A second important result of this study was the disclosure of additional evidence for the existence of radicals of Type A and Type B. First of all, the momentary appearance of a blue-green color, followed by decoloration and precipitation of the amorphous oxide during the decomposition of the phenol salts, coincides with the behavior of the ordinary trihalogenated phenol derivatives. The colored intermediate products have been assumed, in previous work, to be the free radicals. The present work adds strength to the previous theory, since similar observations have now been made on substances quite different in chemical constitution.

More important, however, is the fact that the results of the present study make it appear less likely than ever that the metallic salt decompositions are intermolecular reactions involving the "splitting-off" of metal halide between molecules, forming the diphenyl ether type linkages. If such a mechanism actually were correct, then it would appear most probable that halogen atoms in Ring B of I would be involved. A correlation of the work of Hunter and Joyce⁴ on the decomposition of salts of

⁴ Hunter and Joyce, *THIS JOURNAL*, **39**, 2640 (1917).

the type indicated, where X_1 and X_2 are different halogens, with the results of the new decompositions, would indicate that a reaction mechanism involving intermolecular reaction is almost mathematically impossible in the case of certain trihalogenated phenols of the above type. This is especially true in the case where X_1 represents Cl and X_2 is Br. If intermolecular condensation is not possible as an explanation of the decompositions, the mechanism involving the Type A and Type B radicals receives added confirmation.

Experimental Part

4-Methoxy-2',6'-diiodo-4'-nitrodiphenyl Ether.—The above substance was prepared according to the synthesis described by Harington and Barger.⁵

This method was found to give excellent results when pure starting materials were used. However, the reaction failed entirely when impure ethyl methyl ketone was used as a solvent, and gave poor results unless the other starting materials were of high purity. The best experiments in this work gave condensation yields of 70% of the theoretical, as compared with the 67% yield reported by the above authors.

4-Methoxy-2',6'-diiodo-4'-aminodiphenyl Ether Hydrochloride.—The method of Harington and Barger was used for the reduction of the above nitro compound to this amine. The yield was usually about 65% of the theoretical.

4-Methoxy-2',6'-diiodo-4'-chlorodiphenyl Ether.—Twenty-five grams of the hydrochloride of 4-methoxy-2',6'-diiodo-4'-aminodiphenyl ether was ground very finely in an agate mortar. It was then suspended in 150 cc. of glacial acetic acid to which had been added 10 cc. of water. The suspension was agitated with a high-speed stirrer and cooled externally to 15°. Eight cubic centimeters of *tert.*-amyl nitrite was now added slowly, the temperature being held at 15°. The mixture was then stirred at this temperature for one-half hour, to allow the diazotization to go to completion.⁶

Fifty grams of cuprous chloride was dissolved in 250 cc. of concd. hydrochloric acid and 150 cc. of water was added to the solution. It was then heated to about 60° on the steam-bath, and the diazo solution prepared as above added slowly with vigorous stirring. Much nitrogen was evolved, and the product settled out as a black oil. The mass was heated on the steam-bath for about one hour to complete the replacement, and was then cooled to room temperature. The product solidified to a black crystalline mass and was filtered. It was dissolved in benzene, dried overnight over calcium chloride, and the benzene removed by distillation at atmospheric pressure. The product was then distilled in a vacuum. The fraction boiling at 200–218° under 4 mm. pressure was collected. It distilled as a yellow oil which quickly solidified. The yield at this point was 15.4 g. or about 64% of the theoretical. The product was recrystallized from a mixture of 67 parts absolute alcohol and 33 parts benzene until it showed a constant melting point.

Anal. (Carius) Calcd. for $C_{13}H_9O_2ClI_2$: Cl, 2I, 59.47. Found: X, 59.41, 59.21.

The product crystallizes from alcohol in long white plates melting at 101–102°.

⁵ Harington and Barger, *Biochem. J.*, **21**, 175 (1927).

⁶ Harington and Barger used the above method of diazotization in the conversion of this base to the corresponding nitrile. It was found in the present work that the use of *tert.*-amyl nitrite gave better results than the mixture of amyl nitrites prepared from commercial amyl alcohol. It was also found that the addition of a small quantity of water facilitated the diazotization process.

4-Methoxy-2',6'-diiodo-4'-bromodiphenyl ether.—This material was prepared by a process similar to the above. The product crystallizes from alcohol in bunches of white plates, melting at 123–123.5°, and boiling at 209–219° under 2 mm. pressure.

Anal. (Carius). Calcd. for $C_{13}H_9O_2BrI_2$: Br, 2I, 62.87. Found: X, 62.78, 62.62.

4-Methoxy-2',4',6'-triiododiphenyl Ether.—This material, similarly prepared, showed the following properties.

Anal. (Carius). Calcd. for $C_{13}H_9O_2I_3$: I, 65.89. Found: I, 65.92, 65.72.

The substance crystallizes from a benzene–alcohol mixture in white needles melting at 132–132.5°, and boiling at 220–230° under 1–2 mm. pressure.

4-Hydroxy-2',6'-diiodo-4'-chlorodiphenyl Ether.—Five grams of the corresponding methoxy compound was dissolved in 35 cc. of boiling glacial acetic acid, 0.1 g. of red phosphorus added, and then 44 cc. of pure 57% hydriodic acid was poured in through the reflux condenser. The mixture was held at the boiling point until all of the methoxy compound, which separated as an oil upon the addition of hydriodic acid, redissolved. The mixture was then cooled and poured into an equal volume of water, precipitating the phenol as a white solid.

The crude product obtained as above was dissolved in warm dilute sodium hydroxide solution, filtered, and the phenol reprecipitated by the addition of hydrochloric acid. The product was filtered, washed with water, and then crystallized from 50% alcohol. The yield at this point was about 82% of the theoretical. Repeated crystallization from alcohol gave a product melting sharply at 154.5°. The hydroxy compound crystallizes in the form of very small white needles. The sodium and potassium salts of the phenol are only slightly soluble in cold water, but dissolve readily at the boiling point.

Anal. (Carius). Calcd. for $C_{12}H_7O_2ClI_2$: Cl, 2I, 61.24. Found: X, 60.57, 60.55.

4-Hydroxy-2',6'-diiodo-4'-bromo-diphenyl Ether.—This phenol was prepared from the corresponding methoxy compound by a process similar to the above. It crystallizes from alcohol in white needles melting at 162–163°. The sodium and potassium salts are quite insoluble in cold water but dissolve readily at the boiling point.

Anal. (Carius). Calcd. for $C_{12}H_7O_2BrI_2$: Br, 2I, 64.57. Found: X, 64.54, 64.47.

4-Hydroxy-3,5-dibromo-2',6'-diiodo-4'-chlorodiphenyl Ether.—2.7 grams of 4-hydroxy-2',6'-diiodo-4'-chlorodiphenyl ether was dissolved in 20 cc. of glacial acetic acid in an acetylating flask, and the solution was heated to about 75°; 1.88 g. (3% excess) of bromine was dissolved in 20 cc. of glacial acetic acid and added to the solution of the phenol through the reflux condenser. The solution was heated to boiling for ten minutes, cooled and poured into about 200 cc. of water. The phenol was filtered, washed with water, and crystallized from a mixture of chloroform and alcohol. It was then crystallized repeatedly from absolute alcohol containing a little benzene until a product melting at 194.5° was obtained. The yield on bromination was practically the theoretical, but much material was lost in the purification process.

Anal. (Carius). Calcd. for $C_{12}H_5O_2ClBr_2I_2$: Cl, 2Br, 2I, 71.26. Found: X, 70.92.

The phenol crystallizes from absolute alcohol in white micro needles. It is very slightly soluble in alcohol, moderately soluble in benzene and very soluble in chloroform. The sodium and potassium salts are quite insoluble in cold water but dissolve readily on heating.

Silver Salt of 4-Hydroxy-3,5-dibromo-2',6'-diiodo-4'-chlorodiphenyl Ether.—One gram of the phenol was dissolved in 30 cc. of hot, very dilute sodium hydroxide. The solution was filtered and cooled, the sodium salt separating from the filtrate in white plates. The sodium salt was filtered, washed with a little cold water, and then suspended in 20 cc. of distilled water. The suspension was heated to bring the salt into solution,

then cooled rapidly in order to obtain the product in the form of very fine crystals. Two-tenths gram of pure silver nitrate was dissolved in distilled water and added to the suspension of the sodium salt. The silver salt immediately formed as a gelatinous white solid. It was filtered, washed with water and dried overnight in a vacuum desiccator.

Catalytic Decomposition of the Potassium Salt of 4-Hydroxy-3,5-dibromo-2',6'-diiodo-4'-chlorodiphenyl Ether. A. **By Bromine.**—Three grams of the phenol was dissolved by heating with 25 cc. of a very dilute solution of potassium hydroxide. A cubic centimeter of bromine water was then added. The solution immediately turned bluish-green, and an amorphous oxide quickly appeared as an almost white gelatinous precipitate. The solution was boiled for one-half hour to insure complete decomposition. It was then filtered, and the oxide was collected and dried. The filtrate was reserved for qualitative tests for halogen (see below).

The oxide was purified by dissolving in 20 cc. of warm benzene, filtering, and reprecipitating by the addition of 40 cc. of low-boiling ligroin. The process was repeated four times and the product was then white and practically pure; melting point, 245–257° with decomposition. The yield of crude amorphous oxide was 2.2 g., corresponding to 85% of the theoretical. About 2 g. of purified material was obtained from this crude product.

Anal. (Carius) Calcd. for $(C_{12}H_4O_2ClBrI_2)_x$: Cl, Br, 2I, 67.21. Found: X, 66.38, 66.17. *Analysis* of silver salts by electrolysis: 0.2967 g. of mixed silver salts gave 0.1592 g. Ag. Calcd. for AgCl, AgBr, 2AgI: 0.1599.

Tests for Halogen in Filtrate from Amorphous Oxide Precipitation.—The filtrate from the above decomposition of the potassium salt was acidified with nitric acid and filtered. A little pure sodium bisulfite was added to reduce all halogen to halide ion, and the solution boiled to remove excess bisulfite. It was then extracted with benzene to remove organic matter.

The solution was now tested for each of the halide ions by the usual qualitative procedure. The test for bromide ion was positive; all other halides were absent.

B. **By Iodine.**—Another sample of the phenol was treated in the same manner, except that a drop of a solution of iodine in potassium iodide was substituted for bromine water. Apparently the same decomposition took place and the same amorphous oxide was produced. Analyses of the amorphous oxide corresponded with the results given above. The filtrate from this decomposition was also tested for halide ions, and was found to contain bromide and iodide ions. The iodide ion undoubtedly was introduced by the decomposition catalyst.

Catalytic Decomposition of the Silver Salt of 4-Hydroxy-3,5-dibromo-2',6'-diiodo-4'-chlorodiphenyl Ether. A. **By Ethyl Iodide.**—A small sample of the dry salt was suspended in 5 cc. of dry benzene. A drop of ethyl iodide was added. The solution turned bluish-green in color almost immediately. This color persisted for about ten minutes, then disappeared, and the solution remained a light yellow. The solid remaining was filtered and qualitative tests showed it to be silver bromide mixed with a little unchanged silver salt. The addition of an equal volume of ligroin to the filtrate precipitated an amorphous oxide. Analysis of this material showed it to be identical with the product obtained from the decomposition of the potassium salt.

B. **By Iodine.**—The above experiment was repeated, using a small crystal of iodine instead of ethyl iodide as the catalyst. The same decomposition occurred, yielding the same products.

C. **By Heat.**—A small sample of the silver salt was suspended in 5 cc. of benzene and the solution heated to about 70°. The mass turned blue-green momentarily, then faded to a pale yellow. A precipitate of silver bromide was obtained, and from the filtrate the same amorphous oxide was isolated.

Attempted Catalytic Decomposition of the Potassium and Silver Salts of 4-Hydroxy-2',6'-diiodo-4'-chlorodiphenyl Ether.—The potassium and silver salts of 4-hydroxy-2',6'-diiodo-4'-chlorodiphenyl ether were prepared by the usual methods. They were subjected to the action of the above catalysts under similar conditions, but in no case did a decomposition to amorphous oxide occur.

Summary

1. 4-Hydroxy-3,5-dibromo-2',6'-diiodo-4'-chlorodiphenyl ether, a new halogenated phenol related to the symmetrically trihalogenated phenols, has been prepared.

2. The catalytic decomposition of metallic salts of the new phenol has been studied. The decomposition occurs in a manner entirely analogous to that of the trihalogenated phenols previously studied. It was observed that only the halogen in the hydroxyl-bearing nucleus is removed in such decomposition.

3. Additional confirmation of the mechanism previously suggested for the catalytic decomposition of metal salts of halogenated phenols has been obtained.

4. Additional evidence for the existence of Type A and Type B radicals has been disclosed.

RESEARCHES ON HYDANTOINS. L.¹ THE SYNTHESIS OF HYDANTOINS POSSESSING THE PROPERTIES OF HYPNOTICS

BY ROBERT M. HERBST² AND TREAT B. JOHNSON

RECEIVED JANUARY 29, 1932

PUBLISHED JUNE 6, 1932

That the hydantoin nucleus exhibits hypnotic properties has been known for several years. This pharmacological behavior is most pronounced in the drug "*nirvanol*" (phenylethylhydantoin) I, which is the hydantoin analog of the pyrimidine "*luminal*" or phenylethylbarbituric acid II. The latter cyclic ureide and several of its representatives have been used effectively as sedatives and hypnotics in simple insomnia, hysteria, neurasthenia, thyroid disease, chorea, epilepsy and certain mental disturbances.

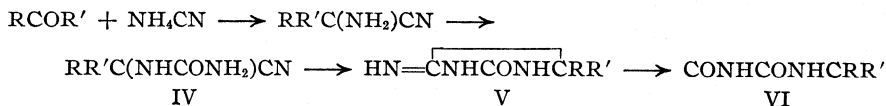

Although nirvanol I has fallen into disrepute in recent years as an hypnotic because of the fever and skin eruptions induced by its continued ad-

¹ Constructed from a dissertation presented by Robert M. Herbst to the Faculty of the Graduate School of Yale University in partial fulfilment of the requirements for the degree of Doctor of Philosophy, June, 1930.

² Eli Lilly Company Graduate Scholar, 1928-1929.

ministration, it has recently been found to exert a valuable therapeutic action on certain nervous disorders. Several physicians working in hospitals have reported to this Laboratory remarkable successes in the clinical treatment of chorea (St. Vitus' dance) with this hydantoin I.³ However, here too the drug must be administered continuously over a period of time, and the undesirable reactions are also manifested. Particularly, the disappearance of the characteristic skin eruptions and fever induced by nirvanol is coincident with the disappearance of the symptoms of chorea. The work discussed in this paper represents a part of a co-operative research program, organized for the purpose of synthesizing a group of new hydantoin derivatives which might be better suited than *nirvanol* to the treatment of chorea and other nervous disorders. Very little attention has thus far been paid to the pharmacology of this class of organic compounds.

For the preparation of dialkyl-hydantoins we have employed a method first applied by Urech⁴ and recently studied by Read⁵ of this Laboratory, and also by Biltz and Slotta,⁶ whereby the desired hydantoins may be prepared from ketones in three steps as is expressed by the formulas

In the third step of this process (IV \longrightarrow VI) we postulate that the reaction takes place through the formation of an intermediate imino-hydantoin V, which in strongly acid solution is immediately decomposed, giving the corresponding dialkyl-hydantoin VI. The conversion of the hydantoin nitrile IV to the hydantoin VI in hot acid solution proceeds with such rapidity that the reaction is practically instantaneous. This suggests that another reaction mechanism than that involved in the normal hydrolysis of a cyanide group, which is usually a slower reaction, is to be considered. In a previous paper⁷ the authors have described a rearrangement of an hydantoic-nitrile IV, to a stable 4-aminohydantoin, a molecular change which, we believe, lends support to the mechanism of reaction suggested above.

³ Private communication from Dr. S. W. Clausen of the Strong Memorial Hospital, University of Rochester, Rochester, New York. Also the drug has been used with success in the clinics of several medical schools, including Yale, during the past two years. Experimental Part

Preparation of Ketones.—Several of the ketones employed in the synthesis of alkylated hydantoins were prepared by the catalytic method of Senderens,⁸ in which thorium oxide carried on pumice served as the catalyst. Methyl benzyl ketone was prepared by passing the vapors of a mixture of acetic acid and phenylacetic acid over the catalyst at a temperature of 430–450°. Similarly ethyl benzyl ketone and ethyl β -phenylethyl ketone were prepared catalytically by heating mixtures of propionic acid with phenylacetic and hydrocinnamic acids, respectively. Varying amounts of the two possible symmetrical ketones are always formed as by-products and may be recovered. Benzylacetone was prepared for our research by reducing benzalacetone⁹ with hydrogen gas at a pressure of 2 to 3 atmospheres in the presence of Adams' platinum oxide catalyst.¹⁰

The Preparation of Nitriles of Amino Acids from Ketones.—The amino acid nitriles corresponding to the ketones were prepared by the action of anhydrous hydrocyanic acid and ammonia on a solution of the respective ketone in absolute ethyl alcohol. These compounds are usually isolated most conveniently in the form of their hydrochlorides. The technique employed was as follows.

A solution of 0.25 mole of the ketone in 25 cc. of absolute ethyl alcohol is thoroughly cooled with ice water; 0.25 mole of anhydrous hydrocyanic acid is added, followed by 0.25 mole of anhydrous ammonia. During the addition of the ammonia the flask in which the reaction is applied is thoroughly cooled, and equipped with a good reflux condenser to prevent loss of hydrocyanic acid, since considerable heat is evolved in the formation of ammonium cyanide. This procedure is much more convenient than that previously recommended by Read⁵ in which solid ammonium cyanide is first prepared for the reaction with the ketone.

The solution containing the ketone and ammonium cyanide is transferred to a pressure bottle, and the mixture allowed to stand from twenty-four to seventy-two hours until the reaction is complete, or equilibrium is established. The contents are then poured into a mixture of 200 g. of cracked ice and 50 cc. of concentrated hydrochloric acid. Any unreacted ketone separates as an oil, and may be removed by extraction with ether. The desired amino-nitrile is liberated by the addition of a slight excess of concentrated ammonia, keeping the solution well cooled by the addition of cracked ice. It separates as an oil which takes up in the ether and is separated from the aqueous layer, which is further extracted twice with fresh ether. The ether solutions are combined and dried over sodium sulfate. The hydrochloride of the amino-nitrile is precipitated from the ether solution by the addition of dry hydrogen chloride.

The hydrochloride of α -amino- α -methyl- γ -phenylbutyronitrile, from benzylacetone, precipitates practically completely from the acid water solution and the steps involving liberation of the aminonitrile and subsequent precipitation from ether solution are omitted in this case. The hydrochloride of 1-amino-1-cyanocyclohexane precipitates partially from the acid water solution. The remainder is obtained in the manner described above. The hydrochloride of α -amino- α -ethyl- γ -phenylbutyronitrile is not precipitated readily as a solid from ether solution with dry hydrogen chloride; consequently it was used as the free base, which was obtained by evaporating the ether from the dry solution of the amino-nitrile under reduced pressure at room temperature. A small amount of the hydrochloride was prepared by dissolving the amino-nitrile in dilute aqueous hydrochloric acid, and saturating the cold solution with hydrogen chloride,

^a The yields are calculated allowing for recovered ketone, which never amounted to more than 25-30% of the original material.

The amino acid nitrile hydrochlorides are all soluble in water, somewhat soluble in 95% ethyl alcohol, and insoluble in most other organic solvents. The hydrochlorides of α -amino- α -methyl- γ -phenylbutyronitrile and 1-amino-1-cyanocyclohexane are stable; the rest decompose slowly on standing. Also the free nitriles are oils in the crude state, very slightly soluble in water, and somewhat unstable, especially toward heat. Since it was impossible to distil them under reduced pressure, purification was not attempted.

The acetyl-amino-nitriles were prepared by treating the free amino acid nitriles with acetic anhydride in the usual manner. The new compounds prepared are given in Table II.

The Ureido-nitriles.—The method used by Read⁵ for the preparation of ureido-nitriles from amino acid nitrile hydrochlorides was employed with slight modification in technique. The amino acid nitrile hydrochloride, suspended or dissolved in a suitable medium, is treated carefully with two equivalents of potassium cyanate. Read employed glacial acetic acid as a solvent for this reaction. We have also used this medium, but have found 50% acetic acid better suited in several cases. Moreover, we have found it necessary to neutralize the acetic acid with ammonia in order to obtain complete precipitation of the ureido-nitriles after the reaction mixture is diluted with water accord-

Hydantoins from the Ureido-nitriles.—The formation of hydantoins from the corresponding ureido-nitriles is brought about by warming the nitriles in 20% hydrochloric acid solution, from which the hydantoins precipitate on forming. These are purified by recrystallization from 50% alcohol, from which they usually separate as colorless needles or prisms. The new hydantoins prepared by us are recorded in Table IV.

^a The ureido-nitrile corresponding to this hydantoin melts under hot aqueous hydrochloric acid, and does not dissolve completely, hence the mixture should be stirred vigorously during heating to ensure complete reaction.

5,5-Cyclopentamethylenehydantoin crystallizes from 50% alcohol with one molecule of water of crystallization, which is lost on heating to 105-110°. The following analysis was made on a sample dried to constant weight at 105-110°.

Anal. Calcd. for C₅H₁₂O₂N₂·H₂O: H₂O, 9.67. Found: H₂O, 9.48.

Salts of the Hydantoins with Metals.—The sodium salts of the above hydantoins are easily prepared by treating a small amount of the hydantoin with the calculated quantity of a 5% solution of sodium hydroxide in 95% alcohol. On evaporating the alcohol in a vacuum desiccator, the sodium salt of the hydantoin remains as a colorless, crystalline residue. These salts are very soluble in water, slightly soluble in 95% alcohol, and insoluble in most other organic solvents. Acetic or mineral acids, and carbon dioxide precipitate the hydantoins from aqueous solutions of their sodium salts. Aqueous solutions of the sodium salts absorb carbon dioxide from the air with subsequent precipitation of the free hydantoins. However, the sodium salts are quite stable in aqueous solution when carbon dioxide is excluded. A water solution of the sodium

salt of nirvanol¹³ was kept for six weeks in a sealed tube at 40–50°, after which the hydantoin was recovered almost quantitatively on addition of carbon dioxide.

The mercury salts of the hydantoins precipitate as flocculent, colorless solids when a saturated solution of mercuric chloride is added to aqueous solutions of the sodium salts of the hydantoins. Similarly crystalline calcium and magnesium salts of the hydantoins precipitate when strong solutions of calcium chloride and magnesium sulfate, respectively, are added to aqueous solutions of the hydantoin sodium salts.

α -Amino- α -phenylbutyric Acid, $\text{C}_6\text{H}_5\text{C}(\text{C}_2\text{H}_5)(\text{NH}_2)\text{COOH}$.—This amino acid was obtained by Jawelow¹¹ from propiophenone through the action of ammonium cyanide, followed by hydrolysis of the amino acid nitrile formed. His description of the compound is limited to the statement that it separates from water in groups of needles. We have prepared this same amino acid by hydrolyzing phenylethylhydantoin with barium hydroxide.

A mixture of 10 g. of the hydantoin, 50 g. of crystallized barium hydroxide, and 100 cc. of water is refluxed for one hundred hours, when the evolution of ammonia will have practically ceased. The excess of barium hydroxide is precipitated as the carbonate by bubbling carbon dioxide into the mixture. After filtering off the barium carbonate and washing with hot water, the combined filtrate and washings are concentrated until the amino acid begins to crystallize from the solution. On cooling, α -amino- α -phenylbutyric acid separates in the form of clusters of needles. The amino acid is purified by dissolving in dilute ammonia water, and concentrating on the steam-bath until crystallization begins. A yield of 79 g. of the amino acid, melting at 275° (corr.) with charring, was obtained.

Anal. Calcd. for $\text{C}_{10}\text{H}_{13}\text{O}_2\text{N}$: C, 67.00; H, 7.32; N, 7.82. Found: C, 67.09; H, 7.25; N, 7.50, 7.50.

The compound shows all the characteristic properties of an α -amino acid. It is soluble in hot water and glacial acetic acid, slightly soluble in cold water and insoluble in most other organic solvents.

Hydrochloride.—This is a colorless, crystalline solid, very soluble in water and melting at 271° (corr.) with charring and effervescence.

Anal. Calcd. for $\text{C}_{10}\text{H}_{14}\text{O}_2\text{NCl}$: N, 6.50; Cl, 16.47. Found: N, 6.62; Cl, 16.76.

α -Phenylureido- α -phenylbutyric Acid, $\text{C}_6\text{H}_5\text{C}(\text{C}_2\text{H}_5)(\text{NHCONHC}_6\text{H}_5)\text{COOH}$, crystallizes from 75% alcohol in small, colorless needles, melting at 190–190.5° (corr.) with complete disappearance of all the material.

Anal. Calcd. for $\text{C}_{17}\text{H}_{19}\text{O}_3\text{N}_2$: N, 9.40. Found: N, 9.60.

α -Amino- α -methyl- β -phenylpropionic Acid, $\text{C}_6\text{H}_5\text{CH}_2\text{C}(\text{CH}_3)(\text{NH}_2)\text{COOH}$.—This amino acid was prepared from 5-methyl-5-benzylhydantoin in the same manner as that described for α -amino- α -phenylbutyric acid. In this case the hydantoin is completely broken down after thirty hours of boiling with barium hydroxide solution. It crystallizes from water in bunches of colorless needles, melting at 293–294° (corr.) with charring.

Anal. Calcd. for $\text{C}_{10}\text{H}_{13}\text{O}_2\text{N}$: C, 67.00; H, 7.32; N, 7.82. Found: C, 66.90; H, 7.18; N, 7.76.

This compound has about the same solubility in various solvents as its isomer, α -amino- α -phenylbutyric acid.

The hydrochloride is a colorless crystalline acid, melting at 244–246° (corr.) with charring and gas evolution.

Anal. Calcd. for $\text{C}_{10}\text{H}_{14}\text{O}_2\text{NCl}$: N, 6.50; Cl, 16.47. Found: N, 6.44, 6.46; Cl, 16.49.

¹³ Prepared according to Read's method, Ref. 5.

α -Phenyl-ureido- α -methyl- β -phenylpropionic Acid, $C_6H_5CH_2C(CH_3)(NHCONHC_6H_5)COOH$, crystallizes from 50% alcohol in small, colorless prisms, melting at 187° (corr.) with complete disappearance of the material.

Anal. Calcd. for $C_{17}H_{18}O_3N_2$: N, 9.40. Found: N, 9.49.

Pharmacological Report

The results of a preliminary pharmacological examination of the above hydantoins are summarized in Table V, compiled from a report kindly submitted by Mr. C. L. Rose,¹⁴ of the Lilly Research Laboratories, Indianapolis, Indiana. The hypnotic value of the compounds was tested in the usual manner, by intraperitoneal injection of white rats with a definite volume dose of the material to be tested. The doses were measured in milligrams per kilogram of rat weight, and the results read in terms of dosage, as, Minimum Hypnotic Dose (M. H. D.), Maximum Tolerated Dose (M. T. D.), Minimum Lethal Dose (M. L. D.), and the safety factor or Ratio of M. H. D. to M. T. D.

TABLE V
PHARMACOLOGICAL BEHAVIOR

Compound	M. H. D.	M. T. D.	M. L. D.	Ratio
Ethylphenylhydantoin (nirvanol)	165	190	200	1.21
Methylbenzylhydantoin	550	650	700	1.28
Ethylbenzylhydantoin	500	450	500	1.00
Methyl- β -phenylethylhydantoin	250	500	550	2.20
Ethyl- β -phenylethylhydantoin	275	390	400	1.45
Cyclopentamethylenehydantoin	None	150	200	...

Discussion of the Pharmacological Data

5-Methyl-5- β -phenylethylhydantoin stands out as the best hypnotic of the group. It is less than half as toxic as nirvanol, and its effective dose somewhat approaches that of nirvanol, while its margin of safety is nearly twice that of nirvanol. Next best is 5-ethyl-5- β -phenylethylhydantoin, which is only 9% less effective and 27% more toxic than its methyl analog.

Although 5-methyl-5-benzylhydantoin is 21% less toxic than 5-methyl-5- β -phenylethylhydantoin, it must be ruled out because of the convulsions it causes in low doses. 5-Ethyl-5-benzylhydantoin is but 9% more toxic than 5-methyl-5- β -phenylethylhydantoin, but it is not effective outside the toxic range. 5,5-Cyclopentamethylenehydantoin has about the same toxicity as nirvanol, but has no effective range and causes a considerable increase in the activity of the salivary gland. Several of these new hydantoins of the nirvanol type are now being tested clinically by different medical investigators.

The authors desire to acknowledge the assistance of Mr. W. Saschek of the Department of Biochemistry, Columbia Medical School, New York

¹⁴ The authors desire to express here their appreciation of the assistance given by the Lilly Research Laboratories in carrying out these preliminary pharmacological tests.

City, who made the microanalyses for carbon and hydrogen, which are reported in this paper.

Summary

1. A series of new 5,5-dialkyl-hydantoins has been prepared.
2. A report of a preliminary pharmacological study is included.
3. Several of these hydantoins, 5-methyl-5- β -phenylethylhydantoin, and its 5-ethyl analog, have marked hypnotic properties, and are being subjected to clinical study to determine whether they possess any therapeutic value in the treatment of nervous diseases.
4. Two new α -amino acids related to the hydantoins have been prepared.

THE DIRECTIVE INFLUENCE OF THE ALKYL SULFONAMIDO AND DIALKYL SULFONAMIDO GROUPS

BY R. L. SHRINER, M. T. GOEBEL AND C. S. MARVEL

RECEIVED FEBRUARY 1, 1932

PUBLISHED JUNE 6, 1932

There have been numerous attempts to formulate rules which will allow one to predict the position which a group will take when it enters a monosubstituted benzene ring. Interest in this general problem has been revived by the appearance of two papers¹ which set forth new empirical rules which are apparently less subject to exceptions than are the previous generalizations. It is obvious, however, that a general rule based on theoretical considerations cannot be formulated until all of the common substituents in the ring have been considered. The present work concerns the sulfonamido and disulfonamido groups, which have not been fully considered in the earlier papers.

Hammick and Illingworth^{1b} have stated the following orientation rule: "If in the benzene derivative C_6H_5XY , Y is to the right of X in the periodic table, or if, being in the same group, Y is of a lower atomic weight than X, a second atom or group will enter the nucleus in the meta position. In all other cases including that in which XY is a single atom, a second entering group or atom goes to the ortho and para positions." The effect of ionic charges on XY is also discussed and it is pointed out that positive charges direct meta and negative charges direct ortho and para. In the application of their rule they do not clearly indicate what may be expected from a group such as CH_2Cl or $CHCl_2$ where X is C and Y may be H or Cl. In such a case it is obvious that following the rule alone one would predict mixtures of ortho, meta and para isomers. This agrees

¹ (a) Latimer and Porter, *THIS JOURNAL*, **52**, 206 (1930); (b) Hammick and Illingworth, *J. Chem. Soc.*, 2358 (1930). A review of the earlier literature can be found in these articles.

fairly well with the facts which have been established by experiment. A group such as the sulfonamido $\text{—N} \begin{smallmatrix} \text{SO}_2\text{R} \\ \text{H} \end{smallmatrix}$ is another of this doubtful type, for the hydrogen atom is to the left of the nitrogen in most arrangements of the periodic table and sulfur is to the right of nitrogen. Hence, according to the above rule, a mixture of all three isomers would be predicted. Another factor which must be considered is the acidic properties of the monosulfonamides. This property would lead one to expect a behavior similar to that of the aci-nitro compounds which, as Baker² has shown, direct the entering group meta.

However, the aryl sulfonamido group is known to be a group which directs mainly to the ortho and the para positions. Without attempting to cite all of the literature references it can be stated that many aryl sulfonanilides have been halogenated and nitrated and that the products formed were ortho and para substituted derivatives. Quite recently Bell³ has studied carefully the nitration and halogenation of certain aryl sulfonanilides and has compared the directive effect of the aryl sulfonamido group with that of the acetamido group. His results indicate clearly that the aryl sulfonamido group is an ortho-para directing group.

The disulfonamido group $\text{—N—(SO}_2\text{R)}_2$ has been less thoroughly examined and the only information concerning its effect is the statement by Bell^{3b} that it is more difficult to nitrate a diaryl sulfonanilide than an aryl sulfonanilide and that under vigorous conditions of nitration nitro groups are introduced in both the aryl sulfonyl and the aniline residues. The rule of Hammick and Illingworth^{1b} would lead one to predict that the disulfonamido group would direct an entering group to the meta position only.

Latimer and Porter^{1a} base their predictions of the position taken by a group entering a monosubstituted benzene ring on values obtained by calculating in a semi-quantitative manner the residual charge on the atom attached to the ring. By a study of most of the known groups they show that if the residual charge on this atom has a high positive value ($> +0.6$), the new group enters the meta position; whereas if the value of the residual charge is negative, zero or slightly positive ($< +0.1$), ortho and para substitution occur. Mixtures result in the case where the residual charge is between $+0.1$ and $+0.6$. If Latimer and Porter's method of calculating residual atomic charges is applied to the sulfonamido and disulfonamido groups the results are as follows

Residual charge on nitrogen equals

$$\begin{array}{c} \text{H} \\ | \\ \text{C}_6\text{H}_5 : \ddot{\text{N}} : \\ | \\ \text{SO}_2\text{R} \end{array} + 5 - 2 - (2 \times \frac{1}{2}) - (2 \times \frac{5}{9}) - (2 \times \frac{5}{11}) = -0.02$$

² Baker, *J. Chem. Soc.*, 2257 (1929).

³ Bell (a), *ibid.*, 2770 (1928); (b) 2787 (1929); (c) 2338 (1931).

$$\begin{array}{c} \text{SO}_2\text{R} \\ \text{C}_6\text{H}_5:\ddot{\text{N}}: + 5 - 2 - (2 \times \frac{5}{9}) - (4 \times \frac{5}{11}) = +0.07 \\ \text{SO}_2\text{R} \end{array}$$

Residual charge on nitrogen equals

It will be noted that the charge on the nitrogen atom is negative in the monosulfonanilide, and slightly positive but less than +0.1 in the disulfonanilide. Hence, both of these groups would fall in the ortho and para directing class.

The present work was undertaken to confirm the previously reported directive effects of the sulfonamido group and to determine that of the disulfonamido group. Methanesulfonanilide and dimethanesulfonanilide were selected for study because each contains only one aromatic nucleus and the alkyl sulfonyl group is small so that steric effects should be of less consequence. Nitration was selected as a suitable reaction for introducing a new group since it is a characteristic reaction and usually gives crystalline derivatives. The nitration of methanesulfonanilide proceeded smoothly and the crystalline product isolated from the nitration mixture in yields of over 80% of the theoretical amount was 2,4-dinitro-methanesulfonanilide. Some hydrolysis occurred during nitration. Hydrolysis and mechanical losses account for the difference between the actual yield and the theoretical yield. No other isomer could be detected.

The nitration of dimethanesulfonanilide was more difficult to bring about. The fact that nitration proceeded more slowly was in agreement with the statement of Bell^{3b} concerning substitution in diaryl sulfonanilides. In addition to the well-defined crystalline *p*-nitro derivative, a mixture of lower-melting products, including a resinous impurity, was obtained. The lower-melting fractions were hydrolyzed and by steam distillation some *o*- and *m*-nitroanilines were carried over. A further quantity of *p*-nitroaniline was recovered in the non-volatile portion. By repeated distillation with steam and recrystallization, rather pure *m*-nitroaniline was obtained. A very small amount of crystalline *o*-nitroaniline was obtained by sublimation. With this evidence of its presence further estimation of the amounts of the ortho and meta isomers which were present in the material could be made by use of Tingle and Roelker's⁴ data on the melting points of mixtures of these compounds.

The results of this separation of products indicate that the nitration of dimethanesulfonanilide gave over 61% of the para isomer, and approximately 13% of meta and 6% of the ortho isomers. This estimation of the ortho isomer is the least satisfactory and probably the portion unaccounted for was the ortho isomer. It is thus established that the di-methanesulfonamido group is essentially an ortho-para directing group.

⁴ Tingle and Roelker, *THIS JOURNAL*, **30**, 822 (1908).

Experimental Part

Methanesulfonyl chloride and methanesulfonanilide were prepared by the procedures previously described.⁵

Dimethanesulfonanilide.—A solution of 27 g. of methanesulfonanilide and 20 g. of methanesulfonyl chloride in 100 cc. of dry benzene was refluxed for two hours. The solvent was then removed by distillation under reduced pressure and the sirupy residue was treated with about 200 cc. of cold 10% aqueous sodium hydroxide solution to extract the unreacted methanesulfonanilide. The insoluble residue was collected on a Büchner funnel and washed repeatedly with hot alcohol. The white crystalline material thus obtained weighed 29 g. (71% of the theoretical amount); m. p. 201–202°.

Anal. (Kjeldahl) Subs., 0.5032, 0.4420: 20.2, 17.6 cc. of 0.101 *N* HCl. Calcd. for $C_8H_{11}O_4NS_2$: N, 5.62. Found: N, 5.68, 5.64. (Parr Bomb) Subs., 0.6355, 0.3370: $BaSO_4$, 1.1969, 0.6317. Calcd. for $C_8H_{11}O_4NS_2$: S, 25.7. Found: S, 25.80, 25.67.

Nitration of Methanesulfonanilide.—To a well-stirred mixture of 100 cc. of concentrated nitric acid (sp. gr. 1.42) and 50 cc. of concentrated sulfuric acid (sp. gr. 1.84) maintained at 30–40° was slowly added 20 g. of methanesulfonanilide. The addition required an hour and the mixture was allowed to stand for three hours longer. It was then poured into 400 cc. of ice and water in order to precipitate the nitration product. By filtering this solution and air drying the precipitate, there was obtained 27 g. of light yellow product, m. p. 120–170°. This product was washed four times with 50-cc. portions of hot alcohol. The insoluble residue weighed 23 g. and melted sharply at 171–172°.

The alcoholic solution was evaporated and yielded 4 g. of a product melting at 130–160°. This was renitrated with 50 cc. of red fuming nitric acid at 40°. On working up this mixture as before 1.5 g. of product melting at 170–172° was obtained. From the alcoholic mother liquors about 1 g. of low melting material was again recovered.

Further recrystallization of the nitration product gave pure 2,4-dinitromethanesulfonanilide which melted at 173.5–174.5°.

Anal. (Parr Bomb). Subs., 0.6625, 0.6588: $BaSO_4$, 0.6000, 0.5945. Calcd. for $C_8H_7O_2SN(NO_2)_2$: S, 12.25. Found: S, 12.41, 12.36.

The total yield of dinitro compound (m. p. 170–172°) was 24.5 g. (80.6% of the theoretical amount). The fact that the low-melting compound could be further nitrated to yield the higher-melting compound indicated that the first product was a mixture of ortho- and para-mononitro derivatives.

Identification of the Dinitromethanesulfonanilide.—Five grams of the dinitromethanesulfonanilide (m. p. 170–172°) obtained as described above was hydrolyzed by refluxing it for six hours with a mixture of 30 cc. of concentrated sulfuric acid and 30 cc. of water. The reaction mixture was poured into a large volume of ice water and the precipitate of 2,4-dinitroaniline was filtered. After washing with water and alcohol and air drying, the yellow crystalline material melted at 176.5–178° and weighed 3.5 g. (practically a quantitative yield). A mixture of this product with known 2,4-dinitroaniline (m. p. 180°) melted at 179–180°.

The 2,4-dinitroaniline from the hydrolysis mixture was further characterized by treating a sample (0.5 g.) with excess acetyl chloride. The 2,4-dinitroacetanilide thus obtained melted at 119–120°. The melting point recorded for this product is 120–121°.

The same dinitromethanesulfonanilide was obtained by nitrating *p*-nitromethanesulfonanilide prepared by the method of Morgan and Pickard.⁶

⁵ Marvel, Helfrick and Belsley, *THIS JOURNAL*, 51, 1272 (1929).

⁶ Morgan and Pickard, *J. Chem. Soc.*, 97, 61 (1910).

Nitration of Dimethanesulfonanilide.—Preliminary experiments showed that nitration did not take place when dimethanesulfonanilide was treated with a mixture of concentrated nitric and sulfuric acid at 30–40°, or at 60–70°. The use of fuming nitric acid gave satisfactory results.

To a mixture of 100 cc. of red fuming nitric acid (sp. gr. 1.60) and 50 cc. of concentrated sulfuric acid (sp. gr. 1.84) was added slowly 30 g. of dimethanesulfonanilide. The mixture was stirred and the temperature maintained at about 20°. The mixture was stirred for two hours after the addition of the anilide was complete, diluted with ice water, and filtered. The crude air-dried nitration product weighed 30 g. (85% of the theoretical yield of mononitro compound).

Repeated extraction with hot alcohol and subsequent recrystallization yielded, from 24 g. of the crude product, the following fractions: (I) m. p. 215–225°, 12 g.; (II) m. p. 160–195°, 3 g.; (III) m. p. 140–150°, 5 g.; (IV) m. p. 110–135°, 1.5 g.; (V) resinous material, 1 g.

Fraction (I), which was almost insoluble in hot alcohol, was further washed, and finally recrystallized from benzene. The pure product melted at 230–231°. It was analyzed for sulfur and results of the analysis show that it is a mononitro derivative.

Anal. (Parr Bomb). Subs., 0.3985: BaSO₄, 0.6379. Calcd. for C₈H₁₀O₄NS₂(NO₂); S, 21.77. Found: S, 21.91.

***p*-Nitrodimesulfonanilide.**—The structure of the compound constituting Fraction I was established by synthesis from *p*-nitromethanesulfonanilide and by hydrolysis to *p*-nitroaniline. One gram of *p*-nitromethanesulfonanilide was refluxed with 2 cc. of methanesulfonyl chloride and 2 cc. of tributylamine in toluene solution. The toluene was distilled under reduced pressure and the residue was washed with sodium carbonate solution and dilute hydrochloric acid. The insoluble residue (0.5 g.) was recrystallized from an excess of hot alcohol. The product melted at 225–228°. A mixture with the product obtained in fraction I above melted at 228–230°.

Hydrolysis of Nitration Products.—Five grams of fraction (I) was refluxed for six hours with a mixture of 30 cc. of concentrated sulfuric acid and 30 cc. of water. The reaction mixture was cooled, diluted with water to 200 cc., made slightly alkaline by the addition of 20% sodium hydroxide solution, cooled and extracted with three 200-cc. portions of ether. The residue after evaporating the ether from the extract weighed 2.2 g. and melted at 141–145°. A mixed melting point with known *p*-nitroaniline showed no depression.

One gram of this product was refluxed with a slight excess of acetic anhydride for fifteen minutes. The *p*-nitroacetanilide, recovered by dilution with water, melted at 203–207°. The melting point of *p*-nitroacetanilide is given as 207–210°.

The lower melting fractions which remained after separating the pure *p*-nitrodimesulfonanilide could not be separated into pure substances by further crystallizations. No simple or accurate method of analysis was available but by the following methods it was possible to show that some meta- and some ortho-nitrodimesulfonanilide were formed in the nitration.

Two grams of fraction (II) was hydrolyzed with 50% sulfuric acid. This reaction mixture was then diluted, neutralized with sodium hydroxide solution, and steam distilled. Two liters of distillate were collected. Each portion of distillate was extracted with ether. Fraction (VI), recovered from the first liter of distillate as a residue when the ether was evaporated, weighed 0.1 g. and melted at 80–90°. Fraction (VII), recovered in the same manner from the second liter, weighed 0.2 g. and melted at 90–110°. The residue remaining in the distilling flask was also extracted with ether to yield fraction (VIII) which weighed 0.4 g. and melted at 135–141°. Fraction (VIII) when mixed with known *p*-nitroaniline melted at 140–145°.

Three grams of fraction (III) was hydrolyzed and the products of hydrolysis were separated as above. Fraction (IX) weighed 0.2 g. and melted at 55–80°. Fraction (X) weighed 0.2 g. and melted at 85–100°. Fraction (XI), recovered from the residue, melted at about 90°. It was recrystallized from alcohol and yielded 0.4 g. of material (fraction (XII)) melting at 127–139°. This was mainly *p*-nitroaniline. Fraction (XIII), recovered from the alcoholic mother liquors, weighed 0.2 g. and melted at 85–95°.

One gram of fraction (IV) was hydrolyzed as described above. It was then extracted with ether. The material recovered from this extract weighed 0.4 g. and melted at 48–80°. This residue was not entirely soluble in dry ether, however. About 0.05 g. was recovered as an insoluble residue, melting above 260°, which burned explosively when held over the Bunsen flame. This product was isolated in only one experiment, and so could not be investigated further. The ether-soluble portion now melted at 48–70°.

Fractions (VI), (VII), (X), and (XIII) were combined and dissolved in 10 cc. of dilute hydrochloric acid. This solution was made slightly alkaline. On long standing, and cooling in an ice-bath, 0.4 g. of material precipitated out as yellow needle-like crystals, melting at 108–112°. A mixed melting point with known *m*-nitroaniline (m. p. 114°) showed no depression.

The *m*-nitroacetanilide was prepared by treatment with acetic anhydride and melted at 147–149°. This checks the melting point reported for *m*-nitroacetanilide.

Fraction (IX) was combined with the low melting product recovered by hydrolysis of fraction (IV). This was placed in a porcelain dish, covered with a watch-glass, and allowed to stand for several days. At the end of this time, 0.1 g. of sublimate was recovered from the watch-glass. This material melted at 65–68°, and melted at 67–70° when mixed with known *o*-nitroaniline.

By this rather complicated method, from 24 g. of nitration product there was recovered 12 g. of substantially pure *p*-nitrodimethanesulfonanilide and 1.25 g.⁷ of *p*-nitroaniline. This corresponds to 61% of the theoretical amount of *p*-nitro isomer.

There was also isolated 1.1 g. of impure *m*-nitroaniline which melted 87–104°. Tingle and Roelker⁴ have found that a mixture of nitroanilines containing 20–22% of the ortho isomer and 80–78% of the meta isomer melts in this range. In calculating the approximate yields of the isomers formed in our experiments, this mixture was assumed to contain 20% of the ortho isomer.

A further fraction of 0.95 g. of a mixture of *o*- and *m*-nitroanilines melting from 60–80° was obtained. The melting point curves indicate that the mixtures of the ortho and meta isomers which melt in this range contain about 40% of the ortho compound. This figure was used in calculating the composition of this fraction.

This indicates that the original nitro derivative contained approximately 13% of meta and 6% of the ortho isomer. These figures represent the minimum amounts of each which must have been formed during the nitration of dimethanesulfonanilide.

Summary

1. The nitration of methanesulfonanilide results in an 80% yield of 2,4-dinitromethanesulfonanilide.
2. The nitration of dimethanesulfonanilide yields a mixture of mononitro derivatives which have been shown to contain at least 61% para, 13% meta and 6% ortho. The estimation of the ortho isomer is the least satisfactory.

⁷ This figure is calculated as the total amount of *p*-nitroaniline and is based on the results of the hydrolysis of an aliquot part of fraction (VI).

3. These results indicate that the directive effect of the monosulfon-amido and disulfonamido groups in the benzene ring is predominantly ortho-para.

THE PREPARATION OF CERTAIN KETO-CHLORIMINES BY THE ACTION OF CHLORINE ON COMPOUNDS OF THE TYPE

BY C. R. HAUSER, H. A. HUMBLE AND G. J. HAUS

RECEIVED FEBRUARY 1, 1932

PUBLISHED JUNE 6, 1932

In connection with a study of ald-chlorimines² we were desirous of obtaining certain keto-chlorimines in order to make a comparative study of these compounds. Several keto-chlorimines previously have been prepared by Peterson³ by a method which involves several steps. Thus, benzophenone was converted into benzophenone dichloride, which in turn was converted, by means of urethan, into the imine hydrochloride. The latter was treated with hypochlorous acid, yielding the chlorimine according to equation (1).

In the hope of developing a shorter method for the preparation of certain keto-chlorimines, it seemed worth while to attempt the chlorination of nitrogen-magnesium compounds of the type $R'R''C=NMgX$,⁴ which may readily be obtained from Grignard reagents and nitriles,⁵ by means of chlorine (2), and of alkyl hypochlorites (3).

Since Durand and Naves⁶ have shown previously that ethyl hypochlorite reacts with the nitrogen-magnesium compound obtained from aniline and ethylmagnesium bromide to yield presumably a chloramine (4), it might

¹ This paper is in part constructed from portions of a thesis presented by G. J. Haus in partial fulfilment of the requirements for the degree of Master of Arts in the Graduate School of Arts and Sciences, Duke University.

² Hauser and Gillaspie, *THIS JOURNAL*, **52**, 4158, 4517 (1930).

³ Peterson, *Am. Chem. J.*, **46**, 325 (1911).

⁴ Since compounds of the type $R'R''C=NMgX$ might be considered as salts of imines ($R'R''C=NH$) and $MgX(OH)$, chlorine might be expected to react with the nitrogen-magnesium linkage under certain conditions. Doubtless other reactions also occur. A discussion of these reactions is withheld pending further investigation.

⁵ Blaise, *Compt. rend.*, **132**, 40 (1901).

⁶ Durand and Naves, *Bull. soc. chim.*, **37**, 717 (1925).

be expected that under certain conditions a chlorimine could be prepared according to equation (3). In this work *tert.*-butyl and *tert.*-amyl hypochlorites have been used since these are far more stable than either primary or secondary hypochlorites.⁷

It has been found that when diphenylmethylene-iminemagnesium bromide, obtained from phenylmagnesium bromide and benzonitrile, is treated with an equivalent quantity of chlorine or tertiary alkyl hypochlorite, an orange-red color develops and, after filtering and removing the ether, a red product is obtained which apparently contains about 60% of benzophenone chloramine as calculated from its active chlorine content. The pure chlorimine has not yet been isolated but its presence is further indicated by the fact that when the crude product in ether or benzene solution is treated with dry hydrogen chloride, a precipitate is obtained, which, presumably, is benzophenone-imine hydrochloride,⁸ since benzophenone is obtained on hydrolysis.

The action of chlorine on the nitrogen-magnesium compound obtained from phenylmagnesium bromide and *p*-chlorobenzonitrile yields *p*-chlorobenzophenone chlorimine, which has a melting point of 104°, agreeing with that of the higher melting stereoisomer obtained by Peterson.³ None of the lower melting stereoisomer has been found.

The action of chlorine on the nitrogen-magnesium compound obtained from *p*-chlorophenylmagnesium bromide and *p*-chlorobenzonitrile yields *p,p'*-dichlorobenzophenone chlorimine.

Further work is in progress.

Experimental

Preparation of Tert.-Butyl and Tert.-Amyl Hypochlorites.—These hypochlorites were prepared by the method of Chattaway and Brackenberg.⁷ The tertiary alcohol (1 mol) was added to a strong solution of sodium hydroxide (2 mols) and the resulting mixture diluted with water until a clear, homogeneous solution was obtained. After transferring to a brown bottle, the solution was cooled in an ice-bath and chlorine passed in as long as it was freely absorbed. The alkyl hypochlorite collected on the surface as a yellow oil and, after separating, was dried quickly with three successive portions of calcium chloride by shaking with the latter for a few seconds and then pouring the hypochlorite onto fresh calcium chloride, keeping the substance cold throughout the procedure. Eastman's *tert.*-butyl and *tert.*-amyl alcohols were used in this work. It was found that practical *tert.*-butyl alcohol gave a hypochlorite which decomposed within a short time.

Preparation of Nitrogen-Magnesium Compounds of the Type $R'R''C=NMgX$.—These compounds were prepared by Blaise's method.⁵ The calculated amount of nitrile dissolved in ether was added to an ether solution of a Grignard reagent and the mixture warmed to complete the reaction. In our first experiments the amount of nitrile used

⁷ Chattaway and Brackenberg, *J. Chem. Soc.*, **123**, 3000 (1923).

⁸ Peterson has converted this imine hydrochloride into the chlorimine by means of hypochlorous acid (see eq. (1)).

was calculated by assuming a 75% yield of the Grignard reagent, but generally the reagent was analyzed by the acid titration method,⁹ and the calculated amount of nitrile added, assuming that the substances react mole for mole. Sufficient Grignard reagent was always prepared so that one-eighth to one-quarter mole quantities of the nitrile were required in the preparation of the nitrogen-magnesium compound. The latter, which partially precipitated from the ether solution (volume about 150 to 300 cc.), was generally chlorinated as a suspension in this solvent, avoiding excess chlorine. In a few cases when the ether was first evaporated and benzene added, practically the same results were obtained.

Reaction of Tert.-alkyl Hypochlorites and of Chlorine with the Compound $(C_6H_5)_2C=NMgBr$.—To a suspension in ether of the nitrogen-magnesium compound, obtained from phenylmagnesium bromide and benzonitrile, was added slowly with shaking an equivalent¹⁰ amount of cold ether solution of *tert.*-butyl or amyl hypochlorite, cooling the reaction mixture in an ice-bath throughout the procedure. An orange-red color developed. After shaking vigorously for several minutes¹¹ the mixture was rapidly filtered with suction and the ether solution allowed to evaporate or distilled from a water-bath. A red oily residue with only a slight odor was obtained which was found to contain 10 to 11% of active chlorine. Calculated from its active chlorine content¹² the product contained more than 60% of benzophenone chlorimine. Yields were generally about 50% of crude product or about 30% of the chlorimine calculated from the benzonitrile used.

Similar results were obtained when the nitrogen-magnesium compound suspended in ether or benzene was treated with an equivalent of chlorine instead of the hypochlorite as described above. No hydrogen chloride was observed. After filtering rapidly the solvent was evaporated under vacuum by drawing the air through a calcium chloride drying tower. It had been found that when the red ether solution of the crude chlorimine was shaken with cold dilute sodium hydroxide, a yellow emulsion was produced which finally separated into two yellow layers. When the ether layer was dried and evaporated a lighter colored oily residue was obtained which contained about 10% of active chlorine; when the alkaline layer was acidified a few drops of red oil separated, which is being further studied.

Attempts thus far to obtain the pure chlorimine¹³ by recrystallization of the crude products, obtained by both methods described above, have been unsuccessful. Oils which contained a slightly higher percentage of active chlorine and small quantities of crystals which contained no active chlorine were obtained.

A portion of the crude chlorimine (5 g.) in ether (100 cc.) was shaken with dilute sulfuric acid, then washed with water, shaken with dilute potassium hydroxide and again washed with water. After drying by shaking with calcium chloride in the cold, the

¹⁰ The amount of hypochlorite used was equivalent to the amount of benzonitrile employed in the preparation of the nitrogen-magnesium compound.

¹¹ In several cases when the reaction mixture was allowed to stand at room temperature for several hours before filtering, practically the same results were obtained.

¹² The analysis for active chlorine was carried out by dissolving a sample in acetic acid, adding potassium iodide, and titrating with sodium thiosulfate, or by the method recently used for ald-chlorimines.²

¹³ Benzophenone chlorimine (m. p. 37°) has been prepared by Peterson.³ Since we were especially desirous of obtaining the chloro substituted chlorimines described in this paper, no further attempt has been made to isolate benzophenone chlorimine.

ethereal solution was saturated with dry hydrogen chloride. A precipitate was obtained which when warmed with water yielded benzophenone. When repeated without extracting with acid and alkali, similar results were obtained. When the acid extract, which had been separated from the ether solution of the crude chlorimine described above, was made alkaline, a trace of an organic solid was obtained, and when the alkaline extract was acidified, a small amount of red oil was obtained.

Preparation of *p*-Chlorobenzophenone Chlorimine.—To a suspension in ether of the nitrogen-magnesium compound, obtained from phenylmagnesium bromide and *p*-chlorobenzonitrile, was added slowly with shaking the calculated amount of chlorine, keeping the mixture cold throughout the procedure. An orange-red color developed, being the darkest when approximately the calculated amount of chlorine had been added. After shaking vigorously, the mixture was filtered rapidly with suction and the ether solution either evaporated directly or first extracted with dilute sodium hydroxide, dried rapidly with calcium chloride, and then evaporated using a drying tower as described above. If the extraction with alkali is carried out carefully by shaking just sufficiently to remove the red color and yet not produce a heavy emulsion, the crude chlorimine obtained by the evaporation of the ether is generally a purer product having a lighter color, but the yield is smaller. The yield of chlorimine calculated from the nitrile used in the preparation of the nitrogen-magnesium compound was about 32% as calculated from the active chlorine content of the crude product. Two recrystallizations from ligroin or chloroform yielded white crystals melting at 104°, agreeing with the melting point of the higher melting stereoisomer obtained by Peterson.³ Analysis for active chlorine gave the following result.

Anal. Calcd. for $\text{ClC}_6\text{H}_4\cdot\text{C}_6\text{H}_5\text{C}=\text{NCl}$: Cl, 14.18. Found: Cl, 14.13.

An attempt was made to isolate a stereoisomer by following the procedure by which Peterson³ isolated an isomer melting at 56°, but when a chloroform–ligroin solution of the product, from which a portion of the higher melting isomer had been separated, was cooled to –12°, more of the same isomer was obtained, and even after evaporating almost all of the solvent the substance obtained melted above 100°. None of the lower melting isomer was found. Since the precipitate obtained by filtering the ethereal reaction mixture yielded *p*-chlorobenzophenone when treated with acid, it appeared as if some of the suspension of the nitrogen-magnesium compound had not reacted with the chlorine, yet when a portion of this same precipitate was again suspended in ether or benzene and treated with more chlorine, only a small additional amount of product was obtained which contained active chlorine. When the preparation was carried out using sufficient ether to keep the nitrogen-magnesium compound in solution, about the same yield of chlorimine was obtained.

Preparation of *p,p'*-Dichlorobenzophenone Chlorimine.—The nitrogen-magnesium compound obtained from *p*-chlorophenylmagnesium bromide and *p*-chlorobenzonitrile was treated with chlorine as described in the preparation of *p*-chlorobenzophenone chlorimine. An orange color developed which, after filtering, was not entirely removed from the ether solution of the chlorimine by shaking carefully with dilute sodium hydroxide. When the ether was evaporated a red residue was obtained. When the latter was treated with hot ligroin, most of the red material dissolved, leaving a slightly colored crystalline solid, and when the ligroin solution was cooled, more of the slightly colored crystalline solid was obtained. After recrystallization from hot ligroin an analysis showed that the substance contained 11.86% of active chlorine; the theoretical amount, calculated for *p*-dichlorobenzophenone chlorimine, is 12.47% active chlorine. The yield was about 35–40% calculated from the nitrile used for the preparation of the nitrogen-magnesium compound. Further recrystallization from ligroin yielded white prisms, melting at 74° and containing 12.05, 12.06% active chlorine.

Summary

1. Certain keto-chlorimines have been prepared by the action of chlorine on nitrogen-magnesium compounds of the type $R'R''C=NMgX$, which may readily be obtained from Grignard reagents and nitriles.

2. The action of chlorine on the nitrogen-magnesium compound obtained from phenylmagnesium bromide and *p*-chlorobenzonitrile yields *p*-chlorobenzophenone chlorimine, m. p. 104° . No stereoisomer has been isolated.

3. The action of chlorine on the nitrogen-magnesium compound obtained from *p*-chlorophenylmagnesium bromide and *p*-chlorobenzonitrile yields *p,p'*-dichlorobenzophenone chlorimine, m. p. 74° .

POLYMERIZATION OF DIOLEFINS WITH OLEFINS. I. ISOPRENE AND PENTENE-2

BY CHAS. ALLEN THOMAS AND WM. H. CARMODY

RECEIVED FEBRUARY 2, 1932

PUBLISHED JUNE 6, 1932

When anhydrous aluminum chloride is placed with pure isoprene in which there is no appreciable amount of olefin present, and the mixture shaken, there is no temperature rise or any other obvious chemical reaction even when a considerable portion of anhydrous aluminum chloride has been added. Upon prolonged standing slow polymerization takes place, producing mainly the insoluble polymer described below. If to this mixture a small amount of olefin, such as pentene-2 or trimethylethylene, is added and the mixture shaken, an obvious reaction starts immediately which becomes violent if much of the olefin has been added, and unless the mixture is cooled the products will soon boil away. This interesting reaction, some phases of which were also observed and discussed by Aschan,¹ has led to the following investigation.

If an equimolar mixture of isoprene and pentene-2 or trimethylethylene is diluted with an inert hydrocarbon solvent and the mixture cooled with constant stirring, there can be added portion-wise small amounts of anhydrous aluminum chloride. After several hours a point is reached where there is no more evolution of heat. From the reaction mixture there is obtained, after decomposition of the aluminum chloride complex, two organic polymers, one soluble, the other insoluble in hydrocarbon solvents.

Soluble Polymer.—This polymer ranges from a viscous oil to a hard resin, depending upon the proportions of the olefin and diolefin employed and the subsequent treatment to which the product is subjected. The

¹ Aschan, *Chem. Abstracts*, **14**, 3823 (1916); *Ofversigt Finska Vetenskaps Soc.*, **58**, 42 (1916).

product consists of a mixture of higher oils and a hydrocarbon resin, the hardness depending upon the amount of oils removed. The color of the resin ranges from light straw to dark brown, the darker color resulting from elevated or prolonged heating in removing the associated oils. If low boiling inert solvents are used, such as hexane, a harder resin can be obtained with less heating as the solvent can be taken off at a lower temperature and its high vapor pressure helps to distil the associated oils. The resin is soluble in most hydrocarbon solvents such as gasoline, benzene, toluene, chlorinated hydrocarbon solvents, and drying oils such as linseed and china wood oil. It is virtually insoluble in ethyl and methyl alcohol and acetone and can be precipitated out of the hydrocarbon solution by them. It is also difficultly soluble in ethyl acetate but appreciably soluble in the higher acetates such as butyl and amyl. It has been found that when this resin polymer is exposed in a thin film to air it slowly oxidizes, becoming harder upon oxidation. A thin film was obtained by flowing on a glass plate a solution of the resin polymer in benzene and allowing the solvent to evaporate, and the iodine and acid numbers of portions of the film were taken and recorded daily. Initially the iodine value was 202 and the acid value 0.4, but after twenty-seven days the iodine value had irregularly fallen to 136 and the acid number risen to 16. After this apparently an equilibrium was reached and the polymer did not change appreciably. Ozone is absorbed rapidly at first when bubbled through a solution of this polymer in carbon tetrachloride, the absorption slowing down and finally stopping, yet the iodine number of the solution in some cases was as high as 140. If the carbon tetrachloride is distilled off there remains a brittle amorphous yellow solid which is now insoluble in carbon tetrachloride. This indicates that further polymerization has taken place during the heating to remove the solvent.

Insoluble Polymer.—This polymer occurring with the residue filtered from a solution of the above-described soluble polymer is freed from inorganic matter by repeatedly digesting and washing with 10% hydrochloric acid and water. There remains on drying at low temperatures, a white, granular organic polymer which by combustion was proved to conform to the formula $(C_8H_8)_x$. No molecular weight has yet been determined, as this polymer is characterized by its extreme insolubility, having been found insoluble in the solvents tried, with the exception of nitrobenzene and some of the higher amines in which it is only very slightly soluble. Strong acids decompose the product and phenols react giving a reddish-violet coloration with decomposition. This polymer begins to depolymerize when heated to around 116° . It first contracts, becoming more spongy and rubbery, and changes to a tan or brown color with small globules of oil being formed. On continuing the heating to 299° the whole mass begins to fuse and slowly changes to a dark heavy oil with some foaming which on cooling

solidifies to a transparent dark resin which is soluble in most hydrocarbon and chlorinated hydrocarbon solvents.

By varying the amounts of olefin polymerized with the isoprene, under the conditions recorded below, various amounts of the two polymers can be obtained as shown in Fig. 1, in which pure pentene-2 was polymerized in varying molar amounts with a mole of isoprene. The ordinates of the

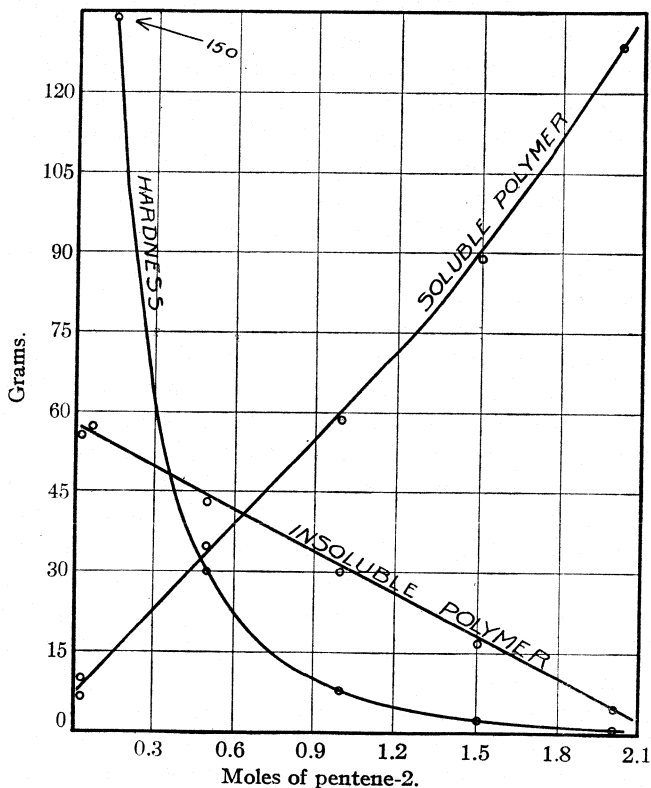

Fig. 1.—Yield of soluble and insoluble polymers formed when pentene-2 is varied, keeping isoprene constant at 1 mole. Variation in hardness of soluble polymer.

curve marked "Soluble Polymer" show the increase in grams of this polymer proportional to the pentene-2 used up to two moles, while the curve "Insoluble Polymer" shows the reverse relationship. When pentene-2 alone is polymerized with anhydrous aluminum chloride, no insoluble polymer is obtained, the product being an oil consisting of the various polymers of the olefin.² It appears therefore that the "Insoluble Polymer" curve approaches zero as a limit. The hardness of the soluble polymer is shown by

² F. W. Sullivan, Jr., V. Voorhees, A. W. Neeley and R. V. Shankland, *Ind. Eng. Chem.*, **23**, 604-611 (1931).

the lower curve, the ordinates of which are the reciprocals of the penetration value as measured by the A. S. T. M. penetration apparatus at 0° and 200 g. for sixty seconds, multiplied by 150. As can be seen, the hardness of the polymer rapidly decreases with the amount of pentene-2 in the mix. The product with two moles of the olefin is a heavy oil at the arbitrary end-point of hardening at 190°. By heating the product to a higher temperature or placing it under a vacuum, more of the oils can be distilled off, the polymer likewise being harder. However, if the temperature is taken too high, depolymerization starts as in the case of the insoluble polymer.

In this work no isoprene could be obtained which did not contain a small amount of olefin, so it is not known whether chemically pure isoprene polymerized under the prescribed conditions would give zero amount of soluble polymer. If this is the case, the whole "Soluble Polymer" curve would move down as the same isoprene was used for all points. The molecular weights on these soluble polymers vary from 845 to 1240 depending on the amount of lower polymers distilled from the resin. In general the more olefin present in the mixture, the lower the molecular weight. Likewise the combustions vary, the greater the amount of lower polymers removed, the closer the formula approaches to $(C_5H_8)_x$. Other diolefins and olefins give this characteristic reaction, the mechanism of which will be discussed in a later paper.

Experimental Procedure

The isoprene used was obtained by the destructive distillation of rubber, and the pentene-2 by dehydrating methylpropylcarbinol. The solvent was a paraffin hydrocarbon, boiling range 95–135°.

The mixture of isoprene, pentene-2 and solvent was carefully measured into a vessel equipped with a good agitator and cooled to 1°. At suitable intervals, depending on the temperature rise, approximately 0.8-g. portions of aluminum chloride were poured into the agitated mixture. When the reaction was nearly completed the catalyst was added in larger quantities, the temperature varying from 1 to 4°. The amount of aluminum chloride used was proportional to the isoprene and pentene-2 in the mix, 0.2 and 0.1 mole of aluminum chloride being used per mole of isoprene and pentene-2, respectively. The reaction mixture was agitated for twelve hours, after which an alcohol-aqueous ammonia mixture was used for neutralization and precipitation of the catalyst and insoluble polymer. The products were separated by filtration. The precipitate after digestion with 10% hydrochloric acid was washed well with water, dried and weighed. The filtrate was evaporated to recover the soluble polymer. When reduced to a small volume the solution was heated in an electric furnace at a uniform temperature of 190° for forty-five minutes.

Summary

1. Isoprene and pentene-2 react in the presence of anhydrous aluminum chloride to form two polymers, one insoluble, the other soluble in hydrocarbon solvents.
2. The amount of the soluble polymer formed is a function of the pentene-2 present. The hardness is an inverse function of the amount of pentene-2 present.
3. The amount of the insoluble polymer is an inverse function of the pentene-2 present.

ALKAMINE ESTERS OF AROMATIC ACIDS: NOVOCAINE ANALOGS. II¹

BY HARVEY C. BRILL

RECEIVED FEBRUARY 5, 1932

PUBLISHED JUNE 6, 1932

A search of the chemical literature relating to the novocaine type of anesthetic reveals very few compounds of the type $-\text{O}(\text{CH}_2)_n\text{N}^{\text{x}}_{\text{y}}$. A small number² have been made by comparison with the number of the type with identical substituents.

The difficulty of preparing secondary amines with dissimilar alkyl groups appears to have inhibited the investigative curiosity of workers in this field.

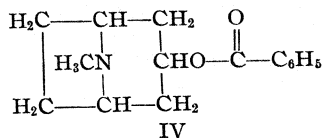

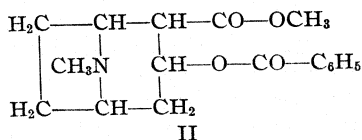

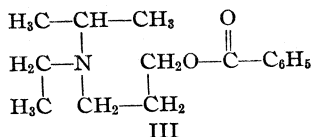

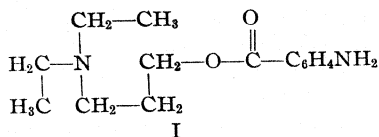

A study of the effects on the properties of the novocaine class of compounds of groups of this sort seemed worth while when the influence of such arrangements in the properties of the barbituric acid type of hypnotics, *e. g.*, Ipral, Amytal, Luminal, etc., is considered. In the absence of any considerable number of trustworthy generalizations that relate chemical

¹ Brill, *THIS JOURNAL*, **47**, 1134 (1925).

