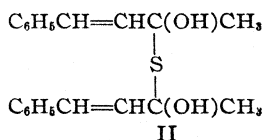

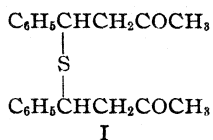

PUBLISHED MAY 7, 1932

The writer has recently¹ had occasion to examine certain β -mercapto ketones of the type $C_6H_5CH(SR)CH_2COR'$, particularly from the point of view of their instability toward alkaline reagents. These ketones were readily obtained by the addition of mercaptans to α,β -unsaturated ketones in the presence of alkalis. To use β -*p*-tolylmercapto- β -phenylpropiophenone as an example, two characteristic reactions are as follows: (a) with alkali, easy loss of tolyl mercaptan to form benzalacetophenone; (b) with phenylhydrazine, easy loss of the mercaptan to form 1,3,5-triphenylpyrazoline.

¹ Nicolet, *THIS JOURNAL*, 53, 3066 (1931).

An examination of the literature failed to reveal any β -sulfhydryl ketone ($\text{RCH}(\text{SH})\text{CH}_2\text{COR}'$) described as such, but some work by Fromm attracted attention. He described² the condensation with benzalacetone and benzalacetophenone, of sodium sulfide, disulfide and hydrosulfide, processes which should presumably be analogous to the addition of alkali mercaptides to these same ketones. The structures he assigned to the products obtained were, however, rather unusual and require discussion here.

For his "duplobenzylideneacetone monosulfide," for example, he considered and rejected Formula I, and chose instead Formula II.

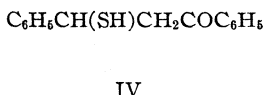

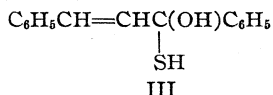

For this choice he gave two reasons: (a) the substance was readily decomposed by alkali, regenerating benzalacetone; (b) it reacted with phenylhydrazine, with loss of hydrogen sulfide, and yielded benzalacetophenonephenylhydrazone. One point against Formula II, he admitted, was that attempts at acylation gave no evidence of the presence of hydroxyl groups.

From what has been said of the β -mercapto ketones, all these properties are now seen to be entirely consistent with Formula I.

Fromm and Hubert³ felt they had finally proved the correctness of a structure of type II, when they isolated the corresponding monosulfide of benzalacetophenone in three forms, each of which gave, on oxidation, a different sulfone. They interpreted these three sulfides as geometrical isomers of a substance analogous to that represented in Formula II. This result still requires investigation although Formula I presents the possibility of two geometrical isomers, with the possibility of additional enolized forms.

This discussion has been given to make clear the fact that Fromm's "benzalacetophenone hydrosulfide," to which he gave Formula III, is almost certainly β -sulfhydryl- β -phenylpropiophenone (IV), and, as such,

the first β -sulfhydryl ketone. As might be expected, it loses hydrogen sulfide with ease, especially in the presence of alkali.

In attempting to prove the structure of this compound, Fromm found that on benzylation it would take up only a single benzoyl group, which

² Fromm and Haas, *Ann.*, **394**, 290 (1912).

³ Fromm and Hubert, *ibid.*, **394**, 301 (1912).

became attached to sulfur. No free hydroxyl group could be demonstrated. This same thiobenzoate has now been obtained by the direct addition of thiobenzoic acid to benzalacetophenone in alkaline solution. The thioacetate is similarly formed from thioacetic acid. Since these thio acids are even more similar than is hydrogen sulfide to the mercaptans whose addition has already been studied, the structures given by Fromm can scarcely be maintained.

Experimental Part

β -Sulphydryl- β -phenylpropiophenone (IV).—The directions of Fromm and Hubert³ were followed. A solution of the substance in dilute alcohol gave with lead acetate a test for sulfide after standing for only a few minutes at room temperature. The rate of sulfide formation increased rapidly on heating, or on the addition of small amounts of alkali.

β -Benzoylmercapto- β -phenylpropiophenone, $C_6H_5CH(SCOC_6H_5)CH_2COC_6H_5$.—A solution of two moles of potassium hydroxide in 10 parts of alcohol was saturated with hydrogen sulfide, then shaken with one mole of benzoyl chloride. When this solution (A) was added to one mole of benzalacetophenone, and 2 *N* sodium ethylate then added (0.5 cc. more than required to give a pink color with phenolphthalein) there was immediate evidence of reaction. After an hour, acidification with acetic acid gave almost entirely a sulfide (formula analogous to I) which proved to be identical with Fromm's β -duplobenzylideneacetophenone sulfide. This product also resulted when the benzoyl chloride was omitted.

When, however, solution A was acidified, the thiobenzoic acid extracted with ether, and this extract (after removal of ether) dissolved in alcohol and condensed with benzalacetophenone as described above (reaction time, however, ten hours at room temperature), the main product obtained was the benzoylmercapto derivative. After purification it melted at 123° and proved to be identical with the product obtained by Fromm when he benzoylated the mercaptan.

Anal. (Parr bomb). Calcd. for $C_{22}H_{18}O_2S$: S, 9.25. Found: S, 8.91, 9.02.

β -Acetylmercapto- β -phenylpropiophenone.—This substance was prepared as described for the benzoyl derivative, but with the use of thioacetic acid. It separated as a yellow oil, which solidified on cooling, and after purification from somewhat diluted alcohol melted at 75–77°. The crystals were still slightly yellow.

Anal. (Parr bomb). Calcd. for $C_{17}H_{16}O_2S$: S, 11.27. Found: S, 11.15.

Summary

Reasons have been given for the belief that Fromm's "benzalacetophenone hydrosulfide" is really β -sulphydryl- β -phenylpropiophenone.

STUDIES OF CONJUGATED SYSTEMS. XI. THE OXIDATION OF CIS-PHENYLBUTADIENE BY MEANS OF PERBENZOIC ACID¹

BY IRVING E. MUSKAT AND MARGARET HERRMAN

RECEIVED DECEMBER 26, 1931

PRINTED MAY 7, 1932

Perbenzoic and peracetic acids have been used for some time to determine the degree of unsaturation and the rate of oxidation of olefinic compounds.² Of particular interest in our investigations is the work of Böeseken and Blumberger on the three isomeric phenylbutenes, $\Delta^{1,2}$ -C₆H₅-CH=CH-CH₂-CH₃; $\Delta^{2,3}$ -C₆H₅-CH₂-CH=CH-CH₃; $\Delta^{3,4}$ -C₆H₅-CH₂-CH₂-CH=CH₂; and also on cinnamic acid and its methyl ester.³ In the case of the phenylbutenes they found that the nearer the double bond is to the phenyl group the greater is the rate of oxidation; while both cinnamic acid and its ester are insensitive to oxidation by means of perbenzoic acid. From these facts they concluded that the phenyl group hastens the oxidation while the carboxyl group, at least when it is situated next to the double bond, hinders oxidation by means of perbenzoic acid.

Meerwein⁴ has reported results similar to those on the phenylbutenes, from his study of the rate⁵ of oxidation of safrole, isosafrole, eugenol and isoeugenol.

Arbuzov and Mikhailow⁶ have studied the oxidation of unsaturated compounds by means of peracetic and perbenzoic acids and from their work have concluded that the first step in the oxidation reaction is the formation of cyclic oxides. Böeseken and his collaborators⁷ recently have accepted this view although they had previously assumed that peracetic acid is absorbed by the double bond to give the monoacetate of the diol while perbenzoic acid oxidized the double bond directly to the cyclic oxide.

¹ Presented before the Organic Division of the American Chemical Society at its meeting in Buffalo, N. Y., 1931.

Several authors⁸ have studied the oxidation of unsaturated fatty acids and their esters by means of both peracetic and perbenzoic acids. It has been found that in the case of compounds containing two double bonds, whether conjugated or not, a dioxide is formed. Smit⁸ found that in the case of 9,12-linolic acid the dioxide that is formed can be hydrolyzed but in the case of the conjugated 9,11-linolic acid the dioxide cannot be hydrolyzed. He suggests, therefore, these two possible structures for the dioxide of the conjugated compound.

In our work on the oxidation of *cis*-phenylbutadiene by means of perbenzoic acid, we have found that the products obtained depend largely on the temperature at which the reaction takes place. At 0° only one double bond of the unsaturated compound is attacked, while at 25° both double bonds are attacked.

If equimolar quantities of *cis*-phenylbutadiene and perbenzoic acid in chloroform solution are allowed to react at 0°, a white crystalline compound, m. p. 81–82°, is formed. This compound was proved by analysis to be an hydroxybenzoate formed by the addition of a mole of perbenzoic acid to one of the double bonds. The position of the remaining double bond was established by the isolation of the semicarbazone of benzaldehyde on ozonization. This proves, therefore, that the perbenzoic acid is absorbed in the 3,4-positions of phenylbutadiene and the benzoate must have one of the structures

No effort was made to distinguish between these two possible structures, but on the basis of previous work⁹ on the addition reactions of phenylbutadiene, and on the basis of the chemical reactions of the benzoate, which are to follow, structure I is favored.

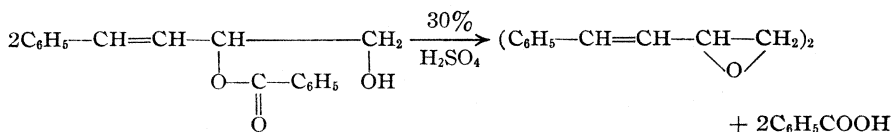

The fact that the double bond farther removed from the phenyl group is attacked more readily than is the one next to the phenyl group is in agreement with the previous work of Muskat and co-workers⁹ but contrary to the conclusions drawn by Böeseken³ and Meerwein.⁴ Also,

⁹ Muskat and Huggins, *ibid.*, **51**, 2496 (1929); Muskat and Grimsley, *ibid.*, **52**, 1574 (1930).

the fact that a hydroxybenzoate was isolated as the *primary oxidation product* indicates that oxidation by means of perbenzoic acid occurs by the preliminary absorption of the peracid by the unsaturated compound, rather than through the formation of cyclic oxides as is postulated by Böeseken⁷ and Arbuzov.⁶

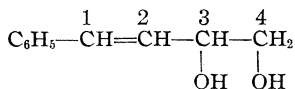

The benzoate was warmed on the steam-bath for twenty-four hours with 30% sulfuric acid. A white solid, m. p. 192°, and benzoic acid were isolated. The white solid, m. p. 192°, was found to be a dimer of phenylbutadiene monoxide. The position of the double bond was established by the isolation of benzoic acid on ozonization.

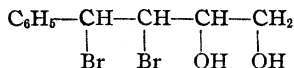

The fact that the double bond is not involved in the polymerization was established by the amount of benzoic acid isolated from ozonization—80% calculated on the basis of two moles of benzoic acid per mole of dimer—and confirmed by bromination. One mole of the dimer of phenylbutadiene monoxide absorbed two moles of bromine to give the tetrabromide of the dimer, m. p. 220°.

When the benzoate was treated with dilute sodium hydroxide solution at room temperature or even at 0°, it was hydrolyzed to a dihydroxy derivative of phenylbutadiene, a white crystalline material, m. p. 74°. When ozonized, the dihydroxy derivative yielded benzaldehyde, which proved the 3,4-structure of the dihydroxy derivative.

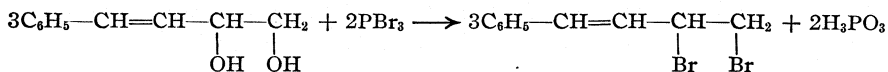

The dihydroxy derivative was dehydrated by means of phosphorus pentoxide in anhydrous ether solution and also by heating with 30% sulfuric acid in a bomb tube. The product obtained in each case was the dimer of phenylbutadiene monoxide, m. p. 192°. The dihydroxy derivative absorbed bromine to form 1,2-dibromo-3,4-dihydroxy-1-phenylbutane, m. p. 94°.

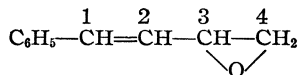

In order to link the work on oxidation with that on other addition reactions of conjugated compounds,⁹ the dihydroxy derivative was treated

with phosphorus tribromide in anhydrous ether solution. The known 3,4-dibromide of phenylbutadiene, m. p. 94°, was obtained.

The tetrabromide of phenylbutadiene, m. p. 146°, was formed when the dihydroxy derivative of phenylbutadiene was treated with phosphorus pentabromide in anhydrous ether solution.

Accompanying the hydroxybenzoate there was always a small amount of the monoxide of phenylbutadiene, b. p. 88° under 1 mm. pressure. Again, the position of the double bond was determined by ozonization. Benzaldehyde was isolated as one of the ozonization products, which proved the 3,4-structure of the monoxide of phenylbutadiene.

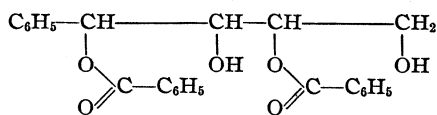

The monoxide yielded the dimer of phenylbutadiene monoxide when heated with 30% sulfuric acid on the steam-bath.

In addition to the small amounts of monoxide separated from the original reaction mixture, the monoxide has been obtained in very small amounts by heating the hydroxybenzoate at atmospheric pressure. Fifty per cent. of the theoretically possible yield of monoxide has been obtained by heating, in a bomb tube, the hydroxybenzoate in methyl alcohol solution containing a drop or two of dilute hydrochloric acid.

If two moles of perbenzoic acid are allowed to react with one mole of *cis*-phenylbutadiene at 25°, an oil is obtained from which two products were isolated: (1) an oil which distilled at 97° under 1 mm. pressure and was proved by analysis to be the dioxide of phenylbutadiene (A); and

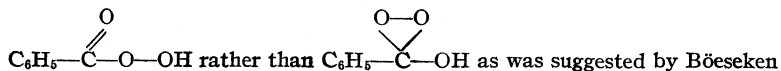

A

B

(2) a crystalline residue, m. p. 186°, which proved to be the dihydroxy-dibenzoate of phenylbutadiene. The most probable structure for this compound is (B).

From the work presented above it is quite evident that the structure of perbenzoic acid must be represented as

The electronic structure of perbenzoic acid would then be indicated as

Experimental Part

Oxidation at Zero Degrees

Preparation of the Hydroxybenzoate of Phenylbutadiene.—A chloroform solution of perbenzoic acid was prepared by the method of Tiffeneau,¹³ by treating benzoyl peroxide with sodium ethylate, liberating the perbenzoic acid with sulfuric acid and extracting with chloroform. The dried perbenzoic acid solution was cooled to 0° and slightly less than an equivalent amount of *cis*-phenylbutadiene was added, so that about a 2% excess of perbenzoic acid was present. The mixture was allowed to stand at 0° until oxidation was complete as indicated by iodimetric titration. The time required for this is about forty-eight hours. The chloroform was removed by means of suction without warming and the resulting pasty mass of crystals and oil was taken up in ether. The ether solution was shaken with iced 5% sodium hydroxide for half to three-quarters of an hour to remove the benzoic acid.¹⁴ Care was taken to prevent heating and consequent increased hydrolysis when the alkali was added. The ether solution was separated, washed with water, dried over anhydrous sodium sulfate and filtered. The ether was removed by vaporization. A mass of flaky white crystals remained, which was recrystallized from hot low-boiling ligroin. The pure crystals melted at 81–82°.

Anal. Calcd. for $C_{17}H_{16}O_3$: H, 5.97; C, 76.12. Found: H, 5.63, 5.57; C, 76.16, 76.05. *Mol. wt.* Calcd. for $C_{17}H_{16}O_3$: mol. wt., 268. Found: mol. wt. (freezing point method), 273, 273.

The analysis proved this compound to be an hydroxybenzoate of phenylbutadiene. The hydroxybenzoate is very soluble in most organic solvents: benzene, chloroform, carbon tetrachloride, methyl and ethyl alcohol, ether, glacial acetic acid and acetone; but is only slightly soluble in hot low-boiling ligroin, and insoluble in water, dilute alkali and dilute acid. It may be recrystallized by adding ligroin to a benzene solution, water to a methyl alcohol solution, or by allowing the compound to crystallize slowly from hot low-boiling ligroin.

That the hydroxybenzoate was formed directly in the chloroform solution of perbenzoic acid and phenylbutadiene, and not from an esterification of the dihydroxy derivative which might have resulted from the hydrolysis of the oxide in alkaline solution, was established in two ways. (1) The pure monoxide was shaken with six times its equivalent of sodium benzoate in 5% sodium hydroxide solution for twenty-four hours, but no hydroxybenzoate could be detected. (2) The chloroform was evacuated from a portion of an original reaction mixture. The resulting pasty mass of solid, oil and a small amount of solvent was not treated with alkali but filtered to remove benzoic acid. As the filtration was very slow, more solvent was removed while filtering and crystals separated out in the filtrate. The first crystals obtained proved to be benzoic acid, but after several filtrations the crystals obtained, on recrystallization from hot low-boiling ligroin, melted at 79°, and a mixture with known hydroxybenzoate melted at 81.5°. This proved that the hydroxybenzoate was formed by the direct addition of perbenzoic acid to phenylbutadiene.

The hydroxybenzoate was subjected to ozonization in a manner entirely analogous to that described in previous work.⁹ One gram of the hydroxybenzoate gave 0.08 g. of the semicarbazone of benzaldehyde and 0.63 g. of benzoic acid. This corresponds to an 82.5% yield of benzoic acid calculated on the basis of two moles of benzoic acid for each mole of hydroxybenzoate.

¹³ "Organic Syntheses," John Wiley and Sons, Inc., New York, 1928, Vol. VIII, p. 30.

¹⁴ The chloroform solution of perbenzoic acid, prepared by the method of Tiffeneau, always contains benzoic acid.

The hydroxybenzoate did not absorb bromine readily at room temperature but on boiling with bromine in carbon tetrachloride solution a dibromide, m. p. 154–155°, was formed.

Anal. Calcd. for $C_{17}H_{16}O_3Br_2$: H, 3.74; C, 47.66; Br, 37.38. Found: H, 3.71, 3.79; C, 47.49, 47.69; Br, 37.38, 37.34.

The dibromide is soluble in benzene, ether, methyl and ethyl alcohol, chloroform and carbon tetrachloride, and only slightly soluble in hot low-boiling ligroin.

The Preparation of the Dimer of Phenylbutadiene Monoxide.—The hydroxybenzoate was heated on the steam-bath for twenty-four hours with 30% sulfuric acid. The reaction mixture was made alkaline and shaken with ether. A white crystalline product remained suspended in the ether layer. This was removed and carefully washed with ether. The pure crystals melted at 192°.

Anal. Calcd. for $(C_{10}H_{10}O)_2$: H, 6.90; C, 82.15. Found: H, 7.00, 7.33; C, 82.18, 82.35. *Mol. wt.* Calcd. for $(C_{10}H_{10}O)_2$: mol. wt., 292. Found: mol. wt. (boiling point method), 303, 307.

Benzoic acid was obtained when the alkaline extract was acidified.

The dimer of the monoxide is very slightly soluble in most of the common organic solvents but sufficiently soluble in warm ether to permit recrystallization from boiling ether.

The dimer of the monoxide of phenylbutadiene (0.45 g.), dissolved in chloroform, was ozonized for twelve hours. Most of the material (0.30 g.) was recovered unchanged, and 0.1 g. of benzoic acid, which represents 80% of the material decomposed by ozonization, was isolated.

The dimer of the monoxide of phenylbutadiene was brominated by boiling with bromine in chloroform solution. The product, a tetrabromide of the dimer, melts at 220°.

Anal. Calcd. for $C_{20}H_{20}O_2Br_4$: H, 3.27; C, 39.23. Found: H, 3.36, 3.34; C, 39.01, 39.17.

The Preparation of 3,4-Dihydroxyphenylbutadiene.—The hydroxybenzoate was shaken for three-quarters of an hour with twice the equivalent amount of 10% sodium hydroxide. The mixture was extracted with large volumes of ether, the ether extract dried over anhydrous sodium sulfate, the drying agent removed by filtration and the ether evaporated on the steam-bath. The oily mass that remained was taken up in hot benzene, from which solution crystals of the dihydroxy derivative, m. p. 74°, separated on cooling.

Anal. Calcd. for $C_{10}H_{12}O_2$: H, 7.37; C, 73.13. Found: H, 7.12, 7.38; C, 73.08, 73.11. *Mol. wt.* Calcd. for $C_{10}H_{12}O_2$: mol. wt., 164.1. Found: mol. wt. (boiling point method), 164.8, 167.5.

The dihydroxy derivative has also been obtained from the alkaline extract which results from the purification of the hydroxybenzoate.

The dihydroxy derivative is very soluble in hot benzene, soluble in methyl and ethyl alcohol, ether, acetone, warm acid and warm alkali, very slightly soluble in hot low-boiling ligroin and cold benzene, and insoluble in carbon tetrachloride, chloroform and cold water.

One gram of the dihydroxy derivative was ozonized for five hours. The ether extract of the alkaline solution yielded benzaldehyde, which was identified by the formation of its semicarbazone (0.2 g.). Benzoic acid (0.4 g.) was recovered from the alkaline extract. The amount of the two products isolated corresponds to 74.2% of the sample ozonized.

The dihydroxy derivative absorbed one mole of bromine in ligroin solution at room temperature to form a dibromide of the dihydroxy derivative, m. p. 94°.

Anal. Calcd. for $C_{10}H_{12}O_2Br_2$: H, 3.73; C, 37.04. Found: H, 3.41, 3.68; C, 36.87, 36.97.

The dibromide of the dihydroxy derivative has the same melting point as the dibromide of phenylbutadiene but a mixture of the two melts at 86°. The dibromide of the dihydroxy derivative is much less soluble in ligroin than is the dibromide of phenylbutadiene.

The dihydroxy derivative was dissolved in ether and treated with five times the equivalent amount of phosphorus tribromide. The mixture was allowed to stand overnight, and the remaining phosphorus tribromide decomposed with ice. The water layer was extracted with ether and the ether was vaporized. The solid 3,4-dibromide of phenylbutadiene, m. p. 94°, remained. A mixture of this material with the known 3,4-dibromide of phenylbutadiene also melted at 94°. The dihydroxy derivative was treated in an analogous manner with phosphorus pentabromide. The product obtained was the tetrabromide of phenylbutadiene, m. p. 146°. A mixture with known tetrabromide of phenylbutadiene also melted at 146°.

The dihydroxy derivative was dehydrated to the dimer of the monoxide of phenylbutadiene, m. p. 192°, when an ether solution was treated with phosphorus pentoxide. The same product was isolated when the dihydroxy derivative was heated with 30% sulfuric acid at 100° for four hours in a bomb tube.

The Preparation of the Monoxide of Phenylbutadiene.—The hydroxybenzoate, in a methyl alcohol solution to which a few drops of dilute hydrochloric acid were added, was heated in a bomb tube at 120–130° for four to five hours. The methyl alcohol solution was then removed, a large volume of water was added and the mixture extracted with ether. The ether solution was dried over anhydrous sodium sulfate, filtered and the major portion of the ether removed by means of suction. The remaining oil was distilled under reduced pressure. The fraction which distilled at 88° under 1 mm. pressure was a monoxide of phenylbutadiene.

Anal. Calcd. for $C_{10}H_{10}O$: H, 6.90; C, 82.15. Found: H, 7.02, 7.29; C, 82.16, 82.36. *Mol. wt.* Calcd. for $C_{10}H_{10}O$: mol. wt., 146. Found: mol. wt. (freezing point method), 142.

One gram of the monoxide of phenylbutadiene was ozonized for five hours. Benzoic acid (0.45 g.) and the semicarbazone of benzaldehyde (0.13 g.) were isolated. The amount of the products isolated represented 65.4% of the material ozonized.

The monoxide of phenylbutadiene was warmed with 30% sulfuric acid on the steam-bath and the resulting viscous oil extracted with ether. From the ether extract the dimer of the monoxide of phenylbutadiene, m. p. 192°, was obtained.

The dry hydroxybenzoate was heated at atmospheric pressure for a short time. Most of the benzoate remained unchanged but a small amount of it was decomposed to the monoxide of phenylbutadiene and benzoic acid.

As has already been stated, small amounts of the monoxide oil always accompanied the hydroxybenzoate in the original reaction mixture.

Oxidation at 25°

Preparation of the Dioxidation Products.—*Cis*-phenylbutadiene was added to a slight excess of two equivalents of perbenzoic acid in chloroform solution at 25° and allowed to stand at that temperature until iodimetric titration indicated that no perbenzoic acid remained. This required eighteen to twenty hours. The resulting mixture was treated as described above for the hydroxybenzoate. The oil which remained

after the ether was removed was distilled under reduced pressure. At 97° under 1 mm. pressure a small amount of dioxide oil was distilled.

Anal. Calcd. for $C_{16}H_{10}O_2$: H, 6.22; C, 74.04. Found: H, 6.06, 6.35; C, 74.23, 74.06.

The residue in the distilling flask was taken up in benzene and the solution allowed to stand overnight. Crystals of a dihydroxydibenzoate separated and were recrystallized from hot benzene; their melting point after recrystallization was 186°.

Anal. Calcd. for $C_{24}H_{22}O_6$: H, 5.42; C, 70.93. Found: H, 5.20, 5.35; C, 70.86, 70.75. *Mol. wt.* Calcd. for $C_{24}H_{22}O_6$: mol. wt., 406. Found: mol. wt. (boiling point method), 371.4.

The dibenzoate is only slightly soluble in most organic solvents but moderately soluble in chloroform and acetone.

Summary

1. The 3,4-hydroxybenzoate of phenylbutadiene was isolated as the primary product of the oxidation of *cis*-phenylbutadiene by means of perbenzoic acid, when the reaction was carried out at 0°. A dihydroxybenzoate was obtained from the same reagents at 25°.

2. The 3,4-hydroxybenzoate of phenylbutadiene was hydrolyzed with alkali to 3,4-dihydroxyphenylbutadiene and derivatives of the dihydroxy compound were prepared.

3. The 3,4-hydroxybenzoate of phenylbutadiene was decomposed by acids to the monoxide or the dimer of the monoxide of phenylbutadiene. The product obtained depended upon the acid used and the conditions under which the reaction took place.

ORIENTING INFLUENCES IN THE BENZENE RING. THE SULFONATION OF BENZOIC ACID¹

BY JOHN S. REESE IV

RECEIVED DECEMBER 26, 1931

PUBLISHED MAY 7, 1932

Generally speaking, previous work has shown that benzoic acid may be sulfonated readily with strong sulfuric acid at high temperatures (*ca.* 200°) and by long duration of heating (two to twenty-four hours).² In this way about 90% of the product is the *m*-sulfobenzoic acid and the balance is the para isomer. Furthermore, Maarse,² incidental to a lengthy investigation of this problem, demonstrated that the meta isomer may be converted under the ordinary reaction conditions into the para isomer

¹ From a dissertation submitted to the Board of University Studies of the Johns Hopkins University in conformity with the requirements for the degree of Doctor of Philosophy. Presented before the Division of Organic Chemistry at the 82d Meeting of the American Chemical Society, Buffalo, N. Y., September, 1931.

² Maarse, *Rec. trav. chim.*, **33**, 207-238 (1914).

to the extent of about 15% although the reverse reaction was found to occur to about a three-fold greater degree. Now despite the fact that ortho substitution had been reported as totally absent and that metallic sulfates had no effect upon the sulfonation reaction, Dimroth and Schmaedel³ have stated that the presence of mercuric sulfate not only increases the degree of sulfonation but also permits sulfonation in the ortho position to the extent of 5%.³ Furthermore, Auger and Vary,⁴ sulfonating variously in the presence of iodine, always obtained all three isomeric sulfo-benzoic acids, of which the ortho amounted to only 1%. Although the main facts as presented above appear to be quite satisfactory, there are a few questions which are as yet unsettled. If the influence of such catalysts as iodine and mercuric sulfate is correctly reported, why does no ortho substitution normally take place? Why are the meta and para isomers so closely associated whereas all theories regarding orienting influences in the benzene ring demand that only the ortho and para isomers be so related? In addition, however, there were other rather interesting aspects which caused this problem to be investigated.

Without going thoroughly into the matter here, it was observed by the author from an extended study of the general problem of orienting influences that there was no substantial basis for the assumption that ortho and para substitution are closely related and opposed to meta substitution. Nevertheless it is perhaps well to present some of the more significant evidence for this particular point of view.

Although a superficial consideration of the evidence indicates that ortho substitution occurs frequently and perhaps always together with para substitution, whereas meta substitution takes place alone, a thorough examination will reveal that in nearly every case where an exhaustive study of the reaction products has been made, all three isomers are simultaneously formed.⁵ Indeed it is rather the great number of cases in which all three isomers do occur that leads one to believe that such is the normal circumstance. True enough the amount of meta substitution is almost negligible in cases where para substitution predominates, yet when meta substitution is the greatest, para substitution is always less than the accompanying ortho substitution. Table I clearly illustrates the argument.

The above figures show that whether para or meta substitution predominates it is accompanied principally by ortho substitution and consequently that ortho is no more closely related to para than to meta substitu-

³ Dimroth and Schmaedel, *Ber.*, **40**, 2411 (1907).

⁴ Auger and Vary, *Compt. rend.*, **173**, 239 (1931).

⁵ Exceptions are those such as sulfonation of nitrobenzene and benzene sulfonic acid where only the ortho isomer is absent. In such cases molecular rearrangements are known to occur and possibly account for the absence of the ortho isomer. Where halogenation gives no meta isomer, nitration shows that all three can occur as with toluene, and *vice versa* as with chlorobenzene.

TABLE I
NITRATION OF MONO-SUBSTITUTED BENZENES

Original substituent	% Meta	% Ortho	% Para
—COOH	76.5	22.3	1.2 [a]
—NO ₂	90.9	8.1	1.0 [b]

tion. Furthermore, the simultaneous formation of the ortho and the meta isomer to the exclusion of the para is illustrated by the nitration of benzaldehyde in the presence of acetic anhydride, where 70% of the meta and 30% of the *o*-nitrobenzaldehyde were obtained.⁶ Also, Reddelien⁷ has found that benzaldehyde forms under certain conditions an addition compound with nitric acid which may be isolated as such. He then showed that this addition compound when treated with sulfuric acid alone yielded pure *m*-nitrobenzaldehyde. This, of course, was to be expected since the aldehyde group is a strong meta orienting substituent. But when this same benzaldehyde nitrate was treated with acetic anhydride in addition to the sulfuric acid, he obtained pure *p*-nitrobenzaldehyde. He further showed that whereas traces of *o*-nitrobenzaldehyde were found in both cases, at neither time did the para and the meta derivatives occur together. This experiment certainly suggests that ortho substitution takes place in any case and may be accompanied by either para or meta substitution. Generally, therefore, a careful examination of the evidence indicates that ortho substitution is midway between and equally related both to para and meta substitution and consequently this conception is proposed in place of the old and accepted one.

Closely related to the above aspect is the conclusion reached by Blanksma⁸ that indirect substitution occurs only when the substituents —OH, —NH₂, —NHR, —OR or —CH₃ are present in the ring. Furthermore, it has been stated by Holleman⁹ that indirect substitution leads always to ortho-para substitution, whereas direct substitution may lead to either ortho-para or to meta substitution, though principally to the latter. Now, as it

will be shown later, it appears quite probable that in the sulfonation of benzoic acid, not only are ortho and meta substitution closely related but also they do occur indirectly. It may therefore be readily understood that the present investigation offered an opportunity to throw considerable light not only upon the specific question of the sulfonation of benzoic acid but also upon the general problem of orienting influences.

Indeed the available evidence suggests that the sulfonation of benzoic acid is actually an indirect substitution involving several intermediate compounds. Thus the first step, formation of an addition compound with the sulfuric acid, $\text{C}_6\text{H}_5\text{COOH} \cdot \text{H}_2\text{SO}_4$, is suggested by the work of Kendall and Carpenter,¹⁰ who have indicated the existence of this addition compound by cryoscopic measurements. Support for a second step, a condensation under the influence of excess sulfuric acid to form benzoyl sulfuric acid, is given by Oppenheim's¹¹ preparation of this latter compound from benzoyl chloride and sulfuric acid. As for a third step, Oppenheim observed that benzoyl sulfuric acid changed on long standing to sulfobenzoic acid though he did not specify exactly which isomer. This scheme, involving an addition compound, a condensation, and a rearrangement, is by no means uncommon, being known to take place in the sulfonation of aniline,¹² and in all probability in the sulfonation of both toluene and phenol.¹³ Yet these examples all lead to ortho and para substitution whereas no similar case of meta substitution is definitely known. Assuming, however, that with benzoic acid such a course of reaction does occur, a significant question is still unanswered. Are the para and meta isomers formed by a direct rearrangement of the benzoyl sulfuric acid or by a rearrangement of a possible intermediate *o*-sulfobenzoic acid? Indeed, it was the probability of the latter scheme that suggested the first step of this investigation.

Thus to determine whether the *o*-sulfobenzoic acid would rearrange to another isomer under the reaction conditions, it was heated with a large excess of concentrated sulfuric acid at 200° for various intervals of time from one-half hour to twelve hours. Upon recovering the potassium salts of the sulfobenzoic acids, they were converted to the hydroxybenzoic acids by fusion with caustic potash and the salicylic acid or the ortho isomer was removed from the mixture by extraction with chloroform in which it is readily soluble whereas the meta and para isomers are not. In this way it was found that the *o*-sulfobenzoic acid was converted solely to the meta isomer and the rate of conversion was thus quite readily determined.

Plotting the percentage of meta isomer against the time gave a regular curve approaching a maximum of about 85% in twelve hours (see Fig. 1). On the other hand, the natural logarithm of the concentration of the unchanged ortho isomer against the time gave a straight line as demanded by a monomolecular reaction. Similarly, with a view to the reported effect of mercuric sulfate on the sulfonation reaction, its influence upon this isomerization was studied. The rate of conversion was found to be greatly increased, over two-fold up to four hours of heating. The plot for the natural logarithm of unchanged ortho-isomer against the time was a straight line, suggesting as is very probable that this also is a mono-molecular reaction.

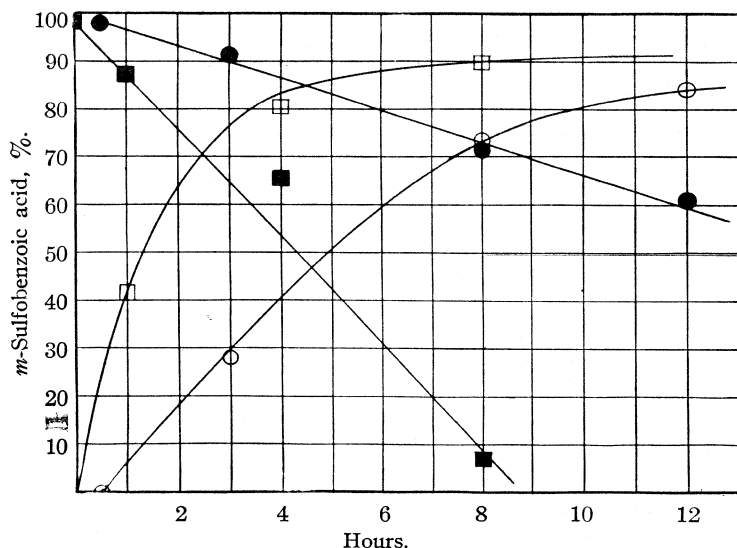

Fig. 1.—Isomerization of *o*-sulfobenzoic acid: ○ and ●, without mercuric sulfate; □ and ■, with mercuric sulfate; ● and ■, logarithm of the concentration of *o*-sulfobenzoic acid.

The sulfonation of benzoic acid at 200° both in the absence and presence of mercuric sulfate and for intervals of time where incomplete sulfonation would be obtained was then investigated. Thus, excepting that the unreacted benzoic acid was removed before fusion by extraction with ether of the solution of sulfobenzoic acids, an exactly similar procedure was followed and the degree of sulfonation and proportion of the isomers was determined for three, one, one-third and one-twelfth hours. The following results were obtained.

It is perfectly apparent that the sulfonation proceeds far more rapidly than is indicated by previous work. Furthermore, the percentage of recovered product decreases markedly from the percentage of sulfonation

TABLE II

Time, hrs.	SULFONATION OF BENZOIC ACID AT 200°			
	% Sulfonation (reacted C_6H_5COOH)	Recovered product, %	Ortho substitution, %	
3	99.1	98.3	6.3 (high)	2.3
1	95.5	93.3	5.8	3.8
1/3	81.0	75.0	14.3	7.3
1/12	35.9	11.6	^a	^a

^a Only a trace of hydroxybenzoic acid was obtained (less than 0.05 g.).

calculated from the recovered unreacted benzoic acid. At five minutes practically no products were obtained although an apparent 36% sulfonation is definitely indicated. The same results are obtained when mercuric sulfate is present; but an explanation of this anomaly is suggested by a study of reaction velocity curves (see Fig. 2). The curve for the percent-

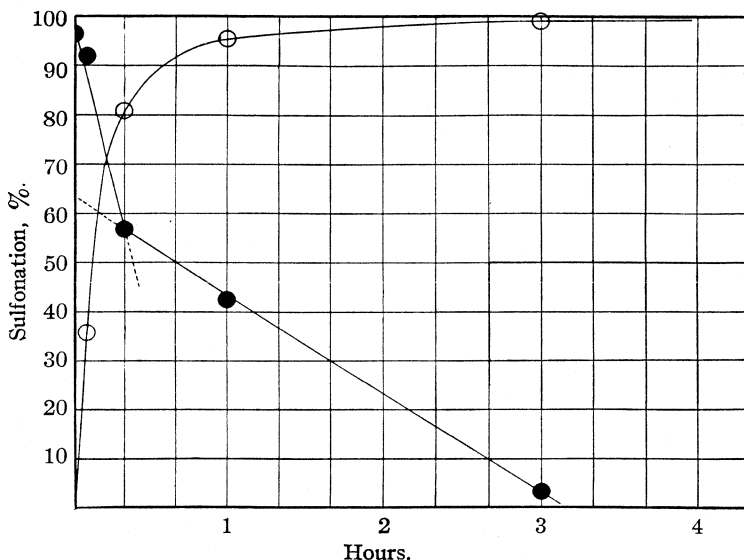

Fig. 2.—Sulfonation of benzoic acid at 200°: O, % sulfonation; ●, logarithm of the concentration of unreacted benzoic acid.

age of sulfonation against time is perfectly regular in every respect. However, the plot of the natural logarithm of the concentration of the unreacted benzoic acid against the time breaks rather abruptly at about twenty minutes. This great divergence can scarcely be attributed to an experimental error since a correction in the direction of less sulfonation would only increase it, whereas a correction in the other direction would indicate entirely too great a degree of sulfonation to be on the curve at all. Furthermore, the twenty-minute sulfonation as well as the others also was virtually run in duplicate since it has been shown that the presence of

mercuric sulfate in no way influences the degree of sulfonation. To continue, therefore, from twenty minutes to three hours, the plot is a perfect straight line, whereas from zero time to twenty minutes it is probably a slight curve though of a decidedly greater slope. It is scarcely to be doubted therefore that this curve represents two distinct reactions, a primary and a subsequent one. Indeed, the most plausible explanation of these facts is that the portion of the curve up to twenty minutes represents the condensation of the addition compound to the benzoyl-sulfuric acid, possibly accomplished through the agency of the excess sulfuric acid. This part of the line though not indicated in this way should curve where the inevitable shading off to the subsequent reaction takes place. From this point on the straight line demands a monomolecular reaction and probably represents the isomerization of the benzoyl-sulfuric acid not to the *m*-sulfobenzoic acid but to the ortho isomer. An examination of the figures in the table above reveals this fact since increasingly larger amounts of the ortho isomer are formed in the absence of mercuric sulfate than in its presence as the sulfonation becomes more incomplete. This fact coupled with the effect of mercuric sulfate on the conversion of the ortho to the meta isomer indicates very strongly that the ortho isomer is actually an intermediate product.

The above interpretation presents a fairly probable picture of the reaction mechanism and agrees with the scheme as originally proposed. For a complete explanation, however, one must consider the formation of the para isomer. Yet recalling the work of Maarse,² it appears very likely that this isomer is formed by a conversion of the *m*-sulfobenzoic acid. Indeed, preliminary work on the isomerization of the meta isomer reveals that certainly no more than a trace of the ortho isomer is formed although it is perfectly obvious from a regular decrease in the melting point that a slight admixture of another substance is present in increasingly larger amounts as the time of heating is lengthened. Although further study would be of considerable interest, it is believed nevertheless that a clear insight into the nature of this reaction has already been obtained.

In conclusion, however, it may be added that the above work bears directly on the general problem of orienting influences. Not only has the total absence of ortho substitution as previously reported been explained, but it has also been shown that the apparently simultaneous and exclusive formation of the meta and para isomers is not an anomalous case. Indeed, considerable support has been obtained for a more nearly correct view of the relation of the three isomeric positions among di-substituted benzenes. Inasmuch as direct conversion of the ortho to the para isomer is a well-known reaction (see above) and since the present work offers the conversion of the ortho to the meta isomer as a complementary case, it at once appears that ortho substitution occupies a unique place between meta and

para substitution and is equally related to both. This proposition is obviously not in harmony with the long-accepted and time-honored point of view upon which has been based all previous and present hypotheses to explain orienting influences in the benzene ring. Closely related to this aspect of the question are the contention of Holleman and also the proposition of Blanksma concerning the occurrence of direct and indirect substitution. However, it is perfectly obvious from the present investigation that the sulfonation of benzoic acid, a well-recognized case of meta substitution, is actually an example of indirect substitution. Thus with all due respect to the weight and value of Holleman's opinion, this study is offered as support for ideas which are at complete variance with his. In addition it must be mentioned that in the light of this investigation, the work of Dimroth and Schmaedel as previously presented is apparently in error.

Experimental Part

Pure *o*-sulfobenzoic acid was prepared by the hydrolysis of *o*-sulfobenzoic anhydride, recrystallized from benzene (m. p. 118.5°).¹⁴ Five grams of *o*-sulfobenzoic acid and 30 cc. of concentrated sulfuric acid (1.84) were placed in an Erlenmeyer flask and heated at 200° in an oil-bath for the desired length of time. The contents of the flask were run into about 800 cc. of water and neutralized with either barium carbonate or barium hydroxide. The precipitate of barium sulfate was removed by decantation of the supernatant liquid and filtration. The barium sulfate was also thoroughly washed with water, the washings being added to the filtrate. The residual barium contained in the filtrate as the barium salts of the sulfobenzoic acids was precipitated completely by addition of the necessary amount of dilute sulfuric acid. Following evaporation to about 400 cc. the barium sulfate was removed by decantation and filtration, the filtrate further evaporated, neutralized with potassium carbonate and finally evaporated to complete dryness.

The potassium salts of the sulfobenzoic acids thus obtained were powdered and fused with 10–15 g. of potassium hydroxide at 200–210° for two hours. The melt was completely dissolved with about 200 cc. of water and acidified with concentrated hydrochloric acid. The acidified solution was then extracted four times in a separatory funnel with 40 cc. of ether and the hydroxybenzoic acids obtained as a residue by distilling off the ether. This residue was then purified by extraction with absolute ether and a practically pure residue of hydroxybenzoic acids was thus obtained. Upon powdering this residue was extracted with 25 cc. of chloroform and removal of the chloroform by distillation gave a residue consisting of the *o*-hydroxybenzoic acid with a slight admixture of the meta isomer. The portion insoluble in chloroform was found to be practically pure *m*-hydroxybenzoic acid. The isomers were identified by their melting points and mixed melting points with the pure isomers. After weighing, a correction determined through solubility measurements was made for the admixture of the meta with the ortho isomer. It was thus readily possible to calculate the percentage conversion of the ortho to the *m*-sulfobenzoic acid.

The influence of mercuric sulfate was studied in a precisely similar fashion by the addition of 0.5 g. of this salt to the *o*-sulfobenzoic acid and sulfuric acid before heating.

The sulfonation of benzoic acid was investigated in the same way by dissolving 2.34

¹⁴ Obtained from Hynson, Westcott and Dunning, Baltimore, Md., through the courtesy of Dr. F. Dunning.

g. of benzoic acid (c. p.) in 30 cc. of concentrated sulfuric acid (1.84) and heating for the desired length of time, namely, three, one, one-third and one-twelfth hours. The influence of mercuric sulfate was again studied in a similar fashion by the addition of 0.5 g. of this salt to the reaction mixture. The subsequent procedure was identical with the isomerization experiments except for the removal of the unreacted benzoic acid. This was accomplished by extraction of the acid solution of the sulfobenzoic acids reduced to about 125 cc. three times with 25 cc. of ether. The benzoic acid was weighed and the percentage sulfonation calculated. Finally, to identify absolutely the presence of the ortho isomer, the chloroform soluble residue was powdered in the small extraction flask, placed on a boiling water-bath with a water filled test-tube held in the neck of the flask through a stopper, and the ortho isomer or salicylic acid allowed to sublime onto the outside of the test-tube. In this way the presence of the least trace of salicylic acid could be demonstrated, since it gave the characteristic purple color in a water solution when tested with ferric chloride. This procedure was found necessary both on account of the slight amount of residue and since the melting point method was not completely satisfactory.

The percentage sulfonation was determined not only by the recovered unreacted benzoic acid, but also by the recovered potassium salts and the yield of hydroxybenzoic acids.

The author herewith desires to express his appreciation and gratitude for the generous advice and kindly encouragement of E. Emmet Reid, Professor of Chemistry, Johns Hopkins University.

Summary

A reaction scheme for the sulfonation of benzoic acid has been proposed and supported by a study of the isomerization of *o*-sulfobenzoic acid and the actual sulfonation reaction.

A new relation between ortho, meta and para substitution has been proposed and evidence from the sulfonation of benzoic acid added to that already found in the literature.

ORGANIC REACTIONS WITH BORON FLUORIDE. I. THE PREPARATION OF ESTERS

BY H. D. HINTON AND J. A. NIEUWLAND

RECEIVED DECEMBER 31, 1931

PUBLISHED MAY 7, 1932

Bowlus and Nieuwland¹ found that boron fluoride united with acetic acid in the proportion of one mole of boron fluoride to two moles of acetic acid. This compound is a heavy liquid, fuming strongly in moist air. Analyses pointed to the formula $(\text{CH}_3\text{COOH})_2\text{BF}_3$. By the use of this compound as a catalytic agent a series of esters has been prepared. The question as to whether the catalytic effect observed is due to the acid-boron fluoride compound, or to the reaction of this substance with some of the alcohol to form the boron fluoride compound, is at present unanswered.

¹ Bowlus and Nieuwland, *THIS JOURNAL*, 53, 3835 (1931).

If the alcohol-boron fluoride compound is formed, it probably catalyzes the reaction in a manner similar to hydrochloric or sulfuric acid, since it has been shown to be acidic in character.²

Experimental

Ethyl Acetate.—The acetic acid-boron fluoride compound was prepared by passing boron fluoride gas into two moles of glacial acetic acid until one mole of the gas was absorbed. A flask containing 25 g. of acetic acid, 19.18 g. of ethyl alcohol and the catalyst was attached to a reflux condenser, and the contents refluxed from one to nine hours. After refluxing, a saturated solution of sodium carbonate was added to the reaction mixture, and the ester layer was recovered. A yield of 47–50% was obtained. An increase of the catalyst above one or two per cent. concentration did not increase the yield of ethyl acetate. One hour of refluxing produced practically the same amount of ester as a reflux of nine hours.³

Propyl Acetate.⁴—Seven grams of boron fluoride was passed into a mixture of 59.4 g. of propyl alcohol and 60 g. of glacial acetic acid. After refluxing for one-half hour, two layers separated, the top layer containing the ester. A yield of 53.5% of the ester was obtained.

Bowlus and Nieuwland¹ found that propionic acid absorbed one mole of boron fluoride to form a propionic acid-boron fluoride compound boiling at 62–63° (17 mm.). A series of alcohols was refluxed with this propionic acid-boron fluoride compound, each for forty-five minutes, and the corresponding esters were obtained in yields varying from 37 to 66%. Ethyl, propyl, *n*-butyl and *n*-amyl alcohols were used.⁵

Bowlus and Nieuwland did not report a butyric acid-boron fluoride compound. Experiments are being conducted in this Laboratory at the present time to determine if such a compound can be prepared. If it can, a series of esters with this compound should be possible. It was also found that on passing boron fluoride into aliphatic alcohols other than methyl and ethyl, hydrocarbon oils were obtained. After removing the oils, a strongly acid, fuming liquid similar to the methyl and ethyl alcohol solutions of boron fluoride was obtained. This solution, possibly, could be used as a catalytic agent for the preparation of esters. Experiments are being carried out in this Laboratory to find out if the reaction is possible. Evidence obtained up to the present time seems to prove that the above reaction can be used in the preparation of esters.

Summary

Using an acetic acid-boron fluoride compound, and a propionic acid-boron fluoride compound with a series of aliphatic alcohols, the corresponding series of esters has been prepared.

ORGANIC REACTIONS WITH BORON FLUORIDE. II. THE
REARRANGEMENT OF ALKYL PHENYL ETHERS

BY F. J. SOWA, H. D. HINTON AND J. A. NIEUWLAND

RECEIVED DECEMBER 31, 1931

PUBLISHED MAY 7, 1932

The rearrangement of allyl and alkyl phenyl ethers has been a subject of study before and a number of isolated cases reported. Claisen,¹ by heating certain O-allyl aryl ethers to a high temperature, transformed them into the isomeric nuclei substituted phenols (C-allyl phenols). If the alkyl group is substituted for an allyl group, isomerization does not take place under the influence of heat, the presence of inorganic substances being necessary in most cases. In order to explain the substituted phenols obtained by Koenigs² and Schrauth and Quasebarth,³ Niederl and Natelson⁴ treated *o*-cresyl di-isobutyl ether with zinc chloride and hydrochloric acid. They also studied the action of a mixture of concentrated sulfuric acid and glacial acetic acid on saturated alkyl phenyl ethers, obtaining substituted phenols.

The purpose of the following investigation is to study the action of boron fluoride as an agent in the rearrangement of alkyl aryl ethers, to demonstrate its advantages as such, and to show that the products obtained by this method follow the same rules as those products obtained by Niederl and Natelson.⁴

Experimental

Preparation of Alkyl Phenyl Ethers.—One mole of phenol or cresol was weighed in a liter flask, fitted with a reflux condenser and a dropping funnel. A sufficient amount of water was added to 59 g. (excess) of potassium hydroxide to make a thick mixture, and this was added to the phenol. The whole mass was heated until solution became complete; 125 g. (excess) of isopropyl bromide was added slowly while shaking and warming. After all of the bromide was added, the contents were refluxed for one and a half hours, then poured into 400 cc. of water to dissolve the sodium bromide formed. The oil which separated at the top was washed several times with 10% sodium hydroxide solution, and finally with water. The oil was then dried over calcium chloride and distilled; yields from 50 to 75% were obtained.

Rearrangement of Alkyl Phenyl Ethers.—The procedure for the rearrangement of alkyl phenyl ethers is very nearly uniform and may be illustrated by the rearrangement of isopropyl *m*-cresyl ether.

Ninety-eight grams of the ether was weighed into a 500-cc. flask fitted with a three-holed stopper. A thermometer and an inlet tube were inserted below the surface of the liquid. Boron fluoride gas was passed into the ether. The preparation of the boron

⁴ Niederl and Natelson, *THIS JOURNAL*, **53**, 1928 (1931).

fluoride followed the procedure of Bowlus and Nieuwland.⁵ The temperature ranged from 27 to 43° when 3 g. of boron fluoride was added. The absorption was stopped and the mixture, which had a reddish tinge, was shaken vigorously. The temperature gradually went to 75° and the solution became dark red in color. The flask was heated to 85° and then shaken for about five minutes or allowed to stand overnight. At this point the boron fluoride gas was given off quantitatively. The solution was placed in a 500-cc. separatory funnel and washed once with 150 cc. of water and then extracted with 10% potassium hydroxide solution. The alkali insoluble layer was separated and washed with water until free from alkali. This was the reclaimed ether. The alkali-soluble layer was kept cool and neutralized with concentrated hydrochloric acid. Two layers appeared. The oily layer was separated and the other layer extracted with ether. The oily layer and the ether extract were combined. The ether was removed and the residue subjected to several fractionations.

From 98 g. of the ether, 63 g. of rearranged product was obtained, and 8 g. of the unchanged ether. This is a 64% yield based on the total quantity of ether used or 72% yield when the reclaimed ether is allowed to enter the calculations.

TABLE I
ETHERS AND REARRANGED PRODUCTS

	Ether	B. p., °C.,	d_4^{20}	n_D^{20}	Taken, g.

4	4-Methyl-2-isopropylphenol	36	52.2	233–236	.982	1.5270

Discussion

The compounds which appear in this article have been reported previously and the structures established, with the exception of the rearranged product from isopropyl *m*-cresyl ether. The position of the isopropyl group in the ring is at present being studied at New York University.⁴

The method described in this investigation should be rather desirable: first, because never more than thirty-five minutes was required to complete a rearrangement studied. Second, the boron fluoride gas was easily recovered by merely heating the mixture. The temperature at which the gas was evolved varied from 85 to 150° for the different phenols. The amount of boron fluoride required for these rearrangements varied from one to five grams. When the minimum amount was used, warming and shaking were necessary.

The above ethers could be rearranged spontaneously by simply adding an excess of boron fluoride and allowing the temperature to rise.

⁵ Bowlus and Nieuwland, *THIS JOURNAL*, **53**, 3835 (1931).

Solvents are not necessary but in certain cases they increase the yield. At present, an investigation regarding solvent action and the preparation of a series of new compounds of various phenolic ethers is being studied in this Laboratory.

Summary

1. The rearrangement of a series of alkyl phenyl ethers has been accomplished by the use of boron fluoride.
2. The boron fluoride can be recovered quantitatively.
3. The time required for the rearrangement of alkyl phenyl ethers has been materially shortened by this process.

THE BEHAVIOR OF PHENYLACETONITRILE AND ALPHA-PHENYLBUTYRONITRILE WITH SODIUM ETHYLATE¹

BY MARY M. RISING AND KEITH T. SWARTZ

RECEIVED DECEMBER 31, 1931

PUBLISHED MAY 7, 1932

The isolation of the pure alkali salts of phenylacetonitrile and α -phenylbutyronitrile by Rising in collaboration with Zee,^{2a} Muskat and Lowe^{2b} and Braun,^{2c} and of the former nitrile by Upson,³ involved the treatment of the nitriles with the alkali metals or amides. As observed by E. von Meyer⁴ and his co-workers, and by Upson, and shown quantitatively for phenylacetonitrile by Braun, the reaction of the nitriles with sodium takes the course

The use of sodamide instead of sodium incurs no reduction of the salts.

It was suggested earlier^{2a} that sodium ethylate might prove to be a useful reagent for obtaining the salts of these and other nitriles. The present paper describes the behavior of phenylacetonitrile and α -phenylbutyronitrile with solid sodium ethylate in dry boiling ether in an atmosphere of nitrogen. The ethylate has been used successfully in a great number of condensation reactions of nitriles⁵ and the intermediate formation of sodium salts of the nitriles used is ordinarily assumed. We planned to

isolate the intermediate products in the case of the nitriles studied, using the extremely delicate technique developed by Braun for handling the very unstable salts.

Under the conditions used by us phenylacetoneitrile reacts with sodium ethylate to form a considerable quantity of sodium phenylacetoneitrile. The major part of the salt formed apparently condenses with phenylacetoneitrile to form a dimer of the nitrile, since the main product of the reaction is α,γ -phenyl- α -iminopropionitrile (dimolecular phenylacetoneitrile), $\text{C}_6\text{H}_5\text{CH}_2\text{C}(=\text{NH})\text{CH}(\text{C}_6\text{H}_5)\text{CN}$, formed in about 25% yield. Sodium phenylacetoneitrile was not isolated from the reaction mixture, in which it is soluble, but its presence there, and the quantity formed, were shown by treatment of this mixture with benzyl bromide, and the resulting formation of α,β -diphenylpropionitrile, $\text{C}_6\text{H}_5\text{CH}(\text{CH}_2\text{C}_6\text{H}_5)\text{CN}$, in 11% yield. The identity of the dinitrile was established by the analytical data for the compound and by the results of molecular weight determination. Its structure was proved by its conversion into α,γ -diphenyl- β -oximinopropionitrile, $\text{C}_6\text{H}_5\text{CH}_2\text{C}(=\text{NOH})\text{CH}(\text{C}_6\text{H}_5)\text{CN}$, and by a study of the products of hydrolysis of the dimer. The equations are

It is to be concluded that the mononitrile condenses with itself in the presence of sodium ethylate to form the dimer with intermediate formation of the sodium salt of the mononitrile. The product of this aldol-like condensation is the sodium salt of the dimer, which is hydrolyzed to the dinitrile. The dinitrile obtained, of molecular weight 228–235, was a viscous yellow oil of b. p. 222–223° (uncorr.) at 2.75 mm. pressure.

Dimolecular phenylacetoneitrile was first prepared by von Meyer,⁴ repeating the work of Wache,⁴ who studied the behavior of phenylacetoneitrile with sodium in ether but failed to isolate the dinitrile. Von Meyer obtained a viscous oil from which he prepared an oxime of melting point 107°,

identical with that obtained from cyanodibenzyl ketone, and he concluded that the oil was α, γ -phenyl- β -iminopropionitrile. Atkinson and Thorpe⁶ prepared the dimolecular nitrile by heating phenylacetone with sodium in alcohol for half an hour. Rondou⁷ obtained the dinitrile by a Grignard reaction.

α -Phenylbutyronitrile, $C_6H_5CH(C_2H_5)CN$, was not found by us to condense with itself under the influence of sodium ethylate. After treatment of this nitrile with the ethylate under the conditions used in the case of phenylacetone, 83% of the mononitrile used was recovered. The material obtained in a reaction of the nitrile with sodium ethylate was treated with methyl alcohol and hydrogen chloride. The products of this reaction were methyl α -phenylbutyrate and a substance of melting point 83° (uncorr.), thought to be α -phenylbutyramide. The amide, hitherto unprepared, was synthesized from α -phenylbutyryl chloride, also previously unknown, and ammonia, and showed a melting point of 83° (uncorr.). The melting point of a mixture of the amides obtained by the two methods was 83° . α -Phenylbutyryl chloride of boiling point 122 – 125° at 20 mm. was obtained from α -phenylbutyric acid and thionyl chloride.

The investigation of the tautomerism of nitriles is being continued in this Laboratory. An exhaustive study of the conductivities of a series of nitriles is under way, and the results of this work should form a logical basis for selection of nitriles best suited to the study of separation of tautomers. Salts of the nitriles with heavy metals are being studied.

Experimental

1. **Reaction of Phenylacetone with Sodium Ethylate in Ether.**—Sodium ethylate was prepared from sodium (4 g.) and absolute alcohol (85 cc.) containing 25 cc. of absolute ether in an atmosphere of nitrogen. When the excess of liquids was removed by evaporation, solid white ethylate remained. Phenylacetone (25.5 g., a 25% excess) was dropped into an ether suspension of sodium ethylate in an apparatus essentially like that used by Braun,²⁰ the reaction being carried out in an atmosphere of nitrogen. All reagents and apparatus were dried thoroughly. The reaction mixture was refluxed for four hours, then 15 cc. of ligroin was added to precipitate unchanged sodium ethylate. The mixture was allowed to stand overnight; it was then filtered and three volumes of ligroin added to the filtrate to precipitate sodium phenylacetone. The precipitate obtained consisted largely of sodium benzoate.⁸ Sodium phenylaceto-

⁶ Atkinson and Thorpe, *J. Chem. Soc.*, **89**, 1906 (1906).

⁷ Rondou, *Bull. soc. chim. Belg.*, **31**, 231 (1922).

⁸ It is evident that in spite of the precautions used to exclude air from apparatus and reagents some oxygen was present. The formation of benzoic acid may signify the breakdown of sodium phenylacetone as follows

as previously postulated by Rising and Zee,^{2a} who obtained benzyl alcohol after the treatment of the salt with aqueous acid. Upson and Thompson [*THIS JOURNAL*, **44**, 186 (1922)] obtained benzoic acid from the impure salt following its exposure to air. A study of controlled oxidation of the salt will presently be made.

nitrile was not isolated from the reaction mixture, but its presence there was proved by treatment of a reaction mixture, obtained as just described, with benzyl bromide, whereupon α,β -diphenylpropionitrile was obtained in 11% yield. This nitrile melted at 57.5° (uncorr.), boiled at 163–164° (uncorr.) at 3 mm., and yielded on hydrolysis α,β -diphenylpropionic acid of melting point 81–82° (uncorr.).¹⁰

2. α,γ -Diphenyl- β -iminopropionitrile. **Preparation.**—The reaction of phenylacetoneitrile (46.1 g.) with sodium ethylate (prepared from 7.3 g. of sodium and 140 cc. of alcohol) was carried out as just described. The reaction solution was filtered after being refluxed, and was then treated with water; the ether layer was separated and dried over fused calcium chloride. The ether was then removed by evaporation and the oily residue was distilled, yielding about 16 g. of phenylacetoneitrile and 10 g. (a 25% yield) of the dimolecular nitrile, of boiling point 222–223° (uncorr.) at 2.75 mm.

Anal. Calcd. for $C_{16}H_{14}N_2$: C, 82.00; H, 6.03; N, 11.97; mol. wt., 234. Found: C, 81.92, 82.11; H, 6.14, 6.28; N, 11.95, 12.06; mol. wt., 231 (av., benzene as solvent).

Proof of Structure. (a) **Oxime Formation.**—Treatment of the dinitrile in alcohol with hydroxylamine hydrochloride and barium carbonate (Equation 3) produced an oxime of melting point 106–107°, α,γ -diphenyl- β -oximinopropionitrile.^{4,6}

(b) **Hydrolysis.**—(a') Treatment of the dinitrile with concentrated hydrochloric acid¹¹ in a bomb tube at 150° for eight hours (Equation 6) produced carbon dioxide, phenylacetic acid¹² of melting point 76° (uncorr.), and dibenzyl ketone¹³ of melting point 34–35° (uncorr.). The identity of the ketone was established by its conversion into dibenzyl ketone phenylhydrazone¹⁴ of melting point 125–126° (uncorr.). (b') Treatment of the dinitrile (4 g.) with methyl alcohol (15 cc.) and hydrogen chloride gas at 0° to saturation (Equations 4 and 5) produced phenylacetophenylacetamide of melting point 163.5–164° (uncorr.) formed in 76% yield.¹¹ The amide was hydrolyzed by alkali to phenylacetic acid of melting point 75–76° (uncorr.).

3. α -Phenylbutyryl Chloride.— α -Phenylbutyric acid (14 g.) was refluxed with thionyl chloride (100 g.) for eight hours. The reaction mixture was fractionated and the fraction of distillate, 14 g. in quantity, of boiling point 122–125° (uncorr.) at 20 mm. was found to be pure butyryl chloride, produced in 89.9% yield.

Anal. Calcd. for $C_{10}H_{11}OCl$: Cl, 19.42. Found: Cl, 19.37, 19.56.

4. α -Phenylbutyramide.—Dry ammonia was passed into an ether solution containing 5 g. of α -phenylbutyryl chloride. A vigorous reaction followed and precipitation of the amide and of ammonium chloride occurred. The precipitate was brought on a filter and washed with water to remove the salt. The amide was recrystallized from alcohol and melted at 83° (uncorr.). The yield was 63% of the theoretical. The amide was also obtained, together with methyl α -phenylbutyrate, by treatment of the crude reaction product, obtained by treatment of α -phenylbutyronitrile with sodium ethylate as previously described for phenylacetoneitrile, and consisting largely of unchanged α -phenylbutyronitrile, with methyl alcohol and hydrogen chloride at 0°. The melting point of a mixture of the amide obtained by the two methods was 83° (uncorr.).

Summary

1. Under the conditions used by us sodium ethylate is not a useful reagent for obtaining the sodium salt of phenylacetonitrile.
2. A considerable quantity of sodium phenylacetonitrile is undoubtedly formed in the reaction of the nitrile with sodium ethylate but much of the salt condenses with the mononitrile to form a dinitrile.
3. α -Phenylbutyronitrile was not found to condense with itself under the influence of sodium ethylate in ether.
4. The syntheses of the chloride and amide of α -phenylbutyric acid are reported.

CARBON TETRABROMIDE AS A BROMINATING AGENT¹

BY W. H. HUNTER AND D. E. EDGAR

RECEIVED JANUARY 2, 1932

PRINTED MAY 7, 1932

During the study of certain reactions of carbon tetrabromide and aniline in xylene solution, it was observed that the xylene was brominated. Accordingly, an investigation was started with the point of view of determining the possible use of carbon tetrabromide as a brominating agent. In the case of the majority of compounds studied, bromination with this reagent took place, and when this occurred bromoform was always a by-product. Most of the bromo compounds prepared in this work can be made more easily by other methods, so that, as a rule, the use of carbon tetrabromide does not have any advantages over the commoner methods, but our experiments indicate that there are certain regularities with brominations using carbon tetrabromide that may be very useful, and the most important of these is the preferential side chain bromination of alkylbenzenes.

Experimental Part

Preparation of Carbon Tetrabromide.—The method of Wallach² served as a basis for our modified preparation of carbon tetrabromide from acetone and sodium hypobromite. The preparation as described is suitable for the production of large quantities of carbon tetrabromide in good yield. Since bromoform is a by-product in all cases of brominations described here, use was also made of a method similar to Habermann's,³ involving bromoform and aqueous sodium hypobromite. Although Habermann stated that direct light was necessary, it was found that as good a yield of carbon tetrabromide could be obtained in the complete absence of light.

¹ The work described in this paper constituted part of a thesis submitted to the graduate faculty of the University of Minnesota by Donald E. Edgar in partial fulfillment of the requirements for the degree of Doctor of Philosophy, May, 1927. This paper was prepared by the junior author after the death of Dr. Hunter.—[L. I. SMITH.]

² Wallach, *Ann.*, **275**, 149 (1893).

³ Habermann, *ibid.*, **167**, 174 (1873).

(a) **From Acetone.**—A four-liter container (fitted with a mechanical agitator) was approximately half-filled with shaved ice. To this was added 2500 cc. of sodium hydroxide solution containing 150 g. of sodium hydroxide to the liter; 200 cc. of bromine was added rapidly with stirring. Then 60 cc. of acetone was added in small portions (5–10 cc.), time being allowed after each addition for the milky precipitate formed (probably bromoform) to be converted into lumps of carbon tetrabromide. After addition of this amount of acetone, 1-cc. portions were added cautiously until the characteristic yellow hypobromite color had been discharged. The crude carbon tetrabromide was separated by filtration and purified by crystallization from alcohol.

(b) **From Bromoform.**—A sodium hypobromite solution was prepared as in (a) but with only one-fourth of the amounts of materials. This is sufficient to convert 150 g. of bromoform to carbon tetrabromide. All of the bromoform was added at one time and the mixture was shaken or stirred vigorously.

Procedure in Bromination Experiments.—The reactions were carried out by heating carbon tetrabromide with various materials in sealed tubes, in the proportions of 1:1 unless otherwise noted. The temperature, in general, was 150–180°, and the time of heating about eight hours. In practically all cases, separation and purification of resulting products was accomplished by fractional distillation under diminished pressure. Identification of the products was by analysis for bromine, together with physical properties. The method of analysis was that of Stepanoff, as modified by Drogin and Rosanoff,⁴ which was found to be rapid and convenient.

TABLE I

^a Two moles of carbon tetrabromide to one of reactant. ^b Room temperature in carbon disulfide solution.

⁴ Drogin and Rosanoff, THIS JOURNAL, **38**, 711 (1916).

In the study of aromatic hydrocarbons, described above in Table II, several interesting facts were noted. Bromination, by this method, takes place preferentially in the side chain rather than in the ring: the first point of attack being, in these cases, the alpha carbon of the chain. The decomposition of isopropylbenzene, whereas *n*-propylbenzene is brominated, suggests a method of differentiating between normal and iso linkages to the ring.

Duryl Monobromide ($C_{10}H_{13}Br$).—This compound, which has not heretofore been prepared, resulted from the reaction of carbon tetrabromide and durene in the general manner described above and in Table II. Duryl monobromide is a clear, practically colorless liquid boiling at 110–112° under a pressure of 4 mm. It has a not unpleasant odor, somewhat resembling that of benzyl bromide, but is free from lachrymatory action. With alcoholic silver nitrate it gives an immediate precipitate of silver chloride, while monobromodurene, a solid having a melting point of 61°—the only other monobromo derivative of durene—gives no precipitate.

Anal. Calcd. for $C_{10}H_{13}Br$: Br, 37.51. Found: (Stepanoff) Br, 37.78, 37.69; (Carius) Br, 37.88, 37.82; (alc. $AgNO_3$) Br, 37.81, 37.86.

Durene—Carbon Tetrabromide Addition Product ($C_{10}H_{14}CBr_4$).⁵—Durene and carbon tetrabromide were dissolved in equivalent molecular proportions in an excess of carbon disulfide. The solution was allowed to stand at room temperature until the carbon disulfide had evaporated. The material remaining was in the form of large, well-defined crystals different in form from those of durene or of carbon tetrabromide, m. p. 84–86°. Mixed melting points of this material with either durene or carbon tetrabromide gave a lowering of the melting point.

Anal. Calcd. for $C_{10}H_{14}CBr_4$: Br, 68.62. Found: Br, 68.29, 68.51.

TABLE III
REACTIONS WITH AROMATIC COMPOUNDS

Reactants with CBr_4	Product	Yield, %
Bromobenzene	<i>p</i> -Dibromobenzene	42.5
<i>p</i> -Dibromobenzene	No reaction	..
Benzyl bromide	Benzal bromide	55.3
	Benzal bromide	74.5 ^d
Benzyl bromide ^a	Benzotribromide	21.4
Benzal bromide	Benzotribromide	27.2
Phenol ^b	(Aurin)	..
Aniline ^c	(Pararosaniline)	..

Nitrobenzene, *m*-dinitro benzene, and benzoic acid gave no reaction, even on prolonged heating, while hydroquinone was completely decomposed.

^a Two moles of carbon tetrabromide to one of reactant. ^b One mole of carbon tetrabromide to ten of reactant; refluxed for thirty minutes. ^c One mole of carbon tetrabromide to thirteen of reactant; refluxed for one hour. ^d Temperature, 210°.

Table III records the reactions of various aromatic compounds. It is interesting to note that bromination did not take place with any of the compounds having a meta orienting group already present. Phenol and carbon tetrabromide when heated together at atmospheric pressure gave a bright red material which was not studied further at this time. It was perhaps aurin, since Gomberg and Snow⁶ have described the formation of this dye from phenol and carbon tetrachloride. Likewise, in the case of aniline, para-

⁵ We wish to express our thanks to Dr. L. I. Smith for his generosity in providing the durene and bromodurene which made possible these experiments.

⁶ Gomberg and Snow, *THIS JOURNAL*, **47**, 198 (1925).

rosaniline was perhaps the product since Hofmann⁷ obtained it similarly by the action of carbon tetrachloride.

It will be noted in Table III that benzotribromide was the product of two reactions. This compound is described here for the first time, as far as the writers are aware. A search of the literature revealed only one mention⁸ of this compound and that was in a statement to the effect that benzotrichloride (or bromide) is readily hydrolyzed by water or potassium hydroxide to benzoic acid. It was found that several hours of heating with 10% sodium hydroxide was required to bring about hydrolysis of a 3-g. sample.

Benzotribromide ($C_7H_5Br_3$).—Benzotribromide resulted from the reaction of two equivalents of carbon tetrabromide with one of benzyl bromide and also from one equivalent of carbon tetrabromide with one of benzal bromide. Hydrolysis of the product resulted in the formation of benzoic acid.

Benzotribromide is a colorless crystalline material, very soluble in alcohol or ether, less soluble in petroleum ether, insoluble in water: m. p. 56–57°.

Anal. Calcd.: Br, 72.91. Found: Br, 72.76, 72.61 (Stepanoff); 72.85 (alc. $AgNO_3$).

Summary

1. Carbon tetrabromide will react with various organic materials through the exchange of a bromine atom for a hydrogen. Bromoform is always the by-product of such bromination.

2. Carbon tetrabromide brominates selectively the side chains of the benzene hydrocarbons instead of attacking the ring.

3. Duryl monobromide, benzotribromide, and an addition product of durene and carbon tetrabromide are described.

SUBSTITUTED PHENYLACETONITRILES AND DERIVATIVES. 1-PHENYL-1-CYANOCYCLOPROPANE, ALPHA-PHENYL- GAMMA-HYDROXYBUTYRONITRILE, ALPHA-PHENYL-GAMMA- CHLOROBUTYRONITRILE AND ALPHA- PHENYLCROTONONITRILE¹

BY EDWIN C. KNOWLES AND JOHN B. CLOKE

RECEIVED JANUARY 2, 1932

PUBLISHED MAY 7, 1932

In the development of a series of investigations on sundry cyclic ketimines, imino esters and heterocyclic nitrogen compounds, supplies of α -alkyl and α -aryl- γ -chlorobutyronitriles and alkyl and aryl substituted cyclopropyl cyanides were required. The present paper describes the preparation of one of the chloro and two of the cyclic compounds.

¹ This paper is from the first part of a thesis presented by Edwin Chandler Knowles in June, 1931, to the Graduate School of the Rensselaer Polytechnic Institute in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

The Preparation of 1-Phenyl-1-cyanocyclopropane, $\text{CH}_2\text{CH}_2\text{C}(\text{C}_6\text{H}_5)\text{CN}$.—Two methods have been developed for the preparation of 1-phenyl-1-cyanocyclopropane (I). In the first method one mole of phenylacetonitrile (XIII) in ether was first treated with two moles of sodium amide, and this reaction mixture was then allowed to react with ethylene chlorobromide or dibromide under suitable conditions to give 40–45% yields of (I). This procedure, therefore, constitutes an extension of the work of Bodroux and Taboury² on the alkylated phenylacetonitriles to the alkylene derivatives.

The first stage in the formation of (I) by the foregoing method involves the reaction of the sodium amide with (XIII) to give the monosodium salt. In accordance with the views of Rising³ and others the carbide tautomer of this salt may then be assumed to react with the ethylene chlorobromide to give primarily sodium bromide and α -phenyl- γ -chlorobutyronitrile (XIV).

In the third stage of the reaction, (XIV) may be supposed to react with the excess sodium amide and with the salt of (XIII) to give the tautomeric carbide and nitride salts, and, finally, the carbide salt may be regarded as undergoing a very rapid internal condensation to give (I) and sodium chloride

The mechanism which has been suggested for the latter ring closure is the same as that which has been given in detail for the preparation of cyclopropyl cyanide from γ -chlorobutyronitrile.⁴

That the formation of (I) by Method 1 actually goes through the stages as sketched above seems clear from other considerations. Thus, in the first place, slightly less than one equivalent of ammonia is liberated for each mole of (XIII) which is used, even though twice as much sodium amide is present. In the second place (XIV), whose existence as an intermediate has been postulated in Equation 1, has been found to react with sodium amide to give (I). This reaction, which is formulated in Equation 2, constitutes the second method for the preparation of (I).

α -Phenyl- γ -chlorobutyronitrile.—Compound (XIV) was obtained by the action of thionyl chloride on α -phenyl- γ -hydroxybutyronitrile in pyridine solution

² Bodroux and Taboury, *Bull. soc. chim.*, **7**, 666 (1910); *Compt. rend.*, **150**, 531, 1241 (1910).

³ Rising and Zee, *THIS JOURNAL*, **49**, 541–545 (1927); **50**, 1699–1707 (1928); Rising, Muskat and Lowe, *ibid.*, **51**, 262 (1929).

⁴ Cloke, Anderson, Lachmann and Smith, *ibid.*, **53**, 2791 (1931).

This procedure was suggested by the work of Darzens⁵ on the replacement of hydroxyl in alcohols and hydroxy esters by chlorine.

α -Phenyl- γ -hydroxybutyronitrile.—The hydroxynitrile which was required in Equation 3 was prepared by the action of ethylene chlorohydrin on the sodium salt of (XIII).

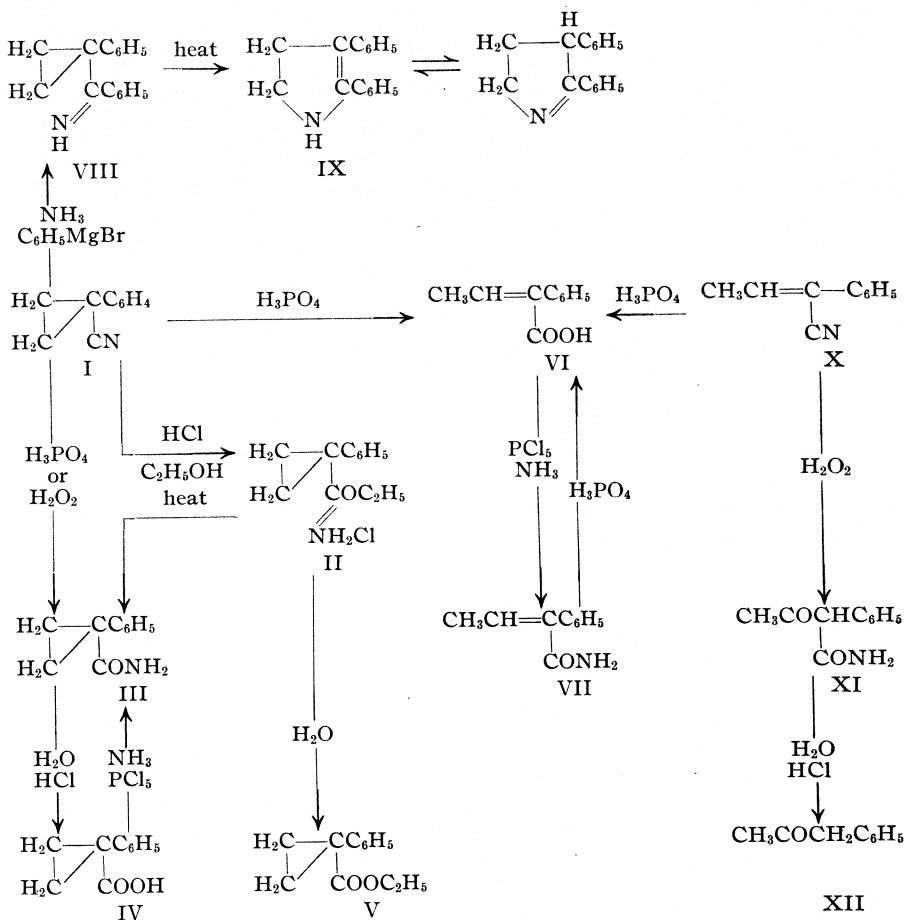

The Structure of the 1-Phenyl-1-cyanocyclopropane.—At one time it appeared likely that our nitrile (I) which was obtained by Method 1 might be one of the geometrical isomers of the isomeric α -phenylcrotononitrile (X), since the amide which was obtained from (I) was found to have the same melting point as that which had been reported by Pfeiffer, Engelhardt and Alfuss⁶ for the α -phenylcrotonamide (VII). It seemed possible, therefore, that the isomeric (X) might either have arisen directly from (I) by a ring rupture or from the rearrangement of α -phenylvinylacetoneitrile, which might have been the initial product by Method 1. Now, however, several lines of evidence point unquestionably to the cyclopropane structure (I).

In the first place nitrile (I) is different from (X). Thus (I) was saponified by phosphoric acid and also by alkaline hydrogen peroxide to give the amide of 1-phenylcyclopropanecarboxylic acid (III), which was distinct from the amide (VII) which can be prepared from the α -phenylcrotonic acid (VI) by the action of phosphorus pentachloride and ammonia. It is true that the amides melted at practically the same temperature, but they had distinct crystalline structures and gave a decidedly lower mixed melting point. Moreover, the real (X) was difficultly saponified by hydrogen peroxide and dilute alkali to give α -phenylacetoacetamide (XI), which was recognized from its analysis and from the fact that it gave methyl benzyl ketone (XII) on hydrolysis. It is also of interest to note that (I) reacted with hydrogen chloride and ethanol to give the imino ester hydrochloride (II), which in turn gave the amide (III) on heating, whereas the isomeric nitrile (X) failed to react under these conditions. Finally (I) and (X) gave characteristic ketimines.

The saponification of (I) with hot phosphoric acid gave not only the amide (III) but also the acid (VI), which originated as the result of a ring rupture. The acid, indeed, was the main product. Cyanocyclopropane itself under the same conditions gave cyclopropanecarboxylic acid. The corresponding acid (IV) was obtained from the amide (III) by saponification with boiling dilute hydrochloric acid. That no ring rupture had occurred in this reaction was established by the reversion of the acid (IV) into the amide (III) by means of phosphorus pentachloride and ammonia.

⁵ Darzens, *Compt. rend.*, **152**, 1314, 1601 (1911).

⁶ Pfeiffer, Engelhardt and Alfuss, *Ann.*, **467**, 189 (1928).

That the nitrile (I) could not be the α -phenylvinylacetonitrile was shown, on the one hand, by its failure to react significantly either with bromine in carbon tetrachloride or with alkaline potassium permanganate solution, and, on the other hand, by its saponification to the acid (IV) which failed to rearrange to (VI) when it was treated with a base. Independent work of Gilman and Harris⁷ and by the writers on the vinyl-phenylacetic acid has established this point.

That the nitrile (I) is not the geometric isomer of (X) and that it actually has the cyclic structure (I) was finally established beyond question by the complete analogy which exists between the behavior of phenylcyclopropyl ketimine, $\text{CH}_2\text{CH}_2\text{CHC}(=\text{NH})\text{C}_6\text{H}_5$,⁸ and the 1-phenylcyclopropyl phenyl ketimine (VIII), which has been prepared from (I) by the Grignard

⁷ Gilman and Harris, *THIS JOURNAL*, **53**, 3544-3545 (1931).

⁸ Cloke, *ibid.*, **51**, 1174 (1929); Doctorate Dissertation, University of Chicago.

reaction. Thus, the two ketimine hydrochlorides react with water at almost the same rate, and, second, and this is of most significance, both ketimines rearrange to give the corresponding pyrrolines, *e. g.*, (IX). An account of this work will appear later. Finally, it may also be noted that the structure (I) would likewise be indicated from the second method of synthesis, namely, from (XIV), since the γ -chlorobutyronitrile gives cyanocyclopropane under the same conditions.

α -Phenylcrotononitrile.—The nitrile (X), which was required in connection with the study of the structure of (I), was obtained in a 36% yield by the condensation of acetaldehyde with benzyl cyanide in the presence of sodium ethylate at 0°

Pfeiffer, Engelhardt and Alfuss, who obtained the nitrile by another method, assigned to it the *cis* configuration, namely, $\begin{array}{c} \text{C}_6\text{H}_5-\text{C}-\text{CN} \\ \parallel \\ \text{H}-\text{C}-\text{CH}_3 \end{array}$, in view of the fact that the compound is very slowly esterified. Our failure to transform it into the ethyl imino ester hydrochloride constitutes evidence of the same type for this structure.

Experimental Part

Preparation of 1-Phenyl-1-cyanocyclopropane by Method 1.—A one-liter, three-necked, round-bottomed flask was provided with a 500-cc. dropping funnel, a mechanical stirrer, which operated through a mercury seal, and a reflux condenser. The open ends of the funnel and condenser were provided with drying tubes. In the later runs a suction arrangement, which is illustrated in Fig. 1, was also attached to the apparatus, whereby the contents of the flask could be transferred to the funnel without the necessity of their exposure to the moist air of the laboratory. Finally the apparatus was thoroughly dried with a current of warm dry air.

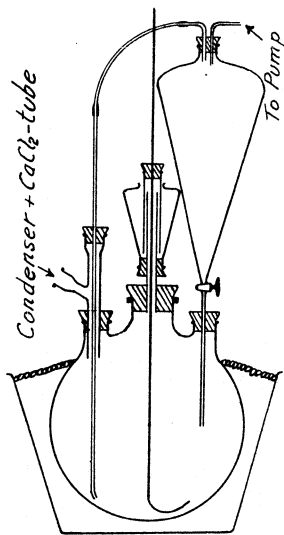

Fig. 1.

A weight of 75 g. (1.92 moles) of Kahlbaum's sodium amide was halved and each part was converted into a flocculent condition under about 200 cc. of anhydrous ether by a process of elutriation. Throughout this alternate process of grinding and decantation care was taken to avoid as much as possible the direct exposure of the sodamide to moist air. In passing it may be added that no explosive decompositions have occurred with us since we have ground the sodium amide under ether, although several took place before. The finely ground compound was at once transferred to the reaction flask with 400–450 cc. of the ether under which it had been pulverized. One mole (117 g.) of phenylacetonitrile⁹ was then added to the well-stirred sodium amide suspension from the dropping funnel with sufficient rapidity to give a vigorous refluxing of the ether. As soon as all of the nitrile

⁹ Adams and Thal, "Organic Syntheses," John Wiley and Sons, Inc., New York, 1922, Vol. II, p. 9.

had been added and the vigor of the reaction began to abate, the mixture was refluxed gently on a water-bath for four to five hours, whereby about 0.9 mole of the mono-sodium salt was formed upon the basis of the quantity of ammonia evolved. Longer periods of refluxing did not serve to increase this amount of salt. Furthermore, no noticeably increased yields of the desired nitrile were obtained when the reaction was carried out in an atmosphere of nitrogen, although the color of the reaction mixture was lighter in this case.

At the end of this first stage in the preparation the yellow to dark red reaction mixture was cooled and transferred, preferably by means of the suction arrangement, to the 500-cc. dropping funnel. A weight of 130 g. (0.9 mole) of redistilled Eastman Kodak Co. ethylene chlorobromide¹⁰ in twice its volume of anhydrous ether was then poured into the flask, which at this stage was cooled in an ice-salt bath to -15° . The stirrer was started, and as soon as the solution was thoroughly cold, the sodium salt mixture in the funnel was added to the chlorobromide solution at such a rate that scarcely any refluxing of the ether could be detected.¹¹ Following the addition of the salt mixture, which required about two hours, the stirring was continued during the next seven hours, while the temperature of the bath was allowed to rise to that of the room. At this stage the temperature of the bath was raised to the point where droplets of ether began to collect in the condenser, where it was held for an hour, and finally it was raised sufficiently to give a gentle refluxing, which was maintained for two hours while the stirring was continued. At the end of this period the evolution of ammonia had completely ceased.

At the conclusion of the foregoing operation enough water was added to the mixture in the flask to dissolve the solid material. The ether layer was then separated and dried over anhydrous sodium sulfate for ten hours. Distillation of the dry filtered ether solution under diminished pressure on the water-bath gave 15 g. of a fraction which boiled from $81-83^{\circ}$ at 1 mm.; this was mainly benzyl cyanide. The continuation of the distillation under the same pressure but with direct heating gave 91.5 g. of the main product, which boiled from $110-113^{\circ}$, and 18-20 g. of a tarry residue which was not examined. Redistillation of the main fraction through a modified Claisen-Vigreux flask with a 1.8×30 cm. column gave 60-64 g. of distillate which boiled from $98-100^{\circ}$ at less than 1 mm.; this corresponds to a 44% yield upon the basis of the benzyl cyanide used. The freshly distilled product was a colorless oil with a slightly aromatic odor.¹² This liquid boiled from $250-253^{\circ}$ at 751 mm. with little decomposition. It possessed a density, d_4^{20} , of 1.0156 and a refractive index, n_D^{20} , of 1.3676, which correspond to a molecular refractivity, $MR_D^{20}(n^2)$ of 43.24 as compared with the calculated value of 43.10.

Anal. Subs., 8.44 mg., 9.78 mg.: N_2 (corr.), 0.657 cc.; N_2 (corr.), 0.763 cc. Calcd. for $C_{10}H_9N$: N, 9.79. Found: N, 9.72, 9.75.

Preparation of 1-Phenyl-1-cyanocyclopropane by Method 2.—The 1-phenyl-1-cyanocyclopropane was also prepared by the action of 8.1 g. of sodium amide on 31.5 g. of α -phenyl- γ -chlorobutyronitrile in 200-250 cc. of liquid ammonia by a process similar

¹⁰ In one run in which 42 g. of sodium amide, 58 g. of benzyl cyanide and 92 g. of ethylene dibromide were employed, 12 g. of product was obtained. This yield could doubtless be improved.

¹¹ In one experiment in which the ethylene chlorobromide was added to the sodium salt mixture, the result was practically as good as in the procedure described, although we believe the latter method is safer.

¹² The last traces of benzyl cyanide may be removed from the final product by its condensation with benzaldehyde in accordance with the process of Meyer and Frost, *Ann.*, 250, 157 (1889).

to that of Cloke, Anderson, Lachmann and Smith. A 73% yield (18.5 g.) of product was obtained.

α -Phenyl- γ -chlorobutyronitrile.—In the first run 77 g. (0.48 mole) of α -phenyl- γ -hydroxybutyronitrile from the following preparation and 38 g. (0.48 mole) of pyridine were placed in a 500-cc. three-necked flask, which was equipped with a reflux condenser, a mechanical stirrer and a dropping funnel. To this solution, which was cooled by the immersion of the flask in an ice-bath, 57 g. (0.48 mole) of thionyl chloride was slowly added from the dropping funnel with constant stirring. At the end of this addition the mixture was heated in a water-bath at 80–85° for thirty minutes. Water was then added and the heating was continued for about two hours. At this stage the mixture was cooled and extracted with ether. The ether extract in turn was extracted with dilute acid, which was followed by water, 10% sodium carbonate solution and finally by several portions of water. The ether extract was then dried over calcium chloride and distilled in a Claisen flask. The fraction which boiled from 97–135 at 3–4 mm. and which weighed 50 g. was redistilled in a Claisen-Vigreux flask. Two fractions were collected: the first (15 g.) was collected between 98–125°; and the second (31.5 g.), which was taken for analysis, boiled from 127–129° at 3–4 mm.; d_4^{20} 1.1251; n_D^{20} 1.5327; mol. ref. calcd., 49.42; found (n^2 formula), 49.51. The product was an oily liquid with a pleasant aromatic odor and was tinged slightly yellow, doubtless on account of the presence of a trace of impurity.

Anal. Subs., 11.12 mg.: N₂ (S. T. P. corr.), 0.699 cc. Calcd. for C₁₀H₁₀NC1: N, 7.80. Found: N, 7.88.

In a second run the α -phenyl- γ -hydroxybutyronitrile was mixed with a small excess of pyridine in the dropping funnel and added to the thionyl chloride which was contained in the flask. This procedure, however, reduced the yield of the desired product to 13 g., which was less than half of the amount which was obtained in the first run.

α -Phenyl- γ -hydroxybutyronitrile.—A weight of 120 g. (1.03 mole) of benzyl cyanide was allowed to react with 40 g. of sodium amide in the presence of 200 cc. of anhydrous ether. Enough ether was then added to bring the total volume to about 700 cc., and the mixture was refluxed gently on the water-bath for four hours with constant stirring. Here the water-bath was replaced by an ice-bath and, as soon as the mixture was well chilled, 85 g. (1.06 mole) of ethylene chlorohydrin was added slowly and with constant stirring over a period of about two hours. The ice-bath was then removed and the stirring was continued at room temperature for five hours, when the amount of precipitate seemed to have become constant. Enough water was then added to dissolve all of the solid, when the ether layer was separated and dried over anhydrous sodium sulfate. Three fractions were obtained: the first (34 g.) was mainly benzyl cyanide; the second (64 g. of b. p. 160–168° at 2–3 mm.) was primarily the desired nitrile; while the residue was not examined. Redistillation of the middle fraction gave a product of b. p. 146–149° at 1.5–2.0 mm., and this was taken for analysis. The freshly distilled compound was a nearly colorless and very viscous oily substance. A sample which had been allowed to stand for two years was found to have changed into a pasty wax-like substance. The density of the freshly distilled compound, d_4^{20} , was 1.065; and its index of refraction, n_D^{20} , was 1.5411.

Anal. Subs., 0.3125 g.: CO₂, 0.8500; H₂O, 0.1976. Subs., 19.91 mg., 17.18 mg.: N₂ (S. T. P. corr.) 1.394, 1.183 cc. Calcd. for C₁₀H₁₁ON: C, 74.49; H, 6.88; N, 8.69. Found: C, 74.18; H, 7.08; N, 8.76, 8.61.

Mol. wt. Subs., 0.2725; ethyl acetate, 17.38 g.; boiling point rise, 0.265°. Calcd. for C₁₀H₁₁ON: mol. wt., 161.09. Found: 158.7.

In a second run, in which the sodium salt of benzyl cyanide in ether was added to

a 25% excess of ethylene chlorohydrin, the yield of nitrile was somewhat smaller than by the above process. In a third run, which was similar to the first, but in which the temperature of the reaction flask was lowered to -15° during the addition of the chlorohydrin, a larger quantity of benzyl cyanide was recovered, but the yield of the hydroxy compound was not materially increased.

1-Phenyl-2-methyl-1-cyanocyclopropane, $\text{CH}_2\text{CH}(\text{CH}_3)\text{C}(\text{C}_6\text{H}_5)\text{CN}$.—Two moles (80 g.) of finely pulverized sodium amide in about 200 cc. of anhydrous ether was treated with 0.9 mole (105 g.) of benzyl cyanide as in the preparation of the 1-phenyl-1-cyanocyclopropane. To this mixture, which was cooled in an ice-bath, 0.9 mole (180 g.) of propylene dibromide was added. A very vigorous reaction ensued. The completion of the reaction gave 26 g. of a colorless oil with a slightly ethereal odor of b. p. $257-260^{\circ}$ at 761 mm.; d_4^{20} 1.0115; n_D^{20} 1.5316.

Anal. Subs., 13.880 mg.: N_2 (corr.), 0.982 cc. Calcd. for $\text{C}_{11}\text{H}_{11}\text{N}$: N, 8.91. Found: N, 8.84.

The Amide of 1-Phenylcyclopropanecarboxylic Acid.—By the general process of Radziszewski¹³ the 1-phenyl-1-cyanocyclopropane was converted into the amide by the first method. The fine, glistening, needle-shaped crystals melted at $81-83^{\circ}$ when heated rapidly and at $95-96^{\circ}$ when heated slowly. The product which had been dried at $50-60^{\circ}$ under diminished pressure for several hours softened at 96° and melted completely at $97-98^{\circ}$ (uncorr.) or at $100-101^{\circ}$ (corr.). From these results it was assumed that the air-dried product was hydrated. No evidence was secured which suggested the ring rupture of the amide below 250° .

Anal. Subs., 11.69 mg.: N_2 (corr.), 0.803 cc. Calcd. for $\text{C}_{10}\text{H}_{11}\text{ON}$: N, 8.69. Found: N, 8.59.

Mol. wt. (Rast) Subs., 2.59 mg.; camphor, 24.52 mg.; freezing point lowering, 26.13° . Calcd. for $\text{C}_{10}\text{H}_{11}\text{ON}$: mol. wt. 160.1. Found: 161.7.

The foregoing amide was also obtained in a second way by the heating of ethyl imino-1-phenylcyclopropane-carboxylate hydrochloride to approximately 110° .

By a third method 2 g. of nitrile was heated at 140° with 30 g. of "100%" phosphoric acid (70 g. of 85% H_3PO_4 + 30 g. of P_2O_5) for three and one-half hours by the Berger-Olivier¹⁴ method. The cooled acid solution was poured onto cracked ice, the aqueous solution was extracted with ether, and the ether was finally extracted twice with sodium hydroxide solution and once with water. Evaporation of the dried and filtered ether extract gave the amide of m. p. $100-101^{\circ}$ (corr.) after two recrystallizations.

The Rupture of the Ring in the Formation of α -Phenyl-crotonic Acid from 1-Phenyl-1-cyanocyclopropane.—The acidification of the sodium hydroxide solution from the preceding reaction gave the acid of m. p. $135.5-137^{\circ}$ ¹⁵ after two recrystallizations. A mixed melting point determination with the acid which was obtained from α -phenylcrotononitrile by the same method gave no depression.

The Action of Hot Phosphoric Acid on Cyanocyclopropane.—The unsubstituted cyclopropyl cyanide by the foregoing saponification method gave the cyclopropanecarboxylic acid, which gave an anilide of m. p. $110-111^{\circ}$ by the method of Autenrieth and Pretzell.¹⁶

¹⁴ Berger and Olivier, *Rec. trav. chim.*, **46**, 600-604 (1927).

¹⁵ Dimroth and Feuchter, *Ber.*, **36**, 2238 (1903).

¹⁶ Autenrieth and Pretzell, *ibid.*, **38**, 2548 (1905).

1-Phenylcyclopropanecarboxylic Acid.—By the saponification of the amide of the 1-phenylcyclopropanecarboxylic acid with boiling concentrated hydrochloric acid, the corresponding acid was obtained. The dry needle-like crystals melted at 86–87° (uncorr.). That no ring rupture had occurred in this reaction was demonstrated by the reconversion of the acid into the original amide by means of phosphorus pentachloride and ammonia.

α -Phenylcrotononitrile.—A solution of 160 g. (1.36 moles) of benzyl cyanide, 250 g. of absolute alcohol and 88 g. (2 moles) of acetaldehyde, which was prepared by the depolymerization of paraldehyde, was chilled to -5° and treated gradually with 15 cc. of freshly prepared 20% sodium ethylate so that the temperature did not rise above 0° . The yellowish-red solution was then placed in a refrigerator for a day, when an additional 10-g. portion of acetaldehyde was added, which was followed by a further sixteen-hour stand in the ice box. Three hundred cc. of water was then added to the mixture, which was well shaken, and the oily layer was separated and washed with another 300-cc. portion of water. The fractionation of the dried oil gave finally 70 g. (35.8% yield) of the nitrile, b. p. 100–103° at 1 mm. or less. The freshly distilled oily compound was colorless with a somewhat musty unpleasant odor, but it turned slightly yellowish on standing. It boiled at 244–246° at 751 mm. with a marked discolorization: d_4^{20} 1.013, n_D^{20} 1.5555, MR_D^{20} 45.41; calcd., 45.10.

Anal. Subs., 10.844 mg.: N_2 (corr.), 0.841 cc. Calcd. for $C_{10}H_9N$: N, 9.79. Found: N, 9.70.

Excessively alkaline solutions were found to be disadvantageous for the foregoing condensation, since they led to the formation of large amounts of resinous tarry materials, which was also the case when the condensation of ethylidene chloride and benzyl cyanide with sodium amide was attempted. Moreover, the use of such condensing agents as acetic acid–acetic anhydride, alcoholic ammonia and piperidine was unsuccessful.

α -Phenylacetoacetamide.—With the expectation of obtaining α -phenylcrotonamide, the α -phenylcrotononitrile was subjected to the action of alkaline hydrogen peroxide. The pure white solid which was formed was insoluble in cold water, fairly soluble in ether, alcohol and acetone and readily soluble in dioxane. The dried sample melted at 177–178°. Solutions of the compound in acetone and dioxane did not appear to be changed by long exposure to an ultraviolet light.

Anal. Subs., 10.478 mg., 11.838 mg.: N_2 (corr.), 0.642 cc.; N_2 (corr.) 0.749 cc. Calcd. for $C_{10}H_{11}NO_2$: N, 7.91. Found: N, 7.66, 7.91.

Mol. wt. Subs., 1.108 mg., 0.871 mg.; camphor, 10.576 mg., 10.099 mg.; temperature lowering, 23.73, 19.68°. Calcd. for $C_{10}H_{11}NO_2$: mol. wt. 177.09. Found: 176.6, 175.3.

Methyl Benzyl Ketone from the α -Phenylacetoacetamide.—In order to establish the identity of the acetoacetamide it was saponified with boiling concentrated hydrochloric acid. The semicarbazone into which the resulting ketone was converted melted at 188.5–189.5°, whereas the recorded value¹⁷ for this derivative of the methyl benzyl ketone is 188–189°, although higher values have been reported.

α -Phenylcrotonic Acid from the Nitrile.—The saponification of α -phenylcrotononitrile by the hot phosphoric acid method gave the acid, m. p. 136–137°.

α -Phenylcrotonic Acid from Phenylvinylacetic Acid.—In order to show that phenylvinylacetic acid would rearrange to give the isomeric crotonic acid, the following program was followed. First phenylvinylcarbinol was prepared from 48.5 g. of magnesium, 314 g. of bromobenzene, 580 cc. of anhydrous ether and 92 g. of freshly prepared acrolein

¹⁷ Wolff, *Ann.*, **325**, 146 (1902).

by a modification of the process of Klages and Klenk.¹⁸ The carbinol was then converted into 1-phenyl-1-chloropropene-2 by the saturation of its ether solution with dry hydrogen chloride,^{18,19} which gave, with certain modifications, 215 g. of the chloride. Finally a Grignard reagent was prepared by a special procedure from 18 g. of magnesium, 100 cc. of ether and 30 g. of the chloride in five volumes of ether. This reagent was then carbonated as usual, and the salt was decomposed in a cold acid solution. Evaporation of the ether extract of the acid under diminished pressure left 7-8 g. of a brownish oil, which crystallized after several hours in an ice-salt bath and which was presumably the phenylvinylacetic acid. This was then treated with 15 cc. of 10% sodium hydroxide solution, and from this the α -phenylcrotonic acid was prepared. The acid was characterized by its melting point and by its transformation into the *p*-nitrobenzyl ester, m. p. 80-81°, and the amide.

Summary

1. 1-Phenyl-1-cyanocyclopropane can be obtained in 40-45% yields by the condensation of ethylene chlorobromide with phenylacetonitrile by means of sodium amide. The same cyclic compound has been prepared in 73% yield by the action of sodium amide on α -phenyl- γ -chlorobutyronitrile. Several derivatives and reactions of the cyclic nitrile have been described in connection with a critical proof of its structure.

2. The preparation of 1-phenyl-2-methyl-1-cyanocyclopropane has been described.

3. α -Phenyl- γ -chlorobutyronitrile can be obtained by the action of thionyl chloride on α -phenyl- γ -hydroxybutyronitrile in pyridine solution.

4. α -Phenyl- γ -hydroxybutyronitrile has been obtained in a 40% yield by the action of ethylene chlorohydrin on the sodium salt of phenylacetonitrile.

5. α -Phenylcrotononitrile has been prepared in a 36% yield by the condensation of acetaldehyde with benzyl cyanide.

6. The action of alkaline hydrogen peroxide solution on α -phenylcrotononitrile led to the formation of α -phenylacetoacetamide.

7. The preparation of α -phenylcrotonic acid from the α -phenylcrotononitrile, the 1-phenyl-1-cyanocyclopropane and by a Grignard synthesis has been described.

Other papers will follow on the extension of the work described in this paper to other analogous compounds and their derivatives.

RESEARCHES ON PYRIMIDINES. CXXVII.¹ THE STRUCTURE OF CONVICINE²

BY HARRY J. FISHER AND TREAT B. JOHNSON

RECEIVED JANUARY 5, 1932

PUBLISHED MAY 7, 1932

The fact that the nucleic acids on hydrolysis yield purine and pyrimidine nucleosides lends great interest to the occurrence in nature of simple pyrimidine glucosides. The only known compounds of this type are the two substances vicine and convicine, isolated by Ritthausen³ from vetch some sixty years ago.

After various investigations by Ritthausen and others⁴ it was finally established by Levene⁵ that vicine was a glucoside of 2,5-diamino-4,6-dioxypyrimidine I, with the sugar probably attached to the nitrogen of the pyrimidine ring. As Hérissé and Cheymol⁶ have recently shown that vicine is hydrolyzed by emulsin, it must be classed as a β -glucoside.

Convicine, which occurs with vicine in vetch, has not, previous to the present study, been isolated by any other investigator than Ritthausen. He showed that it possessed the empirical formula $\text{C}_{10}\text{H}_{15}\text{N}_3\text{O}_8 \cdot \text{H}_2\text{O}$, was distinguished from vicine by not being readily soluble in dilute acids, and on hydrolysis yielded alloxantin and ammonia and a mother liquor which was strongly dextrorotatory and "reacted like sugar solutions to known sugar reagents." Schulze and Trier⁴ in 1910 proposed a formula corresponding to alloxantin diglucoside plus two molecules of ammonia attached in some unknown manner. Johnson⁴ later pointed out that the formula $\text{C}_{10}\text{H}_{15}\text{N}_3\text{O}_8$ corresponded exactly to that of either an amino-glucoside of dialuric acid or a glucoside of uramil.

¹ A report of this research was presented at the Organic Chemistry Symposium held in the Sterling Chemistry Laboratory of Yale University, New Haven, Connecticut, on December 28, 29 and 30, 1931.

² This paper is from a portion of a dissertation presented by Harry Johnstone Fisher to the Graduate School of Yale University, in partial fulfillment of the requirements for the degree of Doctor of Philosophy, June, 1931.

In an attempt to settle the question of the structure of convicine, the present authors have prepared a sample of this compound from broad beans (*vicia faba*), and have studied its products of hydrolysis and its behavior toward certain reagents.

About nine grams of convicine and a small amount of vicine were isolated from the beans. Our convicine was obtained in the form of perfectly colorless glistening, thin flat plates, decomposing without melting at 287° , and analyzing for the formula $C_{10}H_{15}N_3O_8 \cdot H_2O$ found by Ritthausen. It gave a positive murexide test, and a positive Molisch test for carbohydrate. The Wheeler-Johnson test⁷ and the color test with ammonia and phosphotungstic acid proposed by Johnson and Johns⁸ as a test for the presence of a free amino group in the 5-positions of the pyrimidine cycle, were both negative. Diazobenzene sulfonic acid gave a deep orange-red color with both convicine and vicine. This red color was not found by Johnson and Clapp⁹ to be given by pyrimidines which were substituted in the 3-position of the ring. The reaction of convicine with nitrous acid in the Van Slyke apparatus indicated the presence of a free amino group.

The convicine on hydrolysis with sulfuric acid yielded alloxantin (equal to 21.82% of the sample) and one molecule of ammonia. The presence of dextrose in the hydrolysis product was indicated by the formation of glucosazone. Tests for ketoses and pentoses were negative.

If convicine is a monoglucoside, the formula of the nitrogenous base must be $C_4H_5N_3O_3$. The base cannot be alloxantin itself, but must yield alloxantin and ammonia on acid hydrolysis. It is well known¹⁰ that alloxantin in water solution is largely dissociated into alloxan II and dialuric acid III. Any base of the formula $C_4H_5N_3O_3$ which would readily lose one nitrogen atom as ammonia to give either alloxan or dialuric acid would satisfy the structural requirements of the convicine base, as, since there is an oxidation-reduction equilibrium between alloxan and dialuric acid, and since alloxantin is more insoluble than either of these compounds, if either alloxan or dialuric acid were formed by acid hydrolysis of convicine, alloxantin would crystallize from the solution.

Derivatives of alloxan are excluded from consideration by the fact that they would contain one too many oxygen atoms.

Three possible derivatives of dialuric acid suggest themselves:

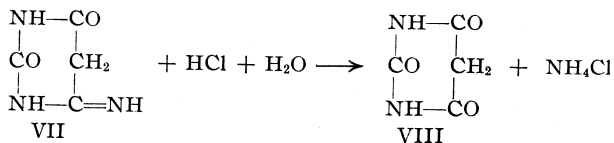

Formula IV is that of 2-iminodialuric acid, V is uramil and VI is 4-iminodialuric acid.

Levene⁵ showed that divicine I was oxidized by potassium chlorate and hydrochloric acid with rupture of the pyrimidine ring to yield guanidine. We oxidized some of our convicine in the same manner, and from the reaction product urea was isolated, but no guanidine. This indicates that the convicine base does not contain a 2-imino group, and consequently does not possess the structure IV. There is further no evidence in the literature that a 2-imino group is split off from pyrimidines by dilute acids as ammonia.

If the convicine base possessed the structure of uramil, the 5-amino group should condense with cyanic acid to form a pseudouric acid derivative. Baeyer¹¹ showed long ago that this reaction did take place with uramil, and Levene⁵ in like manner prepared 2-iminopseudouric acid from divicine. We found it impossible to cause any reaction to take place between convicine and potassium cyanate. From this positive evidence, and for the negative reason that there is no evidence in the literature that a 5-amino group is easily lost from a pyrimidine,¹² we believe that the convicine base cannot be uramil, V.

For the third possibility for the structure of the convicine base, that of 4-iminodialuric acid VI, there is strong evidence. While this compound has never been synthesized, its reduced form VII has been prepared by Traube¹³ and by Conrad.¹⁴ It is very significant that Conrad found that VII on warming with dilute acids was converted quantitatively to barbituric acid VIII and ammonia

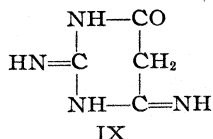

¹¹ Baeyer, *Ann.*, **127**, 3 (1863).

¹² The statement of Beilstein [3d ed., *Ergänzungsband I*, p. 767] that 1,3-dimethyluramil is converted into ammonia and tetramethylalloxantin on boiling with hydrochloric acid is evidently due to a misreading of a paper by Fischer and Ach, *Ber.*, **28**, 2475 (1895).

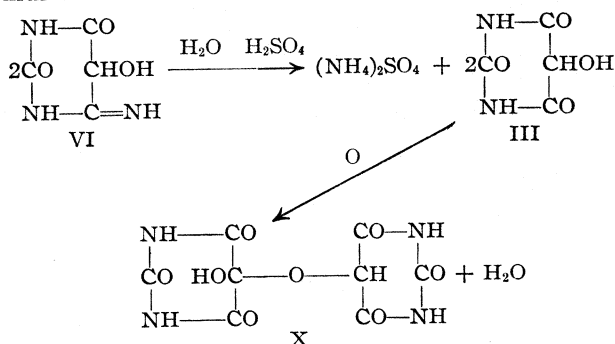

¹³ Traube, *Ber.*, **33**, 1381, 3043 (1900).

¹⁴ Conrad, *Ann.*, **340**, 310 (1905).

Of particular interest in connection with the relative stability of amino groups in the 2- and 4-positions of the pyrimidine cycle is Conrad's finding that the compound IX was hydrolyzed by dilute acids to 2-iminobarbituric acid and ammonia.

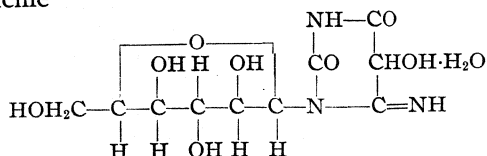

If the imino group in position 4 is so unstable in the barbituric acid derivatives, it is not to be anticipated that it would be any more stable in a dialuric acid derivative such as VI. The quantitative formation of one molecule of ammonia on hydrolysis of convicine with acids, and the presence of alloxantin in the hydrolysis product, are then very simply explained as being due to the hydrolysis of VI to dialuric acid III, which is readily oxidized to alloxantin X

For these reasons the authors believe that the properties of convicine can best be explained by assigning to the pyrimidine nucleus in convicine the structure VI. While the position of attachment of the sugar to this pyrimidine is in doubt, from analogy with vicine and the nucleosides of nucleic acid, and because the Wheeler-Johnson test is negative, the attachment of the sugar to a nitrogen of the pyrimidine ring seems most probable. It is true that convicine is not so highly resistant to acid hydrolysis as are the natural pyrimidine ribosides, which are nitrogen-linked, but the resistance to hydrolysis of the latter is apparently associated with the presence of a 4,5-double bond, and disappears on reduction of this double bond.

The following structure is therefore proposed for the naturally occurring glucoside convicine

Work is now in progress in this Laboratory on methods of synthesizing both vicine and convicine.

The authors wish to express their thanks to Doctors Bailey and Vickery of the Connecticut Agricultural Experiment Station for extending the facilities of their laboratories for part of this investigation, and to Professor W. E. Ford of the Department of Mineralogy, Yale University, for the crystallographic examination of alloxantin.

Experimental Part

The Isolation of Convicine.—Five kilograms of finely powdered broad beans was mixed with 10 liters of 3% sulfuric acid and allowed to stand overnight. The next day the mixture was neutralized with warm 20% barium hydroxide solution and made into a thick paste with filter paper clippings. This paste was squeezed under a hydraulic press, the turbid filtrate made barely acid with sulfuric acid and filtered again on a Buchner funnel through paper pulp. The clear yellow filtrate was treated with an excess of a 10% solution of mercuric sulfate in dilute sulfuric acid, and made alkaline with barium hydroxide solution. The heavy precipitate which came down was allowed to settle, and most of the supernatant liquid was siphoned off. The precipitate was separated from the balance of the liquid and washed with water in a centrifuge. It was then suspended in water with some barium carbonate and the mixture saturated with hydrogen sulfide. The mercuric sulfide was filtered off, and the filtrate concentrated at atmospheric pressure to a volume of 400 cc. The dark red solution was cooled, made just acid to litmus with sulfuric acid, and mixed with 1600 cc. of 95% alcohol. The precipitate which came down was filtered off and the light yellow filtrate was further concentrated *in vacuo* to incipient crystallization. The residue was transferred to a crystallizing dish and placed in a desiccator over sulfuric acid. On standing overnight it usually solidified. It was treated with a little water and the nearly white convicine filtered off. Recrystallization from about 100 parts of boiling water with the addition of a little norite yielded glistening, perfectly white leaflets, decomposing without melting at 287°.

Re-concentration of the mother liquor yielded further amounts of less pure convicine; total yield from 5 kg. of broad beans, 2.32–2.35 g. of crude convicine.

For analysis, the convicine was crystallized four times from boiling water and dried to constant weight at 100°.

Anal. Calcd. for $C_{10}H_{18}N_4O_8 \cdot H_2O$: C, 37.14; H, 5.27; N, 13.01. Found: C, 38.20; H, 5.37; N, 13.08.

Amino nitrogen determinations were run in the micro Van Slyke apparatus on samples of convicine dissolved in half-normal sodium hydroxide: convicine, 0.0100 g., 0.0100 g.: N_2 , 0.83, 0.89 cc. at temperature, 30°. Amino N found: 4.5, 4.8.

Convicine is soluble to the extent of about one per cent. in boiling water. It is readily soluble in normal sodium hydroxide and insoluble in chloroform and glacial acetic acid. Its cold saturated aqueous solution does not give a precipitate with potassium mercuric iodide, aqueous iodine–potassium iodide or saturated mercuric chloride, but does give a white precipitate with acid mercuric nitrate solution. Its aqueous solution boiled for two minutes with Fehling's solution shows no copper reduction.

A small amount of vicine was isolated by fractional crystallization of the material obtained by concentration of the mother liquor of the first crop of convicine. It was identified by its melting point (241–242°)¹⁵ and by analysis.

Anal. Calcd. for $C_{10}H_{16}N_4O_7 \cdot H_2O$: N, 17.39. Found: N, 17.72.

Hydrolysis with Sulfuric Acid.—2.000 g. of well-crystallized convicine and 40 cc. of

¹⁵ Levene found 242°; Winterstein, 239–242°.

six normal sulfuric acid were heated for six minutes in a boiling water-bath in a closed flask connected with a hydrogen generator. The convicine dissolved. The mixture was allowed to stand under hydrogen for four days. On one day's standing, a few crystals could be seen around the edges of the liquid, and at the end of the fourth day a considerable quantity of quite large and well-formed alloxantin crystals had separated. The flask was cooled in ice water, opened and the contents filtered in a current of carbon dioxide through a filter paper into a 200-cc. volumetric flask. The residue on the paper was washed with ice water, the washings being collected in the 200-cc. flask. The crystals were then dried in a vacuum desiccator over sulfuric acid at room temperature. They weighed 0.4363 g., or 21.82% of the convicine taken.

Identification of Alloxantin.—The crystals turned violet-pink with ammonium hydroxide solution, and this solution turned deep blue on adding a little ferric chloride.

A crystallographic comparison with an authentic sample of alloxantin by Prof. W. E. Ford showed that the two were identical in crystal habit and refractive indices, and gave the same interference figure.

The crystals were recrystallized from boiling water in an atmosphere of carbon dioxide, dried and analyzed.

Anal. Calcd. for $C_8H_6N_4O_8 \cdot 2H_2O$: N, 17.40. Found: N, 17.62.

Determination of Ammonia Formed.—The contents of the 200-cc. volumetric flask were made to volume, and a 10-cc. aliquot was diluted, an excess of magnesium oxide and a small piece of paraffin added, and distilled into standard tenth-normal hydrochloric acid. The distillate was titrated with standard tenth-normal sodium hydroxide. Ammonia N found from 0.1000 g. of convicine, 0.00398 g., or 3.98%; per cent. total N in convicine, $C_{10}H_{15}N_3O_8 \cdot H_2O$, 13.00. The ammonia N is then 30.6% of the total N.

Identification of Dextrose.—The balance of the solution, not used for the ammonia determination, was treated with an excess of lead carbonate, filtered, and the residue washed with cold water. The filtrate and washings were saturated with hydrogen sulfide and the lead sulfide filtered and washed with water. The filtrate and washings from the lead sulfide were concentrated *in vacuo* on the water-bath to a small volume, filtered again and the concentration continued at room temperature in a vacuum desiccator. The solution, which was straw-colored until almost dry, turned to a deep red thick sirup.

This sirup was extracted ten times with boiling 95% alcohol, and the alcoholic extracts evaporated to dryness at room temperature in a vacuum desiccator. The residue was a clear scarlet sirup.

This sirup was dissolved in a little water, 1 cc. of 10% mercuric sulfate solution was added and the orange-pink precipitate was filtered and washed with water. The light yellow filtrate was made alkaline with barium hydroxide solution, saturated with carbon dioxide, filtered and the precipitate washed.

The clear pale straw-colored filtrate was evaporated in a vacuum desiccator over sulfuric acid at room temperature to constant weight; wt. of brownish-yellow sirup, 1.1035 g.

The sirup was dissolved in 10 cc. of water and a 2-cc. portion was heated with 0.2 g. of phenylhydrazine hydrochloride and 0.3 g. of sodium acetate in a boiling water-bath. In a few minutes the osazone began to crystallize out. After heating for an hour and a half, the reaction mixture was cooled and the osazone filtered and washed with water. Recrystallized once from 1:1 alcohol-acetone and once from 50% alcohol, it melted at 207–208°, and had the characteristic crystalline appearance of glucosazone. A mixed melting point with a known sample of glucosazone showed no depression. The weight of twice recrystallized material was 0.0506 g.

Portions of the sirup gave no color when heated with hydrochloric acid and resorcin and no violet-red color with hydrochloric acid and phloroglucinol.

The balance of the sirup was treated with nitric acid by the technique of van der Haar¹⁶ for the isolation of potassium acid saccharate. A few crystals separated, but on recrystallizing till colorless their weight was only 2.8 mg.

Oxidation with Potassium Chlorate.—0.2000 g. of pure recrystallized convicine was mixed with 1.5 cc. of 1:1 hydrochloric acid, and 0.04 g. of potassium chlorate added in portions. The mixture was agitated from time to time. The convicine gradually dissolved. On standing overnight, the solution still smelled of chlorine. It was concentrated *in vacuo* at room temperature over stick potassium hydroxide to dryness. The residue was taken up in a little alcohol, filtered and the filtrate evaporated to dryness at room temperature *in vacuo*. The residue was taken up in a little water, made alkaline with sodium hydroxide and sodium picrate solution added. There was an odor of ammonia, but no trace of a precipitate.

The solution was diluted, acidified with hydrochloric acid and extracted with ether until there was no more color in the ether layer. The aqueous solution was then evaporated to dryness at room temperature over stick potassium hydroxide, taken up in 1 cc. of water, 3.5 cc. glacial acetic acid and 0.5 cc. of a 10% methyl alcoholic solution of xanthidrol added. A precipitate came down which under the microscope consisted of small needles clustered together at the ends. It was filtered, washed with alcohol and dried *in vacuo*.

Anal. Calcd. for dixanthylurea, $C_{27}H_{26}N_2O_8$: N, 6.67. Found: N, 6.88.

Reaction with Potassium Cyanate.¹⁷—0.526 g. of convicine was warmed to about 70° with a mixture of 15 cc. of glacial acetic acid and 5 cc. of absolute alcohol. It did not appear to dissolve. One gram of potassium cyanate was added in portions from time to time. There was no odor of hydrocyanic acid. The mixture was digested on the water-bath for two and one-half hours, the temperature rising to 79°. It was then allowed to stand overnight. The next day the insoluble matter was filtered off, washed with absolute alcohol and dried in a vacuum desiccator. It weighed 0.450 g., or 85.6% of the convicine taken. An analysis showed that it was unchanged convicine.

Anal. Calcd. for $C_{10}H_{16}N_8O_8 \cdot H_2O$: N, 13.00. N found in this sample of convicine, 12.31. N found in reaction product, 12.86.

Summary

1. The presence of convicine in broad beans (*vicia faba*), reported by Ritthausen, has been confirmed.
2. On acid hydrolysis convicine yields alloxantin, one molecule of ammonia and glucose which gives its corresponding glucosazone by interaction with phenylhydrazine.
3. Potassium chlorate oxidizes convicine with the formation of urea. No guanidine is formed.
4. Convicine did not react with potassium cyanate to form a urea derivative.

TRIPHENYLVINYLMAGNESIUM BROMIDE

BY C. FREDERICK KOELSCH¹

RECEIVED JANUARY 5, 1932

PUBLISHED MAY 7, 1932

During the course of an investigation on the unusual reactivity of the halogen in benzoyldiphenylmethyl bromide, a need was felt for a method by which substituted derivatives of the parent diphenylacetophenone could be prepared. It was thought that the enol forms of such ketones might be obtained by a reaction analogous to that sometimes used for the preparation of phenols, namely, by the oxidation of a properly chosen Grignard reagent. Such a Grignard reagent would have the —MgX group attached to an unsaturated carbon atom and would be of the type $\text{RR}'\text{C}=\text{C}(\text{MgX})\text{C}_6\text{H}_5$, where R and R' are aromatic radicals.

A compound of this type has not been prepared previously. The most closely related Grignard reagents are styrylmagnesium bromide² and β,β -diphenylvinylmagnesium bromide.³ Whether or not the more highly substituted triphenylvinylmagnesium bromide could be obtained was a question which had to be settled by experiment. In the present paper it is shown that triphenylvinyl bromide forms a Grignard reagent, and some reactions of this compound are described.

A number of so-called negative results were obtained in the study of this Grignard reagent. With *dry air* or *oxygen*, a yellow ether-insoluble substance was formed, but decomposition of this with dilute acids gave a tarry oil from which no diphenylacetophenone could be obtained; on steam distillation of this tar no trace of benzophenone, which would be formed from a possible peroxide, $(\text{C}_6\text{H}_5)_2\text{C}=\text{C}(\text{C}_6\text{H}_5)_2$, was obtained.

Thionyl chloride reacted vigorously to give an unworkable oil, while *benzyl chloride* was recovered nearly quantitatively after six hours' refluxing in ether; *triphenylchloromethane* was rapidly and completely converted into triphenylmethyl, isolated as the peroxide; the other product was a yellow ether-soluble glassy substance from which no crystalline material could be obtained. *Acetone* was apparently condensed by the reagent with the formation of mesityl oxide and triphenylethylene. *Benzophenone* gave a deep red solution, but carbonation followed by hydrolysis showed that the whole of the Grignard reagent was still present, and the ketone was recovered unchanged.

¹ National Research Fellow in Chemistry.

³ Lipp, *ibid.*, **56**, 571 (1923); Ziegler, *ibid.*, **55**, 2257 (1922); Ziegler and co-workers, *Ann.*, **443**, 161 (1925); and previous papers.

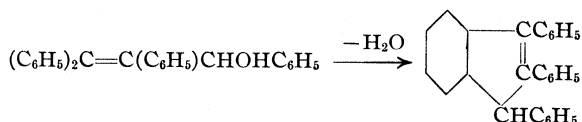

More significant and interesting results were obtained when the Grignard reagent was treated with certain other substances.

With *iodine*, triphenylvinyl iodide was obtained. Contrary to expectations, no iodide dichloride could be obtained from this compound. When a carbon tetrachloride solution of it was treated with chlorine, iodine was liberated immediately even at -5° .

Treatment of the Grignard reagent with *water* gave the hydrocarbon from which it is derived, triphenylethylene.

Formaldehyde gave β,γ,γ -triphenylallyl alcohol. This alcohol was etherified by allowing it to stand in methyl or ethyl alcoholic solution in the presence of sulfuric acid. The ethers obtained were also prepared from β,γ,γ -triphenylallyl bromide by boiling with the corresponding alcohol.⁴

Benzaldehyde gave $\alpha,\beta,\gamma,\gamma$ -tetraphenylallyl alcohol, which, however, could not be obtained crystalline or pure enough for analysis. By treating this alcohol with sulfuric acid in acetic acid, the known 1,2,3-triphenylindene⁵ was formed.

Benzoyl chloride gave the long known triphenylacrylophenone $\text{C}_6\text{H}_5\text{-COC}(\text{C}_6\text{H}_5)=\text{C}(\text{C}_6\text{H}_5)_2$.

Benzoyl peroxide reacted vigorously to give the enol benzoate of diphenylacetophenone,⁶ which was hydrolyzed to diphenylacetophenone by warming with alkali.

In this indirect way the original object of this research was attained, but the reactions involved are impractical from a preparative standpoint.

Carbon dioxide gave triphenylacrylic acid, and *carbon disulfide* gave the sulfur analog, triphenylvinylcarbithionic acid, a beautifully crystalline red substance.

Experimental

Triphenylvinyl Bromide.—To a solution of 40 g. of triphenylethylene⁷ in 250 ml. of glacial acetic acid was added with cooling 25 g. of bromine at such a rate that the temperature remained below 40° . The solution was distilled for a short time to drive off the hydrogen bromide, water was added almost to turbidity, and the solution was

⁴ Cf. Meisenheimer, *Ann.*, **456**, 147 (1927).

⁵ Kohler, *Am. Chem. J.*, **40**, 230 (1908).

⁶ Cf. Gilman and Adams, *THIS JOURNAL*, **47**, 2816 (1925).

⁷ Hell and Wiegandt, *Ber.*, **37**, 1431 (1904).

cooled. The product was pure after one washing with dilute acetic acid and melted at 114–115.5°; yield, 95–98%.

Triphenylvinylmagnesium Bromide.—Ten grams of triphenylvinyl bromide, 0.8 g. of magnesium, and a small crystal of iodine were covered with 200 ml. of dry ether, 0.05 ml. of ethyl bromide was added, and the mixture was refluxed. The reaction usually started within ten minutes; in even the most obstinate cases, reaction could be started by the addition of a small piece of magnesium separately etched with ethyl bromide. Nearly all of the magnesium was dissolved in less than two hours after the reaction had started. A U-shaped mercury seal closing the top of the condenser satisfactorily prevented the diffusion of air.

In most cases one-half the quantity of ether specified above was used. Then the reagent separated as a crystalline solid toward the end of the reaction, but its yield and its reactivity appeared to be unaffected.

Reaction with Iodine.—To the Grignard reagent from 10 g. of triphenylvinyl bromide was added solid iodine until the color was permanent. After hydrolysis with dilute sulfuric acid and removal of the ether, the product was crystallized from alcohol and finally from ligroin. There was obtained 6 g. of triphenylvinyl iodide which melted at 125–126°.

Anal. Calcd. for $C_{20}H_{15}I$: C, 62.8; H, 3.92. Found: C, 63.0; H, 3.94.

Reaction with Water.—Hydrolysis of the Grignard reagent from 10 g. of triphenylvinyl bromide gave 5 g. of triphenylethylene which boiled at 240–250° (33 mm.) and melted at 66–68°. This took up the calculated quantity of bromine to give triphenylvinyl bromide melting at 114–115°.

Reaction with Formaldehyde.—An excess of formaldehyde was led over the Grignard reagent from 5 g. of triphenylvinyl bromide. After the exothermic reaction was over, the product was decomposed with dilute ammonium chloride solution. Evaporation of the ether left a sirup which crystallized on rubbing with petroleum ether. Recrystallization from 50% ethanol gave 2.05 g. of β,γ,γ -triphenylallyl alcohol which melted at 126–128°, and was easily soluble in the common solvents. It gave a yellow solution in cold concd. sulfuric acid which became green on warming.

Anal. Calcd. for $C_{21}H_{18}O$: C, 88.1; H, 6.29. Found: C, 88.0; H, 5.96.

α -Methoxy- β,γ,γ -triphenyl- β -propene.—A solution of 0.5 g. of β,γ,γ -triphenylallyl alcohol in 15 ml. of methanol containing 2 drops of concd. sulfuric acid was refluxed for fifteen minutes. The product crystallized out on cooling, and was recrystallized from methanol. It melted at 131–132.5°.

Anal. Calcd. for $C_{22}H_{20}O$: C, 88.0; H, 6.66. Found: C, 87.9; H, 6.35.

A mixed melting point showed the identity of the product with the one obtained when β,γ,γ -triphenylallyl bromide was boiled with methanol.

α -Ethoxy- β,γ,γ -triphenyl- β -propene.—The ethyl ether was prepared in the same way from β,γ,γ -triphenylallyl alcohol and ethanol. It melted at 125–128° alone or mixed with a sample of the same compound prepared according to the method of Meisenheimer.⁴ Mixtures of the methyl and ethyl ethers or of either of these with the parent alcohol melted at 100–115°.

Reaction with Benzaldehyde.—To the Grignard reagent from 5 g. of triphenylvinyl bromide was added 1.6 g. of freshly distilled benzaldehyde. The crystalline magnesium compound which separated on standing was filtered off and decomposed with dilute sulfuric acid. An oil was obtained which could not be induced to crystallize. A portion (2.7 g.) was boiled for two minutes with 20 ml. of acetic acid containing 3 drops of concd. sulfuric acid. The 1,2,3-triphenylindene which crystallized out on cooling

weighed 2.3 g. and melted at 128–131°. Two recrystallizations from alcohol raised the melting point to 132–134°.

Anal. Calcd. for $C_{27}H_{20}$: C, 94.2; H, 5.82. Found: C, 94.1; H, 5.90.

A solution of 0.9 g. of the crude tetraphenylallyl alcohol in 15 ml. of methanol containing 2 drops of concd. sulfuric acid was allowed to stand at room temperature for six hours in an attempt to form a methyl ether, but again triphenylindene crystallized out.

Reaction with Benzoyl Chloride.—To the Grignard reagent from 10 g. of triphenylvinyl bromide was added 4 ml. of benzoyl chloride, and the mixture was refluxed for two hours. Hydrolysis with dilute sulfuric acid and removal of the ether left an oil which solidified on rubbing with alcohol. Recrystallization from ligroin gave 5 g. of triphenylbenzoylethylene which melted at 147–149° and whose melting point was not depressed by admixture with the same compound prepared by the method of Kohler.⁸

Reaction with Benzoyl Peroxide.—To the Grignard reagent from 5 g. of triphenylvinyl bromide was added slowly and with cooling 3.5 g. of finely powdered benzoyl peroxide. After forty-eight hours the mixture was decomposed with dilute sulfuric acid. Most of the triphenylvinyl benzoate crystallized from the ether layer. A total of 1.05 g. of the compound was obtained which after one recrystallization from alcohol melted at 151–153°. On boiling this for three minutes with a little 5% alcoholic potash there was obtained diphenylacetophenone which melted at 134–136° alone or mixed with an authentic sample.

Reaction with Carbon Dioxide.—Carbonation of the Grignard reagent from 10 g. of triphenylvinyl bromide was carried out in the usual way. After acid hydrolysis of the magnesium compound, the product was extracted from the ether layer with sodium carbonate solution, and was precipitated from this with hydrochloric acid. Crystallization from acetic acid gave 8.0 g. of triphenylacrylic acid which melted at 217–218° and gave the red diphenylindone melting at 151–152° on heating with zinc chloride.

Reaction with Carbon Disulfide.—To the Grignard reagent from 10 g. of triphenylvinyl bromide was added 2 ml. of carbon disulfide. The mixture slowly became orange in color and deposited a lemon-yellow crystalline substance. After forty-eight hours the ether was decanted, and the deposit was washed with a little dry ether. It was then dissolved in water. The addition of hydrochloric acid to the red solution obtained precipitated an oil which rapidly solidified. Crystallization from hot glacial acetic acid gave 4.7 g. of triphenylvinylcarbithionic acid which separated in the form of deep red plates that melted at 135°.

Anal. Calcd. for $C_{21}H_{16}S_2$: S, 19.3. Found: S, 19.4.

Summary

Triphenylvinyl bromide with magnesium forms a Grignard reagent. Although this compound does not react or reacts abnormally with some few substances, it gives normal products with iodine, water, formaldehyde, benzaldehyde, benzoyl chloride, benzoyl peroxide, carbon dioxide and carbon disulfide.

PHENYL-PARA-TOLYLACETOPHENONE

BY C. FREDERICK KOELSCH¹

RECEIVED JANUARY 5, 1932

PUBLISHED MAY 7, 1932

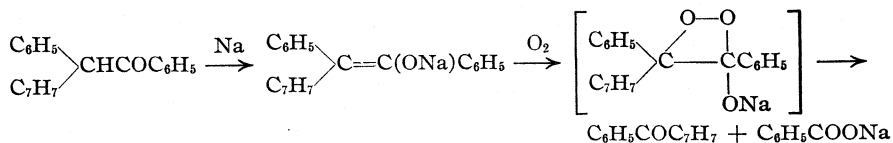

By the action of phenyl-*p*-tolylacetyl chloride on benzene in the presence of aluminum chloride, McKenzie and Widdows² obtained in poor yield a compound melting at 160° which they believed to be phenyl-*p*-tolylacetophenone. Recently McKenzie, Mills and Myles³ by the dehydration of α,β -diphenyl- α -*p*-tolylethylene glycol obtained the isomeric *p*-diphenylacetotoluene which melted at 97–99.5°.

Needing some phenyl-*p*-tolylacetophenone, the writer essayed its preparation by the method of McKenzie and Widdows. All attempts, however, to duplicate the results of these authors were unsuccessful; the only product which could be isolated was diphenylmethane. This was quite surprising in view of the fact that diphenylacetyl chloride and toluene under the usual conditions of the Friedel–Crafts reaction were found to give an excellent yield of *p*-diphenylacetotoluene.

Phenyl-*p*-tolylacetophenone was finally obtained in nearly quantitative yield from toluene, desyl chloride, and aluminum chloride, but it melted at 98° and not at 160° as reported by McKenzie and Widdows. That the product actually had the structure assigned to it was shown by its reactions.

Cleavage by boiling with alcoholic potash gave benzoic acid and phenyl-*p*-tolylmethane.

Sodium in boiling toluene reacted slowly to give a sodium salt which was cleaved by oxygen, probably through an intermediate peroxide, into phenyl-*p*-tolyl ketone and sodium benzoate.⁴

With phenylmagnesium bromide there was obtained a carbinol isomeric with the one obtained from *p*-tolylmagnesium bromide and diphenylacetophenone. Both of these carbinols gave triphenyl-*p*-tolylethylene on dehydration.

¹ National Research Fellow in Chemistry.

³ McKenzie, Mills and Myles, *Ber.*, **63**, 904 (1930).

⁴ For analogous reactions see Kohler, *Am. Chem. J.*, **36**, 531 (1906); Staudinger, *Helv. Chim. Acta*, **5**, 663 (1922).

Phenyl-*p*-tolylacetophenone.—To a solution of 25 g. of desyl chloride⁸ in 150 ml. of toluene was added with cooling 16 g. of anhydrous aluminum chloride in small portions. The mixture, which evolved hydrogen chloride slowly in the cold, was refluxed for thirty minutes, cooled and decomposed with iced hydrochloric acid. Steam distillation of the toluene layer left a yellow residue which became solid on cooling. Crystallization from alcohol gave 24 g. melting at 94–95° which was still slightly colored. Recrystallization from benzene-ligroin gave a pure white product melting at 97–98°. The substance distilled undecomposed at 270–275° (29 mm.).

Anal. Calcd. for $C_{21}H_{18}O$: C, 88.0; H, 6.30. Found: C, 87.8; H, 6.33.

Diphenylacetophenone.—Twenty-five grams of desyl chloride, 125 ml. of benzene, and 16 g. of aluminum chloride refluxed for fifteen minutes gave diphenylacetophenone, which after one crystallization from acetic acid melted at 135–136° and weighed 23 g.