² (a) Volwiler and Adams, U. S. Patent 1,476,934 (Dec. 11, 1923), have made γ -butylallyl, γ -*n*-propylallyl, γ -isopropylallyl and γ -isoamylallylaminopropyl esters of benzoic acid; (b) v. Braun and Kirschbaum, *Ber.*, **52**, 2011 (1919), described a phenyl analog of novocaine, namely, the β -*p*-aminophenylmethylaminoethyl ester of *p*-aminobenzoic acid; (c) v. Braun and Braunsdorf, *ibid.*, **54**, 208 (1921), listed β -ethylallyl, β -ethylstyryl and β -ethylfuromethylaminoethyl esters of *p*-aminobenzoic acid; (d) Thorp has patented the hydrochloride of the benzoic ester of 1-methylethylamino-3-methylethylamino-2-hydroxypropane, U. S. Patent 1,193,649 (Aug., 1916). These compounds are reported to possess anesthetic properties.

structure and physiological activity, the only means of learning of the effects of such relationships is to prepare compounds of slight structural differences and study the effects of such changes.

Kamm³ has made the γ -diethylaminopropyl ester of *p*-aminobenzoic acid (I) and pointed out its structural similarity to cocaine (II). The structural resemblance between cocaine and γ -isopropylethylaminopropyl benzoate (III) appears more striking than between the pair pointed out by Kamm. This resemblance is really still more pronounced between (III) and tropacocaine (IV).

If close similarity of structures between anesthetics of the novocaine type and cocaine or tropacocaine is conducive to high anesthetic activity, it should be worth while to study γ -isopropylethylaminopropyl benzoate. The hydrochloride of this ester in water solution is acid to litmus, and would be somewhat irritating to the tissues on this account. Such compounds are improved in their effects by lowering their acidity by the introduction of an amino group in the aromatic radical or by forming salts with acids that are weaker than hydrochloric or sulfuric.⁴ Even when an aromatic group is substituted for one of the substituent alkyls in the amino, v. Braun and Kirschbaum^{2b} found that these compounds possessed marked anesthetic properties, provided they were made basic by the introduction of amino groups. When the acidity is allowed to rise, however, the compound becomes irritating, as is evidenced by the properties of β -phenylethylaminoethyl benzoate, which has a numbing effect but is pepper-like in its irritation on the tongue.

Experimental Part

The hydrochlorides of these anesthetic compounds can be made readily by condensing a benzene solution of the acid chloride taken in about 10% excess of the theoretical amount with a benzene solution of the theoretical quantity of the amino alcohol. The reaction is completed by occasionally shaking and warming on a steam-bath under a reflux for several hours. White crystalline precipitates form during the heating or immediately on cooling.

³ Kamm, *THIS JOURNAL*, **42**, 1030 (1920).

⁴ Pope, British Patent 260,346 (July, 1925), preparation of borocaines; Watson Williams, *Lancet*, **1**, 16 (1926); Copeland and Notton, *Brit. Med. J.*, **11**, 547 (1925).

The mixed secondary amines are most readily prepared in the pure state by alkylating the mono-alkyl aniline by means of the alkyl halide under a reflux, warming for one to five hours on a steam-bath to complete the reaction. The salt of this tertiary amine that results precipitates as a solid mesh of crystals or as a thick gelatinous paste in the case of the higher alkyls. It is dissolved in 12% hydrochloric acid solution, nitrosated at low temperature in the presence of ice with energetic stirring and the secondary amine released by the use of sodium hydroxide and steam distillation in the regular manner as described by Vanino and other laboratory manuals. No attempts were made to separate the nitroso derivative. Yields of these secondary amines ranged from 35 to 73% of the theoretical. The low yields are obtained with the low molecular weight alkyl halides and the higher molecular weight members, hexyl halide and above. To obtain high yields the former should be condensed in a closed vessel to prevent loss through volatilization of the halide, while the high molecular weight members react too slowly to give high yields before appreciable decomposition takes its toll.

The Tertiary Amines.—The dialkyl amino alcohols were made by condensation on the steam-bath of the secondary amine with 20% excess over the equivalent amount of the chlorohydrin. The tertiary base is set free, removed from the water solution by ether extraction, dried by means of anhydrous sodium sulfate and recovered by careful fractional distillation. The use of reduced pressure lessens the decomposition and increases the yields.

SYNTHESES WITH TRIARYLVINYLMAGNESIUM BROMIDES. TRIARYLACRYLIC ACIDS AND THE INDONES DERIVED FROM THEM

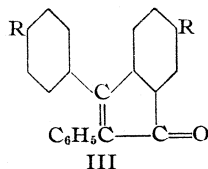

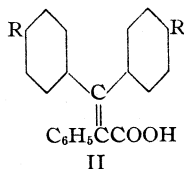

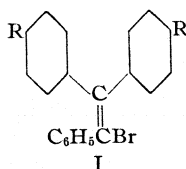

By C. FREDERICK KOELSCH¹

RECEIVED FEBRUARY 6, 1932

PUBLISHED JUNE 6, 1932

It has been shown recently² that triphenylvinyl bromide reacts with magnesium to form a Grignard reagent which can be carbonated to give triphenylacrylic acid. The present paper describes the results obtained in similar reactions where certain substituted triphenylvinyl bromides were used.

Two disubstituted triphenylvinyl bromides were studied: α -phenyl- β , β -di-*p*-tolylvinyl bromide (I, R = CH₃) and α -phenyl- β , β -di-*p*-anisylvinyl bromide (I, R = OCH₃). Both of these compounds reacted with magnesium to form Grignard reagents which on carbonation yielded the correspondingly substituted acrylic acids (II). The elimination of water from these acids led to the formation of 6-methyl-2-phenyl-3-*p*-tolylindone (III, R = CH₃) and of 3-*p*-anisyl-6-methoxy-2-phenylindone (III, R = OCH₃).

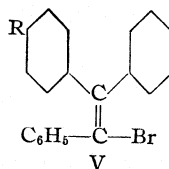

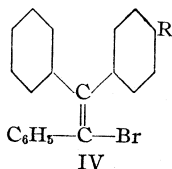

While all monosubstituted triphenylvinyl bromides having the substituent in one of the β -phenyl groups should exist in two stereoisomeric forms, the isolation of both of these forms was accomplished in only one of three cases studied. α , β -Diphenyl- β -*p*-chlorophenylvinyl bromide was obtained in the *cis* form (IV, R = Cl) and in the *trans* form (V, R = Cl); only the *cis* form of α , β -diphenyl- β -*p*-tolylvinyl bromide (IV, R = CH₃),

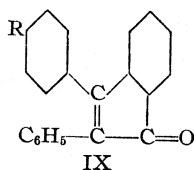

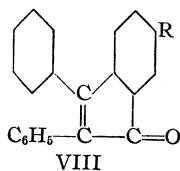

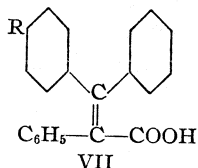

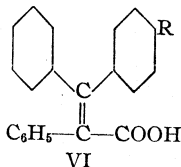

¹ National Research Fellow in Chemistry.

² Koelsch, THIS JOURNAL, 54, 2045 (1932).

and only the *trans* form of α,β -diphenyl- β -*p*-anisylvinyl bromide (V, R = OCH₃) could be isolated.

These bromides all reacted readily with magnesium to form Grignard reagents whose subsequent carbonation gave triarylacrylic acids. α,β -Diphenyl- β -*p*-tolylvinylmagnesium bromide gave one acid, *cis*- α,β -diphenyl- β -*p*-tolylacrylic acid (VI, R = CH₃). α,β -Diphenyl- β -*p*-anisylvinylmagnesium bromide gave a mixture of *cis*- α,β -diphenyl- β -*p*-anisylacrylic acid (VI, R = OCH₃) and the corresponding *trans* acid (VII, R = OCH₃) in the ratio of about one part of the *cis* to seven parts of the *trans* compound. The Grignard reagent from *cis*- α,β -diphenyl- β -*p*-chlorophenylvinyl bromide gave a mixture of *cis* and *trans* α,β -diphenyl- β -*p*-chlorophenylacrylic acids in which the *cis* acid (VI, R = Cl) greatly predominated; the Grignard reagent from the isomeric *trans* bromide gave a similar mixture of which *trans*- α,β -diphenyl- β -*p*-chlorophenylacrylic acid (VII, R = Cl) was the more abundant constituent.

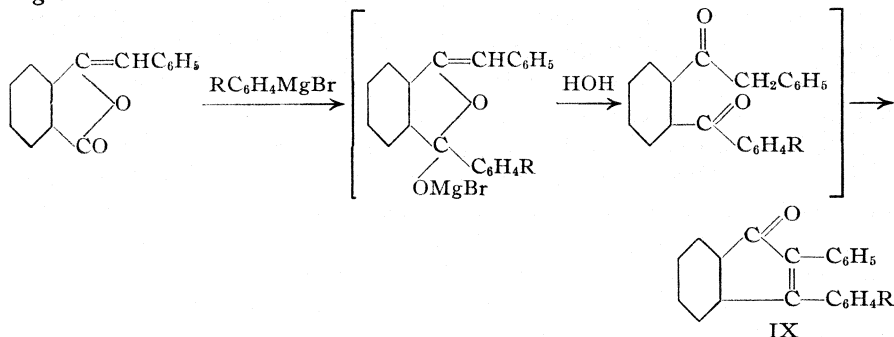

In determining the steric relationship of the phenyl groups in these triarylacrylic acids, *i. e.*, in assigning them to the *cis* or *trans* series, use was made of their ring closure to indones. It is apparent from an inspection of their formulas that a *cis* acid (VI) will give a 6-substituted-2,3-diphenylindone (VIII), while a *trans* acid (VII) will give a 3-*p*-substituted-phenyl-2-phenylindone (IX).

Thionyl chloride in carbon tetrachloride was found to be an ideal reagent for bringing about this ring closure, in that by its use the high temperature (200°) necessary when zinc chloride is employed³ was avoided. Such a high temperature has been shown to bring about isomerization of

³ Meyer and Weil, *Ber.*, **30**, 1284 (1897).

certain substituted cinnamic acids.⁴ Sulfuric acid, which has been used for the preparation of 2,3-diphenylindone from triphenylacrylic acid,⁵ was found to be unusable because of its destructive action toward the methoxylated acids. Under the conditions developed for carrying out the reaction with thionyl chloride, a pure triarylacrylic acid gave practically the theoretical yield of a pure indone, pointing to the absence of rearrangement.

One of each pair of structurally isomeric indones corresponding to one of each pair of stereoisomeric triarylacrylic acids was synthesized according to the reactions⁶

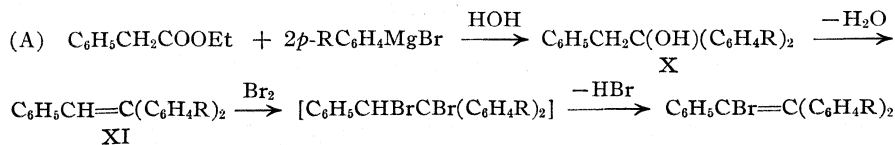

After the structure of one of the isomeric indones had been determined by this synthesis, that of the other was assigned by elimination.

The assignment of *cis* and *trans* structures to the triarylvinyl bromides rests on grounds less secure than those underlying the assignment of these structures to the triarylacrylic acids. To give structures to the bromides, it was necessary to assume that no "inversion" had taken place during two reactions, each of which involved the replacement of an atom or group whose presence was responsible for the isomerism. Such an assumption appears to be little warranted, especially since it is here shown that *some* "inversion" at least occurred in the synthesis of α,β -diphenyl- β -*p*-chlorophenylacrylic acid and of α,β -diphenyl- β -*p*-anisylacrylic acid. In the present paper, the prefixes *cis* and *trans* have been applied to the bromides mainly for convenience in nomenclature.

Experimental

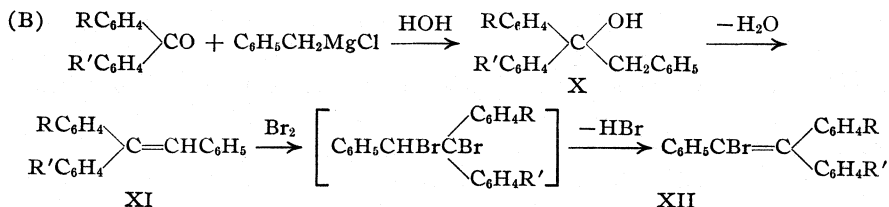

Two methods are available for the preparation of triarylvinyl bromides

⁴ Stoermer and Voht, *Ann.*, **409**, 40, 53 (1915).

⁵ Weitz and Scheffer, *Ber.*, **54**, 2341 (1921).

⁶ Löwenbein and Ulich, *ibid.*, **58**, 2662 (1925); Weiss and Sauermann, *ibid.*, p. 2736.

While method (A) is applicable to the synthesis of only disubstituted compounds and was used to prepare only α -phenyl- β , β -di-*p*-anisylvinyl bromide, method (B) is of general application and was used for the preparation of the other bromides described in this paper (XII, R = R' = CH₃; or R' = H and R = CH₃, OCH₃, or Cl). The yields in all reactions involved in either method were usually over 90%.

The Carbinols (X). Table I.—In order to isolate the carbinols, it was necessary to decompose the intermediate ROMgX compounds with ammonium chloride solution and to exclude mineral acids, which readily effect the elimination of water. The carbinols may be converted directly into the bromides by treating their 30% solutions in acetic acid with a slight excess of a 40–50% solution of bromine in acetic acid. They were recrystallized from ethanol containing a little ammonia.

TABLE I
THE CARBINOLS

()-ethanol	M. p., °C.	Formula	Analyses

<i>trans</i> - β - <i>p</i> -Chlorophenyl- α,β -diphenyl-	103–105	C ₂₀ H ₁₄ ClBr	65.0	3.79	64.6	3.54

Extended fractional crystallization of α,β -diphenyl- β -*p*-anisylvinyl bromide and of α,β -diphenyl- β -*p*-tolylvinyl bromide from benzene, carbon tetrachloride or acetic acid did not effect a separation of either compound into two forms. In both cases a small amount of low melting substance was obtained from the first mother liquors, but no pure substance could be isolated from this.

Separation of α,β -Diphenyl- β -*p*-chlorophenylvinyl Bromide into *Cis* and *Trans* Forms.—Water was added to the acetic acid solution in which the bromide had been prepared and the crude bromide thus obtained, which slowly solidified, was crystallized from ethanol, in which it is quite difficultly soluble, to remove a small amount of oily impurities. The crystalline mixture (60 g.) was dissolved in 50 ml. of hot benzene, and 50 ml. of methanol was added. On cooling the solution, 27 g. of bromide melting at 155–157° crystallized. This, redissolved in 30 ml. of hot benzene and reprecipitated by the addition of 30 ml. of methanol, gave 25 g. of pure *cis* bromide, m. p. 156–158°. The oily residue left after the removal of the solvents from the combined mother liquors by distillation under reduced pressure was dissolved in 200 ml. of hot ethanol. Cooling this solution gave 27.5 g. of practically pure *trans* bromide, m. p. 100–105°.

Carbonation of the Triarylvinylmagnesium Bromides. The Triarylacrylic Acids. Table IV.—The Grignard reagents were prepared from 10 g. of a bromide, 0.05 ml. of ethyl bromide, a small crystal of iodine, 1.1 equivalents of magnesium and 100 ml. of ether.

The Grignard reagents were carbonated by leading in dry carbon dioxide as long as it was absorbed. Decomposition of the magnesium compounds with dilute sulfuric acid and extraction of the resulting ethereal solutions with dilute sodium carbonate gave aqueous solutions of the sodium salts

of the triarylacrylic acids. From these the organic acids were precipitated with dilute hydrochloric acid. They were recrystallized from acetic acid.

Separation of α,β -Diphenyl- β -*p*-anisylacrylic Acid into *Cis* and *Trans* Forms.—Fractional solution in ether followed by crystallization from acetic acid gave the two forms of this acid. The higher melting *cis* acid is nearly insoluble in ether, while the *trans* acid is readily soluble.

α,β -Diphenyl- β -*p*-chlorophenylacrylic Acids.—The mixture of *cis* and *trans* acids obtained from 10 g. of the pure *cis* (or *trans*) bromide was separated by repeated fractional crystallization from carbon tetrachloride into 3–3.5 g. of *cis* (or *trans*) acid and an approximately equal weight of a mixture of *cis* and *trans* acids (neut. equiv., calcd.: 335; found: 327) which melted at 178–195° and which gave a separable mixture of isomeric chlorodiphenylindones on treatment with thionyl chloride.

α,β -Diphenyl- β -*p*-tolylacrylic Acid.—Despite the unsharp melting point of this acid, the presence of isomers in it could not be demonstrated by repeated fractional crystallizations. Furthermore, the indone obtained from it was homogeneous.

The Indones. Table V.—To a solution of 0.5 g. of a triarylacrylic acid in 2 ml. of dry carbon tetrachloride was added 0.5 ml. of thionyl chloride. The solution was refluxed for four hours, cooled and poured into water. The carbon tetrachloride was expelled by boiling, leaving the indone crystalline and melting only a few degrees lower than the pure compound. Recrystallization from acetic acid gave the pure ketone in a yield of 0.35–0.45 g.

TABLE V
 THE INDONES

No.	()-indone	M. p., °C.	Form	Color ^a

The preparation of 2-phenyl-3-*p*-substituted-phenylindones from benzalophthalide was carried out according to the procedure described in the literature.⁶ Mixed melting points proved the identity of the compounds thus prepared with the appropriate ones obtained from the triarylacrylic acids.

Summary

It has been shown that the formation of Grignard reagents from triarylvinyl bromides is a quite general reaction.

A number of triarylacrylic acids have been prepared from triarylvinylmagnesium bromides, and in the cases where these acids exist in stereoisomeric forms it has been possible to assign structures to the isomers isolated.

The triarylacrylic acids have been found to undergo ring closure to form indones when they are treated with thionyl chloride.

THE STEREOCHEMISTRY OF CARBODIIMIDES. XXII^{1,2}

BY L. J. ROLL AND ROGER ADAMS

RECEIVED FEBRUARY 6, 1932

PUBLISHED JUNE 6, 1932

The preparation of stereoisomeric allenes of Type I (a and b) has been the subject of many investigations from the time van't Hoff first predicted that such compounds should be capable of existing in optically active forms. Somewhat analogous to the allenes is another class of asymmetric molecules, the carbodiimides II (a and b).

On the assumption that the nitrogen atom has a fixed tetrahedral structure, it may be seen that the two substituting R groups are in planes different from those of the C=N linkages and, therefore, a pair of mirror images may exist even though the two R groups in the molecule are the same. If, on the other hand, the R groups may vibrate through the axis common to the N=C=N nucleus, isomerism will disappear whether the R groups are the same or different.

The results of many researches have indicated that trivalent nitrogen compounds of the type $RR'R''N$ can be obtained optically active only with great difficulty or not at all. In fact, as yet no optically active trivalent nitrogen compounds have been isolated and as a consequence it has been assumed that the nitrogen atom in such molecules is probably very mobile and that the three valence bonds and the pair of unshared electrons may vibrate through such positions that optical isomerism will be prevented. On the other hand, *cis-trans* isomerism in the oximes is commonly explained on the assumption of a fixed tetrahedral nitrogen atom. It would follow, therefore, that the lack of mobility of the groups on the nitrogen atom in these molecules is due, presumably, to the presence of C=N. Since double bonds exist in carbodiimides, optical isomerism may be anticipated in this class of compounds.³

¹ For previous paper see White and Adams, *THIS JOURNAL*, **54**, 2104 (1932).

² This communication is an abstract of a portion of a thesis submitted by L. J. Roll in partial fulfillment of the requirements for the degree of Doctor of Philosophy in Chemistry at the University of Illinois.

³ Faltis, Pirsch and Bermann, *Ber.*, **63**, 691 (1931), were unable to obtain stereoisomers of certain allene derivatives and have suggested a different conception of allene linkages which would involve no optical isomerism. Such an argument, though not too convincing, might also be applied to carbodiimides.

In this preliminary investigation an attempt has been made to obtain optically active carbodiimides. The results thus far have been unsuccessful, due to certain inherent properties of these compounds which have introduced difficulties not as yet overcome. Carbodiimides are not only very reactive to reagents such as water, acids, etc., but they polymerize readily merely on standing at room temperature. The possibility of studying an amino or carboxy substituted diphenylcarbodiimide which might be resolved in the usual way was soon eliminated since the carboxy and amino derivatives of diphenyl carbodiimide could not be prepared by the ordinary methods. Even if such compounds could be synthesized, the probability of the formation of the salts and subsequent resolution without decomposition seemed remote. A much more feasible line of attack appeared to be the preparation of a mono- or dicarbo-*l*-menthoxythiocarbanilide which, upon elimination of hydrogen sulfide, should yield a mixture of separable diastereoisomeric carbodiimides. Unfortunately, the resulting reaction mixture after such treatment of monocarbo-*l*-menthoxy carbanilide was an oil which did not solidify but which polymerized gradually on standing. From this experiment it is obvious that the carbodiimide synthesized for the purpose proposed must be of such a character that the monomer is a solid which can be separated and kept in the solid form so as to prevent or greatly diminish the rate of polymerization.

The dicarboethoxy and the monocarboethoxy diphenylcarbodiimides were also oils and the dibromo derivative which has been reported previously in the literature would not solidify at room temperature.

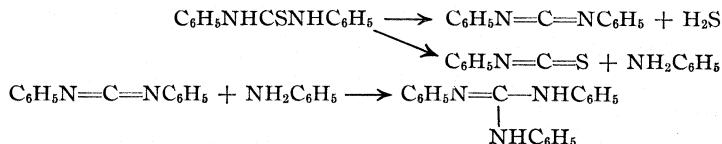

A considerable portion of the time of this preliminary investigation was devoted to the general study of carbodiimides. Without attempting to review in detail the previous literature,⁴ it may be pointed out that diphenylcarbodiimide is an unstable liquid which polymerizes with ease. There appears to be an authentic crystalline tripolymer and a higher amorphous polymer. That two dimers exist also seems probable.

More recently Herzog⁵ has patented what he calls diphenylcarbodiimide resins. He reports a number of reagents for eliminating hydrogen sulfide from thiocarbanilides in order to obtain the carbodiimide from which the polymer may be produced. It is questionable, however, whether Herzog ever obtained resinous carbodiimides.

Chem.*, **53**, 11, 139 (1896); *Ber.*, **27**, 2696 (1894); Short and Smith, *J. Chem. Soc.*, **121**, 1803 (1922).

⁵ Herzog, *Z. angew. Chem.*, **33**, 140 (1920); see also Merz, Weith, *Chem. Zentr.*, **40**, 977, 993 (1869); Hoffmann, *Ann.*, **70**, 148 (1849); Ellis, "Synthetic Resins and Their Plastics," The Chemical Catalog Company, New York, 1923, p. 245.

In this investigation a careful study of the conversion of thiocarbanilide into carbodiimide has indicated that if the temperature during the reaction is much above 80°, not only is diphenylcarbodiimide produced, but simultaneously the thiocarbanilide is broken up into aniline and phenylisothiocyanate. Aniline then immediately reacts with the diphenylcarbodiimide with the formation of triphenylguanidine, which is the main product of the reaction.

Herzog claims to have obtained polymeric diphenyl carbodiimide by heating thiocarbanilide with aniline in the presence of arsenious oxide. Upon repetition of his experiment, however, an excellent yield of triphenylguanidine was produced. Moreover, substitution of the arsenious oxide by cadmium carbonate or mercuric oxide gave consistently the same result. It was noticed, also, that if triphenylguanidine was heated somewhat above its melting point and allowed to cool, a brittle, transparent resin was produced which leaves a hard, transparent film on evaporation of a solution in the usual lacquer solvents. This resin was essentially monomeric in character as shown by molecular weight determinations.

At 80° the only satisfactory reagent for conversion of the thiocarbanilides was mercuric oxide. Under these conditions an excellent yield of monomeric diphenylcarbodiimide was produced which, however, gradually polymerized upon standing. A number of new substituted thiocarbanilides were made but it was found that the elimination of hydrogen sulfide takes place only with great difficulty when certain types of substituents are present. This fact has greatly limited the number of substituted diphenylcarbodiimides which could be prepared and studied.

Experimental

Elimination of Hydrogen Sulfide from Thiocarbanilide with Various Reagents. Triphenylguanidine.—A mixture of 22.8 g. (1 mole) of thiocarbanilide, 13.2 g. of arsenic trioxide (6 moles) and 11 g. (2 moles) of calcium oxide was placed in a 500-cc. flask fitted with a stirrer, thermometer and a reflux condenser. To this was added 75 cc. of dry xylene, then the stirrer was started and heat applied. The reaction mixture was held at 145° for fourteen hours and then filtered hot. From the filtrate a white solid separated. The triphenylguanidine was purified by recrystallization from benzene and then melted at 142–143°. The yield was 10 g. (70%).

By using cadmium carbonate in place of arsenic trioxide, a 48% yield of triphenylguanidine resulted, and with yellow mercuric oxide a 35% yield.

Elimination of Hydrogen Sulfide from Thiocarbanilide. Diphenylcarbodiimide.—By following exactly the procedure just described using yellow mercuric oxide except that benzene was substituted for xylene and the reaction was run at 80° instead of 145°,

diphenylcarbodiimide was produced which boiled at 142° at 5 mm. From 22.8 g. of thiocarbanilide, 8.5 g. of product was obtained. After five or six days the liquid carbodiimide had completely solidified to a product melting at $158-160^{\circ}$. Molecular weight determination indicated the liquid to be monomolecular.

No elimination of hydrogen sulfide took place at 80° when arsenic trioxide was used in place of the mercuric oxide.

Formation of a Resin-like Substance from Triphenylguanidine.—Two grams of triphenylguanidine was heated in a small crucible at 180° for two hours. Upon cooling, an amber-colored, brittle, glass-like solid which melted at $129-137^{\circ}$ resulted. The molecular weight of this product by freezing point in benzene showed it to be 318 as compared with a theoretical of 287 for triphenylguanidine.

This resin, when dissolved in a mixture of benzene, butyl alcohol and ethyl acetate and poured on to a glass surface, yielded a transparent, hard film upon evaporation of the solvent.

***p*-Carbo-*l*-menthoxythiocarbanilide.**—A solution of 6.75 g. of phenyl isothiocyanate and 13.75 g. of menthyl *p*-aminobenzoate in 50 cc. of benzene was refluxed on a steam-bath for twenty hours. Two-thirds of the solvent was then distilled and the product allowed to crystallize. It was purified by crystallizing first from a mixture of benzene and $60-70^{\circ}$ petroleum ether, and then from benzene and finally from alcohol. The yield was 15 g. of a product melting at $124-125^{\circ}$.

Anal. Calcd. for $C_{23}H_{30}O_2N_2S$: N, 6.83. Found: N, 7.43.

***p*-Carbo-*l*-menthoxydiphenylcarbodiimide.**—Sixteen grams of *p*-carbo-*l*-menthoxydiphenylthiourea, 16 g. of yellow mercuric oxide and 10 g. of powdered anhydrous calcium chloride were mixed with 100 cc. of dry benzene and refluxed with stirring for five hours. The cold mixture was filtered and the filtrate warmed on the steam-bath until the solvent was removed. A dark viscous oil was obtained which solidified upon standing overnight to an amorphous mass, insoluble in benzene.

***p,p'*-Dicarboethoxydiphenylcarbodiimide.**—From 22 g. of the *p,p'*-dicarboethoxydiphenylthiourea,⁶ following the same procedure for the preparation of *p*-carbo-*l*-menthoxydiphenylcarbodiimide, there was obtained 17 g. of an amber-colored viscous liquid which on standing at room temperature for about thirty days gradually solidified to a transparent, amber-like solid melting at $78-90^{\circ}$.

Anal. Calcd. for $C_{19}H_{18}O_4N_2$: N, 8.28. Found: N, 8.48.

Symmetrical Tri-(*p*-carboethoxy-phenyl)-guanidine.—A mixture of 11 g. of *p,p'*-dicarboethoxydiphenylthiourea, 13 g. of yellow mercuric oxide and 4 g. of powdered calcium oxide was placed in a 500-cc. flask fitted with a thermometer, mechanical stirrer and reflux condenser. Seventy-five cc. of dry xylene was added, heat applied and the reaction mixture stirred. After four hours at 135° , the solution was filtered while hot and the filtrate concentrated to 20 cc. The white precipitate which formed upon cooling was crystallized from a mixture of pyridine and petroleum ether. The product melted at $170-171^{\circ}$. The yield was 4 g.

Anal. Calcd. for $C_{25}H_{23}N_3O_6$: C, 65.73; H, 4.99. Found: C, 65.01; H, 5.18.

***p,p'*-Dibromodiphenylcarbodiimide.**⁷—The *p,p'*-dibromodiphenylthiourea was made according to the procedure of Fry and treated according to the previously described procedure with mercuric oxide and calcium chloride in dry benzene. A dark, viscous residue was obtained which distilled under diminished pressure at $208-212^{\circ}$ at 4 mm. Upon standing, this viscous distillate gradually solidified to a resin-like solid.

⁶ Fry, THIS JOURNAL, **35**, 1539 (1913).

⁷ Ingold, J. Chem. Soc., **125**, 101 (1924).

Summary

1. The structural relationship of allenes and diaryl carbodiimides has been pointed out and a method for proving the asymmetry of the carbodiimide proposed.

2. Experiments on the preparation of various carbodiimides have been described and the difficulties in the study of these substances pointed out.

INVESTIGATIONS ON THE STEREOISOMERISM OF UNSATURATED COMPOUNDS. I. THE COMPOSITION OF CROTONALDEHYDE

BY WILLIAM G. YOUNG¹

RECEIVED FEBRUARY 8, 1932

PUBLISHED JUNE 6, 1932

The program of research undertaken includes a study of the physical and chemical properties of a series of aliphatic hydrocarbons containing conjugated systems of double bonds. Since these compounds may occur in several stereoisomeric forms, it is necessary to isolate the individual isomers in order to obtain reliable physico-chemical measurements. Such procedure will enable one to determine the influence of the configuration of the individual double bonds on the physical and chemical properties of these hydrocarbons.

The keynote in this work is purity of materials. For this reason the separation of isomeric mixtures by fractional distillation was avoided because of the inherent difficulties.² Instead of this, the author is studying methods of synthesis which will lead to the production of pure isomers, the first of which is *trans,trans,trans*-dimethylhexatriene. To do this, one must know the configuration of the starting materials as well as the intermediate compounds.

One of the starting materials investigated is the so-called crotonaldehyde which is commonly obtained from aldol. This material might be a mixture of *cis*- and *trans*-crotonaldehydes and vinyl acetaldehyde. If this is the case the resulting hexatriene might be a mixture of as many as eight different isomeric hydrocarbons. Therefore a quantitative study of ordinary crotonaldehyde³ was undertaken by several different methods. The first re-

¹ The experimental part of this work was completed while the author was a National Research Fellow in Chemistry at Stanford University. This paper was presented at the Pasadena meeting of the American Association for the Advancement of Science, June 19, 1931. Original manuscript received June 29, 1931.

² Lucas, Dillon and Young, *THIS JOURNAL*, **52**, 1949 (1930).

³ Commercial crotonaldehyde was obtained from one manufacturer in order to ensure an unlimited supply of material of constant composition.

sults are presented in this article, namely, oxidation with oxygen and with silver oxide.

Previous Investigations on the Composition of Crotonaldehyde by Oxidation.—Several investigators⁴ have reported the oxidation of crotonaldehyde preparations but the composition of none of these has been conclusively established. Kekulé^{4a} and Charon^{4b} obtained *trans*-crotonic acid by oxidation with air or oxygen and concluded that their material was *trans*-crotonaldehyde. Duchesne and Délépine^{4c} recovered in addition some acetic acid and Kaufler,^{4f} using a more elaborate method, isolated still another product, *cis*-crotonic acid in 6% yields. Unfortunately neither the source of the aldehyde nor the method of oxidation was adequately described by Kaufler.

Kekulé,^{4a} Charon^{4b} and Délépine and Bonnet^{4d} used silver oxide in the oxidation of crotonaldehyde. Of these, only Charon carefully avoided stereomutation of the materials, and indicated that his product was pure *trans*-crotonic acid. Inasmuch as he extracted this product from the acidified reaction mixture with ether, it is quite possible that appreciable quantities of the extremely soluble *cis*-crotonic acid may have been lost in the mother liquor. In view of the uncertainty of this question we have attempted to ascertain whether or not *cis*-crotonic acid is actually a product of the oxidation of crotonaldehyde.

Any chemical reactions to which crotonaldehyde is submitted must be performed under carefully controlled conditions in order to avoid stereomutation either in the aldehyde or in its reaction products. Stereomutation of *cis* isomers readily occurs in the case of *cis*-crotonic acid and its homologs,^{5,6} especially if traces of catalysts are present, and equilibria involving stereomutation of *trans* isomers have been observed at temperatures as low as 100°. ^{7,8} Another possible rearrangement, shifting of the double bond from the α,β to the less stable β,γ position is very unlikely, since there is no substitution in the γ position.⁹

Method of this Investigation.—In the oxidation of crotonaldehyde the experiments were designed to account quantitatively for all of the crotonic acids formed during the oxidation and to avoid conditions favoring molecular rearrangements during the oxidation process and subsequent treatment.

For comparison two series of experiments were run: one on the commer-

cial crotonaldehyde, the other, on *trans*-crotonaldehyde. The *trans*-crotonaldehyde was prepared by treating the original aldehyde with hydrogen chloride and strong sunlight for several hours to transform any possible *cis* isomer which may have been originally present. It is well known that hydrochloric acid catalyzes this change in closely related substances.^{5,6}

The original and sunlight-irradiated aldehydes were separately oxidized by two different reagents, gaseous oxygen and alkaline silver oxide. The content of *cis*- and *trans*-crotonic acids in the oxidation mixtures from both series of experiments was estimated by fractional crystallization of their sodium salts.¹⁰ The different salt fractions were analyzed for total crotonate content by titration with bromine water. Although Buckwalter and Wagner¹¹ reported that crotonic acid is not brominated readily, we have found that the sodium salt is rapidly and quantitatively brominated in neutral solution.

Discussion of Results.—There was excellent agreement between the results on the commercial and sunlight-irradiated aldehydes with both oxygen and silver oxide. No *cis*-crotonic acid was isolated in any of the controlled experiments, though as much as 5% was isolated from the gaseous oxidation of both aldehydes when the temperature of the reaction mixture was *not controlled*. It was therefore concluded that the aldehyde under investigation was free from the *cis* isomer and that *cis*-crotonic acid is not produced during the oxidation of crotonaldehyde under *controlled* conditions. It is indeed unfortunate that Kaufler^{4f} did not discuss his method of oxidation, since this part of the work requires the most careful regulation. His *cis*-crotonic acid may readily be accounted for if the reaction temperature were not controlled.

Experimental Procedure

Purification of Crotonaldehyde.—The commercial crotonaldehyde obtained from the Niacet Chemical Corporation was purified by two distillations through an 80-centimeter Vigreux column: b. p. of distillate, 101.3–102.0°; n_D^{20} 1.4356.

Preparation of *Trans*-Crotonaldehyde.—Commercial crotonaldehyde was placed in a quartz flask with a few cubic centimeters of concentrated hydrochloric acid and exposed to strong sunlight for several hours to remove any *cis*-crotonaldehyde originally present. The reaction mixture was then twice distilled through an 80-cm. Vigreux column: b. p. 101.3–101.7; n_D^{20} 1.4362.

The Oxidation of Crotonaldehyde with Gaseous Oxygen.—The gaseous oxidations of crotonaldehyde were carried out by shaking the material in a closed system in order to follow the oxygen absorption quantitatively. The temperature of the reaction mixture was kept below 30°, since in preliminary experiments the reaction temperature often reached 50–90° in ten or fifteen minutes, accompanied by the formation of some *cis*-crotonic acid and large quantities of resin. When oxygen was no longer absorbed the unchanged crotonaldehyde was distilled from the reaction mixture at 70-mm. pressure

¹⁰ This method of analysis has been used by Wislicenus⁵; Kaufler^{4f}; Auwers and Wissebach, *Ber.*, **56**, 715 (1923); and Braun, *This Journal*, **51**, 228 (1929).

¹¹ Buckwalter and Wagner, *ibid.*, **52**, 5248 (1930).

and again shaken in the absorption apparatus. The products from both oxidations were then combined and separated into four fractions; fraction 1 (b. p. (18 mm.) 31–45°), acetic acid; fraction 2 (b. p. (15 mm.) 45–83°); fraction 3 (b. p. (15 mm.) 83–87°); and an acid-resin residue. The boiling point rose from 45 to 83° in less than thirty seconds and only a few drops of liquid distilled. This indicated the absence of *cis*-crotonic acid and vinylacetic acid. As a further proof for the absence of these substances the crotonic acid, fraction 3, was converted into its sodium salt by neutralization with sodium ethylate and analyzed according to Kaufler.^{4f} If the temperature of the reaction mixture was not controlled during the oxidation process, both fraction 2 and fraction 3 contained detectable quantities of *cis*-crotonic acid. Typical results of the experiments with gaseous oxygen are shown in Table I.

The Oxidation of Crotonaldehyde with Silver Oxide.—To make sure that the gaseous method gave dependable results, an entirely different process was resorted to, namely, oxidation with silver oxide. This reagent was more satisfactory than oxygen since the reaction products were free from resin acids and could be readily isolated without danger of rearrangements.^{4b} The reaction was performed as follows.

The aldehyde was shaken vigorously with a water suspension of silver oxide at 15–20°. The reaction was complete in six hours. Through metathesis, the silver salt was converted into the sodium salt by shaking with sodium carbonate or sodium hydroxide. The solution was filtered and the filtrate neutralized with 6 *N* sulfuric acid. After the crotonate content of the solution had been determined, the water was removed at 27° under reduced pressure. The residue was then analyzed for *cis*- and *trans*-crotonic acids by Kaufler's method.^{4f} All of the crotonate in the solution was thus accounted for as the *trans* isomer. Typical experiments on the original and irradiated aldehydes

A is the weight of salt at the start of extraction process.

C, F, H are weights of salt dissolved in extractions 1, 2 and 3, respectively.

B, D, G are weights of salt undissolved in extractions 1, 2, 3, respectively.

* The weight of the crude salt was not determined in this case.

are listed in Table I. In all experiments the *cis*-sodium crotonate should be found in the last extract H. From the table it is seen that of the salt dissolved a negligible quantity reacts with bromine, except in experiment 5 where the reaction temperature was not controlled. Therefore if any *cis*-crotonic acid is formed on oxidation with silver oxide or oxygen it is formed in very small amount.

In conclusion the writer desires to express his appreciation of the kindly interest shown by members of the Chemistry Staff at Stanford University and at the Division of Plant Biology of the Carnegie Institution of Washington, located at Stanford, especially to Doctors H. A. Spoehr and J. H. C. Smith, who offered many helpful suggestions and criticisms.

Summary

The composition of crotonaldehyde has been investigated by oxidation with gaseous oxygen and alkaline silver oxide under conditions designed to

avoid molecular rearrangements. It was shown that "niacet" crotonaldehyde is the *trans* isomer by comparison with *trans*-crotonaldehyde prepared by treatment with hydrogen chloride and sunlight. Both aldehydes gave only *trans*-crotonic acid on oxidation under controlled conditions, but some *cis*-crotonic acid when the temperature was not controlled.

It was concluded that the *cis*-crotonic acid reported by Kaufler^{4f} was probably formed from the *trans* isomer by stereomutation during the oxidation process.

THE REDUCING ACTION OF THE GRIGNARD REAGENT. II. COMPARISON WITH THE EASE OF REMOVAL OF HYDROGEN BROMIDE FROM ALKYL BROMIDES AND WITH THE AMOUNT OF DIALKYL MAGNESIUM IN THE GRIGNARD REAGENT

BY C. R. NOLLER AND F. B. HILMER

RECEIVED FEBRUARY 8, 1932

PUBLISHED JUNE 6, 1932

The theory proposed by Hess and Rheinboldt¹ to account for the reducing action of certain alkylmagnesium halides is that a primary addition product with the carbonyl compound is first formed and that this may either rearrange to give the normal addition product or may lose unsaturated hydrocarbon and then rearrange to give the reduction product.

Meisenheimer² proposed a similar mechanism except that the postulation of the intermediate compound II is omitted.

One might predict, if Hess' formulation represents the mechanism of the reaction, that for a series of alkylmagnesium halides the relative ease with which unsaturated hydrocarbon is lost from the complex $R_2CO \cdots Mg(X)R'$ and hence the relative amount of reduction might be comparable with the relative ease with which alkenes are formed from alkyl halides. A rough evaluation of the relative ease with which pyridine reacts with alkyl bromides to form alkene and pyridine hydrobromide has been reported recently³ and it is the purpose of this paper to present data on the amount of reduction brought about by Grignard reagents from these same alkyl

¹ Hess and Rheinboldt, *Ber.*, **54**, 2043 (1921).

bromides. At the same time data on the amount of dialkylmagnesium in the Grignard reagent will also be given.

The method of Blicke and Powers⁴ for estimating the amount of reduction, which is based on the insolubility of the bromomagnesium salt of benzohydrol in ether, is probably the most satisfactory for comparing the reducing action of various reagents. Their data, however, are not sufficiently complete to compare with the data on the relative ease of formation of alkenes from alkyl bromides. We have made use of their method and extended their data taking the precautions to use filtered solutions, to use solutions of the same concentration and in definite excess, and to carry the reaction out within the narrow temperature range of 0–5°.⁵

The amount of dialkylmagnesium in the solutions was determined by a modification⁶ of the method of Schlenk and Schlenk, Jr.⁷ The combined data are summarized in Table I which gives the average values of at least two determinations.

The work on the reaction of alkyl bromides with pyridine³ showed that *tert.*-butyl bromide loses hydrogen bromide about eighty times more rapidly than the secondary bromides, isopropyl and *sec.*-butyl, and these in turn about ten times more rapidly than the primary bromides, ethyl, *n*-propyl, isobutyl and *n*-butyl. On comparing this order with that given in Table I, it is readily seen that there is no observable relation between the amount of reduction and the ease with which alkenes are formed from alkyl bromides.

On the other hand, it appears that the amount of reduction increases with increasing dialkylmagnesium content of the solution. There is, however, no direct relationship between the two since the *tert.*-butyl solution causes no reduction although there is 32 equivalent per cent. of dialkylmagnesium present, the isobutyl solution causes 86% reduction although only 78% of dialkylmagnesium is present, and the isopropyl and *sec.*-butyl solutions have almost the same dialkylmagnesium content but cause 13 and 40% reduction, respectively. None of the explanations that have suggested themselves will satisfy the data obtained thus far.

Our modification⁶ of the excellent method used by Schlenk and Schlenk, Jr.,⁷ for determining the amount of dialkylmagnesium is by no means as exact as theirs but the greater ease of carrying out the determination and its applicability to solutions of the Grignard reagent as directly pre-

⁴ Blicke and Powers, *THIS JOURNAL*, **51**, 3378 (1929).

⁵ The necessity for using filtered solutions and for keeping the Grignard reagent in excess have been reported in a previous paper.⁶ Rheinboldt and Roleff, *J. prakt. Chem.*, **109**, 175 (1925), have shown that the amount of reduction increases with the temperature, and we have reason to believe that the amount of reduction also varies with the concentration of the Grignard reagent.

⁶ Noller, *THIS JOURNAL*, **53**, 635 (1931).

⁷ Schlenk and Schlenk, Jr., *Ber.*, **62**, 920 (1929).

pared give it certain advantages. In the two instances where a direct comparison is possible the two methods check fairly well. Thus Schlenk, Jr.,⁸ finds for ethylmagnesium bromide solutions 29.5% diethylmagnesium and for *n*-propylmagnesium bromide 38% of di-*n*-propylmagnesium as compared with our values of 25.5 and 35.5%, respectively.

It appears that the generalization of Schlenk, Jr., that the amount of dialkylmagnesium increases with increasing molecular weight, must be modified to take the structure of the hydrocarbon radical into consideration. Our results for example indicate that the amount of dialkylmagnesium in the solution of *tert.*-butylmagnesium bromide is lower than that in any of the Grignard reagents including the ethyl and propyl solutions.

Experimental

Grignard Reagents.—Solutions of the alkylmagnesium bromides were prepared in the usual manner from purified alkyl bromides and filtered by pressure through a 3-mm. layer of ignited kieselguhr on a sintered glass filter. They were analyzed by titration with standard acid and then concentrated or diluted to give a concentration of approximately 1.75 *N*, after which the concentration was checked again by titration.

Reduction Procedure.—To a 300-cc. Erlenmeyer flask fitted with a 30-cc. dropping funnel and thermometer was added 25 cc. of the Grignard reagent. The solution was cooled to 0° in an ice-salt bath. The amount of benzophenone to be used was calculated for the particular Grignard reagent so that the latter was present in 10% excess, and this amount dissolved in 8 cc. of warm dry benzene. This solution was added dropwise from the separatory funnel at such a rate that the temperature remained between 0 and 5°. The contents of the flask was swirled continuously to keep the mixture well stirred.⁹ When all the benzophenone had been added the contents of the flask was allowed to come to room temperature. The precipitate was filtered with suction on a 5-cm. Büchner funnel and washed carefully with three 10-cc. portions of dry benzene, care being taken not to suck air through the precipitate before the last washing. The cake was transferred to the Erlenmeyer flask, decomposed with 50 cc. of saturated ammonium chloride solution and extracted with three 50-cc. portions of ether. The combined ether extracts were evaporated in a tared 150-cc. beaker over a warm hot-plate. To prevent benzohydrol from creeping over the edge of the beaker, the ether vapors were removed by a tube attached to a water pump and extending into the center of the beaker. When practically all of the ether and benzene had been removed, the warm beaker was placed in a vacuum desiccator over phosphorus pentoxide, the desiccator evacuated and allowed to stand for two hours. The amount of benzohydrol was weighed and the percentage reduction calculated.

In checking the accuracy of the method we have determined roughly the solubility of the bromomagnesium salt of benzohydrol in ether, benzene and ether-benzene mixtures (25:8 by volume) and obtained the values 0.006, 0.007 and 0.006 g. per cc. of solution, which corresponds to 0.0038, 0.0045 and 0.0038 g. of benzohydrol. This solubility does not account for the fact that Blicke and Powers⁴ recovered only 81% of the

⁸ Schlenk, Jr., *Ber.*, **64**, 734 (1931).

⁹ In all cases the usual transient red color was observed. In the case of *sec.*-butylmagnesium bromide, however, the color was permanent for as long as two weeks and was not destroyed by passing air through the solution for ten minutes. The *tert.*-butylmagnesium bromide likewise gave a permanently colored solution.

benzohydrol added to a solution of ethylmagnesium bromide. On repeating their work with 7.54 g. of freshly recrystallized benzohydrol, m. p. 66–67°, under exactly the same conditions used for determining the amount of reduction, we recovered 7.24 g. or 96% of the benzohydrol, m. p. 62–66°, from the precipitate and 0.26 g. or 3.4% from the filtrate. This indicates a mechanical loss of 0.6%. The value of 0.26 g. in the filtrate checks very closely with the calculated value of 0.27 g. based on the solubility determinations. This indicates that the values for the amount of reduction are low by about 4%.

Determination of Dialkylmagnesium.—The procedure was identical with that previously reported.⁶

All data are tabulated in Table I.

TABLE I
COMPARISON OF AMOUNT OF REDUCTION WITH DIALKYL MAGNESIUM CONTENT OF THE GRIGNARD REAGENT

Alkylmagnesium bromide	Concentration, equiv. per cc.	Dialkyl- magnesium, equiv., %	Benzohydrol, %	M. p. of Benzohydrol, °C.
<i>Tert.</i> -butyl	0.00172	32	0 ¹⁰	
Ethyl	.00175	51	2	50–70
Isopropyl	.00165	59	13	61–63
<i>Sec.</i> -butyl	.00183	62	40	61–64
<i>n</i> -Propyl	.00179	71	58	60–63
<i>n</i> -Butyl	.00177	74	59	61–64
Isobutyl	.00174	78	86	62–66

Summary

1. Comparison of the amount of reduction of benzophenone by Grignard reagents from seven alkyl bromides with data on the relative ease with which alkenes are formed from these bromides shows that no relationship between the two exists.

2. The amount of reduction increases with the increasing dialkylmagnesium content of the solutions but is not proportional to the amount of dialkylmagnesium present.

3. The amount of dialkylmagnesium present in Grignard solutions appears to be influenced more by the structure than by the molecular weight of the hydrocarbon radical.

STANFORD UNIVERSITY, CALIFORNIA

¹⁰ From 7.1 g. of benzophenone there was obtained 7.1 g. of a viscous liquid distilling almost completely between 155–160° at 4 mm. Marvel and Bateman, *THIS JOURNAL*, **49**, 2917 (1927), give the b. p. of *tert.*-butyldiphenylcarbinol as 148–150° at 2.5 mm. This behavior of *tert.*-butylmagnesium bromide is surprising since Conant and Blatt, *THIS JOURNAL*, **51**, 1227 (1929), found that in general *tert.*-butylmagnesium chloride caused more reduction than either isopropyl or *n*-butylmagnesium bromide and Konovalov, Miller and Timtschenko, *Chem. Zentr.*, **II**, 312 (1906), have obtained 38.5% benzohydrol from the reaction of benzophenone with *tert.*-butylmagnesium bromide. We believe that these apparent discrepancies may be due to variation in the conditions under which the reaction takes place, cf. Note 5.

THE NITRATION OF THE METHYL, ETHYL AND TERTIARY-BUTYL ESTERS OF PHENYLACETIC ACID

BY DAVID L. YABROFF AND C. W. PORTER

RECEIVED FEBRUARY 15, 1932

PUBLISHED JUNE 6, 1932

This paper deals with the nitration of three of the esters of phenylacetic acid. The work reported here is a continuation of an investigation of the orienting influences of various groups in the benzene ring. The purpose of the research was formulated in an earlier paper.¹ In general it is an attempt to evaluate the orienting influences of atoms and groups not directly attached to the ring. The residual charge on the key atom in phenylacetic acid and its esters as estimated by Latimer and Porter² is zero; that in toluene is also zero. In benzoic acid and its esters the residual charge on the atom attached to the ring is +1.4.

Table I gives our results for the nitration of phenylacetic acid¹ and its esters and Zaki's results³ for the three esters of benzoic acid. The values for toluene⁴ and for benzoic acid⁵ are those of Holleman.

TABLE I

Nitration of	Meta, %	Nitration of	Meta, %
$\text{C}_6\text{H}_5\text{CH}_2\text{COOH}$	14.4	$\text{C}_6\text{H}_5\text{COOH}$	80.2
$\text{C}_6\text{H}_5\text{CH}_2\text{COOCH}_3$	12.1	$\text{C}_6\text{H}_5\text{COOCH}_3$	72.6
$\text{C}_6\text{H}_5\text{CH}_2\text{COOC}_2\text{H}_5$	10.3	$\text{C}_6\text{H}_5\text{COOC}_2\text{H}_5$	69.9
$\text{C}_6\text{H}_5\text{CH}_2\text{COOC}(\text{CH}_3)_3$	5.6	$\text{C}_6\text{H}_5\text{COOC}(\text{CH}_3)_3$	59.4
$\text{C}_6\text{H}_5\text{CH}_3$	4.4		

As may be seen in Table I the percentage of the meta derivative is highest in the case of the free acid. Replacement of the hydrogen by alkyl groups causes a successive diminution in the percentage of the meta isomer. This was explained by Zaki³ for the benzoic esters as due to the electron affinity of the various alkyl groups as compared with that of hydrogen. In our language we should say that the replacement of hydrogen by the various alkyl groups must modify the residual charge on the key atom. In the case of the esters the effective residual charge must be slightly more negative than that of the free acid, since less of the meta derivative is formed.

Methyl phenylacetate and tertiary-butyl phenylacetate heretofore have not been nitrated although nitro derivatives of the methyl ester have been obtained by esterification of the corresponding nitrophenylacetic

¹ Yabroff and Porter, *THIS JOURNAL*, **54**, 1199 (1932).² Latimer and Porter, *ibid.*, **52**, 206 (1930).³ Zaki, *J. Chem. Soc.*, 983 (1928).⁴ Holleman, *Rec. trav. chim.*, **33**, 1 (1914).⁵ Holleman, *ibid.*, **18**, 278 (1899).

acids.^{6,7,8} Tertiary-butyl phenylacetate was included in order to ascertain the accentuated effect of the three methyl groups in the alcohol residue. Ethyl phenylacetate has been nitrated by Baker and Ingold,⁹ who found that approximately 9% of the meta derivative was formed and by Flürscheim and Holmes,¹⁰ who obtained about 12% of the meta isomer.

The analytical method used for determining the percentage of the meta derivative for the three esters of phenylacetic acid was the same as that described for phenylacetic acid itself.¹

Experimental Section

Reagents.—Eastmans ethyl and methyl phenylacetates were purified by fractional distillation under reduced pressure. The preparation and purification of tertiary-butyl phenylacetate has been described.¹¹

Nitration.—The methyl and ethyl esters were nitrated by adding approximately 5 g. of the purified ester in small amounts to 30 cc. of nitric acid (d 1.495) freed from oxides of nitrogen. The temperature was maintained at 0° and the flask was thoroughly shaken after each small addition of the ester. The mixtures were allowed to stand for four hours longer at 0°.

Attempts to nitrate the tertiary-butyl ester in the same manner led to a great amount of hydrolysis (60–80%). Nitration was finally accomplished by allowing a mixture of 25 cc. of nitric acid (d 1.52) and 25 cc. of acetic anhydride to run slowly into a solution of the ester (about 7 g.) in 30 cc. of acetic anhydride. The temperature was maintained at 0°. The nitric acid solution was added at a steady rate of about 1 cc. per minute and the mixture was stirred vigorously during the entire time of addition. The mixture was then allowed to stand for one and one-half hours longer at 0°.¹²

After the period of nitration was over the nitration mixture obtained from each ester was poured into cracked ice and just neutralized with potassium hydroxide solution. The temperature was maintained at 0° by the further addition of ice. The nitro bodies which separated as a semi-solid oil were taken up with ether and the aqueous layer was extracted twice with ether. The ether extracts were combined, washed with ice water and dried over anhydrous sodium sulfate. Evaporation of the ether left a very pale yellow oil which became semi-solid upon standing. Equivalent weight determinations and analyses were made as described in the earlier paper.¹

The results of the nitrations and analyses are given in Tables II, III and IV where the figures for the molecular weights, the titrations and the brominations represent averages of three determinations made with aliquot

Summary

As a continuation in the study of the influences of remote atoms on the residual charge of the key atom in benzene derivatives, the quantitative nitration of the methyl, ethyl and tertiary-butyl esters of phenylacetic acid has been accomplished. The percentages of the meta derivatives formed were 12.1, 10.3 and 5.6, respectively.

NITRATION OF META-DIPHENYLBENZENE AND DERIVATIVES OF NITRO-META-DIPHENYLBENZENE¹

BY C. ARTHUR WARDNER WITH ALEXANDER LOWY

RECEIVED FEBRUARY 20, 1932

PUBLISHED JUNE 6, 1932

In the process for the preparation of diphenyl from benzene, considerable amounts of high boiling products are produced. *m*-Diphenylbenzene is one of the constituents of this high boiling material. Since the trinitro compound is the only nitro derivative of *m*-diphenylbenzene which has been recorded, a study of the nitration of this hydrocarbon was undertaken with the object of synthesizing the mono and dinitro compounds and some of their derivatives.

¹ Abstracted from a thesis presented by C. Arthur Wardner to the Graduate School in partial fulfillment of the requirement for the Ph.D. degree.

References to the literature² deal mainly with the preparation of *m*-diphenylbenzene from various sources.

The only derivatives which have been recorded for this hydrocarbon are the trinitro, triamino, bromo and tetrabromo compounds.

The writers are indebted to Mr. R. E. Bowman of Wilmington, Delaware, who is investigating the high boiling material furnished by the Swann Corporation, for providing a generous supply of *m*-diphenylbenzene. The *m*-diphenylbenzene thus obtained was recrystallized twice from ethyl alcohol, producing white needle-shaped crystals, m. p. 85°, as reported by Schultz, Schultz and Schmidt, Olgiati, Adam, Möhlun and Berger, Chattaway and Evans.² *m*-Diphenylbenzene is described in Beilstein³ as white needle-shaped crystals. It is soluble in ethyl alcohol, ethyl ether, benzene and acetic acid. It boils at 363° under atmospheric pressure.

Several preliminary experiments were conducted, in which such factors as time, concentration of nitrating agent, temperature and solvent were varied, before the following procedures were adopted.

A. Nitration of *m*-Diphenylbenzene

Nitro-*m*-diphenylbenzene.—Fifty grams of *m*-diphenylbenzene and 200 cc. of acetic anhydride were mixed thoroughly with a mechanical agitator in a 600-cc. beaker until a uniform suspension was obtained and then cooled to 0°; 17.5 cc. of fuming nitric acid (sp. gr. 1.5) was added drop by drop with continuous stirring in the course of twenty minutes. As the reaction proceeded, the *m*-diphenylbenzene gradually dissolved. The same low temperature was maintained for fifteen minutes after the last drop of fuming nitric acid had been added. The solution was then warmed gradually to a temperature of 25°, which required twenty minutes. To ensure complete nitration, the reaction mixture was heated at 50° for thirty minutes.

The oily nitro compound separated as a distinct layer at the bottom when the nitrating mixture was poured into 500 cc. of ice water. The water layer was decanted and the nitro compound was washed with 500 cc. of warm water (temp. 50°). This was followed by several washings with warm five per cent. sodium carbonate solution. It was then washed with warm water. The oily product was dissolved in 150 cc. of ethyl ether and the resulting solution was dried over calcium chloride for twelve hours. The solution was filtered and the solvent was removed. The residual oil was vacuum distilled and the portion boiling at 197–198° (1 mm.) or 203° (2 mm.) was collected; yield, 36 g.

Attempts to crystallize this nitro compound were futile. Although it could be frozen to a solid with carbon dioxide snow, it acquired the characteristic viscous property when it warmed to room temperature. A portion of the nitro compound was kept in a refrigerator, while another portion was kept in a vacuum desiccator for ten months but there was no crystal formation in either of these samples.

³ Beilstein, "Handbuch der organischen Chemie," 4th ed., Vol. V, System No. 450–498, p. 695.

Experiments were also conducted to crystallize the nitro compound from organic solvents. It was dissolved in ethyl ether, benzene, acetic acid and acetone, but these solvents did not affect crystallization, even after the solutions were concentrated and cooled. The nitro compound is insoluble in water.

Anal. Calcd. for $C_{18}H_{13}O_2N$: C, 78.54; H, 4.72; N, 5.09. Found: C, 78.00, 78.17; H, 4.50, 4.94; N, 5.03, 5.21.

Dinitro-*m*-diphenylbenzene.—A mixed acid solution was prepared, consisting of 30 cc. of sulfuric acid (sp. gr. 1.82), 15 cc. of nitric acid (sp. gr. 1.42) and 7.5 cc. of water. This mixture was kept at a constant temperature of 40° and stirred while 20 g. of *m*-diphenylbenzene was added in small portions, over a period of twenty minutes. A yellow oil formed which was insoluble in the nitrating acid. At this stage 10 cc. of nitric acid (sp. gr. 1.42) was added drop by drop. The product became pasty. The formation of this insoluble viscous product made further nitration almost impossible, and since higher temperature in this acid medium is conducive to oxidation, the operation was discontinued. The nitrating acid was decanted and the insoluble material was washed with cold water. The solid material thus obtained was crystallized from acetic acid, washed with water and dried. A yield of 14 g. was obtained, which had a melting point range of 160–190°. The product was crystallized six times from acetic acid, washed with water and dried in an oven at 80°; m. p. 214°; yield, 7 g. This product is soluble in acetic acid, benzene and acetone when heated.

Anal. Calcd. for $C_{18}H_{12}O_4N_2$: N, 8.75. Found: N, 8.76, 8.85.

The mother liquor from the first acetic acid crystallization was poured into 200 cc. of cold water. The oily material which separated was washed with water, dissolved in ether and the resulting solution was dried over calcium chloride for twelve hours. After filtration and evaporation of the solvent, a small amount of an oily liquid was obtained.

Trinitro-*m*-diphenylbenzene. 1. From *m*-Diphenylbenzene.—Five grams of *m*-diphenylbenzene and 25 cc. of acetic acid were mixed thoroughly in a 250-cc. round-bottomed flask; 16 cc. of fuming nitric acid (sp. gr. 1.5) was added in the course of one hour, while stirring and heating at 30°. The reaction mixture was heated for another hour on a boiling water-bath. A red coloration was noted in the solution at this point. Upon cooling, white needle-shaped crystals separated which were filtered by suction, washed with water and recrystallized three times from acetic acid. The resulting product was again washed with water and dried in an oven at 80°; m. p. 204°; yield, 4.5 g.; soluble in hot acetic acid, hot benzene and hot acetone, and slightly soluble in hot ethyl alcohol.

Anal. Calcd. for $C_{18}H_{11}O_6N_3$: N, 11.50. Found: N, 11.25, 10.96.

2. From Nitro-*m*-diphenylbenzene.—Five grams of nitro-*m*-diphenylbenzene was dissolved in 25 cc. of acetic acid in a 250-cc. round-bottomed flask; 16 cc. of fuming nitric acid (sp. gr. 1.5) was added slowly to the solution in the course of one hour, while the temperature was maintained at 25°. The temperature was raised gradually to 96–100°, where it was maintained for four hours. On cooling, white needle-shaped crystals separated, which were filtered and washed with water. These were crystallized three times from acetic acid; m. p. 204°; yield, 1 g.

The filtrate from the reaction mixture was poured into 250 cc. of cold water. A viscous semi-solid material separated, which was washed with water. This material was dissolved in ethyl ether and the solution dried over calcium chloride for twelve hours. One gram of a yellow solid separated. It was filtered but it could not be purified to a constant melting point by crystallization. Upon evaporation of the ether, a yellow oil having the appearance of the original mononitro derivative was obtained.

Oxidation of Nitro-*m*-diphenylbenzene.—Five grams of the nitro compound was dissolved in 25 cc. of acetic acid. To this solution while refluxing there was added a solution containing 40 g. of chromic acid in 40 cc. of acetic acid and 25 cc. of water in small quantities. After the last portion had been added, boiling was continued for one and a half hours. The reaction mixture was poured into 500 cc. of ice water, and the yellow precipitate which formed was filtered by suction and washed with water. It was dissolved in a 10% sodium hydroxide solution and reprecipitated with 1:1 hydrochloric acid. The resulting product was recrystallized twice from dilute ethyl alcohol (one part of alcohol to three parts of water). It was filtered by suction and dried in a vacuum desiccator; m. p. 224°. The product sublimed and this gave a melting point of 227°; yield, 0.9 g.

There are several possible oxidation products of nitro-*m*-diphenylbenzene, but only a few of these are recorded in the literature. The ones that are recorded with their respective melting points are as follows: 1-nitrobenzene-2,4-dicarboxylic acid, 245–246°; 1-nitrobenzene-3,5-dicarboxylic acid, 248–249°; 2-nitrobenzene-1,3-dicarboxylic acid, 300°; 2-nitrobenzoic acid, 148°; 3-nitrobenzoic acid, 140–141°; 4-nitrobenzoic acid, 238–240°.

The product obtained in the above oxidation experiment did not correspond with any of the compounds listed above. With the idea that one of these compounds might be obtained, the nitrodiphenylcarboxylic acid was subjected to a chromic acid oxidation for six hours more. However, the original acid was recovered. The product of oxidation is evidently a hitherto unreported nitrodiphenylcarboxylic acid.

Anal. Calcd. as nitrodiphenylcarboxylic acid ($C_{13}H_9O_4N$): N, 5.76; mol. wt., 243. Found: N, 5.51, 5.74; mol. wt. by titration of its neutral equivalent, 246.1, 245.9.

Oxidation of Dinitro-*m*-diphenylbenzene.—One gram of dinitro-*m*-diphenylbenzene was dissolved in 25 cc. of acetic acid. The procedure from this point was identical with that of the above oxidation experiment, except that the oxidizing agent consisted of 10 g. of chromic acid in 10 cc. of acetic acid and 5 cc. of water. White needle-shaped crystals formed which were recrystallized twice from water and dried in a vacuum desiccator; m. p. 238°; yield, 0.1 g. This melting point corresponds to that of *p*-nitrobenzoic acid. A mixed melting point indicated that the product was *p*-nitrobenzoic acid.

All attempts to oxidize the trinitro compound were futile, which is in accordance with the results of Schultz and Schmidt.²

Discussion of the above Results.—Theoretically, there are six mono-nitro derivatives of *m*-diphenylbenzene. Since in the nitration of diphenyl the ortho and para derivatives predominate, the mononitro products that would most likely form during the nitration of *m*-diphenylbenzene would be the following: (a) 2-nitro-5'-phenyl-diphenyl, (b) 4-nitro-5'-phenyl-diphenyl, (c) 1,3-diphenyl-2-nitrobenzene, (d) 1,3-diphenyl-4-nitrobenzene. The oxidation of nitro-*m*-diphenylbenzene yielded a hitherto unreported nitrodiphenylcarboxylic acid instead of a nitro-isophthalic acid or a nitrobenzoic acid, as would be expected. *o*-Nitrodiphenyl is not attacked by oxidizing agents while⁴ *p*-nitrodiphenyl yields *p*-nitrobenzoic acid. This seems to indicate⁵ that a phenyl group adjacent to a nitro group on a benzene nucleus is protected against oxidation. Reasoning by analogy from similar diphenyl type oxidations the formulas designated by (a) and

⁴ Schultz, Schmidt and Strasser, *Ann.*, **207**, 348 (1881).

⁵ Schultz, *ibid.*, **174**, 201 (1874).

(d) may be regarded as the two possible structures for nitro-*m*-diphenylbenzene, since a nitrodiphenylcarboxylic acid was isolated as an oxidation product.

The fact that *p*-nitrobenzoic acid was isolated as an oxidation product of dinitro-*m*-diphenylbenzene proves that a nitro group is attached in the para position on an end ring.

B. Derivatives of Nitro-*m*-diphenylbenzene

Amino-*m*-diphenylbenzene.—Ten grams of nitro-*m*-diphenylbenzene was dissolved in 30 cc. of ethyl acetate; 0.2 g. of platinum oxide, prepared according to the directions given in "Organic Syntheses,"⁶ was used as a catalyst. The reduction was performed in a Parr catalytic hydrogenation machine. One hour was allotted for the completion of the reaction. The resulting solution was filtered to remove the platinum black. The solvent was removed and the resulting product was treated with 25 cc. of 1:5 hydrochloric acid. The white hydrochloride salt was filtered by suction, washed once with dilute hydrochloric acid and twice with 50 cc. of ethyl ether. The hydrochloride was then neutralized with a five per cent. solution of sodium carbonate. A small amount of ether was added to the mixture to dissolve the amine as it was formed. The ether was allowed to evaporate, and the amine separated in the form of a light gray solid. It was filtered and recrystallized three times from ethyl alcohol; m. p. 64°; yield, 6 g.; soluble in ethyl alcohol, ethyl ether, ethyl acetate, benzene and acetone.

Anal. Calcd. for $C_{18}H_{15}N$: N, 5.71. Found: N, 5.69, 5.81.

This product was also prepared by using the iron reduction method for reducing nitrodiphenyl.⁷

Amino-*m*-diphenylbenzene Hydrochloride.—One gram of amino-*m*-diphenylbenzene was dissolved in 20 cc. of ethyl acetate. This solution was agitated with dry hydrogen chloride gas until the amine had been precipitated as the white hydrochloride salt. It was filtered and dried in a vacuum desiccator.

Anal. Calcd. for $C_{18}H_{15}NCl$: N, 4.97. Found: N, 4.87, 4.80.

Acetylamino-*m*-diphenylbenzene.—One gram of amino-*m*-diphenylbenzene was dissolved in 5 cc. of acetic anhydride. The solution was heated for three minutes and then cooled. The addition of 5 cc. of water decomposed the excess acetic anhydride and caused the acetylated derivative to separate as a white solid. It was filtered by suction and recrystallized twice from 50% ethyl alcohol; m. p. 117°; yield, 1 g.

Anal. Calcd. for $C_{20}H_{17}ON$: N, 4.86. Found: N, 5.11, 4.96.

Benzoylamino-*m*-diphenylbenzene.—Two grams of amino-*m*-diphenylbenzene was dissolved in 5 cc. of pyridine. While stirring, three cc. of benzoyl chloride was added drop by drop. The reaction mixture became warm. On cooling, white needle-shaped crystals were deposited which were filtered by suction and washed with 0.5 *N* sulfuric acid. It was recrystallized from ethyl alcohol; m. p. 152°; yield, 2 g.

Anal. Calcd. for $C_{26}H_{19}ON$: N, 4.01. Found: N, 4.13, 3.78.

***m*-Diphenylbenzene-azo- β -naphthol.**—*m*-Diphenylbenzenediazonium chloride was prepared by diazotizing 2 g. of amino-*m*-diphenylbenzene hydrochloride in a solution of 100 cc. of distilled water and 10 cc. of hydrochloric acid (sp. gr. 1.18) at a temperature of 5°. This diazotized solution was poured slowly into a cooled solution containing 1.5

⁶ Adams, Voorhees and Shriner, "Organic Syntheses," John Wiley and Sons, Inc., New York, 1928, Vol. VIII, p. 92.

⁷ Jenkins, McCullough and Booth, *Ind. Eng. Chem.*, **22**, 31 (1931).

g. of β -naphthol and 5 g. of sodium hydroxide in 100 cc. of water. A red precipitate formed, which was filtered by suction and washed with water. A red crystalline product was obtained after crystallization from acetic acid; yield, 2 g.

Anal. Calcd. for $C_{28}H_{20}ON_2$: N, 7.00. Found: N, 6.67, 6.86.

Other compounds were also coupled qualitatively with *m*-diphenylbenzenediazonium chloride, *e. g.*: 1,8-dihydroxynaphthalene-3,6-disulfonic acid, red-purple; 1-naphthol-4-sulfonic acid, bright red; 1,8-aminonaphthol-3,6-disulfonic acid, blue-purple; 2-naphthol-7-sulfonic acid, bright red; 1,8-aminonaphthol-2,4-disulfonic acid, purple; 2-naphthol-3,6-disulfonic acid, light purple.

Summary

1. The mononitro, dinitro and trinitro derivatives of *m*-diphenylbenzene have been prepared.

2. The oxidation of nitro-*m*-diphenylbenzene yielded a nitrodiphenylcarboxylic acid. The oxidation of dinitro-*m*-diphenylbenzene yielded *p*-nitrobenzoic acid. No reaction was observed in the attempted oxidation of trinitro-*m*-diphenylbenzene.

3. The nitro-*m*-diphenylbenzene was reduced to the corresponding amine. The following new derivatives of amino-*m*-diphenylbenzene were prepared: (a) amino-*m*-diphenylbenzene hydrochloride, (b) acetylaminom-*m*-diphenylbenzene, (c) benzoylamino-*m*-diphenylbenzene, (d) *m*-diphenylbenzene-azo- β -naphthol, and other dyes.

PHENYL SUBSTITUTED ALIPHATIC ACIDS

BY J. HARMON AND C. S. MARVEL

RECEIVED FEBRUARY 25, 1932

PUBLISHED JUNE 6, 1932

The mechanism of the oxidation of the fatty acids in the animal body has long been the subject of speculation by chemists interested in metabolism. The most satisfactory theory that has been advanced to account for the oxidation of fatty acids to carbon dioxide and water in the animal was propounded by Knoop¹ in 1904. His theory of beta oxidation has been tested on various omega substituted fatty acids of the type $C_6H_5-(CH_2)_xCOOH$ where the phenyl group which is not generally oxidized in the animal body acted as a barrier to further oxidation and left an identifiable residue to be eliminated as a waste product from the body. In these studies all of those acids in which x had an uneven value were found to be burned in the body to phenylacetic acid and those in which x had an even value were burned to benzoic acid.

Thus far most of the experiments which have been devised to test Knoop's theory of β -oxidation have confirmed it. However, it has been

¹ Knoop, *Beitr. Chem. Physiol. Path.*, **6**, 150 (1905).

pointed out by Professor R. C. Corley² that only omega substituted acids in which the aliphatic chain is fairly short have been examined and he has suggested that a study of longer straight chain fatty acids with the phenyl group at different distances from the carboxyl group and not in the omega position would be of interest.

Several aliphatic acids containing a phenyl group substituted in other than the alpha or omega positions have been prepared previously. Eijkman³ prepared γ -phenylvaleric acid by the action of γ -valerolactone on benzene in the presence of aluminum chloride. When he tried to prepare the same acid from Δ^4 -pentenoic acid and benzene⁴ he obtained a mixture of the γ - and δ -phenyl substituted acids. The same method has been used by other investigators but mixtures of isomers seem invariably to result.⁵ For the purpose for which these compounds were desired it seemed essential that pure compounds of known structures should be available. Accordingly, procedures which are known to produce compounds of definite composition were used in this work.

The acids desired for metabolism studies were those with ten to eighteen carbon atoms and having the phenyl group on various even numbered positions beyond six. Since the natural fatty acids have an even number of carbon atoms most of the compounds were of this type. Only one compound with an odd number of carbons in the aliphatic chain was prepared. The compounds which were obtained in sufficient quantity for animal experiments were 6-phenyldecanoic acid, 8-phenyldodecanoic acid, 10-phenyltetradecanoic acid, 6-phenylpentadecanoic acid, 8-phenylhexadecanoic acid, 9-phenyloctadecanoic acid, and 10-phenyloctadecanoic acid.

The last two of these acids served a double purpose; for in addition to being made available for study in the physiological work, they were used to compare with the phenyloctadecanoic acid which Nicolet and deMilt^{5b} and Schmidt^{5c} have prepared from oleic acid and benzene in the presence of aluminum chloride. The two synthetic acids of known structures were solids whereas the acid prepared from oleic acid is an oil. Comparison of the physical properties of the acids and also of the *p*-bromophenacyl esters which are given in detail in the experimental part showed that the acid from oleic acid is a mixture of about equal parts of the 9- and 10-phenyloctadecanoic acids.

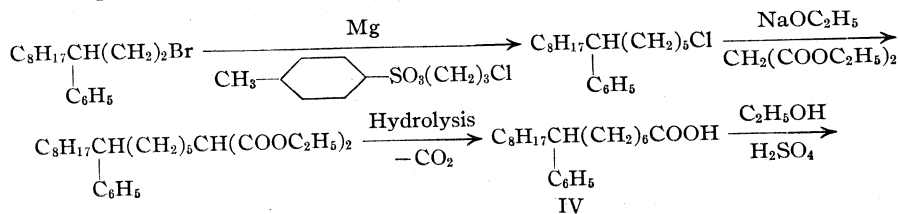

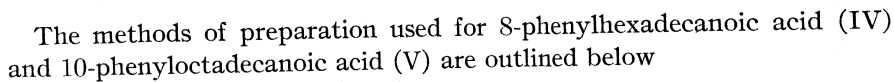

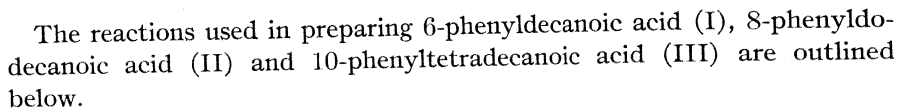

In the synthesis of these acids the first few reactions were of the same general type and may be represented as follows

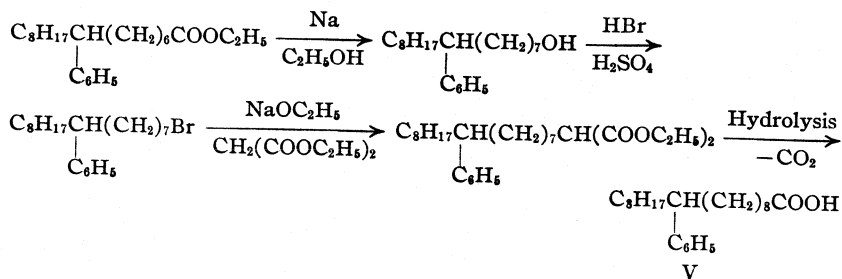

² R. C. Corley in a private communication has suggested these facts to us and it was at his suggestion that this synthetic work was undertaken.

³ Eijkman, *Chem. Weekblad*, **1**, 421 (1904).

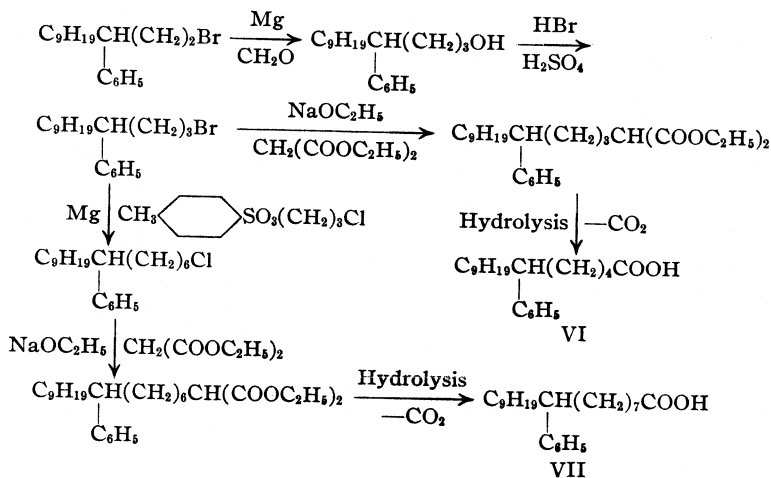

⁴ Eijkman, *ibid.*, **4**, 727 (1907).

⁵ (a) Eijkman, *ibid.*, **5**, 655 (1908); (b) Nicolet and deMilt, *THIS JOURNAL*, **49**, 1103 (1927); (c) Schmidt, *ibid.*, **52**, 1172 (1930); (d) Martin and Adams, private communication; (e) Fournau and Baranger, *Bull. soc. chim.*, [4] **49**, 1161 (1931).

The methods used for 6-phenylpentadecanoic acid (VI) and 9-phenyloctadecanoic acid (VII) are outlined in the following diagram

The alkyl phenyl carbinols and chlorides of the type $\begin{array}{c} \text{R-CHOH} \\ | \\ \text{C}_6\text{H}_5 \end{array}$ and $\begin{array}{c} \text{R-CHCl} \\ | \\ \text{C}_6\text{H}_5 \end{array}$, respectively, were not usually purified for use in further syntheses

because they partially decomposed with the loss of water and hydrogen chloride, respectively, when an attempt was made to distill them. In the preparation of 6-phenyldecanoic acid an attempt was made to prepare the Grignard reagent from *n*-butylphenylchloromethane and to build up the chain by two methylene groups with ethylene oxide. The method could be used but it was not reliable and slight variations in the procedure which did not seem to be controllable resulted in a Würtz synthesis to give 5,6-diphenyldecane, and no Grignard reagent could be found. The malonic ester synthesis from the alkyl phenyl chloromethane gave about 75% yields on the average.

All of the other reactions were carried out according to the usual procedures described in the literature. Each of the new phenyl fatty acids

was characterized by the preparation of the *p*-bromophenacyl ester according to the procedure of Judefind and Reid.⁶

The results of the physiological experiments will be reported at a later date by Professor Corley.

Experimental Part

Grignard Reagents.—The Grignard reagents were prepared by the usual procedure using, on the average, seven moles of ether⁷ per mole of alkyl halide. The ether was dried by distilling from ethylmagnesium bromide. The ether solution of the alkyl halide was added to the reaction mixture at such a rate as to cause very gentle refluxing.

Alkylphenylcarbinols.—The method of Conant and Blatt⁸ for the preparation of alkylphenylcarbinols was applied to *n*-butylphenylcarbinol, *n*-octylphenylcarbinol and *n*-nonylphenylcarbinol. The *n*-butylphenylcarbinol, b. p. 97–104° (5 mm.), was obtained in the same yield which they have reported.

***n*-Octylphenylcarbinol.**—Several 2-mole runs of this alcohol were made and the yield of undistilled carbinol averaged 92% of the theoretical amount. It decomposed slowly on distillation under reduced pressure so that it was inadvisable to purify the product to be used in further work. A small sample was purified for analysis: b. p. 124–129° (3 mm.); n_D^{20} 1.4966; sp. gr.₂₅²⁵ 0.9238.

Anal. Subs., 0.2089: CO₂, 0.6237; H₂O, 0.2037. Calcd. for C₁₈H₂₄O: C, 81.75; H, 10.98. Found: C, 81.45; H, 10.85.

***n*-Nonylphenylcarbinol.**—The crude yield of this alcohol from a 2-mole run was 97% of the theoretical amount. The constants were determined on a purified sample: b. p. 121–124° (0.2 mm.); n_D^{20} 1.4953; sp. gr.₂₅²⁵ 0.9194.

Anal. Subs., 0.2224: CO₂, 0.6684; H₂O, 0.2223. Calcd. for C₁₆H₂₆O: C, 81.98; H, 11.19. Found: C, 81.97; H, 11.18.

Alkylphenylchloromethanes.—The alkylphenylcarbinols were converted to the chlorides by saturating with dry hydrogen chloride and heating the mixture. As a typical case dry hydrogen chloride was passed into 275 g. of crude carbinol contained in a 500-cc. gas washing bottle. Heat was generated and the carbinol at first became turbid and then two layers separated. When the reaction began to subside the bottle containing the reaction mixture was placed in a hot water-bath maintained at 60–70° and the current of dry hydrogen chloride was passed through the mixture about two hours longer. Ether was added to take up the chloride and the layers were separated. The ether solution was washed thoroughly with water and sodium bicarbonate solution to remove hydrogen chloride. It was then dried first over anhydrous magnesium sulfate, filtered and then dried over phosphorus pentoxide. The solution was again filtered and the ether was removed by distillation from a steam cone. The chloride was heated to 100° under 25 mm. pressure for a half an hour to remove low boiling impurities. Only *n*-butylphenylchloromethane was distilled under reduced pressure. The yield was 83% of the theoretical amount of a product; b. p. 84–87° (4 mm.); n_D^{20} 1.5125; sp. gr.₂₅²⁵ 0.9976. This material was not pure but contained some of the unsaturated hydrocarbon due to loss of hydrogen chloride. Chlorine analyses were about 1% too low. The other two chlorides were not distilled. The crude yields were 93% for the *n*-octyl derivative and 91% for the *n*-nonyl derivative.

Malonic Ester Synthesis.—All of the substituted malonic esters prepared in this work were made according to the method described in "Organic Syntheses"⁹ except that the alcohol was dried with magnesium methyllate¹⁰ and the halide which was used was added more slowly (about 40–60 drops per minute). The reaction mixture was held at about 70° during the addition of the halide.

A record of the various preparations is given in Table I.

TABLE I
MALONIC ESTER SYNTHESSES

Conversion of RMgX to RCH₂OH.—The reactions between the Grignard reagent and formaldehyde were carried out according to the procedure described in "Organic Syntheses."¹¹ The end of the reaction was noted by the fact that when all of the Grignard reagent had been used the ether ceased to reflux. No more formaldehyde was distilled into the reaction mixture after this drop in temperature of the reaction mixture was noted. The reaction mixture was decomposed with a small volume of saturated ammonium chloride solution and the alcohol was isolated by separating the ether solution, washing it with water and then drying with anhydrous magnesium sulfate. The ether was removed and the alcohol

⁹ "Organic Syntheses," **4**, 11 (1924).

¹¹ "Organic Syntheses," **6**, 22 (1926).

fractionated under reduced pressure. In each reaction of this type a high boiling residue of the acetal formed by the action of formaldehyde on the alcohol was left behind.¹² In the one case where this amounted to 34% of the total yield, hydrolysis to the desired alcohol was effected in 50% yield by refluxing it with alcoholic hydrogen chloride for twenty-two hours.

3-Phenyldodecyl bromide gave a 61% yield of 4-phenyltridecanol-1 and 11% of high boiling acetal which was not treated further.

3-Phenylheptyl bromide gave a 45% yield of 4-phenyloctanol-1 and 34% yield of acetal. This was hydrolyzed and the final yield of alcohol amounted to 62% of the theoretical amount. In the last preparation a low boiling fraction was isolated; b. p. 68–71° (3 mm.); sp. gr.₂₅²⁵ 0.8585; n_D^{20} 1.4871.

Anal. (3-Phenylheptane) Subs., 0.2092; CO₂, 0.6785; H₂O, 0.2132. Calcd. for C₁₃H₂₀: C, 88.56; H, 11.44. Found: C, 88.48; H, 11.34.

The constants on the two new alcohols are given in Table III.

Conversion of RMgX to RCH₂CH₂OH.—The reactions between the Grignard reagents and ethylene oxide were carried out as described in "Organic Syntheses"¹³ except that the reaction mixture was not allowed to heat much above 0° during the addition of ethylene oxide and after decomposition of the reaction mixture, the ether–benzene solution was thoroughly washed with water, dried over anhydrous magnesium sulfate and the solvent distilled. The residue was distilled under reduced pressure.

5-Phenylnonanol-1 was obtained in 55% of the theoretical amounts from 3-phenylheptyl bromide and 6-phenyldecanol-1 was obtained in 54% of the theoretical amount from 4-phenyloctyl bromide.

The constants of these alcohols are given in Table III.

Preparation of Phenyl Alkyl Bromides.—The method used for preparing the bromides from the various alcohols was essentially that described in "Organic Syntheses"¹⁴ for the higher alcohols. A mechanical stirrer was used on account of the low solubility of the alcohols. It was found necessary to reduce the amount of sulfuric acid to somewhat less than that used on the simple alcohols. The refluxing period was six to eight hours.

¹² Conant, "Organic Syntheses," **8**, 124 (1928); Conant, Webb and Mendum, *This Journal*, **51**, 1246 (1929).

¹³ "Organic Syntheses," **6**, 54 (1926).

¹⁴ "Organic Syntheses," **1**, 7 (1921).

The bromides were purified by separating them from the mixture of sulfuric and hydrobromic acid, washing thoroughly with water and sodium bicarbonate solution, drying over anhydrous magnesium sulfate and distilling under reduced pressure. The once distilled bromide was then washed at 0° with small portions of 92.5% sulfuric acid. Stronger acid caused excessive charring and some sulfonation. After treating with five to six portions of sulfuric acid, the acid was no longer colored. This acid treatment had to be carefully done to avoid excessive loss. The bromide was then again washed, dried and distilled as before.

The results of these experiments are recorded in Tables IV and V.

Conversion of RMgX to RCH₂CH₂CH₂Cl.—The procedure used for converting the Grignard reagent to the alkyl chloride containing three more methylene groups was that described by Rossander and Marvel.¹⁵ The yields were increased by avoiding an excess of magnesium in the solution of the Grignard reagent. The impure chlorides obtained by distilling once under reduced pressure and collecting a 20° fraction were purified by carefully washing with small portions of 92.5% sulfuric acid at 0°. Four or five extractions with acid were necessary. The chlorides were

¹⁵ Rossander and Marvel, *THIS JOURNAL*, **50**, 1491 (1928).

then washed thoroughly with water and sodium bicarbonate solution, dried over anhydrous magnesium sulfate, and distilled under reduced pressure.

The results of these experiments are collected in Table VI.

Preparation of Phenyl Fatty Acids.—All of the phenyl fatty acids were prepared by hydrolysis of the corresponding malonic esters followed by elimination of carbon dioxide. The esters were first saponified by adding one mole of ester to a hot solution of four moles of sodium hydroxide dissolved in alcohol. Four cc. of alcohol was used per gram of ester. The reaction was vigorous and the salt separated at once. When the ester had all been added, enough alcohol was added to make stirring efficient. The mixture was stirred occasionally and refluxed for about ten hours. The mixture was then evaporated to dryness in an open vessel on a steam cone. The salt was made into a paste with water and again evaporated to dryness in order to insure complete removal of the alcohol. The salt was then dried in an oven at 100-120°. The free organic acid was obtained by adding the powdered salt to an excess of hot 16% hydrochloric acid. Stirring was used during this operation. Then the mixture was heated until all of the precipitated organic acid had melted. After cooling the crude malonic acid which was thus formed was transferred to a Claisen flask and converted to the monocarboxylic acid by heating slowly to 190°. Sometimes it was necessary to use ether extraction to separate the organic dibasic acids from the aqueous acid in which they were precipitated.

After decomposition of the malonic acid, the mixture was cooled and the monobasic acid was taken up in ether. The ether solution was washed with water to remove all of the suspended salt and was then dried over anhydrous magnesium sulfate, and the ether was distilled. The residual acid was distilled under reduced pressure. A few of the acids were not purified (except for a small amount of material for analysis) but were used directly for other preparations.

A summary of these preparations is given in Table VII.

Preparation of Ethyl Esters.—In certain cases these phenyl fatty acids were converted to the ethyl esters by the general procedure outlined in "Organic Syntheses"¹⁶ except calcium oxide (small lumps) was used as the drying agent. It was renewed after about three hours in order to prevent violent bumping. The time allowed for esterification was about twenty

¹⁶ "Organic Syntheses," 5, 59 (1925).

hours. To hasten the esterification about 12 cc. of concentrated sulfuric acid for each mole of organic acid was used as a catalyst. The ester was purified by distilling the excess alcohol, washing the residue with water and distilling under reduced pressure. The results of these preparations are summarized in Table VIII.

Reduction of Ethyl Esters to Primary Alcohols.—The reduction of the esters was carried out according to the general procedure described in "Organic Syntheses";¹⁷ however, the details were varied considerably. About 0.4 mole runs were made using eight gram atoms of sodium per mole of ester and 290 cc. of absolute alcohol⁹ per gram atom of sodium.

The sodium was cut into small pieces and placed in the flask under a little dry benzene. The ester was dissolved in about one-fifth of the total volume of ethyl alcohol in one separatory funnel and the remainder of the ethyl alcohol was placed in another separatory funnel. The benzene was warmed nearly to boiling, the alcohol solution of the ester was added all at once and just as the last of it ran in the stirrer was started and the alcohol from the other separatory funnel was added all at once. The sodium usually balled up into a large porous mass and was dashed back and forth in the solution by the stirrer. As soon as the initial vigorous reaction had subsided the reaction mixture was heated on a boiling water-bath and as soon as the sodium had dissolved the water-bath was removed and the hot sodium ethylate solution was decomposed by the cautious addition of a volume of water equal to about one-fourth the volume of the reaction mixture. The almost colorless solution was transferred to another flask and as much alcohol and benzene as possible was distilled from a steam cone. When more than one run was made it was advantageous to combine them at this point. After cooling, the layers were separated and the non-aqueous layer was taken up in an equal volume of ether and carefully washed with water several times. The ether solution was dried over anhydrous magnesium sulfate, filtered, the ether distilled and the residual alcohol was distilled under reduced pressure. The results of these experiments are summarized in Table IX.

Phenylstearic Acid from Oleic Acid.—This acid was prepared according to the procedure of Nicolet and deMilt.^{5b}

The *p*-bromophenacyl ester was prepared⁵ and it melted below 50° when first obtained. Crystallization from alcohol raised the melting point until finally after fourteen recrystallizations the melting point was 79–82°. To compare this acid with the pure samples of 9- and 10-phenyloctadecanoic acids prepared in this work, the properties of all these are summarized in Table XI.

TABLE XI
COMPARISON OF NICOLET AND DEMILTS' PHENYLSTEARIC ACID WITH KNOWN 9- AND 10-PHENYLOCTADECANOIC ACIDS

Acid	°C.	B. p.,		M. p., °C.
		Mm.		
Phenyl stearic from oleic acid and benzene	199–203	0.08		Below 0
9-Phenyloctadecanoic	200–204	.09		36.5–38
10-Phenyloctadecanoic	199–205	.09		40–41.5

n_D^{20}	Sp. gr. ²⁵	M. p. of <i>p</i> -bromophenacyl ester, °C.		Number of crystallizations
		Crude	Purified	
1.4906	0.9377	Below 50°	79–82	14
1.4891	.9340	81–83	83.5–84.5	7
1.4894	.9338	68–70	71–72	6

A mixture of equal parts of the *p*-bromophenacyl esters of the 9- and 10-phenyloctadecanoic acids melted at 65–73°. When the ester from Nicolet and deMilt's acid had been crystallized six times it melted at 66–73°. This seems to indicate that it is roughly an equal mixture of the two expected isomers.

Summary

1. Ten new phenyl substituted fatty acids have been prepared in order that certain of them could be used to test Knoop's beta oxidation theory for fatty acids.

2. The phenylstearic acid of Nicolet and deMilt has been compared with 9- and 10-phenyloctadecanoic acids and it has been found to be a mixture of approximately equal parts of these isomers.

3. A number of intermediate compounds used in the preparation of these compounds have been characterized.

THE FATTY ACIDS ASSOCIATED WITH CASSAVA STARCH

By LEO LEHRMAN

RECEIVED FEBRUARY 25, 1932

PUBLISHED JUNE 6, 1932

Some of the common cereal starches (corn, rice and wheat) have been shown to have fatty acids combined with carbohydrate in the α -amylose component.¹ The individual fatty acids found in each of these starches are the same though the amounts are different. Two tuber starches, cassava and potato, also contain combined fatty acids,² but in a much smaller percentage. Beyond this meager information no tuber starch has been investigated from the point of view of the combined fatty acids occurring in it. It would be important to know whether the fatty acids in a tuber starch such as cassava are the same as those found in the common cereal starches.

As in the investigations on the cereal starches a search for sterols and other substances that might occur in the starch and then be present in the liberated fatty acids must be made. This is necessary if there is to be any comparison of the fatty acids found in the different starches. It is also requisite to investigate the aqueous filtrate from the hydrolysis of the starch for glycerol to be sure that the fatty acids are not present in the starch as extraneous glycerides.

Experimental Part

Mixed Fatty Acids from Cassava Starch.—A sample of the cassava starch³ was extracted with petroleum ether for several hours and showed a negligible amount of extractable material. The starch was hydrolyzed by hydrochloric acid^{1b} in 2000-g. portions, a portion yielding 2 g. of a light yellow fatty semi-solid, equal to 0.1% "fat by hydrolysis" and having an iodine number of 78.8.^{1a}

Examination of Filtrate for Glycerol.—Four liters of filtrate, dark brown in color, from the hydrolysis, was evaporated to 400 cc. of a thick sirupy liquid. As there is a great deal of frothing during the evaporation it was necessary to heat a volume not ex-

² Taylor and Nelson, *ibid.*, **42**, 1726 (1920).

³ The author wishes to thank Stein, Hall and Co., Inc., New York City, for their kindness in supplying this material.

ceeding 500 cc. in a 2-liter beaker. To the thick sirupy liquid an equal volume of alcohol was added, stirred well and filtered. The dark brown filtrate was evaporated to dryness on the steam-bath. The residue was ground up, alcohol added, the mixture stirred well and filtered. The filtrate was again evaporated to dryness on the steam-bath. This procedure was repeated several times until a small amount of residue, dark brown in color, completely soluble in alcohol, was obtained. This solution gave a negative test for glycerol.⁴

Isolation and Identification of Saturated Fatty Acid.—In the course of the separation of the unsaturated fatty acids from the saturated by means of the magnesium soap-alcohol method,⁵ the insoluble magnesium soap was decomposed by heating with concentrated hydrochloric acid. The liberated fatty material on purification¹⁰ yielded a white solid melting at 62°. The phenylhydrazide was made⁶ and gave a melting point of 110°. ⁷

The molecular weight of the acid was determined by dissolving a weighed amount in methyl alcohol and titrating with a standardized solution of barium hydroxide in methyl alcohol, using phenolphthalein as an indicator.⁸

Anal. Calcd. for palmitic acid, $C_{16}H_{32}O_2$: mol. wt., 256.3. Mol. wt. found (monobasic acid), 248.

Anal. Calcd. for palmitic acid, $C_{16}H_{32}O_2$: C, 74.91; H, 12.59. Found: C, 75.15; H, 12.44.

The above data indicate the presence of palmitic acid in the mixed fatty acids.

Identification of Unsaturated Fatty Acids. A. Oxidation.—The mixture of unsaturated fatty acids separated from the saturated fatty acid by means of the magnesium soap-alcohol method was a yellow oil having an iodine number of 100.6.^{1a} When a solution of these unsaturated fatty acids in petroleum ether is chilled with an ice-salt mixture a small amount of solid forms. This was filtered off by suction while cold, washed with cold petroleum ether and allowed to dry. The dried solid has a cream color and melts at 70–71°. On account of the small amount no other data could be obtained.

A 2-g. portion of the unsaturated fatty acids was oxidized by potassium permanganate in alkaline solution.⁹ The white solid oxidized acids, after being filtered off and allowed to dry, were extracted with chloroform in order to make a separation^{1b} of the oxidized acids, if any. On evaporation of the chloroform a fatty material was obtained which was re-oxidized and gave a product different from the one obtained in the first treatment.

The solid oxidized acid (residue from the chloroform extraction) was extracted with hot water. The silky white solid obtained when the water cooled was redissolved in hot water and the solid allowed to crystallize out. This solid was filtered off and dried and gave a melting point of 155–156°.

Anal. Calcd. for tetrahydroxystearic acid, $C_{18}H_{36}O_6$: C, 62.02; H, 10.42. Found: C, 62.20; H, 10.23.

The data indicate the presence of linolic acid in the unsaturated fatty acids.

The product of the second oxidation was completely soluble in chloroform, showing the absence of tetrahydroxystearic acid. The chloroform solution was allowed to evaporate, yielding a white solid mixed with a small amount of fatty material. The

⁷ J. van Alphen, *Rec. trav. chim.*, **44**, 1064 (1925).

⁸ Escher, *Helv. Chim. Acta*, **12**, 103 (1929).

⁹ Lapworth and Mottram, *J. Chem. Soc.*, **127**, 1628 (1925).

fatty material was removed with a little ether and the white residue dissolved by extraction with chloroform. On evaporation of the chloroform a white solid, m. p. 123–124°, was obtained.

Anal. Calcd. for dihydroxystearic acid, $C_{18}H_{36}O_4$: C, 68.29; H, 11.47. Found: C, 68.39; H, 11.36.

These data indicate the presence of oleic acid in the unsaturated fatty acids.

The fact that no tetrahydroxystearic acid is found in the product of the second oxidation apparently indicates that it had been completely oxidized before the oleic acid.

The filtrate from the first oxidation was examined for higher hydroxy acids¹⁰ but the results were negative, indicating the possible absence of acids more unsaturated than linolic in the mixture of unsaturated fatty acids.

B. Bromination.—One and one-half grams of the unsaturated fatty acids was brominated,¹¹ yielding a white precipitate in the cold anhydrous ether. After washing with cold anhydrous ether and drying, the white brominated derivative gave a melting point of 175–176°.

The cold ether solution after the removal of free bromine was evaporated and the residue refluxed with hot petroleum ether. A white solid, insoluble in the hot petroleum ether, was filtered off, washed and dried. It gave a melting point of 170–172°. This solid was mixed with the precipitate obtained in the bromination above, extracted with hot petroleum ether and the petroleum ether extract combined with the same solution above. The residue of this extraction gave a melting point of 180–181°.

Anal. (Carius). Calcd. for hexabromostearic acid, $C_{18}H_{30}O_2Br_6$: Br, 63.34. Found: Br, 63.25.

These data indicate the presence of linolenic acid in the unsaturated fatty acids. It is interesting to note the detection of this acid as its bromide and the failure to find it as the oxidized product, hexahydroxystearic acid. This apparently shows that bromination is a more delicate method for detecting linolenic acid than oxidation.

When the petroleum ether from the above cooled, white crystals deposited. These were filtered off, redissolved in hot petroleum ether, allowed to crystallize and filtered. The white crystals obtained gave a melting point of 113–114°.

Anal. (Carius). Calcd. for tetrabromostearic acid, $C_{18}H_{32}O_2Br_4$: Br, 53.33. Found: Br, 53.23.

These results are additional evidence of the presence of linolic acid in the unsaturated fatty acids.

Examination for Other Substances.—The result of a sodium fusion on the mixed fatty acids showed the absence of nitrogen, sulfur and halogens. A fusion of another sample of the mixed fatty acids with a mixture of equal parts of sodium carbonate and sodium nitrate showed the absence of phosphorus.

During the alcoholic saponification of the mixed fatty acids necessary in the preparation of the magnesium soaps for the separation of unsaturated fatty acids from the saturated, no unsaponifiable matter was noticed. The Liebermann–Burchard test for phytosterol¹² was negative. The test with 1% alcoholic digitonin¹³ was also negative.

The results show the presence of four fatty acids—palmitic, oleic, linolic and linolenic—and the probable absence of other substances in the fatty acid mixture obtained by extracting the solid material resulting from the acid hydrolysis of cassava starch.

¹³ Ref. 10, p. 264.

Summary

The fatty acids liberated by the hydrolysis of cassava starch free from extraneous fatty material have been found to be palmitic, oleic, linolic and linolenic.

The detection of small amounts of linolenic acid in the presence of oleic and linolic acids by bromination is a more delicate method than by oxidation.

This is the first time that linolenic acid has been found in a starch.

FURAN REACTIONS. I. THE PYROLYSIS OF FURAN

BY CHARLES D. HURD AND A. R. GOLDSBY

RECEIVED FEBRUARY 26, 1932

PUBLISHED JUNE 6, 1932

Two possibilities of pyrolysis suggest themselves in the pyrolysis of furan. Either it should yield difuryl, a change analogous to the transformation of benzene into diphenyl, or it should break into carbon monoxide and gaseous hydrocarbons. Since no difuryl was found, the C-H union must be stronger than the C-O bond. Actually, the products formed were carbon monoxide and hydrocarbons. Because of the high temperature required (about 700°) it is interesting that methylacetylene was identified and that evidence was also obtained for cyclopropene: $C_4H_4O \rightarrow CO + C_3H_4$. In addition, acetylene, ethylene, propylene, methane and butadiene were identified.

Preliminary work¹ in this Laboratory demonstrated the stability of furan at 600° if the hot contact time was less than one second. This is higher than the value of 450–490° reported by Sinkinson² as the "initial conducting temperature." It may be noted³ that with a nickel catalyst (nickel on pumice, the oxide being reduced in a hydrogen stream at 280°) furan started to decompose at 360° when the contact time was thirteen to twenty seconds.

Furan was forced by displacement with mercury into an unpacked quartz tube (43 × 2 cm.) which was heated electrically for 32 cm. of its length. Within the tube was a glass-encased thermocouple. To condense the vapors, two empty flasks, cooled to -15°, were connected to the exit end of the tube, following which was a condensing coil at -80°.

Using 31–33 g. samples of furan it was found that by changing the duration of the experiment from 405 minutes to 110 minutes (a change of 59 to 15.6 sec. contact time) the percentage decomposition at 670–680°

¹ With F. D. Pilgrim.

² Sinkinson, *Ind. Eng. Chem.*, **17**, 31 (1925).

³ From results obtained with John W. Garrett.

dropped from 41 to 12%. Similarly, at 740°, a change from 154 to 20 minutes (19.4 to 2.59 sec. contact time) diminished the decomposition from 74 to 17%. In the last two cases, the volumes of gas produced, respectively, were 9.3 and 1.5 liters.

In the 670° experiments, the gas was approximately three-fourths carbon monoxide, one-eighth saturated hydrocarbons and hydrogen, one-eighth unsaturated hydrocarbons. In the 740° experiments, analysis showed less carbon monoxide and more saturated hydrocarbons and hydrogen.

The Unsaturated Hydrocarbons.—The 11% of unsaturated hydrocarbons in the off-gas of the 740° and 2.59 sec. experiment was composed⁴ of 3.1% acetylenes, 5.5% ethylene and 2.4% propylene admixed with undetermined amounts of allene, cyclopropene and butadiene. Longer contact times lowered the acetylene content but did not influence materially the others. That the acetylene content was largely methylacetylene was proved by liquefaction at -80° and conversion to dipropinylmercury, $(\text{CH}_3\text{C}\equiv\text{C})_2\text{Hg}$, with alkaline potassium iodomercurate. With one crystallization from alcohol this derivative⁵ melted at 196–204°. A small amount of acetylene resisted liquefaction. It gave the characteristic dull red cuprous derivative, Cu_2C_2 .

Since methylacetylene is known⁶ to pyrolyze into allene and since barium furoate has been reported⁷ to yield cyclopropene, it is reasonably certain that both of these C_3H_4 gases were present. There is good evidence from an analogous study of furfural that butadiene was probably present also.

Benzene was definitely identified (as *m*-dinitrobenzene) in the liquid products of the reaction. Only 0.2 cc. of it was found in the experiment at 670° and 59 seconds, but 1.3 cc. was found in the experiment at 740° and 19.4 seconds. These aromatic liquids are traceable as secondary products through the unsaturated hydrocarbons mentioned above.

Summary

Furan decomposes at 670–740° in a quartz tube as contrasted with a temperature of 360° when heated in the presence of catalytic nickel. The pyrolysis proceeds by rupturing the nucleus into gaseous products. A condensation reaction leading to difuryl was not observed.

FURAN REACTIONS. II. FURAN FROM FURFURALBY CHARLES D. HURD, A. R. GOLDSBY AND E. N. OSBORNE¹

RECEIVED FEBRUARY 26, 1932

PUBLISHED JUNE 6, 1932

The present method² for making furan from furfural involves two steps: namely, a Cannizzaro oxidation of furfural to furoic acid, followed by thermal decarboxylation of the acid. In searching for a method which would give furan directly from furfural, two reactions were studied. One of these, which was very successful, consisted in allowing furfural to react with hot alkali. Furan was also formed in the pyrolysis of furfural, but the yields were less satisfactory than in the first reaction.

Furan from Furfural by Hot Alkali.—Fused alkali is an oxidizing agent capable of converting aldehydes into acids (as salts). Thus, acetaldehyde³ gives rise to sodium acetate. With salts it is also a decarboxylating agent and it is pertinent that Limpricht⁴ first prepared furan by heating barium furoate with soda lime. In the present investigation, excellent yields of furan were realized by dry-distilling an intimate mixture of sodium furoate and sodium hydroxide.

To ascertain if these two effects might be combined in the case of furfural in accordance with the equations

the behavior of fused sodium hydroxide and hot soda lime on furfural was investigated. Using this plan, excellent yields of furan were realized.

The flow method seemed to be the better of the two plans tried. In it, furfural vapors were passed through a hot iron pipe which was packed with soda lime. With a rapid flow, furan was isolated in yields as high as 86% of the theoretical. With the other method, furfural was dropped onto a molten mixture of sodium and potassium hydroxides. Yields of about 60% of furan were obtained. Encrustation of the surface of the molten alkali, due to carbonate formation, introduced difficulties which were not encountered in the flow method. Considerable quantities of carbon monoxide and traces of methylacetylene (or acetylene) accompanied the hydrogen in the gas. That these were secondary products of decomposition was established since they were also formed when furan (not furfural) was dropped on the fused alkali.

Pyrolysis of Furfural.—At high temperatures benzaldehyde breaks

⁴ Limpricht, *Ann.*, **165**, 281 (1873).

down chiefly into carbon monoxide and benzene.⁵ With a similar type of pyrolysis, furfural should yield carbon monoxide and furan. Preliminary work⁶ demonstrated that no gases were formed as furfural was heated for three hours in a sealed tube at 200 or 275°. Most of the furfural was recoverable, leaving only a small amount of tarry residue on distillation. Using a flow method, 565° was found to be the initial decomposition temperature for a contact time of twenty seconds. With a reduced nickel catalyst, the decomposition temperature was lowered to 345°, which is somewhat higher than the temperature reported by Padoa and Ponti.⁷ However, their catalyst may have been different and their contact time may have been longer.

With the flow method, furfural was found to give fair yields of furan. With a contact time of 0.2 second, only one-twentieth of the furfural decomposed at 660° and one-half at 900°. By increasing the contact time to four or five seconds, two-fifths of it decomposed at 725° whereas four-fifths was altered at 800° and three seconds. At 555° and sixty seconds furfural was found to decompose somewhat but over four-fifths of it was recoverable. The best conditions for furan production by pyrolysis were found to be 725° and a contact time of about five seconds. This gave a 16.5% yield.

Experimental Part

Furfural and Hot Alkali

Fused Alkali.—An iron flask about 30 cm. tall was improvised from a small gas-storage cylinder by removing the connections and drilling away the threads so as to leave a smooth hole in the top. A rubber stopper, bearing a reflux condenser tilted at an angle of 45°, was fitted into this hole. In the top of the condenser was a 2-holed rubber stopper which carried a dropping funnel the stem of which was drawn out to a capillary tip and a tube leading to another condenser which was directed downward for condensation. The first condenser was filled with hot water (about 75°) so as to let the furan escape but to return the furfural. The second condenser, which was cooled with tap water, was connected to a helical lead pipe which was surrounded by a freezing mixture of ice and salt. The condensed furan dropped into a cooled flask. The uncondensed furan was scrubbed out of the escaping gas by conducting it through four bottles (in series) of furfural (50 cc. each), all immersed in a freezing mixture at -20°.

Two moles of furfural were placed in the dropping funnel. In the iron flask were placed two moles of technical sodium hydroxide and two of potassium hydroxide. The furfural was added at the rate of about 0.4 g. per minute after the temperature of the salt-bath surrounding the iron flask reached 300°. Eight hours was taken for the addition. Gas evolution continued for about thirty minutes after all the furfural was introduced.

Of the 192 g. of furfural which was taken, 164 g. was decomposed since 28 g. was recovered. The liquid which distilled below 40° on the first fractionation was considered to be furan. It weighed 67.5 g., which was a 59% yield based on the decomposed furfural.

⁵ Hurd and Bennett, *THIS JOURNAL*, 51, 1197 (1929).

⁶ With John W. Garrett.

⁷ Padoa and Ponti, *Atti accad. Lincei*, [2] 15, 610 (1906).

Several different modifications were tried without material benefit. The yields ranged from 54 to 64%. When the flask was heated by a direct flame considerable carbonization ensued although the yield of furan did not suffer. Curiously, only about 25–30% yields of furan were obtainable if the furfural which had been used for scrubbing was used directly on the hot alkali. One hundred cc. of this "scrubbing" furfural was found to contain 8 g. of water, 79 g. of furfural and 8 g. of a tarry residue. After redistillation this furfural again gave furan satisfactorily.

Other Products of the Reaction.—In a similar experiment wherein 29.0 g. of furfural was treated with 23.2 g. of fused sodium hydroxide, 19.7 g. of furfural was recovered. The 9.3 g. (0.097 mole) of furfural which underwent decomposition gave rise to 4.2 g. of furan (a 56% yield), 905 cc. of gas, and a carbonate residue. The gas was 71% hydrogen (0.029 mole), 22.2% carbon monoxide (0.009 mole), 4.2% methylacetylene or acetylene (0.0017 mole), and 2% carbon dioxide. The carbonate residue on acidification gave 1618 cc. of carbon dioxide. The carbonates in the original alkali gave but 20 cc. of carbon dioxide, hence 1598 cc. was generated in the reaction.

Similarly, when 9.44 g. of furan was dropped onto 10.2 g. of the fused alkali, 6.94 g. of furan was recovered and 137 cc. of gas was collected. *Anal.* CO, 67.14% or 0.0041 mole; H₂, 24.83, 0.0015; acetylenes, 7.94, 0.0005.

The gas formed when a mixture of 13.5 g. of sodium furoate and 4.0 g. of sodium hydroxide was dry distilled at 350–360° was similar. In all, 178 cc. was collected. It analyzed as follows (per cent. and mole): CO, 65.17, 0.0052; H₂, 26.42, 0.0021; acetylenes, 8.37, 0.0007. The yield of furan in this experiment was 6.2 g. or 92.6%.

Flow Method with Soda Lime.—Furfural (760 g.) was distilled during three hours into an iron pipe, 120 × 5 cm., which was about half filled with soda lime. Rubber stoppers were used for the connections. The pipe was heated for about half of its length and an inside temperature of 350–360° was maintained, as shown by a thermometer inside the pipe.

Furfural and furan were condensed from the effluent gas as previously described and the uncondensed gas was stored in a gasometer. On working up the products, 696 g. of furfural was recovered and 39 g. of furan formed, a yield which is 86% of the theoretical.

In a similar experiment wherein 600 g. of furfural was admitted during twelve hours (thus, a slower rate of flow), 318 g. was recovered and 94.5 g. of furan was formed. Here the percentage yield is only 47.5.

A 63% yield (18.5 g.) of furan was realized at 450° (a thermocouple used for the inside temperature) by distilling 192 g. (151 g. recovered) of furfural during three hours through a Pyrex tube which contained a charge of soda lime.

Pyrolysis of Furfural

Apparatus.—The apparatus used was similar to the one described for the pyrolysis of furan, furfural being introduced by displacement with mercury (see preceding paper). The 2-cm. quartz tube was used in most of the experiments but a tube of 0.55 cm. bore was used for the experiments with contact times of less than one second. Furfural and some furan was condensed from the effluent gas by cooling it to –15°. The remaining furan was removed either by cooling in a coil at –80° or by scrubbing with furfural at –15°. The effluent gas was metered and stored over salt solution in a gasometer. The essential data for six characteristic runs are given in Table I.

Gas.—The gas from each run was analyzed, a typical case showing 80% carbon monoxide, 3% carbon dioxide, 6.5% unsaturated hydrocarbons, 10% hydrogen plus saturated hydrocarbons. Generally, about one-fifth of the unsaturated hydrocarbons was ethylene; two-fifths was a mixture of methylacetylene and acetylene, chiefly the former; the remaining two-fifths was absorbed in 82.4% sulfuric acid and was a mixture

of propylene, allene, butadiene and cyclopropene. The methylacetylene was established through the mercury derivative, $(\text{CH}_3\text{C}\equiv\text{C})_2\text{Hg}$.

In several runs, the unsaturated content of the gas was converted into bromide derivatives. The dibromide fraction was found by refractive index measurements to be a mixture of about equal weights of ethylene and propylene bromides. For each cc. of dibromides there was produced about 1.5 cc. of tetrabromides. From the latter, butadiene tetrabromide, m. p. 116–116.5°, separated easily. Its identity was confirmed by a mixed melting point determination with an authentic specimen prepared from phosphorus pentabromide and erythritol. In the experiment wherein 805 g. of furfural was taken, 11 g. of pure butadiene tetrabromide was secured and, of course, more was held in the mother liquor. The latter contained tetrabromides of methylacetylene, acetylene, allene and cyclopropene. This material evolved hydrogen bromide⁸ at room temperature.

The mixture of tetrabromides from which the butadiene tetrabromide had been filtered off was added dropwise on zinc dust and boiling alcohol. Analysis of the unsaturated hydrocarbons which were thus regenerated showed the presence of 20% acetylenes and 80% other gases which were soluble in 82% sulfuric acid. The latter points to allene, cyclopropene or butadiene inasmuch as propylene should have been largely eliminated.

Liquid Products.—Furan, benzene and toluene were separated from the liquid products by distillation. Yields of 13–16.5% of furan were realized at 725° and about five seconds contact time. Higher temperatures, even with a diminished contact time, lessened the yield.

The benzene fraction was characterized by converting it into *m*-dinitrobenzene, m. p. 89°. In the 105–115° fraction, toluene was identified as 2,4-dinitrotoluene, m. p. 69–70°.

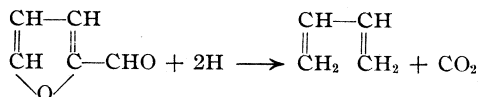

After distillation of the unused furfural, considerable residue boiling above 185° remained. This was largely phenolic. From the 88.5 g. (of furfural) run at 680° and 19.4 sec., 15 g. of this residue was encountered. Eleven grams of this was extracted with 10% sodium hydroxide solution whereupon 6 g. of phenolic material was obtained. Another 3 g. of similar material was extracted from the residue by refluxing for half an hour with 50 cc. of 20% sodium hydroxide solution. This material was not soluble in sodium bicarbonate solution. Hence, it could not have been furoic acid and, therefore, furfuryl furoate could not have been present in the original mixture. It will be recalled that under certain conditions of pyrolysis benzaldehyde changes into benzyl benzoate.

⁸ Freundler, *Compt. rend.*, **124**, 1157 (1897), reported that cyclopropene tetrabromide behaved in this way.

The tarry material which was not soluble in alkali would have contained any difuryl. α, α' -Difuryl is reported⁹ to distil at 240° and 7 mm. Our residue gave no distillate in this range.

Distillation of the phenolic portion gave a fraction, b. p. 183–190°. This was identified as phenol, for it yielded pure tribromophenol readily with bromine. An unidentified phenolic fraction was collected between 205–245° but the 245–250° fraction solidified on cooling. The latter melted at 46°, which suggests 2,6-dimethylphenol, m. p. 49°. The α -naphthyl isocyanate derivative¹⁰ of this phenol is not listed, but the higher melting 2,5-dimethylphenol gives a derivative melting at 172–173°. Our 46° material gave a derivative which melted at 174–175°. Molecular weight evidence on the 46° material was satisfactory for a xylenol. Trinitrotoluene was used as a cryoscopic solvent¹¹ and to test the method cresol gave a value of 104.5 as compared with the theoretical value of 108. The 46° crystals gave a value of 115, whereas the mol. wt. of xylenol is 122.

Dilution Experiment with Hydrogen.—No carbon dioxide was formed in the pyrolysis of furan (see preceding paper) but with furfural it comprised 2 to 3% of the gas. Since its formation was approximately equivalent to that of butadiene, it suggested the following equation

Accordingly, it was of interest to study the effect of hydrogen on furfural at high temperatures. The results showed a minor increase in the total unsaturated gases but in general no marked change resulted. For example, using a temperature of 750°, 245 g. of furfural was passed through the furnace in 218 minutes together with a current of dry hydrogen, introduced at a rate of 50–300 cc. per minute. There were formed 6 g. of furan, 4 g. of benzene and 3.5 g. of butadiene tetrabromide. The other liquid and gaseous products were also similar to those obtained without the admixed hydrogen.

Summary

Toward heat alone, furfural changes above 550° into furan and its decomposition products, carbon monoxide, methylacetylene, etc. Also, butadiene, benzene, toluene, phenol and a xylenol were identified. Excellent yields of furan were realized by passing furfural vapors through soda lime at 350° or through fused sodium hydroxide. Hydrogen was liberated and the hydroxide was changed to carbonate. The hot alkali converted a small portion of the furan into gaseous products.

TOXICAROL. IV. CONCERNING THE STRUCTURE OF TOXICAROL

BY E. P. CLARK

RECEIVED MARCH 16, 1932

PUBLISHED JUNE 6, 1932

Toxicarol when refluxed with 5% alcoholic potassium hydroxide solution loses the elements C_5H_6 and yields a colorless phenolic substance, $C_{18}H_{16}O_7$. This new compound, which has been named apotoxicarol, has the following properties. It contains a grouping having two hydrogen atoms that are readily removed by gentle oxidation, forming a dehydro derivative, $C_{18}H_{14}O_7$. It contains no readily reducible double bond; it has one more phenolic hydroxyl group than its precursor, toxicarol; and, upon oxidation with alkaline hydrogen peroxide, two acids are obtained, the structure of which can be deduced from facts now available.

The experimental evidence upon which the foregoing statements are based is as follows. When oxidized with iodine in hot alcoholic potassium acetate solution, apotoxicarol formed an iodo compound which, when treated with zinc dust and boiling acetic acid, was readily dehalogenated, forming dehydroapotoxicarol, $C_{18}H_{14}O_7$. The transformation is exactly analogous to the one which occurs when toxicarol is similarly treated¹ and indicates that the grouping responsible for the change is the same in both substances.

The readily reducible double bond present in toxicarol is absent in apotoxicarol, as shown by the latter's failure to absorb hydrogen when treated with this reagent in the presence of an active platinum catalyst.

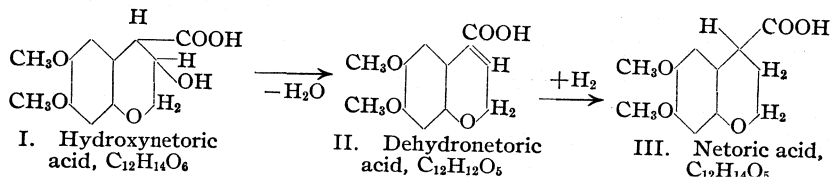

It has been shown that acetylation of toxicarol with boiling acetic anhydride and sodium acetate yields a diacetyl derivative,¹ but methylation, irrespective of the methods employed, has consistently given negative results. Apotoxicarol, however, when subjected to acetylation and methylation, as employed for toxicarol, gave, respectively, a triacetyl derivative and a monomethyl ether. It thus follows that the reaction involved in the formation of apotoxicarol consists of the loss from toxicarol of the elements C_5H_6 , and the generation of a new hydroxyl group. It also shows that the double bond existing in toxicarol is undoubtedly associated with the grouping eliminated. These facts may be explained in several ways, but because there is not yet sufficient evidence available on which to base a decision, no interpretation of the reaction will be made at this time.

The oxidation of apotoxicarol with alkaline hydrogen peroxide, however, has yielded products which materially clarify the problem of the structure of toxicarol.

¹ Clark, *THIS JOURNAL*, **53**, 2264 (1931).

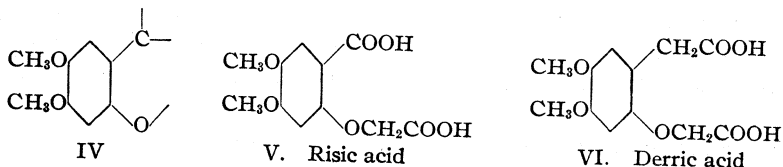

When apotoxicarol dissolved in aqueous alkali was treated with hydrogen peroxide, a vigorous reaction occurred, and two monocarboxylic acids were formed. One was a colorless substance whose molecular composition was $C_{12}H_{14}O_6$. The second acid was a brownish-yellow crystalline material, $C_{12}H_{12}O_5$. It was possible by regulating the conditions of the reaction to obtain dominantly either one or the other substance; furthermore, the first acid could be readily converted to the second by treatment with acetic anhydride.

The second acid, $C_{12}H_{12}O_5$, contained a double bond which was readily reduced, and the dihydro derivative thus formed was shown by comparison with an authentic sample to be netoric acid.² The yellow acid, $C_{12}H_{12}O_5$, was therefore dehydronetoric acid, whereas the white acid, $C_{12}H_{14}O_6$, was hydroxynetoric acid. The structure of netoric acid has not been determined, but evidence now available indicates that, as LaForge, Haller and Smith³ have already suggested, it may be represented by III. Dehydro- and hydroxynetoric acid would then be represented, respectively, by II and I.

The reasoning involved in these statements is as follows. It has been shown in the third communication of this series⁴ that permanganate oxidation of dehydrotoxicarol yields 2-hydroxy-4,5-dimethoxybenzoic acid and risic acid (V), which is 2-carboxy-4,5-dimethoxyphenoxyacetic acid. It was also shown that treatment of dehydrotoxicarol with alcoholic alkali yields a non-crystallizable acidic material probably consisting essentially of a compound analogous to derric and deguelic acids.

This acidic material when oxidized with aqueous permanganate also yields risic acid, but if it is oxidized with alkaline hydrogen peroxide, derric acid (2-carboxymethyl-4,5-dimethoxyphenoxyacetic acid, VI) is formed. These reactions prove that in the methoxylated portion of dehydrotoxicarol the grouping IV exists.

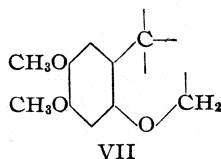

² Smith and LaForge, *THIS JOURNAL*, **52**, 4595 (1930).

³ LaForge, Haller and Smith, *ibid.*, **53**, 4402 (1931).

⁴ Clark, *ibid.*, **54**, 1600 (1932).

It is now evident that the methylene group in the $-\text{O}-\text{CH}_2\text{COOH}$ complex in risic acid (V) must have existed as such in dehydrotoxicarol, for there is no conceivable reaction whereby permanganate oxidation could cause two hydrogen atoms to be added to or exchanged for other substituents upon the carbon atom under discussion. It will also be shown later that the $-\text{O}-\text{CH}_2$ portion of the oxyacetic acid radical in derric acid (VI) was likewise present in dehydrotoxicarol.

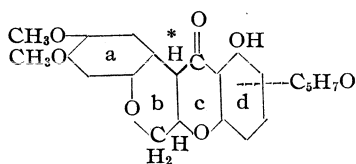

From what has just been presented it follows that in dehydrotoxicarol there exists the atomic grouping VII consisting of $\text{C}_{10}\text{H}_{10}\text{O}_3$. The difference between this formula and that of netoric acid, $\text{C}_{12}\text{H}_{14}\text{O}_5$, after deducting a carboxyl group, is CH_3 . This must of necessity form a saturated ring, and the conclusion therefore emerges that netoric acid is represented by III or by the isomeric form in which the carboxyl group is attached to the carbon atom β to the oxygen of the pyran ring.

That formula I is undoubtedly the correct interpretation follows from facts previously published together with some new observations which will now be considered.

All direct attempts to prove the presence of a carbonyl group in toxicarol by securing characteristic derivatives such as oximes or semicarbazones have failed, but evidence of a different character definitely indicates the presence of a carbonyl group in toxicarol. The facts to be considered in this connection also indicate that the phenolic hydroxyl group in toxicarol is ortho to the carbonyl group and that one of the hydrogen atoms which is readily removed by mild oxidation in the dehydro formation is attached to a carbon atom adjacent to the carbonyl group.

In order conveniently to present the evidence in support of the state-

ments just made, a formula which is provisionally submitted as representing the structure of toxicarol (VIII) will be used.

Previously recorded information concerning the acyl derivatives of toxicarol¹ is as follows. Toxicarol when treated with benzoyl chloride in pyridine forms a monoben-

zoyl derivative; but when it is acetylated with acetic anhydride and sodium acetate, a diacetate is obtained. The diacetate is more reactive toward oxidizing agents than is toxicarol, and it is capable of reduction to monoacetyldihydrodesoxytoxicarol.

These data when considered together with other reactions to be subsequently discussed may be explained on the basis of a keto-enol mechanism.

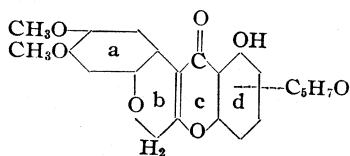

Benzoylation of toxicarol in the manner in which the reaction was conducted affected only the hydroxyl group on the benzene ring *d*; but

acetylation with boiling acetic anhydride and sodium acetate caused the acetylation not only of the phenolic hydroxyl group but also of the enol formed by the migration of the hydrogen marked with the asterisk to the carbonyl group. Reduction of the enol-acetate to monoacetyldihydrodesoxytoxicarol is in harmony with the results recently recorded by Roll and Adams⁵ in which they show that enol-acetates are reduced to desoxy compounds with the elimination of the acetoxyl group. According to the mechanism here proposed, diacetyltoxicarol would be an enol compound with a double bond in ring *c* and consequently would be more susceptible to oxidation than would toxicarol.

In order to supplement these deductions the results obtained by hydrolyzing diacetyltoxicarol are also presented. When rapidly hydrolyzed with sodium methylate, a product was obtained differing from toxicarol in crystalline habit and in having a lower melting point (160–170°). Upon several rapid recrystallizations of this material, the low-melting rods changed to plates whose melting point was 220°, which is characteristic of toxicarol. This phenomenon may be accounted for by the fact that an enol form of toxicarol is liberated which upon recrystallization reverts to the keto form.

Dehydrotoxicarol is characterized by its ability to enter into reactions which yield the several acids mentioned before, and forms only one acetyl derivative. It undergoes the Dakin reaction⁶ when treated with alkaline hydrogen peroxide, in which process the linkage between the carbonyl group and the benzene ring to which it is attached is split, with the formation of carboxyl and a new phenolic hydroxyl group.

These reactions become intelligible if the formation of dehydrotoxicarol

IX. Dehydrotoxicarol

is explained by the elimination of the two hydrogen atoms attached to the carbon atoms common to the two pyran rings. The removal of these two hydrogen atoms generates a double bond between the carbon atoms under discussion so that dehydrotoxicarol would be represented by IX.

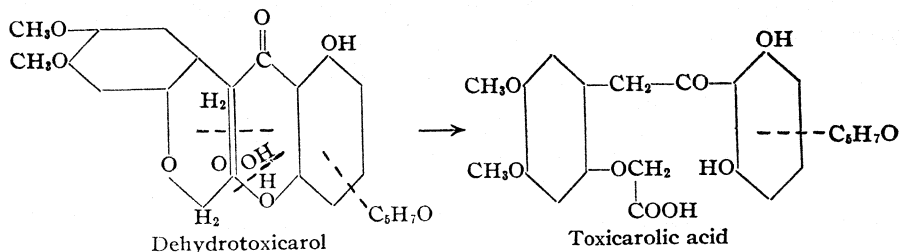

A compound of this structure would be expected to undergo the reactions given as characteristic of dehydrotoxicarol. For example, in considering the methoxylated portion of the molecule, it would be anticipated that permanganate would attack the double bond first, forming a diol which, as the reaction proceeded, would be further oxidized to risic and then to 2-hydroxy-4,5-dimethoxybenzoic acid. The two latter products, as stated before, are invariably formed when dehydrotoxicarol is treated with permanganate. Dehydrotoxicarol, according to the structure postu-

⁵ Roll and Adams, *THIS JOURNAL*, 53, 3469 (1931).

⁶ Dakin, *Am. Chem. J.*, 42, 477 (1909).

lated for it, no longer contains a hydrogen atom capable of migrating to the carbonyl oxygen to form an enol. Consequently it is only possible, as found experimentally, to form a monoacetyl derivative.

The splitting of dehydrotoxicarol with alcoholic alkali to form an acid analogous to derrisic and deguelic acids may also be explained on the basis of the structure represented by IX. This reaction is in all probability a simple hydrolysis which occurs at a double bond adjacent to a carbonyl group.⁷ It may be represented thus

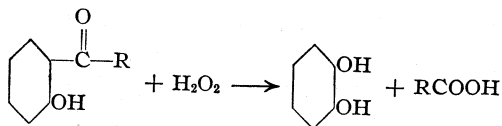

As pointed out before, no crystalline material corresponding to toxicarolic acid has been obtained, doubtless due to the lability toward alkali of the C_6H_7O group. However, when dehydrodihydrotoxicarol¹ was treated with alcoholic alkali, there was obtained in very good yield a crystalline monocarboxylic acid which analyzed for dihydrotoxicarolic acid. When treated with boiling acetic anhydride, this acid underwent a reaction which was the reverse of that by which it was formed, yielding a monoacetyl dehydrodihydrotoxicarol. This process is analogous to the way in which derrisic and deguelic acids, respectively, revert to dehydrorotenone and dehydrodeguelin. It was possible, however, to block the condensation by esterifying the carboxyl group. When this was done and the hydroxyl groups were acetylated with acetic anhydride and pyridine, a diacetyl-dihydrotoxicarolic acid ester was produced, showing that in the formation of the acid a new phenolic hydroxyl group was developed which, according to the equation given above, was due to the breaking of the oxygen bridge in ring *c*. This reaction is exactly analogous to the one which occurs with dehydrorotenone⁸ and dehydrodeguelin.⁹

The Dakin reaction to which previous reference has been made is of unusual importance when applied to dehydrotoxicarol and its derivatives. It may be described as the oxidation of ortho- and para-hydroxy derivatives of benzaldehyde, acetophenone and related substances to polyphenolic compounds and an acid. The reaction may be illustrated by the equation

⁷ Houben, "Die Methoden der org. Chem.," III auf., 1925, p. 1021.

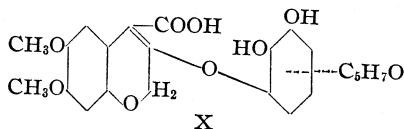

⁸ Butenandt, *Ann.*, **464**, 272 (1928).

⁹ Clark, *THIS JOURNAL*, **53**, 2369 (1931).

The formation of derric acid by alkaline hydrogen peroxide oxidation of toxicarolic and dihydrotoxicarolic acids, when considered in relation to the reaction above, furnishes more direct evidence that the structures assigned the last-named acids are probably correct.

When the same reaction was applied to dehydrotoxicarol a similar split occurred at the carbonyl group and gave an acid, $\text{C}_{23}\text{H}_{22}\text{O}_9$ (X).

This material has been designated as dehydrotoxicarol monocarboxylic acid. In the formation of this material, according to the Dakin reaction, the oxygen linkage of ring *c* remained intact, thus forming an ether. The compound was hydrogenated to a dihydro derivative, indicating that the double bond adjacent to the carboxyl group was not affected. In support of this contention an excess of hydrogen peroxide in a boiling strongly alkaline solution oxidized the ether to risic acid.

When the monocarboxylic acid was acetylated by the method of Chattaway,¹⁰ only a monoacetyl derivative was formed, whereas a diacetate was to be expected. Attempts to obtain a diacetyl compound by more drastic methods of acetylation only resulted in material which would not crystallize. However, the presence of a free hydroxyl group in the monoacetyl derivative was indicated by a faint ferric chloride test.

The formation of dehydrotoxicarol monocarboxylic acid by means of the Dakin reaction is significant as it shows that the phenolic hydroxyl group in ring *d* of dehydrotoxicarol and consequently of toxicarol is either ortho or para to the carbonyl group. However, the results relative to the failure to methylate toxicarol, reported earlier in this discussion, are sufficient proof that the position of the OH group is ortho to the carbonyl, for it is well known that an hydroxyl ortho to a carbonyl group is refractory to methylation.¹¹

It follows from what has preceded that apotoxicarol may be represented by VIII with the $\text{C}_6\text{H}_7\text{O}$ group replaced by an hydroxyl. From this structure it is possible to decide which of the two configurations proposed for netoric acid (III) is correct. The Dakin reaction applied to apotoxicarol

¹⁰ Chattaway, *J. Chem. Soc.*, 2495 (1931).

¹¹ Gomm and Nierenstein, *THIS JOURNAL*, 53, 4408 (1931), and references quoted therein.

should cause ring *c* to be split, converting the carbonyl group to a carboxyl group. With the substituents on ring *d* differing from those in toxicarol, the reaction proceeds with the elimination of ring *d* in such a manner that the oxygen atom in ring *c* forms an hydroxyl group on the carbon atom ortho to the methylene group of ring *b*. Thus hydroxynetoric acid (I) is formed, and this, as pointed out, loses the elements of water, forming dehydronetoric acid (II). The latter upon reduction yields netoric acid (III). It follows from this series of reactions that the position of the carboxyl group in netoric acid is as represented in III.

With the exception of optical activity, all available experimental data relative to the structure of toxicarol are in agreement with formula VIII. In this formula there are two optically active centers, namely, the carbon atoms common to rings *b* and *c*. In preparing toxicarol, however, it is necessary to treat with alkali the non-crystallizable extractives in which it is found and this process undoubtedly causes complete racemization. It would certainly occur at the carbon atom containing the hydrogen adjacent to the carbonyl group because alkali has been shown to cause a keto-enol change. No importance, therefore, is attached to the fact that toxicarol is optically inactive.

The reactions involved in the foregoing discussion which are presented for the first time are summarized in the accompanying chart.

Experimental

Apotoxicarol.—A mixture of 5 g. of toxicarol, 100 cc. of absolute alcohol and 10 cc. of a 50% aqueous potassium hydroxide solution was refluxed for three hours. The resulting liquid was then diluted with 1 liter of water and treated with 100 cc. of a 7.5% solution of calcium chloride. The resulting precipitate was removed by means of a folded filter, and the filtrate was acidified to Congo red with hydrochloric acid.

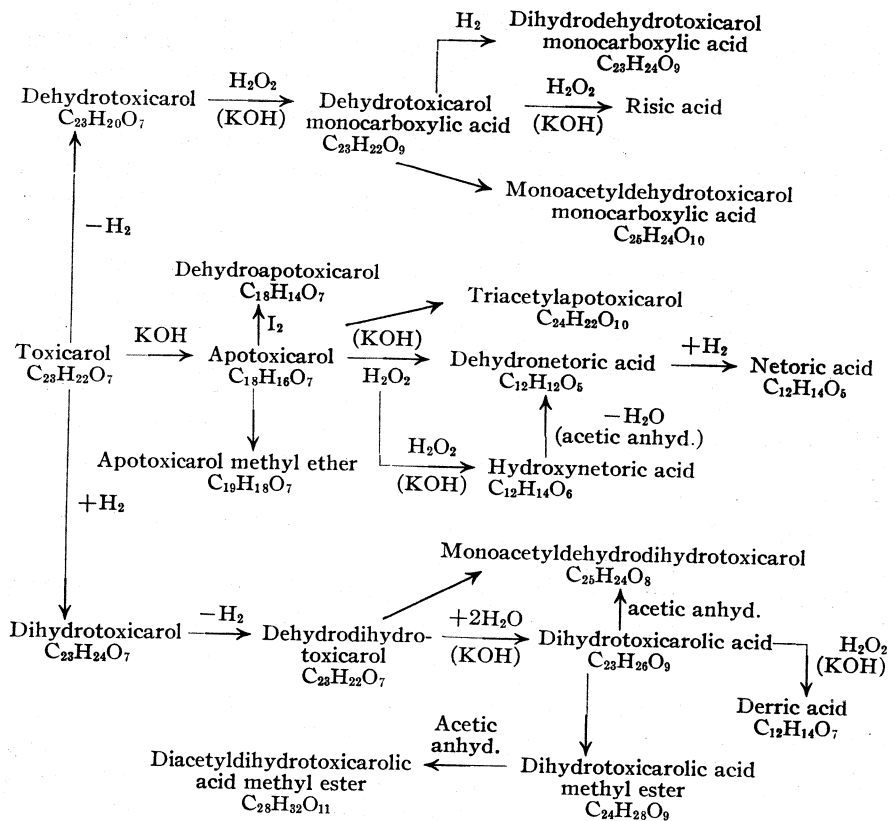

The flocky precipitate thus formed was allowed to settle, and the greater part of the supernatant solution was decanted. The remaining liquid with the precipitate was transferred to a separatory funnel and shaken with ether. The aqueous liquid was discarded, and the ether with the insoluble precipitate was shaken with fresh water, which in turn was discarded. The solid material suspended in the ether was collected upon a filter and dried.

It was purified by recrystallization from a hot saturated acetic acid solution by the addition of two volumes of methanol. The yield from 50 g. of toxicarol was usually 6 g. of crude material. Upon recrystallization this gave 4 g. of apotoxicarol whose melting point was 244°. For analysis it was recrystallized until it had a constant melting point of 246–247°. It consisted of small white rods, which frequently occurred in rosets, and it gave a deep reddish-violet color with ferric chloride.

Anal. Calcd. for $C_{18}H_{16}O_2$: C, 62.78; H, 4.69; OCH_3 (2), 18.1. Found: C, 62.91; H, 4.81; OCH_3 , 18.3.

Dehydroapotoxicarol.—One gram of apotoxicarol and 1.5 g. of potassium acetate were dissolved in 50 cc. of absolute ethanol and treated portion-wise with 20 cc. of an absolute ethanolic solution of 1 g. of iodine. The reaction mixture was allowed to stand for a day, after which the yellow crystalline iodo compound (0.65 g.) was removed by filtration. The substance evolved iodine at approximately 200°, but it did not melt

NEW REACTIONS OF TOXICAROL AND SOME OF ITS DERIVATIVES

even when heated to 310° . When the iodo compound was boiled for one and one-half hours with 25 cc. of acetic acid and 1 g. of zinc dust, dehalogenation occurred, yielding 0.2 g. of dehydroapotoxicarol. When treated with water, the mother liquors from which the crystalline iodo compound was obtained gave an amorphous precipitate. This material after having been dried was treated with zinc dust and acetic acid as above, yielding 0.1 g. of dehydroapotoxicarol.

For analysis the dehydroapotoxicarol was crystallized from a hot phenol solution by adding two volumes of methanol. It separated as light greenish-yellow rods and needles, which upon heating gradually darkened and sintered and finally melted at 298° . In parallel polarized light (crossed nicols) the extinction was straight and the elongation was negative. The polarization colors were brilliant. No interference figures were observable in convergent polarized light (crossed nicols), but the substance appeared to be biaxial: η_α , 1.543 (lengthwise); η_β , 1.685 (crosswise); $\eta_\gamma > 1.740$ (crosswise). Some rods, however, matched a liquid of η 1.740; all ± 0.003 .¹²

Anal. Calcd. for $C_{18}H_{14}O_7$: C, 63.15; H, 4.12; OCH_3 (2), 18.1. Found: C, 63.10; H, 4.28; OCH_3 , 18.3.

¹² The optical data reported in this communication were determined by George L. Keenan of the Food and Drug Administration, U. S. Department of Agriculture.

Triacetylaptopoxicarol.—A mixture of 0.5 g. of apotoxicarol, 4 cc. of acetic anhydride and 0.1 g. of anhydrous sodium acetate was boiled for fifteen minutes. The condenser was then removed, and three-fourths of the anhydride was boiled away. When the residue was treated with water the acetyl compound became solid. The yield was 0.6 g. The crude material was purified by dissolving it in 15 cc. of hot acetic acid, filtering the solution through norit and then adding two volumes of methanol.

The pure acetyl compound (0.3 g.) separated as colorless square micaceous plates which melted at 206° . The plates extinguished sharply in parallel polarized light (crossed nicols), precluding satisfactory interference figures. However, the material appeared to be biaxial when examined in convergent polarized light (crossed nicols): η_{α} , 1.547 (common); η_{β} , indeterminate; $\eta_{\gamma} > 1.740$; an intermediate value η , 1.645 is commonly found; all ± 0.003 .

Anal. Calcd. for $C_{24}H_{22}O_{10}$: C, 61.26; H, 4.72; OCH_3 (2), 13.2; acetyl, 27.5. Found: C, 61.38; H, 4.75; OCH_3 , 13.4; acetyl, 27.8.