Cleavage of Phenyl-*p*-tolylacetophenone with Alkali.—Ten grams of phenyl-*p*-tolylacetophenone was refluxed for five hours with a solution of 5 g. of potassium hydroxide in 60 ml. of alcohol. Most of the alcohol was then distilled, and the residue was steam distilled. From the distillate was obtained 3.8 g. of phenyl-*p*-tolylmethane boiling at 275–280°; from the non-volatile part there was obtained 2.5 g. of benzoic acid, identified by melting point and neutral equivalent. There was recovered 3.8 g. of unchanged ketone.

Cleavage of the Sodium Salt with Oxygen.—A solution of 10 g. of phenyl-*p*-tolylacetophenone in 75 ml. of dry toluene was refluxed with 0.8 g. of sodium. A pale yellow flocculent substance appeared as the metal reacted, and after six hours no more sodium was present. Dry air was then aspirated through the cooled suspension for two hours. Washing with water removed sodium benzoate, from which there was obtained 2.75 g. (65%) of benzoic acid. The non-aqueous layer, after the toluene was steam distilled, gave 3.5 g. of phenyl-*p*-tolyl ketone boiling at 190–210° (35 mm.) and melting at 52° (mixed melting point). This cleavage product was further identified by the formation of diphenyl-*p*-tolylcarbinol melting at 69–70° from it and phenylmagnesium bromide.

α,α,β -Triphenyl- β -*p*-tolylethanol.—Six grams of phenyl-*p*-tolylacetophenone was added to the Grignard reagent from 7.9 g. of phenyl bromide. After refluxing for thirty minutes, the solution was decomposed with iced ammonium chloride. The residue after removal of the ether was boiled out with alcohol, and the undissolved part was crystallized from ligroin (80–110°) and then from methanol, giving 1.2 g. which melted at 169–170°.

Anal. Calcd. for $C_{27}H_{24}O$: C, 88.9; H, 6.58. Found: C, 88.7; H, 6.27.

α,β,β -Triphenyl- α -*p*-tolylethanol.—The reaction product from 5.5 g. of diphenylacetophenone and the Grignard reagent from 9 g. of *p*-tolyl bromide was worked up in the usual way, giving 1.2 g. which melted at 185–187°. (McKenzie, Mills and Myles³ give 180–181° for the compound prepared from *p*-diphenylacetotoluene and phenylmagnesium bromide.)

Anal. Calcd. for $C_{27}H_{24}O$: C, 88.9; H, 6.58. Found: C, 88.8; H, 6.40.

α,α,β -Triphenyl- β -*p*-tolylethylene.—Eight-tenths of a gram of α,α,β -triphenyl- β -*p*-tolylethanol was refluxed for one hour with 10 ml. of acetyl chloride. The product was crystallized from acetic acid, giving 0.55 g. of the hydrocarbon, which melted at 150–151°.

Anal. Calcd. for $C_{27}H_{22}$: C, 93.6; H, 6.35. Found: C, 93.4; H, 5.90.

The dehydration of α,β,β -triphenyl- α -*p*-tolylethanol was carried out in the same way. A mixed melting point showed the identity of the products.

⁸ Prepared according to Schroeter and Caspar, *Ber.*, **42**, 2348 (1909).

Summary

Phenyl-*p*-tolylacetophenone could not be prepared from phenyl-*p*-tolylacetyl chloride and benzene, but it was obtained from desyl chloride and toluene. It reacted normally with phenylmagnesium bromide, and it gave a sodium salt which oxygen cleaved into phenyl *p*-tolyl ketone and sodium benzoate.

The work of McKenzie, Mills and Myles on the dehydration of α,β -diphenyl- α -*p*-tolylethylene glycol has been repeated and confirmed.

THE HYDROGEN CHLORIDE ADDITION PRODUCTS OF TYROSINE N-PHENYLACETIC ACID AND OF THE CORRESPONDING METHYL AND ETHYL ESTERS

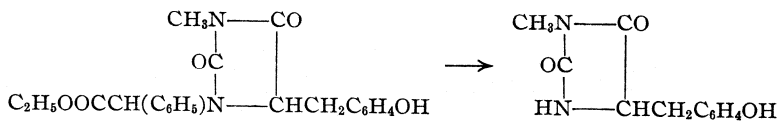

BY DOROTHY A. HAHN AND ANNE L. WHITE¹

RECEIVED JANUARY 6, 1932

PUBLISHED MAY 7, 1932

The following account of certain transformations of the N-phenylacetic acid derivative of tyrosine, $\text{NH}(\text{CHC}_6\text{H}_5\text{COOH})\text{CH}(\text{CH}_2\text{C}_6\text{H}_4\text{OH})\text{COOH}$, represents a continuation of work previously reported.² The imino dibasic acid was prepared by the same general method that has already been described,³ but due to the fact that larger quantities of material were used in the reactions, a few additional facts in regard to this preparation need to be noted.

It was found, for example, during the process of digesting 50 g. of ethyl N-3-methyl-5-anisalhydantoin-N-1-phenylacetate⁴ with hydrogen iodide and then hydrolyzing the product with barium hydroxide, that a slight amount of decomposition had taken place in the sense

The decomposition product, N-3-methyl-5-*p*-hydroxybenzylhydantoin, was found mixed with the imino dibasic acid in the filtrate from the barium sulfate. Both substances separated in crystalline condition on concentrating the solution and were readily separated due to the fact that the hydantoin is very soluble in hot water while the imino acid is relatively insoluble. After several recrystallizations from water the hydantoin was

¹ This work was offered in partial fulfilment of the requirements for the degree of Master of Arts at Mount Holyoke College.

² Hahn and Dyer, *THIS JOURNAL*, **52**, 2494 (1930).

³ Hahn and Dyer, *ibid.*, p. 2503.

⁴ Hahn and Dyer, *ibid.*, p. 2497.

analyzed and finally identified by comparison with a specimen of N-3-methyl-5-*p*-hydroxybenzylhydantoin which had been synthesized according to the method described by Johnson and Nicolet.⁵

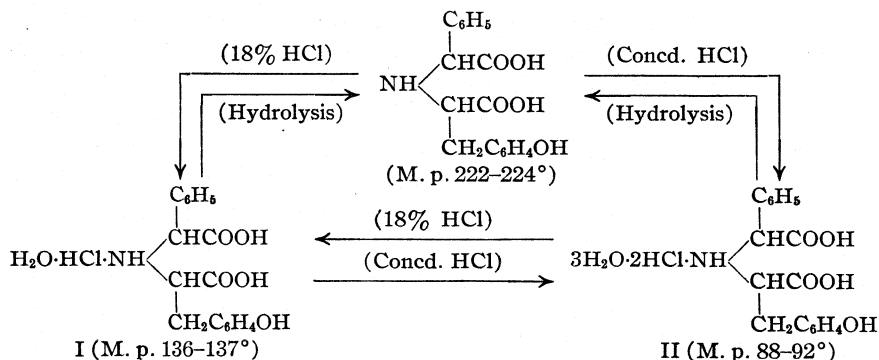

Due to the relatively great insolubility of the imino dibasic acid in boiling water, considerable difficulty was experienced at first in attempting to prepare it in quantity. For example, when starting with 50 g. of ethyl N-3-methyl-5-anisylhydantoin-N-1-phenylacetate and proceeding in the usual way,⁶ it was found convenient to precipitate the barium sulfate in approximately one liter of boiling solution. The filtrate under these conditions when concentrated was found to yield only about 2-3 g. of the imino acid, the bulk of the product being retained along with barium sulfate as an insoluble white precipitate. The fact that one gram of imino acid requires about 500 cc. of boiling water for solution made the matter of separating it from the barium sulfate extremely difficult. The problem was finally solved by extracting the barium sulfate with small quantities of boiling aqueous hydrochloric acid (18%). Under these conditions the imino acid reacted to form the corresponding hydrochloride, which is very soluble in boiling acid of this concentration and only slightly soluble in the cold solution. The hydrochloride, which separates in well-defined crystals and is readily purified by recrystallization from aqueous hydrochloric acid, is further characterized by the fact that it dissociates hydrogen chloride when boiled with water, passing quantitatively into the free imino dibasic acid. If the precaution is taken of first extracting the barium sulfate precipitate with boiling alcohol to remove all traces of organic coloring matter, approximately 65% of the amount of imino acid required by theory may be obtained in exceptionally pure condition by then extracting the barium sulfate precipitate with aqueous hydrochloric acid in the manner just described.

The N-phenylacetic acid derivative of tyrosine reacts with aqueous hydrochloric acid to form two different addition products melting at 136-137° and 88-92°, respectively, with the evolution of a gas. They represent the addition of one and two molecules of hydrochloric acid to one molecule of imino acid, and separate, respectively, from dilute and concentrated solutions of hydrochloric acid. Of the two the first represents the more stable form but each may be readily transformed into the other and also be hydrolyzed to the free imino acid. These relationships are shown by means of the chart.

The hydrochloride, I, $C_{17}H_{17}O_6N \cdot HCl \cdot H_2O$, m. p. 136-137°, was prepared by dissolving 7.0 g. of imino acid, m. p. 222-224°, in 15 cc. of boiling 18% aqueous hydrochloric acid. The clear solution on cooling deposited 6.9 g. of fine white crystals which melted at 136-137°. An additional 0.8 g. was obtained by concentrating the mother liquor, thus bringing the yield up to approximately the amount required by theory.

⁵ Johnson and Nicolet, *Am. Chem. J.*, **47**, 470 (1912).

⁶ Hahn and Dyer, *ibid.*, **52**, 2503 (1930).

The substance was purified by recrystallization from hot 18% aqueous hydrochloric acid in which it is extremely soluble (1 g. in 1.5 cc.) and from which it separates on cooling in clusters of small hard white crystals which form on the bottom of the beaker.

Anal. Calcd. for $\text{C}_{17}\text{H}_{17}\text{O}_5\text{N}\cdot\text{HCl}\cdot\text{H}_2\text{O}$: N, 3.79; Cl, 9.61. Found: N, 3.79, 3.85; Cl, 9.53, 9.57.

Although the analyses indicate the presence of water of crystallization, it was impossible to determine this separately because of the fact that the substance dissociates hydrochloric acid on heating. Solution in alcohol or water produces the same effect but under these conditions quantitative yields of the free imino dibasic acid are obtained as a result of the hydrolysis. When concentrated hydrochloric acid, sp. gr. 1.18, is added to solutions of this hydrochloride in hot aqueous 18% hydrochloric acid, the mixture on cooling deposits a white crystalline precipitate which melts at 88–92° and which represents the second modification referred to above.

The hydrochloride, II, $\text{C}_{17}\text{H}_{17}\text{O}_5\text{N}\cdot 2\text{HCl}\cdot 3\text{H}_2\text{O}$, m. p. 88–92°, was prepared by adding 4.5 cc. of concentrated hydrochloric acid, sp. gr. 1.18, to a solution of 2.0 g. of imino acid, m. p. 222–224°, in 9 cc. of hot 18% aqueous hydrochloric acid. Under these conditions a substance crystallizing in long soft white needles and filling the entire space occupied by the solution separated on cooling. The product consisted of 1.8 g., m. p. 88–92°, and corresponded to a yield of 64% of the theoretical. On concentrating the mother liquor, 0.25 g. of the hydrochloride, I, m. p. 136–137°, was deposited.

In order to recrystallize the hydrochloride, II, m. p. 88–92°, it was always necessary to dissolve it in hot 18% aqueous hydrochloric acid and treat the solution with twice its volume of concentrated hydrochloric acid, sp. gr. 1.18. After purification by several recrystallizations, the melting point was found to remain constant, 88–92°, with the evolution of a gas.

Here again it was found to be impossible to dehydrate the substance before making the analyses since decomposition begins at about 90°. The results of analysis would seem to indicate, however, that three molecules of water are held in the form of water of crystallization.

Anal. Calcd. for $\text{C}_{17}\text{H}_{17}\text{O}_5\text{N}\cdot 2\text{HCl}\cdot 3\text{H}_2\text{O}$: N, 3.17; Cl, 16.07. Found: N, 3.18, 3.20; Cl, 16.05, 15.93.

The hydrochloride, m. p. 88–92°, is extremely soluble in alcohol but cannot be obtained from this solvent in crystalline form since it separates as a gummy mass on concentrating the solution. The substance is also very soluble in water but hydrolyzes immediately to give the free imino acid, which separates as a flocculent precipitate. The transformation to the free acid may be carried out almost quantitatively by boiling 4.0 g. of the hydrochloride with 50 cc. of water for an hour. The substance is very

soluble in hot 18% aqueous hydrochloric acid (1 g. in 1.8 cc.) and less soluble in hot concentrated hydrochloric acid, sp. gr. 1.18 (1 g. in 10 cc.).

This hydrochloride is of interest because of the fact that it is extremely unstable, tending to dissociate hydrochloric acid under a variety of different conditions. For example, when a sample of the substance was dissolved in 18% aqueous hydrochloric acid and the solution allowed to cool, the product was found to lose one molecule of hydrochloric acid, passing quantitatively into the hydrochloride, I, m. p. 136–137°. The same general effect was produced by heating the dry crystals, m. p. 88–92°, in a test-tube at a temperature of 80°. In this case the evolution of hydrogen chloride gas was demonstrated by collecting the gas in water and testing the solution with silver nitrate. That the substance dissociates hydrochloric acid even on standing in the air at ordinary temperatures has also been demonstrated, the change having been followed by means of melting point determinations and analyses for chlorine. For example, a sample, m. p. 88–92°, was allowed to stand in a stoppered bottle for five months. At the end of this time the melting point had changed from 88–92° to 93–138°, approaching the melting point of the hydrochloride I. In analyzing for halogen it was found that a freshly prepared sample showed 15.93 and 16.05% of chlorine while a specimen that had stood in a stoppered bottle for two months gave 15.88% and 15.82%. The same specimen was then allowed to stand in an open bottle in a desiccator and was analyzed three days later, when the percentage of chlorine was found to have dropped to 15.74 and 15.70%.

The diethyl ester hydrochloride of the imino acid⁷ was readily prepared by dissolving 7.7 g. of imino acid, m. p. 222–224°, in 100 cc. of absolute alcohol which had been saturated with dry hydrogen chloride gas. The mixture, after heating on a steam-bath for five hours, with a reflux condenser, was concentrated to one-third its original volume and allowed to cool. Since no precipitate formed under these conditions, 60 cc. of dry ether was added, when a gum separated out which gradually became crystalline on standing. The product, which was filtered and washed with a little alcohol-ether mixture, weighed 2.2 g. and melted at 160–162° with the evolution of a gas. Purified by recrystallization from absolute alcohol-ether mixtures (1:3), the melting point changed to 161–162° with the evolution of a gas.

Anal. Calcd. for $C_{21}H_{25}O_5N \cdot HCl$: N, 3.44. Found: N, 3.44, 3.43.

This substance is extremely soluble in alcohol, dissolving in less than its own volume of the solvent. It is insoluble in ether and may be precipitated from alcohol solution by the addition of about three volumes of ether.

When treated with water it undergoes hydrolysis and an oil separates at once. The aqueous solution, when decanted, was found to contain hydrochloric acid.

The corresponding dimethyl ester hydrochloride, m. p. 180–180.5°, was prepared according to Fischer's esterification method.

For example, 10 g. of imino acid, m. p. 222–224°, was dissolved by warming with 50 cc. of a saturated absolute methyl alcohol solution of hydrogen chloride. After heating the mixture with a reflux condenser, the alcohol was distilled off under reduced pressure and the process repeated until the gummy residue remaining in the flask after the distillation of alcohol finally changed into a hard brittle mass. This was then dissolved in 30 cc. of a saturated absolute methyl alcohol solution of hydrogen chloride and 30 cc. of ether added. Under these conditions the solution became cloudy and on standing a crystalline precipitate was formed. The product obtained in this way when filtered and washed with a small quantity of an absolute methyl alcohol-ether mixture (1:1) weighed 6.0 g. and melted at 177–180°. Additional quantities of this substance were obtained on concentrating the mother liquor and then adding ether. When purified by recrystallization

⁷ Acknowledgment is made to Elizabeth Dyer for preparation of this substance.

tallization from absolute methyl alcohol-ether mixtures, it separates in the form of very fine white needles which melt at 180–180.5° with the evolution of a gas.

Anal. Calcd. for $C_{13}H_{21}O_5N \cdot HCl$: N, 3.69; Cl, 9.37. Found: N, 3.67, 3.68; Cl, 9.32, 9.29.

The dimethyl ester hydrochloride is extremely soluble in absolute methyl alcohol, dissolving in less than its own volume, and is insoluble in ether. While stable in alcohol-ether mixtures, it readily dissociates hydrochloric acid when dissolved in water. Solution in this solvent is accompanied by the immediate separation of an oil and the water layer when decanted gives a precipitate of silver chloride when tested in the usual way.

Summary

An improved method for separating and purifying tyrosine-N-phenyl-acetic acid is described. Two distinct hydrogen chloride addition products of this acid have been prepared, together with the hydrochlorides of the corresponding methyl and ethyl esters.

RESEARCHES ON PYRIMIDINES. CXXVIII. THE REARRANGEMENT OF 2-ETHYLMERCAPTO-4-METHYL-6-THIOCYANOPYRIMIDINE INTO ITS ISOTHIOCYANATE MODIFICATION^{1,2}

BY YUOH FONG CHI AND YUN HWANG CHEN

RECEIVED JANUARY 6, 1932

PUBLISHED MAY 7, 1932

Since Wheeler, Johnson and their co-workers began the study of the chemistry of thiocyanopyrimidine compounds,³ no specific change has proved to be more interesting to the writers than the rearrangement of 2-ethylmercapto-5-carbethoxy-6-thiocyanopyrimidine into its isomeric isothiocyante modification, a transformation which was described recently in a paper by Johnson and Chi.⁴ They found that this thiocyanate could be distilled without decomposition and without molecular conversion to the isothiocyante form, while its molecular rearrangement into the isothiocyante form could be accomplished easily, under specific experimental conditions, at a temperature much below that of its boiling point.

¹ This publication is a report of one phase of a research program dealing with the chemistry of certain pyrimidine thiocyanates, which was started originally in the Sterling Chemistry Laboratory of Yale University under the direction of Professor Treat B. Johnson.

² This research has been accomplished and arranged for publication through the support of a grant of \$750 from the Rockefeller Foundation. The authors desire to express here their appreciation and heartiest thanks for this liberal assistance.

³ Wheeler and Bristol, *Am. Chem. J.*, **33**, 450 (1905); Johnson and McCollum, *ibid.*, **36**, 143 (1906); Johnson and Storey, *ibid.*, **40**, 131 (1908).

⁴ Johnson and Chi, *THIS JOURNAL*, **52**, 1580 (1930).

This behavior was so interesting that the writers decided to examine the stability of another pyrimidine representative which has not been investigated. We now find that a similar behavior is observed in the case of the molecular rearrangement of 2-ethylmercapto-4-methyl-6-thiocyanopyrimidine (I) into its isomeric form represented by formula II.

This thiocyanopyrimidine I exhibits a chemical behavior similar to Johnson and Chi's 2-ethylmercapto-5-carbethoxy-6-thiocyanopyrimidine. It can be distilled under diminished pressure (b. p. 155–158° at 5 mm.) without decomposition and without conversion into its isothiocyanate form II. The stability of the pyrimidine I, however, is greatly influenced by the presence of other reagents, and a molecular rearrangement to the isothiocyanate II can be accomplished easily at a temperature very much below that of the boiling point of the thiocyanate. This instability of molecular structure is quite remarkable. The conditions under which the transformation is brought about are described in the experimental part of this paper.

It has been the previous experience in the pyrimidine thiocyanate researches that thiocyanates corresponding to I may lead to the formation of polymeric forms of the thiocyanate after continued distillation.⁵ These new constructions result from the polymerization of the isothiocyanate modification resulting by molecular rearrangement. In the case of the thiocyanate I, this polymerized form is not produced directly by distillation, but it is formed by prolonged heating of the rearranged form II. The polymer is distinguished from the isothiocyanate form by its non-reactivity toward ammonia, aniline and ethyl alcohol.

Experimental Part

2-Ethylmercapto-4-methyl-6-thiocyanopyrimidine. I.—This pyrimidine is easily prepared as follows: 20 g. of the corresponding chloropyrimidine⁶ and 11 g. of potassium thiocyanate are dissolved in 120 cc. of 95% alcohol and the solution heated to boiling for one hour. The solution is then filtered hot to separate potassium chloride and then cooled, when the thiocyanate separates immediately in the form of colorless crystals. The yield was 19 g. or 81%. It was purified by crystallization from alcohol, melts at 69–70° to a clear liquid, and boils at 155–158° under 5 mm. pressure. The thiocyanate is insoluble in alkali, soluble in benzene, toluene and xylene. It is very soluble in hot alcohol, and insoluble in ether.

Anal. Calcd. for $\text{C}_8\text{H}_9\text{N}_3\text{S}_2$: N, 19.90. Found: N, 20.01, 19.62, 19.63.

This same thiocyanate compound I is likewise formed by refluxing 2-ethylmercapto-4-methyl-6-chloropyrimidine with potassium thiocyanate in both toluene and xylene solutions for one hour. The thiocyanate can be crystallized repeatedly from alcohol

⁵ Johnson and Storey, *Am. Chem. J.*, **40**, 131 (1908).

⁶ Johns, *ibid.*, **40**, 350 (1908).

without conversion to a thionurethan; it does not undergo any change leading to the formation of thioureas when exposed to the action of ammonia and aniline.

Molecular Rearrangement of the Thiocyanate I

2-Ethylmercapto-4-methyl-6-isothiocyanopyrimidine. II.—Four grams of the thiocyanate I was refluxed in 10 cc. of xylene for eight hours, giving a red colored solution. After distilling off the xylene, the isothiocyanate residue was triturated with cold ether and the ether finally evaporated, leaving behind the crude isothiocyanate as a red oil. This showed no signs of solidifying, and the yield corresponded to 67% of the theoretical. When this oil was subjected to distillation under diminished pressure, it slowly underwent a profound decomposition. A fraction distilling at 146–158° at 1 to 3 mm. exhibited all the properties of a true isothiocyanate. This reacted immediately with aniline, ammonia and alcohol in accordance with its isothiocyanate structure. Notwithstanding this characteristic behavior the oil did not respond to a good analysis for nitrogen and it could not be purified by further distillation.

Anal. Calcd. for $C_8H_9N_3S_2$; N, 19.90. Found: N, 21.00, 21.05.

Formation of the Polymerized Form of the Isothiocyanate.—Twenty grams of the thiocyanate I was treated as in the previous experiment to accomplish rearrangement to the isothiocyanate form. Attempts to purify the rearrangement product by distillation under diminished pressure led to the formation of a mixture of compounds. At 150–180° under a pressure of 4 to 10 mm., the impure isothiocyanate was collected. The distillation was then continued until the temperature rose to 220°, when a viscous oil was obtained which solidified almost immediately in the receiver. This dissolved in boiling benzene and separated on cooling in colorless crystals melting at 108–109°. The same crystalline compound was also obtained by redistillation of the crude isothiocyanate fraction boiling at 150–180° (see above). This substance is apparently a polymerized form of the isothiocyanate II. It can be recrystallized from alcohol without change, and does not combine with aniline and ammonia to form the corresponding thiourea derivatives.

Anal. Calcd. for $(C_8H_9N_3S_2)_x$; N, 19.90; S, 30.3. Found: N, 20.2, 20.00; S, 30.4.

Proof of Structure of the Isothiocyanate II

2-Ethylmercapto-4-methyl-6-thioureapyrimidine, $C_8H_{12}N_4S_2$.—The thiocyanate I was rearranged into the isothiocyanate form II, and an ether solution of the latter combined with an excess of concentrated aqueous ammonia. The corresponding thiourea was formed immediately and 1.8 g. of this was obtained from 2 g. of the thiocyanate. It was purified by crystallization from alcohol and melted at 229–231°.

Anal. Calcd. for $C_8H_{12}N_4S_2$; N, 24.55. Found: N, 24.35, 24.42.

2-Ethylmercapto-4-methyl-6-phenylthioureapyrimidine, $C_{14}H_{16}N_4S_2$.—Two grams of the rearranged thiocyanate gave 2.8 g. of this compound by treatment with aniline at ordinary temperature. This was purified by crystallization from 95% alcohol and separated in prisms melting at 209–210°.

Anal. Calcd. for $C_{14}H_{16}N_4S_2$; N, 18.41. Found: N, 18.28, 18.32.

2-Ethylmercapto-4-methyl-6-thionethylurethan Pyrimidine, $C_{10}H_{15}ON_3S_2$.—This is formed by warming the crude isothiocyanate II with absolute alcohol. The urethan separates from alcohol in the form of flat prisms melting at 97–98°.

Anal. Calcd. for $C_{10}H_{15}ON_3S_2$; N, 16.33. Found: N, 16.27, 16.31.

2-Ethylmercapto-4-methyl-6-thionmethylurethan Pyrimidine, $C_9H_{13}ON_3S_2$.—Prepared by the action of methyl alcohol on the crude isothiocyanate II. It crystallizes from ethyl alcohol in the form of needles melting at 84–86°.

Anal. Calcd. for $C_9H_{13}ON_3S_2$; N, 17.28. Found: N, 17.30.

Experimental Conditions Influencing the Rearrangement of the Pyrimidine Thiocyanate I

A.—Heating of the thiocyanate I at 115–120° for four hours and at 100° for eight hours did not give any detectable amount of the isothiocyanate modification.

Digestion of the pyrimidine thiocyanate I in toluene did not produce a rearrangement but the change was brought about by refluxing in xylene solution.

B. Rearrangement of the Thiocyanate I by Heating with Alcohol.—At the boiling point of ethyl alcohol the pyrimidine thiocyanate I undergoes no change and can be recrystallized repeatedly from this solvent without structural alteration. On the other hand, when heated in alcohol solution at 100° for six hours (55° below its boiling point), the thiocyanate is transformed completely into the isothiocyanate II, and the latter combines with the alcohol, giving the corresponding thionurethan. The yield is excellent, and the thionurethan melts sharply after one crystallization at 97–98°.

Summary

1. 2-Ethylmercapto-4-methyl-6-thiocyanopyrimidine is formed by interaction of potassium thiocyanate with 2-ethylmercapto-4-methyl-6-chloropyrimidine in boiling ethyl alcohol solution.

2. This thiocyanate distils at 155–158° at 5 mm. and is rearranged to its isomeric form, the isothiocyanate, (1) by heating with alcohol at 100° and (2) by digestion in boiling xylene.

3. 2-Ethylmercapto-4-methyl-6-isothiocyanopyrimidine cannot be distilled without decomposition. It is slowly transformed into a polymeric modification.

4. The thiocyanate does not react with alcohols, ammonia or aniline. The isothiocyanate interacts with these same reagents to form the corresponding thionurethans and thioureas, respectively.

THE PARA-PHENYLPHENACYL ESTERS OF CERTAIN ORGANIC ACIDS¹

BY NATHAN L. DRAKE AND JAMES P. SWEENEY

RECEIVED JANUARY 6, 1932

PUBLISHED MAY 7, 1932

The advantages of *p*-phenylphenacyl bromide as a reagent for identifying organic acids have been previously described by Bronitsky and one of us.² We have made frequent use of the reagent in this Laboratory in research and in a course in organic qualitative analysis, and because of the success we have experienced in its use, we have deemed it desirable to report the melting points and solubility behavior of certain *p*-phenylphenacyl esters not prepared in the earlier work.

¹ From a thesis submitted to the Graduate School of the University of Maryland by J. P. Sweeney in partial fulfilment of the requirements for the degree of Master of Science.

² Drake and Bronitsky, *THIS JOURNAL*, **52**, 3715 (1930).

Judefind and Reid³ found that *p*-bromophenacyl bromide did not yield esters smoothly with dibasic acids; however, from phenacyl bromide, Rather and Reid⁴ were able to prepare satisfactorily the esters of succinic and glutaric acids. They did not attempt to prepare esters of any of the other dibasic acids.

p-Phenylphenacyl bromide, was found to yield esters smoothly with all the members of the α,ω -dibasic acid series from malonic acid to sebacic acid.

Experimental

Preparation of the Reagent.—The reagent was prepared as previously described.² In order to obtain a colorless *p*-phenylacetophenone with a minimum of effort, it has been found essential to wash the crude ketone obtained from the decomposition of the Friedel-Crafts addition product very carefully until entirely free from acid. If this precaution is taken, one or two crystallizations from alcohol are sufficient to give a colorless product with the correct melting point. Similarly in the preparation of the bromide, it is essential that *all* the acid be washed out of the crude material before recrystallization. One recrystallization from hot 95% alcohol is then sufficient to yield a pure colorless product. If these simple precautions are not observed, much difficulty will be encountered in obtaining a satisfactory reagent.

TABLE I
RESULTS OBTAINED
Melting or decomposition point
of *p*-phenylphenacyl ester

Acid	Melting or decomposition point of <i>p</i> -phenylphenacyl ester	Solvent for recrystallization
Malonic	175 (dried at 100°C.)	Alcohol
Glutaric	152	Acetone
Adipic	148	Acetone
Pimelic	145–148 dec.	Alcohol
Suberic	151	Acetone
Azelaic	141	Acetone
Sebacic	140	Acetone
Phenylacetic	63 dec.	Alcohol
Hydrocinnamic	95	Alcohol
Isocaproic	70	Alcohol
Tartaric	203–204 dec.	Alcohol
<i>p</i> -Nitrobenzoic	182	Benzene
3,5-Dinitrobenzoic	154	Benzene
<i>o</i> -Bromobenzoic	98	Alcohol
Salicylic	148 (dried at 100°C.)	Alcohol
<i>p</i> -Hydroxybenzoic	240	Acetone
<i>o</i> -Methoxybenzoic	131	Alcohol
Anisic	160	Alcohol
Gallic	195–198 dec.	Aq. alcohol
<i>o</i> -Phthalic	167.5	Alcohol
4-Nitrophthalic	120	Benzene
Tetrachlorophthalic	193	Acetone
Benzilic	122	Alcohol

³ Judefind and Reid, *THIS JOURNAL*, **42**, 1043 (1920).

⁴ Rather and Reid, *ibid.*, **41**, 75 (1919).

Preparation of the Esters.—The method used was similar to that employed in the former work, but it was found more convenient to use a solution of 1 *N* sodium hydroxide for neutralization of the acid, taking care to have the final salt solution slightly acid to prevent formation of colored by-products. The neutral equivalent of an unknown acid may thus be obtained with no additional effort.

The sodium salts of some of the dibasic acids were found to be insoluble in aqueous alcohol, and caused trouble. Mere substitution of the ethyl ammonium salt for the sodium salt did not obviate the difficulty. If, however, the acid was dissolved in a little water and neutralized with ethylamine, alcohol could be added until the salt started to come out of solution. By use of salts prepared in this way it was possible to obtain the di-esters satisfactorily; 0.0025 mole of acid and 0.005 mole of reagent were used in the experiments with dibasic acids.

Many of the esters listed below were found to be sparingly soluble in 95% alcohol, and accordingly their solubility was tested in acetone, ether and benzene.

Melting points were taken in a small beaker containing concd. sulfuric acid which was well stirred during the determination. No corrections were applied to the melting points, but the thermometer used was calibrated, and registered correctly at 0, 100 and 121.25°, the melting point of pure benzoic acid.

With but two acids were we unable to obtain satisfactory results. The ester of methylanthranilic acid was a gum which could not be induced to crystallize, and the ester of trinitrobenzoic acid was a red colloid which could not be filtered. It was also found that under the conditions used in this work, no esters were obtainable from sulfonic acids.

Summary

A number of common acids have been characterized by the preparation of their *p*-phenylphenacyl esters.

PENTHAZOLINES. I. THE ACTION OF HALOGENS ON THE DIMETHYL MALONATE ADDITION PRODUCT OF ALLYL MUSTARD OIL¹

BY DAVID E. WORRALL

RECEIVED JANUARY 7, 1932

PUBLISHED MAY 7, 1932

It has been shown previously that the aromatic isothiocyanates react smoothly with certain esters² containing an active methylene group, forming substituted thioamides that have been found useful for the preparation of heterocyclic ring compounds. The aliphatic derivatives have been much less studied. Ruhemann was unable to obtain a tractable³ substance from the action of allyl mustard oil on malonic ester. Methyl isothiocyanate, however, and its homologs have been observed to form

¹ Original manuscript received July 3, 1931.

² Worrall, *THIS JOURNAL*, **44**, 1551 (1922); **45**, 3092 (1923); **46**, 2832 (1924).

³ Ruhemann, *J. Chem. Soc.*, **93**, 621 (1908).

crystalline addition⁴ products with malonic ester. The resulting esters did not react smoothly with hydroxylamine or hydrazine, substances used in the aromatic series for the preparation of isoxazolones and pyrazolones,⁵ moreover, the product contained sulfur in spite of the fact that hydrogen sulfide was evolved in the reaction. Because of these facts and the meager amount of material available, the reaction was not further investigated at the time. In resuming the study of this reaction, allyl mustard oil suggested itself in spite of Ruhemann's discouraging results. The substitution of dimethyl malonate for the usual ethyl ester resulted in a crystalline product, low melting to be sure, but tractable and easily purified. The reaction may be formulated as follows

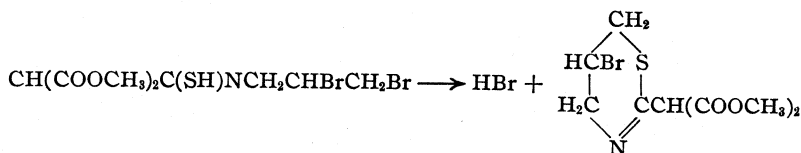

The product was precipitated from water by the addition of hydrochloric acid.

The resulting ester was found to react readily with hydrazine. Hydrogen sulfide was evolved and a small amount of a crystalline product was eventually obtained which was identified as malonic acid monothioallylamide. Hydrolysis, not condensation, takes place in the presence of this base. The presence of hydrogen sulfide is due to further decomposition of the new thioamide.

In this respect the alkyl thioamides differ markedly from the corresponding arylated substances. Bromine was absorbed by the new ester, but the product contained one equivalent only of bromine. It is well known that thioamides, through the enolic form, condense with certain halogenated compounds producing thioazoline bases. Moreover, Dixon⁶ has shown that a penthiazoline is formed by the action of bromine on allyl urea. A similar reaction is probable here.

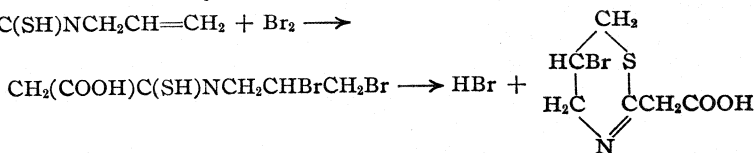

The penthiazoline ester shows only slight evidence of basic character. It readily undergoes hydrolysis when heated with water even without the addition of acid or alkali. Some evidence was found of the presence of hydroxypenthiazoline-acetic acid, but no traces of the intermediate bromo

⁴ Worrall, *THIS JOURNAL*, **50**, 1456 (1928).

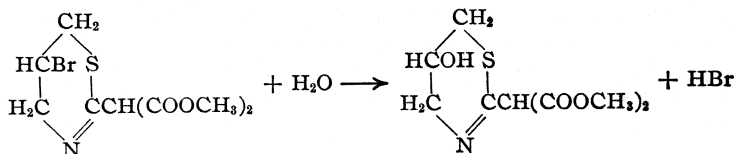

⁵ Unpublished results.

⁶ Dixon, *J. Chem. Soc.*, **69**, 24 (1896).

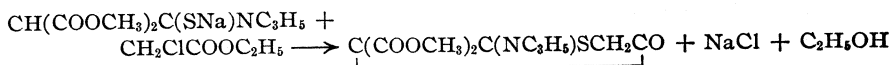

derivative. However, the latter is easily obtained by the action of bromine on malonic acid monothioallylamide.

No difficulty was experienced in replacing halogen in the penthiazoline ester with an hydroxyl group without disturbing the ester radical. Alcoholic silver nitrate quickly brought about the desired change.

The product of the action of malonic ester on allyl mustard oil reacts smoothly in the presence of sodium methylate with ethyl chloroacetate, a reaction discovered by Ruhemann, to form a thiophene derivative.

Experimental

Carbomethoxy Methyl Malonate Monothioallylamide.—To 11.5 g. of sodium suspended in 500 cc. of dry ether were added 66 g. of dimethyl malonate and (the next day) 49 g. of allyl mustard oil. The mixture was allowed to stand for some hours with occasional shaking at room temperature, after which it was heated under a reflux condenser for two hours. The entire contents was poured into ice water and the resulting aqueous layer after separation was added slowly with stirring to a freezing mixture of crushed ice and hydrochloric acid. The resulting bulky precipitate was filtered, washed free from chlorides with cold water and then extracted with a rather large volume of a mixture of approximately equal parts of ordinary ethyl alcohol and water warmed merely to room temperature. On cooling to the freezing point of water, a colorless precipitate of flat needle-like crystals quickly appeared. A yield of 77 g. or approximately 66% of the theoretical amount of fairly pure material was obtained in this manner.

Anal. Calcd. for $\text{C}_9\text{H}_{13}\text{O}_4\text{NS}$: S, 13.9. Found: S, 13.7.

The pure substance separates from alcohol-water mixtures in the form of brilliant narrow plates melting at $42-43^\circ$. It is easily dissolved by the usual organic solvents, also by aqueous sodium hydroxide, from which it may be recovered unchanged in the cold by the prompt addition of dilute acetic acid. The alkaline solution undergoes decomposition on standing at room temperature.

Malonic Acid Monothioallylamide.—Attempts to prepare this substance by the action of alkali on the ester failed. However, by the use of a less vigorous reagent, namely, hydrazine, the above acid was obtained. To 10 g. of the ester dissolved in alcohol was added the molar equivalent of hydrazine. The mixture was then heated under a reflux condenser for four to five hours and allowed to concentrate to a small

volume. The crystalline product separating on the addition of an excess of hydrochloric acid to the dark red solution was recrystallized from water; yield of crude product, approximately two grams.

Anal. Calcd. for $C_6H_9O_2NS \cdot 2H_2O$: S, 16.4. Found: S, 16.4.

It crystallizes from warm water in brilliant plates. The melting point is not sharp, the substance softening at 115° and partially melting with foaming due to the elimination of water at 120 – 121° . The new thioamide is very soluble in alcohol, although only sparingly soluble in benzene, chloroform and similar solvents.

The preparation of the thiazoline esters may be illustrated by the following experiment. To 30 g. of carbomethoxymethylmalonate monothioallylamide dissolved in a small volume of chloroform and cooled with a freezing mixture was added dropwise the molar equivalent of bromine mixed with chloroform. The clear mixture, after several extractions with cold water to remove hydrobromic acid, was concentrated to a small volume and alcohol added. A prompt removal of the acid is essential as otherwise the substance decomposes even when cold, eventually changing into a tar. The resulting solid after thorough washing with water was crystallized from alcohol; yield of pure material, 27 g.

TABLE I
HALOGEN DERIVATIVES OF PENTHAZOLINE-2-DIMETHYLMALONATE

	Formula	M. p., $^\circ C$.	Cryst. form	Halogen, % Calcd. Found	
-5-Chloro	$C_9H_{12}O_4NSCl$	145–146	Microscopic needles	13.4	13.4
-5-Bromo	$C_9H_{12}O_4NSBr$	153–154	Flat needles	25.8	25.6
-5-Iodo	$C_9H_{12}O_4NSI$	156–157	Flat needles	35.6	35.8

A more complete analysis was made of the bromine compound. Calcd. for $C_9H_{12}O_4NSBr$: C, 34.8; H, 3.9; S, 10.3. Found: C, 35.0; H, 4.2; S, 10.3.

These halogen derivatives are sparingly soluble in hot alcohol, but very soluble in chloroform. They are insoluble in cold sodium hydroxide solution or dilute mineral acids and exhibit marked stability toward concentrated nitric acid even after short heating. Permanganate dissolved in acetone is not reduced. Cold concentrated hydrochloric and sulfuric acids dissolve the substances. On heating with water the bromine derivative gradually dissolves. Carbon dioxide is set free, also hydrobromic acid, and a non-tractable gum is formed which gives forth a pyridine-like odor on neutralization with alkali. It is not changed after several hours' heating with methyl iodide and is recovered unchanged after decomposition with water of the addition product with CH_3MgI in ether.

2-Hydroxypentthiazoline-2-dimethylmalonate.—To 5 g. of the bromothiazoline ester dissolved in alcohol was added the molar equivalent of silver nitrate and the mixture heated for several hours. Sodium bicarbonate was then added to neutralize the nitric acid formed in the reaction and the mixture filtered. The filtrate was concentrated to a small bulk from which crystals separated on cooling; yield, 3.5 g. It was recrystallized from alcohol.

Anal. Calcd. for $C_9H_{13}O_5NS \cdot 2H_2O$: S, 11.3. Found: S, 11.3.

The hydroxy derivative is soluble in hot water and readily soluble in hot alcohol, separating in slender flat needles melting at 104 – 105° with preliminary softening.

While no satisfactory results were obtained in attempts to hydrolyze the above-mentioned esters, it was found possible to obtain the monocarboxyl derivatives by the action of halogens on malonic acid monothioallylamide as follows. To the substance dissolved in glacial acetic acid was added the appropriate amount of the halogen. A prompt precipitation of the halogen acid salt of the carboxyl derivative took place. The

salt was decomposed after filtration by trituration with water mixed with alcohol, following which the penthiazoline was recrystallized from water.

TABLE II
HALOGEN DERIVATIVES OF PENTHAZOLINE-2-ACETIC ACID

	Formula	M. p., °C.	Cryst. form	Halogen, %	
				Calcd.	Found
-5-Chloro	$C_6H_8O_2NSCl \cdot 2H_2O$	179-180	Powder	15.5	15.3
-5-Bromo	$C_6H_8O_2NSBr \cdot 2H_2O$	188-190	Flat needles	29.2	28.5
-5-Iodo	$C_6H_8O_2NSI \cdot 2H_2O$	213-214	Feathery needles	39.6	39.8

Considerable difficulty was experienced in obtaining satisfactory results with the bromine derivative, for this substance was acted upon by the vapors of fuming nitric acid and apparently bromine was lost before the tube was sealed. After heating, the inside of the Carius tube was spattered with silver bromide. A sulfur determination was made with the following satisfactory results. Calcd. for $C_6H_8O_2NSBr \cdot 2H_2O$: S, 11.7. Found: S, 11.7.

Apparently water of crystallization is lost on standing, for the bromo derivative was observed to change to a crystalline powder.

Anal. Calcd. for $C_6H_8O_2NSBr$: C, 30.5; H, 3.4. Found: C, 30.3; H, 3.5.

These halogen derivatives soften before the melting point is reached and partially decompose with foaming at the melting point. They are very soluble in glacial acetic acid, moderately so in water and insoluble in alcohol, ether, etc. The addition of hydrogen chloride to a glacial acetic acid solution of these substances precipitates the corresponding salt. They are slowly decomposed by hot water, liberating the corresponding halogen acid and forming a gum similar to that obtained by the hydrolysis of the penthiazoline ester.

2-Allylimino-3-dicarbomethoxy-4-ketotetrahydrothiophene.—A solution of 10 g. of carbomethoxy methylmalonate monothioallylamide in methyl alcohol was mixed with the equivalent amount of sodium methylate and ethyl chloroacetate. Considerable heat developed and on standing a dark green color developed. After an hour or so, a small amount of dilute acid was added to decolorize the solution, which was then poured into water. A bulky precipitate of slender lustrous needle-like crystals formed. It was recrystallized from water containing approximately 10% alcohol.

Anal. Calcd. for $C_{11}H_{13}O_6NS$: S, 11.8. Found: S, 11.8.

It is very sparingly soluble in hot water, from which it separates in long snow-white needles melting at 78-79°. On separation from alcohol the substance retains a yellow color which is not removed by repeated crystallization.

Methylcarbomethoxymethylmalonate Monothioallylamide.—Ten grams of methyl dimethylmalonate was condensed in the customary manner with allyl mustard oil and the product shaken with ice water. Then the water extract was slowly run into a freezing mixture of crushed ice and hydrochloric acid. The crude product was recrystallized by shaking with alcohol at room temperature, cooling with ice, and adding a few drops of water. An oil separated out, but on pouring off the turbid liquid and seeding, small colorless crystals resulted. The substance, which melted on warming to room temperature, was not further examined but was allowed to react in chloroform solution cooled to 0° with bromine. Then water was added to extract the hydrobromic acid. However, the solid product quickly changed to a tar on standing. Apparently a penthiazoline was formed, but it subsequently decomposed.

Summary

Allyl mustard oil forms addition products with dimethyl malonate and methyl dimethylmalonate.

The first addition product undergoes hydrolysis in the presence of hydrazine into methyl malonate monothioallylamide.

It forms addition products with halogens which through the loss of halogen hydride are immediately converted into penthiazolines.

Carbomethoxymethylmalonate monothioallylamide in the presence of sodium methylate forms a thiophene derivative with ethyl chloroacetate.

THE FORMATION OF FURO- α,β' -DIAZOLES FROM ACYL IMIDOTHIOCARBONATES AND ACYL PSEUDOTHIUREAS¹

BY SHAO TSENG YANG² AND TREAT B. JOHNSON

RECEIVED JANUARY 12, 1932

PUBLISHED MAY 7, 1932

A review of the literature of the chemistry of furo- α,β' -diazoles or 1,2,4-oxdiazoles reveals the fact that there are essentially two different methods which are available for the synthesis of representatives of this type of heterocyclic compounds, namely, (1) by interaction of amidoximines with acyl chlorides or acid anhydrides according to Tiemann's well-known reaction expressed below, and which has been extensively studied and applied,³ and (2) by the action of hydroxylamine on acyl imidothiocar-

bonates and acyl pseudoureas, or reactions which were reported by Johnson and Menge in 1904.⁴ This latter method of synthesis has never been carefully studied since its discovery; furthermore, the structures of the resulting diazoles were by no means definitely settled in the original contribution. In this paper we shall describe experimental methods which permit us to decide definitely the constitution of the heterocyclic condensation products obtained by the application of Johnson and Menge's reaction.

Johnson and Menge described one experiment illustrating the behavior of hydroxylamine toward an acyl imidothiocarbonate. They observed that hydroxylamine interacted with diethyl benzoylimidothiocarbonate I at ordinary temperature with formation of a compound to which they as-

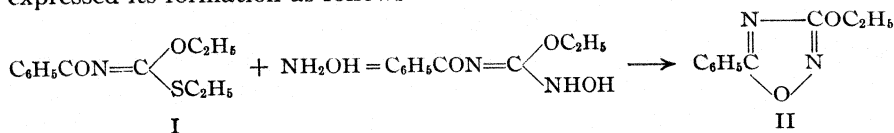

¹ Constructed from a dissertation presented by Shao Tseng Yang to the Faculty of the Graduate School of Yale University, June, 1931, in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

signed the constitution of α' -phenyl- β -ethoxyfuro- α,β' -diazole II, and expressed its formation as follows

In trying to reproduce the original experiment difficulty was at first encountered in establishing experimental conditions favoring the formation of this furo- α,β' -diazole. Unless a definite technique is applied benzamide is the major product of reaction. The formation of this amide is explained by the fact that the thiocarbonate I is very susceptible to the action of warm alkali and to add hydroxylamine hydrochloride simultaneously with the thiocarbonate I to an alcoholic solution of potassium hydroxide will invariably give benzamide. A free hydroxylamine solution must be first prepared in order to accomplish successfully the desired reaction.

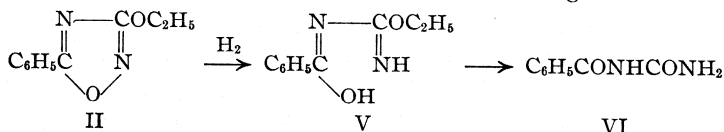

In the second place, the regulation of the temperature when applying the reaction is another very important factor as the change is an exothermic one leading to secondary reactions unless the reaction temperature is kept low. In this respect the dimethyl benzoylimidothiocarbonate is far more sensitive to temperature changes than the diethyl ester I.

The thiocarbonate I and its corresponding dimethyl ester react with hydroxylamine to form the respective furo- α,β' -diazoles represented by formulas II and III. In neither case does hydroxylamine interact with the imidothiocarbonate with formation of a mercaptofuro- α,β' -diazole derivative as represented by formula IV. Furthermore, the two imidothiocarbonates, dimethyl benzoylimidothiocarbonate and O-methyl-S-ethyl benzoylimidothiocarbonate, react with hydroxylamine to give the same furo- α,β' -diazole III. In other words, the mercapto group of the imidothiocarbonate is more readily eliminated by treatment with hydroxylamine than the alkyloxy group. A compound corresponding to formula IV was never detected as a product of this reaction. The formation of such mercapto derivatives of a furo- α,β' -diazole may be predicted by allowing hydroxylamine to interact with acyl imidodithiocarbonates, a reaction which has not hitherto been studied.

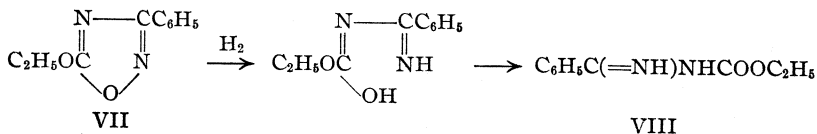

As to the structures of the furo- α,β' -diazoles formed in the above reactions, it was necessary to decide between the two possible isomeric constructions, namely, an α' -phenyl- β -alkoxyl-furo- α,β' -diazole II or α' -

alkoxy- β -phenyl-furo- α,β' -diazole VII. This was accomplished by reduction of our respective furo- α,β' -diazoles with zinc dust and acetic acid. Both of our condensation products II and III were reduced practically quantitatively to benzoylurea VI as is expressed by the equation below. This change involves theoretically the intermediate formation of an acyl-imido ester V. These results confirm the original conclusions of

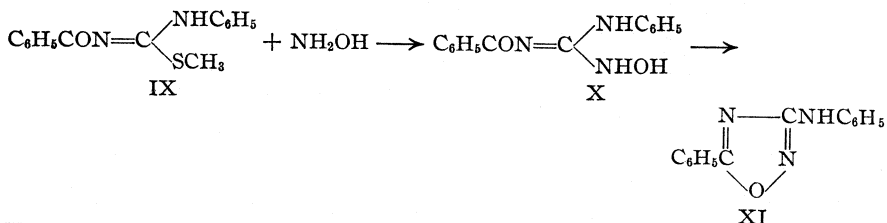

Johnson and Menge. An isomeric α' -alkoxyl- β -phenyl-furo- α,β' -diazole VII would be expected to give by reduction an entirely different product or a urethan derivative of benzamidine VIII as is illustrated by the equation

The behavior of our furo- α,β' -diazoles on reduction is entirely in accord with that of the anhydroximes on reduction, which were investigated by Rose and Scott.⁵ This method of establishing structure is undoubtedly applicable to other heterocyclic constructions containing the furo- α,β' -diazole ring.

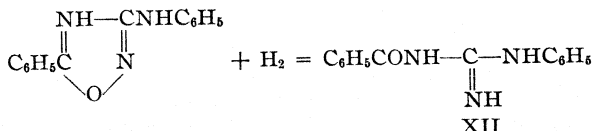

α' -Phenyl- β -anilino-furo- α,β' -diazole XI is formed by the action of hydroxylamine on benzoylpseudomethylphenylthiourea in pyridine solution.⁶ Johnson and Menge state in their original paper that this type of transformation is accomplished by interaction of hydroxylamine with an acylimidopseudourea, but no experimental evidence in support of this was presented. It has been our experience that the oxygen pseudoureas are not as reactive toward hydroxylamine as the corresponding sulfur analogs; therefore, we confined our work to the study of the sulfur derivatives. The reaction leading to the formation of an anilino-furo- α,β' -diazole is given below

⁵ Rose and Scott, *THIS JOURNAL*, **39**, 273 (1917).

⁶ Wheeler and Merriam, *ibid.*, **23**, 293 (1901).

The pseudothiurea IX used in this work, which was first prepared by Wheeler and Merriam⁶ by the action of aniline on dimethyl benzoylimido-dithiocarbonate, was synthesized by the direct alkylation of *sym.*-benzoyl-phenylthiurea with methyl iodide. When the furo- α,β' -diazole XI was reduced with zinc and acetic acid it was converted smoothly into benzoyl-phenylguanidine XII, a change which establishes its constitution. The

free guanidine melted at 90–91°, and the picrate of the guanidine melted at 187–188°. These results, therefore, identify the reduction product as the guanidine derivative previously described by Wheeler and Johnson.⁷ In other words, the acyl imidothiocarbonates and the corresponding pseudothiureas interact with hydroxylamine in a similar manner with evolution of mercaptan and formation of well characterized, crystalline furo- α,β' -diazole compounds.

Experimental Part

Preparation of Acylimidothiocarbonates.—Dimethyl benzoylimidothiocarbonate, $\text{C}_6\text{H}_5\text{CON}=\text{C}(\text{OCH}_3)\text{SCH}_3$,⁸ was prepared by alkylation of methyl benzoylthioncarbamate⁹ in alkaline solution with methyl iodide. It melted at 46° after recrystallization from ether. The corresponding diethyl imidothiocarbonate was prepared in an analogous manner by alkylation of ethyl benzoylthiocarbamate with ethyl bromide. It boiled at 200–203° at 16 mm. (Wheeler and Johnson reported the temperature of 209–212° at 19 mm.). The mixed ester O-methyl-S-ethyl benzoylimidothiocarbonate, which was prepared by the action of ethyl bromide on the potassium salt of methyl benzoylthioncarbamate, boiled at 195–205° at 14 mm.

Preparation of Acyl Pseudothiureas.—The pseudomethyl benzoylphenylthiurea, $\text{C}_6\text{H}_5\text{CON}=\text{C}(\text{SCH}_3)\text{NHC}_6\text{H}_5$, and the corresponding pseudoethyl compound used in this work were prepared by the direct alkylation of *sym.*-benzoylphenylthiurea in sodium alcoholate solution with methyl iodide and ethyl bromide, respectively. The pseudomethyl compound was obtained in a yield of 70% and melted at 104–105°,¹⁰ and the pseudoethyl compound melted at the temperature of 88°, as originally reported by Wheeler and Merriam.

α' -Phenyl- β -methoxy-furo- α,β' -diazole, $\text{C}_8\text{H}_8\text{O}_2\text{N}_2$ (III).—This compound is easily prepared as follows: 56 g. of dimethyl benzoylimidothiocarbonate is dissolved in 50 cc. of 95% alcohol and the solution combined with an alcoholic solution of hydroxylamine, prepared by adding 19 g. of hydroxylamine hydrochloride to a solution of 15 g. of potassium hydroxide in 100 cc. of methyl alcohol. The solutions were mixed at a low

temperature and then allowed to stand in an ice chest for forty-eight hours. The alcohol solution was then poured into cold water when the furo- α,β' -diazole separated as an oil which soon solidified. It was purified by crystallization from dilute alcohol and separated in the form of prisms. Some of these crystals were more than one inch in length. The yield of purified furo- α,β' -diazole was 31 g. It melted at 58–59°.

Anal. Calcd. for $C_9H_8O_2N_2$: C, 61.36; H, 4.54; N, 15.90. Found: C, 61.28; H, 4.60; N, 16.05.

The furo- α,β' -diazole is insoluble in water, moderately so in ligroin and very soluble in alcohol, ethyl acetate, chloroform, ether and benzene.

α' -Phenyl- β -ethoxy-furo- α,β' -diazole, $C_{10}H_{10}O_2N_2$ (II).—This furo- α,β' -diazole was prepared according to the same technique described in the previous experiment by allowing hydroxylamine to interact with diethyl benzoylimidothiocarbonate at ordinary temperature. After standing in an ice chest for thirty-six hours, the alcohol solution was poured into water, when the furo- α,β' -diazole separated as an oil which solidified almost immediately. It was purified by recrystallization from 95% alcohol and separated in the form of stout prisms melting at 49–50°. The solubility of this compound is similar to that of the corresponding methoxy compound.

Anal. Calcd. for $C_{10}H_{10}O_2N_2$: N, 14.73. Found: N, 14.83.

These two furo- α,β' -diazoles are characterized by their great stability and extreme inertness. Notwithstanding the fact that they contain an imido ester grouping they do not form salts with the acids—hydrochloric, nitric and sulfuric. In concentrated hydrochloric acid they remain undissolved in the cold and on warming the acid the furo- α,β' -diazoles melt without alteration. In concentrated sulfuric and nitric acids both furo- α,β' -diazoles dissolve in the cold and are reprecipitated unchanged by dilution of the acid solutions with water. They are not attacked by concentrated nitric acid when the acid solution is heated at the boiling point for several minutes. They can be heated to 250° without decomposition. They do not react with aniline at its boiling point, and can be heated with alcoholic ammonia at 200–250° for hours without alteration. We obtained no evidence that Wieland and Bauer's¹¹ α' -phenyl- β -amino-furo- α,β' -diazole is formed by interaction with ammonia. Neither of the two furo- α,β' -diazoles responds favorably to the experimental conditions employed in applying a Zeisel reaction. The furodiazole nucleus is completely destroyed by hydriodic acid at 100° with the formation of benzoic acid.

Reduction of α' -Phenyl- β -methoxy-furo- α,β' -diazole with Zinc and Glacial Acetic Acid.—Five grams of this furo- α,β' -diazole was dissolved in 25 cc. of cold glacial acetic acid and ten grams of zinc dust added. The mixture was then heated at 85–90° for one hour and finally allowed to stand for three hours, when the unchanged zinc was removed by filtration and the excess of acetic acid evaporated on a water-bath. A crystalline residue was obtained. This was identified as a mixture of the unaltered furo- α,β' -diazole and benzoylurea. About one-half of the furo- α,β' -diazole was recovered unchanged. On recrystallizing the crude reduction product from alcohol the urea was obtained in pure form melting at 208°.

Anal. Calcd. for $C_8H_8O_2N_2$: N, 17.07. Found: N, 17.00.

When the corresponding α' -phenyl- β -ethoxy-furo- α,β' -diazole was reduced with zinc dust and acetic acid under the same conditions it was also converted into benzoylurea. After digesting with zinc at 95–100° for three hours, about one-half of the furo- α,β' -diazole was still recovered unaltered.

α -Phenyl- β -anilino-furo- α,β' -diazole, $C_{14}H_{11}ON_2$ (XI).—This furo- α,β' -diazole is

¹¹ Wieland and Bauer, *Ber.*, **40**, 1691 (1907).

formed by the action of hydroxylamine on pseudomethyl benzoylphenylthiourea or pseudoethyl benzoylphenylthiourea. One experiment will be described in order to illustrate the technique employed. Ten grams of pseudomethyl benzoylphenylthiourea was dissolved in 25 cc. of pyridine and two molecular proportions of hydroxylamine hydrochloride added to the solution while cooling. After allowing to stand for about forty-eight hours the pyridine solution was diluted with water, when the above furo- α,β' -diazole separated in a crystalline condition. This crude reaction product was washed with dilute sulfuric acid to remove traces of pyridine and then recrystallized from benzene. It separated, on cooling, in the form of rectangular prisms melting at 139–140°. It did not respond to a test for sulfur and also crystallized from alcohol in prisms melting at 139–140°. For analysis the compound was dried at 110–120° to constant weight.

Anal. Calcd. for N, 17.72. Found: N, 17.62, 17.70.

The furo- α,β' -diazole did not interact with acetic anhydride by refluxing with this reagent for three hours. It dissolved in concentrated sulfuric acid in the cold, giving a red colored solution. On diluting the acid solution with water the furo- α,β' -diazole was precipitated unchanged.

Behavior on Reduction.—Two grams of the anilino-furo- α,β' -diazole was reduced with zinc dust and glacial acetic acid at 90–95° for three hours. After removing the excess of zinc and evaporating the acetic acid, a crystalline substance was obtained which was purified by crystallization from benzene. It was identified as benzoylphenylguanidine and melted at 90–91°. When picric acid was added to an alcoholic solution of the base, the picrate separated as reported previously by Wheeler and Johnson.⁷

Anal. (Picrate). Calcd. for $C_{20}H_{16}O_8N_6$: N, 17.94. Found: N, 17.80.

β -Chlorethyl Benzoylthioncarbamate, $C_6H_5CONHCSOCH_2CH_2Cl$.—This compound is easily prepared by allowing freshly distilled benzoyl isothiocyanate to interact at ordinary temperature with ethylene chlorohydrin. The thioncarbamate was purified by crystallization from acetone or alcohol and crystallized in the form of needles melting at 179–180°.

Anal. Calcd. for $C_{10}H_{10}O_2NSCl$: N, 5.71. Found: N, 5.74, 5.83.

Summary

1. Acylimidothiocarbonates react with hydroxylamine to form alkoxyl furo- α,β' -diazoles.
2. Pseudoalkylacylphenylthioureas react with hydroxylamine to form anilino-furo- α,β' -diazoles.
3. The structures of heterocyclic combinations of the furo- α,β' -diazole type are established by their behavior on reduction with zinc and acetic acid. The alkoxyl compounds are broken down with formation of acylureas while the anilino derivatives give acyl derivatives of substituted guanidines.

THE FORMATION OF 1,4-DIPHENYLHEXADIENE-1,5 IN THE REACTION BETWEEN CINNAMYL CHLORIDE AND MAGNESIUM

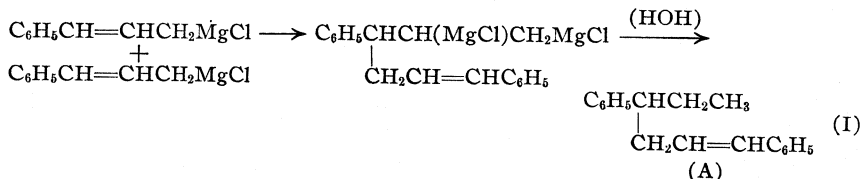

BY HENRY GILMAN AND STANTON A. HARRIS

RECEIVED JANUARY 12, 1932

PUBLISHED MAY 7, 1932

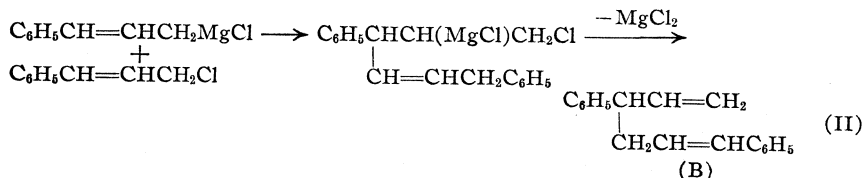

Introduction

Two hydrocarbons have been isolated in the unusual reaction between cinnamyl chloride and magnesium.¹ One of these has been identified definitely as the solid dicinnamyl, $\text{C}_6\text{H}_5\text{CH}=\text{CHCH}_2\text{CH}_2\text{CH}=\text{CHC}_6\text{H}_5$. The other hydrocarbon, a liquid, has been designated as 1,4-diphenylhexene-1 and is said to owe its origin to the following reactions

That is, Compound (A) is formed as a consequence of the addition of one molecule of the so-called cinnamylmagnesium chloride to the ethylenic linkage of another molecule of this Grignard reagent. The evidence in support of (A) turns on its ultimate analysis and its oxidation to phenylsuccinic and benzoic acids.

It has also been suggested² that the liquid hydrocarbon might be a diolefin formed as follows

In this mechanism, one molecule of the RMgCl compound adds to the ethylenic linkage of a molecule of cinnamyl chloride to give a new Grignard reagent which then loses magnesium chloride.

Each of these mechanisms suffers from the disadvantage that it postulates addition of a Grignard reagent to an ethylenic linkage. No such addition has been established, and present evidence is overwhelmingly against it.³ We have shown that the liquid hydrocarbon is Compound

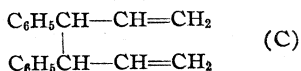

¹ Rupe and Bürgin, *Ber.*, **43**, 172 (1910).

² V. Braun and Köhler, *ibid.*, **51**, 79 (1918).

³ A recent article with leading references on the non-addition of RMgX compounds to an ethylenic linkage is Gilman and Harris, *Rec. trav. chim.*, **49**, 762 (1930). It should be stated that the postulation of such addition was made at a time when there appeared

(B), 1,4-diphenylhexadiene-1,5. This was demonstrated: first, by ultimate analysis, the values for carbon and hydrogen agreeing better for Compound (B) than for (A); second, by catalytic reduction whereby exactly two moles of hydrogen were taken up; third, by ozonization that gave formaldehyde and benzaldehyde, which together with the phenylsuccinic acid obtained previously¹ by permanganate oxidation, definitely supports (B) and makes (A) altogether unlikely because it would hardly be expected to give any formaldehyde, and phenylsuccinic acid is rather to be expected with (B) than (A); and, fourth, by definitely establishing the identity of the reduction product with an authentic specimen of 1,4-diphenylhexane.

The evidence based on reduction to 1,4-diphenylhexane obviously supports both (A) and (B). It has been presented, however, in order to exclude a third possible compound, namely, 3,4-diphenylhexadiene-1,5.

Actually, Compound (C) has been suggested⁴ tentatively as a structure for the oil obtained in related reactions between cinnamyl bromide and ethylmagnesium bromide and phenylmagnesium bromide, respectively. Were it not for the facts that Compound (C) does not agree with the reduction and oxidation products of the liquid hydrocarbon, it might be considered a possibility for the following reasons.

First, it appears altogether probable that the first step involved in a reaction between an RX compound and magnesium in ether is the formation of a free radical which can undergo several reactions, among which are coupling to give an R·R compound, rearrangement to a different free radical and disproportionation.⁵ Second, the R·R compound can be formed as follows, also through the intermediate free radicals.⁵

Third, the reaction between cinnamyl chloride and magnesium gives a to be some basis for such reaction, and that Professor Rupe is now of the opinion that a Grignard reagent does not add to an ethylenic linkage. See, in this connection, Gilman and Schulz, *THIS JOURNAL*, **53**, 2799 (1931).

⁴ Prévost and Danjat, *Bull. soc. chim.*, **47**, 588 (1930). See, also, Kirrmann, *ibid.*, **47**, 834 (1930). V. Braun and Köhler, *Ber.*, **51**, 83 (1918), earlier studied the reaction between cinnamyl bromide and ethyl- and phenylmagnesium halides.

In a paper by Prévost, *Bull. soc. chim.* **49**, 1372 (1931) [*C. A.* **26**, 1574 (1932)], which became available after our manuscript was submitted for publication, it has been shown that the second hydrocarbon is 1,4-diphenylhexadiene-1,5.

⁵ A recent article with leading references is Gilman and Zoellner, *THIS JOURNAL*, **52**, 3984 (1930).

Grignard reagent which reacts⁶ with a wide variety of compounds as though its formula were $\text{C}_6\text{H}_5\text{CHCH}=\text{CH}_2$ and not $\text{C}_6\text{H}_5\text{CH}=\text{CHCH}_2\text{MgCl}$.

For these reasons, the two radicals expected in a reaction between cinnamyl chloride and magnesium are

The union of two of the former (cinnamyl) radicals would give dicinnamyl; the union of two of the latter (α -phenylallyl) radicals would give Compound (C), 3,4-diphenylhexadiene-1,5; and the union of one of each of these radicals would give Compound (B), 1,4-diphenylhexadiene-1,5.

We thus see that there is no basis of expectation, on theoretical grounds, for Compound (A), 1,4-diphenylhexene-1. Compound (C) may be contained in the oily mixture of hydrocarbons which has so far definitely yielded dicinnamyl and 1,4-diphenylhexadiene-1,5 (B). The proportions of R·R compounds in such reactions varies with experimental conditions and with the nature of halogen in the RX compound. For example, with cinnamyl bromide and magnesium the chief hydrocarbon is dicinnamyl¹² and not, as with cinnamyl chloride, 1,4-diphenylhexadiene-1,5.

Experimental Part

Preparation of Hydrocarbon Mixture.—In a typical experiment, 60.8 g. (0.4 mole) of cinnamyl chloride (melting at 7–8°) dissolved in 100 cc. of ether, was added to 5 g. (0.205 atom) of magnesium, the reaction being first started with a small quantity of ether. At the end of the reaction, there was a slight positive color test⁷ showing the presence of a small quantity of Grignard reagent.⁸ This was destroyed by the addition of 2 cc. of cinnamyl chloride. The solution was then hydrolyzed, and the ether layer dried over calcium chloride and then distilled. On the first distillation, a total yield of 34.9 g. or 74.5% of hydrocarbons was obtained, boiling over the range 165–180° (3–4 mm.). The last portion of the distillate crystallized in the receiver, and was identified as dicinnamyl. After five fractionations, 20 g. or a 42.9% yield of hydrocarbon, distilling at 157–160° (2 mm.), was obtained: n_D^{20} 1.5890; d_4^{20} 0.9919. The higher fraction yielded 4.1 g. or 8.75% of dicinnamyl. An intermediate fraction was not investigated.

Anal. Calcd. for $\text{C}_{18}\text{H}_{18}$: C, 92.26; H, 7.74. Found: C, 92.08; H, 7.95.

Catalytic Reduction of Liquid Hydrocarbon.—The reduction of 11.7 g. (0.05 mole) of hydrocarbon in 50 cc. of alcohol was effected with 0.15 g. of Adams' catalyst. In ten minutes, 7.6 pounds (0.1 mole) of hydrogen was absorbed, showing the presence of two ethylenic linkages. Like results were obtained with 0.025 mole of the hydrocarbon.

⁶ Gilman and Harris, *THIS JOURNAL*, **49**, 1825 (1927); *ibid.*, **53**, 3541 (1931). This latter reference and that of Gilman and Kirby, *ibid.*, **54**, 345 (1932), describe several mechanisms proposed for the allylic rearrangements of Grignard reagents like cinnamylmagnesium chloride. See, also, Austin and Johnson, *ibid.*, **54**, 647 (1932).

⁷ Gilman and Schulze, *ibid.*, **47**, 2002 (1925).

⁸ Cinnamylmagnesium chloride can be prepared in an 87% yield. See Gilman and Harris, *Rec. trav. chim.*, **50**, 1052 (1931).

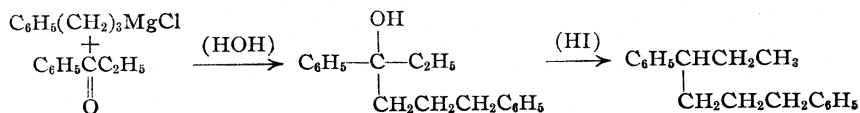

The product, subsequently identified as 1,4-diphenylhexane, boiled at 147–148° (3 mm.); n_D^{20} 1.5456; d_{20}^{20} 0.9608.

Anal. Calcd. for $C_{18}H_{22}$: C, 90.75; H, 9.24. Found: C, 90.4; H, 9.16.

Dicinnamyl likewise took up the theoretical quantity of hydrogen.

Ozonization of Liquid Hydrocarbon.—Ozonization, by the procedure of Doeuvre,⁹ gave formaldehyde and benzaldehyde. Under the same conditions, dicinnamyl yielded benzaldehyde but no formaldehyde.

Synthesis of 1,4-Diphenylhexane.—The following transformations were used in the preparation of 1,4-diphenylhexane.

The γ -phenylpropyl chloride was obtained in an 82% yield by heating an ether solution of 80 g. (0.59 mole) of γ -phenylpropyl alcohol with 75 g. (0.63 mole) of thionyl chloride for one hour. The corresponding Grignard reagent, γ -phenylpropylmagnesium chloride, was obtained in a 98% yield¹⁰ in a 0.5 mole run, the reaction being started with activated magnesium-copper alloy. When treated in a customary manner with propiophenone, the Grignard product yielded 81.5 g. or a 64% yield of 1,4-diphenylhexanol-4; b. p. 177–179°; n_D^{20} 1.5508; d_{20}^{20} 1.0284.

Anal. Calcd. for $C_{18}H_{22}O$: C, 85.04; H, 8.66. Found: C, 84.96; H, 8.69.

Twelve and one-half grams of the carbinol was heated in a pressure bottle with 25 cc. of constant boiling hydriodic acid and some red phosphorus for two hours at 140–150°. The synthetic 1,4-diphenylhexane obtained in this manner had the following constants: b. p. 147–149° (3–4 mm.); n_D^{20} 1.5460; d_{20}^{20} 0.9660.

Anal. Calcd. for $C_{18}H_{22}$: C, 90.75; H, 9.24. Found: C, 90.57; H, 9.19.

Summary

The liquid hydrocarbon formed from cinnamyl chloride and magnesium in ether has been shown to be 1,4-diphenylhexadiene-1,5 and not 1,4-diphenylhexene-1, as previously reported. Mechanisms have been proposed for its formation.

PREPARATIONS OF URACIL-4-ACETIC AND OROTIC ACIDS. OROTIC ACID AS THE POSSIBLE INTERMEDIATE IN THE SYNTHESIS OF PURINES FROM HISTIDINE

By GUIDO E. HILBERT

RECEIVED JANUARY 22, 1932

PUBLISHED MAY 7, 1932

The excellent method of Davidson and Baudisch¹ for the synthesis of uracil consists in treating malic acid and urea with fuming sulfuric acid.

This synthesis is of considerable significance since it allows an easy mode of entrance into the pyrimidine series of compounds. With uracil as a starting material, many pyrimidines substituted in the 1, 2, 3, 5 and 6 positions can easily be made. Hilbert and Johnson² have taken advantage of this procedure and synthesized cytosine by a new method. More recently³ it has been demonstrated that thymine can also be prepared directly from uracil in a manner analogous to Kircher's⁴ synthesis of 4,5-dimethyluracil from 4-methyluracil. The reaction was carried out by treating uracil with formaldehyde and hydrochloric acid. The resulting uracil-5-methyl chloride was reduced with tin and hydrochloric acid and yielded thymine. Since the method of Davidson and Baudisch for the preparation of uracil is far superior to the older one of Wheeler and Merriam,⁵ it was of interest to determine if it could also be applied for the preparation of other pyrimidines.

The Syntheses of Uracil-4-Acetic and Orotic Acids.—It is reasonable to expect that other α -hydroxy- α,β -dicarboxylic acids will also break down with fuming sulfuric acid in a manner typical of α -hydroxy acids to yield products which will combine with urea to form cyclic ureides. The easily available citric acid has such a configuration and should yield, with urea, uracil-4-acetic acid, a view which has now been confirmed.

As is well known, citric acid in the presence of fuming sulfuric acid breaks down to form acetonedicarboxylic acid. It was either this or more probably the enol form which condensed with the urea to form uracil-4-acetic acid. The structure of the pyrimidine was proved beyond reasonable

doubt since the properties of it and a number of derivatives were the same as those recorded by Wheeler and Liddle.⁶ The method is recommended the best for the preparation of this substance.

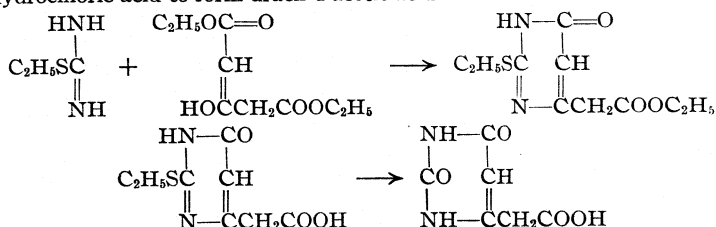

The limitations of this method for the synthesis of pyrimidines are well illustrated by the failure to isolate any products when ethyl acetoacetate and ethyl sodiumformylpropionate were used (for other examples see experimental portion) in place of malic or citric acids. Theoretically, one would have expected the synthesis of 4-methyluracil and thymine, respectively. The fact that these latter experiments were unsuccessful seems surprising, since these compounds are so similar in structure to formylacetic and acetonedicarboxylic acids which react so smoothly.

The attempt to decarboxylate uracil-4-acetic acid by treatment with barium hydroxide solution was unsuccessful, since the pyrimidine ring was ruptured, yielding the insoluble barium salt of β -carbamidoglutaconic acid. This was readily decomposed by hydrochloric acid and regenerated uracil-4-acetic acid, indicating that the salt probably was the *cis*⁷ modification. Although the rupture of a pyrimidine having a double bond in the 4,5 posi-

tion was odd, it was not new. Müller⁸ condensed ethyl oxaloacetate with methylurea and obtained 3-methyluracil-4-ethylcarboxylate. When the sodium salt of this substance was treated with hydrochloric acid a β -methylcarbamidoacrylic acid, $\text{—H}_2\text{NCON}(\text{CH}_3)\text{CH}=\text{CHCOOH}$, was obtained. Neither acids nor alkali converted this substance into 3-methyluracil.

⁶ Wheeler and Liddle [THIS JOURNAL, 30, 1156 (1908)] previously synthesized uracil-4-acetic acid. Acetonedietethylcarboxylate was condensed with 2-ethylpseudothiourea in alkaline solution and yielded 2-ethylmercapto-6-oxypyrimidine-4-ethylacetate. This was saponified and the resulting mercapto acid digested with concentrated hydrochloric acid to form uracil-4-acetic acid.

⁷ *Cis* with respect to the newly formed carboxyl and ureido groups.

⁸ Müller, *J. prakt. Chem.*, 56, 498 (1897).

Johnson and Shepard⁹ have reported a similar case. They isolated a by-product in the reaction of 2-thiouracil with sodium ethylate and ethyl chloroacetate which they believed to be β -thiocarbamidoacrylic acid, that was unaffected by acids. The fact that these acrylic acid derivatives did not yield pyrimidines on acid treatment was interpreted as indicating that they had the *trans* configuration.¹⁰

In order to obtain further information on the ease of hydrogenation of the 4,5 double bond in keto pyrimidines, uracil-4-ethylacetate and 3-methyluracil were hydrogenated using Adams and Shriner's platinum oxide as catalyst. The saturation of the double bond in both cases was found to be very slow.

Biscaro and Belloni¹¹ in 1905 isolated orotic acid from milk. Recently Bachstetz¹² showed that it was identical with uracil-4-carboxylic acid, which has been synthesized a number of times. Müller¹³ prepared the ethyl ester by condensing urea with ethyl oxaloacetate in acetic acid. This was subsequently saponified to the acid by Wheeler.¹⁴

Later Behrend and Struve¹⁵ synthesized the acid by the oxidation of 4-methyluracil in potassium hydroxide solution with potassium ferricyanide. More recently Johnson and Schroeder¹⁶ have prepared it by the oxidation of uracil-4-aldehyde with chromic acid. Of these methods, that of Behrend and Struve appears to be the best since 4-methyluracil is readily available and the oxidation can easily be carried out, resulting in a good yield of orotic acid. As uracil-4-acetic acid can now be made as easily as 4-methyluracil, its smooth oxidation would be expected to lead to another convenient synthesis of orotic acid. The action of potassium ferricyanide on uracil-4-acetic acid in alkaline solution was studied. The oxidation did not go as smoothly as that of 4-methyluracil; the yield of orotic acid was somewhat less. It is possible that the ease in rupture of the ring was partly responsible for the decreased yield. Under the conditions operated, the method, as yet, cannot be recommended as being better than that of the oxidation of 4-methyl-uracil.

⁹ Johnson and Shepard, *Am. Chem. J.*, **46**, 345 (1911).

¹⁰ A number of examples have been reported in which the acrylic acid derivative was converted to a pyrimidine by treatment with acid. Behrend, *Ann.*, **229**, 8 (1885), noted that a carbamidocrotonic ester was converted to 4-methyluracil and Johnson and Clapp [*Am. Chem. J.*, **32**, 130 (1904)] found that α -methyl- β -guanidinoacrylic acid was changed to 2-amino-5-methyl-6-oxypyrimidine. In these cases the acid was assigned the *cis* structure.

Orotic Acid as the Possible Intermediate in the Synthesis of Purines from Histidine.—The occurrence of orotic acid in milk arouses interest as to the possible mechanism of its formation and the role that it may play in metabolism.¹⁷ Because of the carbon grouping in position 4 it seems improbable that it is a degradation product of either purines or the pyrimidine nucleosides. The possibility that uracil might be the precursor of orotic acid is also unattractive. The conversion of uracil into orotic acid requires considerable energy as, in general, decarboxylations involve a decrease in free energy. One might thus expect that the synthesis of this product at the expense of considerable energy would necessitate its playing a rather important role in the organism regarding which, as yet, there is a lack of any positive information. A more plausible explanation is that which is suggested by the relationship of kynurenic acid to tryptophane.

Kynurenic acid (II) was first isolated from the urine of dogs by Liebig. Ellinger¹⁸ in 1904 definitely proved that it was a metabolic product of tryptophane. A number of mechanisms¹⁹ for the formation of kynurenic acid have been suggested; however, that proposed by Kotake and co-workers²⁰ is the most probable one. They have been able to isolate an intermediate—kynurenine (I)—that was converted either by an organism or barium hydroxide solution to kynurenic acid. They have offered the following scheme for the conversion of tryptophane to kynurenic acid.

An inspection of the structures of tryptophane and histidine shows that they have in common the grouping $\begin{array}{c} \text{—CCH}_2\text{CH(NH}_2\text{)COOH} \\ \parallel \\ \text{—NH—CH} \end{array}$ which, in the case of tryptophane, is directly involved in the conversion of the indole

¹⁷ It is possible that the orotic acid comes directly from the diet, that is, it might be a plant product. It has not as yet, however, been shown to occur in plants.

histidine and purines in animal metabolism but such results cannot be considered as invalidating the positive indications that have been observed."

In the absence of any experimental work on a relation between histidine and orotic acid, it must be emphasized that the above discussion is of a speculative nature but has been offered as it might prove of value in the elucidation of the intermediary metabolism of histidine and the anabolism of pyrimidines and purines.

I am greatly indebted to Dr. Reid T. Milner and Mrs. Mildred Sherman for carrying out the microanalyses recorded in this paper.

Experimental

In the course of various investigations on pyrimidines large quantities of uracil were required, so attempts were made to improve upon the method of Davidson and Baudisch. The modification consisted of reversing the procedure of Davidson and Baudisch with regard to the addition of urea and malic acid to fuming sulfuric acid, and heating to 85°. This was an improvement inasmuch as it cut down to one-half the time devoted to the experiment and also increased the yield by 20%.

Uracil-4-acetic Acid.—A large number of experiments was carried out under different experimental conditions. The success of the experiment was dependent upon the amount of sulfur trioxide in the fuming sulfuric acid and the temperature to which the reaction mixture was heated. Much variation of these two factors decreased the yield enormously. The following procedure was found to give the best results. To a 3-liter three-necked flask equipped with a stirrer was added 400 cc. of fuming sulfuric acid containing 15% sulfur trioxide. The acid was cooled to -10° and 80 g. of finely ground citric acid added at such a rate that the temperature did not rise above 5° ; this usually required about fifteen minutes. If the temperature rose to 10° , an appreciable amount of the acetone dicarboxylic acid was formed. Since this reaction took place with the evolution of heat, considerable trouble was experienced in attempting to lower the temperature. The remainder of the citric acid, 80 g., and 100 g. of finely ground urea were then quickly added; a vigorous reaction took place with considerable foaming and the evolution of large quantities of carbon monoxide and carbon dioxide. The temperature of the reaction mixture immediately rose to $55-60^{\circ}$ and then with the help of a burner was brought to 75° and held there for thirty minutes. The straw colored reaction mixture was cooled and poured on 1200 g. of ice. On inoculation, uracil-4-acetic acid started to separate out at once and was completely separated on standing in the ice box for two days, yield of crude dry product 42-43 g. It was decolorized with bone black and recrystallized from water. When a hot water solution was rapidly cooled it separated in the anhydrous condition (fine needles); on very slow cooling, as the monohydrate (stout prisms); it did not melt at 300° .

Anal. Calcd. for $C_6H_6N_2O_4 \cdot H_2O$: H_2O , 9.58. Found: H_2O , 9.61. Calcd. for $C_6H_6N_2O_4$: C, 42.34; H, 3.56; N, 16.47. Found: C, 42.46, 42.40; H, 3.63, 3.80; N, 16.44.

The conditions (acidic) of the above reaction preclude the preparation of the analogous thiopyrimidines by the substitution of urea by thiourea. The preparation of 4-methyluracil and thymine from ethyl acetoacetate and ethyl sodiumformylpropionate, respectively, was unsuccessful; the conditions of the experiment were widely varied with respect to the strength of the sulfuric acid and the temperature at which the reaction was carried out. It was also impossible to synthesize quinolones by heating aniline with either malic or citric acid in fuming sulfuric acid.

Uracil-4-methylacetate.—Large blocky plates, m. p. 220°.

Anal. Calcd. for $C_7H_8N_2O_4$: N, 15.22. Found: N, 15.41, 15.23.

Uracil-4-ethylacetate.—It separated from a 50% alcohol-water solution as colorless plates containing one molecule of water of crystallization and melting at 191–192° (Wheeler and Liddle reported 187–188°).

Anal. Calcd. for $C_9H_{12}N_2O_5$: H_2O , 8.33. Found: H_2O , 8.55. Calcd. for $C_8H_{10}N_2O_4$: N, 14.14. Found: N, 14.24, 14.27.

The Action of Barium Hydroxide on Uracil-4-acetic Acid.—When a solution of uracil-4-acetic acid was mixed with a solution of barium hydroxide, there was no immediate precipitate. However, if this was warmed or allowed to stand for some time, an insoluble barium salt precipitated. This behavior would seem to indicate that the pyrimidine has been altered. The barium salt was best obtained by the following procedure. Two grams of uracil-4-acetic acid was dissolved in 25 cc. of hot water and treated with a hot solution of 15 g. of barium hydroxide hydrate in 75 cc. of water. A clear solution resulted which, on standing overnight, precipitated star-like clusters of prisms, yield 2.9 g. It was insoluble in boiling water. The analysis agreed best with that of the barium salt of β -carbamidoglutaconic acid.

Anal. Calcd. for $C_6H_6O_6N_2Ba$: Ba, 42.47. Found: Ba, 42.25.

It dissolved readily in hot dilute hydrochloric acid and on cooling deposited uracil-4-acetic acid.

Orotic Acid.—A solution of 7.4 g. of uracil-4-acetic acid in 475 cc. of water was treated with 27.5 g. of potassium hydroxide and 78 g. of potassium ferricyanide. The reaction mixture was a dark reddish-brown, characteristic of this type of oxidation. It was allowed to stand at room temperature for twenty-two days; there was a slight decrease in the color of the solution at the end of this time. On acidification with acetic acid, considerable carbon dioxide was evolved and the brown potassium salt separated. This was allowed to stand for a few hours and filtered. The precipitate was recrystallized from boiling water and separated as star-like clusters of prisms; yield of potassium orotate 2.2 g. It was dissolved in water acidified with hydrochloric acid, cooled and filtered. The product after decolorization with bone black and recrystallization from water was compared optically with an authentic specimen. They were found to be identical. The crystals were biaxial negative, had a medium angle, and were strongly birefringent. The angle of extinction was either zero or very small. The low index was 1.66 and the high index was somewhat over 1.74.

Anal. Calcd. for $C_6H_4O_4N_2 \cdot H_2O$: H_2O , 10.35. Found: H_2O , 10.38. Calcd. for $C_6H_4O_4N_2$: C, 38.45; H, 2.58; N, 17.95. Found: C, 38.54, 38.60; H, 2.53, 2.56; N, 17.95, 17.99.

4,5-Dihydrouracil-4-ethylacetate.—A solution of 2.2 g. of ethyluracil-4-acetate in 100 cc. of warm alcohol was treated with 0.2 g. of platinum oxide and subjected to 42 pounds' pressure of hydrogen for twenty-four hours. The reaction at the end of this time was complete and the reduction product had crystallized out. It was brought into solution by heating and the platinum black removed by filtration. The filtrate was concentrated to 50 cc. and cooled. The 4,5-dihydrouracil-4-ethylacetate that separated was recrystallized from 25 cc. of ethyl alcohol, from which it separated as a mass of colorless prisms melting at 155–156°, yield 1.5 g.

Anal. Calcd. for $C_8H_{12}N_2O_4$: C, 47.98; H, 6.04; N, 14.00. Found: C, 47.92, 48.14; H, 6.16, 6.31; N, 14.08, 14.12.

3-Methyl-4,5-dihydrouracil.—This was prepared by reducing 6 g. of 3-methyluracil in the same manner as described above. The filtrate from the reduction mixture was

concentrated to 25 cc. and cooled; long thick needles separated. It was recrystallized from 25 cc. of hot alcohol, in which it was very soluble; m. p. 175–176°; the yield was very good.

Anal. Calcd. for $C_6H_8O_2N_2$: C, 46.84; H, 6.30; N, 21.87. Found: C, 47.15, 46.93; H, 6.27, 6.21; N, 21.89.

Summary

1. Uracil-4-acetic acid was prepared by treating urea and citric acid with fuming sulfuric acid. This pyrimidine ring was easily ruptured by barium hydroxide solution and yielded the barium salt of β -carbamido-glutaconic acid.

2. Orotic acid was synthesized by oxidizing uracil-4-acetic acid in alkaline solution with potassium ferricyanide.

3. The possibility that orotic acid may be an intermediate in the synthesis of purines from histidine has been discussed.

THE ACTION OF ACETIC ACID UPON CERTAIN CARBOHYDRATES¹

BY H. T. CLARKE AND H. B. GILLESPIE

RECEIVED JANUARY 23, 1932

PUBLISHED MAY 7, 1932

It has been shown² that native cellulose is esterifiable by the action of boiling acetic acid to a limited extent represented in the formula $C_{24}H_{39}O_{20}(COCH_3)$, whereas hydrated cellulose under the same conditions can yield an ester of the limiting composition $C_{24}H_{36}O_{20}(COCH_3)_4$. A study of the behavior of other carbohydrates toward acetic acid was therefore undertaken in the hope of finding a clue to the nature of the factors which tend to restrict the esterifiability of cellulosic hydroxyl groups.

Reducing carbohydrates, such as glucose and fructose, caramelize under the influence of boiling acetic acid alone or in the presence of sodium acetate. This applies also to the two non-reducing carbohydrates of the furanose type which have been examined, namely, sucrose and inulin—a finding which need occasion no surprise, in view of the well-established ease with which the five-membered ring of sugars may be opened by acid reagents. The cyclic structure of non-reducing glycosides of the pyranose type, on the other hand, withstands the action of boiling acetic acid, and such compounds ultimately yield fully esterified products. Thus α -methylglucoside, β -methylglucoside and α -methylmannoside are converted into the corresponding tetraacetates, while potato starch yields a “tri-acetate.” Similarly, mannitol is converted into its hexaacetate.

¹ Work supported by a research grant from The Chemical Foundation.

² C. J. Malm and H. T. Clarke, *THIS JOURNAL*, **51**, 274 (1929).

These experiments thus throw little light upon the problems raised by the case of cellulose, beyond adding indirect confirmation of the view advanced by Hess and Trogus³ that reactions with undissolved cellulose take place upon micellar surfaces.

The results obtained with potato starch nevertheless offer a certain intrinsic interest. This starch, which appears^{4,5,6} to contain 96 to 98% of β -amylose, is at first esterified on treatment with boiling acetic acid in much the same way (though far more rapidly) as is hydrated cellulose, yielding as a primary product a "monoacetate" $C_6H_9O_5(COCH_3)$. At this stage the starch becomes soluble in acetic acid, and esterification continues until the composition approximates that of the "triacetate" $C_6H_7O_5(COCH_3)_3$.

The general properties of the products at various stages are shown in Table I. The faculty of yielding a blue color with iodine disappears when about 6% of acetyl has been introduced, but returns on removal of the acetyl groups by alkaline hydrolysis, the regenerated starch closely resembling ordinary "soluble starch." Progressive esterification is

accompanied by increasing solubility in non-polar solvents, though in no case was solubility in 95% ethyl alcohol or ethyl ether observed. The lower esters are soluble in water; those of intermediate composition are soluble in aqueous ethyl alcohol of various ranges of concentration.

The products obtained by boiling potato starch with acetic acid alone for seventy-two hours and more yield, on alkaline hydrolysis, solutions possessing reducing power, the extent of this increasing with the duration of the treatment. This effect appears to be mainly due to the degrading action of the phosphoric acid which exists in combination with the 3% of α -amylose present in the starch, and may be largely suppressed by the addition of sodium acetate. In Table II are summarized the results of an experiment in which 110 g. of potato starch was boiled with 2200 cc. of acetic acid containing 1 g. of sodium acetate. The reducing power, estimated by the method of Folin and Wu,⁷ is expressed as percentage of glucose in the starch acetate; detectable reduction occurred only with products obtained on boiling for 192 hours or more. Addition of the sodium acetate markedly retards the rate of esterification.

Apart from its reducing properties, the final product of the action of boiling acetic acid upon potato starch resembles the starch triacetates obtained by the methods of other workers, particularly that of Tsuzuki.⁸ A triacetate of the same general properties, but lacking reducing power, may also be prepared by boiling the starch with acetic acid until it has dissolved and then completing the acetylation with acetic anhydride; we believe that this two-step process provides the most convenient method for preparing a starch triacetate. The products obtained by the methods of Haworth, Hirst and Webb⁵ and of Hess and Smith⁹ appear to be somewhat less degraded, inasmuch as they dissolve less readily and less completely in organic liquids.¹⁰

Table III shows the acetyl contents, reducing power and rotation in three solvents of triacetates obtained by various methods from the same

sample of potato starch. With the exception of the product prepared according to the directions of Hess and Smith, which gelatinized rather than dissolved in pyridine and chloroform, the solubilities were roughly the same in every case.

Experimental

The method of acetyl determination was in all cases essentially the same as that adopted for the cellulose derivatives.

α -Methylglucoside Tetraacetate.—A mixture of 50 g. of α -methylglucoside and 500 cc. of glacial acetic acid was boiled under reflux in an all-glass apparatus. After twenty-four hours the acid was distilled through a column until the temperature of the vapor reached 115°. The distillate amounted to 175 cc.; this volume of glacial acetic acid was replaced in the reaction mixture and the boiling under reflux continued for forty-eight hours longer. On distilling off the moist acid up to 115°, 125 cc. of distillate was obtained and a similar volume of fresh acid replaced. This process was continued, moist acid being removed at increasing intervals until boiling had been continued for a total time of 240 hours. The acetic acid was then removed by distillation under reduced pressure, the dark brown viscous residue was dissolved in ethylene chloride and this solution shaken with dilute potassium carbonate, filtered, separated and distilled under reduced pressure from the steam-bath. The residue, weighing 81 g., was distilled under 4 mm. pressure, when 64 g. of a pale yellow, very viscous oil passed over at 158–160°. This contained 47.7% acetyl (calculated for C₇H₁₀O₆(COCH₃)₄, 47.5%). This distillate remained liquid almost indefinitely at room temperature if not inoculated. On addition of a crystal of α -methylglucoside tetraacetate it crystallized very slowly, becoming completely solid only after a lapse of several months. It was, however, rapidly converted into the crystalline form by rubbing under cold water with a crystal of the tetraacetate. After one recrystallization from alcohol it melted at 100.5–101.5° and showed no depression of melting point when mixed with authentic α -methylglucoside tetraacetate. On hydrolysis of a sample of the sirupy product by means of alcoholic barium hydroxide, α -methylglucoside, m. p. 166°, was regenerated.

β -Methylglucoside Tetraacetate.—By heating 10 g. of β -methylglucoside and 200 cc. of acetic acid, as above, for 240 hours (acetyl content after 144 hours, 41.0%). Distilled product (b. p. 185–187° (5 mm.)) analyzed 46.9% acetyl (calcd. 47.5%) and crystallized on inoculation, m. p. 101–102.5°, from toluene; did not depress melting point of a sample prepared with acetic anhydride.

α -Methylmannoside Tetraacetate.—From 50 g. of α -methylmannoside and 500 cc. of acetic acid for 144 hours; b. p. 204–207° (5 mm.), contained 47.6% acetyl; m. p. 65–66° from alcohol; mixed m. p. 65–66°.

Mannitol Hexaacetate.—From mannitol and 10 parts of acetic acid for 240 hours;

crystallized on concentrating the reaction mixture; m. p. 119° ; ¹¹ acetyl 59.2% (calcd. 59.5%).

Acetylation of Potato Starch.—Commercial potato starch, containing about 12% of moisture, was suspended in twenty times its weight of glacial acetic acid and heated to boiling. Continual mechanical stirring was necessary to avoid bumping. The water was removed at the outset and then at frequent intervals, the distillates being replaced by equal volumes of glacial acetic acid. Samples were withdrawn periodically; during the first eighteen hours the undissolved portions were separated by centrifuging and well washed with acetic acid; the solution was freed of the bulk of the acetic acid by distillation under reduced pressure and the residue precipitated by means of 95% ethyl alcohol. Subsequently, samples of the homogeneous solution were merely concentrated under reduced pressure and precipitated with alcohol. The products were repeatedly washed with alcohol until free of acetic acid and then dried *in vacuo* over phosphorus pentoxide.

Rotations were determined on samples obtained after twelve to seventy-two hours' boiling; those secured after longer periods were too dark to read. The material produced by boiling for 384 hours in the presence of sodium acetate (Table II) was subjected to fractional precipitation, and so obtained free of color. The dark solution in acetic acid was slowly diluted with water until about half of the dissolved ester had precipitated. The supernatant liquor, containing 53% of acetic acid, was practically colorless; on dilution with much water it yielded Fraction 1. The first precipitate was then dissolved in ethyl acetate and ether added to the solution until the supernatant portion was colorless. This process was repeated six times with the dark coagulum. The clear solution was concentrated to a small volume and treated with excess of ether, when Fraction 2 precipitated. The dark, gummy residue was discarded. The properties of Fractions 1 and 2 are shown in Table III.

Preparation of Starch Triacetate.—A suspension of 50 g. of potato starch (containing 12% moisture) in 1000 cc. of acetic acid containing 1 g. of sodium acetate was boiled under reflux, with stirring, for twenty-eight hours, aqueous acetic acid being periodically removed and replaced with anhydrous acid. The volume was then reduced to 500 cc. by distillation under diminished pressure. The residual clear solution was mixed with 150 cc. of 95% acetic anhydride and 75 cc. of pyridine, and boiled for six hours. The volume was then reduced, by distillation under diminished pressure, to about 200 cc., and the sirupy residue was poured into a liter of ice water. The granular precipitate was well washed with water and then with alcohol, and dried *in vacuo* over phosphorus pentoxide. The starch triacetate (44.5% acetyl) weighed 76.6 g. (98% of the theoretical amount); it was readily soluble in acetic acid, chloroform, dioxane, ethyl acetate and pyridine, almost completely in acetone, slightly in benzene, insoluble in ethyl alcohol, ethyl ether and water. Other properties are recorded in Table III.

Summary

On treatment with boiling acetic acid:

1. Reducing carbohydrates and the non-reducing furanoses, sucrose and inulin, caramelize.
2. Mannitol and non-reducing glycosides of the pyranose type become fully esterified.
3. Potato starch yields a continuous series of amorphous acetates, the acetyl content of which increases with time of treatment and reaches

¹¹ Bouchardat, *Ann. chim.*, [5] 6, 107 (1875), reports 119° .

a limit with the introduction of three acetyl groups for each glucose residue.

**THE REACTIVITY OF ATOMS AND GROUPS IN ORGANIC
COMPOUNDS. XII. THE PREPARATION AND PROPERTIES
OF MIXED ALIPHATIC ETHERS WITH SPECIAL REFERENCE
TO THOSE CONTAINING THE TERT.-BUTYL RADICAL**

BY JAMES F. NORRIS AND GEORGE WAYNE RIGBY¹

RECEIVED JANUARY 26, 1932

PUBLISHED MAY 7, 1932

The influence of structure on the lability of bonds in organic molecules is shown in a marked degree by compounds which contain a tertiary radical. For example, the *tert.*-butyl alcohol reacts with concentrated hydrochloric acid over 200,000 times as rapidly as does *n*-butyl alcohol. It seemed of interest, therefore, to determine whether or not the facts accumulated in connection with the study of the lability of the carbon-oxygen and of the hydrogen-oxygen bonds in alcohols² by means of rates of reaction could be utilized in devising improved methods for the preparation of ethers and esters. A study of these classes of compounds from the standpoint of their relative reactivities with reagents would lead to a fuller understanding of the influence of structure on the lability of atomic linkings.

Certain *tert.*-butyl alkyl ethers have been prepared by the commonly used methods, but the results, as measured by yields and purity, have been far from satisfactory. One of the methods used is based on the view that the mechanism of ether formation from alcohols involves the intermediate formation of an alkyl sulfuric acid and consequently concentrated sulfuric acid was used to bring about the reaction between *tert.*-butyl alcohol and ethyl alcohol. Since the acid rapidly converts the tertiary alcohol into polymers of isobutylene, the yields obtained were very small.

When the Williamson synthesis is used difficulties are encountered as the result of the unique behavior of compounds containing a tertiary radical. Sodium *tert.*-butylate is formed very slowly and reacts very slowly with alkyl halides. The chief reaction between tertiary alkyl halides and the sodium derivatives of normal alcohols is the removal of hydrogen halide from the alkyl halide. When these methods are used the yields are also very small.

¹ From the thesis of George Wayne Rigby submitted in partial fulfillment of the requirement for the degree of Doctor of Philosophy, 1930.

It seemed probable that advantage could be taken of the great reactivity of the hydroxyl group in *tert.*-butyl alcohol and of the alcoholic hydrogen in primary alcohols in the preparation of mixed ethers through the catalytic influence of dilute acids in the way used to prepare esters.

A series of experiments showed that mixed ethers containing the *tert.*-butyl and primary alkyl radicals could be readily prepared in this way. The best yield of *tert.*-butyl ethyl ether, 95% of the theoretical, was obtained when one mole of the tertiary alcohol was added slowly to a boiling mixture of two moles of ethyl alcohol and a 15% aqueous solution of sulfuric acid, the volume of which was about 2.5 times that of the ethyl alcohol. The vapors were passed through a column at such a rate that the minimum boiling mixture of the ether and water was allowed to pass over. Other mixed *tert.*-butyl ethers containing primary radicals were prepared in a similar way.

The fact that the hydrogen of the hydroxyl group in secondary alcohols is much less reactive than the corresponding atoms in primary alcohols necessitated a change in conditions where an attempt was made to prepare *tert.*-butyl isopropyl ether. When 15% sulfuric acid was used the reaction was very slow with the resultant formation of large quantities of isobutylene. In order to increase the rate, a greater molecular ratio of the secondary alcohol was used and to decrease the decomposition of the tertiary alcohol an aqueous solution of sodium hydrogen sulfate was employed as the catalyst. The yield of the mixed ethers was 82% of the theoretical.

The formation of mixed ethers containing secondary and primary alkyl radicals was next investigated. The reactivity of the hydroxyl group in secondary alcohols is very much less than that of the same group in tertiary alcohols. The results of the study of the preparation of ethers of this class were found to be in accord with this fact. Much higher concentrations of sulfuric acid were required to bring about the reaction. The product in all cases was a mixture of the three possible ethers. The differences between the reactivities of the hydroxyl groups in primary and secondary alcohols is not sufficiently great to lead to the formation of only the mixed ether as was the case when *tert.*-butyl alcohol was used. By varying the amount and the concentration of sulfuric acid the ratio of mixed ether to simple ethers could be changed. In one experiment with *sec.*-butyl alcohol and ethyl alcohol when 50% sulfuric acid was used the total yield of the three ethers amounted to 49.5% of the theoretical of which 8% was diethyl ether and 72.5% *sec.*-butyl ethyl ether. The tendency for a larger proportion of the mixed ether to form is in accord with the differences in reactivity of the hydroxyl group and the hydrogen atoms in primary and secondary alcohols.

A number of ethers were prepared by the methods outlined above and by the application of the Williamson synthesis, which gave satisfactory

results when primary and secondary alcohols were used. Especial care was taken to obtain the ethers in a very pure condition since the physical constants recorded in the literature are not concordant. The boiling points, densities and indices of refraction were determined and are recorded in the experimental part of this paper.

One of the chief objects of this research was the study of ethers containing two different alkyl radicals to determine if their reactions are in accord with the relative reactivities of the carbon-oxygen bonds present as determined by a study of the rates at which these bonds react when present in the corresponding alcohols. It was expected that the ethers containing the *tert.*-butyl radical would show unusual reactivity, and the results proved to be in accord with the expectation. The reactions studied were those with hydrochloric acid, sulfuric acid, acetic acid, acetyl chloride, benzoyl chloride and acetic anhydride.

The aliphatic ethers are more or less soluble in solutions of hydrochloric acid. It has been shown that certain ethers form molecular compounds with hydrogen chloride at low temperatures.³ It is highly probable that these addition products are oxonium compounds. It is possible that such compounds are formed when ethers dissolve in aqueous solutions of hydrochloric acid. It is to be expected that the tendency of the oxygen atom in ethers to form oxonium compounds would vary with the radicals which they contain. A quantitative study of the solubilities of the isomeric butyl ethyl esters was accordingly made. The solubility of an ether is determined by the concentration of the acid and the temperature. The results are shown in Figure 1. The relative solubilities of the butyl ethyl ethers in the same concentration of acid and at a definite temperature vary markedly with the structure of the butyl radicals. The solubilities show a striking relationship with the labilities of the bond linking the butyl radicals to the oxygen atom, the more labile the bond the greater the solubility. If oxonium compounds are present in the solution, it follows that the tendency for oxygen to exhibit oxonium valencies is determined by the lability of the bond linking the oxygen atom to carbon—the more reactive this bond, as measured by the rate at which it is broken by hydrochloric or hydrobromic acid, the greater the tendency to form oxonium compounds with hydrochloric acid.

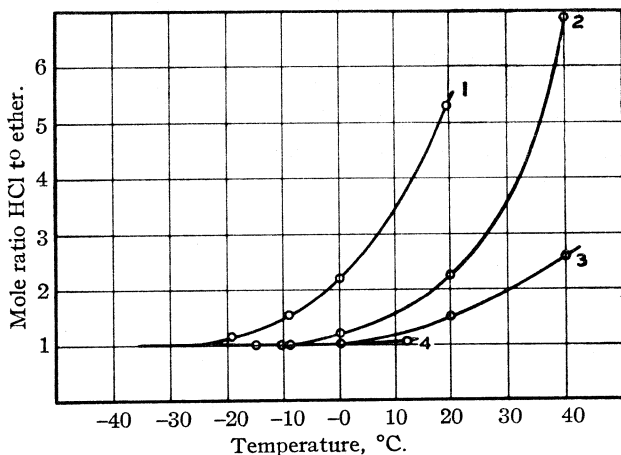

It is a striking fact that with decreasing temperature the molecular ratio of the ether to hydrogen chloride in the solution approaches one to one.

The isomeric butyl ethyl ethers react extremely slowly at room temperature with concentrated hydrochloric acid, with the exception of the *tert.*-butyl compound. When *tert.*-butyl ethyl ether and concentrated hydrochloric acid in the molecular ratio of one of the former to five of the latter are mixed the ether dissolves, but is rapidly converted into *tert.*-butyl

³ Maass and McIntosh, *THIS JOURNAL*, **34**, 1274-1290 (1912).

chloride, which separates. When such a mixture was allowed to stand overnight 99% of the theoretical quantity of the chloride was obtained.

In order to get a definite idea of the effect of the structure of the butyl radical on the lability of the carbon-oxygen linkage in these ethers, the rates of the reactions with hydrochloric acid at 25° were measured. The ethers were dissolved in the acid in a vessel so constructed that the volume of the chloride formed could be measured. The tubes were sealed, placed in a thermostat and the volume of chloride noted from time to time. Density determinations of the products showed that they were the pure butyl chloride corresponding to the ether used.

(1) *Iso*-butyl ethyl ether, (2) *n*-butyl ethyl ether, (3) *sec.*-butyl ethyl ether, (4) *tert.*-butyl ethyl ether.

Fig. 1.—Solubilities of isomeric butyl ethyl ethers in 35.21% hydrochloric acid.

There was an induction time before the chlorides separated. In order to have the results comparable zero time was taken when a measurable amount of chloride had separated—1 to 3% of the theoretical amount. When velocity constants were calculated on the assumption that the reaction was one either of the first or second order, the values of the constants obtained dropped off rapidly after 50% of the calculated amount of chloride had separated. In order to avoid postulation in regard to the order of the reaction as the cause of the change in the value of the constant, the results are represented in Table I as time required for the several reactions to proceed to the extent of 25%. These values serve to compare the relative reactivities of the bonds involved.

Experiments 1, 2 and 3 show the effect of change in structure of the butyl radical on the rate at which the carbon-oxygen bond is broken by concentrated hydrochloric acid with the consequent formation of the

TABLE I
FORMATION OF BUTYL CHLORIDES FROM THE ISOMERIC BUTYL ETHYL ETHERS

No.	Compound	Temp., °C.	Mol. ratio compd. to HCl	Concn. of HCl, %	Time in hours to 25% con- version

6	<i>Tert.</i> -butyl ethyl ether	.0	1:10	26.75	0.83

butyl chlorides. The order of reactivity is the same as that previously obtained in the study of the rates at which the corresponding butyl alcohols react with aqueous solutions of hydrobromic acid, with the formation of the butyl bromides.

The tertiary butyl ethers react so rapidly with concentrated hydrochloric acid at 25° that it was necessary to study them under different conditions. Experiments 4, 5 and 6 show the effect of the change from H to CH₃ and to C₂H₅ on the lability of the bond linking the carbon atom of the butyl radical to oxygen. The results bring out an important point. When the alcoholic hydrogen atom in methyl alcohol and that in ethyl alcohol are replaced by a *p*-nitrobenzoyl radical, the former reacts about twice as rapidly as the latter.^{2c} The results in the table show that when similar ethers of these alcohols are converted into the respective alcohols the ethyl ether reacts almost five times as rapidly as the methyl ether. When RO—H is converted into RO—R' the reaction is more rapid when R is CH₃ than when it is C₂H₅. When RO—R' is converted into RO—H the reverse is true. These results bring out the important fact, often overlooked, that the relative lability of a bond, as measured by rates of reactions, is not a fixed property of the radical but is determined both by the nature of the radical itself and the nature of the group with which it is brought into combination in the reactions studied. It has been shown, for example, that *tert.*-butyl chloride reacts much more rapidly with water than does *n*-butyl chloride, but that the tertiary chloride reacts more slowly with potassium iodide than does the normal chloride.⁴ The relative lability of the carbon-chlorine bonds in the two chlorides is different when measured by different reagents. In one case chlorine is replaced by hydroxyl and in the other by iodine. It should be noted in this connection that *tert.*-butyl alcohol reacts rapidly with hydrochloric acid, whereas it reacts much more slowly with hydriodic acid. These facts and those of a similar nature must be considered in comparing the relative activating effects of radicals on atomic linkings.

The action of sulfuric acid with the ethers was studied. One mole

⁴ Conant and Hussey, *THIS JOURNAL*, **47**, 476 (1925).

of normal or isobutyl ethyl ether dissolves in one mole of concentrated sulfuric acid. When ice is added to the mixture the ethers are recovered unchanged. All the *tert.*-butyl ethers are quickly decomposed by concentrated sulfuric acid. If the temperature of the mixture is allowed to rise the higher polymers of isobutylene are obtained. If the reactants are cooled to 0° and mixed so that the temperature does not rise, the polymer formed is almost entirely tri-isobutylene. When heated with dilute sulfuric acid (10%) the tertiary ethers are slowly hydrolyzed; at the same time some isobutylene is formed.

All the butyl ethyl ethers react at room temperature with acetyl chloride in the presence of zinc chloride. Two reactions occur: the one yielding *n*-butyl chloride and ethyl acetate takes place to the extent of 34%, and the one yielding ethyl chloride and *n*-butyl acetate, 58%. Both the ethyl-oxygen and the *n*-butyl-oxygen bonds are broken. At 60° the chief products are ethyl chloride and butyl acetate. The effect of increase in temperature on the relative labilities of the two bonds is marked in the case of the two normal radicals.

At room temperature isobutyl ethyl ether gives chiefly isobutyl acetate and ethyl chloride. At 80° the reaction produced a number of products among which were *tert.*-butyl chloride and isobutylene. The bond broken in the ethers containing secondary and tertiary radicals is the one between these radicals and oxygen. *Sec.*-butyl ethyl ether at room temperature in the presence of zinc chloride gave only *sec.*-butyl chloride and ethyl acetate. *Tert.*-butyl ethyl ether under these conditions reacted rapidly and gave a theoretical yield of *tert.*-butyl chloride and ethyl acetate.

Acetic anhydride did not react with the ethers at room temperature or at 100° in the absence of a catalyst. Reaction did take place slowly at room temperature in the presence of zinc chloride. In all cases the pure acetates containing the two radicals were formed.

New methods of preparing *tert.*-butyl acetate which yielded the compound in a state of high purity are described in the experimental part of this paper. The ester was converted rapidly by concentrated hydrochloric acid into *tert.*-butyl chloride and acetic acid. The preparation and properties of *tert.*-butyl benzoate, prepared for the first time, also are given.

The work shows clearly the practical value from the standpoint of the synthesis of organic compounds of the results obtained from the study of the reactivity of bonds as measured by rates of reactions. They also give additional information in regard to the mechanism of ether formation under the influence of sulfuric acid. The older view of Williamson that an alkyl sulfuric acid is formed as an intermediate product does not appear to apply in the case, at least, of the ethers containing the *tert.*-butyl radical. Experiments showed that there was no evidence of the formation of an

alkyl sulfuric acid when ethyl alcohol alone, or mixed with *tert.*-butyl alcohol, was heated at 70° with 15% sulfuric acid. The solutions when cooled and carefully titrated showed the presence of the amount of sulfuric acid used. The fact that primary, secondary, and tertiary alcohols required different strengths of acid to bring about the formation of ethers is in accord with the relative stabilities toward water of the addition products of the alcohols and sulfuric acid.

Even in the case of a primary alcohol it is doubtful whether or not the mechanism involves the intermediate formation of an alkyl sulfuric acid. It has been shown by Barbet⁵ that diethyl ether is best prepared, with a yield of 95% or better, when alcohol is passed through concentrated sulfuric acid heated to 140°. When alcohol vapor was passed into ethyl sulfuric acid at the same temperature the yield was 70% and much sulfur dioxide was evolved.

Experimental Details

Materials Used.—The most convenient way to purify the four butyl alcohols is to fractionate their constant boiling mixtures with water. The products obtained in this way, which boiled within 0.5°, were dried, first with potassium carbonate and then with lime, and were fractionated. The alcohols obtained boiled within 0.1°.

In some of the larger scale preparations involving the use of *tert.*-butyl alcohol, a commercial sample of the alcohol was used, which was found to contain 10% of water but was otherwise quite pure.

The acetic anhydride when distilled in an all-glass apparatus boiled at 137°. The acetyl chloride was obtained from a so-called "practical" sample. Seven distillations with precautions against superheating were necessary to obtain a product that boiled constantly at 50.9° (corr.) at 760 mm. and had the density d_4^{25} 1.0922. The chloride reacted very slowly when added to a large volume of cold water. A sample remained in contact with bright sodium chips for nine months at room temperature without apparent action. Care was used in the preparation because the constants given in the literature are not concordant and because it was found that the presence of impurities in the chloride affected its behavior with the ethers studied. The boiling point obtained agrees with that given by Thorpe.⁶

The benzoyl chloride used boiled at 198° at 760 mm. and at 77° at 2 mm. pressure.

The alkyl halides were prepared from the alcohols and aqueous solutions of the acids and gave constants in agreement with the literature.

Determination of Boiling Points.—Distillations were carried out through columns of the Vigreux type fitted with condensing heads and covered with insulating material. In the final purifications and the determinations of boiling points vacuum jacketed spiral columns of the Davis⁷ type were used.

In the distillations heat was supplied from an electric heater connected in series with a slide-wire rheostat. Attention was paid to the heat furnished and the amount of reflux. Under the conditions used the flat portion of a distillation curve of the pure compound included almost the entire sample, with a variation in temperature of less than 0.05°.

⁵ Barbet, British Patent 100,406 (1915) and 101,724 (1916).

⁶ T. E. Thorpe, *J. Chem. Soc.*, 37, 188 (1880).

⁷ Davis, *Ind. Eng. Chem., Anal. Ed.*, 1, 61 (1929).

The distillation curve of a sample of *tert.*-butyl ethyl ether serves to detect the presence of a trace of *tert.*-butyl alcohol, which can be separated only with great difficulty. The shape of the curve makes it possible to detect as little as 0.05% of the alcohol and a smaller quantity of water.

The physical constants of the *tert.*-butyl ethers reported in the literature show that the compounds have not been hitherto prepared in a state of purity. Samples prepared by the published methods gave the constants reported, but when distillation curves were made the presence of impurities was evident. The behavior of the ethers with certain reagents is affected by the presence of these impurities.

The careful study of the problem leads to the conclusion that accurate distillation curves made with an efficient column are a better criterion of purity than density determinations. Bennett and Philip,⁸ who worked with *tert.*-butyl methyl ether, have expressed the opinion that density is a better criterion of purity than boiling point.

All accurate boiling points were determined with short range "normal glass" Anschütz thermometers, graduated to 0.2°. They were compared with thermometers calibrated by the Reichsanstalt and by the United States Bureau of Standards. Corrections were made for atmospheric pressure.

Determinations of Density.—These determinations were made with a glass-stoppered Sprengel tube having a capacity of about 13.5 cc. The temperature was $25 \pm 0.005^\circ$. The weights were checked against a set calibrated by the United States Bureau of Standards. Densities are reported to the fourth decimal place and appear to be accurate to 2 in this place.

Preparation of *Tert.*-butyl Ethers.—*Tert.*-butyl methyl ether was made by the methods described in the literature. The preparation from sodium *tert.*-butoxide and methyl iodide⁹ gave a yield of 60% of a product which boiled at 53–55°, and was difficult to purify. The yield, by similar methods, of the ethyl ether was 50%, of the *n*-propyl ether 25% and the *n*-butyl ether 65%.

Tert.-butyl ethyl ether was also prepared by the action of a small amount of concentrated sulfuric acid on the two alcohols.¹⁰ The yield of the crude ether was 48%.

Since these methods were not entirely satisfactory, the effect of other catalysts was studied. Potassium hydrogen sulfate gave good results. When a mixture of 10 cc. of commercial 90% *tert.*-butyl alcohol, 6 cc. of ethyl alcohol (95%) and 1.3 g. of powdered potassium hydrogen sulfate was distilled very slowly, the yield of crude ether (b. p. 64 to 70°) was 91% of the theoretical.

The best practical method of preparation was found to involve the use of dilute sulfuric acid as a catalyst. In this way the methyl, ethyl, *n*-propyl and *n*-butyl ethers derived from *tert.*-butyl alcohol were prepared. The details of the preparation of one ether by this process which is new, are given below.

Preparation of *Tert.*-butyl Ethyl Ether.—In a 3-liter flask are mixed 988 cc. of distilled water and 98 cc. of pure sulfuric acid (sp. gr. 1.84). When the solution has cooled, 0.5 g. of powdered silicic acid to ensure regular boiling and 450 cc. of 95% ethyl alcohol are added. The flask is attached to a 2-bulb Wurtz column by means of a stopper which carries a 100-cc. separatory funnel and a thermometer. A thermometer is inserted in the column, which is connected with a condenser and heat is applied. When the temperature in the flask reaches 70°, 100 cc. of *tert.*-butyl alcohol (90%) is added from the funnel. The product is distilled slowly, care being taken by the regulation of the supply of heat to keep the temperature of the issuing vapors at 64°, which is the boiling point of the minimum boiling mixture of the ether and water. From 0.5 to 0.75

⁸ Bennett and Philip, *J. Chem. Soc.*, 1930 (1928).

⁹ Henry, *Rec. trav. chim.*, **23**, 329 (1904).

¹⁰ Mamontroff, *J. Russ. Phys.-Chem. Soc.*, **29**, 230 (1897).

cc. of distillate collects per minute. From time to time 25 cc. of the butyl alcohol is added until the total amount is 350 cc. The final distillate measures about 460 cc.

The product is washed in a separatory funnel repeatedly with 25 cc. of water. From ten to fifteen treatments are necessary to remove the last traces of *tert.*-butyl alcohol. When all the alcohol has been removed, the two layers separate instantly and completely, leaving the ether layer absolutely clear. The product is shaken with potassium carbonate and finally dried by refluxing over sodium for one hour. The pure ether boils at 73.1°. The yield is 95% of the theoretical calculated from the *tert.*-butyl alcohol used.

In the above directions the alcohols are in ratio of approximately one of butyl alcohol to two of ethyl alcohol. The excess of the latter serves to hasten the reaction and diminishes the formation of isobutylene. An efficient column is not advisable during the preparation as it holds back the ether and partial decomposition takes place in the flask. The distillation should not be stopped and the mixture left overnight because 15% sulfuric acid in the presence of ethyl alcohol slowly converts *tert.*-butyl alcohol, on standing, into isobutylene and its polymers.

If larger quantities of the crude ether are to be separated from *tert.*-butyl alcohol, it is preferable to redistil the product with a large amount of water and collect a second time the minimum boiling mixture of the ether.

A saturated aqueous solution of *tert.*-butyl ethyl ether contains at 25° 1.3% and at 0° 3.4% of the ether.

According to Henry⁹ *tert.*-butyl methyl ether reacts slowly with sodium. This observation was no doubt due to the fact that the sample studied contained some of the butyl alcohol from which it was prepared. A sample of the highly purified ether was heated with sodium in a sealed tube at 90° for six weeks; only slight superficial action on the metal was observable.

The preparations of the following mixed ethers containing the *tert.*-butyl radical were made according to the directions just given, using the alcohols in the molecular ratio of one of the tertiary to two of the primary alcohol: methyl, *n*-propyl, and *n*-butyl. On account of the boiling points, the tertiary alcohol must be added very slowly in the preparation of the *n*-butyl ether. The yields of the purified ethers were CH₃, 95%; C₂H₅, 95%; *n*-C₃H₇, 68%; *n*-C₄H₉, 51.5%.

Preparation of Tert-butyl Isopropyl Ether.—Isopropyl alcohol reacts with *tert.*-butyl alcohol more slowly than does *n*-propyl alcohol. When the ether is prepared under the conditions used in making the *n*-propyl compound, the yield is reduced as the result of the formation of isobutylene by the long continued action of the dilute sulfuric acid. It was found that an aqueous solution of sodium hydrogen sulfate gave excellent results. The ether was prepared as follows.

In a 500-cc. flask with three necks were placed 120 cc. of water, 22 g. of sodium hydrogen sulfate, 70 cc. of isopropyl alcohol and 0.5 g. of silicic acid. In one neck of the flask was placed a 2-bulb Wurtz column, in the second a dropping funnel and in the third a thermometer which extended into the liquid. Heat was applied and 50 cc. of *tert.*-butyl alcohol (90%) allowed to drop in slowly during ten hours. The distillate boiling at 70–71° was collected. The yield of the crude ether was 82% of the theoretical. The product was purified in the way described above. The ether boiled at 87.6° and had the density 0.7365²⁵.

Henry¹¹ reports that this ether boils at 75–76° and has the density 0.7734²⁰. We obtained a product that boiled constantly at 77.2° and had the density 0.7543²⁵. It reacted rapidly with sodium, however. After repeated treatment with the metal the ether had the boiling point and density recorded above. It was not affected by sodium.

¹¹ Henry, *Rec. trav. chim.*, **23**, 329 (1904).

***n*-Butyl Ethyl Ether.**—This ether was prepared from sodium butylate and ethyl bromide. It was purified by shaking with a mixture of one volume of sulfuric acid and one volume of water and by fractional distillation. Its physical properties are given in Table II.

Preparation of Sec.-butyl Ethyl Ether.—This compound has not been described. It was prepared as follows: to 1 liter of anhydrous *sec.*-butyl alcohol (b. p. 99.5°) was added 8.5 g. of sodium. When the metal had dissolved, 25 cc. of pure ethyl bromide was added and the mixture allowed to stand for two days. Ten grams of sodium was added and later 25 cc. of ethyl bromide and the mixture allowed to stand for two days. The process was repeated until 175.5 cc. of ethyl bromide had been used. The product was distilled and the part boiling between 80 and 85° collected. This was mixed with 1 liter of water, distilled, and the portion boiling at 67–72° collected. This was redistilled with water and the portion boiling at 71–72° collected. The ether was separated, dried, refluxed with sodium and fractionated. The physical properties are given in Table II.

Preparation of Sec.-butyl Ethyl Ether with Sulfuric Acid as Catalyst.—The formation of an ether from a secondary and a primary alcohol requires a much higher concentration of sulfuric acid than is needed when one of the reactants is tertiary alcohol. A series of experiments was made with 25 cc. of *sec.*-butyl alcohol and 25 cc. of ethyl alcohol. When 100 cc. of 25% sulfuric acid was used, no ether was formed. With 400 cc. of 40% acid the yield was 5.5%. With 300 cc. of 50% acid the yield of the three ethers was 49.5% calculated as the secondary ether formed. When 150 cc. of 75% acid was used the crude ethyl ether in the product amounted to 38%. No ethers were formed when a 15% solution of sodium hydrogen sulfate was used. The products in all cases contained the three possible ethers, the mixed ether predominating. This fact is in accord with the labilities of the bonds involved.

Isobutyl Ethyl Ether.—This ether was prepared from isobutyl alcohol (b. p. 107.9), sodium and ethyl bromide. The yield of purified ether was 66%.

Preparation of Isopropyl Ethyl Ether.—In the study of the formation of this ether from the alcohols and sulfuric acid the following results were obtained.

When 200 cc. of isopropyl alcohol, 300 cc. of ethyl alcohol and 534 cc. of sulfuric acid (75%) were used the yield of ethers formed was 77.5% calculated as isopropyl ethyl ether. The mixture on fractionation was shown to contain 34% diethyl ether and 61% isopropyl ethyl ether. A series of experiments showed that the yield of ethers decreased with decrease in the strength of the acid, but that the proportion of mixed ether increased.

When 25 cc. of each alcohol was slowly distilled with 200 cc. of 50% acid, the yield of the product, which was shown to be chiefly the mixed ether, was 33.8%.

The isopropyl ethyl ether boiled at 53–54° and had the density 0.720₄²⁵.

In all the preparations the reaction was very slow. Fourteen hours were required to complete the experiments noted above.

Preparation of Tert.-butyl Acetate.—This compound was prepared by a number of different methods. The method described in the literature¹² furnishes a yield of impure ester of 45% of the theoretical.

When 10 cc. of *tert.*-butyl alcohol, 14 cc. of acetic acid and 10 cc. of 15% sulfuric acid were used, the yield of ester was 24%.

When 100 cc. of the alcohol, 78.5 cc. of acetic acid and 100 cc. of an aqueous solution of sodium hydrogen sulfate were used, the yield of ester before purification was 65%.

Acetic anhydride gave better results. The ester can be prepared conveniently from commercial 90% *tert.*-butyl alcohol as follows: 100 cc. of the alcohol, 100 cc. of acetic anhydride and 1 g. of zinc dust are refluxed for two hours. The product is dis-

¹² Kondakow, *Bull. soc. chim.*, [3] 7, 583 (1892).

tilled and the portion boiling below 98° is refluxed with 50 cc. of acetic anhydride. The yield (94%) was 114 cc. of the ester which boiled at 97.8°. Equally good results were obtained when zinc was replaced by magnesium.

Significant results using anhydrous *tert.*-butyl alcohol were as follows: 10 cc. of the alcohol and 10 cc. of the anhydride reacted under the influence of 0.004 g. of anhydrous zinc chloride. On standing for twelve hours at room temperature, or by refluxing for one hour, the yield of crude ester was the theoretical.

The preparation of the ester from the alcohol and acetyl chloride furnished an explanation of the behavior of tertiary alcohols with acyl chlorides. It has been concluded in the past that tertiary alcohols behave abnormally in their reactions with acyl chlorides in that tertiary halides and acetic acid are formed instead of an ester and hydrochloric acid.

In the presence of a molecular quantity of dimethylaniline, a 98% yield of the ester was obtained. In the absence of the amine and when heated to boiling for ten minutes, 50% ester and 50% chloride were formed. When the temperature was kept below 20°, a quantitative yield of the chloride was formed.

These facts show that the primary reaction between the alcohol and the acyl chloride is the formation of the ester. The latter subsequently reacts with the hydrochloric acid and is converted into the butyl chloride. The ester is rapidly converted into the chloride by concentrated hydrochloric acid.

When *tert.*-butyl acetate (5 cc.) was refluxed with methyl alcohol (1 cc.) and 2 drops of concentrated sulfuric acid, the chief product was methyl acetate.

Preparation of *Tert.*-butyl Benzoate.—Twenty cc. of anhydrous *tert.*-butyl alcohol, 24.4 cc. of pyridine and 16.8 cc. of benzoyl chloride were mixed. Heat was evolved and white crystals separated. The next day the mixture was treated with water and the oil dried and distilled at 2 mm. pressure. The yield of the ester was 80%. Its physical properties are given in Table II.

The compound decomposed completely into isobutylene and benzoic acid when distilled at atmospheric pressure. Dilute sulfuric and hydrochloric acids hydrolyze it rapidly; it appears to be quite stable toward a solution of sodium hydroxide.

TABLE II

Chemical Reactions of the Mixed Ethers with Acetic Acid.—None of the highly purified ethers reacted with glacial acetic acid at room temperature or when heated at 100° for forty-eight hours. The reported formation of the acetate from *tert.*-butyl ethyl ether was no doubt due to the presence of the alcohol in the ether used. In the presence of a trace of sulfuric acid this ether was converted almost quantitatively by acetic acid into ethyl acetate and *tert.*-butyl alcohol. The latter may not have been the primary products of the reaction since it was shown, as stated above, that *tert.*-butyl acetate is converted by methyl alcohol in the presence of sulfuric acid into methyl acetate and the tertiary alcohol.

At room temperature there was no reaction between any of the ethers and acetic acid in the presence of zinc chloride.

With Acetyl Chloride.—There was no reaction between the ethers and acetyl chloride in the absence of a catalyst. All the mixed ethers reacted slowly with acetyl chloride at room temperature in the presence of anhydrous zinc chloride.

When *n*-butyl ethyl ether was used and the reactants were allowed to stand for twenty-one days in a sealed tube, the products obtained were separated and determined. The reaction which led to the formation of ethyl acetate and normal butyl chloride took place to the extent of 33.6% when measured by the amount of the former product and 36.6% by the amount of the latter. The reaction by which *n*-butyl acetate and ethyl chloride were formed was found to be 58.3% from the former and 58.6% from the latter. At 60° the reactions by which ethyl acetate and *n*-butyl acetate were formed took place to the extent of 23 and 76%, respectively.

When isobutyl ethyl ether was allowed to stand with acetyl chloride and zinc chloride at room temperature for sixteen days, the ethyl acetate reaction took place to the extent of 22.8% (from ethyl acetate formed) and 21% (from *n*-butyl chloride) and the *n*-butyl acetate reaction 65% (from acetate) and 64% (from ethyl chloride).

When *sec.*-butyl ethyl ether was used the products, after twelve days, were as follows: 95.6% ethyl acetate and 76.5% secondary butyl chloride.

Tert.-butyl ethyl ether reacted rapidly at room temperature. After standing overnight the theoretical yield of ethyl acetate and *tert.*-butyl chloride was obtained. The same result was obtained when the mixture was heated for ten minutes.

With Benzoyl Chloride.—All the ethers reacted at room temperature with benzoyl chloride in the presence of zinc chloride. The reaction was slower than with acetyl chloride. Analogous products were obtained—*n*-butyl ethyl ether gave 86% *n*-butyl benzoate, after standing for sixty-one days; the isobutyl ether 62.5% isobutyl benzoate; the *sec.*-butyl ether 98% *sec.*-butyl chloride and the *tert.*-butyl ethyl ether, on standing for twelve hours, gave 99% of *tert.*-butyl chloride and ethyl benzoate.

With Acetic Anhydride.—The ethers did not react at room temperature. In the presence of zinc chloride the results were as follows: *n*-butyl ethyl ether in sixty-two days, 13% each of butyl acetate and ethyl acetate; the isobutyl ether in sixty-two days, 8% of the two acetates; the *sec.*-butyl ether in forty-three days, 23%; *tert.*-butyl ethyl ether, overnight, 82%. In all cases the two acetates were formed in equivalent amounts.

Zinc dust can be used instead of zinc chloride. When equivalent quantities of *tert.*-butyl ethyl ether and acetic anhydride were refluxed with zinc dust for two hours, a quantitative yield of the two esters was obtained.

Zinc Chloride as Catalyst.—Zinc chloride does not act as a true catalyst in the reaction described above. When acetic acid, acetyl chloride, or acetic anhydride was used, the chloride at first dissolved and later zinc acetate separated in crystalline form. The salt was identified by its melting point, 342.5–343° (uncorr.) and by its properties. The reactions brought about by zinc chloride took place when zinc acetate or magnesium dust was used.

At room temperature zinc chloride does not decompose the mixed ethers, but forms a compound with them. When a solution of zinc chloride in *tert.*-butyl methyl ether which had stood for eighty-one days was opened there was no evidence of the presence of an unsaturated hydrocarbon. When the excess of the ether was removed an oil was obtained which decomposed at 80° and yielded a gas which showed the properties of methyl chloride. When the evolution of gas ceased, the product was heated to 165°; at this temperature there was a second evolution of gas, which proved to be an unsaturated hydrocarbon. When some of the liquid obtained by heating the addition product to 165° was treated with concentrated hydrochloric acid, *tert.*-butyl chloride was formed.

Summary

1. The results of the previous study of the relative reactivities of the hydroxyl group and the hydrogen of this group in the three classes of alcohols have been utilized in devising new and improved methods for the preparation of certain mixed ethers.
2. Mixed ethers which contain the *tert.*-butyl radical and a methyl, ethyl, *n*-propyl, *n*-butyl or isopropyl radical can be prepared conveniently with satisfactory yields, when the two alcohols are heated with a 15% aqueous solution of sulfuric acid or of sodium hydrogen sulfate.
3. In order to prepare ethers containing a secondary and a primary radical, the strength of the acid to effect the reaction must be 50% or greater. In all cases the three possible ethers are formed, the mixed ether being produced in the largest amount.
4. The results indicate that the mechanism of the formation of ethers with the use of sulfuric acid does not involve the intermediate formation of an alkyl sulfuric acid. An addition product of an alcohol and sulfuric acid is probably the active material involved.
5. A number of mixed ethers have been prepared in a very pure condition and their physical constants determined.
6. The behavior of a number of mixed ethers with hydrochloric acid, sulfuric acid, acetic acid, acetyl chloride, benzoyl chloride and acetic anhydride has been studied. The results obtained are in accord with labilities of the bonds involved, as determined by rates of reactions.
7. *Tert.*-butyl acetate and benzoate have been prepared by new and improved methods and their behavior studied.

PARA-HALOGEN-PHENACYL ESTERS OF THE NORMAL FATTY ACIDS

BY CARRIE GUTMAN MOSES AND E. EMMET REID

RECEIVED FEBRUARY 10, 1932

PUBLISHED MAY 7, 1932

A number of these esters were prepared by Judefind and Reid¹ and others by Hann, Reid and Jamieson.² It has seemed desirable to fill the gaps in the series both for the sake of completeness and to study the relations of the melting points of the various derivatives to each other.

It is well known that the melting points of the normal hydrocarbons and of their simple derivatives show alternations as we go from one member to the next in a series. It has recently been found by Malone and Reid³ that the melting points of the 3,5-dinitrobenzoates of the normal alcohols show the same phenomenon. It was of interest to see whether this would also be found to be true with these derivatives of the acids.

In order to have strictly comparable data, all of the derivatives have been fully prepared whether they had been made previously or not. On recrystallization most of the esters appear as brilliant white plate-like

TABLE I

crystals. The acetic esters are tinged with yellow which becomes more pronounced with exposure to the light. The formic esters suffer this change more quickly and melt with decomposition.

The melting points are given in Table I and are plotted in the figure.