Apotoxicarol Methyl Ether.—One gram of apotoxicarol suspended in 10 cc. of hot methanol was dissolved by adding 10 cc. of a 10% methanolic potassium hydroxide solution. Two and five-tenths cc. of dimethyl sulfate was then added all at once, and after the reaction had subsided the mixture was again subjected to the same treatment with 10 cc. of potassium hydroxide solution and 2.5 cc. of dimethyl sulfate. The reaction was completed by boiling the mixture for five minutes, after which the product was separated by adding 10 volumes of water. Nine-tenths gram of crude material whose melting point was approximately 218° was obtained. The substance was recrystallized from a hot chloroform solution by adding two volumes of methanol. Purification by this procedure was repeated until the product had a constant melting point of $236-237^{\circ}$. It consisted of sheaves and rosets of fine colorless needles and gave a dark brownish color with ferric chloride. In parallel polarized light (crossed nicols) the extinction was inclined, and the elongation was negative. The crystals were apparently biaxial: η_{α} , 1.600; η_{β} , indeterminate; $\eta_{\gamma} > 1.740$ (both ± 0.003).

Anal. Calcd. for $C_{19}H_{18}O_7$: C, 63.68; H, 5.06; OCH_3 (3), 26.0. Found: C, 63.75; H, 5.14; OCH_3 , 25.8.

Hydroxynetic Acid.—Two grams of apotoxicarol was dissolved in 35 cc. of 7.5% potassium hydroxide solution and treated portion-wise with 10 cc. of 30% hydrogen peroxide. A vigorous reaction occurred in which the color of the solution became first brown, then deep claret and finally a dark straw color. At the same time the liquid became boiling hot. After the reaction had subsided, the mixture was boiled for several minutes and then made acid to Congo red with sulfuric acid. Approximately 0.1 g. of dehydronetic acid separated (see below). This was removed by filtration, and the filtrate was allowed to evaporate to dryness in the air. The residue was extracted with acetone, and the resulting solution was concentrated to a volume of 8 cc. Upon standing, 0.35 g. of hydroxynetic acid separated. It was recrystallized from its solution in butyl ether, obtained by dissolving the acid in boiling acetone, adding two volumes of butyl ether and removing the acetone by distillation. The pure acid separated as colorless irregular-shaped plates, and occasionally rhomb-like forms, which melted at 189° . In parallel polarized light (crossed nicols) the plates extinguished sharply and showed second and third order polarization colors. In convergent polarized light (crossed nicols) the material appeared to be biaxial, although interference figures were rarely found: η_{α} , 1.513 (common); η_{β} , indeterminate; η_{γ} , 1.660 (both ± 0.003).

Anal. Calcd. for $C_{12}H_{14}O_6$: mol. wt., 254.2; C, 56.67; H, 5.57; OCH_3 (2), 24.4. Found: mol. wt. (titration), 258; C, 56.98; H, 5.66; OCH_3 , 24.4.

Dehydronetic Acid.—When 10% potassium hydroxide solution was used in the procedure described above for the preparation of hydroxynetic acid, the reaction

gave exclusively dehydronetic acid. This was obtained by acidifying the reaction mixture with sulfuric acid. The yields from experiments with 2 g. of apotoxicarol were variable, ranging from 0.35 to 0.8 g. The crude acid was purified by treating with norit an aqueous solution of the potassium salt acidified with acetic acid, after which the free acid was obtained by acidifying the filtrate with sulfuric acid.

The material had a brownish-yellow color and melted at 212° with decomposition. It consisted of short isodiametric prisms, longer rod-like prisms with square ends, and still more slender forms resembling needles. In parallel polarized light (crossed nicols) the extinction was straight and the elongation was negative. The material was biaxial, although in convergent polarized light (crossed nicols) interference figures were rarely found: η_{α} , 1.533 (commonly shown lengthwise on rods with square ends); η_{β} , 1.678 (very common on rods crosswise); $\eta_{\gamma} > 1.740$. Many rods, however, matched a liquid of η 1.740 (crosswise); all ± 0.003 .

Anal. Calcd. for $C_{12}H_{12}O_6$: mol. wt., 236.2; C, 60.99; H, 5.12; OCH_3 (2), 26.27. Found: mol. wt. (titration), 233; C, 60.98; H, 5.17; OCH_3 , 26.1.

Action of Acetic Anhydride upon Hydroxynetic Acid.—Three-tenths gram of hydroxynetic acid and 2 cc. of acetic anhydride were gently heated until the solution began to boil. The liquid was then allowed to cool for one minute, after which most of the solvent was removed by a rapid blast of air. Methanol was then cautiously added to decompose the remaining acetic anhydride, and the resulting solution was again evaporated with a current of air. When water was added to the residue, 0.25 g. of crude material was obtained, which, after recrystallization by the method given in the preceding paragraph, possessed all the properties recorded for dehydronetic acid.

Reduction of Dehydronetic Acid.—An ethyl acetate solution of 0.3 g. of dehydronetic acid was reduced with hydrogen and the platinum catalyst of Voorhees and Adams.¹³ The product obtained after removing the catalyst and solvent was dissolved in 5 cc. of boiling water and purified by filtration through norit. Upon cooling, the solution rapidly crystallized. The product contained water of crystallization, which was readily lost when the material was dried at 60° in a vacuum over potassium hydroxide. The dried acid melted sharply at 134° , and when mixed with an authentic sample of netoric acid, recrystallized in the same manner as the material under investigation, no depression of the melting point occurred. The reduction product was therefore netoric acid.

Dihydrotoxicarolic Acid.—A mixture of 5 g. of dehydrodihydrotoxicarol,¹⁴ 5 g. of zinc dust, 120 cc. of ethanol and 30 cc. of 50% potassium hydroxide solution was refluxed for thirty minutes. The clear solution was then separated from the zinc, diluted to 500 cc. with water and ice and carefully acidified to Congo red with sulfuric acid. The precipitate which was formed rapidly crystallized, yielding 5.2 g. of material which melted between 110 and 120° . When a solution of the substance in hot methanol was diluted with an equal volume of hot water, the dihydrotoxicarolic acid separated as thin, frequently elongated, hexagonal plates which melted at 129° with the evolution of gas. It gave a purple color with ferric chloride. In parallel polarized light (crossed nicols) the extinction was straight and the elongation was negative. Double refraction was extremely strong. The plates usually extinguished sharply: η_{α} , 1.515 (common lengthwise on elongated plates); η_{β} , indeterminate; η_{γ} , 1.600 (common on elongated plates crosswise); both ± 0.003 .

¹³ Voorhees and Adams, *THIS JOURNAL*, **44**, 1397 (1922).

¹⁴ This compound may advantageously be made by oxidizing dihydrotoxicarol with iodine in potassium acetate solution in the manner recorded for the preparation of dehydrotoxicarol.¹ The yield is usually 75%.

Anal. Calcd. for $C_{23}H_{26}O_9$: mol. wt., 446.3; C, 61.87; H, 5.87; OCH_3 (2), 13.9. Found: mol. wt. (titration), 451; C, 61.54; H, 6.13; OCH_3 , 14.0.

Monoacetyldehydrodihydrotoxicarol from Dihydrotoxicarolic Acid.—One gram of dihydrotoxicarolic acid, 4 cc. of acetic anhydride and 0.25 g. of anhydrous sodium acetate were refluxed for fifteen minutes. The condenser was then removed and most of the anhydride was boiled away, after which 10 cc. of methanol was added to the residue. Two-tenths gram of material separated which, after it was recrystallized by treating a chloroform solution of the substance with five volumes of methanol, melted at 238° . The material was shown to be monoacetyldehydrodihydrotoxicarol by comparison with a sample of this compound prepared by acetylating dehydrodihydrotoxicarol according to the procedure just given.

Dihydrotoxicarolic Acid Methyl Ester.—One gram of dihydrotoxicarolic acid was dissolved in 25 cc. of 4% absolute methanolic solution of hydrochloric acid. After the liquid was refluxed for thirty minutes, it was poured into crushed ice, the mixture was diluted with water and the ester was removed by filtration. The yield was 0.9 g. When recrystallized from dilute methanol it consisted of thin plates and rhombs which melted at 174° . In parallel polarized light (crossed nicols) only partial extinction of many of the plates occurred when the microscope stage was revolved. Partial biaxial interference figures were frequently shown in convergent polarized light (crossed nicols). Double refraction was extremely strong: η_α , 1.535 (common); η_β , indeterminate; η_γ , 1.740; both ± 0.003 .

Anal. Calcd. for $C_{24}H_{28}O_9$: OCH_3 (3), 20.2. Found: OCH_3 , 20.2.

Diacetyldihydrotoxicarolic Acid Methyl Ester.—One gram of the methyl ester dissolved in a mixture of 6 cc. of pyridine and 8 cc. of acetic anhydride was allowed to stand for three hours. The solution was then poured into 100 cc. of water, and the aqueous liquid was decanted from the yellow oil which adhered to the flask. The latter was washed several times with water and then dissolved in boiling methanol. Upon adding water to the solution until a slight turbidity was produced, 0.9 g. of the diacetate crystallized. It was recrystallized from its solution in hot methanol obtained by dissolving the material in chloroform, adding ten volumes of methanol and boiling the solution until the chloroform was removed. It separated as groups of rods, which melted at $143\text{--}144^\circ$.

Anal. Calcd. for $C_{28}H_{32}O_{11}$: acetyl, 15.81; OCH_3 (3), 17.10. Found: acetyl, 14.4; OCH_3 , 17.06.

Derric Acid from Dihydrotoxicarolic Acid.—Dihydrotoxicarolic acid was oxidized with alkaline hydrogen peroxide according to the directions given for the preparation of derric acid from deguelic acid.¹⁵ The product obtained melted at 168° and was shown by comparison with an authentic sample to be derric acid.

Dehydrotoxicarol Monocarboxylic Acid.—One gram of dehydrotoxicarol, suspended in 25 cc. of boiling ethanol, was quickly dissolved by the addition of 4 cc. of 50% aqueous potassium hydroxide solution. Four cc. of 30% hydrogen peroxide diluted with 6 cc. of water was then added at once, and the reaction was allowed to continue for fifteen seconds. One hundred twenty-five cc. of water was then quickly added, and the solution was filtered from a small quantity of unchanged starting material. The filtrate was then four-fifths neutralized with sulfuric acid, after which acetic acid was added until a slight turbidity resulted. The liquid was now allowed to crystallize. The yield of the acid was 0.75 to 0.9 g. The material, when recrystallized from dilute alcohol and thoroughly dried at 75° under reduced pressure, melted at 230° with the evolution of gas. It gave a dark green color with ferric chloride.

¹⁵ Clark, *THIS JOURNAL*, 53, 2370 (1931).

Anal. Calcd. for $C_{23}H_{22}O_6$: mol. wt., 442.3; C, 62.43; H, 5.01; OCH_3 (2), 14.03. Found: mol. wt. (titration), 448; C, 62.53; H, 5.12; OCH_3 , 14.0.

Risic Acid from Dehydrotoxicarol Monocarboxylic Acid.—One-tenth gram of the monocarboxylic acid was dissolved in an aqueous potassium hydroxide solution and boiled with 2 cc. of 30% hydrogen peroxide until the liquid became practically colorless. Upon acidifying the solution with sulfuric acid, a crystalline precipitate formed, which melted at 262° . This material was proved, by comparison with an authentic sample, to be risic acid.

Dihydrodehydrotoxicarol Monocarboxylic Acid.—A solution of 2.5 g. of dehydrotoxicarol monocarboxylic acid in 250 cc. of hot ethanol was reduced with hydrogen and the platinum catalyst of Voorhees and Adams.¹³ The resulting solution was filtered from the catalyst, evaporated to 50 cc., diluted with water until a slight turbidity resulted, and then allowed to crystallize. The yield was 2 g. The material was recrystallized from a hot acetic acid solution by the addition of two volumes of hot water. It separated as stout rods, which when dried under reduced pressure at 75° effloresced. The anhydrous material melted at 211° with the evolution of gas. It gave a purple color with ferric chloride.

Anal. Calcd. for $C_{23}H_{24}O_6$: C, 62.15; H, 5.44; OCH_3 (2), 13.97. Found: C, 62.20; H, 5.54; OCH_3 , 14.0.

Monoacetyldehydrotoxicarol Monocarboxylic Acid.—A mixture of 1 g. of free acid, 10 cc. of 5% potassium hydroxide, 10 g. of ice and 1 cc. of acetic anhydride was shaken for two minutes. The liquid was then acidified to Congo red, causing 1.1 g. of crude product to separate. This material was dissolved in 15 cc. of hot methanol. The solution was filtered through norit and then treated with 10 cc. of hot water. Crystallization began at once and yielded 0.7 g. of crystalline acetyl compound. It was recrystallized from its solution in hot methanol by adding an equal volume of hot water. It consisted of colorless rods which melted at 163° . It gave a faint greenish-yellow color with ferric chloride.

Anal. Calcd. for $C_{25}H_{24}O_{10}$: C, 61.98; H, 5.00; OCH_3 (2), 12.8; acetyl, 8.88. Found: C, 61.97; H, 5.08; OCH_3 , 13.1; acetyl, 8.7.

Summary

Experimental evidence herewith presented concerning the formation and reactions of apotoxicarol, dihydrotoxicarolic and dehydrotoxicarol monocarboxylic acids, when considered in conjunction with previously published data, demonstrates that quite probably the configuration of toxicarol is that represented by formula VIII (in the text). At this time no suggestion concerning the nature of the C_5H_7O grouping or its position or positions of attachment to ring *d* will be made.

REARRANGEMENT OF THE ALPHA-FURFURYL GROUP. II. 5-METHYLFURFURYL CHLORIDE AND 5-METHYLFURYLACETIC ACID¹

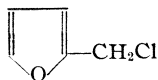

BY E. W. SCOTT AND JOHN R. JOHNSON

RECEIVED MARCH 23, 1932

PUBLISHED JUNE 6, 1932

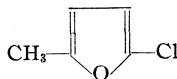

It has been observed² recently that the nitrile obtained by the action of α -furfuryl chloride upon aqueous sodium cyanide produces 5-methylfuroic acid upon hydrolysis, but the experimental data are too meager to fix with certainty the exact stage at which the rearrangement occurs. The present study was undertaken with the object of establishing this point and of investigating the mechanism of the rearrangement.

The possibility of a rearrangement of α -furfuryl chloride (I) into the isomeric 5-methyl-2-chlorofuran (II), or a dynamic isomerism of these halides, was considered to be unlikely on theoretical grounds. The synthesis of 5-methyl-2-chlorofuran through the decarboxylation of 2-methyl-5-chloro-3-furoic acid³ now excludes definitely this possibility, since the two halides are found to be entirely distinct individuals. The relationship between them is analogous to that of benzyl chloride and the chlorotoluenes; α -furfuryl chloride has the higher boiling point and the more labile halogen atom. Likewise, the possibility of a rearrangement during hydrolysis of the nitrile has now been excluded through the synthesis of

authentic 5-methyl-2-furonitrile, by the dehydration of 5-methylfurfuraldoxime. A comparison of the physical properties of 5-methyl-2-furonitrile and of α -furfuryl cyanide with those of the nitrile obtained from α -furfuryl chloride and aqueous sodium cyanide, indicate that the latter is a mixture of approximately 85% 5-methyl-2-furonitrile and 15% α -furfuryl cyanide. This result demonstrates clearly that the rearrangement of the α -furfuryl group occurs in the production of the nitrile.

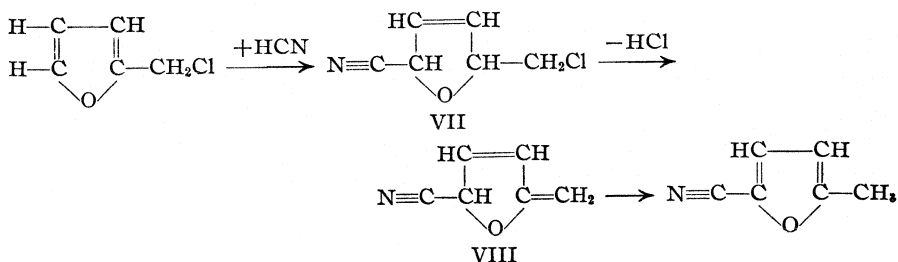

In dealing with the mechanism of rearrangement it seemed of interest to prepare a derivative of α -furfuryl chloride with a substituent in the 5-position and to observe its behavior toward aqueous sodium cyanide.

¹ This article is an abstract of a portion of a thesis submitted by E. W. Scott to the Faculty of the Graduate School of Cornell University, in partial fulfillment of the requirements for the degree of Doctor of Philosophy, in July, 1931.

² (a) Reichstein, *Ber.*, **63**, 749 (1930); (b) Runde, Scott and Johnson, *THE JOURNAL*, **52**, 1284 (1930).

³ This synthesis was carried out by Mr. G. F. Rundel.

⁵ It is probable that none of the isomeric 2,5-dimethyl-3-furoic acid is produced from 5-methylfurfuryl chloride, since this acid is sparingly soluble in water and could be detected readily.

(VII). This addition would be followed by elimination of hydrogen chloride and rearrangement of the resulting 5-methylene-2,5-dihydro-2-furonitrile (VIII) into 5-methylfuronitrile.

The postulation of 1,4-addition to the furan ring finds support in the interpretation of the behavior of furan derivatives in halogenation, nitration and ring-opening reactions. 1,4-Addition of hydrogen cyanide to the furan ring may occur, likewise, in the synthesis of aldehydes⁶ by the action of hydrogen cyanide on furan in the presence of hydrogen chloride. The observation that the aldehyde synthesis can be effected with furan derivatives containing one substituent in the 2- or 5-position, but is unsuccessful when substituents are present in both positions, can be explained satisfactorily by this hypothesis. An investigation of the addition of hydrogen cyanide to various types of furan derivatives and to conjugated aliphatic systems is now in progress.

In comparing the aromatic character of the benzene and furan rings it is of interest to note that the analogous benzene derivative, benzyl chloride, does not undergo rearrangement on treatment with sodium cyanide.⁷ This difference can be interpreted as an indication of the ethylenic, or non-aromatic, character of the furan ring and places the simple furan derivatives in an intermediate position between the 1,3-butadienes and benzene. In the benzene series the aromatic⁹ character of the ring is augmented by the presence of certain substituents (COOH, NO₂, SO₃H) and is decreased by the presence of others (OH, NH₂). In the furan series an analogous effect is observed: the presence of certain substituents (especially COOH) increases the aromatic character of the ring, and the pres-

⁶ Reichstein, *Helv. Chim. Acta*, **13**, 345 (1930).

⁷ No *o*- or *p*-tolunitrile could be detected in the nitrile produced by the reaction of benzyl chloride or benzyl iodide with sodium cyanide. On the other hand, benzylmagnesium chloride undergoes abnormal reaction with certain substances and gives rise to *o*-tolyl derivatives.⁸

⁸ Gilman and Kirby, *THIS JOURNAL*, **54**, 345 (1932); Austin and Johnson, *ibid.*, **54**, 647 (1932).

⁹ It is difficult to formulate a concise definition of the term aromatic. It is used here to mean a closely integrated, cyclic, conjugated system (containing two or more double bonds) characterized by a marked tendency to resist alteration of the conjugated system and rupture of the ring (especially through oxidation).

ence of others (OH , NH_2) causes a marked decrease of stability and a closer approach to the unsaturated aliphatic type. Since the thiophene ring is generally considered to be one of the most highly aromatic heterocycles, it would be of interest to investigate the behavior of the thiophene analog of α -furfuryl chloride, 2-chloromethylthiophene, toward aqueous sodium cyanide. A study of this reaction is in progress.

Experimental

5-Chloro-2-methyl-3-furoic Acid.—Ethyl 2-methyl-3-furoate was obtained by Benary's¹⁰ modification of the Feist synthesis, from 1,2-dichloroethyl ether and acetoacetic ester. It was found advantageous to use aqueous pyridine¹¹ in effecting this reaction instead of ammonia, since the production of a pyrrole derivative is thereby obviated and the yield of the furan derivative is increased to 50–60% of the theoretical.

The chlorination of ethyl 2-methyl-3-furoate was carried out in the manner described by Hill and Jackson¹² for the chlorination of ethyl furoate. The ester was heated in a distilling flask in an oil-bath at 145° , and a stream of dry chlorine was introduced beneath the surface of the liquid. When the gain in weight attained 80–90% of the amount calculated for the introduction of one chlorine atom, the chlorination was stopped. The reaction mixture was saponified by heating with an excess of alcoholic sodium hydroxide solution, and after adding water the alcohol was distilled off. After pouring into dilute hydrochloric acid, the crude acid was filtered with suction and washed with a small quantity of water. After recrystallization from hot water, 5-chloro-2-methyl-3-furoic acid separated in glittering plates, m. p. $122\text{--}123^\circ$ (uncorr.). The yield was 35–50% of the theoretical.

Anal. Calcd. for $\text{C}_6\text{H}_5\text{O}_3\text{Cl}$: Cl, 22.1. Found: Cl (Parr bomb), 21.85, 22.00. Neutralization equivalent: calcd., 160.5; found, 161.3.

In this product the chlorine is shown to be attached in the ring and not in the side chain since it is not removed by heating with alcoholic sodium hydroxide solution. It is inferred with reasonable certainty that the halogen entered the 5-position in preference to the 4-position, since the introduction of halogens always occurs by preference in an α -position of the furan ring. Experiments are in progress with a view to establishing the position of the halogen by means of a direct proof of structure.

5-Methyl-2-chlorofuran.—5-Chloro-2-methyl-3-furoic acid was decarboxylated in 5-g. portions by heating in the presence of high-boiling coal tar bases (b. p. $150\text{--}200^\circ$ at 16 mm.) and copper bronze.¹³ The decomposition began at $250\text{--}260^\circ$, and was quite rapid at $260\text{--}270^\circ$. From 33 g. of the acid there was obtained 12 g. of 5-methyl-2-chlorofuran (50% yield). The purified product was a colorless liquid with an odor resembling that of chloroform; b. p. $108\text{--}110^\circ$ at 740 mm., $48\text{--}49^\circ$ at $70\text{--}75$ mm., n_D^{20} 1.4579, n_D^{20} 1.4611, n_F^{20} 1.4714, n_C^{20} 1.4781, d_4^{20} 1.1204, d_4^{20} 1.1184; MR_D (calcd.) 28.67, (obs.) 28.56.

Anal. Calcd. for $\text{C}_6\text{H}_5\text{OCl}$: Cl, 30.44. Found: Cl (Parr bomb), 29.90, 30.55.

This halide is distinctly different from α -furfuryl chloride, for which Kirner¹⁴ re-

¹⁰ Benary, *Ber.*, **44**, 493 (1911).

¹¹ This modification was developed by Mr. M. O. Baker. Details of the method will be published elsewhere.

¹² Hill and Jackson, *Proc. Am. Acad. Arts Sci.*, **24**, 320 (1888).

¹³ Shepard, Winslow and Johnson, *THIS JOURNAL*, **52**, 2083 (1930).

¹⁴ Kirner, *THIS JOURNAL*, **50**, 1959 (1928).

ported the following constants: b. p. 49.6–50° at 27 mm., d_{20}^{20} 1.1804, d_4^{20} 1.1783, n_D^{20} 1.4941; MR_D (obs.) 28.788. 5-Methyl-2-chlorofuran is considerably more stable than α -furfuryl chloride toward metathetical reagents, has no lachrymatory action and does not undergo rapid spontaneous decomposition on standing. Samples of this halide have been kept for more than six months (under alkaline hydroquinone) without appreciable resinification.

5-Methylfurfural.—After preliminary experiments had been made, in which 5-chloromethylfurfural was isolated and reduced with stannous chloride, it was found that the desired aldehyde could be obtained directly by heating levulose, inulin or sucrose with dilute mineral acid in the presence of stannous chloride. Although the yield is low, this modification decreases the time required and is far less tedious than other methods.

In a 12-liter round-bottomed flask fitted with a separatory funnel and a short fractionating column, 500 g. of technical stannous chloride crystals, 2 kg. of sodium chloride and 4 liters of 12% sulfuric acid were mixed thoroughly and heated to boiling over a large gas-plate. When vigorous ebullition began, a solution of 800 g. of sucrose in 1 liter of hot water was added slowly through the separatory funnel over a period of thirty to forty-five minutes. The aldehyde distils out rapidly as it is formed, and an efficient condenser is necessary to avoid loss. The distillation was continued after all the sucrose had been added, until the distillate came over colorless. The entire distillate was carefully neutralized with sodium carbonate, saturated with sodium chloride and distilled. From the second distillate, which had separated into two layers, the methylfurfural was removed by several extractions with benzene. After distilling off practically all of the benzene, the residue was distilled under reduced pressure; b. p. 94–95° at 52 mm., 106–107° at 60 mm. The freshly distilled methylfurfural is an almost water-white liquid, but it darkens quickly on standing; it distils under atmospheric pressure at 179–184°, with slight decomposition. The yields in the above preparation varied from 8–14% of the theoretical (on the basis of the levulose residue only); usually 27–35 g. (10–13% yield) of 5-methylfurfural was obtained in a single preparation.

The 5-methylfurfural was identified by several reactions. On treatment with aqueous ammonia it gave methylhydrofurfamide, m. p. 84–85° (reported 86–87°); with hydroxylamine it gave an oxime (described below). This aldehyde underwent the Cannizzaro reaction with the production of 5-methylfuroic acid, m. p. 107–108°, and 5-methylfurfuryl alcohol; in the Perkin reaction with acetic anhydride and sodium acetate it gave 5-methylfurylacrylic acid, m. p. 153–154°.

5-Methylfuronitrile from 5-Methylfurfural.—In order to obtain a pure specimen of 5-methylfuronitrile for comparison with the nitrile obtained from furfuryl chloride this substance was prepared by the dehydration of 5-methylfurfuraldoxime.

Twenty-two grams (0.2 mole) of freshly distilled 5-methylfurfural was mixed with a solution of 25 g. of hydroxylamine sulfate and 35 g. of sodium acetate crystals in 250 cc. of water, and the mixture was allowed to stand at 20°. After the first hour a heavy semi-solid mass had separated but after twenty-four hours the reaction mixture contained a mass of long pale yellow needles. These were filtered with suction and found to melt at 110–112°, corresponding to the form described by Fromherz and Meigen¹⁵ as the *syn*-form of the oxime (m. p. 112°). Ether extraction of the aqueous filtrate gave an additional quantity of crystals which melted at 104–108°. The two fractions, amounting to 25 g., were combined for the next preparation.

Twenty-five grams of crude 5-methylfurfuraldoxime was dissolved in 42 g. of acetic anhydride and the solution was boiled gently for three minutes. After cooling

¹⁵ Fromherz and Meigen, *Ber.*, 40, 403 (1907).

the solution was poured carefully into a slight excess of sodium carbonate solution and was subjected to steam distillation. The 5-methylfuronitrile was extracted from the distillate with ether, and after drying over anhydrous magnesium sulfate was distilled under reduced pressure; b. p. 65–67° at 15 mm. The yield was 13 g. (67% yield, based upon 5-methylfurfural). 5-Methylfuronitrile is a colorless liquid with an agreeable aromatic odor; it is appreciably soluble in water and is miscible with the usual organic solvents. For analysis and determination of physical constants, the material was carefully refracted under diminished pressure: b. p. 74–75° at 27 mm., n_D^{20} 1.4848, d_4^{20} 1.0399, d_4^{25} 1.0348; MR_D (calcd.) 28.24, MR_D (obs.) 29.49. A Kjeldahl analysis gave 12.77% N; calcd. for C_6H_5ON , N, 13.08.

For comparison, the physical properties of the nitrile obtained from α -furfuryl chloride (A), pure 5-methyl-2-furonitrile (B) and α -furfuryl cyanide (C) are given.

- (A) Nitrile from $C_4H_5O-CH_2Cl$:¹⁶ b. p. 74–75° (26 mm.); d_4^{20} 1.0463; n_D^{20} 1.4833; MR_D (obs.) 29.24
(B) 5-Methyl-2-furonitrile: b. p. 74–75° (27 mm.); d_4^{20} 1.0399; n_D^{20} 1.4848; MR_D (obs.) 29.49
(C) α -Furfuryl cyanide: b. p. 78–80° (20 mm.); d_4^{25} 1.0854; n_D^{25} 1.4715; MR_D (obs.) 27.60

A rough calculation from these data indicates that the nitrile from α -furfuryl chloride described by Kirner and Richter¹⁶ contained approximately 85% of 5-methylfuronitrile and 15% of α -furfuryl cyanide.

5-Methylfurfuryl Alcohol.—5-Methylfurfural was converted into the corresponding alcohol by catalytic hydrogenation, following the method of Adams and Kaufmann¹⁷ for the preparation of furfuryl alcohol from furfural. After careful fractionation, the alcohol distilled at 70–73° (6 mm.), or 97–99° (36 mm.). The yields were 65–70% of the theoretical. The preparation of this alcohol has been described previously by Blanksma,¹⁸ who obtained it by treating 5-methylfurfural with strong potassium hydroxide solution. He reported a boiling-point of 100° at 11 mm., which is widely different from that observed in the present work, but gave no other physical constants.

5-Methylfurfuryl alcohol is a colorless liquid of pleasant odor; it is quite soluble in water and is miscible with alcohol and ether. Under atmospheric pressure (744 mm.) it boils with slight decomposition at 194–196°. A sample freshly distilled under reduced pressure had the following constants: d_4^{20} 1.0769, n_D^{20} 1.4853; MR_D (calcd.) 29.94, (obs.), 29.83. The diphenylurethan was prepared by heating for thirty minutes 1 g. of the alcohol and 1 g. of diphenylcarbonyl chloride in 5 cc. of pyridine. After two crystallizations from petroleum benzene (b. p. 60–70°), the diphenylurethan was obtained as a white crystalline solid, m. p. 52–53°.

5-Methylfurfuryl Chloride.—5-Methylfurfuryl alcohol was converted into the chloride by the method that Kirner used for the preparation of furfuryl chloride from furfuryl alcohol.¹⁴ Since this chloride appeared to be even more unstable than furfuryl chloride, the product was not isolated but was prepared in ethereal solution and used directly for the next step.

5-Methylfurfuryl Cyanide (5-Methylfuryl-2-acetonitrile) and 5-Methylfuryl-2-acetic Acid.—An ethereal solution of 5-methylfurfuryl chloride, prepared from 18 g. (0.15 mole) of 5-methylfurfuryl alcohol, was treated with aqueous sodium cyanide according to the procedure of Kirner and Richter.¹⁶ Steam distillation of the reaction

¹⁶ Kirner and Richter, *THIS JOURNAL*, **51**, 3131 (1929).

¹⁷ Adams and Kaufmann, *ibid.*, **45**, 3029 (1923).

¹⁸ Blanksma, *Chem. Weekblad*, **9**, 186 (1912).

mixture gave 2.0 g. (11% yield) of 5-methylfurfuryl cyanide, which separated as a pale straw colored liquid sparingly soluble in water.

The nitrile was hydrolyzed by boiling with 20% potassium hydroxide solution, and after acidification the acid was removed by ether extraction. After two recrystallizations from petroleum benzine, there was obtained 0.5 g. (25% yield) of colorless crystals of 5-methylfuryl-2-acetic acid, m. p. 57–58°. This acid showed no depression of the melting point when mixed with an equal quantity of authentic 5-methylfuryl-2-acetic acid synthesized from 5-methylfurfural. None of the isomeric 2,5-dimethylfuroic acid (m. p. 134°) was detected in the reaction products.

5-Methylfuryl-2-acetic Acid from 5-Methylfurfural.—This synthesis was effected through the series of reactions used previously for the preparation of 2-furylacetic acid from furfural.^{2b} Fifty-five grams (0.5 mole) of 5-methylfurfural was condensed with 30.5 g. of nitromethane (0.5 mole) in the presence of aqueous potassium hydroxide, according to the procedure of Thiele and Landers.¹⁹ After one crystallization from benzene, the 5-methylfurylnitroethylene was obtained in yellow crystals, m. p. 75–76°. An ethereal solution of this substance was reduced with zinc and acetic acid to 5-methylfuryl-2-acetaldoxime. The crude oxime was boiled for three minutes with an excess of acetic anhydride and the resulting solution was poured into an excess of sodium carbonate solution. Steam distillation of the alkaline solution gave 3 g. of 5-methylfurfuryl cyanide, which was hydrolyzed by boiling for one hour with an excess of 30% aqueous potassium hydroxide. Upon acidification there was obtained 1.5 g. of 5-methylfuryl-2-acetic acid, which after two crystallizations from petroleum benzine (b. p. 60–70°) formed colorless needles, m. p. 57–58°. This acid is moderately soluble in cold water, and is very soluble in alcohol, acetone and ether. The observed neutralization equivalent was 142.0 (calcd. 140).

2,5-Dimethylfuroic Acid.—For purposes of comparison, this isomer of 5-methylfuryl-2-acetic acid was prepared from the monoethyl ester of methronic acid (5-methyl-4-carboxyfuryl-2-acetic acid), which was obtained by warming ethyl acetoacetate with sodium succinate and acetic anhydride.²⁰ Since it is not known definitely whether the esterified carboxyl group in this ester is the one attached in the ring or that in the side chain, the reactions were carried out in such a way that the position of the esterified carboxyl group could be determined. This was accomplished by subjecting the monoethyl ester to decarboxylation, hydrolyzing the resulting ester and identifying the corresponding acid. Since the latter proved to be 2,5-dimethylfuroic acid, the esterified carboxyl in monoethyl methronate is shown definitely to be the one attached in the ring. If the side chain carboxyl had been esterified, 5-methylfuryl-2-acetic acid would have been the final product.

The decarboxylation of monoethyl methronate was followed in an approximately quantitative manner, as described previously for the decarboxylation of 2-furylacetic acid.^{2b} A sample of 5.222 g. (0.026 mole) of monoethyl methronate (m. p. 73–74.5°) on heating for thirty minutes in an oil-bath at 290–300° gave 0.860 g. (0.020 mole) of carbon dioxide and 3.462 g. (0.021 mole) of ethyl 2,5-dimethylfuroate. These quantities correspond, respectively, to 77 and 80% of the theoretical. The liquid distillates from several decarboxylations were united, washed with dilute alkali to remove undecomposed acid, dried and distilled under diminished pressure. Upon redistillation ethyl 2,5-dimethylfuroate (ethyl pyrotritarate)²¹ was obtained as a colorless liquid with a very characteristic aromatic odor: b. p. 83–85° at 6 mm., 99–101° at 14 mm.,

²¹ We are indebted to Dr. R. C. Tallman for the determinations of several of the physical constants here reported.

d_4^0 1.0718, d_4^{20} 1.0537, d_4^{23} 1.0490, n_D^{20} 1.46535, n_D^{20} 1.46897, n_F^{20} 1.47812, n_G^{20} 1.48607; MR_D (calcd.) 43.93, (obs.) 44.43. This ester has previously been described by Brühl,²² who reported: $n_D^{23.1}$ 1.46862, $d_4^{23.1}$ 1.0478.

Two grams of the ester was hydrolyzed by refluxing for several hours with 2 g. of potassium hydroxide dissolved in 50% alcohol. After distilling off the alcohol, the cooled alkaline solution was poured into ice-cold 5% hydrochloric acid. The precipitated 2,5-dimethylfuroic acid was filtered with suction and dried; without further purification the acid melted at 132.5–133.5 (corr.). After crystallization from petroleum benzine (b. p. 100–110°), the acid formed white needles, m. p. 134°. This acid has previously been obtained by several methods; the melting points reported by various investigators lie in the range 133–135°.²³

Summary

It has been shown that rearrangement of the α -furfuryl group into the 5-methylfuryl group occurs in the reaction of α -furfuryl chloride with aqueous sodium cyanide. The resulting nitrile contains approximately 85% of 5-methyl-2-furonitrile and 15% of α -furfuryl cyanide.

5-Methylfurfuryl chloride was synthesized and was found to react normally with aqueous sodium cyanide to give 5-methylfuryl-2-acetonitrile. The latter upon hydrolysis gave 5-methylfuryl-2-acetic acid. This acid was also synthesized by an independent method from 5-methylfurfural.

It is suggested that the mechanism of the rearrangement reaction involves 1,4-addition of hydrogen cyanide to the furan ring.

ITHACA, NEW YORK

NOTES

The Preparation of Tetrathiopentone

By STEPHEN A. KARASIEWICZ

In the course of attempts to iodize oleic acid by means of hydrogen sulfide and iodine, employing acetone as solvent, it was observed that white crystals of tetrathiopentone, $C_{15}H_{28}S_4$, were formed as a by-product of the reaction. This substance was first described by Fromm and Baumann.¹

The course of the reaction between iodine, hydrogen sulfide and acetone is probably analogous to the method of Fromm and Baumann, who used concentrated hydrochloric acid, hydrogen sulfide and acetone, since there is

¹ Fromm and Baumann, *Ber.*, **22**, 1044 (1889).

conversion of iodine into hydriodic acid during the reaction. A larger yield is obtained from the new method, as 20 g. of tetrathiopentone is obtained from 60 cc. as compared to 16 g. from 100 cc. of acetone. In repeating the Fromm and Baumann method only 3 g. of tetrathiopentone was obtained. The method of preparation and purification used for tetrathiopentone during this study also appeared easier. The substance crystallizes readily from the acetone and when filtered and washed with fresh acetone is pure.

When tetrathiopentone was reduced in liquid ammonia with sodium, isopropyl mercaptan was isolated and identified as the 3,5-dinitrobenzoyl derivative.²

Experimental.—Twenty grams of pulverized iodine is dissolved in 60 cc. of acetone and a stream of hydrogen sulfide is passed through this solution for seven hours. Fresh acetone should be added to replace that evaporated by the heat evolved at the beginning of the reaction. The completion of the reaction is marked by a reddish-brown discoloration of the solution and by the appearance of white crystals, which increase in number upon standing in the refrigerator. The crystals are filtered and carefully washed with acetone, in which they are sparingly soluble. When 30 cc. of oleic acid is added to the above solution and hydrogen sulfide used as previously, there appear at the interface between the two non-miscible layers very pure crystals of tetrathiopentone.

These crystals, recrystallized from acetone or alcohol, melted sharply at 170–171°. The mixture melting point of equal amounts of tetrathiopentone made by both methods was 170–171°.

Mol. wt. (Camphor method).³ Calcd. for $C_{15}H_{28}S_4$: 336. Found: 333.4, 337.0.

Anal. Calcd. for $C_{15}H_{28}S_4$: S, 38.09. Found: S, 37.92, 38.13.

To 150 cc. of dry liquid ammonia in a Dewar flask is added 1 g. of powdered tetrathiopentone, which is treated with 0.3 g. of metallic sodium. After disappearance of the blue color ether is added and the ammonia allowed to evaporate. The remaining white precipitate is quickly filtered and covered with fresh ether. The suspension obtained is cooled in a salt-ice freezing mixture, while hydrogen chloride gas is passed through. When the ether solution was neutralized and the ether distilled, isopropyl mercaptan was isolated according to Wertheim's procedure. The lead salt of isopropyl mercaptan was also prepared.

Furan Reactions. III. Absorption of Furan Vapors

BY CHARLES D. HURD AND A. R. GOLDSBY

Mixtures of furan and air were made by introducing furan from a pipet into a 2-liter flask. Using a stopcock attachment, this gas was readily transferred into the buret of a modified Orsat type apparatus.¹ Fuming sulfuric acid (8% SO_3) was found to absorb the furan quickly and quantitatively, hence it was used to determine the percentage by volume of furan in the gas. The mixtures which were studied below contained about 10% of furan. The fuming acid is immediately darkened in color as the furan reaches it.

Using 40% potassium hydroxide solution in an absorption pipet, only one-third of the furan content of the gas was removed after thirty passes in and out of the reagent. With alkaline potassium iodomercurate (the reagent for acetylene) or 52% sulfuric acid solution, about 35 to 40% of the furan was removed by seven two-minute passes. With 62.5, 67.5 and 72.5% sulfuric acid, the percentage of furan removed after seven passes, respectively, was 57, 90 and 95. Using 82.5% sulfuric acid, the furan was absorbed completely in three passes. The 82.5% acid is the reagent which is used for the absorption of propylene, α - and β -butylenes, butadiene, etc. Furan was also removed quantitatively with mercuric acetate solution (50 g. in 225 cc. of water) thereby forming² tetraacetoxymercurifuran, $\text{C}_4\text{O}(\text{HgOAc})_4$. Unfortunately for its use in separating furan from other gases, this reagent also removes carbon dioxide and unsaturated hydrocarbons.

Conclusions.—Furan (gas) may be absorbed quantitatively by 82.5% sulfuric acid. A mixture of furan and ethylene could be analyzed in this manner since ethylene is not absorbed unless fuming sulfuric acid is used. The absorption method is not applicable for the quantitative analysis of furan when it is admixed with other unsaturated hydrocarbon gases. With such mixtures, liquefaction and distillation (by precise methods of fractionation) would be necessary for exact analysis.

COMMUNICATIONS TO THE EDITOR

SIR JAMES IRVINE'S VIEW ON THE CONSTITUTION OF DI- AND POLYSACCHARIDES

Sir:

In a recent communication Irvine and McGlynn [THIS JOURNAL, **54**, 358 (1932)] comment on the use of 2,3,6-trimethylglucose as a reference substance in structural investigations and urge that "much further work and the application of new methods are alike necessary before definite constitutions can be assigned to the disaccharides and polysaccharides which are convertible into 2,3,6-trimethylglucose." These conclusions are valid in so far as work initiated by Irvine is concerned, but they do not represent the present state of carbohydrate chemistry. No less than six years ago, and before the publication of Irvine and Black's paper on maltose [*J. Chem. Soc.*, 862 (1926)] an explicit statement of the ambiguity caused by the use of 2,3,6-trimethylglucose as a reference substance was given by Charlton, Haworth and Peat [*ibid.*, 98 (1926)] and in the same year (1926) Haworth and Peat [*ibid.*, 3094 (1926)] developed a new experimental method which solved completely the problem left undecided by the isolation of a trimethylhexose as a scission product of a fully methylated disaccharide. This method has been employed to determine the constitution of maltose, lactose, cellobiose, melibiose, 4-glucosido-mannose and 4-galactosido-mannose [*ibid.*, 544, 1527, 2809, 3146 (1927); 1349, 1354 (1931)]. Recently its use has been extended to problems connected with the polysaccharides, starch, glycogen and xylan [Haworth and Percival, *ibid.*, 1342, 2850 (1931)]. In addition to the full treatment given in the original papers, an ample discussion of the various problems has appeared in a monograph [Haworth, "Constitution of Sugars," Edward Arnold and Co., London, 1929] and on various occasions in summary form [see, for example, *Helv. Chim. Acta*, 534 (1928)]. No reference whatever to any of this work is made by Irvine and McGlynn.

In describing the conversion of 2,3,6-trimethylglucose, *via* its γ -methylglucoside into tetramethyl- γ -glucose, the latter authors have not observed that this series of transformations was carried out by Schlubach and Bomhard in 1926 [*Ber.*, **59**, 845 (1926)]. Comment is necessary also on the conclusions drawn by Irvine and McGlynn from their experiments on the oxidation of 2,3,6-trimethylglucose. It is well known that in aqueous solution both γ - and δ -lactones enter into equilibrium with their parent acids. In those cases where both γ - and δ -lactones are obtainable from one acid (as with 2,3,6-trimethylgluconic acid) it is clear that no evidence of preferential oxidation to one particular lactone can be obtained by treatment of the sugar with bromine water, extraction of the aqueous solution with chloroform several hours after the commencement of the

reaction, and the mere isolation of that lactone on evaporation of the chloroform. Similar considerations apply when the oxidation is conducted in the presence of an excess of calcium carbonate, with the additional complication that under these conditions most of the product may pass through the stage of the calcium salt from which the organic acid, not the lactone, is liberated on acidification. The experimental procedure of these authors is ill-adapted to the problem they have in view and definite conclusions concerning the preferential formation of either lactone during the oxidation cannot be drawn from their present results.

THE EFFECT OF FOREIGN GASES ON UNIMOLECULAR REACTIONS

Sir:

The recent communication by Steacie [THIS JOURNAL, **54**, 1695 (1932)] suggests a generalization that has apparently not been made hitherto, *viz.*, that foreign gases do not activate unimolecular reactions. The earliest experimental evidence on this subject is the work of Daniels [THIS JOURNAL, **47**, 1602 (1925)], who showed that the rate of decomposition of nitrogen pentoxide in the presence of nitrogen falls off at about 0.01 mm. partial pressure. Later experiments show that the behavior is the same in the absence of nitrogen.

The conspicuous exception to this generalization is the action of hydrogen on certain organic compounds at elevated temperatures. The explanation of this exceptional behavior is to be sought in the fact that a reaction between the hydrogen and organic molecule would be predicted by an organic chemist.

While we do not know much about the conditions under which translational energy is converted into vibrational energy [see Kassel, Rice, *Chem. Rev.*, **10**, 11 (1932)], the evidence is that this process does not take place readily. The early attempts to calculate the limiting pressure for the unimolecular decomposition of nitrogen pentoxide were without significance because only translational energy was considered.

On the other hand, vibrational energy is only transferred readily when there is a sharp resonance between the colliding molecules.

POLYHALIDES CONTAINING FLUORINE

Sir:

The literature contains no evidence of the existence of polyhalides containing fluorine, save a mention by Cremer and Duncan [*J. Chem. Soc.*, **133**, 2243 (1931)], in a study of the dissociation pressures and other properties of the polyhalides, of the absorption of iodine bromide by cesium fluoride. On the basis of absorption taking place, they concluded that a compound, probably having the formula CsFIBr , was formed.

Several years ago work was started in this Laboratory on the preparation of polyhalides containing fluorine. We have found the following four methods for the preparation of alkali polyhalides containing fluorine.

(1) To a saturated solution of the alkali fluoride one equivalent of iodine is added and the solution chlorinated to the disappearance of the iodine color. On cooling crystals which were very nearly homogeneous were obtained.

(2) The same process as (1) with the modification of using a solution acidified with hydrochloric acid gave a better yield. Recrystallization of the products from either of these methods gave homogeneous anisotropic needle-like orange crystals.

(3) A mixture in the proportion of one molecule of alkali fluoride to one atomic weight of iodine was intimately mixed by grinding and chlorinated to constant weight. The final product was an orange-yellow solid which on recrystallization from water gave a good yield of the same orange-yellow crystals as before.

(4) To the acidulated saturated solution of the alkali fluoride was added a slight excess of an aqueous solution of iodine trichloride. The same orange-colored polyhalide immediately separated as gleaming needles.

Adsorbed water was carefully removed before analysis. Since the crystals tend to lose halogen, it is best to keep them in tightly stoppered bottles. The potassium salt is very unstable and so far we have been unable to get consistent analyses of it. However, the rubidium and cesium salts are quite stable, decomposing in the open air to white salts of the corresponding fluorides, respectively, at approximately 300° , and well above 300° .

Anal. Calcd. for CsFICl_3 : Cs, 34.49; Cl, 27.62; I, 32.96. Found: Cs (perchlorate method), 34.27, 34.33; Cl, 27.61, 28.06; I, 33.38, 32.81.

The melting point of the CsFICl_3 in a sealed tube is 194° . The crystals exhibit parallel extinction and have a specific gravity of 3.565.

Anal. Calcd. for RbFICl_3 : Rb, 25.30; Cl, 31.50; I, 37.58. Found: Rb, 25.27, 25.47; Cl, 31.46, 31.52; I, 37.52, 38.05.

The melting point of the RbFICl_3 in a sealed tube is 172° . It has a specific gravity of 3.159 and exhibits parallel extinction under crossed nicols.

The potassium salt has the same crystal form as the others and qualitative analysis shows the presence of potassium, chlorine, fluorine and iodine. The investigation of this and other polyhalides containing fluorine is being continued and will be reported in detail later.

THE ATOMIC WEIGHTS OF H(2) AND Be(9)

Sir:

Among the lighter elements there are two whose atomic weights are of especial interest at this period, H(2) and Be(9). Since H(2) is a probable nuclear building unit and is also the simplest complex nucleus reported to date (excluding neutrons) an accurate knowledge of its atomic weight gives a measure of the interaction energy of two protons and one electron, which energy may be a fundamental unit of the nucleus.

Another such unit may be the proton-electron interaction energy obtainable from the difference in mass of the neutron(1) and an atom of H(1). The accurate mass of Be(9) is necessary in calculating the mass of the neutron(1) [Chadwick, *Nature*, Feb. 27, 1932].

Until these atomic weights have been accurately determined we may predict values, that for H(2) being obtained by a simple calculation, based on the assumption that the lighter $4N + 2$ elements contain $N \alpha$ particles and one H(2) nucleus. Aston [*Proc. Roy. Soc. (London)*, **A115**, 487 (1927)] gives for the packing fractions of Li(6) and B(10), 2.00 ± 0.10 and $1.35 \pm 0.05 \times 10^{-3}$ mass units (probable errors are assumed to be $\frac{1}{3}$ maximum allowable error). Using the packing fraction for helium, 0.54 ± 0.03 , we obtain from the data for Li(6)

$$\begin{aligned} 4(0.54 \pm 0.03) + 2A_1 &= 6(2.00 \pm 0.10) + D_1 \\ \text{or } A_1 &= (4.92 \pm 0.36) + D_1/2 \end{aligned} \quad (1)$$

and for B(10)

$$A_2 = (4.59 \pm 0.37) + D_2/2 \quad (2)$$

where A_1 and A_2 represent the packing fraction of H(2) and the D 's the mass defects of Li(6) and B(10) with respect to He(4) and H(2). Although these equations do not uniquely determine the packing fraction of H(2), they set a lower limit to its atomic weight at $(2.0098 + D_1 \pm 0.0007)$ from (1) and $(2.0092 + D_2 \pm 0.0007)$ from (2). From a consideration of the binding energies in some of the lighter nuclei, we may estimate values for the mass defects of Li(6) and B(10) to be $D_1 = 1.2 \pm 0.4$ and $D_2 = 2.4 \pm 0.6 \times 10^{-3}$ m. u. These values give H(2) an atomic weight of 2.0110

± 0.0011 from (1) and 2.0116 ± 0.0013 from (2); mean 2.0113 ± 0.0012 (mass spectrograph scale). The agreement is satisfactory. This gives $4.3 \pm 1.2 \times 10^{-3}$ m. u. for the binding energy of the H(2) nucleus.

The chemical atomic weight of beryllium determined by Hönigschmid [*Ber.*, **55B**, 4 (1922)] is 9.018 ± 0.002 . This is almost certainly too high, for while beryllium exists to 99.95% as Be(9) and to about 0.05% as Be(8) [Watson and Parker, *Phys. Rev.*, **37**, 167 (1931)], no isotope of mass number greater than 9 has been reported. Assuming the nucleus of Be(9) to contain 2 α particles, 1 proton and 1 electron, an upper limit for its atomic weight is 9.011 (chemical scale). This value has neglected the binding occurring between the constituents of the nucleus, which from disintegration experiments [Chadwick, *Proc. Roy. Soc. (London)*, **A130**, 463 (1931)] has a value $5 \pm 2 \times 10^{-3}$ m. u., which is about that expected from the differences in mass defects of corresponding members of the $4N + 1$ and $4N$ series. Assuming this as a mass defect for Be(9), its atomic weight becomes 9.006 ± 0.002 , and correcting for 1 part in 2000 of Be(8) gives 9.005 ± 0.002 for the atomic weight of beryllium. Since this is 0.013 m. u. less than the present chemical value a redetermination is necessary.

From the probable value of the mass of Be(9) and Chadwick's disintegration experiments we can make a rough estimate of the mass of the neutron(1), which indicates that it is little different from that of its isobar, H(1). If neutrons are formed exothermically from protons and electrons, it would seem highly probable that their formation could be effected in the laboratory and the energy change detected as radiation. The existence of H(2) nuclei [Urey, Brickwedde and Murphy, *Phys. Rev.*, **39**, 164 (1932)] and neutrons(1) suggests that all known atomic nuclei could originate from protons and electrons through a succession of *two body collisions*, e. g., $2\text{H}(2) \text{ nuclei} \rightarrow 1 \alpha \text{ particle}$, etc.

KINETICS OF THE THERMAL DISSOCIATION OF GASEOUS ETHYL BROMIDE

Sir:

More exact experimental data on simple reactions are urgently needed for testing theories of unimolecular reactions, particularly with reference to the falling-off of the rate-constant at low pressures. The reaction

has been studied for several years in this Laboratory, and a preliminary

report by E. T. Lessig is now in press. With improved technique and proper allowance for the reverse reaction, this reaction now appears to be as satisfactory a unimolecular reaction as any yet reported.

The data at pressures above 100 mm. in the range 390 to 420° are well expressed by the formula

$$k = 3.85 \times 10^{14} e^{-54,800/RT}$$

Below 120 mm. k falls off, and at 20 mm. it has only about one-third of its high pressure value. In this low pressure region the reaction appears to be purely second order. Calculations indicate 22 squared terms on the basis of present theories. Theory I of Rice and Ramsperger [THIS JOURNAL, **49**, 1617 (1927)] is not adequate to explain the facts. Temperature coefficients at the low pressures suggest that Kassel's Theory III [*J. Phys. Chem.*, **32**, 225 (1928)] may fit better than Theories II or I.

The addition of nitrogen, and of hydrogen, causes the value of k at low pressures to *decrease*. According to present accepted theories the addition of foreign gases should increase the value of k . Unless some unexpected specific chemical effect exists, the results suggest that certain aspects of present theories of unimolecular reactions should be critically reassessed.

The influence of other foreign gases of increasing complexity is now being investigated.

THE EINSTEIN RELATION AND TEMPERATURE COEFFICIENT IN THE PHOTOBROMINATION OF CINNAMIC ACID

Sir:

Exact measurements on the photobromination of cinnamic acid, now in progress, show clearly that it is possible to obtain a quantum efficiency of 1 and a temperature effect of zero in agreement with simple photochemical theory, when accompanying thermal reactions are suppressed. They show, too, how the temperature coefficient of the total reaction can vary with the concentration.

The experiments were carried out in a quartz cell of 15-cc. capacity. Light of 4358 Å. was isolated from the spectrum of a capillary quartz mercury arc by means of a monochromator. The change in bromine concentration after fifteen minutes' illumination was measured and compared with the change in the control kept in the dark. The concentration of cinnamic acid was the same in all cases.

The results are summarized in the accompanying figure where Φ , the number of molecules of bromine consumed per quantum of light absorbed, is plotted against the concentration of bromine. This concentration is expressed in moles of bromine per liter of 0.00567 molar cinnamic acid in carbon tetrachloride. The reaction is a chain reaction, the products of the bromination apparently contributing some of their energy to activate new molecules of bromine.

The striking regularity with which Φ decreases as the dilution increases suggests that the energized products of the reaction gradually lose their activation by collision with the molecules of carbon tetrachloride. At infinite dilution the deactivation of products by the solvent should be so complete that no chain reaction is possible. Under these conditions, where secondary thermal reactions are eliminated, the quantum yield should be exactly 1. Extrapolation of the experimental curves to infinite dilution shows that this prediction is correct.

Furthermore, at infinite dilution where the reaction is purely photochemical, the temperature effect should be zero. Again the graphs support this prediction in a striking manner. The curves at 30 and 0° both extrapolate, within the limit of experimental error, to the same value of Φ , namely 1.

In the more concentrated solutions the reaction is about eight times as fast at 30 as at 0°. The ratio of rates for a 10° difference in temperature is 1 at infinite dilution and increases to a limiting value of 2 in the more concentrated solutions. This value is in agreement with that of ordinary thermal reactions.

Experimental measurements and calculations are being continued.

ISOLATION OF GLUTATHIONE FROM POTATO TUBERS TREATED WITH ETHYLENE CHLOROHYDRIN¹

Sir:

Treatment of freshly-harvested potato tubers with ethylene chlorohydrin, a chemical that breaks their dormancy,² increases the sulfhydryl content of the expressed juice as shown by the nitroprusside test and by the sulfur reduction method.³ In order to find whether this increase in sulfhydryl was due to an increase in glutathione, the procedure of Hopkins⁴ for the isolation of glutathione was applied to the juice of potatoes treated with ethylene chlorohydrin.

Cut pieces of freshly-harvested potato tubers were dipped in a 1.6% solution of ethylene chlorohydrin, the excess solution drained off and the pieces placed in a closed container for twenty-four hours. They were then planted in moist soil for five days. After washing free of soil, the pieces were peeled, ground through a food chopper, the juice was expressed through cheesecloth, and the starch centrifuged out. The juice was boiled to coagulate the proteins, cooled, and filtered through glass wool. Following the procedure of Hopkins the cuprous salt of glutathione was isolated. In one experiment 1.5 liters of the boiled, filtered juice yielded 870 mg. The copper content was 17.48%; calcd., 17.26%.

The cuprous salt prepared by the above method was suspended in water and decomposed with hydrogen sulfide. After filtering out the cupric sulfide, the hydrogen sulfide was removed in a stream of hydrogen and the filtrate evaporated in a vacuum desiccator over sulfuric acid. When reduced to small volume, absolute alcohol was added and the glutathione allowed to crystallize. The yield from 395 mg. of the cuprous salt was 190 mg. of crystalline glutathione. An additional 70 mg. was obtained by bringing the mother liquor to dryness. The crystalline fraction was analyzed for nitrogen (micro Kjeldahl) and sulfur (Parr bomb).

Anal. Subs., 23.04 mg.: 10.8 cc. of *N*/50 H₂SO₄. Subs., 0.1141 g.: 0.0862 g. BaSO₄. Calcd. for C₁₀H₁₇N₃O₆: N, 13.7; S, 10.42. Found: N, 13.1; S, 10.38.

By the same procedure, 970 mg. of the cuprous salt yielded 650 mg. of glutathione. This was recrystallized and the first fraction, which weighed 275 mg., was analyzed.

Anal. Subs., 30.99 mg.: 14.7 cc. of *N*/50 H₂SO₄. Subs., 0.1024 g.: 0.0771 g. BaSO₄. Found: N, 13.3; S, 10.34.

Using the same procedure, no glutathione could be isolated from the juice of untreated tubers, although qualitative tests indicated that a small

amount was present. When potatoes that had been stored for several months were treated with ethylene chlorohydrin, the cuprous salt could be isolated, but in smaller yield than with freshly-harvested tubers. In one experiment, 1 liter of juice yielded 280 mg. of the cuprous salt; in another 600 cc. yielded 60 mg. The copper content of the latter preparation was 17.15%.

This is believed to be the first isolation of glutathione from a seed plant.

E. L. HIRST'S COMMENTS ON IRVINE AND MCGLYNN'S PAPER ON
"A POSSIBLE SOURCE OF ERROR IN DETERMINING THE CONSTITUTION
OF DI- AND POLYSACCHARIDES"¹

Sir:

The criticisms made by Dr. E. L. Hirst reveal that in his reading of the paper to which he refers he has overlooked the essential features of the work described. Constitutions are not assigned to di- and polysaccharides but attention is directed, systematically and on the evidence of experimental work described for the first time, to possible sources of error in determining the constitution of these compounds by the methylation method. It is the case that the possibility of 2,3,6-trimethylglucose functioning in both a normal and a γ -form has already been suggested but our omission of any reference to Schlubach and Bomhard [*Ber.*, **59**, 845 (1926)] does not involve that we overlooked previous work on the subject. It is at least unlikely that, as the originator of the method of solving the constitution of di- and polysaccharides by methylation, the efforts of other workers in this field should have been overlooked by me. But it may be pointed out that Schlubach and Bomhard merely converted the sugar into tetramethyl- γ -glucose through the intermediate formation of an unpurified glucoside, while in our case this glucoside was isolated after vacuum distillation as a pure compound, was analyzed and, among other reactions, was subjected to the graded hydrolysis which is obviously an essential part of the experimental scheme. The tautomerism of 2,3,6-trimethylglucose is in consequence no longer conjectural but is based on experimental evidence.

With regard to his criticisms of our studies on the oxidation of trimethylglucose, Dr. Hirst assumes that, when this reaction is carried out in the presence of calcium carbonate under the conditions we describe, the whole of the acid produced is transformed into the calcium salt. Such is

¹ Irvine and McGlynn, *THIS JOURNAL*, **54**, 358 (1932).

not the case and his criticism is pointless. The remaining papers he quotes were known to us.

AMMONIUM ACETATE AS A NEUTRAL BUFFERED STANDARD

Sir:

On theoretical grounds, Williams and Lyman [THIS JOURNAL, 54, 1911 (1932)] point out that ammonium acetate should be a good buffer at the neutral point, with P_H value practically independent of concentration. They suggest it, therefore, as a practically useful standard for hydrogen ion work and accurate titrations to P_H 7, which can be prepared in one minute. They do not describe the method for preparing the solution, but the emphasis upon the brief time required and statement that concentration is of minor importance suggest that it is only necessary to dissolve a few grams of the dry salt in a little water to secure a standard solution accurately buffered at P_H 7.

In this Laboratory, ammonium acetate solutions buffered near P_H 7 have been much used in the extraction of exchangeable bases from soil. In a description of the procedures employed [Schollenberger and Dreibebis, *Soil Science*, 30, 161 (1930)] attention has been directed to the fact that solutions of "C. P. Analyzed Reagent" ammonium acetate in pure water are likely to be far from neutral; with several lots of the salt, normal solutions so prepared were near P_H 5, indicating the presence of about one mole of free acetic acid to two of ammonium acetate. Preparation of the solution by mixing equal volumes of accurately prepared 2 *N* solutions of acetic acid and ammonia was recommended. Experience has been that a solution so prepared is invariably very nearly neutral.

According to a well-known authority [Morley and Muir, "Watt's Dictionary of Chemistry," 1899, Vol. I, p. 9], pure ammonium acetate may be prepared by saturating glacial acetic acid with dry ammonia, and is then dry, white and odorless. It is difficult to crystallize, the aqueous solution tending to lose ammonia on evaporation, leaving an acid salt.

The crystalline salt sold as a reagent is often quite moist, with a strong odor of acetic acid, indicating either improper preparation or subsequent deterioration. Hence, a solution of commercial reagent quality ammonium acetate may be of doubtful value as a neutral buffer standard. Implicit reliance upon the purity and neutrality of a solution of the crystallized salt is certainly unjustifiable.

AN ADDITION COMPOUND OF DIETHYLAMINE AND PHENYLBORIC ACID

Sir:

An addition compound has been prepared with diethylamine and phenylboric acid. It was expected that these should combine in a one to one ratio since boron trifluoride forms stable one to one addition compounds with ammonia or amines¹ and triphenylboron behaves in a similar manner.² Analyses, however, have shown that this substance contains three molecules of phenylboric acid to one of diethylamine.

This compound is readily prepared by allowing equal molal quantities³ of the two substituents to react in anhydrous ether solution. There is a slight initial rise in temperature and after a few minutes a white solid (m. p. 85°) is precipitated. It is readily soluble in alcohol, acetone, benzene, chloroform, glacial acetic acid and dioxane, and sparingly soluble in diethyl ether, petroleum ether, water and carbon tetrachloride. When heated with water it decomposes, giving off diethylamine quantitatively.

The nitrogen content was obtained by heating the substance in dilute alkali and titrating the diethylamine which was volatilized with the vapors. It was observed that phenylboric acid could be titrated in the presence of glycerine just like boric acid itself, so the phenylboric acid (or possibly boric acid) residue in the Kjeldahl flasks was titrated in this manner. Independent boron analyses were obtained by heating the substance in bomb tubes with nitric acid, neutralizing the nitric acid to the methyl red end-point, and titrating the boric acid to the phenolphthalein end-point in the presence of glycerine.

Determination	Found, %		Calculated for (C ₆ H ₅ B(OH) ₂) ₃ ·(C ₂ H ₅) ₂ NH, %
Nitrogen	3.20	3.18	3.19
Boron from residue of N ₂ analysis	7.63	7.37	7.40
Boron, Carius determination	7.21	7.28	7.40

It should be pointed out that these analyses do not preclude the possibility that this compound may have lost one molecule of water. This work is being continued.

ALLYL ETHERS OF HETEROCYCLIC ENOLS

Sir:

During research carried out in connection with the preparation of substances allied in structure to the alkaloid coniine, it became necessary to study the preparation and pyrolysis of the allyl ethers of heterocyclic enols. It is well known that α - and γ -N-heterocyclic enols show a marked tautomeric mobility of the enolic hydrogen between oxygen and nitrogen with preferential attachment to the nitrogen. The O-ethers are more difficult to prepare than the N-ethers, the best yields of the former being obtained via the silver salts or chlorine substituted derivatives.

The alkoxy ethers on heating usually undergo a rearrangement of the alkyl group, which wanders invariably to the nitrogen atom in preference to a nuclear carbon atom. One might expect that the allyl group would undergo an analogous migration [cf. Hurd, "The Pyrolysis of Carbon Compounds," The Chemical Catalog Company, 1929, pp. 205 and 223]. Tschitschibabin and Jeletsky [*Ber.*, **57**, 1158-61 (1924)] report having pyrolyzed O-allyl-carbostyryl into the N-isomeride.

It has been found in the course of the present work that the migration of the allyl group can occur from oxygen to the adjacent β -unsaturated carbon atom. Thus 4-allyloxyquinaldine pyrolyzes almost quantitatively on heating for a short time, at 200°, to 3-allyl-4-hydroxyquinaldine, the constitution of which has been proved by its synthesis from α -allyl- β -phenylaminocrotonic ester. This is interesting since, in the case of 4-methoxyquinaldine, migration of the methyl group takes place to the nitrogen atom [Conrad and Limpach, *Ber.*, **20**, 956 (1887)].

The significance of these results, and of those obtained with other oxy-N-heterocyclic substances, will be reported shortly in greater detail.

NEW BOOKS

Chemistry at the Centenary (1931) Meeting of the British Association for the Advancement of Science. W. Heffer and Sons, Ltd., Cambridge, England, 1932. Price, 7/6, net.

The experience of a century has taught scientists in general and chemists in particular to expect papers of interest and pronouncements of lasting importance at the meetings of the British Association. It is hard for us to say whether the attractively published volume before us, a complete record of the Proceedings of the Chemistry Section, contains any pronouncement of an epoch-making character, but it is easy to discover that every paper is an interesting account of some of the very latest work. A scholarly dis-

course on "Michael Faraday and the Theory of Electrolytic Conduction" by Sir Harold Hartley opens the Proceedings. It contains an excellent historical survey of the development of thought and experiment on solutions of ionized solutes. There follow discussions on "The Influence of the Medium on the Properties of Electrolytes" which in spite of much writing is still far from being a solved problem, "Vitamin-A and the Carotenoids," "The Chemistry of Vitamin-B and Related Problems" and "The Structure of Simple Molecules," and a symposium on "The British Fuel Problem."

In all these discussions the contributors, a truly international array of celebrities, have given consideration to the general scientific reader and as a result the very latest advances are presented most comprehensibly. The fearless and scientific way in which the coal and oil problems of Britain are treated makes the book worth buying for this symposium alone.

While this collection, containing, as it does, contributions not yet published elsewhere from authorities all over the world, will surely be of surpassing interest to those actively pursuing research in the subjects mentioned above, we heartily recommend it to those general readers who wish to keep themselves posted on the latest news from the front of these rapidly advancing lines of investigation.

R. E. GIBSON

Rechnenverfahren und Rechenhilfsmittel mit Anwendungen auf die analytische Chemie. (Methods of Calculation, Aids to Calculation and Applications to Analytical Chemistry.) By Prof. Dr. OTTO LIESCHE, Seelze bei Hannover. Verlag von Ferdinand Enke, Stuttgart, Germany, 1932. viii + 203 pp. 24 figs. 16.5 × 25.5 cm. Price, RM. 20; bound, RM. 22.

There are innumerable manuals devoted to chemical arithmetic and there are many textbooks of higher mathematics particularly designed for the enlightenment of chemists. I am not acquainted with any book covering the important aspects of chemical computation discussed in this volume.

The initial chapter of fifty or more pages is devoted to methods of simple numerical computation, particularly multiplication and division. The author first points out that these subjects are usually taught us so early in our intellectual development that they cannot be presented at that time from the abstract point of view which is necessary both for their thorough comprehension and their most efficient use. Moreover, arithmetic in general and the simpler parts of algebra are neglected in our higher mathematical training so that their application to the most frequent computational requirements of our later work is frequently lost. The author thereupon gives an excellent presentation of the so-called Ferrol methods of multiplication and division, and in a form particularly adapted for self-instruction. Many of these rapid methods should, according to the author, greatly lessen the need of resorting to logarithms, etc.

The second chapter sets forth the utilization of the various aids to multiplication and division—namely, logarithms, slide-rules and calculating machines.

The third chapter discusses at length specifically chemical computations and their algebraic formulation, taking up simple gravimetric analysis, "indirect" analysis (utilizing determinants), analysis of complex mixtures, errors and computations dealing with gases. The final chapter discusses nomography.

This is certainly a most instructive book.

ARTHUR B. LAMB

The Preparation of Pure Inorganic Substances. By E. H. ARCHIBALD, Professor of Analytical Chemistry, University of British Columbia. John Wiley and Sons, Inc., 440 Fourth Ave., New York City, 1932. x + 383 pp. 14.5 × 22.5 cm., 20 figs. Price \$3.75.

The guiding principle followed in the compilation of this work is clearly set forth in the opening paragraph of the Preface:

"The past thirty years have seen a marked advance in the precision and accuracy of physical and chemical, as well as other scientific measurements. In order to take advantage of these improvements, it is frequently necessary for the chemist to supply substances of a much higher degree of purity than corresponds to our "C. P." products. Fortunately, during these thirty years, many methods have been devised, and a great many principles have been set forth, according to which the purification of a large number of chemicals can be effected. What are thought to be the more dependable and simple of these methods are set forth in the following pages."

The author is eminently qualified to speak with authority upon this subject, by reason of his long contact with and his outstanding success in atomic weight determinations, which involve the preparation of materials approaching absolute purity and the careful elimination of errors in the use of such reagents. Many of the methods described have been followed with utmost care by the author and his associates and most of the others are familiar to him by reason of the close parallel in his own work. Such a setting gives the reader a justified confidence in the authority and integrity of the author.

Chapter 1 is devoted to a general discussion of the methods of purification and the refinements which may be employed in each. For example, crystallization is discussed in detail with respect to the effect of inclusion, adsorption, the solid solution of isomorphous substances, the size and form of the crystals, the percentage of the salt crystallizing out, and the efficiency of centrifugal drainage and washing. In addition, attention is paid to the danger of contamination from laboratory utensils of various sorts, and to the adsorption of gases. Each of the remaining sixteen chapters is devoted to a family of the Periodic Table, beginning with the Noble Gases and

concluding with Ruthenium, Palladium and Platinum. A few of the least important elements are not included, but the list includes seventy-three of the elements which are most frequently encountered. There are numerous quotations from original papers and the abundant references will be extremely useful in case additional detail is required. Both a subject index and an author index are included.

This book will be a valuable time saver for all chemists who are concerned with the preparation of pure inorganic compounds.

B. S. HOPKINS

A Course in Quantitative Analysis. By J. SAMUEL GUY, Professor of Chemistry, Emory University, and AUGUSTA SKEEN, Assistant Professor of Chemistry, Agnes Scott College. Ginn and Company, 15 Ashburton Place, Boston, Massachusetts, 1932. xiv + 242 pp. 14.5 × 21.5 cm. Price, \$2.20.