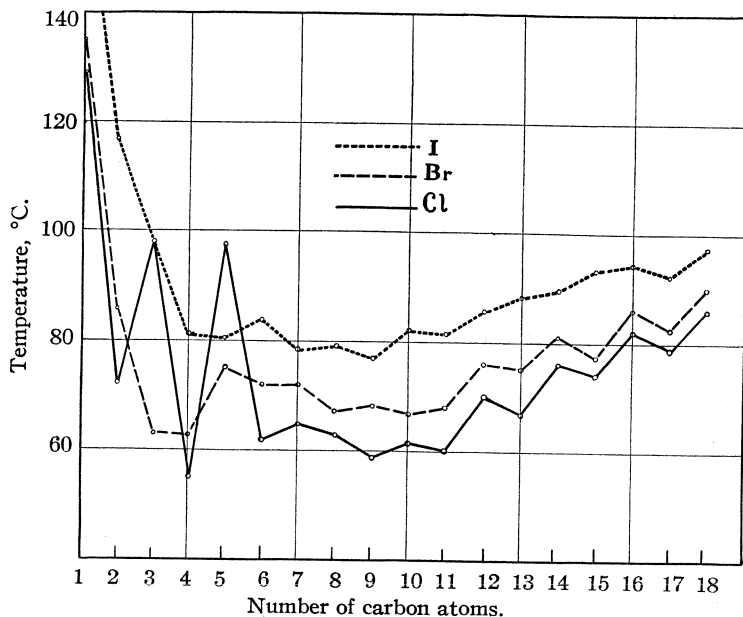

Fig. 1.

The chloro series shows well-defined alternations, the swings being very wide for the first six compounds. At the eighth compound there is a reversal of the alternation, the odd-numbered compounds melting higher up to that point and after it the even. In the bromo series this reversal takes place at the eleventh member. In the iodo series there is a well-defined alternation from five to twelve and again from fifteen to eighteen but in the reversed sense. In this series the butyric and valeric esters melt at nearly the same point while in the bromo series this is true of the propionic and butyric.

It seemed of interest to compare the melting points of the *p*-bromophenacyl derivatives from mixtures of palmitic and stearic acids with that of the margaric acid derivative. The results are given in Table II.

The derivative from 2:1 mixture does not change its melting point on recrystallization. That of 1:2 derivative approximates that of the margaric acid derivative, 82.6°, but is not sharp and is raised on recrystallization. The appearance of the derivative from the mixture is very different from one of the pure acids.

TABLE II

MELTING POINTS OF *p*-BROMOPHENACYL ESTERS OF PALMITIC AND STEARIC ACIDS AND THEIR MIXTURES

Palmitic	Stearic	Crude, °C.	Recryst., °C.
1	0		86.0
0	1		90.0
1	1	79.0	80.4
1	2	82.5	83.8
2	1	80.6	80.6

Experimental

The methods used were substantially those already described in the papers quoted. The one uniformly giving best results was found to be the neutralization of a weighed amount of the acid with slightly less than the theoretical amount of sodium alcoholate, heating (the higher acids) until all was in solution, testing for acidity with slightly moistened litmus paper (the solution must be slightly acid) and, if necessary, adding a minute quantity of the acid itself or, in case of the higher acids, hydrochloric acid. The alcoholate was made by adding three grams of sodium to one liter of 95% alcohol. An amount of the reagent calculated for the quantity of base used was then introduced and the whole refluxed for an hour. With the lower acids a small quantity of water was required but the esters of the higher acids precipitated from the alcoholic solution on cooling under the tap.

The precipitate was filtered rapidly with suction, well washed with cold alcohol, dilute alcohol and water and then dried between filter paper for at least twenty-four hours, after which the melting point was taken and the compound recrystallized. This procedure was repeated until a constant melting point was obtained. The melting points were determined in a Thiele tube filled with mineral oil, using a thermometer corrected by the Bureau of Standards.

Summary

The para chloro, bromo and iodophenacyl esters of the normal acids from acetic to stearic have been prepared and their melting points compared.

Alternation in the melting points appears in all these series.

STEREOCHEMISTRY OF DIPHENYL. XXI.
RESOLUTION OF 2,4,6,2',4',6'-HEXACHLORO-
3,3'-DICARBOXYDIPHENYL^{1,2}

BY JULIUS WHITE AND ROGER ADAMS

RECEIVED FEBRUARY 11, 1932

PUBLISHED MAY 7, 1932

In previous papers two compounds have been described in which all four groups in the 2,2',6,6' and one compound in which three groups in the 2,2',6 positions in diphenyl have been substituted by the same groups. These are 2,4,6,2',4',6'-hexamethyl-3,3'-diaminodiphenyl (I), 2,4,6,2',4',6'-hexanitro-3,3'-dicarboxydiphenyl (II) and 2,4,6,2',4'-pentanitro-3-carboxydiphenyl (III).³ Since each ring in itself is asymmetrically substituted in these compounds, enantiomorphic forms of each are capable of existence and were actually produced in the laboratory.

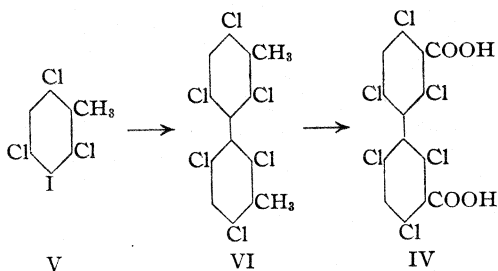

Another example of this type is described in this communication in which the chlorine atom is present in the positions adjacent to the diphenyl linkage. The substance prepared was 2,4,6,2',4',6'-hexachloro-3,3'-dicarboxydiphenyl (IV). It was resolved through the brucine salt. The *d*-active compound was stable to racemization in boiling alcohol, glacial acetic acid and, as the sodium salt, in boiling water.

The compound was synthesized by starting with trichloro-*m*-toluidine and converting it first to 2,4,6-trichloro-3-iodotoluene (V). By means of copper powder 2,4,6,2',4',6'-hexachloro-3,3'-dimethyldiphenyl (VI) was produced. By means of a mixture of potassium permanganate and nitric acid, in a sealed tube at 180°, 2,4,6,2',4',6'-hexachloro-3,3'-dicarboxydiphenyl resulted.

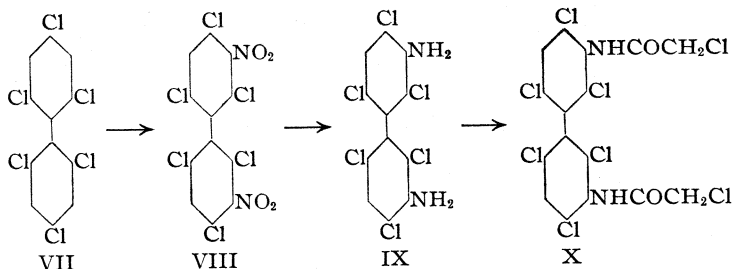

¹ For the last papers in this field see: Woodruff and Adams, *ibid.*, **54**, 1977 (1932); Hill and Adams, *ibid.*, **53**, 3453 (1931); Bock and Adams, *ibid.*, **53**, 3519 (1931).

² This communication is a portion of an abstract of a thesis submitted by Julius White in partial fulfillment of the requirements for the degree of Doctor of Philosophy in Chemistry at the University of Illinois.

³ Moyer and Adams, *THIS JOURNAL*, **51**, 630 (1929); Bock, Moyer and Adams, *ibid.*, **52**, 2054 (1930); Stearns and Adams, *ibid.*, **52**, 2070 (1930).

Before the above procedure was developed a number of interesting but unsuccessful experiments were performed to obtain compounds containing a properly substituted chlorinated diphenyl with salt-forming groups. In particular 2,4,6,2',4',6'-hexachlorodiphenyl (VII) was readily nitrated to the 3,3'-dinitro-2,4,6,2',4',6'-hexachlorodiphenyl (VIII) and this in turn was reduced to the corresponding diamine (IX).

The diamine, on account of the lack of basicity of the amino group, could not be converted into stable salts. To introduce salt-forming groups the diamine was converted to the di-chloroacetamido compound (X) and then this product was treated with ammonia and amines to replace the halogens. No well-characterized compounds were obtained from the di-chloroacetamido compound.

Experimental

2,4,6-Trichloro-*m*-toluidine.—The general method of Bures and Rubes⁴ was employed. To 90 g. of *m*-toluidine in a 3-liter round-bottomed flask connected with a mechanical stirrer and a reflux condenser was added cautiously 1 liter of acetic anhydride. A continuous stream of chlorine was passed in. The reaction mixture became warm but no external cooling was necessary. At the end of six to eight hours the reaction was complete as indicated by the reaction mixture becoming cold and a portion of the chlorinated product separating out. Water was slowly and carefully added to decompose the excess of acetic anhydride and to precipitate completely the product from solution. It was purified from hot ethyl alcohol and melted at 180–181°. To this acetylated derivative 250 g. of 50% sulfuric acid was added and the trichloro-*m*-toluidine was steam distilled. No recrystallization was necessary, m. p. 77–78°.

1-Iodo-2,4,6-trichloro-3-methylbenzene.—A solution of 65 g. of trichloro-*m*-toluidine⁴ in 400 cc. of concentrated sulfuric acid was cooled to 15–20°, stirred, and

⁴ Bures and Rubes, *Coll. Czechoslov. Chem. Communications*, **1**, 648 (1929).

32.5 g. of solid sodium nitrite was slowly added. The mixture was stirred for one hour after addition of the nitrite and then carefully poured into a very large excess of cracked ice. A solution of 65 g. of potassium iodide dissolved in 125 cc. of water was now slowly added with stirring. The solution was warmed to 40° until no more oxides of nitrogen were liberated and the excess of iodine was removed by the addition of sodium bisulfite. The crude iodo product was recrystallized from acetone as white crystals, m. p. 95–97°.

Anal. Calcd. for $C_7H_4Cl_3I$: Cl + I, 72.3. Found: Cl + I, 72.12.

2,4,6,2',4',6'-Hexachloro-3,3-dimethyldiphenyl.—A mixture of 50 g. of the trichloriodotoluene and 50 g. of copper bronze was heated on an oil-bath for three hours at 235–250°. The mixture was cooled and extracted with hot ethyl alcohol several times. Crystals of hexachlorodimethyldiphenyl separated on cooling and could be recrystallized from alcohol as white crystals, m. p. 119–120°.

Anal. Calcd. (Parr Bomb): Cl, 54.75. Found: Cl, 54.92.

2,4,6,2',4',6'-Hexachloro-3,3'-dicarboxydiphenyl.—The hexachlorodimethyldiphenyl was oxidized to the hexachlorodicarboxydiphenyl by means of potassium permanganate and nitric acid (sp. gr. 1.15–1.20). The general method of Rupp⁵ was used. A mixture of 5 g. of hexachlorodimethyldiphenyl, 3.2 g. of solid potassium permanganate, 23 cc. of concentrated nitric acid and 25 cc. of water was placed in a Carius tube and heated on an oil-bath at 175–185° for eight hours. After the tube was cooled, the reaction mixture was treated with water and the precipitate filtered. The acid was dissolved in very dilute sodium hydroxide and reprecipitated with dilute hydrochloric acid. It was further purified by recrystallization from a mixture of ethyl acetate and petroleum ether; white crystals, m. p. 318–320°.

Anal. Calcd. for $C_{14}H_4O_4Cl_6$: C, 38.4; H, 0.89. Found: C, 38.76; H, 0.83.

Resolution of 2,4,6,2',4',6'-Hexachloro-3,3'-dicarboxydiphenyl.—To 450 cc. of anhydrous ethyl acetate containing 5.384 g. (0.0136 mole) of anhydrous *l*-brucine was added 3.0675 g. (0.0068 mole) of hexachlorodicarboxydiphenyl dissolved in 350 cc. of anhydrous ethyl acetate. An immediate precipitate resulted. This was allowed to stand overnight. It was then filtered and washed with a small amount of anhydrous ethyl acetate. The weight of the salt was 3.4 g. melting at 209°.

Rotation. 0.2050 g. made up to 15 cc. with ethyl alcohol (95%) at 25° gave $\alpha_D -0.20^\circ$; $l = 2$; $[\alpha]_D^{25} -7.3^\circ$. The salt was purified by washing with boiling ethyl acetate but with no change in melting point or rotation.

Anal. Calcd. for $C_{60}H_{56}Cl_6N_4O_{12}$: C, 56.66; H, 4.53; Cl, 17.08; N, 4.49. Found: C, 56.93; H, 4.68; Cl, 16.79; N, 4.58.

The mother liquor was evaporated to 100 cc. and allowed to stand overnight. More salt separated. It weighed 1.2 g. The mother liquor was further concentrated *in vacuo* to 50 cc. and allowed to stand overnight. The weight of this last fraction of salt was 3.7 g., m. p. 206–210°.

Rotation. 0.2050 g. made up to 15 cc. with ethyl alcohol (95%) at 25° gave $\alpha_D -0.49^\circ$; $l = 2$; $[\alpha]_D^{25} -15.5^\circ$. The salt was recrystallized from a mixture of ethyl acetate and petroleum ether, melting again at 206–210° and with no change in rotation.

Anal. Calcd. for $C_{60}H_{56}Cl_6N_4O_{12}$: C, 56.66; H, 4.53. Found: C, 57.13; H, 4.74.

***d*-2,4,6,2',4',6'-Hexachloro-3,3'-dicarboxydiphenyl.**—The pure dibrucine salt was dissolved in chloroform and shaken with dilute hydrochloric acid several times. The chloroform layer was then separated and shaken with dilute sodium hydroxide. The

⁵ Rupp, *Ber.*, 29, 1625 (1896).

sodium hydroxide layer was separated and treated with dilute hydrochloric acid. The acid which precipitated out was filtered off and recrystallized from a mixture of ethyl acetate and petroleum ether. It was found to be brucine-free and melted at 293–294°. Further recrystallization did not change the melting point.

Rotation. 0.4442 g. made up to 15 cc. in ethyl alcohol (95%) at 25° gave $\alpha_D +0.10$; $l = 2$; $[\alpha]_D^{25} +1.7^\circ$. The acid was again recrystallized and the rotation taken. 0.3234 g. made up to 15 cc. in ethyl alcohol (95%) at 25° gave $\alpha_D +0.08^\circ$; $l = 2$; $[\alpha]_D^{25} +1.8$.

Further recrystallization did not alter the rotation.

Anal. Calcd. for $C_{14}H_4O_4Cl_6$: C, 38.4; H, 0.89. Found: C, 38.79; H, 1.08.

l-2,4,6,2',4',6'-Hexachloro-3,3'-dicarboxydiphenyl.—The more soluble salt was hydrolyzed in a manner similar to the less soluble salt. The acid thus obtained was recrystallized from a mixture of ordinary ethyl acetate and petroleum ether, and melted at 292–293°.

Rotation. 0.4425 g. made up to 15 cc. in ethyl alcohol at 25° gave $\alpha_D -0.09^\circ$; $l = 2$; $[\alpha]_D^{25} -1.52^\circ$.

The acid was recrystallized and the rotation again taken.

0.4204 g. made up to 15 cc. in ethyl alcohol (95%) gave $\alpha_D 0.096^\circ$; $l = 2$; $[\alpha]_D^{25} -1.7^\circ$.

Racemization Experiments

1. A sample of the *d*-acid was dissolved in ordinary ethyl alcohol and refluxed in a flask with a ground-glass joint for eight hours. No change in rotation was observed.

Rotation. 0.4464 g. made up to 15 cc. with ethyl alcohol at 25° gave $\alpha_D +0.11$; $l = 2$; $[\alpha]_D^{25} +1.8^\circ$.

2. A second sample of the *d*-acid was dissolved in glacial acetic acid and the rotation taken. 0.4520 g. of acid in 15 cc. of glacial acetic acid at 25° gave $\alpha_D +0.18$; $l = 2$; $[\alpha]_D^{25} +3.01$.

3. After refluxing for periods of two and six hours, respectively, no change in rotation occurred.

4. 0.4005 g. of acid was exactly neutralized with 36.3 cc. of 0.0554 *N* sodium hydroxide and the solution concentrated *in vacuo* to dryness. This was made up with water to 15 cc. of 25° and the rotation taken. $\alpha_D +0.22$; $l = 2$; $[\alpha]_D^{25} +4.01$ based on the sodium salt of 0.4005 g. of acid.

The water solution was then refluxed at intervals of three hours, two hours and nine hours. No change in rotation was observed.

2,4,6,2',4',6'-Hexachloro-3,3'-dinitrodiphenyl.—To 60 g. of fuming nitric acid (sp. gr., 1.50) cooled in an ice-bath was added slowly with rapid stirring 10 g. of hexachlorodiphenyl.⁶ The temperature was maintained at 0° and stirring continued for one hour after all of the hexachlorodiphenyl had been added. The mixture was poured into cracked ice and the precipitate was purified by recrystallization from hot alcohol, m. p. 230–231°.

Anal. Calcd. for $C_{12}H_2Cl_6N_2O_4$ (Parr Bomb): Cl, 47.23. Found: Cl, 47.38.

2,4,6,2',4',6'-Hexachloro-3,3'-diaminodiphenyl.—To a solution of 2 g. of 2,4,6,2',4',6'-hexachloro-3,3'-dinitrodiphenyl in 50 g. of glacial acetic acid and 5 g. of water was added gradually with constant stirring 5 g. of zinc dust. The mixture was allowed to heat up from the heat of reaction (about 80°). It was then heated on a water-bath for fifteen minutes to complete the reaction. The mixture was diluted with water and filtered. The amine was separated from the excess of zinc by several extractions with

⁶ Ullmann, *Ann.*, **332**, 40 (1904).

hot 95% ethyl alcohol. It was purified by recrystallization from hot 60–70° petroleum ether; white crystals, m. p. 167.5–168.5°.

Anal. Calcd. for $C_{12}H_5Cl_6N_2$ (Parr Bomb): Cl, 54.50. Found: Cl, 54.88.

2,4,6,2',4',6'-Hexachloro-3,3'-chloroacetaminodiphenyl.—A mixture of 2 g. of the hexachlorodiaminodiphenyl and an excess of chloroacetyl chloride was refluxed for several hours on a steam cone. The mixture was then cooled and the excess of chloroacetyl chloride was decomposed with cracked ice. The product was recrystallized from 70–80° petroleum ether as white crystals, m. p. 125–126°.

Anal. Calcd. for $C_{16}H_5Cl_6N_2O_2$ (Parr Bomb): Cl, 52.2. Found: Cl, 52.3.

Attempts to condense hexachlorodiaminodiphenyl with *d*-camphorsulfonic acid and oxymethylenecamphor, respectively, proved unsuccessful.

Summary

1. 2,4,6,2',4',6'-Hexachloro-3,3'-dicarboxydiphenyl was prepared by the condensation of 1-iodo-2,4,6-trichloro-3-methylbenzene with copper and oxidation of the product.

2. The product was resolved through the brucine salt. The active forms were stable to ordinary methods of racemization.

THE ACTION OF MERCURY ON ORGANIC IODIDES. I. THE FORMATION OF METHYLMERCURIC IODIDE AND BENZYL MERCURIC IODIDE¹

BY J. LEWIS MAYNARD

RECEIVED FEBRUARY 12, 1932

PUBLISHED MAY 7, 1932

Introduction

For over eighty years it has been known that when mercury is allowed to stand in the sunlight with methyl or ethyl iodide, reactions occur with the formation of organomercuric iodides, $RHgI$, and certain gaseous products.² In addition to the instances cited, the direct action of mercury with organic iodides has been noted only in the cases of allyl iodide,³ methylene iodide and iodoform,⁴ and propargyl iodide.⁵ With the higher saturated alkyl iodides it is possible that a very slow reaction with mercury takes place, but no accurate data are available.⁶ Up to the present time,

¹ A part of this material has been presented in a thesis submitted to the University of Minnesota.

no other halogen alkyls or any aryl halides have been found to react with mercury to give organomercuric halides.

Preliminary Observations.—The preparation of a large quantity of methylmercuric iodide, CH_3HgI , was carried out by the action of mercury on methyl iodide in the sunlight. During the course of this work it was noted that in each batch there was a lag of from three to ten hours before the presence of methylmercuric iodide could be detected in the reaction mixture. The first observable mercury compound to be formed was invariably found to be mercurous iodide, its presence being detected by the appearance of green specks on the surface of the layer of mercury. The formation of this compound resulted from the action of an excess of mercury on iodine liberated photochemically from methyl iodide. After a lapse of time of a few minutes, methylmercuric iodide in steadily increasing concentration was found in solution in the methyl iodide. A reason was sought for the failure of the organomercuric iodide to appear until after the formation of mercurous iodide.

Discussion and Further Observations.—From the observed behavior of a mixture of mercury and methyl iodide it was concluded that mercurous iodide facilitated the formation of methylmercuric iodide.⁷ Acceptance of this conclusion demanded that there be no lag in the formation of methylmercuric iodide on exposure of a mixture of mercury, mercurous iodide and methyl iodide to the sunlight. This proved to be the case, for, after a few minutes of exposure of such a mixture, methylmercuric iodide was found to be present. Since the mixture did not react in the dark, and since pure mercurous iodide alone reacted with methyl iodide in the light in the absence of an excess of mercury, it was decided that the mercury necessary for the reaction in either case was produced by the photochemical decomposition of mercurous iodide. Thus: $\text{Hg}_2\text{I}_2 \rightarrow \text{Hg} + \text{HgI}_2$. The metal formed in this manner was in a finely divided condition.

The conclusion reached was supported by further experimental evidence. It must be noted at this point that the course of the reactions between mercury and methyl iodide was the same whether the source of light was the sun, a mercury vapor lamp or a carbon arc. In this study the arc was selected as the most convenient source of illumination. Light from this source brought about the liberation of iodine from methyl iodide, and, with an excess of massive mercury present, the formation of mercurous iodide took place. This was followed shortly by the formation of methylmercuric iodide. If, however, the photochemical decomposition of the methyl iodide was prevented by passing the light through a screen of cod liver oil, neither mercurous iodide nor methylmercuric iodide was formed during an exposure of seventy-two hours. It was found also that the photochemical decomposition of methyl iodide was not necessary for the

⁷ Cf. Maynard and Howard, *J. Chem. Soc.*, 123, 963 (1923).

reaction between mercury and the alkyl iodide, because a mixture of the latter with mercurous iodide reacted behind a screen of cod liver oil to form the organomercuric iodide. Mercurous iodide was photochemically decomposed in the shielded system.

Conclusions.—Thus it has been shown that, while the reaction between massive mercury and methyl iodide must be extremely slow, the finely divided metal reacted readily with the alkyl iodide. This was further demonstrated by the fact that finely divided mercury prepared by the action of ammonium hydroxide on mercurous chloride reacted with methyl iodide protected by a screen of cod liver oil. From this experiment it seemed logical to conclude that mercurous iodide functioned solely as a source of supply of finely divided mercury in the reactions previously noted.

The Action of Mercury on Benzyl Iodide.—With a convenient source of finely divided mercury at hand, it has seemed of interest to attempt to broaden the scope of this action between the metal and an organic iodide by its application to other iodides. Benzyl iodide was the first to be selected for this study, and it was found to react readily and completely with finely divided mercury to form benzylmercuric iodide. The latter compound has been prepared previously in a pure condition only by the action of mercuric iodide on mercury dibenzyl.⁸

This organomercuric iodide has proved to be interesting because work now in progress shows that it reacts with acid chlorides, a reaction not previously noted with a compound of the type RHgI . Studies of the action of mercury with other organic iodides are also being made.

Experimental Part

Reaction between Mercury and Methyl Iodide in the Sunlight.—A stoppered Pyrex test-tube containing 10 g. of mercury and 20 g. of methyl iodide was exposed to direct sunlight at a temperature of 30° . Frequent tests over a period of three hours showed an absence of methylmercuric iodide. At the end of this time the first speck of mercurous iodide had appeared on the surface of the mercury. Ten minutes later, evaporation to dryness of the methyl iodide left a small quantity of a slightly yellowish crystalline solid. This was recrystallized from a small volume of alcohol, and was identified as methylmercuric iodide by its melting point of 144° . The experiment was repeated five times, and although the period of lag varied considerably because of the obscuring of the sun by clouds during parts of the exposure, in no case was the presence of methylmercuric iodide detected previous to the appearance of mercurous iodide.

The use of larger quantities of reactants, 45 g. of mercury and 80 g. of methyl iodide, yielded 30.9 g. of methylmercuric iodide after an exposure of one week in a sealed Carius tube. This represented a yield of 80.7% of that calculated for 45 g. of mercury reacting in the following way

⁸ Wolff, *Ber.*, **46**, 64 (1913).

The iodine appearing in reaction (1) was formed by the photochemical decomposition of methyl iodide. It can be seen that when the mercurous iodide reacted as shown in equation (2) it was regenerated from the mercuric iodide and the excess of massive mercury present. The methylmercuric iodide was obtained from the reaction product by extraction with boiling benzene.

The Action of a Mixture of Mercury, Mercurous Iodide and Methyl Iodide in the Sunlight.—To a solution of 1 g. of iodine in 10 ml. of methyl iodide contained in a Pyrex test-tube there was added 13 g. of mercury. The mixture was shaken vigorously to effect the formation of mercurous iodide, and was then exposed to the sunlight at a temperature of 31°. A sample taken after a five-minute exposure showed methylmercuric iodide to be present in solution in the methyl iodide. The organomercuric iodide was identified by its melting point of 144°.

The Action of Mercurous Iodide on Methyl Iodide in the Sunlight.—A mixture of 5 g. of pure yellow mercurous iodide⁹ and 10 ml. of methyl iodide was exposed to direct sunlight at 28° in a stoppered Pyrex test-tube. After a ten-minute exposure methylmercuric iodide was found in solution in the methyl iodide.

Mercury and Methyl Iodide in a Shielded System.—A stoppered clear quartz test-tube containing a mixture of 5 g. of mercury and 10 ml. of methyl iodide was suspended in cod liver oil contained in a square, clear quartz container. This system was then exposed to light from a carbon arc placed 25 cm. from the outer quartz container. The light passed through a 3-mm. layer of cod liver oil and at the end of a seventy-two hour exposure the contents of the test-tube remained unchanged. The temperature was 34°.

Mercurous Iodide and Methyl Iodide in a Shielded System.—A mixture of 10 g. of mercurous iodide and 15 ml. of methyl iodide was placed in a stoppered quartz test-tube shielded by a 3-mm. layer of cod liver oil. At the end of a fifteen-minute exposure to light from the arc, methylmercuric iodide was found in solution in the methyl iodide. The temperature was 34°.

Finely Divided Mercury from Mercurous Chloride.—Mercurous chloride was prepared by precipitating it from a 0.1 *N* solution of mercurous nitrate with dilute hydrochloric acid. The precipitate was washed repeatedly with water, and then added in small portions to a concentrated solution of ammonium hydroxide. Mechanical stirring maintained a fine state of division of the product. The black insoluble material was filtered off, washed with water and then dried at room temperature.

Reaction of the Black Precipitate with Methyl Iodide.—A mixture of 10 g. of the black precipitate prepared in the preceding experiment and 15 ml. of methyl iodide was exposed in the shielded system to light from the arc at a temperature of 34°. At the end of a ten-minute exposure enough methylmercuric iodide was obtained for a melting point determination.

The Preparation of Benzylmercuric Iodide.—To 5 g. of iodine dissolved in 10 ml. of alcohol there was added 30 g. of mercury. The mixture was thoroughly shaken until a dark green product was obtained. This was sucked free from alcohol on a Büchner funnel, and then sealed up with 15 g. of benzyl iodide in a short length of Carius tubing. The tube was exposed to light from the arc for three hours at a temperature of 50°. The reaction product was found to be free from benzyl iodide, for no lachrymatory action was noted on opening the tube. The benzylmercuric iodide was extracted with boiling alcohol. The yield of pure product, melting at 117°, was 26 g. or 94.5% of that calculated for 15 g. of benzyl iodide.

⁹ Prepared according to directions given in Mellor, "A Comprehensive Treatise on Inorganic and Theoretical Chemistry," Longmans, Green and Co., London, 1923, Vol. IV, p. 896.

The author wishes to acknowledge with appreciation the kindly advice and criticism given by Dr. William H. Hunter during the course of this investigation.

Summary

1. Methylmercuric iodide is not formed from methyl iodide and mercury on exposure to light until after the appearance of mercurous iodide in the reaction mixture.

2. Finely divided mercury produced by the photochemical decomposition of mercurous iodide enters into reaction readily with methyl iodide to form methylmercuric iodide.

3. The action of mercury with organic iodides to form organomercuric iodides has been extended to benzyl iodide.

THE PINACOL-PINACOLIN REARRANGEMENT. THE REARRANGEMENT OF UNSYMMETRICAL AROMATIC PINACOLS

By W. E. BACHMANN

RECEIVED FEBRUARY 23, 1932

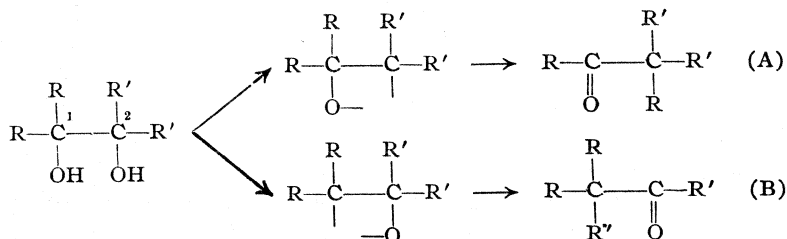

PUBLISHED MAY 7, 1932

The rearrangement of symmetrical mixed pinacols of the type $RR'(OH)CC(OH)RR'$ has received considerable attention because the reaction offers an excellent method for determining the relative migration aptitudes of groups. The groups R and R' are in structurally identical positions, and the mode of water elimination from the molecule is therefore immaterial; the principal factor determining the course of the rearrangement is the relative migration aptitudes of the groups. Moreover, it has been shown that in such pinacols each group may be assigned a definite numerical value which represents the migration aptitudes of that group relative to some other group. The most recent series¹ showing the migration aptitudes of a number of groups with respect to the phenyl group taken as unity is the following: anisyl, 70 or more; *p*-tolyl, 15; *p*-biphenyl, 11.5; *p*-isopropylphenyl, 9; *p*-ethylphenyl, 5; *m*-tolyl, 1.95; *p*-fluorophenyl, 1.85; *p*-iodophenyl, 1; phenyl, 1; *p*-bromophenyl, 0.7; *p*-chlorophenyl, 0.66; *m*-methoxyphenyl, 0.2; *o*-tolyl, *o*-bromophenyl and *o*-chlorophenyl, very small. It has further been demonstrated that by means of these values it is possible to calculate the course of rearrangement of a symmetrical pinacol containing two of these groups.

We have now undertaken an investigation to determine whether the same series holds in the rearrangement of unsymmetrical pinacols of the type $RR(OH)CC(OH)R'R'$. Various investigators have pointed out that in pinacols of this type the nature of the rearrangement depends practi-

¹ Bachmann and Moser, *THIS JOURNAL*, **54**, 1124 (1932).

cally entirely on the possible mode of elimination of water and not at all on the migration aptitudes of the groups. From the following formulation it is apparent that two isomeric pinacolins are possible, the nature of which depends on the particular H and OH that are eliminated.

Meerwein² considered that formation of A is an indication that the OH group attached to C² is held more loosely than the OH of C¹. The strength with which the OH group is held to the carbon atom is considered to be dependent upon the nature of the radicals R and R'; if the radicals attached to a particular carbon atom have large affinity capacities, then the OH will be held proportionately loosely to that carbon atom. Formation of A exclusively is, therefore, an indication that R' has a greater affinity capacity than R. On this basis, the rearrangement offers a method for studying affinity capacities and not migration aptitudes of groups. The view is held by some that the elimination of the hydroxyl group occurs preferentially from that carbon atom to which are attached the groups with the greatest capacity for electron release.³ Whether these views can be applied also to the unsymmetrical aromatic pinacols is not known because no simple aromatic pinacol of this type has been prepared previous to this investigation. Meerwein studied mixed aliphatic-aromatic pinacols and also the unsymmetrical pinacol containing the phenyl and biphenylene groups and recently Bergmann and Schuchardt⁴ rearranged two additional pinacols of this type. In this paper are reported the results obtained by rearranging three unsymmetrical pinacols containing only aryl groups. In each pinacol one carbon atom holds two phenyl groups; to the other carbon atom are attached two anisyl, two *p*-tolyl and two *m*-tolyl groups, respectively, thus offering a comparison of four groups.

In the following table the results obtained previously in the rearrangement of symmetrical pinacols are compared with the results obtained now on unsymmetrical pinacols containing the same groups.

It is immediately apparent that the series representing the relative migration aptitudes of the groups in symmetrical pinacols does not hold for the unsymmetrical pinacols. The series for the latter type of mole-

³ "Annual Reports," Vol. 27, 1930, p. 117.

⁴ Bergmann and Schuchardt, *Ann.*, **487**, 285 (1931).

TABLE I
 MIGRATION OF GROUPS

Groups R,R'	RR'(OH)CC(OH)RR' Migration, %	RR(OH)CC(OH)R'R'
<i>p</i> -CH ₃ OC ₆ H ₄	98.6	28
C ₆ H ₅	1.4	72
<i>p</i> -CH ₃ C ₆ H ₄	94	49
C ₆ H ₅	6	51
<i>m</i> -CH ₃ C ₆ H ₄	66	50
C ₆ H ₅	34	50

cule may be represented as follows: phenyl, 1; *m*-tolyl, 1; *p*-tolyl, 0.96; anisyl, 0.39. It is especially striking that the anisyl group, which in the symmetrical pinacol migrates nearly exclusively with respect to the phenyl group, migrates to a lesser extent than the phenyl group when these two groups are in the unsymmetrical molecule. If these results are indications of affinity capacities, then the affinity capacities of the groups are: anisyl, 2.57; *p*-tolyl, 1.04; *m*-tolyl, 1; phenyl, 1. It is evident that the value representing the migration aptitude of a group in a certain type of molecule cannot be applied indiscriminately to that group when situated in a different type of molecule.

Work is in progress to determine the relative migration aptitudes of a large number of groups in unsymmetrical pinacols. We wish, moreover, to determine whether it is possible to predict the rearrangement of pinacols containing any two given groups when the relative migration aptitude of each group with respect to a third mutual group is known. Thus, from the results given in Table I, one can calculate that the unsymmetrical pinacols, di-*p*-tolyl dianisylglycol, di-*m*-tolyl dianisylglycol and di-*p*-tolyl di-*m*-tolylglycol, will rearrange to pinacolins with migration of the groups in the following ratios: *p*-tolyl, 71%; anisyl, 29%; *m*-tolyl, 72%; anisyl, 28%; *p*-tolyl, 49%; *m*-tolyl, 51%. Experiment will show whether these predictions are justified and it is hoped that the results will throw light upon the question of affinity capacities.

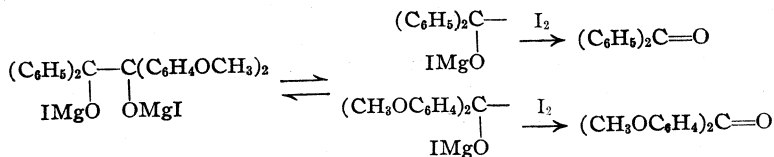

At this time we take the opportunity of pointing out certain facts which were apparently overlooked by Bergmann and Schuchardt⁴ when they criticized adversely our interpretation of the mechanism of the reduction of aromatic ketones to pinacols by the system magnesium and magnesium iodide.⁵ The failure to find benzophenone and benzhydrol on hydrolysis of the reaction mixture does not prove that iodomagnesium ketyl is not initially formed and is not present in small amount. Bergmann and Schuchardt entirely overlooked our formulation of an equilibrium between the iodomagnesium ketyl radicals initially formed and the iodomagnesium pinacolate, $2 R_2COMgI \rightleftharpoons R_2(OMgI)CC(OMgI)R_2$. Obviously, if this equilibrium is nearly entirely in favor of the dimolecular form, then

⁵ Gomberg and Bachmann, *THIS JOURNAL*, **49**, 236 (1927).

only pinacol will be formed on hydrolysis. The situation is analogous to that of diphenyldibiphenyleneethane which in solution dissociates to a very limited extent only into phenylbiphenylene radicals. Bergmann and Schuchardt attribute the color formation in the solution to a small amount of a saturated ketone-magnesium compound, analogous to benzophenone-disodium, $R_2C(ONa)Na$, instead of to the free iodomagnesium

ketyl, $R_2\overset{\text{O}}{\text{C}}MgI$, which we consider is responsible. In doing so they forget that the solution of pinacolate reacts with iodine and with oxygen at room temperature, that in this reaction the color of the solution is discharged and the ketone is formed; moreover, that even after 90% of the pinacolate has been converted to ketone by this process, the color returns to the solution provided that oxygen and iodine be excluded. They agree with us that the magnesium pinacolate⁶ $R_2C(OMgO)R_2$ is capable of dissociation into colored radicals but, curiously enough, they seem to deny this property to the corresponding iodomagnesium pinacolate, $R_2(OMgI)CC(OMgI)R_2$. Finally, Bergmann and Schuchardt have overlooked the fact that by the action of a Grignard reagent such as methylmagnesium iodide on pure pinacol, there is obtained the equilibrium system, iodomagnesium pinacolate \rightleftharpoons iodomagnesium ketyl, which exhibits the same color and the same reactions as the system obtained by reduction of the ketone by the binary mixture. It is evident that the reaction between pinacol and Grignard reagent cannot possibly give rise to a saturated ketone-magnesium compound analogous to the ketone-disodium compound.

In this connection it was of interest to see whether the pinacolate of an unsymmetrical pinacol would behave like the symmetrical pinacolates. Accordingly, the pinacolate of *as*-diphenyldianisylglycol was made by adding ethylmagnesium iodide to a solution of the pinacol. The pinacolate solution absorbed iodine and the pinacolate was converted to a mixture of benzophenone and 4,4'-dimethoxybenzophenone. The behavior of the pinacolate is best explained by the following formulations

The pinacolate obtained from *as*-diphenyldi-*m*-tolylglycol behaved in a similar fashion. It remains to be seen whether it is possible for two symmetrical pinacols, $RR(OMgI)CC(OMgI)RR$ and $R'R'(OMgI)CC-$

⁶ Bergmann and Schuchardt confirm the results we obtained on the composition of the reduction product; by indirect means they showed the presence of magnesium pinacolate, a result that we had obtained by direct analysis.

(OMgI)R'R', to be formed by recombination of the radicals which are formed by dissociation of the pinacolate of an unsymmetrical pinacol, RR(OMgI)CC(OMgI)R'R'.

Experimental

Preparation of the Pinacols.—Acree⁷ isolated benzopinacol from the reaction between methyl benzilate and an excess of phenylmagnesium bromide. Meerwein² attempted the preparation of *as*-diphenylditolylglycol and *as*-diphenyldianisylglycol by a similar reaction but he reported that the hydroxy ketone and not the glycol resulted. We have employed Acree's method with modifications and were able to synthesize several unsymmetrical pinacols, including those which Meerwein wished to make, although in two cases the hydroxy ketone and not the glycol was isolated.

The general procedure consists in adding a solution of 0.05 g. mole (12.1 g.) of methyl benzilate in 50 cc. of benzene to the Grignard reagent which has been prepared from 0.2 g. mole of the appropriate aryl halide (*p*-bromotoluene, bromoanisole, etc.). After being refluxed for twelve hours the mixture is hydrolyzed with cold ammonium chloride solution. The ether-benzene solution is filtered and evaporated. The crude pinacol is digested with ligroin or alcohol in order to remove oily impurities and the pinacol is filtered off and recrystallized.

Rearrangement of the Pinacols.—The pinacols were rearranged according to the general procedure described in a preceding paper.¹ In the case of the diphenylditolylglycols the rearrangement did not seem to be complete; in these cases the reaction was completed by heating the partially rearranged material with acetic acid and iodine.⁵ The mixture of pinacolins was cleaved with potassium hydroxide in the customary manner, $RRRCCOR + KOH \rightarrow RRRCH + KOOCR$; from the nature of the mixture of acids so obtained it is possible to calculate the extent of migration undergone by each group. Unlike the symmetrical pinacols, the acid which is isolated corresponds to the group which has migrated; thus, the amount of benzoic acid in the mixture indicates the extent of migration of the phenyl group. It is noteworthy how closely the results of several rearrangements agree with one another.

***as*-Diphenyldi-*p*-tolylglycol.**⁸ $(C_6H_5)_2(OH)CC(OH)(C_6H_4CH_3)_2$.—The pinacol was recrystallized by adding alcohol to a hot acetone solution of the compound; the pinacol crystallized in colorless needles; yield, 54%; m. p. 167–168° with decomposition. The pinacol is not very soluble in hot alcohol but it dissolves readily in hot acetone and in hot benzene.

Anal. Calcd. for $C_{28}H_{26}O_2$: C, 85.2; H, 6.6. Found: C, 84.9; H, 6.6.

The mixture of benzoic acid and *p*-toluic acid which was obtained by cleavage of the pinacolins was analyzed by oxidizing the *p*-toluic acid to terephthalic acid¹ which in virtue of its insolubility in water is easily separated from benzoic acid. At the same time a control oxidation was carried out on a synthetic mixture of the two acids of approximately the same composition. The mixtures from two rearrangements were found to have the following compositions by weight: benzoic acid, 47.9%, 47.7%; *p*-toluic acid, 52.1%, 52.3%; average composition by moles: benzoic acid, 50.7%; *p*-toluic acid, 49.3%. Yield of acids: 93%, 94% of the theoretical amount based on the pinacol employed; yield of triarylmethanes: 97%, 98%.

⁷ Acree, *Ber.*, **37**, 2761 (1904).

⁸ According to Tiffeneau and Lévy, *Bull. soc. chim.*, [4] **49**, 1650 (1931), Erdmann [Thesis, Rostock, 1910] prepared diphenyldi-*p*-tolylglycol but did not study its rearrangement. We did not have Erdmann's thesis at hand and have been unable to find any reference in the literature to the pinacol.

From the mixture of pinacolins which is formed on rearrangement of the pinacol it was possible to isolate one of them in a pure state. Three and one-half grams of pinacol was heated with 10 cc. of acetic acid and 0.5 g. of iodine for ten minutes; the solution was cooled and decolorized with sulfur dioxide. On standing for several days, the solution deposited 1.1 g. of benzoyldi-*p*-tolylphenylmethane, $\text{C}_6\text{H}_5\text{CO}(\text{C}_6\text{H}_4\text{CH}_3)_2\text{C}_6\text{H}_5$. After recrystallization from acetic acid, the compound melted at 133–135° and was found to be identical with the compound of known structure, which is formed on rearrangement of symmetrical diphenyldi-*p*-tolylglycol. The isomeric pinacolin which was obtained from the mother liquors was difficult to obtain in a pure state.

***as*-Diphenyldi-*m*-tolylglycol**, $(\text{C}_6\text{H}_5)_2(\text{OH})\text{CC}(\text{OH})(\text{C}_6\text{H}_4\text{CH}_3)_2$.—By recrystallization from a mixture of acetone and alcohol the pinacol was obtained in the form of needle-like prisms; yield, 56%; m. p. 156–158° with decomposition. The pinacol is very soluble in hot benzene and in hot acetone, but it is not very soluble in alcohol.

Anal. Calcd. for $\text{C}_{28}\text{H}_{26}\text{O}_2$: C, 85.2; H, 6.6. Found: C, 85.1; H, 6.6.

The amount of *m*-toluic acid present in the mixture of acids was determined by oxidizing the toluic acid to isophthalic acid which, being little soluble in water, can be readily separated from benzoic acid. Composition by weight of acid mixture (two rearrangements): benzoic acid, 47%, 48%; *m*-toluic acid, 53%, 52%; average composition by moles: benzoic acid, 50.2%; *m*-toluic acid, 49.8%; yield of acids: 90%, 91%; yield of triarylmethanes: 98%, 100%.

***as*-Diphenyldianisylglycol**, $(\text{C}_6\text{H}_5)_2(\text{OH})\text{CC}(\text{OH})(\text{C}_6\text{H}_4\text{OCH}_3)_2$.—Recrystallization of the crude pinacol from a mixture of acetone and alcohol gave colorless needles; yield, 60%; m. p. 166–168°. The pinacol is not very soluble in hot alcohol but it dissolves readily in hot acetone and in hot benzene.

Anal. Calcd. for $\text{C}_{28}\text{H}_{26}\text{O}_4$: C, 78.8; H, 6.1. Found: C, 78.8; H, 6.1.

The mixture of benzoic acid and anisic acid was analyzed by making a methoxyl determination. Composition of acid mixture by weight: benzoic acid, 67.1%, 66.8%; anisic acid, 32.9%, 33.1%; average composition by moles: benzoic acid, 71.6%; anisic acid, 28.4%. Yield of acids: 92%, 97%; yield of triarylmethanes: 102%, 100%. By recrystallization of the mixture of triarylmethanes from alcohol, pure phenyldianisylmethane (m. p. 100°) was isolated.

Diphenyl-*o*-toluylcarbinol, $(\text{C}_6\text{H}_5)_2(\text{OH})\text{CCOC}_6\text{H}_4\text{CH}_3$.—The action of *o*-tolylmagnesium bromide on methyl benzilate gave an oil from which a small amount of crystals was isolated. These crystals proved to be not the pinacol but the hydroxy ketone, diphenyl-*o*-toluylcarbinol, resulting by the addition of only one molecule of Grignard reagent to the ester group. Recrystallization from acetone and alcohol gave colorless needles; m. p. 116–117°. The compound was split quantitatively into benzhydrol and *o*-toluic acid when it was heated with three parts of a 25% solution of potassium hydroxide in methyl alcohol⁹ for five minutes. The carbinol gives an orange-red color with concentrated sulfuric acid.

Anal. Calcd. for $\text{C}_{21}\text{H}_{18}\text{O}_2$: C, 83.4; H, 6.1. Found: C, 83.5; H, 6.1.

Diphenyl- α -naphthoylcarbinol, $(\text{C}_6\text{H}_5)_2(\text{OH})\text{CCOC}_{10}\text{H}_7$.—The reaction between methyl benzilate and α -naphthylmagnesium bromide gave an oil and several grams of crystals of diphenyl- α -naphthoylcarbinol. Recrystallization from a mixture of acetone and alcohol gave colorless needles; m. p. 156–157°. On being heated with a methyl alcohol solution of potassium hydroxide the carbinol was cleaved quantitatively into benzhydrol and α -naphthoic acid. The carbinol gives a dark brown color with sulfuric acid.

Anal. Calcd. for $\text{C}_{24}\text{H}_{18}\text{O}_2$: C, 85.1; H, 5.4. Found: C, 84.7; H, 5.3.

⁹ Acree, *Am. Chem. J.*, 29, 597 (1903).

It is planned to prepare the desired *as*-diphenyl-*o*-tolylglycol and *as*-diphenyldi- α -naphthylglycol by the action of phenylmagnesium bromide on the esters of *o*-tolilic acid and α -naphthilic acid, respectively.

Reaction between Iodomagnesium-diphenyldianisylglycolate and Iodine.—Two grams of *as*-diphenyldianisylglycol was added to a solution of ethylmagnesium iodide in a mixture of ether and benzene; a red color developed but quickly disappeared. The solution absorbed iodine, slowly at room temperature, much more rapidly when heated. The solution was finally warmed with iodine for several hours, then cooled and hydrolyzed. The ether-benzene solution yielded a mixture of benzophenone and 4,4'-dimethoxybenzophenone. The benzophenone was extracted by warming the mixture of ketones with 10 cc. of petroleum ether and filtering the hot mixture. The residual dimethoxybenzophenone after recrystallization from benzene and ligroin melted at 142–144°; yield, 1.0 g. or 87%.

Summary

Three unsymmetrical aromatic pinacols, *as*-diphenyldi-*p*-tolylglycol, *as*-diphenyldi-*m*-tolylglycol and *as*-diphenyldianisylglycol, have been synthesized and rearranged to pinacolins.

These pinacols rearrange to pinacolins with migration of the groups in the following ratios: *p*-tolyl, 49%, phenyl, 51%; *m*-tolyl, 50%, phenyl, 50%; anisyl, 28%, phenyl, 72%.

NOTE

Note on the Preparation of Mercury Dibenzyl

By J. LEWIS MAYNARD

The preparation of this substance in a pure condition and in good yields has heretofore presented certain difficulties. An attempt to prepare it by a reaction of general application to this type of compound failed to yield the desired substance. Benzyl bromide and sodium amalgam do not react to form mercury dibenzyl.¹ It was first prepared by the Grignard reaction between benzylmagnesium chloride and mercuric chloride.² The product was slightly impure, as was shown by the melting point of 104°, seven degrees below the true melting point. No yield was given, and the substance was said to possess a characteristic sweet odor. This is not shown by the pure substance.

Other investigators have also used the Grignard reaction to prepare mercury dibenzyl, but the yields either have not been given, or have not

¹ Wurtz, *Compt. rend.*, **68**, 1300 (1869); Dreher and Otto, *Ann.*, **154**, 93 (1870). Cf. Campisi, *Compt. rend.*, **61**, 861 (1865). The product obtained by the latter melted over 90° higher than pure $(C_6H_5CH_2)_2Hg$.

² Pope and Gibson, *J. Chem. Soc.*, **101**, 735 (1912).

exceeded 10%.³ L. W. Jones reported a yield of 40 g. of mercury dibenzyl by the action of 35 g. of benzylmercuric chloride on benzylmagnesium chloride, but this is obviously an error because the theoretical yield is only 38 g.⁴ Apparently the Grignard reaction does not go to completion because it is reported that by means of fractional crystallization it is impossible to separate the mixture of mercury dibenzyl and benzylmercuric chloride formed as a reaction product.^{3b} However, treatment of the mixture with copper is said to produce a 75% yield of mercury dibenzyl.^{3c} This method has a disadvantage in that it is necessary to carry on the reaction with copper in an inert atmosphere of either nitrogen or carbon dioxide.

A convenient reaction that has been used by the author to prepare mercury diphenyl in excellent yield from phenylmercuric iodide,⁵ has been applied successfully to the preparation of mercury dibenzyl. Sodium stannite is one of many reagents used to transform organic mercury compounds of the type RHgX to those of the type R_2Hg .⁶ The reaction of the reagent with benzylmercuric iodide is

Experimental Procedure.—Fifteen grams of benzylmercuric iodide, prepared by the action of mercury on benzyl iodide,⁷ was suspended in a solution of 10 ml. of alcohol in 225 ml. of water. A solution containing 25 g. of sodium hydroxide in 125 ml. of water was added to 10 g. of stannous chloride dissolved in 125 ml. of water. This reagent was added to the suspension of benzylmercuric iodide, and the mixture was stirred vigorously with a mechanical stirrer for a period of one hour. At the end of this time the precipitate was filtered off, washed with water, and allowed to dry at room temperature. The mixture was then extracted with acetone. Difficulty was experienced in obtaining a clear filtrate with the extract, so a few grams of powdered zinc was added to amalgamate the finely divided mercury present. After this treatment a clear filtrate was obtained by filtering through an asbestos pad in a Gooch crucible. Water was added to the filtrate until a permanent turbidity was obtained, whereupon cooling to -15° caused the separation of long, needle-like, colorless crystals of mercury dibenzyl, m. p. 111° . The total yield was 64 g. or 93.2% of the theoretical yield.

It has been noted previously in this article^{3b,c} that the reaction between

benzylmagnesium chloride and mercuric chloride leads to a mixture of mercury dibenzyl and benzylmercuric chloride. Since sodium stannite will convert benzylmercuric chloride to mercury dibenzyl, it is suggested that the product of the Grignard reaction be treated with sodium stannite. This procedure would not only eliminate the difficulty of separating the two mercury compounds, but would increase the yield of the desired mercury dibenzyl.

COMMUNICATIONS TO THE EDITOR

THE RELATION BETWEEN THE ACTIVITY OF THE WATER AND THE POTENTIALS OF THE GLASS ELECTRODE

Sir:

In the differential thermodynamic equation recently used to explain the potentials of the glass electrode [M. Dole, *THIS JOURNAL*, **53**, 4260 (1931)] the correction for possible transference of solvent [see P. B. Taylor, *J. Phys. Chem.*, **31**, 1480 (1927)] was purposely omitted for two reasons. In the first place it was not certain that water could be carried through the glass by ions on the passage of an electrical current, and in the second place the activity of the water was maintained in the actual experiments nearly the same and constant on both sides of the glass membrane; hence if there had been any transfer of water, there would have been no increase or decrease in the free energy of the water as it passed through the glass from one solution to the other and consequently no contribution to the total e. m. f. due to this effect. MacInnes and Belcher [*THIS JOURNAL*, **53**, 3315 (1931)] have shown that water may be drawn out of the glass, and there have also been recently published [G. Buchböck, *Z. physik. Chem.*, Abt. A, **156**, 232-236 (1931); D. A. MacInnes and D. Belcher, *THIS JOURNAL*, **53**, 3315 (1931)] data of experiments performed under conditions in which the activity of the water was not maintained constant, but was reduced by the addition of concentrated acids. The observed potentials did not agree with those of the hydrogen-platinum electrode, the resulting error being negative in sign in contrast to the errors of the glass electrode in alkaline solutions which are positive in sign [Dole, *loc. cit.*]. Considering a possible transfer of water, the equation for the glass electrode in acid solutions (where only hydrogen ions are assumed to carry the current across the boundary) becomes

$$E_1 = \frac{RT}{F} \ln \frac{a'_H}{a_H} + S \frac{RT}{F} \ln \frac{a'_{H_2O}}{a_{H_2O}} \quad (1)$$

In this equation a_H is the hydrogen ion activity, S is the number of moles of water carried across the boundary by one mole of hydrogen ions and a_{H_2O} is the activity of the water. If the glass electrode acted as a perfect hydrogen electrode, the equation would be

$$E_2 = \frac{RT}{F} \ln \frac{a_H'}{a_H} \quad (2)$$

Subtracting E_2 from E_1 , an equation for the error of the glass electrode in acid solutions is obtained, namely

$$\Delta E = E_1 - E_2 = S \frac{RT}{F} \ln \frac{a_{H_2O}'}{a_{H_2O}} \quad (3)$$

If the activity of the water is decreased in solution ($'$), the error will be negative, as is actually observed (Ref. 4). In order to test equation (3) further experiments have been carried out in alcoholic solutions and in acid solutions of various salts; they will be fully described in a paper to be submitted shortly for publication. At this time it should be emphasized that this apparent connection between the activity of the water and the proper functioning of the glass electrode must be considered by those who are using or hope to use the glass electrode for determining the P_H in non-aqueous solutions.

MALCOLM DOLE

THE CATALYTIC INFLUENCE OF DRIED CELLULOSE ON THE HYDROLYSIS OF SUCROSE

Sir:

The writers have found that the rate of hydrolysis of sucrose in aqueous solution is subject to a many-fold increase in the presence of dried cellulose fiber at elevated temperatures.

The cellulose fiber which was used as a catalyst in these studies was prepared from the purest quantitative filter paper (Whatman number 43). The paper was disintegrated to a pulp by boiling with distilled water. This treatment was repeated five times with fresh supplies of water. The pulp was pressed into a cake on a Büchner funnel and dried in air at atmospheric pressure at 130–135° for eighteen hours. The fiber was pulled apart with tweezers into a fluffy mass. It was reheated at the same temperature for several hours, and placed in a desiccator over a fresh charge of Dehydrite. Ash determinations on this fiber showed no more than 0.10% of non-volatile matter.

The hydrolysis of the sucrose was brought about by heating a 10% solution of the sugar at 80–85° in a thermostat for several hours. The increase in the rate of hydrolysis of the sucrose was studied originally by the quantitative determination of the ratio between the amount of reducing sugar formed in the control solution (containing no cellulose) and the amount formed in the solution containing cellulose. In later experiments the effect was studied by comparison of the specific rotation of the unhydrolyzed (unheated) sugar solution with that of the control solution, and that of the solution containing cellulose, respectively.

In a typical determination of the relative amounts of reducing sugar formed in the catalyzed and uncatalyzed hydrolysis of sucrose, the controls showed less than 0.01% of reducing sugar, whereas the cellulose catalyzed solutions showed $0.1 \pm 0.02\%$ of reducing sugar. This corresponds to a ten-fold difference. A one hundred and thirty-fold difference was observed in an hydrolysis carried out at 96–98°.

The writers are at present investigating the catalytic properties of dried cellulose fiber for the purpose of determining: (1) the conditions best suited to the activation of cellulose fiber; (2) the relationship (if any) between the structure of disaccharides and the effectiveness of dried cellulose fiber in promoting their hydrolysis; (3) the nature of the effect herein described.

A full account of this investigation will be submitted shortly to THIS JOURNAL.

THEBAINONE

Sir:

The investigations of Clemens Schöpf have shown that the ketone originally called thebainone, resulting from reduction of thebaine with stannous chloride in concentrated hydrochloric acid, contains a new structural skeleton, differing from that present in the starting material. The ketone has been renamed metathebainone. In a recent publication [Schöpf and Hirsch, *Ann.*, **489**, 224 (1931)] the isolation of the true thebainone from the mother liquors of metathebainone preparation is described. In a footnote the statement is made that the true thebainone is undoubtedly different from the "sulfur-free ketone" obtained by Pschorr in 1910 by hydrolysis of β -ethylthiocodide.

In the course of studies which we have been conducting in the thiocodide series we have prepared a quantity of the "sulfur-free ketone" and find it to

be identical in every respect with Schöpf's true thebainone. A sample of the latter, generously supplied by Professor Schöpf, showed no depression in melting point with the "sulfur-free ketone." Schöpf's base shows $[\alpha]_D^{26} -45.7^\circ$, while Pschorr's shows $[\alpha]_D^{28} -46.4^\circ$, -46.9° in 95% alcohol. Schöpf bases his statement that the two ketones are different upon discrepancies in the melting points of the methiodide and hydriodide, and the fact that Pschorr's hydriodide is hydrated. The methiodide which we obtain from Schöpf's thebainone sample melts at $250-251^\circ$. that from the "sulfur-free ketone" at 251° . When the hydriodide of Schöpf's thebainone is crystallized from a large amount of water, it separates hydrated, and shows two melting points, $163-165^\circ$ and $257-260^\circ$, like the "sulfur-free ketone" hydriodide, whose melting point it does not depress.

The structure of Pschorr's "sulfur-free ketone" is thus settled, and another case of supposed isomerism in the thebainone series eliminated. The true thebainone is obtained in nearly quantitative yield by the hydrolysis of β -ethylthiocodide, which constitutes a very convenient preparative method.

THE HEAT OF DISSOCIATION OF THE SODIUM MOLECULE

Sir:

The original determination of the heat of dissociation of Na_2 from the band spectrum indicated a value of about 1 volt (= 23,000 cal.). If this were the case saturated sodium vapor should show an abnormal density at all pressures. Rodebush and Walters [THIS JOURNAL, 52, 2654 (1930)] found this to be true but the abnormality is small and the value of the heat of dissociation calculated from their best results is 0.79 volt (= 18,200 cal.).

Lewis [*Z. Physik*, 69, 786 (1931)] calculated the heat of dissociation from a vapor density determination by a molecular ray method and obtained the value 0.73 volt (= 16,900 cal.). Recently Nusbaum and Loomis [*Phys. Rev.*, 39, 179 (1932)] have carried out an accurate analysis of the vibrational bands and find the heat of dissociation to be 0.76 volt (= 17,500 cal.) with an uncertainty of 0.02 volt. It seems quite certain that 0.76 volt is the lower limit and that the true value is in the interval of 0.76-0.78 volt.

FERRYL ION, A COMPOUND OF TETRAVALENT IRON

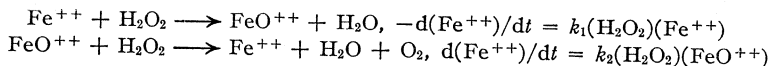

Sir:

Several independent kinetic investigations in this Laboratory have furnished evidence that a compound of tetravalent iron, FeO^{++} , is formed as an intermediate. The results are in agreement with the theory that

is a reversible and fairly rapid reaction. The equilibrium constant has the form $K = (\text{Fe}^{++})(\text{FeO}^{++})(\text{H}^+)^2/(\text{Fe}^{+++})^2$.

If H_2O_2 reacts with both Fe^{++} and "ferryl ion" but not directly with Fe^{+++}

then a steady state will be reached in which $(\text{FeO}^{++})/(\text{Fe}^{++}) = k_1/k_2 =$ a constant, and the above equilibrium is maintained. The rate of catalytic decomposition of H_2O_2 , $-d(\text{H}_2\text{O}_2)/dt$, is then equal to

$$2k_1(\text{Fe}^{++})(\text{H}_2\text{O}_2) = 2(\sqrt{Kk_1k_2})(\text{H}_2\text{O}_2)(\text{Fe}^{+++})/(\text{H}^+) = k(\text{H}_2\text{O}_2)(\text{Fe}^{+++})/(\text{H}^+)$$

This rate law was determined by von Bertalan in 1920 and has been confirmed in this Laboratory [Bray, *Chem. Rev.*, **10**, 171 (1932), $k = 0.125$ (not 125) at 40°]. The proposed mechanism explains also the decomposition of H_2O_2 during the very rapid oxidation of Fe^{++} to Fe^{+++} .

If in the reduction of Fe^{+++} by a stannous salt Sn^{++} reacts with FeO^{++} but not with Fe^{+++} , and the equilibrium between 2, 3 and 4-valent iron is established relatively rapidly, the rate law will be $-d(\text{Sn}^{++})/dt = k'(\text{Sn}^{++})(\text{Fe}^{+++})^2/(\text{Fe}^{++})(\text{H}^+)^2$. This has now been established as a limiting law in solutions in which the only negative ion is ClO_4^- . Also, by raising the temperature and lowering the concentration of Fe^{++} , another limiting condition has been found where the rate is independent of the concentration of Sn^{++} , and the indicated rate-determining reaction is $2\text{Fe}(\text{OH})^{++} \longrightarrow \text{Fe}^{++} + \text{FeO}^{++} + \text{H}_2\text{O}$.

Other investigators have already observed and studied the retarding effect of ferrous salts during the reduction of ferric salts by hydroxylamine and by iodide. The results of Mitchell [*J. Chem. Soc.*, 336 (1926)] with hydroxylamine and Fe^{+++} , published in 1926, are in accord with the ferryl ion mechanism. In the case of the reactions of iodide with ferric salt and with ferricyanide, Wagner [*Z. physik. Chem.*, **113**, 271 (1924)] in 1924 postulated the formation of I_2^- as an intermediate. There seems, however, to be no supporting evidence for the existence of this compound.

In order to obtain more information about the reaction between Fe^{++} and I^- , Bray and Hershey are studying the reverse reaction between Fe^{++} and I_2 . The first experiments, in the presence of AgI , AgBr and Br^- , *i. e.*, at very low concentrations of I^- , are in agreement with the rate law, $-d(\text{I}_2)/dt = k''(\text{Fe}^{++})(\text{I}_2)/(\text{I}^-)(\text{H}^+)$. This result and the analogy with

other reactions of iodine in aqueous solution have led to the conclusion that the rate-determining reaction is $\text{Fe}^{++} + \text{HIO} \longrightarrow \text{FeO}^{++} + \text{H}^+ + \text{I}^-$.

Additional experiments have been planned which, it is hoped, will furnish further information about the properties of ferryl ion.

THE EXISTENCE OF NEUTRONS IN THE ATOMIC NUCLEUS

Sir:

In my article on the Arrangement of Protons and Electrons in the Atomic Nucleus [THIS JOURNAL, 53, 981 (1931)] the discussion was limited to nuclei in which the numbers of protons and electrons are multiples of four and two, respectively. These atoms are by far the most abundant and in terms of the proposed coupling pattern represent the highest symmetry attainable. Although it is not yet possible to make a definite extension to the other nuclear series, it is of interest to discuss the problem briefly in reference to recent investigations.

It appears significant that the next most abundant nuclear type is that which resembles the symmetrical or $4n$ proton type most closely and may be derived from it by the removal of a single proton. This series, *i. e.*, with $4n-1$ protons, follows very closely the $4n$ series: the first and second "extra electron pair" enter at the corresponding atomic numbers. All other nuclei, *i. e.*, those with $4n-2$ and $4n-3$ protons and those with uneven numbers of electrons constitute but a fraction of one per cent. of the atoms of the earth's crust and appear in general to owe their instability to the presence of incomplete or unsaturated groups. More information about nuclear spins and a knowledge of the coupling rules in these cases are necessary before definite conclusions can be drawn regarding these structures. At present we can only discuss certain possibilities.

As an illustration we may consider carbon 13. In the accompanying figure, this nucleus is pictured in the same symbols formerly employed, a proton, or the direction of the proton spin vector, by a bar and an electron pair by a ball. The structure is the same as that of carbon 12 plus one proton and one electron (half ball). Of course we do not know where the extra proton is coupled but we do know that such a bond of two protons and one electron as suggested in the figure (two bars and the half ball) is stable from the existence of the hydrogen isotope [Urey, Brickwedde and Murphy, *Phys. Rev.*, 39, 154 (1932)] of mass 2. Beryllium 9 must also contain such a group and when it captures a high speed alpha particle to form carbon 13 it is not difficult to imagine that occasionally the loosely bound

proton and electron are detached and emitted as a neutron leaving carbon 12, as postulated by Chadwick [*Nature*, **129**, 312 (1932)].

The essential point may be stated in this way. In the proposed structure alpha particles and neutrons do not exist as such in any nucleus, merely protons and electrons coupled in a certain definite pattern. When these couplings are broken, alpha particles and electrons in pairs are normally formed as in the radioactive series. However, it should also be possible to break the bonds in such a way as to give neutrons, mass one or two, hydrogen, mass one or two, helium mass 5, etc., and it is to be expected that such particles would be formed more readily from nuclei containing unsymmetrical or unsaturated groups.

ROTENONE. XXI. THE STRUCTURE OF ISOROTENONE, β -DIHYDROROTENONE AND DEHYDROROTENOL

Sir:

In a recent publication [S. Takei, S. Miyajima and M. Ōno, *Bul. Inst. Phys. and Chem. Research* (Tokyo), **11**, 1-4, Feb. 1932] Takei and his associates proposed a formula for rotenone which differs from the one (I) proposed by us [F. B. LaForge and H. L. Haller, *THIS JOURNAL*, **54**, 810 (1932)] only in the point of attachment of the isopropenyl side chain on the substituted dihydrocoumarone ring as indicated in formula II.

I

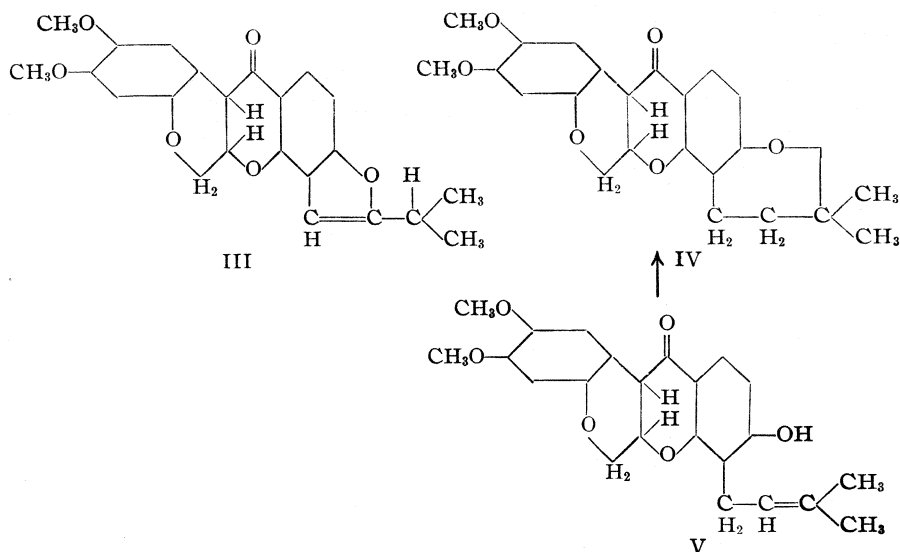

II

The formula of Takei takes no account of the loss of optical activity by cleavage of the oxygen bridge with the resultant formation of the phenolic hydroxyl in position 4 by hydrogenation of tubaia acid and the analogous formation of tetrahydro derivatives from other rotenone derivatives. Moreover, the mechanism suggested by us is strongly supported by analogy with that of certain codeine derivatives, which is referred to in a previous article [H. L. Haller and F. B. LaForge, *THIS JOURNAL*, **54**, 1988 (1932)].

Both these results are to be expected from the groupings present in formula I but would not be possible according to Takei's formula II.

As the complete formula for rotenone is now known, it is possible to propose a formula for isorotenone [S. Takei, *Biochem. Z.*, **157**, 1 (1925); *Ber.*, **61**, 1003 (1928)] and for β -dihydrorotenone. [H. L. Haller, *THIS JOURNAL*, **53**, 733 (1931)]. However, a modification of the structure proposed for dehydrorotenol [H. L. Haller and F. B. LaForge, *THIS JOURNAL*, **53**, 2271 (1931); F. B. LaForge, H. L. Haller, and L. E. Smith, *THIS JOURNAL*, **53**, 4403 (1931)] is necessary.

It has been shown that rotenone and isorotenone differ from each other in the position of a double bond. Therefore, structure III, which accounts for all the facts, is proposed for isorotenone.

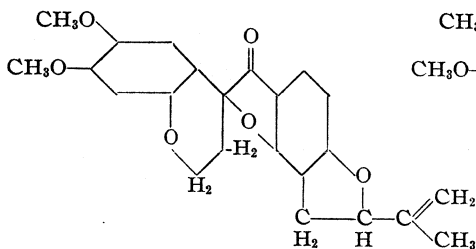

β -Dihydrorotenone (IV), an isomer of dihydrorotenone, which gives many of the typical reactions of dihydrorotenone, is obtained when rotenonic acid (V) is dissolved in a solution of acetic and sulfuric acids. The formation of β -dihydrorotenone is in a measure analogous to the formation of a saturated lactone by the isomerization of an unsaturated acid.

Dehydrorotenol, which is obtained on mild oxidation of rotenol, is colorless, unlike all other dehydro derivatives of the rotenone series, which are yellow. It also differs from these in that it can be reconverted into rotenol by reduction.

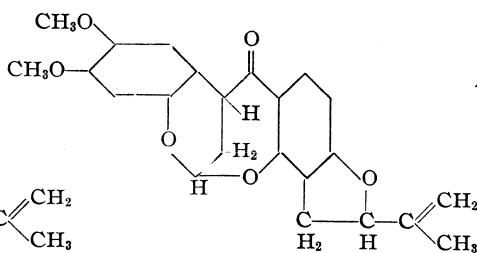

Dehydrorotenol, like rotenol, can be hydrogenated to a tetrahydro derivative which is alkali soluble but which differs from the tetrahydrorotenol (dihydrorotenolic acid) in that it is not cleaved by alkaline hydrogen peroxide. Rotenol possesses a free hydroxyl group in the tubaic acid half of the

molecule, and this free hydroxyl group is essential for the cleavage of the carbonyl group with alkaline hydrogen peroxide. It follows therefore that this group is not present in dehydrorotenol. Rotenol gives a color test with ferric chloride, whereas dehydrorotenol does not. Thus it follows that the hydrogen atom of the free hydroxyl group is involved in the formation of dehydrorotenol. If the original ether linkage in rotenone was reformed in the formation of dehydrorotenol from rotenol, dehydrodihydro-rotenolic acid and *dl*-dihydrorotenonic acid [H. L. Haller and F. B. LaForge, *THIS JOURNAL*, **53**, 3426 (1931)] should be identical as the asymmetric center I [*ibid.*, p. 3427] is racemized in the formation of rotenol. Besides, dehydrorotenol does not react with iodine and alcoholic potassium acetate to lose two hydrogen atoms and to form dehydrodihydrorotenone. It is possible, therefore, that the structure for dehydrorotenol is either VI or VII.

The product obtained from dehydrodihydrorotenolic acid and acetic anhydride, which was thought to be a mixed anhydride [H. L. Haller and F. B. LaForge, *THIS JOURNAL*, **53**, 2271 (1931)], is in fact a true acetyl derivative, the hydroxyl group in the 4 position having been acetylated.

THE RELATION BETWEEN THE DISSOLUTION OF METALS IN ACIDS AND THE ELECTROLYTIC EVOLUTION OF HYDROGEN

Sir:

The finding of Brönsted and Kane [*THIS JOURNAL*, **53**, 3624 (1931)] that the velocity of the reaction of sodium amalgam with aqueous solutions is proportional to a fractional power of the concentration of sodium in the amalgam suggests strongly that the rate of hydrogen evolution on a sodium amalgam surface is essentially the same as on a mercury surface polarized electrically to a potential equal to that established by the sodium-sodium ion equilibrium. From the precise and definitive work of Bowden [*Trans.*

Faraday Soc., **24**, 473 (1928)] we know that the coefficient n in the Tafel polarization equation

$$E = \frac{RT}{nF} \ln I + \text{constant}$$

is 0.5 on mercury surfaces at current densities below about 10^{-4} amp. per sq. cm., and changes discontinuously at higher current densities to 0.27. Since

$$E = \frac{RT}{F} \ln \frac{a_{\text{Na}^+}}{a_{\text{Na}}} + E_0$$

and since current is proportional to reaction velocity, the above hypothesis indicates such a fractional order of reaction as was found.

$$v \propto \frac{[\text{Na}]^n}{[\text{Na}^+]^n}$$

This assumes, of course, that these amalgams are so dilute that there is approximate proportionality between activity and concentration of the sodium.

It also follows that the reaction velocity should vary inversely as the same fractional power of the sodium-ion activity. While Brönsted and Kane seem not to have expected any such effect, and report no quantitative results on the effect of sodium ion, they do report that addition of sodium chloride decreases the reaction velocity.

It should therefore be possible to apply to the amalgam reaction all of the electrochemical evidence that the reaction $\text{H}^+ + e \rightleftharpoons \text{H}$ is reversible and very rapid compared with the process of formation of H_2 from the atomic hydrogen or its alloy with the metal. In particular it is extremely difficult to understand the saturation effects observed in the electrochemical oxidation of hydrogen to hydrogen ion [see Hammett, *THIS JOURNAL*, **46**, 7 (1924)] on the basis of any other mechanism.

The contrary conclusion of Brönsted and Kane that the first step in the formation of molecular hydrogen from hydrogen ion is the rate-determining one depends upon their observation of a direct effect of the concentration of the reacting acid upon the velocity. This would be strong evidence if it could be proved that diffusion was not a factor in the determination of the reaction velocity in their experiments and in those of Kilpatrick and Rush-ton [*J. Phys. Chem.*, **34**, 2180 (1930)]. Certainly Bowden showed that the electrolytic evolution of hydrogen on mercury is determined by hydrogen-ion concentration and is subject to no generalized acid effects when the reaction velocity is so low that diffusion is not a significant factor.

THE ELECTROMOTIVE FORCE OF CELLS CONTAINING DILUTE HYDROCHLORIC ACID

Sir:

In a recent paper Carmody [THIS JOURNAL, **54**, 188 (1932)] has published the results of some very accurate measurements of the e. m. f. of cells containing dilute solutions of hydrochloric acid. Mainly owing to the use of silica vessels these results differ from those of Linhart [THIS JOURNAL, **41**, 1175 (1919)] and of Nonhebel [*Phil. Mag.* [7] **2**, 1085 (1926)] but it can be shown that the results of these earlier workers are not incompatible with those of Carmody.

It has been suggested elsewhere [*J. Phys. Chem.*, **31**, 1647 (1927)] that the conductivity data for strong acids and bases in dilute solution can be corrected for the effect of impurities by the equation

$$\Lambda = \Lambda_0 - bc^{1/2} - k/c$$

where b is a constant calculable from Onsager's theory or determinable experimentally and k is a measure of the amount of acid removed by the

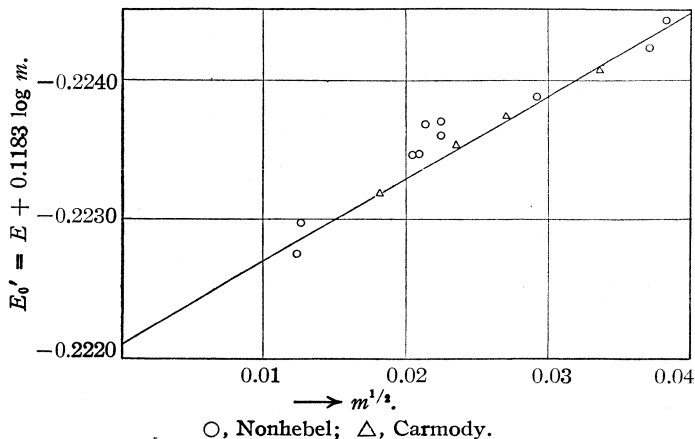

Fig. 1.

impurities which either have dissolved from the glass or were originally present in the water. By the courtesy of Sir Harold Hartley, F.R.S., I have been able to avail myself of some measurements by Marshall on the conductivity of dilute solutions of hydrochloric acid in cells of similar glass and water of comparable conductivity to those employed by Nonhebel. Using the above equation, I have calculated from these data that Nonhebel's results are about 0.0010 volt high at 0.0001 molal and 0.0001 volt high at 0.001 molal. Even Carmody's results require a slight correction which can be calculated from the recent conductivity data of Jeffery and Vogel [*J. Chem. Soc.*, 400 (1932)], who employed silica cells and water of

about the same conductivity as that used by Carmody: the correction lowers Carmody's most dilute point by 0.00012 volt.

The corrected data are plotted in the accompanying diagram and the straight line is drawn with the slope required by the limiting equation of Debye and Hückel. It is evident that the agreement is satisfactory and that the most probable value of E_0 is 0.2221 volt, which is the value previously adopted by Randall and Young [THIS JOURNAL, 50, 989 (1928)].

THE ESTIMATION OF IRON IN SOLUTIONS CONTAINING BOTH BIVALENT IRON AND TRIVALENT TITANIUM

Sir:

It is known that sulfuric acid solutions of ferrous sulfate undergo oxidation but very slowly at room temperatures.¹ Thus, Baskerville and Stevenson² found that upon passing air for twelve hours through a sulfuric acid solution of Mohr's salt, there resulted but 0.0001 g. of Fe^{+++} out of a total of approximately 0.71 g. of Fe^{++} .

Furthermore, titanous sulfate solutions of ordinary acidity are extremely unstable in air. Thus, while reduction of titanium in the Jones reductor proceeds quantitatively to the trivalent condition, the deoxidized substance is usually collected under a protective solution, such as ferric sulfate, whereby the titanium is immediately converted to the quadrivalent state with the formation of an equivalent amount of the more stable ferrous sulfate.³

These facts, namely, the stability of acidified ferrous sulfate solutions and the instability of acidified titanous sulfate solutions toward atmospheric oxidation, suggested the possibility of estimating Fe^{++} in the presence of Ti^{+++} by subjecting the solution containing these ions to an air-bubbling process. It was hoped that in the time required to effect the complete oxidation of the Ti^{+++} the amount of Fe^{++} oxidized would be negligible, so that titration of the aerated solution with standard potassium permanganate would give a value corresponding to the iron alone.

This hope has indeed been realized and we have found that results obtained by the method outlined above are in good agreement with those obtained by the well-known method of Gooch and Newton,⁴ wherein the Ti^{+++} is oxidized by bismuth trioxide, which does not affect the Fe^{++} , the metallic bismuth thus precipitated and excess bismuth oxide removed by

filtration, and the filtrate, containing the Fe^{++} , titrated with standard permanganate in the usual manner.

Lundell and Knowles⁵ have shown that sulfuric acid solutions of uranous sulfate, like ferrous sulfate, exhibit marked stability toward air oxidation, and we hope to employ our differential oxidation procedure in the evaluation of uranium in solutions containing U^{++++} and Ti^{+++} .⁶ Other determinations, involving similar combinations, suggest themselves as possibilities in the further application of this method.

In the course of this work, a technique has been developed for the preparation of very pure solutions of titanous sulfate and titanous sulfate.

We expect to publish a complete account of this work in the near future.

PENTAVALENT BORON

Sir:

A compound of boron has been prepared which has the formula BR_3Na_2 in which R is the α -naphthyl group. This compound seems to be of a type not heretofore known and to be of particular interest from the standpoint of valence theory.

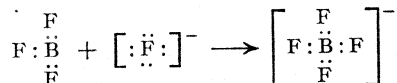

The compound has been prepared by treating tri- α -naphthyl boron in ether solution with 40% sodium amalgam in the absence of air and water.¹ The solution turns first yellow and finally black as the reaction progresses. Upon hydrolyzing the ether solution and titrating with acid the number of mols of sodium was found to be twice (1.97-1.98) the number of mols of the tri- α -naphthylboron originally introduced into the solution. The compound was then prepared in crystalline form from a mixture of ethyl ether and petroleum ether. It is nearly black in color, somewhat resembling iodine in appearance. This material was analyzed for sodium and boron. A second crop of crystals was obtained from the mother liquor. This had the same appearance and gave the same analysis. The analyses indicated one molecule of ether of crystallization, which was removed quantitatively by evacuating and heating to 175°. The first analysis given below is for the first crop of crystals, the second for the crop

¹ A solution of this compound was undoubtedly first obtained by Krause and Nobbe [*Ber.*, **63**, 934 (1930)] but inasmuch as they did not analyze their product they naturally assumed that it was a monosodium addition compound as in the case of triphenylboron.

from the mother liquor before heating and the third for this same material after heating to remove ether.

Anal. Calcd. for $C_{30}H_{21}BNa_2$: Na, 10.50; B, 2.47. Found: Na, 10.59; B, 2.49. Calcd. for $C_{34}H_{31}OBNa_2$: Na, 8.98; B, 2.11. Found: Na, 8.92; B, 2.15. Calcd. for $C_{30}H_{21}BNa_2$: Na, 10.50; B, 2.47. Found: Na, 10.53; B, 2.40.

Compounds of boron showing a valence of more than three are of course known, such as KBF_4 . In such cases an octet is completed by four covalent bonds thus

No compound has been reported, however, in which the boron completes its octet by taking two electrons from different atoms to give ionic linkages. Thus no compound is known of the formula Na_2BF_3 . It now appears that in case the three fluorine atoms are replaced by three naphthyl groups, then the boron atom can complete its octet by taking two electrons from two sodium atoms. How these sodium atoms are held is a question to be decided by further experiment. This work is being continued.

THE ACTIVATOR OF CATALASE¹

Sir:

The activation of glandular proteinase (cathepsin) by glutathione² and other —SH compounds points to a connection between enzymic hydrolysis and the sulfur oxidation–reduction system of Hopkins. A connection of the sulfur system to enzymic oxidation is also indicated, however, by our findings that the catalase activity (of pig's or lamb's liver) is increased by S–S derivatives, namely, cystine, insulin and oxidized glutathione. In liver juice, which contains sulfhydryl derivatives, the catalase may therefore be activated by all manner of oxidizing agents, such as iodine, ferric iron, oxygen and hydrogen peroxide, so that in the usual preparations of catalase the enzyme will be found completely active.

The natural activator which occurs in the liver press juice is not cystine, since in larger amounts this again inhibits the catalase action, but in view of the quantity of glutathione present in liver, it may be that the natural activator is, in part at least, composed of oxidized glutathione.

Since the presence of —SH derivatives accelerates proteolysis, and that of S–S derivatives, the decomposition of hydrogen peroxide, it would there-

¹ Food Research Division Contribution No. 145.

NEW BOOKS

Matière et Atomes. (Matter and Atoms.) By A. BERTHOUD, Professor of Physical Chemistry at the University of Neuchâtel. Second edition. G. Doin et Cie, 8 Place de l'Odéon, Paris, France, 1932. 324 pp. 28 figs. 11.5×18 cm. Price, 26 fr.

This is a revised and enlarged second edition of "New Conceptions of Matter and the Atom." The earlier book has been conscientiously revised and brought up to date. The present chapters include: Historical Introduction, Classical Theories of Light and of Electrons, Theory of Relativity and Mass, x-Rays and Atomic Numbers, Radioactivity and Isotopes, Rutherford Atom and Transmutation, Bohr Atom and Quantum Theory, Complex Atoms, x-Rays and Chemical Affinity, Wave Mechanics.

The style is clear and readable throughout and the selection of material judicious. The book is addressed to "a wide circle of cultivated readers," and the plan is to present selected facts, intelligently grouped, and then to state the conclusions drawn from them. The names of Prout and Proust are frequently confused.

NORRIS F. HALL

Gmelins Handbuch der anorganischen Chemie. (Gmelin's Handbook of Inorganic Chemistry.) Edited by R. J. MEYER. Eighth edition. System-Number 7. **Bromine.** Issued by the Deutsche Chemische Gesellschaft. Verlag Chemie G. m. b. H., Corneliussstrasse 3, Berlin W 10, Germany, 1932. xxi + 342 pp. 17×25 cm. Price, to subscribers, M. 56; singly, M. 49.

This volume presents the chemistry of bromine itself and of its compounds with those elements of smaller System-Numbers (1-6): namely, chlorine, fluorine, nitrogen, oxygen, hydrogen and the inert gases. The relevant literature has been covered up to August 1, 1931.

The great extension of our knowledge of this element, since the previous edition, particularly as regards its physico-chemical properties and those of its compounds, is most impressive. Attention should also be called to the section on the history of our knowledge of this element and on its economics.

The present volume is a worthy addition to this invaluable encyclopedia of inorganic chemistry.

ARTHUR B. LAMB

The Corrosion of Metals. Part II. Special Researches Concerning the Dissolving of Metals. By Professor WILH. PALMAER, D.Sc. Proceedings of the Royal Swedish Institute for Engineering Research 100,108. Svenska Bokhandelscentralen A.-B., Stockholm, Sweden, 1931. 198 pp. 51 figs. 10 plates. 16.5 × 24 cm.

Part I of this Memoir (in English) dealing with the General Theory of Corrosion has already been reviewed in THIS JOURNAL [Vol. 51, p. 3172 (1929)].

In the present Part II (also in English) a further series of experimental investigations are reported which confirm the conclusions reached in Part I, namely, that the primary factor in the corrosion of metals is the activity of local galvanic elements. The specific materials studied here are malleable cast iron, soft iron, electrolytic iron and certain other pure metals and amalgams. Special chapters are devoted to the alleged formation of a hydrogen film on dissolving metals, the theory of resistance capacity, the theory of isohydric solutions, the occurrence of an induction period, the diffusion theory of corrosion and a criticism of the work in this field of Centnerszwer and his collaborators.

Part III, which is to deal with the special theory of the corrosion of iron, is being prepared for the press.

ARTHUR B. LAMB

Chemisches Fachwörterbuch. Für Wissenschaft, Technik, Industrie und Handel. (Chemical Dictionary for Science, Industry and Business.) Edited by A. W. MAYER. Vol. II. English-German-French. Verlag von Otto Spamer, Heinrichstrasse 9, Leipzig C 1, Germany, 1931. 943 pp. 18 × 25.5 cm. Price, Rmk. 70; bound, Rmk. 75.

Volume I (German-English-French) of this three-volume work was reviewed by the present reviewer on page 1614, Volume 53, 1931, THIS JOURNAL. Volume II (English-German-French) is fully as complete and more voluminous than the first volume, containing 943 pages, and is unquestionably well done. Little can be said that was not said about the first volume, for one will find here undoubtedly the best scientific chemical dictionary available. It should enable not only the scientific man but the industrial and technical expert to find quickly the equivalent German and French word or phrase for almost any like phrase in English, with various synonyms as well. It will be invaluable to any translator whether interested in scientific or chemical trade literature. Volume III (French-German-English) will appear later.

The reviewer has the greatest respect and wonder for the persistence, detailed investigation and untiring labor which the author has put into its production. The statement in the first review applies equally to this: *viz.*, those who are fortunate enough to have this volume in their libraries should have no difficulty in obtaining a correct French or German equiva-

lent for almost any English word or technical phrase required in chemical parlance.

CHARLES L. PARSONS

Die Katalyse. Die Rolle der Katalyse in der analytischen Chemie. (Catalysis. The Role of Catalysis in Analytical Chemistry.) By Dr. GERTRUD WOKER. II. Special Part, Second Section, Biological Catalysts. Second Half, Atmungsfermente. Verlag von Ferdinand Enke, Stuttgart, Germany, 1931. xix + 592 pp. 2 figs. 16.5 × 25.5 cm. Price, unbound, RM. 76; bound, RM. 79.

This is hardly a treatise on analytical chemistry, it is really a monograph on a special group of the enzymes, those which are associated with the mechanisms of fermentation and oxidation.

The first two hundred pages are devoted to zymase and the various enzymatic phenomena which are encountered in fermentation problems. In this section there is an extended discussion of the chemical mechanism of fermentation, including the intermediate products, methods whereby intermediate products may be isolated or identified and the inter-molecular and intra-molecular reactions which such products may undergo.

Those who are interested in the chemistry of the physiology of the action of insulin will find in this section an excellent discussion of certain theories of its action. Insulin is regarded as the "coenzyme" of tissue zymase. The mixture; α, β -glucose + H_3PO_4 + the synthesizing enzyme, phosphatase + insulin, results in the formation of γ -glucosediphosphate which breaks down in the organism to yield γ -glucose which, because of its great instability, is readily oxidized. Incidentally the graphic formulas of many of the sugars as given do not conform to our best present knowledge. Thus the normal form of glucose is given as containing the 1,4-oxide ring instead of the correct 1,5-oxide ring and γ -glucose is depicted as possessing the 1,6-oxide ring instead of the 1,4-oxide ring. Accordingly in the section on insulin action, the reader should recognize that while the discussion of the mechanism of the reaction may be correct, the formulas which depict the probable reactions are incorrect.

The second section of 335 pages deals with the oxidases, peroxidases and reductases, and here again all phases of the chemistry of the action of this important group of enzymes are considered in detail. The various theories of oxidation are considered at length and the evidence for or against each theory is excellently presented. The systems considered range in complexity from simple inorganic systems to such complex biological systems as the purines and amino acids. Here the reviewer notes an inexplicable omission. In spite of the fact that the cystine \rightleftharpoons cysteine reaction is considered at some length, glutathione is mentioned only once and that only casually in a footnote (p. 196) in the section on fermentation.

The book is not strictly up to date. The reviewer did not make a de-

tailed search to determine the date of the latest reference cited, but a general inspection failed to locate any references to literature later than 1928. As a monograph on this special group of enzymes prior to that date it is highly recommended.

ROSS AIKEN GORTNER

Kapillarchemie. (Capillary Chemistry.) A Presentation of the Chemistry of the Colloids and of Related Fields. By Prof. Dr. HERBERT FREUNDLICH, Member of the Kaiser Wilhelm-Institut für Physikalische Chemie und Elektrochemie. Vol. II. Fourth edition. Akademische Verlagsgesellschaft m. b. H., Markgrafenstrasse 6, Leipzig C 1, Germany, 1932. xi + 955 pp. 113 figs. 17.5 × 25 cm. Price, unbound, M. 60; bound, M. 69.

The first volume of the fourth edition of this handbook, treating the general principles of the subject, appeared in 1930 and has already been reviewed in *THIS JOURNAL* [52, 3033 (1930)]. The present second (and last) volume discusses the properties and behavior of individual, colloiddally dispersed systems.

This volume follows closely the order of treatment and subdivisions of the previous edition. The revision has, however, been a thorough one. The many researches that have appeared in the intervening ten years have been thoroughly considered and incorporated. As a consequence many parts have been completely rewritten and many entirely new chapters or subdivisions have been added, such, for instance, as those discussing the anisotropy of colloidal solutions, the hydrosols of the proteins and the behavior of gels. All told, the number of pages in this volume represents an increase of more than fifty per cent. over the number of pages in the corresponding part of the last edition.

This edition, like its predecessors, is not merely a comprehensive survey of an immense field; it is a critical, thoughtful and penetrating discussion of that field, replete with illuminating deductions and suggestions. It constitutes an impressive intellectual achievement.

Needless to say, it remains an invaluable handbook of colloid chemistry and of related branches of our science.

ARTHUR B. LAMB

A Shorter Course in Organic Chemistry. By J. C. COLBERT, Assistant Professor of Chemistry in the State University of Oklahoma. The Century Co., 353 Fourth Avenue, New York, 1931. xviii + 352 pp. 15 × 22 cm. Price, \$3.60.

This is a book which both merits and needs another edition. The conversational tone of the book is in refreshing contrast to the proverbial dryness of textbooks; many charts are used to give the student a "birds-eye view" of structural relationships; and in the index when two names refer to the same substance, page numbers are given in both places. The author's judgment as to the division of space between the branches

of organic chemistry is good, and the illustrative material includes such up-to-date references as "Jake" paralysis and the Cleveland Clinic disaster.

On the other hand, the book is marred by a multitude of minor errors, not all of which can be blamed on the compositor. In a book particularly designed for premedical students it is strange to find no mention of carotene, and no reference to Vitamin D. The normal blood sugar content is stated on p. 203 to three significant figures, and the uses of hexylresorcinol as an external antiseptic and an anthelmintic are not only not mentioned, but are by implication disavowed, p. 308. The "hemlock" of Socrates is not the hemlock with which most readers of the book will be familiar.

The configuration of *d*-glucose on p. 199 is the enantiomorph of that on p. 195, and starch is pictured as derived from *d*-allose, p. 212, with the warning that no attention has been given to the position in space of the hydroxyl groups and the lactone rings. The discussion of the polariscope on pp. 160-161 gives the impression that tourmaline rather than calcite is used in Nicol prisms. The discussions of amino acids and of indicators could be improved if the author would recognize "intramolecular ionization," but the references to J. U. Nef on pp. 43, 44, 82, 128 and 285 are not calculated to help the student.

ELLIOT Q. ADAMS

Ergebnisse der Enzymforschung. (Reviews of Enzyme Research.) Edited by F. F. NORD and R. WEIDENHAGEN. Vol. I. Akademische Verlagsgesellschaft m. b. H., Markgrafenstrasse 6, Leipzig C 1, Germany, 1932. xi + 377 pp. 63 figs. 16 × 24 cm. Price, M. 27; bound, M. 29.

This book contains seventeen chapters on various phases of recent enzyme research. Each chapter is written by a different author and represents a critical rather than comprehensive treatment of a particular problem. Among a number of general problems considered are the thermodynamics of cell reactions; the significance of oxidation-reduction potentials; the physico-chemical mechanism of enzyme action; bacterial enzyme reactions; and the formation of enzymes. The more specific problems treated are alcoholic fermentation; proteolytic enzymes; carbohydrases and their specificity; acetic acid fermentation; tyrosinase; bone phosphatase; crystalline urease; crystalline pepsin; the oxygen-carrying ferment of respiration; and the biochemistry of the lower fungi. Additional volumes will presumably appear covering an expanded range of topics.

A highly commendable feature is that the collaboration is international, involving German, English, American and French workers. Leaders of the respective fields have been secured for the most part. The personal outlook of each collaborator is strongly emphasized, and very often a con-

siderable summary of his own work is reported. Willstätter, Euler, J. B. S. Haldane and Waldschmidt-Leitz do not write chapters in the present volume.

The book is written by the expert for the expert and will consequently be of greatest use to the research worker. It raises problems quite as much as it presents their solutions.

DEAN BURK

Ergot and Ergotism. A Monograph Based on the Dohme Lectures Delivered in Johns Hopkins University, Baltimore. By GEORGE BARGER, F.R.S., Professor of Chemistry in Relation to Medicine in the University of Edinburgh. Gurney and Jackson, 33 Paternoster Row, E.C., London, England, 1931. xvi + 279 pp. 15 X 23 cm. 41 figs. Price, 15 s., net.

In the preface the author remarks that "this book was planned more than twenty years ago during a happy partnership in research" (with H. H. Dale) but that other activities caused its abandonment. It is most fortunate now that the author has returned to this plan by taking the opportunity to expand his recent Dohme Lectures into the present invaluable monograph. There is now placed at our disposal a work in which for the first time the essential facts about ergot and ergotism have been gathered together and critically presented by the outstanding authority on the subject. The book is gracefully dedicated to the memory of Charles Tanret, the discoverer of ergotinine, ergothioneine and a pioneer worker with ergosterine. In spite of the diversity of the topics and the compactness of presentation, it is written in a most interesting, clear, readable and scholarly fashion.

The first chapter deals with the history and distribution of rye and of ergot and the early obstetrical use of ergot which resulted eventually in its introduction into official medicine first in the United States and later in European countries. The second chapter discusses the two types of ergotism—convulsive and gangrenous—from descriptive, historical and geographical standpoints. The interesting suggestion is developed that deficiency in Vitamine A is a probable factor in convulsive ergotism. A third chapter is devoted to the botany of the ergot fungus, its life cycle and its relation to agriculture. There follows a description of the numerous species of *Claviceps* and of the so-called "biological" races characterized by their infectiousness for definite hosts.

This is followed by a chapter on the chemistry of ergot—brought right up to date—containing the essentials of what is known concerning the substances peculiar to it, viz., the alkaloids ergotoxine, ergotinine, ergotamine and ergotaminine, and which are responsible for its characteristic physiological action. Discretion is used in regard to the space devoted to other constituents.

The fifth chapter discusses fully the pharmacology and the toxic effects of the alkaloids and of the other active amines, such as histamine, which are found in ergot. The last chapter is devoted to ergot in the pharmacopoeias and to the methods of making extracts and assays and finally to ergot in forensic medicine.

A most valuable feature is the extensive bibliography which ends the volume and which bears witness to the industry and thoroughness of the author in preparing this work. Because of the complexity of the material presented, the plan of dividing the various chapters into paragraphs with appropriate headings has been found most useful to the reader. These together with the page headings are distinct aids for ready reference. Finally, excellent judgment has been used in the inclusion of the illustrations to be found in the book.

THE SPACING OF NON-POLAR MOLECULES IN CRYSTAL LATTICES. THE ATOMIC DOMAIN OF HYDROGEN. A NEW FEATURE OF STRUCTURE OF THE BENZENE RING

BY EDWARD MACK, JR.¹

RECEIVED SEPTEMBER 25, 1931

PUBLISHED JUNE 6, 1932

Our knowledge of the structure of the crystal lattices of organic compounds is gradually increasing. But the progress is dishearteningly slow, due, of course, to the very great difficulties inherent in the problem. Several score of organic crystals have been subjected to x-ray analysis. In by far the larger number of these cases the analysis has not been rigorous enough to do more than tell us the dimensions of the unit cell and define the space group, if indeed it tells us as much as this. In only a very few cases has the more intimate structure been indicated, the orientation of the molecules with respect to the crystal axes and the arrangement and spacing of the atoms within the molecule.² One of the most disappointing features of the present technique of x-ray analysis is its inability to locate the hydrogen atoms. Most organic molecules contain a larger population of hydrogen than of any other kind of atom, and as a rule the hydrogen atoms, because of their single valence bond, occur at the ends or on the exterior surface of the molecule. As a consequence, x-ray analysis of an organic crystal generally presents us with a picture of a three-dimensional array of molecules hung in empty space, with large gaps between neighbor molecules, a picture more like that of a gas than of a solid. A question which immediately comes to mind is whether such intervening spaces can be filled up, by attachment of the missing hydrogen atoms on the proper chemical bonds, so that neighbor molecules then interlock. The present paper undertakes, in part, to answer this question.

In "A Note on the Crystalline Structure of Certain Aromatic Compounds," Sir William Bragg³ remarks "when cell dimensions and space

group have been determined the really difficult and the more fascinating problem still remains in finding the distribution of the atoms in space." In the present, although undoubtedly only temporary, default of x-ray intensity methods in determining the lattice positions of atoms in most of these aromatic molecules, the present author wishes to advance a stereochemical solution of some of these three-dimensional picture puzzles. The solution is based on the theory that the benzene ring is the flat graphite ring, a contention strongly supported⁴ by the rigorous analysis which Mrs. Lonsdale has made of the structure of crystalline hexamethylbenzene.⁵ From a stereochemical consideration of the probable structures of these aromatic crystals, we shall be able to draw some consistent conclusions regarding the size of the hydrogen atom, and shall also be led to the proposal of a new feature of structure for the benzene ring, based, as will be seen, on empirical evidence.

To begin with, before we proceed to a consideration of the size of the hydrogen atom and of the possibility of interlocking between neighbor lattice molecules, it would be well to define clearly just what we intend the expression "size of an atom" to mean.

Definition of Radius of Atomic Domain

The size of an atom, or molecule, will depend on the nature of the experimental probe which is used in its exploration. An atom which appears to be of a certain size under one set of conditions may present itself quite differently in another situation. Thus, for example, has arisen the well-recognized distinction between the "gas kinetic radius" and the "crystal radius" of an atom. Such a difference is not only to be expected on theoretical grounds, but is fully supported by a comparison of atom sizes actually obtained under different experimental conditions. The meaning of the expression "the size of an atom" is therefore ambiguous, unless the circumstances of the determination are defined. In the present paper we are interested in the size of hydrogen atoms under the conditions existing in the crystal lattice. This means that we are concerned with the size which the hydrogen atom (on a molecule) possesses in collision with hydrogen atoms on the surfaces of neighbor molecules, as a result of thermal motions which these molecules are undergoing, generally vibration, although sometimes also rotation.⁶

⁴ Since the manuscript of this article was submitted for publication, two other papers have appeared which indicate that the benzene ring is really the flat graphite ring: "An X-ray Analysis of the Structure of Hexachloro benzene, etc.," Mrs. Lonsdale, *Proc. Roy. Soc. (London)*, **A133**, 536 (1931); and "The Molecular Association, The Apparent Symmetry of the Benzene Ring, etc.," Hendricks and Hilbert, *THIS JOURNAL*, **53**, 4280 (1931).

⁵ Mrs. Lonsdale, *Proc. Roy. Soc. (London)*, **A123**, 494 (1929).

⁶ Pauling, *Phys. Rev.*, **36**, 430 (1930).

Gas Kinetic Radius.—We may attempt to represent the geometrical factors of a typical gas collision by Fig. 1. H represents a hydrogen atom bonded chemically to a carbon atom C, which in turn is connected to the other atoms in the molecule of which it is a part. The distance between the two nuclei C-H is about 1.08 \AA . This may be calculated from the moment of inertia 5.17×10^{-40} for methane.⁷ About the same value, 1.08 \AA ., is also readily calculated from the smallest moment of inertia found by Patty and Neilsen⁸ for formaldehyde, namely, about 2.7×10^{-40} for the rotation of the molecule $\text{H}_2\text{C}=\text{O}$ about the horizontal axis. This distance of separation of the nuclei of the two atoms is likely to remain approximately the same for methane molecules in the solid, liquid and gaseous states, and over a considerable temperature range, because of the difficulty of exciting vibration along the C-H bond, and this distance is also likely to hold for a hydrogen bonded to aliphatic carbon in *any* organic molecule.

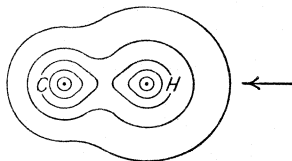

Fig. 1.

In accordance with the somewhat vague picture fostered at the present moment by the quantum mechanics, the two electrons of the electron pair which holds the two nuclei together, one electron supplied by the hydrogen and the other by the carbon, one electron with a right-handed and the other with a left-handed spin, are circulating around both nuclei, throughout both atomic domains, but spending a large share of their time, because of the eccentricity of the virtual orbits, between the two nuclei. The distribution of the electron density in such a system possibly resembles somewhat that calculated by London⁹ for the hydrogen molecule, and may be represented by the contour lines shown in Fig. 1. The positions of these contours given in the present figure are not to be considered the true ones, which must wait upon the actual calculation, but as merely indications of the fact that the electron density is greatest near the central portions of the system, and from there grades off exponentially toward the outer regions of the atomic domain. In a certain sense, then, the atomic domain of the hydrogen may be said to extend out from the nucleus to a very large distance, indeed to an infinitely large distance.

Now, when another molecule approaches from the direction indicated by the arrow, presenting one of its hydrogen atoms so that collision will occur with Hydrogen Atom H of Fig. 1, the two approaching hydrogen atoms first interact to develop an attractive force, the so-called van der Waals force. As the approaching hydrogen atom is carried deeper into

⁷ Dickinson, Dillon and Rasetti, *Phys. Rev.*, **34**, 582 (1929).

⁹ London, *Z. Physik*, **46**, 455 (1928).

the contours of Atom H, a mutual repulsive force begins to make itself effective. Rebound will finally set in, and the visitor atom will be driven elastically back out of the reach of the field of Atom H. Thus we may define the gas kinetic radius by dividing the distance of closest approach of the two hydrogen nuclei (one of which is shown in Fig. 1) by 2, and, taking this distance as radius, circumscribe two virtually hard spherical shells about the two nuclei, so that the two shells touch at the mid-distance. The depth of penetration, and hence the atomic domain radius, will depend on the violence of the impact blow; the radius would be expected to *become smaller as the temperature increases*, and in general will be smaller for a gaseous collision than for a solid or liquid.

Crystal Radius.—In a crystal the momentum of the approaching hydrogen atom is the momentum of the molecule to which it is rigidly attached, and the motion of the molecule is a vibration of the molecule as a whole about an average position within the lattice. As the approaching molecule moves out of its average position to approach Atom H, the blow against Atom H is very greatly softened because an attractive force seated in a neighbor molecule on the other side of the vibrating molecule slows it down, in the same way that a pendulum is slowed down after it passes through the bottom of its swing. In a gaseous collision, on the other hand, there is no source of attraction to hold the approaching molecule in check, and its blow of impact is delivered in full force. An organic crystal which is warmed up through a considerable temperature range suffers an expansion of its lattice to accommodate the increasing amplitude of the thermal vibration of the molecules with more free space or co-volume, and even as fairly low temperatures it is to be supposed that some free space will exist. It is therefore to be expected that the crystal radius, in contrast with the gas kinetic radius, will *increase with increasing temperature*.

Figure 2 diagrams the situation. A and B represent the framework of two lattice molecules vibrating about their average positions. When the two hydrogen atoms H_A and H_B move far enough toward each other, due to the motion of A and B, to which the hydrogen atoms are attached, repulsive forces cause them, and consequently also A and B, to retreat. On the other hand, when the molecules A and B recede beyond their average positions, the hydrogen atoms are pulled back together by attractive forces. We may define the crystal radius as half of the *average distance* between the hydrogen nuclei.¹⁰ This definition of atomic domain radius in crystals will also hold approximately for the domain radius of atoms on the

¹⁰ If this picture of the spacing of molecules in a lattice is pushed to its logical conclusion, it is to be noted that over the whole temperature range in which the lattice is stable, even at the absolute zero (because of the zero-point energy), the molecules will never occupy true equilibrium positions, that is, positions at which the repulsive and attractive forces balance, but will be occupying average positions. In the average positions the hydrogen atoms will be attracting one another.

surface of a liquid molecule. To adopt such a definition of atomic domain in the case of two vibrating neighbor molecules in a crystal lattice is, of course, begging the question of the space gaps between neighbor molecules which we have set out to answer, unless the particular size of hydrogen atom domain which is employed can be justified independently or unless the particular size which will explain the spacing of this molecule along one crystal axis will also account for the spacings along all other axes of the same crystal and along all axes of all other crystals in which the H . . . H contact is involved.

The electron density contours of the hydrogen atoms of Fig. 2 may be thought of as being compressed on approach, and as expanding on recession, like two balloon surfaces always in contact; or they may be thought of as undergoing a penetration into one another, as shown in the figure. In the present paper we fortunately need not concern ourselves with this precise mechanism, or with the origin and mechanism of the attractive and repulsive forces, since *the intention is to approach the problem in a purely empirical manner, to determine whether the spacing of organic molecules in crystal lattices can be explained in terms of atom domains of constant size in the same way that the spacing in inorganic crystals is at present accounted for in terms of ion domains of substantially constant radii.*

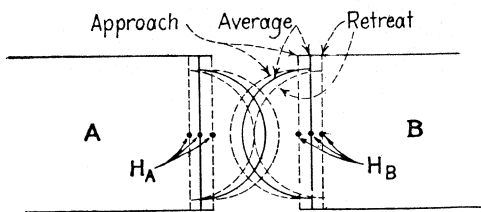

Fig. 2.

It is extremely convenient to describe the positions and spacings of the molecules with respect to one another by means of drawings and three-dimensional lattice models. For this purpose it is almost essential to represent the outer regions of the atom domain as a hard surface, and, since there is good reason for believing that the atom domain possesses approximately spherical symmetry, we shall employ a hard spherical surface. To call an atom a hard sphere is, admittedly, using a figure of speech. But if we recognize that it is figurative language, no harm is done and much advantage is gained in the simplicity and usefulness of the conception for the purposes of model building.

It is now possible to proceed with the estimation of the actual size of the hydrogen atom domain. It will be done first for a gaseous molecule, and then it will be shown that a reasonable extrapolation to a larger size will give a hydrogen atom crystal domain which will account consistently for the spacings of organic molecules in a crystal lattice. To complete the argument it would be desirable to compute the radius of the hydrogen atom domain on liquid molecules; but the difficulty of knowing the precise packing of the molecules in the liquid state and of allowing for the free

space arising from the probably more or less chaotic orientation of the molecules, seems to make the computation impossible in most cases. The situation of oriented molecules in the monomolecular oil film may eventually afford the opportunity of making such a computation, but at present our ignorance of the nature of the lateral packing and interlocking of the hydrocarbon chains does not encourage the attempt.

Empirical Estimation of Gas Kinetic Radius for Hydrogen.—The radius of the atomic domain of hydrogen bonded to carbon in a gaseous molecule may be obtained probably more easily from methane than from anything else. Rankine and Smith¹¹ have found from viscosity measurements, and by calculation with Chapman's equation, that the collision area of methane is 7.72 sq. Å. In so far as the Sutherland model is not valid, and to the extent to which Rankine and Smith's value is not reliable because of the small temperature range of the viscosity measurements (only from 17 to 100°), our own calculation of the atomic domain will be in error. The value is probably substantially correct, and at any rate is good enough for our present needs.

In a gaseous encounter with another like molecule, a molecule of methane probably presents itself as a sphere of revolution. The reasons for believing that this is so are as follows.

From the principle of the equipartition of energy the energy, E , of rotation of the methane molecule about a single axis is $\frac{1}{2} kT$, where k is the Boltzmann constant and T the absolute temperature. If, at let us say 25°, we assume that the equilibrium partition of energy is attained, $E = 2.04 \times 10^{-14}$ ergs. From the equation $\nu = \sqrt{2E/I}/2\pi$, where I is the moment of inertia, the frequency of spin ν may be calculated to be about 1.42×10^{12} r. p. s., and the time for one complete revolution to be about 7×10^{-13} seconds. Since both colliding molecules may be thought of as spinning simultaneously about four three-fold symmetry axes, or about three rectangular axes, and, furthermore, since the molecule would only have to execute about one-sixth of a revolution, it would behave effectively as a sphere if allowed a time not less than about 0.2×10^{-13} seconds. During such a time interval the translatory velocity of the bombarding molecule would carry it through a distance on the average of only about 0.14 Å.

If we further neglect any possible acceleration of velocity as the two molecules approach each other,¹² due to the attractive van der Waals forces, and any possible orientation as they get into one another's field, it is not likely that the approaching molecule would be able to penetrate appreciably into the spherical envelope of the molecule undergoing attack in regions where the hydrogen atoms do not happen to be at the instant of impact.

¹¹ Rankine and Smith, *Phil. Mag.*, **42**, 615 (1921).

¹² Herzfeld and Smallwood, Taylor's "Treatise on Physical Chemistry," 2d ed., D. Van Nostrand Co., New York, 1931, Chapt. IV, Vol. I, p. 241.

It therefore seems difficult to escape the conclusion that the spinning molecule is able to guard its envelope of revolution against invasion, and that it will present itself almost as a total sphere (Fig. 3). If this is true, the collision area of such a sphere would be Rankine's value of 7.72 sq. Å., with a radius of 1.57 Å. Since the distance from the carbon nucleus to a hydrogen nucleus is 1.08 Å., the radius of the atomic domain of hydrogen beyond the nucleus would be about 0.50 Å. (0.49 Å.). This is the minimum size: it may be slightly larger, to an amount depending on the extent to which the methane molecule behaves as a partial rather than a total sphere of revolution.¹³

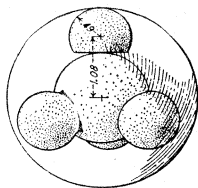

Fig. 3.

Empirical Crystal Radius for Hydrogen.—In view of what has already been said it is now reasonable to expect to find the crystal radius for hydrogen atom domain to be very much larger than the gas kinetic radius. Such an increase in domain size in passing from the gaseous through the liquid to the solid state is very likely to be a perfectly general behavior, characteristic of all atoms. For example, Natta and Nasini have recently shown that the xenon atom,¹⁴ crystallizing in a face-centered cubic lattice, has a radius of 2.18 Å., whereas the gas kinetic radius¹⁵ is 1.70 Å. For krypton the radius in the crystal is reported to be 1.98 Å.¹⁶ and 2.04 Å.,¹⁵ in a face-centered cubic lattice, while the radius in the gas is about 1.55 Å. For argon the respective crystal and gas radii are 1.92 Å.¹⁷ and about 1.44 Å.¹⁸ Approximately the same ratio holds for neon, and the same effect can be readily demonstrated for chlorine, bromine, iodine and other atoms.

Thus it will be noted that the crystal domain radius is larger than the gas kinetic radius by a factor of about $\frac{4}{3}$ or $\frac{5}{4}$ for the rare gases; the factor is 2 or more for hydrogen in the C-H group, for in the following sections the crystal lattice data indicate hydrogen atom domain radii of about 1.165 Å. (at about -195°) and 1.29 Å. (at room temperature), as compared with about 0.50 Å. for the gas kinetic radius. The hydrogen radius would seem to depend to some extent on the nature of the atom to which it is bonded. For example in crystalline H_2 (hexagonal close-packed and assuming rotating molecules) it is necessary to assign a value of about 1.5 Å. to the radius. In the present paper, however, we are interested only in hydrogen bonded to carbon. It is to be noted also that the crystal radius of hydrogen may be reduced by rotational rubbing.

¹³ The problem of collision between rotating molecules has been treated by Pidduck, *Proc. Roy. Soc. (London)*, **A101**, 101 (1922); and by Chapman and Hainsworth, *Phil. Mag.*, **48**, 593 (1924).

¹⁸ Rankine and Smith, *Phil. Mag.*, **42**, 601 (1921).

Crystalline Methane.—Mooy, whose results are undoubtedly more reliable than those of McLennan and Plummer,¹⁹ has recently shown by x-ray²⁰ examination of methane at liquid nitrogen temperature that the molecules are cubic close-packed in a unit cell of 5.88 Å. edge length. Pauling, basing his argument in part on heat capacity data, has demon-

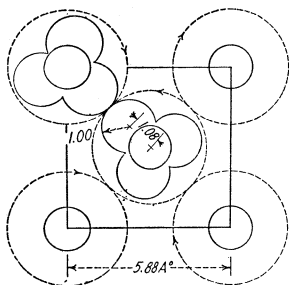

Fig. 4.

strated that the methane molecules are almost certainly rotating in the lattice above 20°K. (−253°). These effective spheres of revolution, without points of strong attraction for their neighbors, would be expected to pack together, as they do, in a face-centered cubic lattice, just as do the spherically symmetrical argon, krypton and xenon atoms.

The x-ray analysis shows, of course, the positions of the carbon atoms only. The space gaps may be filled up so that the spheres of revolution

osculate in the lattice, as shown diagrammatically in Fig. 4, by attaching hydrogen atoms to the carbon atoms at tetrahedral angles, with a C–H internuclear distance of 1.08 Å., and a hydrogen atom domain of radius 1.002 Å. This radius, probably reduced to the given size by rotational rubbing against neighbor molecules, would be expected to be somewhat larger if the molecules were not rotating. Perhaps some “cog-wheel” rotation occurs.

Crystalline Ethane.—Mark and Pohland²¹ have made an x-ray examination of crystalline ethane, using the powder photograph method, also at liquid nitrogen temperature (−195°), and report the hexagonal structure shown in Fig. 5. (This figure is similar to one given in Hendricks' review.) The carbon atom pairs in the figure are the C–C atoms of the C₂H₆ molecule. Now, if hydrogen atoms of size a little larger than that in methane, namely, with atomic domain radius of 1.165 Å., are attached to the carbon atoms at tetrahedral angles and with C–H internuclear distance of 1.08 Å., the space gaps are all filled up, so that the *hard spherical surfaces of the hydrogen atom domains of neighbor molecules just kiss*, on the supposition that the molecules

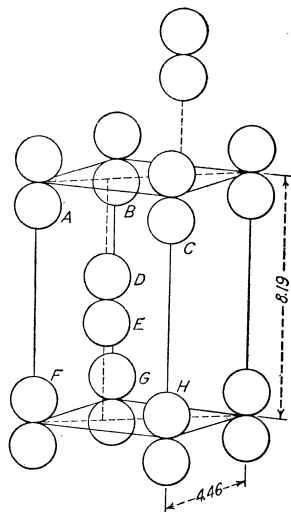

Fig. 5.

¹⁹ McLennan and Plummer, *Phil. Mag.*, **7**, 761 (1929).

²⁰ Mooy, Dissertation, *Nature*, **127**, 707 (1931); *Proc. Acad. Sci. (Amsterdam)*, **34**, 550 (1931).

²¹ Mark and Pohland, *Z. Krist.*, **62**, 103 (1925).

are not rotating. Figure 6, which is a photograph of a three-dimensional model made to scale, shows the manner of the interlocking. This hydrogen atom size accounts exactly not only for the horizontal edge length of the unit cell, 4.46 Å., but also for the vertical height, 8.19 Å. The hexagonal symmetry of the lattice is most beautifully accounted for in terms of the interlocking of the molecules, which themselves possess hexagonal symmetry, as is clearly to be seen from the photograph of the model, and also from Fig. 7, which

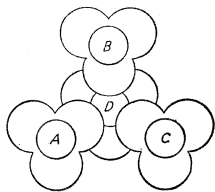

Fig. 7.

presents a view from above. Every ethane molecule in the body of the lattice makes six double contacts with its six immediate neighbors, contacts which resemble the meshing of teeth in gears.

It is of course possible that the molecules are rotating in the lattice about their own vertical axes. The hydrogen domain radius would then be about 0.96 Å., approximately the same as in methane, and is to be thought of as reduced to this size from 1.165 Å. by rotational rubbing. Possibly the rotation is more or less of a "cog-wheel" type. On the whole perhaps the non-rotating molecule solution is more satisfying, but both solutions seem possible stereochemically, and the question of whether the molecules are really spinning or not below the melting point of crystalline ethane will have to be determined by some independent method.

Crystalline Hexamethylenetetramine, $(\text{CH}_2)_6\text{N}_4$.

Figure 8 is the well-known diagram of the arrangement and spacing of the hexamethylenetetramine molecules in the body-centered cubic lattice, worked out by x-ray analysis by Dickinson²² and Raymond. Inspection of the figure shows the large space gaps between neighbor molecules. The spacing of the molecules

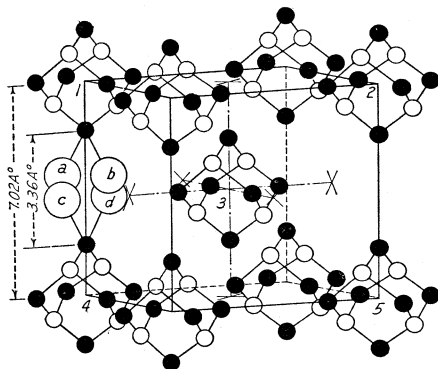

Fig. 8.

is determined by contact between the missing hydrogen atoms along the cube edges. Such a contact is illustrated in Fig. 8 by the insertion of Hydrogen Atoms, a, b, c, d to complete the two methylene groups. (The carbon atoms are represented by the solid black circles.)

²² Dickinson and Raymond, *THIS JOURNAL*, 45, 22 (1923); and Mark, *Z. physik. Chem.*, 107, 181 (1923).

If hydrogen atoms of crystal radius 1.29 Å. and with C-H internuclear distance of 1.08 Å. are now attached to the carbon atoms, distant 3.36 Å. from one another, the unit cube edge 7.02 Å. is precisely accounted for. The radius 1.29 Å. may be thought of as being assumed *ad hoc* or as derived empirically; but this same radius will now account extraordinarily satisfactorily for the spacings along all axes of all other crystals (where H . . . H contacts are involved and at room temperature) so far studied by the author. This is the radius which will be used in the stereochemical solutions of aromatic molecule lattices in the following pages.

The molecules also contact along the cube diagonals. Figure 9 is a diagonal plane section through the cube from one edge to the edge opposite; two of the cube diagonals lie in this plane, running from 1 to 5 and from 2 to 4, in the figure. The carbon atoms, diameter 1.54 Å., are represented by

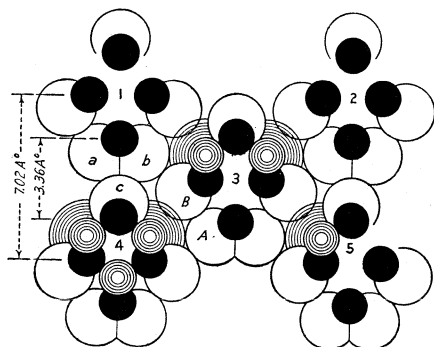

Fig. 9.

the solid black circles, the nitrogen atoms by the systems of concentric rings and the hydrogen atoms by the large single circles. Hydrogen Atom A of Molecule 3 (the middle molecule) kisses the nitrogen atom of Molecule 4 in the plane of the paper; and Hydrogen Atom B, which is somewhat forward of A, and a third hydrogen atom lying directly behind B, and deeper than A into the plane of the paper, both also kiss the nitrogen atom. Thus the domain of the

nitrogen atom on Molecule 4 rests in a nest of three hydrogen atoms belonging to the neighbor Molecule 3, with the triplicate contact centering along the cube diagonal.

The radius of the nitrogen atom domain which will permit contacts of this sort is about 1.5 Å. A nitrogen atom, with five valence electrons, uses only three in bonding itself chemically to the three carbon atoms to which it is linked in the hexamethylenetetramine molecule, and accordingly is left with a residuum of two unshared electrons. It is entirely reasonable to suppose that these two electrons will form an atomic "bulge" or projecting domain considerably larger than the hydrogen atom domain. More quantitatively, 1.5 Å. is about the domain radius size which one would expect the nitrogen atom to possess, in view of the fact, already noted, that atoms in general will exhibit a larger domain in crystals than in gases, and in view of the further fact that in order to account for the collision area of the gaseous ammonia molecule, 6.40 sq. Å. (reported by Rankine),²³ on the assumption that the molecule has a tetrahedral shape,

²³ Rankine, *Phil. Mag.*, **42**, 613 (1921).

nitrogen atom at the top and the three hydrogen atoms at the base, with a moment of inertia of 2.78×10^{-40} (reported by Robertson and Fox),²⁴ it is necessary to assign the nitrogen atom domain a radius size of about 1.2 Å. in the gaseous state. The ratio 1.5:1.2 for the crystal and gas radii is about the same as for the rare gases.

Hence it seems very probable that every molecule in the lattice partakes in eight such contacts, as illustrated by Molecule 3 in Fig. 9, two contacts along every one of the four diagonals of the unit cell. The spacing and symmetry of the lattice are thus accounted for in a most satisfactory manner, both along the cube edges and diagonals of the unit cell, in terms of the dimensions and symmetry of the molecule.

A Proposed New Feature of Structure for the Benzene Ring.—In spite of the large number of proposals of benzene molecule structure that have been made in classical organic chemistry and the more recent accretions to the list, the disposition of the fourth bond of the carbon atoms is still a baffling problem. x-Ray analysis is beginning to indicate quite clearly, as has already been noted on a previous page, that the unsaturated benzene "ring" is indeed a six-carbon atom ring and that the ring is flat, like the graphite ring rather than the "puckered" ring of diamond, although the saturated cyclohexane ring may be puckered as in diamond or as in the camphor molecule.

Not long ago Pauling made a most interesting suggestion that the fourth electron of every carbon atom is circulating,²⁵ in so-called μ -orbits, across the flat ring and around the carbon atom nucleus in the para position, thus forming chemical bonds connecting the para carbon atoms; but in a more recent paper he²⁶ suggests the possibility that every carbon atom is connected to one neighbor carbon by two single bonds and to the other by a double bond, and explains away the susceptibility to chemical addition, which is to be expected from such an unsaturated structure, by supposing that there is oscillation of the double bonds from one position to another, a supposition which in terms of the quantum mechanics would probably lead to chemical stability. At any rate it now appears, in apparent default of decisive chemical evidence to render judgment among the claims of the various benzene structure theories, that we may not be unduly optimistic to hope for an early solution of the difficulty either by means of x-ray intensity measurements, or even perhaps at the hands of the quantum mechanics.

But, in the meantime, whatever the answer to the question of fourth bond disposition may eventually be, it would seem abundantly clear that the unsaturation of the benzene ring manifests itself in the form of a pro-

²⁴ Robertson and Fox, *Proc. Roy. Soc. (London)*, **A120**, 189 (1928).

²⁵ Pauling, *THIS JOURNAL*, **48**, 1132 (1926).

²⁶ Pauling, *ibid.*, **53**, 1367 (1931).

tubercance or "bulge," extending out perpendicularly from each face of the flat ring. This idea may be said to be strongly supported by empirical evidence. As the idea developed in the author's mind it was at first supposed that the bulge might take the form of a crater-like elevation protruding above and below the carbon ring; then that the bulge might be cone-like, with the summits above and below the center of the ring; but finally that it must take the form of hemispherical domes, with a dome on each face of the ring. This dome is to be thought of as an electron domain, analogous to the domain of the hydrogen atom and the nitrogen atom, already discussed in preceding pages. The space occupied by this dome domain is guarded more or less against invasion by approaching atoms and molecules depending on the violence of the impact below. The best evidence for the existence of the dome arises from the possibility of explaining quite satisfactorily the observed manner of the spacing and packing of aromatic molecules in crystal lattices, if such a dome is assumed to be present, and the apparent difficulty of so doing without the dome.

In the present paper, while we are primarily interested only in the empirical evidence supporting the idea of the presence of the dome, it may be noted, in passing, that a seemingly sound theoretical justification for the idea is to be found in Pauling's first proposal of benzene ring structure. His virtual electronic μ -orbits, encircling para carbon atoms, would be expected to repel one another, and to flare out symmetrically from both faces of the ring to give effectively two hemispherical domes.

Now we may proceed to the proposed stereochemical solutions of graphite, anthracene and naphthalene, benzene and hexamethylbenzene; then some additional arguments for the presence of the benzene dome will be presented.

Structure of Graphite.—x-Ray analysis has now shown without doubt that the carbon atoms of graphite are arranged in flat hexagonal rings in flat layers, in contrast to the puckered layers of diamond. These flat layers are superimposed above one another, but are separated from one another at a surprisingly large distance²⁷ (3.40 Å.), a structure for which it has hitherto been difficult to find a satisfactory explanation. Such a large distance between these molecule layers certainly strongly suggests the presence of protuberances perpendicular to the flat layers, that is, to the faces of the hexagonal rings. It is these protuberances which hold the layers apart at the observed spacing.

Figure 10 shows the nature of the suggested structure. Every hexagonal graphite ring possesses a hemispherical dome on each of its two faces, with a dome domain radius, measured from the mid-point of the ring, of about 1.84 Å. This dome radius is considerably smaller in graphite than

²⁷ Hassel and Mark, *Z. Physik*, **25**, 317 (1924); Bernal, *Proc. Roy. Soc. (London)*, **A106**, 749 (1924).

in benzene, as will be seen later, because in the graphite structure every carbon atom is a part of three different rings, and must share its fourth electron among three different domes. Thus every graphite ring can claim only two electrons for the formation of its two domes, whereas benzene builds its two domes from six electrons. A dome in one layer fits into a nest of three domes in the adjacent superimposed layer, and this relative arrangement of superimposed layers explains exactly the relationship deduced from x-ray analysis. In the observed arrangement a six-carbon hexagon in one layer is so placed that three of its carbons (all in meta positions with respect to one another) lie directly above and below carbon atoms in adjacent horizontal layers, and the other three carbons (also in *meta positions*) lie directly above and below the centers of rings in adjacent layers. Furthermore, while the carbon atoms within a flat layer are held together by chemical bonds, the interlayer forces, by virtue of the contacting between the electron

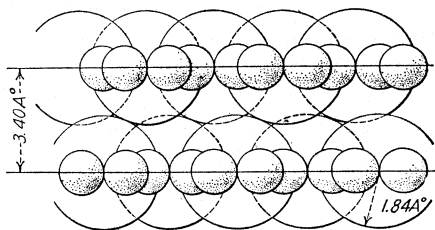

Fig. 10.

domain domes, are merely van der Waals forces. Hence these layers would be expected to be susceptible to slippage and gliding with respect to one another, in a manner which accords with the facts.

Anthracene and Naphthalene.—In Sir William Bragg's²⁸ original examination of crystals of naphthalene and anthracene, and even in Robertson's more recent analysis,²⁹ it was supposed that the carbon rings in the two molecules were puckered diamond rings. But, still more recently, in a letter to *Nature*, Banerjee³⁰ presents what is undoubtedly just about the correct solution of these crystal structures, and his analysis shows that the carbon rings are flat, and further differs from the solutions of Bragg and Robertson in placing the flat faces of the molecules more nearly in the *bc* than in the *ac* planes. In the same number of *Nature* Robertson admits the essential correctness of Banerjee's conclusions and also presents reasons based on unpublished work of his own and of Bragg in further support of these conclusions. Banerjee was apparently able to make his successful analysis because of the work of Bhagavantum on the magnetic anisotropic properties of naphthalene. Bhagavantum,³¹ taking advantage of the peculiarly strong magnetic susceptibility of the benzene ring in a direction perpendicular to its flat face, suspended small crystals from silk fibers in a strong magnetic field, and from the position assumed by the

²⁸ Bragg, *Proc. Phys. Soc. (London)*, **34**, 1, 33 (1921); **35**, 3, 167 (1923).

²⁹ Robertson, *Proc. Roy. Soc. (London)*, **A125**, 542 (1929).

³⁰ Banerjee, *Nature*, **125**, 456 (1930).

³¹ Bhagavantum, *Proc. Roy. Soc. (London)*, **A124**, 545 (1929).

crystals in the field deduced the placement of the naphthalene and anthracene molecules with respect to the crystal axes of the lattice. With this much of a guide to the probable parameters of the individual carbon atoms, Banerjee very cleverly obtained a good match between calculated and observed x-ray intensities, thus establishing an extremely probable structure.

According to Banerjee, "the correct positions of the molecules are obtained by first placing them along the bc planes, then rotating them through 25° about the c axis (the two molecules in the unit cell being rotated in opposite directions), and then rotating them about b axes through 12 and 9° for naphthalene and anthracene, respectively." This statement together with the cell dimensions and space group will be taken as the basis of our stereochemical solution.

Since the molecules of any lattice normally arrange themselves so that the maximum number of contacts between atoms attracting one another with van der Waals forces is obtained, and the minimum possible potential energy achieved, we should expect the molecules of anthracene, for example, to pack together face to face, with the ten hydrogen atoms of one molecule contacting with the ten of a neighbor molecule. But since the presence of the dome-like protuberance on the faces of the rings prevents as close a packing as this, just as it does in the case of graphite, the molecules have to be content with the next closest possible packing, which would seem undoubtedly to be the one described by Banerjee.

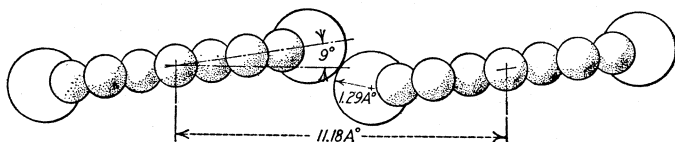

Fig. 11.

The dimensions of the anthracene monoclinic unit cell are: $a = 8.58$, $b = 6.02$, $c = 11.18 \text{ \AA}$, $\beta = 125^\circ$. The space group is C_{2h}^5 . Let us consider Fig. 11, where two anthracene molecules (with the domes temporarily omitted) are inclined to the c axis at an angle of 9° , in accordance with the specifications of Banerjee. The distance between molecule centers is 11.18 \AA . (length of c axis). The three rings of the anthracene molecule are graphite rings with carbon atom diameters of 1.42 \AA . The hydrogen atoms are placed in the plane of the rings, with a C-H internuclear distance of 1.02 \AA . This distance is reduced from 1.08 \AA , the H-*aliphatic* C internuclear distance, to correspond with the analogous reduction observed from aliphatic C-*aliphatic* C (1.54 \AA) to aliphatic C-*aromatic* C (1.48 \AA). It cannot be in error by more than a few hundredths of an Angstrom unit, and probably is just about right. In the figure there are contacts between

two end hydrogen atoms of one molecule and two of the other, although the second hydrogen atoms are hidden directly behind those shown in the drawing. With the molecules in the position shown, the hydrogen domain radius which just gives contact is 1.29 \AA . In *naphthalene*, the c axis length is 8.68 \AA , and when these two molecules, shorter than anthracene, are set along the c axis, with their centers at this distance apart, and with their end hydrogen atoms (radius 1.29 \AA .) just kissing, the angle of inclination of the molecules to the c axis is 12° , which accords beautifully with Banerjee's requirement.

It is indeed difficult to represent clearly in two-dimensional drawings the details of these fairly complicated three-dimensional models. In Fig. 12, where we look into the ab face of the anthracene unit cell, we may avoid some confusion of lines by looking directly into the ends of the molecules rather than perpendicularly into the face. Such a view foreshortens the a axis, reducing it from 8.58 to 7.71 \AA . In this figure the five molecules Nos. 1, 2, 3, 4, 5, the centers of which lie in the nearer ab face, have their carbon atoms shaded; the others, Nos. 6, 7, etc., which lie in the farther ab face, are unshaded. It will be noted that Molecules 1 and 2 (at the top) as well as Molecules 4 and 5 (at the bottom) are inclined at angles of 25° to the bc plane, and that when their centers are spaced 6.02 \AA . apart, their three

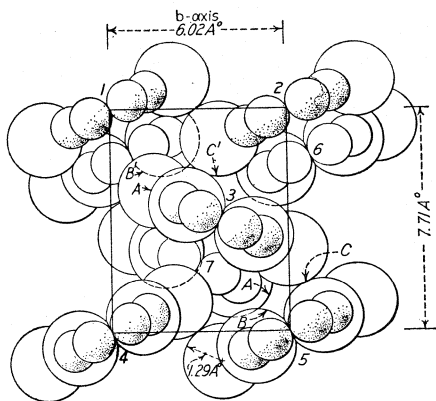

Fig. 12.

outlying side hydrogen atoms (two of which are hidden in the drawing directly behind the first) all just contact with three of a neighbor molecule, when the hydrogen domain radius is 1.29 \AA . Molecule 3, which is located a little to the right of the face center, is rotated 25° clockwise, in contrast with the counter-clockwise rotation of Molecules 1, 2, 4 and 5. Of the three outlying hydrogen atoms on the lower right-hand side of Molecule 3, the one farthest to the front rides on the upper right-hand end hydrogen atom (farthest to the front) on Molecule 5, as shown at C. A similar contact in the next layer above is shown at C'. All three of these hydrogen atoms of Molecule 3 also ride on the domes of Molecule 5, although the domes are not drawn in Fig. 12. But the manner in which the side hydrogen atoms (not shown in Fig. 12) of Molecule 7 ride up on the domes of Molecule 8, which lies below Molecule 5, is clearly indicated in Fig. 13, which gives a view looking into the ac face. The size of the domes on anthracene is small enough to permit Molecule 7 to slip far enough to the

left (in Fig. 13) and far enough to the front (in Fig. 12) to let Hydrogen Atom A of Molecule 7 ride up on top of Hydrogen Atom B of Molecule 5. The same sort of contact occurs between Molecules 7 and 4 (Fig. 12). These hydrogen-hydrogen, and hydrogen-dome contacts between the oppositely inclined layers, repeated over and over again from layer to layer, account very satisfactorily for the observed spacings along the a axis. The angle β (125°) between the a and c axes is also quite exactly explained in terms of the contacts described.

The dimensions of the unit cell of naphthalene are: $a = 8.34$, $b = 5.98$, $c = 8.68$ Å., $\beta = 122^\circ 44'$. The arrangement of the molecules in the cell is almost identically the same as in anthracene. We have already accounted for the spacing along the c axis. The smaller a axis in naphthalene

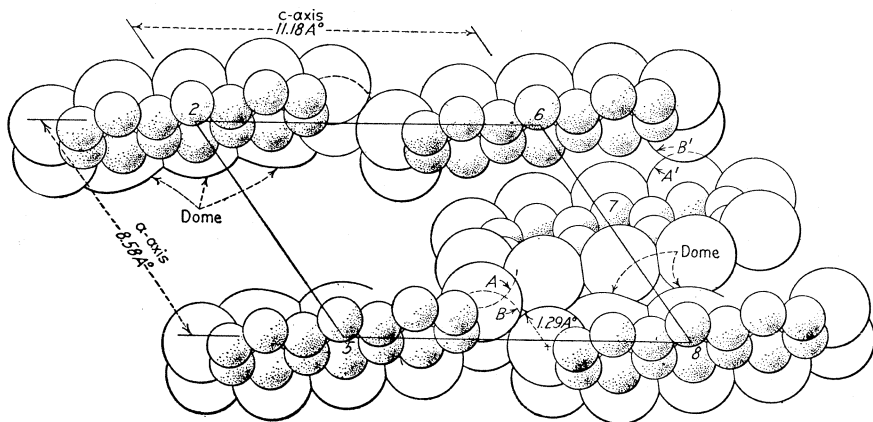

Fig. 13.

as compared with anthracene is to be attributed to the presence of a larger dome size at the two extremities of the naphthalene molecule as compared with anthracene. The domes over the middle ring of anthracene are distinctly small, probably not much larger than the graphite dome. At the extremities of the anthracene molecule the dome size becomes larger because there the fourth electrons do not have to be shared between the domes of an adjacent ring. To put the matter in most general terms, without attempting to give a detailed description of the exact size and shape of these domes, we may observe that in naphthalene we have ten electrons to distribute through the domes over two rings, whereas in anthracene we have only fourteen electrons to distribute over three rings. It is to be expected, then, that the dome size at the two extremities of the anthracene molecule would be appreciably smaller than in naphthalene. This larger dome in naphthalene prevents Molecule 7 (Fig. 13) from slipping quite as far to the left as it does in anthracene, and hence gives a smaller value of the angle β ; and prevents Atom A from riding quite as high up

on Atom B (Figs. 12 and 13), and hence also reduces slightly the length of the a axis in the case of naphthalene. The b axes are almost exactly the same in the two crystals, but it is likely that the slightly different arrangement of the molecules in naphthalene results in tipping the molecules with respect to the bc plane (Fig. 12) slightly more than in the case of anthracene, enough to reduce the b axis from 6.02 to 5.98 Å.

It may be of interest to note that essentially the same stereochemical solution can be obtained, as far as spacing along the c axis is concerned, by employing the puckered diamond ring. However, along the b and a axes the staggering of the hydrogen atoms above and below the plane of the puckered ring is such that no consistent contacting between hydrogen atoms occurs. If the nature of the packing here suggested is accepted as correct, then the stereochemical argument strongly favors a graphite instead of a diamond ring.

Benzene.—Eastman,³² Broomé,³³ Mark³⁴ and Cox³⁵ have subjected crystalline benzene to x-ray examination. All of the analyses agree roughly as to the orthorhombic cell dimensions. Probably Cox's results, obtained with crystals at -22° , are most reliable; $a = 7.44$, $b = 9.65$, $c = 6.81$, 4 molecules per unit cell and space group Q_h^{15} .

The stereochemical solution is shown in Fig. 14, looking into the ac face. The five shaded molecules, with their centers lying in the plane of the ac face, form a part of an end-centered lattice. At the opposite end of the cell, in the farther ac face, lying directly behind the shaded molecules of Fig. 14, is an exactly similar stack of molecules. In between these two lies a third similar stack, connecting the two together, but displaced in the lattice. In Fig. 14, the four unshaded molecules belong to this middle stack. On these unshaded molecules the domes have

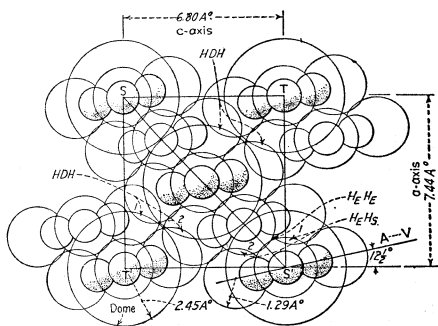

Fig. 14.

been omitted to avoid some confusion of line. This middle stack of molecules nestles into the nearer stack of the ac face and also into the farther stack, in such a way as to determine the length of the b axis (shown in Fig. 15) as well as the lengths of the a and c axes (Fig. 14). The details of this "nestling-in" are as follows. The farther end hydrogen atom of Molecule S', in the lower right-hand corner of the cell (Fig. 14), supports the nearer

³² Eastman, *THIS JOURNAL*, **46**, 917 (1924).

³³ Broomé, *Physik. Z.*, **24**, 124 (1923); *Z. Kryst.*, **62**, 325 (1925).

³⁵ Cox, *Nature*, **122**, 401 (1928).

end hydrogen atom of a molecule in the middle stack, as shown at $H_E H_E$. This type of contact is repeated over and over again from layer to layer up through the diagonal plane $S'S$. Also the farther end hydrogen of Molecule S' contacts perfectly with the nearer side hydrogen atom of the middle stack molecule as shown at $H_E H_S$, Arrow 1; and the nearer end hydrogen of the middle stack molecule contacts perfectly with the farther side hydrogen of Molecule S' , as shown at $H_E H_S$, Arrow 2. In order to make these $H_E H_S$ contacts perfect it is necessary to suppose that the benzene molecules are all tipped at an angle of $12\frac{1}{2}^\circ$ to the bc plane, and they have been so drawn in Fig. 14. The $H_E H_E$ and $H_E H_S$ contacts are also illustrated in Fig. 15.

It is interesting to note that, when the molecules (Fig. 14) are tipped $12\frac{1}{2}^\circ$ as just described, the two side hydrogen atoms on the left-hand side of the middle molecule of the nearer ac face (shaded) make a perfect contact

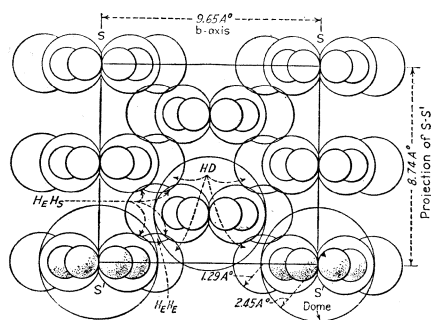

Fig. 15.

with the dome of Molecule T' , if the dome is assigned a radius of 2.45 \AA , as shown at HDH , Arrow 1. And similarly the right-hand side hydrogen atoms of Molecule T contact perfectly with the dome of the molecule at the center of the face, as shown at HDH , Arrow 2. Thus these HDH , $H_E H_E$ and $H_E H_S$ contacts explain the spacings along the a and c axes. It will be noted that the side hydrogen atoms (radius 1.29 \AA) of Molecule S' do not contact with the side hydrogen atoms of Molecule T' along the horizontal axis, as was the case in naphthalene and anthracene.

In Fig. 15 we are looking into the ab face, but in order to simplify the drawing we are not looking normally into the face but into the Section SS' (see Fig. 14), into the plane of the molecules themselves, that is, along the line $A \dots V$ (see Fig. 14), at an angle $12\frac{1}{2}^\circ$ to the bc planes. This stereochemical solution accounts for the symmetry and all of the dimensions of the unit cell down to the last hundredth of an Ångström unit. The only further *ad hoc* assumption that must be made, except for the radius 2.45 \AA for the dome, is that the dome is very slightly deformable near the carbon atoms of the benzene ring, so that the end hydrogen atoms of neighbor molecules can penetrate a little into the spherical domain, as shown at HD in Fig. 15. Such a penetration is quite reasonable, since the hydrogens enter between the carbons, and can be thought of as slipping in between the ridges of Pauling's μ -orbitals.

In concluding our discussion of the benzene lattice it may be pointed out that the stereochemical solution suggested here gives four molecules

per unit cell, strongest reflections for the 111 plane (as observed by Cox) and space group Q_h^{15} with the four molecules of the middle stack (Fig. 14) displaced somewhat, however, out of the face centers. As in the cases of naphthalene and anthracene, the puckered ring does not yield a satisfactory solution.

Hexamethylbenzene, $C_6(CH_3)_6$.—Mrs. Lonsdale's analysis⁴ of the triclinic crystal hexamethylbenzene demonstrates the general features of structure shown in Fig. 16. This diagram gives a view looking into the ab face of a unit cell, where the a and b axes are inclined to one another at an angle of $119^\circ 34'$. In this face the four corners are occupied by benzene hexagonal plane rings, made up of carbon atoms of diameter 1.42 \AA ., and in the figure numbered 1, 2, 3, 4, 5, 6. Attached to these at carbon bond

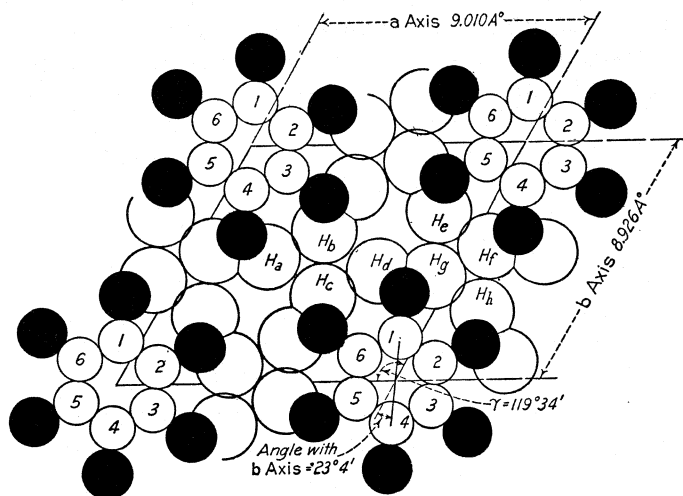

Fig. 16.

angles of 120° are the aliphatic carbon atoms (solid black circles) of diameter 1.54 \AA ., co-planar with the aromatic ring. The presence of large space gaps between the carbon atom clusters is evident from the figure. The question which we wish to have answered is: Can these gaps be filled up by attachment of the missing hydrogen atoms?

Regarding the methyl group Mrs. Lonsdale herself makes the following remarks. "In scattering power it is heavily weighted at the end nearer to the benzene ring by its carbon atom, which appears to retain its own electronic system more or less unchanged. . . . In fact the methyl group acts toward x-rays like an electronic shuttlecock, whereas single atoms behave rather like tennis balls. . . . Possibly if the exact shape and orientation of the methyl groups could be determined the problem of the crystal system would resolve itself into a question of the most convenient packing. . . .

The easy distortion of the crystals by slipping about the crystallographic axes may be caused by the rolling of methyl groups upon one another."

Following out Mrs. Lonsdale's suggestion, one may now attach the missing hydrogen atoms of the methyl groups with the C-H internuclear distance 1.08 Å., as we have done in the case of the preceding *aliphatic* bonds. We must bear in mind, at this point, that Pauling has shown that the methyl groups in hexamethylbenzene are probably rotating,⁶ at room temperature. With a hydrogen atom domain of 1.29 Å. radius no rotation could occur because of the interference of neighboring methyl groups (ortho positions) on the benzene ring, unless the violence of the rotation were sufficiently great to compress the atomic domains. This is probably just what happens. The collisions between the hydrogen atoms of rapidly rotating adjacent methyl groups resemble in many respects gaseous collisions. The momentum of the approaching hydrogen atoms would easily carry them rather deeply into one another's domain, probably without altering appreciably the nature of the rotation, thus allowing one methyl ring of revolution to roll against another. At the same time, the bumping of these rotating methyl groups against one another would be expected to produce a little bond bending, and in the supplementary stereochemical solution which we are offering here to account for the spacings actually observed by x-ray analysis, we are making the very reasonable assumption that the hydrogens of a methyl group, while maintaining their distance of 1.08 Å. from the carbon atom, are pushed together slightly, or, stated more exactly, that the normal tetrahedral angle ($109^{\circ}28'$) between the line connecting a hydrogen atom to the aliphatic carbon and the line connecting the aliphatic to the aromatic carbon is distorted to an angle of about 125° .

In Fig. 10 the positions which the hydrogen atoms in the ring of revolution would occupy in the plane of the paper are shown. The rubbing of a methyl ring against a ring of *another molecule* would also be expected to reduce the atomic domain radius of the hydrogen atoms to some extent, and in the diagram the radius has been taken as 1.06 Å., reduced to this extent from 1.29 Å. by the impact of rotational collision. The reduction of the size of the hydrogen domain by rubbing between methyl groups on the *same* molecule is even more than this, to an extent illustrated in the drawing by the overlapping of Hydrogen Atoms H_c and H_d, H_g and H_h, etc.

The nature of the contact between methyl groups on vicinal molecules is clearly shown. Along the *b* axis, Methyl Group 1 makes a double contact with Methyl Groups 4 and 5 of the neighboring molecule, Hydrogen Atom H_g with Hydrogen Atoms H_c and H_f. Methyl Group 4 makes a double contact with Methyls 1 and 2.

We may now observe the lattice by looking perpendicularly into the *bc* face, Fig. 17. Since the 1-4 axis of the molecule is inclined $23^{\circ}4'$ to the

b axis (Fig. 16), we shall not be looking directly into Methyl Group 3, but shall be viewing it somewhat obliquely. It is extremely difficult to make the nature of the contacts, viewed in this direction, as obvious in a plane drawing as it is in a three-dimensional model of the lattice. But with

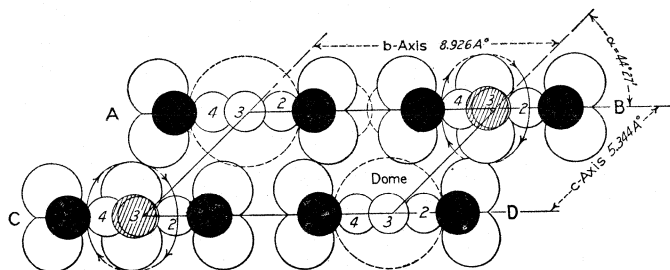

Fig. 17.

the aid of Fig. 17 and with the following list of the observed contacts, the general type of packing can be made fairly clear.

Upper layer	Lower layer
Methyl group 1 rolls on Methyl group 5	
Methyl group 2 rolls on Methyl group 4	
Methyl group 3 rolls on Methyl group 2	
Methyl group 4 rolls on Methyl group 3 and Dome	
Methyl group 5 rolls on Methyl group 6 and Dome	
Methyl group 6 rolls on Methyl group 1	

In these contacts made between molecules in the upper and lower layers, the hydrogen atom exhibits a domain radius approximately the same as in the *ab* plane, namely, 1.06 Å. Because of the presence of, and size of, the dome over the center of every benzene ring the molecules cannot pile directly over one another, center over center, and this is the reason, no doubt, why the crystal is not monoclinic or hexagonal. The lattice is triclinic because of the manner in which the Molecule A (Fig. 17) in the upper layer bridges the Molecules C and D in the lower layer.

In Fig. 16 it will be observed that the contacting between the spinning methyl groups of neighbor molecules along the *a* axis is almost, but not quite, the same as along the *b* axis, as indeed is to be expected from the slightly different lengths of the *a* and *b* axes. Dr. Pauling has very kindly suggested that this different spacing is controlled by the nature of the superposition of *ab* layers on one another. This is very probably the case. The spacing of the molecules in the *bc* stacks or nets is determined both by the rolling contact between methyl groups on vicinal molecules and by the nature of the bridging between layers, as already described. The different stacks of molecules along the *a* axes (Fig. 16) must then fit into one another as best they can. While the contacts along the *a* axes are good, and resemble quite closely those along the *b* axes, the contacts near the center of

the *ab* face are not so good. Here Atom H_b makes a single contact with Atom H_c , and Atom H_d just fails to touch Atom H_b , and H_a similarly fails to kiss H_c , or at least the interaction is looser than in the other contacts.

On the whole, this stereochemical solution for hexamethylbenzene has required more *ad hoc* assumptions than for the other crystals reported in this paper. But it must also be remembered that its structure is much more complicated than any of the others. In a later paper solutions of diphenyl, phenanthrene, indigo, *p*-dichloro-, dibromo- and di-iodobenzene, will be presented. In fact no crystal so far studied by this stereochemical method has failed to yield a reasonable and consistent result. With a little more experience in matching the stereochemical solution against the x-ray analysis, and with a more complete knowledge of the domain radii of oxygen and nitrogen and other atoms, it is probably not too much to hope that we shall be able to predict, accurately, the structural details of unit cells of organic crystals without x-ray analysis, simply from crystallographic and density data. At the very least, such a stereochemical approach should become an important aid, like Bhagavantum's studies on magnetic susceptibility, in determination of the parameters of the individual atoms in the skeletal organic molecules of the lattice.

Other Arguments for the Benzene Dome

In addition to the empirical crystallographic evidence already presented, we may marshal some further arguments in support of the postulate of the presence of an electronic dome domain over the face of the benzene ring.

1. **Collision Area of the Gaseous Molecule.**—Nasini and Lowry³⁶ have reported a collision area of 19.0 sq. Å. for the benzene molecule, determined by gaseous viscosity measurements. The satisfactory correspondence which one can obtain between collision areas of molecules in general and the collision areas predicted from a shadow-graphic treatment of probable models made to scale,³⁷ would seem to warrant an extension of this method of approach to the problem of gaining a decision among various disputed spatial configurations of organic molecules.

In the present case, a model of benzene made to scale (1 inch = 1 Å.) from a graphite ring, with six attached hydrogen atoms of *gas kinetic* radius about 0.63 Å. (taken as 0.63 instead of 0.50 Å. because probably *two* hydrogen atoms on each molecule on the average partake in the collision),³⁸ with a C-H internuclear distance of 1.02 Å., and with due consideration of the spins of the gaseous molecule gives a shadow area of

³⁶ Nasini and Lowry, *Proc. Roy. Soc. (London)*, **A123**, 686, 692 (1929).

³⁷ Melaven and Mack, *THIS JOURNAL*, **54**, 888 (1932).

³⁸ Adam, *Proc. Roy. Soc. (London)*, **A103**, 676 (1923); Adam, Berry and Taylor, *ibid.*, **A117**, 532 (1928).

just 16.0 sq. inches. This average area is much too small, and suggests strongly that the benzene molecule must certainly possess some structural feature which causes it to present a much larger target to molecular bombardment. When a hard-surfaced spherical dome is attached to each face of the ring, with a *gas kinetic* dome radius of about 2.0 Å. (reduced 20% from the crystal dome radius of 2.45 Å. by analogy with the similar reduction suffered by the rare gas atoms), the collision area comes out to be about 18.6. This is very good correspondence with the result of Nasini and Lowry. The argument is reasonable, and its force cannot be ignored.

2. Oil Films.—Adam³⁸ and his students, in their study of oil films made up of long chain molecules attached to polar heads which were phenol groups, with the molecules probably oriented vertically in the water surface, have found a surface area of 24.0 sq. Å. for every benzene ring in the condensed film, on the assumption, of course, that the OH group plays no part in the spacing. Since this film is reported to be a *solid* film, it would be

very plausible to suppose that the packing resembles that of the end-centered lattice in the *ac* face of crystalline benzene, Fig. 14. The nature of the close-packing which we here propose for this film is illustrated in Fig. 18. The hydrogen atom dimensions (1.29 Å.) and the dome dimensions (2.45 Å.) are here exactly the same as in Fig. 14. It will be remembered that the lengths of the *a* and *c* axes in Fig. 14 are determined by the nestling in of the middle stack of benzene molecules.

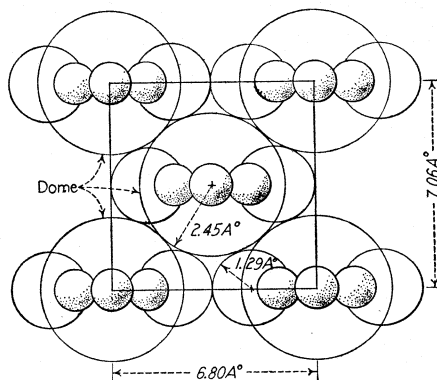

Fig. 18.

Here, in Fig. 18, the domes would be expected to pack together tightly, allowing the setting up of the system of perfect contacts between hydrogen and hydrogen, dome and dome, and dome and hydrogen pairs, shown in Fig. 18.

The author has considered various other possible packings, involving the hydrocarbon chains as well as the benzene rings, but cannot find any arrangement that is nearly as quantitatively satisfactory as this one. The film area of this unit rectangle, which contains two molecules, is exactly 48.0 sq. Å., giving 24.0 sq. Å. per molecule. The possibility of this arrangement and spacing depends, of course, on the presence of the dome. This argument for the presence of the dome would therefore seem to carry considerable force.

3. x-Ray Examination of Liquid Aromatics.—Stewart³⁹ has deduced from his x-ray examination of liquid benzene and other liquid aromatics

³⁹ Stewart, *Chem. Rev.*, **6**, 495 (1929).

some spacings of the order 4.7 \AA ., which he supposed to correspond with the thickness of the rings as they are packed together in the liquid state. But, as Adam⁴⁰ points out, it is difficult to account for such a large spacing in terms of the ordinary conception of benzene molecule structure. Such spacings can, quite evidently, be satisfactorily explained with the aid of the dome.

4. Molecular Domain Due to Unsaturation.—In general it is to be expected that unsaturation such as that of the benzene ring, or of a double bond, or of a triple bond, will manifest itself as a geometrically symmetrical bulge more or less impenetrable by approaching atoms and molecules. For example, Titani⁴¹ has calculated from his gaseous viscosity measurements the collision areas (he expresses the results in terms of radii) of 10.63, 10.29 and 10.63 sq. \AA ., respectively, for molecules of ethane, ethylene and acetylene. These results obviously indicate, even when the spins are taken into consideration, that ethylene and acetylene, which in spite of their smaller number of hydrogen atoms and smaller internuclear C—C distances present about the same target area in collision as ethane, acquire considerable domain by virtue of their unsaturation. Very likely the acquired bulge is produced by the repulsion of the bonding electrons.⁴²

In addition to the arguments given above, mention may be made of a curious x-ray diffraction effect which Raman observed when working with graphite.⁴³ It seems likely that this effect, as well as the peculiar magnetic⁴⁴ properties of the aromatic ring, may be related to the dome.⁴⁵

And now, at the end, if it may be granted that the empirical evidence presented here constitutes a reasonably good case for the existence of the dome, there are certain implications which follow from the presence of the dome on the aromatic ring. For example, it becomes possible to make a

⁴⁰ Adam, "The Physics and Chemistry of Surfaces," Oxford University Press, 1930, p. 106.

⁴¹ Titani, *Bull. Chem. Soc. Japan*, **4**, 277 (1929); **5**, 98 (1930).

⁴² In this general connection it is possible to marshal the arguments of the Sugden parachor and the various treatments of liquid molecular volume to show the probability of a bulge on the benzene ring due to unsaturation. We shall, however, refrain from so doing because of the well-founded suspicion that such arguments, based on an application of the additive principle to skeletal organic molecules, are likely to be extremely misleading.

⁴³ Raman, *Nature*, **124**, 53 (1929).

⁴⁴ Raman, *ibid.*, **123**, 945 (1929); Ehrenfest, *Physica*, **5**, 388 (1925).

⁴⁵ Since the present manuscript was submitted for publication, Mrs. Lonsdale has published a paper (Ref. 4) in which she gives a map of electron density contours for hexachlorobenzene. It is exceedingly interesting to note that she does find a considerable electron density over the face of the benzene ring, and it seems quite possible to interpret the density distribution as being that which one would expect for a dome. There is a question, however, as to what interpretation can be put on the curious figure-8 shape of the contours over the center of the ring, if indeed the resolution of the analytical method is powerful enough to establish the form definitely.

calculation of the compressibility of graphite, and also of the compressibility of the single-layer phenol films studied by Adam. The working out of the Crum-Brown rule and its modifications is probably in part a matter of the steric hindrance of the dome. The benzene molecule is inert chemically because it is sheathed in the fairly impenetrable electron cloud of the dome. When a foreign atom or group does manage to displace a hydrogen atom under the dome-deforming influence of such a thing as a catalytic surface, for example, then the electrical character of the substituent itself, when it has entered the ring, will play a controlling role in the precise nature of the resulting distortion of the dome, and the resultant guarding and unguarding of the various positions around the ring. A detailed consideration of conclusions to which some of these implications lead must be left for a future paper.

The author wishes to express his gratitude to Dr. Preston M. Harris, and especially to Dr. Linus Pauling, for many helpful suggestions received during the preparation of this paper.

Summary

The problem of the space gaps between molecules in organic crystals and the interlocking of the molecules in the lattice is stated, and the question of whether the molecular spacing can be accounted for by contact between out-lying hydrogen atoms is considered.

The "size of atomic domain" is defined for the purposes of the problem, and the actual sizes of the hydrogen domain radius in the gaseous and crystalline states are derived empirically.

In terms of a probable hydrogen atom size the spacings of the molecules and the symmetry of the lattice are explained for crystalline methane, ethane and hexamethylenetetramine.

From a consideration of some aromatic crystal lattices there emerges a proposed new feature of structure of the benzene ring, namely, *a dome-shaped electronic domain protruding symmetrically from both faces of the flat hexagonal ring*. In terms of this dome a stereochemical solution of the spacing of the layers in crystalline graphite is offered, and in terms of the dome and a constant hydrogen crystal radius of 1.29 Å. explanations are offered of the lattice symmetry and molecular spacing of anthracene, naphthalene and benzene. An attempt is also made to give a stereochemical solution of the structure of the hexamethylbenzene lattice.

Further arguments are presented for believing in the existence of the dome, including the empirical evidence of collision area, oil films, x-ray examination of liquid aromatics and molecular volume.

THE FLAME TEMPERATURES OF MIXTURES OF AMMONIA AND ITS PRODUCTS OF DISSOCIATION¹

By G. W. JONES,² BERNARD LEWIS³ AND HENRY SEAMAN⁴

RECEIVED NOVEMBER 2, 1931

PUBLISHED JUNE 6, 1932

The United States Bureau of Mines has received many inquiries relative to the flame temperature of ammonia and its products of dissociation. Ammonia can now be manufactured rather cheaply and is being produced in such quantities that there are difficulties in finding an adequate market. The gas can be compressed in the liquid form in cylinders, and if it can be burned directly with air, or, if necessary, partially or completely cracked at the place where it is used, it may become of industrial importance as a heating, welding or cutting gas.

Ammonia decomposes according to the following reaction

Completely "cracked" ammonia therefore consists of a mixture containing 75% of hydrogen and 25% of nitrogen.

The method of determining the flame temperatures was the same as described in previous publications,^{5a,b,c} with certain modifications (described later) when ammonia was one of the constituents.

The Flame Temperature of Hydrogen-Nitrogen-Air Mixtures.—The flame temperatures of hydrogen-air mixtures have been measured^{5c} and the maximum temperature was found to be 2045°. The flame temperatures of hydrogen-nitrogen-air mixtures were measured to determine the effect of adding nitrogen to the hydrogen-air mixtures. The results are shown graphically in Fig. 1. A mixture containing three volumes of hydrogen and one of nitrogen (representing completely cracked ammonia) has a maximum flame temperature of 1885°. The addition of this amount of nitrogen has therefore reduced the flame temperature about 160°. Incidentally, this temperature is approximately the same as the maximum flame temperature of methane or Pittsburgh natural gas in air.

Further additions of nitrogen depress the maximum flame temperature still more. For nitrogen and hydrogen in equivalent amounts it is 1680°,

whereas when approximately two volumes of nitrogen are present to one of hydrogen it has dropped to 1465° .

These results are of interest in showing the marked effect that inert gases such as nitrogen have on the maximum flame temperature of combustibles when burned with air and emphatically suggest the importance of keeping inerts in manufactured gas and other industrial gaseous fuels to a minimum if a maximum flame temperature is desired.

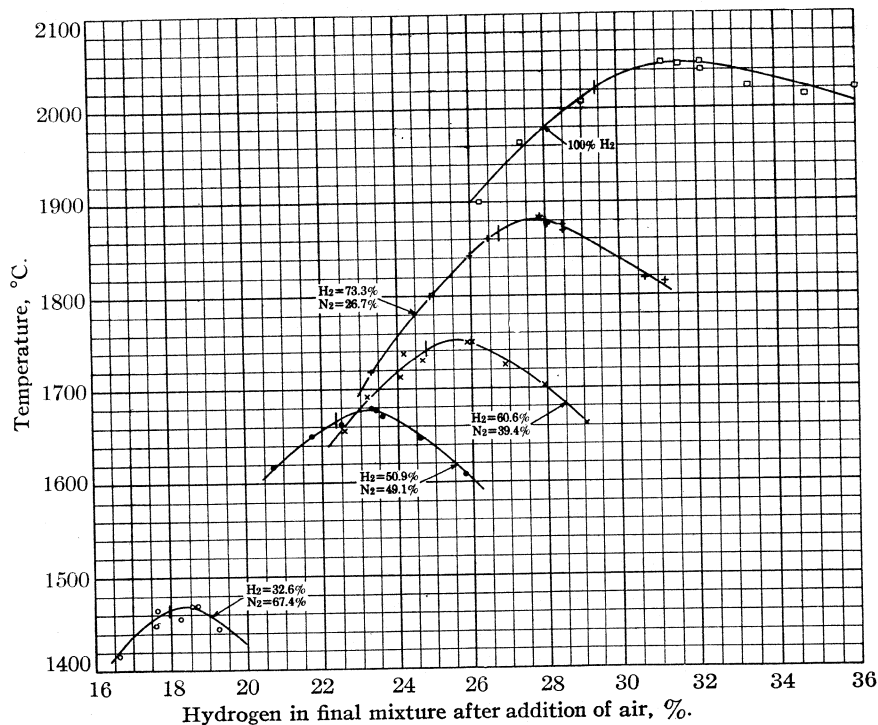

Fig. 1.—Flame temperatures H_2 - N_2 -air mixtures.

In the curves shown in Fig. 1, the percentages of hydrogen present representing complete combustion are indicated by short vertical lines crossing the curves. In agreement with results previously obtained for other combustibles,^{5a,b,c} the maximum temperatures occur slightly on the rich side.

Figure 2 shows graphically the decrease in the maximum flame temperature with increase in nitrogen content. The decrease is almost directly proportional to the percentage of nitrogen in the original hydrogen-nitrogen mixture before the addition of air. It was found impossible to obtain flame temperatures, by the method used, when more than about two volumes of nitrogen was present for one volume of hydrogen, because

the reversal of the sodium line was too indistinct. Determinations with larger proportions of nitrogen were abandoned.

The Flame Temperatures of Ammonia-($3\text{H}_2 + \text{N}_2$)-Air Mixtures.—

It was found impossible to burn straight ammonia in air (in order to obtain its flame temperature) at laboratory temperature with the various burners tried. The rate of flame propagation is too small to prevent the flame from blowing off the burner ports. Determinations were made with mixtures of ammonia and its dissociation products ($3\text{H}_2 + \text{N}_2$). An extrapolation for the maximum flame temperature of pure ammonia might then be made from these data.

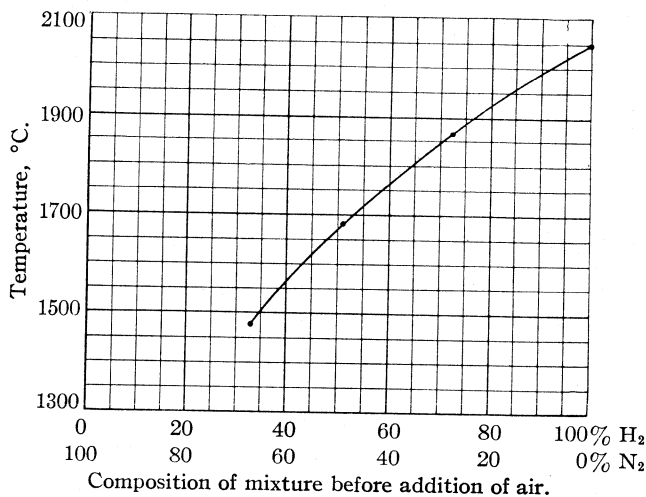

Fig. 2.—Maximum flame temperatures H_2 - N_2 -air mixtures, determined values.

Since ammonia is very soluble in water and glycerin-water mixtures the procedure for preparation of the gas mixtures had to be altered. They were prepared and stored in a high-pressure cylinder. Ammonia, nitrogen and hydrogen under high pressure (in tanks) were measured into an empty cylinder by means of a calibrated pressure gage in desired amounts. The gases were mixed by tilting the cylinder and applying gentle heat on one side near the bottom. Due to the convection currents set up, it was found that one hour was sufficient to mix the gases thoroughly. Samples of gas were then withdrawn for analysis. One sample was stored over dilute acid solution to absorb the ammonia. The unabsorbed gases, hydrogen and nitrogen were then transferred to a Bone and Wheeler gas analysis apparatus and determinations made for hydrogen, oxygen and nitrogen (the latter by difference). The percentage of oxygen present in the sample was assumed to be due to contamination by air. Correction for the amount of nitrogen associated with oxygen in air was made. If the ratio

of hydrogen to nitrogen was not three to one, more of one of the gases was added and the analysis repeated. For the analysis of ammonia the gas was passed into a 240-cc. calibrated sample tube and the sample taken over clean dry mercury. The temperature and pressure were recorded. The gas sample was passed through two efficient absorption bulbs (Bowen type) containing $N/10$ sulfuric acid. The unneutralized acid was titrated back with standard ammonium hydroxide solution using a cochineal indicator. The percentage of ammonia could then be calculated. Knowing the ammonia content the percentage of hydrogen and nitrogen in the original mixture could then be evaluated.

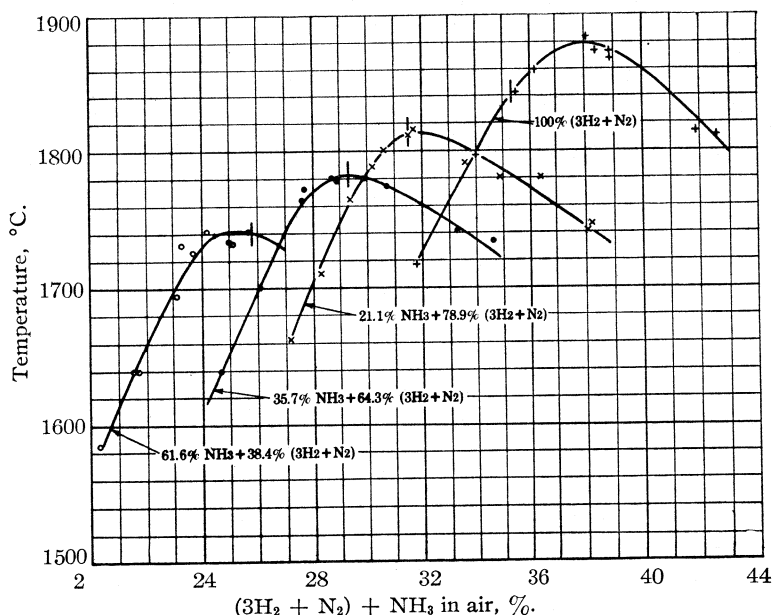

Fig. 3.—Flame temperature of mixtures of ammonia and its products of dissociation in air.

The flame temperatures of mixtures of ammonia and its dissociation products are shown in Fig. 3. The maximum flame temperature decreases with increasing proportions of ammonia. For 61.6% ammonia in the original combustible mixture it is 1740° . It was impossible to determine flame temperatures on the rich side of this mixture because the flames elongated and blew off the burner ports. Determinations for mixtures containing more than 61.6% ammonia were discontinued. The maximum flame temperatures occur slightly on the rich side except for the mixture containing the highest proportion of ammonia.

The maximum flame temperatures are plotted in Fig. 4. It is of interest to compare these with the maximum flame temperatures of the mixtures

calculated by the method described elsewhere^{5b} and represented by the upper curve in Fig. 4. They are about 75° higher than the observed, which is attributable to radiation losses. This difference is constant over the range investigated. The calculated maximum flame temperature for ammonia-air mixtures is 1775° . On this basis, assuming the difference to hold throughout the entire range, the observed maximum flame temperature of ammonia-air mixtures, if a laboratory burner could be developed to burn them, would be about 1700° .

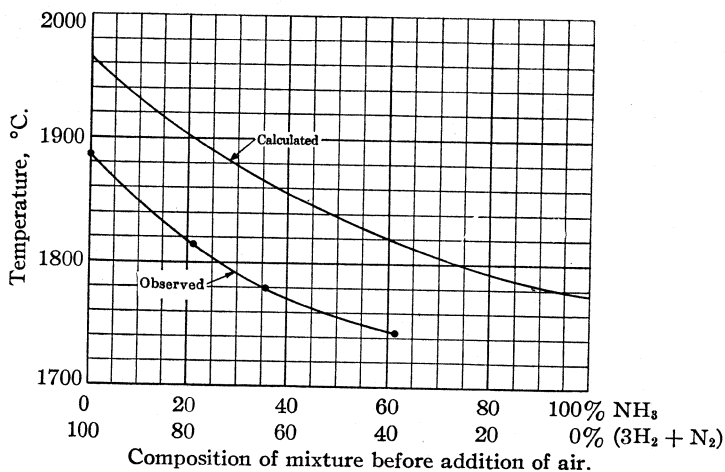

Fig. 4.—Maximum flame temperatures of ammonia-($3\text{H}_2 + \text{N}_2$)-air mixtures.

Summary

The flame temperatures of hydrogen-nitrogen-air mixtures and ammonia-($3\text{H}_2 + \text{N}_2$)-air mixtures have been measured by the sodium line reversal method.

The maximum flame temperature of a mixture $3\text{H}_2 + \text{N}_2$ is 1885° —about the same as that found for methane or Pittsburgh natural gas burning in air. Temperatures for other proportions of hydrogen and nitrogen are given.

The maximum flame temperature of ammonia, as determined by extrapolation, is 1700° .

The flame temperatures have been calculated and are in good agreement with the observed values.

A THEORY FOR THE ACTIVITY OF CONTACT CATALYSTS

By H. G. TANNER

RECEIVED NOVEMBER 4, 1931

PUBLISHED JUNE 6, 1932

During a study of the reaction of hydrogen and oxygen at low pressures on platinum wires¹ the observation was made that the activity of the wire was a function of the difference in temperature between the wire and the wall of the reaction tube. The pressure was such that the mean free path of the molecules was greater than the distance from the wire filament to the wall of the tube. If the wire and tube were at the same temperature the reaction would not proceed. When the wire was heated 50 to 100° higher than the temperature of the wall a reaction occurred. This was true for wall temperatures ranging from -180 to +200°. If a reaction was progressing, its speed would be increased merely by cooling the wall, and retarded if the wall temperature was made to approach the wire temperature. Appropriate experiments proved that this peculiar effect was not due to gas concentration, nor to the rate at which water vapor was removed from the reaction tube. The vessel wall had no catalytic effect since it made no difference whether the wall was Pyrex, fused silica, aluminum or molybdenum oxide-coated Pyrex. There was no alternative to the conclusion that the reaction rate was a function of the dissipation of energy from the catalyst wire, or, in other words, of the difference in temperature between the catalyst wire and the vessel wall. This conclusion led to a modified concept of catalytic activity.

Accurate measurements of the amounts of energy supplied to the wire were made as follows.

A small resistance of 0.30 ohm was connected in series with the catalyst. The construction of this resistance was such that its temperature would not depart appreciably from room temperature during the course of the experiment. A Leeds and Northrup thermocouple potentiometer was connected across this resistance as shown in Fig. 1. This arrangement furnished a precision null method by which the current through the catalyst arm of the Wheatstone bridge could be determined without disturbing the Wheatstone bridge balance.

As an example of the data obtained the voltage across the auxiliary resistance was found in a typical experiment to be 19.4 millivolts when the bulb of the catalyst tube was at 23°. The current flowing through this arm of the Wheatstone bridge was therefore 0.0647 ampere. Since the resistance of the catalyst filament was at that time 9.00 ohms (correspond-

¹ H. G. Tanner and G. B. Taylor, *THIS JOURNAL*, 53, 1292 (1931).

ing to 100°), the power supplied to the filament was 0.0377 watt. When liquid air was placed around the bulb the current through the catalyst arm of the Wheatstone bridge had to be increased to 0.138 amp. in order to maintain the catalyst resistance (average temperature) constant at 9.00 ohms. The power, therefore, was 0.171 watt. The ratio of these two wattages is as 1 is to 4.5. This means that four and a half times as much energy was being dissipated from the wire when the bulb was at -180° as when the bulb was at room temperature.

The ratio of the energies dissipated with bulb at room temperature and at liquid air temperature varied not only with the gas pressure, the nature

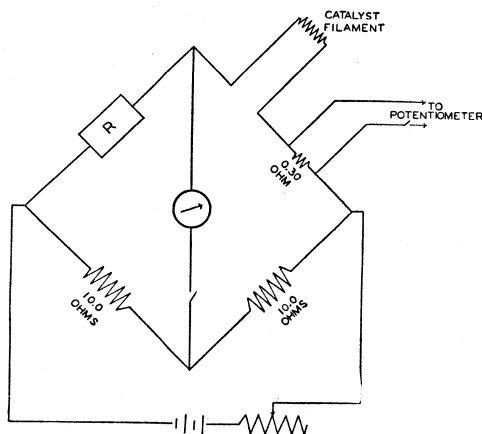

Fig. 1.—Diagram of electrical connections.

of the gas and other obvious factors, but also with the condition of the wire surface. The higher the catalytic activity of the wire the greater the effect of the bulb temperature upon the rate of reaction, and upon the abnormal cooling of the filament. These observations show that an intimate connection exists between thermal accommodation coefficient and catalytic activity and indicate that the accommodation coefficient itself may be a function of temperature difference.

It may be mentioned that the peculiar effect of bulb temperature upon the heat transfer from the wire was proved to depend upon the gases present and not upon the filament end-losses, or radiation. When the bulb was exhausted to a pressure below 1×10^{-6} mm., the heat losses from the filament were practically independent of the bulb temperature.

Speculations about catalytic activity frequently have been concerned rather with the mechanism of catalytic activation than catalytic activity in the strict sense of the term. Catalytic activity is an expression of the efficiency of a catalyst, and it should always be distinguished from the mechanism of catalytic activation. Concepts such as "elementary spaces," "stretched molecules," etc., assist in giving a definite picture of the way in which adsorption may occur, and how certain areas on a catalytic surface activate molecules, but these concepts are not sufficient to account for the difference in activity of two or more catalysts which may be chemically identical. This difference in activity has always been regarded as due to a difference in the number of active spots exposed. There is another possibility, however, which is worthy of consideration, *e. g.*, the rate

at which the active spots function. The efficiency of the active spots rather than their number may be the controlling factor.

The mechanism of adsorption plays a prominent part in current theories of catalysis. Although adsorption undoubtedly is of great importance, yet a catalyst functions only when molecules get up to the active spots, react, and the reaction products depart. Adsorption is but a part of this process. In a sense, a catalyst (more accurately the active spots) must "breathe" in order to function. Current theories stress adsorption, but give little or no consideration to the "exhalation" part of the cycle. The complete cycle of "respiration" and the rate of its occurrence are fully as important as the mechanism of adsorption.

The respiratory action is explained in this paper by assuming that the active spots fluctuate in temperature. During moments when one of them is below the average temperature, adsorption occurs. A little later this spot becomes hot (from Brownian motion of adjacent molecules, or chemical reaction, etc.), and the adsorbed molecule departs as a different chemical entity. When the spot has cooled the process repeats. From this viewpoint, catalytic activity is governed by those forces which control the temperature fluctuations of the active spots.

In the experiments above described no reaction occurred, for example, when the wire and wall were both at 100° . Maxwell's law of temperature probability could be applied to any given atom on the wire surface because a condition of thermal equilibrium existed. The probability that an atom departed a hundred degrees, say, from the average temperature was very small. Maxwell's law cannot be applied, however, when thermal equilibrium does not exist. It is not applicable to "steady state" conditions. When, in the experiment, the bulb was cooled by liquid air, gas molecules at -180° struck the filament whose average temperature was maintained at 100° . The probability that a given atom on the filament would be at 0° , for instance, was very much increased. The average temperature of the filament, however, was forcibly maintained at 100° . Therefore the probability of a given atom on the filament having a temperature of 200° , say, was greatly increased, as compared to thermal equilibrium conditions. In other words, for a given degree of probability, an atom on the wire surface fluctuated through a wider temperature range. The "time-lag" of gas molecules striking the filament was increased by their having a lower temperature at the moment of collision, and the probability of their subsequent activation, reaction and desorption was increased by their attainment of the postulated abnormally high temperatures. The rate of "respiration" of the active spots was increased because their fluctuations in temperature were either extended, or, for a given temperature change, made more rapid. The increased reaction rate which accompanied the temperature difference in the experiments described above is therefore explained.

The rate of clean-up of certain pure gases by hot filaments was found by I. Langmuir² to be increased when the temperature of the bulb was lowered. Nitrogen, for example, was cleaned up by a hot molybdenum filament very rapidly when the bulb was cold. Langmuir's explanation for the bulb-temperature effect was built upon the assumption that the rate of evaporation of the molybdenum was independent of the bulb temperature. The increased rate of clean-up was attributed to a higher reaction efficiency per collision of molybdenum vapor molecules and nitrogen when the bulb temperature was low.

An alternative explanation can be offered from the viewpoint of the hypothesis developed in this paper by assuming that the rate of evaporation of molybdenum was the controlling factor involved, and that this rate was affected by the temperature of the bulb. When a cold molecule of nitrogen struck the filament, a cooling effect occurred at that point. Since the average temperature of the filament was kept constant, an adjacent atom of molybdenum must therefore have acquired an abnormally high temperature. Since the rate of evaporation of molybdenum was shown by Langmuir to be an exponential function of temperature with a high coefficient, the greatly increased rate of evaporation from the abnormally high temperature areas would produce a net increase in the gross rate of evaporation. The greater amount of molybdenum vapor produced would of course account for the increased rate of reaction with nitrogen. If this interpretation be accepted there appears to be no fundamental difference in the effect of bulb temperature in these clean-up experiments, and in the catalytic experiments just described. Conversely, the fact that two independent examples of the bulb-temperature effect can be explained on a common basis lends support to the theory.

In the ordinary use of a catalyst the abnormal temperature fluctuations of the active spots are probably set up by any condition capable of disturbing thermal equilibrium. Adsorption desorption, and chemical reaction, for example, are processes involving large heat changes. Each of these processes would greatly disturb the normal Maxwellian variation of temperature of an active spot. An active spot may momentarily attain a temperature many degrees, perhaps many hundred degrees in case of gases, above or below the average temperature. Even when a liquid surrounds a catalyst, as for example an oil around nickel-on-kieselguhr, Armstrong and Hilditch³ found evidence that some of the nickel particles during hydrogenation must have attained a temperature above 300°, although the oil appeared always to be below 180°. This is significant, because it means that the particles of nickel fluctuated in temperature between these limits at least.

² Langmuir, *THIS JOURNAL*, **41**, 167 (1919).

³ Armstrong and Hilditch, *Proc. Roy. Soc. (London)*, **A108**, 111 (1925).

If the foregoing postulates concerning the temperature variation of active spots and catalytic activity be granted, other catalytic phenomena can be explained with the help of a few minor postulates. The beneficial effect of a rough surface, for example, is easily explained provided one grants that temperature oscillations are greater for an active spot located on a spire of a rough surface compared to the temperature variations of an active spot on a smooth surface. This assumption is not unreasonable because an atom located on the tip of a microscopic spire has less chance to stay in thermal equilibrium with its surroundings than an atom lying on a smooth surface.

The difficulty of correlating catalytic activity with adsorption can likewise be explained. Porous substances are good adsorbents. Some of them are good catalysts. Adsorption, however, is unidirectional and not "respiratory" or cyclic in character. Furthermore, adsorption probably occurs to a major extent *within* the capillary spaces of a porous substance, whereas catalysis is postulated to occur *on* the surface, *e. g.*, on the projecting spires at the mouths of the capillaries. A porous material may be one having capillaries highly branched within the body of the substance, or it may have a capillary structure such that most of the capillaries are short, and terminate on the external surface. The former would not be as rough a surface as the latter, but would probably adsorb a greater quantity of material. Porosity and roughness are therefore related. Similarly, adsorption and catalytic activity are related, but the relationship in either case will always evade any general quantitative treatment.

There is nothing in this explanation which would preclude some catalysis occurring in the depths of the capillaries of a porous substance, but in view of the respiratory nature of catalysis, and the slow rate of diffusion into and out of tiny capillaries, the interior surface of any capillary less than 1000 Å. in diameter probably plays but a minor role.

Catalyst supports must profoundly influence the temperature variations of the catalyst particles distributed thereon. When nickel oxide is precipitated on kieselguhr, for example, and subsequently reduced, the nickel does not form a continuous surface. The catalyst support protrudes here and there all over the surface. Ultramicroscopic specks of nickel are "imbedded" in a thermally different material. This heterogeneity of the surface is favorable to large temperature fluctuations of the nickel specks. A reaction occurs on a speck of nickel, thereupon the temperature is raised perhaps a hundred degrees or more.³ If this heat be not dissipated too rapidly, desorption occurs. Later the speck cools so that adsorption and reaction can again occur. Were it not for the thermal insulating effect of the catalyst support, the nickel speck could not attain as high a momentary temperature. A spot on massive smooth nickel would, in comparison, stay nearly constant in temperature because of the easier exchange of energy with neighboring atoms.

Promoters which do not act chemically may function by increasing the physical heterogeneity of the surface, and thereby accentuate the local temperature fluctuations. Clean liquid surfaces rarely, if ever, function as heterogeneous catalysts. The reason for this may well be that the active spots (elementary spaces) maintain a relatively uniform temperature.

Electron emission from heated filaments varies exponentially with temperature, and is always observed under thermal conditions far removed from equilibrium. Therefore, the concept of abnormal surface temperatures developed above may find application in explaining some of the peculiarities of electron emission. Roughness of surface, the rate of heat transfer from core metal to oxide coating, and a heterogeneous ("promoted") surface may each be factors to be considered. A study of the flicker effect⁴ with variation in the temperature of the gas striking the filament might yield information of value in substantiating or refuting the above developed theory, especially if K. H. Kingdon's⁵ suggestion that the flicker effect involves surface temperature fluctuations is found to be true.

Summary

Catalytic activity is postulated to depend upon the rate at which active spots function.

The action of an active spot is regarded as respiratory in character, and dependent upon fluctuations in temperature of these spots.

The concept of "average temperature" is discussed, and the probable thermal behavior of rough, heterogeneous surfaces is contrasted with that of smooth, homogeneous surfaces.

These concepts afford a partial explanation of variations in catalytic activity occasioned by promoters, supports, roughness of surface, porosity, etc.

The suggestion is made that electron emission may be influenced by the same thermal conditions which affect catalytic activity.

THE RATE OF DECOMPOSITION OF XANTHIC ACID

BY CECIL V. KING AND EMILIE DUBLON

RECEIVED DECEMBER 19, 1931

PUBLISHED JUNE 6, 1932

Introduction

It was suggested by Brönsted in 1925 that a study of the kinetics of the decomposition of the xanthic acids in aqueous solution would be valuable, and preliminary experiments were carried out by one of the present writers (C. V. K.). These experiments were discontinued because no convenient method was available for measuring the rates accurately.

The methyl and ethylxanthic acids are neither as strong as hydrochloric nor as weak as the ordinary organic acids, but are somewhat stronger than dichloroacetic acid. Both primary and secondary salt effects influence their decomposition rates, in the acid solution alone and in buffer solutions. Accurate measurements of the rates were made and the results were analyzed by v. Halban and his co-workers before the development of salt effect theory; consequently the importance of both types of salt effect was neglected entirely.

The rate of decomposition was first studied in detail by v. Halban and Kirsch,¹ who prepared the free methyl and ethylxanthic acids, found a method of stabilizing them, and studied their decomposition in a number of solvents. Roughly, the rate increases with the polarity of the solvent; in solvents of low dielectric constant it is autocatalytic because of the alcohol formed, but this is not true in alcohol itself or in water.

V. Halban and Hecht² published the results of an extensive study of the rates in aqueous solution. Potassium ethyl or methyl xanthate solutions were mixed with hydrochloric acid in known concentrations and the solutions analyzed at suitable time intervals; although the reaction was very rapid, the measurements were carried out with such precision, over such a wide concentration range and to such low ionic strengths that in some respects they are ideal for reinterpretation on the basis of the newer theories.

It was assumed that the reaction was a unimolecular decomposition of undissociated xanthic acid, although v. Halban recognized that this is kinetically identical with a bimolecular reaction between the hydrogen and xanthate ions. The unimolecular " k " increases and reaches a maximum value as the hydrochloric acid concentration is increased; from the ratio of the rate constants the dissociation constants were calculated. The values obtained were 0.030 for ethylxanthic acid, 0.034 for methylxanthic

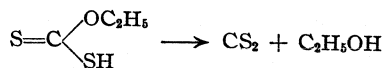

¹ V. Halban and Kirsch, *Z. physik. Chem.*, **82**, 325 (1913).

² V. Halban and Hecht, *Z. Elektrochem.*, **24**, 65 (1918).

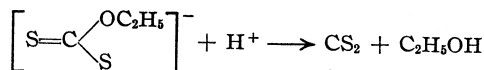

acid; we shall show later that these are correct for zero ionic strength but not for finite salt concentrations.

Experimental

Our own experiments were carried out with ethylxanthic acid in acetic acid-sodium acetate and aniline-aniline hydrochloride buffers. Since the xanthic acid is so strong, no appreciable amount of undissociated acid will remain in these buffers, and salt effect on this equilibrium can be neglected. The reaction may take place by either of the following mechanisms

or

but since the concentration of undissociated xanthic acid is controlled by the xanthate and hydrogen-ion concentrations, these lead to the same kinetic equation

$$\frac{dx}{dt} = k C_{\text{H}^+} C_{\text{X}^-} \frac{f_1^2}{f_0} \quad (1)$$

where X^- is used for the xanthate ion, f_1 and f_0 are activity coefficients of the univalent ions and neutral reaction complex.

Since the hydrogen-ion concentration of an acetic acid-acetate buffer is given by

$$C_{\text{H}^+} = K_{0, \text{HAc}} \frac{C_{\text{HAc}} f_0}{C_{\text{Ac}^-} f_1^2}$$

the final rate equation in such a buffer becomes with close approximation

$$k = \frac{2.3}{K_0} \left[\frac{a+c}{b-a} \log \frac{a}{a-x} - \frac{b+c}{b-a} \log \frac{b}{b-x} \right] \quad (2)$$

where a is initial xanthate concentration, b is initial acetic acid concentration, c is initial acetate-ion concentration; this is formally identical with the classical rate expression where salt effects are neglected.

In the aniline-anilinium ion buffer, however

$$C_{\text{H}^+} = K_{0, \text{AnH}^+} \frac{C_{\text{AnH}^+}}{C_{\text{An}}} \frac{1}{f_0}$$

and when this is substituted in (1) the activity coefficients do not cancel. Consequently, when the classical expression (2) is used for calculating the rates in these buffers, we shall expect that as the ionic strength is increased, the values of k will diminish in accordance with the relation³

$$k = k_0 \frac{f_1^2}{f_0^3}$$

³ See Brønsted and Pedersen, *Z. physik. Chem.*, 108, 185 (1924), for a discussion of salt effects in these buffers.

Potassium xanthate was recrystallized from aqueous alcohol until the fresh solution was neutral to phenolphthalein; the crystals were sucked dry and further dried over sulfuric acid. Standard acetic acid was partially neutralized to prepare buffers. Aniline was distilled three times and weighed amounts dissolved in standard hydrochloric acid for stock solutions.

The reactions were followed by measuring the increase in vapor pressure above the solutions, chiefly due to the carbon disulfide formed, in a modification of the apparatus designed by Brönsted.⁴ After introducing 100 cc. of the buffer solution into the reaction flask, a weighed amount of potassium xanthate in a glass capsule was suspended from a hook in the neck, the neck was sealed off and the entire apparatus was evacuated (while shaking) and sealed. When the pressure reading became constant the xanthate was dropped in and quickly dissolved, and pressure readings taken at frequent intervals. The thermostat was kept at $25 \pm 0.02^\circ$.

Several pressure readings which fell on a smooth curve through all readings were selected to calculate the rate constants. These can be calculated from equation (2) by using pressure readings directly or by calculating and using actual concentrations.

Acetic Acid-Acetate Buffers.—Details of a typical experiment are given in Table I.

Table II summarizes a number of experiments in which the hydrogen-ion concentration was kept approximately the same at the beginning of each experiment, and shows that there is no unusual effect of the undissociated acetic acid. Table III summarizes experiments in which the initial hydrogen-ion concentration was varied, and shows that the values of k are independent of this factor (which is also indicated by the constancy of k in individual experiments, since C_{H^+} decreases considerably during the reaction with the buffer concentrations used). Table IV shows that k is not affected by changing the initial xanthate concentration, although the limitations of the apparatus used made it impossible to vary this over a wide range.

hydrogen-ion concentration. The value of K_{AnH^+} used in calculating the constants in Tables VI and VII may be several per cent. in error for 25° , but not enough to obscure the results. Since the ionic strength decreases during the reaction, and the buffer equilibrium has no positive salt effect to neutralize the negative effect on the reaction, the values of k should increase during each experiment. Actually the decrease in ionic strength was not sufficient in any of our experiments to make this evident. Details of typical experiments are given in Table VI.

Table VII summarizes several experiments in which the hydrogen-ion concentration and the ionic strength were varied. It is evident that only the change in ionic strength affects the value of k . At the ionic strength 0.094, $k = 200$, much lower than the average value $k_0 = 271$ obtained from the acetic acid buffers. The sign and magnitude of the salt effect agree well with the predicted.

Analysis of the Data of v. Halban and Hecht.—The measurement of v. Halban and Hecht were all made at 0° , mostly in such dilute solutions that the change in ionic strength during each reaction was considerable. When k is calculated from the classical bimolecular expression

$$\frac{dx}{dt} = k C_{\text{H}^+} C_{\text{X}^-}$$

the changing salt effect causes the values of k to increase during each experiment, as is shown in Table VIII.

Because of the complication of undissociated acid formation it is impossible in this case to apply the method outlined by Scatchard for reactions in a changing environment.⁶ We have tabulated the initial values of k (bimolecular) for v. Halban's measurements on ethylxanthic acid, and

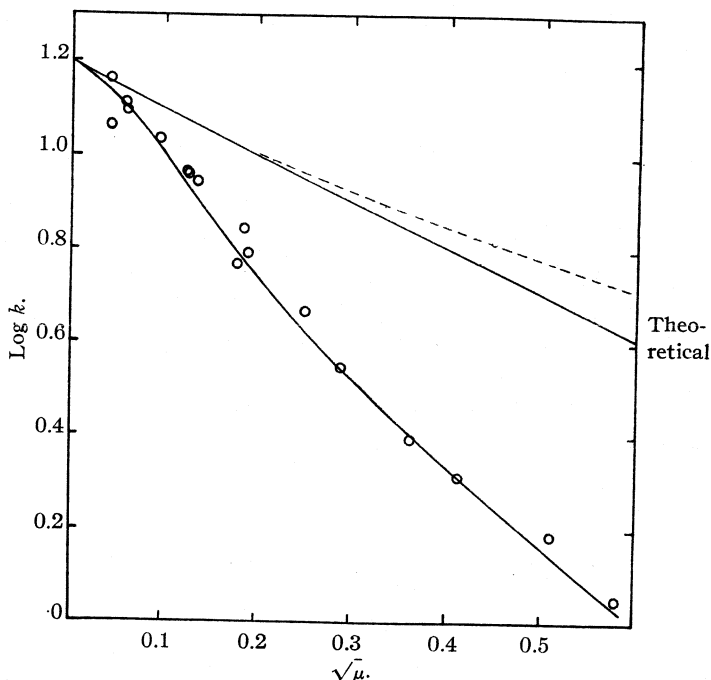

Fig. 1.—Comparison of observed rates with the theoretical for ethylxanthic acid at 0° : theoretical slope, -0.97 .

also the mean values of the ionic strength during each initial measurement (Table IX). In Fig. 1 the values of $\log k$ are plotted against $\sqrt{\mu}$. If we could use the correct ion concentrations to calculate k , the experimental points should approach the theoretical relation

$$\log k = \log k_0 - 0.97 \sqrt{\mu} \text{ (at } 0^\circ \text{)}$$

⁶ Scatchard, THIS JOURNAL, 52, 52 (1930).

as the ionic strength decreases, and deviations from this should be positive rather than negative, as indicated by the dotted line of Fig. 1. On the other hand, the change in dissociation constant with ionic strength at low concentrations is given by

$$\log K = \log K_0 + 0.97 \sqrt{\mu} \quad (3)$$

and deviations from this with increasing ionic strength will be negative. These two relations can now be used to evaluate K .

^a "Interval constant" from the last two measurements.

For equal concentrations of H^+ and X^- , the k we have calculated is given by

$$k = \frac{1}{at} \frac{x}{(a-x)}$$

But if m is the average concentration of undissociated xanthic acid during the measurement, the rate is more correctly given by

$$k_w = \frac{1}{(a-m)t} \frac{x}{(a-m-x)}$$

and as $x \doteq 0$

$$\frac{k_w}{k} = \frac{a^2}{(a-m)^2}$$

Since $2a-m = \mu$, this gives finally

$$m = \mu \frac{\sqrt{k_w/k} - 1}{\sqrt{k_w/k} + 1} \quad (4)$$

The dissociation constant can be expressed by

$$K = \frac{(\mu - m)^2}{4m} \quad (5)$$

and substituting (4) in (5) gives

$$K = \frac{\mu}{k_w/k - 1} \quad (6)$$

By a series of trials, equation (6) was used to draw the curve shown in Fig. 1 through the experimental points. The values of k_w/k used are given in Table X, and Fig. 2 shows that these values make equation (3)

TABLE X

is 0.035, again in good agreement with the "average" of v. Halban. The broken lines again show the type of deviations from the theoretical to be expected for $\log k$ and $\log K$. We estimate that these values of K_0 cannot be in error by more than $\pm 5\%$.

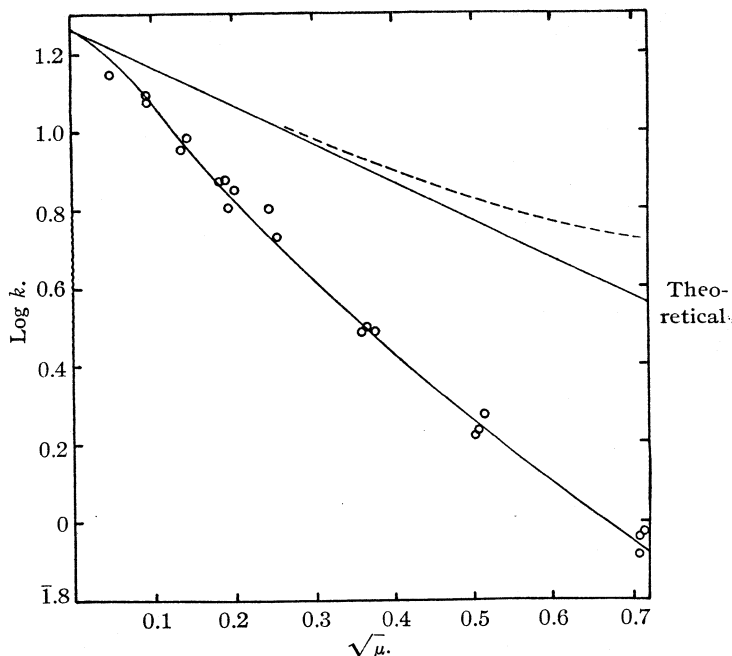

Fig. 3.—Comparison of the observed rates with the theoretical for methylxanthic acid at 0° : theoretical slope, -0.97 .

The Temperature Coefficient.—It is perhaps inaccurate to calculate the temperature coefficient from the data of v. Halban and Hecht at 0° and ours at 25° , since the rates were measured by different methods and at far different hydrogen-ion concentrations. However, the coefficient is certainly unusually high, as is to be expected from the rapidly decreasing stability of solutions of the acids and their salts as the temperature rises.

Using k_0 for ethylxanthic acid as 16.0 at 0° (Fig. 1) and 270 at 25°, we obtain an average coefficient per 10° rise of 6.75.

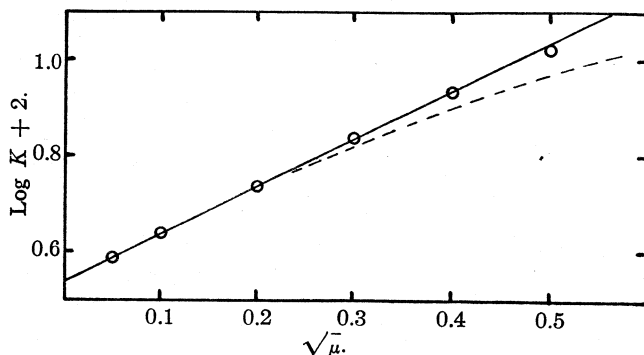

Fig. 4.—Variation in dissociation constant of methylxanthic acid with ionic strength (see Table XII): theoretical slope, +0.97.

Summary

Measurements of the rate of decomposition of ethylxanthic acid have been made at 25° in acetic acid–acetate and aniline–anilinium ion buffers and the primary and secondary salt effects analyzed.

Previous measurements of the rates for ethyl and methylxanthic acids have been analyzed and shown to be complicated by salt effects. The influence of salts on the dissociation constants of these acids has been shown.

The temperature coefficient of the rate has been calculated and shown to be unusually high.

THE DISSOCIATION PRESSURE OF SILVER OXIDE BELOW 200°

BY ARTHUR F. BENTON AND LEONARD C. DRAKE

RECEIVED DECEMBER 21, 1931

PUBLISHED JUNE 6, 1932

Introduction

Le Chatelier¹ first showed that the reaction $\text{Ag}_2\text{O} = 2\text{Ag} + \frac{1}{2}\text{O}_2$ is reversible. Careful measurements of the equilibrium pressure were subsequently made by Lewis² over the temperature range 302–445°, and by Keyes and Hara³ from 374 to 500°. Close agreement was shown between the results of these two investigations.

Aside from the considerable interest which attaches to this system

¹ Le Chatelier, *Z. physik. Chem.*, **1**, 516 (1887).

² Lewis, *THIS JOURNAL*, **28**, 139 (1906).

³ Keyes and Hara, *ibid.*, **44**, 479 (1922).

per se, it represents an essential step in one of the available methods⁴ of calculating the thermodynamically important value of the free energy of formation of water at 25°. For this purpose, however, it is necessary to extrapolate the observations over a range of temperature of about 300°, without adequate specific heat data to serve as a guide. In addition a correction must be made because of the fact that at the high pressures obtaining in the measurements of Lewis and of Keyes and Hara (20 to 390 atm.), the fugacity of oxygen differs markedly from its pressure, and the thermodynamic activity of the solid phases is also affected. For these reasons a determination of the silver oxide equilibrium at lower temperatures has appeared desirable.

In the present work it has been found that even at temperatures as low as 160–170°, finely divided silver slowly takes up oxygen in indefinitely large quantities, and the pressure finally reached after each addition of gas is *independent of the amount already taken up*. Similarly, when gas is withdrawn from the system the pressure gradually builds up and finally approaches the same value as before. From an extensive series of such measurements the dissociation pressure of the oxide has been determined at five temperatures over the range 173–191°. From these results new values have been calculated for the free energy of formation of silver oxide, and for the free energy of formation of water at 25°.

Apparatus and Procedure

The apparatus was of the type recently used in this Laboratory for studies on gaseous sorption, and has been described by Benton and White.⁵ Its essential parts are a bulb containing the solid under investigation, a mercury manometer to indicate the pressure in the bulb, a mercury-filled buret to measure the quantities of gas admitted or withdrawn, and a Töpler pump. The only difference between this new apparatus and the one previously described was the presence of a stopcock between the bulb and the remainder of the apparatus. This stopcock, the key of which was mercury-sealed at both ends, was the only one in the parts of the line communicating with the bulb, mercury seals being used elsewhere. The volume of the "free space" in the bulb and connecting capillary amounted to about 32 cc.

The bulb was maintained at the desired temperatures by means of an electrically heated vapor-bath, lagged with asbestos paper, in which ethylene glycol was boiled under reduced pressure. The pressure in this bath was accurately controlled by means of a regulator similar to that described by Smith.⁶ Fluctuations in temperature did not exceed 0.05°, even over the long periods of observation which were found necessary. The temperatures were measured with a mercury thermometer graduated to 0.2°, which was carefully standardized by reference to a similar thermometer newly calibrated by the U. S. Bureau of Standards. The necessary corrections for the exposed thread of mercury were applied.

Materials.—Metallic silver was prepared as follows. A solution of the calculated amount of barium hydroxide was added to an 8% solution of twice recrystallized silver

⁴ Lewis and Randall, "Thermodynamics," 1923, p. 479.

⁵ Benton and White, *THIS JOURNAL*, **52**, 2325 (1930).

⁶ Smith, *Ind. Eng. Chem.*, **16**, 22 (1924).

nitrate at 80°. The precipitate was washed with conductivity water until no trace of barium could be detected, and then with ten liters of conductivity water in one-liter portions. It was then dried in air for twelve hours at 50°, and in oxygen for twenty-four hours at 100°. The oxide was reduced with purified electrolytic hydrogen, first for thirty hours at 30° and then for one hundred and fifty-three hours at temperatures gradually increasing to 100°. To avoid subsequent changes in the activity of the sample, it was finally heated for four hours at 150° and for ten hours at 300°. The mass employed was 39.4 grams.

Oxygen was generated by electrolysis of c. p. sodium hydroxide solution between nickel electrodes. It was purified by successive passage over heated platinized asbestos, calcium chloride, soda lime and phosphorus pentoxide.

Procedure.—After the bulb containing the sample was sealed to the apparatus, the silver was again reduced for an hour or two at 250°, and then subjected to thorough evacuation at this temperature. The bulb was then brought to 173.0° and oxygen was admitted in successive small portions. After each addition, to a pressure of approximately one atmosphere, the pressure dropped rapidly at first and then more slowly, finally tending toward a constant value after many hours. This procedure was repeated until a total of about 190 cc. of oxygen had been taken up, equivalent to the conversion of 9.3% of the silver to silver oxide. In these measurements the times of observation were not long enough to give more than an upper limit to the true equilibrium pressure. For the final measurements of dissociation pressures, the system which had been partially oxidized to the extent just described, was treated with a further portion of oxygen at about atmospheric pressure, and the decrease in pressure as a function of time was followed until equilibrium had apparently been reached. A constant value was usually obtained in five or six days. Similar measurements were then carried out at successively higher temperatures, equilibrium being approached in each case from the side of higher pressures. The bulb was then thoroughly evacuated at room temperature, and heated to 173°. The approach to equilibrium could now be followed from the opposite side, by observing the pressure built up by decomposition of the oxide. Measurements of the latter kind were repeated at successively higher temperatures. All pressures recorded below are given in mm. of mercury at 0°.

Experimental Results

The results of the final measurements on the dissociation pressure of silver oxide are collected in Table I. The direction in which equilibrium was approached is indicated by the plus or minus sign following the pressures given in Column 2, the plus sign denoting approach from the side of lower pressure, and the minus sign the reverse. In all cases the change of pressure in the last twenty-four hours of observation was less than 0.5 mm. The numerous experiments in which equilibrium was less closely approached will not be detailed here. The values of the average pressure

TABLE I
DISSOCIATION PRESSURE OF SILVER OXIDE

<i>t</i> , °C.	<i>P</i> , mm.		<i>P</i> , av.	$1/T \times 10^4$	Log <i>P</i>	
173.0	420.9+	422.9—	422	22.42	2.625	
178.0	(514.2—)	511.6±	506.2+	509	22.17	2.707
183.1	607.0—	603.3+	605	21.92	2.782	
188.2	713.4+	721.5—	717	21.68	2.856	
191.2	790.0±	786.0+	790	21.54	2.898	

shown in Column 3 were obtained by weighting all the measurements in accordance with the times of observation.

A plot of the logarithm of the average pressure against the reciprocal of the absolute temperature is shown in Fig. 1. The extreme values of $\log P$ indicated at each point show the limits within which the dissociation pressure has been determined with certainty. It will be seen that the observed points lie rather closely on a straight line. A curve very slightly concave toward the axes would fit the observations even better, indicating a very small decrease in the heat of formation with increasing temperature. However, the range of the observations is too small to permit a definite conclusion on this point. From the straight line drawn in Fig. 1 we find for the formation of one mole of silver oxide, $\Delta H_{455} = -7020$ cal. Again because of the short range this value may be in error by as much as 200 cal.

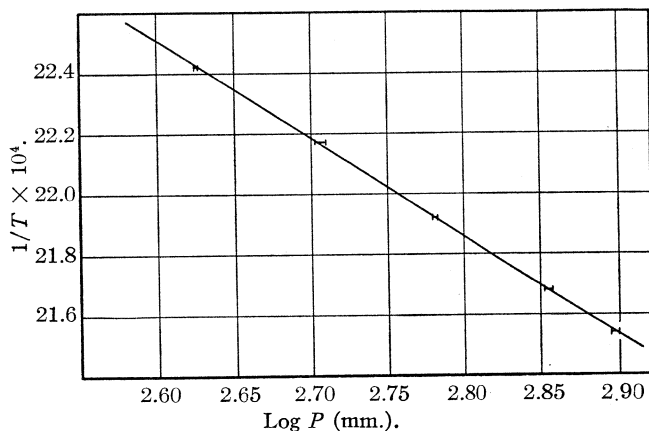

Fig. 1.—The dissociation pressures of silver oxide at 173–191°.

Rate of Attainment of Equilibrium.—The rates of formation and decomposition of silver oxide here observed are very much greater than those found by previous workers. This fact will be evident from Table II, which compares the rate of decomposition obtained by Lewis² at 325° with that found by us in an experiment at 173.0° (in this experiment the temperature was 174° for the first forty-nine hours).

TABLE II

RATE OF DECOMPOSITION OF SILVER OXIDE

A. Data of Lewis. Temperature 325°								
Time, hrs.	0	12	24	48	72	96	120	144
Pressure, atm.	0	18.5	26.5	29.8	30.1	31.5	31.8	31.8
B. Data of Benton and Drake. Temperature 173.0°								
Time, hrs.	0	59	71	99	144	154	168	
Pressure, mm.	0	395	402	415	420	421	421	

Thus the time necessary to reach apparent equilibrium was approximately the same in spite of the difference in temperature of more than 150° . The much greater reactivity of our sample is doubtless attributable to three main causes: (1) our oxide was prepared synthetically at 170 – 180° and had never been sintered by heating above 191° , (2) in our sample the original formation of the 9% of oxide presumably occurred in such a manner as to furnish a very large interface between the oxide phase and the unchanged silver—a situation which is known⁷ to lead to relatively high rates in reactions of this type, (3) the extended preliminary measurements with our sample, involving repeated formation and decomposition of oxide at low temperatures, would be expected greatly to enhance the reactivity.

We have repeatedly observed that the rate of the reaction in either direction is affected to only a slight extent by the proportion of the silver which is oxidized. Typical data illustrating this point are shown in Table III, which gives the average rate of pressure drop, which is proportional to the rate of formation of oxide, as observed over the range 550–500 mm., with different amounts of oxide already present.

TABLE III
RATE OF FORMATION OF OXIDE AT 173.0°

Oxide present, %	0.7	1.0	5.3
Av. pressure drop, mm. per hr.	2.8	3.3	3.0

It is probable, however, that with substantially larger proportions of oxide there would be less available interface between the solid phases, and slower rates would obtain.

A more detailed discussion of rates and their bearing on the catalytic action of silver in oxidation reactions will be given in a subsequent report.

Discussion

While the results obtained show that a perfectly definite equilibrium is reached in the temperature range 173 to 191° , it is necessary to consider further the nature of the phases present at equilibrium. Since the system is found to be univariant, there must be three phases present—metallic silver, gaseous oxygen and a third phase which is an oxide of silver. It has been found that this oxide is formed from its elements with an evolution of heat which in the above range of temperature is close to 7000 cal. per mole. The averaged value⁸ for the heat of formation of ordinary Ag_2O is 6960 cal. at 18° and slightly less at higher temperatures. The agreement of these two heats within the limits of error of our value appears to be conclusive evidence that we are dealing with the ordinary oxide Ag_2O , and not with a possible lower or higher oxide, nor with an allotropic form of Ag_2O . It is of

⁷ Lewis, *Z. physik. Chem.*, **52**, 310 (1905). See also Langmuir, *THIS JOURNAL*, **38**, 2221 (1916).

⁸ "International Critical Tables," **5**, 188 (1929).

course possible that both the silver and the oxide might exist in allotropic forms, whose differences in heat content as compared with the ordinary modifications might approximately cancel, but there is no definite evidence of any such allotropes in either case between room temperature and at least 500°. It is probable that the metallic silver phase is in reality a saturated solution of oxygen, or Ag_2O , in silver. However, estimates of the solubility based on the measurements of Steacie and Johnson⁹ put the mole fraction of oxygen at these temperatures at not over 2×10^{-4} , so that the heat content and free energy of the silver would not be appreciably affected.

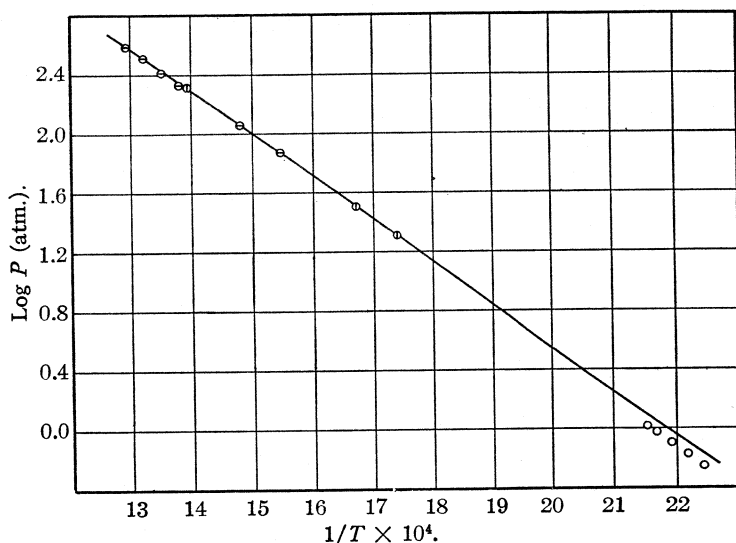

Fig. 2.—Comparison between the pressures observed at 173–191° and those obtained at higher temperatures by Lewis and by Keyes and Hara: □, Lewis; ○, K. and H.; ○, B. and D.

The relationship of the data obtained in the range 173–191° to those observed by Lewis² and by Keyes and Hara³ is shown in Fig. 2. The curve there drawn is a plot of the equation employed by Lewis and Randall,¹⁰

$$\frac{\Delta F^\circ}{T} = -R \ln K = -\frac{7240}{T} - 1.0 \ln T + 21.95$$

It will be seen that our equilibrium pressures are considerably lower than those given by the above equation. At 183.1°, for example, we find a pressure of 605 mm., as compared with 728 mm. from the equation. The temperatures at which the pressure reaches one atmosphere are 190.0 and 184.5°, respectively.

⁹ Steacie and Johnson, *Proc. Roy. Soc. (London)*, **A112**, 542 (1926).

¹⁰ Ref. 4, p. 481.

Activities at the Higher Pressures.—Comparison of the present data with those obtained in the higher temperature range requires that the latter be corrected for the effect of the high pressures on the activity of each of the three phases. Lewis and Randall¹¹ have calculated these corrections for two experimental points which lie on the best representative curve. Thus at 598.1°K. they find a corrected pressure of 32.2 atm., compared with 32.0 observed; at 773.3°K. the corresponding values are 392.1 and 388.3. The details of the calculations are not given.

We have repeated these calculations as follows. In the absence of experimental data on the molecular volume of oxygen at temperatures above 200°, we have employed the equation of state for this gas developed by Keyes.³ For the two points above mentioned, the molecular volumes of oxygen are thus found to be 1547.5 and 186.9 cc., respectively; the corresponding activities a , obtained from the equation $a/P = P_v/RT$, which is a sufficiently close approximation at these temperatures and pressures, are 32.3 and 444 atm. The activities of the silver and silver oxide have been calculated from the equation $RT \ln a = \int_1^P V dP$. The molecular volumes V have been taken as 10.27 for silver and 31.9 for the oxide¹² (the latter being the value derived from x-ray measurements), and both values have been assumed to be independent of temperature and pressure. The activities thus obtained are as follows: for silver, 1.006 at 598.1 and 1.065 at 773.3°K.; for silver oxide, 1.020 and 1.215 at the same two temperatures. A more exact calculation leading to slightly higher values can be carried out in the case of silver by introducing the change of volume with temperature and pressure. However, since the corresponding data are lacking for silver oxide, it seems best to perform the calculation in the same way for both solid phases.

For the reaction $2\text{Ag} + \frac{1}{2}\text{O}_2 = \text{Ag}_2\text{O}$, the true equilibrium constant K is given by the expression $1/K^2 = a_{\text{Ag}}^4 \cdot a_{\text{O}_2} / a_{\text{Ag}_2\text{O}}^2$. When the activities given above are introduced, $1/K_{598.1}^2 = 31.8$ and $1/K_{773.3}^2 = 386.9$. These values do not differ greatly from 32.2 and 392.1 calculated by Lewis and Randall. It is difficult to estimate the reliability of these true equilibrium constants, in view of the approximations necessary in calculating the corrections. It appears that the uncertainty at 598.1° is probably very small. At 773.3°, however, the corrections amount to 29% for a_{Ag}^4 , 14% for a_{O_2} and 48% for $a_{\text{Ag}_2\text{O}}^2$. In these circumstances an uncertainty of 5 to 10% in $1/K_{773.3}^2$ appears possible. No corrections are necessary in the case of the data reported in the present paper.

Thermal Data.—The heat of formation ($-\Delta H$) at room temperature of one mole of silver oxide was found to be 5900 cal. by Thomsen, 7000

¹¹ Ref. 4, p. 480.

¹² "International Critical Tables," 1, 103, 342 (1926).

by Berthelot, and 6800, 7200 and 6300 in calculations by Lewis.² The value 5400 obtained by Mixter¹³ is certainly too low. The conclusion may be drawn that the true value probably lies between 6300 and 7000. There are no data of any kind for the heat capacity of silver oxide. Application of Kopp's rule suggests that ΔC_p for the formation of one mole of silver oxide at room temperature probably lies between 0 and 2. In the closely analogous case of cuprous oxide the existing data are consistent with the equation, $\Delta C_p = -1.0 + 0.006 T$.

Comparison of Equilibria in the Two Temperature Ranges.—If ΔC_p is assumed to be independent of temperature, the equilibrium constant K is given by the expression

$$-R \ln K = \frac{\Delta H_0}{T} - \Delta C_p \ln T + I \quad (1)$$

It is evident from Fig. 2 that the corrected K values at high temperatures are inconsistent with the new results unless ΔC_p exceeds the value 1.0 employed by Lewis and Randall. To bring all the data into agreement on the basis of Equation 1, a value of $\Delta C_p = 3.2$ is necessary, and $-\Delta H_{291}$ would then be 7800 cal. Both these values appear to be too large. The discrepancy is perhaps best appreciated by noting that if the values of $1/K^2$ at 598.1 and 456.2°K. are taken as correct, the average heat of reaction in this range, $\Delta H_{527} = -7050$; thus if ΔC_p is positive, ΔH_{291} must have a larger negative value, and thus lie outside the probable limits of uncertainty.

It does not appear unreasonable to assume that, in analogy with the case of cuprous oxide, ΔC_p increases rapidly with temperature. We find that all the equilibrium measurements can be brought into agreement if $\Delta C_p = -0.494 + 0.006 T$, so that

$$-R \ln K = -\frac{7610}{T} + 0.494 \ln T - 0.003T + 14.80$$

Nevertheless, $-\Delta H_{291}$ on this basis becomes 7500, which appears too large.

In view of the uncertainty in the heat capacity and heat of formation of silver oxide, and in the calculations of fugacities at the higher temperatures, we conclude that the measurements recorded in the present paper are not necessarily in disagreement with the earlier work. Direct thermal measurements on silver oxide are obviously badly needed.

Because the activity corrections are negligible and the extrapolation to room temperature covers a much shorter interval, the new results are better adapted to a calculation of ΔF_{298}° . If for lack of better values we adopt $\Delta H_0 = -7240$ and $\Delta C_p = 1.0$, as given by Lewis and Randall, our data give the equation

$$\frac{\Delta F^\circ}{T} = -R \ln K = -\frac{7240}{T} - 1.0 \ln T + 21.76$$

¹³ Mixter, *Am. J. Sci.*, **32**, 202 (1911).

Thus ΔF_{298}° becomes -2450 , which is 2.3% less than the value derived by the above authors, -2395 . It must be emphasized however, that a change in ΔC_p can seriously affect the value of ΔF_{298}° .

By combination of ΔF_{298}° for silver oxide with certain other equilibria two methods are available for the calculation of the free energy of formation of water.⁴ With the new value for silver oxide the two methods give for the formation of one mole of liquid water $\Delta F_{298}^{\circ} = -56,520$ and $-56,580$, respectively. The average, $-56,550$, is within 30 cal. of the mean value obtained by three other independent methods, namely, $-56,580$.

Summary

1. Metallic silver obtained by low-temperature reduction of the oxide reacts with oxygen at temperatures of 170 – 200° , forming a definite phase of silver oxide.
2. The equilibrium pressures have been determined in this range of temperature. Values obtained by formation and by decomposition of the oxide agree to within two to four mm., or about 0.5%.
3. The calculated heat of formation is the same within experimental error as that for ordinary silver oxide, Ag_2O .
4. The equilibrium pressures are about 17% lower than those which have been obtained by extrapolation of the results of other workers at 300 – 500° . This apparent discrepancy is probably to be attributed to uncertainties in the thermal and other data necessary for the extrapolation rather than in the equilibrium measurements themselves.
5. A value of -2450 cal. is calculated for the free energy of formation of one mole of silver oxide at 25° . In spite of the fact that the new data diminish the extrapolation here necessary to a range of 150° , the above figure may be materially affected by the value chosen for the undetermined heat capacity of the oxide.

SOLUBILITY RELATIONS OF SILVER CHLORIDE IN AQUEOUS SOLUTIONS OF STRONG ELECTROLYTES

BY EDWARD W. NEUMAN¹

RECEIVED DECEMBER 21, 1931

PUBLISHED JUNE 6, 1932

In an earlier article² a method was described for the determination of the solubility of inorganic precipitates in aqueous solutions of strong electrolytes. The method was applied to silver chloride in solutions of various nitrates and it was shown that the activity coefficients calculated from the measurements obeyed, at least approximately, the limiting law of Debye and Hückel. The method has here been extended to include solubility measurements of silver chloride in solutions of various valence type sulfates, and the data on some of the nitrate solvent salts, previously investigated, have been extended to higher concentrations.

Theoretical

Solubility measurements are analogous to vapor pressure measurements, in that in one case the solute escapes into a solvent, and in the other into a vacuum. When the solute in the saturated solution is in equilibrium with the solid phase, the activity of the solute in solution is fixed; so that, if foreign substances are added to the solution in equilibrium with the solid, the stoichiometric solubility S may change, but the activity A of the solute must remain constant. Hence for a series of solutions, 0, 1, 2, . . . n

$$A = f_0 S_0 = f_1 S_1 = f_2 S_2 = \dots = f_n S_n \quad (1)$$

where f_1 is the activity coefficient of the solute in a given solution of the system. If $f_0 S_0$ denotes the activity of the solute in the otherwise pure solvent and fS its activity in the same solvent containing also an electrolyte, then, by determining the solubility of the solute at various concentrations of the added electrolyte, it is possible to evaluate f and f_0 from the relation

$$f_0 S_0 = fS$$

or, more conveniently³

$$-\log f = \log (S/S_0) - \log f_0 \quad (2)$$

The value of $\log f_0$ may be evaluated by extrapolation, to zero concentration, of a plot of $\log (S/S_0)$ against some linear function of the total concentration.

Debye and Hückel⁴ have developed a theory of solutions of strong

electrolytes. Their equation for the activity coefficient of a salt in a solution is

$$-\log_e f_{\pm} = \frac{\alpha(-Z_1 Z_2)(\mu)^{1/2}}{1 + a\kappa} \quad (3)$$

Here α is a constant depending on the dielectric constant D of the solvent, the absolute temperature T , and various universal constants, and is defined for decadic logarithms by

$$\alpha = \frac{\epsilon^2(2\pi n)^{1/2}}{2.3026 (DkT)^{3/2}} \quad (4)$$

The reciprocal of κ is an important quantity in this theory. It has the dimensions of distance and its introduction avoids some of the difficulties encountered by many investigators. It is defined by

$$\kappa^2 = \frac{\epsilon^2 4\pi n\mu}{DkT} \quad (5)$$

The quantity a is the distance of closest approach of the ions and is expressed in Ångström units; ϵ is the unit charge in E. S. U., k is Boltzmann's constant; n is Avogadro's number; and μ is the ionic strength of the solution, based on moles per unit volume of solution, and defined by

$$\mu = \frac{1}{2} \sum C_i Z_i^2 \quad (6)$$

where C_i is the number of moles per liter of solution, and Z_i is the valence of an ion of the i -th kind. For aqueous solutions at 25°, $\alpha = 0.5066$,⁵ and $\kappa = 0.32875(\mu)^{1/2}10^8$.

The relation (3) seems to have been generally accepted for aqueous solutions of low valence type salts up to about 0.2μ , but is inadequate for most high valence-type salts and for many non-aqueous solutions. If constancy of the value of a , calculated from the experimental data, be taken as a criterion for applicability of the theory, it will be shown that this relation holds only as a first approximation, if at all, for solutions of a uni-univalent salt in the presence of relatively simple valence-type electrolytes at concentrations as low as 0.002μ . From the form of the equation it may readily be seen that deviations of observed values derived from formula (2), when positive, can only be accounted for in equation (3) by physically absurd negative values of a .

The formula of Debye and Hückel was based on the first approximation of the solution of the Poisson-Boltzmann equation. Gronwall, La Mer and Sandved⁶ have succeeded in obtaining a complete solution of this equation. They derived additional terms in powers of a for equation (3) and proposed, for the activity coefficient of a salt, the relation

⁵ The numerical values of the constants used in the computation of these factors are: $n = 6.061 \times 10^{23}$; $k = 1.372 \times 10^{-16}$; $T = 298.1$; $\epsilon = 4.774 \times 10^{-10}$; $D = 78.54$. The value for D , the dielectric constant for water, is that given by Wyman, *Phys. Rev.*, **35**, 623 (1930).

⁶ Gronwall, La Mer and Sandved, *Physik. Z.*, **29**, 358 (1928).

$$\log_e f_{[5]} = \frac{-\epsilon^2 Z^2 x}{2aDkT(1+x)} + \sum \left[\frac{\epsilon^2 Z^2}{aDkT} \right]^{2m+1} [{}^{1/2}X_{2m+1}(x) + 2mY_{2m+1}(x)] \quad (7)$$

where $x = a\kappa$, and κ is defined as in (5). For aqueous solutions⁷ at 25° this formula becomes

$$-\log_{10} f_{[5]} = \frac{0.5043(\mu)^{1/2}}{1 + 0.3283a(\mu)^{1/2}} - 0.15382 F_3(x)10^3/a^3 - 0.007700 F_5(x)10^5/a^5 \quad (8)$$

when m is extended to $m = 2$. The first term on the right of equation (7) is the well-known Debye approximation, (equation 3). The X and Y terms are complicated functions of x , and have been evaluated over a wide range of x values. This formula is applicable only to electrolytes of the symmetric valence type in both the solute and the solvent salt and has been evaluated to the fifth approximation.⁶

Recently La Mer, Gronwall and Greiff⁸ have extended the treatment to include unsymmetric valence type electrolytes. The computations have been extended to the third approximation. In the case of the activity coefficient of a solute electrolyte in aqueous solution at 25° in the presence of one other electrolyte, their formula becomes

$$\begin{aligned} -\log_{10} f_{[3]} = & -Z_1 Z_2 \left\{ \frac{1.53636}{a(1+x)} x + \frac{0.12740}{a^2} q_2^2 [{}^{1/2}X_2(x) - Y_2(x)]10^2 + \right. \\ & \frac{0.43480}{a^2} q_2(Z_1 + Z_2 - q_2)Y_2(x)10^2 - \frac{0.15382}{a^3} q_2^2 q_3 [{}^{1/2}X_3^*(x) - 2Y_3^*(x)]10^3 - \\ & \frac{0.15382}{a^3} q_3^2 [{}^{1/2}X_3(x) - 2Y_3(x)]10^3 - \frac{0.15382}{a^3} q_2[2(Z_1 + Z_2)q_3 + \\ & (Z_1^2 + Z_1 Z_2 + Z_2^2)q_2 - 3q_2 q_3]Y_3^*(x)10^3 - \\ & \left. \frac{0.30764}{a^3} q_3 [(Z_1^2 + Z_1 Z_2 + Z_2^2) - q_3]Y_3(x)10^3 \right\} \quad (9) \end{aligned}$$

The X and Y factors are again complicated functions of x and have been evaluated and tabulated by the authors so that the formula readily yields to computation of values of $\log f_{[3]}$ for comparison with experiment. The factor Z_1 is the valence of the cation, and Z_2 is the valence of the anion of the solute salt. The a value, appearing in Ångström units in the formula, has the same significance as before. In this relatively simple case of only two electrolytes, q_ν has the form

$$q_\nu = \frac{n[\nu_1 Z_1^{\nu+1} + \nu_2 Z_2^{\nu+1}] + n'[\nu_3 Z_3^{\nu+1} + \nu_4 Z_4^{\nu+1}]}{n[\nu_1 Z_1^2 + \nu_2 Z_2^2] + n'[\nu_3 Z_3^2 + \nu_4 Z_4^2]} \quad (10)$$

wherein n is the number of moles of solute consisting of ν_1 cations of valence Z_1 and ν_2 anions of valence Z_2 ; and n' is the number of moles of solvent salt consisting of ν_3 cations of valence Z_3 and ν_4 anions of valence Z_4 . In

⁷ Drude's value for the dielectric constant of water was used [*Ann. Physik*, **59**, 61 (1896)]: $D = 88.23 - 0.4044 t + 0.001035 t^2$.

⁸ La Mer, Gronwall and Greiff, *J. Phys. Chem.*, **35**, 2245 (1931).

the symmetric case of both salts, q_2 is zero and formula (9) simplifies accordingly.

When using the extended formulas for the calculation of a values which are to fit the experimental points, recourse must be had to methods of interpolation, since the forms of the x functions do not readily yield to a direct solution for values of a . Thus, for each total concentration there is a value of κ and a series of x values corresponding to the assumed values of a in Ångström units, for which values the functions $x_2(x)$, $Y_2(x)$, etc., may be found by interpolation on large-scale charts of the tables already computed. The values of $\log f_{[3]}$ or $\log f_{[5]}$ for each assumed a value are then obtained by substitution in formula (8) or (9), as the case may be, and the value of a , corresponding to the experimentally determined $\log f$, obtained by interpolation on the curve $\log f_{[3]}$ or $\log f_{[5]}$ against a .

The formula (9) is given as correct to terms of the third order inclusive. The development is based, in part, on the assumption that $a_1 = a_2 = a_3 = a_4 = a$ in a solution of two electrolytes; that $\log f_{0[3]}$ is equal to $\log f_{0[1]}$; and that there is no specific interaction among the various ions of the two electrolytes such as would result in an alteration of the number of ions from that required by a complete dissociation. This obviates the effects of Bjerrum's⁹ ion association and lends the extended theory pertinent significance in view of the theory of complete dissociation of strong electrolytes.

Materials

Water.—Twice distilled, second distillation through a block tin condenser. Specific conductivity, 1.2×10^{-6} mhos. Used in all final recrystallizations, in the preparation of all solutions, and in all experimental work.

Silver Salts.—The nitrate was thrice recrystallized. The sulfate was prepared according to Richards and Jones.¹⁰ During purification and subsequent storage the salts were protected from light as much as possible. As a result no photodecomposition could be noted. Stock solutions were analyzed gravimetrically, and experimental solutions containing 1×10^{-4} mole of Ag^+ per liter were prepared by dilution.

Acids.—Hydrochloric and sulfuric acids were subjected to two distillations retaining only the middle one-third.

Salts.—All salts were carefully purified by two, and in some cases three, recrystallizations. The calcium salts were prepared from pure calcium carbonate. The concentrations of all solutions were checked by analysis. All solutions of the solvent electrolytes were tested for chlorides under the conditions obtaining in the experimental runs. The lanthanum salts were tested for cerium by the hypochlorite method. Only a trace was found in lanthanum chloride and, since the concentration of this salt was never more than 2×10^{-6} M per liter, the effects of cerium salts were disregarded.

Experimental

A series of solutions containing a constant quantity of the solvent electrolyte and varying, but equivalent, amounts of silver nitrate or sulfate

⁹ Bjerrum, *Kgl. Danske Videnskab. Selskab, Det. Mathk.-fys. Medd.*, VII, No. 9, 1926.

¹⁰ Richards and Jones, *THIS JOURNAL*, 29, 831 (1907).

and the metallic chloride, corresponding to the solvent salt used, were made up in 100-cc. oil sample bottles. The bottles were sealed with corks, which had been soaked in chloride-free paraffin, and were agitated in a water thermostat at 25° until equilibrium was attained. The solutions were examined, at intervals of about eight hours, for turbidity in a Tyndallometer. The standard for comparison was a solution similar in composition to the solutions of the series but containing no silver ions.

The bottles in which the solutions were prepared and examined were carefully selected so that they all had a minimum, and equal, point of reflection when filled with twice distilled water and examined in the Tyndallometer. When used thereafter they were always examined in the calibrated position. The shaker for the bottles was arranged so that the bottles were held upright. This prevented the solutions from coming in contact with the corks and decreased the chances of contamination.

The solutions of the series were measured with calibrated burets. Chloride and silver solutions were measured with micro burets having a capacity of 20 cc. and readable to 0.005 cc. All glass apparatus was washed with cleaning solution, rinsed with distilled water ten times, and finally rinsed five times with redistilled water before use. The temperature of the room was kept at about $25 \pm 1^\circ$ during the preparation.

The solubility of the salt was taken to lie at some point between the concentration showing no turbidity, and the first concentration showing the Tyndall beam. By preparing another series having smaller increments of the concentration of silver chloride and having a range, between and overlapping, for purposes of a more certain control, the last clear and first turbid concentration, it was possible to fix the solubility within still narrower limits. The smallest increments employed at the lowest concentration of solvent electrolytes were $4 \times 10^{-8} M$ per liter, and $5 \times 10^{-8} M$ per liter at the higher concentrations. The preliminary series for the approximate location of the point of solubility were usually prepared with increments of $2 \times 10^{-6} M$ per liter, or more. Table I gives data for one of the experimental points illustrating the preliminary and the final location of the solubility.

TABLE I

DATA ILLUSTRATING METHOD OF OBTAINING THE END-POINT FROM THE TYNDALLOMETER INDICATION

Preliminary Series A		Preliminary Series B		Final Series	
Molality of AgCl $\times 10^6$	Turbidity	Molality of AgCl $\times 10^6$	Turbidity	Molality of AgCl $\times 10^6$	Turbidity
1.470	— — — —	1.490	— — —	1.500	— — — —
1.490	— — — —	1.500	— — —	1.505	— — — —
1.510	— + — —	1.510	— — —	1.510	— — — —
1.530	— + + +	1.520	+ + +	1.515	— — + +
1.550	+ + + +	1.530	+ + +	1.520	+ + + +

In series A, the solubility lies between 1.510 and 1.530; in series B, which has narrower limits, the solubility is located between 1.510 and 1.520; and, finally, in the last series having the narrowest limits the solubility is fixed between 1.510 and 1.515.

The criterion for equilibrium was that the Tyndallometer readings became constant. The readings given in Table I extend, for each series, over a period of about seventy-two hours. The first readings were taken at the end of twenty-four hours. It was found that more time was required for the solutions to come to equilibrium in the case of the higher concentrations of the solvent electrolytes. Sulfuric acid proved most troublesome in this respect, and, in addition, the turbidities occurring in solutions of the acid were much less sharply defined than in the case of the salts. Generally, when first prepared, all of the solutions were clear when examined in the Tyndallometer, and in most cases at least twelve hours was required for the first signs of turbidity. In general, solutions that had been cooled until all were turbid, after first having come to equilibrium at 25°, returned to the original state when again agitated in the thermostat at 25°.

The Tyndallometer used for detecting the first appearance of turbidity in the solutions has already been described.² Light from a 150-watt, compact-filament tungsten bulb entered the solution through the side of the oil sample bottles. Light, scattered by the solid phase, passed through the bottom of the bottles, whence it was reflected through the optical system of the Macbeth illuminometer and thence to the eye. The illuminometer light was adjusted so that the field of the telescope had a uniform intensity when the standard solution was placed in the apparatus. The color of the reflected light was blue and in order accurately to match the two fields of the telescope it was necessary to insert an appropriate filter in the light path of the illuminometer. Since the amount of solid phase which is formed in the neighborhood of the end-point is necessarily very small, the intensity of the reflected light is very low, necessitating working in a dark room. Occasional solutions which exhibited a relatively bright Tyndall beam were rejected as contaminated and the experiment was repeated.

Data and Discussion

The solubility of silver chloride was determined in aqueous solutions of sulfuric acid, potassium sulfate, calcium sulfate, magnesium sulfate, lanthanum sulfate, potassium nitrate, barium nitrate and lanthanum nitrate. The concentration range covered was from the amount of the solvent electrolyte equivalent to the solute salt, to about 0.04μ , except in the case of calcium sulfate, where the highest concentration was about 0.01μ . The range for potassium and for barium nitrate was from 0.01 to 0.04μ , extending the measurements of Popoff and Neuman. The five lowest points on lanthanum nitrate were measured in the Chemical Laboratory

of the State University of Iowa with the collaboration of Professor Stephen Popoff.

The value of S_0 , the solubility of silver chloride in otherwise pure water, can only be obtained by methods of extrapolation from this type of experimental data. This is due to the fact that there is always present, in the solutions, an amount of solvent salt equivalent to the amount of solute salt, or silver chloride. Values of S'_0 were determined from the data below 0.01μ for each solvent electrolyte and the results averaged to give the value S_0 . The lower portions of the curves S vs. $(M)^{1/2}$, where M is the moles of solvent salt per liter of solution, approximated a straight line, and, by assuming the function

$$S = S'_0 + A(M)^{1/2} \quad (12)$$

the S'_0 values were readily evaluated by the method of moments. Similarly, the values of $\log f'_0$ were determined by assuming the function

$$\log (S/S_0) = (\log f'_0) + b(\mu)^{1/2} \quad (13)$$

The arithmetic mean of S'_0 and of f'_0 was taken as the most probable value of the solubility and activity coefficient, respectively, of silver chloride in water at 25° .

The value of S_0 (mean) is 1.273×10^{-5} as compared to the value of 1.30×10^{-5} mole/liter reported in the "International Critical Tables."¹¹ Assuming that f_0 (mean) = 0.9985 = f_+ f_- the activity product constant for silver chloride becomes 1.616×10^{-10} .

While not strictly the most accurate method of extrapolation in view of the peculiarities of some of the curves, as will be seen later, the treatment at least eliminates the uncertainties of individual error in graphical extrapolation. The parameters of the statistical equations (12, 13) are given in Table II.

¹¹ "International Critical Tables," 1929, Vol. VI, p. 256.

The values of b in the last column of the data are analogous to the factor α in the limiting Debye equation, $-\log f = \alpha\mu^{1/2}$, and as such should very closely approximate the value 0.5066, assuming that the dielectric constant of Wyman is correct, and that the limiting law is obeyed in the region below 0.01μ . The average value from the nitrate solvent salts seems to be in good agreement with the theoretical and it might be said that, for the nitrates at least, the limiting law is obeyed below 0.01μ . The mean slope for the sulfates, however, is about 4% higher than the theoretical, a rather significant deviation. The ratios¹² in the middle column, although proportional to the square roots of 1, 3, 4, 6 and 15, in the case of (1, -1), (1, -2), (2, -1), (2, -2), (3, -1), and (3, -2) valence type electrolytes, respectively, have much greater deviations in the case of the sulfates than in the case of the nitrates.

The experimental data appear in Table III. The mean values, $S_0 = 1.274 \times 10^{-5}$ and $\log f_0 = -0.00064$ are used throughout for the calculation of $-\log f(\text{obs.})$. The values $-\log f_{[1]}$ were calculated from the limiting law of Debye and Hückel, $\log f_{[1]} = -0.5066\mu^{1/2}$. The apparent ionic diameters $a_{[1]}$ are from the Debye first approximation (3) arranged according to the formula

$$a_{[1]} \text{ (in Ångström units)} = \frac{0.5066\mu^{1/2} + \log f(\text{obs.})}{-\log f(\text{obs.}) \times 0.3287\mu^{1/2}}$$

The apparent ionic diameters, $a_{[5]}$, are obtained to the fifth approximation from the Gronwall, La Mer and Sandved⁶ treatment for the case of symmetrical valence type solvent salts, and the diameter $a_{[3]}$ are obtained to the third approximation from the La Mer, Gronwall and Greiff⁸ treatment for unsymmetrical cases.

The differences between $f(\text{obs.})$ and $f(\text{L.L.})$ [limiting law] tabulated in the column headed Δ clearly indicate a peculiar mode of deviation from the limiting law. In the case of the unsymmetrical sulfates the change of sign in the deviations is in the order +, -, +, -, with increase in concentration of the solvent salt, and leads to a series of maxima and minima in the experimental curve $-\log f/\mu^{1/2}$, shown in Fig. 1. This phenomenon has not

¹² The value 1.5 is an approximation, for purposes of comparison, of the theoretical parameter A in the equation for the solubility of a slightly soluble (1, -1) salt in a solution of ionic strength μ , given by

$$S = S_0 + A\mu^{1/2} + B\mu + C\mu^{3/2} + \dots$$

The terms after the second are assumed to be negligible. The equation may be established from the limiting law and from equation (1) as follows: From (1), $Sf = \zeta$ (a constant), and from the limiting law, $-\log_{10} f = \alpha\mu^{1/2}$, or $f = 10^{-\alpha\sqrt{\mu}}$; then, $S = \zeta 10^{\alpha\sqrt{\mu}}$. Expanding the exponential, we have

$$S = \zeta + \frac{\zeta\alpha \log_e 10 \mu^{1/2}}{1!} + \frac{\zeta\alpha^2 (\log_e 10)^2 \mu}{2!} + \frac{\zeta\alpha^3 (\log_e 10)^3 \mu^{3/2}}{3!} + \dots$$

Since S_0 is of the order of 10^{-5} , f_0 is almost unity and the difference between ζ and S_0 may be disregarded for purposes of approximation.

hitherto been recorded. The symmetrical sulfates and lanthanum nitrate behave quite differently, the curves exhibiting but one maximum above the

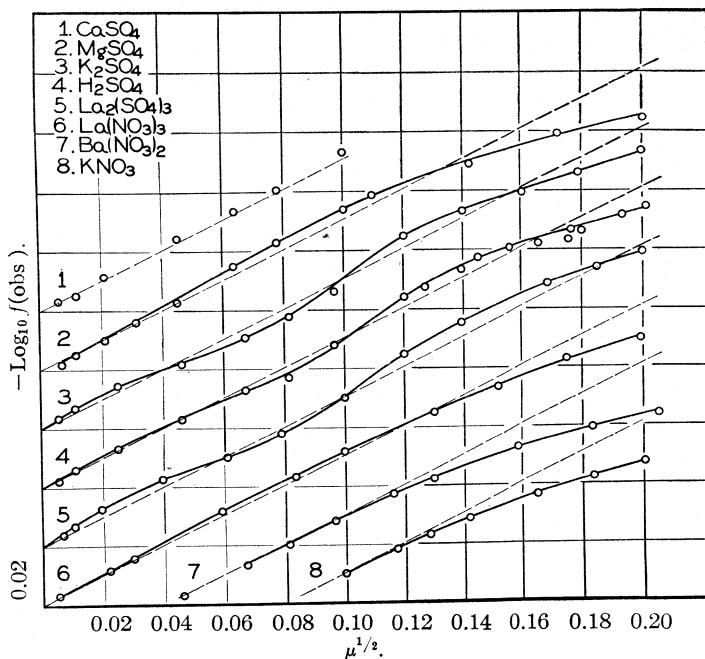

Fig. 1.—Activity relations of silver chloride in aqueous solutions of electrolytes at 25°. The ordinates, $-\log f(\text{obs.})$, have been separated by 0.02 unit (one square). The scale is the same for all curves. 1, Calcium sulfate; 2, magnesium sulfate; 3, potassium sulfate; 4, sulfuric acid; 5, lanthanum sulfate; 6, lanthanum nitrate; 7, barium nitrate; 8, potassium nitrate.

slope of the limiting law. A similar tendency is only very slightly indicated, if at all, in the case of barium and potassium nitrate. "Deviations" of this nature have already been widely noted, chiefly by La Mer and his co-workers.¹³

¹³ La Mer and Mason, *THIS JOURNAL*, **49**, 410 (1927); La Mer and Goldman, *ibid.*, **51**, 2632 (1929).

The characteristics of the curves are clearly illustrated in the graphs of Fig. 1. In this figure the ordinates for each curve, representing $-\log f(\text{obs.})$, have been separated 0.02 unit in order to bring out the characteristics of each curve without the confusion of crowding. The scale is the same for all salts and has the same magnitude as the scale of the abscissas. The broken lines represent the slope of the Debye limiting law, and are identical for all of the salts. The points on curves 7 and 8 below 0.1μ are points already published² and are here included merely to indicate the degree of agreement of the later data at higher concentrations. The variation in sign is still more strikingly brought out in the $a_{[1]}$ values, a clear indication that the Debye formula fails to apply to the data even in most dilute cases, except as a rough first approximation. The formulas of Gronwall and La Mer are in good agreement with the data. None of the $a_{[3]}$ or $a_{[5]}$ values assume a negative sign and the magnitudes, while small, are not altogether impossible. They exhibit, however, a decided trend in the cases of all of the solvent salts, and the theoretical treatment, in so far as it has been developed, does not account for the first positive and negative "humps" of the unsymmetric sulfate curves. It should be noted, before criticizing the theory too severely, that with decreasing concentration of the solvent salt, very small errors in the value of $\log f(\text{obs.})$ are increasingly magnified in the values of " a ," whether derived from the Debye theory or from the extended treatments of Gronwall and La Mer.

In Table IV appear the points of maximum and minimum deviation of the experimental curves from the limiting law. These values expressed in $\Delta = \log f(\text{obs.}) - \log f(\text{L.L.})$ were read directly from large scale graphs of the experimental curves appearing in Fig. 1.

Predictions based on the assumption that sulfuric acid is incompletely dissociated, and the calculations of Sherrill and Noyes,¹⁴ would indicate that curve 4 in Fig. 1 should lie somewhat lower than it does. Actually the acid seems to have the same effect as potassium sulfate.

The author wishes to acknowledge the helpful criticism and suggestions of Professors A. A. Noyes and S. J. Bates of the California Institute of Technology, and is indebted to Professor Victor K. La Mer of Columbia University for his valuable criticisms and suggestions in the interpretation of the data.

Summary and Conclusions

The solubilities of silver chloride at 25° in aqueous solutions of the sulfates of hydrogen, potassium, calcium, magnesium and lanthanum, and of the nitrates of potassium, barium and lanthanum, were determined by a synthetic method. The solubility of the chloride in water was approximated statistically and found to be 1.273×10^{-5} mole per liter, and its activity coefficient was found to be 0.9985.

The activity coefficients of silver chloride in the various solutions were calculated from the experimental data. Marked deviations from the Debye-Hückel limiting law as well as from the first approximation formula appear, even at the lowest concentrations, in the case of the sulfates and lanthanum nitrate. The unsymmetric sulfates exhibit positive, negative, positive and finally negative deviations from the limiting law when the logarithm of the observed activity coefficient is plotted against the square root of the ionic strength. The symmetric sulfates show only one such positive deviation, and a similar deviation is barely, if at all, indicated in the case of potassium and barium nitrates.

Apparent ionic diameters, a , calculated on the basis of the Debye first approximation indicate that the theory is inadequate for silver chloride in the presence of the substances studied even at the lowest concentrations. The a values calculated on the basis of the Gronwall and La Mer extensions of the theory are in good agreement with experiment in the case of the symmetrical sulfates and nitrates. These extensions do not explain, however, the peculiar behavior of the unsymmetrical valence type sulfates, except possibly as a first approximation.

KINETICS OF A THERMAL CIS-TRANS ISOMERIZATION. II

BY M. NELLES¹ AND G. B. KISTIAKOWSKY

RECEIVED DECEMBER 23, 1931

PUBLISHED JUNE 6, 1932

Isomerization reactions involving a rotation around a carbon double bond have frequently been studied from a chemical point of view. In recent years kinetic studies of the process have been undertaken and some progress in this direction has been made. Most of this work however has been concerned with the photochemical and catalyzed reactions and therefore it need not concern us here.

Höjendahl² has studied the thermal isomerization of the maleic into fumaric acid in liquid state. He found a unimolecular reaction with an activation energy of some 15,000 cal. It is somewhat doubtful whether Höjendahl was not dealing with a reaction due to ionic catalysis in view of the low activation energy observed.

Ebert and Büll³ have announced that measurements on the rate of isomerization of gaseous *cis* and *trans* dichloroethylenes are in progress. They reported that in thermal equilibrium at 300° the mixture contains about 65% *cis* and 35% *trans* compound.

The homogenous isomerization of the dimethyl ester of maleic acid in gaseous state has been recently described by the present authors.⁴ The results presented there tend to show that the reaction is of the unimolecular type, although in the pressure range investigated (500 to 45 mm.) the activation rate is insufficient to maintain a unimolecular reaction rate. From the temperature dependence of the rate in the range 270–380°, the activation energy was calculated to be 26,500 cal.

The only secondary reaction which in any way complicated the measurements was a slow decomposition of the fumaric ester formed in the main reaction. The decomposition reaction is accompanied by pressure change, one molecule of carbon dioxide and one molecule of a substance (probably $\text{CH}_3\text{—CH=CH—COOCH}_3$), which condenses on cooling to room temperature, being formed.

Further experiments seemed necessary to establish more conclusively some of the results obtained. The present paper deals with the reaction rate at pressures above atmospheric, with the influence of inert gases on the rate and with an attempt to determine the position of thermal equilibrium.

Experimental Details

The preparation of the materials and the analysis of the reaction mixtures by the freezing point method have been described in the first paper.

A static method was used in the high pressure experiments. Two quartz tubes (capacity 185 and 55 cc.) with heavy walls served as reaction vessels. The following procedure was adopted after several other methods proved unsatisfactory in that they gave unreplicable results. One end of the quartz tube was drawn to a capillary (B in Fig. 1) and the other sealed, through a graded seal, to a T joint. One end of this was connected through a mercury cut-off to the mercury pump and the other ended in a ground joint to which fitted a small tube containing a weighed amount of the ester. The system was evacuated, the ester cooled by carbon dioxide-ether mixture and the quartz vessel degassed at 500–600°. The mercury cut-off was closed, the cooling mixture transferred to the quartz vessel and the ester allowed to distil at room temperature. The quartz vessel was sealed off and placed in a molten lead-tin bath (Fig. 1) for a suitable length of time. It was then quickly cooled by a blast from a carbon dioxide tank. The capillary end of the vessel was attached to a mercury manometer by a cement joint. The manometer was evacuated and the capillary broken by a magnetic plunger while the esters were cooled by carbon dioxide-ether mixture. From the manometer readings and the volume of the system the pressure of carbon dioxide at the end of the heating period could be readily calculated. The liquid products were then analyzed by the freezing point method.

The effect of inert gases on the reaction rate was also studied in a static system which is shown in Fig. 2. The ester was introduced through B into C and the former sealed off. The system was then evacuated through A while the ester was cooled by solid carbon dioxide. The inert gas was admitted through a three-way stopcock placed between A and the pump. The system was sealed off at A and the ester vaporized by applying a smoky flame. Finally C was covered with a small electric furnace heated to the temperature of the main furnace. On completion of a run C was cooled and immersed in a carbon dioxide cooling mixture. A rubber tubing attached to the pumps was slipped over A and the tip of this broken with a pair of pliers. The inert gas was slowly pumped out while the ester condensed in C. Appropriate manometer readings were taken to determine the pressure of the inert gas, the total pressure and its change in the course of a run. All gases studied were taken from commercial cylinders. Nitrogen and hydrogen were passed through a purifying train containing a heated tube with copper gauze, wash-bottles with sodium hydroxide solution and sulfuric acid and a tube with phosphorus pentoxide. Propane was purified by passing it through wash-bottles containing fuming sulfuric acid, dilute sulfuric acid, alkaline potassium permanganate and concentrated potassium hydroxide solution. After drying over phosphorus pentoxide it was fractionated several times in vacuum. Carbon dioxide was subjected only to a repeated fractional sublimation in vacuum. With the last two

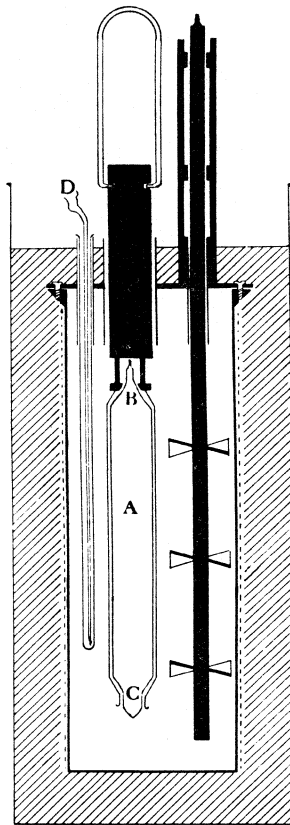

Fig. 1.—The thermostat for high pressure experiments.

gases it was found that a very thorough purification was required, quite erratic results being obtained otherwise.

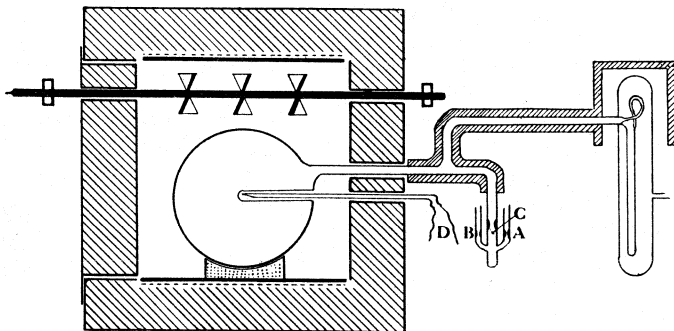

Fig. 2.—The apparatus for low pressure experiments.

Experimental Results and Discussion

Table I presents the results of the final series of experiments on the rate at high pressures.

TABLE I

In column 5 is given the amount in mm. of carbon dioxide formed at the temperature of the experiment. It was set equal to the amount of fumaric ester decomposed and added to the fumaric ester found by analysis in calculating the rate constants. The rest of the table is self-explanatory. It will be noticed from these data that with increasing pressure the rate tends to become unimolecular. This is particularly well shown by Fig. 3, in which the new data as well as those obtained previously (I) have been plotted. The velocity constant at 45 mm. pressure has not been included in Fig. 3 in order not to reduce the scale of the drawing too much. This constant does not fall on the straight line drawn, being about 30% too high. The measurements at this pressure, however, were rather unsatis-

Hydrogen and nitrogen are both found to be without influence on the reaction. Propane has a feeble accelerating action, equal to about one-tenth of the effect of the esters themselves. The effect of carbon dioxide is more pronounced. It is obscured somewhat by a rapid decomposition of the esters induced apparently by carbon dioxide. Because of this the isomerization rate constants have been calculated here neglecting the decomposition reaction. They represent therefore the minimum values of the acceleration produced. Inasmuch as it is not known whether fumaric ester alone or maleic ester also decomposes in presence of carbon dioxide, a more accurate calculation is impossible.

Some experiments have been carried out to determine the position of thermal equilibrium. The decomposition of fumaric ester precludes the study of equilibrium by the usual methods. The procedure adopted was to heat known mixtures of the esters for a short time and to determine the change in the freezing point. It was found that at 280° the freezing point remained unchanged in a 1 : 1 mixture. It was lowered in mixtures richer in fumaric ester and raised in mixtures richer in maleic ester. On studying the temperature dependence of this apparent equilibrium over the range 255–320°, the following expression was found to represent it approximately

$$\ln K = \frac{6000}{RT} - 5.5$$

Such a large entropy change in a reaction of the present type seemed to be quite unlikely and suggested that the equilibrium was fictitious. Further experimentation showed indeed that the liquid formed on heating fumaric ester was not maleic ester. The lowering of the freezing point is due therefore chiefly to decomposition reactions. Although this finding precludes an accurate determination of the equilibrium, still the conclusion can be reached that in the true state of equilibrium more than 50% of fumaric ester is present. This is to be compared with the observation of Ebert and Büll that, of the two dichloroethylenes, the *cis* modification is the more stable one.

It has been pointed out in the first paper that the isomerization process is unusually slow as compared with other unimolecular reactions. The measured rate of activating collisions, equal to the reaction rate at low pressures, is of the order of $10^{28} e^{-24,500/RT} c^2$ (c , concentration in moles per liter). The rate of collisions with energy in excess of 26,500 cal. contained in two square terms is about $7 \cdot 10^{31} e^{-24,500/RT} c^2$. Experiments at higher pressures indicate that the limiting velocity constant at infinite pressure is

$$K_{\infty} = 1.3 \times 10^5 e^{-26,500/RT} \text{ sec.}^{-1}$$

Usually the temperature independent factor is at least of the order of 10^{10} . The other unimolecular reactions which have activation rate not exceeding the rate of collisions with energy contained in two square terms are the decompositions of nitrous oxide⁵ and of nitril chloride.⁶ As both these molecules consist of only very few atoms, a much greater rate could hardly be expected. The decompositions of larger molecules, studied thus far, all require the assumption of internal energy exchange between several degrees of freedom. It has been noticed, however,^{7,8} that most frequently not all degrees of freedom, available from the point of view of specific heats, participate in the reaction. The barriers which partially prevent energy exchange within the molecules must be particularly effective in the isomerization process, as shown by the present measurements. This should be attributed to the character of mechanical motion responsible for the reaction: a rotation of heavy atomic groups around the double bond instead of the longitudinal vibrations active in decomposition processes. From this point of view it is comprehensible also that only heavy molecules like carbon dioxide and propane are able to participate in the activation process of the isomerization, while in decomposition reactions of organic molecules hydrogen seems to participate more readily than any other molecule.

⁵ Volmer, *Z. physik. Chem.*, **9B**, 141; **10B**, 414 (1930).

⁶ Schumacher and Sprenger, *ibid.*, **12B**, 112 (1931).

⁷ Rice, *ibid.*, **7B**, 226 (1930).

⁸ Ramsperger and Leermakers, *THIS JOURNAL*, **53**, 2061 (1931).

In view of the slowness of the activation rate, it could be assumed that energy is transferred in collisions directly to the oscillatory motion around the double bond. When energy in excess of 26,500 cal. has been accumulated, free rotation results. On the next inelastic collision accompanied by energy loss a maleic or fumaric ester molecule is formed depending on the orientation of the two rotating halves of the molecule in the instant of collision. The relative yields of the two are determined by the average times spent by the rotating molecule in the *cis* and the *trans* configuration. There are no grounds to assume that the times spent in either form differ considerably and therefore about a 50% yield of fumaric ester should be expected. On the basis of this mechanical model the gradual falling off of the reaction rate, as compared with activation rate, with increasing pressure is due to the fact that some molecules lose their energy before carrying out a 90° rotation. A considerable difficulty appears, however, if this assumption is made. It will be noticed from equation (1) that half of all activated molecules lose their energy, before free rotation has been established, at 1400-mm. pressure. The collision frequency at this pressure is about 10^{11} sec.⁻¹. Activation occurs on less than one in a thousand possible collisions and, since the statistical energy distribution must be maintained, the same is true of deactivation. Therefore the average time between activation and deactivation is of the order of 10^{-8} sec. This is a considerably longer time interval than the likely period of a rotation. Thus the possibility must be considered that some time elapses between the instant of the activating collision and the setting in of free rotation. This would occur if the energy was first transferred to some other mode of motion within the molecule and only later supplied to the rotation around the double bond. A proposal of this kind, while eliminating one difficulty, is not entirely satisfactory in that it obscures the cause of the exceptional slowness of energy exchange between ester molecules and also the lack of energy exchange with any but heavy inert gas molecules. Experiments on other esters of maleic acid, now in progress in this Laboratory, will perhaps settle this problem.

The position of equilibrium with dichloroethylenes as determined by Ebert and Büll³ shows that dipole interaction in these molecules is quite small. In dimethyl esters of maleic acid the interaction should be even weaker on account of larger distance between the dipoles. It is thus apparent that the activation energy observed (26,500 cal.) represents almost exclusively the straining of the double bond on a 90° rotation of the two atomic groups composing the molecule.

Summary

1. The rate of homogenous isomerization of gaseous dimethyl maleic ester into dimethyl fumaric ester has been studied at pressures up to 5

atm. and also in the presence of hydrogen, nitrogen, propane and carbon dioxide.

2. The variation of the velocity constant with pressure can be represented by the equation

$$K_{573^{\circ}} = \frac{7.7 \times 10^{-4}}{1 + (1400/P)} \text{ min.}^{-1}$$

from which the limiting value at infinite pressure is obtained to $K_{\infty} = 1.3 \times 10^5 e^{-26500/RT}$ sec.⁻¹.

3. Hydrogen and nitrogen have no effect on the reaction velocity, while propane and carbon dioxide accelerate it.

4. In the thermal equilibrium the ratio of fumaric to maleic ester is greater than unity.

5. The slowness of the activation process in the reaction is discussed and is linked to the nature of the mechanical motion responsible for the reaction.

THE PREPARATION AND PROPERTIES OF TITANIUM TETRABROMIDE AND TITANIUM TRIBROMIDE HEXAHYDRATE¹

BY JOHN C. OLSEN AND EMMETT P. RYAN

RECEIVED DECEMBER 26, 1931

PUBLISHED JUNE 6, 1932

Very few of the salts of titanium have been prepared in pure form and their properties studied. Considerable work has been done at the Polytechnic Institute on titanium compounds. As a part of this research titanium tetrabromide and titanium tribromide hexahydrate have been prepared and studied.

Duppa² prepared the tetrabromide and describes it as an amber-yellow substance, attracting moisture with the greatest avidity and being converted into titanous and hydrobromic acids, boiling at 230° and melting at 39°. Thorpe³ describes it as a dark yellow or orange crystalline mass melting at about 40° and boiling at 229° uncorrected. Its density is reported as 2.6 by Duppa and 3.37₄²⁵ by Klemm, Tilk and Müllenheim.⁴

Preparation of Titanium Tetrabromide.—The tetrabromide was prepared in three ways.

¹ From the thesis submitted in partial fulfillment of the requirements for the degree of Master of Science by Emmett P. Ryan. This paper was read at the Buffalo Meeting of the American Chemical Society, August 30–September 4, 1931.

² Duppa, *Proc. Roy. Soc. (London)*, **8**, 42 (1857).

³ Thorpe, *J. Chem. Soc.*, **47**, 126 (1885).

⁴ Klemm, Tilk and Müllenheim, *Z. anorg. allgem. Chem.*, **176**, 1–22 (1928).

(1) **A Modification of Duppa's Method.**—An intimate mixture of pure titanium dioxide and carbon black was placed in an inclined 25-mm. Pyrex tube. By means of a two-way stopcock, carbon dioxide, dry and free from oxygen, was passed either directly into the reaction tube or first into a flask containing bromine, heated to 60° to increase its vapor pressure. The tube was heated and swept free from air and moisture by the carbon dioxide after which the stopcock was turned and the bromine-saturated gas passed over the mixture of titanium dioxide and carbon heated to 640° . Titanium tetrabromide, carbon tetrabromide and excess bromine collected in the distilling flask at the end of the tube. The bromine was removed by distillation on a water-bath in a stream of carbon dioxide, and the carbon tetrabromide by later distillation. The titanium tetrabromide remained in the flask as an amber-yellow solid at room temperature. It was purified by distillation as described later.

(2) **Thorpe's Procedure.**—Hydrogen bromide was passed into titanium tetrachloride heated just below its boiling point. The hydrogen bromide, prepared by the action of bromine on red phosphorus and water, was freed from entrapped bromine fumes by passing through a U-tube filled with glass wool and red phosphorus, and dried by passing over soda lime. The hydrogen bromide was passed intermittently for thirty hours before the boiling point of the contents of the flask rose from that of titanium tetrachloride, namely, 136.4 , to 228° , the boiling point of titanium tetrabromide. The hydrogen bromide was passed for five hours more, the boiling point remaining constant. This product was also purified by distillation.

(3) **Ruff and Eisner's Method.**⁵—This method is similar to (1) except that titanium carbide was used in place of titanium dioxide and carbon black. This method was abandoned after one run because we were unable to secure an iron-free sample of titanium carbide. Thorpe's method requires the longest time but gives the purest product. A large quantity can also be most easily prepared by this method. Sixty grams was made by Duppa's method in two runs, while 450 g. was made by Thorpe's method in one run.

The titanium tetrabromide made by either method was twice distilled in an atmosphere of dry carbon dioxide, collecting that portion boiling at 228° uncorrected. Samples were collected in constricted glass tubes. The air was displaced by dry carbon dioxide and the bromide distilled into the tubes, which were immediately sealed off at the constriction.

The tetrabromide was analyzed by carefully breaking these tubes under water acidulated with a small amount of nitric acid. This was made up to a known volume and aliquot portions were withdrawn. The bromine was precipitated with silver nitrate and weighed as silver bromide. The titanium was precipitated with ammonium hydroxide and weighed as titanium oxide after bringing to constant weight over a Méker burner.

Anal. Calcd. for TiBr_4 : Ti, 13.03; Br, 86.97. Found: Ti, 13.21, 13.19, 13.30; Br, 86.62, 86.76.

The properties as determined were found to be as follows. Titanium tetrabromide is readily and completely soluble in 34% hydrobromic acid at room temperature and also in concentrated hydrochloric acid.

Concentrated nitric acid decomposes it. Nitrogen peroxide is given off, bromine settles to the bottom of the tube and titanous acid remains in solution.

Concentrated sulfuric acid decomposes the tetrabromide, liberating hydrogen bromide. Part of the hydrogen bromide reacts with the excess sulfuric acid forming bromine, water and sulfur dioxide. A reddish-brown solution is formed.

⁵ Ruff and Eisner, *Ber.*, **41**, 2260 (1908).

Ammonium hydroxide and a 20% aqueous solution of sodium hydroxide decompose the tetrabromide, forming a heavy white precipitate of $\text{Ti}(\text{OH})_4$. The reaction is analogous to that of ammonium hydroxide on titanium tetrachloride, forming a precipitate of $\text{Ti}(\text{OH})_4$.

Titanium tetrabromide is soluble in chloroform, carbon tetrachloride, absolute ether and absolute alcohol.

Quantitative Determination of the Solubility of Titanium Tetrabromide in Alcohol and Ether.—Titanium tetrabromide was distilled in a stream of dry carbon dioxide into a small flask which was quickly stoppered. A quantity of alcohol or ether, insufficient to dissolve the tetrabromide, was added. The flask was allowed to stand overnight. It was then brought to 20° and kept there for two hours with frequent shaking. A portion of the supernatant liquid was drawn off into a pycnometer and weighed at 20° . The contents was dissolved in water and the bromine content determined.

Two hundred and eighty-seven grams of titanium tetrabromide is soluble in 100 cc. of absolute alcohol at 20° . The density of this solution is 2.29_4^{20} ; 3.6 grams of titanium tetrabromide is soluble in 100 cc. of absolute ether at 20° .

Density.—As titanium bromide is hydrolyzed by water, mercury was used for the determination of density. A sample of titanium tetrabromide was distilled in an atmosphere of carbon dioxide and collected in a small test-tube drawn out near the top. On cooling, the tetrabromide solidified in the bottom of the tube and adhered firmly to the tube which was then sealed. The narrow portion of the tube was marked with a file in two places about an inch apart and the tube weighed. At the upper of the two file marks the tube was broken under mercury and filled, the temperature brought to 20° and the mercury level adjusted to the mark. The tube and contents were then weighed. The tube was now cleaned out, dried, and weighed with the glass tip broken off from the tube on filling. Its weight filled to the mark with mercury at 20° was then found. The density of the tetrabromide was 3.23_4^{20} .

The density was also determined in a vacuum. The sample was prepared as before but now the tetrabromide was but little more than covered with mercury. It was placed in a vacuum in a desiccator to wet the surface of the sample thoroughly. The tube was then removed from the desiccator, filled to the mark with mercury at 20° and weighed. The density was 3.25_4^{20} .

Duppa gives 2.6 as the density and Klemm, Tilk and Müllenheim 3.372_4^{25} . Duppa, who was the first to prepare titanium tetrabromide, does not give his method of determining the density. Handbooks have evidently taken his figure. Klemm, Tilk and Müllenheim give their method. They took especial care before filling the tubes up to the mark with mercury to place them under high vacuum to remove (as they state) any moisture that may have entered while getting the samples in the tubes. As moisture rapidly hydrolyzes titanium tetrabromide to hydrogen bromide and titanium dioxide, part of the tetrabromide would be hydrolyzed before the moisture could be removed by vacuum. As titanium dioxide has a density of from 3.75 to 4.25 any of this oxide formed would give high results especially where small samples were taken. The samples used for the two determinations which they made weighed 0.5943 and 0.3889 grams.

In filling our sample tubes, the tetrabromide was distilled in an atmosphere of dry carbon dioxide into dry test-tubes from which the air

had been displaced by carbon dioxide. They were then sealed off from the air and broken under mercury. Furthermore, samples of 8.3450 g. and 5.2538 g. were used. For these reasons we believe 3.24_4^{20} , the average of our two determinations 3.25_4^{20} and 3.23_4^{20} , more accurate than the 3.37_4^{25} , the average of Klemm, Tilk and Müllenheim's two determinations, 3.36_4^{25} and 3.38_4^{25} . Duppa's results are obviously low.

Titanium Tribromide Hexahydrate.—Stähler⁶ prepared titanium tribromide hexahydrate by electrolyzing a solution of titanium tetrabromide in hydrobromic acid. He describes the crystals as dark violet, intermediate in stability between the corresponding chloride and iodide and deliquescing in air to a brown, strongly fuming liquid. We prepared the hydrated tribromide in a similar manner and present the following additional data.

Preparation.—Twenty-six grams of titanium tetrabromide was dissolved in 23 g. of 34% hydrobromic acid and placed in a porous cup 41 mm. in diameter and 76 mm. in height. This was placed in a 400-cc. beaker containing 34% hydrobromic acid. The liquids in the porous cup and beaker were kept at the same level. Two carbon rods served as the electrodes, with the porous cup as the cathode compartment. A current of 2.5 amperes was passed through the solution for two hours. When dry hydrogen bromide gas was passed into the ice cooled flask containing the violet colored solution, crystals of hydrated titanium tribromide separated out. The crystals were filtered on Gooch asbestos, washed with ether, and dried in a desiccator over soda lime until constant. The following analysis indicates that the crystals were very nearly pure $\text{TiBr}_3 \cdot 6\text{H}_2\text{O}$.

Anal. Calcd. for $\text{TiBr}_3 \cdot 6\text{H}_2\text{O}$: Ti, 12.10; Br, 60.58; TiBr_3 , 72.69. Found by gravimetric analysis: Ti, 12.16, 11.75; Br, 59.52, 59.24; TiBr_3 , 71.68, 70.99.