This little volume covers an elementary course requiring only meager preparation in chemistry (or mathematics). Introducing volumetric studies first, eleven, well-assorted, approximately 0.1 *N* stock solutions are prepared and standardized, $\text{H}_2\text{C}_2\text{O}_4 \cdot 2\text{H}_2\text{O}$ being preferred as a primary standard because of its availability for titration with both sodium hydroxide and potassium permanganate. The other solutions are standardized directly or indirectly from these. Sixteen volumetric exercises are described, followed by five gravimetric determinations, the latter including water by loss on heating, copper by precipitation as cupric hydroxide and by electrolytic deposition, sulfate by precipitation, and carbon dioxide by loss in weight on dissolving in hydrochloric acid. Details are also given for the use of other primary standards (Fe , Na_2CO_3 , NaCl , As_2O_3 , and $\text{Na}_2\text{C}_2\text{O}_4$), for a number of optional gravimetric experiments, and for the colorimetric determination of hydrogen-ion concentration.

For the teacher who feels that the present courses are unwieldy, this book will prove refreshing in its simplicity. Unfortunately, however, in the attempt to simplify, the authors have failed rather frequently in scientific accuracy. The following cases will serve as illustrations: (1) two contradictory procedures are given for determining the resting point of a balance; (2) the need of boiling out carbon dioxide when titrating sodium carbonate with hydrochloric acid (using phenolphthalein as indicator) is discussed in terms of the reaction of carbonic acid with sodium chloride; (3) the electronic description of the reaction between potassium permanganate and ferrous sulfate (pp. 57-58) is obviously unsound.

On the whole, the student who completes a course based solely on this book will have become acquainted with a fair variety of quantitative manipulations, but he may fail to understand the errors of quantitative analyses or the way in which various procedures avoid them.

R. K. McALPINE

The Microscopic Characters of Artificial Inorganic Solid Substances or Artificial Minerals. By ALEXANDER NEWTON WINCHELL, Professor of Mineralogy and Petrology, University of Wisconsin. With a Chapter on the Universal Stage, by Richard Conrad Emmons, Associate Professor of Geology, University of Wisconsin. Second edition. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, 1931. xvii + 403 pp. Illustrated. 15×23.5 cm. Price, \$5.00.

The appearance of this book marks an important step in the education of the chemical fraternity in the application of the methods developed by mineralogists for the description and identification of crystalline compounds. No one who has had an opportunity to make use of these methods can fail to be impressed with their power and convenience, and the rapidly increasing use of the petrographic microscope in research and industrial laboratories shows that they are appreciated. There has long been a need for a book containing optical data for artificial crystalline compounds, and also for a textbook of optical crystallography in English that would teach the fundamental principles and main facts, and the methods by which they are applied in the measurement and observation of crystallographic properties.

Winchell's book represents the most complete set of tables and synoptic data for artificial inorganic compounds thus far published and as such will be found valuable by all who use the polarizing microscope. This assemblage of crystallographic data constitutes Part II, while Part III comprises a well arranged set of determinative tables based thereon. In connection with Parts II and III the reviewers commend plate V as a useful chart classifying artificial inorganic solid substances on the basis of birefringence optic sign, and refringence.

The amount of critical judgment that it is fair to expect of an author of tables is difficult to fix. It should be noted, however, that Winchell himself states in the introduction that "the general rule in this book is to give the values of the indices of refraction of pure substances to the fourth decimal place and in three kinds of light (C, D and F). . . . The indices of refraction of some pure substances have not been measured with accuracy and accurate measures have not always been made on strictly pure material; in such cases the indices of refraction are given only to the second or third decimal place." This implies a critical discrimination that has not been carried out. In some cases inaccurate values have been given instead of accurate values well known in the literature (example: $\text{CuSO}_4 \cdot 5\text{H}_2\text{O}$). In other cases more than one set of values of the indices of a compound are given, all expressed to four places of decimals but differing among themselves in the third place (examples: NaNO_3 , KNO_3 , $\text{NiSO}_4 \cdot 7\text{H}_2\text{O}$, NH_4Cl). Refractive indices of numerous compounds are quoted to four places of decimals although the measurements were made by means of an indefinite series of wave lengths through colored screens; several of the values thus obtained are inaccurate in the third place owing to the high dispersions of

the compounds and the failure to use monochromatic light (examples: $\text{Nd}_2(\text{MoO}_4)_3$, $\text{Ce}_2(\text{MoO}_4)_3$, CaWO_4 , SrMoO_4). Little or no attention has been given to recorded divergences of measurements, or to irregularities in the curves of dispersion or of optic axial angle, $2V$, such as are indicated in "International Critical Tables," Volume VII. The exercise of critical judgment is of course difficult and laborious and the reviewers do not state that the author of a table is bound to exercise it. They consider it necessary to point out, however, that the claim made by Winchell that he has exercised such judgment is not made good in his tables. Moreover, he has not taken advantage of careful critical work previously done.

Part I entitled "Principles and Methods" "consists in large part of revised selections from the author's 'Elements of Optical Mineralogy,' Part I, 3d Edition." It represents an attempt to give the reader an understanding or working knowledge of the methods whereby the data of Parts II and III have been obtained and are applied. The phenomena observed in crystals in convergent light are not discussed, however; Winchell refers the reader to his "Elements of Optical Mineralogy, Part I" (Chapters XIV and XVIII) for a treatment of this subject, which of course must be understood by all who intend seriously to use microscopic methods for the description and determination of crystalline compounds. The treatment of crystallographic principles and methods in Part I of "The Microscopic Characters of Artificial Minerals" is clearly set forth and well illustrated but contains some erroneous theoretical statements of matters now well established. These are discussed in detail in a forthcoming article in the *American Mineralogist*.

Chapter 2 (of Part I) discusses apparatus and preparation of material, and Chapter 3 (also of Part I) the optical properties of isotropic substances. Winchell uses the symbol N instead of the customary (in all or nearly all countries but France) n ; in later chapters he also uses N_o , N_e and N_g , N_m and N_p for the indices of refraction of uniaxial and biaxial crystals, respectively. The use of the customary symbols n , ω , ϵ , γ , β , α , for refractive indices in the descriptive tables would have segmented the long lines of Roman type and eliminated the small subscripts adopted by the publisher, which are difficult to read.

The phenomena observed under the microscope with central illumination of powdered grains immersed in a liquid, sometimes called the "Becke line," are improperly so-called;¹ the expression, "Becke line," was coined by Salomon² to designate the phenomena associated with total reflection at a vertical interface, which differ in theoretical interpretation from the phenomena obtained with central illumination of irregular grains; the latter are properly known as the central illumination effect.

¹ Cf. F. E. Wright, *J. Wash. Acad. Sci.*, 5, 104 (1915).

² W. Salomon, *Z. Kryst. Min.*, 26, 182 (1896).

The prominence given the "double variation" method of determination of index of refraction, together with the failure to describe the usual methods adequately, is a serious shortcoming. The ease in application of the usual methods, which has already been proved in many places and by many workers, warrants their careful description in a book of this character. The majority of measurements of indices of refraction are made for the purpose of the identification of the substance and the greater speed and convenience of the simplest immersion method make it the unquestionable choice in nearly all determinative work. In measuring refractive indices for record it is desirable to obtain them with an accuracy of ± 0.001 or better, which can be accomplished by the usual methods or by the variation of the wave length in the dispersion method or by the variation of both wave length and temperature in the double variation universal stage method of Emmons. Incidentally, it should be noted that the methods called by Winchell "immersion," "single variation" and "double variation" methods are all immersion methods.

Winchell's statement (p. 65): "The technique of measuring indices of refraction by this [dispersion] method is the same as that involved in using the double variation method with the single exception that all measures are made at room temperature...." is hardly justified by the facts; the reviewers would say that the technique required in the double variation method is more complicated. Although Winchell does not claim that the double variation method is superior in point of accuracy to the dispersion method, he does state that the double variation method is more convenient. On this question there is difference of opinion. Attention should be called to the fact that a very important sacrifice, recognized as a disadvantage by Winchell's collaborator, Emmons, is made in securing the ability to vary the temperature over a range by means of Emmons' apparatus. The variation of temperature is accomplished by means of a water cell between the condenser and the preparation and according to Emmons³ this makes it impossible to obtain interference figures in convergent light from the grains the refractive indices of which are being measured. Without the possibility of using the conoscope (convergent light) to obtain interference figures and unless the universal stage is used, it is impossible to recognize optic normal grains. Now in all cases it is highly desirable to supplement the purely statistical method of determining α and γ (n_p and n_g) by checking the orientations of the grains believed to exhibit α and γ . If the mineral has no cleavage, α and γ can be obtained by the purely statistical method, but one is never sure even in this case that the lowest index, α , and the highest index, γ , have really been obtained unless the orientations of the grains are established. In cases of minerals with good cleavage the statistical method is unreliable and the student or investigator who relies

³ R. C. Emmons, *Am. Min.*, 14, 425 (1929).

upon it exclusively in such cases will come to grief sooner or later. The orientation of the grain believed to exhibit the minimum or maximum index can be established, either by means of its interference figure in the dispersion method or by the use of the universal stage in the double variation method as described by Emmons. In the dispersion method the establishment of the orientation of the grain by means of its interference figure involves merely the removal of the eyepiece and a glance down the tube, or if the grain is small the use of one of the numerous special eyepieces available for this purpose. It is to be noted that finer grains can be handled accurately by the dispersion method than by the double variation universal stage method of Emmons, an important point in the study of artificial materials, which are so often obtained only in a fine-grained condition. Interference figures can be obtained from grains 0.005 mm. in diameter in many cases and 0.01 mm. in nearly all cases in the dispersion method; in the double variation method Emmons⁴ claims that grains as small as 0.03 mm. in diameter can be handled with the universal stage.

This review may be summarized and concluded with the statement that the book contains a very valuable collection of optical and geometrical crystallographic properties to which has been added a rather unsatisfactory account of selected aspects of optical crystallography.

⁴ R. C. Emmons, *Am. Min.*, **16**, 554 (1931).

GEORGE TUNELL
GEORGE W. MOREY

The Structure and Composition of Foods. Vol. I. Cereals, Starch, Oil Seeds, Nuts, Oils, Forage Plants. By ANDREW L. WINTON, Ph.D., and KATE BARBER WINTON, Ph.D. John Wiley and Sons, Inc., 440 Fourth Ave., New York, 1932. 710 pp. 274 figs. 15.5 × 23.5 cm. Price, \$8.50.

This is a unique and convenient book. It combines a description of the macroscopic and microscopic structure of cereals, nuts, oil seeds and forage plants, with a discussion of their composition. The latter includes not only the results of the conventional proximate analysis, but the products of hydrolysis of the native proteins, physical and chemical constants of the fats and other organic constituents, composition of the ash, and the nature of the enzymes present as well, when such data are available in the literature. In numerous instances the authors have also described manufactures based on these materials and the fractionation of the constituents of the original seed or fruit into the several commercial products. Thus one secures a rather detailed physical and chemical "picture" of these food and forage plants. Of course, the authors cannot trace the chemical technology of the 173 or more materials in as much detail as is attempted in manuals dealing with a limited group or a single fruit or seed. One cannot but be impressed by the volume of useful information recorded on the

seven hundred pages of this book, however, and also by the care and discretion exercised in its selection from the mass of data in the literature.

The structures of the individual forage grasses are not detailed in Part III, although the histology of timothy stems and leaves is shown in three plates. Discussion of the composition of these forage grasses is confined to proximate analyses. The value of the forage plant section might have been enhanced by the inclusion of some reference to cyanogenetic glucosides and the conditions attendant upon their appearance in the forage in lethal concentrations.

Taxonomists may not agree with the Wintons' inclusion of buckwheat, chestnuts, legumes and various weed seeds with the "cereals"; in fact the titles used in this connection are somewhat confusing to the extent that the book contains material which might not be expected to be present. The reviewer feels that the section dealing with the chemical nature of starch would be strengthened by the inclusion of a brief summary of the views of Samec, Haworth and Irvine. The inference that endosperm and pericarp of the cereal grains are essentially devoid of fat, which might be drawn from the first sentence under fats, on page 61, is hardly supported by certain critical studies.

The book cannot fail to be of great service to food chemists and others who desire to learn how these groups of foods are constituted structurally and chemically. The other two volumes in this series are anticipated with interest.

C. H. BAILEY

Glastechnische Tabellen. Physikalische und chemische Konstanten der Gläser. (Glass Tables. The Physical and Chemical Constants of Glasses.) Edited by DR. WILHELM EITEL, DR. MARCELLO PIRANI and DR. KARL SCHEEL. Verlag von Julius Springer, Linkstrasse 23-24, Berlin W 9, Germany, 1932. xii + 714 pp. Illustrated. 20 × 28.5 cm. Price, RM. 145; bound, RM. 149.80.

This vast compendium of technical tables on glass is like the Landolt-Börnstein Physikalisch-chemische Tabellen. It has been made possible through the subsidy of the Deutsche Glastechnische Gesellschaft, the editors named above and their associates.

It is divided into three parts. Section 1 covers equilibria in glass-forming systems, conditions under which they may best function, the proportions of the components and their crystalline phases. It takes up the glass-forming oxides, borate systems, carbonate systems, phosphate systems and silicates. Space is then devoted to two, three and four, or more, component systems as well as to organic substances which may enter a glassy state. This section is replete with phase diagrams which indicate the particular substances possible under various conditions and the point at which eutectic mixtures result. The crystal forms which are obtained are generously illustrated. Section 1 covers the first 88 pages.

Section 2 is devoted to physical and chemical constants such as viscosity, surface tension, internal strain, tensile strength, softening point, specific gravity, coefficient of elasticity, compressibility, cohesion, hardness, refractoriness, porosity to gases, adsorption and evolution of gases, thermal expansion, specific heat, heat conductivity, dielectric constants, electrical capacity, electrical conductivity, sparking point, potential differences, magnetic susceptibility, crushing strength, photo-elasticity, effect of electric fields on refraction, spectral transmission, ultraviolet transmission, infra-red transmission, total light transmission, properties of light filters, dispersion data, chemical susceptibility with methods of testing and results, devitrification. 536 pages are covered by this section, which not only contains numberless tables and diagrams but copious references to the literature covering every item discussed. Here, every glass has a key number which refers to some part of Section 3 of the publication.

Section 3 contains a systematic record of the chemical composition of the glasses covered in Section 2. These are the alkali silicates; the alkali-lime silicates, containing up to 1% of alumina; the alkali-lime-alumina silicates; the alkali silicates with those of calcium, magnesium, strontium, barium, iron, manganese and aluminum; the alkali-alkaline-earth-alumina-lead silicates; the alkali-alkaline-earth-boro silicates; glasses both clear and clouded containing the halogens and phosphorus; silica-free glasses like the borates, phosphates and arsenates; glassy organic substances. With each analysis there is not only a key number but a reference to pages in Sections 1 and 2, where the particular glasses are discussed as to their properties. Section 3 covers 83 pages.

This gigantic undertaking is priceless. The type is clear, the diagrams and illustrations are clean-cut, the cross references are well ordered and the reviewer has thus far not found a single fault in the use of such references. Here is a compilation of data never before available to glass technologists and scientists in other fields who are interested in the properties of glass. It should prove indispensable to serious workers in the field. There is a good table of contents, but the index might be more complete.

The authors and their collaborators are certainly to be congratulated for having made a precious contribution. It is to be hoped that these tables may be translated into English and thus made available for those who are unable to use the German publication.

ALEXANDER SILVERMAN

The Glycosides. By E. F. ARMSTRONG, D.Sc., Ph.D., LL.D., F.R.S., and K. F. ARMSTRONG, B.A., B.Sc. Longmans, Green and Co., 55 Fifth Ave., New York, 1931. vii + 123 pp. 15.5 × 25 cm. Price, \$4.25.

An earlier monograph by E. F. Armstrong in the series of Monographs on Biochemistry edited by R. H. A. Plimmer and F. G. Hopkins bears the

title, "The Simple Carbohydrates and the Glucosides." Since the date of publication of the last edition, the activity of chemists in the field of sugars as well as in the field of glycosides (the newly-accepted term) has been greater than in any other field of organic chemistry, so that the division of the material into two separate monographs is very natural, particularly for the reason that to many workers in the field of glycosides the chief interest lies in the chemistry of the aglucones. Indeed, the work of Willstätter on anthocyanin glycosides, which has been continued by Robinson and his associates, and the investigations of Jacobs and of Windaus on cardiac glycosides—which will remain of outstanding interest to organic chemists—are concerned principally with the structure of the aglucones.

The new monograph on glycosides, which introduces to the chemical world the third generation of Armstrongs, should be regarded as a brief summary of the more recent work on natural and synthetic glycosides rather than as an exhaustive treatise on the subject. The authors emphasize that "no attempt has been made to do more than list the various glycosides and indicate their structure and relationships." In this manner are discussed glycosides containing the following aglucones (should it not be aglycones?)—phenols, hydroxyanthraquinones, hydroxycoumarins, anthoxanthins and anthocyanins, cardiac aglucones, glycosides of mustard oils, cyanophoric glycosides, nucleosides, indican and pentosides. This list of glycosides is a striking illustration of the heterogeneity of the substances capable of coupling with sugars and of the difficulty in correlating all glycosides on a rational genetic basis. Yet the work of recent years has aimed at a chemical correlation of certain groups of glycosides, if not of all, and much success has been attained in this respect in the glycosides of anthoxanthin and anthocyanin groups and perhaps even more so in the group of the cardiac glycosides. The idea of genetic relationship of the components of glycosides, of the sugars and of the aglucones runs through every chapter dealing with the natural glycosides as the basic pattern unifying the heterogeneous material.

In Chapter II of the book, which is the first chapter devoted to natural glycosides, the authors write:

In time the facts available may make it possible to explain the progressive building up of more complicated aglucones and correlate these perhaps with species or plant habitat. With so few primary materials available, with carbon dioxide as its sole source of carbon, it is an unending source of wonder that the plant has created an apparently limitless range of organic compounds, sometimes of fantastic complexity.

In subsequent chapters, again and again the thought is advanced that the anthoxanthin and the anthocyanin, the aglucones and the phenolic aglucones may have their origin in a common hexose (namely, glucose) and in some cases, in hexoses and trioses. The reviewer would hesitate to attribute to Nature this very inefficient way of operating, yet he must admit

that from a literary and didactic viewpoint, the thought serves a useful purpose.

Another expedient used by the authors to unify the heterogeneous material is the frequent reference to the biological aspects of the glycosides. Among them some are important from a practical viewpoint and may be of little familiarity to the organic chemist; for instance, the method of diagnosing sugars by the inhibition method, which is based on the fact that an enzyme specific for a certain glycoside is inhibited in its activity only by the sugar that enters into the structure of the glycoside. Of all natural glycosides those of anthoxanthins and anthocyanins are discussed in greater detail.

Only a few inaccuracies came to the attention of the reviewer. Two may be mentioned. Referring to digitalis glycosides, the authors attribute the activity of the glycoside to the unsaturated lactone group and later in the same chapter, reviewing the properties of the strophanthus glycosides, they state that the activity of the entire molecule is enhanced by the unsaturation of the lactone group. The latter statement is correct and applies to all the cardiac glycosides. The first statement was for a time the generally-accepted one but it has been abandoned. In speaking of nucleosides, the authors state that ribose and deoxyribose nucleosides can be prepared by the identical hydrolytic agents. This is not correct inasmuch as the deoxyribose nucleosides are at present obtainable only through the action of enzymes. The emphasis of the authors on the probability of the formation of *d*-ribose from xylosephosphoric acid seems to the reviewer exaggerated inasmuch as the author of the suggestion, Robinson, viewed it in the light of a mere possibility to be borne in mind—a possibility which thus far has no experimental evidence in its favor.

In addition to the chapters on natural glycosides, the monograph contains an introductory chapter dealing with definitions of the terminology, with the theories of the origin of hexoses, with theories aiming to explain the prevalence of glucose as compared with other hexoses, with speculations on the transformation of hexoses into inositols and into polyhydroxyphenols and with the general properties of glycosides.

The chapters on synthetic glycosides, on uronic acids, on the function of glycosides in plants and on the utilization of carbohydrates in plants, containing a discussion on ripening of fruit, are very brief and rather incomplete.

The monograph will be read with great benefit by all not yet acquainted with the chemistry of natural glycosides.

THE CRYSTAL STRUCTURES OF ELECTRODEPOSITED ALLOYS. AN X-RAY DIFFRACTION STUDY OF SILVER-CADMIUM DEPOSITS¹

BY CHARLES W. STILLWELL AND LAWRENCE E. STOUT

RECEIVED NOVEMBER 20, 1931

PUBLISHED JULY 6, 1932

The electrodeposition of alloys is a comparatively recent development. The number of binary alloys which may be successfully electroplated has increased greatly during the last few years due to a realization of their many practical applications. Very little is known of the structure of these alloys, however, since in all phase rule studies of binary alloys the system is usually in equilibrium when the several phases are identified. These results cannot be applied to electrodeposited alloys, since the latter are probably not in equilibrium. An x-ray diffraction study of electrolytic brass made some years ago² proved that under specified conditions a true α -phase is deposited, a solid solution rather than a mixture of the metals. Recently several rather superficial papers have been published³ giving diffraction data for the electrodeposited alloys: Cd-Ag, Cu-Zn, Cd-Sn, Cd-Ni. The only definite conclusion drawn is that the plate is not a mixture of the two metals, but contains compounds or solid solutions. The compounds are not identified, nor has any one of the binary alloys been systematically studied.

There are several variables which might influence the structure of an electrodeposited alloy. Among these are: (1) the composition of the plate, (2) the current density, (3) the temperature of deposition, (4) the rate of stirring and (5) the nature of the base metal. The aim of the present investigation of electrodeposited silver-cadmium alloys has been to study systematically by means of x-ray diffraction data the relation between the composition and the crystal structure of the plates. All deposits

have been prepared at constant temperature and constant current density without stirring, and the effect of these other variables will be studied later.

Experimental

Some of the deposits investigated were prepared and analyzed by Stout at Washington University. Chemical analyses and the x-ray diffraction studies of all the plates were made at the University of Illinois. The baths from which the alloys were deposited were made as described by Stout and Thummel.⁴ The alloy was deposited on sheet copper, 10 × 2 cm. and 0.1 cm. in thickness. Two duriron anodes were used, the cathode being adjusted between them and equidistant from each. The deposits were made at room temperature (27°) using a current density of one ampere per square decimeter. Three plates were prepared for each composition studied. In each case the first and third were analyzed and the second was used to determine the diffraction data. The equilibrium diagram for the silver-cadmium system has been studied by x-ray diffraction methods by several investigators⁵ and the compositions of the alloys which were electroplated were chosen after a consideration of these equilibrium data.

The composition of the plates was determined by precipitating silver as silver chloride, removing the copper electrolytically from an acid solution and precipitating cadmium electrolytically from a basic cyanide solution.⁶ The composition of the edge of a plate is different from that of the center. The center area was the portion analyzed in each case since the x-ray diffraction pattern was obtained from this area.

The relation between the composition of the bath and the composition of the deposit is shown in Table I.

TABLE I⁷

Silver in bath, %	9.1	12.0	23.1	25.9	41.2
Silver in deposit, %	18.5	23.4	47.4	52.0	69.0

The x-ray diffraction data were obtained by the powder method, using the General Electric multiple apparatus and a Coolidge tube with a

⁷ These values do not agree with those of Stout and Thummel.⁴ The values in Table I have been checked independently by the present authors. The errors in the earlier values will be corrected in a publication by Stout soon to appear.

The relations between the crystal structures and compositions of the deposits, set forth in a previous note [Stillwell, *THIS JOURNAL*, **53**, 2416 (1931)] are invalidated by this revision of the chemical analyses of the deposits. The conclusions drawn in the note were based on the earlier data of Stout and Thummel.

molybdenum target. A firmly adhering electrodeposited layer may be very conveniently handled by this method. The copper strip on which the alloy was deposited was cut to a convenient size and bent through an angle of 180° , the radius of curvature of the outer plated surface being about 2.0 mm. Mounted properly at the center of curvature of the quadrant cassette, this affords a sharply curved surface from which the x-rays are reflected. The specimen is thick enough to prevent transmission of the x-ray beam, so that the lines of the resulting diffraction pattern are clearly defined and as narrow as it is possible to get them. The length of exposure is cut to a minimum under these conditions. Good patterns of a homogeneous deposit were obtained in fifteen to twenty hours with 20 m. a. It is convenient to reflect the radiation from a curved surface for another reason. When metals are electrodeposited, the crystals often assume a preferred orientation in respect to the base metal. If the orientation is sufficiently regular many of the planes of the crystal would not be in the proper position to diffract the x-rays and the pattern would be incomplete and more difficult to identify. In using a curved specimen, although the crystals may be oriented with respect to the base metal, there is sufficient variation in their orientation with respect to the x-ray beam to permit reflection from many more planes.

The alloy deposit was thin enough in every case to permit diffraction of the x-rays by the copper base, and the diffraction pattern for copper which was present in every film was used as a reference in measuring the patterns of the alloy phases, affording much greater accuracy than would otherwise be possible.

Analysis of Data

The diffraction data for the ten different alloys examined have been recorded and analyzed. The general procedure is illustrated in Table II for alloy 82.0% cadmium. The others were analyzed in the same way. The composition of the alloy is expressed in atomic per cent. of cadmium. The interplanar spacings, in Ångström units, are in the first column. The intensity of the lines was estimated as very strong (vs), strong (s), medium (m), weak (w) or very weak (vw). The lines of the copper pattern used as a calibration are designated "Cu." All of the alloys proved to be heterogeneous and the identifications of the several different crystalline phases are included in the table.

The accuracy with which the size of the unit cell may be determined from films obtained by this method is limited. The maximum probable error for the determination of the values of a_0 in the several phases has been estimated in the following way. As different values of the constant are tried in the $\sin^2 \theta$ equation, the difference between constants may be reduced to the point where the calculated values for two successive constants

satisfy the experimental values equally well, but constants greater or smaller than these two are unsatisfactory. At this point the values for a_0 have been calculated from each of these constants, the mean value of the constants has been used in the equation, and the error of the determination is indicated as plus or minus half the difference between the values of a_0 originally computed. For example, the experimental values for the β' -phase in alloy 82.0 (Table II) are satisfied equally well by values calculated from the constants 0.01855 and 0.01865, but are not satisfied by values from constants 0.01850 or 0.01870. The values of a_0 calculated from the accepted constants are 3.010 Å. and 3.002 Å., respectively. The constant used in the final equation is 0.0186, the value of $a_0 = 3.006 \pm 0.004$ Å. It is believed that this method of expressing the error gives a true picture of the degree of accuracy of the results. Since the purpose of this study is merely to identify the several phases present, great accuracy is not demanded in most cases. In connection with the discussion below, however, it is desirable to know as nearly as possible the values of a_0 for the β' -phase, and the limit of error on this phase has been carefully estimated.

The analyses of the specimens should be considered in the light of the following factors.

1. The multiplicity of phases and reflecting planes recorded in each pattern leads to the possible superposition of important lines of one phase on those of another. Thus in some cases it may be said that a certain phase may be present, but is not necessarily so, if the positions which would be taken by all of its important diffraction lines are already occupied by lines identified with other patterns. A weak pattern for the β -phase in particular may be obscured by the γ -phase pattern.

2. A consideration of relative intensities cannot be used in establishing

the presence or absence of the pattern of a phase, since some, and possibly all, of the crystalline phases are deposited in a preferred orientation with respect to the base metal. Although this difficulty has been minimized by curving the specimens, the intensities are still abnormal, as may be seen by a casual examination of the intensities of the reflections from the more important planes of the ϵ -phase in the several specimens. A direct comparison of the films brings out these abnormal intensities most strikingly.

3. It should also be noted that some evidence points to an apparently non-uniform distribution of the phases over the surface of the electrode.

Of several specimens chosen from the same plate (82.0% cadmium) some give only the pattern of the ϵ -phase even after long exposure, while others show in addition the patterns of the other phases.

4. There is a minimum concentration for each phase, below which it cannot be detected by this method. This concentration will depend to a considerable extent on the thickness of the deposit. In general, the weight of alloy deposited on the plates used for this investigation was about 0.3 g. If thicker deposits were made, smaller concentrations of the several phases could be detected.

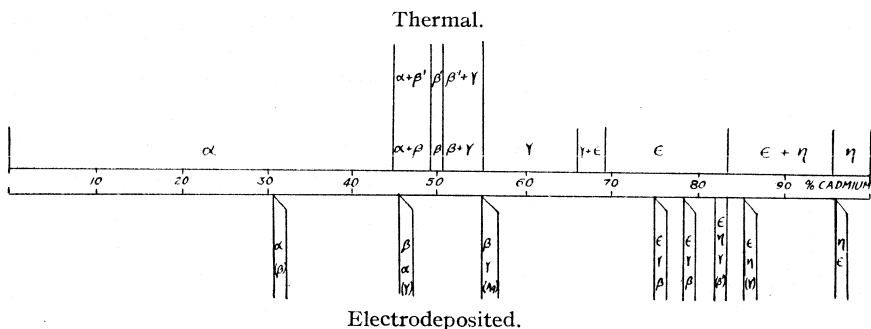

Fig. 1.—A comparison of the composition ranges of the several phases of the thermal silver-cadmium alloys with those of the same phases in the electrodeposited alloys.

The conclusions drawn from the several analyses are assembled in Table III and Fig. 1. For convenience the phases identified in the electrodeposited alloy are compared with those found by Astrand and Westgren^{5a} in the thermal alloys of corresponding composition. The η -phase has the close-packed hexagonal structure—a solid solution of silver in cadmium. The ϵ -phase (AgCd_3) is also close-packed hexagonal, but of a different axial ratio. The γ -phase ($4\text{Ag}_5\text{Cd}_8$) is body-centered cubic, containing fifty-two atoms in the unit cell. The β -phase (AgCd) is of the cesium chloride type; while the α -phase is face-centered cubic, a solid solution of cadmium in silver. The β' -phase is metastable at room temperature for the compositions indicated. It is more fully discussed below. In each case the phase which predominates in the electrodeposited alloy is placed nearest

^a The intensity of most of these twelve lines shows conclusively that the α -phase is present.

the center of the dividing line between thermal and electrodeposited alloys. This order is observed in both table and figure. After the most predominant phase has been recorded, the order of the other phases listed is usually arbitrary, since their relative concentrations cannot be accurately estimated. Column 1 lists the total number of lines measured on each film. The figure beneath each phase designates the number of lines on a particular film which may indicate the presence of this phase. The figure in parentheses is the number of lines which indicate only this phase and can belong to no other phase. The presence of most of the phases listed is definitely indicated by the diffraction patterns. The phases which may or may not be present, when considered in the light of diffraction data, are listed in parentheses.

Discussion

The β' -Phase.—Astrand and Westgren^{5a} have obtained the β' -phase by heating the β -phase for five to ten hours just below 460°. The β' -phase is recorded in Table III in such a way as to indicate that it is a phase, stable at higher temperatures over the range of composition occupied by the β -phase at room temperature. The β' -phase has the close-packed hexagonal structure and the same axial ratio as the ϵ -phase, differing from the latter only in the size of the unit cell. Moreover, the magnitude of this difference in the size of the unit cell suggests that the β' -phase is a continuation of the ϵ -phase; that the ϵ -phase at the higher temperature extends over the range of composition occupied by the β - and γ -phases at room temperature. This is the interpretation suggested by Astrand and Westgren. If it be the correct one it should be possible to heat and quench the γ -phase and prepare a metastable close-packed hexagonal phase in which the value of a_0 lies between 2.989 Å. (the upper limit for the metastable $\beta'(\epsilon)$) and 3.040 Å. (the lower limit for the stable ϵ -phase). Astrand and Westgren were unable to do this. Natta and Frerri^{5b} claim to have prepared a $\beta'(\epsilon)$ phase in which $a_0 = 3.01$ Å., leaving a gap only from $a_0 = 3.01$ Å. to $a_0 = 3.04$ Å. Since electrodeposition seems to be a good method for the preparation of metastable metals, it was hoped that this gap between $a_0 = 3.04$ for the ϵ -phase and $a_0 = 3.01$ Å. for the $\beta'(\epsilon)$ phase might be closed. As may be seen from the data, however, no close-packed hexagonal lattice with a value of a_0 between these two has been identified in any of the specimens.

It is questionable whether the $\beta'(\epsilon)$ phase is deposited at all under the conditions of the experiment. There is no positive evidence of a $\beta'(\epsilon)$ lattice on the patterns for plates of 55 and 49% cadmium where it should naturally occur. The possibility of its presence in these plates is indicated in Table III. The most evidence in its favor exists in the pattern analyzed in Table II. Even here there are only three unique lines. Furthermore,

it is difficult to account for the occurrence of the metastable phase in this composition range. It means that there are two phases of close-packed hexagonal structure and identical axial ratios coexistent in the same deposit. If the interpretation of the nature of the β' -phase is correct, they may be thought of as two disconnected "sections" of a supposedly continuous phase. They differ only in the size of the unit cell, by which size one of them (ϵ) is identified as a stable phase at ordinary temperatures and the other (β') as metastable. Needless to say, this relation is not apt to exist.

General Discussion.—The unexpected complexity of the results obtained makes it difficult to draw a complete comparison between the electrodeposited and thermal alloys. The data bring out several interesting points, however, some of which may have a practical bearing.

The heterogeneous nature of the deposits is noteworthy. A consideration of Fig. 1 shows that the predominant phase in any alloy is the one predicted from the thermal equilibrium diagram. The minor phases are present in considerable amounts, however, and their presence cannot be predicted from the equilibrium diagram. There is a general overlapping of phases evident, particularly for the γ - and β -phases. The former, stable in the range 55–67% cadmium, may be found in electrodeposited alloys in the composition range 46–83% cadmium. The latter, stable in a narrow range at 50% cadmium, may be electrodeposited in alloys containing 46–78% cadmium. The η - and ϵ -phases and the α -phase seem to remain within their expected bounds.

Fink and Gerapostolou⁸ have studied silver-cadmium deposits microscopically and have reported that pure silver is deposited first. It should be noted that the results of the x-ray diffraction analysis do not contradict this. For most of the deposits analyzed, the positions of the lines of the diffraction pattern for pure silver (if $a_0 = 4.068$ is used for calculating d_{hkl}) are already occupied by lines belonging to the patterns of other phases known to be present. Small amounts of silver, therefore, may or may not be present in the deposits. If an appreciable amount were present, the diffraction lines for the smaller spacings should be found.

It is not difficult to offer a reasonable explanation for the heterogeneous nature of the deposits. The composition of the plate deposited at any instant depends upon the relative concentration of silver and cadmium ions in the solution, particularly in the stationary film of electrolyte around the cathode. Generally this ratio will be such as to cause the deposition of the phase to be expected from the chemical analysis of the plate. Occasionally the ratio of silver to cadmium ions in the stationary film will

⁸ Fink and Gerapostolou, *Metal Ind. (New York)*, **28**, 519, 562 (1930). The results of these authors do not bring out the complexity of the deposits. They distinguish only two phases—pure silver and a phase which appears brown and is a cadmium-rich alloy.

vary, due to momentary convection currents and other local conditions, and for short periods, then, the composition of the deposit will vary from the average composition, and the phase deposited will vary accordingly. The composition of some of the plates is such that, judging from the thermal equilibrium diagram, a mixture of two phases is to be expected even under uniform conditions of deposition.

A homogeneous deposit may have advantages which would make it preferable to a heterogeneous deposit for practical purposes. Certainly vigorous stirring during deposition should produce a more homogeneous deposit if the above explanation of the heterogeneity is correct. The effects of stirring, current density and temperature on the nature of the deposit are being investigated at the present time.

Summary

The crystal structures of electrodeposited silver-cadmium alloys ranging in composition from 96.0% cadmium to 31.0% cadmium have been obtained from x-ray diffraction data. All known factors, other than the composition of the plate, which might affect the structure of the alloys have been held constant.

The results are summarized in Table III and Fig. 1.

The most significant points brought out by the study are:

1. Every deposit consists of solid solutions or compounds. In no case is the deposit merely a mixture of cadmium and silver.
2. The phase stable in a given range of composition of the thermal alloys is the predominant phase in an electrodeposited alloy in that same composition range. Therefore the predominant phase in the electrodeposit may be predicted from its chemical composition.
3. In general the deposits are heterogeneous, containing appreciable amounts of phases which do not exist in an annealed alloy of the composition in question. The complete composition of the electrodeposit, therefore, cannot be predicted from its chemical composition.
4. There is little evidence indicating the formation of a metastable (β' -phase) deposit under the conditions of the experiment.

MAGNETIC SUSCEPTIBILITY OF $\text{Sm}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$

BY F. H. SPEDDING*

RECEIVED NOVEMBER 30, 1931

PUBLISHED JULY 6, 1932

Hund¹ calculated values for the magnetic susceptibility of the rare earth ions, employing basic levels he had predicted from rules of spectra. His results, except for Sm^{+++} and Eu^{+++} ,² were in excellent agreement with the values which had been obtained experimentally with solids and solutions.

Freed³ has shown very conclusively in his magnetic researches that the discrepancy in the case of Sm^{+++} is due to the presence of electronic isomers. That is, at very low temperatures the electronic configuration of most of the samarium ions is that predicted by Hund ($4f^6$, $^6\text{H}_{5/2}$). At higher temperatures, however, Freed showed that many of the atoms due to the Boltzmann distribution are in excited states, the energy values of which are but slightly greater than that of the $^6\text{H}_{5/2}$ term.

A confirmation of the existence of these isomers was found by Freed and Spedding⁴ from the absorption spectrum of $\text{SmCl}_3 \cdot 6\text{H}_2\text{O}$ crystals. They found that as the temperature of the crystal was lowered certain lines tended to become more intense while others, usually a few hundred inverse centimeters to the red, faded out and finally disappeared.

At the time these researches were performed Freed was unable to determine the electronic configuration of the excited states as all the usual systems of coupling gave susceptibilities which could not be brought into accord with his data.

Since then from researches on the Gd^{+++} ion it has been shown⁵ that a new type of magnetic coupling is probably effective in the case of the rare earths. In a letter to *Physical Review*,⁶ experimental evidence was presented which showed that when a rare earth ion is excited, a 4f electron jumps through the 5s, 5p completed shells to a 5d, 5f or 5g orbit. Due to its electrical nature this orbit is strongly coupled to the electrical fields of the crystal and cannot orient in the magnetic fields obtainable in the laboratory.

It will, however, have a magnetic moment which will couple with the resultant moment of the remaining 4f electrons and the energy of this

² J. H. Van Vleck, *Phys. Rev.*, **31**, 587 (1928), has explained the discrepancy in the case of Eu^{+++} .

³ Freed, *THIS JOURNAL*, **52**, 2702 (1930).

⁴ Freed and Spedding, *Nature*, **123**, 525 (1929).

⁵ F. H. Spedding, *Phys. Rev.*, **37**, 771 (1931).

⁶ F. H. Spedding, *ibid.*, **38**, 2080 (1931).

coupling will presumably be so great that ordinary magnetic fields will not disrupt it. Therefore the 4f electrons will not contribute anything as a first approximation to the magnetic susceptibility of the ions. The spin of the external electron, however, will be loosely coupled, as its resonance effect with the other spins will be negligible due to the shielding action of the 5s, 5p shells and it will orient rather freely in ordinary magnetic fields. Thus all the excited levels will have a susceptibility corresponding to the spin of one electron.

While in gaseous Sm^{+++} ions one would expect the $((^5J_4 \cdot d)_6)_{11/2}$ term to be the one of lowest energy, in solids, due to the effect of the surrounding ions in a crystal the $((^5J_4 \cdot g)_8)_{11/2}$ or $((^5J_4 \cdot f)_7)_{11/2}$ might be the lowest due to the greater symmetry of the f and g orbits. In any case the energy difference between them will not be great as they resemble somewhat the single electron in the alkali spectra.

If one assumes the basic level of Sm^{+++} ion in $\text{Sm}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$ to be a $^6H_{5/2}$ which is free to orient in a magnetic field (Hund's assumption) and that the first excited level is a $((^5J_4 \cdot g)_8)_{11/2}$ in which the g orbit is bound, then the Curie constants per mole using the customary formula

$$C = \frac{N}{3k} j(j+1)g^2\beta^2$$

where N is Avogadro number, k Boltzmann constant, and β the Bohr magneton $eh/4\pi m_0 c$ will be

$$C_0 = \frac{g^2 j(j+1)}{(2.838)^2} = \frac{\left(\frac{2}{7}\right)^2 \frac{5}{2} \times \frac{7}{2}}{(2.838)^2} = 0.08867$$

for the normal state and

$$C_1 = \frac{2^2 \left(\frac{1}{2} \times \frac{3}{2}\right)}{(2.838)^2} = 0.3724$$

for the excited states. The susceptibility at any temperature can be calculated from the relation⁷

$$\frac{C_0 N_0}{T + \Delta_1} + \frac{C_1 (1 - N_0)}{T + \Delta_2} = \chi$$

where T is the absolute temperature, N_0 the percentage of ions in the normal state, χ is the susceptibility per mole, and Δ is a blanket correction factor, covering such factors as the effect of restraints on the free orientation of the permanent moment due to the coupling of the spin with the orbit in the excited states, and of the orbits with the crystal fields in the normal term. It would also include any magnetic contributions which might arise from having the orbits warp in the excited state.

⁷ The Van Vleck "forgotten term" can be neglected here as the levels are well separated and do not belong to the same multiplet. When N_0 becomes 100% this equation becomes the Curie Weiss Law $\chi = C/(T + \Delta)$.

Not much is known about this Δ ; however, in the case of $\text{Er}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$ ⁸ where the basic level has a term composed of spin and orbital moments somewhat similar to $\text{Sm}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$ it is small, amounting to 1.9°K .

In these calculations both Δ_1 and Δ_2 were assumed to be 2°K . N_0 is calculated in the ordinary way⁹

$$\frac{1 - N_0}{N_0} = \frac{S_1 e^{-\frac{h\Delta\nu}{kT}}}{S_0(1)}$$

where S_1 and S_0 are the statistical weights of the levels and $\Delta\nu$ is the separation in inverse centimeters between them. Using one of Freed's experimentally determined points, $\Delta\nu$ was calculated. It is 195 cm^{-1} . Then, using this value, other points on the curve were calculated. They are given in Table I and are in good agreement up to 150°K ., after which they deviate. This deviation, however, is to be expected as other terms become effective at higher temperatures; the $(^5\text{J}_4\text{f}_7)_{15/2, 13/2}$ $((^5\text{J}_4\text{d})_6)_{13/2, 11/2}$ are not much higher and also terms of the type $((^5\text{J}_4\text{g})_7)_{15/2, 13/2}$ $((^5\text{J}_4\text{g})_6)_{13/2, 11/2}$ would occur within a few hundred cm^{-1} of the $((^5\text{J}_4\text{g})_8)_{17/2}$ term.¹⁰ From the equations it can be seen that χ is very sensitive to the value of C_1 . The statistical weight of the excited state, since it enters into the calculation of N_0 only and not C , can be varied somewhat if $\Delta\nu$ and the Δ 's are varied also as χ is not very sensitive to them when they are varied as a group. However, for states other than $(^5\text{J}_4\text{g})$ and $(^5\text{J}_4\text{f})$ the Δ 's become so large as to seem improbable. Table II gives the calculated values for a $((^5\text{J}_4\text{f})_7)_{13/2, 15/2}$ excited level. $\Delta\nu$ comes out 165 cm^{-1} and Δ has to be 7°K .

⁸ De Haas, Wiersma and Capel, Leiden Communication 201b.

⁹ The statistical weight of the lower level will be equal to $2j + 1$ or 6 as j is equal to $5/2$. The statistical weight of the excited level depends on the fact that the g orbit is bound to the crystal field. This orbit can take $(2j + 1)$ orientations to this field or 9 since j is 4, and as the spin can be either with or against the orbit the total value is 2×9 or 18.

The contribution of the frozen $4f$ electrons enters into the weight in giving rise to terms of different energy such as $(^5\text{J}_4\text{g})_8$ and $(^5\text{J}_4\text{g})_7$, where, due to the bound orbit, the multiplicity is again 18.

$\Delta\nu$ is, of course, the mean distance between the weighted center of the multiplets as both upper and lower levels are non-degenerate due to the electric field of the crystals. (Some of these levels may become degenerate in crystals of high symmetry.) While the splitting in the lower level is negligible, it may be rather large in the excited state, amounting to 70 cm^{-1} or 80 cm^{-1} (as in the case of $\text{GdCl}_3 \cdot 6\text{H}_2\text{O}$). However, the weighted mean (according to the Boltzmann factor) is not very sensitive to temperature in the case calculated here.

¹⁰ In the case of Gd^{+++} where the basic level is known to be single ($^8\text{S}_{7/2}$) there are over sixty lines occurring in the space of 700 cm^{-1} . These excited terms are probably of the type

$$((^7\text{F}_1\text{g})_5)_{9/2}, ((^7\text{F}_1\text{g})_4)_{7/2, 9/2}, ((^7\text{F}_1\text{d})_3)_{5/2, 7/2}, \text{etc.}$$

The multiplet of lowest energy is well separated from the rest and they become closer together toward higher frequencies, just as would be expected.

TABLE II

MAGNETIC SUSCEPTIBILITY OF $\text{Sm}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$

Excited Level $((^6\text{J}_4\text{f})_7)_{13/2, 15/2}$. $\Delta = 7^\circ$. $\Delta\nu = 165 \text{ cm}^{-1}$

T, Absolute	N_0	N_1	N_0C_0	N_1C_1	Calcd. $\chi \times 10^6$	Obs. $\chi \times 10^6$
73.8	0.9130	0.0870	810	324	1403	1402
80	.8912	.1088	790	405	1374	1375
90	.8551	.1449	758	540	1337	1338
100	.8196	.1804	727	672	1307	1308
120	.7519	.2481	667	924	1256	1254
140	.6982	.3018	619	1124	1185	1206
160	.6520	.3480	578	1296	1122	1171

From the above it would appear that the excited electronic isomers of $\text{Sm}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$ consist of $4f^65g$, $4f^65f$, $4f^65d$ configurations where the $4f^6$ electrons combine among themselves and the resultant couples firmly with the orbit of the excited electron, which itself is firmly coupled with the electric field of the crystal lattice. Thus only the spin of the external electron contributes to the magnetic susceptibility and all excited terms have a Curie constant of 0.3724. At present it is impossible to determine whether the excited electron in the first excited state is in a $5g$ or $5f$ orbit but it is hoped an answer will be found shortly from a study of the absorption spectra which is being carried out by Mr. Bear and myself.

Since the above paper was written considerable work has been done in this field.

Spedding and Bear, *Phys. Rev.*, **39**, 948 (1932), have investigated the absorption and reflection spectra of $\text{SmCl}_3 \cdot 6\text{H}_2\text{O}$ and have identified a group of levels occurring about 160 cm^{-1} above the basic level. Recently they have also identified another group of levels occurring between 250 cm^{-1} and 300 cm^{-1} from the basic level, just as predicted above, and will publish their results shortly in *Physical Review*. Preliminary photographs with $\text{Sm}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$ indicate that the same levels occur in approximately the same positions.

Ahlberg and Freed have measured the specific heats of $\text{Sm}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$ and $\text{Gd}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$, *ibid.*, **39**, 540 (1932), and have concluded that Sm^{++} in $\text{Sm}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$

has "electronic isomers" which are separated from the basic level by about 160 cm.^{-1} and which have approximately twice the statistical weight of the basic level. These values are in excellent agreement with those calculated in Table II above.

Amelia Frank, *ibid.*, 39, 119 (1932), in extending the work of J. H. Van Vleck and A. Frank, has attempted an alternative explanation. In view of the experimental facts, her calculations cannot be correct as stated, as her first excited level occurs around 900 cm.^{-1} . However, the ${}^6\text{H}_{1/2}$ term would be expected to occur at a slightly greater value than that and at higher temperatures an effect such as they predict probably exists.

THE KINETICS OF THE REACTION BETWEEN POTASSIUM PERMANGANATE AND OXALIC ACID. I

BY HERBERT F. LAUNER

RECEIVED DECEMBER 21, 1931

PUBLISHED JULY 6, 1932

Introduction

The over-all reaction between permanganate and oxalic acid is expressed by the equation

The rate of this reaction has been studied by several investigators¹ all of whom used an iodimetric method for the analysis of the reaction mixtures.

In this paper are presented the results of a new investigation of the reaction between permanganate ion and oxalate ion.

The author wishes to express here his appreciation of the aid and criticisms of Prof. Don M. Yost and Dr. J. B. Ramsey.

A large number of experiments were made on this reaction by an improved method which show that the mechanism previously suggested by Skrabal is not consistent with all of the experimentally found facts. Because of the rather complicated nature of the reaction the outstanding experimental results and theoretical conclusions will, for greater clearness, be stated briefly at this point.

When a solution of permanganate ion is added to one of manganous ion in which acid and oxalate ion are also present, a cherry-red solution of a complex ion formed from manganic ion and oxalate ion results, whereas in the absence of oxalate ion or other anion capable of forming a complex, a precipitate of manganese dioxide is obtained. It will be shown that the formula of the manganic complex ion is $\text{Mn}(\text{C}_2\text{O}_4)_2^-$.

The rate of the reaction when manganous ion was present initially in

¹ Harcourt and Esson, *Phil. Trans.*, 201 (1866); Schilow, *Ber.*, 36, 2735 (1903); Skrabal, *Z. anorg. Chem.*, 42, 1 (1904).

excess and when the solution was in contact with a constant gas space was found to be represented by the following differential equation

$$\frac{dp_{\text{CO}_2}}{dt} = \frac{k_1(\text{Mn}(\text{C}_2\text{O}_4)_2^-)}{(\text{C}_2\text{O}_4^{2-})} \quad (2)$$

The following series of reactions provides a mechanism that is in accord with equation (2).

It will be noted that the existence of an unknown ion CO_2^- is postulated in equation 5—a matter which is further considered below. Reaction 3 is to be regarded in the present connection only as the source of tripositive manganese, the concentration of whose ion (Mn^{+++}) is determined by the equilibrium conditions of reaction 4. This reaction also involves the concentration of oxalate ion, which is itself dependent upon the acidity of the solution. The rate of the reaction is then determined by reaction 5, whose rate should be expressed by the equation

$$\frac{dp_{\text{CO}_2}}{dt} = k_2(\text{Mn}^{+++})(\text{C}_2\text{O}_4^{2-}) \quad (7)$$

By substituting for (Mn^{+++}) in equation 7 the expression $(1/K_4)(\text{MnC}_2\text{O}_4^-)/(\text{C}_2\text{O}_4^{2-})^2$ given by the mass action law, there results equation 2, which was found to express the experimental results.

This mechanism is in sharp contrast with that of Skrabal, which required that the measurable step be the dissociation of a manganic-oxalate complex, and that the reaction in which manganic ion is reduced be rapid and of third order.

Method of Experimentation

An apparatus for measuring the pressures of carbon dioxide produced was constructed and is shown diagrammatically in Fig. 1. In the reaction vessel was placed 90 cc. of solution, containing all but one of the reactants. Since the apparatus is rigid above the thermostat, a jar, kept overflowing with water from the thermostat, may be raised so that C is surrounded by water of the desired temperature. The stirrer A is so constructed that it not only churns the liquid but also forces the vapor phase through the liquid. The stirrer is connected to the system by means of the mercury seal K which is so designed that the maximum increase in pressure, accompanied by a difference in mercury levels in the seal, will cause a negligibly small increase (less than 1%) in the volume of the vapor phase.

From the buret 10 cc. of the last reactant was then introduced, the stopcock F_1 was closed, and readings were taken on the water manometer at suitable intervals. The reservoir D contains the water that must be forced up the manometer tube on the scale G in order that the hydrostatic pressure balance the gas pressure in C, and that the meniscus I return to its initial position.

The pressures p_{CO_2} of carbon dioxide as read on the manometer are proportional to the number of moles of carbon dioxide evolved in the reaction, inasmuch as carbon di-

oxide obeys Henry's law at pressures of one-tenth atmosphere and inasmuch as the volume and temperature are essentially constant. The total pressure in the system was always in the neighborhood of one atmosphere.

A series of blank experiments in which the rate of stirring was varied over wide limits above a certain high value, all gave the same curve, showing that equilibrium between the gas and liquid phases was established with sufficient rapidity.

All experiments were carried out at $25.14 \pm 0.02^\circ$. Although most of the specific reaction rates show some trend, yet a comparison of the slopes at corresponding points on two curves (representing systems which differ only in the concentration of one component) allows conclusions to be drawn as to the effect of that component on the reaction rate, and as to the order of the reaction with respect to that component. The best obtainable materials were used throughout.

The Effect of Manganous Ion on the Reaction Rate.—With the exception of one series all rate data are grouped at the end of this article.

The typical "induction" curve, curve (1), Fig. 2 (corresponding to experiment (1)), was obtained when no manganous ion was initially added. As indicated, point P is coincident with an abrupt color change in the solution. The abrupt simultaneous changes of rate and color make it seem reasonable that curve (1) from O to P represents at least three changes in the oxidation states of manganese, one from permanganate to some intermediate state, another from the intermediate state to the manganic state, and the third from the manganic state to the manganous state. From point P to the end, however, the curve seems to represent only the change from the manganic to the manganous state, the steadily increasing manganous ion concentration having served to eliminate all stages of manganese higher than the tri-positive one.

The Existence of the Manganic Oxalate and Fluoride Complexes.—In

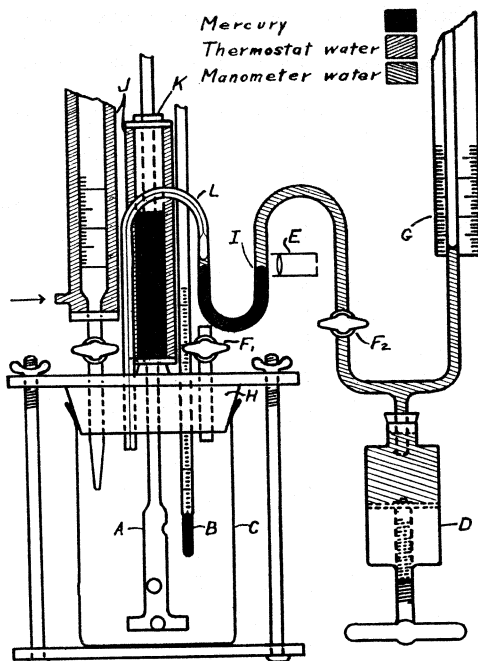

Fig. 1.—Gasometric apparatus: *A*, special centrifuging stirrer; *B*, thermometer; *C*, reaction vessel (a 200 cc. spoutless beaker); *D*, manometer-water reservoir (an "Aleomite" grease gun); *E*, small thermometer telescope to observe meniscus *I*; *F*₁ and *F*₂, stopcocks; *G*, meter stick; *H*, rubber stopper, size 12; *I*, meniscus of mercury; *J*, water jackets through which is circulated (by a small pump) water, from thermostat; *K*, mercury seal device; *L*, capillary tubing.

experiment (2), represented by curve (2), Fig. 2, the manganous ion initially present served to reduce the permanganate as rapidly as the latter could be added, with the formation of a cherry-red solution.

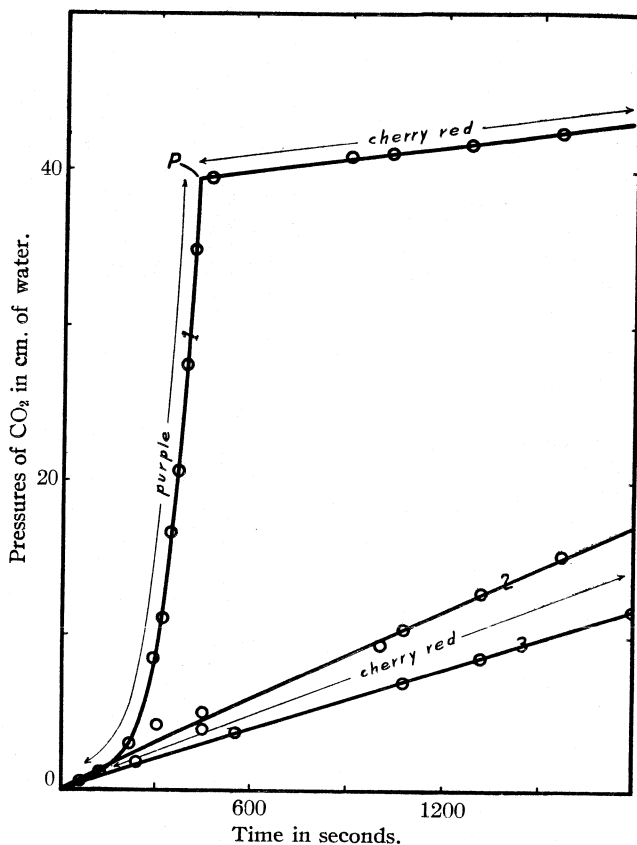

Fig. 2.—The effect of manganous ion and acid.

1	1	98.4	246	0
2	1	98.4	246	13
3	1	72.2	246	13

To prove that the cherry-red color is due to tripositive manganese the following experiment was performed. Two equal portions of permanganate solution were treated with an excess of manganous ion in slightly acid solution. The manganese dioxide precipitates were each filtered and washed free from manganous ion. One portion was placed in an acidified potassium iodide solution and the liberated iodine titrated with thiosulfate, of which 20.10 cc. was required. The other portion was placed in a solution

of sulfuric acid and potassium oxalate like that of experiment (1). The manganese dioxide dissolved rapidly and gave a cherry-red solution, indistinguishable in color from those previously observed. Potassium iodide was immediately added and the iodine titrated, using this time 9.95 cc. of thiosulfate. The tetrapositive manganese evidently lost one-half of its oxidizing power and was converted therefore into the manganic state, the latter being responsible for the color observed above. The reaction that took place was evidently

Next, freshly precipitated manganese dioxide was introduced into an acidified solution of potassium fluoride. No manganese dioxide dissolved until manganous ion was added, whereupon the rapid reaction

doubtless took place with the subsequent formation of a manganic fluoride complex.

The Effect of Acid, Oxalate Ion and Manganic Ion on the Reaction Rate.—A comparison of curves (2) and (3), Fig. 2, shows the effect of acid on the rate. It is to be noted, however, that the concentration of oxalate ion is inversely proportional to the concentration of hydrogen ion, since oxalic acid is weak. The following experiments show that acid is without influence on the rate if the concentration of oxalate ion is fixed. A buffer, consisting of a mixture of acetic acid and ammonium acetate, served to maintain constant the concentration of the oxalate ion. The concentration of hydrogen ion could be varied four-fold while that of the oxalate ion remained essentially constant. Independent experiments showed that the acetic acid is stable in the presence of manganic salts.

TABLE I
THE EFFECT OF ACID ON THE REACTION RATE

28:30	38.1	28:30	38.8	28:30	39.2

The rates vary only 1-2% while the acidity varies 200%, the concentration of oxalate ion remaining essentially constant. The results show

that the effect of acid upon the rate is due solely to its effect on the concentration of oxalate ion.

A series of experiments was made in which the acidity and ionic strength were maintained constant while the concentration of oxalate ion was varied. In preliminary experiments the quinhydrone electrode was used to determine the relative proportions of sulfuric acid and potassium oxalate

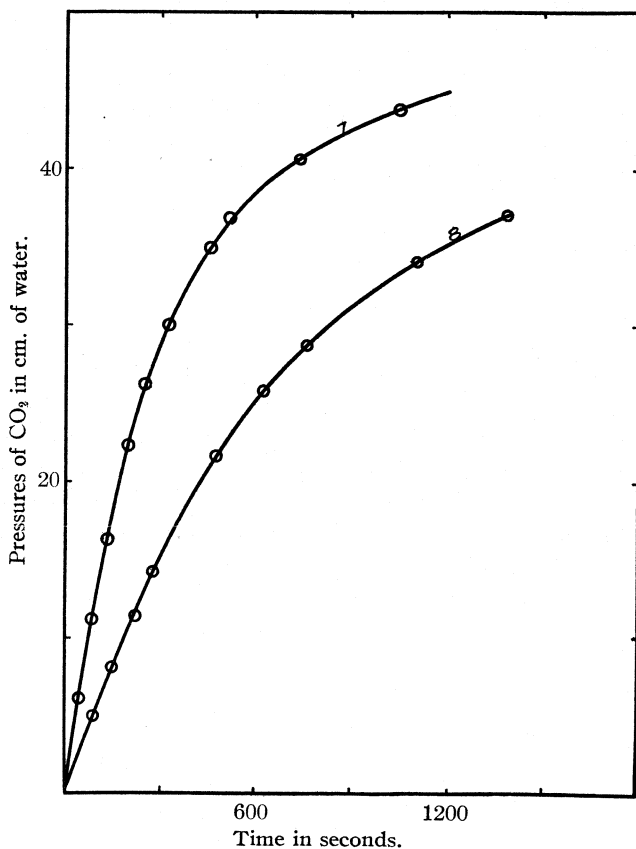

Fig. 3.—The effect of oxalate ion.

Experiment	Formula weights in 1312 liters of solution					Activity of H ⁺
	KMnO ₄	K ₂ C ₂ O ₄	H ₂ SO ₄	K ₂ SO ₄	MnSO ₄

8	1	125	164	0	13	.0276

necessary to keep the activity of the hydrogen ion, and hence its concentration, constant. The potassium sulfate was used to adjust the ionic strength of the solutions. In Fig. 3 the slopes of curve (7) are 2.5 times the slopes of curve (8) at corresponding points, while the concentration of oxalate ion in (8) was 2.5 times that in (7).

Next, a mixture of potassium sulfate, bisulfate and acid oxalate was used to keep the acidity fixed but to permit the oxalate-ion concentration to vary. In Fig. 4 the slopes of curve (9) are twice those of curve (10) and four times those of curve (11) at corresponding points, the concentration

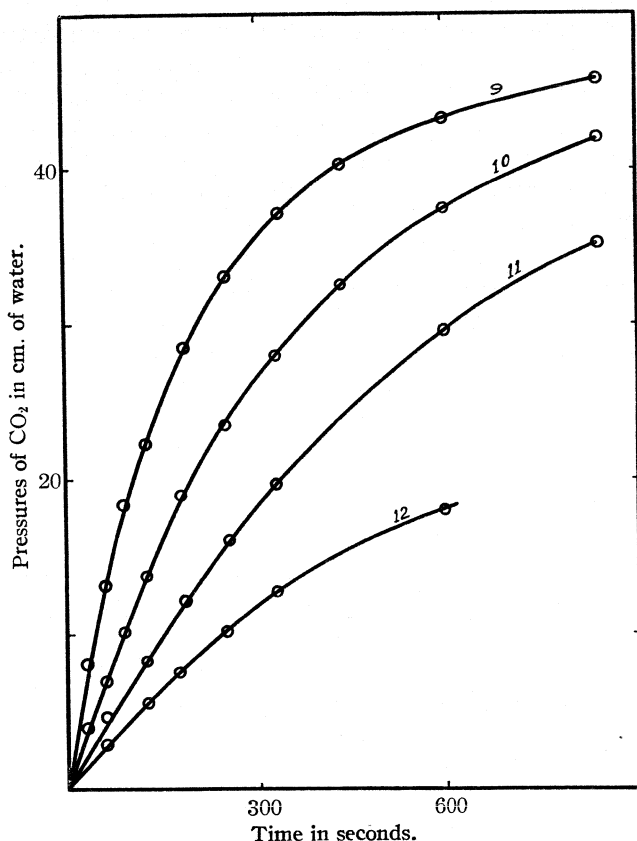

Fig. 4.—The effect of oxalate ion.

Experiment	Formula weights in 1312 liters of solution				
	KMnO ₄	KHC ₂ O ₄	KHSO ₄	K ₂ SO ₄	MnSO ₄
9	1	29	271	200	13
10	1	58	271	200	13
11	1	116	271	200	13
12	0.5	58	271	200	13

of oxalate ion in (10) and (11) being twice and four times, respectively, that in (9). From these results it follows that the rate is inversely proportional to the oxalate-ion concentration.

From the results of previous investigators,¹ and also from the fact that in Fig. 4 the slopes of curve (10) are twice those of curve (12), the concen-

tration of oxidizing agent being in the ratio of two to one, it is evident that the reaction is first order with respect to the oxidizing agent. The concentration of the oxidizing agent is essentially equal to the concentration of the complex manganic oxalate anion since this complex dissociates but little, as will be shown below.

It is evident that the effect of oxalate ion on the rate of reaction (5) (see Introduction) was not directly observable because of its effect on the concentration of manganic ion as shown by equation (4). Experiments were next made in which fluoride was added to suppress the formation of the manganic oxalate complex through the formation of a fluoride complex. This served to make the concentration of manganic ion independent of the concentration of oxalate ion.

Rather crude experiments, the details of which will be given later, show that the manganic fluoride complex is much more dissociated than the manganic oxalate complex. The equilibrium between the two complexes may be represented by the following chemical equation. (It will be shown later that the formulas given for the complexes are probably correct.)

The mass action expression for (10) is

$$\frac{(\text{MnF}_4^-)(\text{C}_2\text{O}_4^{2-})^2}{(\text{Mn}(\text{C}_2\text{O}_4)_2^-)(\text{F}^-)^4} = \frac{K}{K_4} = K_{10} \quad (11)$$

In equation (11), K_{10} , which is the ratio of the dissociation constants of the two complexes, has a value of approximately 0.05, and the ratio $(\text{C}_2\text{O}_4^{2-}) : (\text{F}^-)$ must be 1:7 as a maximum value, if 99% of the manganic ion is to be in the fluoride complex. This condition was attained by placing the reducing agent in deficiency and the oxidizing agent in such excess that changes in the concentration of the latter during the first third of each experiment were negligible.

In Fig. 5 the slopes of curve (17) are twice those of curve (19), and the slopes of curve (18) are twice those of curve (20). Also, the slopes of curves (18) and (19) are equal (at corresponding points). Since, as may be seen from the data given under Fig. 5, the various concentrations are, at corresponding points, in the same ratio as the slopes just compared, it follows that the rate is directly proportional to the concentrations of manganic and oxalate ion. This indicates, therefore, that the slow step is the oxidation of oxalate ion by manganic ion (reaction 5) and not the dissociation of the manganic oxalate complex as assumed by Skrabal.

The Manganic Oxalate and Fluoride Complexes.—Aside from reaction rate data it is desirable to prove that the formula of the manganic oxalate complex is $\text{Mn}(\text{C}_2\text{O}_4)_2^-$.

The following experiments were based on the fact that if the concentration of manganic ion exceeds a certain value manganese dioxide will

precipitate. In each experiment was determined the concentration of oxalate or fluoride ion necessary to prevent the formation of manganese dioxide from a given amount of permanganate, manganous ion and sulfuric acid.

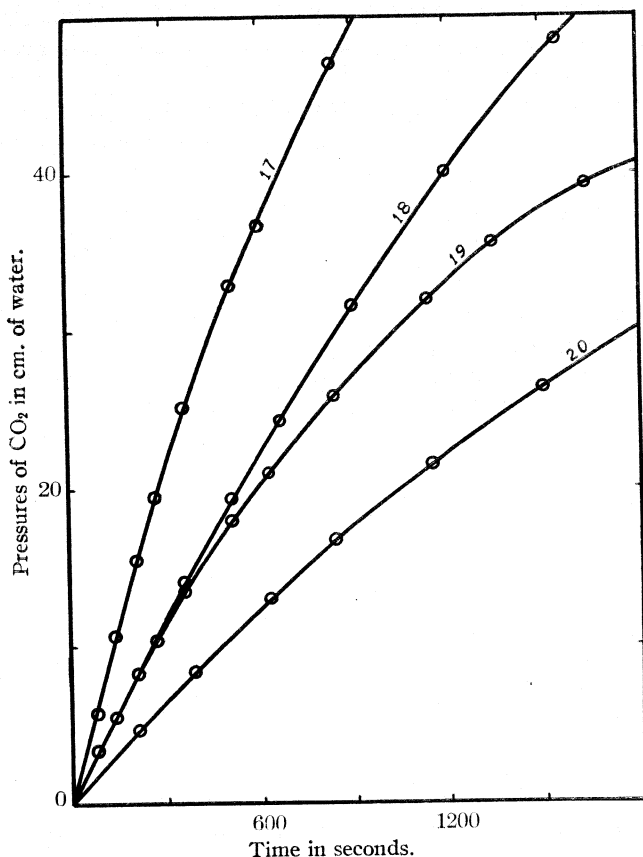

Fig. 5.—The effect of oxalate ion when tripositive manganese is present principally as a complex fluoride.

Experiment	Formula weights in 647 liters of solution					
	KHC ₂ O ₄	KMnO ₄	MnSO ₄	KF	KHSO ₄	(NH ₄) ₂ SO ₄
17	2	2.36 (6-fold excess)	26	155	201	65
18	2	1.18 (3-fold excess)	13	155	201	65
19	1	2.36 (12-fold excess)	26	155	201	65
20	1	1.18 (6-fold excess)	13	155	201	65

Equal portions of permanganate were added to solutions consisting of an excess of acid and of manganous ion, and of varying amounts of potassium oxalate such that the ratio moles of K₂C₂O₄: moles of tripositive manganese was 1.00, 1.25, 1.5, 1.75, 1.875 and 2.00. Only in the last case was a clear

solution obtained, thus showing that two oxalate ions combine with one manganic ion to form the complex.

With this information the following experiment was carried out. Ten (10.00) cc. of 0.00762 *M* permanganate (equivalent to 39.20 cc. of thio-sulfate) was added to 6.80 cc. of a solution consisting of manganous ion in excess and 0.0007415 mole of potassium acid oxalate. One drop more caused a precipitate of manganese dioxide. This solution was immediately treated with iodide ion and acid. The volume of thiosulfate now necessary was 36.80 cc. From this the following concentrations were calculated

	KHC ₂ O ₄ remaining.....	0.04340 <i>M</i>
	MnIII remaining.....	0.02125 <i>M</i>
Hence	Mn(C ₂ O ₄) ₂ ⁻ remaining.....	0.02125 <i>M</i>
and	C ₂ O ₄ ⁼ remaining (maximum).....	0.00090 <i>M</i>

By analogy to the manganic oxalate complex the formula MnF₄⁻ was adopted as being the probable one. Next, 0.90 cc. of 0.00762 *M* permanganate was added to 20 cc. of a solution consisting of 0.000824 mole of potassium fluoride, 0.0005 mole of sulfuric acid and 0.00101 mole of manganous sulfate. A clear solution was obtained which gave a precipitate of manganese dioxide upon the addition of one more drop of permanganate. The concentrations of fluoride ion and of the manganic fluoride complex were calculated to be 0.03285 *M* and 0.001638 *M*, respectively. Since now the concentrations of free manganic ion in both this experiment and the oxalate experiment were such that a precipitation of manganese dioxide was barely averted, it may be assumed that the manganic ion concentration was the same in both experiments. The concentrations of the two complexes and the fluoride and oxalate ion may, accordingly, be substituted in equation (11) and yield for *K*₁₀ the value 0.05.