Properties.—Titanium tribromide hexahydrate is a light reddish-violet crystalline substance. It deliquesces in air to a heavy brown liquid but may be kept in a desiccator over soda lime, with but slight decomposition. The crystals melt at 115.0° .

It is soluble in water giving a violet color in concentrated solutions, and is soluble in hydrobromic acid giving a brownish solution.

Titanium tribromide hexahydrate is also soluble in methyl alcohol, absolute ethyl alcohol, and acetone, insoluble in carbon tetrachloride and benzene, and decomposes on standing with absolute ether.

Summary

Titanium tetrabromide was prepared by three methods. It is soluble in chloroform, carbon tetrachloride, absolute ether, absolute alcohol and hydrobromic and hydrochloric acids. It is decomposed by nitric acid, sulfuric acid, ammonium hydroxide and an aqueous solution of sodium hydroxide; 287 g. of titanium tetrabromide is soluble in 100 cc. of absolute alcohol at 20° and 3.6 g. in 100 cc. of absolute ether at 20° . The correct density determination is 3.25_4^{20} .

Titanium tribromide hexahydrate was prepared. It melts at 115° . Solubilities in various solvents and other properties are given.

STUDIES OF VARIOUS METHODS FOR THE SEPARATION OF THE COMMON ELEMENTS INTO GROUPS.

I. THE PRECIPITATION BY AMMONIUM HYDROXIDE

BY ERNEST H. SWIFT AND R. C. BARTON

RECEIVED JANUARY 2, 1932

PRINTED JUNE 6, 1932

Introduction

During the course of an attempt to develop a system of qualitative analysis for the so-called common elements which would provide more quantitative information than that usually obtained, it became one of the first problems to examine the methods commonly used for the qualitative separation of these elements into groups. The extensive investigations of Noyes and Bray and their co-workers^{1,2,3} have furnished much information as to the qualitative value of many of these separations, with special reference to the detection of very small amounts of one element in the presence of large amounts of the other, but very little information with respect to the completeness of the separation when each element is present in moderate or large amounts. Although these same separations are used in quantitative methods, surprisingly little systematic information of this nature seems to be collected in texts or reference works; while that in the original literature is widely scattered, gathered under such varying conditions as to be difficult to correlate, and apparently quite incomplete. Therefore it has seemed worth while to present the results of these studies in this series of papers.

The Precipitation by Ammonium Hydroxide.—The precipitation by ammonium hydroxide can well be termed one of the classical analytical separations and, as is stated by Hillebrand and Lundell,⁴ "One of the commonest operations the analyst has to perform . . . , with the object either of weighing the precipitated compound or of effecting a joint separation of two or more metals from others." That it may be inadequate even as a qualitative separation in certain cases is shown by the experiments of Noyes and Bray⁵ in which, with large amounts of aluminum or ferric iron (100–200 mg.) and with amounts of cobalt, zinc or nickel up to 20 mg., from 75 to 99% of the latter elements were found to be carried down

⁵ Ref. 3, pp. 153–155.

in the precipitate. Noyes, Bray and Spear⁶ also state that "a large quantity of zinc may be quantitatively precipitated by ammonium hydroxide when a larger proportion of chromium is present; and manganese will in any case be partially precipitated by that reagent owing to its oxidation by the air." In a careful study of the conditions necessary for securing complete precipitation of aluminum by ammonia, Blum⁷ has found that these are attained by carefully neutralizing the solution, using methyl red (or rosolic acid) as indicator, and avoiding an excess of ammonia. Concerning its separation from other elements the following statement is made: "It is well recognized that the separation of aluminum from such elements as zinc, manganese, nickel and cobalt by means of ammonia is unsatisfactory since the alkalinity required for the resolution of their hydroxides is such as to cause appreciable solution of the aluminum hydroxide also. Moreover, it was found that even in solutions just alkaline to methyl red, oxidation and precipitation of the manganese occurred so rapidly as to preclude a quantitative separation."

However, Lundell and Knowles⁸ in an extensive series of experiments, in which the precipitations were carried out according to the procedure developed by Blum,⁷ show that moderate amounts of iron and aluminum can be separated from manganese and nickel quite satisfactorily; under the same conditions considerable amounts of cobalt, copper and zinc were found in the precipitates. It was also found that an excess of ammonia, although apparently improving the separation of aluminum and iron from copper and zinc, made the separation of these two elements from manganese, nickel and cobalt less satisfactory. The striking experiments of Noyes and Bray, cited above, in which a relatively large excess of ammonia was present, seem to confirm this latter observation and to raise considerable question as to whether a more effective separation is obtained by having an excess of ammonia present. This would seem to depend upon whether the bivalent elements remain in solution due to the solubility of their hydroxides (as is most probable with manganese) or due to the formation of the soluble ammonia complexes, and, furthermore, to the relative tendency of these two molecular types to be carried down with the precipitate. The effect of the *P_H* of the solution upon the adsorbing tendency of the precipitate has also to be considered. In spite of this uncertainty, the proper attention apparently has not been given, in qualitative procedures (or in quantitative methods where the complete precipitation of aluminum is not involved), to the effect of making a careful neutralization or of exactly adjusting the excess of ammonia. It will be shown in the experiments to be presented that the proper control of the excess of am-

⁷ Blum, *THIS JOURNAL*, **38**, 1291 (1916).

⁸ Lundell and Knowles, *ibid.*, **45**, 676 (1923).

monia is a most important feature in the separations which have been included in the present investigation, and that many of these separations are quite inadequate even for crude qualitative separations unless the neutralization with ammonia is carefully performed.

This study has been restricted mainly to the elements iron, aluminum, chromium, manganese, nickel, cobalt and zinc; however, since in the qualitative analysis of the common elements, the ammonium hydroxide separation is likewise used to separate bismuth from copper and cadmium, a few experiments are shown to indicate the sharpness of these separations. The effect of phosphate has not been included in this paper. It has not seemed worth while to give separate references to all of the previous work dealing with each of the individual separations here studied. In most cases these can be found, with a brief discussion, in the reference work of Rüdissile.⁹

Experimental Procedure

The separations were carried out according to three general procedures. The first of these, designated Procedure I, was designed to conform to usual qualitative technique, and, except where explained by notes, was as follows.

To a boiling solution containing the elements to be separated and 60 milli-equivalents of hydrochloric acid in a volume of 100–125 ml., 6 normal ammonium hydroxide was slowly added until red litmus paper just turned a distinct blue color. The mixture was then boiled for one to three minutes and filtered; it was kept hot during the filtration. The precipitate was washed with hot water until the washings were colorless or had no perceptible effect on red litmus.

Procedure II, conforming more closely to the procedure outlined by Blum, was as follows.

To a boiling solution, which contained 10 g. of ammonium chloride and 6–12 milli-equivalents of hydrochloric acid in a volume of approximately 250 ml., 6 normal ammonium hydroxide was added dropwise until a color change was noted using methyl red, or in a few cases rosolic acid, as the indicator. Where the color of the solution prevented the use of the internal indicator, litmus test papers were used and the ammonia added until the color of the litmus matched that obtained from a similar solution of ammonium chloride and hydrochloric acid to which ammonium hydroxide had been added until the methyl red (or rosolic acid) color transition occurred. Extreme care was taken in these neutralizations; if the color transition was over-run, the mixture was made acid and the process repeated. The mixture was boiled for one to two minutes and filtered; it was kept hot until the filtration was completed. To expedite filtering and washing two separate filters were used in most cases. The precipitate was washed with a hot 2% solution of ammonium chloride until the washings gave no appreciable precipitate when tested with ammonium sulfide solution.

Procedure II differs from Procedure I in that the solution was diluted to a larger volume, a larger quantity of ammonium chloride was present and extreme care was taken to avoid an excess of ammonium hydroxide.

⁹ Rüdissile, "Nachweis, Bestimmung und Trennung der chemischen Elemente," Max Drechsel, Bern.

In order to compare more exactly the effect of an excess of ammonium hydroxide the experiments labeled III were performed. These duplicated Procedure II except that after carefully neutralizing with ammonia an excess of 2 ml. of 6 normal solution was added.

In each of the experiments 250 milligrams of one of the elements listed in the first column of the table was precipitated from a solution which also contained 250 milligrams of one of the elements listed at the top of the four major columns. Observations and variations from the procedures outlined above are contained in the notes to the table. The precipitate was then analyzed in order to determine the amount of the soluble element carried down. Limitation of space has made it necessary to omit a detailed description of the methods used in analyzing these precipitates. In every case the precipitate was so treated as to separate the two elements—thus the ferric hydroxide precipitates were dissolved in hydrochloric acid, the concentration of the acid properly adjusted and the iron removed by repeated extraction with ether—or the element carried down was converted into a form in which it could be directly estimated; for example, the manganese in the aluminum precipitate was converted directly into manganese dioxide, or, when very small in amount, oxidized to permanganate. The methods used were checked by blanks and by confirmatory analyses of prepared mixtures. The results of these experiments, showing the amount of co-precipitation in each separation, have been collected in Table I. It is felt that significance should be attached to the general magnitude, rather than the exact value for any individual experiment, as it is impossible to duplicate exactly all the conditions, such as local concentration of the precipitant during precipitation, and as in many cases the results are apparently highly dependent upon such conditions.

TABLE I

THE SEPARATION OF CHROMIUM, ALUMINUM AND IRON FROM MANGANESE, NICKEL, COBALT AND ZINC BY PRECIPITATION WITH AMMONIA

In these experiments 250 mg. of one of the elements in the first column was precipitated from a solution containing 250 mg. of one of the elements listed at the top of the four major columns.

NOTES TO TABLE I

1. The manganese in this precipitate was separated by precipitation as dioxide by addition of potassium chlorate to a nitric acid solution. The precipitate was washed free of chromate and chlorate and the manganese determined iodometrically.

2. The chromium hydroxide precipitate obtained in Expt. 3 required about 100 ml. of wash solution. However, the precipitate in Expt. 5 required 500 ml. The washings were tested for manganese by addition of ammonia and hydrogen peroxide.

3. In this neutralization a slight excess of ammonia was added, so 6 normal hydrochloric acid was added until the methyl red was distinctly pink and the neutralization repeated.

4. A slightly larger excess of ammonia was added in Expts. 7 and 8 than in 6.

5. Five grams of ammonium chloride was used in addition to that formed by neutralization of the hydrochloric acid.

6. The nickel was estimated by comparing with standards the precipitate produced by dimethylglyoxime in one-tenth the filtrate.

7. The solution was made just neutral to litmus without using a reference solution with an internal indicator. Probably slightly more ammonia was added than in Expt. 13.

8. The volume and other conditions were as in Procedure I. Neutralization was made and an excess of ammonia avoided as in Procedure II.

9. Only 160 mg. of zinc was taken.

10. In Expts. 49 and 51 an excess of 5 ml. of 15 normal ammonia was added; otherwise Expts. 48 and 49 and Expts. 50 and 51 were carried out in exact duplicate to note the effect of the larger excess of ammonia.

11. Expts. 48 and 49 were carried out in this Laboratory by Mr. Francis Hunter and Mr. Elvin Lien.

Discussion of the Data of Table I

An inspection of the data in Table I would seem to lead to two general conclusions: first, in about half of the separations studied the separation is quite unsatisfactory even under the most favorable conditions. Second, in every case studied the separation is more effective when an

excess of ammonia is avoided and, in most cases, unless this excess is avoided the separation is so imperfect that little is gained by reprecipitations; thus, under the conditions studied, when an excess of ammonia is added, more than 50% of the nickel, cobalt or zinc is carried out by either chromium or aluminum. This would seem to indicate that the ammonia separation is more effectively carried out, at least in dilute solutions, as a process of selective hydrolysis and not as one depending on the formation of the soluble complex ammino ions. In support of this it is to be noted that manganese, where the tendency toward this complex formation is least, is much less co-precipitated than nickel, cobalt or zinc.

Also, the *P_H* values at which these divalent elements are precipitated from solution are given by Britton¹⁰ as follows: zinc, 5.2; nickel, 6.7; cobalt, 6.8; and manganese, 8.5–8.8. It is seen that the co-precipitation in the experiments carried out by Procedure II in every case varies in amount in this same order—zinc, the least soluble hydroxide, showing the greatest tendency to be carried with the precipitate. The same order in general holds for the experiments by Procedures I and III, which is somewhat surprising, as, with an excess of ammonia present, it would be expected that the formation of the soluble ammonia complexes would be a more deciding factor; for the same reason it would have been predicted that the large excess of ammonia added in Expts. 49 and 51 would have decreased markedly the amount of co-precipitation; however, the difference is within the experimental variations. That the effect is due to an adsorption process and not to mechanical inclusion or local precipitation is indicated by the experiments of Ibbotson and Breatly¹¹ and of Noyes and Bray,¹² showing that when an ammoniacal solution of the bivalent element is added to a suspension of the freshly precipitated hydroxide, the effect approaches that obtained by precipitation in the presence of the bivalent element. That the complex ammonia compounds are not extensively carried down was shown by the fact that relatively little ammonia was found upon analyzing an aluminum precipitate, produced by Procedure III, which had co-precipitated with it about 200 mg. of nickel. Further studies are being made of certain of these separations in which the co-precipitation is pronounced in an attempt to ascertain the various factors affecting it and the mechanism of the phenomenon.

Specifically, in addition to confirming the results of Lundell and Knowles that, by proper methods of neutralization, a satisfactory separation of manganese from aluminum and from iron is obtained, it is shown that under these same conditions manganese can be separated from chromium. However, it is to be noted that the co-precipitation of manganese is in-

¹⁰ Britton, "Hydrogen Ions," D. Van Nostrand Co., New York, 1929, p. 254, 278.

¹¹ Ibbotson and Breatly, *Chem. News*, **81**, 193 (1900).

¹² Ref. 3, p. 154.

creased much more by an excess of ammonia in the separation from chromium than it is in the separation from either aluminum or iron. The separations of nickel from aluminum and chromium show from 50 to 90% of this element brought down when an excess of ammonia is added, demonstrating the futility of reprecipitations; the same general behavior is obtained with these elements and cobalt. Even under the most favorable conditions these separations are hardly adequate for quantitative work. The separations of nickel and cobalt from iron, made from carefully neutralized solutions, show about 2% co-precipitation so that a reprecipitation would probably reduce this to satisfactory limits. The separation of zinc under these conditions is unsatisfactory regardless of methods of neutralization. It is to be noted that the co-precipitation in method I is usually greater than that in method III, showing the favorable effect of an increased volume with thereby a decrease in the concentration of the co-precipitated substance.

It is perhaps worthy of note that the procedure, almost universal in qualitative textbooks, which directs that a *slight excess* of ammonia be added to a relatively small volume of solution, produces conditions which are apparently the *least* favorable of those studied for the separations desired.

The Ardagh Method of Carrying out the Ammonia Separation.—Recognizing the inadequate nature of the conventional ammonia precipitation for the separation of iron (and aluminum) from zinc, Ardagh and his co-workers^{13,14} have devised a procedure for carrying out the separation which employs radically different conditions from those existing in any of the procedures thus far described. In it the precipitation is made by the addition of a large excess of 15 *N* ammonium hydroxide to a very small volume of an acid solution which has been previously saturated with solid ammonium chloride. These conditions produce a more compact and granular precipitate than that usually formed and a satisfactory separation of zinc from iron or aluminum is obtained by a single precipitation. An extension of this method to other separations would seem desirable and, since no such data seemed available, such a study was made and the results are shown in Table II. The general procedure used was as follows. A hydrochloric acid solution of the elements to be separated was evaporated to a volume of 3 to 5 ml., cooled and 5 g. of solid ammonium chloride then intimately mixed with the solution. Following this 10 ml. of 15 *N* ammonium hydroxide was added, the resulting mixture thoroughly mixed with a stirring rod, 25 ml. of water added and the precipitate filtered, usually equally dividing it between two separate filters in order to facilitate washing. The precipitates were washed with a solution containing 5 g. of ammonium chloride and 5 ml. of 15 *N* ammonium hydroxide in a volume of 100 ml.

¹³ Ardagh and Broughall, *Can. Chem. Met.*, **7**, 198 (1923).

¹⁴ Ardagh and Bongard, *Ind. Eng. Chem.*, **16**, 297 (1924).

Variations from this procedure are explained in the notes accompanying the table. It should be mentioned that chromium cannot be precipitated under the conditions of this procedure as it remains to a large extent in solution due to the formation of complex ammines. Also from 2-5 milligrams of aluminum is dissolved and has to be recovered subsequently from the filtrate.

In these experiments 250 milligrams of one of the elements listed in the first column of the table was taken together with 250 milligrams of one of the elements listed at the top of the four major columns. Observations and variations from the outlined procedure are contained in the notes to the table.

TABLE II

THE SEPARATION OF ALUMINUM AND IRON FROM MANGANESE, NICKEL, COBALT AND ZINC BY THE ARDAGH METHOD OF PRECIPITATION WITH AMMONIA

In each experiment 250 mg. of one of the elements in the first column was taken with 250 mg. of one of the elements listed at the top of the four main columns

Element precipitated	Manganese Found in ppt.			Nickel Found in ppt.,			Cobalt Found in ppt.,			Zinc Found in ppt.,		
	Expt.	mg.	Notes	Expt.	mg.	Notes	Expt.	mg.	Notes	Expt.	mg.	Notes

	2	105	2							6	8	6, 8
										7	2	7, 8
											0-0.4	14
Iron	8	25		10	0.1-0.2		11	25	10	14	0.5	12
	9	8	9	16	0.7-0.9	13	12	5	10	15	0.6	13
							13	6	11		0 2-0.5	14

NOTES TO TABLE II

1. The precipitate was equally divided between two filters and each half required 150-200 ml. of wash solution; it darkened during the washing.
2. Only 5 cc. of 15 *N* ammonium hydroxide was used.
3. Found 5 mg. of aluminum in the filtrate.
4. Filtration and washing difficult; 200 ml. wash solution required.
5. Only 2 ml. of 15 *N* ammonium hydroxide was added and the mixture was diluted to 50 ml. before filtering. Less than 0.5 mg. of aluminum remained in the filtrate.
6. Only 3 ml. of ammonia added, mixture diluted to 25 ml. 1-2 mg. of aluminum found in filtrate.
7. Only 5 ml. ammonia added. 2-3 mg. of aluminum in filtrate.
8. In Expts. 5, 6, 7 only 125 mg. of aluminum was taken with 250 mg. of zinc.
9. Only 5 ml. of ammonia added.
10. In this experiment (No. 11) the original solution was evaporated to 3-4 ml. and this solidified upon cooling. Two ml. of 6 *N* hydrochloric acid was added to dissolve this residue. Upon adding the ammonium chloride this solution was absorbed and even after long maceration with a stirring rod the mixture did not seem homogeneous. In Expt. 12 the original solution was evaporated to 5 ml. and after adding the ammonium chloride, 6 *N* hydrochloric acid was added (2 cc.) until a homogeneous, thoroughly wet mixture was obtained.
11. A repetition of Expt. 12, except that the mixture was heated to 70-80° before filtering and the wash solution was also heated. The precipitate was more difficult to wash, requiring 500 ml. of wash solution.

12. 5 g. of ammonium nitrate was used instead of ammonium chloride.
13. A nitric acid solution was evaporated to 3–4 ml. and 8 g. of ammonium nitrate used instead of the ammonium chloride. Ammonium nitrate was substituted for ammonium chloride in the wash solution.
14. Values taken from experiments of Ardagh and Bongard¹⁴ using about 200 mg. of iron and zinc.

Discussion of the Data of Table II

An inspection of the data of Table II, and a comparison with Table I, shows, as was to be expected, that the Ardagh method cannot be used for separations involving manganese, due to the oxidation of this element in the more alkaline solution. The separation of nickel from aluminum is improved and the separation of nickel from iron is so nearly perfect that only one precipitation would be required for most quantitative work. The separation of cobalt from aluminum is more complete than by any method of precipitation by ammonia in a dilute solution; although the separation of cobalt from iron is fairly satisfactory it is no more complete than that obtained by a careful neutralization. Where, as is the case in many qualitative systems, it is desired to separate iron from nickel, cobalt and zinc, the Ardagh method of precipitation offers decided advantages.

Attempts to reduce the amount of aluminum dissolved by decreasing the ammonia concentration caused, in the separation from zinc, an increase in the co-precipitation of that element (Expts. 5, 6, 7). This indicates that in this separation, contrary to those studied in Table I, the bivalent elements are held in solution mainly due to the formation of the ammonia complexes. That, in spite of the use of small volumes and more concentrated solutions, better separations are obtained by this method, is probably due to this more complete conversion of the bivalent elements into the ammonia complexes and, in addition, to the more granular and less hydrous nature of the precipitates obtained, these physical characteristics usually indicating a less effective adsorbing agent.¹⁵ Experiments 14, 15 and 16 show that the substitution, in the cases studied, of an equivalent amount of ammonium nitrate for ammonium chloride has relatively little effect, indicating that the presence of chloride ion is not highly essential to the separation.

The Separation of Bismuth from Copper and Cadmium

In most systems of qualitative analysis this separation follows the detection and removal of lead as sulfate. In precipitating lead the solution is fumed with sulfuric acid, then cooled and diluted. To conform to these conditions the procedure used was as follows: to 250 mg. each of bismuth and of copper or cadmium (as the nitrates), was added 10 ml. of 6 *N* sulfuric acid and the volume made from 80–100 ml. There was then added

¹⁵ Weiser, "The Hydrous Oxides," The McGraw-Hill Book Co., New York, 1926, p. 1.

6 *N* ammonia until in one case the solution was just neutral to litmus or, in the alternative case, there was 5 ml. of ammonia in excess. The precipitates were washed with 2% ammonium sulfate solution and then analyzed for the copper and cadmium present. In the separations in which the solution was made just neutral and an excess of ammonia was avoided, 150–180 mg. of copper and 2 mg. of cadmium were found in the bismuth precipitates; in the separations with the 5 ml. excess of ammonia added 0.5 mg. of copper and 2 mg. of cadmium were found. This indicates, as would be expected from the *P_H* value at which copper precipitates, that the separation of copper from bismuth in a sulfate solution requires an excess of ammonia sufficient to form the complex ammine; on the other hand, the separation of cadmium, due to the greater solubility of the hydroxide, is equally effective with or without an excess of ammonia.

Summary

Data are presented for the separation of chromium, aluminum and iron from manganese, nickel, cobalt and zinc by various modifications of the ammonia separation.

It is shown that when working with the usual dilute solutions the separation is more effective when a careful neutralization is made using methyl red (or its equivalent) as indicator, and an excess of ammonia avoided. Under these conditions, with 250 mg. of each element present, the chromium precipitate carried out only 0.4–0.8 mg. of manganese, but 30–40 mg. of nickel, cobalt or zinc; the aluminum precipitate carried out only 0.2–0.3 mg. of manganese, but 8–10 mg. of nickel or cobalt and 75 mg. of zinc; the iron precipitate carried out 0.8–1.5 mg. of manganese, 3–4 mg. of cobalt or nickel and 11 mg. of zinc.

When an excess of ammonia is used the separation is so imperfect, regardless of the presence of a large amount of ammonium chloride, that in the majority of cases it is not recommended even for qualitative purposes.

When the precipitation is made by addition of concentrated ammonium hydroxide to a small volume (3–5 ml.) of a solution saturated with ammonium chloride, even with 250 mg. of each element present, less than a milligram of the soluble element was co-precipitated in separating iron from nickel or zinc, or aluminum from zinc, and 4–5 mg. was co-precipitated in separating iron from cobalt, or aluminum from nickel or cobalt. Under the conditions of the procedure aluminum dissolves to the extent of about 5 mg., and chromium is very soluble.

When separating bismuth from copper in a dilute sulfate solution an excess of ammonia is required; the separation from cadmium can be made either from a carefully neutralized solution or one containing an excess of ammonia.

EQUILIBRIUM IN BINARY SYSTEMS UNDER PRESSURE. II. THE SYSTEM, $K_2SO_4-H_2O$, AT 25°

By L. H. ADAMS

RECEIVED JANUARY 7, 1932

PUBLISHED JUNE 6, 1932

In a previous paper¹ the results of an investigation of the system, $NaCl-H_2O$, under high pressures were presented. Measurements of the effect of hydrostatic pressure on the volumes of the several phases were made, and thence, by the application of a simple thermodynamic principle, the conditions of equilibrium between the various phases were calculated for pressures somewhat greater than 10,000 bars (metric atmospheres). The freezing-point and solubility curves thus delineated were confirmed by direct measurements, but the indirect, *i. e.*, thermodynamic, method was the one that was found to be the most convenient for the study of multi-component systems under high pressure.

In this paper are given results for the system, $K_2SO_4-H_2O$, at 25° and at pressures up to approximately 10,000 bars. The experimental and calculatory methods were essentially the same as those used in the previous investigation, and the nomenclature, except where the contrary is specifically noted, is the same as that of the former paper.

Measurements of the Compression of the Solutions

Low-Pressure Experiments.—Since the high-pressure apparatus is not suitable for measurements at pressures below 1000 bars, the compression at this pressure was determined by means of the glass piezometer previously described.² The solutions were made up by weight from potassium sulfate that had been recrystallized from water and dried at about 800°. On account of the transition with large volume change, which potassium sulfate undergoes at 588°, heating the salt above this temperature not only insures thorough drying but also reduces the crystals to a convenient granular condition.

The most concentrated solution used contained 10% by weight, since the solubility of potassium sulfate at 25° and atmospheric pressure is only 10.76%. Table I shows the results for the compression, k (fractional diminution in volume), at 1000 bars for solutions of four different concentrations, and the previously determined value of k for pure water. The weight fraction of salt is denoted by x_2 . In Table I are given also the values of the important compression-concentration gradient, $\partial k / \partial x_2$, and the values of \bar{v}_1 and \bar{v}_2 , the fictive volumes of water and potassium sulfate at 1000 bars, or rather the change in these quantities caused by the pressure

TABLE I

COMPRESSION, k , OF POTASSIUM SULFATE SOLUTIONS AT 1000 BARS AND 25°

x_2	k	$-\partial k/\partial x_2$	$\bar{v}_1 - (\bar{v}_1)_0$	$\bar{v}_2 - (\bar{v}_2)_0$
0.0	0.03930	0.0640	-0.0394	0.0568
.025	.03787	.0624	— .0393	.0513
.05	.03647	.0608	— .0392	.0470
.075	.03470	.0592	— .0389	.0429
.10	.03322	.0576	— .0385	.0391

mentioned. The values of $\partial k/\partial x_2$ were obtained by differentiating the equation

$$k = 0.03930 - 0.0640 x_2 + 0.032 x_2^2 \quad (1)$$

which, over the limited concentration range obtainable with this salt, seemed to give a fair representation of the data except possibly at concentrations very close to zero. The values of \bar{v}_1 and \bar{v}_2 were obtained from the relations [equations (29) and (28), respectively, of the previous paper]

$$\bar{v}_1 - (\bar{v}_1)_0 = -(\bar{v}_1)_0 k + x_2 v_0 \frac{\partial k}{\partial x_2} \quad (2a)$$

and

$$\bar{v}_2 - (\bar{v}_2)_0 = -(\bar{v}_2)_0 k - x_1 v_0 \frac{\partial k}{\partial x_2} \quad (2b)$$

in which v is the specific volume of the solution, and the subscript zero refers to atmospheric pressure.

High-Pressure Experiments.—For pressures above 1000 bars the measurements of the compression, k , were made by the usual piston-displacement method. The directly determined quantity was the difference between the compression of the solution (reckoned from 2000 bars, the arbitrary "initial" pressure) and that of pure water, that is, $\Delta k - \Delta k'$, the superscript prime referring to $P = 2000$. The results are shown in Table II, which includes also the values of k itself for the various concentra-

tions and pressures, as obtained by combining³ the results for $\Delta k - \Delta k'$ with those for Δk at 1000 bars given in Table I and with the previously determined values for the compression of water. A comparison of the compression of solutions of potassium sulfate with the previous results for sodium chloride shows that the addition of a given *weight* of potassium sulfate reduces the compression of water (at any pressure) almost the same amount as the addition of the same weight of sodium chloride, although the latter salt produces a slightly greater effect.

Density of Potassium Sulfate Solutions.—Before use can be made of these measurements for determining the equilibrium in the system, $K_2SO_4-H_2O$, it is necessary to have reliable data on the densities of the solutions at atmospheric pressure. These densities should be known to about one unit in the fifth place after the decimal point in order to obtain the desired accuracy in the fictive volumes of the two components. Unfortunately, there are only a few salts for which the densities of their aqueous solutions have been measured with reasonable accuracy—despite the fact that the determination of density is one of the simplest and the most fundamental of measurements. The best values for potassium sulfate solutions (as shown in the "International Critical Tables") are given only to the fourth figure after the decimal, and, as has now been found, there are errors as great as eight units in this place. It was necessary, therefore, to make a series of measurements on the densities of the solutions at 25°. This was done, with the recrystallized and carefully dried salt, according to the same method and by the use of the same pycnometer as that described in connection with earlier density determinations at this Laboratory.⁴ The temperature of the thermostat was $25^\circ \pm 0.003$ and the volume of the pycnometer at 25° was 55.0373 ml. This volume agreed well with the previous determinations, *viz.*, 55.0384 (Hall, 1920), 55.0365 (Gibson, 1927), and 55.0371 (Gibson, 1930).

The results are shown in Table III, and the "densities," d , in ml./g. and the "specific volumes," v , in g./ml. at round concentrations are given in Table IV. It was noted that for potassium sulfate, and also for other salts, $\Delta v / \Delta x_2$ when plotted against x_2 gave a line which curved notably at the origin but with increasing concentration rapidly approached a straight line. This at once suggested that the data might be represented well by an equation of the form

$$v = A + Bx_2 + Cx_2^2 + D(1 - e^{-Ex_2}) \quad (3)$$

in which A , B , C , D and E are constants, A being the specific volume of pure water (1.002932 at 25°). It was found that with $B = 0.79032$, $C = 0.297$, $D = 2.40 \times 10^{-4}$ and $E = 100$, this equation represented the

data with gratifying accuracy. As indicated by the last column of Table III, the average deviation (without regard to sign) between the observed values of v and those calculated from equation (3) was only 4×10^{-6} , which was no greater than the error of measurement.

The fictive volumes, \bar{v}_1 and \bar{v}_2 , of water and potassium sulfate in solution were calculated from the equations

$$\bar{v}_1 = v - x_2 \frac{dv}{dx_2} \quad (4a)$$

and

$$\bar{v}_2 = v + x_1 \frac{dv}{dx_2} \quad (4b)$$

the values of dv/dx_2 being obtained by differentiating equation (3); except that, because there was good reason for believing that equation (3), despite the satisfactory way in which it fits the data, does not give precisely the right slope at zero concentration, the value of \bar{v}_2 at $x_2 = 0$ was determined by plotting the values of \bar{v}_2 against $\sqrt{x_1/x_2}$ and extrapolating the (nearly linear) curve back to zero. The results for \bar{v}_1 and \bar{v}_2 are shown in Table IV.

Fictive Volumes under Pressure.—The change of the fictive volumes under pressure is determined by the compression, k , of the solutions. The most convenient method of carrying out the calculation depends on the ease with which k can be represented as a function of x_2 (at constant P) or of P (at constant x_2). With potassium sulfate solutions, just as was

found previously for sodium chloride solutions, the compression reckoned from 2000 bars (that is, $k - k'$) seems to vary linearly with the concentration at constant pressure. Hence it was advantageous to deal directly with $k - k'$ and to calculate the increase in \bar{v}_1 and \bar{v}_2 , respectively, due to an increase of pressure from 2000 to P , by the relations

$$\bar{v}_1 - \bar{v}_1' = -(\bar{v}_1)_0(k - k') + x_2 v_0 \frac{\partial(k - k')}{\partial x_2} \quad (5a)$$

and

$$\bar{v}_2 - \bar{v}_2' = -(\bar{v}_2)_0(k - k') - x_1 v_0 \frac{\partial(k - k')}{\partial x_2} \quad (5b)$$

The first step consisted in finding $\partial(k - k')/\partial x_2$ at each pressure. This was done by representing $k - k'$ as a linear function of x_2 using the method of least squares. Next, the values of this compression-concentration gradient were smoothed by means of the equation

$$-10^5 \frac{\partial(k - k')}{\partial x_2} = 0.304(P - P') + 8000(1 - e^{-3.4 \times 10^{-4}(P - P')}) \quad (6)$$

which fitted the results for the gradient with an average deviation (regardless of sign) of 0.0014. Then, $\bar{v}_1 - \bar{v}_1'$ and $\bar{v}_2 - \bar{v}_2'$ at each pressure from 1000 to 10,000 bars were computed by means of equations (5a) and (5b); and finally, by use of the change in \bar{v}_1 and in \bar{v}_2 from 1 to 1000 bars, as shown in Table I, the values of \bar{v}_1 and \bar{v}_2 at the various pressures were obtained.

The fictive volumes under pressure were calculated also by another method, suggested by the recent discovery⁵ that the "apparent molal volume" of electrolytes is a linear function of the square root of the concentration per unit volume for dilute solutions, and is very approximately so for concentrated solutions. The approximate linear relation holds also if the mole ratio or the mass ratio is substituted for the volume concentration. If φ be defined⁶ by the relation, $\varphi = v/x_2 - x_1 v_w/x_2$, in which v_w is the specific volume of pure water, and if φ is a linear function of $\sqrt{x_2/x_1}$ not only at atmospheric pressure but also at all other pressures, then it follows that

$$\Delta_P \varphi \equiv \frac{\Delta_P v - x_1 \Delta_P v_w}{x_2} = a + b \left(\frac{x_2}{x_1} \right)^{1/2} \quad (7)$$

in which a and b are constants (for a given salt and at a given temperature and pressure). Furthermore, from equation (7) in combination with

⁵ D. O. Masson, *Phil. Mag.*, [7] **8**, 218-235 (1931); A. F. Scott, *J. Phys. Chem.*, **35**, 2315-2319 (1931); W. Geffcken, *Z. physik. Chem.*, **155A**, 1-28 (1931). See also the accurate measurements by A. B. Lamb and R. E. Lee [THIS JOURNAL, **35**, 1666-1693 (1913)] on the densities of very dilute aqueous salt solutions. From a study of these results it may be seen that the square root plot for moderate concentration may be extrapolated with safety to zero, or at least to extremely small concentrations.

⁶ It should be noted that here φ is not the "apparent molal volume" (as usually defined); it is that quantity divided by the formula weight of the salt, and might be called the "apparent specific volume" of the salt in solution.

equations [similar to (4a) and (4b)] for the fictive volumes under pressure in terms of Δv , it may readily be shown that

$$\Delta_P \bar{v}_1 \equiv \bar{v}_1 - (\bar{v}_1)_0 = \Delta_P v_w - \frac{b}{2} \left(\frac{x_2}{x_1} \right)^{3/2} \quad (8a)$$

and

$$\Delta_P \bar{v}_2 \equiv \bar{v}_2 - (\bar{v}_2)_0 = a + \frac{3b}{2} \left(\frac{x_2}{x_1} \right)^{1/2} \quad (8b)$$

The supposition that (7) would give a faithful representation of the compression results was confirmed by applying the equation to the previously obtained data for sodium chloride solutions.

In order to calculate \bar{v}_1 and \bar{v}_2 under pressure by these equations, the values of k for the potassium sulfate solutions, as given in Table II, were converted to Δv 's by the relation, $\Delta_P v = -v_0 k$, then $\Delta_P \varphi$ was calculated, and a and b at each pressure determined graphically by plotting $\Delta_P \varphi$ against $\sqrt{x_2/x_1}$. These values of a and b were then used in equations (8a) and (8b) to calculate \bar{v}_1 and \bar{v}_2 at the various pressures. The fictive volumes thus calculated agreed well with those calculated by the previous method,

except for \bar{v}_2 at $x_2 = 0$. It seems probable that equation (7) takes account of the peculiar relations in very dilute solutions of electrolytes much better than the previous method; therefore, for \bar{v}_2 at $x_2 = 0$ only the values obtained from (8b) are here recorded. The final results are given in Tables V and VI, which include also the values of $\Delta_x \bar{v}_1$ (the change with concentration, of \bar{v}_1 at a given constant pressure), and of $\Delta_x \bar{v}_2$.

Figure 1 is a graphical representation of the way in which pressure affects the fictive volume, \bar{v}_2 , of potassium sulfate in aqueous solution. With increasing pressure, \bar{v}_2 for each concentration *increases*. In other words, the fictive compressibility is negative. This is similar to what was previously observed for sodium chloride in water. In the present case, however, no maximum is seen when \bar{v}_2 is plotted against P . This is probably because a maximum is more readily attained only at high concentrations, and the solubility of potassium sulfate is not large enough for the maximum to appear unless the pressure were appreciably higher than 10,000 bars, in which event (at 25°) the solution would freeze.

A plot of \bar{v}_2 or \bar{v}_1 against x_2 (at constant P) would again demonstrate the striking fact that under high pressure, solutions tend to become more simple in nature, that is, more

nearly "normal." At atmospheric pressure the change of \bar{v}_1 or \bar{v}_2 with varying concentration is large for salts such as potassium sulfate, but at 10,000 bars both \bar{v}_1 and \bar{v}_2 are much less affected by changes in concentration, and the solutions thus behave more nearly like ideal solutions.⁷

⁷ Cf. Adams, Ref. 1, p. 3795.

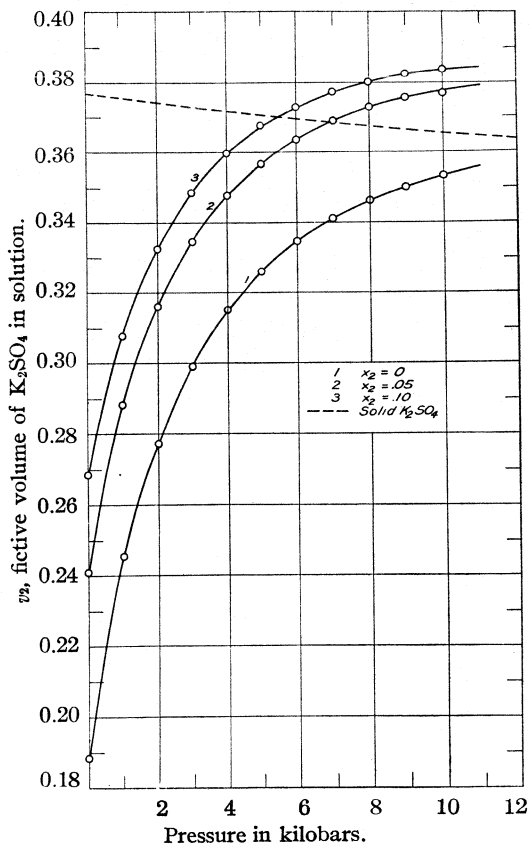

Fig. 1.—The effect of pressure on the fictive volume, \bar{v}_2 , of potassium sulfate in aqueous solutions. Pressure produces a notable increase in \bar{v}_2 , especially in dilute solutions. The dotted line shows the volume of solid K_2SO_4 at various pressures.

Determination of Equilibrium by the Thermodynamic Method

Calculation of μ_1 and μ_2 .—Equilibrium between the various phases in a system is always in accord with the principle, enunciated by Gibbs, that for any actual component its chemical potential, μ , shall have at equilibrium the same value in all of the phases. The μ 's may be readily calculated from the fictive volumes when these are known. As previously explained,⁸ the most convenient method, in actual practice, is to use the equation

$$(x_1 \text{ constant}) \quad \Delta_x \mu_1 \equiv \mu_1 - (\mu_1)_w = \Delta_x (\mu_1)_0 + \int_1^P \Delta_x \bar{v}_1 dP \quad (9)$$

for μ_1 , and the similar equation for μ_2 . As before, the subscript zero refers to atmospheric pressure and the subscript w to pure water (zero concentration).

In Table VII are shown the results of the calculation concerning μ_1 . Under each concentration are two columns; the first gives $\Delta_x/(\mu_1)_0 - \Delta_x \mu_1$, that is, the negative of the definite integral in equation (7), and the second gives $-\Delta_x \mu_1$, obtained by subtracting the value of $\Delta_x (\mu_1)_0$ (at that concentration) from the values in the first column.

TABLE VII

CHEMICAL POTENTIAL, μ_1 , OF WATER IN POTASSIUM SULFATE SOLUTIONS UNDER PRESSURE

$\Delta_x \mu_1$ is the difference (in joules) between the value of μ_1 for the particular concentration and the value for pure water at the same pressure.

Pressure in bars	$(\Delta_x \mu_1)_0 - \Delta_x \mu_1$ $x_2 = 0$		$(\Delta_x \mu_1)_0 - \Delta_x \mu_1$ $x_2 = 0.025$		$(\Delta_x \mu_1)_0 - \Delta_x \mu_1$ $x_2 = 0.05$		$(\Delta_x \mu_1)_0 - \Delta_x \mu_1$ $x_2 = 0.075$		$(\Delta_x \mu_1)_0 - \Delta_x \mu_1$ $x_2 = 0.10$

The values of $\Delta_x (\mu_1)_0$, that is, $\mu_1 - (\mu_1)_w$ at atmospheric pressure, were obtained from data on the freezing points and vapor pressures of potassium sulfate solutions given in the "International Critical Tables" and from Åkerlöf's⁹ measurements on the e. m. f. of cells containing potassium sulfate solutions, the method of calculation being the same as that described in the previous paper. The weighted mean of $\Delta_x (\mu_1)_0$ computed from the various kinds of data is shown in the first row of Table VII opposite $P = 1$.

⁸ Adams, Ref. 1, p. 3798.

⁹ G. Åkerlöf, THIS JOURNAL, 48, 1160-1176 (1926).

Table VIII similarly gives the results of the calculation concerning the effect of pressure on μ_2 . In this instance only $\Delta_x\mu_2 - \Delta_x(\mu_2)_0$ is shown, and

TABLE VIII

EFFECT OF HIGH PRESSURE ON THE CHEMICAL POTENTIAL OF POTASSIUM SULFATE IN AQUEOUS SOLUTIONS

$\Delta_x\mu_2 - (\Delta_x\mu_2)_0$ is equivalent to $\Delta_P\mu_2 - (\Delta_P\mu_2)_w$. Here $\Delta_x\mu_2$ is the difference between the value of μ_2 for the particular concentration and the value at zero concentration and the same pressure.

Pressure in bars	$\Delta_x\mu_2 - (\Delta_x\mu_2)_0$ in joules				
	$x_2 = 0$	$x_2 = 0.025$	$x_2 = 0.05$	$x_2 = 0.075$	$x_2 = 0.10$

4000	0	11.5	15.7	19.2	22.7
5000	0	13.7	18.5	22.7	26.7
6000	0	15.7	21.2	25.8	30.4
7000	0	17.5	23.7	28.7	33.7
8000	0	19.3	26.0	31.4	36.8
9000	0	21.0	28.2	34.0	39.7
10000	0	22.6	30.2	36.4	42.5

here $\Delta_x\mu_2$ means $\mu_2 - (\mu_2)_w$, not as in the first paper, $\mu_2 - (\mu_2)_s$, the subscript s referring to a fixed and arbitrary concentration. However, the values of $\Delta_x\mu_2 - \Delta_x(\mu_2)_0$ given in Table VIII may by simple subtraction be transformed into the corresponding values on the former basis. It is important to remember that, although $\Delta_x\mu_2$ as now defined is always negatively infinite, this does not prevent its change with pressure, $\Delta_x\mu_2 - \Delta_x(\mu_2)_0$, from having a finite value.¹⁰

The Freezing Pressure Curve of Ice_{VI}.—At 25° pure water freezes to ice_{VI} at 9630 bars, but upon the addition of potassium sulfate (or almost any other solute) the freezing pressure is raised, by an amount determined by the equality of the μ 's of ice_{VI} and the water in solution at the given pressure. For convenience the consequent identity of $\mu_1 - (\mu_1)_w$ (*i. e.*, $\Delta_x\mu_1$) and $\mu_{VI} - (\mu_1)_w$ is utilized in the calculation of the freezing pressure curve. The values of the latter quantity¹¹ were taken from the previous paper. In order to find the freezing pressures at several concentrations, the values of $\Delta_x\mu_1$ for each concentration were plotted against pressure, and the intersections of these curves with the curve for $\mu_{VI} - (\mu_1)_w$ were then the freezing pressures at the respective concentrations. The results are shown in Table IX, which also gives for comparison the lowering of freezing temperature (of ice_I) at atmospheric pressure and at the same concentration. As in the case of sodium chloride and water, the freezing pressure curve shows a greater curvature than that of the freezing temperature.

¹⁰ It may be useful to note that $\Delta_x\mu_2 - \Delta_x(\mu_2)_0$ is identical with $\Delta_P\mu_2 - \Delta_P(\mu_2)_w$.

¹¹ Adams, Ref. 1, last column of Table X, p 3802.

It is interesting to calculate the theoretical initial slope of the freezing pressure curve. In general, for the change of freezing pressure

$$\frac{dP}{dx_2} = \frac{\partial\mu_1/\partial x_2}{v_{VI} - \bar{v}_I} \quad (10)$$

by analogy with the equation for the change of solubility under pressure.¹² By substitution of the value of $\partial\mu_1/\partial x_2$, as given by Gibbs' approximation for dilute solutions,¹³ there is obtained

$$\frac{dP}{dx_2} = \frac{RT}{x_1^2 M_2' (\bar{v}_I - v_{VI})} \quad (11)$$

for the slope at high dilutions. Taking $x_1 = 1$, $\bar{v}_2 - v_{VI} = 0.071$, $T = 298$, $R = 83$ decijoules, and $M_2' = 174.2/3 = 58.1$, we find dP/dx_2 at $x_2 = 0$ to be 60 bars for 1% change in salt concentration, which is slightly greater than the average slope from 0 to 2.5% as shown in the third column of Table IX.

TABLE IX

FREEZING PRESSURES OF ICE_{VI} IN CONTACT WITH POTASSIUM SULFATE SOLUTIONS AT 25°

x_2 , wt. fraction of K ₂ SO ₄	P in bars	$P - P_0$ (ice _{VI})	$t_0 - t$ (ice _I)	$10^2 \frac{t_0 - t}{P - P_0}$
0.0	9630	0	0.000	..
.025	9770	140	0.615	0.44
.05	9930	300	1.168	.39
.075	10100	470	1.742	.37
.10	10290	660		

For the initial slope of the freezing temperature curve we have the relation, similar to equation (11)

$$\frac{dT}{dx_2} = - \frac{RT^2}{x_1^2 M_2' \Delta \bar{h}_I} \quad (12)$$

in which $\Delta \bar{h}_I$ is approximately the heat of melting of ice_I per gram. Combining equations (11) and (12) we obtain

$$\frac{(-dT/dx_2)_I}{(dP/dx_2)_{VI}} = \frac{T_I^2 (\bar{v}_I - v_{VI})}{T_{VI} \Delta \bar{h}_I} \quad (13)$$

which is an important relation for determining the limiting ratio, in dilute solution, between the freezing temperature lowering and the freezing pressure elevation. (This equation closely resembles the Braun equation for the relation between the effect of pressure and of temperature on solubility.) This limiting ratio is independent of the nature of the solute, and

¹² Adams, Ref. 1, equation (45), p. 3804.

¹³ This may be written $\partial\mu_1/\partial x_2 = -RT/x_1^2 M_2'$. See R. W. Goranson, "Thermodynamic Relations in Multi-component Systems," Carnegie Institution of Washington, Publ. No. 408, 1930, p. 320. In general M_2' is the effective molecular weight of the solute, i. e., one-third of the formula weight for a tri-ionic salt such as potassium sulfate in very dilute solutions.

depends only on the solvent; for water (if T_{VI} is 298°) it is 0.53×10^{-2} , which is in accord with the trend of the ratio given in the last column of Table IX.

The Solubility Curve of Potassium Sulfate.—The solubility at various pressures was calculated by means of the equation, used in the former paper

$$x_2 = (x_2)_0 + \int_1^P \frac{v_s - \bar{v}_2}{\partial \mu_2 / \partial x_2} dP \quad (14)$$

The values of v_s , the specific volume of the solid salt under pressure, were taken from the measurements by Adams and Gibson;¹⁴ \bar{v}_2 is given in Table VI; $(x_2)_0$, the solubility at atmospheric pressure, was taken as 0.1076 according to the "International Critical Tables"; and $\partial \mu_2 / \partial x_2$ was calculated from the data used above for the calculation of μ_1 . From the e. m. f. data $\partial \mu_2 / \partial x_2$ at $x_2 = 0.1076$ was found to be 273 joules. The coefficient was also computed, by the method described in the earlier paper, from the heat of solution of the salt and change of solubility with temperature. With $\Delta \bar{h}_2 = 112$ joules and $(dx_2/dt)_{\text{satn.}} = 0.00148$, $\partial \mu_2 / \partial x_2$ at $x_2 = 0.1076$ was found to be 254. Probably more weight should be given to the first value, and we shall take $\partial \mu_2 / \partial x_2$ as 265 joules at atmospheric pressure and at $x_2 = 0.1076$. The e. m. f. data allow us to calculate the change of $\partial \mu_2 / \partial x_2$ with concentration. Thus at $x_2 = 0.10$, $\partial \mu_2 / \partial x_2$ is 290, and at $x_2 = 0.15$ (by extrapolation) is 185. At pressures other than atmospheric the magnitude of $\partial \mu_2 / \partial x_2$ was computed by numerical integration of the equation

$$\frac{\partial \mu_2}{\partial x_2} = \left(\frac{\partial \mu_2}{\partial x_2} \right)_0 + \int_1^P \frac{\partial v_2}{\partial x_2} dP \quad (15)$$

The variation under pressure of $\partial \mu_2 / \partial x_2$ for potassium sulfate at concentrations near saturation is considerably greater than for sodium chloride. In the present instance, an increase of pressure from 1 to 10,000 bars changes $\partial \mu_2 / \partial x_2$ at $x_2 = 0.10$ to 502, and at $x_2 = 0.15$ to 380.

In Table X are shown the results for the solubility of potassium sulfate in water at pressures up to 12,000 bars, together with the most important steps in the calculation. The results above 10,000 bars were obtained by extrapolation of the data from which the solubility was determined. Since \bar{v}_2 and $\partial \mu_2 / \partial x_2$ pertain to the saturation-concentration at each pressure, and since this concentration changes by a considerable amount under pressure, it was necessary to carry out the computation by a series of approximations. First, \bar{v}_2 and $\partial \mu_2 / \partial x_2$ at $x_2 = 0.1076$ were used in equation (14), and a first approximation thus obtained. Then, new values of \bar{v}_2 and $\partial \mu_2 / \partial x_2$ were calculated at the approximated x_2 's, and the integration repeated. The third approximation differed very little from the second, and is the one shown in Table X.

The Equilibrium Diagram.—The course of the freezing pressure curve for ice_{VI} and of the solubility curve of potassium sulfate is illustrated in Fig. 2. Initially the solubility rises rapidly with increase of pressure, but the rate of increase falls off, and attains a maximum at 3800 bars, at

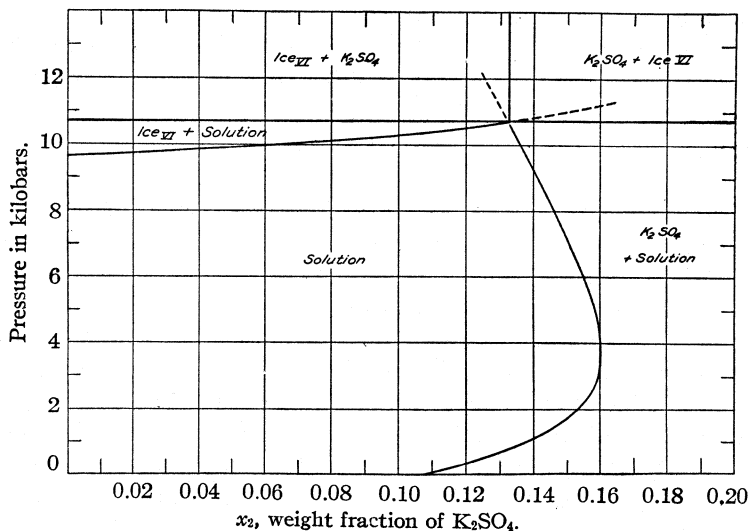

Fig. 2.—The equilibrium diagram for the system, $\text{K}_2\text{SO}_4\text{--H}_2\text{O}$, under pressure.

which point the solubility is 16.3%. At higher pressures the solubility diminishes steadily until the curve intersects the freezing pressure curve of ice_{VI} at $P = 10,750$ and $x_2 = 13.3$, and subsequent increase of pressure would cause complete solidification to a mixture of ice_{VI} and solid salt.

This invariant point is analogous to an ordinary eutectic in a temperature-concentration diagram, and may be called a pressure-eutectic. A comparison with the diagram for $\text{NaCl-H}_2\text{O}$ shows the following differences: (1) in general appearance the diagram is much more simple, mainly on account of the lack of formation of a solid hydrate, such as was observed in the former system; (2) the variation of solubility is much greater in the present case, although a maximum solubility is attained at nearly the same pressure; (3) the total increase of freezing pressure of ice_{VI} is much less than with $\text{NaCl-H}_2\text{O}$ (partly due to the low solubility of potassium sulfate), so that the eutectic pressure is not far above the freezing pressure of pure water.

Direct Determinations of Equilibrium

No direct measurements of the solubility of potassium sulfate under pressure were made, but a direct determination of the freezing pressure of a 10% solution was carried out by the method described in the previous paper.¹⁵ The mean of two measurements, which differed by 19 bars, was 10,200 bars (rounded off to the nearest 10). The agreement with the indirect determination, 10,290 bars, is not quite as satisfactory as was expected. The discrepancy is probably mainly due to the uncertainty in the value of μ_1 at atmospheric pressure, especially in the concentrated solutions.

Since the eutectic pressure is so comparatively low it was found possible to make a direct determination of this also. All that was required was to continue to increase the pressure on the solution until sufficient ice_{VI} had frozen out to bring the concentration of salt in the solution up to the saturation value, whereupon the pressure remained constant although the volume was further decreased—provided equilibrium was attained. Figure 3 illustrates the procedure in determining the eutectic pressure and also the freezing pressure of the solution. The latter was at the point marked A in the diagram. As increasing amounts of ice_{VI} froze out the equilibrium pressure followed along the line AB, and at B was saturated with respect to the salt. The solid salt did not immediately precipitate, however; some supersaturation was observed as shown by the dotted prolongation of AB. After the solution had been allowed to remain undisturbed for about one hour, salt had crystallized out and the pressure had fallen to practically the equilibrium value. Along the line BC the pressure remained substantially constant and at C the solution had entirely solidified to a mixture of ice_{VI} and solid potassium sulfate. The directly measured eutectic pressure was 10,880 bars, which is to be compared with 10,750 bars, the result of the indirect determination. The agreement is not so close as in the determination of the freezing pressure of the 10% solution by the two methods. It may be noted that the eutectic pressure (by the indirect

¹⁵ Adams, Ref. 1, pp. 3811 *et seq.*

determination) is dependent on the course of the solubility curve, which in turn is considerably affected by any uncertainty in the value of μ_2 at atmospheric pressure. The principal difficulty here arises from the necessity for extrapolating μ_2 into a region of concentration far beyond that in which it has been measured. Indeed, the weakest link in the chain of data used for the determination of equilibrium in systems under pressure is probably the simple physical properties of the concentrated solutions at atmospheric pressure.

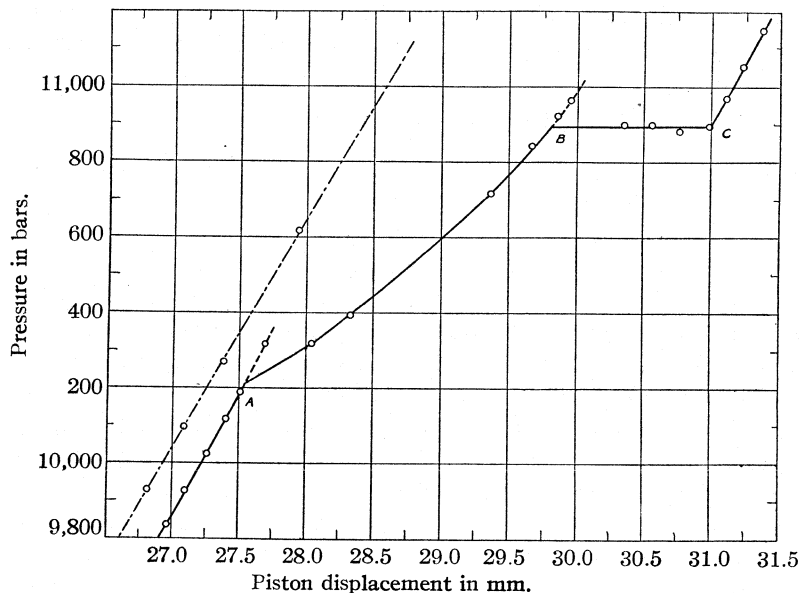

Fig. 3.—Diagram showing the method used in the direct determination of the freezing pressure of a 10% K_2SO_4 solution and also the eutectic pressure. The point A indicates the beginning of freezing, B the eutectic pressure and C complete solidification.

Summary

The compression of aqueous solutions of potassium sulfate was measured at pressures up to 10,000 bars, and from these measurements the fictive (partial) volumes and the chemical potentials of the two components were calculated according to the procedure described in a former communication.

Under pressure the fictive volume of the salt shows the same striking *increase* that was observed previously for sodium chloride. This phenomenon suggests that pressure causes solutions to become more nearly ideal.

From the values of the chemical potentials at various pressures the solubility curve of the salt and the freezing pressure curve of ice_{VI} were calculated, and an equilibrium diagram for the system, K_2SO_4 - H_2O , under high-

pressure was constructed. Direct measurements of the eutectic pressure, and of the freezing pressure of a 10% solution, showed a fair agreement with the indirect determinations.

THE USE OF THE ANTIMONY ELECTRODE IN THE ELECTROMETRIC ESTIMATION OF MAGNESIUM¹

BY B. B. MALVEA AND JAMES R. WITHROW

RECEIVED JANUARY 13, 1932

PUBLISHED JUNE 6, 1932

Introduction.—Extended work on "lime" in this Department demanded determination of magnesium at frequent intervals, especially in control work. The standard methods for such determinations were long and tedious. Their precision also has been a subject of controversy in recent years. The ordinary hydrogen electrode method suggested itself but was complicated and too highly sensitive to permit of ready handling without error. The convenience and simplicity of the antimony electrode made it desirable to investigate its application to the determination of magnesium. The present paper deals with this investigation.

Literature.—Hildebrand and Harned^{1a} were the first to use the hydrogen electrode method for the determination of magnesium in the presence of calcium in dolomite and limestone. They considered their method as fairly rapid and accurate. H. S. Harned² applied the conductimetric method for the determination of magnesium in magnesium sulfate. According to him, the value "agreed with that from a gravimetric analysis." Later I. M. Kolthoff³ confirmed the above work and stated that satisfactory results were obtained by precipitating the magnesium hydroxide with excess standard alkali, filtering and titrating back with standard acid. Gilbert A. Freak,⁴ using the conductimetric method, studied the "effect of dilution in electro-titrimetric analysis." I. M. Kolthoff⁵ confirmed Pinkhoff's result (Diss., Amsterdam, 1919) and made an extensive study of this magnesium reaction, using the hydrogen electrode. He declared that the method was of little practical use.

The Use of the Antimony Electrode.—The antimony electrode has found application in recent years in electrometric work. For the most

part, the workers starting with Uhl and Kestranek⁶ have used it for the measurement and standardization of P_H values or latterly for the measurement of high alkalinity in the black liquors from paper pulp cooks, where the hydrogen electrode for one reason or another failed. Among the chief workers with the antimony electrode may be mentioned E. J. Roberts and F. Fenwick,⁷ who showed the special advantages of the antimony electrode. Kolthoff and Hartong⁸ have made extensive studies of the application of the antimony electrode. K. W. Franke and J. J. Willaman⁹ studied the effect of the nature of the metal constituting the electrode and also the effect of various gases in titration work. Lucius W. Elder, Jr.,¹⁰ says "The antimony electrode shows an abnormal titration curve in acid solutions of ferric chloride, probably because of the presence of pentavalent antimony in the solutions."

However, we are not aware of any published work on the use of the antimony electrode for such estimations as that of magnesium.

Experimental

Apparatus.—The usual set-up for potentiometric titrations, using a calomel half-cell, was employed. The antimony electrode was made from commercial "stick" antimony sand-papered to a smooth surface.

Procedure.—A quantity each of standard solutions of chemically pure magnesium chloride (hexahydrated crystals) and calcium chloride was prepared such that one cc. of each contained a definite amount of MgO and CaO. The determination of MgO in the stock solution was made according to the standard gravimetric method and that of CaO by titration of the precipitated oxalate with a standard solution of potassium permanganate. From these stock solutions several mixtures of known strength of MgO and CaO were prepared. The amount of magnesium was kept constant but that of calcium was allowed to vary. The magnesium in these mixtures was then estimated. As a check several gravimetric-volumetric analyses and estimations with the hydrogen electrode were made side by side and the results compared.

To make a determination, measured amounts of magnesium and calcium solutions were diluted to 150 cc., acidified with a few drops of dilute hydrochloric acid and methyl orange indicator added. When the e. m. f. had become constant, a normal (or 0.1 *N* with dilute solutions) solution of sodium hydroxide free from carbonate was added in portions of 0.2 cc., allowing sufficient time for the e. m. f. readings to become constant, which required from two to ten minutes. The potential was plotted against volume of alkali used.

Determination of Alkali Used for Magnesium Precipitation.—The curve obtained showed two inflections corresponding to the beginning and to the end of the precipitation of magnesium hydroxide. A vertical line projected through the point of first inflection to the horizontal axis (alkali) gave the initial alkali reading to be used in calculation. The other inflection ordinarily was not quite so sharp as the first and consequently it was a little difficult to locate the exact end-point of the titration. In our method an "oscula-

¹⁰ Elder, *Trans. Am. Electrochem. Soc.*, **57**, 383 (1930).

tory" tangent between the two arms of the inflection was drawn and from a point midway between the points of contact of this tangent and the curve a vertical line was projected to the horizontal axis. The point where this line met the horizontal axis gave the final reading of the alkali. As a check, however, by plotting $\Delta E / \Delta V$ against volume a differential curve was obtained which showed two well-defined peaks. Vertical lines projected through these points to the horizontal axis (volume) gave the volume of alkali used for titration. From this the amount of magnesium present in the solution could be easily calculated.

Reagents.—All reagents and chemicals used were chemically pure. The strength of potassium permanganate used for volumetric estimation of calcium was 0.099 normal. Standard solutions of magnesium and calcium chloride contained 0.01 g. of MgO and CaO per cc., respectively (in dilute solutions 0.001 g.). Standard sodium hydroxide was 1.01 normal (0.118 normal in the case of dilute solutions).

Data

From a series of curves obtained as a result of fourteen different runs, an example is included here. The results have been summarized in the table.

The accompanying figures illustrate the curves obtained. The differential curve, Fig. 2, shows how the amount of alkali used for magnesium precipitation was ascertained. This value is the same as that obtained by the "osculatory" tangent method, Fig. 1.

Runs 1–9 were made using fairly strong solutions. Runs 10–14 were with dilute solutions. The results indicate that the antimony electrode gave fairly accurate values for magnesium when it was alone in strong or in dilute solutions. However, if the dilution was lower than 0.01 g. of MgO in 150 cc. of solution, the results were not dependable. When calcium was present, in fairly strong solutions, estimations could be made until the concentration of calcium was as much as eight times that of magnesium. The maximum error was under 3.5%. When the concentration of calcium was increased to twenty-five and fifty times that of magnesium,

^a Dilute sodium hydroxide in this and subsequent estimations.

the method failed. In dilute solutions of magnesium, if calcium was present even to the extent of equivalent proportions with magnesium, the results showed high errors and were not dependable.

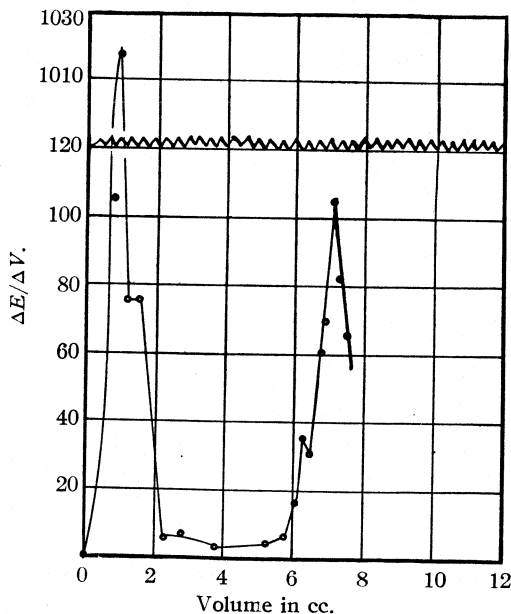

Fig. 2.—Differential curve for Curve 1; volume of alkali, ± 6.2 cc.

Several advantages over the hydrogen electrode characterized the antimony electrode—simplicity of construction, ease of manipulation, free-

dom from the necessity of electrodeposition of a metal, apparent absence of poisoning effect, freedom from both manipulation and control of a gas phase.

Summary

1. The antimony electrode made of commercial stick antimony was a satisfactory substitute for the hydrogen electrode in the electrometric estimation of magnesium in its salts and in mixtures of calcium and magnesium salts.

2. Calcium could be present to the extent of eight to twenty-five times the amount of magnesium.

3. The minimum concentration of MgO was 0.10 g. in 150 cc. of solution. At low dilutions the results were unsatisfactory if calcium was present in any appreciable amount, or was even equivalent in amount to the magnesium.

THE FREE ENERGY, HEAT CONTENT AND ENTROPY OF IODINE MONOCHLORIDE

BY JOHN MCMORRIS AND DON M. YOST

RECEIVED JANUARY 19, 1932

PUBLISHED JUNE 6, 1932

Introduction

The absorption bands of iodine monochloride have been studied by Gibson and Ramsperger,¹ Wilson,² Curtis and Darbeyshire³ and Curtis and Patkowski;⁴ and from the results of this work the thermodynamic constants of iodine monochloride may be computed. The uncertainties in interpretation of these spectroscopic data, however, make it desirable that the thermodynamic constants be also derived from some entirely independent source. Two separate chemical studies of this problem are presented in this paper.

The combination in the vapor phase of iodine and chlorine to form iodine monochloride is not accompanied by a change in the total number of molecules. Since there is no total pressure change, the methods employed in this research for studying the reaction are necessarily indirect.

The first method used depends upon the presence of solid barium chloroplatinate which is in equilibrium with the chlorine, barium chloride and platinum, of which only the chlorine reacts with iodine. The dissocia-

tion pressures of barium chloroplatinate as a function of temperature have already been determined by Gire.⁵ Starting with pure iodine and barium chloroplatinate, two molecules of iodine monochloride will result for each molecule of iodine reacting and the equilibrium state can then be determined by measuring the resulting pressure increase. This will be designated in the later discussion as Method I.

A study was also made of the reversible gas phase reaction

and the results were combined with the data of Dixon⁶ for the reaction

thus making it possible to calculate the equilibrium constants at various temperatures for the reaction

This will be designated as Method II. In all cases iodine monochloride was observed in the reaction vessels at the conclusion of the experiments.

An attempt was also made to study the reaction between phosgene (COCl_2) and iodine, but it was found to be immeasurably slow at temperatures below 200°.

Experimental Method I

A Pyrex bulb of known volume was charged with about seven grams of very dry barium chloroplatinate. One side arm of small bore Pyrex tubing connected the reaction bulb to a glass diaphragm click gage which was in turn connected to the manometer system. Another side arm contained an evacuated glass capsule within which was an accurately weighed amount of pure iodine. The capsule had a tip which could be broken readily by means of a glass-inclosed iron plunger and an external solenoid. A tube by-passing the click gage was provided so that, in evacuating the reaction vessel, no excess pressure would be exerted on either side of the diaphragm. An electric furnace, built according to the recommendations of Gray,⁷ surrounded the reaction bulb. Since the temperature required for the reaction to be conveniently measurable was in the region of 400°, the inclusion of the click gage within the furnace was impracticable. The gage was therefore allowed to project a few centimeters from the furnace and was separately heated to a constant temperature of 150° by a small second furnace immediately adjoining the larger one.

The click gage was accurately calibrated before connecting the gage to the reaction bulb. The constants for the gage used were found to be independent of the temperature over the range from 25 to 175°. After sealing on the click gage, the system was evacuated and the large furnace brought to a temperature of 300°. The system was re-evacuated every few hours for a period of three days, after which time the gain in pressure in the system overnight was less than 0.1 mm. The furnace was then heated to 490°, producing a pressure of chlorine from barium chloroplatinate of about 20 mm., the click gage was heated to 150° and the chlorine was pumped off several times. The by-pass tube was then sealed off, the furnace cooled, and the constants of the click gage re-

⁵ Gire, *Ann. chim.*, **4**, 186 (1925).

⁶ Dixon, *Z. physik. Chem.*, Bodenstein Festband, 679 (1931).

⁷ Gray, Publication of Bureau of Standards, S219.

determined. All experiments were carried out at a temperature below 490°; the prolonged baking out doubtless prevented any interference from the presence of water vapor or other foreign gas at the lower temperatures. During these preliminary manipulations, the temperature variation over the length of the large furnace was also determined and the ends were found to be less than one degree cooler than the center. The temperatures were measured by means of chromel-alumel thermocouples calibrated against standardized thermometers, the boiling point of purified naphthalene and the freezing point of zinc.

When the furnace had cooled to room temperature, the iodine capsule was broken by means of the magnetic device. The iodine was driven over into the reaction bulb and the side arm was then sealed off and removed. The furnace surrounding the click gage was heated to 150° and the reaction bulb was heated to the temperature of the experiment.

The chemicals used were of high quality. The iodine was of analytical quality marked 99.97% pure. The barium chloroplatinate was prepared by carefully neutralizing chloroplatinic acid with barium hydroxide solution and dehydrating the resulting solution in a vacuum desiccator over sulfuric acid.

Results of the Experiments

The reaction whose equilibrium constant is to be found is

The corresponding mass action expression is

$$\frac{(\text{I}_2)^{1/2} (\text{Cl}_2)^{1/2}}{(\text{ICl})} = K \quad (2)$$

The partial pressure of the chlorine at any given temperature is fixed and is calculated from the following formula, which was constructed from Gire's data

$$\log_{10} p_{\text{mm}} = -\frac{6171}{T} + 9.356 \quad (3)$$

Some pressure measurements, made at various temperatures before admitting iodine, confirmed Gire's results.

If p_1 is the partial pressure of chlorine, p_2 the calculated pressure of iodine for no reaction and p_3 the total pressure in the system, then

$$2(p_3 - p_1 - p_2) = \text{partial pressure of ICl} \quad (4)$$

$$2p_2 - p_3 + p_1 = \text{partial pressure of I}_2 \quad (5)$$

In Table I are presented the results of the experiments. Equilibrium was approached from both directions but the extreme slowness of the reaction made the exact attainment of equilibrium somewhat uncertain. Five or six days were usually required to reach a constant pressure in the system. The most accurate values of K are probably those for 681.7 Å. and 682.8 Å., not merely because of their good agreement but also because the rate of reaction is much greater than at the lower temperatures and because the magnitudes of the various partial pressures are less subject to errors than those at the higher temperatures. It is to be noted that the pressure of chlorine varied twenty-fold over the range

of temperatures investigated. Quantities of iodine differing by 20% were used in two different sets of experiments. All pressures are expressed in mm. of mercury.

TABLE I

Experimental Method II

The reaction vessel of known volume consisted of a Pyrex bulb equipped with a click gage, a closed side arm, an open side arm and a tube by-passing the click gage. The closed side arm contained a capsule inclosing very pure nitrosyl chloride and a glass incased iron plunger. After introducing through the open side arm an evacuated glass capsule containing a known weight of iodine, the side arm was sealed off. The apparatus was then evacuated and baked out. The by-pass tube was sealed off and removed. The nitrosyl chloride in the side arm was then frozen with liquid air, the capsule broken, and the nitrosyl chloride allowed to evaporate. After coming to room temperature the pressure and temperature of the nitrosyl chloride were carefully determined. The iodine capsule was broken by shaking the reaction bulb. The apparatus was then connected to the manometer system and both the reaction bulb and gage were submerged in an electrically heated oil thermostat.

Experiments were made at various temperatures and with two separate loadings of the apparatus. The reaction was found to be rapid and readily reversible, less than an hour being required for constant pressure to be attained. Most of the final readings were made, however, after twenty-four hours with the given temperature held constant to $\pm 0.2^\circ$.

The iodine used was of the same quality as that previously employed. The nitrosyl chloride was kindly furnished by Mr. J. Leermakers from the material prepared by him for the determination of its absorption spectrum.⁸

Results of the Experiments

From these experiments the equilibrium constant can be calculated for the reaction

and is given by the expression

$$\frac{(\text{NOCl})^2(\text{I}_2)}{(\text{NO})^2(\text{ICl})^2} = K_1 \quad (7)$$

Starting with NOCl and I₂, the total pressure measured will be greater by Δp than the sum of the NOCl and I₂ pressures calculated for no reaction. If *p*₁ and *p*₂ are the pressures of iodine and nitrosyl chloride, respectively, assuming no reaction, then 2 Δp is equal to the partial pressure of the iodine monochloride and also that of the nitric oxide while

⁸ Leermakers and Ramsperger, *THIS JOURNAL*, **54**, 1837 (1932).

$p_1 - \Delta p$ and $p_2 - 2\Delta p$ give the partial pressures of the iodine and nitrosyl chloride, respectively. All pressures are expressed in millimeters and the values of K_1 in atmospheres.

TABLE II

RESULTS OF THE EQUILIBRIUM MEASUREMENTS

$T, ^\circ\text{C.}$	Initial pressure		Pressure		Pressure increase, Δp		Equilibrium pressure of NO ICl		Equilibrium pressure of		$K_1, \text{atm.}$	$\log_{10} K_1$

The equation relating the equilibrium constant K_1 in atmosphere units with temperature is

$$\log_{10} K_1 = \frac{2888}{T} - 7.638 \quad (8)$$

Thermodynamic Constants of Iodine Monochloride

J. K. Dixon⁶ recently has made a very careful study of the reversible reaction

and finds that the equilibrium constants $K_2 = (\text{NO})^2(\text{Cl}_2)/(\text{NOCl})^2$ in atmospheres may be represented as a function of the temperature by the equation

$$\log_{10} K_2 = -\frac{3860}{T} + 3.348 \log_{10} T - 0.002457T - 1.1275 \quad (9)$$

It follows at once that $(K_1 K_2)^{1/2} = K$ where K is the equilibrium constant for reaction (1).

In Table III are given the data leading to values of K at the various temperatures investigated by Method II.

TABLE III

EQUILIBRIUM CONSTANTS FOR THE DISSOCIATION OF NITROSYL CHLORIDE AND IODINE MONOCHLORIDE

Temp., $^\circ\text{C.}$	$10K_1$	$\log_{10} K_1$	$10^4 K_2$	$\log_{10} K_2$	$10^3 K$	$\log_{10} K$
136.4	2.55	-0.593	3.09	-3.510	8.89	-2.051
136.9	2.65	-.576	3.16	-3.500	9.16	-2.038
145.5	1.91	-.718	5.04	-3.298	9.82	-2.008
149.0	1.60	-.796	6.08	-3.216	9.86	-2.006
153.6	1.31	-.882	7.66	-3.116	10.02	-1.999
164.4	0.898	-1.047	13.12	-2.882	10.84	-1.965
178.8	.552	-1.258	25.71	-2.590	11.91	-1.924

When the values of $\log_{10} K$ in the last column are plotted against the corresponding reciprocal temperatures, a straight line may be drawn through the points with an uncertainty of about 10% in the slope. The

points for the three highest temperatures fall very closely on a straight line from whose slope ΔH is found to be 2620 cal. However, the remaining four points fall somewhat to one side of this line so that the best linear representation of all the points is a line whose slope gives ΔH the value 2500 cal. Considering the fact that the whole temperature range is only 42° , not a great deal of reliance should be placed on any value of ΔH computed from the results of these experiments alone.

A value of ΔH obtained by combining the data from experiments using Method I with those using Method II is probably much more reliable, since the extreme temperature interval is then 337° and the constants for each set of experiments are probably reasonably good. The value of ΔH so derived is 3125 cal. The experimental error involved in this result is estimated to be between ± 5 and $\pm 10\%$, the value of ΔH given being probably low.

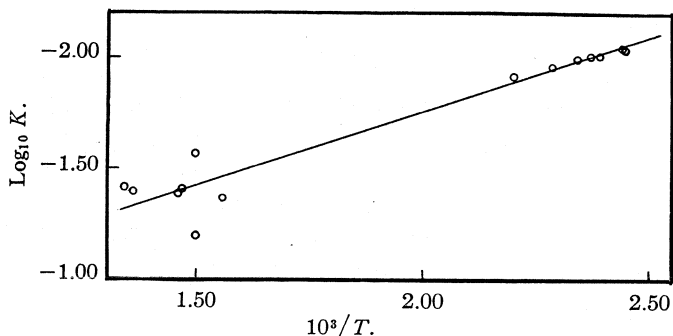

Fig. 1.—Equilibrium constants for the dissociation of gaseous iodine monochloride.

A graph of $\log_{10} K$ against $1/T$ for all experiments by both methods is shown in Fig. 1.

The free energy equation which best represents the experimental data for the reaction

is

$$\Delta F^\circ = -3125 - 1.77T \quad (11)$$

Since for a reaction of this type ΔC_p is certainly small, the absence of non-linear terms does not affect the validity of the equation even over a fairly large temperature range.

The spectroscopical investigations of iodine monochloride make it possible to derive, quite independently, a free energy equation for reaction (11). Gibson and Ramsperger¹ and Wilson² have determined the absorption limit corresponding to the dissociation of the monochloride. If we take their value and assume that the dissociation results in normal atoms and if, in accordance with the extensive work of Patkowski

and Curtis,⁴ the absorption is due to molecules in their lowest vibrational state, then the following thermochemical equations may be written.

This value of -3461 cal. refers to the absolute zero of temperature and must be corrected to ordinary temperatures before a comparison with the thermochemical value may be made. It may be shown, however, that the heat of the reaction depends but little on the temperature and the correction is therefore very small. The agreement between the spectroscopic and thermochemical values of ΔH is quite satisfactory.

If the dissociation of the iodine monochloride by radiation were to result in an activated chlorine atom, the value of ΔH would be -2041 cal. or -951 cal. depending on whether the absorbing molecule were in the first or in the lowest vibrational state. If, on the other hand, the dissociation products are normal atoms, then ΔH has the value -4551 cal. if the absorbing molecule is in the first vibrational state and -3461 cal. if in the lowest state. All of these values except the last differ from that obtained from the equilibrium measurements by an amount considerably greater than corresponds to the experimental error. The present results show, therefore, that the absorption limit results from a molecule in its lowest vibrational state being dissociated into normal atoms of iodine and chlorine.¹¹ It may also be added that Thomsen's calorimetric result combined with accurately known heat data gives $\Delta H = -3748$ cal., which gives added support to this conclusion.

It is also possible to compare the present value of 1.77 cal./deg. for ΔS of reaction 10 with that derived spectroscopically. Using Giauque's¹² values of 62.29 cal./deg. and 53.31 cal./deg. for the entropies of iodine and chlorine vapors, respectively, and the value 59.2 cal./deg. for iodine monochloride vapor which we have calculated from spectroscopic data,¹¹ a value of $\Delta S = 1.40$ cal./deg. is found. This is in satisfactory agreement with the thermochemical value.

The two standard free energy equations obtained from entirely independent types of experiments are then

$$\Delta F^\circ = -3125 - 1.77T \text{ (thermochemical measurements)} \quad (12)$$

$$\Delta F^\circ = -3461 - 1.40T \text{ (spectroscopic measurements)} \quad (13)$$

⁹ Brown, *Phys. Rev.*, **38**, 709 (1931).

¹⁰ Sponer, Landolt-Börnstein-Roth, "Phys. Chem. Tab.," Julius Springer, Berlin, 1931, Part 2, second *Ergänzungsband*, p. 1615.

¹¹ This same behavior is also observed in the case of iodine monobromide. Cf. Badger and Yost, *Phys. Rev.*, **37**, 1548 (1931).

¹² Giauque, *THIS JOURNAL*, **53**, 507 (1931); **54**, 1731 (1932).

The thermodynamic constants of iodine monochloride may be calculated from the present results by combining them with the following thermal data. For iodine the values given in a previous paper¹³ will be used and for the entropy of chlorine we use the value 53.31 cal./deg. employed above. The vapor pressure of liquid iodine monochloride has been accurately measured by one of us (D. M. Y.)¹⁴ and is given by the empirical equation

$$\log_{10} p_{\text{mm}} = -\frac{2079.7}{T} + 8.5038 \quad (14)$$

from which the free energy change attending vaporization at 25° has been calculated. Thomsen's¹⁵ value for the heat of formation of the monochloride is also presented but not used in any of the calculations. We use 2668 cal.¹⁶ for the heat of fusion of the solid monochloride at the melting point, 27.2°.

Table IV contains the so-calculated thermodynamic constants at 25° (expressed in calories) for one mole of the substance given in the first column. The reference states are indicated in each case. In the case of entropy values the state referred to is that indicated in the first row, the gases being present at a pressure of one atmosphere. The values for the heat contents given in parentheses are based on Thomsen's determination of the heat of formation of the liquid monochloride and are not employed elsewhere in the table.

TABLE IV
THERMODYNAMIC CONSTANTS OF IODINE MONOCHLORIDE AT 25°

Substance	ICl(g)	ICl(g)	ICl(l)	ICl(s)
Reference substances	I ₂ (g)	I ₂ (s)	I ₂ (s)	I ₂ (s)
	Cl ₂ (g)	Cl ₂ (g)	Cl ₂ (g)	Cl ₂ (g)
Free energy (thermochemical)	-3653	977	- 867	- 887
Free energy (spectroscopical)	-3879	751	-1093	-1113

Entropy (spectroscopical)	59.2	59.2	56.6	47.7
Heat of vaporization			9520	12,188

Discussion

As pointed out in a former paper,¹³ the entropies of the diatomic interhalogen compounds in the gaseous state appear to lie between those of the diatomic elements from which they are formed, and the data for iodine

¹³ McMorris and Yost, *THIS JOURNAL*, **53**, 2625 (1931).

¹⁴ The experiments were carried out with the assistance of Mr. John B. Hatcher and the results have not been published. The values calculated from the equation agree with the observations to within the limits of experimental error ± 0.2 mm. The equation is valid over the temperature range 0 to 70°, the liquid being supercooled below 27.2°, the melting point.

¹⁵ Thomsen, *Ber.*, **15**, 3021 (1882).

¹⁶ "International Critical Tables," 1929, Vol. V, p. 131.

monobromide and bromine monochloride were adduced in support of this statement. The value obtained for iodine monochloride is also in complete accord with this ordering of the entropies. The values of the entropy changes attending the formation of iodine monobromide and monochloride from the gaseous diatomic elements do not differ greatly (1.74, 1.77 (1.40)) and this fact might indicate that the same would be true for bromine monochloride and chlorine monofluoride, but the value calculated for bromine monochloride is less numerically than those just given and of opposite sign. However, the data available¹⁷ are stated to be in error by an amount that could give a positive value for ΔS of the order of magnitude found for iodine monobromide and chloride.

In Table V are given the entropy values for the halogens and diatomic interhalogen compounds at 25° and one atmosphere.

TABLE V

ENTROPIES OF THE HALOGENS AND DIATOMIC INTERHALOGEN COMPOUNDS AT 25° AND ONE ATMOSPHERE

Substance	I ₂	IBr	ICl	Br ₂	BrCl	Cl ₂	ClF	F ₂
Entropy	62.29	62.2	59.15	58.63	56.9	53.31	?	48.0

It is to be noted that the order of the substances is that which would obtain if the chemical and physical properties were used instead of the entropies.

Summary

The equilibrium between barium platonic chloride, barium chloride, platinum, gaseous iodine and iodine monochloride, and that between nitrosyl chloride, nitric oxide, iodine and iodine monochloride have been measured. From the results the free energy equation for the reaction $\frac{1}{2} \text{I}_2(\text{g}) + \frac{1}{2} \text{Cl}_2(\text{g}) = \text{ICl}(\text{g})$ has been found to be $\Delta F^\circ = -3125 - 1.77T$.

This resulting value of ΔH (-3125 cal.) was used to interpret existing spectroscopical data. A free energy equation, $\Delta F^\circ = -3461 - 1.40T$, was then derived using spectral data alone.¹⁸ The agreement between the two equations is satisfactory.

¹⁷ Jost, *Z. physik. Chem.*, [A] **153**, 143 (1931).

¹⁸ W. G. Brown, in a recently received private communication, has kindly given us the results of his recent spectroscopic investigation of iodine monochloride, bromine and chlorine. He finds the entropies of these substances to be 59.15, 58.63 and 53.29 cal./deg., respectively. Using his newly determined values for the entropies and heats of dissociation of iodine monochloride and chlorine, the standard free energy equation for reaction (10) becomes $\Delta F^\circ = -3280 - 1.36T$. The value $\Delta H = -3280$ cal. is in excellent agreement with the one derived from the results of the equilibrium experiments, -3125 cal. The new data have been used in reconstructing Table V but are not employed elsewhere. The new entropy value for bromine has changed those for iodine monobromide and bromine monochloride, but this does not, of course, affect the free energy equations for the latter substances.

With iodine and chlorine in their standard states of solid and gas, the free energies of formation of the various forms of iodine monochloride as determined by physical chemical methods are as follows: ICl(g) , 977 cal.; ICl(l) , -867 cal.; ICl(s) , -887 cal.

The degree of dissociation of iodine monochloride gas into gaseous iodine and chlorine has the value 0.42% at 25° and 1.58% at 100°.

The entropy of ICl(g) at 25° and one atmosphere is 59.6 cal./deg. (59.2 cal./deg. spectroscopical).

THE CRYSTAL STRUCTURE OF RHOMBIC AMMONIUM NITRATE

By C. D. WEST

RECEIVED JANUARY 28, 1932

PUBLISHED JUNE 6, 1932

No x-ray measurements on the rhombic form (IV) of ammonium nitrate have been published other than the three axial lengths. In addition to rounding out the univalent nitrate group, a complete structure is desirable for the interpretation of some of the unusual properties of this compound, such as birefringence, polymorphism and plastic deformation.

Crystallographic.—According to Groth the crystals are of the rhombic bipyramidal class, axial ratios 0.9092 : 1 : 1.0553, density 1.725, optic axial plane (100), acute bisectrix b . Bowen¹ found $2V = 35^\circ$ and the refractive indices: electric vector parallel to b , $\alpha = 1.41$; parallel to a , $\beta = 1.61$; parallel to c , $\gamma = 1.64$. This form is stable only in the interval -16 to +32°.

Methods.—Recrystallization from water at room temperature gave suitable (110) prisms. Molybdenum radiation was employed exclusively; it was filtered in taking powder photographs and a set of 30° oscillation diagrams about the three axes. In a set of Laue patterns with the primary beam nearly parallel to the three axes, the minimum wave length was 0.30 Å. Intensities of reflections were estimated visually. All Miller indices refer to the above axes.

Lattice Constants.—The constants determined from zero lines of accurate rotation photographs are: $a = 4.92_8$, $b = 5.43_4$, $c = 5.73_2$, ratios 0.9069 : 1 : 1.0548, $Z = 2$, $V = 76.7$, density = 1.720. The former are identical with Bragg's values to three figures.²

Choice of Structure.—The only systematic extinctions noted were for $(0kl)$ when $k + l$ is odd; assuming holohedral symmetry this indicates V_h^{13} . In disposing the atoms in this space-group primary consideration was

¹ N. L. Bowen, *J. Phys. Chem.*, **30**, 722 (1926).

² W. H. Bragg, *Trans. Faraday Soc.*, **20**, 59 (1924).

given to intensity data. It is probable that the nitrate group is a triangle of side 2.10 Å. with the distance between oxygen atoms in different groups greater than 3.2 Å.³ It has been shown that some nitrates owe their strong double refraction to the arrangement of the nitrate groups in parallel planes, the ray with the electric vector parallel to these planes being the slower, that with the vector perpendicular to them the faster; also the molecular birefringence, $R\omega - R\epsilon$, tends to be constant as the metal ion is changed.⁴ Bragg's extended table proves that ammonium nitrate follows this rule; it is thus to be expected that in it the nitrate planes lie perpendicular to b .

	M/ρ	ω	ϵ	$R\omega$	$R\epsilon$	$R\omega - R\epsilon$
LiNO_3	28.9	1.735	1.435	11.60	7.54	4.06
NaNO_3	37.45	1.587	1.336	12.58	7.75	4.83
KNO_3	47.85	1.506	1.335	14.36	9.90	4.46
NH_4NO_3	46.35	1.625	1.41	16.38	11.48	4.90

There are two orientations of the crystal axes abc in the structure axes XYZ that give the extinctions noted, (A) abc in ZYX and (B) abc in YZX. There are two arrangements which give nitrate groups of the desired configuration; taking point designations from Wyckoff and indicating ammonium and nitrate nitrogens by Nh and No, respectively, these are (I) Nh in (a), No and O in (b), O in (e) and (II) Nh in (b), No and O in (a), O in (f). Of the four arrangements IA and IIB have the same structure factor, which is constant for sets of reflections where only l varies by 2; they are excluded by the following sets: 101 absent, 103 vs; 201 vw, 203 vs; 111 vs, 113 w. Similarly in IB and IIA sets where only k varies by 2 have the same structure factor; the observed intensities consistently follow this relation through Table I. IB alone has the too low oxygen-oxygen distance 2.84 Å., depending only on a and the side of the nitrate triangle; also IIA is more consistent with the abnormal intensity decline of reflections ($h00$) than IB. Finally IIA alone has the nitrate planes perpendicular to b . It was selected and the coördinates rewritten.

Position, V_h^3	$k + l$ even	$k + l$ odd
Nh (b) $z^{1/2}0, \bar{x}0^{1/2}$	$\pm 2F \cos h2\pi z$ (plus for l even)	$\pm 2F \sin h2\pi z$ (plus for l odd)
No (a) $x00, \bar{x}^{1/2}^{1/2}$	$2F \cos h2\pi x$	$2F \sin h2\pi x$
O (a) $y00, \bar{y}^{1/2}^{1/2}$	$2F \cos h2\pi y$	$2F \sin h2\pi y$
O (f) $v0u, \bar{v}^{1/2}^{1/2} + u$ $v0\bar{u}, \bar{v}^{1/2}^{1/2} - u$	$4F \cos l2\pi u, \cos h2\pi v$	$4F \cos l2\pi u, \sin h2\pi v$

Choice of Parameters.—In calculating structure factors F curves for ammonium,⁵ nitrogen and oxygen⁶ were used. Since the structure factor

for reflections ($0kl$) depends only on u , their observed intensities offer a check on this parameter, $2cu$ being one side of the nitrate triangle; the value cited showed satisfactory agreement and was retained. It makes the shortest oxygen-oxygen distance independent of x 3.26 Å. Assuming the nitrate triangles are equilateral, only x and z now remain independently

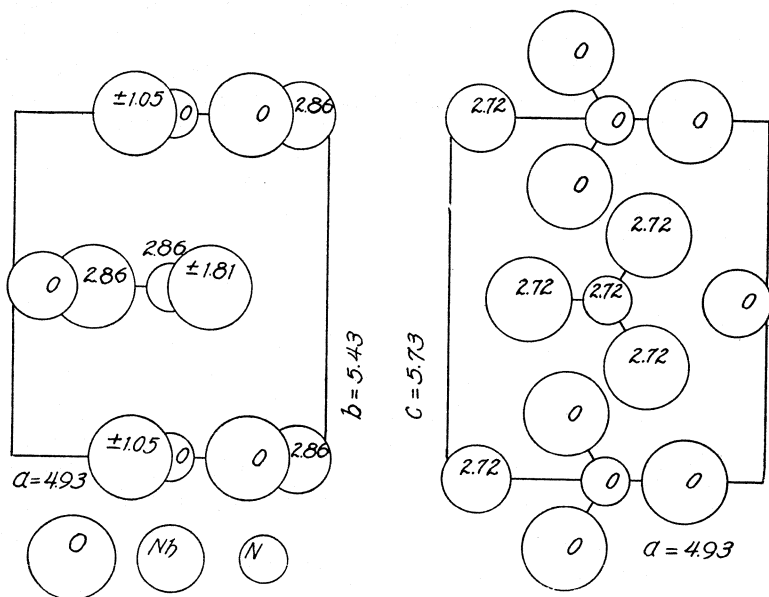

Fig. 1.—Unit cell of ammonium nitrate projected on (001) and (010). The height of each atom is indicated in Ångström units.

variable. The value of x was estimated from the intensities of Laue reflections at large $\sin \vartheta/\lambda$ where F_{Nh} is one-third or less of F_{O} or F_{No} , and z follows from the intensities of powder and oscillation reflections. The structure factors (F^2) of Table I are calculated for the tabulated values

Parameters				Distances	
u	66°	0.183	1.05 Å.	Nh—No:	3.36, 3.48
x	180	.500	2.47	O—O:	3.08, 3.26, 3.33
y	—90	.750	3.70	Each Nh:	2.96 (two oxygen atoms), 2.96 (two atoms)
v	135	.375	1.85		3.18 (two atoms), 3.21 (two atoms)
z	35	.097	0.48		3.22 (four atoms), average of 12 = 3.13

of the parameters; the disagreements with observed intensities are unsystematic and are not considered prohibitive. The calculated distances are similar to those prevailing in like substances except that the first oxygen-oxygen distance is about 3% below the minimum observed and predicted by Zachariasen.⁷

* Powder reflection.

Discussion.—A marked feature of the structures of lithium, sodium and potassium nitrates is the separation into alternate layers of metal ions and nitrate groups which lie parallel to the nitrate planes. In the present form of the ammonium compound this characteristic is absent, although there is a suggestion of such layering in the direction of the *a*-axis perpendicular to the nitrate planes. This structure may be considered as related to the cesium chloride type if the nitrate groups are taken as units.

I am grateful to Professor Albert Sauveur for the use of x-ray apparatus.

Summary

A complete structure is proposed for rhombic ammonium nitrate in the space group V_h^{13} . As in some other univalent nitrates, the strong double refraction is probably to be explained by the arrangement of the nitrate groups in parallel planes.

**ELECTRIC MOMENT AND MOLECULAR STRUCTURE. VIII.
COMPLEX DIPOLES AND LONG-CHAIN MOLECULES**

BY C. P. SMYTH AND W. S. WALLS

RECEIVED JANUARY 30, 1932

PUBLISHED JUNE 6, 1932

Previous papers have treated the moments of the ethyl esters of dicarboxylic acids,¹ the glycols,² and the polymethylene bromides³ and the results obtained in these papers have been graphically examined by Ebert and Höjendahl,⁴ whose conclusions are in essential agreement with those drawn in the original papers. It has seemed desirable to measure tetramethylene bromide for comparison with the bromides containing three-carbon and five-carbon chains and to measure in benzene solution the other long-chain bromides which were previously measured in heptane, thus obtaining data under identical conditions for careful comparison. Other more or less similar molecules have been studied and the data will be subjected to a quantitative treatment in an attempt to gain further information concerning the resolution of two or more moments in a molecule and the shape of a long carbon chain.

Resolution of Moments

In the ethylene halide molecules, rotation around the C-C bond makes it possible for the dipoles to occupy different positions relative to one another, the positions not being equally probable, however, because of the mutual potential energies of the dipoles and of steric effects. This problem has been treated in a previous paper.⁵ Since, in more complex molecules, it becomes even more difficult to calculate the potential energy and its effect upon the oscillation of the dipoles, we shall, in these calculations, disregard the mutual potential energies of the dipoles, their variable inductive effects upon one another, and steric effects, and assume that, in rotation about any single bond, all positions are equally probable. Cases in which the results of these calculations may be thrown into serious error by the neglected potential energy may then be examined qualitatively. With the assistance of Dr. Henry Eyring, each type of molecule was treated separately in order to derive an equation for its moment, but, finally, the matrix algebra was employed by Dr. Eyring⁶ to derive a general equation, from which the equations for the different types could be derived. The equations for the moments of the particular molecules studied here are

Preparation of Materials

Heptane, benzene,⁸ trimethylene bromide³ and dioxane,² were purified as in earlier work. The dioxane was kept standing over sodium and was freshly distilled just before using. Its physical constants depended somewhat upon the duration of the drying and were newly determined for each lot used.

Tetramethylene Bromide.—Furfuran obtained from the Miner Laboratories, Chicago, was converted into tetrahydrofuran under the direction of Dr. Wallace H. Carothers of E. I. du Pont de Nemours and Company by catalytic reduction in butyl alcohol solution. This material, having been purified by fractional distillation, was treated with three times the theoretical amount of 48% hydrobromic acid. After heating at $100\text{--}105^\circ$ for seven to eight hours, the reaction mixture was very slowly distilled and the heavy layer of tetramethylene bromide in the distillate was separated, the yield being 70% of the theoretical. Experiments carried out at a slightly higher temperature with a more rapid distillation of the product led to decomposition and a decreased yield. As suggested by Dr. J. R. Johnson in a communication to Dr. Carothers, a little pure ethyl bromide was added as a solvent to prevent the formation of troublesome emulsions, and the mixed bromides were washed with ice water, with cold strong sulfuric acid, with water, twice with dilute sodium bicarbonate solution, and several times with water. The product was dried with anhydrous calcium chloride, the ethyl bromide distilled off with a steam-bath and the residual tetramethylene bromide fractionally distilled under reduced pressure. The fraction distilling at $85\text{--}85.5^\circ$ (18 mm.) was redistilled; b. p. 81° (15 mm.).

Pentamethylene Bromide.—Material kindly loaned by Dr. Carothers was dried with anhydrous calcium chloride and fractionally distilled under reduced pressure; b. p. $106.9\text{--}107.4^\circ$ (24 mm.).

Decamethylene Bromide.—Material loaned by Dr. Carothers was distilled under reduced pressure; b. p. $182\text{--}183^\circ$ (22 mm.). The material was further purified by three fractional crystallizations; m. p. 23.5° .

1,2,3-Tribromopropane.—Material obtained from the Eastman Kodak Company (b. p. $143\text{--}145^\circ$, 80 mm.) was dried with anhydrous calcium chloride and fractionally distilled under reduced pressure; b. p. $96.0\text{--}96.2^\circ$ (13 mm.).

⁷ Smyth and Walls, *THIS JOURNAL*, **54**, 1854 (1932).

⁸ Ref. 7, p. 1857.

Ethylene Chlorohydrin.—Material from the Dow Chemical Company was twice fractionally distilled; b. p. 128.1–128.2° (752 mm.).

Trimethylene Chlorohydrin.—Material from the Eastman Kodak Company was twice fractionally distilled under reduced pressure; b. p. 66.0–66.2° (16 mm.).

Trimethylene Bromohydrin.—Material from the Eastman Kodak Company was fractionally distilled under reduced pressure three times; b. p. 77–78° (16 mm.).

β,β' -Dichloroethyl Ether.—Material loaned by Dr. W. L. Ruigh of Merck and Co., Inc. (a fraction of some material obtained from the Carbide and Chemical Company) was dried with anhydrous calcium chloride and twice fractionally distilled under reduced pressure; b. p. 75.0 \pm 0.1° (20 mm.).

β,β' -Diiodoethyl Ether.—Material loaned by Dr. Ruigh, which had become slightly colored from standing, was twice shaken with "Darco" to remove coloration, then shaken with mercury, dried over anhydrous calcium chloride and twice fractionally distilled under reduced pressure; b. p. 102.3 \pm 0.1° at 4 mm., distilling at the rate of four drops in three seconds with the bath at 130°.

The densities and refractive indices given in Table II may be taken as criteria of purity.

Experimental Results

The densities and dielectric constants of the solutions of the polar substances in the non-polar were measured with the apparatus and methods previously employed,¹ a wave length of 1000 meters being used in the dielectric constant determinations. In Table I the first column gives the mole fraction c_2 of the polar substance in the solution and the succeeding columns give the values at 25 and 50° of the dielectric constants ϵ , the densities d of the solutions and the polarizations P_2 of the polar substance. The values of the moment in Table III were obtained as in previous papers.¹

^a Calculated from measurements upon solutions.

Discussion of Results

The values for the moments of trimethylene bromide, pentamethylene bromide and decamethylene bromide are 0.2×10^{-18} lower than the corresponding values previously found in heptane solution.³ As the value given in Table III for tetramethylene bromide in benzene is higher than that in heptane by an amount too small to be significant and as the values for the ethylene halides are decidedly higher in benzene than in heptane, the reason for the discrepancy is not apparent. The bromides used were the same materials employed in the previous measurements, and had been subjected to further purification without appreciable alteration of the refractive indices. As the present measurements form part of a long series carried out with great care in the same way, they will be regarded as correct. In any event, the small difference does not materially affect the conclusions to be drawn.

The value for ethylene chlorohydrin is 0.20×10^{-18} higher in dioxane

than in benzene solution, while the trimethylene compound is 0.11×10^{-18} higher. As dioxane may introduce complications through compound formation with the solute, it appears probable that the values obtained in benzene are the more accurate, the possible error in the dioxane values decreasing with increasing separation of the dipoles. This suggests that the values obtained for the two- and three-carbon glycols in dioxane solution² may be from 0.1 – 0.3×10^{-18} high, which would make the moments of ethylene and propylene glycol about 2.0×10^{-18} . The values for the six- and ten-carbon glycols should be but little low, as the two hydroxyl groups should be almost independent of one another at these distances and it was shown that butyl alcohol had almost the same moment in dioxane as in benzene solution. However, it appears consistent to lower the former values for the three-, six- and ten-carbon glycols by 0.2×10^{-18} .

In the quantitative treatment of these moments, the results of which are given in Table IV, a value of 1.5×10^{-18} is assigned to the C–Br moments in 1,2,3-tribromopropane, as in ethylene bromide, 1.7×10^{-18} to the C–Br moments in trimethylene bromide, and 1.9×10^{-18} in the three longer molecules.³ The difference in the values used is the result of a rough approximation made in an attempt to take care of the small effects of induction upon the carbon chain and of the possible C–H moments. The lumping of these effects in a single moment in the C–Br line may introduce an error of as much as 0.2×10^{-18} , but in the four-, five- and ten-carbon molecules, at least, the error should be practically the same. The other moments used in Table IV are taken from data previously summarized.⁹ The possible error resulting from the assumption that the

oxygen valence angle is 110° is no greater than that in the values for the C-O and H-O moments.

The moment of the ethylene bromide molecule is far lower than the calculated value because the two C-Br dipoles lower each other's moments by greater inductive action as they approach more closely the *cis* position, the position of maximum resultant moment, because the mutual potential energy of the dipoles tends to make this *cis* position least probable,⁵ and because of the interatomic forces characterized by the term "steric effect." This steric effect is so complicated by the necessity of considering the interaction of bromine with bromine, bromine with hydrogen, and hydrogen with hydrogen, that the quantitative treatment of all the combined effects requires a separate communication. As is to be expected, these effects diminish with increasing length of the carbon chain until, in decamethylene bromide, the difference between the observed and the calculated values is less than the probable error, and the increase of the moment with rising temperature has disappeared. Calculation shows that if pentamethylene bromide had an extended rod-like molecule, the potential energy between the two C-Br dipoles would still not be wholly negligible in comparison with kT , as it is in an extended decamethylene bromide molecule. If there is sufficient freedom of rotation about the C-C bonds to give a great variety of forms to the molecules, those forms in which the dipoles point more or less in the same direction should be less probable in the shorter molecules and the moments should be smaller than the calculated values, the difference decreasing with increasing length of the chain. The observed and calculated values of decamethylene bromide are indistinguishable from that which would result from a completely random orientation of the two dipoles relative to each other. This theory of more or less free rotation about the C-C bonds explains all the results for the polymethylene bromides except the close proximity of the value for tetramethylene bromide to that of trimethylene bromide.

From preliminary considerations it appears that a hydrocarbon chain is in a position of minimum potential energy when in the zigzag form indicated for it in solids, in films, and even in liquids.¹⁰ For the polymethylene bromides, this would give structures somewhat as follows:

etc. The C-Br dipoles would not necessarily cancel each other in the even-numbered chains as shown above, but there would certainly be a sharp alternation of moment in going up the series. If there is freedom of rotation only about the end C-C bonds, where the inhibition of rotation should be less than in the case of a bond with another C-C on each side, it is evident

¹⁰ Gane and Ingold, *J. Chem. Soc.*, 2153 (1931); Ingold, *ibid.*, 2170 (1931).

that the even-numbered molecules should have moments equal to the value 2.52×10^{-18} calculated for the ethylene compound and the odd-numbered molecules values equal to that for the trimethylene compound, 2.63×10^{-18} , the C-Br moment being taken as 1.9×10^{-18} . The differences between these values and those calculated for the longer molecules on the assumption of free rotation about the C-C bond are not sufficient to permit of distinction between the fixed and the variable structures. However, the fact that a higher moment is indicated for the odd-numbered molecules offers an explanation of the proximity of the moment of tetramethylene bromide to that of trimethylene bromide, while, if there were freedom of rotation about the C-C bonds, it should be closer to the value for pentamethylene bromide. The moment calculated for 1,2,3-tribromopropane is much higher than the observed values in Table IV because of these same effects.

The reason that the observed moments of ethylene and propylene glycol do not lie far below the calculated as in the case of ethylene bromide is apparent when the structure is considered. If, as an extreme case, the potential energy between the dipoles caused the hydroxyls to occupy a *trans* position,

a position in which ethylene bromide would have zero moment, the two C-O moments would cancel each other, but the two H-O moments would rotate around the extensions of the C-O lines in such a way that their mutual potential energies would lower the resultant moment only a little below the calculated value in Table IV. Evidently, little lowering of the moment below the calculated value is to be expected unless there is a tendency toward ring formation in the longer molecules and the uniformity of the observed values indicates the absence of such formation. It is not surprising, therefore, to find in the longer glycols the only case in Table IV in which the observed moments are higher than the calculated, the difference very possibly arising from the use of too low values for the C-O moment, if not for the H-O. If the not unreasonable value 1.1×10^{-18} is used for the C-O moment, the calculated value for the glycols is 2.25×10^{-18} . As is to be expected, the behavior of the chloro- and bromohydrins is intermediate between that of the glycols and that of the polymethylene halides. The trimethylene compounds have moments not far below the calculated and the same is true of the β, β' -dihalogenated ethers.

It has not seemed worth while to calculate the moments of the diethyl esters of the dicarboxylic acids because each half of the molecule contains three dipoles, one C=O and two C-O, the moments of which, as well as the angles, have to be estimated, and the mutual inductive action of which may be considerable because of the large size of the C=O moment. Evidently, the situation in these molecules is somewhat analogous to that in the

glycols. The large mutual potential energies of the dipoles have little effect upon the resultant moment, so that the ethyl oxalate molecule has a moment practically the same as those of the very long molecules. It is only in the diethyl succinate molecule, where there is good reason to believe in the formation of a ring, that any considerable difference in moment occurs. The results justify the conclusion originally drawn that the long chains do not bend around upon themselves to form ring structures.

The writers wish to thank Dr. Wallace H. Carothers for the loan of materials and for assistance and advice in preparation and purification, and Dr. Henry Eyring for his assistance in the derivation of the equations.

Summary

Equations have been derived for the calculation of the electric moments of molecules of various lengths, containing two, three and four dipoles which may move relatively to one another.

The moments of four polymethylene bromides, 1,2,3-tribromopropane, two chlorohydrins, a bromohydrin and two dihalogenated ethers have been determined and the results, together with previously measured values for the glycols, now slightly revised, are compared with the values calculated by means of the equations. It is shown that dipoles not far apart on a carbon chain affect one another's positions in such a way as to diminish the resultant moment of the molecule. The results for the liquids may be explained by supposing that free rotation about the C-C bonds gives a great variety of forms to long-chain molecules, some of which are excluded because of high mutual potential energies of the dipoles, but a more satisfactory explanation is given by the supposition of an extended zigzag structure of the carbon chain with complete freedom of rotation only at the ends of the chain. In these solutions, any considerable bending around of the polar molecules to form ring structures is excluded in most cases.

**THERMODYNAMIC PROPERTIES OF SOLID SOLUTIONS OF
LEAD CHLORIDE AND LEAD BROMIDE**BY A. WACHTER¹

RECEIVED FEBRUARY 2, 1932

PUBLISHED JUNE 6, 1932

The investigation described in this paper represents an extension of the experimental methods described in a previous paper² for the determination of the thermodynamic properties of solid salts and their solid solutions by a study of the e. m. f. of cells containing solid electrolytes. Such measurements give accurate data concerning activities over a large temperature range and are of great interest in connection with the general theories of solution and with the theories concerning the structure and properties of solid solutions. In the previous investigation a study was made of solid solutions of sodium chloride in silver chloride. In the present work solid solutions of lead bromide in lead chloride were studied. This system is especially suitable for the application of these experimental methods since the freezing point is a linear function of the composition,³ indicating the existence of a continuous series of solid solutions and the absence of either compound formation or a separation into two or more phases. The close proximity of the liquidus and solidus branches of the equilibrium diagram is of considerable assistance in the rapid attainment of a homogeneous solution when the molten mixture is cooled and annealed.

Experimental Part

The cell studied in this research can be represented by Pb/PbCl_2 , $\text{PbBr}_2/\text{AgCl}$, Ag , where all the materials are solid and lead bromide is in solid solution with lead chloride. The cell reaction is

The preparation and purification of the substances employed in the cells as well as the experimental procedure are essentially the same as those described for the silver chloride-sodium chloride system,² with the following exceptions. Lead bromide was purified by bubbling dry hydrogen bromide, which was obtained by passing a mixture of hydrogen and bromine over a heated platinum catalyst, through the molten salt. The cell was prepared by pouring a molten solution of the lead salts into a Pyrex glass U-tube until the bend was completely filled. Before the melt solidified a silver wire was inserted into one arm of the tube about 1 cm. below the surface of the melt. It was then annealed at a temperature just below its melting point for about twenty-four hours. After slowly cooling to room

temperature a 5-mm. layer of molten silver chloride was poured into the arm containing the silver wire and a layer of lead poured into the other arm. A tungsten wire made electrical contact to the lead electrode. The cells were then placed in a high temperature bath which could be varied from 200 to 300°. This bath was made up of a half liter wide-mouthed Pyrex Dewar flask filled with a low melting Wood's metal alloy. It was heated by means of an immersion resistance unit and stirred with a glass spiral.

This construction insured a uniform temperature throughout the system. Within two days equilibrium was attained and potential measurements were made by means of a Leeds and Northrup Type K potentiometer in conjunction with a high sensitivity galvanometer. The composition of the cells was varied from mole fraction 0.200 to 1.000 of lead chloride.

The results of the e. m. f. measurements for eight different compositions are given in Table I and plotted in Fig. 1. The values for pure lead

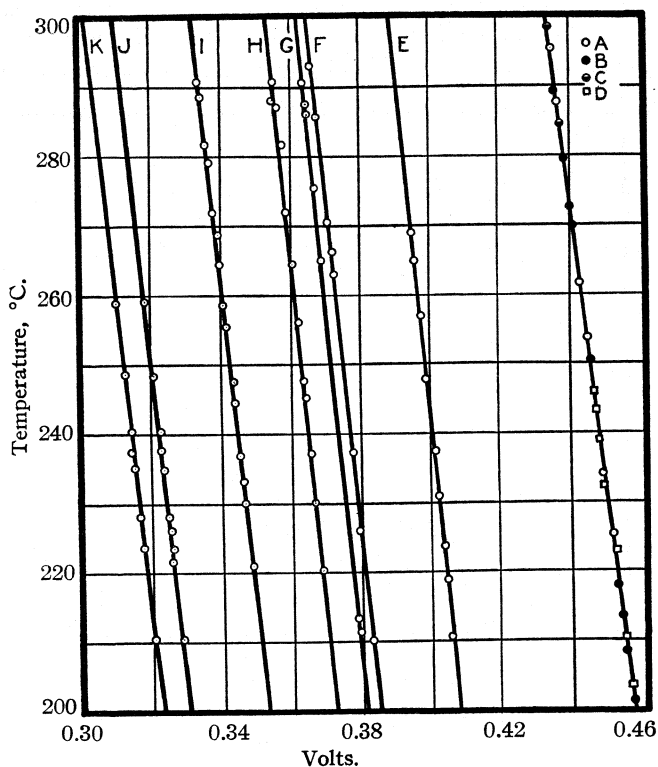

Fig. 1.—Temperature variation of e. m. f. of cells containing different lead chloride-lead bromide solid solutions. Mole fraction of lead chloride in A, B, C and D is 1.000, E is 0.892, F is 0.781, G is 0.752, H is 0.680, I is 0.539, J is 0.303 and K is 0.200.

chloride represent four different cells, indicated in the figure by points of different styles. The average deviation of the points from the straight lines of the plot is less than 0.3 mv. These curves were easily reproduced ascending and descending the temperature scale even after several weeks in the high temperature bath. From a large scale plot of Fig. 1 the e. m. f. at temperatures of 200, 250 and 300° were read off for each solution and plotted against the composition. This is given in Fig. 2.

Discussion of Results

The thermodynamic calculations employing the data obtained for this system were made as described in the previous paper on the silver chloride-sodium chloride system.² The results of the calculations are given in Table II and the activities, a_1 and a_2 , of both constituents of the solid solutions plotted against the mole fraction, N_1 , of lead chloride in Fig. 3. The broken diagonal lines in the figure represent Raoult's law. ΔF is the free energy of the cell reaction; $\Delta \bar{F}_1$, the partial molal free energy of lead chloride; ΔH , the change in heat content of the cell reaction; $\Delta \bar{H}_1$, the partial molal heat content of lead chloride; ΔS , the entropy change of the

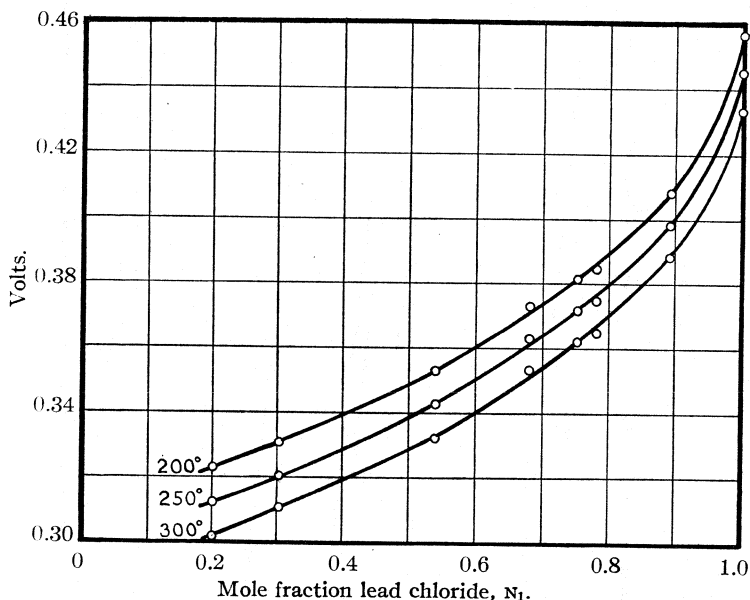

Fig. 2.—Change in e. m. f. of cells upon dilution of lead chloride with lead bromide at 200, 250 and 300°.

cell reaction; $\Delta \bar{S}_1$, the partial molal entropy; and a_1 and a_2 , the activity of lead chloride and lead bromide, respectively. The partial molal quantities and the activity of lead chloride in its solutions were calculated taking the pure salt as the standard state. Pure lead bromide was taken as the standard state for lead bromide in the solid solutions.

The activity curves of Fig. 3 are particularly interesting. It is observed that when lead bromide is added to lead chloride an enormous decrease in the activity of the latter occurs. Below mole fraction 0.9 of lead chloride its activity is less than 0.1. This large negative deviation from Raoult's law is most probably ascribable to a very strong tendency toward compound formation. On the other hand, the activity curve for lead bromide

at first shows a small positive deviation when lead chloride is added which, beyond mole fraction 0.4 of lead chloride, rapidly becomes a larger and larger negative deviation. From the large downward pull on the curves in

the region of solid solutions most concentrated in lead chloride, one would suspect the existence of a rather strong compound or of a regular arrangement of the bromide ions in the lead chloride crystal lattice. Such a factor would reduce the activities of both components and would tend to annul the effect of any factor which produces abnormally large activities. This striking result is entirely unpredictable from the freezing point diagram, which gives no indication of any abnormality.

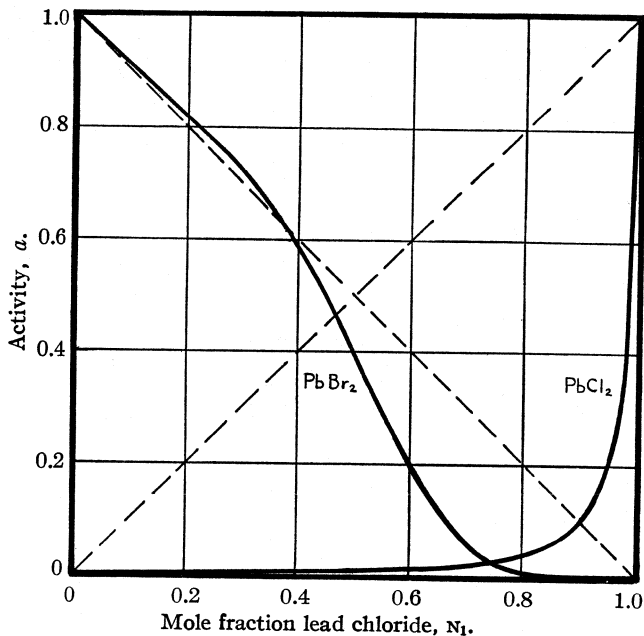

Fig. 3.—Activity curves for the system lead chloride-lead bromide at 200°.

Measurements of the partial vapor pressures of this system by Jellinek and Bolubowski,⁴ who found Raoult's law obeyed by the vapor pressures at temperatures from 660 to 740°, indicate that at these high temperatures the compound is completely dissociated and that the constituents form ideal liquid solutions. Salstrom and Hildebrand,⁵ making an electrochemical investigation of molten solutions of these fused salts at temperatures from 450 to 550° and at mole fractions 1 to 0.45 of lead bromide, found that the activities in this range are less than the simple mole fractions. Although, making allowance for the differences in temperature, the values they give at mole fractions 0.5 and 0.45 of lead bromide are in good agreement with those herein obtained, those given at higher concentrations of lead bromide are in marked disagreement.

⁵ Salstrom and Hildebrand, *THIS JOURNAL*, **52**, 4641 (1930).

For the existence of any one arrangement of foreign ions in a crystal lattice to be more probable than any other of the infinite variety of possible arrangements, that distribution must give the most stable solution. Tammann⁶ has strongly supported the assumption which originated with him that a regular or "normal" distribution is to be expected in solid solutions and that the most stable arrangements can be represented as multiples of one-eighth mole of one of the two constituents. Thermodynamically, the greatest total free energy change of solution must occur at some composition which can be expressed as a multiple of one-eighth mole in order

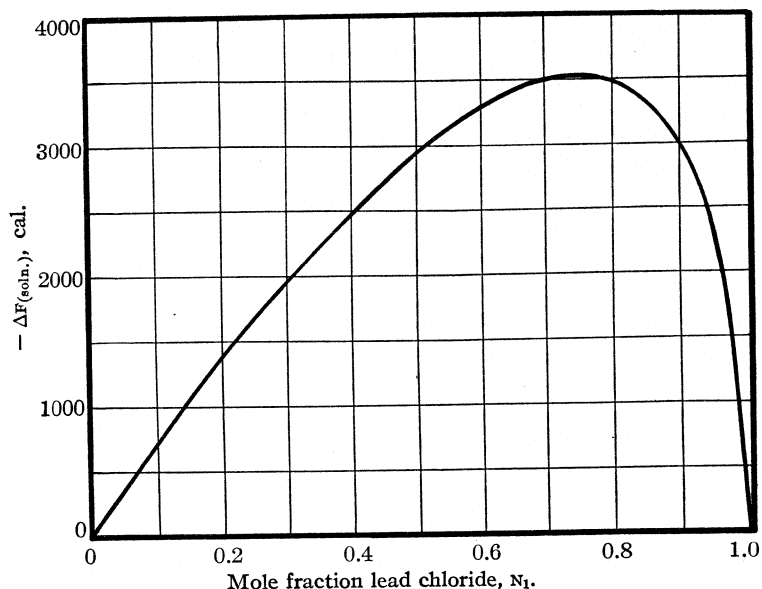

Fig. 4.—Variation with composition of the free energy change for the reaction $N_1 \text{ PbCl}_{2(s)} + N_2 \text{ PbBr}_{2(s)} = N_1 \text{ PbCl}_{2} \cdot N_2 \text{ PbBr}_{2(s, \text{soln.})}$ at 200° .

to be in accord with the above views. The total free energy of solution as employed here signifies the free energy change involved in the formation of one mole of solution from the pure constituents at a given temperature. It can be calculated from the partial molal free energies by the relationship $\Delta F_{\text{(soln.)}} = N_1 \Delta \bar{F}_1 + N_2 \Delta \bar{F}_2$. When this is done for the lead chloride-lead bromide system and the results are plotted against the mole fraction of lead chloride, as in Fig. 4, one observes a rather sharp maximum at six-eighths mole of lead chloride. Tammann's conclusions are based upon the striking discontinuities observed in variations of the intensity of chemical action with the concentration. These resistance limits occur at compositions which can be expressed as multiples of one-eighth mole of one of the two constituents. In accordance with these ideas one would predict

⁶ Tammann, *Z. anorg. allgem. Chem.*, **107**, 1 (1919).

that the lead chloride-lead bromide solid solutions would exhibit a discontinuity in chemical action at mole fraction 0.75 of lead chloride.

Summary

1. The energy changes of solid lead chloride upon dilution with lead bromide have been determined at mole fractions of lead chloride varying from 1 to 0.200, between the temperatures of 200 and 300°.

2. The solid solution containing 0.75 mole of lead chloride is shown to be the most stable.

3. The thermodynamic properties of these solutions are considered compatible with the existence of a regular arrangement of bromide ions in the lead chloride lattice.

4. A discontinuity in chemical action of the solid solutions at mole fraction 0.75 of lead chloride is predicted.

A NEW USE OF THE VACUUM TUBE IN ELECTROMETRIC TITRATIONS. I. POLARIZATION OF PLATINUM ELECTRODES IN OXIDATION AND REDUCTION REACTIONS¹

By J. L. KASSNER, R. B. HUNZE AND J. N. CHATFIELD

RECEIVED FEBRUARY 2, 1932

PUBLISHED JUNE 6, 1932

Introduction

Since the advent of the radio it is generally known that electrons are drawn across the tube by means of a positive potential impressed on the plate. The plate current in the tube is controlled largely by means of a grid which is placed between the filament and the plate. If a positive potential is placed on the grid, electrons flow to the plate in greater number, and if a negative potential is placed on the grid fewer electrons will flow to the plate, lowering the plate current. Goode² utilized the fact that the grid will not pick up electrons when it is charged negatively with respect to the filament and connected the indicator electrode directly to the grid. This same principle has been employed by other investigators.³ In all of the investigations reported, in which a single electron tube was employed, it has been necessary to plot $\Delta E/\Delta v$ or to plot galvanometer deflections in place of ΔE to obtain the equivalence point. Daniels, Mathews and

¹ Paper presented before the Buffalo meeting of the American Chemical Society.

Williams⁴ state that the characteristics of a vacuum tube should always be determined before it is used for any purpose, and since the characteristics of a vacuum tube vary with the age of the tube as well as with new tubes of the same type, the application of vacuum tubes to electrometric titrations has not been widely adopted. This investigation was started to find, if possible, a method of utilizing the vacuum tube in electrometric titrations in such a way that the results of the titrations are less dependent upon the characteristics of the tube and to avoid the necessity of plotting curves to obtain the equivalence point. The following "hook-up" and data are presented as evidence of how well this has been accomplished. A diagram of the apparatus is shown in Fig. 1.

This apparatus differs from Goode's in that a positive potential is impressed on the grid of the vacuum tube; a Cunningham amplifier, 301A or R. C. A., 201 A, whose filaments operate normally at 6 volts, drawing 0.25 ampere; and the grid current has been employed to polarize bimetallic platinum electrodes which have been substituted for the monometallic system. Part of the grid current (the grid current is very small because of the construction of the vacuum tube) is shunted around the electrodes.

When electrodes have been placed in the solution to be titrated and the resistance R adjusted so that the galvanometer reads zero; the points M and N are at the same potential. Electrons are flowing through the tube in three distinct circuits: the filament, filament to grid, and filament to plate. The electrons that are picked up by the plate may be considered as flowing through the B -battery, R , and back to the A -battery. The strength of this current depends upon the temperature of the filament, the voltage of the B -battery, the value of R , and the potential impressed on the grid. The current in the three circuits will remain constant during the course of a titration as long as the potential difference between F and C remains constant if the other adjustments are not changed. A slight change in the potential between F and C will produce a corresponding

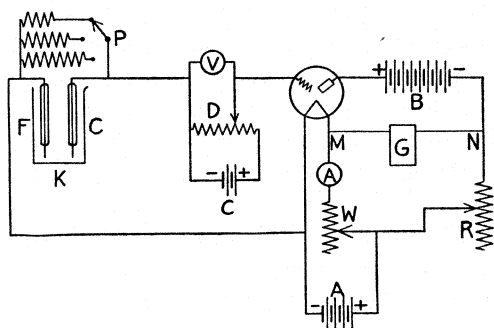

Fig. 1.— F and C , platinum electrodes, B , and S. No. 28 about 3 cm. long; P , shunt; V , voltmeter reading in units of 0.1 volt; D , potential divider; C , 4.5-volt C -battery; B , 22.5-volt B -battery; G , galvanometer of about 1000 ohm resistance; A in circle, milliammeter; W , 59-ohm variable resistance; R , 5000-ohm variable resistance; A , 6-volt storage battery. A motor-driven stirrer is not shown.

⁴ Daniels, Mathews and Williams, "Experimental Physical Chemistry," McGraw-Hill Book Co., Inc., New York, 1929, p. 402.

change in the potential impressed on the grid. This will produce a relatively large change in the plate current, which will unbalance the system. M and N will no longer be at the same potential and the galvanometer will deflect.

Experimental

The theory of polarized electrodes has been studied in detail by Willard and Fenwick⁵ and Van Name and Fenwick.⁶ They have shown that polarized platinum electrodes owe their effect in electrometric titrations to gas reactions taking place on the surface of the electrodes and that the potential difference between the electrodes remains practically constant up to about 0.5 ml. of the equivalence point.

For the successful operation of this apparatus it is necessary for the potential difference between the electrodes to remain constant up to the equivalence point, and this has been accomplished by shunting part of the polarizing current around the electrodes. Shunted electrodes were first used by Foulk and Bawden.⁷ They stated that no current flows through the solution when the drop in potential across the shunt is equal to the back e. m. f. due to polarization. For this reason it was thought that it would be necessary to control the shunt within narrow limits, but it was found that the shunt could be varied over a comparatively wide range without vitiating the results. The results of the titrations using different shunts are presented in Table I.

TABLE I
TITRATION OF APPROXIMATELY 0.1 *N* SODIUM THIOSULFATE WITH IODINE
V, 1.6 volts; filament current, 0.25 ampere; B-battery, 22.5 volts

Run	Iodine Calcd., ml.	Found, ml.	Error, ml.	Shunt P, ohms
1	25.15	25.13	0.02	20,000
2	25.15	25.12	.03	5,000
3	25.15	25.15	.00	35,000

No attempt was made to determine the absolute limits of the shunt. The calculated ml. are the average of three concordant determinations using starch as the indicator. When no shunt resistance was employed the needle of the galvanometer drifted off the scale after the addition of about 2 ml. However, it is possible to titrate with a shunt of infinite resistance if the correct voltage is impressed on the grid, but more difficulty is experienced in balancing the potentials. As is shown by the table, the end-point obtained by the electrometric method is slightly in advance of the end-point obtained by the starch indicator. Attention was also called to this fact by Foulk and Bawden.⁸ It has been found that it is possible,

⁵ Willard and Fenwick, *THIS JOURNAL*, **44**, 2504 (1922).

⁶ Van Name and Fenwick, *ibid.*, **47**, 9, 19 (1925).

⁷ Foulk and Bawden, *ibid.*, **48**, 2045 (1926).

⁸ Foulk and Bawden, *ibid.*, **48**, 2047 (1926).

keeping the other conditions the same as those given in the table, to vary the shunt over the same range in the titrations of bichromate with ferrous ammonium sulfate, arsenite with bromate, and arsenite with iodine.

Reference to Fig. 1 shows that the potential impressed on the grid is less than the reading of the voltmeter, V , by the potential of the counter e. m. f. due to polarization. Since the plate current is a function of the potential impressed on the grid it can be seen why the system remains balanced up to the equivalence point if the potential difference between the electrodes remains constant, and then suddenly changes at the end-point. Table II is offered in support of the theory that the potential difference between the electrodes remains constant up to the equivalence point if the right conditions are employed. The slight fluctuations in the potential difference from 1 to 13.84 ml. are, undoubtedly, the result of experimental error.

TABLE II

POTENTIAL DIFFERENCE BETWEEN POLARIZED PLATINUM ELECTRODES IN THE TITRATION OF SODIUM ARSENITE WITH POTASSIUM BROMATE

Ml. of 0.1 <i>N</i> KBrO ₃	E. m. f. with respect to N-calomel electrode		<i>F</i> minus <i>C</i> , mv.	Galv., zero center
	<i>C</i> , cathode, mv.	<i>F</i> , anode, mv.		
0.00	284	529	245	0
1.00	270	527	257	2, left
6.00	269	525	256	3, left
12.00	266	525	259	6, left
13.40	268	528	260	8, left
13.70	269	529	260	9, left
13.80	266	525	259	10, left
13.83	262	527	265	10, left
13.84	359	622	263	12, left
13.85	679	872	193	Extreme right

In making these measurements a 50,000-ohm resistance was kept in series with the electrodes, but even then enough current was drawn from them, in the process of balancing, to change the potential of the electrodes slightly. In carrying out titrations in which the potential of the electrodes was not measured, the drift of the galvanometer needle was of less magnitude. The two additions of potassium bromate from 13.83 ml. to 13.85 ml. were made with the aid of a stirring rod, and the readings are offered merely to show that the change at the equivalence point is very sharp. The change is confined to within 0.05 ml. of 0.01 *N* solution in a volume of 250 to 300 ml.

The main objection offered to the use of polarized bimetallic electrodes is that the approach of the end-point is indicated only about 0.3 ml. in advance. This indication is far enough in advance for the successful use of this apparatus, because the operator has only to control the buret and

observe the galvanometer, since it is not necessary to make any adjustments after the titration is begun. Furthermore, this "hook-up" possesses an additional characteristic in that the indication of the approach can be controlled by placing the electrodes in the solution in such a position that there will be a slight difference in the composition of the solution surrounding one of them as the equivalence point is approached. This difference in composition will be only momentary due to the process of mixing. This will be manifested by a temporary instability of the galvanometer. The galvanometer again becomes stable if the addition of the titrating solution is discontinued. After the indication of the approach⁹ of the end-point is obtained, the titration can be continued dropwise until the needle of the galvanometer "kicks" off the scale and remains there.¹⁰

If the operator does not wish to rely upon the indication of the approach in order to avoid overstepping the end-point, a small portion of the unknown solution can be withheld in a small dropper until the apparent end-point is obtained. Upon the addition of this small portion the needle will return to its former position. The end-point can then be approached dropwise.

In order to show that it is not necessary to control the different variables in this apparatus within narrow limits the following data are presented.

The Bichromate-Ferrous Iron Reaction.—The results of titrations with the apparatus described in this paper in comparison with those obtained with the Wendt electrometric titration apparatus are given in Table III.

⁹ Best results are obtained when the standard solution is added at a constant rate of about 1 ml. in seven seconds up to this point.

¹⁰ For three of the determinations (arsenite with iodine, arsenite with bromate, and thiosulfate with iodine) reported in this paper the optimum positions of the electrodes were found to be as follows. With the stirrer placed in the center and near the bottom of a 400-ml. beaker containing 200–250 ml. of solution, electrode F with the wire running in an almost horizontal position toward the back of the beaker was placed about 2 cm. above the stirrer and to the extreme right of the beaker. Electrode C was placed to the left of the stirrer with the wire running almost in a horizontal position toward the front of the beaker a little below the stirrer, the stirrer rotating in the direction of electrode F. The solution was added from a buret placed about 1 cm. to the left and about 1 cm. in front of the stirrer. If the indication of the approach of the end-point is given too soon it can be postponed by lowering electrode F, or if too late it can be advanced by raising electrode F. After a little experience the operator will have no difficulty in adjusting the electrodes so as to obtain an indication of the approach at the point he most desires. Although not necessary to do so, it has been found advantageous to reverse the relative positions of electrodes F and C in the titration of potassium bichromate with ferrous ammonium sulfate, for when the solution is thrown upon electrode C in this titration, the indication of the approach is obtained by the needle "kicking" left, whereas, in the other three titrations, "kicks" to the left were obtained when the solution was thrown upon electrode F. By left is meant the opposite direction to that in which the needle of the galvanometer goes at the end-point.

TABLE III

TITRATION OF APPROXIMATELY 0.1 *N* BICHROMATE WITH FERROUS SULFATE

Run	Tube	FeSO ₄		Error, ml.	Current		B- battery, volts	V in volts	P in ohms
		Calcd., ml.	Found, ml.		Plate, Ma	Filament, Ampere			
1	1	26.60	26.60	0.00	1.25	0.25	22.5	1.6	20,000
2	1	26.60	26.57	.03	0.65	.20	18.0	1.2	15,000
3	1	26.60	26.59	.01	2.50	.27	36.0	2.0	25,000
4	2	26.60	26.60	.00	2.10	.26	36.0	2.0	25,000
5	2	26.60	26.62	.02	0.51	.20	18.0	1.2	15,000

Initial volume, 200–250 ml.; deflection of galvanometer to extreme right.

In most cases the needle drifted five or more spaces to the left during the course of the titration. The calculated values are the average of several concordant determinations with the Wendt apparatus.

The following titrations were carried out and essentially the same results were obtained when the variables were varied as shown in Table III: sodium thiosulfate with iodine, sodium arsenite with iodine and with bromate. Other tubes of the same type but with different characteristics were used with equal success.

The conditions given in Run 1 of Table III have been selected as the optimum. No attempt was made to determine the exact limits of the different variables. Each variable can be varied independently over the following range if the other factors are left constant as given in Run 1: P, 5000–35,000 ohms; V, 0.4–2.2 volts; B, 18–45 volts; filament current, 0.18–0.27 ampere. These are not absolute limits.

Accuracy.—Approximately 0.01 *N* solutions were prepared by diluting the 0.1 *N* solutions employed above ten times and for this reason the calculated values of the 0.01 *N* have been considered numerically equal to those of the 0.1 *N*. Table IV gives the results of a typical titration.

TABLE IV

TITRATION OF APPROXIMATELY 0.1 *N* BICHROMATE WITH FERROUS SULFATE

	1	2	3
Ferrous sulfate, calcd. ml.	26.60	26.60	26.60
Ferrous sulfate, found ml.	26.64	26.62	26.65
Error, ml.	0.04	0.02	0.05

Total volume 200–250 ml.

When the galvanometer employed had a sensitivity of 0.5 microampere per millimeter, a deflection of only ten scale divisions was obtained with 0.01 *N* solutions but when a galvanometer which had a sensitivity of 0.025 microampere per millimeter was employed a deflection of more than thirty scale divisions per drop was obtained. The addition of one drop of 0.001 *N* iodine solution to a volume of 250 ml. of a slightly acid solution gave a deflection of twenty scale divisions with the latter galvanometer. Because of the extreme precautions that must be taken when working with 0.001 *N*

solutions it will be necessary to delay the report on this dilution until a later date.

Summary

1. A positive potential has been impressed upon the grid instead of the usual negative.
2. The polarization of platinum electrodes by means of a grid current has been used to advantage in the electrometric titrations of some oxidation-reduction reactions.
3. The different variables in this "hook-up" may be varied over a range of 20% without vitiating the results.
4. The equivalence point is indicated by the "kick" of a sensitive galvanometer and possesses the following characteristics: (a) approach is indicated, (b) high sensitivity, (c) over-stepping is immediately apparent, (d) the plotting and recording of readings is unnecessary, (e) tubes of the same type give the same equivalence point, (f) adjustments are unnecessary during titration.

THE CLASSICAL DISSOCIATION CONSTANT OF BROMCRESOL GREEN, CHLORPHENOL RED AND METHYL RED IN POTASSIUM CHLORIDE SOLUTIONS¹

BY ELWYN F. CHASE AND MARTIN KILPATRICK, JR.

RECEIVED FEBRUARY 2, 1932

PUBLISHED JUNE 6, 1932

A great part of the work in the colorimetric determination of hydrogen-ion concentration has been based on the incorrect assumption that equal color in solutions of equal indicator concentration meant equal hydrogen-ion concentration. That this assumption leads to errors of considerable magnitude has been clearly pointed out by Güntelberg and Schiödt.² They show that for the case studied by Szyszkowski³ the error due to the above assumption amounted to several hundred per cent. Consequently, this error is of the greatest importance and a clear understanding of the factors involved is essential.

An indicator is nothing more than a weak acid, or base, where the acid form, or basic form, or both, is colored due to some structural rearrangement. Thus we can have a buffer system just as with any weak electrolyte

¹ Abstracted from the thesis of Elwyn F. Chase presented to the Faculty of the Graduate School of the University of Pennsylvania in partial fulfilment of the requirements for the degree of Doctor of Philosophy, June, 1931.

² Güntelberg and Schiödt, *Z. physik. Chem.*, **135**, 393 (1928).

³ Szyszkowski, *ibid.*, **58**, 420 (1907).

and the classical dissociation constant is a good measure of the acid strength. If we consider the acid HI the classical dissociation constant is

$$K_o = \frac{C_{H^+} \cdot C_{I^-}}{C_{HI}} \quad (1)$$

where C_{H^+} really represents $C_{H_3O^+}$. At the half transformation point $C_{HI} = C_{I^-}$ and

$$K_o = C_{H^+} \quad (2)$$

Now it is generally known that K_o changes with change in electrolyte concentration. In the case of monobasic acids these changes depend not only on the electrolyte concentration but also on the particular acid and electrolyte.⁴ The magnitude of these changes will also depend on the ion charge types involved but this will not affect the general equations derived below. If we consider two solutions I and II at the half change point or any other degree of transformation, *i. e.*, C_{I^-}/C_{HI} ratio, from equation (2) it follows that

$$\left(\frac{C_{H^+}}{K_o}\right)_I = \left(\frac{C_{H^+}}{K_o}\right)_{II} \quad (3)$$

If I is the known and II is the unknown, then

$$(C_{H^+})_{II} = (C_{H^+})_I \cdot \frac{(K_o)_{II}}{(K_o)_I} \quad (4)$$

an equal color means equal hydrogen-ion concentration when $(K_o)_{II}/(K_o)_I$ is equal to unity. In other words, $(K_o)_{II}/(K_o)_I$ is the term expressing the so-called "salt error" of indicators. The ratio $(K_o)_{II}/(K_o)_I$ may change several fold⁴ so that the determination of the classical dissociation constants of indicators is essential to the use of the colorimetric method. The present paper deals with the determination of the classical dissociation constants of bromcresol green, chlorphenol red and methyl red in aqueous potassium chloride solutions.

The method of determining the classical dissociation constant depends upon having solutions of suitable known hydrogen-ion concentration and determining experimentally the ratio of the basic and acid forms of the indicator in such solutions. Substitution of these values in equation (1) gives the dissociation constant directly. This method has been used by Friedenthal⁵ and improved upon by Gillespie.⁶ For indicators having half-change points around 0.01 molar hydrogen-ion concentration, it is convenient to use solutions of strong acid as standard but it is not practicable to work in glass with large amounts of salt present at concentrations of strong acid much below 1×10^{-3} . Besides, in unbuffered solutions of this sort one must take into account the buffering action of the

⁴ For examples see Chase and Kilpatrick, *THIS JOURNAL*, **53**, 2589 (1931).

⁵ Friedenthal, *Z. Elektrochem.*, **10**, 114 (1904); Salm, *Z. physik. Chem.*, **57**, 471 (1906).

indicator system.⁷ In the present study the standards have been the buffer systems of benzoic acid-benzoate, acetic acid-acetate, cacodylic acid-cacodylate and hexahydrobenzoic acid-hexahydrobenzoate. In the first case the hydrogen-ion concentrations were those calculated from the values of the classical dissociation constant of benzoic acid in potassium chloride solutions as given by Chase and Kilpatrick.⁴ In the other cases the hydrogen-ion concentrations were determined by means of the quinhydrone electrode under the same assumptions used in the standardization of the benzoic acid-benzoate system.⁸

Experimental Method

As preliminary experiments showed that different samples of indicator gave different values, we attempted to obtain the purest possible samples of the indicators.⁹ Two samples of bromocresol green (tetrabromom-cresolsulfonephthalein) were used. The first was crystallized from acetic acid. The second was also crystallized from glacial acetic acid and analysis showed 44% bromine as against a calculated value of 45.8%. The indicator solutions were prepared by shaking a weighed amount of the indicator acid with a dilute solution of sodium hydroxide containing the calculated amount to form the sodium salt. The solution was then centrifuged and diluted to a convenient concentration. Preliminary experiments¹⁰ with another indicator (bromphenol blue) have shown that in the presence of sodium hydroxide of concentration 3×10^{-3} molar and an indicator concentration of 2×10^{-5} molar the blue color disappears completely in about fourteen days. This change seems to be proportional to the hydroxyl-ion concentration and from a study of the increase in the rate of the reaction with increasing potassium chloride concentration (primary kinetic salt effect) appears to be a reaction between two ions. Since the solutions gave tests for the bromide ion, it seems likely that the bromine is replaced by the hydroxyl ion in the compound. For this reason we avoided using the method recommended by Clark¹¹ in which the indicators are ground up with 0.01 molar sodium hydroxide solutions. In fact in later work we have been using the following method to carry out the neutralization more quickly and thus avoid an excess of sodium hydroxide. The indicator is dissolved in alcohol, the calculated amount

⁷ This has been pointed out by Fawcett and Acree, *Ind. Eng. Chem., Anal. Ed.*, **2**, 78 (1930), and Kolthoff, *THIS JOURNAL*, **53**, 825 (1931).

⁸ Kilpatrick and Chase, *ibid.*, **53**, 1732 (1931).

⁹ The bromocresol green and chlorphenol red were specially purified and furnished to us through the kindness of Drs. D. Twiss and W. C. Harden of the Chemical Research Laboratory of Hynson, Westcott and Dunning Co., Baltimore, Md.

¹⁰ Experiments carried out with C. E. Gulezian.

¹¹ Clark, "The Determination of Hydrogen Ions," 3d ed., Williams and Wilkins Co., Baltimore, Md.

of aqueous sodium hydroxide added, the alcohol evaporated under reduced pressure and the residue taken up in distilled water.

Two samples of chlorphenol red (dichlorophenolsulfonephthalein) were used. The first was purified by repeated solution in sodium carbonate and precipitation by hydrochloric acid. This sample did not dissolve completely in sodium hydroxide. A second sample purified by Harden¹² dissolved completely and immediately in very dilute sodium hydroxide. The second sample gave the following analysis: calcd., sulfur, 7.58; chlorine, 16.76. Found: S, 7.60; Cl, 16.66. A comparison of the dissociation constants of these samples will be given later.

Methyl red (*o*-carboxybenzene-azo-dimethylaniline) was purified by repeated crystallization from toluene. The sample gave a sharp melting point between 176 and 177°.

The stock solutions of the indicators were diluted to a concentration of 5×10^{-4} molar and contained potassium chloride ranging from 0.1 to 3 molar. The colorimeter was of the Gillespie type and is described by Clark.¹³ In all cases the acid form and the basic form were obtained by adding the calculated amount of hydrochloric acid or sodium hydroxide for over 99% conversion.

X, anion of acid used in buffer. *k*, values chosen by Kolthoff.

Table I gives the results with bromcresol green. Column I gives the electrolyte concentration, which is largely potassium chloride. Column II gives the average value of K_e with a value calculated from the values of Kolthoff, given in his recent survey of indicator constants.¹⁴ Kolthoff gives the values in terms of pK_1 and states that the accuracy is supposed to be within 0.05 of a logarithmic unit (12% in K_1). K_1 does not represent the classical dissociation constant but a dissociation constant defined by the equation

¹² Harden, THIS JOURNAL, **52**, 4611 (1930).

¹³ Clark, Ref. 11, p. 169.

¹⁴ Kolthoff, J. Phys. Chem., **34**, 1466 (1930).

$$pK_1 = P_H - \log \frac{C_B}{C_A} \quad (5)$$

where P_H is the Sørensen P_H . The classical dissociation constant is related to this constant (K_1) by the equation

$$pK_e = pK_1 - pf_H + 0.04 \quad (6)$$

$-\log f_H$ was evaluated, with sufficient accuracy, from the empirical equations of Bjerrum and Unmack¹⁵ and K_e was calculated from the values of Kolthoff for K_1 . Our observed values, which are higher than those given by Kolthoff, were obtained with two different indicator samples and three different buffer systems.

TABLE II

THE CLASSICAL DISSOCIATION CONSTANT OF CHLORPHENOL RED IN POTASSIUM CHLORIDE SOLUTIONS

¹⁵ Bjerrum and Unmack, *Kgl. Danske Videnskab. Selskab. Math.-fys. Medd.*, **9**, 1 (1929)

of indicator were much lower and are not included. For example, the dissociation constant for the first sample at one molar potassium chloride concentration was 7.7×10^{-7} as compared with 16.2×10^{-7} for the second sample.

Table III gives the results for methyl red. Methyl red is of particular interest in that it is an indicator of the amphi-ion type. Considering the structure

the molecule contains a basic group as well as an acid group. The amino group will tend to pick up protons to form the amphi-ion

In acid solution we have the form

and in basic solution

The dissociation constant is related to the dissociation constant at zero ion concentration by the equation

$$K_e = K_{\infty} \frac{f_{\text{HI}^\pm}}{f_{\text{H}^+} f_{\text{I}^-}}$$

Now Bjerrum¹⁶ has shown that in dilute solution an amphi-ion behaves like a neutral molecule and in more concentrated solution like two ions. Consequently in very dilute solution

$$K_e = K_{\infty} \frac{1}{f_{\text{I}}^2}$$

Thus in dilute solution an exponential salt effect would be expected. In more concentrated solution the activity factor would be such

$$K_e = K_{\infty} \frac{f_{\text{I}}^2}{f_{\text{I}}^2}$$

that a linear salt effect would be expected. The curve for methyl red in Figure 1 shows this effect. The exponential effect below 0.1 molar was not investigated due to the fact that the assumptions involved in the electrometric method for determining the hydrogen-ion concentration are not valid below 0.1 molar. Güntelberg and Schiödt² do indicate the exponential part in the case of methyl orange. In this connection we cannot agree with the statement of Kolthoff¹⁴ that the salt error of methyl orange is extremely small between 0.0 and 0.5μ . If we express the salt error as K_e/K_{∞} and use the results of Güntelberg and Schiödt, the error is 32% between $\mu = 0.0$ and $\mu = 0.1$.

The curves for bromcresol green and chlorphenol red show that K_e increases with increasing electrolyte concentration, passes through a maximum and then decreases.

¹⁶ Bjerrum, *Z. physik. Chem.*, **104**, 147 (1923).

The Colorimetric Method.—In using the colorimetric method to determine the hydrogen-ion concentration of an unknown solution, one may simply reverse the method employed here in determining the dissociation constant of the indicator, that is, the ratio of the acid form to the basic form of the indicator is determined and the concentration of the hydrogen ion calculated from the equation

$$C_{H^+} = K_c \frac{C_A}{C_B}$$

where K_c is the correct value of the dissociation constant of the indicator for the particular electrolyte, electrolyte concentration and medium used.

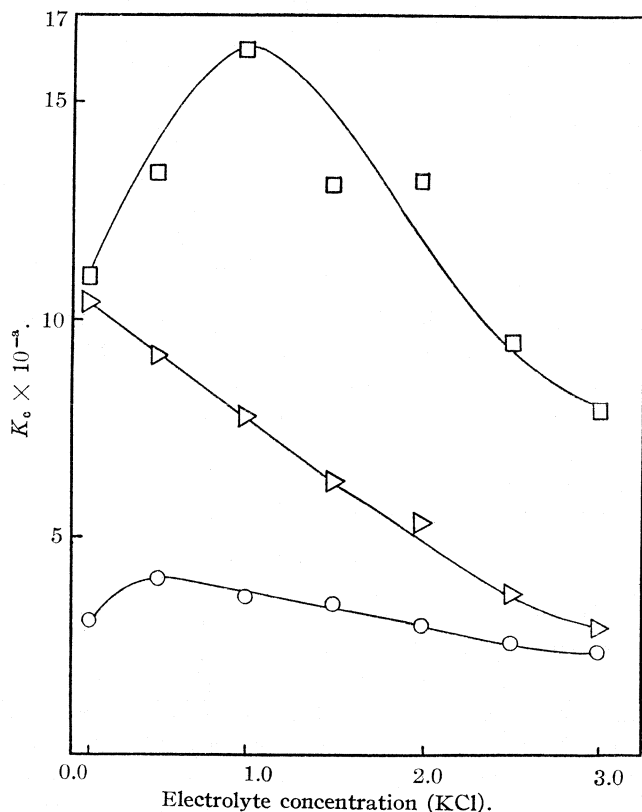

Fig. 1.— K_c for bromocresol green, chlorphenol red and methyl red in potassium chloride solutions: ○, B.C.G. (scale $\times 10^{-6}$); □, C.P.R. (scale $\times 10^{-7}$); ▷, M.R. (scale $\times 10^{-6}$).

More often the unknown is matched with a standard and the hydrogen-ion concentration calculated by equation (4). In other words the ratio of the values of the dissociation constant of the indicator in the unknown and in the standard must be known. At present these standards are

usually given in Sørensen pH or $p\alpha H$ units, because the electrometric method is considered the standard. The resulting confusion can be avoided in dealing with aqueous solutions by calibrating a suitable set of standard solutions in terms of the hydrogen-ion concentration. A convenient standard is a buffer system: 0.01 molar in a suitable monobasic acid, 0.01 molar in the salt of the same acid and 0.09 molar in potassium chloride. The hydrogen-ion concentration of such buffers can be determined electrometrically, catalytically or colorimetrically, the measurements being referred directly to a solution of strong acid. In order to standardize colorimetrically one would determine the dissociation constants of a less sensitive indicator and then use that indicator to standardize a buffer system of an acid of slightly lower dissociation constant than the indicator. By extending this process to weaker acids the range could be extended.

Table IV gives the values of $K_c/K_{c(0.1)}$ for the three indicators and Fig. 2 presents these ratios graphically. Figure 2 also includes the $K_c/K_{c(0.1)}$ values for the acids used in determining the dissociation constant of the indicators.

TABLE IV

THE $K_c/K_{c(0.1)}$ RATIOS IN POTASSIUM CHLORIDE SOLUTIONS

Electrolyte, KCl + NaX, moles per liter	B. C. G.	C. P. R.	M. R.
0.1	1.00	1.00	1.00
0.5	1.31	1.22	0.89
1.0	1.18	1.48	.75
1.5	1.13	1.20	.61
2.0	0.95	1.20	.51
2.5	.83	0.86	.35
3.0	.78	.72	.28

In order to determine the hydrogen-ion concentration the unknown is matched with the standard at equal indicator concentration and the hydrogen-ion concentration of the standard multiplied by the appropriate value from Table IV. If another concentration of electrolyte is used as standard then we simply multiply the above values by the $K_{c(0.1)}/K_{c(\text{standard})}$ ratio. If another electrolyte than potassium chloride is present in the unknown it would be necessary to know the dissociation constant of the indicator in a solution of that electrolyte at the concentration in question. The magnitude of these differences can be seen from a comparison of the dissociation constants of acetic acid in potassium chloride and sodium chloride solutions as taken from Larsson and Adell.¹⁷ The differences up to 0.2 molar are within the experimental error and then increase so that at 3 molar the difference is 12%. Harned and Murphy¹⁸

¹⁷ Larsson and Adell, *Z. physik. Chem.*, [A] **156**, 352 (1931).

¹⁸ Harned and Murphy, *THIS JOURNAL*, **52**, 5079 (1930).

report differences at 0.1 molar concentration. For bromphenol blue Güntelberg and Schiödt give K_e in 3 molar potassium chloride as 11.0×10^{-5} and in 3 molar sodium chloride as 9.4×10^{-5} . For higher valence types the differences would be greater and for accurate work it would be necessary to know the dissociation constant in the medium used. It might be emphasized here that no method of expressing the salt error will avoid these second order effects. The same statement should be made in regard to the effect of non-electrolytes and this part of the solute effect may be more important than is generally realized. In any case it is believed that the above method of expressing salt error in indicator work calls attention to the magnitude of the effect and gives a simple method of correcting for it.

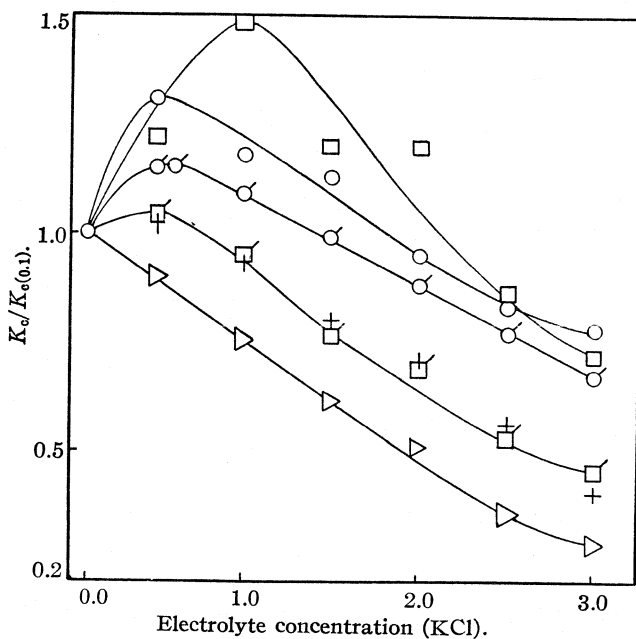

Fig. 2.— $K_e/K_{e(0.1)}$ for B. C. G., C. P. R., M. R., benzoic acid, acetic acid and cacodylic acid in potassium chloride solutions: ○, B. C. G.; □, C. P. R.; ▷, M. R.; ○·, benzoic acid; □·, cacodylic acid; +, acetic acid.

Summary

The classical dissociation constants of bromcresol green, chlorphenol red and methyl red in potassium chloride solutions have been determined.

A simple method of expressing salt errors in colorimetric determinations of hydrogen-ion concentration has been given.

THE ABSORPTION OF OXYGEN BY BENZALDEHYDE

BY H. J. ALMQUIST AND G. E. K. BRANCH

RECEIVED FEBRUARY 9, 1932

PUBLISHED JUNE 6, 1932

Introduction

The reaction of oxygen with benzaldehyde has been the subject of much investigation since the time of Wöhler and Liebig,¹ who observed that benzaldehyde is converted into benzoic acid in air, more rapidly in the light. Excellent historical reviews of the general subject of autoxidations have been prepared by Moureu and Dufraisse² and by Jorissen and Belinfante.³ Bibliographies more particularly concerned with this reaction may be found in recent papers by Jorissen and van der Beek,⁴ Bäckström and Beatty,⁵ and Raymond.⁶ Since these lists are practically complete it is unnecessary to repeat all of the references here.

The reaction has aroused much interest because it has been found that traces of other substances may either accelerate or inhibit the absorption. The influence of an inhibitor disappears after a period of time during which the inhibitor is itself oxidized, even though it may be a substance that in the pure state would not be affected appreciably by oxygen.

Apart from the influence of inhibitors and accelerators many peculiarities have been found in the reaction. These may be summarized as follows. (1) The reaction is photosensitive. (2) The reaction is probably a chain reaction both in the dark and in the light. (3) Earlier rate measurements have usually shown an induction period. (4) The rate constantly diminishes as time proceeds. (5) The walls of the containing vessel seem to play a part in the reaction, although there is little agreement on this point among investigators. (6) The reaction is presumably an excellent example of consecutive reactions, the first step being the formation of an intermediate peroxide, the second step the interaction of the peroxide with benzaldehyde to form benzoic acid.

We have investigated to some extent the influence of change of oxygen pressure on the rate of the reaction, but our chief efforts have been directed toward determining the distribution of absorbed oxygen between peroxides and benzoic acid during the reaction at a constant pressure of oxygen. In the present paper we shall report on the results obtained when, as far as possible, only benzaldehyde, oxygen and the products of their interaction are present.

Materials

Benzaldehyde.—The benzaldehyde was purified by many fractional distillations in a current of dry carbon dioxide gas. The apparatus was so arranged that as many fractionations as desired could be obtained without contact between the benzaldehyde and air, stopcocks or rubber. The purification was continued until the usual induction period in the reaction of benzaldehyde with oxygen had disappeared. The product was stored in the dark under an excess pressure of carbon dioxide, in a flask so constructed as to permit a stream of gas to pass through and prevent the entrance of air when opened for the removal of samples.

Benzoic Acid.—Benzoic acid of a high grade was repeatedly recrystallized from water and dried over calcium chloride.

Oxygen.—The oxygen was obtained from a commercial manufacturer. Analysis showed it to contain more than 99.5% oxygen.

Variation of the Rate with the Oxygen Pressure.—When pure benzaldehyde is shaken at a constant speed in the dark and in contact with a fixed volume of oxygen, the rate of change of the logarithm of the oxygen pressure decreases with time much faster than would be expected from the using up of the benzaldehyde to form benzoic acid. Milas⁷ has explained similar results in other autoxidations by assuming the removal of the active substance by an induced polymerization. This explanation is not valid in the case of benzaldehyde. On analyzing for the benzaldehyde left after the reaction had decreased considerably in rate, we found it to be practically equal to the original quantity less the benzaldehyde converted to benzoic acid and peroxides.

When similar experiments were performed with benzaldehyde containing 3% of benzoic acid the rate of change of the logarithm of the oxygen pressure was, after the first few minutes, slightly more constant than would be expected from the decrease in the concentration of the benzaldehyde. The reaction between benzaldehyde and oxygen is, therefore, of the first order with respect to oxygen. The rate is decreased probably by the action of small quantities of substances produced in the reaction. In the presence of benzoic acid the formation of these inhibitors is prevented or they rapidly reach a steady state concentration.

Table I shows the data from an experiment on the autoxidation of a benzaldehyde-benzoic acid mixture, the rate of reaction being measured by the decrease of the oxygen pressure with time. The total oxygen absorbed corresponded to 55 cc. at 25° and 760 mm. of mercury. The initial benzaldehyde and benzoic acid were equivalent to 263 cc. and 9.1 cc. of oxygen, respectively. The rate constant was calculated as $K = d \log_{10} P/dt$, where P is the oxygen pressure in mm. of mercury and t is the time in minutes.

⁷ Milas, *THIS JOURNAL*, **52**, 734 (1930).

40	567.5	6.88			

The Distribution of Absorbed Oxygen.—The absorption of oxygen gas and the quantities of benzoic acid and of peroxides formed were measured during the reaction at 25° and 1 atmosphere pressure of oxygen and in the absence of light. The more important parts of the apparatus used are shown in Fig. 1.

The automatic gas buret, C, was filled with oxygen just before starting an experiment and then closed off from the remainder of the apparatus until needed. The buret was kept at a temperature of 25° by a water jacket and a water circulating system.

The reaction vessel, B, was immersed in a thermostat filled with water blackened by the addition of India ink. Before each experiment the vessel was thoroughly cleaned and steamed out. It was charged with a 2.25-cc. portion of benzaldehyde or a benzaldehyde-benzoic acid mixture under an atmosphere of carbon dioxide. The container above the reaction vessel was filled with a solution of potassium iodide in methyl alcohol and water. This solution was readily miscible with the autoxidized benzaldehyde.

The manometer, D, connected to the gas buret, C, was so adjusted that a very slight fall in pressure caused an electrical circuit to be broken. By the use of electric switches, etc., the breaking of the circuit was caused to activate a mechanism for lifting the mercury bottle, E. When the pressure in the system was restored to 1 atmosphere the circuit in D again closed and the ascent of E automatically stopped. The mechanism for raising E was composed of an electric motor, a speed-reducing gear and a small rotating shaft upon which a cord attached to E was wound. The manometer controlled the pressure with a variation of about 0.2% during the course of a reaction.

Reactions were started by filling the reaction vessel with oxygen after evacuating other gases, connecting in the gas buret and then shaking the vessel by the use of a mechanism driven by a constant speed motor. The time elapsed from the admission of oxygen until the shaker was started was three to five seconds. The volume of oxygen absorbed was noted at short intervals.

At a chosen time the potassium iodide solution was run into the reaction vessel and the shaker stopped. The iodine liberated by the action of the peroxides was titrated with sodium thiosulfate solution and, following this, the benzoic acid was titrated with sodium hydroxide solution. It was assumed that the following reaction took place on adding the potassium iodide solution to the contents of the reaction vessel.

Each equivalent of iodine represents half a mole of peroxide and the loss of half a mole of acid. This benzoic acid was added to that found later by the titration with standard alkali. On this basis the absorbed oxygen in the form of peroxides and benzoic acid at the instant of the stopping of the reaction was calculated. That these assumptions give essentially the correct results is shown by the facts that the initial rate of formation of peroxides is equal to the rate of absorption, while the initial rate of formation of benzoic acid is practically zero, and that the sum of the peroxide and benzoic acid oxygen is

approximately equal to the oxygen absorbed. When necessary in the early stages of the reaction, known quantities of benzoic acid were added to the potassium iodide solution to furnish the required acid for the above reaction.

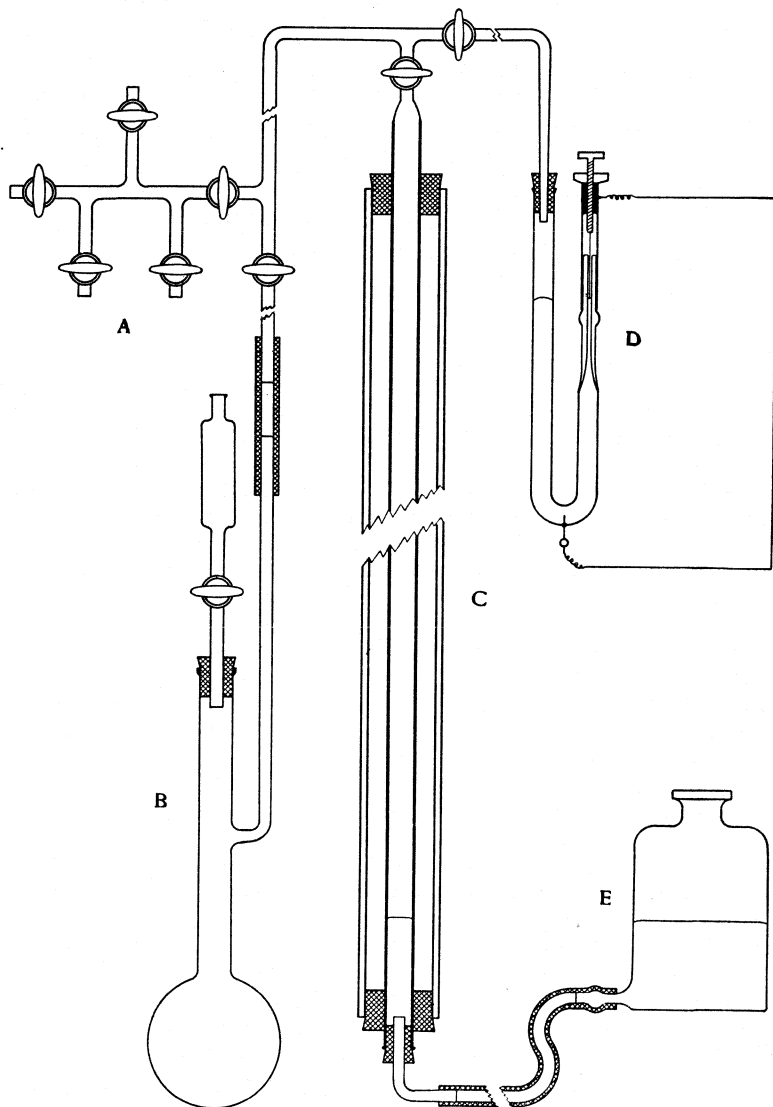

Fig. 1.—Automatic gas buret used for measuring the oxygen absorbed at constant pressure: A, connections to oxygen supply, manometer, vacuum pump and vent; B, reaction vessel and container for potassium iodide solution; C, buret tube with constant-temperature water jacket; D, mercury manometer which controls the mechanism for raising the mercury bottle; E, mercury bottle.

The sum of the peroxide and benzoic acid oxygen averaged about 3% less than the oxygen measured volumetrically. This discrepancy is probably real and due to the formation of substances not included in our analysis. Some indication of an unknown side reaction is found in the fact that benzaldehyde which has undergone extensive autoxidation acquires a yellow color and may produce small amounts of a yellow solid.⁸

In an effort to secure an explanation of this oxygen discrepancy we searched for the following substances: benzil, phenolic materials, carbon dioxide, carbon monoxide, peroxides that react rapidly with iodide ion only in strongly acid solution and peroxides that lose oxygen gas in the presence of iodide ion. All of these were found to be absent and would have been detected readily if present in quantities sufficient to explain the disagreement in our measurements.

In our method the complete time curve for the absorption of oxygen could be obtained by a single experiment, while the amounts of peroxides and benzoic acid could only be obtained for a particular instance by one experiment. It was necessary to perform many experiments over varying intervals of time in order to secure the data for the construction of the peroxide and benzoic acid time curves. The absorption time curve shown in Fig. 2 was taken from one of the faster reactions which was chosen as a standard. The unshaded points along this curve are those of the standard reaction, while the shaded points indicate the final total absorptions of the separate reactions. In some cases the results were weighted according to the agreement of the reaction with the standard. The results of the experiments started with the purified benzaldehyde are shown in Table II. The curves for the total absorption, the formation of benzoic acid, the formation of peroxides and the difference between the calculated and the

observed oxygen are shown in Fig. 2. All results are expressed in terms of volumes of oxygen at 25° and 760 mm. of mercury.

It is apparent from Fig. 2 that the benzoic acid is formed in a follow reaction between the peroxide and the benzaldehyde. The results also

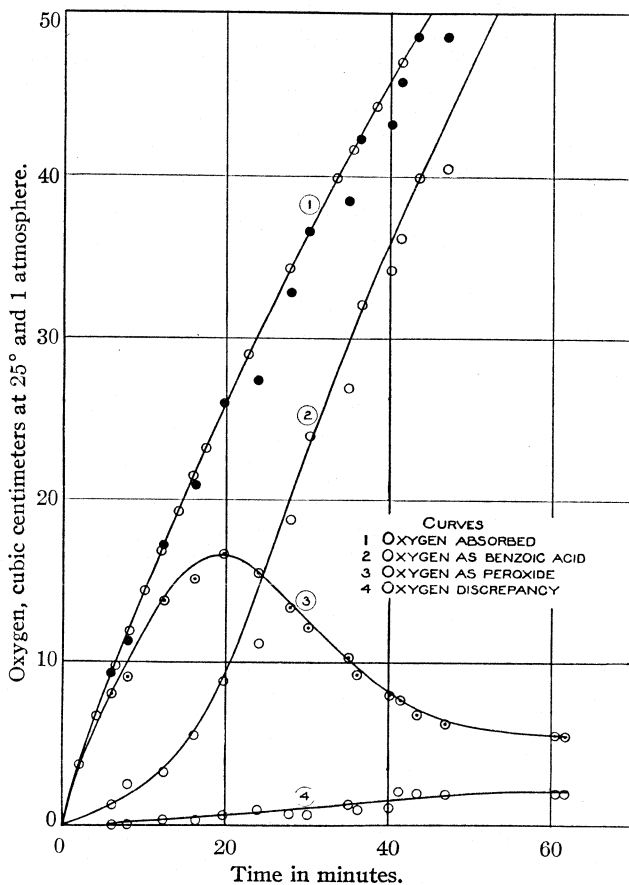

Fig. 2.—Reaction of purified benzaldehyde: curves showing the variation with time of, 1, the total oxygen absorbed, 2, the oxygen used to form benzoic acid, 3, the oxygen in the form of peroxides and, 4, the discrepancy between the volume of oxygen absorbed and the oxygen accounted for by analysis.

show that the rate of this reaction increases markedly as the reaction proceeds. Thus the rate of formation of benzoic acid is 0.3 cc. of oxygen per minute when 9.0 cc. of peroxide oxygen is first present, but it is 1.2 cc. per minute when the peroxide is again present in this amount in a later stage of the reaction. The increase in the rate is apparently due to the presence of benzoic acid. This relation was tested further by adding

benzoic acid equivalent to 9.1 cc. of oxygen in the usual charge of benzaldehyde. The data from these experiments are presented in Table III and Fig. 3 in the same manner as before.

5.4	34.9	1.00	1.85

either Figs. 2 and 3 or Tables IV and V shows that the oxidation of benzaldehyde by the peroxides is much faster in the presence than in the absence of benzoic acid, but that only a small amount of the acid is required to obtain the maximum rate. When the autoxidation is started in the absence of benzoic acid the slowness of the formation of benzoic acid permits the accumulation of peroxides over the steady state concentration. This accounts for the marked maximum in curve 3 of Fig. 2. The excess of peroxide, however, is not the original peroxide formed, for, even after sufficient benzoic acid is present, this peroxide is a less effective oxidizer than that formed in the presence of benzoic acid. This is to be seen by comparing the last columns of Tables IV and V, in which the rates of formation of benzoic acid divided by the peroxide concentration are shown. The less reactive peroxide is probably perbenzoic acid, which is formed from another peroxide by a reaction that is inhibited in the presence of benzoic acid. The simplest explanation of this inhibition is that the precursor of perbenzoic acid combines with benzoic acid, forming a compound which readily oxidizes benzaldehyde.

When no benzoic acid is present initially perbenzoic acid is formed and only slowly oxidizes benzaldehyde to benzoic acid which, in turn, inhibits the formation of more perbenzoic acid, the peroxide-benzoic acid compound being formed instead. At the point where the rate of formation of benzoic acid is greatest the ratio between this rate and the peroxide concentration is small because a large fraction of the peroxide is in a less reactive form. As the less reactive peroxide is now being used up faster than it is produced, the peroxides become richer in the peroxide-benzoic acid compound. Hence the values in the last column of Table IV increase, approaching the more constant values of Table V.

When benzoic acid is present initially, very little perbenzoic acid is formed and the peroxides rapidly reach a steady state concentration and a constant composition. This steady state concentration is practically constant when the oxygen pressure is constant and the concentration of benzaldehyde changes only slowly. The change in the concentration of benzaldehyde probably affects the rates of formation and removal of the peroxide in the same way. The values shown in the third and fourth columns of Table V are, consequently, practically constant after the first few minutes.

When benzoic acid is present initially, the rate of absorption of oxygen does not continue to decrease after the first few minutes but the rate is less than the initial rate in the absence of benzoic acid. The peroxide-benzoic acid compound is presumably an inhibitor. This action may be explained if it is assumed that activated benzaldehyde molecules are links in the chain for the absorption of oxygen, and that they can react with the peroxide-benzoic acid complex. The constancy of the rate of absorption of oxygen,

therefore, depends upon the constancy of the steady state concentration of the peroxide-benzoic acid compound. We have ignored the fact that the initial absorption rate is smaller in the presence than in the absence of benzoic acid. This observation is probably not significant, because only after many crystallizations is benzoic acid sufficiently pure that its addition does not produce a distinct induction period, and it is not certain that this influence is entirely absent.

Finally, in the absence of initial benzoic acid, the absorption rate may fall below the constant rate obtained with initial benzoic acid. There is, probably, another reaction path which produces a poison, but which is prevented when a reaction is started in the presence of benzoic acid. It may be seen by comparing the total absorption points of Fig. 3 with those of Fig. 2 that the reactions of the benzaldehyde-benzoic acid mixture were much more reproducible in rate than those started with pure benzaldehyde. This marked difference may be the result of an uncontrolled production of a poison in the latter case. Conditions that favor such a side reaction would rapidly bring the autoxidation to a stop. We have occasionally observed this phenomenon in reactions whose rate at the start was normal but, in a few minutes, decreased below the limits of observation. Rieff⁹ shows some similar curves and attributes the phenomenon to extreme dryness. Kuhn and Meyer¹⁰ have obtained inactive benzaldehyde and attribute its inactivity to freedom from traces of catalysts. We did not succeed in obtaining these aborted reactions at will, but we found no such examples in reactions started in the presence of benzoic acid.

Summary

The distribution of oxygen between peroxides and benzoic acid during its absorption by purified benzaldehyde and by benzaldehyde containing benzoic acid has been quantitatively determined. The reaction is of the first order with respect to oxygen and consists of a series of reactions which involve the formation of peroxides from benzaldehyde and oxygen and the subsequent reaction of these with benzaldehyde to produce benzoic acid.

Certain respects in which the reaction differs from simple, consecutive reactions are due to the autocatalytic nature of the formation of benzoic acid. In the reactions started in the absence of benzoic acid, the peroxides accumulate at first but later their concentration decreases to that of a steady state. In reactions started in the presence of benzoic acid the concentration of peroxides quickly reaches an almost constant value. In both cases the reactions tend to become identical. A mechanism to account for these results has been proposed.

PUBLISHED JUNE 6, 1932

Introduction

Preceding Observations on Germanium Dioxide.—Germanium dioxide, as it is ordinarily prepared by the hydrolysis of the germanium tetrahalides or the alkali germanates, forms an exceedingly fine-grained precipitate, the individual particles of which do not reveal any definite structure under the microscope at the highest attainable resolving power. However, when examined by powder x-ray diffraction methods, the solid gives a well-defined pattern and therefore is microcrystalline. If the dioxide is formed under conditions more favorable for crystal growth, grains of appreciable size may be obtained. According to Goldschmidt,² germanium dioxide obtained by crystallization from its aqueous solution yields trigonal crystals that closely resemble the trigonal-trapezohedral low-quartz. Zachariasen³ has investigated the crystal structure of this form of germanium dioxide by powder x-ray diffraction methods and confirms Goldschmidt's observations. The fundamental lattice is simple hexagonal.

Crystalline germanium dioxide may also be secured by the devitrification of the glass obtained when the fused dioxide solidifies. Müller⁴ has shown that crystals prepared in this way give the same x-ray diffraction patterns as the crystals produced by hydrolysis of the tetrachloride or by crystallization from aqueous solution and, therefore, are the same crystalline modification. This form of germanium dioxide is somewhat soluble in water, and hence has been termed "soluble" germanium dioxide.

Müller and Blank⁵ announced the discovery of a second crystalline modification, designated by them as "insoluble" germanium dioxide. They prepared the new form by igniting at about 380° the residue left upon evaporation of an aqueous solution of the oxide. Conversion to the insoluble form was never complete and the yield secured depended upon the conditions of evaporation of the solution and upon the time and temperature of ignition of the residue. Higher or lower temperatures of ignition decreased the yield, and it increased with time of ignition at a decreasing rate, approaching a maximum of about 15%. This

insoluble form of germanium dioxide is, according to Müller, extraordinarily inert toward substances which readily act on the oxide in its usual condition. Besides being virtually insoluble in water, it does not react with hydrochloric or hydrofluoric acid. It yields a powder x-ray diffraction pattern completely different from that of the "insoluble" modification. No attempt was made by Müller to interpret the diffraction patterns in terms of crystal structure.

It has been established, therefore, by preceding investigations that germanium dioxide can crystallize in at least two different modifications. One of these is moderately soluble in water and is chemically reactive, while the other is practically insoluble in water and is chemically inert. As regards the stability relations, it follows from the data on solubility that the insoluble form is stable at ordinary temperatures, but there is no conclusive evidence as to whether soluble germanium dioxide is monotropic or enantiotropic with respect to the insoluble form. No convenient method for preparing the insoluble modification has been worked out, and its properties have been determined only incompletely.

Object of this Investigation.—In the present investigation a systematic study of germanium dioxide as a one-component system has been undertaken, involving a determination of the phases occurring, their equilibrium relations and their more important properties.

Experimental

I. Materials

The germanium dioxide was prepared by the hydrolysis of redistilled germanium tetrachloride. It was ignited to remove water and traces of chloride and spectroscopic examination⁶ showed that the total sum of metallic impurities present was less than 0.01%.

Fused Germanium Dioxide.—Fused germanium dioxide was made by the method described by Dennis and Laubengayer.⁷

Soluble Crystalline Germanium Dioxide.—The soluble crystalline modification was prepared by heating fused germanium dioxide at 1080° for four hours to ensure complete devitrification. The product appeared entirely crystalline and homogeneous under the microscope.

Insoluble Crystalline Germanium Dioxide.—This form was prepared according to Müller's method⁵ which was, however, found to be tedious and to yield poorly formed crystals that were so small as to render difficult their identification under the microscope. Preliminary experiments showed that rapid inversion of the soluble dioxide to the insoluble modification could be secured by a hydrothermal method that produced well-formed crystals. Large samples were prepared by this procedure, which will be described later.

These three forms of germanium dioxide were examined and their properties were determined in order to gain familiarity with their distinguishing features, so that they could be identified when they appeared in the course of the investigation.

⁶ The authors wish to acknowledge the kind assistance of Professor J. Papish, who made frequent spectroscopic examinations of the samples.

⁷ Dennis and Laubengayer, *J. Phys. Chem.*, **30**, 1510 (1926).

II. Determination of Stability Relationships

Procedure.—The facts already known regarding the behavior of germanium dioxide, and the close analogy between this oxide and silica, made it evident that the changes in the system are of the sluggish type. Therefore the common dynamic methods for the determination of monovariant equilibrium could not be employed. In the static method the system is maintained at a suitable constant temperature long enough to assure the attainment of equilibrium, and then is rapidly quenched to a temperature where the rate of progress toward equilibrium is very slow. The phase distribution corresponding to equilibrium at the higher temperature is thereby preserved and can be examined at leisure. Upon trial, this static or quenching method was found to be satisfactory for the study of germanium dioxide.

Persistence of the Modifications in the Pure State.—In order to obtain some information about the readiness with which the various forms of germanium dioxide tend to invert, samples of the soluble crystalline dioxide and of the insoluble dioxide were heated for forty-eight hour periods at 485, 620, 695, 810, 970 and 1050° ($\pm 20^\circ$). The samples were quenched by dipping the crucibles in ice water and were examined for signs of inversion. In every instance both forms of the oxide persisted unmodified. The inversions are very sluggish and do not proceed with appreciable velocity in the pure state up to at least 1050°. In similar experiments with the fused oxide it was found that complete crystallization occurred at 660°, incipient crystallization at 620°, and no crystallization at 550°. The crystals were invariably the soluble modification.

Inversions by the Hydrothermal Quenching Method.—To secure the inversion of a modification of a substance that, although unstable, persists indefinitely in the pure, dry state, it is necessary to use a catalytically acting solvent or flux, in the presence of which a more rapid approach to equilibrium occurs. In investigations on silica and the silicates the hydrothermal method, employing as the inversion catalyzer water or an aqueous solution confined in a vapor-tight bomb, has been shown to be effective.⁸ This method was therefore tried with germanium dioxide.

The bomb and furnace were similar to those developed at the Geophysical Laboratory at Washington.⁹ The bomb, however, was modified according to the simpler design described by Friedrichs.¹⁰ It was made of stainless steel and could be used at temperatures up to 550° without showing appreciable attack. At higher temperatures the threads had a tendency to weld together, even when lubricated with finely powdered graphite, so that the bomb could not be opened.

⁸ Fenner, *J. Wash. Acad. Sci.*, **2**, 471 (1912).

⁹ Morey and Fenner, *THIS JOURNAL*, **36**, 215 (1914).

¹⁰ Friedrichs, *Sprechsaal*, **61**, 282 (1928).

Preliminary tests of this new method showed that the soluble crystalline form of germanium dioxide was rapidly converted to the insoluble modification when heated in the bomb in the presence of water at 350°. Large samples of insoluble dioxide were then prepared. From 8 to 10 g. of soluble germanium dioxide and 8 g. of water were placed in a platinum crucible which was covered with platinum foil and was set in the bomb. The sealed bomb was heated for four or five days at about 350° and then was cooled rapidly to room temperature. The product was found to be discolored by iron oxide, which was removed by digesting the germanium dioxide on a steam-bath with successive portions of 6 *N* hydrochloric acid. The residue was washed free from acid with hot water, was dried for fifteen hours at 500° and was weighed. Table I gives the data for three preparations.

TABLE I

PREPARATION OF INSOLUBLE GERMANIUM DIOXIDE BY THE HYDROTHERMAL METHOD

Preparation	Soluble oxide, g.	Time heated, hours	Temp., °C., ($\pm 20^\circ$)	Product g.	Yield, %
1	8.023	95	350	7.818	97.5
2	10.481	117	355	10.338	98.6
3	10.407	115	360	9.908	95.2
Total	28.911			28.064	97.1

Spectroscopic examination showed that the product was very pure germanium dioxide. To test for the completeness of inversion to the insoluble form, weighed portions of the material were digested in covered platinum crucibles on the steam-bath with concentrated hydrofluoric acid for one hour. No appreciable weight of the sample dissolved. Microscopic examination also demonstrated that the product was a homogeneous preparation of insoluble crystalline germanium dioxide. The inversion was undoubtedly complete, the 97% yield being due to the loss of slight amounts of the insoluble dioxide in suspension when the product was washed by decantation.

The hydrothermal method of preparing insoluble germanium dioxide possesses several advantages over the method of Müller. By its use a large amount of soluble oxide can be transformed directly and quantitatively into the insoluble modification. Moreover, the product is composed of crystals of resolvable size which can be identified readily under the microscope. Further experience indicated that forty-eight hours' heating is sufficient for effecting complete inversion.

To determine the phase stable at a given temperature by the hydrothermal method, 0.1-g. samples of soluble germanium dioxide, insoluble germanium dioxide and fused germanium dioxide were each placed, with 1.5 cc. of water, in small platinum thimbles which were stacked one above the other in the bomb. The sealed bomb was held at the desired tempera-

ture for forty-eight hours. It was then quenched in ice water and the resulting products, after being dried at 120° , were examined with the microscope to ascertain the nature and relative amounts of the phases present. Identification of the various forms was based primarily on their refractive indices, namely, 1.608 for the fused dioxide, 1.70 for the soluble dioxide and $1.99+$ for the insoluble dioxide. The identifications were also checked by testing the solubility of the specimen with hydrofluoric acid. The range between 140 and 550° was investigated and the results are given in Table II.

TABLE II
INVERSIONS BY HYDROTHERMAL METHOD
Inversion catalyzer, water Time, 48 hours

Temp., $^{\circ}\text{C.}$ ($\pm 10^{\circ}$)	Soluble	Form of GeO_2 used Insoluble Forms present in product	Fused
140	S	I	S, F
180	I	I	S
220	I	I	S, I
260	I	I	I
320	I	I	I
345	I	I	I
450	I	I	I
550	I	I	I

NOTATION: S, soluble crystalline GeO_2 ; I, insoluble crystalline GeO_2 ; F, fused GeO_2 . The more abundant form is listed first.

From these data it is evident that throughout the range studied the insoluble modification of germanium dioxide is stable since it remains unchanged while the soluble and fused dioxide tend to invert to it. At 180° and above, this hydrothermally catalyzed inversion of the soluble crystalline form is completed in forty-eight hours or less. The crystals of insoluble oxide formed, while always very small, are larger the higher the temperature of the inversion. In accordance with Ostwald's rule, the metastable soluble crystalline modification appears as an intermediate product in the process of conversion of the fused oxide to the insoluble oxide at 180 and 220° . No new crystalline form was observed in any of the preparations.

Inversions by the Fusion-Quenching Method.—Since the bomb could not be employed above 550° , it was necessary to use another experimental method to explore the temperature range up to the melting point of germanium dioxide, which was known to be somewhat above 1100° . The addition of a suitable fused salt has been found to accelerate certain sluggish inversions sufficiently to make the equilibrium relations readily ascertainable by a quenching method. Fenner¹¹ employed sodium tungstate for this purpose in working out the stability diagram for silica,

¹¹ Fenner, *Am. J. Sci.*, **36**, 331 (1913).

and van Nieuwenburg and de Nooijer¹² determined the efficiency of a large number of substances for catalyzing the inversion of quartz to tridymite at 1000°.

To ascertain the best catalyst to use for studying the inversions of germanium dioxide in the range of 550 to 1100°, a series of preliminary experiments with sodium tungstate, sodium molybdate, potassium bisulfate, anhydrous magnesium chloride, boric acid and the alkali chlorides were tried. The eutectic melt mixture of potassium chloride and lithium chloride, containing 44.6% by weight of lithium chloride, and melting at 358°, was found to be the most satisfactory. Using this flux a systematic examination of the stability relations of the various forms of the oxide between 550 and 1100° was made according to the following procedure.

Mixtures of each modification of germanium dioxide and the catalyzing flux were prepared in platinum crucibles by evaporating to dryness a suspension of the oxide in 2-3 cc. of water containing the requisite amount of chlorides. The covered crucibles were held at the desired temperature in a muffle furnace which could be maintained constant within $\pm 10^\circ$ for periods varying from one-half to thirty-six hours, according to the temperature employed. In some instances it was necessary to carry out several experiments at a single temperature before a satisfactory combination of conditions with respect to relative amounts of oxide, flux and time of heating was obtained. Of the conditions tried, those reported in Table III were the most effective. After the ignition the samples were quenched in ice water and were washed free from chlorides with hot water. The phases present were ascertained by examination under the microscope and by determination of their solubility in hydrofluoric acid.

8	.05	.0005	0.5	1060	S	I, S	S

These data show that the two crystalline modifications of germanium dioxide are enantiotropic with the reversible inversion point lying between

¹² Van Nieuwenburg and de Nooijer, *Rec. trav. chim.*, **47**, 627 (1928).

1020 and 1060°. At 1020°, and below, the insoluble form persists unaltered, while the soluble crystals and the glass are both more or less completely transformed to it. At 1060°, on the contrary, the insoluble oxide, as well as the fused oxide, invert into the soluble crystalline modification while the latter undergoes no change. The fused oxide, at temperatures at which the insoluble modification is stable, does not as a rule pass directly into the insoluble form, but yields the metastable soluble crystals as an intermediate phase in accordance with Ostwald's law of successive reactions.

In order to fix the temperature of the inversion point more closely, an improved technique was employed. Mixtures of the various modifications with the potassium chloride-lithium chloride flux were heated in small platinum thimbles suspended in the center of a platinum-wound resistance furnace of the type in use at the Geophysical Laboratory.¹³ The thimbles were supported so that the tip of the platinum-platinum-rhodium thermocouple used for measuring the temperature was just above the charge. Throughout the series of experiments the relative amount of catalyst and the time of heating were kept as low as was compatible with decisive results. Fluctuation of the temperature during an experiment never exceeded $\pm 3^\circ$. The charges were quenched, washed and dried and the phases present were identified.

TABLE IV
QUENCHING EXPERIMENTS TO LOCATE INVERSION POINT
Flux: 55.4% KCl, 44.6% LiCl

Experiment	GeO ₂ , g.	Flux, g.	Time, hours	Temp., °C. ($\pm 5^\circ$)	Form of oxide used

10	.10	.001	1.0	1110	Glass	

^a By weighing residue insoluble in hydrofluoric acid.

It is evident from these data that at 1028° and below, the insoluble germanium dioxide is stable, at 1038° and above the soluble modification is stable, while at 1033° the two forms exist in equilibrium. Allowing for

¹³ Shepherd, Rankin and Wright, *Am. J. Sci.*, **28**, 308 (1909).

uncertainties introduced by errors in calibration and temperature measurement, and for the difficulty of deciding the exact point of discontinuity of stability, the inversion point, Insoluble crystalline $\text{GeO}_2 \rightleftharpoons$ Soluble crystalline GeO_2 , may be concluded to be $1033 \pm 10^\circ$.

Experiment 10 at 1110° yielded a clear glass due to the lowering of the melting point of germanium dioxide by the presence of the flux. Experience with the chloride mixture as a catalyzing flux justifies the belief that it is exceedingly conducive to the transformation of germanium dioxide to the most stable phase. Since in experiments 5 to 9 the soluble crystalline modification persisted unchanged, it may be concluded that this form is stable between 1033° and the stable melting point.

Determination of the Melting Points.—Germanium dioxide has a strong tendency to supercool and superheat and therefore the quenching¹⁴ method for the determination of melting points was used. The procedure consisted, essentially, in holding samples at various different constant temperatures in the vicinity of the melting point, quenching them and observing the phases present. The platinum-wound resistance furnace used for the determination of the inversion point was again employed and was maintained at temperatures constant to $\pm 1^\circ$. The data obtained for the two forms of the dioxide are given in Tables V and VI.

TABLE V
DATA FOR MELTING POINT OF SOLUBLE CRYSTALLINE GeO_2

Experiment	Time of heating, hours	Temp., $^\circ\text{C}$. ($\pm 3^\circ$)	Phases in product
1	2	1107.5	S
2	2	1110.0	S, some glass
3	2	1112.5	S, partly glass

5	.5	1087.5	Glass, S
6	.5	1090.0	Glass, S

If the melting point of soluble crystalline germanium dioxide be taken as the lowest temperature at which the crystalline phase vanishes, and allowance be made for all possible sources of error in the measurements,

¹⁴ Morey, *J. Wash. Acad. Sci.*, **13**, 326 (1923)

it follows from the data in Table V that the melting point may be reported as $1116 \pm 4^\circ$. This agrees well with the value $1115 \pm 3^\circ$ reported by Schwartz, Schenk and Giese,¹⁵ who also used the quenching method.

At the melting point of insoluble germanium dioxide both it and the liquid phase are metastable and there is the possibility of melting to metastable glass, of inverting directly to the stable soluble dioxide, or of changing through the glass phase to the stable soluble dioxide. It is possible to determine the metastable melting point of insoluble germanium dioxide because the second and third of these transformations proceed more slowly than the first. In the experiments recorded in Table VI the time of heating was so regulated as to be long enough to realize approximately the metastable equilibrium between liquid and insoluble germanium dioxide, but not long enough to admit of much displacement toward the stable soluble crystalline germanium dioxide. The melting point of insoluble crystalline germanium dioxide may, therefore, be taken as the temperature at which the last traces of insoluble crystals disappeared, or $1086 \pm 5^\circ$.

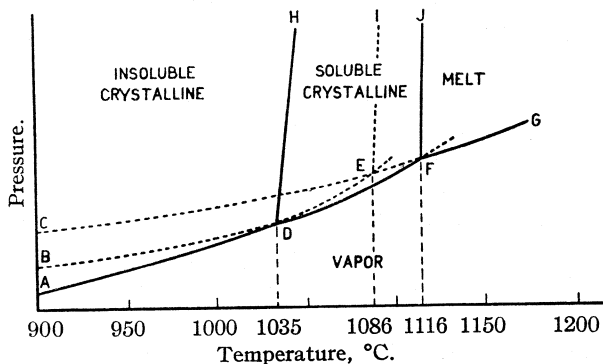

Fig. 1.—Phase diagram of germanium dioxide.

Phase Diagram of Germanium Dioxide.—On the basis of the experimental study it is possible to construct a pressure-temperature diagram of phase equilibria in the one-component system, germanium dioxide. Fig. 1 represents the more important portion of such a diagram. The pressure coordinates have only qualitative significance. Curves ADE, BDF and CEF are the vapor pressure curves of the insoluble, soluble and fused modifications, respectively. They are constructed on the principle that the form having the lowest vapor pressure is the stable form at a given temperature. The curves intersect at D, the inversion point; F, the melting point of the soluble crystalline modification; and E, the metastable melting point of the insoluble modification. The

¹⁵ Schwartz, Schenk and Giese, *Ber.*, **64**, 364 (1931).

lines DH, EI and FJ represent the probable mode of variation of the inversion point and melting points with pressure. From the relative densities of the three forms, it follows that each of these lines has a positive slope; and unless, as is very unlikely, the heat of inversion is considerably greater than the heat of fusion, line DH makes the greatest angle with the axis of pressures.

Improbability of a Third Crystalline Modification.—From the fact that the soluble crystalline form undergoes no inversion when heated with a flux at temperatures between 1033 and 1090°, and that it persists unchanged at temperatures just below its melting point, we have inferred that no third enantiotropic crystalline modification of germanium dioxide exists. This does not exclude the possibility of a monotropic modification, but, if such a form occurs, it has not appeared in appreciable amount in any of our preparations.

Müller and Blank⁵ have postulated the existence of three crystalline modifications of germanium dioxide to explain the fact that only a limited fraction of their "evaporated" oxide can be converted to the insoluble form, no matter how long the material is heated, and the fact that this maximum yield varies with different preparations according to the conditions of evaporation. They suggest that the residue from the evaporation of the aqueous solution is not homogeneous, but contains two soluble modifications, one of which undergoes rapid transformation to the insoluble form while the other inverts very slowly if at all.

The presence of two crystalline modifications, however, was not borne out by the x-ray patterns Müller obtained nor by the patterns secured for similar material in the course of the present investigation, although, according to Müller's theory, from 15 to 20% of the third form should be present.

Another explanation for Müller's results, which does not require the existence of a second soluble crystalline modification, may be suggested. The "evaporated" oxide used in the experiments of Müller and Blank always contained moisture. In view of our own hydrothermal experiments, it appears that this moisture should catalyze the inversion. The inversion will be incomplete because the process stops as soon as the moisture has been expelled. The hypothesis that the presence of moisture is necessary to bring about the inversion may also account for the peculiar form of Müller and Blank's yield-temperature curve, which shows an apparent maximum rate of transformation at 380°. At low temperatures, the rate of inversion is itself small, regardless of the amount of water present. At high temperatures, the excess moisture is expelled before the inversion has progressed very far. At 380° the rates of inversion and of evaporation of the water are so related that the amount of inversion in a given time is a maximum.

It is still necessary to explain why different preparations of the "evaporated" oxide, under identical conditions, show different yields of the insoluble modification, and also why the "hydrolyzed" oxide, which ordinarily contains more water than the "evaporated" variety, is not converted at all upon ignition. It is possible that the "evaporated" oxide, although consisting mainly of the soluble modification, contains also nuclei of the insoluble crystals, formed during the protracted evaporation, which serve as centers of crystallization under conditions favoring a transformation. If these nuclei are sufficiently small, they may be numerous and still escape detection by x-ray analysis, microscopic examination, or solubility tests. The amount of conversion of two different samples, similarly treated, will depend on the comparative number of "insoluble" nuclei initially present in each sample, as well as on the amount of water present. The "hydrolyzed" oxide, having been precipitated from solution by a rapid chemical reaction, may conceivably contain no "insoluble" nuclei whatever.

It is very doubtful whether a third monotropic crystalline modification of germanium dioxide exists. There is no direct evidence of its existence, and the indirect evidence offered by Müller and Blank can, as we have shown, be otherwise interpreted. Recently Schwartz and Huf¹⁶ have reported that solubility measurements for the various forms of germanium dioxide do not warrant the assumption of the existence of a third crystalline modification.

III. Properties of the Crystalline Forms

The existing data concerning the properties of the crystalline modifications of germanium dioxide were so incomplete and, in some cases, so contradictory, that it appeared desirable to determine systematically the more important physical and chemical properties.

Crystal Structure.—Zachariasen's³ analysis of the crystal structure of the soluble crystalline modification has already been cited in the introduction to this article. A table of sine-squares which we calculated from measurements of x-ray powder diffraction photographs of this form agreed closely with his values.

The crystal structure of the insoluble modification of germanium dioxide was determined¹⁷ entirely from x-ray powder diffraction photographs, taken with a General Electric x-Ray Diffraction Apparatus of the type described by Davey.¹⁸

¹⁶ Schwartz and Huf, *Z. anorg. allgem. Chem.*, **203**, 188 (1932).

¹⁷ The authors are indebted to Prof. C. C. Murdock, of the Department of Physics, for his kind assistance in obtaining the x-ray patterns and in the solution of the crystal structure.

¹⁸ Davey, *J. Optical Soc. Am.*, **5**, 479 (1921).

It was found that the fundamental lattice is simple tetragonal, with $c/a = 0.649 \pm 0.002$, and that the dimensions of the unit cell are

$$a_0 = 4.395 \pm 0.010 \text{ \AA.}, \quad c_0 = 2.852 \pm 0.015 \text{ \AA.}$$

The observed interplanar distances corresponding to the first twenty-five lines on the film agreed well with the distances calculated from these parameters.

To correspond to the observed density, 6.239 g./cc., there must be two molecules of GeO_2 in the unit cell. The calculated density is then 6.26 ± 0.06 g./cc.

These data support the hypothesis, already suggested by Zachariasen,¹⁹ that the insoluble modification of GeO_2 has the "rutile" type of structure. In this structure the unit cell is a tetragonal prism, and contains two molecules. The centers of the two metal ions are at $(0, 0, 0)$ and $(\frac{1}{2}, \frac{1}{2}, \frac{1}{2})$, while those of the four oxygen ions are at $(u, u, 0)$, $(\frac{1}{2} - u, \frac{1}{2} + u, \frac{1}{2})$, $(\frac{1}{2} + u, \frac{1}{2} - u, \frac{1}{2})$ and $(1 - u, 1 - u, 0)$. For rutile, $u = 0.30 \pm 0.01$. The space group is D_{4h}^{14} .

Powder diffraction patterns of insoluble GeO_2 and rutile were photographed beside each other on the same film. The patterns were very similar; for every line in one pattern there was a corresponding line in the other, having, usually, about the same relative intensity. The odd order reflections from the 100, 001 and 201 planes were absent from both patterns.

The theoretical intensities of the lines in the pattern of GeO_2 , for an assumed rutile type of structure, were calculated and compared with the experimental values. In the calculations, the general formula for powder patterns,²⁰

$$I_{hkl} \propto F^2 s \frac{1 + \cos^2 2\theta}{\sin^2 \theta \cos \theta} \quad (1)$$

and the atomic scattering powers of O^{2-} , Ti^{4+} and Ge given by James and Brindley,²¹ were employed. The intensities were obtained, not by comparing the lines of the pattern of GeO_2 with each other, but by comparing each GeO_2 line with its counterpart in the pattern of rutile, the intensity of which was calculated from the known crystal structure by formula (1). The observed intensities, and those calculated using values of u from 0.26 to 0.34, are listed in Table VII. All values are expressed as percentages of the intensity of the 002 reflection. The lines beyond those listed were, with few exceptions, too faint to allow of accurate estimates of intensity.

The general agreement between calculation and experiment is best

²¹ James and Brindley, *Z. Krist.*, **78**, 470 (1931).

for $u = 0.30$, and appears close enough to confirm the assumption of the rutile type of structure for insoluble GeO_2 . Values of u below 0.28, or above 0.32, appear to be excluded: otherwise the 120 line would be invisible or else decidedly more intense than the 400 line.

TABLE VII

COMPARISON OF THE THEORETICAL AND OBSERVED INTENSITIES OF THE LINES IN THE POWDER PATTERN OF INSOLUBLE GeO_2

Obs. spacing, Å.	Indices	Obs. intensity	Calculated intensity				
			$u = 0.26$	0.28	0.30	0.32	0.34
3.10	110	1500	1162	1197	1267	1371	1504
2.390	101	920	1043	929	825	730	647
2.194	200	320	144	158	185	228	287
2.104	111	130	126	118	104	85	65
1.965	120	30	2	13	30	47	56
1.618	121	910	700	759	799	812	788
1.556	220	220	268	252	224	194	168
1.424	002	100	100	100	100	100	100
1.389	130	160	203	191	172	152	139
1.299	301 112	660 ^a	348	392	433	464	479
1.195	202	40	59	62	69	80	93
1.117	231	100	172	140	125	128	147
1.096	400	50	76	68	55	41	31

^a Probably too high. The intensity of this compound line is really not comparable with that of the corresponding line in the pattern of rutile, because the component lines in the case of rutile do not fully coincide, on account of its lower axial ratio.

While the sequence of intensities of the lines in the patterns of GeO_2 and of rutile was, for the most part, the same, there were certain exceptions. Of these, the most striking was in the case of the lines 200, 111 and 120. For GeO_2 , $I_{200} > I_{111} > I_{120}$; for TiO_2 , $I_{111} > I_{120} > I_{200}$. This difference in order is accounted for by the difference in the scattering powers of the titanium and germanium ions, and does not necessitate any difference in the ionic arrangement. This is shown in Table VIII, in which the values of F^2s (formula (1)), for a rutile structure with $u = 0.30$ are given.

TABLE VIII

Reflection	F^2s	
	GeO_2	TiO_2
200	3615	522
111	2216	2413
120	740	810

It is concluded that the arrangement of ions in the unit cell of insoluble GeO_2 is of the rutile type, and that the value of the parameter u is 0.30 ± 0.02 .

Drawings of this structure are given by Wyckoff.²² Each germanium ion is surrounded by six oxygen ions, whose centers lie at the corners of a somewhat distorted octahedron. The shortest Ge—O distance is 1.86 Å.;

²² Ref. 20, p. 231.

and the effective radius of the Ge^{4+} ion, on the basis of 1.32 Å. for the radius of the oxygen,²³ is 0.54 Å.

Optical and Crystallographic Properties.—Specially selected, well-defined crystals of both modifications were kindly examined for us under the microscope by Professor C. W. Mason, who reports on them as follows:

"Soluble GeO_2 .—Well-formed approximately cubical crystals, which are rhombohedra of the hexagonal system. They show strong double refraction and symmetrical extinction, and yield uniaxial positive interference figures. $\omega = 1.695 \pm 0.005$; $\epsilon = 1.735 \pm 0.005$.

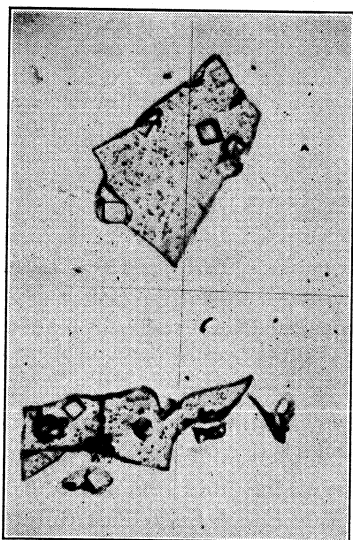

Fig. 2.—Soluble crystalline germanium dioxide.

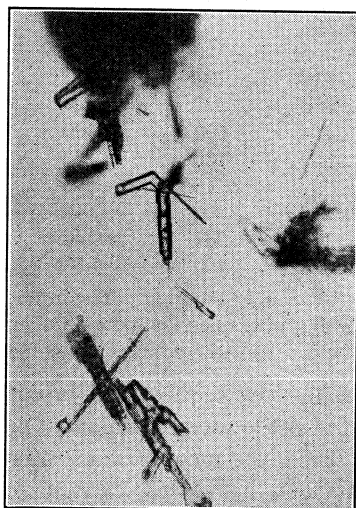

Fig. 3.—Insoluble crystalline germanium dioxide.

"Insoluble GeO_2 .—Clusters and rosetts of prisms and lath-shaped forms, also very fine needles. Some knee turns. The surfaces of the larger crystals are rough and apparently eroded. End faces of definite form are not evident. Double refraction is strong, with the sign of elongation and parallel extinction exhibited by all side views of the prisms. The crystals belong to the tetragonal system. $\omega = 1.99$, $\epsilon = 2.05$ –2.10 (estimated)."

Photomicrographs of the samples examined are reproduced in Figs. 2 and 3. The crystals of the soluble oxide, which are embedded in the fused oxide, were produced by heating the insoluble modification for two hours at 1100°. It would appear that the insoluble oxide melted almost immediately; but the melt was unstable with respect to the soluble modification, which accordingly crystallized out.

²³ Goldschmidt, "Geochemische Verteilungsgesetze," Oslo, Vol. VII, 1926, p. 15.

The specimen of insoluble germanium dioxide shown in Fig. 3 was isolated by extracting with hydrofluoric acid the product of heating the soluble oxide with 1% of its weight of potassium chloride-lithium chloride mixture at 1020°. It contained numerous elbow twins, like the one appearing in the photograph, with an angle of $114 \pm 1^\circ$ between the two members. On the assumption that in these twins the components lie on 010 faces and are joined on the 011 plane, the axial ratio c/a calculated from this angle is 0.65 ± 0.015 , thus confirming the x-ray value, 0.649. Contact twins of this type are often observed on rutile and cassiterite.²⁴

Density.—The values for the density of soluble crystalline germanium dioxide given by different investigators are very discordant, probably due to the difficulty in securing well-crystallized, homogeneous samples.

The densities of our preparations of soluble and insoluble crystalline germanium dioxide were determined pycnometrically, using toluene as the immersing liquid. The samples were dried to constant weight at 950° immediately before each determination. All weighings were corrected to vacuum. The results of duplicate determinations are given together with the value secured by x-ray methods by Zachariasen for the soluble oxide and that obtained by x-ray methods in the present investigation for insoluble germanium dioxide.

TABLE IX

Modification	(1)	Density at 25° (2)	Av.	x-Ray density
Soluble crystalline GeO ₂	4.233	4.224	4.228	4.28
Insoluble crystalline GeO ₂	6.234	6.244	6.239	6.26

It will be noticed that in both cases the difference between the pycnometric and x-ray densities is slight and is in the expected direction, inasmuch as the value measured directly tends to be lowered by the presence of voids in or between the crystals. The samples used by the authors in the determinations cited above consisted of well-formed crystals of appreciable size. When less perfectly crystallized material was used the results were always lower.

Solubility in Water at 25°.—Solubility determinations were made by agitating the solid with water in a Pyrex glass flask in a thermostat until equilibrium was established and then evaporating a given weight of the saturated solution to dryness and weighing the residue; 4.53 g. of soluble crystalline germanium dioxide was found to dissolve in 1000 g. of water at 25°. This is in good agreement with the value 4.47 g. per 1000 g. of water at 25° reported by Pugh.²⁵ The insoluble crystalline modification was not appreciably soluble.

²⁴ Groth, "Elemente der physikalischen und chemischen Krystallographie," 1921, p. 200.

²⁵ Pugh, *J. Chem. Soc.*, 1537 (1929).

Chemical Properties.—Samples of 0.2 g. of the insoluble crystalline oxide, previously dried at 950°, were digested on the steam-bath with 10 cc. of each of the following reagents: 25 *N* hydrofluoric acid, 12 *N* hydrochloric acid, 36 *N* sulfuric acid and 5 *N* sodium hydroxide. After one hour the undissolved residue was separated from the liquid by decantation and filtration, and was washed, ignited and weighed. There was no appreciable solution in any of the three acids, but in the case of the 5 *N* sodium hydroxide, the losses in weight of the sample, in two determinations, were 16.8 and 17.8%, respectively. These figures were corroborated by determining the amount of germanium dioxide in the filtrate and washings by the method of Johnson and Dennis.²⁶ Contrary to the statement of Müller and Blank²⁷ the insoluble oxide is not wholly unattacked by hot alkaline solutions. The rate of solution, however, is slow compared with that of the soluble crystalline form.

In similar tests, the soluble modification was rapidly attacked by 25 *N* hydrofluoric acid, 12 *N* hydrochloric acid and 5 *N* sodium hydroxide, but scarcely at all by 36 *N* sulfuric acid.

The insoluble oxide reacted readily when fused with ten times its weight of sodium hydroxide at 550°, or with five times its weight of sodium carbonate at 900° or above. In both cases the melt was completely soluble in water.

To facilitate comparison, the properties of the two crystalline forms and of the glass are tabulated in Table X. The information on the glass is as given by Dennis.²⁸

TABLE X
PROPERTIES OF GERMANIUM DIOXIDE

	Insoluble crystalline	Soluble crystalline	Glass
Crystal system	Tetragonal	Hexagonal	Amorphous
Crystal structural type	Rutile	Low-quartz	
Density at 25°, g./cc.	6.239	4.228	3.637
x-Ray density, g./cc.	6.26	4.28	
Indices of refraction	$\omega = 1.99$ $\epsilon = 2.05\text{--}2.10$	$\omega = 1.695$ $\epsilon = 1.735$	1.607
Inversion point	1033 \pm 10°	1033 \pm 10°	
Melting point	1086 \pm 5°	116 \pm 4°	
Solubility at 25°, g./1000 g. H ₂ O	Insoluble	4.53	5.184 g./l. (at 30°)

Discussion

Morphotropic Relationships.—A classification of the dioxides of the elements of group IV according to crystal structures is given in Table XI. The soluble or high-temperature modification of germanium dioxide is isomorphous with low-quartz, while the insoluble or low-temperature modification is isomorphous with the dioxides of tin and lead.

TABLE XI

CRYSTAL STRUCTURES OF DIOXIDES OF GROUP IV	
Hexagonal low-quartz structure	Tetragonal rutile structure
Low-quartz, SiO_2 (below 575°)	Insoluble GeO_2 (below 1033°)
Soluble GeO_2 (above 1033°)	Cassiterite, SnO_2
	Plattnerite, PbO_2

It is thus evident that the effect on the crystal structure of germanium dioxide of raising the temperature is the same as that of substituting a small cation for the germanium.

The occurrence of two modifications of germanium dioxide is in accordance with Goldschmidt's²⁹ views on the relation of the crystal structures of compounds of the type AX_2 to the ratio of the ionic radii. The geometrical boundary between structures with coordination numbers 2 and 4, such as the low-quartz type, and those with coordination numbers 3 and 6, such as the rutile type, is at $r_A/r_X = 0.414$. Taking our value of 0.54 \AA . for the radius of the germanium ion, and Goldschmidt's value of 1.32 \AA . for that of the oxygen ion, $r_{\text{Ge}}/r_{\text{O}} = 0.409$. That is, the ionic radial ratio for germanium dioxide is so close to the theoretical boundary between the two structural types that the compound can assume one structure or the other, depending on external conditions of temperature and pressure.

The value of 0.44 \AA . given by Goldschmidt for the radius of the germanium ion is evidently too low. It is to be noted that Pauling's calculated value is 0.53 \AA .

Summary

1. The polymorphism of germanium dioxide is confirmed and methods of preparing the soluble and insoluble modifications in a well-crystallized condition are described.

2. Inversion from either crystalline modification to the other is shown to be of the sluggish type. By the use of the quenching method with an accelerating flux, it is shown that the two modifications are enantiotropic, with the inversion point at $1033 \pm 10^\circ$.

3. Using the quenching method, the stable melting point of the soluble modification, $1116 \pm 4^\circ$, and the metastable melting point of the insoluble modification, $1086 \pm 5^\circ$, have been determined.

²⁹ Goldschmidt, *Trans. Faraday Soc.*, **25**, 253 (1929).

4. The phase relations in the one-component system germanium dioxide are represented diagrammatically and are discussed.

5. From a consideration of the available evidence, it is concluded that a third crystalline modification of germanium dioxide probably does not exist.

6. The crystal structure of the insoluble modification, and the density, solubility, indices of refraction and chemical activity of both modifications have been determined.

7. A discussion of the crystallo-chemical relationships of germanium dioxide to the dioxides of the other elements of the fourth periodic group is submitted.

THE SPARK-IN-FLAME METHOD OF SPECTROGRAPHIC ANALYSIS AND A STUDY OF THE MUTUAL EFFECTS OF ELEMENTS ON ONE ANOTHER'S EMISSION¹

BY RALPH HULTGREN

RECEIVED FEBRUARY 15, 1932

PUBLISHED JUNE 6, 1932

Introduction

In recent years the development of methods for the use of the spectrograph as an instrument for the quantitative as well as qualitative chemical determination of elements has proceeded to such an extent that they may now be regarded as suitable for application to many microchemical problems. While spectrographic methods cannot in general compete with ordinary chemical quantitative analysis in point of accuracy, they possess two important advantages which make them of great value in many special cases. These are great sensitivity, which permits of the semi-quantitative estimation of amounts of material too small to be analyzed by other methods, and the great rapidity with which an analysis can be conducted. For details of procedure, accuracy of estimation, etc., the reader is referred to the literature.²

The three principal means of exciting emission spectra which have been used in quantitative analysis are the electric arc, the spark and the flame. The arc and spark methods combine the advantages of a high and to some extent controllable excitation with certain drawbacks. While the high

¹ Original manuscript received August 19, 1931.

² F. Löwe, "Handbuch der Physik," **21**, 663 (1929); H. Lundegårdh, "Die quantitative Spektralanalyse der Elemente," G. Fischer, Jena, 1929; Eugen Schweitzer, *Z. anorg. Chem.*, **164**, 127 (1927); Walter Gerlach, *ibid.*, **142**, 383 (1925); A. de Gramont, *Bull. soc. chim.*, **33**, 1693 (1923).

excitation makes the method applicable to a large number of elements, and gives a great sensitivity, the difficulty of uniformly introducing representative samples of the material to be analyzed into the spark or arc gases, and the fact that the emission of one element is not independent of the other elements present, lead to some difficulties. These do not seem to be serious in the cases to which the arc and spark methods are usually applied, that is, in the estimation of traces of impurity in a large and nearly constant amount of some other substance, but they impose serious limitations in case that all of the substances in the unknown samples vary largely in relative amounts. The flame method, while very reproducible and nearly free from the objections just cited,² is limited in applicability to those few elements which have relatively low excitation potentials.

Purpose of the Investigation.—

It was the object of the work here described to devise a method of spectroscopic analysis which would retain the advantage of the flame method but overcome some of its limitations by allowing a higher excitation. It was further proposed to study the mutual effects of some elements on each other's emission with a view toward finding conditions under which these are small, so that unknown samples containing several elements might be analyzed without extensive calibration experiments.

Description of Method and Apparatus

The Method.—After some preliminary experiments the following method was found promising. The difficulties inherent in the ordinary spark methods of vaporizing representative portions of the sample to be analyzed were overcome by atomizing solutions of the sample into a hot flame, in the customary way. The excitation in the resulting gases was then increased by passing

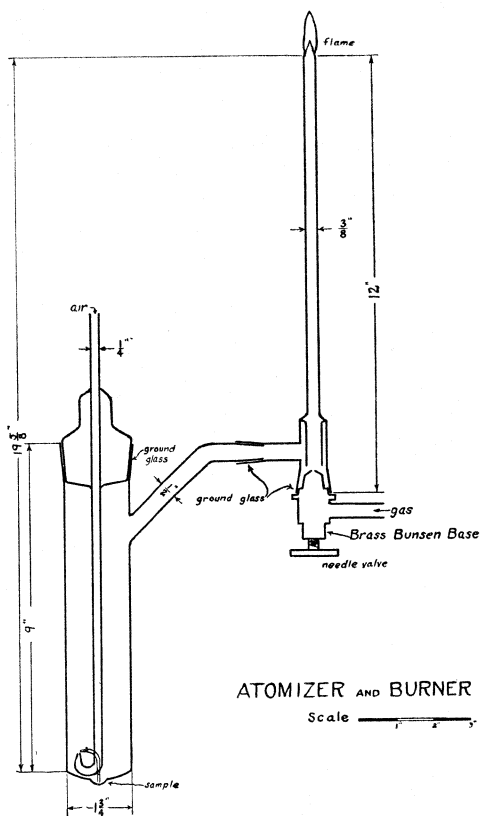

Fig. 1.—Atomizer and burner used for introduction of sample into flame.

through them a condensed discharge.

The Burner and Atomizer.—Figure 1, which represents the burner and atomizer, is self-explanatory. All parts were of Pyrex glass except the jet admitting gas into the

burner, which was of brass. The design was such as to yield a steady flame and to introduce as large a quantity of solution as possible into the flame gases in finely divided drops. Any large drops produced by the spray deposit on the walls of the atomizer vessel and run back quickly, reducing the volume of solution necessary for an analysis to about 3 cc.

The Spark.—The electrical circuit is shown in Fig. 2. The transformer finally used was a 2 k.v.a. American transformer operating on 220 volts and yielding 25,000 volts in the secondary. With this equipment an exposure time of one minute was usually sufficient. A smaller transformer gave nearly as good results with a longer exposure.

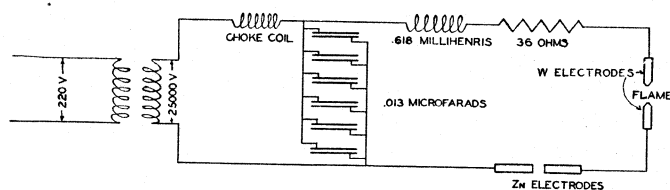

Fig. 2.—Electrical circuit for production of spark-in-flame.

The condenser consisted of 30.5×35.6 cm. plates of heavy window glass on both sides of which 25.4×30.5 cm. sheets of copper foil were cemented with shellac. Six plates were used and the capacity measured by a comparison method was found to be 0.013 microfarad. The inductance consisted of copper wire wound on three Pyrex glass cylinders covered with friction tape. The calculated inductance was 0.618 millihenris. With the combination of inductance and capacity given, the air lines were eliminated in the spark, and the intensity of the general background was not disturbing.

It will be noted in the diagram that an auxiliary spark gap and a fixed resistance were included in the secondary circuit. The former was found desirable since in its absence breakdown occurs at a very low potential due to the high conductivity of the flame gases. The latter serve to minimize variations due to changes in the conductivity of the flame when varying amounts of elements of low ionization potential were introduced into it, as shown in Table I.

TABLE I
EFFECT OF RESISTANCE WIRE, IN SERIES WITH SPARK, ON SECONDARY CURRENT

Solution used for sample	Secondary current	
	Without resistance wire	With 8' 4" res. wire (54 ohms)
Distilled water	3.05	1.58
2 Molal NaCl	1.3	1.5

The Flame.—The fuel in the flame was hydrogen gas saturated with acetone vapor, which gave a very stable flame little affected by the introduction of large amounts of foreign substances. The city gas available is a natural gas and was found quite unsuitable since it burns with a very unstable flame. It is probable, however, that most types of manufactured city gas would work satisfactorily without modification.

The Electrodes.—It was found possible in the following way to produce a spark which over a fairly wide region in its center was completely free from any lines due to the material of the electrodes. Tungsten electrodes 10–12 mm. apart were used, and these projected slightly into the flame from opposite sides. The tungsten vapor evolved is swept away by the flame gases and does not penetrate into the center of the flame. The spark was always passed just above the blue cone of the flame. Tungsten lines are apt to appear if the spark is too far above the cone. No improvement in sensitivity

was noted with closer electrodes, but tungsten lines appeared. The flame was made slightly "lean" in gas. The electrodes of the auxiliary spark were about 7 mm. apart.

Optical Arrangement.—A Bausch and Lomb quartz prism spectrograph was employed which has a dispersion of about 10 Å. per millimeter at $\lambda 2800$. The center of the spark was focused on the slit by means of a cylindric quartz lens, which was found to give a fairly uniform distribution of intensity over the entire slit.

Sensitivity and Excitation.—The excitation obtained under the conditions described above approximates what should be expected in a very high temperature flame. Lines of very high excitation potential which do appear in the spark are not obtained, but, on the other hand, many lines appear, especially at high concentrations, which are so weak in flames that they are not photographed under ordinary conditions. For example, Mg $\lambda 2795$, Mg $\lambda 2802$, and B $\lambda 2479$ appear strongly, and fourteen lines of Na, Mg, Zn, Au, Cd and Tl have been identified which did not appear in the flame in comparison experiments and are absent in the acetylene flame spectrograms of Lundegårdh.² The water and cyanogen bonds, of course, occur in the spectra obtained but on the whole the plates are cleaner and freer of background than those printed by Lundegårdh.

Photometry.—Since the purpose of the work outlined was to compare quantitatively the intensities of pairs of lines in the spark under various conditions, it was necessary to develop a method of rapid photometry. The intensities of two light sources are ordinarily compared photographically by cutting down one or both in a known way until the images which they produce on the photographic plate have the same density. This is most conveniently done by the use of rotating sectors, which are easily constructed and require no calibration. Calibration of wedges over a range of wave lengths is very laborious and screens could not be used in the present work.

The rotating sector has been condemned by some authorities because two effects, the "failure of the reciprocity law" and the "intermittency effect" may introduce large errors, but under certain conditions of operation these are found to counteract each other to a large extent,³ and within sufficient accuracy the intensities of two lines of the same density are inversely proportional to the sector opening. It is necessary that the sector speed be maintained above a certain minimum (120 r. p. m. is sufficient), that the plates used are not too "slow," and that the total exposure time be kept constant. For an intermittent source such as the electric spark, the time of a single opening of the sector should be large in comparison to the duration of the flash, and to the time between flashes.

A step sector wheel was constructed similar to that shown in Fig. 3 except that it had three times as many steps with the same total range of opening. Each opening is the cube root of two times the one below it, corresponding to a 26% increase of exposure, except for a correction which had to be made due to the fact that the cylindrical lens did not give a quite

³ (a) Weinland, *J. Optical Soc. Am.*, **15**, 337 (1927); (b) Weinland, *ibid.*, **16**, 295 (1928); (c) Weber, *Ann. Physik*, **45**, 801 (1914); (d) Howe, *Phys. Rev.*, **8**, 674 (1916); (e) Newcomer, *Science*, **49**, 241 (1919); (f) Rossler, *Ber.*, **59**, 2606 (1926); (g) Gibson and co-workers, Scientific Papers of the Bureau of Standards, No. 440 (1922).

uniform illumination over the entire slit. This sector was mounted as close as possible in front of the spectrograph slit and rotated at about 120 r. p. m. Every image of a spectral line of the plate then consists of a series of sections one above the other, of which the effective exposure increases logarithmically from the bottom to the top of the line.

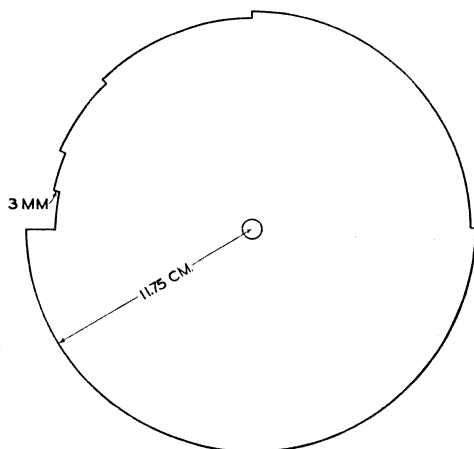

Fig. 3.—Rotating sector wheel used with photoelectric photometer.

If for a given spectral line the densities of the “sections” are plotted against the logarithms of the corresponding sector openings, a curve results whose shape depends on the characteristics of the plate and the development. Two spectral lines, sufficiently close so that the sensitivity and contrast of the plate are the same for both, will give curves of similar shape, but one will be displaced horizontally

with respect to the other by an amount equal to the logarithm of the ratio of the intensities of the two lines in the source (see Fig. 4).

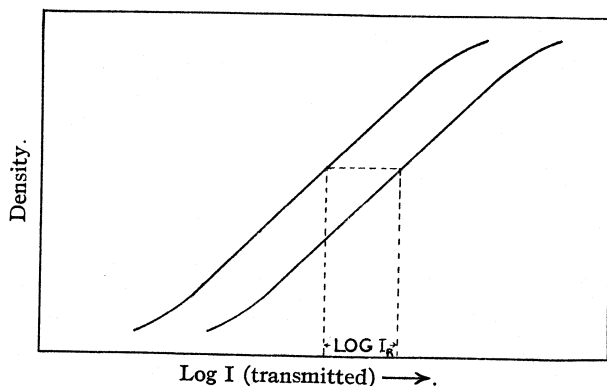

Fig. 4.—Typical intensity-photographic plate density curves for two sources of different intensities.

In practice, however, what one measures is an intensity due partly to the line emission of an element and partly to a continuous background which overlies the whole spectrum, and a correction must usually be made for the latter. It was found that where a sufficiently wide slit was used to permit of photometering the lines with an ordinary photoelectric photom-

eter, the blackening due to the background was such a large part of the total that the errors of measurement were very large.

However, it was found that the spectrograph slit could be narrowed sufficiently to make the density of the background negligible in comparison to that of the spectral lines, leaving the lines still sufficiently wide to be compared visually. When two lines were to be compared the photographic plate was cut between them, and the two portions brought into contact so that the two lines were side by side. One portion of plate was then moved up and down until opposite to one section of one line a section of the other line of equal density was found. If no exact correspondence could be found an interpolation was made. Knowing the sector openings corresponding to the sections chosen the relative intensities of the lines were easily estimated.

Two types of plates were used: Eastman D. C. Ortho with the ordinary Eastman D 61a developer, and Eastman "Regular" lantern slide plates with the contrast developer recommended. The former plates were developed for four minutes, the latter for two, stroking with a camel's hair brush, which gives exceptionally even development.

Experimental Results and Discussion

In order to make an estimate of the accuracy which might be expected of the analysis of simple solutions using the methods outlined, some intensity-concentration curves were first determined, as shown in Fig. 5. In each case the lines of the elements studied were compared with the copper line $\lambda 3247$, which was photographed by making each test solution 0.01 molal in copper nitrate. These curves should not be compared too rigorously with one another, since the plate sensitivity and contrast varies somewhat over the spectral region included.

The mutual effects which various elements have on each other's excitation were then studied. Since, as mentioned above, the atomizing of reasonable amounts of substances into a suitable flame did not appreciably change its temperature or volume, two principal effects remain to be considered. The introduction of substances of low ionization potential into the flame may be expected to change the conductivity and consequently the nature of the discharge and the excitation of all other elements present. Secondly, elements of low resonance potential when added may rob other elements of high excitation potential of their energy in collisions of the second kind, and cause their emission to be diminished.

A standard solution was prepared, 0.01 molal in copper, 0.01 molal in silver, 0.1 molal in thallium and 0.1 molal in cadmium, and the spark-in-flame spectrum of this was photographed beside the spectrum of another solution which was identical except for the addition of a rather large amount (1 molal) of a fifth element. In successive experiments this added element

was varied, elements being chosen with widely different resonance and ionization potentials. The percentage changes in the intensities of certain copper, silver and thallium lines due to the addition of the "impurity" are given in Table II. The four determinations indicate the accuracy of the intensity comparisons.

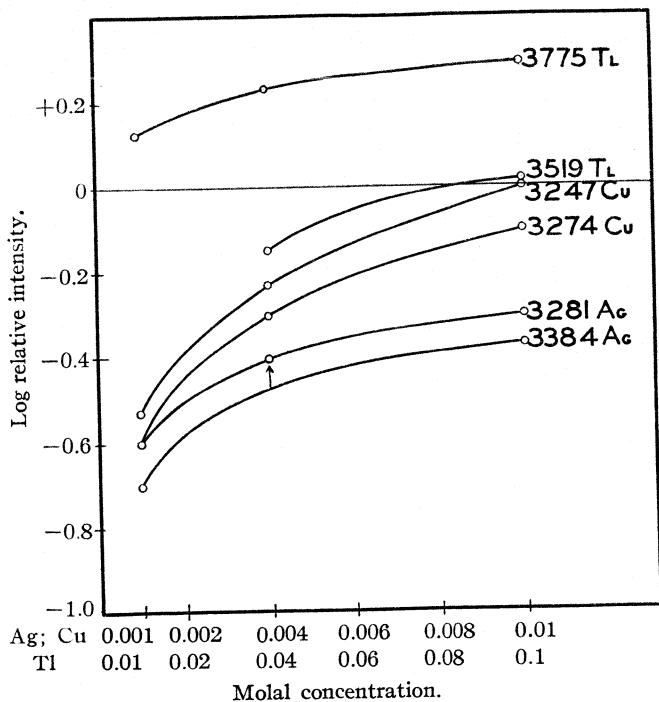

Fig. 5.—Intensity-concentration curves for several elements.

It will be noticed that the line intensities are usually increased by the "impurity" probably due to the increased conductivity of the flame gases. The last four columns of the table show the per cent. errors which these changes in intensity would cause in an analysis for copper, silver and thallium in case unknown solutions of approximately the same composition as those of the four solutions containing the "impurities" were compared directly with a test solution containing the three elements in the same concentration, but without the impurity. It will be seen that these errors are not larger than the average error of estimation except in the case of sodium.

Conclusion

One of the principal objects of the present work was to find conditions under which the spectroscopic analysis of solutions containing several elements in rather widely varying relative concentrations can be made rapidly

without elaborate calibration experiments being necessary for each special case. Since under the conditions of the spark-in-flame the mutual effects of elements are in general not large, it appears that such analyses can be carried out with moderate precision if the intensities of the lines emitted by the unknown solutions are compared directly with the concentration intensity curves which have been determined once and for all on pure test solutions of the elements in which one is interested. In case alkali metals are present in high concentration their effect can be to a considerable extent allowed for by the addition, in known concentration, of a reference element absent in the unknown. This is the method of "Leitlinien" discussed by Lundegårdh.²

Summary

1. A new method of exciting spectra for the purpose of quantitative chemical analysis has been developed and studied. It consists in passing a condensed spark discharge through a flame into which is atomized a solution of the sample to be analyzed.

2. The excitation obtained, though less than that of the ordinary spark, is similar to that which should be expected in a flame of very high temperature, and many lines appear which are absent in ordinary flame spectra.

3. The mutual effects of some elements on each other's emission in the spark-in-flame have been studied, and these have been found small enough to permit of a semi-quantitative analysis of unknown solutions containing several elements, without elaborate calibration experiments.

ACTION OF RADON ON SOME UNSATURATED HYDROCARBONS. II. PROPYLENE AND CYCLOPROPANE

By G. B. HEISIG

RECEIVED FEBRUARY 15, 1932

PUBLISHED JUNE 6, 1932

In a previous paper¹ the action of radon on five unsaturated hydrocarbons was reported. It was shown that the number of molecules condensed per ion pair formed ($-M/N$) was additive and constitutive. A method of calculating the values of $-M/N$ was devised for these hydrocarbons based on the values for ethylene and acetylene whose polymerizations had been studied previously by Lind and Bardwell.² Moreover, the writer³ has shown that the relation between the heats of formation and the $-M/N$ values may be used as a basis for predicting the approximate values of the $-M/N$.

In order to compare these two methods of predicting the $-M/N$ and to obtain further knowledge of the condensations produced by radon so that

the mechanism of the condensation process may be further clarified, the polymerization of the isomers propylene and cyclopropane was investigated.

The procedure and the methods of calculation were those used in the previous paper.¹ The results of this present work may be summarized as follows.

TABLE I

SUMMARY OF RESULTS

	P. drop of HC., mm.	% of P, drop used in calcul. of $-M/N$	$\frac{\Delta(H_2 + CH_4) \times 100}{-\Delta HC.}$	$-M/N$ Product
Propylene	501.2	96.2	14.4	4.9 Colorless mobile liquids
Cyclopropane	411.9	100.0	20.5	3.3

The method for calculating the $-M/N$ in the first paper was to neglect the hydrogen atoms involved and assign 2 for a methyl group, and 4.8 to a double bond. A substituent entering a terminal unsaturated carbon atom reduces the sum of the values by 50%. The calculated $-M/N$ of propylene is $(4.8 + 2)/2 = 3.4$. This is to be compared with an experimental value of 4.9. Cyclopropane acts both as a saturated and as an unsaturated paraffin. For example, it reacts with chlorine to give substitution products. When treated with bromine, concentrated sulfuric acid, or a 2% potassium permanganate solution, it reacts to give derivatives of propane. However, the action is very much slower than the corresponding action with propylene. In lieu of other information, cyclopropane would be expected to have a $-M/N$ which would be intermediate between that of the saturated hydrocarbon propane and that of the corresponding double bonded derivative, propylene. The $-M/N$ for propane is practically 2 and that for propylene is 4.9, which gives an average 3.5.

The $-M/N$ values increase with the increase of the negative heat of formation from atoms in their standard states, and the value for compounds with positive heats of formation is about 2. The heat of formation of ethylene is -6.1 kg.-cal. and the $-M/N$ is 4.8. Since the heat of formation of propylene is -2 kg.-cal., the $-M/N$ for propylene would be expected to be about 4.8 and this value agrees with that obtained by experiment. The change in the $-M/N$ with heat of formation is small. The $-M/N$ for allylene is 8.3 and the heat of formation is -45.2 kg.-cal.

The values of the $-M/N$ were shown¹ to be larger the smaller the value of $\Delta(H_2 + CH_4)/-\Delta HC.$ for the two and four carbon derivatives which had been studied. It was further shown that the order of the increase in the $-M/N$ was: the saturated hydrocarbon, the ethylene derivative and the acetylene derivative. That the same relation holds for the propane derivatives is shown in Table II.

The position of cyclopropane between that of propane and propylene with respect to the $\Delta(H_2 + CH_4)/-\Delta HC.$ is in agreement with its chemical properties.

TABLE II
RELATION OF $-M/N$ AND EVOLUTION OF $H_2 + CH_4$ TO UNSATURATION

	$\frac{\Delta(H_2 + CH_4)100}{-\Delta HC.}$	$-M/N$
Propane	82.3	1.7
Cyclopropane	20.5	3.3
Propylene	14.4	4.9
Propine	6.1	8.3
Allene ($H_2C=C=CH_2$)	4.9	10.4

The condensation products which were obtained from these two hydrocarbons were light mobile oils with similar characteristics. The increase in the $\Delta(H_2 + CH_4)/-\Delta HC.$ as the action progressed indicated that the products lost hydrogen and methane because of their bombardment by the alpha-particles. A quantity of the condensation product of propylene is being prepared with the idea of obtaining some of its physical and chemical properties as well as its average molecular weight. From the molecular weight it is hoped to obtain some idea as to the average number of alpha-particles involved in the formation of the average molecule.

Experimental

Propylene

Purification.—Propylene⁴ having a purity of 99.5% was dried by passing through phosphorus pentoxide, and purified by four low temperature distillations. The vapor pressure of the sample at the temperature of solid carbon dioxide agreed with that given by Burrell and Robertson.⁵

Action with Radon.—Very shortly after mixing the propylene with radon a fog appeared. The product collected as a mobile colorless oil on the bottom of the reaction vessel. The ratio $\Delta(H_2 + CH_4)/-\Delta HC.$ increased from about 10% to about 25% as the action progressed. The results are given in Table III. When these data are plotted, the logarithm of the total pressure against the percentage of radon gives a somewhat concave curve while the plot of the logarithm of the pressure of the hydrocarbon against the per cent. of radon is a straight line. The pressure of the hydrogen and methane evolved when plotted against the percentage of radon gives a slightly convex curve.

Cyclopropane

Purification.—Cyclopropane⁴ having a purity of 99% was bubbled slowly—one bubble a second—through a 1% solution of potassium permanganate and then through 50% potassium hydroxide. The gas after being dried by passing through a trap maintained at -30° , a calcium chloride tube and finally through a tube of phosphorus pentoxide was condensed in a trap immersed in liquid air. It was then further purified by low temperature distillations until the vapor pressure was constant at the temperature of solid carbon dioxide after five distillations. The purity of the sample was further proved by determining the molecular weight using the method and apparatus of Maass and Russell.⁶ A molecular weight of 41.93 was obtained under ideal conditions.

Action with Radon.—Within five minutes after mixing the cyclopropane with radon, a dense fog appeared. After six hours a small pool of a mobile colorless liquid condensate had formed in the reaction sphere. The results are given in Table IV. The graphical representation is quite similar to that of propylene.

Summary

The action of radon on propylene and cyclopropane has been studied and the $-M/N$ ratios have been found to be 4.9 and 3.3, respectively.

The $-M/N$ values calculated by two methods have been compared with the experimental values.

The associations of lower values of $\Delta(\text{H}_2 + \text{CH}_4)/-\Delta\text{HC.}$ with higher $-M/N$ values is again observed

THE ALDEHYDE BISULFITE COMPOUNDS. I. THE RATE OF DISSOCIATION OF BENZALDEHYDE SODIUM BISULFITE AS MEASURED BY ITS FIRST ORDER REACTION WITH IODINE

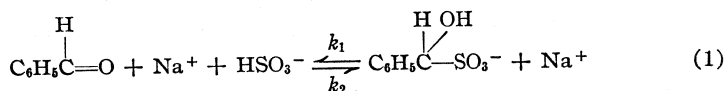

BY T. D. STEWART AND L. H. DONNALLY

RECEIVED FEBRUARY 23, 1932

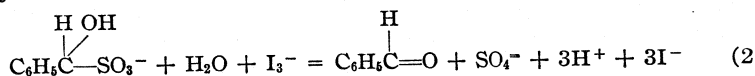

PUBLISHED JUNE 6, 1932

An excellent résumé of the work done prior to 1926 on aldehyde and ketone bisulfites is given by Raschig and Prah1,¹ who also give evidence that in the aldehyde bisulfite ion the sulfur is attached directly to the carbon, as in a sulfonic acid. They leave open, however, the question of why these compounds, as contrasted with most sulfonic acids, are very easily decomposed both in acid and alkaline solution. In spite of the enormous amount of work that has been done upon compounds of this type,² the questions of structure and of mechanism of formation and dissociation may be considered unsettled. For this reason a very detailed study has been undertaken.

The reaction of benzaldehyde with sodium bisulfite to form an addition product is reversible, with the equilibrium favoring the addition product.

This system is oxidized by iodine to form benzaldehyde and sulfate ion.

The first step in this work was to show that the rate of the reaction (2) was independent of the concentration of iodine.

Experiment.—500 cc. of benzaldehyde bisulfite solution equivalent to 51 cc. of 0.1 *N* iodine was put into each of two flasks. In one flask 36 cc. of iodine was added at one time; the iodine was decolorized in 378 minutes. In the other flask 36 cc. was added in 2 to 3 cc. portions, additions being made immediately after the iodine color faded. The 36 cc. of iodine was used up in 379 minutes. The approximate hydrogen-ion concentration in these two experiments was 0.01 *N*. In Fig. 1 the plot of the logarithm of the concentration of the unreacted benzaldehyde bisulfite against time is a straight line, for the second experiment. It will be seen later that small changes in the hydrogen-ion concentration during this experiment were unimportant.

Effect of Hydrogen Ion upon the Rate of the Reaction.—In buffered solutions it was necessary to measure the change in hydrogen-ion concentration as the reaction proceeded because of the sensitiveness of the reaction rate to change in acidity at low acid concentrations, and because of the acid produced by the reaction. The hydrogen-ion

¹ Raschig and Prah1, *Ann.*, **448**, 265-312 (1926).

² See Kerp, "Schweflige Säure und ihre Verbindungen mit Aldehyden und Ketonen," Verlag von J. Springer, Berlin, 1904; Schroeter, *Ber.*, **61**, 1616 (1928); C. Wagner, *Ber.*, **62**, 2873 (1929).

concentrations were measured by means of a glass electrode, using a potentiometer and galvanometer, to an accuracy of 0.02 P_H .³ In order to illustrate the method of obtaining the specific reaction rate at a specified value of P_H the runs made in the region of P_H 6.2 to 6.9 will be described in detail.

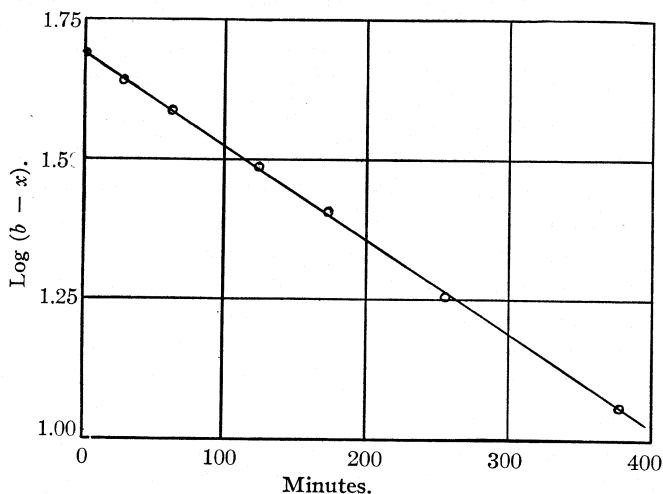

Fig. 1.—The reaction rate of sodium benzaldehyde bisulfite with iodine at about P_H 2.

Experiment.—A stock of buffer solution was made from phosphoric acid and sodium hydroxide (total phosphate, 0.111*M*), to give a P_H within the range desired, as measured by the electrode. To 500 cc. of the buffer solution was added 4.0 cc. of a sodium benzaldehyde bisulfite solution which was equivalent to about 100 cc. of 0.1 *N* iodine, to make the reaction mixture. All solutions were prepared from water boiled to remove oxygen, and were stored in nitrogen. Portions of this reaction mixture were brought to the temperature of the thermostat and 10.00-cc. portions of the standard iodine solution, which was at the same temperature, added. The time for decolorization of the iodine was noted and another portion of iodine added immediately. The data for a typical experiment are given in Table I and plotted in Fig. 2.

TABLE I

THE SPECIFIC REACTION RATE IN PHOSPHATE BUFFER AT P_H 6.46 TO 6.72
 x , amount of iodine used; b , total amount of benzaldehyde bisulfite present expressed in cc. of iodine. Temp., 0°C. $\pm 0.5^\circ$

x	$b - x$	$\log 1/b - x$	Seconds
0.00	90.36	-1.956	0
25.00	65.36	-1.815	5
50.00	40.36	-1.606	15
70.00	20.36	-1.309	32
85.00	5.36	-0.729	74

The points do not lie on a straight line (compare Fig. 1), apparently because of changing hydrogen-ion concentration. This assumption is made because doubling the concentration of the buffer and thereby in-

³ Robertson, *Ind. Eng. Chem., Anal. Ed.*, **3**, 5 (1931).

creasing the ionic strength gave practically the same specific rate of reaction and decreased the above-mentioned curvature. Also the percentage changes in hydrogen-ion concentration and in specific reaction rate during the reaction were of the same order of magnitude, each about 100%. The specific reaction rates at selected points were therefore obtained by drawing tangents to this curve (Fig. 2). The P_H of the solution at these same points was obtained as follows.

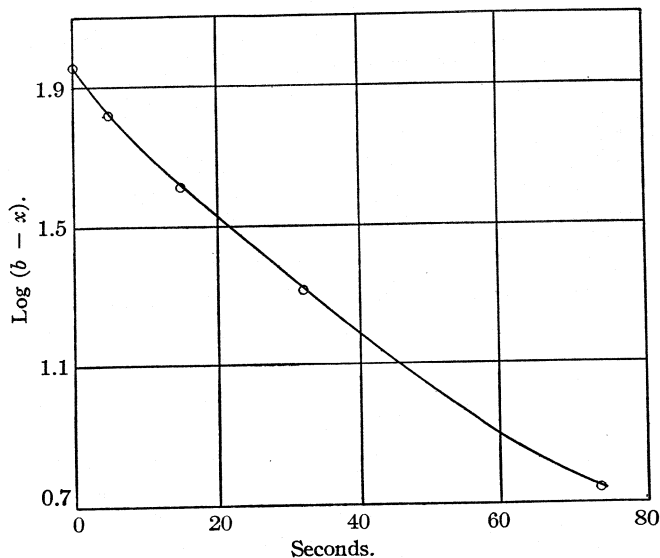

Fig. 2.—The reaction rate in the P_H range 6.45 to 6.72.

A similar portion of the reaction mixture was taken and the iodine added as before. After each decolorization the electrode reading was taken. These readings were plotted against the corresponding calculated P_H value using Sørensen's phosphate buffer solutions of P_H 6.24, 6.81 and 7.38 to calibrate the electrode. The electrode was calibrated both before and after each experiment and shown to be reliable. From this plot (not given), the P_H value of the reaction mixture could be read for any selected time during the reaction. The results of the experiments and calculations in the phosphate buffer range are presented in Table II.

TABLE II

THE SPECIFIC REACTION RATE FOR THE PHOSPHATE P_H RANGE AT VARIOUS TEMPERATURES, IN EQUIVALENTS PER SECOND

0.0°		5.5°		9.5°		21.0°	
k_1 (sec.)	P_H	k_1 (sec.)	P_H	k_1 (sec.)	P_H	k_1 (sec.)	P_H
0.0535	6.72	0.0875	6.72				
.0482	6.66	.0730	6.60				
.0437	6.60	.0596	6.50	.109	6.60		
.0316	6.46	.0538	6.46	.0945	6.50	0.372	6.50

Similar measurements for the P_H range 3.6 to 5.6 were made in exactly the same manner as in the range 6.24 to 7.38. Acetic acid-sodium acetate buffers of Walpole-Clark were used as standards. The stock buffer solution was made with a total acetate concentration of 0.111 M and 500 cc. was used as before for the preparation of the reaction mixture. Table III contains the results of the experiments and calculations in this range.

TABLE III
THE SPECIFIC REACTION RATE FOR THE ACETIC-ACETATE BUFFER RANGE, IN
EQUIVALENTS PER SECOND

k_1 (sec.)	9.5°	P_H	k_1 (sec.)	21°	P_H
0.00292		4.91			
.00276		4.88	0.01015		4.88
.00251		4.84	.00923		4.86
.00218		4.78	.00822		4.78
.00195		4.74	.00785		4.76

Determinations were also made with chloroacetic acid-chloroacetate and phosphoric acid-monosodium phosphate buffers. Both buffer solutions were made up with the total anion concentration 0.111 M and in each of these the hydrogen-ion concentration was measured by a hydrogen electrode. The results are given in Table IV. In Table IV are also results obtained by using measured concentrations of hydrochloric acid.

TABLE IV
THE SPECIFIC REACTION RATE AT HIGHER ACID CONCENTRATIONS, AT VARIOUS
TEMPERATURES, IN EQUIVALENTS PER MINUTE

Part A. Chloroacetate Buffer Range			Part B. Acid Phosphate Buffer Range

4.86	0.554	19,100 \pm 500	1.90	.00328	22,000 \pm 300
3.00	.0101	20,100 \pm 300	1.85	.00322	22,100 \pm 300
2.97	.00923	20,200 \pm 300	1.00	.00529	23,300 \pm 300
2.92	.00849	0.55	.0106	23,800 \pm 300
2.30	.00405	21,300 \pm 300	.03	.0307	24,100 \pm 300

Variation of Specific Reaction Rate with Temperature and the Apparent Heat of Activation.—Practically every determination of the specific reaction rate was made at two or more temperatures. Data for the neutral phosphate range are given in Table II, those for the acetic-acetate range in Table III, those for chloroacetic-chloroacetate, acid phosphate and all others are summarized in Table IV.

The data in Tables II and III were used as follows. The P_H values were plotted against $\log k_1$ for each temperature, and a straight line of unit slope was drawn through the points. This was justified in this range of P_H by the rate of change of reaction rate with change in P_H as given in Fig. 3. In those cases where the accuracy was high the points fell well on the line. From each of these curves at an arbitrary P_H a value of k_1 was taken and in turn plotted against the corresponding value of $1/T$. From the slope of the best straight line was calculated (Table V) the apparent heat of activation, using the equation $Q/R = -d \ln k_1/d(1/T)$. The change in heat of activation with change in P_H is plotted in Fig. 4.

Identity of the Iodine Reaction with the Dissociation Reaction.—Since the rate of reaction (2) is independent of the concentration of iodine, there is little doubt that the rate thus measured is the rate of the reverse step

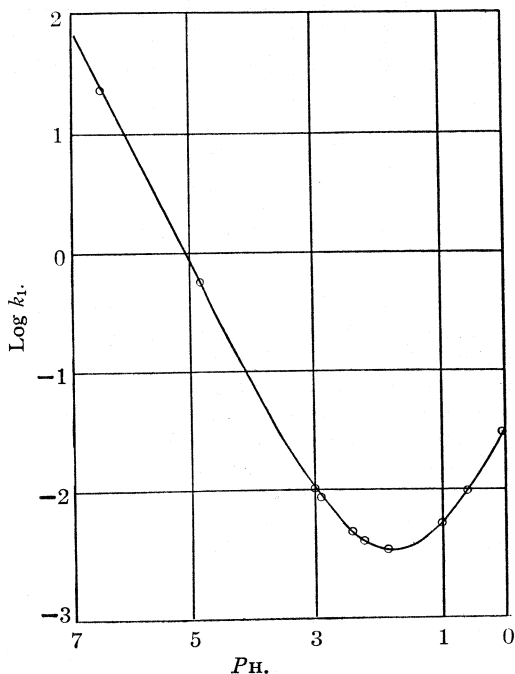

Fig. 3.—The change in the reaction rate with changing P_H .

of reaction (1). In order to test this point, the rate of attainment of equilibrium of (1) was measured.

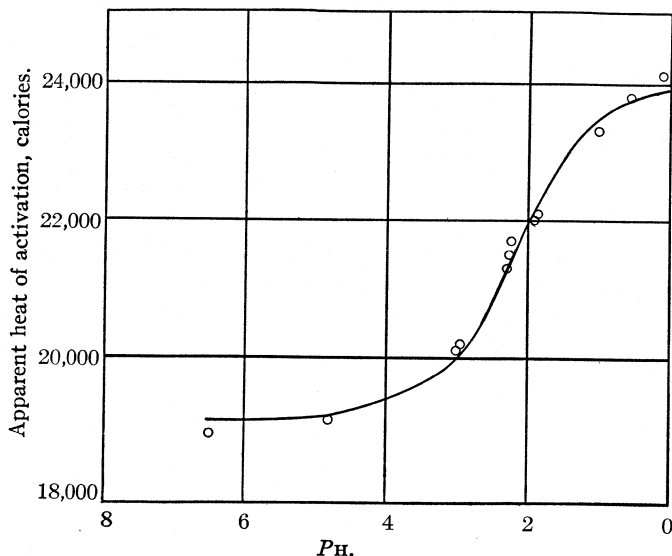

Fig. 4.—Change in the apparent heat of activation with change in P_H .

Experiment.—To 1 liter of 0.25 *N* hydrochloric acid was added an amount of 0.8 *M* sodium benzaldehyde bisulfite equivalent to 0.239 liter of 0.1180 *M* iodine solution; 0.029 liter of the iodine solution was added and the time when the solution became colorless was recorded as zero time. The solution was then allowed to stand for a specified time for dissociation to take place and then iodine in slight excess of the amount of bisulfite ion formed was added and the excess back titrated. The time that iodine was present in the solution was measured to give a correction for the amount of iodine used simultaneously according to equation (2). Sodium bicarbonate was then added and the amount of total unused benzaldehyde bisulfite determined by titration. The data obtained are given in Table VI.

TABLE VI
COMPARISON OF THE IODINE AND DISSOCIATION REACTIONS

cc_1 is the amount of bisulfite ion (in cc. of 0.1180 *N* iodine) produced after time t_1 in the absence of iodine; cc_2 the volume of iodine used up in elapsed time t_2 in the continued presence of iodine; cc_3 the reaction rate calculated by Equation 5 (Fig. 5)

cc_1	t_1	cc_2	t_2	cc_3	t_3
8.30	5.50	5.00	3.4	5.0	3.24
15.15	10.1	10.0	6.78	10.0	6.55
24.30	20.31	20.0	15.6	20.0	13.42
31.07	29.4	25.0	21.2	30.0	20.70
36.90	45.2	27.0	23.7		
39.0	60.3	30	28.7		
41.0		35	40.0		
		38	52.0		

The limiting amount of bisulfite produced in this experiment was taken to be the equilibrium amount and the equilibrium constant was calculated thereby. Experiments were also made to determine the rate of the reaction in the constant presence of iodine for the same solution and the data are given in the third and fourth columns of Table VI. From the rate of the reaction in the continued presence of iodine ($k_1 = 0.00755$) and the

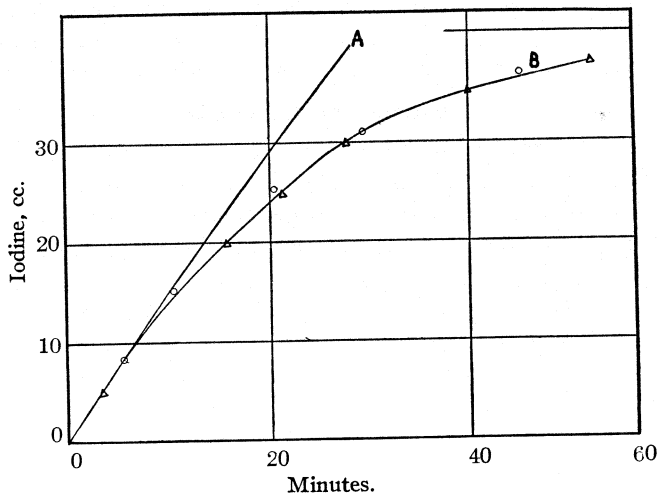

Fig. 5.—Comparison of reaction rate in the presence of (Curve A) and absence of iodine (Curve B); the approach to equilibrium (Δ , calculated; O , experimental, Curve B).

equilibrium constant ($K_E = 0.98 \times 10^3$) the forward rate (k_2) was calculated as equal to 7.4 for P_H of about 1.6. The concentration and time units for these figures are moles per liter and minutes, respectively. The equation expressing the velocity of the net change after t minutes for this bimolecular reaction opposing the monomolecular is

$$\frac{dx}{dt} = k_1(b - x) - k_2x(a + x) \quad (4)$$

where b and a are, respectively, the initial concentrations of addition product and of benzaldehyde.

Integrated, this gives

$$t = \frac{2.3}{k_2 \sqrt{\left(\frac{k_1 + k_2 a}{k_2}\right)^2 + \frac{4k_1 b}{k_2}}} \log \frac{\frac{k_1 + k_2 a}{2k_2} + \frac{1}{2} \sqrt{\left(\frac{k_1 + k_2 a}{k_2}\right)^2 + \frac{4k_1 b}{k_2}} + x}{\frac{k_1 + k_2 a}{2k_2} - \frac{1}{2} \sqrt{\left(\frac{k_1 + k_2 a}{k_2}\right)^2 + \frac{4k_1 b}{k_2}} + x} \quad (5)$$

By substituting the above values in the equation we may calculate the data given in Table VI, columns one and two. These calculations are given in the last two columns of Table VI and together with points for the reaction in continual presence of iodine are plotted in Fig. 5.

The conclusion is drawn from these curves that the dissociation reaction in the absence of iodine has the same specific rate as the reaction in the presence of iodine, since in the limit, as the elapsed time becomes short, the rate of production of instantly titratable sulfite becomes the same in the presence and absence of iodine. The multiple ionizations of sulfurous acid and of the addition compound permit several paths for the reactions of addition and of dissociation but these ionizations are presumably maintained in equilibrium. Any extremely rapid isomerization could not be detected by these measurements. These factors will be discussed in a later paper.

Summary and Conclusion

1. Sodium benzaldehyde bisulfite reacts with iodine at a rate independent of its own concentration and of that of the iodine.
2. The rate determining step is the dissociation into bisulfite or sulfite ion. There is no evidence of the presence of isomers of the bisulfite compound.
3. The rate changes with changing hydrogen-ion concentration, being very rapid at low hydrogen-ion concentration reaches a minimum at P_H 1.8, and increases again with higher concentrations of acid.
4. The apparent heat of activation has been measured and found to vary with changing hydrogen-ion concentration.

position is somewhat as follows. The very surface of the liquid is always practically saturated with dissolved hydrogen; thence the dissolved gas penetrates to the interior of the liquid mainly by diffusion through an unstirred layer beneath the liquid surface (liquid stationary film), it is distributed uniformly through the main body of the liquid by currents and finally passes thence to the surface of the catalyst by diffusion through another unstirred layer of liquid existing at the solid-liquid interface.

The stationary films are by no means monomolecular in thickness, nor must they be confused with adsorbed layers. Even in highly agitated liquids, they are much thicker. Strong evidence for their existence can be cited from the studies of numerous investigators on the rates of solution of solids and gases by liquids. Additional evidence is found in the phenomena attending the transfer of heat between phases. In the present and in the two former papers in this series⁴ it has been assumed that the limits of the stationary films are sharply defined. It is noteworthy that by this same approximation, "The convection loss from bodies of simple geometric form, under widely different fluid conditions, can be computed by means of a few convenient equations," ["International Critical Tables," Vol. V, 1929, p. 234].

The first part of the present investigation deals with a study of the rates of hydrogen absorption during hydrogenations of olefins in alcohol with platinum-platinum-oxide catalyst.

The catalytic reduction apparatus⁵ used was that designed by Professor Roger Adams and his associates. The catalyst, solvent (alcohol) and unsaturated compound were shaken together in a stout bottle connected to a hydrogen pressure tank and the rate of hydrogen absorption was followed by the fall in the gage pressure (1 lb./sq. in. = 286 cc. of hydrogen at atmospheric pressure and 25°). The hydrogen was admitted to the reaction bottle, without first removing the air, so that the gage pressure measured the partial pressure of hydrogen above the alcohol. The absorptions were mostly so rapid that it seemed unlikely that much air or alcohol vapor could penetrate from the bottle to the tank against the intruding hydrogen. Platinum-oxide-platinum black was used, prepared according to the directions of Adams and Shriner⁶ (fusion at about 500°); 150 cc. of reagent alcohol (No. 25 denatured, 95% ethanol and 5% methanol) was used in each experiment.

In any one experiment on the hydrogenation of an olefin, the rate of hydrogen absorption, after a short period from the beginning, remained fairly constant until hydrogen practically equivalent to the olefin had been absorbed.⁷ This is shown by the linear form of the curves in Fig. 1.

The relationship between the magnitude of these uniform absorption rates and the quantity of catalyst can be seen from Table I, columns 2

⁵ Purchased from the Burgess-Parr Co.

⁶ Adams and Shriner, *THIS JOURNAL*, **45**, 2171 (1923).

⁷ Numerous observers have pointed out this striking fact; see Lebedev, Kobliansky and Yakubshchik, *J. Chem. Soc.*, 418 (1925).

and 6. The absorption rate increased from zero, at first in proportion to the quantity of catalyst, but evidently tended toward a maximum value which would have been unchanged by the addition of more catalyst.

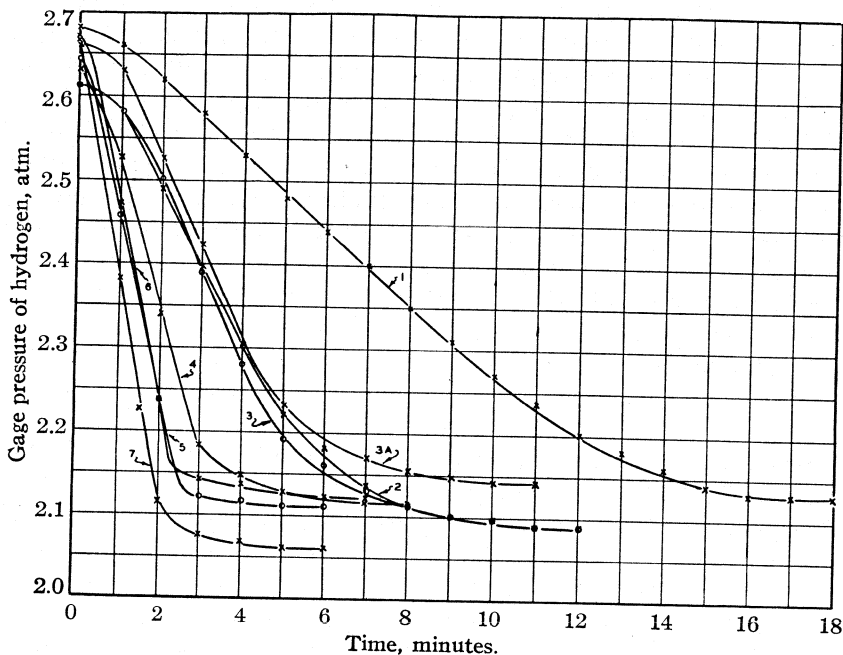

Fig. 1.—Hydrogenation of 10 cc. of 2-pentene in 150 cc. of alcohol, shaken 260 times per min. with various quantities of catalyst: (1) 0.03 g., (2) 0.07 g., (3) 0.10 g., (3A) 0.10 g., (4) 0.20 g., (5) 0.40 g., (6) 0.60 g., (7) 0.90 g.; average hydrogen pressure (gage), 2.4 atm.

In diffusing from the gas-liquid interface to the liquid-solid interface, the dissolved hydrogen must pass through two liquid stationary films by diffusion and the total drop in its concentration between the two interfaces is utilized in driving the dissolved gas through these films.

Let C_i = concn. of dissolved hydrogen at gas-liquid interface

$C_{cat.}$ = concn. of dissolved hydrogen at liquid-solid interface

R_1 = total resistance, to diffusion, of the liquid stationary film at gas-liquid interface

r_2/W = total resistance, to diffusion, of liquid stationary film at liquid-solid interface (W = g. of catalyst, r_2 = resistance per 1 g. of catalyst)

ρ = rate of hydrogen absorption (total)

K = a constant

$$\text{Then } \rho = K \frac{C_i - C_{cat.}}{R_1 + \frac{r_2}{W}} \quad (1)$$

$$\frac{1}{\rho} = \frac{1}{K(C_i - C_{cat.})} \left(R_1 + \frac{r_2}{W} \right)$$

At a fixed rate of shaking R_1 remains unchanged and, for the same lot of catalyst, r_2 is constant. If, finally, the variations in C_{cat} are negligible compared to $C_1 - C_{\text{cat}}$, then

$$\frac{1}{\rho} = \text{Const.} + \text{Const.} \left(\frac{1}{W} \right) \quad (2)$$

Accordingly if $1/\rho$ is plotted against $1/W$, a straight line should result. In Fig. 2 the data from experiments with different quantities of catalyst are plotted in this way for three olefins, trimethylethene, 2-pentene and isopropylethene. For the first two, the points lie quite well on straight lines. In the case of isopropylethene, the second and fifth points are off from, but on opposite sides of, the straight line representative of the other five points. Apparently this is due to experimental errors.

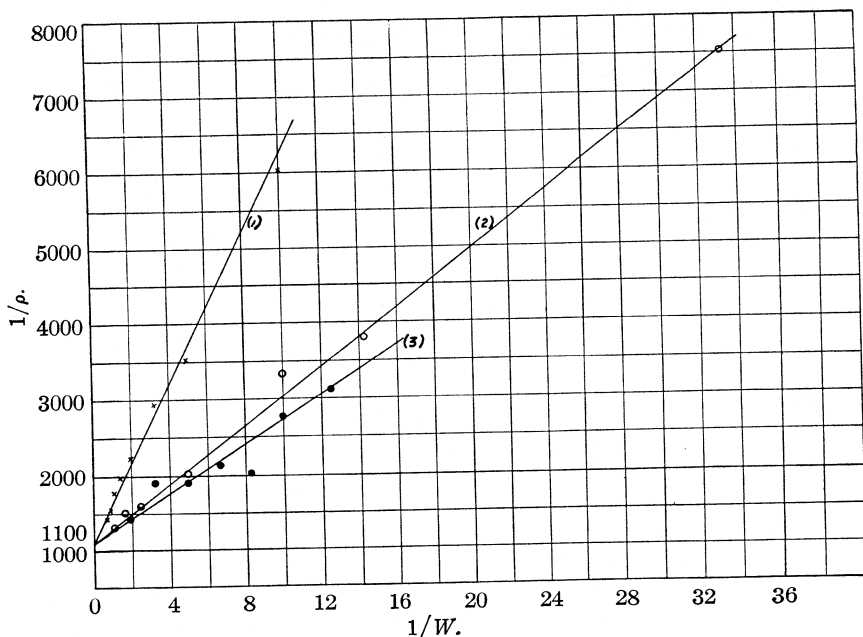

Fig. 2.— ρ =rate of hydrogen absorption, over period of uniformity, in mole/sec.; W =weight of catalyst in grams; (1), trimethylethene; (2), 2-pentene; (3), isopropylethene; average hydrogen pressure (gage) 2.4 atm.; shaking rate 260 times per min.; 150 cc. of alcohol + 10 cc. of hydrocarbon.

Within the accuracy of the data, all three curves converge to the same point at $1/W = 0$ or $W = \infty$. The corresponding value for ρ is 9.1×10^{-4} mole/sec. Under these conditions the concentration of dissolved hydrogen in the main body of the liquid has become equal to C_{cat} and the full drop in concentration $C_i - C_{\text{cat}}$ is utilized in driving dissolved hydrogen through the liquid stationary film at the gas-liquid interface.

The resistances of the two liquid stationary films will be equal ($R_1 = r_2/W$) when the absorption rate is just half the above maximum. The quantity of catalyst corresponding to this condition can be obtained, for each series, from the curves of Fig. 2. Having these values for W , it is now possible to calculate the ratios of the total resistances, $R_1 + r_2/W$, and finally the ratios of the hydrogen absorption rates, for different quantities of catalyst, Table I. The agreement between the calculated and the experimental ratios of the absorption rates is rather striking (last two columns).

Furthermore, it is calculated (by means of equation 3 below) that in the 2-pentene experiments, Table I, for 0.03 g. of catalyst, the main body

^a From the curve of Fig. 2.

of the solution was 86% saturated with hydrogen, and for 0.9 g. only 20%. Since, as shown by Fig. 2 and Table I, $(C_1 - C_{\text{cat.}})$ remained substantially constant, then $C_{\text{cat.}}$ must have remained either constant, unaffected by large changes in the concentration of dissolved hydrogen in the main body of the liquid, or was negligible. If it was negligible, then the limiting rate of absorption reached with an infinite quantity of catalyst should be equal to the initial rate of hydrogen absorption by the solution. To test this conclusion, the rate of physical solution of hydrogen by alcohol in this apparatus was actually measured in the following way.

The bottle containing 150 cc. of alcohol, without any catalyst or olefin, was evacuated to a pressure of 8–10 cm. of mercury and shaken for several minutes to remove dissolved gases. Then with the bottle at rest, hydrogen was admitted to a total pressure of about 1.9 atm. The pressure was registered by the height of the mercury level in a capillary tube dipping into mercury in a closed bottle, 3 cm. in diameter, which sustained the full hydrogen pressure.

With the liquid at rest, the rate of hydrogen absorption was fairly slow; but when shaking started it was rapid, although by no means immeasurable. A fraction of a second was required to start the shaking, so that measurements were taken after the motor was almost up to speed (260 ± 5 shakings per min.). Then the time was determined for the first 2 cm. drop in the mercury pressure out of the last 4 cm., that is, the time required for solution of half the hydrogen still undissolved. Two observers were required. One started the shaking, the other measured the time. To accomplish this, a moving paper was drawn against a pencil, rotating uniformly eleven times per second, when the mercury level reached a fixed mark and withdrawn when it had fallen 2 cm. more. The following were the numbers of the pencil marks in five successive tests: 10, 9, 9, 10, 10. Average, 9.6, corresponding to 0.87 sec.

Let U = The unsaturation of the alcohol in regard to dissolved hydrogen at time t (sec.) expressed as the moles of the gas (in addition to that already dissolved) necessary to saturate the alcohol

$$\text{Then } -\frac{dU}{dt} = \text{Const. } U \quad (3)$$

$$\text{and Const.} = \frac{1}{t} \ln \frac{U_0}{U}$$

$$\text{If } t_{0.5} = \text{time for a fall of 50\% in } U, \text{ then } -\frac{dU_0}{dt} = \frac{0.693 U_0}{t_{0.5}}$$

This relationship holds whatever the value of U , but if the readings could be started before any hydrogen was dissolved, then U_0 would be equal to the total quantity of hydrogen soluble, at this pressure, in the alcohol; 150 cc. of alcohol would dissolve about 1.27×10^{-3} mole of hydrogen at 2.4 atmospheres. Accordingly the initial rate of solution of hydrogen in this quantity of alcohol in our hydrogenation experiments (Adams apparatus, hydrogen pressure 2.4 atm., and shaking rate (260 ± 5) times per min.) would be $(0.693/0.87) \times 1.27 \times 10^{-3} = 10 \times 10^{-4}$ mole/sec.

More than a year later the experiments (first series) were repeated, another observer replacing one of the first two (second series).

COLLECTED RESULTS ON THE INITIAL RATE OF HYDROGEN SOLUTION (AT 2.4 ATM. OF HYDROGEN) BY 150 CC. OF LIQUID SHAKEN 260 ± 5 TIMES PER MINUTE IN THE ADAMS

APPARATUS

1st Series, alcohol only	10×10^{-4} mole/sec.
2d Series, alcohol only	11.5×10^{-4} mole/sec.
2d Series, alcohol 10 cc. 2-pentene	9.6×10^{-4} mole/sec.
2d Series, alcohol 10 cc. trimethylethene	9.0×10^{-4} mole/sec.

The absorption rate for an infinite quantity of catalyst, 9.1×10^{-4} mole/sec. of hydrogen, was therefore approximately equal to the initial rate of physical solution of the hydrogen. The concentration of dissolved hydrogen in the liquid at the liquid-solid interface, $C_{\text{cat.}}$, must have been low in all our hydrogenation experiments.⁸

If these explanations are correct, then with a fixed rate of shaking the changes in the hydrogen absorption rate with the quantity of catalyst are caused by changes in the total resistance, r_2/W , of the liquid stationary film at the liquid-solid interface. On the other hand, one hydrogenation at a faster shaking rate (430 times per min. using 2-pentene and 0.6 g. of catalyst) gave an absorption rate 9.2×10^{-4} mole/sec. of hydrogen, compared to only 6.7×10^{-4} at 260. Undoubtedly this higher rate corresponds mainly to an increased ease of physical solution of hydrogen in the alcohol. (R_1 was less.)

The *absorption rate per unit area of surface* could be calculated if the area of the gas-liquid interface of the shaken liquid were known. An estimate of this surface was made by measuring the rate of absorption of pure ethylene by 150 cc. of 95.8% sulfuric acid, when shaken in the apparatus, and dividing by the rate per unit area into the acid at rest (6×10^{-9} mole/sec.). This method is based on the postulate, which is supported by experimental evidence, that the absorption rate of ethylene per unit area of surface of this acid is unaffected by the rate of shaking.⁹

Rate of shaking per min.....	260	420
Over-all ethylene absorption rate, moles per sec.....	24000×10^{-9}	28000×10^{-9}
Calculated area of liquid surface, sq. cm....	4000	4700

⁸ Carothers and Adams, *THIS JOURNAL*, **45**, 1071 (1923), using a similar method of hydrogenation, studied the rates of the absorption during the reduction of aldehydes. Ferrous chloride was found to "promote" the reaction and, with a fixed quantity of catalyst, 0.23 g., the absorption rate increased with the quantity but approached a maximum asymptotically which was practically attained with 0.001 mole of the iron salt. On the other hand, using 0.001 mole of ferrous chloride, but changing the quantity of catalyst, the absorption rates increased in the same manner as those in Table I, and the rate with 0.23 g. of catalyst (4×10^{-4} mole/sec. of hydrogen) was evidently approaching the maximum that could be obtained with the quantity of alcohol, 50 cc., and the shaking rate (260 \pm 5 times per min.) employed. Further, the fact that this rate is about half the maximum in our experiments where three times as much alcohol was used, indicates that $C_{\text{cat.}}$ was low in their experiments also.

⁹ Davis and Crandall, *THIS JOURNAL*, **52**, 3781-3782 (1930).

The maximum rate of absorption during the hydrogenation experiments (Table I) would, therefore, be 2.3×10^{-7} mole/sec. per sq. cm.¹⁰

In a former communication,¹¹ some evidence has been given that the resistances to solute diffusion (per unit area of interface) through the liquid stationary films at the gas-liquid interface and liquid-solid interface are of the same order. If they are assumed to be *equal*, then it would follow that when their total resistances are the same ($R_1 = r_2/W$), the areas of the two interfaces are also equal. Taking 4000 sq. cm. for the area of the gas-liquid interface in the experiments summarized in Table I, it can now be calculated from the weights of catalyst having an equal film resistance that the average diameters of the platinum particles (if spherical) in the three series of experiments were as follows, trimethylethene series 0.34×10^{-4} cm., 2-pentene series 0.12×10^{-4} cm. and isopropylethene series 0.11×10^{-4} cm. This is in qualitative agreement with the values 0.3 to 1×10^{-4} cm. obtained by Taylor, Kistiakowsky and Perry¹² from direct measurements of the average sizes of the particles in platinum black catalyst prepared by three different methods.