These experiments indicate that the formula of the manganic oxalate complex is Mn(C₂O₄)₂⁻, and give the minimum value for the ratio (F⁻): (C₂O₄⁼) necessary to have tripositive manganese present mainly as the fluoride complex.

In the following experiments, (21) and (22), Fig. 6, the oxalate ion concentration remained unchanged, but the acid oxalate ion concentration varied five-fold. The slight difference in rate indicates that it is the oxalate ion, and not the acid oxalate ion, which forms the complex and which reacts as in equation (5).

Curve (21'), Fig. 6, would represent approximately the rate in experiment (21) if the acid oxalate ion were the principal complex-former.

The Effect of Ionic Strength on the Rate.—In the foregoing experiments precautions were taken to minimize changes in rate due to changes in the ionic strength. A comparison between the curves for experiments (22) and (23), Fig. 6, which differ only in ionic strength, shows that

there is a large positive salt effect on the rate. The change in rate was approximately 500% while the change in the solubility of carbon dioxide was

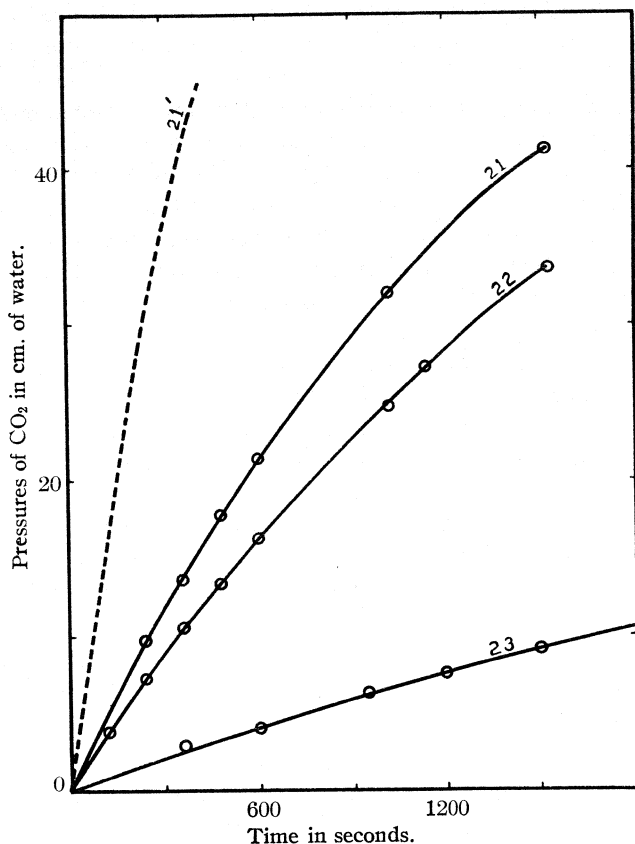

Fig. 6.—The effect of binoxalate ion and the ionic strength on the rate.

Experiment	Formula weights in 1312 liters of solution					
	KMnO ₄	K ₂ C ₂ O ₄	KHC ₂ O ₄	(NH ₄) ₂ SO ₄	MnSO ₄	Ionic strength
21	1	49	28	1310	13	3.26
22	1	49	140	1310	13	3.26
23	1	49	140	0	13	0.26

small, 15%, compared to this. When modified by Brönsted's rate hypothesis the experimentally determined rate equation (2) becomes

$$\frac{dp_{\text{CO}_2}}{dt} = \frac{k(\text{Mn}(\text{C}_2\text{O}_4)_2^-)}{(\text{C}_2\text{O}_4^{2-})} \cdot \frac{f_1}{f_2 f_3}$$

where f_1 , f_2 and f_3 are the activity coefficients of the manganic oxalate complex, the oxalate ion and the unipositive critical complex ion, respectively. This expression, after cancellation of the activity coefficients of the

two singly charged ions, evidently requires that the rate increase rapidly with the ionic strength and this was found experimentally to be the case.

The experimental results presented above are all in accord with the mechanism already described. It is believed that the method of experimentation used has made possible a more precise determination of the mechanism than was possible in the previous studies of the reaction.

The Role of Peroxides in the Manganic Oxalate Reaction.—If the manganic oxalate reaction be allowed to run to completion in the presence of oxygen, the resulting solution will impart a yellow color to a solution of titanous sulfate. The existence of hydrogen peroxide during the permanganate titration has been observed and studied by Kolthoff.²

It is suggested here that the hydrogen peroxide arises from an equilibrium between water and a peroxide of carbon, and that this latter results from a combination of the O_2 molecule and the CO_2^- ion in an effort on the part of both particles to form an electron-pair bond from their unpaired electrons. Rate data show that in the first effective collision between a manganic ion and an oxalate ion, one electron is removed from the latter. This leaves only one electron between the two carbon atoms. Since one electron ordinarily does not constitute a stable chemical bond, the carbon atoms part, becoming CO_2 and CO_2^- , a particle with an unpaired electron. In a later paper on the effect of oxygen upon this reaction will be presented results in support of the above ideas.

The curves given were drawn using the data presented in Table II. The numbers assigned to the curves are the same as those of the corresponding experiments.

Summary

An apparatus was designed for the measurement of rapid reactions in solutions involving even exceedingly small quantities of gaseous product (0.02 millimole) provided either that this gas follow Henry's law or that the deviations therefrom be known.

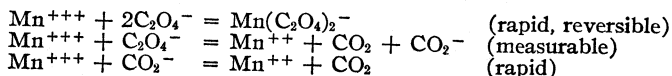

The reaction between tripositive manganese and oxalate ion has been studied and found, in agreement with the work of previous investigators, to be an important step in the reaction between permanganate and oxalic acid. The rate of this reaction was found to be expressible by the equation

$$\frac{dp_{\text{CO}_2}}{dt} = k_1 \frac{(\text{Mn}(\text{C}_2\text{O}_4)_2^-)}{(\text{C}_2\text{O}_4^-)}$$

when oxalate ion is in excess, and by the equation

$$\frac{dp_{\text{CO}_2}}{dt} = k_2(\text{Mn}^{+++})(\text{C}_2\text{O}_4^-)$$

when oxalate ion is in deficiency and fluoride ion is present to form a complex with manganic ion. This led to the adoption of the following mechanism.

The formula of the manganic oxalate complex ion was found to be $\text{Mn}(\text{C}_2\text{O}_4)_2^-$.

The influence of the ionic strength on the rate was found to be in accord with that predicted using the Brönsted hypothesis.

An explanation was proposed for the formation of peroxides when the reaction takes place in the presence of oxygen.

THE HEAT CAPACITY AND ENTROPY OF CARBON MONOXIDE. HEAT OF VAPORIZATION. VAPOR PRESSURES OF SOLID AND LIQUID. FREE ENERGY TO 5000°K. FROM SPECTROSCOPIC DATA

By J. O. CLAYTON¹ AND W. F. GIAUQUE

RECEIVED DECEMBER 28, 1931

PUBLISHED JULY 6, 1932

Carbon monoxide gas is one of the simpler diatomic molecules. Spectroscopically the normal level is a $^1\Sigma$ state and it has no other electronic configurations that are appreciably occupied until temperatures far in excess of the 5000°K. limit of our calculations are reached. While nuclear spin should not produce any appreciable effect on the observed behavior of such a molecule, it is of interest to note that the predominant isotopes of both carbon and oxygen are without nuclear spin.

In view of the molecular simplicity it might be expected that the entropy obtained from the band spectrum would agree with that obtained from the ordinary application of the third law. However, this proves not to be the case and it becomes a matter of considerable practical as well as theoretical interest to determine the extent to which similar effects may exist in other molecules. In attempting to find a definite physical explanation for the discrepancy it is desirable to have an accurate quantitative measure of the amount.

It is also our purpose to consider the equilibrium $\text{C (graphite)} + \frac{1}{2}\text{O}_2 =$

¹ Shell Research Fellow, Academic year 1929-30.

CO, combining thermal data on graphite and the accurately known heat of reaction with spectroscopic data on oxygen and carbon monoxide.

Preparation of Carbon Monoxide.—The carbon monoxide was made by the well-known method of dropping formic acid into concentrated sulfuric acid. The chemically pure reagents were boiled to remove dissolved gases and were later subjected to a vacuum in the closed preparation system. The formic acid was cooled with ice during the latter procedure to prevent too rapid evaporation. The preparation system was evacuated by means of a mercury diffusion pump and found to be vacuum tight before the reagents were introduced. The first portion of the carbon monoxide to be prepared was discarded. The carbon monoxide was passed through a 50% potassium hydroxide solution and then over phosphorus pentoxide. It was then condensed in liquid air and distilled three times, the first and last portions of each distillation being discarded.

Heat Capacity Measurements and Data.—The measurements of heat capacity were carried out in gold calorimeter II described by Giauque and Wiebe.² The method was the same as that given by the above authors and by Giauque and Johnston.³ The discussion of the various factors affecting accuracy and the estimation of the accuracy at various temperatures has been given in the latter paper and applies to the present work. It is believed that the entropy may be computed from the results with an accuracy of two-tenths of one per cent.

Three preparations of carbon monoxide were used in the measurements. These are referred to as I, II and III.

The temperature standard was the copper-constantan thermocouple "W" of Giauque, Buffington and Schulze.⁴ Since the original comparison with the hydrogen gas thermometer it has frequently been checked against the vapor pressure of oxygen. This comparison was repeated in the course of the present experiments and it was found to agree within a few hundredths of a degree at several temperatures in the liquid oxygen range. This is within the limit of the accuracy claimed, namely, 0.05°.

The temperature intervals and warming rates were all measured by means of the gold resistance thermometer. In correcting for the heat effect due to vaporization into the small gas volume above the condensed gas, during a temperature rise, the density of the liquid was taken from the work of Baly and Donnan⁵

$$d_{(l)} = 1.1604 - 0.0045 T$$

As the volume of the solid is not very important in the above correction, it could be estimated with sufficient accuracy by comparison with nitrogen.

⁴ Giauque, Buffington and Schulze, *ibid.*, **49**, 2343 (1927).

⁵ Baly and Donnan, *J. Chem. Soc.*, **81**, 907 (1902).

The amount of material was measured by means of the five-liter volumetric apparatus described by Giauque and Johnston.³ Between series II and III an accident to the measuring bulb necessitated replacement, which was done with the same precautions described for the previous apparatus. The amount of material was determined as follows:

$$\text{Number of moles} = V \times P \times \frac{D}{M} \times \frac{1}{1 + \alpha T} [1 + \alpha (1 - P)]$$

Gas density at 0°C.

Molecular weight

The heat capacity of carbon monoxide has been measured by Eucken¹¹ and by Clusius.¹²

The results of Clusius agree quite well with the present investigation, the largest deviations being below 20°K. and near the boiling point. The average deviation is about 3%. However, the algebraic deviation is only about 0.1%, showing agreement as to total energy input over the region. The earlier work of Eucken does not agree as well.

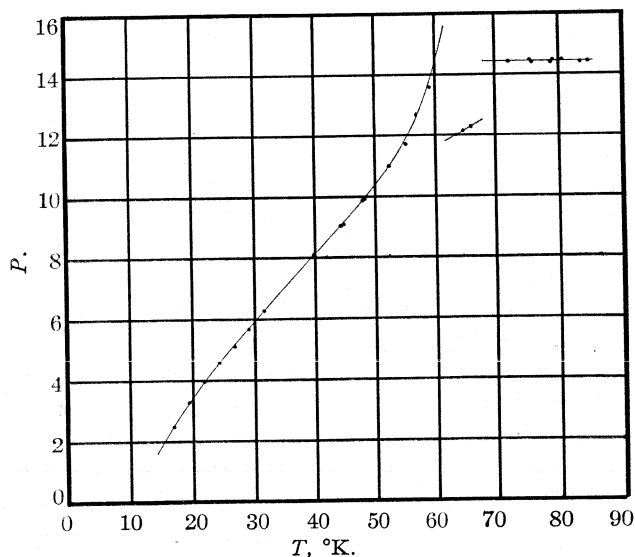

Fig. 1.—Capacity of carbon monoxide in calories per degree per mole.

The results given in Table I are shown graphically in Fig. 1.

Transition and Melting Point Temperatures.—The transition and melting point temperatures were investigated with various percentages trans-

formed. The transition temperature was observed over a period of nineteen hours, the melting point for eighteen hours with preparation I and for sixteen hours with preparation II. The data are collected in Table II.

Purity of Carbon Monoxide.—One of the best methods of estimating an impurity which is soluble in a liquid but insoluble in the solid phase is by calorimetric observation of the premelting effect. The short temperature range of the solid modification stable at the melting point was a slight handicap to this method in the case of carbon monoxide. However, no abnormal rise is apparent in the last point observed below the melting point. The evidence is sufficient to determine that the impurity is not greater than one-thousandth of one mole per cent. The constancy of the melting point confirms the purity although this method is greatly inferior in sensitivity to the premelting method.

Heats of Fusion and Transition.—The heats of fusion and transition were measured by starting the energy input a little below the transition or

It may be noticed that the two determinations of the heat of transition differ by an amount far beyond the ordinary limit of our calorimetric error. This point will be considered later.

Vapor Pressures of Solid and Liquid Carbon Monoxide.—Vapor pressures were measured on the same material used in Series II of the calorimetric measurements but not at the same time as it was undesirable to have the manometer volume connected during calorimetric measurements. The apparatus was essentially the same as that described by Giauque, Johnston and Kelley.¹⁷ A Gaertner cathetometer with an accuracy of 0.05 mm. of mercury was used to compare the large diameter manometer with a standard meter.

The results have been represented by equations 1 and 2. For solid carbon monoxide from the transition point at 61.55° to the melting point at 68.09°

$$\log P_{(\text{cm.})} = -\frac{425.1}{T} + 7.82259 - 0.0075960 T \quad (1)$$

For liquid carbon monoxide

$$\log P_{(\text{cm.})} = -\frac{477.3}{T} + 11.23721 - 0.064129 T + 2.5911 \times 10^{-4} T^2 \quad (2)$$

In addition an equation was calculated for the vapor pressure of the solid stable below 61.55°K. This was done with the assistance of the various calorimetric data, including the heat of vaporization to be given below. In correcting the measured heat of vaporization to the value which would be obtained for evaporation to a dilute gas the thermodynamic equation

¹⁷ Giauque, Johnston and Kelley, THIS JOURNAL, 49, 2367 (1927).

$$\left(\frac{\partial H}{\partial P}\right)_T = V - T \left(\frac{\partial V}{\partial T}\right)_P$$

was combined with Berthelot's equation.

The heat of sublimation of the solid stable at or below 61.55°K. was found to be 1963 calories per mole at 61.55°K. The heat capacity of the solid can be represented very roughly but with sufficient accuracy from 20° to the transition point by

$$C_P = -1.25 + 0.24 T$$

These several data yield the equation, for solid carbon monoxide below 61.55°K.

$$\log P_{(\text{cm.})} = -\frac{418.2}{T} + 4.127 \log T + 1.47365 - 0.02623 T \quad (3)$$

One observation on the vapor pressure of this modification was made, namely, $P = 1.998$ cm. at 60.24°K . The observed and calculated values are included in Table V. The temperatures at which observations were made on the liquid are given to 0.001 degree as they are relatively consistent to better than 0.01 degree. The principal error appears to be in the pressure measurements, the increase in ΔT , observed-calculated, at the lower temperature, being due largely to this source.

The vapor pressure of carbon monoxide has been measured by Clusius and Teske¹⁸ and their data have been compared with our equations in Table VI.

¹⁸ Clusius and Teske, *Z. physik. Chem.*, [B] **6**, 135 (1929).

While the average deviation is very much greater than in the present work, the results are well represented by our equations. In fact, equation 1 represents the data of Clusius and Teske for the liquid range with a slightly smaller average deviation than was obtained with their own equation.¹⁹

From equation 1 the boiling point was found to be $81.61 \pm 0.05^\circ\text{K}$. The boiling point data of several observers are summarized in Table VII.

Heat of Vaporization of Carbon Monoxide.—The entropy of vaporization contributes roughly one-half of the total entropy for the simple gases. For this reason it is very desirable to have a direct and accurate determination of this quantity. The experimental method has been described previously.^{2,3}

The results are given in Table VIII, which also includes the value given by Eucken and that calculated from our vapor pressure determinations. The latter method is in general inferior to the directly determined value due to uncertain correction for gas imperfection at the higher pressures and to increasing error in dP/dT at low pressures.

¹⁹ Since this paper was written our attention has been called to some very accurate vapor pressure measurements by Verschoyle [*Trans. Roy. Soc. (London)*, **A230**, 189 (1931)]. The equation given by Verschoyle does not represent his values in the liquid range, the discrepancy undoubtedly being due to some typographical error. However, we have compared his results from the melting point to 82.2° with our Equation 2. The agreement is extraordinarily good. The maximum deviation is 0.02° and the average deviation 0.01° . However, Verschoyle's results, which extend to a pressure of 143 cm., are not very satisfactorily represented by our Equation 2 above the boiling point. Below the melting point the agreement is not as good. Although Verschoyle's results extend to 54.21°K ., he apparently failed to notice the transition at 61.55°K . and represents all of his results on the solid states by a single equation. Near the transition temperature Verschoyle's temperatures are about 0.06° higher than the present work. Below 61.55°K . Verschoyle's results do not agree well with our equation 3 obtained with the assistance of the calorimetric data. At 54.2°K . his results are 0.12° lower than those given by Equation 3. However, our one observation on this crystal modification at 60.24° is only 0.03° lower than Verschoyle's results in this region.

For comparison: Boiling point, 81.62° (V.), 81.61° (C. and G.).

Triple point temperature, 68.06° (V.), 68.09° (C. and G.).

Triple point pressure, 11.486 cm. (V.), 11.531 cm. (C. and G.).

1434	From vapor pressure equation 2, assuming a Berthelot gas			

The 1434 value for the heat of vaporization obtained from the vapor pressure measurements is of course to be given no weight in comparison with the calorimetric value. This calculation, however, increases the justification for assuming that Berthelot's equation represents the behavior of carbon monoxide. This will be assumed later in connection with the effect of gas imperfection on the entropy.

The Entropy of Carbon Monoxide.—The entropy calculation is summarized in Table IX. A Debye function with $h\nu/k = 79.5$ was used to extrapolate to the absolute zero.

TABLE IX
CALCULATION OF ENTROPY OF CARBON MONOXIDE

0–11.70°K. Debye extrapolation $h\nu/k = 79.5$	0.458
11.70–61.55 Graphical	9.632
Transition 151.3/61.55	2.457
61.55–68.09 Graphical	1.228
Fusion 199.7/68.09	2.933
68.09–81.61 Graphical	2.611
Vaporization 1443.6/81.61	17.689
Entropy of carbon monoxide gas at boiling point	37.01 \pm 0.1
Correction for gas imperfection assuming Berthelot gas	0.21
Entropy corrected to the ideal state	37.2 E. U.

The 0.21 E. U. correction for gas imperfection was calculated by combining Berthelot's equation with the thermodynamic equation

$$\left(\frac{\partial S}{\partial P}\right)_T = -\left(\frac{\partial V}{\partial T}\right)_P \text{ yielding}$$

$$\Delta S_{\text{correction}} = R \frac{27 T_0^3 P}{32 T^3 P_0}$$

The critical data were taken from the review of such data given by Pickering²¹

$$T_0 = 134.1^\circ\text{K.} \quad P_0 = 35 \text{ atmospheres}$$

²¹ Pickering, *Sci. Papers Bur. Standards*, 21, 608 (1926).

The correction to the ideal state is necessary in order that comparison may be made with the entropy which will now be calculated from the band spectrum of carbon monoxide.

The entropy is given by the expression

$$S^{\circ} = \frac{3}{2} R \ln M + \frac{5}{2} R \ln T - R \ln P - \frac{5}{2} R - 7.267 + R \ln Q + RT \frac{d \ln Q}{dT} \quad (4)^{22}$$

$$Q = \sum p e^{-\epsilon/kT} \text{ over all quantum levels}$$

The energy levels of carbon monoxide may be represented by the expressions

$$\epsilon_{\text{rotation}} = [B_e + \alpha(v + 1/2)]m^2 + [D_e + \beta(v + 1/2)]m^4$$

$$\epsilon_{\text{vibration}} = \omega_e(v + 1/2) + \omega_e X_e (v + 1/2)^2$$

Birge²³ has recalculated the data of Snow and Rideal²⁴ and gives $B_e = 1.853$, $\alpha = 0.020$, $D_e = 5.418 \times 10^{-6}$, $\beta = -6.918 \times 10^{-8}$, $\omega_e = 2167.4$, $\omega_e X_e = -12.70$. Mulholland²⁵ has expressed Q as a simple series in terms of B for rigid molecules. Giauque and Overstreet²⁶ have given an expression which is suitable for non-rigid molecules.

$$Q = e^{\frac{hc}{kT} \left(\frac{B}{4} + \frac{D}{16} \right)} \cdot \frac{kT}{Bhc} \left[1 + \frac{B}{12} \left(\frac{hc}{kT} \right) - \frac{2D}{B^2} \left(\frac{kT}{hc} \right) + \frac{12D^2}{B^4} \left(\frac{kT}{hc} \right)^2 + \dots \right] \quad (5)$$

This avoids the considerable labor involved in summing the individual Boltzmann factors for the rotational levels.

From the above expression for Q and the derivative of its logarithm used in equation 4, the entropy of carbon monoxide is calculated and given in Table X. The values for all natural constants are those given in the "International Critical Tables."

TABLE X
COMPARISON OF EXPERIMENTAL AND SPECTROSCOPIC ENTROPIES OF CARBON MONOXIDE

T, °K.	Spectroscopic	Experimental	
		Actual gas	Corrected to ideal state
81.61	38.318	37.0 ± 0.1	37.2 E. U.
298.1	47.313	46.2

The "experimental" value given for 298.1°K. was obtained by adding the calculated increase in column 2 to 37.2.

It is clear from the discrepancy between the spectroscopic and experimental values that some random situation remains in the solid state at liquid hydrogen temperatures. This is in addition to the small amount considered by the Debye extrapolation.

The difference between the two values is roughly $R \ln 2$. We believe that

²² Giauque, *THIS JOURNAL*, **52**, 4808 (1930).

²³ Birge, Personal communication.

²⁴ Snow and Rideal, *Proc. Roy. Soc. (London)*, **A125**, 462 (1929).

²⁵ Mulholland, *Proc. Cambridge Phil. Soc.*, **24**, 280 (1928).

²⁶ Giauque and Overstreet, *THIS JOURNAL*, **54**, 1731 (1932).

the discrepancy arises as follows. If we consider a molecule with two or more otherwise equivalent positions occupied by isotopes of a given element, it is found that such a molecule enters a crystal lattice without any particular isotopic preference. However, it is true that at extremely low temperatures the almost negligible but nevertheless real energy differences between the possible arrangements will become comparable with kT and thus the crystal will attain perfect order on *reversible* approach to the absolute zero. It is evident even when the positions are occupied by different elements that, unless the crystal lattice has a sufficiently strong preference for a certain arrangement to impose an energy difference much larger than kT , the several possible orientations will exist. It is suggested that this is the case in solid carbon monoxide. This seems more probable when one considers the similar atomic sizes and that it has frequently been assumed that carbon monoxide has an electron structure similar to nitrogen. A discussion of this point has been given by Lewis.²⁷

The electron structure, symmetrical in nitrogen, would of course be somewhat deformed by the differing charges on the carbon and oxygen kernels. Nevertheless, it seems entirely reasonable to assume that the polarity thus induced is insufficient to fix the carbon and oxygen atoms in definite positions at the temperature where the solid is formed. It appears that orderly arrangement in the above respect occurs in carbon monoxide below the temperatures investigated or, what is still more probable, that rearrangement to equilibrium is not easily possible in the solid. In this connection it may be recalled that two determinations of the heat of transition given in Table IV differed by an amount considerably beyond the ordinary limit of error. While no definite conclusion is possible, the difference could be attributed to a different degree of approach to equilibrium in the solid stable below 61.55°K. Unfortunately the experiments were concluded before the calorimetric calculations yielded this information. It would be interesting to hold carbon monoxide at various temperatures below 61.55° for considerable periods of time to investigate this effect.

The amount of entropy corresponding to a complete lack of discrimination between the carbon and oxygen ends of the molecule is $R \ln 2 = 1.38$ E. U. The fact that the observed discrepancy is somewhat smaller, namely, 1.1 E. U., indicates also that some approach to order has been made and that inability to obtain equilibrium is a factor.

The above type of difficulty, while possible only in certain special cases, is perhaps the most perplexing feature that has been encountered in the practical application of the third law of thermodynamics. It is perplexing because it is by no means obvious how we are to know when it exists. The crystal under investigation may appear perfect to our present powers of

²⁷ Lewis, "Valence and the Structure of Atoms and Molecules," The Chemical Catalog Co., New York, 1923, p. 126.

observation, including x-rays and yet the effect may be present. Certain types of organic molecules would appear to be susceptible to this effect.

The Free Energy of Carbon Monoxide.—From the expression²²

$$\frac{F^\circ - E_0^\circ}{T} = -\frac{3}{2} R \ln M - \frac{5}{2} R \ln T + R \ln P + 7.267 - R \ln Q$$

and the band spectra data previously given, the values of $(F^\circ - E_0^\circ)/T$ have been calculated. The value of R was taken as 1.9869 calories per degree per mole. The results are given in Table XI. The values given in heavy type have been directly calculated. The others have been interpolated by means of a difference plot making use of the Einstein harmonic oscillator function.

Before considering the reaction

it is necessary to obtain the $(F^\circ - E_0^\circ)/T$ for graphite. The values for oxygen have been tabulated by Johnston and Walker.²⁸

The calculation for graphite was made graphically, using the heat capacity data collected in the "I. C. T." These data extend only to 2400°K. and are not as accurate as might be desired. However, it can be seen, by analogy with other substances, that the heat capacity curve given by the available data is not likely to be much in error. The values ob-

²⁸ Johnston and Walker, have kindly allowed us to use their data in advance of publication.

tained are given in Table XII. The values for graphite have been expressed to 0.001 unit although this is considerably beyond the absolute accuracy of the heat capacity data. This is in accordance with the free energy convention which thus allows accurate differences to be obtained.

		1700	4.704		

$$\frac{\Delta F}{T} = -R \ln K = \Delta \left(\frac{F^\circ - E_0^\circ}{T} \right) + \Delta E_0^\circ \quad (6)$$

ΔE_0° is given by the equation

$$\Delta E_0^\circ = \Delta H^\circ - \left[\frac{5}{2} RT + RT^2 \frac{d \ln Q}{dT} \right]_{\text{co}} + \frac{1}{2} \left[\frac{5}{2} RT + RT^2 \frac{d \ln Q}{dT} \right]_{\text{O}_2} + [H^\circ - E_0^\circ]_{\text{C}} \quad (7)$$

The value of ΔH° was obtained by difference of the heats of combustion of graphite and of carbon monoxide.

For the first of these the value of Roth and Naeser²⁹ was adopted. We have learned from Professor G. S. Parks that a personal communication from Professor Roth states that the graphite weighings were not given on a vacuum basis. The application of the correction for buoyancy leads to a value of 94,240 as the heat of combustion of 12.000 g. of β graphite at 298.1°K.

For the second, the work of Rossini³⁰ gives $67,623 \pm 30$ calories as the heat of combustion of carbon monoxide at 298.1°K.

Combining

For carbon monoxide

$$\begin{aligned} \frac{5}{2} RT + RT^2 \frac{d \ln Q}{dT} &= 1480.7 + 590.2 \\ &= 2070.9 \text{ calories at } 298.1^\circ\text{K.} \end{aligned}$$

²⁹ Roth and Naeser, *Z. Elektrochem.*, **31**, 461 (1925).

³⁰ Rossini, *Bur. Standards J. Research*, **6**, 37 (1931).

For oxygen

$$\frac{1}{2} \left[\frac{5}{2} RT + RT^2 \frac{d \ln Q}{dT} \right] = \frac{1}{2} [1480.7 + 589.6]$$

$$= 1035.2 \text{ calories at } 298.1^\circ \text{K.}$$

For graphite the "I. C. T." give

$$H^\circ - E_0^\circ = 251.4 \text{ calories at } 298.1^\circ \text{K.}$$

Combining the several values in equation 7, $\Delta E_0^\circ = -27,404$ calories per mole of carbon monoxide.

3000	20.279	29.414	2.69×10^6

From this value, the several values of $(F^\circ - E_0^\circ)/T$ and equation 6, $\Delta F^\circ/T$ and K have been computed for the formation of carbon monoxide from the elements. The results are given in Table XIII.

The values of K should be accurate to about 5%. At the lower temperatures the error is chiefly in ΔE_0° and at the higher temperatures the uncertainty is almost entirely due to the data on graphite.

In the absence of better information on the heat capacity of carbon above 3000° it seems preferable to omit values above 3000°. However, the values for carbon monoxide have been extended to 5000° and the values for $(F^\circ - E_0^\circ)/T$ of oxygen given by Johnston and Walker²⁸ extend to this temperature. Thus by extrapolation of the data for graphite above 3000°K. a quite reliable calculation of the equilibrium is available.

We wish to thank H. L. Johnston for assisting with the measurements of series I and R. W. Blue for assisting with series II and III.

Summary

The heat capacities of the two crystalline forms of carbon monoxide and the liquid have been measured from 13°K. to the boiling point.

The transition temperature was found to be 61.55°K. \pm 0.05, the melting point 68.09°K. \pm 0.05 and the boiling point 81.61°K. \pm 0.05. From the calorimetric measurements the heat of transition was determined as 151.3 \pm 1 calories per mole, the heat of fusion 199.7 \pm 0.2 and the heat of vaporization 1443.6 \pm 1.0 calories per mole, measured at 760 mm.

From the experimental data the entropy of carbon monoxide gas was calculated to be 37.0 \pm 0.1 E. U. at 81.61°K. Assuming Berthelot's gas equation a correction amounting to 0.2 E. U. for gas imperfection was added, giving 37.2 E. U. This value can be compared to the value calculated for the ideal gas from the band spectrum, 38.318 at 81.61°K.

The observed entropy is low by an amount corresponding approximately to $R \ln 2$. Reasons are given for believing that this is due to lack of discrimination within the crystal lattice for the oxygen and carbon ends of the molecule. It is suggested that this effect may exist in other molecules and that a quantitative correction will be possible in many cases.

The entropy of carbon monoxide gas at 298.1°K. was found to be 47.313 E. U. from the band spectrum data.

The vapor pressure of solid and liquid carbon monoxide was measured and represented by the equations

Liquid 68.09° - 83.13°K.

$$\log P(\text{cm.}) = -\frac{477.3}{T} + 11.23721 - 0.064129 T + 2.5911 \times 10^{-4} T^2$$

Solid 61.55° - 68.09°K.

$$\log P(\text{cm.}) = -\frac{425.1}{T} + 7.82259 - 0.0075960 T$$

Solid below 61.55°K.

$$\log P(\text{cm.}) = -\frac{418.2}{T} + 4.127 \log T + 1.47365 - 0.02623 T$$

The free energy function for carbon monoxide was calculated from spectroscopic data and tabulated to 5000°K. These data were combined with similar data on oxygen and with the available calorimetric data on graphite to give ΔF for the reaction $\text{C}_{\text{graphite}} + \frac{1}{2}\text{O}_2 = \text{CO}$ to 3000°K.

The free energy of formation of carbon monoxide from β graphite and oxygen at 298.1°K. was found to be $\Delta F_{298.1}^\circ = -33,000$.

THE ACTIVITY COEFFICIENT OF POTASSIUM CHLORIDE IN AQUEOUS SOLUTION FROM BOILING POINT DATA¹

BY BLAIR SAXTON AND RODNEY P. SMITH

RECEIVED JANUARY 18, 1932

PUBLISHED JULY 6, 1932

Although the thermodynamic properties of aqueous salt solutions at ordinary temperatures have been extensively investigated, few data are available for the study of these properties at higher temperatures. Measurements of the boiling point elevation of solutions could be used for such a study if sufficient accuracy in the measurement could be attained. Considerable data² have been published on the boiling point elevation of salt solutions. However, due to superheating, variation of pressure, errors of analysis or temperature measurement, the results are not of sufficient accuracy for a calculation of the activity coefficient. It has seemed worth while, therefore, to attempt to design an apparatus for a more accurate determination of the boiling point elevation.

Apparatus

Of the different methods used for the elimination of superheating, the one suggested by Cottrell³ and used by Washburn and Read,⁴ Pearce and Hicks,⁵ and Bancroft and Davis⁶ seems to be the most satisfactory.

The first apparatus, Fig. 1, consisted of a Pyrex tube, A, 43 cm. long and 7.6 cm. inside diameter, over which was sealed a larger tube, B, 28 cm. long, 11.5 cm. inside diameter. A condenser, C, and a small drain tube, D, were sealed into the outer tube, B. A tube, E, for the "cold" junction of the thermocouple was also sealed into the

¹ Part of this paper is from a dissertation submitted by Rodney P. Smith to the Graduate School of Yale University, in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

⁶ Bancroft and Davis, *ibid.*, **33**, 591 (1929).

outer tube, B. (For all but the dilute solutions, however, it was found that the cold junction was affected by the temperature of the solution tube, thus necessitating the use of an outside hypsometer.) The solution tube, G, fitted into the ground opening, F. A ground-glass stopper carried a tube, J, for the hot junction of the thermocouple, and two small tubes, I, for the lead-wires to the platinum heating coil. The heating coil was of No. 22 wire and had a resistance of about 0.04 ohm. The seal through the lead-wire tubes was made with heavy tungsten wire, the platinum wire being soldered to the tungsten with hard silver solder. Contact between the lead wires and the tungsten was made with mercury. The lead-wires were of sufficient size to carry 20 to 25 amperes without heating. A Cottrell pump, L, was fixed in the center of the solution tube. Samples for analysis were withdrawn through a large capillary tube, N. The pure solvent in the outer tube was heated with a gas flame. The entire apparatus was protected from air currents by a transit box.

The apparatus has the advantages of electric heating and the Cottrell pump as a means of eliminating superheating. Since the solution is heated nearly to its boiling point by the vapor of the pure solvent, only a small amount of heat is required from the electric heating coil. Thus, it is possible to boil the solution with a drop of potential across the heating coil below the decomposition potential of the solution. A small transformer was used as a source of current for the heating coil.

A 20-junction No. 36 copper-No. 30 constantan thermocouple, constructed according to the specification of White,⁷ was used to measure the elevations. The thermocouple was calibrated from the following fixed points: freezing point of mercury, transition point of sodium sulfate, transition point of manganous chloride, boiling point of water and boiling point of naphthalene. The e. m. f. of the thermocouple was measured with a shielded Leeds and Northrup type K potentiometer.

The pressure was maintained constant to less than 0.1 mm. by an apparatus similar to that described by Carroll, Rollefson and Mathews.⁸

The degree of superheating was found to be zero by using pure water, both in the inside and in the outer tubes. The accuracy of this apparatus was found to be 0.0025°.

With the Cottrell pump it is not possible to raise the solution very high above the surface of the liquid; therefore, unless the end of the thermocouple tube is near the surface of the liquid, its immersion depth is not very great. Due to the large heat con-

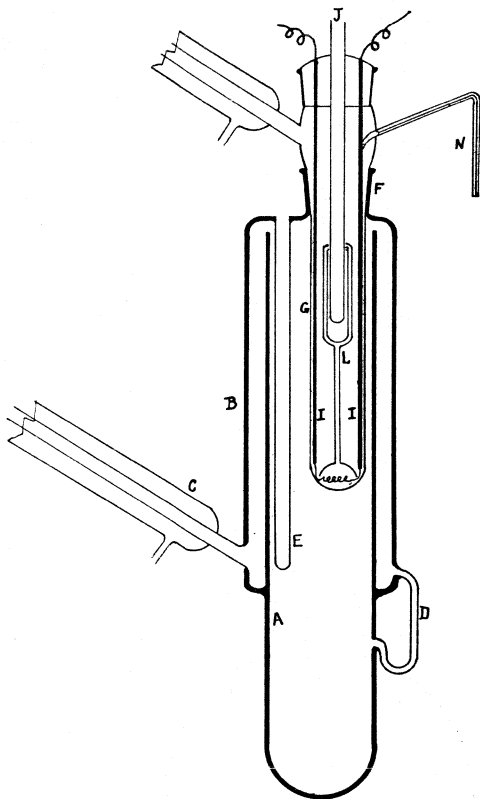

Fig. 1.

⁷ White, *THIS JOURNAL*, 36, 2292, 2313 (1914).

⁸ Carroll, Rollefson and Mathews, *ibid.*, 47, 1791 (1925).

ductivity of multi-junction thermocouples, there is the danger that the observed elevations are too low. With the view of eliminating this possible error, a second apparatus, shown in Fig. 2, was designed. The solution tube consisted of a two-liter Pyrex round-bottomed flask, connected through a ground-glass stopper to an upper chamber, B, by three tubes, C, D and E. The tube, F, for the thermocouple was sealed in the center of the upper chamber, B. By partially closing the stopcock in tube C, a slight pressure was developed in the solution flask, causing the solution to rise slightly in the tube E; vapor was allowed to pass into the tube E through a pin-hole, G. The vapor, in rising through the tube E, carried small amounts of solution with it, thus causing an intimate mixture of liquid and vapor to squirt continuously over the thermocouple tube, F. With this arrangement, the immersion depth of the thermocouple was more than doubled. The tube D served to return the solution to the solution flask. Samples for analysis were withdrawn through the tube H. Since the volume of the solution used with this apparatus was relatively large, it was possible to draw off samples for analysis of 100 to 150 cc., thus decreasing the error due to evaporation while the sample was being taken.

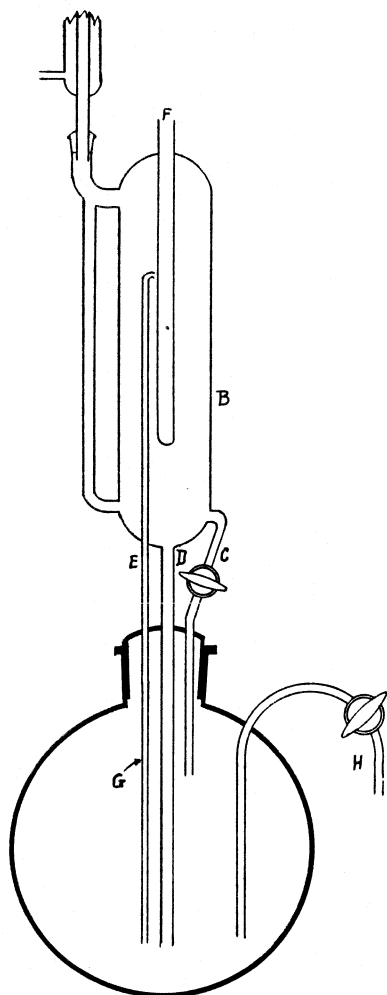

Fig. 2.

The "cold" junction of the thermocouple was in another apparatus of exactly similar design. The entire apparatus was enclosed in an insulating box. Gas flames were used as a source of heat.

A 26-junction copper-constantan thermocouple, calibrated against a standard platinum resistance thermometer with a Bureau of Standards certificate, was used with this apparatus.

Readings constant to 0.0005° could be obtained over time periods of about an hour; however, due to some error which we were not able to eliminate, readings over longer periods of time may vary as much as 0.0015° .

Theory.—The theory of the calculation of the activity coefficient of a non-volatile strong electrolyte from the boiling point of the solution is identical with that developed by Lewis and Randall⁹

for the case of freezing point lowering, the proper changes having been made. Taking the pure liquid solvent as the standard state and expressing T as $T_0 + \theta$, where T_0 is the boiling point of the pure solvent and θ is the elevation of the boiling point; and expressing ΔH as $\Delta H_{(T_0)} + \Delta C_p \theta$, where

⁹ Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., Inc., New York, 1923, pp. 282 ff.

$\Delta H_{(T_0)}$ is the molal heat of vaporization of the pure solvent at its boiling point and ΔC_p is the molal increase in heat capacity of the pure solvent on vaporization, we obtain

$$d \ln a_1' = - \frac{d\theta}{RT_0^2} \left[\Delta H_{(T_0)} - \left(\frac{2\Delta H_{(T_0)}}{T_0} - \Delta C_p \right) \theta + \left(\frac{3\Delta H_{(T_0)}}{T_0^2} - \frac{2\Delta C_p}{T_0} \right) \theta^2 + \dots \right] \quad (1)$$

Using the values given in Volume 5 of the "International Critical Tables," we obtain

$$\begin{aligned} \Delta H_{(T_0)} &= 40.679 \text{ j. mole}^{-1} \text{ }^{10a} \\ C_{p(l)} &= 75.72 \text{ j. mole}^{-1} \text{ }^{10b} \\ C_{p(v)} &= 36.34 \text{ j. mole}^{-1} \text{ }^{10c} \\ \Delta C_p &= -39.38 \text{ j. mole}^{-1} \end{aligned}$$

Hence, taking T_0 as 373.1° and R as $8.315 \text{ j. mole}^{-1} \text{ degree}^{-1}$

$$d \ln a_1' = (-0.03514 + 0.0002224 \theta + \dots) d\theta \quad (2)$$

where a_1' is the activity of the solvent at the boiling point of the solution. The geometrical mean activity of a solute completely dissociated into ν ions is then given by

$$d \ln a_{\pm}' = \frac{d\theta}{\nu \lambda m} - 0.01235 \frac{\theta d\theta}{\nu m} \quad (3)$$

where m is the molality of the solute and $\lambda = d\theta/dm$ at infinite dilution. Hence, $\lambda = 1/55.508 \times 0.03514 = 0.5126$.¹¹ The mean activity coefficient of the solute at the boiling point of the solution is given by

$$d \ln \gamma' = -dj - \frac{j}{m} dm - \frac{0.01235}{\nu} \frac{\theta}{m} d\theta \quad (4)$$

where j , which is equal to one minus Φ , the osmotic coefficient of Bjerrum,¹² is defined as in Lewis and Randall¹³ by the equation

$$j = 1 - \frac{\theta/m}{\nu \lambda}$$

Integration of equation (4) gives the equation

$$\log \gamma' = -0.4343 j - 0.4343 \int_0^m \frac{j}{m} dm - \frac{0.00536}{\nu} \int_0^m \frac{\theta}{m} d\theta \quad (5)$$

These equations differ from that used by Cann and Gilmore¹⁴ in that our value of λ is slightly lower and in accord with that given by Randall¹⁵ (0.5125), but particularly in the numerical coefficient of the last term of the equation. We differ in sign and magnitude. Apparently they have used a value identical with that given by Lewis and Randall for freezing point

¹⁰ "International Critical Tables," Vol. V, p. (a) 138, (b) 113, (c) 82.

¹¹ This value varies slightly with the barometric pressure. See Washburn and Read, *THIS JOURNAL*, **41**, 729 (1919).

¹² Bjerrum, *Z. Elektrochem.*, **24**, 321 (1918).

¹³ Lewis and Randall, Ref. 9, p. 347.

¹⁴ Cann and Gilmore, *J. Phys. Chem.*, **32**, 72 (1928).

¹⁵ Randall, *Trans. Faraday Soc.*, **23**, 502 (1927).

lowering. It is quite obvious that their value is wrong in both sign and magnitude since, for the boiling point, $dT = d\theta$, and the coefficient contains both $\Delta H_{(T_b)}$ and ΔC_p .

Since the last integral in equation (5) is relatively small, it offers no difficulty and is evaluated graphically as usual. The first integral, however, requires that accurate values of j be obtained in very dilute solutions in order that it be similarly treated. This is more difficult to accomplish than it is with the freezing point method, due mainly to the facts that λ is smaller and that it is more difficult to obtain true equilibrium between solution and saturated vapor than it is between solution and ice. We have, therefore, used the Debye-Hückel theory in dealing with the dilute solutions.

In sufficiently dilute solutions the activity coefficient may be calculated by means of the equation of Debye and Hückel; hence, we may write

$$\ln \gamma = \frac{-k \sqrt{c}}{1 + A \sqrt{c}}$$

where c is the concentration in moles of solute per liter of solution and in dilute solutions may be set equal to m , the molality of the solution, times d , the density of the pure solvent. At 100° the error in \sqrt{c} at $0.1 m$ thus introduced is only 0.1%. Making this substitution, we obtain

$$\ln \gamma = \frac{-k \sqrt{d} \sqrt{m}}{1 + A \sqrt{d} \sqrt{m}}$$

At 25° this equation expresses the activity coefficient of potassium chloride up to $0.1 m$ within the accuracy of our measurements. The value of A is, however, different from the value obtained if the equation of Hückel¹⁶ be used. Taking the density of water at 100° as 0.9584,¹⁷ we may write

$$\ln \gamma = \frac{-0.9790 k \sqrt{m}}{1 + 0.9790 A \sqrt{m}} = \frac{-k' \sqrt{m}}{1 + A' \sqrt{m}} \quad (6)$$

Differentiating, and equating the differential to the first two terms in equation (4), we obtain

$$d(mj) = \frac{k' \sqrt{m} dm}{2(1 + A' \sqrt{m})^2}$$

Then

$$j = \frac{k'}{(A')^2 m} \left[1 + A' \sqrt{m} - 2 \ln(1 + A' \sqrt{m}) - \frac{1}{1 + A' \sqrt{m}} \right] \quad (7)$$

or

$$\begin{aligned} j &= k' \left[\frac{1}{3} m^{1/2} - \frac{2}{4} A' m^{3/2} + \frac{3}{5} (A')^2 m^{5/2} - \dots \right] \\ &= -k' \sum_{n=1}^{\infty} (-1)^n \frac{n}{n+2} (A')^{n-1} m^{n/2} \end{aligned} \quad (8)$$

¹⁶ Hückel, *Physik. Z.*, **26**, 93 (1925).

¹⁷ "International Critical Tables," Vol. III, p. 26.

For a uni-univalent strong electrolyte, equation (7) is practically identical with equation (53) of Debye and Hückel^{17a} which they obtained in a different manner. The limiting law of Debye and Hückel has been used in the calculation of j for dilute aqueous solutions near the freezing point by Debye and Hückel^{17a} and by Scatchard.¹⁸ Gronwall, La Mer and Sandved,^{18a} in their equation (113), give, for strong electrolytes of the symmetrical valence type, the additions to the equation for j which result from considering the higher terms of the Debye-Hückel theory, while the corresponding expression for unsymmetrical electrolytes is given by La Mer, Gronwall and Greiff^{18b} in their equation (9). The application to freezing point depression is discussed in each paper. We do not believe the accuracy of our data warrants our use of the "Extended Theory."

From equation (8) the limiting value of j/\sqrt{m} at 100° becomes $k'/3$. Randall¹⁹ has made similar calculations of this limit for lower temperatures.

From equation (7) or (8), the dielectric constant of water at 100°, and an accurate value of j in dilute solution, the value of A' can be calculated and all the values of j and of the first integral of equation (5) can be computed up to $m = 0.1$, or the values of γ for the dilute solutions can be computed, using equation (6). The integration can be performed either graphically or analytically. We have used the latter method, which gives

$$\int_0^m \frac{j}{m} dm = \frac{k'}{A'} \left[\frac{2 \ln(1 + A' \sqrt{m})}{(A')^2 m} - \frac{2}{A' \sqrt{m}} + 1 \right] \quad (9)$$

or

$$\begin{aligned} \int_0^m \frac{j}{m} dm &= k' \left[\frac{2}{3} m^{1/2} - \frac{2}{4} A' m^{3/2} + \frac{2}{5} (A')^2 m^{5/2} - \dots \right] \\ &= -k' \sum_{n=1}^{\infty} (-1)^n \frac{2}{n+2} (A')^{n-1} m^{n/2} \end{aligned} \quad (10)$$

In Table I this is referred to as Method I.

An alternate method which places less weight on a single value of j can be developed by integrating equation (4) between limits, the lower of which is an arbitrarily fixed value of the molality, m_0 . This gives

$$\log \gamma' = \log \gamma'_{m_0} + 0.4343 j_{m_0} - 0.4343 j - 0.4343 \int_{m_0}^m \frac{j}{m} dm - 0.00268 \int_{m_0}^m \frac{\theta}{m} d\theta \quad (11)$$

Since the correction of γ' to 100° is small even in fairly concentrated solutions, we may evaluate $\log \gamma'$ by means of the equation of Hückel¹⁶

$$\log \gamma = \frac{-0.4343 k \sqrt{c}}{1 + A \sqrt{c}} + Bc - \log(1 + 0.036 m)$$

^{17a} Debye and Hückel, *Physik. Z.*, **24**, 185 (1923).

¹⁸ Scatchard, *THIS JOURNAL*, **47**, 648 (1925).

^{18a} Gronwall, La Mer and Sandved, *Physik. Z.*, **29**, 358 (1928).

^{18b} La Mer, Gronwall and Greiff, *J. Phys. Chem.*, **35**, 2245 (1931).

¹⁹ Randall, *THIS JOURNAL*, **48**, 2512 (1926).

Combining the first two terms on the right side of equation (11) into a constant, C , we then have

$$-\frac{0.4343 k \sqrt{c}}{1 + A \sqrt{c}} + Bc - \log(1 + 0.036 m) = C - 0.4343 j - 0.4343 \int_{m_0}^m \frac{j}{m} dm - 0.00268 \int_{m_0}^m \frac{\theta}{m} d\theta \quad (12)$$

The integrals can be evaluated graphically, k can be calculated from the dielectric constant for water at 100° ; hence the constants A , B and C can be determined by solving three such equations simultaneously. The activity coefficients at 0.1 molal or at m_0 and the lower concentrations can then be calculated by using Hückel's equation. In Table I this is called Method II.

The dielectric constant of water has been measured near 100° by Kockel²⁰ and Wyman.²¹ The average of their results for 100° is 55.3. Using this value, $0.4343 k$ becomes 0.612, k' becomes 1.380 and the limiting value of j/\sqrt{m} becomes 0.460.

Experimental Results

The observed values of θ were first plotted against m on a large scale, giving greater weight to the results obtained with the second apparatus. The values of θ read from the plot are given in Table II. Values of j were then calculated and plotted against m on a large scale, giving the values in Table II. The original data are plotted in Fig. 3 in a manner which has been used by Randall²² for freezing point and vapor pressure data. The values of j used in Table II are identical with those read from this curve. Values of $\gamma_{0.1}$ were then calculated by the two methods described above. The results are given in Table I.

TABLE I

Method I

m	j	k'	A'	$\gamma_{0.1}$
0.1	0.082	1.380	1.44	0.741

Method II

m_0	m_1	m_2	m_3	A	B	$\gamma_{0.1}$
0.1	0.2	1.0	2.0	1.22	0.042	0.733
.2	.5	1.0	2.0	1.13	.046	.729

The average value of $\gamma_{0.1} = 0.731$ obtained by the second method agrees with that calculated from the value of $\gamma_{0.1}$ at 25° (see Table IV); hence, we have taken it as our reference value. If it be substituted in equation (6), A' becomes 1.24 and this equation was then used to compute the

activity coefficients of the more dilute solutions. The values so found are identical with those obtained by using the equation of Hückel with $A = 1.18$ and $B = 0.044$, the averages of the values given in Table I. The activity coefficients of these dilute solutions are included in Table II. The value of the integral from $m = 0$ to $m = 0.1$ was then calculated from $\gamma_{0.1}$ and $j_{0.1}$, while the integrals from 0.1 to higher concentrations were determined graphically. The results are given in Table II.

Up to 4 molal solution, there are available sufficient data to correct the values of γ' to 100°. Rossini²³ gives values of \bar{L}_1 at 18° up to $m = 2.0$. Using the heat capacity data of Randall and Rossini²⁴ we have calculated these values to 25°. The values of \bar{L}_1 given by Wüst and Lange²⁵ have been used from two to four molal. Randall and Rossini^{24,26} give values of \bar{C}_{p1} up to $m = 2.5$. Up to this molality, they have shown that \bar{C}_{p1} and Φ , the apparent molal heat capacity of the solute, are both substantially

²⁴ Randall and Rossini, *THIS JOURNAL*, **51**, 323 (1929).

²⁵ Wüst and Lange, *Z. physik. Chem.*, **116**, 161 (1925).

²⁶ Up to $m = 2.0$ the heat capacity data for aqueous solutions of potassium chloride have been summarized by Rossini [*Bur. Standards J. Research*, **7**, 47 (1931)]. He gives an equation for $(\bar{C}_{p1} - \bar{C}_{p1}^0)$ which results in slightly different values for this difference than those we have used. No change in γ would result from their use.

linear functions of \sqrt{m} . We have therefore extrapolated their results to 4 molal. Since the resultant values of \bar{C}_{p2} so obtained are in fairly good agreement with those calculated from the specific heat data in the "International Critical Tables,"²⁷ they are sufficiently accurate for our present

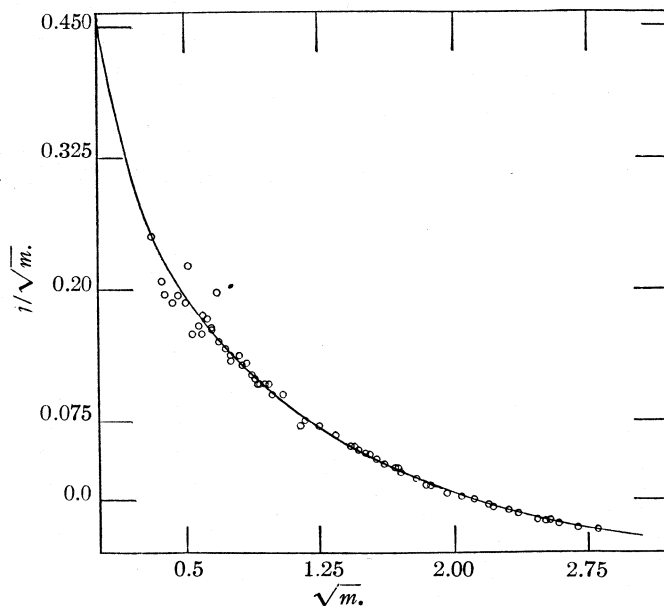

Fig. 3.

purpose. \bar{C}_{p1} was then calculated from \bar{C}_{p2} , Φ , and \bar{C}_{p1}° . The data used and the results obtained are given in Table III.

TABLE III

m	$\bar{L}_1(298.1)$	$(\bar{C}_{p1} - \bar{C}_{p1}^{\circ})(298.1)$	$\gamma_{\pm,1}$

2	—448	23.15	.569	.536	.544

Finally, we have evaluated the constants A and B in the equation of Hückel, using 55.3 as the dielectric constant. The densities used are those given in the "International Critical Tables."²⁹ Up to 4 molal the activity coefficients at 100° can be represented satisfactorily by the equation

$$\log \gamma = \frac{-0.612 \sqrt{c}}{1 + 1.19 \sqrt{c}} + 0.046 c - \log (1 + 0.036 m)$$

The comparison of the observed results with those calculated from the equation are given in Table V.

Although density data are given only up to about 5 molal, we have extrapolated up to our highest concentration and give the calculated values of γ in comparison with the measured values of γ' which will not differ greatly from γ , even at these high concentrations. It is apparent that the equation is satisfactory through the entire concentration range. Since correction to 100° raises the values of γ' , it is probable that the agreement in the concentrated solutions would be improved if such a correction could be made.

From the value of A and the dielectric constant, the parameter, a , representing the distance of closest approach of the ions, becomes 3.40 Å., as

²⁹ "International Critical Tables," Vol. III, p. 87.

compared with 3.28 Å. calculated from Harned's constant at 25°. This increase would seem to confirm the results of Harned and Nims,³⁰ whose data on sodium chloride show that a increases from 3.60 Å. at 25° to 3.78 Å. at 40°. On the other hand, if our value of A is lowered to 1.15, the values of a would be the same at the two temperatures. Such a value of A with an increase in B to 0.049 gives an equation which reproduces our measured values up to 4 molal nearly as well as the one used, but gives larger deviations at the higher concentrations, unless the correction of the activity coefficient to 100° is larger than we think it to be. Thus, our results up to 4 molal may also be said to agree with the findings of Cowperthwaite and La Mer,³¹ who found a to remain constant from 0 to 37.5° for dilute solutions of zinc sulfate. Our results, therefore, offer no conclusive evidence on the effect of temperature on a . The constant B has increased with temperature. From the work of Butler³² it follows that if we assume the lowering of the dielectric constant of the solvent and the ionic radii of the solute to be independent of temperature, the constant B should be inversely proportional to the temperature and the square of the dielectric constant. Using Harned's value of $B = 0.034$ and our own result, the ratio $B_{100^\circ}/B_{25^\circ}$ is 1.35, while the ratio calculated from Butler's relation and Wyman's values of the dielectric constants is 1.61.

Summary

Two new apparatus for measuring the elevation of the boiling point at constant pressure have been described.

The elevations for potassium chloride in water have been measured up to 7.8 molal solution. From the results, the activity coefficients of the solute have been calculated. Up to 4 molal, these coefficients have been corrected to 100°, and up to 2 molal they have been compared with those calculated from 25°. The constants of the equation of Hückel have been evaluated. The equation is satisfactory through the entire concentration range.

THE STRUCTURE OF CELLULOSE ACETATE GELS FROM STUDIES OF DIFFUSION

BY KARL KLEMM AND LEO FRIEDMAN

RECEIVED FEBRUARY 26, 1932

PUBLISHED JULY 6, 1932

The structure of gels of gelatin and agar-agar has been the subject of earlier investigation by one of the authors.¹ This paper is a report of studies made on the gel system cellulose acetate in benzyl alcohol, which was chosen for study in order that the structural investigations might be carried out in the absence of water. By this means the possibility of structural modification resulting from the presence of ions and from contamination of the gels by molds was avoided. As a further precaution against changes of the original structure during the investigations, methyl and ethyl alcohol were selected as diffusates because of their negligible degrees of ionization in benzyl alcohol and the fact that cellulose acetate is insoluble in either.

Method and Materials.—The method of studying diffusion employed in this work was that developed by Friedman and Kraemer,¹ for their study of gelatin and agar-agar systems. In this method, a mass of material, the diffusate, is dissolved in a given mass of the dispersing medium of the gel. A volume of this solution just equal to the volume of the gel to be studied is placed upon the gel and kept stirred. The diffusate penetrates into the gel, the extent of diffusion as a function of time being determined at appropriate intervals.

The equation connecting the diffusion coefficient with the time-concentration data in the liquid layer was developed for this particular method by March and Weaver.² In its expanded form, it becomes

$$V = \frac{1}{2} - [0.327e^{-4.117T} + 0.0766e^{-24.14T} + 0.0306e^{-63.68T} + 0.0160e^{-123T} + \dots] \quad (1)$$

V is the fraction of the material that has diffused into the gel at a given time. $T = Dt/a^2$, where D is the coefficient of diffusion, t is the time in seconds, and a is the height of the gel layer and also that of the liquid layer.

By substituting values for T , it was possible to plot a theoretical curve. To determine the value of the diffusion coefficient, D , for a given system, the value of T corresponding to the experimentally determined value of V is read from the theoretical curve. Then the value of D is calculated from the equation $D = a^2T/t$.

The cellulose acetate used was a chemically pure product obtained from the Eastman Kodak Company and received no treatment beyond

¹ Friedman and Kraemer, *THIS JOURNAL*, **52**, 1295 (1930).

² March and Weaver, *Phys. Rev.*, **31**, 1072 (1928).

sufficient mixing to ensure its homogeneity. Cellulose acetate, although insoluble in water, is of a porous nature, and it was found necessary to remove the adsorbed moisture in an electric oven at 92°. The loss amounted to from 2 to 2.5% by weight. Since water is only very slightly soluble in benzyl alcohol, no drying of the chemically pure solvent, benzyl alcohol, also obtained from the Eastman Kodak Company, was attempted.

Experimental Procedure

Sols of various concentrations were prepared by heating the proper mixtures of cellulose acetate and benzyl alcohol for one hundred fourteen minutes at 100°. The sols were permitted to gel in a thermostat at 25° and after thirty-six hours, a time interval sufficient to ensure complete gelation, a diffusate solution was placed upon the respective gels and the diffusion studies were started. The changes in concentration of the diffusate were measured by tracing the refractive index changes of the solution and the calculation of the diffusion coefficients made as described above. An example of the results obtained is shown in Table I.

Effect of Concentration of Gel on Rate of Diffusion.—To show the effect of concentration of cellulose acetate upon the gel systems studied, determinations of the rates of diffusion were made upon gels of concentrations ranging from 2 to 20% cellulose acetate by weight. The numerical results obtained are shown in Table II and are plotted in Fig. 1.

The diffusate in Runs I, II, and III was C₂H₅OH from a 10% solution; in Run IV from a 3% solution; in Run V, CH₃OH from a 3% solution.

A study of the curves (Fig. 1) reveals that the diffusion coefficient is a linear function of the cellulose acetate concentration. The values of the coefficients for the various runs indicate the impossibility of reproducing a

given system with exactitude. This may be attributed either to the inevitable slight differences in the thermal treatment of the gels of one run from that of another or to the impossibility of even a statistical control of the incomplete or imperfect crystallization that results in gel formation.

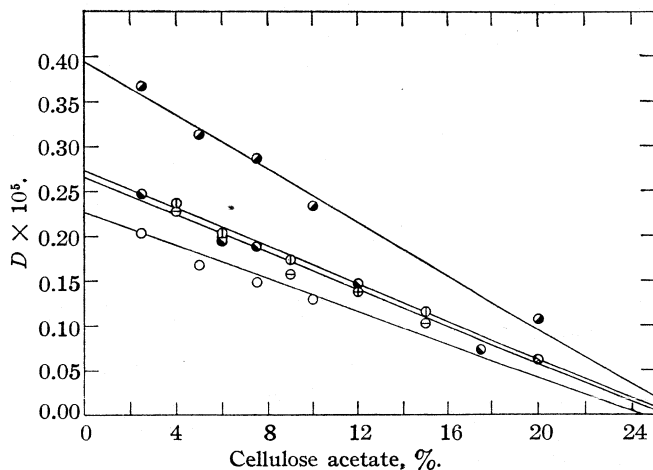

Fig. 1.—Diffusion in cellulose acetate gels: ○, Run no. I; ⊖, Run no. II; ●, Run no. III; ⊕, Run no. IV; ◐, Run no. V.

Determination of the Effective Pore Radii.—In the determination of the effective average pore radius of a given gel the formula derived by Friedman and Kraemer was used,¹ which for these determinations takes the form

$$D_{alc.} = D_{gel} \cdot (1 + \alpha) \cdot (1 + \pi) \cdot (1 + 2.4r/R) \quad (2)$$

$D_{alc.}$ is the diffusion coefficient of the diffusate in benzyl alcohol. D_{gel} is the diffusion coefficient of the diffusate in a given gel system at the same concentration of diffusate employed in determining $D_{alc.}$. α is the correc-

tion factor for the viscosity and is equal to the quotient of $D_{\text{alc.}}$ divided by D_{gel} extrapolated to zero concentration of cellulose acetate. π is the correction for mechanical blocking and is calculated from Dumanski's formula:³ $\pi = \sqrt[3]{(g/d)^2}$ where g is the number of grams of cellulose acetate in 1 cc. of gel, and d is the density of the cellulose acetate. $(1 + 2.4r/R)$ is an approximation for the determination of the average pore size. It was taken from Ladenburg's correction for the fall of bodies in capillary tubes and was originally intended to be applied to Stoke's Law. r is the radius of the diffusate molecule and R is the effective average radius of the pores in the gel.

The values of the diffusion coefficients for methyl and ethyl alcohol in benzyl alcohol at 25° and in the concentrations used in the experiments were not extant and were determined by the method devised by Northrop,⁴ and perfected and standardized by McBain and Liu.⁵

This method depends upon the separation, by means of an indifferent membrane with pores of microscopic size, of two homogeneous bodies of solution. In this way the diffusion gradient is confined within this membrane. The results obtained are relative but are standardized by the measurement of a single standard solution the absolute value of whose diffusion coefficient is known at some definite concentration and temperature.

The equation relating the diffusion coefficient of a given system to the time during which diffusion occurs was derived from Fick's equation, $ds = DA (dc/dx)dt$, and takes the form

$$KD = \frac{\log C_0 - \log (C_0 - 2C)}{t} \quad (3)$$

K is the cell constant. C_0 is the original concentration of the diffusate within the cell used. C is the concentration of diffusate outside the cell at a given time. D is the diffusion coefficient of the diffusate at the concentration and temperature of the experiment. t is the time elapsed between the beginning and end of the diffusion. The values so obtained are shown in Table III.

TABLE III
DIFFUSION COEFFICIENTS OF CH₃OH AND C₂H₅OH IN BENZYL ALCOHOL AT 25°

Diffusate	CH ₃ OH	C ₂ H ₅ OH	C ₂ H ₅ OH
Concn. (% by weight)	3	3	10
$D \times 10^5$	0.8144	0.8080	0.5463

By substitution of the values in Table III into equation (2) the values given in Table IV were obtained.

Discussion of Results

By plotting the pore radii as ordinates against the concentrations as abscissas (Fig. 2), the pore radii are seen to approach $18 m\mu$ at 2% concentration of cellulose acetate and $0 m\mu$ at 23% gel. However, the pore openings would be expected to become discontinuous at a concentration below 23%, providing the preparation of a homogeneous gel of such concentration were not beyond experimental realization.

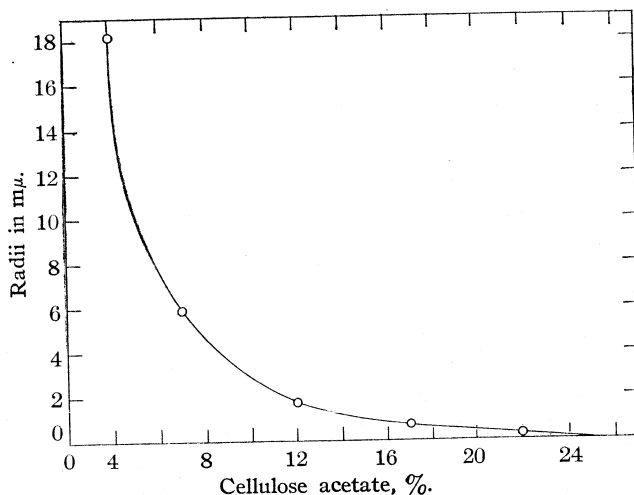

Fig. 2.—Change of pore radii with concentration.

The employment of the theoretical diffusion curve developed by March and Weaver² for the work of Friedman and Kraemer¹ gives a constant diffusion coefficient at any time interval for a given gel, even in such diverse systems as gelatin in water, agar-agar in water, and cellulose acetate in benzyl alcohol. This strongly supports the validity of the diffusion equation employed in the investigation and the values of the coefficients obtained.

It is considered that the above results, if not conclusive proof of the liquid-solid theory of gel structure, are at least very strong evidence in favor of the theory.

That the rate of diffusion decreases with increased gel concentration is in support of the pore theory, since the effective pore radii would be expected to decrease with increased concentration of the dispersed medium until the pores should become discontinuous.

The high values of the determined diffusion coefficients are inconsistent with those to be expected in a solid solution where, as a result of the enormous increase of the viscosity of the system upon gelation, diffusion should practically cease.

The change in magnitude of the pore radii with change in the concentration of cellulose acetate is seen from Fig. 2 to be an exponential function. This is in accord with the liquid-solid theory, which infers a change of effective pore radius with change in concentration. Any change in effective pore radius must be followed by a change in the number of pores within a given volume of gel. Since gel formation is conceded to be an incomplete precipitation of the dispersed medium, the resulting pore openings might be considered as consisting of minute tubes of varying lengths, chaotically arranged, but each intersecting others to form continuous open passages completely through a gel. The thickness of the pore walls is also undoubtedly a function of the concentration. That the radii and the number of the pore openings change with concentration has been demonstrated by this investigation. The fact that approximate equations for the experimentally determined curve, Fig. 2, obtained by the method of least squares lead to curves more nearly symmetrical with the experimental curve as the number of terms (and consequently the degree of the function) increases, supports the postulates mentioned above.

Summary

1. A study of the structure of gels of cellulose acetate in benzyl alcohol has been made by measuring diffusion into the gels with time.
2. It has been shown that the diffusion law holds for the penetration of the employed diffusates into cellulose acetate gels.
3. The validity of the diffusion equation employed in the investigation has been supported by the diffusion coefficients obtained.
4. The values of the effective pore radii of gels of various concentrations have been determined and found to be of the same order of magnitude as those obtained by Friedman and Kraemer for gelatin and agar-agar systems.
5. The high values of the experimentally determined diffusion coefficients render untenable the solid solution theory of gels.
6. The change in pore radii with change in concentration has been shown to be an exponential function, a rate of change to be expected in the liquid-solid theory.

THE CONSTITUTION OF CERTAIN COBALTAMMINE BASES

BY ARTHUR B. LAMB AND ROGER G. STEVENS

RECEIVED FEBRUARY 27, 1932

PUBLISHED JULY 6, 1932

In contrast with the simple hydroxides of cobalt many of the complex bases of cobalt are easily soluble and relatively strong. Triethylenediamine cobaltic hydroxide $[\text{Co}(\text{C}_2\text{H}_4(\text{NH}_2)_2)_3](\text{OH})_3$, for instance, is a very soluble, deliquescent substance which displaces both silver oxide and ammonia from their respective salts and whose solution is caustic, absorbing carbon dioxide from the air.

The conductivities of some nine of these cobaltamine bases were measured some time ago,¹ and it was found, in agreement with the above behavior, that these bases are highly ionized. Thus in 0.00133 molar solution at 0° triethylenediamine cobaltic hydroxide appeared to be 88.6%, while the univalent base, 1,6-dinitro-tetrammine hydroxide, $1,6\text{-}[\text{Co}(\text{NH}_3)_4(\text{NO}_2)_2]\text{OH}$, appeared to be 95% ionized.

These measurements disclosed a further important regularity. When water molecules were present within the complex of the bromide from which the bases were prepared, the ionization of the bases was decidedly less than when they were absent. Thus in solutions of the above concentration, one such molecule of water in the complex lowered the percentage ionization of the base by about 30%, two molecules by about 60%. The assumption was then made that every molecule of water in the complex was replaced by an hydroxyl group as soon as the free base was formed. In other words, for every molecule of water in the complex, one hydroxyl ion was eliminated from the outer sphere. Percentage ionizations were calculated on this basis and were very large, but in no case did they exceed 100%.

Werner² long before had assumed the existence of such hydroxo or "anhydro" bases as he called them. Job³ from observations of the change in conductivity of solutions of aquo-pentammine cobaltic sulfate upon the addition to it of solutions of baryta showed that in this case the first hydroxyl group liberated by the precipitation of barium sulfate became complexly bound, apparently replacing the single water molecule in the complex. The two additional hydroxyl groups liberated remained in an ionized condition. Job made similar observations with diaquo-tetrammine cobaltic sulfate, but in this case, while evidently considering that the two water molecules in the complex were also replaced by the first two hydroxyl

¹ Lamb and Yngve, *THIS JOURNAL*, **43**, 2352 (1921).

² Werner, "Neuere Anschauungen," Braunschweig, 1913, pp. 264-268.

³ Job, "Recherches sur Quelques Cobaltamines," Paris and Lyon (1921); *Compt. rend.*, **174**, 615 (1922).

ions liberated, Job concluded that the resultant ion $[\text{Co}(\text{NH}_3)_4(\text{OH})_2]^+$ was unstable and underwent polymerization of some kind.⁴

In this situation it appeared to us desirable to ascertain more definitely whether such a replacement of complexly bound water molecules by hydroxyl ions does in general take place and, if so, to what extent. To this end we have prepared solutions of some five cobaltammine bases by the action of silver oxide on cobaltammine bromides, containing either 0, 1 or 2 molecules of water in the complex cation, and have titrated them with a relatively concentrated solution of hydrochloric acid by means of conductivity measurements. From the changes in conductivity thus observed it has been possible to infer, as did Job in an analogous case, whether the hydroxyl groups originally present are ionized or un-ionized. Moreover, it has also been possible, from the numerical values of the conductivity at the breaks in the titration curves corresponding to the exact neutralization of one or more hydroxyl groups, to check the correctness of the above inferences, since the conductivities of the corresponding substances are either known or can be computed with reasonable accuracy.

Experimental

Preparation of Materials.—The hexammine and the carbonato tetrammine cobaltic bromides were the same materials as had previously been used by Lamb and Yngve.¹ The aquo-pentammine and diaquo-tetrammine cobaltic bromides were prepared by the methods of Jörgensen;⁵ the aquo-pentammine chromic bromide by the method of Christensen.⁶ The specific conductivity of the water used varied between 0.8 and 1.5×10^{-6} mhos. The solutions prepared from these were all 0.004 molar.

Apparatus.—The conductivity cell consisted of dip-electrodes of platinized platinum held at a fixed position in a closed 200-cc. Pyrex glass test-tube which was almost wholly submerged in an ice-bath (or in a water thermostat maintained at $25.00 \pm 0.02^\circ$). A thermometer legible to 0.01° was placed in the solution itself. The Wheatstone bridge was of the usual spirally-wound type. The uncertainty of the minimum was always less than would correspond to an error of $\pm 0.1\%$ in the conductivity. The cell was standardized against a 0.02 *M* solution of potassium chloride, the specific conductivity of this solution being taken as 0.002768 mhos at 25.00° . The standardization was repeated frequently in the course of the measurements and no variations greater than $\pm 0.1\%$ were observed.

Procedure.—It was necessary not only to guard the solutions of the free bases from contact with the air but also both to prepare and to measure them expeditiously since they undergo a slow decomposition even at 0° , particularly in contact with platinum electrodes. A procedure was therefore adopted to meet these requirements as follows.

A pestle and a small mortar containing a slight excess of moist silver oxide were cooled to 0° . A weighed quantity of ammine bromide sufficient to give a 0.004 *M* solution was then added to the silver oxide and triturated for one minute, and the solution rapidly filtered by suction into a 100-cc. delivery volumetric flask packed in ice. The

⁶ Christensen, *ibid.*, [2] **23**, 27 (1881).

mortar was then washed out several times, and the residue on the filter ten times, with ice-cold conductivity water. The solution was brought up to the mark with more of this water, thoroughly mixed, and poured into the dry cell immersed in an ice-bath. The solution was then rapidly stirred by a guarded movement of the dip-electrodes, since a too violent up and down movement was found to introduce a noticeable amount of carbon dioxide. All of these operations were conducted with the greatest possible dispatch. They usually required between six and ten minutes, counting as zero time the moment when the ammine bromide was added to the silver oxide. The temperature of the solution at this point was usually about $+1^{\circ}$ and several minutes longer was usually required for the temperature to reach substantially 0° when conductivity measurements were begun and continued at frequent intervals. Ice-cold 0.02 *M* hydrochloric acid was then added in 5-cc. portions (corresponding to one quarter of a molecule of acid per molecule of ammine); a minute was allowed for readjustment of the temperature, when stirring was resumed and conductivity measurements were again made.

The Water Correction.—Since the conductivity of ordinary carefully distilled water is chiefly due to the carbon dioxide present, and since this will neutralize two equivalents of hydroxyl ion in alkaline solution, thus replacing a rapid ion by a slow one ($\text{CO}_3^{=}$), the conductivity of a dilute solution of a base in such water will appear slightly too low. The correction for an isolated solution at 0° is equal to $8.3 \times 10^6 \times L_{\text{H}_2\text{O}}^2$, where $L_{\text{H}_2\text{O}}$ is the conductivity of the water; or taking⁷ $L_{\text{H}_2\text{O}} = 1 \times 10^{-6}$ mhos, the correction is -8.3×10^{-6} mhos. This has been applied to the specific conductivities up to but not beyond the point of neutralization (minimum conductivity).

Results.—The results of a single representative experiment, namely, that with aquo-pentammine cobaltic hydroxide, are given in full in tabular form (Table I) to illustrate the procedure. The experimental results as a whole are shown in graphical form in Fig. 1.

As can be seen from the table, the initial conductivities show a slow progressive decrease even after the temperature has become constant. The decrease was more rapid when the solution was not stirred. This indicates a slow decomposition accelerated in the presence of the platinized electrodes. This is in agreement with earlier observations.⁸

The adjustment of the neutralization equilibrium was instantaneous so far as our measurements could disclose, although after the addition of the first portions of acid there was a slight progressive decrease which was evidently caused by the incomplete removal of the heat of neutralization. This instantaneous adjustment of the neutralization equilibrium is what

⁸ Ref. 1, p. 2354. Also Lamb and Larson, *THIS JOURNAL*, **42**, 2025 (1920); and others.

would be expected when free hydroxyl and hydrogen ions interact. It is of great interest that the adjustment should also be instantaneous when all the free hydroxyl ions have been removed and only the complexly bound hydroxyl groups are involved. This indicates either that the equilibrium between hydroxo ion and water on the one hand and aquo ion and hydroxyl

ion on the other is instantaneously adjusted, or that the equilibrium involving the direct combination of hydroxo ion with hydrogen ion, as postulated by Werner,² is instantaneously adjusted.

An examination of Fig. 1 leads to the following deductions relative to the constitution of the several hydroxides.

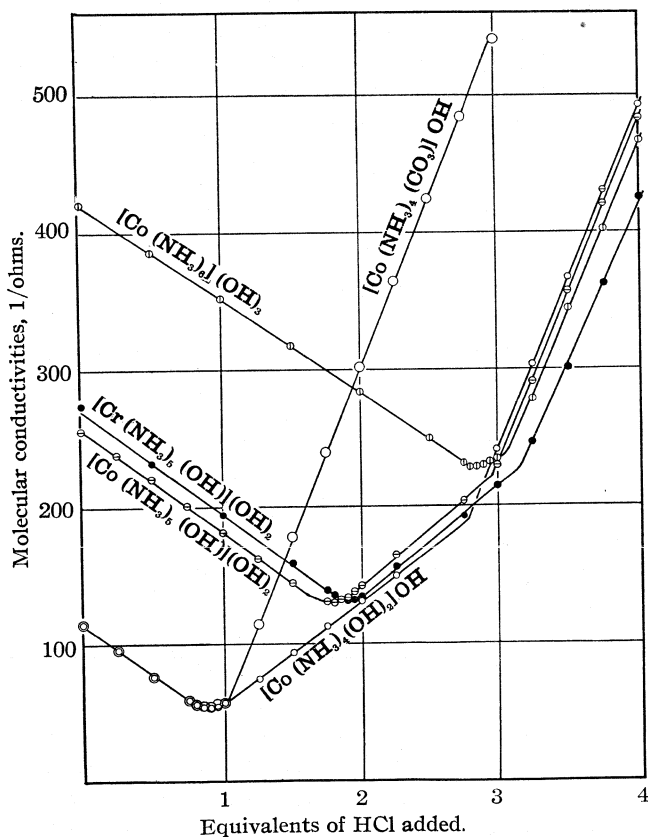

Fig. 1.—Titration of ammine bases by measurements of conductivity.

(a) Hexammine hydroxide, containing no complexly bound water, gives a curve with a uniform downward slope which reaches a minimum

at the point corresponding to an addition of three molecules of hydrochloric acid, and rises sharply thereafter. This is a normal curve such as would be expected for a highly ionized trivalent base.

(b) Pentammine hydroxide gives a curve which starts at a much lower point, indicating a much smaller concentration of hydroxyl ions. It slopes downward nearly parallel to the hexammine curve, but reaches a minimum after the addition of two molecules of acid.

Thereafter the curve rises moderately until another molecule of acid has been added, when it rises more steeply almost in superposition with the hexammine curve.

The part of the curve sloping downward evidently corresponds to the normal behavior shown by the hexammine curve; it records the replacement of fast hydroxyl ions by relatively slow chloride ions with a consequent decrease in conductivity. The next part of the curve, sloping moderately upward, is what would be expected if one un-ionized hydroxyl and one equivalent of added hydrogen ion were eliminated as water with the consequent introduction of a chloride ion into the solution and the conversion of the divalent into the trivalent ammine cation. The remainder of the curve, after the addition of the three molecules of acid, merely records the effect of adding relatively concentrated acid.

This curve, therefore, indicates that in pentammine cobaltic hydroxide one of the hydroxyl groups is complexly held, or but slightly ionized, while the other two are highly ionized at these concentrations.

(c) Tetrammine hydroxide gives a curve which shows the same phenomena as did the pentammine, but to a more pronounced degree. Here there is evidently a single, highly ionized hydroxyl group and two hydroxyl groups that are at most slightly ionized.

(d) Pentammine chromic hydroxide gives a curve corresponding very closely with that of the analogous pentammine cobaltic hydroxide.

(e) Carbonato-tetrammine hydroxide gives a curve that coincides almost exactly with the curve of the dihydroxo-tetrammine hydroxide down to the minimum of conductivity. This shows that it, too, has a single, highly ionized hydroxyl group, and that the two univalent cations have almost exactly the same mobilities. After the minimum, the carbonato curve diverges rapidly upward from the tetrammine curve, running nearly parallel to the curve for the addition of excess acid. It is evident that after the neutralization of the hydroxyl ion only a small fraction of the hydrogen ions combines with the carbonato radical during the time occupied by this measurement; otherwise, the rise in the conductivity would be much less rapid.

It is clear from these curves that in every instance where the base has been derived from an ammine having one or two water molecules in the complex, a corresponding number of hydroxyl groups are complexly

held⁹ or, in other words, the water molecules have been fully displaced by hydroxyl groups which are held firmly in the complex.

The correctness of this conclusion can be checked by a comparison of the conductivities indicated by the titration curves at the various minima and points of inflection with the directly measured conductivities of the substances there present. The data for such a comparison have been collected in Table II.

TABLE II
MOLAR CONDUCTIVITIES AT POINTS OF INFLECTION

Ammine hydroxide	Acid, moles added per mole	Chloride present	Concn. $\times 10^3$ molar	Directly measured	Conductivity molar l/ohms		Ref.
					Directly measured	From curves	
Hexa	3	Hexammine	2.5	Chloride	231	229	10
Penta	3	Pentammine	2.5	Nitrate	224	227	11
Tetra	3	Tetrammine	2.5	Bromide	221	220	12
Penta	2	Hydroxo-pentammine	2.857	Nitrate	135	132	11
Tetra	1	Dihydroxo-tetrammine	3.39	Dinitro chloride	56	54	10
Tetracar-bonato	1	Carbonato-tetrammine	3.39	Chloride	57	55	13

The agreement between the conductivities as read from the curves and those computed from independent measurements is good and confirms the conclusion that the water molecules in the complex have been completely replaced by firmly held hydroxo groups.¹⁴

Apparent Percentage Ionization.—With the hydroxo structure of these hydroxides thus clearly established, it is of interest to consider more fully the significance of the values of the apparent ionizations as calculated

⁹ It can be seen from the curves that the various minima are invariably displaced slightly to the left of the exact integral numbers of added molecules of acid. This is probably due to the above-mentioned slight decomposition of the free base into lower cobaltic or cobaltous ammines and free ammonia. The neutralization of the ammonia in the presence of the residual stronger bases would cause an increase rather than a decrease in conductivity and a consequent premature rise in the curve.

¹¹ King, *J. Chem. Soc.*, **127**, 2107 (1928).

¹² Werner and Miolati, *Z. physik. Chem.*, **12**, 42 (1893).

¹³ From measurements to be published later in another connection.

¹⁴ The firmness with which these hydroxyl groups are held can indeed be calculated in the case of the pentammine and the tetrammine bases from the very skilful and ingenious measurements of Brönsted and Volqvartz [*Z. physik. Chem.*, **134**, 133 (1928)] of the "acid dissociation" of aquo ions. Their constants for this dissociation divided into the dissociation constant of water should give the dissociation constants of the hydroxo bases:

$$K_{B_1} = \frac{C_{OH^-} \times C_{[Co(NH_3)_5(H_2O)]^{+++}}}{C_{[Co(NH_3)_5OH]^{++}} \times C_{H_2O}} \text{ and } K_{B_2} = \frac{C_{OH^-} \times C_{[Co(NH_3)_4(H_2O)_2]^{+++}}}{C_{[Co(NH_3)_4(H_2O)OH]^{++}} \times C_{H_2O}}$$

These are respectively 1×10^{-10} and 3×10^{-11} for the pentammine and tetrammine ions.

on the basis of this structure by Lamb and Yngve from their measurements. For this purpose we have recomputed the values of Lamb and Yngve, using more recent data for the mobilities of certain of the ions than were available at that time. The results are collected in Table III.

\rightleftharpoons [Co(NH ₃) ₃ (NO ₂) ₂ (OH)]	18	136	50	37

The mobilities of the various ammine ions have been computed as follows: that of the hexammine from its chloride and nitrate;¹⁵ that of the triethylenediamine from the data of Werner and Herty¹⁸ on the chloride at 25°, converting to international ohms and using the factor 1.8 derived from their other measurements to convert to 0°; that of the hydroxo-pentammine from the data of King¹¹ on the hydroxo nitrate by first computing n ($= 1.5$) in the Storch-Bancroft equation and then plotting $(C\mu)^{n-1}$ against $1/\mu$; the carbonato-tetrammine from the data of Werner and Miolati¹⁷ on the nitrate at 25° by extrapolation, taking $n = 1.33$ and then converting to ohms and to 0° by the above-mentioned factor; that of the dinitro-tetrammines from the chlorides and nitrates;¹⁸ that of the chromic hydroxo-pentammine on the well-supported assumption that it would be the same as that of the corresponding cobalt ammine; that of the dihydroxo-tetrammine and the dinitro-aquo-tetrammine on the assumption that they would be the same as that of the dinitro-tetrammines.

The apparent percentage ionization of all of these bases, except the last one shown in this table, is strikingly high. Thus the ionization of the univalent bases is only a little less than that of the alkali bases, while that of the trivalent bases is about the same as that of a *salt* of the same type, lanthanum chloride, at the same concentration. This high apparent

¹⁵ Ref. 1, p. 2360.

¹⁶ Werner and Herty, *Z. physik. Chem.*, **38**, 337 (1901).

¹⁷ Werner and Miolati, *ibid.*, **21**, 234 (1896).

¹⁸ Ref. 1, p. 2362.

ionization doubtless indicates, on the basis of present views as to electrolytic solutions, a substantially complete true ionization.

A still more striking feature of these values is their marked similarity irrespective of the nature of the central atom, or of the number or nature of the groups surrounding this atom; and perhaps most surprising of all, irrespective of the number of electric charges on the cation.

Plausible explanations can be advanced for most of the above observations.

(1) The slight ionization of the hydroxyl groups inside the complex and the high apparent and the presumably complete actual ionization of the hydroxyl groups outside the complex may be explained as follows. Water molecules in these quite stable complex substances, though held with considerable firmness to the central atom by coördinate links, are much more readily displaced from the complex by various acido groups than are ammonia, diethylenamine and various other molecules. It is not surprising, therefore, that they can be quite completely displaced by hydroxyl ions. These become attached by strong non-polar links and are but slightly ionized. When, however, all six coördinate positions are occupied by firmly held ammonia molecules or the like, or by firmly held acido groups, the hydroxyl ion cannot penetrate this protective shell, cannot form a non-polar link and, being held at some distance from the central atom, is almost completely ionized.

(2) The similarity in the ionization of the bases may be due to the similarity of the general exterior architecture of the cations of these bases, since they all have six exterior groups held by non-polar valences (six electron pairs) around small central atoms whose outer electron shells are presumably also quite similar.¹⁹

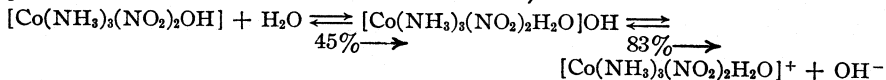

(3) The absence of any marked effect on the ionization of the differences in the number of electric charges on the cation might be due to the "chemical effect" of the acido groups as compared with that of the ammonia molecule. This effect, on the basis of ordinary experience in organic chemistry, would tend to decrease the ionization of the base when the accompanying valence change tended to increase it. However, the lack, as above mentioned, of any apparent difference between the effect of dinitro, dihydroxo and carbonato groups on the ionization when there are no changes in valence argues against this explanation. Another possibility is that the shell of coördinated groups so alters the electrostatic field about the central atom that the simple valence-squared function of the Debye-Hückel equation no longer obtains.

¹⁹ P. Ray, Nineteenth Indian Science Congress, Bangalore, 1932, Section of Chemistry, President's Address, p. 33. It should also be noticed that the most marked contrast among the percentage ionizations shown in our Table III is between the two stereoisomeric dinitro-tetrammines.

One further and significant conclusion may be drawn from Table III. The last hydroxide there listed exhibits a conductivity corresponding to a 37% ionization. Yet according to the above generalization that hydroxyl ions replace water molecules in the complex ion completely, the aquo-dinitro-triammine hydroxide should be converted completely into hydroxo-dinitro-triammine, and since this does not ionize, its solution should exhibit zero conductivity. It is clear that in this case hydroxyl ions do not replace water molecules in the complex at all completely.

Certain hydroxo salts also afford exceptions, although less marked ones, to this generalization, for it has been long known that their solutions exhibit marked alkalinity; hydroxo-aquo-tetrammine cobaltic chloride,²⁰ for instance, is a case in point.

Expressed in terms of the above explanation, either the water molecule in aquo-dinitro-triammine hydroxide is more firmly held, or is replaced with greater difficulty by negatively charged hydroxyl ions, than are the water molecules in the other complex ions that we have studied, so that only a partial replacement occurs. Assuming that the aquo base once formed would show about the same apparent ionization as the other bases (83%), it would follow that about $(0.37/0.83) \times 100$ or 45% of the compound is present in the solution in that form. That is,²¹

Irrespective of any mechanism one can, however, say that this base is a much stronger one than other exclusively hydroxo bases, its dissociation constant being of the order of 10^{-5} as contrasted with 10^{-10} for the hydroxo-pentammine ion.

This restriction of our generalization, however, clarifies rather than darkens the interpretation of these phenomena. It is evident that the hydroxyl ion reacts with these aquo cations quite as do other anions. It is known that many anions will replace water molecules in such complex ions reversibly. Some anions do so extensively, others but slightly; some rapidly, others slowly.²² The hydroxyl ion is thus not unique in its behavior. It is perhaps outstanding as compared with other anions in that it displaces the complexly held water molecules in the aquo ions *both* extensively and *very* rapidly.

²⁰ Werner, *Ber.*, **40**, 4133 (1907).

²¹ The *mechanism* of this equilibrium could be either the direct aqutation here shown or the mechanism postulated by Werner [*Ber.*, **40**, 4133 (1907)] and Brönsted [*Rec. trav. chim.*, **42**, 718 (1923)], namely,

²² Lamb and Marden, *THIS JOURNAL*, **33**, 1873 (1911); Pers, *Compt. rend.*, **153**, 673 (1911); Lamb and Fairhall, *THIS JOURNAL*, **45**, 378 (1923).

Summary

1. It has been shown by conductimetric titration of several nominally trivalent ammine bases prepared from aquo ammine bromides that the complexly held water molecules have in these instances been completely displaced by an equivalent number of the hydroxyl ions. The adjustment of these displacement equilibria is rapid and the hydroxo groups formed are firmly held.

2. The apparent ionizations of the hydroxyl groups remaining outside of the complex are high and are nearly identical in each of these cases, irrespective of the nature of the central atom, the coördinated groups and the valence of the cation.

3. The replacement of the complexly held water molecules is not, however, universally complete. Stated otherwise, the hydroxo group may in certain cases be largely replaced by a water molecule and thereafter ionized.

4. This interaction between these aquo ions and hydroxyl ions is comparable to that between aquo ions and anions in general, although the replacement of water molecules by the hydroxyl group is relatively extensive and the attainment of equilibrium is unusually rapid.

THERMODYNAMIC PROPERTIES OF FUSED SALT SOLUTIONS. V. LEAD BROMIDE IN SILVER BROMIDE

BY EDWARD J. SALSTROM

RECEIVED FEBRUARY 29, 1932

PUBLISHED JULY 6, 1932

The investigation described in this paper represents a continuation of a series of studies on the thermodynamics of fused salt solutions begun by Hildebrand and Ruhle.¹ The system lead bromide in silver bromide was chosen because the melting points of their solutions permitted a study extending over the entire range of their composition. Thus it was believed that the activities of both the solvent and solute could be determined.

Experimental Part

The lead bromide was prepared by precipitation from a solution of lead acetate with excess hydrobromic acid. The precipitate was repeatedly washed by decantation with a 3% solution of hydrobromic acid and finally dried at 150° for several days. Silver bromide was similarly prepared by precipitation from a silver nitrate solution. The bromine and hydrogen bromide were prepared as previously described in the lithium bromide-silver bromide study.²

¹ Hildebrand and Ruhle, *THIS JOURNAL*, **49**, 722 (1927).

² Salstrom and Hildebrand, *ibid.*, **52**, 4650 (1930).

The cells, apparatus and procedure remained essentially unchanged.² In short, the method was as follows. Silver bromide and lead bromide were weighed out in the desired proportions. The salts were carefully melted together in a Pyrex tube, mixed by stirring and poured in the molten state into the Pyrex cell containers. The final traces of moisture, oxidation and hydrolysis products occasioned by filling and sealing the cell containers were swept out by bubbling through the melt a dry stream of hydrogen bromide gas for at least an hour and a half. Bromine gas generated by the electrolysis of fused lead bromide which had been similarly purified was then bubbled through the electrolyte over a treated graphite rod³ which served as the positive electrode. The negative electrode was a pure silver wire inserted into a tube leading into the bottom of the cell. Molten tin served as a thermostat bath. Equilibrium was attained in a couple of hours but in practice the cell was allowed to run overnight. Readings were then taken at regular temperature intervals in both ascending and descending series, all of which were in complete agreement.

The results are given in Table I and plotted in Fig. 1. The e. m. f. values given are the observed results corrected to take into account a thermoelec-

tric effect³ caused by the fact that a definite temperature gradient exists in each electrode. Values for the cell containing pure silver bromide were those obtained in a previous lithium bromide-silver bromide investigation.²

The extreme deviation of the observed values from a straight line drawn through them in Fig. 1 is 0.5 millivolt and the mean deviation is less than 0.1 millivolt.

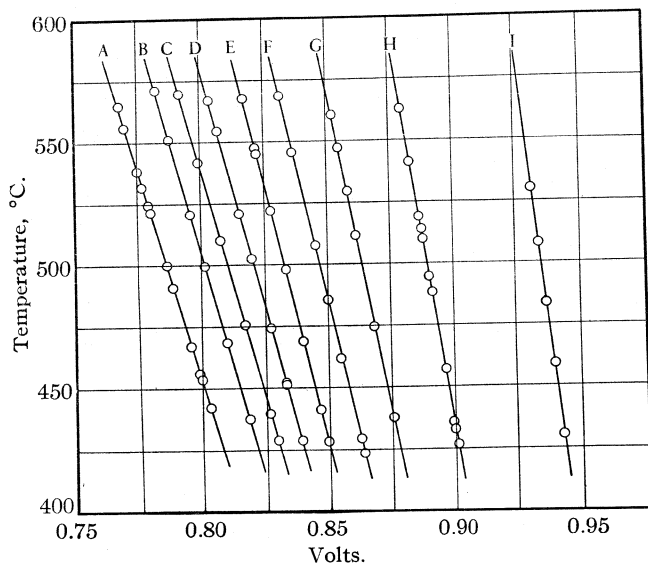

Fig. 1.—Temperature, e. m. f. and composition relations of the cells Ag, AgBr, PbBr₂, Br₂. See Table I for mole fractions of silver bromide.

To determine how the volume of a mole of solution varies with composition, density determinations were made upon a solution containing a half mole fraction of each salt. The method used consisted of weighing a tungsten-weighted quartz bulb, suspended by a very fine platinum wire, first in air, then in water and finally at various temperatures in the fused salt solution, correcting⁴ each time for the expansion of quartz. The bulb was sharply tapped before each reading to remove any adhering bubbles of gas. The fused solution used in the density measurements was purified as in the case of the cells by bubbling dry hydrogen bromide gas through the melt for two hours.

The observed density values may be expressed by the equation, $d' = 6.243 - 0.00146t$ and are given in Table II.

⁴ A calculation of the effect of the buoyancy of air upon the bulb was made and it was found to be negligible. Data are not available for calculating the influence of surface tension of the fused solution upon the suspending wire but since its diameter was less than 0.1 mm. it is believed that such corrections would also prove to be negligible.

TABLE II

DENSITIES OF A 0.5 MOLE FRACTION OF LEAD BROMIDE IN SILVER BROMIDE

507.9	5.502	558.2	5.428
522.0	5.481	572.2	5.409
533.9	5.463	581.6	5.395

With the aid of density values for silver bromide obtained by Lorenz and Höchberg⁵ and for lead bromide obtained by Lorenz, Frei and Jabs,⁶ the molal volumes of silver bromide and lead bromide have been calculated at 500° to be 34.10 cc. and 66.53 cc., respectively. A half mole fraction solution of lead bromide in silver bromide at this temperature has an observed molal volume of 50.32, which is identical with that calculated on the basis of additivity.

Discussion of Results

To show the effect of both temperature and composition upon the properties of the solutions, Fig. 1 was plotted on a large scale and the values of the e. m. f. determined for each composition at the temperatures 450, 500 and 550° by noting the intersections of the curves with these temperature ordinates. By applying the usual thermodynamic equations³ to these e. m. f.'s, values have been calculated for the free energy of formation of silver bromide from solid silver and bromine vapor, ΔF_1 , the free energy of dilution or the partial molal free energy, \bar{F}_1 , the entropy change, ΔS_1 , and the partial molal entropy, \bar{S}_1 , the heat of formation, ΔH_1 , the activity of silver bromide in the solutions taking pure silver bromide as the standard state, a_1 , and the activity coefficient, a_1/N_1 , where N_1 is the mole fraction of silver bromide.

These values are given in Table III, and Fig. 2, curve C, shows the partial molal free energy, $-\bar{F}_1$ at 500°, plotted against $\log (1/N_1)$.

In order to compare this observed curve with that calculated on the assumption that Raoult's law is obeyed it may be assumed, first, that both salts are un-ionized. Then the partial molal free energy is given by the equation, $\bar{F}_1 = RT \ln N_1$, where $N_1 = a_1$. This gives curve B, Fig. 2, which agrees perfectly with the observed results up to a half mole fraction of added lead bromide. With increasing concentration of lead bromide there is a slight but increasing positive deviation of the activity of silver bromide from Raoult's law, since a_1/N_1 becomes greater than unity. However, even at the maximum concentration of lead bromide (0.9 mole fraction) the calculated partial molal free energy of silver bromide is only 110 calories more than the observed. To make sure that these small deviations were not fortuitous, the cells were carefully checked. Their respective

temperature—e. m. f. curves agreed within 0.2 millivolt which would correspond to a deviation of ± 5 calories in the partial molal free energy.

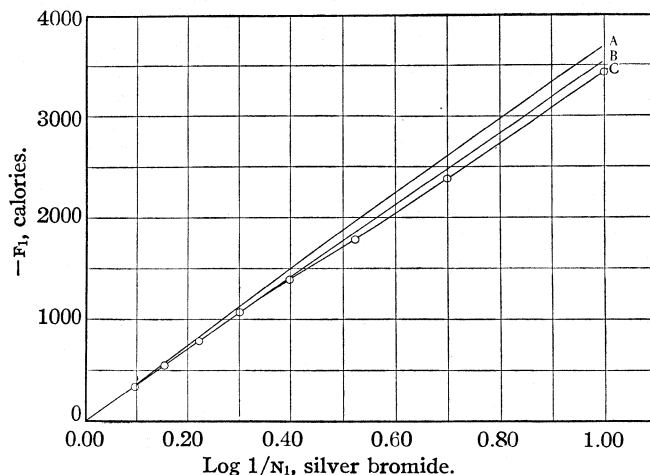

Fig. 2.—Change in free energy of silver bromide at 500° upon dilution with lead bromide: C, observed; A, calculated on the basis of complete ionization of both salts; B, calculated on the basis of no ionization.

If it is assumed, second, that Raoult's law is obeyed and that both salts are completely ionized, but that the partial substitution of silver by lead ion can be made without changing any of the interionic forces, then if n_1 moles of silver bromide and n_2 moles of lead bromide are taken, there will then be n_1 moles of Ag^+ , n_2 moles of Pb^{++} and $n_1 + 2n_2$ moles of Br^- . The activity of Ag^+ would then be $2n_1/(2n_1 + 3n_2)$, the activity of Br^- , $2(n_1 + 2n_2)/(2n_1 + 3n_2)$, and the activity of silver bromide, the product of the two, or

$$a_1 = 4n_1(n_1 + 2n_2)/(2n_1 + 3n_2)^2$$

The $-\bar{F}_1$ calculated on this basis, curve A in Fig. 2, is found to be too high.

Since the deviation of the activity of silver bromide from Raoult's law though small is undoubtedly real, it is believed worth while to calculate the activity of the solute, namely, lead bromide, in the solutions. This may be done by employing the general partial molal equation⁷ showing for any infinitesimal alteration in composition at constant temperature and pressure, the relation between the change in any one partial molal quantity and the change in all others, namely

$$N_1 \left(\frac{\partial \bar{G}_1}{\partial N_1} \right)_{P,T} + N_2 \left(\frac{\partial \bar{G}_2}{\partial N_2} \right)_{P,T} + \dots = 0$$

⁷ Cf. Lewis and Randall, "Thermodynamics and the Free Energy of Chemical Substances," McGraw-Hill Book Co., Inc., New York, 1923, p. 43.

where \bar{G}_1 and \bar{G}_2 are any partial molal quantities. Introducing the free energy into this equation and choosing the standard state of lead bromide in the solution at infinite dilution, *i. e.*, $a_2/N_2 = 1$ when $N_2 = 0$, this general equation may be brought into the form

$$\log a_2/N_2 = - \int_0^{N_2} \frac{N_1}{N_2} d \log \frac{a_1}{N_1}$$

In general when the above equation is integrated graphically by plotting N_1/N_2 against $\log a_1/N_1$ the difficulty is encountered that N_1/N_2 rapidly approaches infinity as N_2 approaches zero. However, in this case it is not necessary to go beyond the value of 1.0 for N_1/N_2 , for from this point on Raoult's law is obeyed, *i. e.*, $a_1/N_1 = 1$, and its logarithm is therefore zero.

By such graphical integration the activity, a_2 , and activity coefficient, a_2/N_2 , of lead bromide were obtained. By using the equation $\bar{F}_2 = RT \ln a_2$ the partial molal free energy, \bar{F}_2 , of lead bromide was also calculated, which when added to the free energy of formation of fused lead bromide³ from molten lead and bromine vapor yields ΔF_2 . The values so obtained are given in Table IV and Fig. 3, curve A, shows $-\bar{F}_2$ plotted against $\log (1/N_2)$. To see how this agrees with Raoult's law it may be assumed first, that both salts are un-ionized. Calculation of $-\bar{F}_2$ on this basis gives curve C, Fig. 3, which agrees very well with the observed results, the maximum positive deviation being less than 80 calories.

TABLE IV
THERMODYNAMIC RELATIONS OF FUSED LEAD BROMIDE-SILVER BROMIDE SOLUTIONS

.400	.400	1.000	-1350	-48980
.300	.300	1.000	-1790	-49420
.200	.200	1.000	-2410	-50040
At 550°				
1.000	0.959	0.959	0	-46230
0.900	.871	.967	- 160	-46390
.800	.781	.977	- 340	-46570
.700	.690	.986	- 540	-46770
.600	.597	.995	- 780	-47010
.500	.500	1.000	-1070	-47300
.400	.400	1.000	-1430	-47660
.300	.300	1.000	-1900	-48130
.200	.200	1.000	-2600	-48830

If it is assumed, second, that both salts are completely ionized and that the partial substitution of lead by silver ion can be made without changing any of the interionic forces, then if n_1 moles of AgBr and n_2 moles of PbBr₂ are taken there would be n_2 moles of Pb⁺⁺, n_1 moles of Ag⁺ and $2n_2 + n_1$ moles of Br⁻. The activity of Pb⁺⁺ would then be $3n_2/(3n_2 + 2n_1)$, the activity of Br⁻ would be $3(2n_2 + 1)/2(3n_2 + 2n_1)$ and the activity of lead bromide the former times the square of the latter, or

$$a_2 = 27n_2(2n_2 + n_1)^2/4(3n_2 + 2n_1)^3$$

Such calculations are represented by curve B, Fig. 3, which is slightly higher than that calculated on the basis of no ionization.

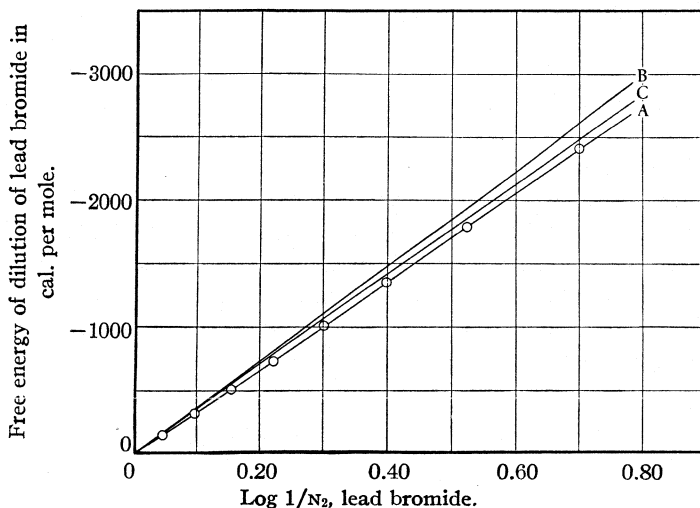

Fig. 3.—Change in free energy of lead bromide at 500° upon dilution with silver bromide: A, observed; B, calculated on the basis of complete ionization of both salts; C, calculated on the basis of no ionization.

It is thus evident that the observed free energies of dilution of both silver bromide (Fig. 2) and lead bromide (Fig. 3) agree very well with that calculated on the basis that Raoult's law is obeyed if it is assumed that both salts are un-ionized, while they agree less well with that calculated on the assumption that both salts are completely ionized. However, the calculations of \bar{F} based on these two assumptions hardly differ sufficiently to warrant a choice between them. The activity coefficients of the two salts in Tables III and IV also show that this close agreement with Raoult's law is not a fortuitous one at a single temperature but persists practically unchanged throughout the whole range of temperature studied. These considerations coupled with the fact that the molal volume of the solution is additive make it clear that we are dealing here with a system that conforms very closely with the perfect solution laws.

Summary

1. Measurements of the e. m. f. of the cell, $\text{Ag(s)}, \text{AgBr(l)}, \text{PbBr}_2\text{(l)}, \text{Br}_2\text{(g)}$ have been made at mole fractions of silver bromide varying from 1.00 to 0.10 between the temperatures 425 and 575°.

2. Densities of a 0.5 mole fraction solution of lead bromide in silver bromide are given by the relation $d' = 6.243 - 0.00146t$ between the temperatures 490 and 580°.

3. The relations between composition and free energy, heat of formation, entropy change and activity coefficient of the solvent, fused silver bromide, have been calculated for 450, 500 and 550°.

4. The relations between composition and free energy and activity coefficient of the solute, fused lead bromide, have been calculated at 500 and 550°.

5. The activities of both solvent and solute agree very well with that predicted by Raoult's law throughout the entire range of temperature studied.

QUANTUM MECHANICS OF ACTIVATED ADSORPTION

BY ALBERT SHERMAN AND HENRY EYRING

RECEIVED FEBRUARY 29, 1932

PUBLISHED JULY 6, 1932

The experiments of Taylor and Sherman¹ showed that activated adsorption is involved in the ortho-para hydrogen conversion at a variety of surfaces. On charcoal the activation energy must be small—approximately 2 kg. cal.—since the conversion occurs at liquid hydrogen temperatures.² The conversion on a given charcoal surface was shown by Taylor and Sherman to be bimolecular at room temperatures, and the surface action exhibited a temperature coefficient less than unity between liquid air temperatures and 0°. It becomes a matter of considerable interest to apply the methods used by Eyring and Polanyi³ for calculation of activation energies to determine the necessary conditions for so low an activation energy. The calculations presented in the following pages seem sufficiently accurate to indicate clearly the process by which the reaction proceeds, although, of course, the exact numerical results are subject to revision.

The mechanism for the conversion of ortho to para hydrogen on charcoal probably involves three steps: (1) activated adsorption; (2) collision

¹ Taylor and Sherman, *Trans. Faraday Soc.*, Symposium on Adsorption (1932).

² Bonhoeffer and Harteck, *Z. physik. Chem.*, **B4**, 113 (1929).

³ Eyring and Polanyi, *ibid.*, **B12**, 279 (1931).

and reaction of two adjacently adsorbed hydrogen molecules; (3) desorption. At very low temperatures step 3, a zero order evaporation process, is undoubtedly the rate determining step. We should thus expect at intermediate temperatures a transition between second and zero order reactions. As the temperature increases, the rate of desorption increases until finally the collision of two adjacently adsorbed molecules is the slow process. With increasing temperature the chance of two hydrogen molecules being adsorbed in adjacent positions approaches zero and simultaneously the conversion of para to ortho hydrogen drops to zero, in keeping with the results of Taylor and Sherman. It is obvious, therefore, that the rate must go through a maximum when the specific reaction rate k is plotted against the absolute temperature T .

Such a temperature variation is probably general for any catalytic reaction involving a collision between adsorbed molecules. The negative slope portion of the curve may not be realizable experimentally in many cases because the temperature at which the maximum occurs may be such as to destroy the catalyst. The part with positive slope may not be realizable because it may correspond to temperatures below the melting point of the reactants. The known experiments of the conversion of ortho to para hydrogen on charcoal correspond only to the part for higher temperatures than that for which the maximum occurs. In the case of a particular sample of a copper catalyst for this same reaction results lying on both sides of the maximum have been found. In the case of ZnO only that portion of the curve with positive slope was realized.

Adsorption Process.—It has already been pointed out that the activation energy E_a of adsorption of hydrogen on charcoal must be very small.

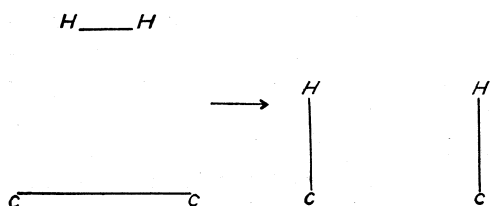

Fig. 1.—Adsorption process.

This reaction may be represented as indicated in Fig. 1.

The surface carbon atoms, of course, have additional bonds which are not indicated.

Since analogous processes are involved in the hydrogenation of ethylene and acetylene we

shall first calculate an approximate activation energy for these reactions. For the purposes of these calculations the C—C distances in ethylene and acetylene were taken equal to that in ethane, 1.54 Å. The effective strength of the C—C bond broken was taken as the difference between the strengths of a double and single bond, $123 - 73.5 = 49.5$ kg. cal., in the first case and in the second case as the difference between the strength of a triple and double bond, $162 - 123 = 39$ kg. cal. The data used for constructing the Morse potential energy curves for C—H and H—H are given in Table I.

The expression for the binding energy of four atoms is

$$E = A_1 + A_2 + B_1 + B_2 + C_1 + C_2 + \sqrt{1/2[(\alpha_1 + \alpha_2 - \beta_1 - \beta_2)^2 + (\alpha_1 + \alpha_2 - \gamma_1 - \gamma_2)^2 + (\beta_1 + \beta_2 - \gamma_1 - \gamma_2)^2]} \quad (1a)$$

where the italic letters are the coulombic potentials corresponding to the six possible distances between four atoms and the Greek letters are the interchange potentials for these same distances. The method of calculation was to construct a potential energy surface for configurations in which the C—C distance was kept at 1.54 Å., the four atoms were kept in a plane, and only configurations symmetrical about the perpendicular bisector of the line joining the two carbon nuclei were considered. Certain of these assumptions have already been discussed⁴ and they are considered in greater detail in a forthcoming paper by Kimball and Eyring.

The activation energies for the hydrogenation of ethylene and acetylene were calculated to be 51.5 and 46.4 kg. cal., respectively, at 0°K. The former value is to be compared with 43.2 kg. cal. recently obtained by Pease.⁵ The discrepancy is probably due to the operation of several factors. The experimentally measured value is for a temperature of approximately 700°K.,⁶ while the calculated value is of course for 0°K. The effect of directed valence will also be to lower the activation energy but we have not attempted a precise evaluation of the magnitude of this lowering. The choice of 10% for the coulombic energy is only approximately correct, although it is probably not greatly in error.

We now consider the analogous process of the reduction of two carbon atoms on a catalytic surface by hydrogen. This is essentially what happens when we have activated adsorption of hydrogen on a charcoal surface. The adsorption process replaces a single bond of 101.5 kg. cal. between the hydrogen atoms and a weaker one between the carbon atoms by two C—H bonds whose combined strength does not exceed by more than approximately two kilogram calories the strength of the two bonds

broken. If the same potential energy curves are used for this calculation as are used for the hydrogenation of ethylene and acetylene, the upper curve in Fig. 2 is obtained, showing how the activation energy of adsorption changes with the distance between the two carbon atoms. The carbon to carbon bond broken was taken as the difference between a triple and double bond at the appropriate distance. The minimum is not shifted if the carbon to carbon bond broken is assumed instead to be a single bond. On the extreme left where the change would be most marked the curve would be raised by 5 kg. cal. Thus the exact nature of this carbon to carbon bond is not significant for our considerations. The curve shows that

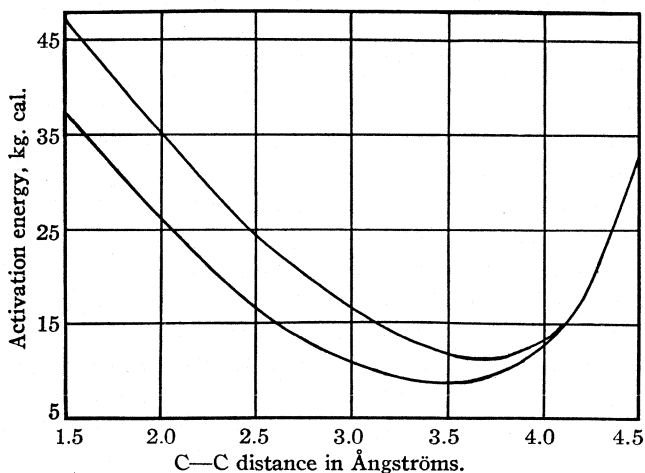

Fig. 2.—The dependence of the activation energy for adsorption of H_2 on charcoal as a function of the distance between surface carbon atoms.

the reaction proceeds with the lowest activation energy for carbon atoms held at a distance of 3.6 Å. The calculated potential surface for the carbon-carbon distance of 3.6 Å. has a minimum which represents the hydrogenation of the carbon atoms with an evolution of 90.5 kg. cal. Actually, as stated previously, hydrogen is adsorbed on charcoal with the liberation of but two kilogram calories, so that there must be forces in the surface preventing the formation of C—H bonds of 96 kg. cal. Since the calculations indicate the adsorption obtained is the so-called atomic adsorption—that is, adsorption in which the hydrogen-hydrogen distance becomes very large—the C—H bonds must have strengths of 51.8 kg. cal. in order that the final bonds will have strengths of only two kg. cal. more than the initial hydrogen bond. We then have the problem of calculating the activation energy for C—H bonds of 51.8 kg. cal. The remaining constants used in the Morse curve are the same as those previously used. Proceeding exactly

as before we obtain the lower curve in Fig. 2. Surprisingly enough, in this case also we find that a carbon-carbon distance of approximately 3.6 Å. is most favorable. This is particularly satisfactory in that it indicates the existence of a most favorable carbon-carbon distance which is practically independent of our choice of the strength of the C—H bond.

That a most favorable carbon-carbon distance is to be expected may be seen from the following qualitative argument. Consider the following two extreme distances between surface atoms. In one case suppose the distance between surface atoms A—A is equal to that of the approaching hydrogen molecule, as illustrated in Fig. 3. In Fig. 3 the subscripts preceding the atomic symbols are used to distinguish the various atoms. In this case there is a large interaction between ${}_3\text{A}$ and ${}_2\text{H}$ and also between ${}_4\text{A}$ and ${}_1\text{H}$. As can be seen from Equation (1a), making the smallest interchange integrals (those between diagonal atoms) larger decreases the total binding energy, thus making the activation energy larger.

Now consider the case in which the surface atoms are very far apart. In this case all the terms in Equation (1a) except those between the two hydrogen atoms are small and this distance must also become very large in order that the hydrogen atoms can be adsorbed. This process, then, is essentially a dissociation of a hydrogen molecule and necessitates an activation energy of approximately 100 kg. cal. Thus, somewhere between these two extremes a most favorable distance of A—A is to be expected. We see that there are no reasons for the assumption sometimes made that it is favorable for the distance between surface atoms to be equal to that of the molecule being adsorbed.

The potential energy surface for the adsorption of hydrogen on two carbon atoms at 3.6 Å. is given in Fig. 4.

Similar surfaces were obtained for other C—C distances used in constructing Fig. 2. These resemble those shown in Fig. 4 and so are not reproduced.

The height of the pass in Fig. 4 separating the valley (corresponding to a hydrogen molecule and two unoccupied carbon atoms) and the basin (corresponding to the two carbon hydrides) is seen to be 8.8 kg. cal. The position of the pass is for an abscissa of 0.77 Å. and an ordinate of 0.80 Å. The course of the hydrogen molecule in the adsorption process is indicated by the arrows in Fig. 4. The activation energy for the desorption of hydrogen will be greater than this by the heat of adsorption, which we have taken to be 2 kg. cal. To agree with experiment we should have obtained 0 kg. cal. for the activation energy instead of 8.8 kg. cal. Thus

Fig. 3.—If the distance A—A is equal to that between the atoms adsorbed, the activation energy will be high.

again, as in the case of the hydrogenation of ethylene, the value obtained for the activation energy is approximately 9 kg. cal. too high. The arbitrary assumption in our calculation is the choice of 10% for the coulombic energy. A slightly higher value for the coulombic energy would have brought closer agreement in both hydrogenation cases as well as for the adsorption process. Taking into account directed valence also tends to lower the activation energy.

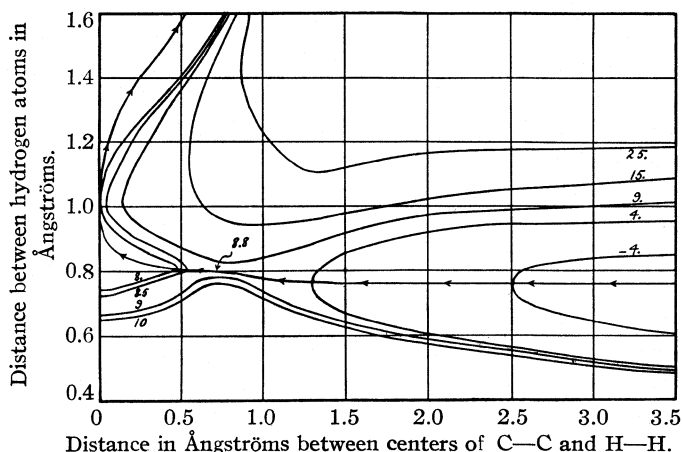

Fig. 4.—Energy contour lines in kg. cal. for the activated adsorption of H_2 on two carbon atoms 3.6 Ångströms apart.

The coulombic energy is known by calculation for the following three cases: H_2 , 10% of the total binding;⁷ Li_2 , 22%;⁸ Na_2 , 28.3%.⁹ If we determine the percentage of coulombic binding for C—H and C—C (14%) by the condition that the calculated value of the activation energy shall agree with the value found experimentally by Pease for the hydrogenation of ethylene, the adsorption of hydrogen on charcoal may be re-determined. Instead of the value of 8.8 kg. cal., we now obtain 5.6 kg. cal., in better agreement with experiment.

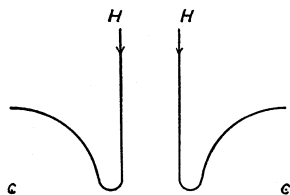

Fig. 5.—Path followed by H_2 when becoming adsorbed on charcoal.

H_2 approaches the carbon-carbon axis before expanding appreciably.

For desorption the path will be just the reverse of that of adsorption.

It might be supposed that it would require a greater activation energy for a second hydrogen molecule to be adsorbed on two carbon atoms adjacent to the pair on which the first hydrogen molecule is adsorbed because of the repulsion of the first two hydrogen atoms already adsorbed. This is not so, however, because of the large distance between the carbon atoms. Thus the activation energy for the successive adsorption of two adjacent hydrogen molecules is just that for the individual processes in this case where the four carbon atoms form a square.

It may be assumed that the actual mechanism for the catalytic conversion of para to ortho hydrogen is not the one just considered but one in which a hydrogen molecule from the gas phase collides with an adsorbed hydrogen molecule. A consideration of this involves solving the six electron problem, one from each of the four hydrogen atoms and one from each of the two carbon atoms, and will be discussed in connection with Table II. The fifth degree equation (4) for the binding energy of six electrons must be used for calculating the potential energy. The value for the elements of this determinant are given in (20) below.

We shall now discuss the evaluation of the activation energy for any configuration such as is indicated in Fig. 6.

At the corners of the quadrilateral *cdef* are four hydrogen atoms having the four eigenfunctions *c*, *d*, *e*, *f*. For the two carbon atoms we have the two eigenfunctions *a* and *b*. The energies corresponding to the fifteen distances between the six atoms are evaluated from the same curves used in the previous calculations. We have assumed as before that the coulombic binding energy is 10% of the total binding energy for each pair of atoms. This enables us to evaluate each of the elements in (4) without further difficulty. We then try values for *E* until we find the numerically largest negative number which satisfies (4). This corresponds to the singlet state of lowest potential energy. In Table II are given the data and resulting binding energies for three configurations.

In Table II, *E* is the potential energy required to break completely all the bonds between the six atoms.

In configurations 1, 2 and 3 all the atoms lie in a plane and there is symmetry about the perpendicular bisector of the C—C bond. First

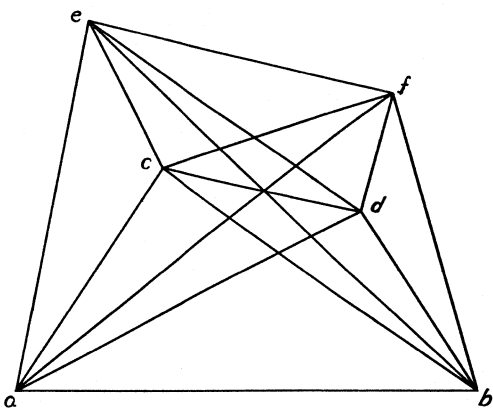

Fig. 6.—The potential curves for pairs of atoms connected by lines determine the potential for the whole configuration.

we may consider the activation energy to bring four hydrogen atoms into a square of 1 Å. on a side, when the carbon atoms are not present. This is 84.2 kg. cal. A square configuration for four atoms of hydrogen is clearly one in which any hydrogen atom is equally apt to depart with either of two neighbors as a partner, so that the square corresponding to the least potential energy is the activated state for the homogeneous ortho-para conversion between two diatomic hydrogen molecules.

Let us now consider the decrease in potential energy for our three configurations of six atoms resulting when we remove the two hydrogen atoms with eigenfunctions e and f to a great distance from the other four atoms but to the normal distance of 0.76 Å. from each other. The other four atoms are held fixed. The decreases in energy are 96.5, 119.8 and 124.5 kg. cal., respectively, for the three configurations. The activation energy for the reverse process will clearly be given by these same figures. Thus it is highly improbable for a second hydrogen molecule to approach an adsorbed hydrogen molecule without the aid of two additional carbon atoms.

Let us next consider the activation energy of four hydrogen atoms in the absence and in the presence of two surface atoms. The activation energy without the surface atoms, as already stated, is 84.2 kg. cal. Instead of being lowered, our calculations for configurations 1, 2 and 3 show that the surface carbon atoms raise this activation energy to the values $2 \times 101.5 - 89.6 = 113.4$, 130.0 and 138.0 kg. cal., respectively.

The process we considered in our first adsorption calculations thus appears to be the true catalytic process. The ortho-para hydrogen conversion has also been discussed recently by Ekstein and Polanyi.¹⁰

¹⁰ Ekstein and Polanyi, *Z. physik. Chem.*, B15, 334 (1932).

The five independent eigenfunctions that we have used in calculating the energy for the six electron problem correspond to five different ways of drawing three bonds, indicated as

ψ'_1	a - b	c - d	e - f
ψ'_2	a - b	c - e	d - f
ψ'_3	a - c	b - d	e - f
ψ'_4	a - c	b - e	d - f
ψ'_5	a - d	b - e	c - f

For a particular set of six monovalent atoms the configuration determines the eigenfunctions associated with each of the energy values which are roots of the secular equation. Thus, if the lowest root of the secular equation is the sum of the heats of dissociation of the three molecular bonds a—b, c—d, e—f, and the three corresponding molecules are remote from each other, the eigenfunction going with this energy is just ψ'_2 . As the six monovalent atoms approach each other the binding can no longer be represented simply by three fixed bonds. Thus for the three configurations in Table II we have instead of some one of the eigenfunctions ψ'_1 to ψ'_5 the following linear combinations

Configuration 1: $0.406\psi'_1 + 0.568\psi'_2 + 0.694\psi'_3 + 0.130\psi'_4 + 0.122\psi'_5$.

2: $0.524\psi'_1 + 0.432\psi'_2 + 0.698\psi'_3 + 0.224\psi'_4 + 0.019\psi'_5$.

3: $0.757\psi'_1 + 0.200\psi'_2 + 0.366\psi'_3 + 0.355\psi'_4 + 0.355\psi'_5$.

The squares of the coefficients of the eigenfunction for each configuration must, of course add up to one. As is well known, the binding energies for most compounds correspond closely to what one calculates if a definite set of bonds is assumed. A chemical reaction consists in passing from a potential minimum corresponding to a single set of bonds such as is represented by ψ'_1 or ψ'_2 , etc., through states of mixed bonds for which the potential energy is higher, such as those corresponding to those of our configurations 1, 2, 3, to a new potential minimum where there is again a single set of bonds.

Molecules involving polyvalent atoms may not reach the ideal state of a single set of bonds because of the mutual interaction of two groups attached to the same atom. This manifests itself as steric hindrance and the eigenfunctions will be of the mixed type just described. Organic molecules never quite have the simple set of bonds ordinarily assigned them.

Bonhoeffer and Farkas¹¹ suggested that the conversion they observed on platinum could be attributed to the pulling apart of the atoms of hydrogen with a subsequent reunion of these same two atoms upon desorption to form a molecule with a changed resultant nuclear spin. Quantum mechanics indicates that such a process will not occur except as catalyzed by radiation or by other hydrogen atoms. Even if the atoms are separated

¹¹ Bonhoeffer and Farkas, *Trans. Faraday Soc.*, Symposium on Adsorption (1932).

to great distances by electrostatic forces, they always return with the same resultant nuclear spin they had initially. Only magnetic perturbations can hasten a change in nuclear spin. The following picture illustrates the situation. Suppose one thinks of the two atoms as two ships, each carrying a gyroscopic compass corresponding to nuclear spins. If the compasses point in the same direction when the ships are each proceeding in a given direction and parallel to each other and if the ships then separate to any distance, it will still be found that upon returning to their original relative positions the gyroscopic needles will be parallel. The needles, of course, may have any relative positions to begin with, which is conserved no matter what forces are applied to the ships so long as these forces do not act directly on the compasses.

Bonhoeffer and Harteck in one of their early papers² on the ortho-para hydrogen conversion include a discussion by Wigner on the rate at which black body radiation affects the conversion and we have had the opportunity of discussing this question in some detail with Professor Wigner. At ordinary temperatures a half life of approximately 300 years is found for the atoms in *s* states. If they are in *p* states the half life is shown to be about twelve hours. Thus to the extent to which a catalytic surface changes the quantum state of the atoms we obtain a greatly increased effect of radiation on the rate of conversion. One can only estimate the magnitude of this change in quantization but it would be surprising if the catalyst raises the binding electrons more than 10% into *p* states, which would still give us a rate far too low to account for the observed rates of conversion at surfaces. In fact a half life of twelve hours, that for atoms in *p* states, is too slow to account for the experimental observations on catalytic surfaces.

Because of the apparent success of the present method of attack we are extending our calculations to other surfaces.

We now give the solution of the six electron problem.

To secure the utmost brevity we shall assume familiarity on the part of the reader with a recent paper by Slater¹² in which the problem of spin degeneracy is solved for three and four electrons. We use his notation. The reader desiring a simple and detailed treatment of this problem may be referred to the thesis of one of us on file in the Princeton Library.

The Schrödinger equation for six electrons is approximately satisfied by the product of the six electronic eigenfunctions $a_1b_2c_3d_4e_5f_6$, where the numbers specify the electrons and the letters the available eigenfunctions. The 720 different products obtained by permutation of the numbers are all equally good solutions of the Schrödinger equation. Any linear combination of them is also a solution. Taking account of electron spins we write for electron 1 having the positional eigenfunction *a* and

¹² J. C. Slater, *Phys. Rev.*, **38**, 1109 (1931).

spin $+1/2$, $(a\alpha)_1$ and for a spin of $-1/2$ the expression $(a\beta)_1$. Now when we use the Pauli principle instead of 720 eigenfunctions in our secular equation we need consider only the 64 antisymmetric eigenfunctions

$$\psi_i = \Sigma \pm p (a\alpha)_1(b\alpha)_2(c\beta)_3(d\beta)_4(e\alpha)_5(f\beta)_6 \quad (1)$$

where $\Sigma \pm p$ signifies the sum of the 720 possible quantities obtained by permutation of the subscripts, using the positive sign if the product may be obtained from the initial product by an even number of interchanges of pairs of subscripts, and otherwise the negative sign (1) may also be written as a determinant. There are just $2^6 = 64$ eigenfunctions of the type (1) since in each of the six parentheses we can insert either an α or β . Terms $\int \psi_i H \psi_j d\tau$ in the secular equation are zero if the sum of the spins in ψ_i is not the same as in ψ_j , where H is the well-known operator for six electrons and the integration is over all the coordinates of the six electrons. This is true because a term of the form

$$\int (a\alpha)_1(b\beta)_2(c\alpha)_3 \dots (f\alpha)_6 H (a\alpha)_1(b\beta)_2(c\alpha)_3 \dots (f\alpha)_6 d\tau$$

for which the spin eigenfunctions of every electron before and after H is the same, is equal to $\int a_1 b_2 c_3 d_4 e_5 f_6 H a_1 b_2 c_3 d_4 e_5 f_6 d\tau$, and if for any single electron the spin eigenfunctions are not the same, the integral is identically zero. This causes our 64 rowed secular determinant to break up into the product of seven determinants corresponding to the integral spin values from 3 to -3 .

The most stable chemical state will correspond to a state for which the sum of the spins for the six electrons is zero; so that we are only concerned with solving the corresponding twenty rowed determinant. The 20 eigenfunctions may be indicated in the following symbolic fashion

	<i>a</i>	<i>b</i>	<i>c</i>	<i>d</i>	<i>e</i>	<i>f</i>		<i>a</i>	<i>b</i>	<i>c</i>	<i>d</i>	<i>e</i>	<i>f</i>		<i>a</i>	<i>b</i>	<i>c</i>	<i>d</i>	<i>e</i>	<i>f</i>
ψ_{23}	α	α	α	β	β	β	ψ_{30}	α	β	β	α	α	β	ψ_{37}	β	α	β	α	β	α
ψ_{24}	α	α	β	α	β	β	ψ_{31}	β	α	β	α	α	β	ψ_{38}	β	β	α	α	β	α
ψ_{25}	α	β	α	α	β	β	ψ_{32}	β	β	α	α	α	β	ψ_{39}	α	β	β	β	α	α
ψ_{26}	β	α	α	α	β	β	ψ_{33}	α	α	β	β	β	α	ψ_{40}	β	α	β	β	α	α
ψ_{27}	α	α	β	α	β	β	ψ_{34}	α	β	α	β	β	α	ψ_{41}	β	β	α	β	α	α
ψ_{28}	α	β	α	β	α	β	ψ_{35}	β	α	α	β	β	α	ψ_{42}	β	β	β	α	α	α
ψ_{29}	β	α	α	β	α	β	ψ_{36}	α	β	β	α	β	α							

Here the table indicates with which italic letters in (1) an α or β should be associated. Actually ψ_i of (1) is ψ_{27} .

If now instead of using the 20 eigenfunctions of (2) we had used the 20 given below, which are a linear combination of them, our 20th order determinant now factors into four sub-determinants of orders 5, 9, 5, 1.

$$\psi'_1 = \frac{1}{\sqrt{8}} (\psi_{28} - \psi_{29} - \psi_{30} + \psi_{31} - \psi_{34} + \psi_{35} + \psi_{36} - \psi_{37})$$

$$\psi'_2 = \frac{1}{\sqrt{8}} (\psi_{25} - \psi_{26} - \psi_{30} + \psi_{31} - \psi_{34} + \psi_{35} + \psi_{39} - \psi_{40})$$

$$\psi'_3 = \frac{1}{\sqrt{8}} (\psi_{27} - \psi_{29} - \psi_{30} + \psi_{32} - \psi_{33} + \psi_{35} + \psi_{36} - \psi_{38})$$

$$\begin{aligned}
\psi'_1 &= \frac{1}{\sqrt{8}} (\psi_{24} - \psi_{26} - \psi_{30} + \psi_{32} - \psi_{33} + \psi_{35} + \psi_{39} - \psi_{41}) \\
\psi'_5 &= \frac{1}{\sqrt{8}} (\psi_{23} - \psi_{26} - \psi_{28} + \psi_{32} - \psi_{33} + \psi_{37} + \psi_{39} - \psi_{42}) \\
\psi'_6 &= \frac{1}{\sqrt{8}} (\psi_{28} - \psi_{29} - \psi_{30} + \psi_{31} + \psi_{34} - \psi_{35} - \psi_{36} + \psi_{37}) \\
\psi'_7 &= \frac{1}{\sqrt{8}} (\psi_{27} - \psi_{29} + \psi_{30} - \psi_{32} - \psi_{33} + \psi_{35} - \psi_{36} + \psi_{38}) \\
\psi'_8 &= \frac{1}{\sqrt{8}} (\psi_{23} - \psi_{24} - \psi_{28} + \psi_{30} + \psi_{35} - \psi_{37} - \psi_{41} + \psi_{42}) \\
\psi'_9 &= \frac{1}{\sqrt{8}} (\psi_{25} - \psi_{26} - \psi_{30} + \psi_{31} + \psi_{34} - \psi_{35} - \psi_{39} + \psi_{40}) \\
\psi'_{10} &= \frac{1}{\sqrt{8}} (\psi_{28} - \psi_{29} + \psi_{30} - \psi_{31} - \psi_{34} + \psi_{35} - \psi_{36} + \psi_{37}) \\
\psi'_{11} &= \frac{1}{\sqrt{8}} (\psi_{24} - \psi_{26} + \psi_{30} - \psi_{32} - \psi_{33} + \psi_{35} - \psi_{39} + \psi_{41}) \\
\psi'_{12} &= \frac{1}{\sqrt{8}} (\psi_{23} - \psi_{26} + \psi_{28} - \psi_{32} - \psi_{33} + \psi_{37} - \psi_{39} + \psi_{42}) \\
\psi'_{13} &= \frac{1}{\sqrt{8}} (\psi_{24} - \psi_{26} - \psi_{30} + \psi_{32} + \psi_{33} - \psi_{35} - \psi_{39} + \psi_{41}) \\
\psi'_{14} &= \frac{1}{\sqrt{8}} (\psi_{24} - \psi_{25} - \psi_{31} + \psi_{32} + \psi_{33} - \psi_{34} - \psi_{40} + \psi_{41}) \\
\psi'_{15} &= \frac{1}{\sqrt{12}} (\psi_{25} - \psi_{26} + \psi_{28} - \psi_{29} + \psi_{30} - \psi_{31} + \psi_{34} - \psi_{35} + \psi_{36} - \psi_{37} + \psi_{39} - \psi_{40}) \\
\psi'_{16} &= \frac{1}{\sqrt{12}} (\psi_{24} - \psi_{26} + \psi_{27} - \psi_{29} + \psi_{30} - \psi_{32} + \psi_{33} - \psi_{35} + \psi_{36} - \psi_{38} + \psi_{39} - \psi_{41}) \\
\psi'_{17} &= \frac{1}{\sqrt{12}} (\psi_{23} - \psi_{26} + \psi_{27} + \psi_{28} - \psi_{31} - \psi_{32} + \psi_{33} + \psi_{34} - \psi_{37} - \psi_{38} + \psi_{39} - \psi_{42}) \\
\psi'_{18} &= \frac{1}{\sqrt{12}} (\psi_{23} + \psi_{24} + \psi_{25} - \psi_{29} - \psi_{31} - \psi_{32} + \psi_{33} + \psi_{34} + \psi_{36} - \psi_{40} - \psi_{41} - \psi_{42}) \\
\psi'_{19} &= \frac{1}{\sqrt{12}} (\psi_{23} + \psi_{24} + \psi_{25} + \psi_{27} + \psi_{28} + \psi_{30} - \psi_{35} - \psi_{37} - \psi_{38} - \psi_{40} - \psi_{41} - \psi_{42}) \\
\psi'_{20} &= (1/\sqrt{20}) \sum_{i=23}^{42} \psi_i
\end{aligned} \tag{3}$$

This new choice is of course permissible since any linear combination of solutions of a Schrödinger equation is still a solution of the equation. The new sub-determinant of order one corresponds to one component of the septet—that is, to no electron pair bonds. The last mentioned 5th order determinant corresponds to the five independent eigenfunctions arising from having one bond among the six electrons. (There are actually fifteen ways of drawing one bond, giving rise to fifteen eigenfunctions, of which not more than five are linearly independent.) Similarly, the 9th and the other 5th order determinants are associated with the independent eigenfunctions arising from drawing two and three bonds, respectively.

The twenty eigenfunctions of (3) thus fall into four non-combining sets—

ψ'_1 to ψ'_5 , ψ'_6 to ψ'_{14} , ψ'_{15} to ψ'_{19} , ψ'_{20} . That is, $\int \psi'_i H \psi'_{20} d\tau = 0$ for i running from 1 to 19. The eigenfunctions ψ'_{15} to ψ'_{19} combine among themselves but not with those outside the group. The same may be said of the groups ψ'_1 to ψ'_5 and ψ'_6 to ψ'_{14} .

Since we are only interested in the energy corresponding to three bonds we need consider only the determinant arising from the eigenfunctions ψ'_1 to ψ'_5 . It is interesting to remark that there are actually fifteen ways of drawing three bonds and therefore 15 eigenfunctions, of which not more than five are linearly independent. Any linearly independent set of five would have served our purpose as well as the set we chose.

Actually the way of forming the eigenfunctions (3) from the set given in (2) is important; for no bonds one simply takes a sum of the twenty eigenfunctions. An eigenfunction for six electrons corresponding to a bond between a and b is obtained by taking a linear combination of the twelve eigenfunctions in the set (2) for which the spins of a and b are opposite. Those for which a is associated with α are taken with a plus sign and those for which a is associated with β are taken with a minus sign. For convenience in calculation we divide by a normalizing factor $\sqrt{12}$. The eigenfunction corresponding to a bond between a and b is ψ'_{15} of (3).

To obtain an eigenfunction with two bonds, say one between a and b and one between c and d , we select a linear combination of the eigenfunctions from (2) which have different spins for a and b and at the same time different spins for c and d . If a particular eigenfunction is taken as positive, e. g., ψ_{28} , then the sign of any other is positive if the spins associated with a , b , c and d may be made the same as those in ψ_{28} by interchanging the spin eigenfunctions of a and b and simultaneously those of c and d . If it is obtained by only one of these interchanges, it is negative. In this case we divide by a normalizing factor $\sqrt{8}$. The eigenfunction just described is ψ'_6 . There are 45 eigenfunctions corresponding to drawing two bonds, of which not more than 9 are linearly independent.

For the case of three bonds connecting the eigenfunctions a to b , c to d , and e to f a linear combination of all eigenfunctions from (2) is chosen in which the spin associated with each atom of these three pairs is different from its partner. If for an arbitrary one, ψ_{28} , a plus sign is taken, the sign of any other one of the 8 is positive if it may be obtained from ψ_{28} by an even number of spin interchanges between atom pairs, and negative if by an odd number. The eigenfunction here described is ψ'_1 .

With more than six electrons exactly the same scheme as outlined above can be used for obtaining an eigenfunction corresponding to an arbitrary number of bonds.

In evaluating our determinant for the singlet state we shall make certain approximations. We shall neglect energy integrals corresponding to more than two electrons jumping simultaneously. When all the atoms

are far apart the electronic eigenfunctions are strictly orthogonal. We shall neglect the fact that this is no longer true as the atoms approach each other. A partial correction for this results automatically from the fact that we use spectroscopic potential curves for evaluating the energy integrals.

The 5th order determinant for the singlet state can be written symbolically as follows

$$\begin{vmatrix} H'_{11} - Ed'_{11} & H'_{12} - Ed'_{12} & H'_{13} - Ed'_{13} & H'_{14} - Ed'_{14} & H'_{15} - Ed'_{15} \\ H'_{12} - Ed'_{12} & H'_{22} - Ed'_{22} & H'_{23} - Ed'_{23} & H'_{24} - Ed'_{24} & H'_{25} - Ed'_{25} \\ H'_{13} - Ed'_{13} & H'_{23} - Ed'_{23} & H'_{33} - Ed'_{33} & H'_{34} - Ed'_{34} & H'_{35} - Ed'_{35} \\ H'_{14} - Ed'_{14} & H'_{24} - Ed'_{24} & H'_{34} - Ed'_{34} & H'_{44} - Ed'_{44} & H'_{45} - Ed'_{45} \\ H'_{15} - Ed'_{15} & H'_{25} - Ed'_{25} & H'_{35} - Ed'_{35} & H'_{45} - Ed'_{45} & H'_{55} - Ed'_{55} \end{vmatrix} = 0 \quad (4)$$

where $H'_{ij} = \int \psi'_i H \psi'_j d\tau$ and $d'_{ij} = \int \psi'_i \psi'_j d\tau$.