A new lot of catalyst was used in each series shown in Fig. 2 but possibly the differences in the slopes of these curves are not caused entirely by variations in the particle size of the catalyst. The bases for these calculations of surface areas and particle sizes are only approximate. However, the qualitative agreement of the calculations with the above-mentioned direct measurements substantiates the theory of the part played by the liquid stationary films in these hydrogenations. More accurate methods of experimentation will be necessary for determining whether all curves extrapolate to exactly the same point at $1/W = 0$, and whether the differences in the slopes are entirely due to variation in the particle size.

The Adams apparatus is not suitable for testing these questions, mainly because the rate of hydrogen solution is very high (the exact purpose of its design). One needs a large body of liquid, moderately stirred, and having only a small liquid-gas interface. Under the latter conditions the time necessary to half saturate the alcohol with hydrogen might become a matter of minutes, instead of less than one second as was the case in our experiments. Absorption rates under various conditions could then be followed accurately.

¹⁰ Conant and Scherp, *THIS JOURNAL*, **52**, 3764 (1930), measured the rate of hydrogen solution by tetrachloroethane shaken 250 times per minute. The initial rate at 2.4 atm. has been calculated from their data to be 2.1×10^{-7} mole per sec. per sq. cm. (The solubility of hydrogen in tetrachloroethane is about 15% lower than in alcohol.)

¹¹ Davis and Crandall, *ibid.*, **52**, 3761 (1930).

¹² Taylor, Kistiakowsky and Perry, *J. Phys. Chem.*, **34**, 749 (1930). The experiments of Bredig and Allolio, *Z. physik. Chem.*, **126**, 41-47 (1927), showed that the particles in the Adams catalyst are also minute.

The Relative Rates of Hydrogenation of the Components in Mixtures of Olefins.—Lebedev and his co-workers¹³ have concluded that olefinic compounds of different types of substitution are hydrogenated consecutively and selectively, in the presence of colloidal platinum, that is to say, in general, one compound is almost completely hydrogenated before the next is attacked.

However, in no case in their experiments were the products from a partial hydrogenation of a mixture of two compounds analyzed by methods entirely independent of their hydrogenation hypotheses. And mostly the products were not analyzed at all, the conclusions being drawn from breaks which appeared in the curves of the rates of hydrogen absorption, which, as pointed out by Lebedev, are not sharp. Furthermore, in many cases there is no rigorous proof of the order of hydrogenation.

They also measured the hydrogen absorption rates for single ethylenic compounds at atmospheric temperature and pressure employing approximately 0.01 mole of the compound, in 10–15 cc. of alcohol with 0.05 to 0.3 g. of catalyst or in a few cases even greater amounts. The averages of the values for the different types of compounds do not appear to be particularly significant. As calculated from their curves they are (expressed in moles of hydrogen per sec. $\times 10^3$) monosubstituted 11, *sym.*-disubstituted 7, *unsym.*-disubstituted 10 and tri- and tetrasubstituted 6.

They state that "in general the effect of doubling the concentration of catalyst in a given case was to increase the rate of absorption of hydrogen by about 50%." On our hypotheses this would indicate relative values for R and r_2/W in their experiments 1 and 2.

Adkins, Diwoky and Broderick,¹⁴ concluded that "the relative ease of reduction of two substances in a mixture may not be certainly determined even qualitatively by determining the rates of reduction of the two substances separately." They measured rates of reduction by the periods required for complete reduction of the compounds under similar conditions. However, these periods are perhaps not so significant as the rates of hydrogen absorption, while still fairly uniform. The rate nearly always falls off near the end of the reduction. Further, Thomson (unpublished data) has shown that the period required to completely reduce olefins depends greatly on their peroxide content.

The writers have, therefore, half hydrogenated four different mixtures of two olefins of different types of substitution and have analyzed the products by methods entirely independent of hydrogenation. The limited experimental data (Table II) indicate that in hydrogenation of mixtures of olefins, as pointed out by Vavon¹⁵ and Lebedev,¹³ the order of reduc-

¹³ Lebedev and others, *J. Chem. Soc.*, 417–440 (1925); 823–837, 2190–2204 (1928); 220–225 (1929); 321–336 (1930).

¹⁵ Vavon and Kleiner, *Compt. rend.*, 177, 401 (1922).

tion is as follows: monosubstituted, disubstituted, trisubstituted. However, the more rapidly reacting constituent was not hydrogenated to the exclusion of the other component, since in all cases there was an appreciable quantity of the latter reduced.

Synthetic mixtures of two pure olefins in approximately equal molecular proportions were hydrogenated until 50% or somewhat more of the total had been converted to paraffins. The proportion of each olefin left unchanged in the mixture was then determined by analysis.

In the case of the first mixture, propene and 2-butene, a 5-liter flask was used the neck of which had been drawn down and a stopcock sealed thereto. The alcohol and catalyst were placed inside, the flask was evacuated and the gas mixture, 0.12 mole of hydrogen and 0.078 mole of each olefin, drawn in. The other experiments, 2, 3 and 4, were carried out in the Adams apparatus already described. The olefins were here measured out in the liquid state, the quantities being checked both by weight and by volume and were poured directly into the chilled reagent alcohol (150 cc.).

As will be seen from Table II, there was a considerable difference between the boiling points of the two olefins chosen for each mixture so that fractional distillation could be utilized in the analyses of the products. By means of a vacuum-jacketed column containing a glass spiral with forty turns,¹⁶ the

TABLE II

COMPETITIVE HYDROGENATIONS OF MIXTURES OF TWO OLEFINS

The corresponding paraffin formed by hydrogenation is given under each olefin in parentheses.

No.	Olefins, paraffin product	B. p., °C.	Formula and type of olefin	Mole in original mixture	% of olefin hydro- genated
I	Propene (Propane)	-47.5 (-44.5)	$\text{CH}_3\text{CH}=\text{CH}_2$ Monosubstituted	0.078	90
	2-Butene (n-butane)	1.5-1.7 (0.6)	$\text{CH}_3\text{CH}=\text{CHCH}_3$ Sym.-disubstituted	.078	20
II	1 Butene (n-butane)	-6.3-5.1 (0.6)	$\text{CH}_3\text{CH}_2\text{CH}=\text{CH}_2$ Monosubstituted	.040	79
	2-Pentene (n-pentane)	36.3-36.5 (36.2)	$\text{CH}_3\text{CH}_2\text{CH}=\text{CHCH}_3$ Sym.-disubstituted	.051	21
III	Isobutene (Isobutane)	-7.0-6.9 (-10.2)	$(\text{CH}_3)_2\text{C}=\text{CH}_2$ Unsym.-disubstituted	.0485	96
	Trimethylethene (Isopentane)	38.2-38.4 (28)	$(\text{CH}_3)_2\text{C}=\text{CHCH}_3$ Trisubstituted	.0530	44
IV	Isopropylethene (Isopentane)	20.1-20.4 (28.0)	$(\text{CH}_3)_2\text{CH}_2\text{CH}=\text{CH}_2$ Monosubstituted	.044	93
	Trimethylethene (Isopentane)	38.2-38.4 (28.0)	$(\text{CH}_3)_2\text{C}=\text{CHCH}_3$ Trisubstituted	.044	20

¹⁶ Davis, *Ind. Eng. Chem.. Anal. Ed.*, **1**, 61 (1929).

mixtures of unchanged olefins and their hydrogenation products were easily separated from the alcohol and were refractionated several times from metallic sodium. Although the quantity of liquid hydrocarbon was in no case greater than 12 cc., it readily separated, in the first three experiments, into two sharply differentiated fractions each of which boiled over the range of one olefin and its corresponding paraffin. The product from No. 4 was more difficult to fractionate because both olefins yield the same paraffin, isopentane, which boils about half-way between them.

The composition of the separate fractions was then determined by chemical tests.¹⁷

Summary

1. A study of the rates of catalytic hydrogenation of three olefins has been made. The results have been examined in the light of the theory that the rate of hydrogen absorption is controlled by the rate of diffusion of hydrogen through liquid stationary films at the gas-liquid and liquid-solid interfaces.

2. The ratios of the hydrogen absorption rates for different quantities of catalyst, in three series of experiments with different olefins, have been calculated from this theory and agreed very well with those determined experimentally.

3. The value of the absorption rate with an infinite quantity of catalyst (obtained by extrapolation) agreed with an approximate value found, by direct measurements, for the initial rate of absorption of hydrogen in alcohol, and in alcohol solutions of olefins, under similar conditions.

4. The average area of gas-liquid interface during these hydrogenations has been determined and, with the aid of this value, the particle size of the catalysts calculated.

5. The relative proportions of two olefins reacting during partial hydrogenation of an equimolecular mixture of the two have been measured for four different mixtures. The products were analyzed by methods independent of hydrogenation.

THE CHEMICAL KINETICS OF HIGH VALENCE TYPE ELECTROLYTES IN DILUTE AQUEOUS SOLUTIONS

BY VICTOR K. LA MER AND R. W. FESSENDEN¹

RECEIVED MARCH 2, 1932

PUBLISHED JUNE 6, 1932

Introduction

In developing the theory of chemical reaction velocity in solution and particularly to account for the anomaly known as neutral salt effect, Brönsted² postulates that the reaction mechanism involves a series of intermediate unstable complexes. The rate of transformation of the most unstable complex, designated as X, determines the tempo of the reaction. For the velocity of a bimolecular reaction like

he gives the expression

$$\frac{dx}{dt} = k_0 C_A C_B f_A f_B / f_x \quad (2)$$

Here the factor, $F = f_A f_B / f_x$, representing the ratio of the activity coefficients is introduced as a correction to the classical expression valid for ideal solutes to account for the changes in velocity resulting from a change in the nature of the medium. Such environmental changes are produced by variation in the concentrations of the reactants or by the addition of chemically inert substances. It is important to subject the theory to a critical analysis to ascertain whether the introduction of activity coefficients, thermodynamic quantities which are independent of time, furnishes a sufficient correction. In a recent paper from this Laboratory³ it was shown that the further assumption of a change in the degree of orientation of complex molecules on collision was necessary to account for the results for specially selected examples.

For an unequivocal test of the theory, it is necessary to measure these activity coefficients in precisely the same medium in which the reaction proceeds. The instability of A and B in the presence of each other frustrates such measurements. However, the theory can be tested by comparing the observed behavior of the factor, F , on changing concentration with predictions based upon measurements of stable ions of the same electric charge type. For this purpose, it has been customary to employ the

¹ This paper is from a dissertation submitted in July, 1931, by R. W. Fessenden to the Faculty of Pure Science of Columbia University in partial fulfilment of the requirements for the degree of Doctor of Philosophy. It was presented at the Symposium on Kinetics of Homogeneous Reactions at the Buffalo (September, 1931) meeting of The American Chemical Society.

Debye-Hückel limiting law to predict the kinetic behavior.⁴ Solubility studies,^{5,6,7} however, have demonstrated that this simple law does not hold when the product of the charges of the ions of opposite sign is greater than four. Instead the solubility measurements have revealed a characteristic behavior which has proved to be at variance with the predictions of the theory as developed by Debye and Hückel but not inconsistent with the fundamental postulates of the theory provided a more complete mathematical solution of the Poisson-Boltzmann equation is employed.⁸

For example, the reaction

involves a critical complex with three negative charges. If the reactants are introduced in the form of their sodium salts, the valence product of ions of opposite sign does not exceed three for any pair in the mixture. Under such conditions the observed rate agrees⁹ with the predictions of the equation

$$\log k = \log k_0 + Z_A Z_B \sqrt{\mu} \quad (4)$$

obtained by introducing the Debye-Hückel limiting law

$$-\log f_i = -0.50 Z_i^2 \sqrt{\mu} \quad (5)$$

into equation (2) and integrating on the assumption that the ionic strength, μ , remains unchanged during the course of the reaction. On the other hand, if the reactants are introduced in the form of their calcium, barium or magnesium salts, there will be ionic pairs involving the critical complex with a valence product equal to six. When bivalent cations are present, equations (5) and (4) will not be obeyed. However, if equation (2) is correct, we should expect the curves obtained on plotting the logarithm of the velocity constant against the square root of the ionic strength to have a form practically identical with those obtained by La Mer and Mason for the solubility of salts of the same valence type. The essential characteristic is an experimental limiting slope two to three times that predicted by the Debye-Hückel limiting law for the region 0.001μ to 0.01μ ; and a point of inflection so that the limiting law is obeyed at extreme dilution.

The reaction between bromoacetate ion and the thiosulfate ion has been studied previously by Slator,¹⁰ Krapivin,¹¹ La Mer⁹ and Kappanna.¹² It is free from interfering side reactions since the constant for the hy-

drololysis of the bromoacetate ion to the glycolate ion with the formation of the hydrogen ion and the bromide ion

is of the negligible order³ of 1×10^{-6} . There is no change in ionic strength as the reaction proceeds. It can be followed precisely by iodine titration even at great dilution.

In studying the effect of changing ionic environment upon this reaction two methods may be used. (a) The total ionic concentration may be changed by varying only the concentration of the reacting salts. (b) Neutral salts may be added to a fixed concentration of reactants. Method (a) is the simpler because only one cation and no foreign anions need be present in addition to the anions of the kinetic reaction. Method (b) has the objection that at least one foreign cation or anion must be introduced into the mixture. It is also not well adapted for work at very small concentrations since it is not possible to have a reasonable concentration of reactants and at the same time keep the ratio of added salts to reactants large. Method (a) was therefore adopted except for the studies with the lanthanum salts.

II. Preparation of Materials

Bromoacetic Acid.—Kahlbaum's bromoacetic acid was redistilled under reduced pressure (10 mm.). The bromine content of the purified acid was 99.5% of the theoretical value. Its acid titration value agreed with the theoretical within 1 part per thousand. When 0.0333 *M* bromoacetate was treated with 0.0666 *M* thiosulfate, 99.7% of the theoretical amount of the thiosulfate reacted in forty-eight hours. At these concentrations the reaction should have been completed to within 1 part per thousand in twelve hours. We may therefore safely assume a purity between 99.5–99.7%. The bromoacetic acid was kept in a desiccator over sulfuric acid in a dark bottle and closet.

Sodium and Potassium Thiosulfate.—The c. p. salts were recrystallized from distilled water.

Barium Thiosulfate.—C. p. barium thiosulfate was recrystallized from distilled water. Since this salt is only slightly soluble in water a saturated solution was prepared at 100°. After cooling to 15°, the crystals were filtered off and dried at room temperature.

Magnesium thiosulfate was prepared by a modification of the method of Rammelsberg.¹³ Sulfur dioxide was passed into a suspension of 100 g. of magnesium oxide in 300 cc. of water until the mixture was slightly acid to litmus. An excess of sulfur was added together with sufficient water to make the total volume one liter. The mixture was boiled for four hours, replacing the water evaporated from time to time. The clear solution was decanted through a filter and allowed to cool. The magnesium thiosulfate was then precipitated by adding alcohol. The product was twice recrystallized from distilled water. In recrystallizing the magnesium thiosulfate it was found that a slight decomposition occurred if the solution was heated. Accordingly the crystals were dissolved in water without heating and the solution was allowed to evaporate at room temperature.

Calcium Thiosulfate.—The method was the same as that used for the magnesium salt.

Sodium Hydroxide.—Sticks of electrolytic sodium hydroxide were rinsed with distilled water and dissolved in freshly boiled water. The solutions were kept in paraffin-

¹³ Rammelsberg, *Pogg. Ann.*, Second Series, **56**, 295 (1842).

coated bottles and protected from carbon dioxide by guard tubes of soda lime. The solutions were standardized against Bureau of Standards potassium acid phthalate using phenolphthalein as an indicator.

Potassium Hydroxide.—Electrolytic potassium hydroxide was used in making up solutions. The same procedure was followed as in the preparation of sodium hydroxide solutions.

Barium Hydroxide.—Solutions were prepared from c. p. barium hydroxide by the method given by Findlay.¹⁴

Calcium Hydroxide.—A suspension of calcium hydroxide was prepared from c. p. calcium chloride by treating a solution of the chloride with an equivalent amount of sodium hydroxide solution. The precipitate was washed by decantation until the clear supernatant solution gave no test for the chloride ion after acidification with nitric acid and the addition of silver nitrate.

Magnesium Hydroxide.—A suspension of the hydroxide was prepared from c. p. magnesium chloride by the method used for the preparation of calcium hydroxide.

Iodine.—Commercial resublimed iodine was used without further purification. All iodine solutions were made up with 4% potassium iodide and standardized against arsenious acid.

Potassium Iodide.—Merck's potassium iodide was used. Samples gave no color with starch in neutral solution after twenty-four hours in the dark and no color with starch after acidification.

Arsenious Acid.—Kahlbaum's "zur Analyse" arsenious oxide was used as a primary standard. Solutions were prepared after the method of Kolthoff,¹⁵ and Washburn's¹⁶ procedure was followed in titration using a sodium bicarbonate buffer.

Nitrogen.—Commercial nitrogen was passed through a solution of potassium pyrogallate to remove traces of oxygen, and next over heated copper gauze to remove any carbon monoxide formed. The gas was then washed with water and passed through a sample of the solution to be used before passing it into the reaction mixture.

Lanthanum Chloride.—A sample of cerium-free lanthanum chloride prepared by the Welsbach Company was used.⁷

All volumetric glassware was calibrated, and the distilled water boiled previous to use to remove oxygen and destroy microorganisms, which interfere with the stability of thiosulfate solutions.

III. Experimental Procedure

All velocity experiments were conducted at $25.00 \pm 0.02^\circ$. The setting of the Beckmann thermometer was checked against a thermometer calibrated by the Bureau of Standards.

The thiosulfate solutions were titrated with a standard iodine solution and adjusted to the exact concentration desired. The bromoacetate solutions were prepared by weighing out the required amounts of bromoacetic acid and neutralizing with the hydroxides of the various metals using phenolphthalein as an indicator. Standard solutions of the soluble hydroxides were used as a check on the weighing. If the hydroxide was insoluble a suspension was used. After neutralization the solutions were diluted to the desired volume. In making up the reaction mixtures solutions of thiosulfate and bromoacetate were freshly prepared and standardized just before use.

¹⁶ Washburn, *THIS JOURNAL*, **30**, 31 (1908).

Experiments were carried out as follows. The two solutions containing the reactants were placed in the thermostat. When they had reached the temperature of the bath, the reactants were pipetted into the reaction vessel, taking the time of half delivery of the pipet when adding the second component as the initial time of the reaction. The very dilute reaction mixtures were prepared by diluting measured amounts of 0.01 *M* solutions of the reactants to the required volume in volumetric flasks and then transferred to the reaction vessel. At suitable intervals aliquots of the mixture were withdrawn and titrated with iodine. In experiments at the higher concentrations (0.01 *M* or greater), where the time error in stopping the reaction becomes important, the aliquot of the reaction mixture was pipetted into an amount of the iodine solution just insufficient to react with all the thiosulfate present in the sample. The conversion of the greater part of the reacting thiosulfate by the iodine effectively stopped the reaction. The titration was then completed by adding the standard iodine solution from a buret as quickly as possible. The dilute solutions in which the time error was small were titrated by introducing all the standard iodine directly into the aliquot of the reaction mixture.

The velocity constants were calculated by the formula $k = \frac{1}{a} \frac{1}{t} \frac{x}{(a-x)}$ where *k* is the velocity constant; *t* is the time in minutes; *a* is the initial concentration of the reactants in moles per liter; and *x* is the amount changed in time *t*. The value of *a* was determined by the dilution of the standard solutions used in making up the reaction mixtures and is expressed in moles per liter. The values of *x* and (*a* - *x*) in the ratio were determined in terms of the volume of iodine solution used in titrating the reaction mixtures since these values do not need to be in absolute units as is necessary for the quantity 1/*a*.

IV. Analytical Precision

In titrating the most dilute thiosulfate solutions there is a perceptible error in detecting the starch-iodine end-point which was corrected by appropriate blanks. Kolthoff¹⁵ states that 1×10^{-5} *M* of iodine per liter is required to give the blue color with starch in the presence of 4×10^{-5} *M* of *I*⁻ per liter. The sensitivity increases on increasing the iodide concentration. In this work the concentration of *I*⁻ ion at the end-point of the titration was always greater than 0.01 *M*. With this concentration of *I*⁻ ion the test was found in a north light to be sensitive to 1.5×10^{-6} *M* of iodine per liter in a volume of 250 cc.

In titrating iodine with thiosulfate in very dilute neutral solutions, Kolthoff¹⁵ states that iodine is hydrolyzed to hypoiodite which oxidizes the thiosulfate to sulfate instead of to tetrathionate. This mechanism requires less thiosulfate than the normal reaction. He states that the reverse titration, that of thiosulfate with iodine, proceeds normally since the iodine is removed at once and has no opportunity to enter into the hydrolytic side reaction. Before we were acquainted with this explanation, experiments had been carried out to test the reliability of the procedure by adding iodine to the reaction mixture and then back-titrating with thiosulfate. In experiments at a concentration of 0.001 *M* it was found that the velocity constants varied with the volume of solution in which the titration was performed. In titrating directly with iodine no difference was detected on varying the volume. The results for the di-

rect titration were somewhat higher than for the back titration. At concentrations of 0.002 *M* and greater no difference in the velocity constants was produced by changing the order of adding the reagents in the titration.

V. Stability of Thiosulfate Solutions

In very dilute solutions the stability of the thiosulfates may exercise a perceptible influence upon the results unless special precautions are taken. By preparing the solutions in freshly boiled water as recommended by Kilpatrick and Kilpatrick¹⁷ we found that 0.01 *M* thiosulfate solutions retain their titer to within 0.1% for a period of one week. However, experiments in which the initial concentration of thiosulfate was of 0.001 *M* or less exhibited a slight increase in the velocity constants after a period of two days. This drift in the values of the constants may be due to decomposition of the thiosulfate, for the increase was accelerated by the addition of traces of cupric ion (1×10^{-6} *M* per liter) in agreement with the studies of Abel.¹⁸

On the other hand, velocity experiments at an initial concentration of 0.00025 *M* thiosulfate performed under an atmosphere of nitrogen instead of air gave excellent constants! A solution of 0.00025 *M* thiosulfate preserved under nitrogen also showed no change in the iodine titration after one week and a change of only 0.5% after two weeks. All velocity experiments with 0.001 *M* thiosulfate or less which continued for more than two days were accordingly carried out under nitrogen. Since no experiment was continued for more than ten days any decomposition of the thiosulfate was negligible. It is not certain whether the decomposition observed in the dilute thiosulfate solutions was due to a reaction between oxygen and thiosulfate induced by minute traces of ions such as cupric or ferric ion present as impurities in our distilled water or whether it was due to bacteria whose growth or action is inhibited by the removal of the oxygen. The important point is that the results in the presence of nitrogen were reproducible in highly dilute solution and the constants under these conditions showed no drift with time!

When it was necessary to use nitrogen in an experiment, the purified gas was bubbled through the reaction mixture for forty-five minutes or more at the start of the experiment to remove the oxygen. Nitrogen was bubbled through the mixture daily to remove any trace of oxygen present due to possible leakages. Samples of the solution were removed by a pressure of nitrogen. The reaction mixtures in experiments performed under nitrogen were kept in glass-stoppered flasks of the type designed by MacInnes and Dole¹⁹ for work in an atmosphere of inert gas.

and five others which showed large deviations from the smooth curve when plotted were rejected.

The results in Table II were obtained by adding salts with trivalent cations to a dilute reaction mixture of the sodium salts. While this method does not permit measurements at very low ionic strengths it shows the profound catalytic effect of trivalent cations upon this reaction.

The theoretical meaning of the results given in the last two columns of Tables I and II will be discussed in detail in another section. Otherwise the headings of the columns are self-explanatory.

VII. Discussion of Results

By plotting the logarithm of the observed velocity constant k against the square root of the ionic strength, equation (4) demands that a straight line be approached having a slope equal to the product of the valences of the reacting ions, namely, $Z_A \cdot Z_B$. The intercept on the ordinate when the ionic strength equals zero corresponds to the value of k_0 , the specific reaction velocity constant, which is free from the disturbing concentration influences of interionic attraction provided the experimental data in finite concentrations obey equation (4) with sufficient precision to render the extrapolation trustworthy. A number of investigators have demonstrated the general validity of equation (4) but examples in which it fails are not lacking.^{20,3}

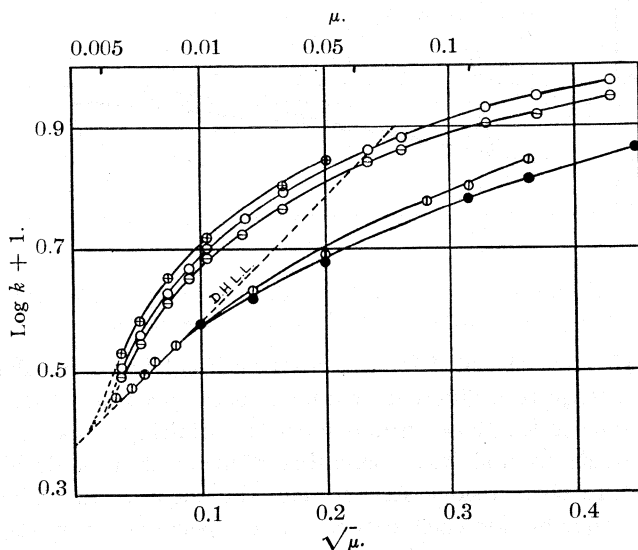

Fig. 1.—⊕, Barium; ○, calcium; ⊖, magnesium; ⊕, potassium; ●, sodium salts.

Our experimental results are shown graphically in Figs. 1 and 2 to test the validity of equation (4). The curve for the univalent potassium ion coincides with the limiting slope ($Z_A Z_B = 2.0$) for values of the square root of the ionic strength less than 0.03. In other words, the limiting law holds for the reaction in the presence of the univalent potassium ion in agreement with the conclusion reached by La Mer⁹ for the reaction in the presence of the sodium ion. The new results for the sodium and potassium ion are also identical within the experimental error for values of $\sqrt{\mu}$ less than 0.1 as shown by Fig. 1. This agreement of the experimen-

²⁰ Conant and Peterson, *THIS JOURNAL*, **52**, 1220 (1930). See page 1227. See Ref. 3 for reaction of β -bromopropionate ion and thiosulfate ion in highly dilute solutions.

tal results with the Debye-Hückel limiting law in the presence of these univalent cations is in accord with the results of the solubility studies, no appreciable discrepancy having been found for trivalent ions in the presence of univalent ions of opposite sign.

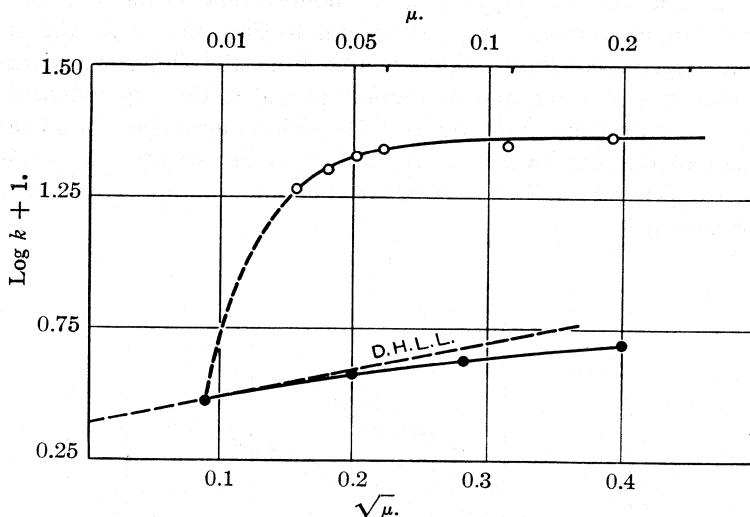

Fig. 2.—Dots, sodium salts; circles, lanthanum chloride added to lowest concentration of sodium salts of reactants.

The kinetic data obtained for this reaction involving a trivalent critical complex are of quite a different character in the presence of divalent cations. The curves for those cations cross the limiting slope at relatively high concentrations and with increasing dilution show a decided downward curvature with a slope steeper than the theoretical. The data are consistently specific for each cation. This specificity persists down to the lowest concentration studied, namely, $\sqrt{\mu} = 0.037$ or $0.00025 M$ for each reacting ion.

The form of these curves can be interpreted by the solubility studies of La Mer and Mason⁵ and the theoretical contributions of Gronwall, La Mer and Sandved.²¹ These authors^{5,6,7} have shown that the activity coefficients of high valence ions in the presence of high valence ions of opposite sign are considerably smaller than the values calculated by the Debye-Hückel limiting law. The kinetic factor in the reaction under discussion is of the type $f_1 f_2 / f_3$ where f_1 refers to the activity coefficient of the bromoacetate ion; f_2 to the thiosulfate ion and f_3 to the triply charged critical complex X. The effect of a high valence cation in the environment will be to give f_3 a value very much smaller than that calculated by the Debye-Hückel limiting law. The values of f_1 and f_2 will also de-

²¹ Gronwall, La Mer and Sandved, *Physik. Z.*, **29**, 358 (1928).

crease somewhat in the presence of a high valence cation but the decrease will not be sufficient to effect the decrease in f_3 . The total effect on changing the environment from a univalent to a divalent or trivalent cation will be to increase the value of $f_1 f_2 / f_3$. The experimental results agree with this prediction. The velocity constants for the reaction in the presence of divalent cations are always greater than those for the univalent potassium or sodium ion. Since this work was completed a paper by King and Jacobs²² upon the kinetics of the persulfate-iodide reaction has been published. Their results furnish another excellent example of the validity of equation (4) in the presence of the univalent potassium ion. In the presence of added *magnesium sulfate* there is also evidence of a "hump" type curve in their reaction. Unfortunately, as they point out, their reaction is complicated by the presence of the thiosulfate added to measure the progress of the reaction and consequently does not constitute an unambiguous example of this anomaly. The large "hump" noted with the persulfate additions is very likely due to reaction between thiosulfate and persulfate and should not be confused with the present anomaly since it appears at high concentrations.

Since the value of k_0 , the velocity constant for the reaction at infinite dilution, must be the same for all cations, all the curves must extrapolate to the same point. Any extrapolation to a limiting value is always burdened with some degree of uncertainty. A linear extrapolation with the aid of a theory based on reasonable postulates and in agreement with the data at finite concentrations involves the least possible uncertainty. We have accordingly evaluated k_0 by a linear extrapolation of the data for the reaction in the presence of the potassium ion in accordance with the limiting slope. The selection of the potassium data is justified by the disappearance of the specific effects of the sodium and potassium ions as demanded by the Debye-Hückel limiting law and by the agreement of the linear portion of the curve with the theoretical value of the limiting slope. This extrapolation gives $\log k_0 = \bar{1}.386$ or $k_0 = 0.243$. Extrapolation of the previous⁹ results for this reaction in the presence of the sodium ion gives $\log k_0 = \bar{1}.385$, or $k_0 = 0.243$.

Since the curves for calcium, barium and magnesium must extrapolate to the same value of $\log k_0$ as those of the univalent cations, a point of inflection must occur in the curves for the divalent cations if the limiting slope is reached at extreme dilution. The existence of such a point of inflection is in harmony with the requirements of the Gronwall, La Mer and Sandved²¹ extension of the Debye-Hückel theory and with recent experimental data on the behavior of the activity coefficients of cadmium sulfate and of zinc sulfate in high dilution.^{23,24}

²² King and Jacobs, *THIS JOURNAL*, **53**, 2704 (1931).

²³ La Mer and Parks, *ibid.*, **53**, 2040 (1931).

²⁴ Cowperthwaite and La Mer, *ibid.*, **53**, 4333 (1931).

A plot of the results with lanthanum chloride added to the reaction mixture (method *b*) is given in Fig. 2. These results demonstrate the profound catalytic effect produced by changing from a divalent to a trivalent cation. Since lanthanum chloride was added to the sodium salts of the reactants, the curve for lanthanum must join the sodium curve at a point corresponding to the concentration of the sodium salts alone. There will be, therefore, an abrupt change of slope at this point just as in the solubility studies where a foreign neutral salt is added to a solute to increase the solubility. This abrupt change in slope will always occur in the kinetic case when method (*b*) is used. With method (*a*) (only one cation and no foreign anions present) the curve will be smooth and pass through a point of inflection.

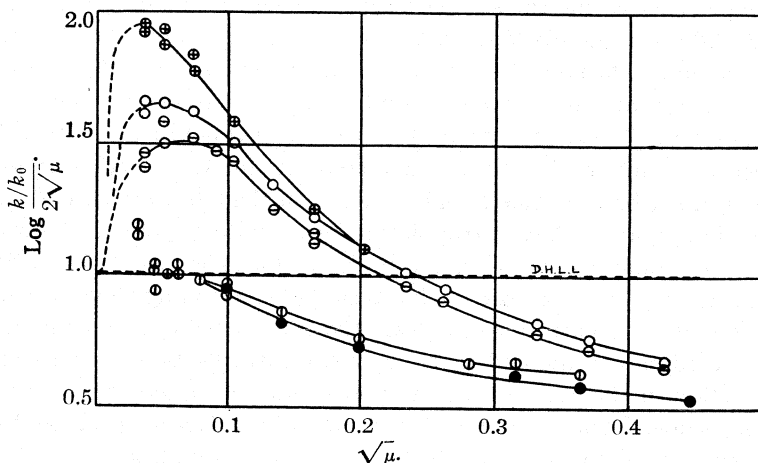

Fig. 3.— \oplus , Ba^{++} ; \circ , Ca^{++} ; \ominus , Mg^{++} ; $\textcircled{+}$, K^{+} ; \bullet , Na^{+} .

The kinetics of the reaction $2[\text{Co}(\text{NH}_3)_6\text{Br}]^{++} + \text{Hg}^{++} \rightleftharpoons [\text{X}]^{++++} \rightarrow 2[\text{Co}(\text{NH}_3)_6\text{H}_2\text{O}]^{+++} + \text{HgBr}_2$ involving a tetravalent positive ion as the critical complex were studied by Brönsted and Livingston⁴ for the purpose of testing the obedience of the kinetic factor to the limiting law. Although precise activity coefficients have never been obtained for tetravalent ions, nevertheless there is reason to surmise from the freezing point data on $\text{K}_4\text{Fe}(\text{CN})_6$ and from the e. m. f. data on the ferro-ferricyanide electrode²⁵ that deviations from the limiting law should persist down to the lowest concentrations studied by Brönsted and Livingston. An examination of their most consistent series (Fig. 5, no added salt) actually yields a limiting *experimental slope* of 7 to 8 instead of the *theoretical value* of 4. This series also exhibits the same curvature we have shown in Fig. 1 for the divalent cations.

²⁵ La Mer and Sandved, *THIS JOURNAL*, 50, 2656 (1928).

Brönsted and Livingston avoid this conclusion by ignoring their data at the lowest concentrations. Instead they²⁶ pass a straight line of theoretical slope through the data at intermediate concentrations. The present investigation shows this to be an unwarranted procedure, particularly for reactions between ions of the same sign. Our interpretation would involve a considerable displacement in the extrapolated value of k_0 employed by these authors.

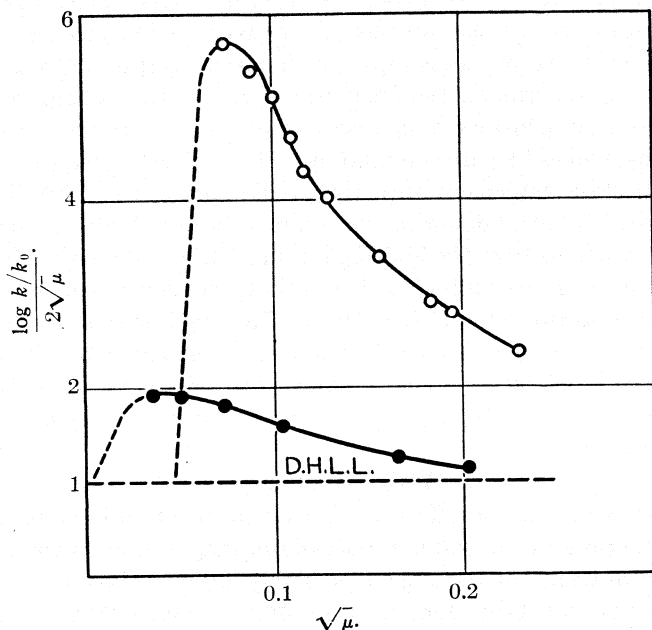

Fig. 4.—O, La^{+++} ; ●, Ba^{++} .

From equation (4) it is evident that $\log(k/k_0)/Z_A Z_B \sqrt{\mu}$ is the ratio between the experimental value of the kinetic activity coefficient factor and the ideal limiting value. The values of $\log(k/k_0)/2\sqrt{\mu}$ are given in Tables I and II and plotted in Fig. 3. This plot furnishes a more severe test of the experimental precision in the dilute region and shows the changes in slope as a function of the $\sqrt{\mu}$. The curves for sodium and potassium give a horizontal line (value equal to unity) agreeing within experimental error with the limiting law up to $\sqrt{\mu} = 0.030$. At higher concentrations the ratio decreases. With barium, calcium and magnesium the curve does not approach the limiting value at the lowest concentrations studied. At the higher concentrations the value of $\log(k/k_0)/2\sqrt{\mu}$ is less than unity as in the univalent case. The ratio increases with dilution until it be-

²⁶ Livingston, *J. Chem. Education*, 7, 2887 (1930), where a part of the data is re-plotted.

comes from 40 to 90% greater than the limiting value. The effect is still more pronounced with the lanthanum ion, Fig. 4. At $\sqrt{\mu} = 0.196$ the ratio is over 100% greater than the limiting value and at $\sqrt{\mu} = 0.90$ it has increased to 5.4.

No attempt has been made to treat the kinetic results quantitatively by use of the mathematical expressions for the higher terms of the Poisson-Boltzmann equation as developed for the unsymmetrical case by La Mer, Gronwall, and Greiff.⁸ To avoid the introduction of more than one arbitrary parameter the assumption of an average ion size for the three salt types involved is necessary. Such an assumption does not seem justifiable. Furthermore, the structure of the critical complex is so uncertain that any arbitrary assignment of an ion size in the present state of knowledge would be pure speculation. However, the forms of the curves are in such close agreement with the predictions of the solubility studies that there can be little doubt of the common origin of the anomaly. The observed deviations from the limiting law may, therefore, be safely ascribed more to failure of the individual ion activity coefficients in high valence mixtures to conform to the Debye-Hückel limiting law than to an incorrect form of the kinetic activity coefficient correction given by the Brönsted rate equation.² However some modifications will very likely be needed to account for orientation,³ viscosity and non-thermodynamic factors of kinetic influence.

VIII. Summary

The kinetics of the thiosulfate-bromoacetate reaction have been studied at 25° in the presence of sodium, potassium, magnesium, calcium, barium and lanthanum ions in the region of highly dilute solution.

The velocity constants for the thiosulfate-bromoacetate reaction are reproducible in an atmosphere of nitrogen at a concentration of 0.00025 *M* and show no drift with time.

The experimental results for the reaction in the presence of the univalent sodium and potassium ions agree with the theoretical equation developed on the basis of the Debye-Hückel limiting law.

In the presence of the divalent cations deviations of 40 to 80% from the limiting equation were observed while in the presence of the trivalent lanthanum ion a deviation of 440% is found at $\sqrt{\mu} = 0.09$.

A plot of $\log k$ against $\sqrt{\mu}$ for the results in the presence of high valence cations exhibits the characteristic types of curves predicted from solubility data for similar valence types and by the La Mer, Gronwall and Greiff extension of the Debye-Hückel theory to unsymmetric valence types, a result which verifies Brönsted's theory of ionic catalysis, but necessarily limits the applicability of the Debye-Hückel limiting law as an extrapolation equation for reactions between ions of the same sign.

THE SOLUBILITY OF THALLOUS CHLORIDE IN THE PRESENCE OF EDESTIN NITRATE¹

BY CRAWFORD F. FAILEY

RECEIVED MARCH 2, 1932

PUBLISHED JUNE 6, 1932

One may well begin a discussion of the interaction of salts and proteins in solution by recalling the fact that thermodynamic reasoning cannot decide from measurements of ion activities and concentrations whether there is combination between salt and protein, or whether a decreased activity is due to interionic attraction. We shall set $\gamma = a/m$, where a stands for activity and m for molality, without making any assumption as to how changes in a are brought about. Some particular hypothesis may, however, appear more probable in the light of other physical theories or by analogy with simpler systems.

It will be shown later that edestin changes the mean activity coefficient of thalious chloride

$$\gamma_{\pm} = \sqrt{\frac{a_{\text{Tl}^+} a_{\text{Cl}^-}}{m^2}} = \sqrt{\gamma_{\text{Tl}^+} \gamma_{\text{Cl}^-}}$$

by about the same amount as an equal edestin concentration changes γ_{Cl^-} . From this we may conclude that γ_{Tl^+} is affected by the addition of edestin equally with γ_{Cl^-} . An equal binding of Cl^- and Tl^+ in spite of considerable hydrogen ion changes seems unlikely. In opposition to the above may be cited the findings of Northrop and Kunitz,² who observed no influence of gelatin on the activity of Li^+ , Na^+ , K^+ , NO_3^- or $\text{SO}_4^{=}$ although these ions should be sensitive to changes in ion atmosphere or dielectric constant if the chloride activity variations be due to these factors.

Experimental

The thalious chloride in this work was the same preparation used by the author in a previous investigation,³ from which paper values for the solubility in 0.025 molal nitric acid and 0.050 molal nitric acid are taken. The edestin, extracted from hemp seed with 10% sodium chloride, was recrystallized five times from 10% sodium chloride by diluting with three volumes of water at 50° and allowing to cool, then recrystallized twice from 7.5% potassium nitrate by the same method. It was washed free from nitrate by suspending five times in water. Experiments with sodium chloride had shown that this would reduce the salt content to a point where its contribution to the ionic strength could be neglected. The preparation was chloride free.

¹ This work was aided by a grant from The Chemical Foundation.

² Northrop and Kunitz, *J. Gen. Physiol.*, **11**, 481 (1928).

³ Failey, *THIS JOURNAL*, **54**, 576 (1932).

Determinations of the solubility at $25.00 \pm 0.01^\circ$ were carried out as described in reference 3 except for the method of analysis. The following procedure gave maximum errors of 0.3% on protein solutions of known chloride content. To weighed samples of approximately 100 g. a 50% excess of silver nitrate was added, then 100 ml. of concentrated chloride-free nitric acid. The flasks were digested for twenty-four hours on the steam-bath with the addition of a few drops of caprylic alcohol to prevent foaming. After cooling the silver chloride was washed thoroughly by decantation and weighed in Gooch crucibles with porous porcelain bottoms. Thallous chloride was shown by analysis to be the solid phase in the most concentrated protein solution.

Discussion

The results are tabulated in Table I where the first column indicates grams of edestin per 1000 g. of water; the second, molality of nitric acid; the third, thallous chloride solubility in moles per 1000 g. of water; the fourth, $-\log \gamma_{\pm}$; and the fifth, γ_{\pm} .

The activity coefficients were obtained by means of the equation $-\log \gamma_{\pm} = \log (1/m_{\pm}^o) - \log (1/m_{\pm})$ on the assumption that $\log (1/m_{\pm}^o) = 1.8630$.⁴

Figure 1 is a plot of Table I with $-\log \gamma_{\pm}$ as ordinate and g. of edestin per 1000 g. of water as abscissa. It may be seen that the points for each acid concentration fall approximately on a straight line. Roughly we may set $-\Delta \log \gamma_{\pm}/g = 1.5 \times 10^{-3}$ where g is grams of edestin per 1000 g. of water. The addition of 10.7 g. of edestin has the same effect on γ_{\pm} TiCl as 0.1 mole = 7.5 g. of glycine.³

Pauli and Stenzinger⁵ have measured the solubility of calcium sulfate in protein solutions. Values of $-\Delta \log \gamma_{\pm}/g$ calculated from their data are shown in Table II.

⁴ "International Critical Tables," Vol. VII, p. 319.

⁵ Pauli and Stenzinger, *Biochem. Z.*, 205, 71 (1929).

TABLE II

Protein	Salt or ion	$-\Delta \log \gamma_{\pm} \times 10^3$ g	Reference
Edestin	TiCl	1.5	This paper
Serum albumin	CaSO ₄	1.5	5
Pseudoglobulin	CaSO ₄	3.9	5
Hemoglobin	CaSO ₄	4.6	5
Edestin	Cl ⁻	1.7	6
Gelatin	Cl ⁻	0.9	6
Gelatin	Cl ⁻	1.3	2

The e. m. f. measurements of Hitchcock⁶ gave results with which the above may be compared. Hitchcock stated that his experiments agree with the assumption that in 0.1 molal hydrochloric acid 1 g. of edestin

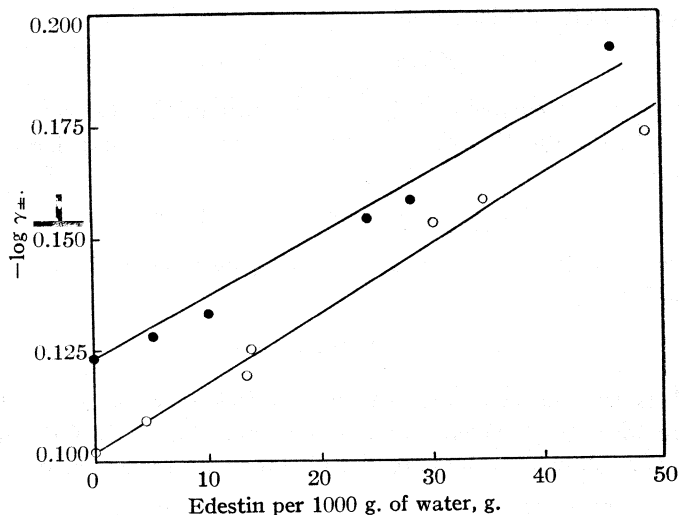

Fig. 1.—O, edestin + HNO₃, M/40; ●, edestin + HNO₃, M/20.

combines with a maximum of 3.9×10^{-4} mole of Cl⁻ and 1 g. of gelatin combines with 2.0×10^{-4} mole of Cl⁻. This would make a_{Cl^-} and also γ_{Cl^-} a linear function of g . For small changes in γ_{Cl^-} it would be true that $\log \gamma_{\text{Cl}^-}$ is also linear. Then for edestin we may set

$$\frac{-\Delta \log \gamma_{\text{Cl}^-}}{g} = \frac{\log 0.1 - \log (0.1 - 3.9 \times 10^{-4}g)}{g} = 1.7 \times 10^{-3}$$

For gelatin the value is 0.9×10^{-3} .

Northrop and Kunitz² concluded from measurements of membrane equilibria that gelatin may bind approximately 3×10^{-4} mole of Cl⁻ in CuCl₂, per g. of protein. Then $-\Delta \log \gamma_{\text{Cl}^-}/g = 1.3 \times 10^{-3}$.

The data of Stadie and Sunderman⁷ on the freezing point of solutions

⁶ Hitchcock, *J. Gen. Physiol.*, **14**, 99 (1930); *ibid.*, **15**, 125 (1931).

⁷ Stadie and Sunderman, *J. Biol. Chem.*, **91**, 227 (1931).

of hemoglobin to which sodium hydroxide has been added offer an opportunity for calculating changes in γ_{Na^+} if one makes the necessary assumption that the authors have been able to "correct for ΔHb ." This assumption postulates that in the four term Duhem equation

$$d \ln a_1 = -\frac{m_2}{55.51} d \ln \gamma_2 m_2 - \frac{m_3}{55.51} d \ln \gamma_3 m_3 - \frac{m_4}{55.51} d \ln \gamma_4 m_4$$

where the subscript 1 refers to H_2O , 2 to Na^+ , 3 to OH^- and 4 to Hb, the m_3 term is negligible and the m_4 term is unaffected by changes in γ_4 . The authors find on adding sodium hydroxide to Hb and also on diluting a solution of NaHb of given Na^+/Hb^- ratio that the observed freezing point depression ascribed to Na^+ is equal to 0.75 the theoretical within the limits of error, or $\varphi_{\text{Na}} = 0.75$. On the assumptions made as to a_{Hb} and a_{OH} the Duhem equation reduces to

$$-d \ln a_1 = \frac{m_2}{55.51} d \ln \gamma_2 m_2$$

Following the treatment of Lewis and Randall,⁸ observing that $j = 1 - \varphi_{\text{Na}^+} = 0.25$ and that $dj = 0$, we have for these small freezing point depressions

$$d \ln \frac{a_2}{m_2} = -j d \ln m_2 = -0.25 d \ln m_2$$

or, changing to the base 10 and integrating between $m = 0.01$ and any given molality

$$\log \frac{\gamma_2}{\gamma_2^\#} = -0.25 (\log m_2 - \log 0.01)$$

where $\gamma_2^\#$ is the value of the activity coefficient when $m_2 = 0.01$. If we assume $\gamma_2^\# = 0.90$, which is an average value for γ_\pm in 0.01 molal salt solutions, the following values are obtained for Na^+ in the presence of Hb^- .

TABLE III

m_2	$\gamma_2/\gamma_2^\#$	γ_2
0.01	1.00	0.900
.02	.841	.757
.03	.760	.684
.05	.669	.602
.08	.593	.535
.10	.558	.502

TABLE IV

C	γ_{Cl^-}	γ_{Na^+}
0.0125	0.86	0.87
.0128	.89	.87
.0178	.80	.78
.0361	.62	.66
.0404	.65	.64
.0405	.59	.64

These may be compared with the results of Adair⁹ on solutions of edestin chloride. The first column given salt concentration; the second, Adair's values for γ_{Cl^-} ; and the third, γ_{Na^+} interpolated from Table III.

Tables III and IV are plotted in Fig. 2 together with values of γ_\pm in sodium chloride solution for comparison.¹⁰ The calculations show that

⁸ Lewis and Randall, "Thermodynamics," 1923, p. 285.

⁹ Adair, *Proc. Roy. Soc. (London)*, A120, 573 (1928).

¹⁰ Taylor, "Treatise on Physical Chemistry," 1931, Vol. I, p. 772.

with a constant φ_{Na^+} there is associated a considerable change in γ_{Na^+} as the molality is varied. Figure 2 indicates the agreement between the work of Adair and that of Stadie and Sunderman, although the latter authors, assuming that constant φ implied constant γ , found contradictions. It may finally be pointed out that Adair's values would give a much greater $-\Delta \log \gamma_{\text{Cl}^-}/g$ than any shown in Table II.

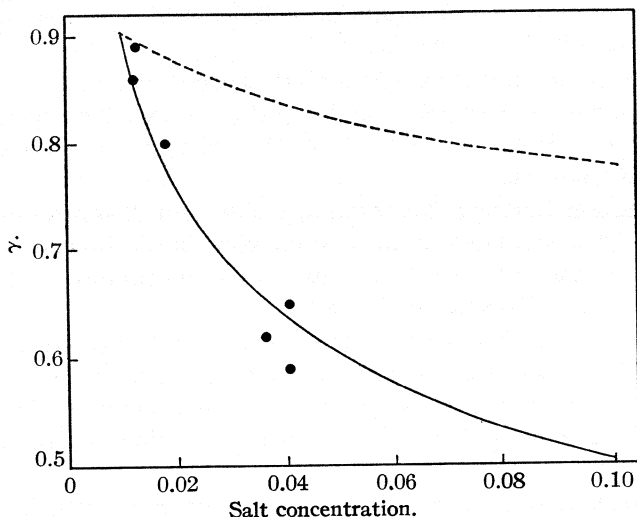

Fig. 2.—The points are Adair's values for γ_{Cl^-} in edestin chloride. The full line represents γ_{Na^+} in the presence of hemoglobin assuming $\varphi_{\text{Na}^+} = 0.75$ and that $\gamma_{\text{Na}^+} = 0.90$ when $c = 0.01$. For comparison the broken line gives γ_{\pm} in aqueous sodium chloride solutions.

Summary

The solubility of thallos chloride in solutions of edestin nitrate has been determined. The negative logarithm of the activity coefficient of thallos chloride is approximately a linear function of grams of edestin per 1000 g. of water. Some existing data on the activity of salts in the presence of protein have been compared.

THE COMPOSITION OF MAGNESIUM OXYCHLORIDE

By H. S. LUKENS

RECEIVED MARCH 3, 1932

PUBLISHED JUNE 6, 1932

The composition of magnesium oxychloride has been the subject of a number of reported investigations.¹

The more recent investigations indicate uncertainty as to the existence of definite compounds of MgO and $MgCl_2$. It was the purpose of this investigation to endeavor to establish the existence or absence of such definite combinations.

The Reaction between Magnesium Oxide and Magnesium Chloride Solutions.—The solubility of magnesium oxide in solutions of magnesium chloride with the subsequent formation of a precipitate in the filtered solutions was first reported by G. André.²

The product of this reaction was subsequently investigated by W. Feitknecht,¹ who showed that the products resulting from the interaction of magnesium oxide and magnesium chloride bear a definite relation to the source of the magnesium oxide, *i. e.*, whether obtained by the ignition of the carbonate or oxalate.

The present investigation had, as an initial objective, the investigation of the reaction between magnesium chloride solutions and magnesium oxide obtained by the ignition of magnesium hydroxide.

Experimental

For the purpose of these experiments, magnesium oxide of the following analysis was used:

The material was digested with an excess of distilled water for twenty-four hours at a temperature of 100° . It was then dried on a steam-bath and heated to constant weight at a temperature of 110° . A sample ignited to constant weight at 1000° showed a loss of 30.86% as contrasted with a calcd. loss of 30.88%.

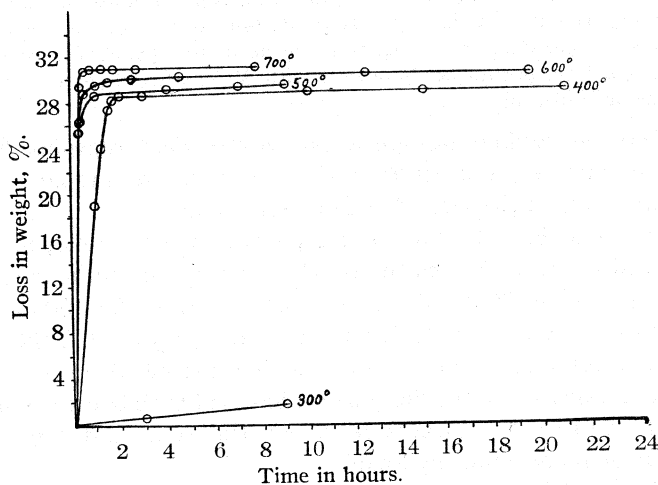

Fig. 1.—Effect of temperature on magnesium hydroxide; $\text{Mg}(\text{OH})_2 \rightarrow \text{MgO} + \text{H}_2\text{O}$ —loss = 30.88 %. Reaction at 800° , complete in 30 min.; reaction at 900° , complete in 15 min.; reaction at 1000° , complete in 10 min.

Lacking data regarding the rate at which magnesium hydroxide loses water at various temperatures, this subject was investigated with the results indicated in the graphs, Fig. 1. The rate of loss was determined by heating 7- to 8-g. samples in platinum in an electrically heated muffle at the desired temperature for ten-minute (or longer) intervals. The crucible and contents were then cooled in a phosphorus pentoxide desiccator and weighed. The oxide produced by low temperature calcination was extremely hygroscopic and the greatest care was required to secure reproducible results. The oxide produced by calcination at 900 and 1000° was quite inert and could be exposed to the atmosphere of the balance case without detectable change over a period of an hour.

The technique adopted for the determination of the rate of solution of magnesium oxide in magnesium chloride solutions was as follows.

A weighed amount of magnesium oxide was triturated in a mortar with a 25-cc. portion of magnesium chloride solution. Mortar, pestle, magnesium oxide and magnesium chloride solution were previously brought to the working temperature selected. The solution was decanted into a test-tube of 125 cc. capacity. The heavy particles which remained, after decanting the liquid carrying considerable solid material in suspension, were ground with the liquid remaining until all the large particles were reduced to a uniform suspension. A second portion of magnesium chloride solution was then added and the same operations repeated. On decanting a third 25-cc. portion from the mortar, all solid particles appeared to have been removed. A fourth 25-cc. portion of magnesium chloride solution served to assure the complete removal of all solid particles and brought the volume of magnesium chloride solution to a total of 100 cc. The stoppered tube and contents were placed in a constant temperature bath and turned end over end at a velocity of fifteen turns per minute throughout the duration of the experiment. At intervals, 10-cc. portions of the contents of the tube were withdrawn and the amount of magnesium oxide in solution determined by filtering and titrating a 5-cc. portion of the filtrate with $N/5$ hydrochloric acid, using phenolphthalein as an indicator.

The above described procedure proved to yield reproducible results, whereas no success was attained in attempting to prepare samples of magnesium oxide of like particle size by screening.

The graphs in Fig. 2 represent results obtained by following the foregoing procedure at a temperature of 30° . The graphs for magnesium oxide prepared at 500 and 600° fall regularly between those for 400 and 700° and are therefore omitted. At higher temperatures, up to 40° , the curves fall in the same relation to one another with the time decreased; at lower temperatures, down to 10° , the time is increased with decrease in temperature. The figures in brackets represent the time and temperature of calcination of magnesium hydroxide.

From the graphs, it is apparent that there is a definite relationship between the thermal treatment of the magnesium oxide and the rate of solution as well as the amount of oxide dissolved. The rate of precipitation of the new compound, once saturation is attained, is substantially the same in all cases.

An increase in the ratio of the amount of oxide to the amount of magnesium chloride solution decreases the time required to attain saturation and the amount of oxide dissolved increases [Graph 2 g., twenty-one hours, 400°]. A decrease in the ratio of oxide to solution retards the rate of formation of the insoluble precipitate to a marked degree [Graph 0.5 g., twenty-one hours, 400°].

In all cases the concentration of magnesium oxide in the solutions decreased as more and more precipitate was formed, finally approaching the solubility of magnesium hydroxide in the solution under investigation.

The following procedure was developed for the preparation of the precipitate. A sample of oxide of known thermal history was triturated in a mortar with magnesium chloride solution, as previously described, and the suspension, contained in a stoppered tube, was then agitated in a constant temperature bath. After the lapse of sufficient time to effect saturation of the solution with oxide, as indicated by the graph correspond-

ing to that oxide, the concentration of the magnesium chloride solution used, and the temperature, the excess oxide was removed from the solution by filtration. The clear filtrate was placed in a clean flask and returned to the constant temperature bath. Here it was allowed to remain until sufficient precipitate collected to provide a sample for analysis. The precipitate was then removed by filtration, dried rapidly by suction, and washed with 75- to 100-cc. portions of absolute alcohol prepared as recommended by G. Frederick Smith.³ The washing with alcohol was conducted by removing the

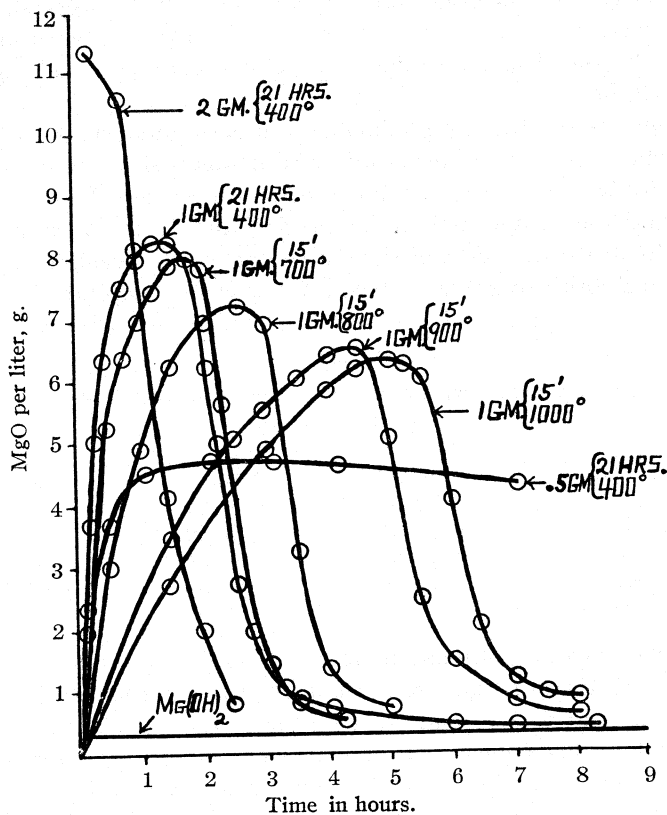

Fig. 2.—Solubility of magnesium oxide in magnesium chloride solution of sp. gr. 1.179; temperature 30°.

gelatinous precipitate to a flask and stirring with a rod while covered with a small portion of alcohol. More alcohol was then added and the mixture shaken violently until a uniform suspension of precipitate in alcohol was attained. The alcohol was then removed by filtration, with suction, and the operation repeated with additional portions of alcohol until successive portions of filtrate, when tested, indicated a low constant chlorine content. This was found to correspond to 0.213 g. of soluble material per liter. From six to eight portions of alcohol were required to complete the washing. The material was then heated at a temperature of 100° to constant weight. As the material was hygroscopic, it was introduced into weighing bottles while warm and samples for

³ Smith, *Ind. Eng. Chem., Anal. Ed.*, 1, 2, 72 (1929).

analysis were measured by determining the weight of bottle and contents before and after pouring out samples.

The precipitates, while forming, appeared to consist of minute crystals. On removal from the solutions they were observed to have all of the characteristics of a gel. On washing with alcohol the precipitates lost their gel-like properties and became decidedly crystalline. This change was accompanied by a marked decrease in volume. It was observed, however, that if a washed and dried precipitate were again treated with magnesium chloride solution, it again attained the gel-like character and regained its former volume.

Many efforts to obtain reproducible results on analysis of samples prepared in this way were unsuccessful, until it was realized that there was a relationship between the time the precipitate remained in the chloride solution and the composition of the precipitate. A few results are tabulated to illustrate the effect of time of contact of the precipitates with the magnesium chloride solutions from which they were precipitated. The chlorine content is assumed to be present in the form of magnesium chloride.

TABLE I
EFFECT OF TIME OF CONTACT WITH MAGNESIUM CHLORIDE SOLUTIONS ON COMPOSITION OF PRECIPITATE

MgO, 1 g., 30 hours, 400°. MgCl ₂ , 100 cc. Sp. gr. 1.179. Temp., 25°			
Time precipitate remained in solution	Composition of precipitate		
	MgO, %	MgCl ₂ , %	H ₂ O, %
1 hour	44.61	20.34	35.05
10 hours	44.34	21.38	34.28
24 hours	38.84	25.08	36.08
10 days	35.96	26.84	37.20
9 months	36.51	27.07	36.42

With such evidence, strongly indicative that the ratio of MgCl₂ to MgO increased with time of exposure of the precipitate to the solution in which it formed, an effort was made to determine whether the precipitate, as formed, was homogeneous. Two portions of a precipitate were collected. One portion represented that which formed at first and which was removed from solution within one hour after precipitation started. The second portion was the precipitate which formed between one hour after and four hours after precipitation started. After removal of the second portion, a further small amount of precipitate formed but this was discarded. On analysis of the two portions of precipitate, the following results were obtained.

TABLE II
COMPOSITION OF INITIAL AND FINAL PORTIONS OF PRECIPITATE

MgO, 1 g., 30 hours, 400°. MgCl ₂ , 100 cc. Sp. gr., 1.179. Temp., 25°				
Period of time after precipitation started during which sample was formed	Composition of precipitate			
	MgO, %	MgCl ₂ , %	H ₂ O, %	Ratio MgO: MgCl ₂
0 → 1 hour	42.42	20.09	37.49	4.97 : 1
1 hour → 4 hours	42.51	20.07	37.42	5.00 : 1

From the above and similar data it was concluded that the precipitate, as formed, was uniform in composition.

To determine definitely whether a precipitate changed in composition on further contact with the solution in which precipitation took place, the following experiment was conducted. Five grams of magnesium oxide (30 hours, 400°) was treated with 250 cc. of magnesium chloride solution of sp. gr. 1.179 at a temperature of 25°. The precipitate formed after filtering remained in contact with the solution at constant temperature for a period of ten days. On analysis the precipitate was found to have the following composition: MgO, 42.35%; MgCl₂, 20.85%; H₂O, 36.80%; ratio of MgO:MgCl₂, 4.79:1. Further data relating to such changes are presented later.

To determine whether the precipitates differed in composition when prepared from samples of magnesium oxide of different thermal history, experiments were conducted from which the following results were obtained.

TABLE III

COMPOSITION OF INITIAL PRECIPITATES OBTAINED FROM MAGNESIUM OXIDE SAMPLES OF DIFFERENT THERMAL HISTORY

Type of MgO	Composition of precipitates				Ratio MgO : MgCl ₂
	MgO, 1 g.	MgCl ₂ , 100 cc.	Sp. gr., 1.179.	Temp., 25°	
	MgO, %	MgCl ₂ , %	H ₂ O, %		
21 hours, 400°	44.62	20.39	34.99		5.12 : 1.00
36 hours, 500°	42.56	20.08	37.36		5.01 : 1.00
30 min., 800°	42.72	19.93	37.35		5.06 : 1.00
10 min., 1000°	44.68	20.28	35.04		5.20 : 1.00

It is evident that within the range covered, the mole ratio of magnesium oxide to magnesium chloride approaches 5:1, irrespective of the thermal treatment of the oxide from which the precipitates are prepared.

Temperature was found to have a marked effect on the velocity of the reaction. At 20° only a slight precipitate formed within twenty-four hours; in forty-eight hours precipitation was complete. Raising the temperature from 25 to 30° increased the rate of solution of oxide approximately 50%. Change in temperature was found to have no detectable effect on the ratio of magnesium oxide to magnesium chloride in the precipitates as is illustrated in Table IV.

TABLE IV

EFFECT OF TEMPERATURE ON COMPOSITION OF INITIAL PRECIPITATES

Temperature during formation, °C.	Composition of precipitates				Ratio MgO : MgCl ₂
	MgO, 1 g., 30 hours, 400°.	MgCl ₂ , 100 cc.	Sp. gr., 1.179		
	MgO, %	MgCl ₂ , %	H ₂ O, %		
20	44.35	21.38	34.27		4.89 : 1.00
25	42.41	20.11	37.48		4.98 : 1.00
30	42.72	20.05	37.23		5.03 : 1.00

To determine whether the composition of the precipitate was influenced by the specific gravity of the magnesium chloride solutions employed, precipitates were made at 25° using magnesium oxide prepared at 400°, and magnesium chloride solutions of sp. gr. 1.124, 1.142, 1.148, 1.151, 1.160, 1.179 and 1.265. The results of the analysis of these precipitates are shown in the graphs, Fig. 3.

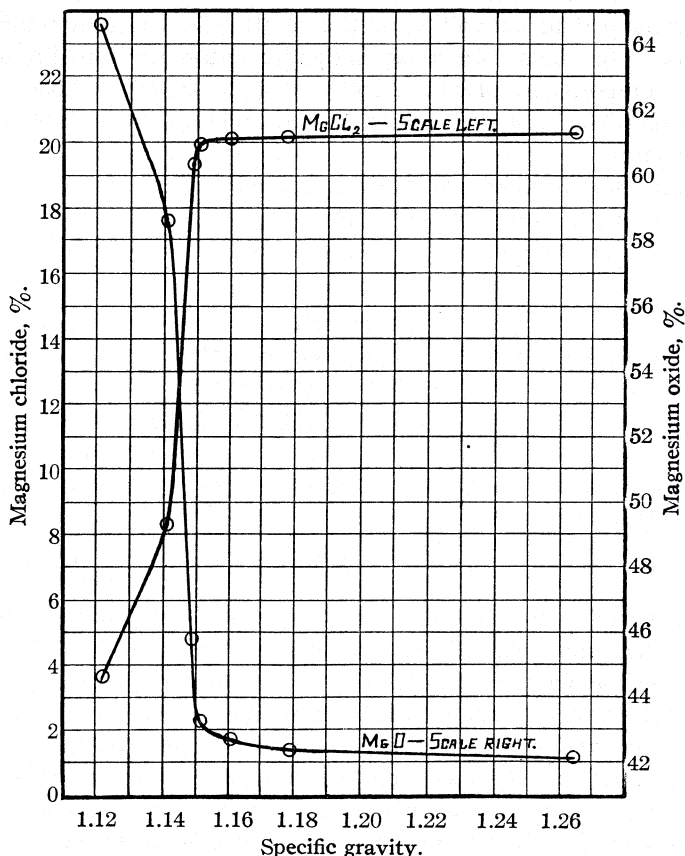

Fig. 3.—Composition of initial precipitates with change in specific gravity of magnesium chloride solutions.

The precipitates were removed from solution within five to six hours after the first contact of the oxide with the solutions. The precipitate produced in solution of sp. gr. 1.151 appeared to be more crystalline than those produced at higher concentrations. The precipitate formed in solution of sp. gr. 1.124 was decidedly flocculent.

It is obvious from the graphs that in solutions of sp. gr. below 1.16 the magnesium oxide content of the precipitates increases while the magnesium

chloride content decreases correspondingly. Such findings may be explained on the assumption that in solutions of low specific gravity, magnesium oxide combines with water to form magnesium hydroxide rather than a compound with magnesium chloride. From solutions of sp. gr. 1.16 up to sp. gr. 1.265 the initial precipitates consist of a combination of magnesium oxide, magnesium chloride and water in which the ratio of magnesium oxide to magnesium chloride is 5 to 1.

Robinson and Waggaman⁴ describe a compound formulated $3\text{MgO} \cdot \text{MgCl}_2 \cdot 10\text{H}_2\text{O}$. As this compound was formed after equilibrium was attained between the interacting constituents, it seemed of interest to investigate further the action of magnesium chloride solutions on the compounds just described. A precipitate corresponding to the 5 to 1 ratio was prepared. One-half was used for analysis, the other portion was covered with 50 cc. of magnesium chloride solution, sp. gr. 1.265, and agitated in a stoppered tube at 25° for ninety hours. The results of the analysis of the precipitates before and after treatment are given in Table V.

TABLE V

CHANGE IN COMPOSITION OF INITIAL PRECIPITATE WHEN AGITATED WITH MAGNESIUM CHLORIDE SOLUTION

Precipitate	Composition of precipitates				Ratio MgO : MgCl ₂ : H ₂ O
	MgO, %	MgCl ₂ , %	H ₂ O, %		
Initial precipitate	42.56	20.08	37.36		5.01 : 1.00 : 9.84
Precipitate after treatment with magnesium chloride for 90 hours	34.86	26.38	38.76		3.48 : 1.00 : 7.76

A precipitate was prepared and allowed to remain in contact with the solution for a period of ten days at 25°. Four samples of 2 g. each were placed in flasks, covered with 100 cc. of magnesium chloride solution, sp. gr. 1.325, the flasks stoppered and allowed to remain undisturbed in a constant temperature bath at 25° until removed for analysis. Analyses were made at intervals over two years with results indicated in Table VI.

TABLE VI

CHANGE IN COMPOSITION OF INITIAL PRECIPITATE ON UNDISTURBED CONTACT WITH MAGNESIUM CHLORIDE SOLUTION

Treatment of precipitate	Composition of precipitates				Ratio MgO : MgCl ₂ : H ₂ O
	MgO, %	MgCl ₂ , %	H ₂ O, %		
Original precipitate	42.35	20.86	36.79		4.79 : 1.00 : 9.32
After 5 months	38.30	24.99	36.71		3.62 : 1.00 : 7.76
After 11 months	36.55	27.25	36.20		3.16 : 1.00 : 7.02
After 18 months	36.45	27.39	36.16		3.14 : 1.00 : 6.98
After 24 months	36.49	27.11	36.40		3.17 : 1.00 : 7.09

The ratio of magnesium oxide to magnesium chloride described by Robinson and Waggaman is confirmed. The water content differs,

⁴ Robinson and Waggaman, *J. Phys. Chem.*, **13**, 673 (1909).

probably due to the difference in the methods used in the preparation of samples for analysis.

Up to the present it has not been possible to devise any method for determining the water content of the precipitates. The gel-like appearance indicates that the amount of water is greater than indicated by the analyses. The water is obviously loosely held, for even protracted washing with absolute alcohol tends to reduce the water content as is evident from the data in Table VII.

TABLE VII

Loss of water by $5\text{MgO} \cdot \text{MgCl}_2 \cdot x\text{H}_2\text{O}$ on washing with alcohol	Composition of precipitate			
	MgO, %	MgCl ₂ , %	H ₂ O, %	Ratio
Number of times washed with anhydrous alcohol				MgO : MgCl ₂ : H ₂ O
7 completed within an hour	42.56	20.08	37.36	5.01 : 1.00 : 9.84
10 over a period of 4 days	51.27	24.14	24.59	5.06 : 1.00 : 5.43

When exposed to the atmosphere of a phosphorus pentoxide desiccator, both compounds lose water steadily. The compounds were not in equilibrium with the desiccator atmosphere even after 111 hours at a pressure of 5 mm. On heating, both compounds will, in time, come to constant weight at any given temperature up to 200°. After heating for thirty-five hours at 200°, the 5 to 1 compound lost 17.16% of its weight after drying over phosphorus pentoxide at 5 mm. for 111 hours; the 3 to 1 compound lost 24.67%.

Summary

Magnesium oxide is shown to dissolve in magnesium chloride solutions with the subsequent precipitation of a compound in which the ratio of magnesium oxide to magnesium chloride is 5 to 1, loosely combined with an unknown amount of water.

The velocity of the reaction is determined principally by the thermal treatment of the magnesium oxide and by the temperature at which the reaction takes place.

The compound initially precipitated in solutions of magnesium chloride of concentrations above sp. gr. 1.16 may be formulated $5\text{MgO} \cdot \text{MgCl}_2 \cdot x\text{H}_2\text{O}$.

The compound $5\text{MgO} \cdot \text{MgCl}_2 \cdot x\text{H}_2\text{O}$ on continued treatment with magnesium chloride solution of sp. gr. above 1.16 is transposed to a new compound which may be formulated $3\text{MgO} \cdot \text{MgCl}_2 \cdot y\text{H}_2\text{O}$.

No satisfactory method has been devised for determining the water content of the compounds as formed in solution.

This lamp¹ was designed to meet the demand for an intense source of ultraviolet light for photochemical investigations and particularly for illuminating the slit of a monochromator. Mercury lamps and other sources of ultraviolet light have been reviewed.^{2,3} Forbes and his co-workers^{4,5} have developed an effective capillary mercury vapor lamp and have studied carefully its characteristics. The lamp described here is less permanent and it must be water cooled, but it is simpler and cheaper. One can afford to run it at a great overload, thus giving a higher intensity.

Description

The simplified lamp, shown in Fig. 1, is made of quartz tubing⁶ with an inside diameter of 1 to 2 mm. and a wall 0.7 to 1 mm. in thickness. Tubes of larger diameter may be used. A tube about 12 cm. long is provided with two bulbs, A and B, blown out in the gas-oxygen flame with a space of 5 to 30 mm. between them when operated on d. c. line voltages of 50 to 600 volts, respectively. The bulbs are blown as thin as is consistent with mechanical strength. Their function is to keep the arc localized between A and B. They prevent the arc from extending farther, because the thin walls are cooler and because the larger diameter reduces the current density. The more completely the arc is thus localized the steadier is the lamp. Tungsten electrodes, 0.5 mm. smaller in diameter than the containing tube, are preferable, but nickel or iron (hay wire) may be used.

The upper, positive electrode, E, is set with de Khotinsky cement (shellac and pine tar) flowed into the warmed tube as shown by the cross hatching. The lamp is filled by placing the open end under purified mercury, evacuating and then releasing the vacuum. The lamp is then inverted and the electrode D is sealed in with cement. Silver chloride or other high melting, sealing cements used with bulbs in the earlier models are unnecessary if a rapid stream of cold water is employed. The uppermost

¹ Preliminary descriptions have been given in *THIS JOURNAL*, 52, 2151 (1930), and in Daniels, Mathews and Williams "Experimental Physical Chemistry," McGraw-Hill Book Co., New York, 1929, p. 423.

⁶ Quartz tubing may be purchased from the Hanovia Chemical and Manufacturing Co. of Newark, N. J., from the General Electric Co., Schenectady, N. Y., from the Thermal Syndicate, Brooklyn, N. Y., or from The Quartz Products Manufacturing Co., 69 Tichenor St., Newark, N. J. The cost of tubing for a lamp is less than a dollar.

bulb, C, serves as the expansion chamber into which the mercury is driven when the arc is struck and the space between A and B is filled with incandescent mercury vapor. The size of this bulb and the level of the mercury determine the expansion volume. The ratio of the arc volume to this expansion volume determines the pressure under which the lamp operates. A small expansion volume gives a high pressure and a correspondingly high resistance. When 550 volts are available, the volume can be small, leading to pressures of 2 to 5 atmospheres and giving high-voltage, low-amperage lamps.

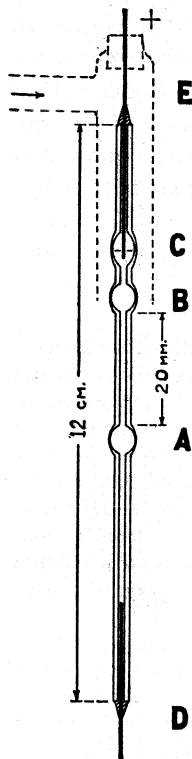

Fig. 1.—Capillary mercury vapor lamp of quartz. Inside diameter, 2 mm. Wall thickness, 0.7 to 1.0 mm.

The protruding electrodes of the lamp are connected with rubber-insulated wires and the bare connections are then insulated by covering with de Khotinsky cement. The wires are connected with a direct current dynamo through an adjustable resistance. A 22-ohm, 5-ampere resistance is sufficient for use on a 110-volt circuit but on a 550-volt circuit several additional resistances are necessary.⁷ The resistance of the lamp varies from nearly zero before the arc is struck, to 20 to 500 ohms when operating depending on the expansion volume and on other factors.

Cooling with a large, rapid stream of cold water is absolutely necessary. Without it the seals and the quartz itself are melted. Hard water may be used if the stream is sufficiently rapid; otherwise, the outside of the lamp becomes hot enough to form a deposit.

To start the lamp the mercury is shaken down, the circuit is closed and the mercury thread in the capillary is then separated by playing on it a small Bunsen flame. The instant the arc strikes, water is turned on. The lamps have been started, also, with a small electric heating coil wound around the capillary just above the bulb A.

The protruding end of the upper electrode passes through a rubber stopper which fits into a T-tube of glass 1 cm. in diameter, extending to the bulb B. The tube is shown by dotted lines in Fig. 1. In this way an encircling stream of water is directed down around the lamp to a waste pipe. Best results are obtained by mounting the lamp in a copper tank provided with a quartz window and drain and overflow tubes, 3 cm. or more in diameter. A brass frame soldered to the tank and a similar frame screwed against it hold the quartz window in place with rubber gaskets. The tank is emptied with the drain, and after the lamp is started the tank is allowed to fill, thus completely immersing the lamp.

Caution.—There is danger from a lamp bursting although the stream of water and particularly the tank mounting minimizes this danger. Special care is necessary to avoid ultraviolet burns.

The lamps operate well on 110 volts and 3 to 5 amperes. A 550-volt source permits greater intensity. If the lamps fail to start properly it may be necessary to (a) increase the voltage, (b) decrease the mercury level, thus giving a greater expansion chamber, a lower pressure and consequently a lower resistance and higher current, or (c) change the diameter of the capillary. If the current increases seriously while the lamp is operating one may suspect a leak at the seals. More effective cooling is then necessary. An inexpensive ammeter should be included in the circuit.

⁷ "Glow" resistances, for radiant heaters, which screw into an electric light socket, are convenient and cheap.

Tests

Each lamp has its own characteristics but in general the intensity of radiation, E_λ , of a particular wave length is nearly proportional to the wattage, W , of the lamp. The formula $E_\lambda = aW$, is a rough approximation to the average behavior between 500 and 1500 watts. When E_λ is determined as ergs per second falling on a sq. mm. of a thermopile after passing through a large monochromator and W is the product of the amperage and the voltage drop across the lamp, the constant a has the following values: 1 for 265 and 280 $m\mu$; 5 for 302 $m\mu$; 7 for 313 $m\mu$; 2 for 334 $m\mu$; from 12 to 20 for 365 $m\mu$; from 4 to 8 for 404 $m\mu$; and from 6 to 12 for 436 $m\mu$. The short ultraviolet lines give about the same intensity per watt regardless of the voltage, but the 404 and 436 $m\mu$ lines are more intense at high voltages. The larger values of a correspond roughly to 500 volts and the smaller values to 100 volts. The distribution of energy will be shown more fully in Fig. 3 of the following article. The lines below 265 $m\mu$ are weak and there is extensive reversal of the line at 253.6 $m\mu$.

Plotting amperes through the arc as ordinates against voltage across the arc as abscissas, the curve passes through a maximum. However, plotting resistance across the arc as ordinates against voltage the curve is linear.

Aging varies. Perhaps twenty-four hours of operation is a common life. When operating below 500 watts, a lamp may last much longer. After heavy usage, a white deposit forms on the inside of the lamp which shows, under the microscope, a distorted honeycomb structure. For the internal 0.05 mm., however, these minute cracks are fused together, showing that the effective temperature of the arc is above the melting point of quartz (1700°). The outside of the tube 0.7 to 1 mm. away from the arc is at about 20° and the cracks may be due to this enormous temperature gradient, or possibly to crystallization. The white region of cracks does not cause a large reduction in intensity but a few cracks spread out and eventually one of them causes the lamp to break. Lamps with thick walls break much sooner than those with thin walls.

The efficiency of the lamps was tested also with 100 cc. of a solution, 0.8 molar in oxalic acid and 0.05 molar in uranyl sulfate, placed in a hollow, cylindrical, quartz cell completely surrounding the lamp. Using a lamp at 570 volts and 2.7 amperes, 6.16 g. of oxalic acid was decomposed in eight minutes, corresponding to 0.77 g. per minute and to 0.24 mole per kilowatt hour. Taking the quantum efficiency of this reaction as 0.6 molecule per quantum⁸ the photochemical action consumed 0.4 einstein ($1 \text{ einstein} = 6.06 \times 10^{23} \text{ quanta}$) per kilowatt hour of energy supplied to the lamp. Similar results were obtained with a stream of solution passing through a concentric, cylindrical cell only 5 cc. in capacity. In experiments with rectangular quartz cells at a distance of about 10 cm. these

⁸ Leighton and Forbes, *THIS JOURNAL*, 52, 3139 (1930).

capillary lamps gave over one hundred times as much photochemical action as a commercial lamp.

The chief reason for the high intensity (per sq. mm. of lamp surface) is the high concentration of energy. The volume of the arc in the capillary lamp is approximately 0.05 cc. as against 20 cc. in a commercial lamp. Although the volume of a commercial lamp is 400 times as great, the total input of energy is less. The dimensions of the capillary lamp are such that a much greater fraction of the radiation emitted by the lamp can be brought to the slit of a monochromator or passed into a reaction cell of ordinary dimensions.

The authors are pleased to acknowledge the help contributed by Mr. Glenn Damon and Mr. Harrison Holmes to the development of the lamp described here.

Summary

An inexpensive quartz mercury vapor lamp of high intensity has been described and tested.

PHOTOCHEMICAL TECHNIQUE. II. CONSTRUCTION AND TESTS OF A QUARTZ MONOCHROMATOR¹

BY LAWRENCE J. HEIDT AND FARRINGTON DANIELS

RECEIVED MARCH 10, 1932

PUBLISHED JUNE 6, 1932

Monochromatic radiation of measured intensity is necessary for the quantitative study of photochemical reactions. Separation of the different wave lengths by refraction in a monochromator offers the most effective method for obtaining this radiation but the energy flux available at any one wave length is extremely low on account of losses due to reflection, absorption, slit dimensions, etc. To minimize this handicap a more intense source of light was developed.² Further efforts to increase the radiation intensity by using a monochromator of large dimensions and favorable optical conditions are described in the present communication.

The subject of monochromators and of photochemical apparatus has been reviewed in detail by G. S. Forbes.³ The dimensions and material of the prism and lenses used in the present investigation are approximately those described by Marshall and Knudson.⁴ The purpose of

¹ Complete details of the dimensions and calculations may be obtained from the Ph.D. Thesis (June, 1930) of the first author, which is on file in the Library of the University of Wisconsin.

this article, then, is to describe and to present tests for an efficient method of mounting an optical system of fused quartz used as a monochromator. The mechanism described automatically keeps the prism at minimum deviation and in the center of the field, and provides automatic focusing. Previously this has been accomplished by means of compound prism arrangements or mirrors. Included in the tests is a study of the photo-decomposition of uranyl oxalate made prior to the publication of the classic paper of Leighton and Forbes.⁵

Description of Monochromator

Side and top views of the monochromator and accessories are shown in Figs. 1 and 2. A is a 60° fused quartz prism 12 cm. on a side and 14 cm. high. B and B'

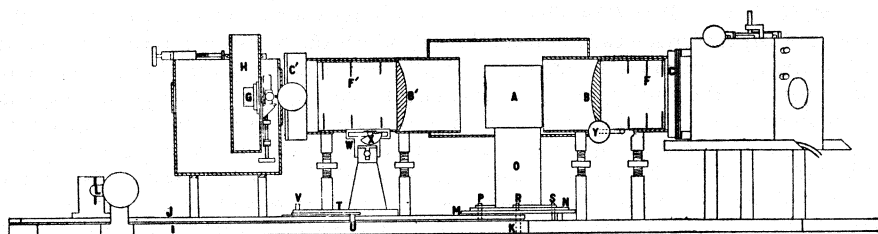

Fig. 1.—Monochromator, side view.

are fused quartz lenses 15.25 cm. in diameter, each with a focal length of 35 cm. for $\lambda 795 \text{ m}\mu$. C and C' are slits shown in detail in Fig. 2a. The pupil C is curved to make the exit beam rectangular. D is the source of radiation previously described.² Fine

adjustments placing the source on the principal axis of B are made by a screw attached to E. F and F' are graduated elliptical diaphragms three of which are placed in each of the collimator and telescope tubes to diminish stray light. The latter are brass tubes

⁵ Leighton and Forbes, *THIS JOURNAL*, 52, 3139 (1930).

telescoping freely without play by means of the rack and pinion arrangements X and Y.⁶ G is a thermopile mounted flush against a slit built into a vertical track in which G slides in a submarine H. Directly in front of G is mounted on H an adjustable support for reaction vessels. Fine adjustments of H, G and the support can be made in three dimensions by means of appropriate screws, not all of which are shown in the cuts. The submarine and the cells are immersed in distilled water thermostated to 0.1°. A double-convex quartz lens (not shown) 5 cm. in diameter with a focal length of 5 cm. for λ 795 $m\mu$ placed between C' and the reaction vessel renders the light parallel when passing through the latter to the thermopile. I is the weathered and planed cast-iron base 200 cm. long. Leveling is accomplished by means of screw supports in the base, not shown. J is a steel plate on which the telescope is mounted. This plate, mounted on brass tracks, is pivoted about the intersection, K, of the principal axes of the collimator and telescope. Gross and fine adjustments of J are made by the screw, L, equipped with a split nut.

M, N, O, P, Q, R and S in Figs. 1, 2 and 2b comprise a mechanism such that (a) the prism is turned through half the angle through which the telescope is turned to keep it at the angle of minimum deviation, and (b) the center of the prism is displaced along the bisector of the angle between the axes of the collimator and telescope to keep it in the center of the field. This displacement (b) is 8.4 mm. in passing from $n_{795\ m\mu}$, 1.4534 to $n_{186\ m\mu}$, 1.5746 for fused quartz. N is a brass plate which slides on a horizontal brass plate M; a pin in N, over K, engages a slot in M. M and N have slots for the passage of pins, P and S. The position of N for a short wave length is shown by its dotted outline in Fig. 2b. O is the prism table. Its center, the center of the fixed pin in N which engages the slot in M, and a point on the perpendicular bisector of the base of the prism, A, lie on a straight line. P is a pin fixed on the principal axis of the telescope lens to J. Q is a pin fixed to N and joined to P by means of a rigid bar equipped with fine adjustments for length. R is a similar pin fixed to N and similarly joined to S. S is a pin fixed on the principal axis of the collimator lens to I. P, Q, R and S and the slot in the center of M are placed such that Q, K and R are always on a straight line in the plane of the perpendicular bisector of the base of the prism.

T, U, V, W and X in Figs. 1, 2 and 2b comprise the mechanism for automatic focusing. T is a metal fork which clears the post supports of the telescope. U is a pin fixed in I. V is a pin free to move along the axis of the telescope in a rectangular slot cut in J. The rod connecting U and V has a fine adjustment for length. W is a rack mounted on T. W rides on a cog wheel X. The turning of X actuates another wheel and rack which moves B' in a corresponding fashion to V. X, which is mounted in a split nut, may be disengaged from the shaft driving B' thus permitting hand adjustment. Y permits hand adjustment of B.

The whole apparatus is adjusted by hand for some definite wave length (one of the known lines of the mercury lamp); the lenses B and B' are then set at equal distances in the tubes. The automatic adjustments are then set. Thereafter the monochromator is set for different wave lengths by turning the screws L and Y. The positions for the different wave lengths are marked on a scale under L in the floor, I, of the instrument. The lens B is set by hand at the same relative position as B', using a depth gage.

Tests of the Monochromator.—Figure 3 is an energy distribution curve⁷ of a mercury vapor capillary arc lamp² as determined with this monochromator. Any adjustments of the prism or lenses by hand follow-

⁶ Internal surfaces are blackened with an alcoholic solution containing lamp black and shellac, which while drying is smoked thoroughly with camphor black.

⁷ Compare with data of Harrison and Forbes, *J. Optical Soc. Am.*, 10, 1 (1925).

ing automatic adjustment to a mercury line always caused a decrease in the energy flux through the exit slit. The upper and lower curves are for slit widths of 0.6 and 0.1 mm., respectively; the height of the slits in both cases was 20 mm. The total energy flux (ordinate) in ergs/sec. (upper curve only) passing through the exit slit was determined by means of a

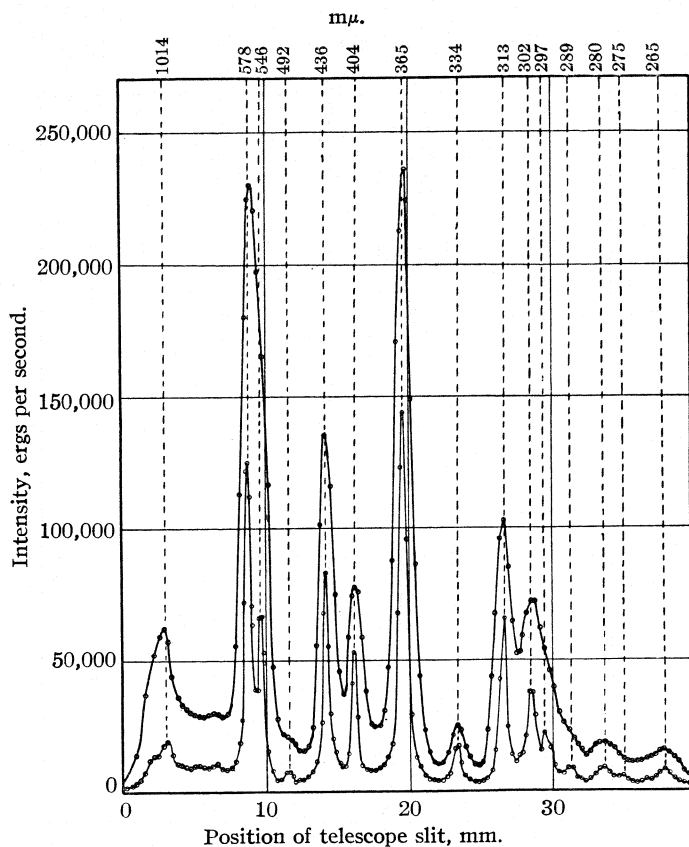

Fig. 3.—Energy distribution: upper curve, 0.6-mm. slits; lower curve, 0.1-mm. slits; capillary lamp, 200 volts, 5.5 amperes, 1100 watts; the scale of ordinates applies only to the upper curve.

large thermopile to be described later. The thermopile-galvanometer circuit and accompanying shunts was calibrated against U. S. Bureau of Standards lamp C44. The abscissa represents clockwise turns of L in terms of the distance between a fixed point on L and its split nut attached to J. The absence of λ 254 mμ due to absorption by the fused quartz should be noted. That this line and shorter wave lengths are present in the source was proved by a spectrogram.

The intensity of radiation of λ 313 mμ was compared under identical

conditions with a commercial monochromator having a prism 3 cm. high. The monochromator described here gave more than ten times as much intensity.

The degree of monochromatism obtainable with this instrument was tested (a) qualitatively by spectrophotometry and (b) quantitatively by radiometry.

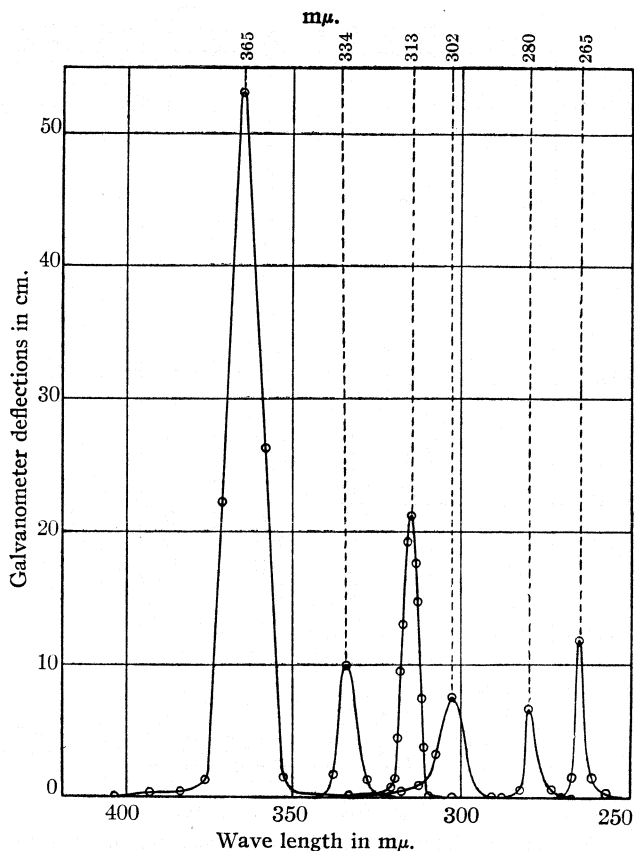

Fig. 4.—Efficiency of the monochromator as determined with a second monochromator.

(a) Using a carbon arc as a continuous source, slit widths of 0.6 mm. and the instrument set at λ 420 mμ, a spectrogram of the emerging light showed a blackening which covered 20 mμ (as determined by reference to the 436 and 404 mμ lines of mercury photographed on the same spectrogram) about this wave length.

Using a mercury arc as source and the monochromator under identical conditions, a spectrogram showed complete isolation of 436 or 404 mμ, depending on the setting of the monochromator. Exposures of several

seconds, however, gave spectrograms showing all the prominent lines of mercury. Similar tests applied to a commercial monochromator showed it to be less efficient than this instrument.

(b) The energy distribution of light emerging from the large monochromator at given settings for maximum intensity of the wave length in question is shown by the curves in Fig. 4. These curves were determined using the mercury arc² as source, slit widths of 0.6 mm. and a second monochromator with thermopile-galvanometer. "Purity" of the light may be obtained by estimating the area (counting squares) under these peaks be-

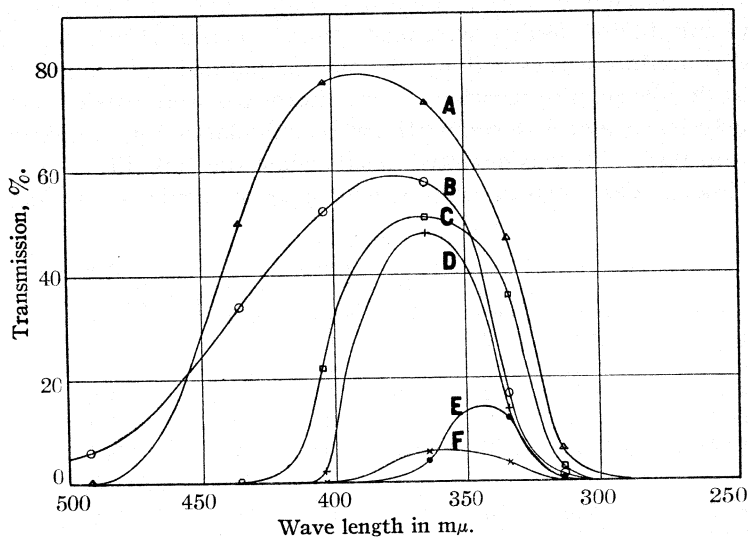

Fig. 5.—Percentage transmission of various glass filters of thicknesses stated: A, blue-purple ultra, 3.91 mm.; B, cobalt glass, 2.61 mm.; C, red-purple ultra, 4.17 mm.; D, red-purple ultra, 5.08 mm.; E, ultraviolet filter IVc, 4.57 mm.; F, ultraviolet glass, 8.91 mm.

tween definite limits. The limits, of course, depend on the energy distribution of the lamp, wave length and the width of the slits of the second monochromator. At 365 and 313 $m\mu$ 98% of the total energy recorded on the thermopile of the second monochromator fell between 353 and 375 $m\mu$ and between 310 and 320 $m\mu$, respectively. It was gratifying, particularly since the quartz lenses and prism contained many small bubbles and some striations, to find that, although all the mercury lines were recorded on a spectrogram, the intensity of the other lines was less than 1% of the one selected by the first monochromator. Spectrograms of any one of 436, 404, 365, 334, 313 and 302 $m\mu$ emerging from the exit slit of the two monochromators in tandem (using slit widths of 0.6 mm.) showed only the wave length in question on exposures as long as ten minutes.

Comparison with Filters.—Purity [method (b) used] of light transmitted by certain filters is shown in Fig. 5. With the exception of B these were standard filters purchased from the Corning Glass Works. Comparison with Fig. 4 shows that the monochromator is much more effective than these filters in restricting the light to a narrow range of wave lengths.

The Photodecomposition of Uranyl Oxalate.—The photolysis of oxalic acid at $313\text{ m}\mu$ and at room temperature in the presence of uranyl salts affords a more direct test of the efficiency of this monochromator in the study of photochemical reactions. Materials used were of c. p. quality and when purchased as such were not subjected to further purification. Uranyl sulfate and oxalate were made from c. p. uranyl nitrate. Experimental procedure was essentially the same as that of Leighton and Forbes.⁵ Several details require mention. Two photolyses were carried out simultaneously by using a two-compartment rectangular cell with quartz plates front and back. It was mounted flush against the exit slit, C' , on a platform (Figs. 1 and 2) which could be moved perpendicular to the axis of the

^a MgSO_4 is 1 Molar.

telescope lens. Solutions in each compartment were photolyzed alternately for ten-minute intervals. Energy flux transmitted by the solution was measured at three-minute intervals by a thermopile, G (a Coblentz twenty junction silver-bismuth thermopile, 20 mm. \times 1 mm.), placed directly behind the reaction cell. The maximum change in per cent. absorption by the solution during photolysis was always less than 2%, usually less than 1%.

Results of this part of the investigation are presented in Table I. Concentrations are given in moles per liter. These results show that the anion of the uranyl sensitizer has little effect on the quantum yield—the oxalate, sulfate and nitrate giving nearly the same results. Even the addition of magnesium sulfate in high concentrations has little effect on the gross quantum yield.

Leighton and Forbes⁵ report gross quantum yields for 0.01 *m* uranyl sulfate in 0.05 *m* oxalic acid of 0.545, 0.53, 0.57, 0.595 and 0.57, giving an average value of 0.561. The good agreement between the two researches gives confidence not only in the monochromator described here, but in the general reliability of quantitative photochemical measurements.

The authors desire to acknowledge the help given by a du Pont Fellowship held by the first named author during the progress of this work.

They desire also to thank Mr. J. H. Hanson for the careful machine work involved in the building of the monochromator.

Summary

1. A monochromator for the investigation of photochemical reactions in the ultraviolet has been described. An automatic device, not using a reflecting mirror or a compound prism arrangement, keeps the 60° prism at minimum deviation and in the center of the field. Another device keeps the telescope automatically in focus.

2. Radiation of over 100,000 ergs per second from the prominent lines of a capillary mercury vapor lamp are obtainable with this monochromator.

3. "Purity" of monochromatic light obtainable from the monochromator has been tested in several ways, and compared with that of filters. Approximately 98% of the radiation at any wave length setting falls within a range of 10 to 20 $m\mu$.

4. In the presence of uranyl sulfate, 0.5g molecule of oxalic acid is photochemically decomposed for each quantum absorbed at 313 $m\mu$ and at $27 \pm 2^\circ$. This result is in close agreement with that of Leighton and Forbes. Uranyl sulfate, nitrate and oxalate used as sensitizers give practically the same results.

NOTES

Needle-Shaped Crystals of Sodium Chloride Obtained by Percrystallization

BY HENRY TAUBER AND ISRAEL S. KLEINER

In 1917 the observation was made by Kober,¹ that if a collodion container, filled with a saturated ammonium sulfate or a saturated sodium chloride solution, and with the open end closed tightly with a cord, was suspended in the air and fanned in a warm room, crystals of these salts "crystallized on the outside and blew off like snow." He called this phenomenon "percrystallization." To our knowledge no use has been made since that time of this method of crystallization. While working on the purification of enzyme material, we thought that this method would afford a practical way of getting rid of the inorganic diffusible salts and at

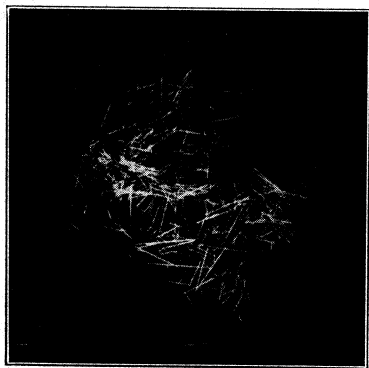

Fig. 1.—Crystals of sodium chloride obtained by percrystallization, natural size.

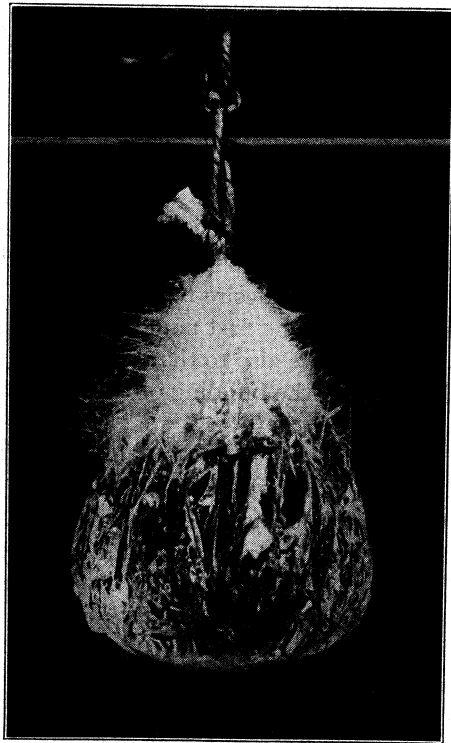

Fig. 2.—Collodion bag with sodium chloride needles forming by percrystallization.

the same time of concentrating the enzyme. We found that the sodium chloride, which was present in the enzyme-salt mixture, crystallized outside the collodion bag, but instead of the usual cubic habit, the sodium chloride crystallized in beautiful needles about 1 cm. long (see Fig. 1).

The procedure (without fanning), repeated with c. p. sodium chloride (Baker's), yielded the same needles. One hundred fifty cc. of a half-satu-

¹ Kober, *THIS JOURNAL*, 39, 944 (1917).

rated solution was placed in a 250-cc. collodion bag at 20°. Within one hour the needles (see Fig. 2) crystallized outside on the upper part of the bag, above the level of solution.

Drs. W. J. McCaughey of Ohio State University and J. B. Niederl of New York University examined these crystals and found that they belong to the regular cubic system.

The fact that the crystals mainly develop in one direction seemed to be worthy of note.

We are greatly indebted to Professors W. J. McCaughey and J. B. Niederl for examining the crystals.

The Generalized Theory of Acid and Base Catalysis Applied to the Rate of Ionic Reactions

BY ROBERT LIVINGSTON

The rate of the catalytic decomposition of hydrogen peroxide in an acid bromine-bromide solution has been measured both in solutions of hydrobromic acid and in solutions containing sulfuric acid and potassium bromide.¹

The corrected rate constant, χ in the equation

$$v = \chi(\text{H}_2\text{O}_2)(\text{H}^+)(\text{Br}^-)\gamma_{\text{HBr}}^2$$

is about 10% higher for the solutions containing sulfuric acid. While it is not impossible that this difference is due to experimental error,² it seems more probable that it is a real effect, probably due to the specific catalytic action of the acid molecule HSO_4^- .⁴ Although the generalized theory of acid (and base) catalysis has never been demonstrated for reactions between ions, there is no *a priori* reason why this type of reaction should not occur. On the assumption that HSO_4^- acts similarly to and simultaneously with H_3O^+ , the total rate equation would be

$$v = (\text{H}_2\text{O}_2)(\text{H}^+)(\text{Br}^-) \left[\chi_{\text{H}_2\text{O}} \gamma_{\text{HBr}}^2 + \chi_{\text{HSO}_4} \frac{(\text{HSO}_4^-)}{(\text{H}^+)} \frac{\gamma_{\text{HSO}_4^-} \gamma_{\text{Br}^-}}{\gamma_x} \right]$$

While this is qualitatively in agreement with the experimental facts, a quantitative test is impossible, owing to uncertainties in the computation

² Livingston, *ibid.*, **48**, 53 (1926).

³ It might be due to "promoter action" or to negative catalysis, caused by a trace of some unknown impurity, or else to a systematic error in the determination of the activity coefficients.

⁴ Brönsted, *Chem. Rev.*, **5**, 231 (1928).

of (HSO_4^-) and the impossibility of determining $\gamma_{\text{HSO}_4^-} \gamma_{\text{Br}^-} / \gamma_{\text{x}}$. In sufficiently dilute solutions these quantities might be computed from the Debye-Hückel limiting law; unfortunately, accurate rate measurements would be practically impossible in this region. The occurrence of generalized acid catalysis in this reaction might be tested by using solutions containing small concentrations of potassium bromide and a moderately weak, chemically inert acid in the presence of a high constant concentration of an inert salt, *e. g.*, sodium perchlorate.

Other ionic reactions might be expected to show a similar effect; for example, the oxidation of hydriodic acid by chloric acid,⁵ or the basic hydrolysis of the nitrourethan ion.⁶

The Entropy of Bromine from Spectroscopic Data

BY WELDON G. BROWN*

A recent fine structure analysis of the visible absorption bands of bromine by the writer¹ has provided data from which accurate values of the thermodynamic constants of bromine may be calculated. These calculations involve nothing essentially new, although certain consequences of a rather unique isotope situation become emphasized. In this note the entropy calculated from band spectrum data is to be compared with a less accurate value obtained from experimental measurements of the specific heat.

There are two isotopes of bromine, 78.92 and 80.92, which, according to Aston's measurements,² are equally abundant. These give rise to three kinds of molecules, Br_2^{79} , $\text{Br}_2^{79,81}$ and Br_2^{81} , in the proportions 1:2:1, respectively. A slight difference in the molecular constants of the Br_2^{79} and Br_2^{81} molecules leads to slightly different entropies, but because of their equal abundance this becomes smoothed out when, in calculations of thermodynamic constants, one uses the data for the $\text{Br}_2^{79,81}$ molecule. There is an additional effect due to the lack of symmetry which results in the entropy of $\text{Br}_2^{79,81}$ being greater than the entropy of either of the symmetrical species by $R \ln 2$ per mole, or $\frac{1}{2} R \ln 2$ per mole of the actual mixture since this species constitutes one-half of ordinary bromine.

The moment of inertia of bromine is sufficiently large and the centrifugal

deformation sufficiently small to make applicable the approximation in summation of the rotational energy terms used by Gibson and Heitler, and by Giauque,³ in the case of iodine, namely

$$Q_{\text{rot.}} = \sum_i p_i e^{-\epsilon_i/kT} = \frac{4\pi^2 I k T}{h^2} = \frac{T}{2c_2 B}$$

where c_2 is the second radiation constant, and B is the fine structure constant obtainable directly from the spectral data. This expression applies to a symmetrical molecule. The entropy is then obtained by the well-known formula⁴

$$S^\circ = R \left[\ln Q + T \frac{d \ln Q}{dT} \right]$$

The band spectrum constants for the normal electronic state of $\text{Br}_2^{79.81}$ are as follows. The subscripts refer to the zero vibrational state.

$$\begin{array}{ll} B_0 = 0.08077 & \omega_0 = 322.2 \\ \alpha = 0.00027 & \omega_0 x_0 = 1.07 \end{array}$$

In the following table the molal entropies (ideal gas, pressure one atmosphere, at 298.1°K.), calculated as indicated above, are given for each of the three molecular species, together with the entropy of the 1:2:1 mixture exclusive of the entropy of mixing. It is to be noted that the entropy of the mixture, 59.32 E. U., is equal to the entropy of $\text{Br}_2^{79.81}$ minus $1/2 R \ln 2$.

	$S_{\text{trans.}}$	+	$S_{\text{vib.}}$	+	$S_{\text{rot.}}$	=	$S_{298.1}^\circ$
$\text{Br}_2^{79.79}$	41.07		1.30		16.19		58.56
$\text{Br}_2^{79.81}$	41.11		1.31		17.59		60.01
$\text{Br}_2^{81.81}$	41.15		1.32		16.23		58.70
1:2:1 mixture	$1/4(58.56)$		$1/2(60.01)$		$1/4(58.70)$		59.32

Comparison with specific heat measurements can be made most conveniently at the melting point temperature, 265.8°K., at which the vapor pressure, according to Henglein,⁵ is 44.12 mm. From the band spectrum data we calculate $S_{265.8^\circ}$ ($p = 44.1$ mm.) = 61.69 E. U., assuming a perfect gas. The specific heat measurements of Suhrmann and v. Lude⁶ extend down to 20.5°K., but are few in number and somewhat erratic. From the smoothed points given by them we obtain, for the entropy of solid bromine at its melting point, 25.5 E. U., the uncertainty in which must be of the order 1.0 E. U. The entropy of vaporization at the melting point is 36.6 E. U. if we accept Henglein's value for the heat of vaporization, 9740 cal. The experimental value for the entropy of bromine gas at this temperature and pressure is then $25.5 + 36.6 = 62.1$ E. U., in good agreement with the value 61.69 calculated from spectroscopic data.

³ Giauque, *THIS JOURNAL*, **53**, 507 (1931).

⁴ Giauque, *ibid.*, **52**, 4808 (1930).

⁵ Henglein, *Z. Physik*, **11**, 1 (1922).

⁶ Suhrmann and v. Lude, *ibid.*, **29**, 71 (1924).

However, the entropy, as calculated above, cannot be used for chemical purposes without reference to the entropy of mixing of isotopes. This entropy of mixing is $\frac{3}{2} R \ln 2$ per mole, while for the free atoms (or for HBr, for example) it is $R \ln 2$ per mole. If, by convention, the entropy of mixing of the atoms is to be excluded, the value for the entropy which we have calculated must be reduced by $\frac{1}{2} R \ln 2$. For bromine gas in its standard state this results in the value $S_{298.1}^{\circ} = 58.63$ E. U. The value is thus the same as if the additional entropy of $\text{Br}_2^{79,81}$ resulting from its additional states had been considered as a part of the entropy of mixing of isotopes. This places Br_2 on the same basis as HBr, the entropy of which has been calculated from band spectrum data by Giaque.⁷

The equilibrium constants for the dissociation of bromine at high temperatures, calculated by means of the Gibson and Heitler⁸ equation and the band spectrum constants, are in poor agreement with the experimental values of Bodenstein.⁹ The discrepancy, for which no explanation is offered, amounts to 0.15 in $\log K$ and is constant with temperature. The writer plans a further check on the entropy of bromine through the use of the experimental data for the dissociation of iodine bromide. An analysis of the iodine bromide absorption bands, which will provide the necessary spectroscopic data, is now in progress.

The Recombination of Hydrogen Atoms

BY GEORGE E. KIMBALL

In a recent paper Steiner¹ has made some very interesting calculations on the rate of recombination of hydrogen atoms by triple collisions with hydrogen atoms and molecules as third bodies. He assumes that the recombination takes place in two steps: (1) the formation of an atom pair, or quasi-molecule, and (2) the stabilization of the energy-rich atom pair by collision with a third body during its lifetime τ . Throughout this work Steiner has overlooked the fact that there is another, equally probable, mechanism for the recombination. This mechanism may also be divided into two steps, but these are now: (1') collision of a hydrogen atom with a hydrogen molecule, and (2') collision of this quasi-molecule with a new hydrogen atom to form two hydrogen molecules.

Steiner finds theoretically that the diameter of a hydrogen atom in (1)

¹ Steiner, *Z. physik. Chem.*, **B15**, 249 (1932).

is $2.5\text{--}3.5 \times 10^{-8}$ cm., and that the lifetime τ of the atom pair is $2.5\text{--}4.5 \times 10^{-14}$ sec. By comparison of the theory with experiment he then finds that the effective diameter of H_2 as a stabilizing third body must be $6.7\text{--}12.5 \times 10^{-8}$ cm. By considering the mechanism (1'), (2') we find that the required diameter of the molecule H_2 is a much more reasonable value.

The rate of process (1') is given by

$$Z_{\text{AM}} = 2 \sqrt{2\pi} N_L^2 \sigma_1^2 \left(\frac{3RT}{2M} \right)^{1/2} [\text{C}_\text{H}][\text{C}_{\text{H}_2}] \quad (1)$$

and the stationary concentration of the quasi-molecules H_3 is given by

$$[\text{C}_{\text{H}_3}] = \frac{Z_{\text{AM}} \bar{\tau}}{N_L} = 2 \sqrt{2\pi} N_L \sigma_1^2 \left(\frac{3RT}{2M} \right)^{1/2} [\text{C}_\text{H}][\text{C}_{\text{H}_2}] \bar{\tau} \quad (2)$$

The symbols used in these equations are those used by Steiner, except that σ_1 is the collision diameter for a hydrogen atom colliding with a hydrogen molecule, and $\bar{\tau}$ is now the mean life of the quasi-molecule H_3 . The number of three-body collisions of this type is then given by

$$\begin{aligned} Z_3 &= 2 \sqrt{2\pi} N_L^2 \sigma_2^2 \left(\frac{4RT}{3M} \right)^{1/2} [\text{C}_\text{H}][\text{C}_{\text{H}_3}] \\ &= 8\pi \sqrt{2} N_L^3 \frac{RT}{M} \sigma_1^2 \sigma_2^2 \bar{\tau} [\text{C}_\text{H}]^2 [\text{C}_{\text{H}_2}] \end{aligned} \quad (3)$$

or, on introducing the statistical weight factor $1/4$

$$Z_3^* = 2\pi \sqrt{2} N_L^3 \frac{RT}{M} \sigma_2^2 \sigma_1^2 \bar{\tau} [\text{C}_\text{H}]^2 [\text{C}_{\text{H}_2}] \quad (4)$$

where σ_2 is the effective diameter for the collisions of H with H_3 .

We may safely assume that σ_1 is about the same as Steiner's σ_{AA} , that is, $2.5\text{--}3.5 \times 10^{-8}$ cm. The value of $\bar{\tau}$ is, however, different. In order to estimate the value of $\bar{\tau}$ we must know the potential energy curve for three hydrogen atoms. Such a curve has been calculated by Eyring and Slater (to appear in *THIS JOURNAL*). The theoretical curve found by these authors agrees well with the empirical curves given by Lennard-Jones.² The curve consists of the coulombic energy, less one-half the interchange energy, plus the van der Waals energy for two hydrogen atoms. There is no minimum in this curve such as that in the curve for two hydrogen atoms, and any definition of the collision distance is somewhat arbitrary. A hydrogen atom with the mean thermal energy of 600 cal. will be at a distance of 2.35×10^{-8} cm. from the hydrogen molecule when it is brought to rest. If we assume that the molecule and atom are in contact when the potential energy between them is one-tenth of its maximum value of 600 cal. a simple calculation shows that the time of contact is 6.58×10^{-14} sec.

We may now use the values we have found for σ_1 and $\bar{\tau}$ to calculate σ_2 from the experimentally found rate of reaction. If we assume that all

² Cf. Fowler, "Statistical Mechanics," Cambridge, 1929, Chap. X.

of the recombination with H_2 as the third body takes place by this mechanism we find that σ_2 lies between 3.6 and 5.5×10^{-8} cm. Since the recombination probably takes place by both this mechanism and Steiner's the true value of the diameter σ_2 is somewhat smaller.

On the other hand, if we assume σ_2 to be equal to Steiner's σ_{AM} , which is not unreasonable, we find that our mechanism will go at a rate three to six times the rate of Steiner's mechanism.

A STUDY OF MOLECULAR ORGANIC COMPOUNDS. IV.¹ THE MOLECULAR ORGANIC COMPOUNDS OF PHENOL, THEIR PARACHORS AND REFRACTIVITIES²

BY C. A. BUEHLER, J. H. WOOD, D. C. HULL AND E. C. ERWIN

RECEIVED NOVEMBER 6, 1931

PUBLISHED JUNE 6, 1932

The molecular organic compounds of phenol, as a group, represent one of the simplest types. These compounds, although possessing fairly sharp melting points, decompose so readily into the original components that attempts to gain any information as to their structure by chemical methods have been unsuccessful. In the present investigation two physical methods have been applied to the study of the structure of some of these molecular compounds.

In Table I are listed the compounds which have been isolated and studied. Most of these have only previously been shown to exist by their freezing point curves. Worthy of note are the great number of them, the usual molecular ratios of 1:1 and 2:1 and the fact that the second components all contain amino groups.

The parachors as determined, both for some of the components and their molecular compounds, by the formula of Sugden³ are given in Tables II and III. Among the components it is to be noted that the observed parachors are lower than the calculated values and with increasing temperature a steady rise occurs much in the same way as with the alcohols and fatty acids.⁴ The same relation exists among the molecular compounds although the temperature coefficients and the differences between

¹ Contribution III, THIS JOURNAL, 53, 4094 (1931).

⁴ Sugden, Ref. 3, p. 167.

the observed and calculated values are greater here. It is likely that we are dealing in both cases with association, the amount of which becomes less and less with an increase in temperature.

It is not possible, at present, by any known method to find the degree of association at any one temperature. However, the differences between the observed and calculated values of the parachors for the molecular compounds, with decreasing temperature, do approach a maximum negative value. According to Sugden⁵ such a negative value is due to a bond consisting either of a pair of electrons (the semi-polar double bond) or of a single electron. Although the latter is used freely by Sugden⁵ it finds less favor in other quarters.⁶ We are discarding it as a possibility since the stability of the compounds concerned does not seem to be of a sufficiently low order to warrant such a type of union. There remains the semipolar double bond which (excluding ring formation, which does not seem likely due to the fact that an unstable four-membered ring would result) may account for the type of formula recently advanced:⁷

From Sidgwick's⁸ work among the ortho substituted phenols it appears that the semipolar bond above has the usual value of -1.6 plus a value of -12.8 due to the rise in covalency of the hydrogen from 1 to 2. The total value, -14.4 , as Table III shows, may in general be considered as the maximum for the differences between the observed and calculated parachors and the formula above may, therefore, be considered as the most probable for the molecular compounds of phenol.

The refractive indices for the components and their molecular compounds are shown in Table IV and the molecular refractions as obtained by the Lorenz and Lorentz formula are given in Table V. A comparison of the observed and calculated molecular refractions at 20° shows in general, in the case of the components, some optical exaltation, while with the molecular compounds optical depression is usually exhibited. In either case the optical exaltation for any amine is greater than that for the molecular compound which it forms with phenol. Although this reduction in refraction was originally attributed⁹ to an increase in the valence of the nitrogen of the amine it may be considered, by the more modern interpreta-

tion of Smyth,¹⁰ as being due to the attachment of the hydrogen of the phenol to the nitrogen of the amine as proposed in the formula above. In Table V these differences are shown in the last column, which is really a comparison of the differences between the observed and calculated molecular refractions of the molecular compounds with the sum of the like differences of the two components.¹¹ It is obvious that if the mixture law were true these values would all be zero. Since they are all negative in value they may be interpreted in terms of a union between the two molecules. The differences, which are approaching zero with increasing temperature, are small doubtless due (1) to the partial dissociation of the molecular complex and (2) as Smyth has suggested to the counterbalancing effect produced by the weakening of the forces which the hydrogen exerts on the oxygen of the phenol.

Experimental Part

The preparation, purification and analysis of the molecular compounds were accomplished in the main from the second components and by the methods already described. In doubtful cases freezing point curves were constructed.

Purification of Components.—The components concerned either as individuals or otherwise in the parachor and refractivity determinations were specially purified as stated below.

Phenol.—Method of Sidgwick and Bayliss;¹² m. p. (corr.) 40.5°.

Aniline.—The commercial product, distilled twice, was converted into acetanilide which was crystallized three times from water containing a little acetic acid. This solid was hydrolyzed, the aniline obtained being treated with acetone to remove thiophene by the method of Hantzsch and Freese.¹³ The amine was finally recovered from the hydrochloride by treatment with sodium carbonate solution and, after being dried over solid potassium hydroxide and fractionally distilled twice, it boiled at 184.3° (corr.).

***o*- and *m*-Toluidines.**—In general, by the method of Berliner and May;¹⁴ b. p.'s *o*- 199.3° (corr.), *m*- 203.0° (corr.).

***p*-Toluidine.**—In general, by the method of Gans and Harkins;¹⁵ m. p. 43.4° (corr.).

4-Amino-1,3-dimethylbenzene.—The c. p. product, first distilled, was converted into the hydrochloride, which was fractionally crystallized twice from absolute alcohol

¹⁰ Smyth, "Dielectric Constant and Molecular Structure," The Chemical Catalog Co., Inc., New York, 1931, p. 160.

¹¹ This method of comparison seemed advisable because of the unreliability of the atomic refractions at temperatures above 20° as well as that of nitrogen at 20°. This latter value varies so much even among aromatic primary amines that the mean loses much of its significance. In contrast to the parachor discussion the differences between the observed and calculated values of the components are attributed to the difficulty with the atomic refractions and not to association.

¹² Sidgwick and Bayliss, Ref. 6, p. 2027.

¹⁵ Gans and Harkins, *ibid.*, **52**, 2292 (1930).

and then twice from water. The product thus obtained was treated with sodium carbonate solution to free the xylidine which was dried over solid potassium hydroxide and then fractionally distilled twice under reduced pressure; b. p. 214.3° (corr.).

Physical Measurements.—Surface tensions were determined by the maximum bubble pressure method of Sugden.¹⁶ The bubbler was immersed in a constant temperature bath and readings of the manometer level were made with a cathetometer. Highly purified benzene was used in the determination of the diameter of the larger bubbler tube after the diameter of the smaller one had been measured by a filar micrometer.

Densities of the liquids were determined with an ordinary 10-cc. pycnometer; the densities of the vapors at the temperatures employed were negligible and were, therefore, undetermined.

The refractivity measurements at 45, 60 and 80° were made by a Pulfrich refractometer.

^a $EMR_D = MR_D$ (obs.) - MR_D^{20} (calcd.). The atomic refractions used are the revised values of Eisenlohr, *Z. physik. Chem.*, **75**, 605 (1911); **79**, 134 (1912). Similar calculated molecular refractions may be obtained by the refractions of the electron groups as given by Smyth, Ref. 10, p. 152. In the latter case 6.02 is used for the aro-

matic group, $\begin{array}{c} \text{C} \\ \diagup \quad \diagdown \\ \text{H} \quad \text{N} \cdot \\ \diagdown \quad \diagup \\ \text{H} \end{array}$.

^b EMR_D (M. C.) - EMR_D (C's) is the difference between the observed and calculated molecular refractions of the molecular compounds minus the sum of the like differences for the components.

Summary

New molecular compounds of phenol have been isolated.

The densities, surface tensions and refractivities of certain of these compounds over a range of temperature have been determined.

The parachors and molecular refractions both increase with increase in temperature.

A comparison between the observed and calculated values for the parachors and molecular refractions indicates that the bond between the components in the molecular compounds has a negative value.

An electronic formula, based upon these determinations, has been proposed.

THE PINACOL-PINACOLONE REARRANGEMENT. THE EXAMINATION OF SOME ORTHO-SUBSTITUTED BENZOPINACOLS

BY COLIN H. BEALE AND HAROLD H. HATT

RECEIVED NOVEMBER 13, 1931

PUBLISHED JUNE 6, 1932

It is generally recognized that the values for the relative migratory powers of aromatic hydrocarbon radicals in the pinacol-pinacolone rearrangement are least liable to error when they are obtained from studies of the rearrangement of tetraarylpinacols, for the reason that in such cases there is the least possibility of the end products of the reaction arising in any other way than by a direct pinacol-pinacolone change. In this connection *o*-substituted benzopinacols have been but little examined; of the simple compounds of this class only *sym*.-2,2'-dichlorobenzopinacol and *sym*.-2,2'-dibromobenzopinacol have been at all fully investigated.¹ These pinacols rearranged slowly and the resulting pinacolones were very resistant to attack by alcoholic potash so that a complete decomposition thereby into the corresponding triarylmethanes and aromatic acids was not effected, but it was concluded that in the rearrangements only the unsubstituted phenyl group underwent migration.

Recently Bailar² stated that *sym*.-2,2'-dimethylbenzopinacol and *sym*.-2,2'-dimethoxybenzopinacol could not be rearranged either by iodine and acetic acid, or by acetyl chloride and acetic acid, prolonged treatment with the latter reagent giving rise to unidentifiable oils. He considered these results to be in good agreement with the theoretical conclusions of Lagrave.³ Bailar overlooked the fact that the rearrangement of *sym*.-2,2'-dimethylbenzopinacol had already been described⁴ and that of the phenyl and *o*-tolyl groups the former had been shown to migrate the more readily.⁵

We therefore decided to repeat the rearrangement of *sym*.-2,2'-dimethylbenzopinacol (I), determining the relative migratory powers of the phenyl

¹ Koopal, *Rec. trav. chim.*, **34**, 115 (1915).

³ Lagrave, *Ann. chim.*, **10**, VIII, 363 (1927).

⁴ Hatt, *J. Chem. Soc.*, 1623 (1929).

⁵ Of the ten pinacols described by Bailar as new, two were already known: *sym*.-2,2'-dimethylbenzopinacol [W. D. Cohen, *Rec. trav. chim.*, **38**, 123 (1919); Boyd and Hatt, *J. Chem. Soc.*, 898 (1927)] and *sym*.-2,2'-dimethoxybenzopinacol [Cohen, *Rec. trav. chim.*, **38**, 123 (1919), and **39**, 258 (1920)].

and *o*-tolyl radicals, and also to examine *sym*.-2,2'-dimethoxybenzopinacol (II).

The Rearrangement of the Pinacols and Evidence for Their Free Radical Dissociation in Acetic Acid Solution.—The rearrangement of these pinacols with a solution of iodine in acetic acid proceeds readily, but a successful rearrangement with acetyl chloride has not been effected. The transformations with the first reagent must be practically complete, for with both pinacols 90% yields of the pinacolones were isolated. A further test was possible in the case of pinacol (II) which gives a strong green-black solution in sulfuric acid,⁶ whereas the resulting pinacolones give only pale yellow-brown solutions. By means of this sensitive test it was shown that no pinacol remained after one hour's refluxing with iodine and acetic acid. Pinacol (I) rearranges at a slower rate than (II) and to be complete the treatment must be continued for eight to twelve hours according to the amount of iodine employed.

Some observations made in connection with this problem throw light upon the nature of the rearranging agent. At its boiling point a solution of iodine in acetic acid attacks the methoxyl groups of pinacol (II). For example, with a rearrangement carried out in the usual Zeisel apparatus for the estimation of methoxyl, the amount of silver iodide collected was equivalent to 1.8% of the methoxyl radicals present in the pinacol. The production of methyl iodide was attributed to the presence of hydriodic acid, which may possibly arise by a reaction such as the following⁷

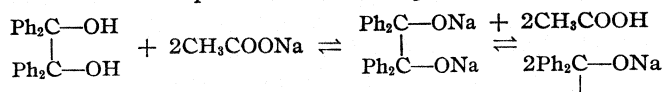

In our experiment, if the iodine had reacted completely in this way, the hydriodic acid could have attacked 1.7% of the pinacol. If sodium acetate was added to the iodine and acetic acid, the reagent was unable to effect rearrangement and the small amount of iodine present was rapidly removed. Failure to rearrange is, nevertheless, not due to lack of iodine, for no rearrangement took place when iodine was added to the solution at a rate which maintained the concentration at a value sufficient in absence of sodium acetate to effect rearrangement.

In further experiments using benzopinacol it was found that sodium acetate and iodine react alone at an appreciable rate, but in presence of the pinacol the iodine disappears more rapidly. Using sufficient iodine the pinacol is converted almost quantitatively to benzophenone. If the iodine does not suffice to convert the pinacol to the ketone, then, as the iodine is used up, the solution becomes first colorless and then rapidly acquires a distinct violet to blue color, which is the more pronounced the greater the concentration of sodium acetate. Subsequent addition of iodine reverses these color changes, and with suitable additions of iodine these variations

⁶ Compare Wizinger and Fontaine, *Ber.*, **60**, 1377 (1927).

⁷ Lapworth, *J. Chem. Soc.*, **85**, 41 (1904); Shaw, *ibid.*, **123**, 2233 (1923).

in color may be obtained several times. Such phenomena suggest that the benzopinacol is partially transformed into free radicals of the metal-ketyl type and of these sodiobenzophenone appears the most likely to arise, being produced in small quantities according to the equation

sodium acetate in acetic acid thus simulating the behavior of sodium ethoxide in ethyl alcohol⁸ and of potassamide in liquid ammonia.⁹ The reaction with iodine would then proceed according to the equation of Schlenk¹⁰

Support for this view is found in the observation that a stream of dry air led through a solution of benzopinacol and sodium acetate in acetic acid oxidizes the pinacol to benzophenone. However, it is necessary to indicate two observations that are not quite in agreement with this view: the first, that we have failed to observe the development of a blue color in a solution of benzopinacol and sodium acetate in acetic acid before the addition of any iodine; the second, that a current of dry air is able to convert benzopinacol in boiling acetic acid into benzophenone. Alternatively, this last observation and those concerning solutions of the pinacol in acetic acid and sodium acetate could be explained by supposing partial dissociation of the pinacol into diphenylhydroxymethyl.

Experiments have shown that benzopinacol is rearranged more slowly in an acetic acid solution of iodine than by a similar equimolecular solution of hydriodic acid (containing but a slight trace of iodine). In the first solution it is possible to observe the complete disappearance of the color due to iodine and to find that the rearrangement is nevertheless complete. Since previous experiments have shown that such solutions always contain hydriodic acid, this latter would seem to be the effectual agent in such rearrangements. Whether the presence of a little iodine has a promoting influence cannot be stated; what appears more important is the hydrogen-ion concentration, any great decrease in the value of which, by the addition of sodium acetate, suppresses rearrangement.

Experimental

The Preparation of Sym.-2,2'-dimethoxybenzopinacol.—2-Methoxybenzophenone was reduced to the pinacol using zinc dust and acetic acid by the method already described for 2-chlorobenzophenone.¹¹ Reduction for five days at 25° gave much the better yield. The pinacol so obtained melted at 165–168° and under the microscope

⁸ Schlenk and Thal, *Ber.*, **46**, 2840 (1913).

¹¹ Hatt, *J. Chem. Soc.*, 1629 (1929).

was seen to consist of two types of crystals: long rectangular prisms (I) and rhombic plates (II), separable by fractional crystallization from chloroform and alcohol, the former being the less soluble. Tetraarylpinacols melt with decomposition,¹² and the melting point depends upon the rate of heating. In the present two cases the melting points lie too close together to provide a method for distinguishing the pinacols. Under comparable conditions (I) melted at 173–175° and (II) at 174–176°. Either is completely liquid after heating for twenty-five minutes at 154°.

Anal. Calcd. for $C_{28}H_{26}O_4$: C, 78.83; H, 6.15. (I) Found: C, 78.72; H, 6.19. (II) Found: C, 78.75; H, 6.19.

Rearrangement of Sym.-2,2'-dimethoxybenzopinacol.—The pinacol (1.93 g.), refluxed for four hours with dry glacial acetic acid (20 cc.) and iodine (0.04 g.) and poured into 50 cc. of water containing a little sodium sulfite, gave a white crystalline precipitate, which, after filtering, washing with water, and drying at 100°, melted at 157–158° and weighed 1.7 g. (92% of theoretical). Four recrystallizations, each time employing a different solvent, raised the melting point to 161°.

Anal. Calcd. for $C_{28}H_{24}O_3$: C, 82.33; H, 5.93; mol. wt., 408. Found: C, 82.43; H, 6.15; mol. wt., 405 (in camphor).

Nevertheless, this was still a mixture of the two possible pinacolones, for rupture with alcoholic potash produced a mixture of *o*-anisic acid and benzoic acid. A second rearrangement in which the time of refluxing was one hour gave precisely the same product in 92% yield.

The Action of Alcoholic Potash on the Pinacolones.—As mentioned, Koopal was unable to transform di-ortho-substituted benzopinacolones completely into the corresponding triarylmethanes and aromatic acids. We have experienced the same difficulty when using the crude pinacolones for the estimation of the migratory powers of groups, although one of us¹¹ found that pure *o*-toluyl-*o*-tolylidiphenylmethane could be transformed almost quantitatively into the methane and acid. Bailar observed that occasionally with meta- or para-substituted benzopinacolones the alcoholic potash solutions became a deep brown color. He found that the values for the migratory powers obtained from such experiments were never concordant and rejected them. In all of our experiments a brown color and finally a brown precipitate were produced. For ortho substituted pinacols we believe the formation of this brown precipitate to be due to the comparatively slow rearrangement of the pinacol permitting of the simultaneous formation of the hydrol and ketone by thermal decomposition, and of the ketone by oxidation, if air is not excluded. The ketone so contaminating the pinacolone is then reduced by the alcoholic potash to the hydrol and the acetaldehyde produced resinifies.¹³ Thus, if benzopinacolone, resulting from the treatment of the pinacol with iodine and acetic acid, is treated, without preliminary crystallization, with alcoholic potash, the solution does not become brown after prolonged boiling. But the brown precipitate is produced if a little benzopinacol is added to the solution, or by prolonged refluxing of the acetic acid solution of the pinacol before rearrangement. The low yields of acids we obtained (not more than 60% of the theoretical) appear to be connected with this phenomenon rather than due to incomplete fission of the pinacolones. In one case where 1.74 g. of the methoxylated pinacolone gave 0.274 g. of acids by refluxing for one hundred hours with alcoholic potash, a further like treatment of the neutral products yielded only an additional 0.016 g. Because, although the yields of acids varied considerably, their composition remained constant, we consider that the migratory powers calculated on this basis are essentially correct and have a maximum error of about 5%.

¹² Thörner and Zincke, *Ber.*, **10**, 1473 (1877).

¹³ Compare Montagne, *Rec. trav. chim.*, **27**, 327 (1908); **31**, 298 (1912).

Determination of Migratory Powers.—The pinacol (2 g.) was converted to the pinacolone as already described, the latter dried, transferred to an all-glass apparatus and there refluxed for one hundred hours with a solution of potassium hydroxide (5 g.) in absolute alcohol (50 cc.). This solution was poured into 300 cc. of water and the liquors evaporated three times to two-thirds of their bulk to remove the alcohol completely. The insoluble material was extracted with chloroform or benzene, the aqueous liquors acidified and extracted with one of the above solvents and these last extracts dried, evaporated, and the acids dried to constant weight at room temperature.

The equivalent weight of the mixed acids was determined by one or more of the following methods. (I) The methoxyl content was determined by the usual Zeisel method. To obtain reliable results it was necessary to remove all foreign ethoxyl containing substances, which was accomplished by repeated evaporation of the alkaline liquors and the use of chloroform or benzene as extractant as described above. (II) By titration with standard baryta solution. (III) The salicylic and benzoic acids generated in method (I), after decolorization in aqueous solution with sulfurous acid, were extracted in benzene, the solution washed with water, evaporated and the salicylic acid estimated according to the method of Bougeault.¹⁴ After removing the purple precipitate of "tetraiododiphenylene quinone," benzoic acid was extracted from the aqueous filtrates and identified in the usual way. The yields of benzoic acid were low but agreed fairly well with the figures obtained by the above three methods.

The estimations of the equivalent weight of the mixed acids by the three methods are in good agreement. Owing to the extra manipulation, method (III) is probably the least accurate. Some of the results are set out in Table I; from them the mean values of the relative migratory powers of the phenyl and *o*-anisyl groups are found to be 1.00 and 0.30.

TABLE I

No.	Pinacol, g.	Yield of acids, g.	Percentage by weight of <i>o</i> -anisic acid in the mixed acids		
			Method (I)	Method (II)	Method (III)
1	2.018	0.274	81.0	80.9	..
2	2.002	.280	81.7	..	77
3	2.000	.327	81.6
4	1.926	.390	83.3

2-Methylbenzophenone and 2,2'-Dimethylbenzopinacol.—Several processes have been given for the preparation of 2-methylbenzophenone. We have found that 2-methylbenzohydrol can be oxidized to this ketone almost without any side chain oxidation. On the other hand, Zincke,¹⁵ Senff,¹⁶ and others found that complete oxidation of the methylene group in the benzyltoluenes could not be accomplished without considerable oxidation of the methyl group.

2-Methylbenzohydrol was readily obtained from *o*-tolylmagnesium bromide and benzaldehyde. 10 g. of the hydrol was added with vigorous stirring to a mixture of 20 g. of potassium dichromate, 16.5 cc. of concentrated sulfuric acid and 95 cc. of water. The mixture was stirred at 45–50° for half an hour and then poured into aqueous sodium hydroxide. After almost neutralizing with sulfuric acid, extraction with ether gave 9.3 g. of almost pure ketone.

Reduction of the ketone with zinc dust and acetic acid proceeded smoothly, giving the pinacol, m. p. 160–161° (from chloroform and alcohol). Heated with glacial acetic

¹⁴ Bougeault, *Compt. rend.*, **146**, 1403 (1908); *J. pharm. chim.*, [VI] **28**, 145 (1908).

¹⁵ Zincke, *Ann.*, **161**, 93 (1872).

¹⁶ Senff, *ibid.*, **220**, 237 (1883).

acid and iodine for twelve hours, the pinacol yielded the stable pinacolone.¹¹ Apart from this extra time required for the rearrangement, the relative migratory powers of the phenyl and *o*-tolyl groups were determined essentially according to the procedure for the previous case.

Ninety-seven to ninety-eight per cent. of the theoretical yields of the crude pinacolone were obtained. In three experiments the weights of acid obtained from 1.834, 1.816 and 2.000 g. of pinacol were, respectively, 0.267, 0.259 and 0.329 g. The equivalent weights determined by method (II) were 136.3, 135.1 and 138.2 (*o*-toluic acid requires 136), showing that there is almost exclusive migration of the phenyl group.

The Oxidation of Benzopinacol in Acetic Acid Solution.—(A) One gram of benzopinacol was added to a mixture of 10 cc. of pure acetic acid,¹⁷ 1 g. of iodine and 2 g. of fused sodium acetate. The mixture was refluxed for one-half hour, excluding moisture, cooled and poured into dilute sulfurous acid. The crystalline benzophenone was filtered off and dried to constant weight (0.98 g.). It melted at 45–47°; 48–49° after one crystallization. In a second experiment the crude benzophenone was refluxed with alcoholic potash and the organic acids produced were estimated as in the fission of a pinacolone; 0.008 g. of benzoic acid was produced.

(B) Two grams of benzopinacol, 2 g. of sodium acetate and 20 cc. of acetic acid were refluxed on an oil-bath in a current of dry air, freed of carbon dioxide. After five hours the products were poured into water and the insoluble matter filtered off. The aqueous liquors did not liberate iodine from potassium iodide solution and experiments showed that had sodium peroxide been produced it would have been destroyed under the conditions of the experiment. The solid product, 1.85 g., was separated with petroleum ether into benzopinacol (0.5 g.) and benzophenone (0.9 g.). The crude material gave a light orange color with sulfuric acid but no benzhydrol could be isolated. In an experiment where the air was replaced by nitrogen, 80% of the pinacol was recovered in a state of purity.

(C) The reaction was carried out as in (B) but in absence of sodium acetate. The oxidation did not proceed so smoothly; using 1.9 g. of benzopinacol there were isolated 0.9 g. of benzophenone and 0.2 g. of benzopinacol.

Conclusion

Sym.-2,2'-dimethylbenzopinacol and *sym*.-2,2'-dimethoxybenzopinacol have been rearranged. From the rearrangement of the second pinacol, a value is obtained for the migratory power of the *o*-anisyl group (0.30) which exceeds that of the *m*-anisyl group (0.20). Lagrave's generalizations are therefore incorrect, in so far as they predict, as Bailar states, the inability of these pinacols to rearrange and of all *o*-substituted groups to undergo migration.

The present observations stand in agreement with the previously existing data in this field. Thus, there seems to be no case of a di-ortho-substituted benzopinacol that has failed to rearrange. And again, although the *o*-anisyl group is the first simple *o*-substituted group whose migration in the rearrangement of tetraarylpinacols has been established, some closely related groups were known to migrate. Examples of this kind occur in the rearrangement of bis-diphenylene-ethylene glycol¹⁸ and of 1,1-diphenyl-2,2-

¹⁷ Purified according to the method of Orton and Bradfield, *J. Chem. Soc.*, **125**, 960 (1924).

¹⁸ Gomberg and Bachmann, *THIS JOURNAL*, **49**, 236 (1927).

diphenylene-ethylene glycol,¹⁹ where in terms of the Tiffeneau-Meerwein mechanism the migration of the "ortho-linked" group is enforced. Observations have also been made pointing to the ability of similar groups to migrate where this does involve competition with the phenyl group. Elbs²⁰ found evidence for this in the case of the 2,5-dimethylphenyl group, and in the tetraarylpinacol series the α -naphthyl group appears to have a greater migratory power than the phenyl group, while its resemblance to an ortho-substituted phenyl group is well known.^{2,20,21}

The data concerning symmetrical di-ortho-substituted benzopinacols may be regarded in the following way. For the corresponding para compounds the series:

is obtained when the migrating groups are arranged in order of their decreasing migratory power. For the ortho compounds this order is modified by the superposition of an "ortho effect." This "effect" may not be entirely sterical in nature,²² but at present the data agree with the simple assumption that the essential difference between the migration of ortho and para substituted radicals is that the former is rendered much more difficult by opposition of a sterical kind. Although sterical effects cannot yet be evaluated with certainty, the earlier investigations,²³ the work of Kindler²² and the calculations from x-ray analysis,²⁴ all agree in the order of increasing sterical effect:

Moreover, that it is difficult to attach three *o*-tolyl groups to the same carbon atom by means of the Grignard reagent,¹¹ whereas, by this means, the addition of three *o*-anisyl groups takes place readily,²⁵ may be taken to indicate that sterical opposition to the *o*-tolyl group is much greater than to the *o*-anisyl group.

The formation of a series indicating the order of increasing migratory power for ortho-substituted radicals can only be obtained by the superposition of this "ortho effect" upon the series for para radicals when the exact relationship between these two quantities is known. But however this combination is to be effected, it can be seen that it must give the order

which is in agreement with the results so far obtained

Summary

Sym.-2,2'-dimethylbenzopinacol and *sym*.-2,2'-dimethoxybenzopinacol have been rearranged to the corresponding pinacolones and the relative migratory powers of the phenyl, *o*-tolyl and *o*-anisyl groups have been determined.

Benzopinacol is oxidized by gaseous oxygen in acetic acid solution, either with or without the addition of sodium acetate, to benzophenone. The same oxidation is accomplished much more rapidly by a solution of iodine and sodium acetate in acetic acid.

CHEMICAL INVESTIGATION OF *RAUWOLFIA CAFFRA*. I. RAUWOLFINE

By J. B. KOEPFLI

RECEIVED DECEMBER 10, 1931

PUBLISHED JUNE 6, 1932

The genus *Rauwolfia*, belonging to the natural order *Apocynaceae*, is widespread throughout the tropics and some forty-two species are known. Although most species are actively poisonous and many are reputed to possess medicinal value, information concerning their chemistry or pharmacology is extremely meager. There are occasional references in the literature wherein the investigators¹ lay claim to having obtained active crystalline bodies from some of the East Indian *Rauwolfia* but the investigations were limited in scope and the reports are vague. Accordingly, when a supply of the bark of a South African species of *Rauwolfia* became available, the present investigation was undertaken with the hope that some definite information would be forthcoming concerning the constituents of the bark responsible for the physiological activity and, furthermore, that if chemical individuals could be isolated, a study of their properties from a chemical and pharmacological viewpoint might prove of value.

The only available information concerning the South African *Rauwolfia* under investigation is contained in a report² from which the following facts are taken. An investigation was made of the nature of the active principle of the so-called "Quinine Tree" of the Transkei, the "*Umjela*" as it is known by the natives. This tree, now identified as *Rauwolfia caffra* (formerly as *Tabernaemontana ventricosa*, Hochst), grows in the Gxwaleni

forest in the Nyanduli district and in the Mpami forest, Elliotdale, where specimens four feet in diameter and fifty feet in height are known to occur. The bark has a bitter taste and is reputed to have the well-known therapeutic properties of quinine. No alkaloids of the cinchona group were detected in the bark but needle-shaped crystals, which were thought to represent a new alkaloid, were isolated from a chloroform extract of the bark. The report concludes with a description of the properties of the crystals which, beyond the fact that they gave a crimson lake (Vitali's test), need not be included here as there is no evidence that an individual alkaloid had been isolated.

The present communication describes the progress made thus far in the investigation of this bark. Three crystalline basic substances have been obtained, one in sufficient quantity to permit of its more detailed study. The name "rauwolfine," derived from the generic name of the tree, is suggested for this base. The other two bases are designated Base A and Base B, respectively, until more is known concerning their chemistry and possible relationship to rauwolfine.

The properties of rauwolfine, such as its apparent instability in solution and in particular its insolubility in all solvents immiscible with water, leave much to be desired in the method used for its isolation from the bark. For the sake of brevity, therefore, only an outline of the operations performed is presented in this paper; a more detailed description is reserved for future communications when the information now available will no doubt have led to more efficient methods. Lastly, certain chemical aspects of rauwolfine, aside from its possible pharmacological importance, seem of sufficient interest to warrant the further efforts which are being made with a view to elucidating the chemical constitution of the base.

Experimental

Material.—Through the kind coöperation of the Division of Plant Industry of the Department of Agriculture and the Forest Department of the Union of South Africa, a supply of the dry bark of *Rauwolfia caffra* Sonder (National Herbarium, Pretoria No. 3358) has been made available for this investigation. The material was collected in 1926, in the Mzwane Forest, Mtambalala Patrol, District Port of St. John's, Transkei, and after arrival in Baltimore was ground and stored in sealed containers.

Extraction of the Bark.—Ten kilograms of the finely ground dry bark³ was completely extracted with hot petroleum ether (b. p. 30–60°) which yielded upon evaporation 100 g. of a light yellow waxy material that solidified in the ice chest and had a characteristic tea-like odor. This material gave negative tests for alkaloids and a portion was set aside for possible future investigation.

After petroleum ether extraction the ground bark was covered with 93% ethanol and boiled for five minutes. When cool the material was collected on a filter, transferred to a percolator and continuously extracted with fresh portions of cold 93%

³ This opportunity is taken to thank the Directors and Laboratory Staff of Hynson, Westcott and Dunning for conducting the petroleum ether and ethanol extractions.

ethanol over a period of several weeks. When 240 liters of solvent had been used, the last percolates were still highly colored and gave copious precipitates with Mayer's reagent. The material was therefore exhausted further with 250 liters of 93% ethanol or until the percolate was but slightly colored and a test portion gave a negligible precipitate with Mayer's reagent. The last 250 liters of percolate, when concentrated under diminished pressure to 1.5 liters and placed in the ice chest for three weeks, deposited 3.5 g. of a crystalline substance which upon investigation proved to be *dl*-inosite melting at 223–224°.

The combined ethanol extracts of the bark were taken to virtual dryness under diminished pressure at 40°, which left 1040 g. of a brown varnish-like residue (representing 10% of the weight of the dry bark). The solid residue was covered with 1.5 liters of water and distilled with steam for five hours. An ethereal extract of the 3.5 liters of distillate yielded 6 g. of a sweet-smelling essential oil, together with 5 g. of *o*-hydroxybenzaldehyde, identified by means of its phenylhydrazone.

The flask containing the residue which had been subjected to steam distillation was allowed to stand overnight. The dark red supernatant liquid was then decanted from 700 g. of tarry residue and diluted with its own volume of water. After standing for several days the solution was filtered from 200 g. of an acid-insoluble resinous precipitate and concentrated to 2 liters under diminished pressure at 40°. After standing overnight in the ice chest the deep red solution, which appeared perfectly clear and was faintly acid to litmus, was repeatedly extracted with chloroform.

Base A.—The 3 liters of chloroform extract, after washing and drying and removal of the solvent, yielded 30 g. of a dark red viscous gum from which 0.015 g. of a crystalline alkaloid, designated Base A, was isolated after a series of operations involving precipitations with sodium carbonate and sodium hydroxide, together with extractions by means of dilute acid and ether. The base may be extracted from an alkaline solution with ether but is apparently insoluble in dry ether when crystalline. It is insoluble in water and petroleum ether but soluble in alcohol, chloroform and acetone and may be best crystallized from hot benzene and petroleum ether, from a mixture of which it separates in tufts of hair-like colorless needles melting at 294–295° (uncorr.) to a dark brown liquid. The Base A yields a yellow crystalline platinic chloride, a purple amorphous auric chloride and an amorphous picrate. It dissolves in concentrated sulfuric acid without color but produces a brilliant orange in concentrated nitric acid and a violet coloration fading to brown with Vitali's reagent. The base is precipitated from acid solution by sodium hydroxide, sodium carbonate and ammonium hydroxide in excess.

The main watery solution, together with the washings of the chloroform extraction, was reduced to 2 liters in volume and at the same time freed from dissolved chloroform by evaporation under diminished pressure at 40° and then precipitated with 150 g. of neutral lead acetate. After removal of the lead precipitate by filtering, the filtrate was delead with hydrogen sulfide, the excess acetic acid partially neutralized by addition of 20 g. of sodium carbonate, and the solution concentrated under diminished pressure at 40° to 2.5 liters. Preliminary experiments had indicated that a fractional precipitation by means of alkaline carbonate should be resorted to at this point in order to remove certain acid-soluble gums. Accordingly, 600 cc. of a 20% solution of sodium carbonate was slowly added, the supernatant liquid was decanted from the red-brown sticky precipitate which separated and the alkaline solution successively extracted with 3 liters of chloroform.

Base B.—The dark red chloroform extract, after washing with water and drying over anhydrous sodium sulfate, was concentrated to 50 cc. and allowed to evaporate at room temperature, which left 5 g. of a dark gum interspersed with crystals. Some of the crystals were picked out and examined and were obviously impure. They gave

copious precipitates with the usual alkaloidal reagents and were soluble in dilute acids; from the acid solutions the substance designated Base B could be recovered after addition of sodium carbonate in excess.

Rauwolfine

Isolation.—The alkaline solution, together with washings and some amorphous precipitate which appeared during the previous chloroform extraction, was made just acid to litmus with 100 g. of glacial acetic acid and the volume reduced to 1.5 liters under diminished pressure at 40°. To the clear liquid was slowly added a saturated solution of 150 g. of potassium carbonate. After standing for some time the solution had clarified and was decanted from the precipitated yellow gum and a further addition of 150 g. of potassium carbonate was made. This last increase in alkalinity threw down a greenish yellow amorphous, though granular, precipitate which was collected on the filter and washed with dilute potassium carbonate. It consisted for the most part of the base designated as rauwolfine. After two crystallizations from boiling water 10 g. of the base, representing 0.1% of the weight of the dry bark of *R. caffra*, was obtained as light buff-colored crystals. The base was further purified by three successive crystallizations from water, conversion into the crystalline chloride (see below) and regeneration of the free base, followed by two more crystallizations from water.

Free Base.—Rauwolfine crystallizes from water in small transparent, very light buff-colored tabular crystals (approximately 0.3 mm. in length). They appear to belong to the rhombic bipyramidal class of the orthorhombic system. The forms present, listed in the order of prominence, are the basal pinacoid, the side pinacoid, and the vertical rhombic prism. The general shape of the tablet is an elongated hexagon; two opposite angles are equal to 88°, the other four to 46° (these are the external angles). Optically the crystals show fairly high birefringence, the index of refraction is always greater than that of Canada balsam, the elongation is negative.⁴ The base (dried at room temperature) has no definite melting point but when heated at a normal rate in an evacuated capillary tube it darkens at 200° and decomposes at 235–238°.

Rauwolfine in aqueous solution is strongly alkaline to litmus. It dissolves readily in all acids and solutions of its salts are neutral in reaction to litmus. The salts are not decomposed by sodium hydrogen carbonate. The free base is insoluble in sodium carbonate although soluble in sodium hydroxide, from a solution of which it is precipitated by carbon dioxide. Rauwolfine gives amorphous precipitates with all the usual alkaloidal reagents. The mercuric chloride precipitate is soluble in dilute sulfuric acid. The brown auric chloride partially reduces in the cold. The yellow picrate is decomposed on warming, likewise the orange iodo potassium iodide precipitate. The phosphotungstate is insoluble in water or alcohol. The tannate, soluble in dilute hydrochloric acid but reprecipitated by excess acid, is insoluble in ammonium hydroxide. A solution of the base in water decolorizes a neutral solution of potassium permanganate in the cold with the formation of a brown precipitate.

Rauwolfine gives two useful color reactions. A small quantity of the base dissolved in concentrated sulfuric acid produces a brilliant yellow solution. In time the color is gradually discharged; upon the addition of a drop of concentrated nitric acid to the colorless solution, a brilliant indigo-blue appears, passing rapidly through purple to a golden brown. The base dissolves in concentrated nitric acid to a deep wine-red fading to golden brown. The base does not give any marked color reaction with ferric chloride although a slight precipitate is produced in concentrated solution. Vitali's test is negative.

⁴ From a cursory crystallographic examination made by Dr. J. D. H. Donnay of the Johns Hopkins University.

The behavior of rauwolfine with solvents is especially noteworthy. The crystalline base is only slightly soluble in cold water but readily so in hot (approximately one part in ten), and it is characterized by its insolubility in all the non-hydrolytic solvents tried, including pyridine and dioxane. The behavior of the base with alcohols seems exceptional—it is extremely soluble in absolute methanol but insoluble in absolute ethanol even on prolonged boiling. When 0.2 g. of the base was dissolved in 5 cc. of hot 90% ethanol and 15 cc. of absolute ethanol was added, the solution on partial cooling set to a jelly-like mass of crystals. When collected on the filter and washed with ether it formed a mat of hair-like colorless crystals weighing 0.050 g., a sample of which (dried at room temperature) decomposed at 227–229° when heated in an evacuated capillary tube. This substance turns green when heated in an air oven at 100° or when kept in an evacuated desiccator over phosphorus pentoxide. Attempts to analyze the substance gave unsatisfactory results but when it was recrystallized from water, rauwolfine of the usual crystal form and decomposition point resulted.

Although colorless specimens of rauwolfine and its salts have been obtained by precipitating them from freshly prepared solution, the application of heat necessary for recrystallization or prolonged exposure in solution always causes the appearance of some color. This color is no doubt due to products of decomposition and suggests that the base is relatively unstable in solution. An aqueous or alcoholic solution of the free base is olive-green and acidified solutions are pink; in either case the color deepens upon long standing.

*Anal.*⁵ Calcd. (I) for $C_{20}H_{26}O_3N_2$: C, 70.17; H, 7.60. Calcd. (II) for $C_{20}H_{26}O_3N_2 + 2.5$ moles of water: N, 7.23. Found (I) (dried at 100°): C, 69.54, 69.64; H, 7.44, 7.23. Found (II) (air-dried): N, 7.13, 7.07. Subs. (air-dried) 5.007, 4.997: loss at 100°, 0.584, 0.598. Calcd. for $C_{20}H_{26}O_3N_2 + 2.5$ moles of water: 11.63. Found: 11.66, 11.97.

A Zeisel-Perkins determination of alkoxyl groups gave completely negative results with rauwolfine and since the base proved to be insoluble in camphor, the determination of its molecular weight will have to be postponed until a suitable solvent is found. Preliminary attempts to prepare an acetyl derivative or a methiodide of the base were unsuccessful.

Halogen Salts.—Rauwolfine chloride was obtained in the anhydrous form by the following procedure. To 0.1 g. of rauwolfine in 2 cc. of cold absolute methanol, 10 cc. of absolute ethanol was added together with 0.05 cc. of concentrated hydrochloric acid. The solution was filtered and, after addition of 10 cc. of anhydrous ether, placed in the ice chest overnight. Next morning 0.06 g. of the salt in the form of faintly pink, pointed plates was collected on the filter and washed with ethanol and ether.

Rauwolfine chloride plus one molecule of water may be prepared by recrystallization of the anhydrous form from water or by dissolving the free base and making the solution just acid to congo paper with hydrochloric acid. The bromide and iodide were prepared in a corresponding manner; no attempt was made to obtain their anhydrous forms.

The halogen salts of rauwolfine are slightly soluble in cold water, soluble in hot; they are furthermore soluble in methanol in the cold but soluble only with difficulty in

⁵ All the analyses in this communication were performed by Dr.-Ing. A. Schoeller of Berlin-Schmargendorf by the micro method and three to five milligrams of substance was usually taken for analysis. The notation "air-dried" signifies that the substance was dried to constant weight in a current of air at room temperature. The notation "dried at 100°" signifies that the substance was dried to constant weight at 100° in a high vacuum over phosphorus pentoxide.

TABLE I
 HALOGEN SALTS OF RAUWOLFINE, $C_{20}H_{25}O_2N_2$ ·HALIDE

Salt	M. p. ^b (with dec.), °C.	Carbon, %			Hydrogen, %		
		Calcd.	Found	Found	Calcd.	Found	Found
Chloride anhydrous	300–303	66.57	66.80	66.70	6.93	7.07	7.00
Chloride + 1 mole H ₂ O	297–300 (darkens 270)	66.57	66.16	66.26	6.93	7.29	7.09
Bromide + 1 mole H ₂ O	250–253 (softens 245)	59.27	59.13	59.10	6.17	6.33	6.19
Iodide + 1 mole H ₂ O	220–225 (dec. 300+)	53.11	53.41	53.40	5.53	5.88	5.89

^a Calculated on "air-dried" basis, + 1 mole H₂O. The other determinations were made on specimens dried at 100°.

^b Normal rate of heating in an evacuated capillary tube.

boiling 95% ethanol. Their melting and decomposition points are not well defined and vary with the rate of heating.

Some difficulty has been experienced in measuring the optical activity of rauwolfine. However, Dr. R. T. Dillon of the Rockefeller Institute for Medical Research, who kindly made some measurements, obtained the approximate value $[\alpha]_D^{20} + 29^\circ$ (in water) and $[\alpha]_D^{20} + 45^\circ$ (in 95% ethanol) for the specific rotation of rauwolfine chloride.

Empirical Formula.—The empirical formulas derived from the analyses of rauwolfine and its salts are of necessity put forward only provisionally at this time. The formula $C_{20}H_{25}O_2N_2Cl$ for the anhydrous form of rauwolfine chloride seems to agree satisfactorily with the analytical data. Until a molecular weight determination can be made, the supposition seems justified that such a naturally occurring alkaloid has two nitrogen atoms rather than four or more and consequently that the molecular formula of the salt is $C_{20}H_{25}O_2N_2Cl$. In the case of the free base of rauwolfine crystallized from water, the empirical formula $C_{20}H_{26}O_3N_2 \cdot 2.5H_2O$ seems best in line with the analytical data. This would mean that the salts of rauwolfine are formed by loss of water although the possibility remains that the crystalline free base still retains some solvent of crystallization even when dried at 100° in a high vacuum over phosphorus pentoxide. No further conjecture need be made beyond the suggestion that rauwolfine may be an alkaloid of the quaternary ammonium base "type" and with the evidence at hand indicating such a possibility the nomenclature rauwolfine chloride rather than rauwolfine hydrochloride has been followed.

Pharmacological Action.—Rauwolfine or its salts, when injected into experimental animals, causes very definite pharmacological and toxico-

logical reactions.⁶ The lethal dose for rats, cats, and rabbits is of the order of 35 mg. per kilogram of body weight. An intravenous or intraperitoneal injection of the drug causes, in the unanesthetized animal, restlessness and definite stimulation of the respiration, both as regards rate and amplitude, and later convulsions and cessation of the respiration occur and in some instances the heart continues to beat for several minutes.

Rauwolfine in doses of 3 mg. or more causes a definite curare-like action when injected into the lymph sacs of frogs, as evidenced by the paralysis of the motor nerve-endings in the skeletal muscles.

Rauwolfine when injected into anesthetized cats, dogs, and rabbits causes a fall in blood pressure and stimulation of the respiration—effects which can be repeatedly elicited and which also occur after a previous injection of atropine sulfate. From a pharmacological analysis it appears that the main site of action in mammals is on the brain centers, rather than in the peripheral structures. The drug has little or no effect on isolated smooth muscle.

Professor Reginald D. Manwell of the Department of Zoölogy, Syracuse University, has kindly carried out a series of tests with rauwolfine on canaries infected with *plasmodium elongatum* and *plasmodium praecox*, two species of avian malarial parasites. He found that the drug does not have antimalarial properties.

In conclusion the author desires to thank Professor John J. Abel and Dr. E. M. K. Geiling for their continued interest and encouragement, and Dr. James F. Couch for valuable criticism.

Summary

A chemical investigation has been undertaken of *Rauwolfia caffra*, a South African tree, the bark of which is reputed to possess therapeutic value. The investigation has thus far yielded three crystalline bases, one of which, identified as a new alkaloid, has been named rauwolfine and provisionally assigned the formula $C_{20}H_{28}O_3N_2 \cdot 2.5H_2O$. Some of the properties of the alkaloid, including its pharmacological action, and the preparation and properties of its halogen salts are described.

BALTIMORE, MARYLAND

⁶ This information is based upon a study of the pharmacological action of rauwolfine by Dr. E. M. K. Geiling, a detailed report of which will be published in the *Journal of Pharmacology and Experimental Therapeutics*.

THE BENZOHYDRYL RULE AND THE CONSTITUTION OF ALKALI TRIPHENYLETHIDES WHICH ARE STABLE IN LIQUID AMMONIA¹

BY CHARLES BUSHNELL WOOSTER AND JOHN F. RYAN

RECEIVED DECEMBER 11, 1931

PUBLISHED JUNE 6, 1932

It has been emphasized by Kraus² that although the systematic investigation of the chemistry of non-aqueous solutions cannot but lead to many valuable results, substantial progress will be achieved only when such a study is made a primary objective rather than a side line, incident to other investigations. An important division of this subject deals with organic reactions, particularly reduction reactions, in liquid ammonia solution. There is a good reason for beginning an investigation of this field with the hydrocarbons. These substances exhibit a greater reactivity toward alkali metal solutions than was originally recognized³ and some notion of the probable behavior of hydrocarbon radicals may be expected to facilitate a study of the reduction of the various types of organic compounds in which such radicals occur.

In general the reduction of hydrocarbons with alkali metals leads primarily to the formation of organo-alkali compounds which may be either stable or subject to ammonolysis in the presence of liquid ammonia. Some basis for predicting the result in particular instances has been obtained by a study of the reaction between hydrocarbons and alkali metal amides in liquid ammonia solution. This reaction is the reverse of ammonolysis

and its occurrence demonstrates the existence of a stable alkali metal derivative of the hydrocarbon in question.

The Benzohydril Rule.—The action of potassium amide on some phenylated methanes and ethanes has been reported previously.⁴ This study has now been extended using sodium amide and including some additional hydrocarbons.

The results obtained with the two alkali metal amides were the same. Reaction was observed with $(C_6H_5)_2CH_2$, $(C_6H_5)_3CH$, $(C_6H_5)_2CHCH_3$, $(C_6H_5)_2CHCH_2C_6H_5$, $(C_6H_5)_2CHCH(C_6H_5)_2$, $(C_6H_5)_2CHCH_2CH(C_6H_5)_2$ and tetrahydronaphthalene, but no reaction took place with $C_6H_5CH_3$, $(C_6H_5)_4C$, $C_6H_5CH_2CH_3$, $C_6H_5CH_2CH_2C_6H_5$, $(C_6H_5)_3CCH_3$, $(C_6H_5)_3CCH_2C_6H_5$ or $C_6H_5CH(CH_3)_2$.

It may be seen that in the case of the *phenylated paraffins* reaction occurred when and only when the benzohydryl group, $(\text{C}_6\text{H}_5)_2\text{CH}-$, was present in the hydrocarbon molecule. This generalization, which has been established for all the phenylated methanes, most of the phenylated ethanes and two of the phenylated propanes (including one with a tertiary structure not involving two phenyl groups), is probably applicable to the other phenylated paraffins and may be conveniently termed the *benzohydryl rule*.

This rule is closely related to that of Vorländer,⁵ who pointed out that the reactivity of a hydrogen atom was increased by the presence of unsaturation in the β -position. The benzohydryl rule is more specific, however, in that it determines the amount of a particular type of unsaturation necessary to render the hydrogen atom reactive toward sodium or potassium amides in liquid ammonia at -33.5° . A comparison of the two rules furnishes two interesting suggestions. First, it indicates that the benzohydryl rule will not generally apply without modification to hydrocarbons containing other types of unsaturation than phenyl groups. This is true even when the additional unsaturation is that of a six-membered ring, as is shown by the behavior of tetrahydronaphthalene. Second, it suggests that the hydrogen atom which is replaced by alkali metal is the one attached to the aliphatic carbon atom of the benzohydryl group. This suggestion as well as other predictions based on the foregoing generalizations has been confirmed in the case of stable alkali triphenylethides prepared by various reactions including addition, substitution and molecular rearrangement. The remainder of this paper is devoted to these results which illustrate the value of the benzohydryl rule.

The Constitution of the Stable Sodium Triphenylethide.—The initial step in the reaction between sodium and triphenylethylene in liquid ammonia is the addition of sodium to the double bond

as is shown by the fact that hydrolysis of the reaction product yields 1,1,2-triphenylethane.⁴ The initial product is, therefore, a 1,2-disodium-1,1,2-triphenylethane and falls within the province of the benzohydryl rule. Only one of the sodium atoms is attached to the aliphatic carbon atom of a benzohydryl group and consequently the other sodium atom is susceptible to ammonolysis.⁶

⁵ Vorländer, *Ber.*, **34**, 1632 (1901).

⁶ The benzohydryl rule requires that *under equilibrium conditions* the system represented in Equation 3 would consist principally of the substances on the right-hand side of the arrow. Consequently, the statement made above involves the assumption that equilibrium is attained under the conditions of the experiment. In all the cases thus far investigated the ammonolysis of an unstable *organo-alkali* compound has been found to proceed rapidly.

The structure of the stable sodium compound was established by the preparation of its ethyl derivative. Ammonia was condensed on a 3-g. sample of triphenylethylene in a reaction tube,⁷ and sodium was added in tenth-gram portions until a permanent blue color was obtained. After stirring for two hours, ethyl bromide diluted with dry ether was added until the color of the liquid ammonia solution was discharged. The reaction residue was washed with water and crystallized from alcohol. Rod-like crystals melting at 79–79.5° were obtained.

Anal. Calcd. for $C_{22}H_{22}$: C, 92.31; H, 7.69. Found: C, 91.94, 92.30; H, 7.17, 7.02.

If the sodium compound actually possessed the structure tentatively assigned, the product of its reaction with ethyl bromide should be 1,2,2-triphenylbutane.

This hydrocarbon is unknown, but its independent synthesis from 1,1-diphenylpropylene-(1)⁸ was accomplished by the method expressed in Equations 5, 6 and 7.

The occurrence of the reaction expressed in Equation 5 was demonstrated by an experiment in which the propylene was slowly added to a concentrated solution of potassium in liquid ammonia so that the alkali metal was always present in large excess. The resulting organo-alkali compound was decomposed with ammonium chloride and the ammonia allowed to evaporate. The residue was a colorless oil, which was washed, dried and distilled under reduced pressure. Its properties were then compared with those of a sample of 1,1-diphenylpropane prepared by the method of Klages and Heilmann.⁹ These two substances were found to be identical; both boiled at 152° under 18 mm., the density of both was 0.9783 ± 0.0001 at 25° and the refractive index (white light) was 1.5743 ± 0.0001 at 17°. It is evident, therefore, that the double bond in 1,1-diphenylpropylene is attacked by a *concentrated* solution of *excess* potassium in liquid ammonia.

The procedure described is essential, however, because in one experiment in which ammonia was condensed on a sample of the propylene and then potassium was slowly added until it was present in slight excess, the reaction with benzyl chloride produced a hydrocarbon melting at 122–124° which decolorized a solution of bromine in carbon tetrachloride and was suspected to be 1,1,4-triphenylbutylene-(1).

⁷ The apparatus employed in these investigations has been described previously [Wooster, *THIS JOURNAL*, **51**, 1858 (1929)].

⁸ Prepared by the method of Hell and Bauer, *Ber.*, **37**, 232 (1904).

⁹ Klages and Heilmann, *ibid.*, **37**, 1450 (1904).

Anal. Calcd. for $C_{22}H_{20}$: C, 92.96; H, 7.04. Found: C, 93.63; H, 7.96.

This might have been formed by reactions of the type expressed in Equations 8 and 9.

Similar substitution reactions have been observed by Schlenk and Bergmann, and Ziegler and Schäfer.¹⁰

Accordingly, another sample of diphenylpropylene was added to a *concentrated* solution of *excess* potassium in liquid ammonia and after stirring the mixture for one hour just enough benzyl chloride was added to discharge the red color which appeared after the excess free potassium had reacted. The product was difficult to purify, probably because it was contaminated with low melting products of the reaction between benzyl chloride and the excess of free potassium. After three crystallizations, the substance possessed a melting point of 77–79° and was then compared with the product of the action of ethyl bromide on sodium triphenylethide.

The identity of the two hydrocarbons was shown by mixed melting points. This evidence established their constitution as that of 1,2,2-triphenylbutane, but since this conclusion is to be applied to the molecular rearrangement of an organo-alkali compound one point deserves emphasis. *The possibility of molecular rearrangements involving the carbon skeleton during the preparation of these organo-alkali compounds is excluded* by the fact that upon decomposition with ammonium chloride the sodium derivative of triphenylethylene (Reactions 2 and 3) yielded 1,1,2-triphenylethane and the potassium diphenylpropide prepared from diphenylpropylene and a *concentrated* solution of potassium in liquid ammonia yielded 1,1-diphenylpropane.

The only ethyl substitution product of 1,1,2-triphenylethane which is identical with a benzyl substitution product of 1,1-diphenylpropane is 1,2,2-triphenylbutane.¹¹ Therefore, the single hydrocarbon prepared by these two methods must be 1,2,2-triphenylbutane and *the tentative structure proposed for the stable sodium triphenylethide on the basis of the benzohydril rule has been independently confirmed.*

The Constitution of the Stable Potassium Triphenylethide.—From considerations regarding the benzohydril rule it may be predicted that the reaction between 1,1,2-triphenylethane and potassium amide follows the course indicated in Equation 10

¹⁰ (a) Schlenk and Bergmann, *Ann.*, **479**, 78 (1930); (b) Ziegler and Schäfer, *ibid.*, **479**, 154 (1930).

¹¹ It can be readily seen that identical products could not be obtained in any case if more than one ethyl or benzyl group were introduced. Also, it will be shown presently that the sodium triphenylethide yields a *monobenzyl* derivative with benzyl chloride.

yielding a substance analogous in constitution to that resulting from the action of sodium on triphenylethylene. This prediction was verified by the preparation of benzyl derivatives of the two organo-alkali compounds as follows. 1,1,2-Triphenylethane was treated with potassium amide in liquid ammonia,⁷ and benzyl chloride was added to the red solution. Rapid decolorization occurred and the residue after evaporation of the ammonia was extracted with ether, the ether evaporated and the product recrystallized from alcohol. Transparent needles melting at 125–127° were obtained.

Sodium was added to a mixture of triphenylethylene and liquid ammonia until the metal was present in slight excess as shown by the blue color of the solution. Enough benzyl chloride in absolute ethereal solution was added to just discharge the color of the reaction mixture. A substance crystallizing from alcohol in needles melting at 124–126° was isolated from the ethereal extract of the reaction residue. When mixed with the product of the previous experiment, a melting point of 125–127° was found showing that the two substances are identical. The analysis also shows that only *one* benzyl radical was introduced, proving that the stable organo-alkali compounds were both *mono*-alkali triphenylethides.

Anal. Calcd. for $\text{C}_{27}\text{H}_{24}$: C, 93.10; H, 6.90; mol. wt., 348. Found: C, 92.57; 92.12; H, 6.87, 7.00; mol. wt., cryoscopic in benzene, 337.

This hydrocarbon is doubtless diphenyldibenzylmethane

but attempts to prepare it, independently, from benzophenone chloride and benzylmagnesium chloride

were unsuccessful, the results indicating that the reaction did not proceed smoothly beyond the first step

The Sodium Triphenylethide Rearrangement.—Sodium reacts with 2-chloro-1,1,1-triphenylethane to give a red-colored organo-alkali compound which is stable in liquid ammonia solution¹²

When this was treated with ammonium chloride the product recovered proved to be 1,1,2-triphenylethane, showing that a molecular rearrangement had occurred.

Attempts to prepare derivatives of the sodium compound by the use of phenyl halides or carbon dioxide proved unsuccessful, but in view of its

¹² Wooster and Mitchell, *THIS JOURNAL*, 52, 1042 (1930).

stability in liquid ammonia a tentative formula, $(\text{C}_6\text{H}_5)_2\text{CNa}-\text{CH}_2\text{C}_6\text{H}_5$, was assigned¹² on the basis of the benzohydryl rule. It is evident that this formula is identical with that of the sodium triphenylethide previously mentioned (Equations 2 and 3) and accordingly experiments were undertaken to prove the identity of the two compounds.

The product of Reaction 14 was first treated with benzyl chloride. However, five recrystallizations of the product failed to yield a satisfactorily purified substance. The material obtained melted at 115–117°; it was shown to be a hydrocarbon and its melting point was not decreased by admixture with the diphenyldibenzylmethane prepared previously. The product is probably diphenyldibenzylmethane but the evidence is obviously inconclusive.

Consequently the experiment was repeated using ethyl bromide. The apparatus and procedure was essentially similar to that formerly described.¹² The product was obtained after a single crystallization from alcohol in the form of transparent rod-like crystals melting sharply at 79–79.5° and was shown to be identical with 1,2,2-triphenylbutane by a mixed melting point, *thus confirming the tentative structure for this sodium compound* and showing that the reaction between 2-chloro-1,1,1-triphenylethane and sodium may be represented by Equations 16 and 17.

Summary

1. It has been noted that reaction between sodium or potassium amides and phenylated paraffins in liquid ammonia at its boiling point occurs only when the benzohydryl group is present in the hydrocarbon. This generalization may be conveniently termed the *benzohydryl rule*.

2. It appears probable that the alkali metal derivatives of phenylated paraffins which are stable in liquid ammonia may be prepared by the action of the alkali metal amides on the corresponding hydrocarbons and that in these reactions the alkali metal replaces hydrogen which is attached to the aliphatic carbon atom of a benzohydryl group.

3. Predictions based on the foregoing generalizations have been confirmed in the case of stable alkali triphenylethides prepared by various reactions including addition, substitution and molecular rearrangement.

THE ACTION OF HALOGENS AND OF ALKYL HALIDES UPON THE SALTS OF TRIBROMOTHIOPHENOL¹

BY W. H. HUNTER AND ARTHUR H. KOHLHASE

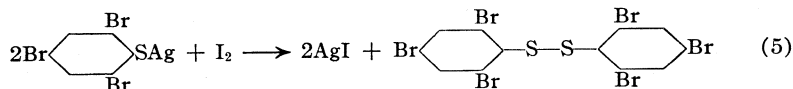

RECEIVED JANUARY 8, 1932

PUBLISHED JUNE 6, 1932

The experiments described in this paper were undertaken in an attempt to substantiate the mechanism written by Hunter and others² for the decomposition of the silver salts of 2,4,6-trihalogenophenols in the presence of a trace of halogen, or simply on heating

In the hope that it might be possible to isolate either the thio analogs of some of the intermediates postulated in the above reactions or derivatives of these analogs, 2,4,6-tribromothiophenol was prepared and a study was made of its behavior under similar conditions. The first experiment, however, showed a marked difference in the behavior of the thiophenol as compared with the oxygen analog. On treatment of the dry silver salt, $\text{C}_6\text{H}_2\text{Br}_3\text{SAg}$, with one equivalent of iodine in dry benzene, no blue or any other color other than that of the iodine, appeared in the solution. There was an almost quantitative yield of 2,4,6,2',4',6'-hexabromodiphenyl disulfide, the reaction proceeding smoothly according to the equation

An amount of reddish, oily by-product, equal to 2 or 3% of the weight of disulfide, was formed. However, analysis showed it was not the analog of the polydibromophenylene oxides obtained from the corresponding phenols, being about 20% low in bromine and 60% low in sulfur.

Repetition of the experiment with one-tenth equivalent of iodine again gave an amount of disulfide equivalent to the iodine used and no other organic product. Boiling the silver salt in dry benzene produced no decomposition, while the addition of one equivalent of iodine to the boiling mixture again gave silver iodide and the hexabromodiphenyl disulfide.

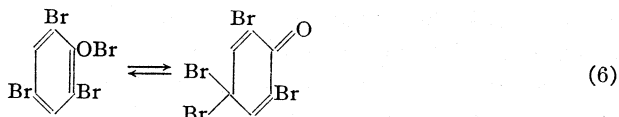

¹ The work described in this paper constituted part of a thesis submitted to the Graduate Faculty of the University of Minnesota by Arthur H. Kohlhasé, in partial fulfillment of the requirements for the degree of Doctor of Philosophy in 1924. This paper was prepared by the junior author after the death of Dr. W. H. Hunter, which occurred on August 19, 1931.—L. I. SMITH.

² For leading references, see Hunter and Seyfried, *THIS JOURNAL*, **43**, 135 (1921).

It was therefore expected that alkyl iodides would also fail to react in any other than a strictly normal fashion and such proved to be the case. Either cold or hot ethyl iodide or methyl iodide gave a smooth reaction leading to the ethyl or methyl thio ether in very nearly quantitative yield.

In the case of the trihalogenophenol silver salts, whatever the mechanism of the decomposition, the net result is the removal of a molecule of silver halide from the silver phenolate. This removal may, in fact, be brought about by heat alone. However, no such decomposition of the silver tribromothiophenolate could be produced by heating to various temperatures up to 180°. This greater stability of the silver thiophenolate toward heat might have been expected from a consideration of the relative stability of silver sulfide and oxide: the former melts at 842°; the oxide *decomposes* at 300–340°. Similar relations hold between some other pairs of compounds containing silver-sulfur and silver-oxygen unions.

Lauer³ has shown that the addition of bromine in sufficient concentration to tribromophenol or its salts results in the formation of tribromophenol bromide, in which he has demonstrated the following equilibrium to obtain

Also Zincke⁴ has prepared aryl sulfur halides (thiophenol halides) analogous to the compound at the left in reaction (6). It therefore seemed probable that in both the abnormal decomposition of the trihalogenated phenolates and the normal reactions of the tribromothiophenolates with halogens the first step is

followed by

In the absence of a large excess of halogen the products in (7) and (8) lose halogen, reaction (7) being followed by (2) and (3), and (8) being followed by (9), giving a disulfide which is stable.

Attempts to isolate the product in (8) resulted in failure, although good evidence for its formation was obtained: treatment of the sodium salt of the tribromothiophenol with a strong aqueous bromine-potassium bromide solution resulted in a fair yield of the sulfonyl bromide. The reaction is probably (8) followed by

³ Lauer, *THIS JOURNAL*, **48**, 442 (1926).

⁴ Zincke, *Ann.*, **391**, 55, 57 (1912).

The product obtained in (10) and the analogs of the product in (8) which Zincke⁴ has prepared, together with the equilibrium demonstrated to exist in (6), all support the existence of the products postulated in (7) and (8).

In equations (1) and (2) free radicals containing univalent oxygen are assumed as intermediates. Support for this assumption is found in the development of a marked color during the catalytic decompositions.²

In the course of the present work it was found that this color was instantly discharged by triphenylmethyl. Further evidence is found in the work of Goldschmidt and co-workers⁵ on free radicals containing oxygen. These substances very readily rearrange or decompose. The intermediates in (1) and (2) would be peroxides or, if dissociated, free radicals. Organic peroxides are rather rare and unstable.⁶ Some such decomposition as that shown in reactions (2) and (3) is therefore to be expected. In the case of sulfur compounds, on the contrary, the formation of disulfides appears to take place at every opportunity.

It is therefore to be expected that in the case of the thiophenols the reaction will stop with equations (8) and (9), the disulfide being perfectly stable.

Experimental Part

Preparation of 2,4,6-Tribromophenyl Ethylxanthate, $C_6H_2Br_3SCSOC_2H_5$.—The method is based on Leuckardt's general method for the preparation of thiophenols.⁷ The chief difficulty in this preparation is the slow diazotization, due to the insolubility of the tribromoaniline in acids.

Pure 2,4,6-tribromoaniline (38 g.) was dissolved in about 75 cc. of cold 95% sulfuric acid. The clear, gray-green solution was poured slowly with stirring into 800 cc. of ice water, precipitating the tribromoaniline in very finely divided condition. The mixture was neutralized, filtered and washed once with water.

The cake was digested in a 3-liter beaker with 200 cc. of concd. hydrochloric acid; 1400 cc. of cold water and 800 g. of ice were added. While maintaining the tribromoaniline in suspension with an efficient mechanical stirrer, about 15 cc. of a solution of 9.5 g. of sodium nitrite in 100 cc. of water was added and the remainder run in drop by drop over a period of about four hours, ice being added as needed to keep the temperature near 0°. After another hour the solution was fairly clear, 97–98% of the aniline having dissolved. About 10 cc. of a 20% solution of urea was then added to destroy excess nitrous acid.

A thin paste of sodium carbonate was added with stirring, as rapidly as the frothing would permit, until most of the free acid was neutralized, after which the neutralization was continued with a solution of sodium bicarbonate until the neutral point was almost, but not quite, reached. The reaction mixture should be faintly acid at the end.

The solution was then filtered through an ice-cold Buchner funnel into a flask containing ice. The filtrate, amounting now to about 2600 cc., was transferred to a broad

⁷ Leuckardt, *J. prakt. Chem.*, [2] **41**, 179–224 (1890).

vessel; about 100 g. of ice and 100 cc. of ether were added and then a solution of 19 g. of potassium ethylxanthate in 75 cc. of water was poured in and the mixture stirred thoroughly for *not more than ten seconds*. A bright yellow oil separated, the color soon changing to orange and brown with the liberation of nitrogen.

The mixture was covered and allowed to remain *undisturbed* while slowly warming to room temperature. If disturbed while warming to room temperature, the oily material emits flashes of light and may even explode. After six hours it was warmed to 70° on a steam-bath. Most of the xanthic ester separated on the bottom as a viscous brown oil. After cooling the aqueous layer was decanted from the oil and extracted once with one-fifth volume of ether and discarded. The oil left adhering to the reaction vessel was dissolved in ether and the solution combined with the ether extract of the aqueous layer.

Solution of the oil in ether left a residue consisting of minute white crystals of di-tribromophenyl dithiolcarbonate, $(C_6H_2Br_3S)_2CO$. This red residue was saved as it also saponifies readily to the thiophenolate.

The combined ether solution of the oil was shaken thoroughly with 5% sodium hydroxide to remove any phenols, then with 5% sulfuric acid and then washed with water. The ether was evaporated and the residual oil was dried in a vacuum desiccator. The yield of oil was 40.6 g. or 81%. The yield of di-tribromophenyl dithiolcarbonate was about 10%, making a total yield of about 90% of products capable of saponification to the 2,4,6-tribromothiophenol.

The ester is a heavy, viscous, red-brown oil of characteristic, not unpleasant, odor; it is miscible with ether in all proportions, insoluble in water, forms about a 1% solution with cold alcohol and about 2% in hot alcohol. The solubility in methyl alcohol is considerably greater; benzene dissolves it readily. When boiled with alcoholic potassium hydroxide, it is saponified to the thiophenolate.

Analysis of the oil showed it was not very pure, probably containing decomposition products of the potassium xanthate.

Anal. Calcd. for $C_9H_7OBr_3S_2$: Br, 55.12; S, 14.74. Found: Br, 53.3; S, 17.5, 17.8.

Saponification of Tribromophenyl Ethylxanthate to 2,4,6-Tribromothiophenol, $(C_6H_2Br_3SH)$.—In a flask provided with a reflux condenser was placed 40.6 g. of the oily ester with 1500 cc. of methyl alcohol containing 12.6 g. of potassium hydroxide. The mixture was refluxed for about thirty minutes, until a 5-cc. sample added to water gave little or no precipitate. Too long boiling with excess alkali causes decomposition. About 80% of the methanol was then distilled off and 900 cc. of a 3% aqueous solution of sodium hydroxide was added. The mixture was warmed and stirred with a little animal charcoal and filtered. The clear, pale reddish-brown filtrate was acidified with 15% acetic acid, depositing 2,4,6-tribromothiophenol as a pale-yellow to pure white, flocculent precipitate. If not white, the precipitate was filtered off, redissolved in excess alkali, treated again with a little bone black and precipitated as before.

For the preparation of the pure thiophenol, free from disulfide, the acidification and washing of the precipitate must be carried out in an atmosphere of carbon dioxide.

The 2,4,6-tribromothiophenol crystallizes from hot alcohol as shiny, pale yellow, short needles, m. p. 115.5–115.9° corrected. It has the characteristic thiophenol odor although not nearly so pronounced or disagreeable as most of the thiophenols. It dissolves in the following solvents arranged in order of decreasing solubility: carbon disulfide, chloroform, ether, benzene, acetone, glacial acetic acid (some acetylation?), methyl alcohol, ethyl alcohol. Ethyl alcohol forms about 1% solution at 20°. It dissolves very readily in caustic alkalies. In solution or when wet it oxidizes readily, forming the disulfide.

This is the first member of the series of trihalogenated thiophenols to be prepared.

Analyses by the Carius method required heating at 285–310° for five hours; derivatives were also refractory.

Anal. Calcd. for $C_6H_2Br_3SH$: Br, 69.12; S, 9.24. Found: Br, 69.15; S, 9.97, 9.80, 9.85.

Preparation of 2,4,6-Tribromophenyl Thiolacetate, $C_6H_2Br_3SCOCH_3$.—Boiling the free thiophenol in acetic anhydride for twenty minutes and pouring the solution into dilute sodium hydroxide left the acetyl derivative as a precipitate. This was filtered off, washed and recrystallized from hot alcohol. It forms long shiny, colorless needles melting at 102.1–102.7°, corrected. It is readily soluble in hot alcohol, glacial acetic acid, and benzene.

Di-2,4,6-tribromophenyl Dithiolcarbonate, $(C_6H_2Br_3S)_2CO$.—Solution of the crude, oily tribromophenyl ethylxanthate in ether (see preparation above) left this dithiolcarbonate as a mass of minute, white crystals, very slightly soluble in ether. These are saponifiable in the same way as the xanthic ester, although requiring about 50% more time. However, the saponification of this dithiolcarbonate yielded a tribromothiophenol which was more easily purified than that from the xanthate.⁸

From hot acetone the dithiolcarbonate crystallizes in long, white, silky needles, melting at 194.2–194.7° corrected. From benzene it forms shorter, thicker needles. It is very soluble in carbon bisulfide, chloroform or benzene, slightly soluble in ether and glacial acetic acid.

Anal. Calcd. for $C_{12}H_4OBr_6S_2$: Br, 66.62; S, 8.91. Found: Br, 66.65, 66.84; S, 8.50, 8.91, 8.94. Molecular weight calcd., 655.6; found, 660.

Preparation of Silver Tribromothiophenolate, $(2,4,6)C_6H_2Br_3SAg$.—Recrystallized 2,4,6-tribromothiophenol was dissolved in an excess of halogen-free sodium hydroxide solution. The excess of alkali was nearly neutralized with 20% acetic acid, completing the neutralization with 4% acid until a slight permanent precipitate was obtained. The solution was stirred with animal charcoal and filtered. To the filtrate about 3 drops of 3% silver nitrate was then added to precipitate any halogen which might be present. The whole was shaken with bone black and again filtered. From this point the preparation was carried on in the dark-room.

To the clear filtrate a slight excess of dilute silver nitrate was added, precipitating the silver tribromothiophenolate as a white, gelatinous material. The silver salt was then washed repeatedly by digesting with water at 60° and filtering. This was repeated until the filtrate gave only a slight opalescence on adding dilute hydrochloric acid. The precipitate was finally drained on a fluted filter and allowed to dry in the air for thirty hours, carefully protected from dust. It was then dried in a vacuum desiccator over calcium chloride for a week.

This formed light-gray, very hard lumps which were crushed to a fine powder. The dried salt was kept in a desiccator in a dark-room, although it does not appear to be sensitive to light when dry. Heating to 80° in water causes considerable darkening. The product was not analyzed; however, the yields obtained in the following experiments indicated it to be quite pure.

Silver Tribromothiophenolate with One Equivalent of Iodine in Benzene.—Finely pulverized silver salt (7.4764 g.) was added to 2.091 g. of iodine in 50 cc. of dry benzene. The mixture was kept in a dark room for three days, with occasional shaking. The color of the iodine gradually disappeared. The solid was then filtered off and digested three times with warm benzene. The combined benzene filtrate and extracts were

⁸ Leuckardt had obtained the analog of this dithiolcarbonate in the course of his preparation of thio-*p*-cresol, *J. prakt. Chem.*, [2] 41, 189–191 (1890).

evaporated to about 4 cc. and cooled. Pale yellow crystals were deposited. The mother liquor was decanted and evaporated to dryness. This left 0.137 g. of a greenish-red oil. The crystalline product, which, as shown below, was 2,4,6,2',4',6'-hexabromodiphenyl disulfide, weighed 5.699 g., a yield of 92%.⁹ The oily product was equivalent to 2.4% of the theoretical yield of disulfide.

That the oily product was not polydibromophenylene sulfide (the thio analog of the polydibromophenylene oxides discussed in the theoretical part) was shown by analysis.

Anal. Calcd. for $(C_6H_2Br_2S)_n$: Br, 60.10; S, 12.05. Found: Br, 50.12; S, 4.77.

The hexabromodiphenyl disulfide, a new compound, was further purified by washing with a small amount of ether and recrystallizing from benzene. It forms pale yellow rhombohedra, melting at 221.8–222.7° corrected. It is quite soluble in hot benzene or toluene, slightly soluble cold, very soluble in hot bromoform, ethylene dibromide, carbon disulfide or chloroform, fairly soluble cold. Ethyl acetate, glacial acetic acid or alcohol dissolve it only slightly.

The disulfide may be reduced to the thiophenol by treating the cold benzene solution, containing a few per cent. of alcohol, with granular sodium, keeping the mixture cool to avoid too vigorous reduction and removal of bromine from the ring. The sodium 2,4,6-tribromothiophenolate may be extracted easily with water and precipitated by acid.

The same disulfide is easily obtained by atmospheric oxidation of the ammonium or sodium salt of the thiophenol, by the action of halogen on the free thiophenol or its salts, or by the reduction of the salts of tribromobenzenesulfonic acid with phosphorus pentabromide.

Anal. (Carius at 300°) calcd. for $(C_6H_2Br_3S)_2$: Br, 69.32; S, 9.78. Found: Br, 69.49, 69.52; S, 9.78. Molecular weight calcd.: 692; found (cryoscopic, ethylene dibromide), 614.

2,4,6- $C_6H_2Br_3S$ Ag with One-Tenth Equivalent of Iodine.—This experiment was carried out in the same way as the preceding one except that the reaction was completed in about thirty minutes, excess silver salt being present. The characteristic rhombohedron crystals of hexabromodiphenyl disulfide, identified by their melting point, were obtained; there was no oily or other by-product.

$C_6H_2Br_3S$ Ag with One Equivalent of Iodine in Boiling Benzene.—The reaction was complete in thirty minutes. The product was hexabromodiphenyl disulfide and a trace of an oily by-product.

$C_6H_2Br_3S$ Ag with Cold Ethyl Iodide.—To 1.994 g. of the dry, finely pulverized silver salt was added 15–20 cc. of dry, colorless ethyl iodide and the mixture kept in a darkened place for two days, when the reaction appeared to be complete. The silver iodide was filtered off and washed with ethyl iodide. Evaporation of the ethyl iodide left a viscous, light yellow oil which was freed of solvent by warming under vacuum and then drying in a desiccator.

The calculated yield was 1.649 g.; the actual yield was 1.655 g. or 100.3%. Analysis indicated the product to be pure ethyl tribromophenyl thio ether, $C_6H_2Br_3SC_2H_5$.

Anal. Calcd. for $C_8H_7Br_3S$: Br, 63.95; S, 8.55. Found: Br, 64.39, 64.02; S, 8.88, 9.04.

$C_6H_2Br_3S$ Ag with Boiling Ethyl Iodide.—The same product was obtained as with cold ethyl iodide and in the same purity.

Anal. Calcd. for $C_8H_7Br_3S$: Br, 63.95; S, 8.55. Found: Br, 64.25; S, 8.86.

⁹ This is not the same as the "hexabromodiphenyl disulfide" prepared by Taboury, *Bull. soc. chim.*, [4] 1, 741 (1907).

C₆H₂Br₃SAg at 110° with Ethyl Iodide.—About 2.0 g. of the silver salt was heated to 110° in an oil-bath and boiling ethyl iodide added; the silver salt was heated again up to 110° and another portion of hot ethyl iodide was added. The mixture was extracted with benzene and also chloroform but the only product obtained was the same light yellow, viscous oil produced with cold or hot ethyl iodide.

C₆H₂Br₃SAg with Cold Methyl Iodide.—An excess of redistilled and dried methyl iodide was added to the finely pulverized, dry silver salt and the mixture allowed to stand in a darkened place for three days. The excess methyl iodide was filtered off and the solids washed with pure benzene. Evaporation of the combined extracts left long, colorless needles, plus about 1 or 2% of reddish oil which was not further investigated. The solid was recrystallized from hot alcohol or acetone and analyzed. It was methyl tribromophenyl thio ether (2,4,6-tribromothioanisole), C₆H₂Br₃SC₂H₅, crystallizing in long, flat, glistening, colorless needles, melting at 59.6–60.5°, very soluble in carbon bisulfide, acetone, chloroform, fairly soluble in glacial acetic acid, slightly soluble in ether or alcohol.

Anal. Calcd. for C₇H₅Br₃S: Br, 66.43; S, 8.88. Found: Br, 66.59; S, 9.12.

Effect of Heat upon C₆H₂Br₃SAg.—The dry salt heated in a test-tube immersed in an oil-bath at various temperatures from 120 to 180° for one hour suffered no detectable decomposition, as shown by extraction of the salt with chloroform, benzene, ether or carbon disulfide. The salt after these treatments was finally treated with iodine in benzene and gave the usual yield of hexabromodiphenyl disulfide in good purity.

2,4,6-C₆H₂Br₃SNa with Bromine in Aqueous Potassium Bromide. **Preparation of C₆H₂Br₃SO₂Br.**—2,4,6-Tribromothiophenol (11.5 g.) was dissolved in a small excess of sodium hydroxide, the excess alkali nearly neutralized and then the mixture diluted to 150 cc., after which it was filtered in a very thin stream, with stirring, into a solution of 25 g. of bromine and about 20 g. of potassium bromide in 45 cc. of water. A reddish oil separated and solidified in a few minutes. The red-brown solid was washed with water several times by decantation and dried in the air.

The dried solid was extracted with ether several times. The insoluble portion was recrystallized from benzene and shown to be the 2,4,6,2',4',6'-hexabromodiphenyl disulfide obtained in the preceding experiments; yield about 45%.

The ether extracts were evaporated to dryness, the residues redissolved in the minimum amount of cold ether and filtered from the small amount of disulfide. From three crops of crystals was isolated 7.55 g. or nearly 50% yield of the sulfonyl bromide,¹⁰ C₆H₂Br₃SO₂Br. Recrystallized from ether, m. p. 74.5–75.7°. It is exceedingly soluble in ether, benzene or chloroform. It forms the ethyl ester on boiling with alcohol. It is rapidly hydrolyzed to the sulfonate by warm alkali; it reacts violently with phosphorus tribromide, being almost instantly reduced to hexabromodiphenyl disulfide. Boiling with dilute acid for one hour hydrolyzed the product to hydrobromic acid, sulfuric acid and 1,3,5-tribromobenzene.

Anal. Calcd. for C₆H₂Br₃SO₂Br: Br, 69.85; S, 7.00. Found: Br, 69.70, 70.10; S, 6.86, 6.83.

2,4,6-C₆H₂Br₃SNa with Liquid Bromine.—Treatment of about a gram of the sodium salt with liquid bromine gave rise to a rather violent reaction yielding a sticky red mass. This was extracted with chloroform but nothing was identified in the chloroform extract except the disulfide.

C₆H₂Br₃SH with Bromine in Benzene.—To 20 cc. of dry benzene containing 1.2

¹⁰ Michaelis and Ruhl prepared C₆H₅SO₂Cl by analogous methods, *Ber.*, **23**, 475 (1890). This sulfonyl bromide is new although Reinke prepared the analogous sulfonyl chloride, C₆H₂Br₃SO₂Cl, *Ann.*, **186**, 277 (1877).

g. of the free thiophenol was added 0.3 cc. of bromine in 10 cc. of benzene and the mixture then allowed to stand for forty-eight hours. Evaporation of the benzene left yellowish granules and a little red oil. On exposure to the air the oil largely solidified. Although the product had first shown definite indications of the presence of considerable amounts of some other products, the procedure resulted in the ultimate identification of about 97% of the product as hexabromodiphenyl disulfide.

Product Formed by Bromine with Thiophenol in Glacial Acetic Acid.—Thiophenol (5.7 g.) was dissolved in 50 cc. of glacial acetic acid. To this was added 11.4 cc. of bromine and it was then allowed to stand for several hours, part of the time in sunlight. The solution was then cooled in an ice-bath, the solid filtered off, washed five times with cold acetic acid and then five times with water. After drying, the solid was recrystallized from alcohol; m. p. 91–93°. The melting point, crystalline form and analysis correspond to the 4,4'-dibromodiphenyl disulfide of Hübner and Alsberg.¹¹

Anal. Calcd. for $(C_6H_4BrS)_2$: Br, 42.50. Found: Br, 42.87.

Summary

1. The salts of 2,4,6-tribromothiophenol, as well as the free thiophenol, react in a perfectly normal manner with halogens and alkyl halides to give the disulfide or thio ethers in nearly quantitative yield. The products contain nothing analogous to the amorphous polydihalogenophenylene oxides obtained from the trihalogenated phenols and phenolates.
2. The first stage in the reaction of both phenolates and thiophenolates is probably the formation of metal halide plus an unstable product containing halogen directly attached to oxygen or sulfur.
3. The first known member of the series of trihalogenated thiophenols has been prepared. From this eight derivatives have been prepared and characterized.

KETENES FROM ACYLPHTHALIMIDES AND OTHER SUBSTITUTED AMIDES

BY CHARLES D. HURD AND MALCOLM F. DULL

RECEIVED JANUARY 11, 1932

PUBLISHED JUNE 6, 1932

Acetylcarbazole is known¹ to regenerate carbazole on heating above its melting point. Propionylcarbazole,² *n*-nonoylcarbazole³ and palmitylcarbazole show a similar instability on fusion. Although carbazole was identified in all cases, no attention was directed to the fate of the acyl radicals.

If the elements of carbazole, $(C_6H_4)_2NH$, are subtracted from those of acetylcarbazole, $(C_6H_4)_2NCOCH_3$, the elements of ketene remain. Whereas

² Oddo, *Mem. accad. Lincei*, [v] **14**, 510 (1923).

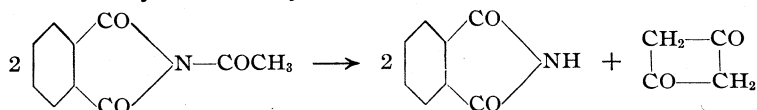

³ Copisarow, *J. Chem. Soc.*, **113**, 816 (1918).

ketene was not found, its dimer was formed when dry acetylcarbazole was refluxed. Ketene dimer is considered⁴ to be cyclobutanedione, $\begin{array}{c} \text{CH}_2-\text{CO} \\ | \quad | \\ \text{CO}-\text{CH}_2 \end{array}$.

The ketene detachment from this acetyl derivative of carbazole was due, in part at least, to the weakness of carbazole as a base, since the acetyl derivative of ammonia, namely, acetamide, gave no incontrovertible evidence⁵ of ketene as a product of pyrolysis. Therefore, other acyl derivatives of neutral or acidic trivalent nitrogen compounds were also tested for similar ketene production.

Acetyldiphenylamine, diacetamide and acetylphthalimide were taken. The first of these, despite its structural similarity to acetylcarbazole, was unchanged after 24 hours of refluxing (290°) or after passage through tubes at 500 or 600°. Diacetamide was less stable, giving good yields of acetic acid and acetonitrile⁶ as it was passed rapidly through a tube at 635°. No evidence was obtained for ketene or its dimer: $(\text{CH}_3\text{CO})_2\text{NH} \rightarrow \text{CH}_3\text{CN} + \text{CH}_3\text{CO}_2\text{H}$.

Acetylphthalimide, previously described by Aschan⁷ to be an active acetylating agent, was found to decompose at a refluxing temperature into phthalimide and to give remarkably good yields of ketene dimer, yields which were considerably better than from acetylcarbazole. This constitutes a very satisfactory new method for synthesizing ketene dimer

Although acetylphthalimide resembled acetylcarbazole in giving rise to ketene dimer, the former (when not especially dried) simultaneously produced acetic acid whereas the latter gave acetone. The acetic acid points to ketene as its precursor, whereas the acetone comes from the cyclobutanedione. Acetylphthalimide decomposed much more readily than acetylcarbazole, a fact which may explain why ketene exists for a moment in the first case but not in the second.

Ketenes from Other Acylphthalimides.—*n*-Propionyl-, *n*-butyryl- and *n*-caproyl-phthalimide were studied in the hope of obtaining, respectively, methylketene, ethylketene and *n*-butylketene or their dimers, but instead only decomposition products of these substances were isolated. *n*-Butyrylphthalimide, which was found to decompose spontaneously on keeping for a few hours, pyrolyzed into phthalimide, butyric anhydride,

⁵ Hurd, Dull and Martin, *THIS JOURNAL*, **54**, 1974 (1932).

⁶ The same products in a sealed tube experiment at 250° were reported by Hentschel, *Ber.*, **23**, 2396 (1890).

⁷ Aschan, *ibid.*, **19**, 1398 (1886).

di-*n*-propyl ketone and carbon dioxide. The butyric anhydride is traceable through ethylketene and water whereas dipropylketone and carbon dioxide are traceable through the dimer of ethylketene and water. The source of such a quantity of water is not apparent for no more than traces should have been present. With acetylphthalimide which was dried in the same way as the butyrylphthalimide (air dried), some water was also present as evidenced by the production of acetic anhydride and acetone but even so, considerable ketene dimer was isolated as such.

Propionylphthalimide, which was purified and dried in such a way that water should have been completely excluded prior to its pyrolysis, behaved like the butyrylphthalimide. Propionic anhydride, diethyl ketone and carbon dioxide were formed between 220–320°. These products point to methylketene and its dimer as intermediates but neither could be isolated as such. Some water was even identified as such in the later stages of the pyrolysis. Its presence has no adequate explanation. Similarly, propionylcarbazole yielded distillation products which were analogous to those obtained from propionylphthalimide, namely, diethyl ketone and propionic anhydride.

Caproylphthalimide, on pyrolysis, gave rise to caproic acid and to an indifferent product which was a trimer of *n*-butylketene. Similar trimers were obtained by Wedekind⁸ by the action of tertiary bases on acid chlorides.

***iso*-Butyrylphthalimide and Dimethylketene.**—When *iso*-butyrylphthalimide, $\text{C}_6\text{H}_4 \begin{array}{c} \diagup \text{CO} \\ \diagdown \text{CO} \end{array} \text{NCOCH}(\text{CH}_3)_2$, was heated to 225°, free dimethylketene was formed in substantial amounts. Even in its present state this method is considerably simpler than the existing method⁹ for the synthesis of dimethylketene and, undoubtedly, the yield from the new method will be increased with further study.

Diphenylacetylphthalimide, $\text{C}_6\text{H}_4 \begin{array}{c} \diagup \text{CO} \\ \diagdown \text{CO} \end{array} \text{NCOCH}(\text{C}_6\text{H}_5)_2$, underwent pyrolysis into diphenylketene and phthalimide.

Comparison of the Methods with Existing Ones

Ketene Dimer.—At present this is best prepared by the slow polymerization of liquid ketene. Although gaseous ketene may be prepared easily from acetone, its liquefaction requires either solid carbon dioxide or liquid air temperatures, preferably the latter. Nothing of this nature is required in the preparation of ketene dimer from acetylphthalimide (or acetylcarbazole), for it is a direct product. Since acetylphthalimide may be prepared merely by refluxing phthalimide with acetic anhydride, the simplicity of the method is striking.

⁸ Wedekind, *Ann.*, **323**, 246 (1902).

⁹ Staudinger, *Ber.*, **39**, 968 (1908).

Dimethylketene.—To make an ether solution of dimethylketene, Staudinger¹⁰ converted *iso*-butyric acid into α -bromo-*iso*-butyryl bromide, which, in ether solution, was dehalogenated with zinc. Ether and dimethylketene are inseparable by distillation. For pure dimethylketene, it was necessary to synthesize dimethylmalonic anhydride and to subject it to pyrolysis. It is obvious that the present method is simpler than either of these for *iso*-butyrylphthalimide is readily synthesized from *iso*-butyryl chloride and potassium phthalimide. From it, dimethylketene may be prepared without contamination by a solvent.

Diphenylketene.—The most satisfactory method for this preparation is the pyrolysis of azibenzil.¹¹ However, azibenzil is difficult to prepare, involving as it does the preparation of benzil hydrazone and dehydrogenation of the latter with mercuric oxide. In contrast, diphenylacetylphthalimide may be synthesized rapidly from diphenylacetyl chloride and potassium phthalimide. This compensates for the lower yield of diphenylketene which is obtained. It is believed that considerably better yields of diphenylketene and of dimethylketene may be developed with further study of the acylphthalimides.

Experimental Part

Preparation of Materials.—Acetyldiphenylamine¹² and acetylphthalimide¹³ were prepared, respectively, in 88 and in 72–78% yields by literature methods. The former, crystallized from xylene and from alcohol, melted at 99°. Acetylphthalimide, after recrystallization from a hot benzene–petroleum ether solution, melted at 135–139° instead of 132–135° (Aschan's value).

Acetylcarbazole.—Graebe and Glaser¹⁴ prepared this by heating acetic anhydride and carbazole in a sealed tube. With the following directions, developed in part by Mr. R. W. McNamee, the sealed tube was avoided.

Carbazole (200 g.) was refluxed with an excess of acetic anhydride (600 cc.) for twenty hours. This hot mixture was poured, with stirring, into one liter of water at 75°. The oily layer was separated, washed with sodium carbonate solution, with cold water till the mass solidified, and then crystallized from alcohol (500 cc. of alcohol for each 100 g. of acetylcarbazole). Decolorizing charcoal was used. The purified crystals were dried in air. They weighed 208 g. (83.3% yield) and melted at 69°.

Propionylcarbazole was also synthesized by refluxing for twenty-four hours 100 g. of carbazole and 300 cc. of propionic anhydride. The purification procedure was the same as with acetylcarbazole. An eighty gram (60%) yield of pure propionylcarbazole was isolated, m. p. 89.5°. Previously, Oddo¹⁵ synthesized this compound from propionyl chloride and magnesium carbazole.

¹⁵ Oddo, *Mem. accad. Lincei*, [v] **14**, 510 (1923).

Diacetamide.—Titherley's procedure¹⁶ was modified. He suspended two moles of acetamide in benzene and treated it with one mole of acetyl chloride. We obtained better results by melting the acetamide (141 g.) and adding it slowly to 1.6 moles of a benzene (200–250 cc.) solution of acetyl chloride (100 g.) which was shaken constantly. Titherley's purification procedure was used. Yields were 35–45 g. (30–37%); m. p. 78–79°.

Propionylphthalimide.—A mixture of 100 g. of phthalimide and 250 cc. of propionic anhydride was refluxed for twelve hours. Crystals formed on cooling which were filtered off, dissolved in hot benzene and caused to crystallize by the admixture of petroleum ether. The fine yellow needles which were obtained in 72% yield (90 g.) melted at 143–144°.

Anal. (Kjeldahl) Subs., 0.2973, 0.3104: cc. of 0.2138 *N* acid, 6.90, 7.01. Calcd. for $C_{11}H_9O_3N$: N, 6.89. Found: N, 6.94, 6.76.

***n*-Butyrylphthalimide** was prepared by the interaction of 50 g. of potassium phthalimide and 45 g. of *n*-butyryl chloride in 450 cc. of dry benzene. Only at the start was warming required. When complete, it was filtered and worked up in a manner identical to that described below for caproylphthalimide. The yield of dry crystals was 23 g. or 39%. Even when freshly crystallized from alcohol or from ethyl acetate, the compound had a pronounced odor of butyric acid. The crystals softened at 70–72° but did not melt completely until the melting point of phthalimide was reached. On standing overnight in a corked bottle the crystals changed into an amorphous powder and acquired a pronounced acid odor.

Caproylphthalimide.—To a suspension of 25 g. of potassium phthalimide in 250 cc. of dry benzene there was added 25 g. of caproyl chloride. The solution was warmed to start the reaction, which completed itself in ten minutes. The potassium chloride was filtered off and the filtrate evaporated at room temperature. The dry residue was extracted for five minutes with 250 cc. of alcohol¹⁷ at 30°. The solution was filtered rapidly by suction and the filtrate placed in a refrigerator until crystallization of the caproylphthalimide was complete, but not sufficiently long to permit separation of unchanged phthalimide. The large, lustrous, plate-like crystals were collected on a filter and air-dried; m. p. 78.5–79.5°; yield, 20 g. or 60%.

Anal. (Kjeldahl) Subs. 0.3177, 0.3097: cc. of 0.2138 *N* acid, 6.01, 6.00. Calcd. for $C_{14}H_{15}O_3N$: N, 5.72. Found: N, 5.77, 5.76.

Iso-butyrylphthalimide was prepared by the general procedure used for caproylphthalimide, taking 43 g. of potassium phthalimide, 50 g. of *iso*-butyryl chloride and 450 cc. of dry benzene. The product separated from alcohol in plate-like crystals; m. p. 96–98°; yield, 23 g. (45.7%).

Anal. (Kjeldahl) Subs. 0.3215, 0.3124: cc. of 0.2138 *N* acid, 6.96, 6.87. Calcd. for $C_{12}H_{11}O_3N$: N, 6.45. Found: N, 6.48, 6.58.

Diphenylacetylphthalimide.—The calculated quantity of diphenylacetyl chloride (23 g.) was refluxed vigorously for five minutes with a suspension of 18.5 g. of potassium phthalimide in 350 cc. of dry benzene. After filtering and evaporating to the consistency of a thin paste, petroleum ether was added and the whole chilled in a refrigerator for four hours. The crude crystals (13–15 g.) of diphenylacetylphthalimide thus pro-

¹⁶ Titherley, *J. Chem. Soc.*, **79**, 411 (1901).

¹⁷ In some cases alcohol cannot be used to extract or to crystallize the acylphthalimides because it is a reaction solvent. Then ethyl acetate may be used, but usually the compounds are too soluble in it for convenience. If ethyl acetate is used, it should be free from alcohol.

duced were contaminated with phthalimide. Purification was effected by crystallization from absolute ethyl acetate. Ordinary ethyl acetate gave trouble, probably due to its alcohol content. Diphenylacetylphthalimide melted at 170–171°. It was rather insoluble in cold alcohol; with warm alcohol it gave phthalimide and ethyl diphenylacetate.

Anal. Subs. 0.3111, 0.3009: cc. of 0.2138 *N* acid; 4.32, 4.36. Calcd. for $C_{22}H_{15}O_3N$: N, 4.14. Found: N, 4.16, 4.19.

Pyrolysis of Diacetamide.—Using the flow method previously described for acetamide,¹⁸ diacetamide vapors were passed through a Pyrex tube (1.6 cm.) at 630–640°. An empty, ice-cold flask was placed between the furnace outlet and the aniline flask. Ketene was not formed since no acetanilide was found. With a 2.2 seconds contact time, 50 g. of diacetamide was passed during ten minutes. Only 1 g. was recovered; 27–27.5 g. of acetic acid and 18–19 g. of acetonitrile were formed. At 510° and 6.2 sec., at least one-third of the diacetamide remained unchanged.

Experiments with Acylphthalimides and Acylcarbazoles

General Procedure.—Quantities ranging from 15 to 75 g. of these amides were heated to gentle refluxing in a 125- or 250-cc. distilling flask, the side arm of which delivered into an empty 25-cc. distilling flask kept at 0°. The uncondensed vapors were conducted from this flask into a flask which contained 10 cc. of aniline.

Acetyl Derivatives

Acetylphthalimide started to decompose at 240° and at 284° the reaction became so vigorous that heating was stopped. Then heating was resumed up to 325° for one to four hours. In several runs, using 50 g., about 10 g. of distillate and only about 0.5 g. of acetanilide were identified. Consistently the distillate contained 3.5–4.5 g. (30–38% yield) of ketene dimer, b. p. 125–127°, and 5–5.5 g. of lower boiling material, three-fourths of which was acetic acid. The ketene dimer was identified by reaction with aniline, producing acetoacetanilide. The latter melted at 84°.

To remove traces of water (as evidenced by acetic acid formation) from the acetylphthalimide, 800 cc. of toluene was added to 150 g. of the material and 200 cc. of the toluene distilled from it at 20 mm. One liter of petroleum ether was poured into the residual solution and the precipitated acetylphthalimide filtered by suction in an atmosphere of dry air. Heating 70 g. of this material for an hour or 50 g. for five hours gave, respectively, 9.2 and 8.7 g. of pure ketene dimer. These values represent 53 and 75% of the theoretical. Only traces of acetic acid were produced.

Acetylcarbazole.—This material started to decompose at 200°, the temperature gradually increasing to 356°. Heating 75 g. for six to seven hours gave 3–3.1 g. of ketene dimer (b. p. 125–127°, and yielding acetoacetanilide with aniline) and 1–1.2 g. of acetone (b. p. 56–57°, and yielding benzylideneacetone, m. p. 111–112°, with benzaldehyde). There was no acetanilide and little or no acetic acid. The yield of ketene dimer was 20%.

When 75 g. of acetylcarbazole was heated at 110° and 15 mm. for three hours to dry it, subsequent pyrolysis for three hours gave rise to a 5.6 g. (37%) yield of ketene dimer and only 0.1 g. of acetone.

Acetyldiphenylamine.—When 75 g. of this amide was refluxed for twenty-four hours, only a few drops of distillate were collected. The amide changed in part to a black tar, but much was recoverable. No ketene or ketene dimer appeared. Following this, 50 g. was passed during twelve to fifteen minutes through a Pyrex combustion

¹⁸ Hurd, Dull and Martin, *THIS JOURNAL*, **54**, 1974 (1932).

tube at 500 or at 600° with a recovery of 45–46 g. of the original amide. Apparently no ketene was formed nor was ammonia evolved. Some charring was observed.

Propionyl Derivatives

Propionylphthalimide.—This compound started to decompose at 220°, the temperature gradually being increased to 322°. The heating was maintained for three hours, but most of it was completed in thirty minutes. Besides phthalimide, the reaction products were diethyl ketone and propionic anhydride, equal weights of the last two substances being formed. After one and one-half hours, droplets of water appeared in the side arm of the condensing flask. This water was characterized by its melting point and by its ability to dissolve anhydrous copper sulfate to a blue solution. In a series of pyrolyses using 15-g. portions, there was formed 1.2–1.5 g. of diethyl ketone (38–47% yield) and 1.2–1.4 g. (25–29%) of propionic anhydride. The ketone was collected by distillation at 101–104° and was identified as 2,6-diphenyl-3,5-dimethyl-tetrahydro- γ -pyrone,¹⁹ m. p. 106°, its reaction product with benzaldehyde and alcoholic potassium hydroxide. The distillate collected between 160–170° was considered to be propionic anhydride since it was neutral to litmus but dissolved slowly in water to give an acid reaction. It gave propionanilide by reaction with aniline and it analyzed as an acid anhydride.

Analysis of Propionic Anhydride.—Whitford²⁰ showed that acetic anhydride reacted quantitatively with anhydrous oxalic acid and dry pyridine to evolve carbon monoxide and carbon dioxide. We found that the method was also adaptable for the quantitative determination of propionic anhydride. With pure propionic anhydride a 100% value was established

Using this method of analysis on the total distillate (8.3 g.) from a 50-g. sample, 21% of propionic anhydride or 1.24 g. was established whereas in the run under consideration, 2.0 g. of distillate was found between 160–178°.

Manner of Drying.—In these experiments the propionylphthalimide was dried in several ways without materially changing the result. Thus, 50 cc. of benzene or 50 cc. of toluene or 50 cc. of xylene was distilled from the 15-g. sample using diminished pressures so that distillation temperatures, respectively, of 40, 75 and 100° were attained. All water was undoubtedly removed by this method, but, as stated above, water was formed during the pyrolysis. Hence, neither methylketene or its polymer were isolated as such. In other similar experiments, propionylphthalimide was dried by heating it in an oven for four hours at 105° before use.

Gas Formed.—In one experiment on a 50-g. sample, 12.3 liters (standard conditions) of gas was collected. Analysis showed 81.9% of CO₂, 6.7% CO, the remainder being nitrogen. This represents 2.0 g. of carbon dioxide, which is equivalent to 3.9 g. of diethyl ketone; actually 2.9 g. of distillate was collected between 101–104°.

Propionylcarbazole.—Decomposition of a 40-g. sample started at 240° and the temperature was increased to 361°. After four hours, 5.1 g. of liquid had distilled. Carbon dioxide was evolved during the pyrolysis. The distillate was very similar to the one from propionylphthalimide and consisted of diethyl ketone and propionic anhydride.

***n*-Butyrylphthalimide.**—Fifteen grams of air-dried material was heated in the usual way. It yielded 3.6 g. of distillate, which contained 1.7 g. of dipropyl ketone

¹⁹ Vorländer and Hobohm, *Ber.*, **29**, 1352 (1896).

²⁰ Whitford, *THIS JOURNAL*, **47**, 2939 (1925).

(b. p. 143–147°), 0.2 g. of butyric acid (b. p. 147–188°), and 1.4 g. of butyric anhydride (b. p. 188–195°).

Caproylphthalimide.—The following is a typical run out of several which were performed. Caproylphthalimide was recrystallized from ethyl acetate and dried in a vacuum desiccator over sulfuric acid for four days or longer. Pyrolysis of 25 g. of it (140–230°) during twenty minutes yielded about half a liter of carbon dioxide. The distillate contained phthalimide and caproic acid, separation of these two being effected by solution of both in petroleum ether and precipitation of phthalimide from the solution at 0°. Distillation of the petroleum ether filtrate yielded 1.8 g. of caproic acid at 200–210°. Its potassium salt was obtained readily by the action of potassium hydroxide solution. Evaporation of the water, extraction of the potassium caproate in hot alcohol, cooling, filtering and washing with ether gave the salt in a pure state.

Anal. Calcd. for $C_8H_{11}CO_2K$: K, 25.03. Found: K, 25.06.

The non-volatile product in the original reaction flask was extracted while still molten with 100 cc. of petroleum ether. Whatever crystals formed on cooling this solution by ice were removed, after which the hydrocarbon was distilled off, leaving 8–9 g. of an oil. When distilled, besides a tarry residue, there was about 3 g. of an oil which was collected at 213–216° (5 mm.). Its molecular weight and analysis designated it to be *n*-butylketene trimer.

Anal. Subs. 0.2247: CO_2 , 0.6045; H_2O , 0.2058. Calcd. for $(C_4H_9CH=C=O)_3$: C, 73.41; H, 10.28. Found: C, 73.34; H, 10.24.

Mol. wt. Subs. 0.2201, 0.3154; benzene, 21.975 g.; f. p. lowering, 0.159, 0.223°. Calcd. for $C_{12}H_{20}O_3$: mol. wt., 294. Found: mol. wt., 322, 329.

This polymer was neutral, insoluble in dilute acids and soluble in concentrated sulfuric acid. It did not react with aniline or with bromine. Reaction evidently was possible with alkali, for on long standing with dilute sodium hydroxide solution the oil dissolved.

It was established that only 6 g. out of 50 of caproylphthalimide was recoverable after twenty minutes of heating at 145–150°.

Iso-butyrylphthalimide.—Thirty grams of the pure *iso*-butyrylphthalimide, which had been recrystallized from ethyl acetate and dried *in vacuo* over sulfuric acid for several days, was heated for thirty minutes in an atmosphere of nitrogen. Decomposition began at 225°. The products of the reaction were passed into a flask which contained ice-cold absolute ether and the unabsorbed gases conducted into aniline. A white solid which remained in the side arm of the reaction flask was scraped into the ether at the end of the heating.

This ether solution was bright yellow in color due to dimethylketene.²¹ In one experiment this color did not disappear completely on standing for three days but in another it disappeared in twenty-four hours due to polymerization to the colorless dimer. Evaporation of the ether left a residue of 2.5 g. of dimethylketene dimer (tetramethylcyclobutanedione) which possessed the characteristic camphor-like odor and which melted at 111–114°. From the aniline, 0.9 g. of *iso*-butyranilide was isolated. The dimethylketene which is thus indicated from *iso*-butyrylphthalimide is 30% of the theoretical.

Diphenylacetylphthalimide.—After remaining for two weeks in a vacuum desiccator over sulfuric acid, 20 g. of diphenylacetylphthalimide was pyrolyzed in a nitrogen atmosphere for twenty minutes. Decomposition was between 300–325°. There was

²¹ For the isolation of pure dimethylketene, the ether trap would be replaced by an empty receiver kept at a sufficiently low temperature for liquefaction, a temperature of –78° favoring non-polymerization.

no distillate. The material in the flask was extracted thrice with 50-cc. portions of hot petroleum ether. About 9 g. of phthalimide resisted solution. After removal of the petroleum ether, 10 g. of a dark red oil remained from which 1.2 g. of diphenylketene distilled at 146–150° (14 mm.) and 6 g. between 150–240°. The latter was a red oil which slowly hardened to a glass. This was shown to contain phthalimide and a dimer of diphenyl ketene.

The diphenylketene was characterized by its vigorous reaction with aniline, giving diphenylacetanilide, m. p. 180°, by its yellow color and sharp, aromatic odor, and by its change into a colorless peroxide on standing in the air.

The 6 g. of higher boiling distillate was worked up by dissolving it in 25 cc. of hot alcohol. Phthalimide, m. p. 225–226°, separated on cooling to room temperature. It was filtered off and the filtrate cooled to 0°. A dark red, semi-crystalline mass separated which was filtered by suction and pressed out on a clay plate. Under these conditions, it gradually became almost clear white. When dry, the melting point was 188–190°, which is the melting point given by Staudinger²² for a dimer of diphenylketene. About 1.7 g. of this substance was obtained.

Repetition of the experiment gave 0.9 g. of diphenylketene and 2.1 g. of the dimer.

Summary

Both acetylphthalimide and N-acetylcarbazole undergo decomposition at refluxing temperatures into cyclobutanedione, the dimer of ketene. *Iso*-butyrylphthalimide and diphenylacetylphthalimide undergo a similar pyrolysis into dimethylketene and diphenylketene. These reactions are suitable for synthetic work.

Propionylphthalimide, propionylcarbazole, *n*-butyrylphthalimide, and caproylphthalimide gave reaction products which pointed to the ketenes as intermediate products but these monoalkylketenes could not be isolated as such. Acetyldiphenylamine and diacetamide were also investigated. All of these acylphthalimides except acetylphthalimide are new compounds. The trimer of butylketene was identified as a product of the pyrolysis of caproylphthalimide.

A NEW REDUCTION OF ARYL SULFONIC ACID SALTS AND DERIVATIVES. PHOSPHORUS PENTABROMIDE AS A REDUCING AGENT¹

BY ARTHUR H. KOHLHASE²

RECEIVED JANUARY 15, 1932

PUBLISHED JUNE 6, 1932

By the action of a strong aqueous solution of bromine and potassium bromide upon the sodium salt of 2,4,6-tribromothiophenol,³ a new compound, tribromobenzenesulfonyl bromide, was obtained. We sought, for purposes of identification, to prepare this compound by heating potassium 2,4,6-tribromobenzenesulfonate with phosphorus pentabromide. However, the only product obtained was 2,4,6,2',4',6'-hexabromodiphenyl disulfide. This efficient reduction by pentavalent phosphorus was very puzzling, and led to the investigation described in this paper.

The following equations are now believed to represent the course of the reaction

The relative speeds of reactions (1) and (3) should be dependent on the nature of the aryl radical, R, and it was found that by varying R the reaction could be made to give almost exclusively the sulfonyl bromide, or varying proportions of the sulfonyl bromide and disulfide, or only the disulfide.

This mechanism would lead one to expect that the intermediate sulfonyl bromide would be reduced by phosphorus pentabromide and, more readily, by phosphorus tribromide. Furthermore, in those cases where no RSO_2Br could be found in the final reaction product it would be expected that the sulfonyl bromide would be rapidly reduced by phosphorus tribromide. As shown in Table I, the results fully confirmed this theory.

That *phosphorus pentabromide is essential for the first step* in the production of disulfides from sulfonic acid salts as indicated in reaction (1) was shown by heating some of the sodium sulfonate with phosphorus tribromide; neither the disulfide nor the sulfonyl bromide was formed in detectable amounts.

It is well known that phosphorus pentabromide dissociates very readily⁴

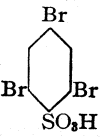

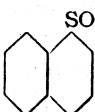

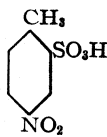

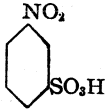

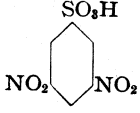

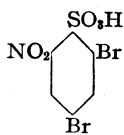

¹ This article is based upon Part I of a thesis presented by Arthur H. Kohlhasé to the Faculty of the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of Doctor of Philosophy, June, 1924. The work was carried out under the direction of the late Professor W. H. Hunter.—L. I. SMITH.

^a The letters A, B, C, etc., used in these columns stand for the aryl radical of the parent sulfonic acids shown in the first column.

^b This was a comparatively crude phosphorus pentabromide prepared in carbon bisulfide; all the remaining experiments were carried out with pure phosphorus bromides or chlorides prepared in carbon tetrachloride.

^c The yield depended to a large extent upon keeping the products thoroughly mixed and also on the rate of heating.

^d Reaction evidently occurred but the products could not be identified.

^e A new compound.

according to reaction (2) and that the pentachloride behaves similarly at somewhat higher temperatures. However, when sodium 2,4,6-tribromobenzenesulfonate was treated with phosphorus pentachloride, it gave a 97% yield of the sulfonyl chloride and no detectable quantity of hexabromodiphenyl disulfide.⁵

Even when the sulfonyl bromide was prepared and then heated with phosphorus trichloride, there was no reduction, in marked contrast to the action of the tribromide. As illustrated in Table I by the sulfonyl bromides and chlorides of tribromobenzene and naphthalene, the substitution of chlorine for bromine in the sulfonyl halide also results in an increased resistance to reduction by phosphorus tribromide.

Reactions (1) and (3) may be combined

By subtracting these two equations, taking account of the heats of formation of each substance,⁶ we obtain the interesting result that reaction (5) is the more exothermic, in the case of *all* sulfonic acids, by 34,000 cal. Yet reaction (5) does not take place at all while reaction (4) proceeds with varying ease, depending on the nature of R. Very similar results are obtained in the case of reaction (3) and its analog.

It is significant that, although the oxidations of the tribromide and trichloride of phosphorus occur with nearly the same heats of reaction, there is other evidence that the tribromide is oxidized far more readily.⁷

One disulfoxide (phenyl-3,5-dinitrobenzene thiosulfonate) was treated with phosphorus tribromide, and reacted with surprising ease to give 3,5-dinitrothiophenol. The 3,5-dinitrodiphenyl disulfide would have been expected but it has been shown⁸ that such unsymmetrical disulfides tend to rearrange to the symmetrical ones.

The production of 3,5-dinitrothiophenol instead of the corresponding disulfide was observed also in the case of α -naphthalenesulfonyl bromide. The final stage of the reduction is probably due to phosphorous acid. Some of these sulfonates have previously been treated with phosphorus pentabromide but the reductions here described were apparently not observed.⁹

This new method is very convenient for the preparation of disulfides which would otherwise be difficult to synthesize, even by the method of

Leuckardt.¹⁰ These disulfides may in turn be converted to the corresponding thiophenols by reduction or by treatment with potassium sulfide.¹¹

Experimental Part

I. Preparation of Sodium 2,4,6-Tribromobenzenesulfonate, $\text{C}_6\text{H}_2\text{Br}_3\text{SO}_3\text{Na} \cdot 1.5\text{H}_2\text{O}$.—Redistilled 1,3,5-tribromobenzene (one degree boiling range) was sulfonated by the method of Bössmann.¹²

The sodium tribromobenzenesulfonate obtained was recrystallized from the minimum amount of boiling water. It formed pure white flakes, readily soluble in hot water, only slightly soluble in cold. The sodium salt has not been previously described.

Anal. Calcd. for $\text{C}_6\text{H}_2\text{Br}_3\text{SO}_3\text{Na} \cdot 1.5\text{H}_2\text{O}$: H_2O , 6.08; SO_3 , 19.20; Br, 57.52. Found: H_2O , 6.09; SO_3 , 18.14; Br, 57.25, 57.96.

II. Reaction between Sodium 2,4,6-Tribromobenzenesulfonate and Phosphorus Pentabromide.—Two grams of the pure, anhydrous sodium salt was intimately mixed with 6.4 g. of phosphorus pentabromide and gently heated to 80–90° above a small flame with repeated remixing until the reaction started and rapidly spread throughout the mass; then about five minutes longer.

The reaction product was extracted twice with 20 cc. of dry, boiling benzene; these extracts were evaporated to a small volume and cooled. The yield of crystals was increased by diluting the oily mixture of benzene and phosphorus oxybromide with ether. The solvent was poured off and the crystals were washed with ether and then recrystallized from boiling benzene. Pale yellow rhombohedra separated, identical in form, color and solubility with 2,4,6,2',4',6-hexabromodiphenyl disulfide prepared by other methods;³ yield, 13–38%; m. p. 218–218.5°, mixed m. p. 218–218.5°; 40–60% of the original sodium salt was recovered. An 86.5% yield of the disulfide was obtained when crude phosphorus pentabromide was used.

Evaporation of the ether washings left a sirupy oil which proved to be phosphorus oxybromide. No tribromobenzenesulfonyl bromide could be found.

III. Reaction between Sodium 2,4,6-Tribromobenzenesulfonate and Phosphorus Tribromide.—Two grams of the anhydrous sodium salt, heated for ten minutes at 90° with 4.0 g. of phosphorus tribromide gave no disulfide, sulfonyl bromide or thiophenol. The mixture left after ether extraction was completely soluble in water. After neutralization and recrystallization 92% of the original sodium salt was recovered.

IV. Reaction between 2,4,6-Tribromobenzenesulfonyl Bromide and Phosphorus Tribromide.—Phosphorus tribromide was added in excess to 1.0 g. of the sulfonyl bromide. The temperature quickly rose to about 175° and the reaction was completed in about two seconds. Ether was added to the cooled mixture which was then carefully treated with 23 cc. of water. The disulfide was recrystallized from benzene; yield, 0.691 g. or 91.5%.

V. Reaction between 2,4,6-Tribromobenzenesulfonyl Bromide and Phosphorus Pentabromide.—An intimate mixture of the reactants was heated for twenty-five minutes at 85–90°. The cooled product was treated with ether and then excess water, causing the separation of disulfide. The ether layer was washed with water and evaporated, leaving the 2,4,6-tribromobenzenesulfonyl bromide; recovery, 17%. The hexabromodiphenyl disulfide was filtered from the water layer, washed with water and ether; yield, 60.6%.

VI. Reaction between Sodium 2,4,6-Tribromobenzenesulfonate and Phosphorus

¹⁰ Leuckardt, *J. prakt. Chem.*, [2] **41**, 179–224 (1890).

¹¹ Otto and Rössing, *Ber.*, **19**, 3129 (1886).

¹² Bössmann, *Ann.*, **191**, 206 (1878).

Pentachloride.—The reaction was carried out as in II and III, with the addition of four drops of phosphorus oxybromide. No disulfide was formed; yield of sulfonyl chloride, 97%.

VII. Reaction between 2,4,6-Tribromobenzenesulfonyl Bromide and Phosphorus Trichloride.—This was carried out as in experiment IV. No reduction occurred.

VIII. Reaction between 2,4,6-Tribromobenzenesulfonyl Chloride and Phosphorus Tribromide.—The reactants when mixed became *colder*. After heating in a bath at 80–85° for twenty-five minutes, the product was isolated as in V; yield of disulfide, 34%. A large portion of the original sulfonyl chloride was recovered unchanged.

IX. Reaction between α -Naphthalenesulfonyl Chloride and Phosphorus Tribromide.—The mixture was treated as in experiment X, but the naphthalenesulfonyl chloride was unchanged.

X. Reaction between α -Naphthalenesulfonyl Bromide and Phosphorus Tribromide.—Two grams of the sulfonyl bromide was warmed at 70° for fifteen minutes with 3.0 g. of phosphorus tribromide; the cooled mixture was dissolved in 15 cc. of ether, filtered and treated dropwise with 5 cc. of water. The sirupy solution, which had begun to deposit crystals, was further diluted until a cloudiness just developed and then cooled to 0°. The crystals were washed with water and dried; yield, 28.7%; m. p. 86.3–88.5°; mixed m. p. 87–88.5°. The known disulfide alone melted at 88–89.5°. ¹³

The filtrate was diluted with excess water, the ether layer was separated and the water was extracted twice with ether. Evaporation of the ether extracts left an oil which was dissolved in ammonia water and oxidized in the air for twelve days, with occasional shaking. The white precipitate was recrystallized from alcohol; m. p. and mixed m. p. proved it to be α -naphthyl disulfide; yield, 19.5%.

Anal. Calcd. for $C_{20}H_{14}S_2$: S, 20.14. Found: S, 20.77.

XI. Reaction between 3-Nitro-6-methylbenzenesulfonyl Chloride and Phosphorus Tribromide.—Four grams of the sulfonyl chloride was heated with 14.4 g. of phosphorus tribromide at 75° for thirty minutes. The cooled mixture was dissolved in 15 cc. of ether. The clear solution was carefully treated with 8.5 cc. of water and cooled to 0°. The small needles, recrystallized from alcohol, melted at 147.3–148°; yield, 2.455 g. or 85.7%.

This disulfide is new. It crystallizes from alcohol in long, silky, white needles. It is soluble with difficulty in hot alcohol, more readily in hot glacial acetic acid, fairly soluble in ether, very soluble in benzene; it is insoluble in cold alkalies or dilute mineral acids. Analysis and its method of synthesis indicated it to be 3,3'-dinitro-6,6'-dimethyl diphenyl disulfide.

Anal. Calcd. for $C_{14}H_{12}O_4N_2S_2$: S, 19.07; N, 8.33; NO_2 , 27.35. Found: S, 19.20, 18.61; N, 8.74; NO_2 (English), ¹⁴ 26.84.

It is worthy of notice that, while the sulfonyl chloride group was reduced, the nitro group was unaffected.

XII. Reaction between Sodium Benzenesulfonate and Phosphorus Pentabromide.—The sodium benzenesulfonate contained 38.7% of sodium chloride; 3.60 g. (equivalent to 2.21 g. of pure sodium benzene sulfonate) was mixed with 30 g. of phosphorus pentabromide and heated at 85–90° for thirty minutes. The cooled mixture was digested twice with absolute ether; 40 cc. of 15% sodium hydroxide was added *slowly* to the ether and then sodium carbonate till nearly neutral. The ether layer was separated and the water layer was extracted twice with ether. The combined extracts were evaporated.

¹³ Schertel, *Ann.*, **132**, 91 (1864), gives m. p. 85°; Leuckardt, *J. prakt. Chem.*, [2] **41**, 217 (1890), gives m. p. 91°.

¹⁴ English, *J. Ind. Eng. Chem.*, **12**, 994 (1920).

The oily, semi-solid residue was digested with 10 cc. of hot, saturated ammonia water for fifteen minutes, diluted with water to 35 cc., heated to 80° and decanted, removing the sulfonyl bromide as the sulfonamide. A few drops of oil were left.

The sulfonamide solution was evaporated to 25 cc. and cooled, depositing 0.90 g., 47% of the sulfonamide.

The few drops of oil left after the extraction with ammonia water were extracted with ether; the ether was evaporated and the residue was boiled with 1.5 cc. of alcohol and decanted. A small amount of oil separated from the cooled alcohol. The alcohol was poured off and cooled in an ice-bath, depositing a few white needles. Recrystallized from 0.6 cc. of alcohol, these melted at 58–59°; mixed m. p. with known diphenyl disulfide, 58–60°; yield, 0.04 g. or 3%.

XIII. Reaction between Sodium Benzenesulfonate and Phosphorus Pentabromide and Tribromide.—The sodium benzenesulfonate, 3.60 g., containing 1.39 g. of sodium chloride, was heated with 20 g. of phosphorus pentabromide and 13.5 g. of the tribromide for fifteen minutes at 85–90°. The products were isolated substantially as in experiment XII: approximately 20 and 40% yields of the sulfonyl bromide and diphenyl disulfide, respectively; m. p. of disulfide 59.5–61.5°; mixed m. p. showed no depression.

Anal. Calcd. for $C_6H_5SSC_6H_5$: S, 29.38. Found: S, 29.99.

XIV. Reaction between Sodium *m*-Nitrobenzenesulfonate and Phosphorus Pentabromide.—The sulfonate used contained 4.2% sodium carbonate and 59.7% of sodium sulfate. This mixture, 4.5 g., was heated with 29 g. of phosphorus pentabromide at 85–100° for seventy minutes. Isolation of the products as in experiment XII gave about a 25% yield of the sulfonyl bromide (determined as the sulfonamide, m. p. 160.5–162.5°)¹⁵ and 0.30 g. or 27.4% yield of 3,3'-dinitrodiphenyl disulfide; m. p. 82–83°, recrystallized from ether.¹⁶

Anal. Calcd. for $C_6H_4NO_2SSC_6H_4NO_2$: S, 20.80. Found: S, 20.51, 21.44.

XV. Reaction between Sodium *m*-Nitrobenzenesulfonate and Phosphorus Pentabromide and Tribromide.—Four and five-tenths grams of the impure sodium salt (see XIV) was heated with 10 g. of phosphorus pentabromide and 14 g. of tribromide at 85–90° for seventy minutes. No sulfonyl bromide was found. The recrystallized disulfide melted at 81.2–82.2°; yield, 0.64 g. or 57.6%.

XVI. Reaction between 3,5-Dinitrobenzenesulfonyl Chloride and Phosphorus Tribromide.—Sodium 3,5-dinitrobenzenesulfonate could not be induced to react with phosphorus pentabromide. Accordingly, 2.00 g. of the sulfonyl chloride was heated with 2.5 cc. of phosphorus tribromide at 100–110° for forty minutes.

Treatment with ether and water, as in previous experiments, caused the separation of unchanged sulfonyl chloride. The filtrate was diluted with water until about to form two layers and cooled to 0°, giving 60% of the calculated quantity of 3,5,3',5'-tetranitrodiphenyl disulfide, a new substance.

Anal. Calcd. for $C_6H_3(NO_2)_2SSC_6H_3(NO_2)_2$: S, 16.10. Found: S, 15.99.

This disulfide crystallizes from benzene on careful dilution with ligroin or ether in small pale yellow crystals, m. p. 175–177.5°. It is about as soluble in cold as in hot solvents, quite soluble in chloroform, fairly soluble in glacial acetic acid, very slightly soluble in ether, ligroin, or alcohol. Heated well above the melting point, it puffs and chars.

Preparation of Phenyl 3,5-Dinitrobenzenethiosulfonate, and Unsymmetrical Disulfoxide.—One mole of 3,5-dinitrobenzenesulfonyl chloride dissolved in benzene was added slowly to a suspension of two moles of anhydrous sodium thiophenolate in benzene. The mixture was thoroughly digested and then stoppered tightly for one hour.

¹⁵ Limpricht, *Ann.*, **177**, 71 (1875), gives m. p. 161°.

¹⁶ Cleve, *Ber.*, **20**, 1534 (1887), gives m. p. 83°.

The solids were filtered off, washed with benzene, again suspended in benzene and treated with a benzene solution of bromine until the bromine color persisted. The solution was filtered and evaporated *in vacuo* at 105° to an oily residue which was then exposed on a watch glass, finally giving a partially crystalline mass consisting of two substances: A, exceedingly soluble (not identified but probably diphenyl disulfide), and B, slightly soluble in ether.

Substance A was separated by ether and B was recrystallized twice from benzene and once from alcohol. It was phenyl 3,5-dinitrobenzenethiosulfonate, a new compound. It crystallizes from alcohol as pale yellow needles, m. p. 139–141°. It is very soluble in benzene, fairly soluble in hot alcohol, slightly soluble in ether. The disulfide group is very readily reduced by phosphorus tribromide.

Anal. Calcd. for $C_6H_5(NO_2)_2SO_2SC_6H_5$: S, 18.84. Found: S, 19.43.

This disulfide gives sodium thiophenolate and sodium dinitrobenzenethiosulfonate when treated with sodium sulfide.¹⁷ The thiophenolate was identified as the disulfide, m. p. 59–60°, mixed m. p. 60.5–61.5°. This proved the presence of a C_6H_5S -group in the disulfide. The presence of a $C_6H_5(NO_2)_2SO_2$ -group was shown by experiment XVII.

XVII. Reaction between Phenyl 3,5-Dinitrobenzenethiosulfonate and Phosphorus Tribromide.—To 0.95 g. of phenyl 3,5-dinitrobenzenethiosulfonate was added 1 cc. of cold phosphorus tribromide. The temperature quickly rose to the boiling point and in about two seconds the reaction was over; 15 cc. of ether was added to the cooled mixture and then 40 cc. of water.

The water layer was neutralized with sodium carbonate, then 4 cc. of ammonia water was added and the mixture was allowed to oxidize in the air. The brown, tarry precipitate formed during the first twenty-four hours was discarded. The succeeding precipitate was filtered after one week and recrystallized from benzene and ligroin. It was shown to be 3,5,3',5'-tetranitrodiphenyl disulfide (see experiment XVI), m. p. 175–177.5°; yield, 85–95%.

Preparation of 2,4-Dibromo-6-nitrobenzenesulfonic Acid.—Blanksma's preparation of the corresponding disulfide by the use of sodium disulfide¹⁸ suggested that this sulfonic acid might be prepared by the interaction of sodium sulfite and 1,2-dinitro-3,5-dibromobenzene.¹⁹

Ten grams of dinitrodibromobenzene was dissolved in 100 cc. of hot 95% alcohol. To this was added 4.63 g. (20% excess) of sodium sulfite dissolved in 90 cc. of water and 50 cc. of alcohol. The mixture was refluxed for three and one-half hours, after which the alcohol was distilled off.

One cc. of 98% sulfuric acid was added and a rapid current of air was passed through the solution at 80° for ten minutes to expel sulfur dioxide and oxides of nitrogen. The cooled solution was extracted twice with ether and then neutralized with sodium carbonate and evaporated to dryness. The residue was extracted three times with 95% alcohol. The combined alcohol extracts were evaporated to 8 cc. and diluted with 35 cc. of ether. The sodium salt of the sulfonic acid separated and was filtered off and washed with ether; yield, 7.0 g. A second crop was isolated from the filtrate and washings; total yield, 8 g. or 70%.

Summary

1. Aryl sulfonic acid salts, when heated with phosphorus pentabromide, are converted to the corresponding aryl sulfonyl bromides and diaryl disulfides.

¹⁷ Otto, *Ber.*, **15**, 131 (1882); **19**, 1239 (1886); **24**, 713 (1891).

¹⁸ Blanksma, *Rec. trav. chim.*, **27**, 46 (1908).

¹⁹ Cf. Willgerodt, *J. prakt. Chem.*, [2] **32**, 117 (1885).

2. The relative yields of sulfonyl bromide and di-aryl disulfide depend upon the nature of the aryl radical: in some cases the disulfide is the only product; in other cases it is formed in very small amounts.

3. In these reactions the sulfonyl bromide is formed first. It is subsequently reduced by the phosphorus tribromide, simultaneously formed by the dissociation of phosphorus pentabromide. The sulfonic acid salts are unaffected by phosphorus tribromide alone.

4. Aryl sulfonyl bromides are readily reduced by phosphorus tribromide; sulfonyl chlorides are reduced with much greater difficulty by the same reagent. Neither the sulfonyl chlorides nor bromides are reduced by phosphorus trichloride.

5. By the use of the bromides of phosphorus certain disulfides, otherwise difficult or impossible to prepare, are readily obtained.

6. One disulfoxide was investigated. It was reduced with extraordinary ease by phosphorus tribromide.

7. In some cases where the reaction products, containing excess phosphorus tribromide, were decomposed with water and ether, the sulfonyl compounds were reduced to the thiophenols.

8. Addition of bromine to an apparently incompletely reacted mixture in the course of an Otto synthesis of a sulfinic acid gave a new mixed disulfoxide.

ESSENTIAL OIL IN DESERT PLANTS. II. EXAMINATION OF THE OIL OF *CHRYSOTHAMNUS NAUSEOSUS*

BY MAXWELL ADAMS AND LEWIS KEHOE

RECEIVED JANUARY 18, 1932

PUBLISHED JUNE 6, 1932

In a former article by one of us¹ attention has been called to the occurrence and physical properties of the essential oil of *Chrysothamnus Nauseosus*. Coulter and Nelson² list eighteen species and four additional varieties of *Chrysothamnus* growing in the arid plateau region of the United States. This entire group of shrubs is known to the western stock men as "Fall Rabbit Brush." Some attention was called to this plant by the work of Hall,³ who found considerable quantities of rubber in the stems of this shrub. In our former work we collected small samples of oil from carefully selected plants of the following varieties of *Chrysothamnus*: *nauseosus*,

¹ Adams, THIS JOURNAL, 49, 2895 (1927).

² Coulter and Nelson, "Manual of Botany of the Central Rocky Mountain Region," page 494.

³ Harvey M. Hall and Thos. H. Goodspeed, University of California publications in Botany.

naphalodes, *viridulus*, *hololeucus* and *mohavensis*, but since these varieties grow together and can be distinguished only with difficulty, no attempt was made to segregate them in this mass collection. The raw material consisted chiefly of *nauseosus* yet small amounts of other species were present. There is very slight variation in the physical properties of the oils from these varieties, and the general chemical composition is doubtless very similar. The oil occurs chiefly in the leaves and small twigs. None was detected in the roots. The amount of oil present in a particular specimen of *Chrysothamnus* was determined by testing a sample gathered from the same plant each month during the year. The portion gathered in February contained the least, 0.39%, and this amount increased until it reached a maximum in October when there was 0.98% present. The amount of oil decreases when the autumn rains begin. A sample from plants grown on moist ground at Berkeley, California, contained only 0.2% of oil.

One sample of the oil was obtained as follows: 20 kg. of leaves and stems was distilled with steam for about twenty-four hours under pressure of about 2 lb. ($1/8$ atm.) until no more oil came over. The oil after separation was redistilled with steam and then dried over anhydrous sodium sulfate; 200 cc. of oil (sp. gr. 0.8651) was obtained corresponding to a material yield of 0.89%. Refraction tests of this oil showed only carbon, hydrogen and oxygen. The oil was insoluble in water and dilute acids, soluble to 2% in solutions of sodium acid sulfate, to 13% in dilute potassium hydroxide solution, and soluble in concentrated sulfuric acid to give a deep red color. It decomposes considerably when distilled at ordinary pressure, but gives a clear distillate at pressures below 100 mm.; 140 cc. of the oil distilled at 45 mm. gave fractions with the following properties.

Fraction	Range in temp., °C.	Yield, cc.	d_{20}^{20}
1	90-100	60	1.4735
2	100-110	20	1.4781
3	110-167	30	1.4838
4	167-174	20	1.4970
5	174 (residue in flask)	10	1.5190

The lowest boiling fraction gave only the qualitative color test showing the presence of a small amount of α -pinene; 100 cc. of this fraction was oxidized with alkaline potassium permanganate according to the method of Wallach⁴ and yielded nopinic acid which melted at 126°. When the alkaline permanganate residue was steam distilled, 40 cc. of oil was recovered, showing roughly that 60% of the oil had been oxidized. This indicates the presence of about 3% of β -pinene in the original oil.

The fraction boiling between 168 and 170° at 650 mm. was redistilled three times over metallic sodium until the boiling point was practically

⁴ Wallach, *Ann.*, **245**, 251 (1888); *ibid.*, **356**, 229 (1907).

constant. The volume of the liquid thus obtained was composed of hydrocarbons. This fraction had a very strong odor of the oil of lemon and was tested for limonene. A bromine addition product was prepared which melted at 120° , indicating the presence of dipentene. The fraction however had a positive rotation of 59.4, which indicates the presence of limonene. Samples of *Chrysothamnus nauseosus* gathered at various places and at different seasons of the year showed great variation in the angle of rotation. Conditions under which the limonene tetrabromide will form do not appear to be well understood. Four fairly distinct methods have been recommended.⁵ None of these methods gave uniformly dependable results. The following method gave us more satisfactory results than any of the above.

The oil to be tested is gently refluxed over metallic sodium for fifteen minutes and then distilled, preferably at reduced pressure, 10 to 20 mm. A second distillation over sodium is desirable. The fraction coming over between 172 – 178° , 760 mm. pressure, or a corresponding temperature at the reduced pressure, is then brominated as follows.

The fraction, or any part, is dissolved in an equal volume of ether. This terpene-ether solution is then added, drop by drop, to a well-cooled solution of bromine and ether. If all the bromine is not used up, more of the terpene-ether solution is prepared and added. If all the bromine is decolorized before all the terpene-ether solution is added, it is best to stop here and not attempt to add more bromine to the reaction mixture. The reaction mixture is placed at once in a desiccator, and by means of a suction pump the excess ether is boiled away. In the meantime the solution is kept cold. As the ether evaporates, the tetrabromide crystallizes out.

Fuchsine reagent shows an aldehyde present in the oil and it was separated by preparing the phenylhydrazone according to the usual method. After standing for several days clear white crystals, which may be washed free from the mother liquor with benzene, separated out. Recrystallized from alcohol the melting point was 126° . A small amount of the phenylhydrazone was hydrolyzed with concentrated hydrochloric acid, the product was evaporated to dryness, and the residue taken up with water. This water solution gave a strong aldehyde reaction with Tollens' reagent. From the amount, melting point, solubility and other properties of the phenylhydrazone it is concluded that the oil contains about 2% of cuminic aldehyde. About 20% of the oil of *Chrysothamnus nauseosus* has a boiling point of over 200° at ordinary pressure and 167° at 45 mm. pressure, which indicates the presence of sesquiterpenes. None were identified.

The results of the work outlined in this paper show that the essential oil of *Chrysothamnus nauseosus* contains about 3% β -pinene, 30 to 40% limo-

nene and dipentene, 2% cuminic aldehyde and 20% sesquiterpenes. That dipentene has been converted into caoutchouc⁶ gives some interest to the fact that these two substances occur together in *Chrysothamnus* and suggests the question, may not the one be changed into the other by the plant metabolism?

IDENTIFICATION OF NITRILES. PREPARATION OF ALKYL (2,4,6-TRIHIDROXYPHENYL) KETONES BY THE HOESCH SYNTHESIS ON A SEMI-MICRO SCALE

BY HENRY P. HOWELLS AND J. GLENN LITTLE¹

RECEIVED JANUARY 18, 1932

PUBLISHED JUNE 6, 1932

In a recent attempt to find an easier means of identifying alkyl cyanides, Shriner and Turner² treated them with the Grignard reagent to give liquid ketones, which were converted finally to solid semicarbazones. Although the method has been found to be satisfactory when limited amount of starting material and time are not important factors, it was thought worth while to develop here a more rapid method in which very small amounts of nitriles could be used, as is recommended by Kamm, Mulliken³ and others in qualitative organic analysis.

The present method adapts the Hoesch synthesis on a semi-micro scale, to give yields of products comparable to those described in the literature for similar preparations using much larger amounts of starting materials. Thus a small quantity of nitrile is combined with phloroglucinol to yield readily a solid phlorophenone in sufficient amount to make identification of the former very easy.

Experimental

A typical procedure for carrying out the modified Hoesch synthesis on a semi-micro scale is illustrated by the preparation of the new ketone in the series.

n-Butyl 2,4,6-Trihydroxyphenyl Ketone (Phloro-*n*-valerophenone), $C_6H_2(OH)_3-COC_4H_9$.—A solution of 0.006 mole of anhydrous phloroglucinol in about 25 cc. of dry ether was shaken up with 0.4 g. of pulverized, fused zinc chloride. To this was added 0.01 mole of *n*-butyl cyanide and a steady stream of dry hydrogen chloride gas about saturated with ether was passed through the mixture. After two to three minutes the

¹ The experimental routine of this paper was carried out largely by Mr. J. Glenn Little during an advanced course in organic preparations at Oklahoma A. and M. College.

solution turned milky and in the course of a few more minutes became clear. At the end of fifteen minutes an amber colored oil⁴ separated out. The reaction was allowed to continue for about ten minutes longer and then the supernatant liquid was decanted. The oil was taken up in 25 cc. of water and washed twice with 50 cc. of ether. The aqueous layer was concentrated to about one-half of its volume by heating. Upon cooling, long, silky needles separated which after two recrystallizations from hot water with norite gave colorless needles and when air-dried melted at 87–88° (corr.). The substance after drying in vacuum at 110° for thirty minutes or in a vacuum desiccator for a few hours lost a molecule of water to give the anhydrous ketone which melted at 149° (corr.); yield, 84.7%.

The crystals dissolved in concentrated sulfuric acid to give a deep yellow color and in dilute ferric chloride solution to form a purple-red color.

⁴ The oil, which must be a ketimide hydrochloride addition product, appeared in some of these syntheses as colorless crystals and in the preparation of phloro-*n*-caprophenone it did not appear. In the latter instance ice-cold water was added directly to the ether solution and the aqueous layer was worked up in the usual manner.

(1921), give 179–180° for the anhydrous form and an analysis of a monohydrate, for which no m. p. is recorded.

^e Klarman and Figdor, *THIS JOURNAL*, **48**, 803 (1926), give 95° for air-dried and 118° for vacuum dried at 100°. They give analysis for $C_{12}H_{10}O_4$ and do not state the degree of hydration.

^f Karrer and Rosenfeld, *Helv. Chim. Acta*, **4**, 707 (1921), give 122° for the anhydrous form and 104° for the monohydrate.

Summary

A number of the more common alkyl cyanides have been combined with phloroglucinol in the Hoesch synthesis on a semi-micro scale to give good yields of phlorophenones which may be used conveniently as solid derivatives in the identification of the nitriles.

The ketones have been studied and their properties described.

THE PREPARATION AND PROPERTIES OF TERTIARY BUTYL PHENYLACETATE

BY DAVID L. YABROFF AND C. W. PORTER

RECEIVED JANUARY 21, 1932

PUBLISHED JUNE 6, 1932

In the course of our work on the nitration of phenylacetic acid and its esters it became necessary for us to synthesize tertiary butyl phenylacetate. This compound is not easily made by direct esterification of phenylacetic acid and hitherto its preparation has not been reported. By a modification of a method used by Houben¹ in the preparation of terpineol acetate we have succeeded in preparing pure tertiary butyl phenylacetate in yields equal to 65% of the theoretical. Since our procedure can be used to obtain other esters from tertiary alcohols and acids of high molecular weight, it seems worth while to describe the method.

A halomagnesium alcoholate is prepared by decomposing ethylmagnesium bromide with tertiary butyl alcohol

The alcoholate, a white solid, is kept suspended and finely divided by vigorous mechanical stirring. An ether solution of phenylacetyl chloride is added to the ether suspension of the halomagnesium alcoholate and the reaction mixture is warmed under a reflux condenser.

A greater yield of the ester is obtained when the mixture is refluxed for one hour than when it is refluxed for a longer time. This is probably due to a gradual conversion of the ester into phenylacetic acid. In the longer runs we actually isolated phenylacetic acid in quantities sufficient to account for the failure to obtain a one hundred per cent. yield of the ester.

¹ Houben, *Ber.*, **39**, 1763 (1906).

Experimental

Bromomagnesium tertiary butylate was prepared in solid form by adding a slight excess of tertiary butyl alcohol to ethylmagnesium bromide and warming the mixture to drive off ethane. Most of the ether was decanted from the solid alcoholate and the rest was removed by passing dry air over the surface of the residue. The alcoholate was then dried under reduced pressure over calcium chloride. It was found to retain one molecule of ether of crystallization. The equivalent weight as determined by titration with standard silver nitrate solution (K_2CrO_4 indicator) was 234–235; calcd. for $MgBrOC_4H_9 \cdot C_2H_5OC_2H_5$, 239.

Preparation of the Ester

Through the Grignard Reaction.—The solid halomagnesium alcoholate was allowed to react with phenylacetyl chloride with one and then the other in excess in different experiments. The time of refluxing also was varied. It made no difference in yield whether the alcoholate or the phenylacetyl chloride was in excess, but the presence of unchanged phenylacetyl chloride made the separation and purification of the ester difficult. From these preliminary experiments the following final procedure was developed.

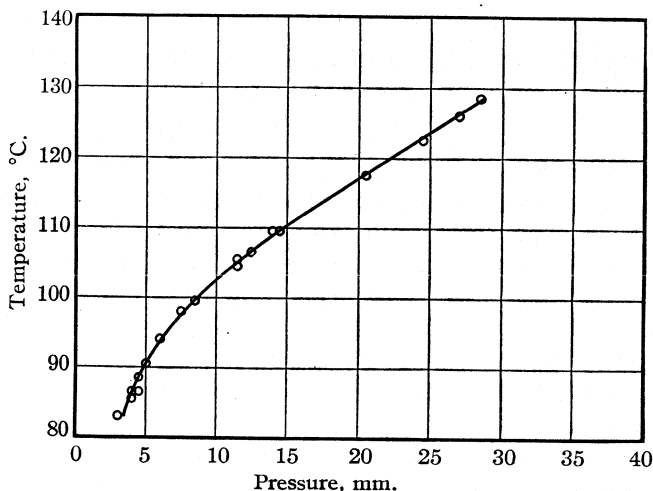

Fig. 1.—Boiling point curve for tertiary butyl phenylacetate.

A solution of 40 g. of tertiary butyl alcohol (0.54 mole) in 50 cc. of ether was added very slowly to approximately one-half mole of ethylmagnesium bromide in 300 cc. of anhydrous ether. The $MgBrOC_4H_9$, which formed as an insoluble white substance was kept in suspension by stirring. The mixture was then warmed to the boiling point of the ether and refluxed for fifteen minutes. Then 46.1 g. of phenylacetyl chloride (0.3 mole) in 50 cc. of ether was added slowly to the hot reaction mixture and refluxing was resumed for one hour.

The content of the flask was then poured on to ice and acidified with dilute sulfuric acid. The ether layer was separated, washed successively with ice-cold water, cold dilute sodium hydroxide solution, and again with cold water. A clear orange-brown liquid remained after the ether had been distilled off. This was fractionated under reduced pressure. Figure 1 shows the boiling points of the ester at various pressures.

By a Direct Method.—Phenylacetic acid was dissolved in a large excess of tertiary butyl alcohol in the presence of a small amount of concentrated sulfuric acid and the

mixture was allowed to stand at room temperature for twenty days in one case and for sixty days in another case. The yields of ester obtained in this way were very small.

Refractive Index of the Ester.—Samples of approximately 25 g. of the ester from each of five preparations were separately purified by fractional distillation. Three of the preparations were made through the Grignard reaction and two were obtained by the direct esterification of the acid by the alcohol. After each fractionation the refractive index of the middle portion of each preparation was determined at 25°. Although the measurements made on different samples were not in agreement, the refractive index of each sample remained nearly constant through repeated distillations. Each preparation was then purified by dissolving the ester in ether and washing with dilute sodium hydroxide solution, dilute sulfuric acid solution, and finally with water. The ether was dried over calcium chloride, distilled off and the ester was fractionated again under reduced pressure. This treatment produced no appreciable change in the refractive index. The last trace of impurity cannot be removed from this ester by repeated washings, extractions and distillations. The refractive index may remain constant on successive distillations and still be incorrect. A similar case is seen in the values reported for tertiary butyl acetate by Henry² and by Smith and Olsson.³

Purification was finally accomplished by fractional crystallization of the compound. A sample of the ester (50 g.) was dissolved in freshly distilled pentane and the mixture was cooled with liquid air. The ester separated as a white snow-like solid. Most of the pentane (which contained about 10 g. of dissolved ester) was decanted, more pentane was added, and the process was repeated a second time. The ester obtained in the second crystallization from pentane was pure and its index of refraction was 1.4825. The density of tertiary butyl phenylacetate (d_4^{25}) was found to be 0.9758 ± 0.0004 , whence the molecular refraction (M_D) by the Lorentz-Lorenz equation becomes 56.19.

Melting Point of the Crystalline Ester.—When the ester is cooled with a mixture of solid carbon dioxide and ether it becomes viscous but fails to crystallize until inoculated with some of the solid ester obtained by cooling a pentane solution of the ester with liquid air. The crystals melt at -23 to -21° . The melting range was obtained in the usual manner by means of warming curves.

Summary

A method is described for the preparation of tertiary butyl phenylacetate which gives a yield of the purified ester equal to about 65% of the theoretical quantity. Physical properties, including boiling points at various pressures, the melting range and the refractive index of the compound have been reported. It is shown that a preparation of this ester which boils at the same temperature after repeated distillations may show a constant but erroneous refractive index.

A CATALYTIC DECOMPOSITION OF CERTAIN PHENOL SILVER SALTS. VI. THE SYNTHESIS OF 4-HYDROXY-3,5-DIBROMO-2',6'-DIIDO-4'-CHLORODIPHENYL ETHER AND THE DECOMPOSITION OF ITS METALLIC SALTS¹

BY W. H. HUNTER AND MILES A. DAHLEN²

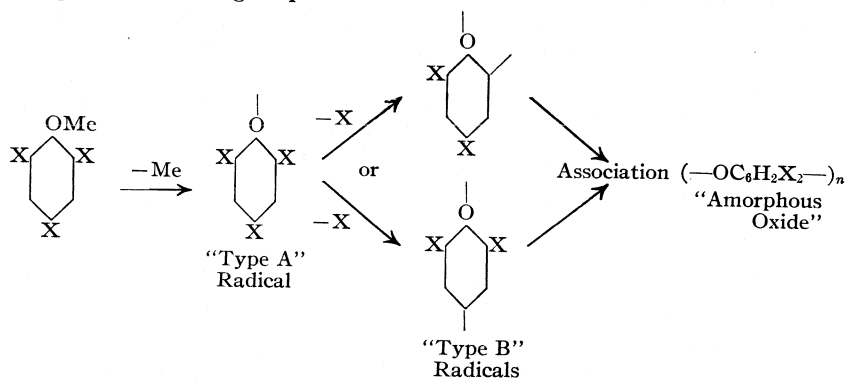

RECEIVED JANUARY 28, 1932

PUBLISHED JUNE 6, 1932

Introduction

Earlier investigations in this Laboratory and elsewhere by Hunter and his students³ have been concerned with the decomposition of the metallic salts of the symmetrically trihalogenated phenols and related compounds. These decompositions have been observed to take place under the influence of certain catalysts, such as the halogens and alkyl halides, and also may be induced by heating the dry salts of the trihalogenated phenols, suspended in an inert medium such as benzene.

As a result of these studies, it has been suggested that the decomposition of these metallic salts under the influence of heat or catalysts proceeds through the following steps

It has been shown that the amorphous oxides are formed by the union of Type B radicals, involving the formation of new oxygen-to-carbon bonds, *i. e.*, that the association results in linkages of the diphenyl ether type. No evidence has been found for the formation of new carbon-to-

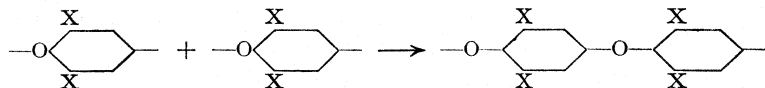

¹ This paper was prepared from a portion of the Thesis of M. A. Dahlen presented to the Graduate School of the University of Minnesota in partial fulfillment of the requirements for the degree of Doctor of Philosophy, June, 1928. The manuscript was written by the junior author after the death of Dr. Hunter in 1931.—L. I. SMITH.

carbon and oxygen-to-oxygen bonds; indeed, tests for peroxides, which would result from the latter type of union, have given negative results in every case.

Therefore, the first stage of this association process may be expressed as follows, assuming that it involves the union of two Type B radicals resulting from the loss of halogen from the para positions of the corresponding Type A radicals

Since the union of radicals of Type A and Type B leads to the formation of products containing linkages of the diphenyl ether type, it was hoped that the preparation and study of a halogenated phenol related to the symmetrically trihalogenated phenols, but already containing a diphenyl ether linkage similar to that present in the oxidation products and amorphous oxides, would cast further light on the nature of the decomposition and oxidation processes previously studied.

A halogenated phenol of the structure (A) was selected as most closely related to the amorphous oxides and trihalophenoxyquinones obtained in the previous work. In order that the subsequent experiments on the

decomposition of the metallic salts of the phenol should provide a maximum of information concerning the lability and reactivity of the various halogen atoms, the product actually synthesized was (I). By "labeling" the various non-equivalent positions in the molecule with different halogens, the interpretation of the results of subsequent decomposition experiments was rendered extremely easy.

Decomposition of the Metallic Salts of the New Phenol.—A preliminary consideration of the possibilities involved in the decomposition of the metallic salts of the new phenol suggested that one of the following results might be expected.

(1) The salts might not decompose under the conditions which cause amorphous oxide formation from the salts of the trihalogenated phenols.

(2) The salts might decompose in a manner analogous with the decomposition of salts of the trihalogenated phenols, and the loss of halogen from the Type A radical first obtained would be confined to Ring "A." The products of such a decomposition would be an amorphous oxide and the metal bromide.

(3) A decomposition would result in which the loss of halogen from the Type A radical would be confined to Ring "B." The products of such

a decomposition would be an amorphous oxide and the metal iodide, chloride, or a mixture of the iodide and chloride.

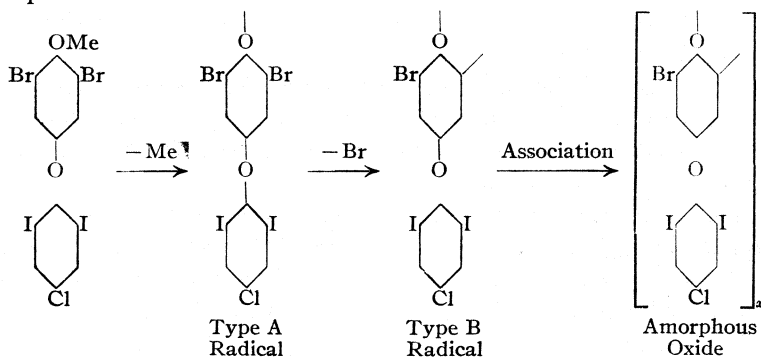

(4) A decomposition would result which would involve all the halogens present in the molecule. The products of such a decomposition would be an amorphous oxide and the mixture of the metal chloride, bromide and iodide.

The potassium salt of the new phenol was decomposed in water solution by the addition of a trace of bromine, following the procedure used in the earlier work on the metal salts of the trihalogenated phenols. The colorless solution of the phenol salt momentarily turned blue-green, then became colorless and a copious precipitate of the white amorphous oxide appeared. The behavior was entirely analogous to the action of the potassium salt of a trihalogenated phenol under the same conditions.

The solution was tested qualitatively for the halogens, but the bromide ion alone was present. The amorphous oxide was analyzed for total halogen and also for the various halogens, and the results were found to correspond closely with the empirical formula $(C_{12}H_4O_2ClBrI_2)_x$. These results indicated that the decomposition had proceeded according to "2" above.

The silver salt of the new phenol was decomposed in benzene suspension by the action of ethyl iodide, iodine and heat, respectively. In each case an amorphous oxide was obtained corresponding with the above empirical formula. The silver halide produced by the decomposition under the influence of heat alone was examined carefully and found to be silver bromide. No trace of iodide or chloride could be found.

The above experiments demonstrated that the decompositions of the salts of the new phenol had taken place in the following manner, assuming that the mechanism previously proposed may be applied to these analogous decompositions

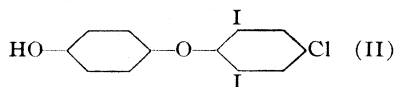

Discussion of the Results

The fact that metallic salts of the new halogenated phenol decomposed in a manner analogous to the decomposition of salts of the symmetri-

cally trihalogenated phenols was not especially surprising, even though the decomposition reaction was confined to the benzene nucleus containing only two halogen atoms; for recent work by Rathmann in this Laboratory^{3g} has disclosed that the salts of dihalogenated ortho and para cresols may be decomposed in a similar manner. However, the fact that halogen atoms were removed only from the hydroxyl-bearing nucleus seems to be most important, especially since in the molecule studied the other benzene nucleus was substituted by three halogen atoms oriented as in the trihalogenated phenols previously studied. On the basis of previous work, it might be expected that the halogen atoms in Ring "B" would be as reactive or labile as those in Ring "A." The fact that all halogen loss occurs from Ring A must be interpreted as meaning that the influences responsible for decompositions of this type are confined to the ring bearing a free hydroxyl group. The conversion of a trihalogenated phenol to an ether apparently results in diminution or complete disappearance of these influences.

In order to check this point, an attempt was made to decompose the salts of the phenol II, which was prepared as an intermediate in the synthesis of I. It was found that the salts of II did not decompose under the conditions which result in rapid amorphous oxide formation in the case of I and of the ordinary trihalogenated phenols. Similar experiments on the salts of 4-hydroxy-2',6'-diiodo-4'-bromodiphenyl ether also gave negative results. These experiments seemed to prove that the hydroxyl group must be present in the halogenated nucleus in order that this type of decomposition may occur.