The separate terms of the determinant are given below. The following notation is used: $ac = \int a_1 H c_3 dx_1 dy_1 dz_1 dx_3 dy_3 dz_3$. Thus ac is the interchange integral between the eigenfunctions a and c , with similar definitions for other terms. Also Q is defined as

$$Q = \int a_1 b_2 c_3 d_4 e_5 f_6 H a_1 b_2 c_3 d_4 e_5 f_6 d\tau \quad (5)$$

Any permutation of the electrons in (5) applied both to the electronic eigenfunctions before and after H does not change the value of the integral. Q is really the sum of the 15 Coulombic integrals between pairs of eigenfunctions—that is, between the atoms if all the atoms are monovalent.

The terms are

$$\begin{aligned} d'_{11} &= d'_{22} = d'_{33} = d'_{44} = d'_{55} = 1 \\ d'_{12} &= d'_{13} = d'_{24} = d'_{34} = d'_{45} = 1/2 \\ d'_{14} &= d'_{23} = d'_{35} = d'_{45} = 1/4 \\ d'_{15} &= -1/4 \\ H'_{11} &= Q + ab + cd + ef - 1/2[ac + ad + ae + bc + bd + be + bf + cf + ce + de + df + af] \\ H'_{22} &= Q + ab + ce + df - 1/2[ac + ad + cd + be + bf + ef + af + cf + bd + de + ae + bc] \\ H'_{33} &= Q + ac + bd + ef - 1/2[ab + ae + be + cd + cf + df + af + bf + de + ce + ad + bc] \\ H'_{44} &= Q + ac + be + df - 1/2[ab + ad + bd + ce + cf + ef + af + bf + cd + de + ae + bc] \\ H'_{55} &= Q + ad + be + cf - 1/2[ab + ac + bd + ce + df + ef + af + bf + cd + de + ae + bc] \\ H'_{12} &= \frac{Q}{2} - cf - de - 1/2 \left[\frac{ad + ae + bc + bf + ac + af + bd + be}{2} - df - ce - ef - cd - ab \right] \\ H'_{13} &= \frac{Q}{2} - bc - ad - 1/2 \left[\frac{af + df + cf + bf + de + be + ce + ae}{2} - cd - ef - ab - bd - ac \right] \\ H'_{24} &= \frac{Q}{2} - bc - ae - 1/2 \left[\frac{ad + de + bf + cf + af + ef + bd + cd}{2} - be - ac - ce - df - ab \right] \\ H'_{34} &= \frac{Q}{2} - bf - de - 1/2 \left[\frac{ab + af + cd + ce + ae + bc + cf + ad}{2} - df - be - ef - bd - ac \right] \\ H'_{45} &= \frac{Q}{2} - af - cd - 1/2 \left[\frac{ab + bf + ce + de + ae + ef + bc + bd}{2} - cf - df - be - ac - ad \right] \\ H'_{14} &= 1/4 Q + 1/4[be + af + bd + ef + cd + ac + ab + ce + df - 2(ae + bf + bc + ad + de + cf)] \\ H'_{23} &= 1/4 Q + 1/4[bd + af + be + ac + ce + df + ab + ef + cd - 2(bf + ad + bc + ae + de + cf)] \\ H'_{25} &= 1/4 Q + 1/4[bf + ad + be + ac + de + cf + ce + df + ab - 2(bd + af + bc + ae + ef + cd)] \\ H'_{35} &= 1/4 Q + 1/4[cf + ae + ef + bd + ac + bc + ad + be + df - 2(ce + af + ab + bf + cd + de)] \\ H'_{15} &= -1/4 Q - 1/4[be + af + bc + ad + ef + cd + ab + cf + de - 2(ae + bf + bd + ac + ce + df)] \end{aligned} \quad (6)$$

Thus for monovalent atoms all the quantities in (4) are determined if we know the Coulombic and interchange integrals between atom pairs.

We wish to express our thanks to Professor Taylor for helpful suggestions in connection with this paper.

Summary

1. It is pointed out that in general for bimolecular surface reactions a plot of the specific reaction rate against the temperature will exhibit a maximum.

2. The quantum mechanical calculations of the activation energies for the hydrogenation of ethylene, acetylene and the activated adsorption of hydrogen on charcoal are given. If the Coulombic binding is taken as 10% of the total for all atom pairs the activation energy is approximately 9 kg. cal. too high in all cases. The significance of this result has been discussed.

3. It is shown that a most favorable distance of carbon-carbon atoms in charcoal exists (approx. 3.6 Å.) such that the activation energy for adsorption is a minimum.

4. The calculations indicate a probable mechanism for the ortho-para hydrogen conversion and point to the improbability of the following three possible mechanisms: (a) a conversion resulting from the dissociation of a single molecule of hydrogen by surface carbon atoms (with subsequent recombination), in the absence of a neighboring hydrogen molecule; (b) the lowering of the activation energy of the homogeneous reaction of two hydrogen molecules due to the presence of two surface carbon atoms; (c) a collision of a hydrogen molecule from the gas phase with an adsorbed hydrogen molecule. This case differs from (b) only that in (c) we assume that two of the hydrogen atoms come much closer to the surface than the other two atoms.

5. The problem of spin degeneracy of six electrons is solved and the equation for the potential energy applied to the calculation of activation energies.

THE FREEZING POINTS OF AQUEOUS SOLUTIONS. I. A FREEZING POINT APPARATUS

BY GEORGE SCATCHARD, P. T. JONES AND S. S. PRENTISS¹

RECEIVED MARCH 2, 1932

PUBLISHED JULY 6, 1932

I. Introduction

The most accurate method of determining the chemical potential or activity of the solvent in very dilute solutions, and the most convenient method in moderately dilute ones, is the measurement of freezing point depressions. The method is applicable whenever the solid phase in equilibrium with the solution is the pure solvent, and is therefore very general. Except where unusually accurate electromotive force measurements in very dilute solutions are possible and in a few other special cases, the most accurate way to determine the chemical potential of the solute is to compute it from that of the solvent. For these reasons an extensive program of freezing point measurements has been inaugurated in our laboratory.

With modern thermocouples and accessories it is possible to measure small freezing point depressions with an accuracy which we estimate as about two hundred-thousandths of a degree centigrade. Some observers quote figures to a two-hundredth of this quantity, but the discussion which follows will explain our estimate. As the molal freezing point depression of water is 1.858° , this means that the freezing point depression of a hundredth molal solution can be measured to one-tenth of a per cent., and that of a thousandth molal solution to one per cent. These figures refer to the total number of solute molecules. For an electrolyte the concentration at which a given accuracy may be attained should be divided by the number of ions corresponding to one molecule of the electrolyte. The chief disadvantage of freezing points for thermodynamic calculations is that the temperature at which the chemical potential of the solvent is measured varies with the composition. For this reason, and because the measurements in concentrated solutions require a different technique, we have taken approximately one molal as the upper limit of our measurements on salt solutions. The accuracy of the temperature measurements sets a thousandth molal as the practicable lower limit.

In the "equilibrium method" of measuring freezing points the problem is to maintain ice and the solution at equilibrium, and to determine the temperature and composition as accurately as possible. We believe that our measurements are accurate to the larger of the two quantities: one

¹ This and the two following articles are abstracts of parts of the theses submitted to the Massachusetts Institute of Technology by P. T. Jones and S. S. Prentiss in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

two-thousandth of the freezing point depression, or one fifty-thousandth of a degree centigrade. To attain this precision demands careful consideration of several points. We shall describe the apparatus from the point of view of the objects to be met. In most respects our apparatus resembles one or another of those recently described,² but in some respects it differs from any known to us.

II. The Freezing Point Vessels and Stirrers

Only differential measurements can attain the above accuracy. Therefore the apparatus consists of two vessels, matched as closely as possible in every respect, one of which contains ice and water, the other ice and the solution. At first silver vessels were used, but, since these tarnished somewhat, the surfaces which came into contact with the solutions or water were later gold-plated.

The vessels are cylindrical with hemispherical bottoms, 8 cm. in diameter and 20 cm. deep. The interior is divided into three compartments by two parallel vanes so arranged that the center compartment is 4 cm. wide, and the two side compartments are 2 cm. wide at the center. The center compartment is the equilibrium vessel proper and contains all the ice. The side compartments are the pump "cylinders." As closely as possible to the bottom of each side compartment is a hinged valve which occupies the whole cross section of the compartment. To allow the free circulation of the liquid several holes, 0.2 cm. in diameter, are bored in the semicircular end of the vanes below the valves. The other end of each vane is cut off 3 cm. from the top of the vessel. To prevent ice from falling back into the pumps, this free space is filled with a silver collar into which 0.3–0.4 cm. holes are bored as closely together as possible. The pump pistons are valves similar to the fixed ones, but supported in a wire frame. All parts of the pumps are of silver heavily plated with gold. The construction of the vessels and pumps is shown by Fig. 1.

The stirring must serve two purposes. The first is to bring all the solution into contact with the ice, and the second is necessitated by the pressure effect on the freezing point of water. The freezing point of water is lowered 0.0075° per atmosphere, or eight millionths of a degree per cm. head of water. To attain an accuracy of two hundred-thousandths of a degree the depth of immersion of the two thermometers must be the same to 2 cm. The set up of the apparatus ensures that the difference in depth is not more than a fifth this large. More serious is the fact that the equilibrium temperature is sixteen hundred-thousandths of a degree higher at the top of the apparatus than at the bottom because of the 20 cm. difference in level. The temperature at any point in the apparatus must be an integrated mean of the equilibrium temperatures at different levels, whose relation to the freezing point at any level must depend upon the nature of the stirring. To obtain the same integration in each vessel to ten per cent. of the temperature range, the vessels must be matched as closely as possible, and the amount of

liquid circulated must be nearly independent of differences in friction due to different packing of the ice, but the stirring must not be turbulent enough to produce local differences of pressure with consequent differences in freezing point.

We believe that valve pumps attain these objectives more efficiently than turbine or gas-lift stirrers. The volume of liquid circulated is practically independent of the friction, the stirring is smooth, with two pumps it is almost continuous, and there is very little heat produced by friction. In our apparatus two strokes of each pump are required to circulate a volume equal to that of all the liquid in the apparatus. It is operated at a rate of twenty-five strokes of each pump per minute. The operation is so smooth that channels appear to form between the ice particles, causing slow drifts in the temperature. This difficulty is obviated by the use of a hand-operated glass ring stirrer which is operated for a few strokes some minutes before each reading.

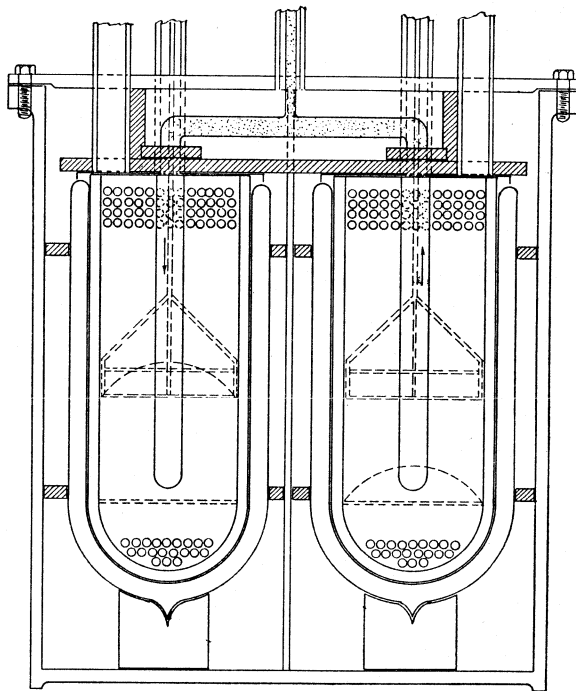

Fig. 1.—Freezing point apparatus.

III. The Containing Apparatus

Any heat added to the vessels either from the stirring or from the outside goes largely to melting the ice, and therefore causes dilution and a change in the equilibrium temperature on the solution side. So it is desirable to make the operation as nearly adiabatic as possible. To accomplish this, the vessels are placed in silvered Dewar flasks which fit snugly, and the Dewars are placed in a cylindrical box, 31 cm. high and 24 cm. in diameter, which is divided through the center, between the vessels, by a 3-mm. iron plate. Each Dewar rests on a large cork and is held in place by two hard rubber shelves which are supported by the iron plate and two small brass legs on the outer side. The cover of this box is bolted on with twelve bolts and the joint made tight with a rubber gasket. From the cover five iron tubes 13 mm. in internal diameter, and two 16 mm. in diameter, project

32 cm. The two larger tubes open above the equilibrium vessels and permit the insertion of pipets, gas tubes and hand stirrers. Four of the smaller tubes are for the pump rods. The fifth at the center of the box contains the lead wires to the thermoelements. All but the last of these tubes were plated on the inner surface with copper and then with silver. These tubes also serve to suspend the box from the cover of the thermostat, which is a can 64 cm. high and 50 cm. in diameter, thoroughly insulated to save ice.

To the lower side of the box cover is attached a hard rubber box, 16.5 cm. long, 5.1 cm. wide, and 3.2 cm. high, with a bottom which projects to form a roof over both vessels. The thermoelements are supported from this roof and the wires connecting the two pass through the box. Above each vessel is a silver lid with a flange which extends outside the vessel, completely protecting but not touching it. The lids and the roof are bored with holes to fit the thermocouples and the openings for the stirrers and pipets.

The stirring mechanism consists of two brass wheels mounted on the same axis as a sprocket wheel which is connected to a reducing gear driven by an electric motor. Each wheel is so connected by a piston to a bar sliding on two perpendicular steel rods that the two bars move in opposite phases. Each sliding bar is connected by a brass rod with a stirrer in each vessel. The connection from the brass rod to the silver-wire frame of the stirrer is through a hard rubber rod 10 cm. long which fits rather closely in the silvered tube. The two vessels are thus stirred synchronously, and in each vessel one stirrer rises as the other falls.

When the apparatus is in use the thermostat can is filled with chopped ice and water, which cover the iron box and surround the lower 15 to 18 cm. of the tubes. The equilibrium vessels are thus quite completely surrounded by an environment at 0° , and they are furthermore well insulated from it. Except through the Dewar flasks and the gas, the vessels are in contact with other bodies only through the stirrers, the pipet tubes, glass stirrers and gas entry tubes and the thermocouples. Any heat leak through the thermocouples is so much more important to the temperature reading that it will be discussed under that head. The lids of the vessels practically prevent convection and therefore any disturbance due to heat leak through the gas. The stirrers are insulated by the 10-cm. rubber rods which are cooled nearly to zero degrees. The glass stirrers and tubes are also cooled nearly to zero degrees by contact with the silvered tubes and are such poor heat conductors that they should carry very little heat into the vessels.

The effect of the sum of the heat added by the stirring and by leakage can be determined for the concentrated solutions, where it gives a measurable change in the equilibrium temperature. This was found to be 0.02% of the freezing point depression per minute. The technique of these measurements was such as to make this the limiting value of a more rapid change from a lower freezing point. Since the removal of a sample for analysis requires only half a minute, and the temperature readings are extrapolated to the time when half the sample has been removed, any error from this cause is negligible. The only other observers who have reported such data for their apparatus are Karagunis,² Hawkinson and Damköhler,^{2m} who found a change of 0.05% per minute.

IV. The Effect of Dissolved Gases

At zero degrees the solubility of nitrogen in water is 0.001 M and that of oxygen is twice as great, so that the dissolved gases cannot be ignored. Their effect on the freezing point has been discussed by Hall and Harkins,^{2g} Randall and Vanselow,^{2j} Karagunis, Hawkinson and Damköhler,^{2m} and Robertson and La Mer,²ⁿ but never completely. Because of salting out, the solubility of these gases in salt solutions is less than in water when the gas is at the same pressure, that is, at the same chemical potential

or activity. It has been customary to consider that the contribution of the gas to the freezing point depression is nevertheless proportional to its concentration.

A more accurate treatment shows that this contribution is more nearly proportional to the activity, which remains constant. We shall designate the solvent water by the subscript 1, the salt by 2, and the gas by 3. We shall assume that at any one salt concentration the gas obeys Henry's law, and that the change in chemical potential of the gas is proportional to the mole fraction of the salt at constant mole fraction of the gas. There has been no experimental test of the first assumption but, since the maximum mole fraction of nitrogen is less than one fifty-thousandth, it is highly probable. The second assumption has been found approximately valid up to salt concentrations of several molal.

We may express these assumptions by the equation

$$\frac{\partial F}{\partial n_3} = RT \ln x_3 + A + B \frac{n_2}{n_1 + \nu n_2} \quad (1)$$

where F is the free energy, x_3 the mole fraction of the gas, ν the number of ions corresponding to one molecule of salt, and A and B are constants. Then

$$F = RT \sum n_i \ln x_i + n_3 A + B \frac{n_2 n_3}{n_1 + \nu n_2} + f(n_1, n_2) \quad (2)$$

$$\frac{\partial F}{\partial n_1} = RT \ln \frac{n_1}{n_1 + \nu n_2 + n_3} - B \frac{n_2 n_3}{(n_1 + \nu n_2)^2} + \frac{\partial f(n_1, n_2)}{\partial n_1} \quad (3)$$

Letting the subscript 0 refer to $n_2 = 0$

$$\left(\frac{\partial F}{\partial n_1} \right)_0 = RT \ln \left(\frac{n_1}{n_1 + n_3} \right)_0 + \left(\frac{\partial f(n_1, n_2)}{\partial n_1} \right)_0 \quad (4)$$

$$\frac{\partial F}{\partial n_1} - \left(\frac{\partial F}{\partial n_1} \right)_0 = RT \ln \frac{n_1}{n_1 + \nu n_2 + n_3} - RT \ln \left(\frac{n_1}{n_1 + n_3} \right)_0 - B \frac{n_2 n_3}{(n_1 + \nu n_2)^2} + \frac{\partial f(n_1, n_2)}{\partial n_1} - \left(\frac{\partial f(n_1, n_2)}{\partial n_1} \right)_0 \quad (5)$$

When $n_3 = 0$ but the ratio n_2/n_1 is unchanged

$$\frac{\partial F}{\partial n_1} - \left(\frac{\partial F}{\partial n_1} \right)_0 = RT \ln \frac{n_1}{n_1 + \nu n_2} + \frac{\partial f(n_1, n_2)}{\partial n_1} - \left(\frac{\partial f(n_1, n_2)}{\partial n_1} \right)_0 \quad (6)$$

The difference is

$$\begin{aligned} \Delta \left[\frac{\partial F}{\partial n_1} - \left(\frac{\partial F}{\partial n_1} \right)_0 \right] &= \Delta = RT \ln \frac{n_1 + \nu n_2}{n_1 + \nu n_2 + n_3} - RT \ln \left(\frac{n_1}{n_1 + n_3} \right)_0 - B \frac{n_2 n_3}{(n_1 + \nu n_2)^2} \\ &= RT \ln \frac{1 - x_3}{1 - (x_3)_0} - B \frac{n_2 n_3}{(n_1 + \nu n_2)^2} \end{aligned} \quad (7)$$

and combining with equation (1), remembering the constancy of $\partial F / \partial n_3$, we obtain

$$\Delta = RT \left[\ln \frac{1 - x_3}{1 - (x_3)_0} - \frac{n_3}{n_1 + \nu n_2} \ln \frac{(x_3)_0}{x_3} \right] \quad (8)$$

So far there have been no approximations. We may take advantage of the fact that x_3 is very small to obtain

$$\begin{aligned}\Delta &= RT \left[(x_3)_0 - x_3 \left(1 + \ln \frac{(x_3)_0}{x_3} \right) \right] \\ &= RT (x_3)_0 [z + (1 - z) \ln (1 - z)]\end{aligned}\quad (9)$$

$$= RT (x_3)_0 \left[\frac{z^2}{2} + \frac{z^3}{6} + \dots \right] \quad (10)$$

where z is the fraction of the gas salted out. Returning to equation (1) we find that

$$z = 1 - \frac{x_3}{(x_3)_0} = 1 - e^{-\frac{B}{RT} \frac{n_2}{n_1 + \nu n_2}} \cong \frac{B}{RT} \frac{n_2}{n_1 + \nu n_2} = \frac{55.5 B}{RT} m = \beta m \quad (11)$$

Combining with equation (10)

$$\Delta \cong RT (x_3)_0 \left[\frac{\beta^2 m^2}{2} + \frac{B^3 m^3}{6} + \dots \right] \quad (12)$$

The simpler theory hitherto used gives

$$\Delta = RT(x_3)_0 [z] \cong RT(x_3)_0 [\beta m] \quad (13)$$

Since z cannot be greater than unity, the complete theory always gives a smaller value than equation (13), and for dilute solutions it gives a very much smaller value. The value in brackets in equation (10), (12) or (13) multiplied by the freezing point depression of the solution of the gas in water at the given pressure gives the error in the freezing point depression due to this effect. For nitrogen this depression is about 0.002° , and the value of β with sodium chloride is $1/3$. With the simpler theory one calculates an error of about 0.02% for all concentrations; the more complete theory gives 0.001% for a molal solution, and even smaller values for lower concentrations. Even for polyvalent ions, for which the relations are less favorable, the effect is much smaller than the experimental error.

There is a second effect due to the change in solubility with the temperature. The solubility of nitrogen increases 2% for each degree drop in temperature; the corresponding change in the freezing point is 0.004% . Since this tends to give too large a depression it tends to compensate the salting out effect. Since each effect is much smaller than the experimental error, it is certain that their difference is also much smaller.

It is essential, however, that the degree of saturation be the same in the two vessels to about 1% of the solubility at one atmosphere. This may be most easily attained when the total pressure is one atmosphere on each side and the gas is bubbled through enough to ensure equilibrium. In our experiments we use nitrogen because it is less soluble than air and because it is chemically inert.

V. The Measurement of Temperature

A multiple thermocouple is the instrument best adapted to the accurate measurement of small temperature differences. The copper-constantan couple is well adapted to this purpose because its temperature coefficient of electromotive force is large, and because both kinds of wire can be obtained with constant properties. We use a 48 element couple of double silk wound No. 36 copper and No. 30 constantan wire. It

consists of two completely independent 24 element couples, each of which is made up of four groups of six elements each, with a wire to the head between each group and at the extremes. Thus a group of 6, 12, 18 or 24 elements from each couple may be used independently, in series, or in opposition. At the head the lead wires are soldered to copper screws whose thread ends project through the lid of the head and are fitted with copper nuts. Connection with the potentiometer circuit is made through No. 14 copper wire with copper leads fastened between two of these nuts. It was found desirable to pack this head in cotton wool to prevent sudden changes in temperature.

Much time and annoyance can be saved in constructing a thermocouple by the method of White³ by the simple expedient of driving a series of nails in the board an inch or two beyond the section required and winding the wires on these nails without cutting. After the wires are clamped in place they are cut and the parts which had been wrapped around the nails are rejected.

The electromotive force is measured by a Leeds and Northrup "White potentiometer" covering 10,000 microvolts (μv) in steps of 1 μv , and their HS galvanometer constructed to fit the 236 ohms resistance of the thermocouple. The fractions of a microvolt are determined from the galvanometer deflections measured on a scale six meters distant. With all 48 elements two hundred-thousandths of a degree corresponds to about 0.04 μv and to about 0.6 mm. on the scale. There is no difficulty in making readings much more closely than this, but it is about twice the accuracy claimed by the makers. However, since the most important difficulty is from parasitic electromotive forces, there is every indication that with an all-copper circuit and with lagging to prevent temperature changes at all junctions, the temperature of the thermocouple heads can be determined with this accuracy.

The maintenance of the thermocouple heads at the same temperature as the solution demands further consideration. It is essential to make the thermal conductance from the solution to the heads as large as possible relative to the conductance from the heads to the outside either through the thermocouple wires or through the support and casing. Since the temperature of the solution changes only very slowly, the thermocouple need not respond very quickly to changes of temperature. The problem is thus essentially different from that of a thermocouple for calorimetry.

Our thermocouples are illustrated in Fig. 2. The outside shell is of platinum, 16 cm. long, 13 mm. in diameter and 0.25 mm. thick. This contains a close fitting brass core with eight longitudinal grooves (A) 2.5 mm. deep and 1.5 mm. wide to conduct the wires, and with a band 2.5 mm. deep cut out from B to C to contain the thermocouple heads. The core is also cut down to 5 mm. from D to E and from F to G, and the space filled with a similarly grooved core of hard rubber. The upper rubber core spreads to a head through which the wires pass, which serves to hold the whole in place. The spaces within the platinum tube are filled with paraffin. We found the method of filling under vacuum to be unsatisfactory because of the

³ White, *THIS JOURNAL*, **36**, 2292 (1914).

excessive shrinking of paraffin on solidification. The cores which had been so treated to impregnate the insulation were then dipped in paraffin. When this had cooled the shells were slipped on, shearing off excess paraffin.

The brass core and platinum shell are in intimate contact over a large area and should therefore be at the same temperature. The thermometer head is essentially the brass core from D to the tip, for the thermocouple heads are in a band only 2.5 mm. deep between two metal surfaces and should have the same temperature as the bulk metal.

Any thermal contact except with the solution must be upward through the 5-mm. brass rod, the hard rubber core, the platinum shell and the thermocouple wires. The purpose of the section from E to F is to bring all these, particularly the wires, to the temperature of the solution well above the thermometer head. This section is constructed just as the head itself, and the surface of contact with the solution is twenty-five times the cross-sectional area. The top is in thermal contact with a box in the same way that the bottom is with the thermometer head.

Within the box the wires are bound to a hard rubber rod to prevent any sharp bend. All joints are covered with a thick coating of picein and the box is filled with paraffin. This box is in contact with the cover of the iron vessel, and is therefore at approximately zero degrees. The only contact with the outside is through the ten copper wires which lead to the thermocouple head.

Any remaining uncertainty due to the conduction of heat to the thermocouple may be further reduced by making the calibration under conditions as nearly as possible identical with those of the freezing point measurements. Exact duplication is impossible because no other method gives sufficiently exact temperatures. Our thermocouple was calibrated by inserting in one vessel a four-lead platinum resistance thermometer,⁴ and measuring the freezing point depression of sodium nitrate solutions from one to ten degrees with the conditions, except for the presence of the resistance thermometer and the larger depressions, just as in our freezing point measurements. The vessel

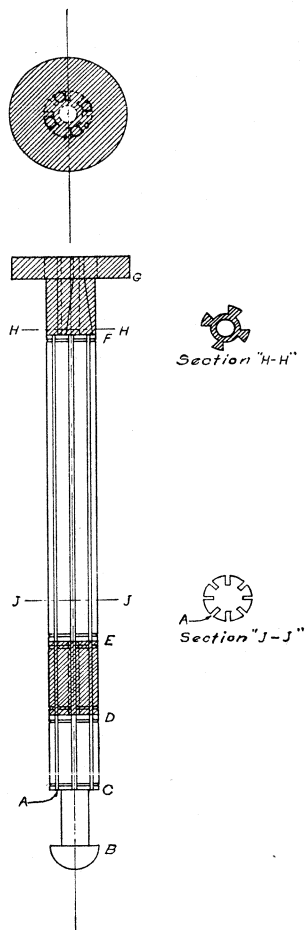

Fig. 2.—Thermocouple core.

⁴ Beattie, Jacobus and Gaines, *Proc. Am. Acad. Arts Sci.*, **66**, 167 (1930).

was somewhat shallow for the resistance thermometer used. With pure water-ice in the vessel and water-ice in the outside thermostat it gave the same ice point as when completely immersed. When the ice and water were removed from the thermostat and the temperature of the iron vessel was 20° , the reading was $+0.016^{\circ}$. With the assumption that this difference is proportional to the difference in temperature between the outer bath and the thermometer head, the platinum resistance temperature was corrected by multiplying by 1.0008.

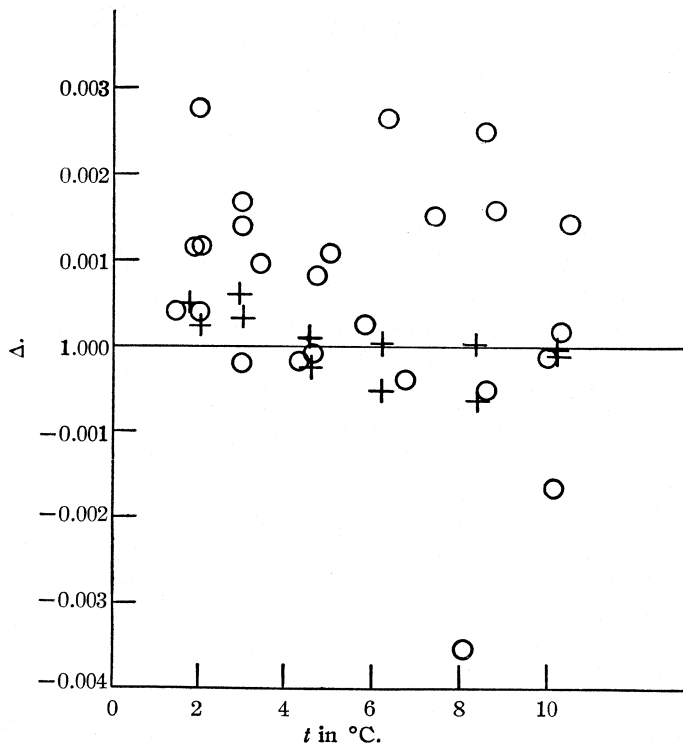

Fig. 3.—Calibration of thermocouple: +, old thermocouple; O, new thermocouple.

The usual method is to calibrate the thermocouple at two points from 20 to 40° each side of the ice-point and to express the results by a quadratic or two-constant exponential equation. The difference between these two forms is not inappreciable over this temperature range, and there is no evidence that the electromotive force follows either within the precision demanded. Our temperatures do depend upon the accuracy of the Callendar formula for the platinum resistance thermometer, which Hening⁵

⁵ Hening, *Ann. Physik*, **40**, 647 (1913); Hening and Heuse, *Z. Physik*, **23**, 105 (1924).

has checked to his accuracy of 0.01° down to -40° , but they can readily be corrected to any other formula if a better one is determined, for they do not depend on the properties of any particular thermocouple.

The relation between the freezing point depression θ and the electromotive force E is expressed by the equation $\theta = 5.385 \times 10^{-4} E + 3.7 \times 10^{-10} E^2$, whose constants were determined by the method of least squares. Figure 3 shows the deviations from this equation of four series of measurements of the thermocouple we used in the freezing point measurements and of two measurements with another couple made from the same reels of wire. For the more concentrated solutions it was necessary to take separate readings on each half of the couple. The fact that no difference could be detected between the readings of the two halves, and the agreement between the readings of the two thermocouples, indicate the homogeneity of the wires. These experiments also showed that the temperature lag of our thermocouple is very nearly the same as that of a "strain-free" platinum resistance thermometer.

VI. The Determination of the Concentration

The concentration is determined by measuring the electrical conductance of the solutions. This method has the advantage that, except for very dilute solutions where the water correction becomes large, the relative error is practically independent of the concentration. Since only 50 cc. of solution is available for rinsing and filling the conductance cells, these must have a small volume. Such cells are not adapted to accurate measurement of the absolute conductance of dilute solutions. Otherwise the cells correspond to the best practice at the time they were built (1927); but today we would have built them with a greater distance between the filling tubes and the connections to the opposite electrode. These deficiencies probably introduce a small error in the determination of the absolute conductance. Since this error should be the same for the standard solutions as for an unknown of the same concentration, it should not affect the determination of the concentration from the conductance.

The cells are of the customary U shape with one arm swollen into the electrode vessel, and have glass stoppers at the ends of the filling tubes. They are made of Jena glass 16 III. The first contains a volume of 9 cc., has a cell constant of 146.892 at 10° , and has heavily platinized electrodes; the second has a volume of 12 cc., a cell constant of 2.5153, and lightly platinized electrodes; the third has a volume of 20 cc., a cell constant of 0.008369, and sand-blasted platinum electrodes. To obtain such a cell constant with so small a volume is rather difficult. The electrodes are three coaxial cylinders, 4 cm. high and 0.7, 1.1 and 1.5 cm. in diameter, held in fixed relative position by three accurately ground quartz rods between each pair. The outer and inner cylinders are connected together as

one electrode so that both surfaces of the middle cylinder are utilized. Figure 4 shows a sketch of this cell.

Since the solutions are saturated with nitrogen at 0° and any excess gas is likely to separate as inconvenient bubbles at the electrodes, it is desirable to measure the conductance of the solutions at as low a temperature as possible.⁶ We attempted an ice-bath and a water-ice-bath, but were not

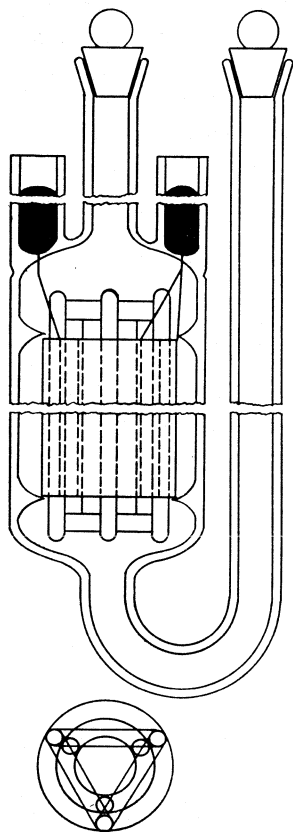

Fig. 4.—Conductivity cell for water.

able to obtain accurate temperature control without too large capacity effects. The thermostat is made of four galvanized iron cans with a heavy wooden cover. The inner can is a twelve liter oil-bath; between this and the second is a 5.1 cm. air space; between the second and third, 15 cm. of water and coarsely chopped ice; and between the third and fourth, 13 cm. of insulation. The thermoregulator is mercury in iron, annular in shape, and with a rapidly operated turbine stirrer on the inside and a bare constantan wire heating coil at the top of the inside so that the oil passes directly from the coil to the inside of the regulator. This type of regulator has the advantage not only of a large-conducting surface well but also that the expansion or contraction of the inside cylinder acts with that of the mercury. The thermostat is regulated to $10.000 \pm 0.002^\circ$ as read on a Beckmann thermometer, frequently checked against a platinum resistance thermometer and showing no variation greater than 0.005° .

The conductances are measured on an equal-arm Wheatstone bridge which differs from that of Jones⁷ only in a little compactness gained through the elimination of the connections for rapid shifting to direct current. The resistances of 1000 ohms and larger are in a specially made, shielded box with 3.8 cm. between the connecting

studs of the ten 1000-ohm coils, and with six 10,000-ohm coils so arranged that when not in use each is entirely disconnected from the system. The resistances are frequently calibrated during the course of the measurements. The source of current is a two-tube push-pull oscillator operated at a frequency of 2700 per second, which seems to be the frequency of greatest

⁶ We have made such measurements accurately though not conveniently in an oil thermostat at 30°.

⁷ Jones and Josephs, *THIS JOURNAL*, 50, 1049 (1928).

sensitivity. The oscillator is five meters distant and connected with shielded wires. The detector system is a two-stage amplifier with telephone.

The first two conductance cells were calibrated with 0.1 *M* potassium chloride, using the specific conductance of Parker and Parker.⁸ To calibrate the third cell, as dilute a solution as possible was measured in the second cell, and then at several frequencies in the third, for the conductance was so great that it varied slightly with the frequency. The resistance was a nearly linear function of the reciprocal of the frequency. The extrapolated value at infinite frequency was used to determine the cell constant. This cell is used only for water, with which there is no detectable variation with the frequency.

A large quantity of concentrated salt solution is prepared and carefully analyzed by a method suitable to the particular salt. More dilute solutions are made by adding weighed amounts of water to weighed amounts of this solution. These solutions are similarly diluted, generally to a tenth, hundredth and thousandth, so that the overlapping of the different series will eliminate any possibility of error from an erroneous weighing. From the resistances of these solutions the specific conductance *L* is determined, and the ratio of the concentration in moles per kilogram of water *M* to *L*. As *L/M* is an approximately linear function of \sqrt{M} , so is *M/L* an approximately linear function of \sqrt{L} . The quantity Δ is determined from the equation

$$\Delta = M/L - A - B \sqrt{L}$$

where *A* and *B* are appropriate constants. Δ is plotted against \sqrt{L} on large sheets of cross-section paper such that 1 mm. corresponds to 0.002–0.02%. A smooth curve is drawn through these points, and more values are measured if necessary to determine the curve. From the specific conductance of a solution of unknown concentration it is a simple matter to determine the concentration from the equation and corresponding curve. The conductance measurements and interpolation appear to be accurate to 0.02–0.03%. The largest error in the determination of the concentration is thus in the analysis of the concentrated solution. This method neglects, of course, any change in conductance due to the presence of the nitrogen. Since the mole fraction of nitrogen is always less than 0.00002, it seems that this neglect is justified.

VII. The Procedure

The water used both for freezing point and conductance measurements is doubly distilled, the second time from alkaline permanganate either in our laboratory still or in a small glass still. Its specific conductance is 0.5–0.7 $\times 10^{-6}$ mhos. It is stored in Jena glass bottles. The ice is selected

⁸ Parker and Parker, *THIS JOURNAL*, **46**, 312 (1924).

from clear pieces of commercial ice from 0.1–1.0 cm. in size, carefully washed with the doubly distilled water.

Two types of run are made: the first for the more dilute solutions, the second for the more concentrated. The two ranges, however, overlap considerably. For the first the freezing point vessels are filled with ice and water and are placed in the apparatus. Two or three hours are allowed for the attainment of equilibrium with mechanical stirring and a rapid stream of nitrogen. The nitrogen is passed through wash-bottles containing (1) potassium hydroxide solution and (2) pure water, but precooling other than that obtained on passage through the entrance tubes was found unnecessary, since no thermal effects from this cause could be noticed even at rates of bubbling much greater than that used. Then the nitrogen is cut down to about forty bubbles a minute, the ice stirred with the hand stirrer, and a temperature reading is taken after three to five minutes. The stirring and subsequent temperature reading are repeated until several concordant results are obtained. This temperature difference, generally about one hundred-thousandth of a degree, is used as a correction to subsequent readings. Then 50 cc. of water is withdrawn with a pipet from one vessel; its conductance is determined and used as the water correction for the salt solutions. The water is replaced by an equal volume of salt solution of appropriate concentration, the rapid stream of nitrogen started again for about thirty minutes, although there is every indication that equilibrium is attained in five to ten minutes. Then the nitrogen stream is cut down, the stirring and temperature reading are repeated, and a 50-cc. sample is withdrawn for analysis. This is repeated for eight to ten points for each run. The mechanical stirring is continuous throughout the run. At the end the conductance of the water in the other vessel is determined as a check against accidental impurities.

For the second method, one vessel is filled with water-ice and the other with ice and the most concentrated salt solution to be used. One or two hours with a rapid stream of nitrogen is allowed for the first attainment of equilibrium. The procedure is otherwise the same except that water is added instead of solution. The conductance of the water in the other vessel is used as the water correction, and the freezing points are so large that any freezing point correction as applied in the first method would be negligible.

VIII. The Presentation of Data

The Lewis and Randall function $j = 1 - \theta/1.858\nu M$ where θ is the freezing point depression, ν the number of ions corresponding to one molecule of salt, and M is again the number of moles per kilogram of water, is very suitable for the presentation of freezing point data.⁹ It is con-

⁹ Lewis and Randall, "Thermodynamics," McGraw-Hill Book Co., Inc., New York, 1923, pp. 286, 347.

venient for thermodynamic calculations, and has the further advantage that a given relative error makes the same change in j at any concentration. It changes too much, however, to permit sufficiently accurate plotting of j itself. We have chosen to retain the other advantages by plotting the deviation function

$$\begin{aligned}\Delta_j &= j - \frac{A\sqrt{\mu}}{1+B\sqrt{\mu}} - C\mu \\ &= j - A\sqrt{\mu} + \frac{AB\mu}{1+B\sqrt{\mu}} - C\mu\end{aligned}$$

where μ is the ionic strength (per kilogram of water) and B and C are empirical constants; A is determined from the theory of Debye and Hückel as 0.3738 times the product of the valence of the ions. From Raoult's law and the value for the heat of fusion of ice, j and Δ_j must be zero when μ is zero. From the theory of Debye and Hückel the tangent of Δ_j plotted against $\sqrt{\mu}$ must be zero when μ is zero. For other concentrations we know only that j , and therefore Δ_j , must be a smooth function of μ . We wish to emphasize that the form of the last two terms does not come from the Debye-Hückel theory and does not even exactly agree with it. We do not pretend that they represent accurately our measurements. They do, however, give a convenient, approximate expression for these measurements. Although j reaches 0.3–0.4, the maximum value of Δ_j is about 0.02. This method permits a very accurate representation of the freezing point measurements even on a small plot, and we will generally use it to smooth our data.

Following Lewis and Randall we will call γ' the activity coefficient—activity divided by the weight molal concentration—calculated from the freezing points with neglect of the generally unknown heat of dilution. Since our temperatures differ from 0° by less than 5°, γ' may be taken as very approximately equal to the activity coefficient at 0°. From the equation of Lewis and Randall we derive

$$\begin{aligned}-\log \gamma' &= 0.4343j + \int_0^M j \alpha \log M - 0.000461 \int_0^{\theta} (1-j) d\theta \\ &= 0.4343(j + C\mu) + \frac{2A}{B} \log(1+B\sqrt{\mu}) + \int_0^M \Delta_j \alpha \log M \\ &\quad - 0.000461 \int_0^{\theta} (1-j) d\theta\end{aligned}$$

The value of the first integral is obtained analytically from $M = 0$ to $M = 0.001$ by assuming that Δ_j is proportional to M . For higher concentration it is determined graphically by measuring the area under the curve of Δ_j plotted against $\log M$. The last integral, which is always very small, is also obtained graphically.

IX. Summary

The description is given of an apparatus and procedure for the measurement of freezing point depressions by the equilibrium method, in which

the solutions are kept saturated with nitrogen at atmospheric pressure, the concentrations are determined from the conductance and the temperatures with a multiple-junction thermocouple.

The method combines many of what seem to us the best features of previous methods with the following new features: the stirring is done by two low-friction valve pumps in each vessel combined with hand stirring of the ice; the thermocouples are constructed so as to give the smallest possible difference between the temperature of the solution and that of the thermal junctions; the thermocouples are calibrated against a platinum resistance thermometer under conditions as nearly as possible the same as those under which they are used.

It is shown that the effect of dissolved gas is approximately proportional to the square of the salt concentration, and is much smaller than had previously been supposed.

A method of smoothing and computing by use of deviation curves is also described.

THE FREEZING POINTS OF AQUEOUS SOLUTIONS. II. POTASSIUM, SODIUM AND LITHIUM NITRATES

BY GEORGE SCATCHARD, S. S. PRENTISS AND P. T. JONES

RECEIVED MARCH 2, 1932

PUBLISHED JULY 6, 1932

It has long been known that the charge and "collision diameter" of the ions are not sufficient to explain quantitatively the properties of electrolyte solutions. One of us¹ has discussed the other factors which must enter, and was able to calculate the properties of aqueous solutions of the alkali halides on the assumption that for noble gas type ions the size of each is the only factor which need be taken into account, though this enters in several ways. To extend and test the theory further it is necessary to have accurate data on more complicated ions. For this reason we have measured the freezing point depressions of potassium, sodium and lithium nitrates in the apparatus and with the procedure described in the previous paper.²

Lithium nitrate was prepared from lithium carbonate and nitric acid. The potassium and sodium salts were manufacturer's c. p. products. All were crystallized three times from doubly distilled water. The concentrated solutions were analyzed by evaporating to dryness in a platinum crucible, adding sulfuric acid, and igniting to constant weight at dull red

¹ Scatchard, *Physik. Z.*, **33**, 22 (1932).

² Scatchard, Jones and Prentiss, Paper I, *THIS JOURNAL*, **54**, 2676 (1932).

heat. A small piece of ammonium carbonate was added to the potassium sulfate before each ignition to convert any acid sulfate to sulfate. All weights were corrected to vacuum. Except for some results obviously in error due to spattering of acid, the mean deviation from the average of three or four determinations was 0.03–0.04%.

The results of the conductance measurements are given in Table I. The first column gives M , the molality (moles per kilogram of water), the second the ratio of M to the specific conductance L , and the third column this ratio minus the smoothed value at the same L . The freezing point results are given in Table II. The first column is the molality, the second j (= one minus the ratio of the freezing point depression to $3.716 M$), and the third the measured j minus the smoothed value. The note gives the temperature difference which corresponds to the third

 Fig. 1.—Conductance curve for potassium nitrate.
 $\Delta = (M/L) - 9.401 - 24.341 \sqrt{L}$.

The smoothed values were obtained from deviation curves made by the methods described in the first paper.² Figures 1 and 2 give illustrative small-scale reproductions of the conductance and freezing point curves for potassium nitrate. The broken line in the latter shows the deviation from the zero line corresponding to two hundred-thousandths of a degree. The crosses give the measurements of Adams.³ The curves extrapolate naturally to a horizontal tangent at zero concentration, that is, to the theoretical limiting law, but the measurements in very dilute solutions are not accurate enough to preclude a change of a few per cent. in the limiting law.

Table III gives at round concentrations the values of j determined from the smooth curves,

³ Adams, THIS JOURNAL, 37, 481 (1915).

and Table IV the values of γ' calculated from the same curves as described in the previous paper.² Both tables give values according to the theoretical limiting law; in no case do we obtain a larger effect. For potassium nitrate the effect is never much smaller even at the highest concentrations. For lithium nitrate, on the other hand, j becomes negative in concentrated solutions.

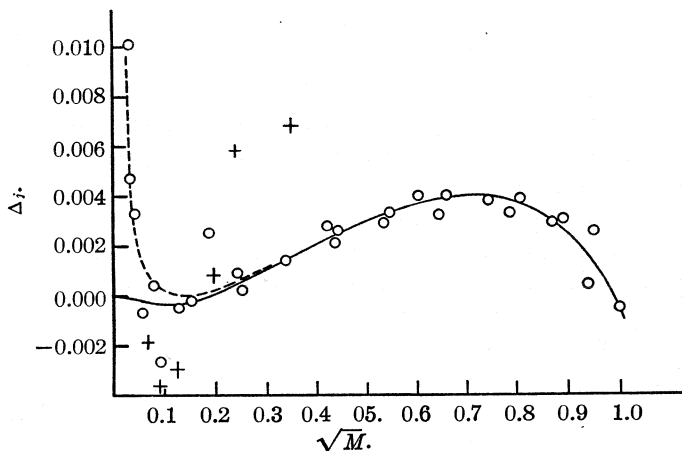

Fig. 2.— Δ_j Values for KNO_3 ; $\Delta_j = j - \frac{0.3738\sqrt{M}}{1 + \sqrt{M}} - 0.1245 M$.

○, our results; +, Adams' results. Broken line represents the deviations for 0.00002°.

The large effects for potassium nitrate have often been attributed to the smallness of the nitrate ion, or to the charge lying near the surface.⁴ The fact that sodium nitrate and lithium nitrate have so much smaller effects is enough to make this explanation highly improbable. From the point of view recently published by one of us,¹ the explanation for the difference between the nitrate and the bromide or iodide ions should lie either in a larger effect of non-ionic forces or in a smaller decrease of the dielectric constant. For the unsymmetrical nitrate ion we should expect both effects to be smaller, in which case the second effect must predominate. Uncertainty concerning the non-ionic forces in solutions containing an unsymmetrical ion make it desirable to leave further theoretical discussion until more salts have been studied. We shall limit ourselves to the fact that our measurements are quantitatively consistent with a size for the nitrate ion which should be expected from the volume of its solutions and from its salting out effects, a size between those of the bromide and iodide ions.

THE FREEZING POINTS OF AQUEOUS SOLUTIONS. III. AMMONIUM CHLORIDE, BROMIDE, IODIDE, NITRATE AND SULFATE

BY GEORGE SCATCHARD AND S. S. PRENTISS

RECEIVED MARCH 2, 1932

PUBLISHED JULY 6, 1932

Another common and interesting ion whose dilute solutions can be studied only by freezing point determinations is the ammonium ion. Since accurate measurements are not available, we have determined the freezing points of ammonium chloride, bromide, iodide, nitrate and sulfate by the method previously described.¹

It might appear that the hydrolysis of ammonium salts should make the interpretation of the measurements complicated. A simple calculation will show, however, that the effect of hydrolysis is well within the experimental error of the freezing point measurements. Given the reaction $\text{NH}_4^+ \rightleftharpoons \text{NH}_3 + \text{H}^+$: at 0° , $K = (\text{NH}_3)(\text{H}^+)/(\text{NH}_4^+) = 10^{-10}$, we can consider that in the hydrolysis H^+ replaces NH_4^+ , so that the net effect is the addition of one ammonia molecule. Since there is no change in the ionic concentration, we may expect the law of mass action to hold well in terms of concentrations, and we can determine the effect on the freezing point accurately enough by assuming ideal solutions. The total number of ions present, neglecting hydrolysis, is twice the number of ammonium ions, so that the fractional increase in the freezing point depression, p , is

$$p = (\text{NH}_3)/2(\text{NH}_4^+) = 0.5 \sqrt{K/(\text{NH}_4^+)} = 0.5 \times 10^{-5}/\sqrt{M}$$

When $M = 0.001$, $p = 16 \times 10^{-5}$ or 0.016% , and it decreases for larger values of M , so it must always be negligible in the range of experimental measurements.

All salts were manufacturer's c. p. or reagent products. The chloride and bromide were recrystallized three times from doubly distilled water; the sulfate was crystallized only twice on account of its great solubility; for the same reason and because of their instability, the iodide and nitrate were not crystallized. The iodide solution was reduced with aluminum amalgam immediately before use. The concentrations of the halide stock solutions were determined gravimetrically as the silver halides; that of the sulfate, gravimetrically as barium sulfate; that of the nitrate was determined by distilling from potassium hydroxide into excess dilute hydrochloric acid and titrating with methyl orange as indicator.² The

¹ Scatchard, Jones and Prentiss, Paper I, *THIS JOURNAL*, **54**, 2676 (1932).

² Dr. P. T. Jones very kindly carried out the determination of the ammonium nitrate concentration.

mean deviation from the average was less than 0.05% for the halides and 0.1% for the sulfate and nitrate. For the chloride and iodide two stock solutions were prepared and analyzed, with excellent agreement between the two series of conductance measurements.

The conductance results are given in Table I and the freezing point results in Table II. The significance of the various symbols is the same

³ Scatchard, Prentiss and Jones, Paper II, *THIS JOURNAL*, **54**, 2690 (1932).

With the ammonium salts there is no question of j approaching the limiting law asymptotically within the range of experimental measurements. The curves all cross the limiting law between 0.005 and 0.02 M . This is illustrated in Fig. 1 by the deviation curve for ammonium bromide, in which the theoretical limiting law is drawn in as a broken line. The existence of this "hump" makes the extrapolation to zero concentration difficult. Since we consider that there is enough evidence from other salts of the general accuracy of the Debye-Hückel limiting law, we have used it, and we have made use of the plot of j/\sqrt{M} to aid in the extrapolation.⁴

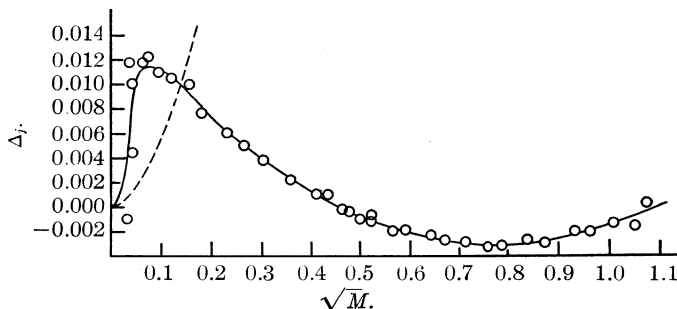

Fig. 1.— Δ_j Values for NH_4Br : $\Delta_j = j - \frac{0.3738 \sqrt{M}}{1 + 1.6 \sqrt{M}} + 0.0349 M$.
Broken line represents the limiting law.

This uncertainty of extrapolation makes no difference of course in the j values in the region where the curve is fixed by the experimental measurements, and would make no difference in the values of γ' if the standard state were chosen in this same region. Since we have chosen zero concentration as the standard state, however, any change in the extrapolation will add the same quantity to each value of $\log \gamma'$, in the region where j is unchanged.

We know of no other uni-univalent salts which show evidence of j values larger than those of the Debye-Hückel limiting law and have therefore searched carefully for some other explanation of our measurements. We have already shown that the effect of hydrolysis would decrease j rather than increase it, and that it is much smaller than the measured increase. If the ammonia formed by hydrolysis were carried away by the stream of nitrogen, the net result would be the replacement of some ammonium salt by the equivalent amount of the corresponding acid. This would not change the freezing point measurement appreciably but would give a much higher conductance and apparent concentration, and so too large a value of j . Although calculations indicated that such an effect must be of a much smaller magnitude than the measured effect, we decided

⁴ Randall and White, *THIS JOURNAL*, **48**, 2514 (1926).

to test it experimentally. A stream of nitrogen was passed through ammonium bromide solution at 0° after passing through potassium bromide solution of about the same concentration. The rate was the same as the rapid flow during the freezing point measurements; the time was 160 minutes, or five times that in a regular run. The initial conductance corresponded to a concentration of $0.017979 M$, the final to $0.017976 M$. The change was -0.017% , again much too small and in the wrong direction to account for our results. An error of more than 1% in analyses that agree to better than 0.1% seems out of the question, and we can find no other reasons to doubt the accuracy of our measurements.

The measurements with ammonium iodide are less accurate because of the instability of this salt. The data definitely indicate a smaller "hump" than for the bromide, and we believe that our extrapolation with a much smaller "hump" best represents the measurements.

Fajans and Karagunis⁵ have noted that the freezing point curves for the alkali halides all belong to a consistent family in the sense that no curve appears to cross any other. On the other hand, the curves for ammonium chloride and bromide cross each other and each appears to cross the curve of the corresponding potassium salt, and presumably those of the rubidium and cesium salts. It must be admitted, however, that only for potassium chloride have we accurate enough measurements to be sure that there is not a "hump" of the same order of magnitude as for the ammonium salts. For the nitrate the evidence is much better because we have for comparison our measurements on the alkali nitrate made in the same apparatus. We have already noted that we obtained in no case a j value larger than the limiting law. Our measurements should be accurate enough to ensure that our curves do not cross the limiting law above $0.005 M$. For ammonium nitrate, on the other hand, the curve crosses the limiting law between 0.01 and $0.02 M$ and shows a hump about the same size as that of ammonium chloride. The ammonium and potassium nitrate curves also cross each other at about $0.04 M$.

There seems little doubt that there is some factor operative with the ammonium salts which is negligible with other uni-univalent salts. Its effect is similar to that of association, which proves only that it is operative only when the ions are close together, except that it is swamped out surprisingly soon by the factors which tend to increase the activity coefficient. We do not believe that it should be attributed to a small value of the "collision diameter," a ,⁶ because the value demanded would be improbably small, and smaller for the bromide than for the chloride. For the uni-

bivalent sulfate a small collision diameter might explain part of the effect, but there is no reason to suppose that the factor which affects the halides is not also operative here. We are unable to say what this factor is.

THE SPECIFIC HEATS OF FIVE ORGANIC LIQUIDS FROM THEIR ADIABATIC TEMPERATURE-PRESSURE COEFFICIENTS

BY WILLIAM T. RICHARDS AND JOHN H. WALLACE, JR.

RECEIVED MARCH 5, 1932

PUBLISHED JULY 6, 1932

Introduction

Although the specific heats of liquids have been measured for nearly two centuries, there remains a distressing lack of agreement in the immense collection of numbers which have been reported to represent them. Because of the complexity of the correction factors which must be applied to the results of calorimetric determinations, it is not uncommon to find a divergence of ten per cent. between two investigations, although the estimated error of each is far below this value. While it is not at present possible to interpret the specific heats of most liquids even to this approximation, accurate knowledge of so fundamental a property must be ultimately both necessary and valuable. Any method other than the calorimetric should, therefore, be considered if it appears to offer a practical alternative.

From the first and second laws of thermodynamics, without further assumption, it follows that the adiabatic temperature-pressure coefficient of a system of heat capacity at constant pressure C_p is given by the expression

$$\left(\frac{\partial T}{\partial p}\right)_s = \frac{T}{C_p} \left(\frac{\partial v}{\partial T}\right)_p$$

where T , p , s and v represent temperature, pressure, entropy and volume, respectively. Oersted¹ appears to have been the first to sense this relationship qualitatively, for he subjected water to a sudden pressure and attempted to measure a rise in its temperature. The formal derivation was carried out by Joule,² who experimentally proved the second law of thermodynamics by measuring the heat capacity, coefficient of thermal expansion and temperature-pressure coefficient of water and of fish oil. Several other investigations have subsequently dealt with the last of these quantities for solids, liquids and gases, although the majority do not lend themselves even to approximate calculation of specific heats, owing to the magnitude of the pressures employed. Creelman and Crocket,³

¹ Oersted, *Ann. chim. phys.*, **2**, 22, 192 (1823).

² Joule, *Phil. Mag.*, **17**, 364 (1859).

³ Creelman and Crocket, *Proc. Roy. Soc. Edinburgh*, **13**, 311 (1885).

Burton and Marshall,⁴ and Pushkin and Grebenshikov,⁵ for example, examined several liquids in this way, but used pressures always in excess of 300 atmospheres. Barus⁶ calculated the specific heat of water from interferometric data using the relationship derived by Joule. Finally, Dixon and Rodebush,⁷ following the republication of the equation by Lewis and Randall,⁸ used it to obtain the heat capacities of several liquid metals, and showed that an accuracy of 2% was attainable. Although it has several times been suggested that experiments of this kind are suitable for the determination of the specific heats of organic liquids, no searching test of the method appears hitherto to have been undertaken.

Experimental Method

It follows from the equation above that measurements of temperature and pressure suffice, if made under securely adiabatic conditions, to determine without correction the specific heat of a liquid, provided that its coefficient of thermal expansion is known. This may safely be taken from the literature, as it is by far the most readily measured of the various characteristic coefficients.

Of the several types of apparatus which suggest themselves for such an investigation the simplest was chosen. This consisted of a Geneva Society pump which was connected by means of a suitable valve system to a Bourdon type gage and to a pressure bomb of conventional design. The system was filled with castor oil, the connections and valves being of 1 cm. internal diameter to secure a rapid response to changes in pressure. The bomb contained a cell of the construction illustrated in Fig. 1. The wires from the copper-constantan thermoelement in the cell were passed out of the bomb through a hard rubber plug and suitable insulating tubing, leaks being effectively prevented by tightening the plug around the wires with a metal collar and gland nut. The other junction of the thermoelement system was immersed in a Dewar flask in the thermostat which contained the pressure bomb. Thus a zero potential difference was secured at the start of each measurement. The change of temperature following a change of pressure was ascertained by calibration of the thermoelement system. A White double potentiometer, one branch of which was connected to a control pair thermocouples outside the bath to indicate stray currents in the electrical system, was used to measure the change of potential corresponding to a given temperature difference. The standard practice with respect to shielding, insulation and prevention of stray currents due to bimetallic junctions in the circuit or motion of wires in the earth's magnetic field was observed. The precision of the results will be discussed below.

After calibrating the thermoelements and filling the cell with a suitable liquid, measurements were obtained by a uniform procedure. A difference of pressure was first established and, after temperature equilibrium had been reached, the reading of the gage was recorded, and the absence of stray currents in the galvanometer circuit con-

⁸ Lewis and Randall, "Thermodynamics," The McGraw-Hill Book Co., Inc., New York, 1923, p. 137.

firmed. An approximate calculation of the temperature drop to be expected from the release of the pressure was then made, and the potentiometer set with the circuit open to balance the corresponding potential difference. The pressure was then reduced to atmospheric by opening a valve, and the galvanometer circuit closed. Any difference between the calculated and the observed deflection was added to the potentiometer setting on the basis of a previous calibration of the galvanometer scale in microvolts per cm., and the result converted into temperature rise in degrees centigrade per bar (or per dyne $\times 10^6$).

Accuracy of Pressure Measurements.—The gage employed was calibrated in divisions of 0.33 atm. to 0.5% accuracy between 15 and 50 atm. The accuracy of the calibration was maintained by frequent checks against an absolute piston gage. The Bourdon gage method of determining pressures, although open to criticism on the ground that it does not permit the highest possible precision, was found both practical and accurate over the necessary range. Gages of several other types were tested and abandoned because of clumsiness, hysteresis or other serious defects.

Temperature.—The absolute temperature of the pressure bomb and the constant temperature side of the thermoelement pair was fixed as desired to $\pm 0.005^\circ$ by a conventional water thermostat. Owing to the thermal inertia of the bomb and its contents, and of the Dewar flask in which the constant temperature junction was fixed, fluctuations about the mean temperature in the bath were imperceptible in the electrical system. The value of the absolute temperature was read from a Bureau of Standards calibrated thermometer to 0.02° .

The difference between the temperature of the liquid before and after a measured change of pressure was a determining factor in the accuracy with which the specific heat could be calculated and was, therefore, given careful attention. Obviously the heat capacity of the junction used must be small enough so that it does not measurably alter the temperature assumed by the liquid after the adiabatic expansion. Also, the thermocouple must reach the temperature of the liquid within a few seconds after the change of pressure in order that the gradual return of the temperature of the liquid to that of the bath shall not measurably lower the observed temperature difference. Finally, since the adiabatic temperature-pressure coefficients of the liquid and of the glass walls into which the thermocouple is sealed are not identical, the length and surface of wire between the walls and the junction must be great enough in relation to the thermal conductivity of the wire to prevent the temperature of the walls from influencing that of the junction.

The optimum dimensions for wires and cell are, therefore, difficult if not impossible to calculate. They were ascertained experimentally by photographing the response of the galvanometer to the potential generated by a release of pressure and comparing this to its response to an instantaneous difference of potential of like magnitude. As expected, the two were not comparable if the thermoelement was too coarse, too near the

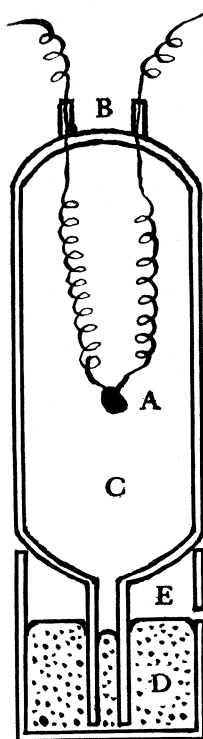

Fig. 1.—Cell for the measurement of the adiabatic temperature-pressure coefficient. The flattened thermoelement A is led out through the glass walls at B. The cell is entirely filled with liquid C, and mercury D employed to transmit the pressure impulse from the castor oil E.

glass walls, or immersed in too small a volume of liquid. In the experimental arrangement finally adopted and illustrated in Fig. 1, the response of the galvanometer to the release of pressure was as rapid as that to an instantaneous difference of potential, the maximum deflection being reached in both cases at the end of the period (5.4 sec.) of the critically damped galvanometer. The characteristic time-deflection curve before the maximum was almost identical in the two cases. The maximum deflection of the galvanometer persisted without measurable change for more than fifteen seconds after the critical period of the galvanometer had elapsed, showing that the slow return of the liquid to the temperature of the bath did not affect the accuracy of the observed temperature difference within a time interval easily sufficient to make the necessary measurements. This behavior is considered adequate proof that the release of the pressure and the response of the thermocouple were attained within a sufficiently short period, and that, therefore, the maximum deflection represented, except for an extremely slight correction due to work done on the galvanometer, the actual adiabatic temperature change corresponding to a given pressure.

The several thermoelements used were calibrated individually in exactly the temperature range for which they were employed by the usual method of immersing one junction in ice water and the other in a bath at the desired temperature and measuring potentiometrically the resulting difference in potential. All thermoelements used gave concordant potentials under similar conditions, the resulting temperature-potential function being essentially in agreement with that of Adams.⁹ The accuracy of the potentiometric system and the Beckmann thermometer employed defined the accuracy of the resulting calibration: the potential could be read to ± 0.05 microvolt, which gave an accuracy of $\pm 0.001^\circ$ to any single observation.

It may, therefore, be stated, to summarize the accuracy of the measurements, that the estimated absolute error of pressure was 0.5%, and of temperature 0.2% in the range used for investigation. It should be pointed out, however, that both pressure and temperature errors were apparently entirely random, and were, therefore, greatly reduced by multiplication of observations.

Purification of Materials

Benzene.—Starting with a guaranteed reagent grade the liquid was washed with sulfuric acid until no further darkening occurred, then repeatedly with dilute sodium hydroxide, and finally with water. It was then twice fractionally crystallized, dried with calcium chloride, and refluxed over phosphorus pentoxide. Finally it was twice fractionated, the second time from sodium wire. For the sample used the corrected b. p. was $80.20 \pm 0.05^\circ$, $n_D^{20} 1.50132$.

Toluene.—This was similarly washed with sulfuric acid, sodium hydroxide and water. It was dried with calcium chloride and refluxed with phosphorus pentoxide. Finally it was twice fractionated, the second time from sodium wire. For the sample used corrected b. p. was $110.50 \pm 0.05^\circ$, $n_D^{20} 1.49630$.

Carbon Tetrachloride.—A reagent grade was refluxed over mercury, washed with sulfuric acid, sodium hydroxide and water, dried with fused calcium chloride, and twice fractionated from freshly fused calcium chloride. For the sample used the corrected b. p. was $76.50 \pm 0.05^\circ$, $n_D^{20} 1.46032$.

Chloroform.—The accepted method of purification was found unsatisfactory for this substance owing to its partial oxidation to phosgene by washing with sulfuric acid, sodium hydroxide and water. Each sample was, therefore, merely fractionated from fresh fused calcium chloride, its boiling range and index of refraction being thus brought within the desired limits. Three samples from widely divergent sources were so pre-

⁹ Adams, "International Critical Tables," Vol. I, p. 57.

pared. They had boiling points and indices of refraction, respectively, of $61.15 \pm 0.05^\circ$, 1.44647; $61.15 \pm 0.05^\circ$, 1.44607; and $61.20 \pm 0.05^\circ$, 1.44598. Since no reason to distinguish between them was apparent, the results obtained with them are combined in the tables given below.

Normal Heptane.—This substance was obtained in a high state of purity from the Ethyl Gasoline Corporation. It was dried by fractionating from sodium wire. For the sample used the corrected b. p. was $98.35 \pm 0.05^\circ$, $n_D^{20} 1.38770$.

Numerical Constants.—Since the measurements reported below demonstrate that the quantity $(\partial T/\partial p)_s$ is effectively independent of pressure over a range of 0–30 atm., it follows that C_p is also sensibly constant over this range, and Equation 1 may be written in the form

$$C_p = \frac{\Delta p}{\Delta T} \left(\frac{\partial v}{\partial T} \right)_p \frac{T}{0.4185}$$

where pressure is now in bars, C_p in 15° calories per gram per degree (15° calorie = 4.185×10^7 ergs) and T in $^\circ\text{K}$. The values for $(\partial v/\partial T)_p$ were obtained in the extensive form by differentiation of the empirical density–temperature equations given in the “International Critical Tables.” This coefficient must not, of course, be confused with the thermal coefficient of expansion, usually designated by α , which is expressed intensively. The volume–temperature differentials were chosen from a single source for the sake of uniformity. If they are subsequently revised a corresponding revision of the calculated specific heat may readily be made.

Typical Determination.—The reproducibility of measurements and

distribution of errors is best illustrated by quoting one series of observations which, in combination with a similar determination with a different thermoelement pair, led to the value for the specific heat of benzene at 40°. The concordance of experimental values was uniform in all determinations, and the results quoted are entirely typical. It will be noted that the temperature-pressure coefficient is sensibly independent of pressure over the observed range. The method is not, however, dependent upon this condition, for a correct value for the specific heat at atmospheric pressure may be obtained by extrapolation if necessary.

Summary of Results

Table II gives in condensed form the results obtained experimentally. Each value for the specific heat is determined by a set of measurements like that quoted in Table I, consisting of from 20 to 30 separate values. The calculated probable error of each value is always far below 0.1%. It has not been recorded, since systematic errors evidently may enter to at least this extent. At least two separate determinations of about twenty observations were made for any particular substance and temperature, always in different cells with different individually calibrated thermoelements.

Discussion

The purpose of this investigation was entirely experimental, and no theoretical discussion will be attempted.

It is believed that the determinations quoted above are sufficiently accurate to fix the values of the various specific heats to better than 0.5%. Since no correction factors were necessary and the conditions of the measurements were thermodynamically satisfactory, it is difficult to estimate the systematic error. The agreement of the specific heats obtained with those of previous investigators is on the whole satisfactory, as Table III demonstrates. This is not the place to undertake a detailed analysis of such divergencies as occur.¹⁰

¹⁰ A tabulation of all the first thermodynamic coefficients of the liquids here investigated from various sources is being compiled for separate publication by one of us.

Apart from calorimetric determinations, which show too great deviations among themselves to provide adequate comparison without attributing undue importance to a single investigation, only one direct check seems at present possible. The recent results of Shiba on the adiabatic and isothermal compressibilities¹¹ of benzene, toluene, chloroform, and carbon tetrachloride permit, with a knowledge of the coefficient of expansion, the calculation of the adiabatic temperature-pressure coefficient by the relationship

$$\frac{\left(\frac{\partial v}{\partial P}\right)_s - \left(\frac{\partial v}{\partial P}\right)_T}{\left(\frac{\partial v}{\partial T}\right)_P} = \left(\frac{\partial T}{\partial P}\right)_s$$

TABLE IV

COMPARISON OF THE MEASURED ADIABATIC TEMPERATURE-PRESSURE COEFFICIENT WITH THAT CALCULATED FROM THE RESULTS OF SHIBA

	Benzene			Toluene	
Temp., °C.	25	30	35	25	30
(dT/dP) _s exptl.	0.02449	0.02503	0.02560	0.02231	0.02274
(dT/dP) _s calcd.	.02376	.02431	.02474	.02093	.02112
	Carbon Tetrachloride			Chloroform	
Temp., °C.	25	30		25	30
(dT/dP) _s exptl.	0.02755	0.02836		0.02768	0.02857
(dT/dP) _s calcd.	.02671	.02718		.02672	.02785

Table IV illustrates the agreement between the values calculated by this means and those measured above. It may be seen that the agreement is far from satisfactory. Since the discordance is even greater if the previously accepted values for the specific heat are used to calculate the adiabatic temperature-pressure coefficient, it can hardly be attributed to errors in the measurements here reported. It seems probable, since Shiba's values for the adiabatic compressibility are in fair accord with those calculated from the velocity of sound, that the responsibility for this deviation must be attributed to his isothermal measurements, but the exact reason for it is not apparent from his communication.

Summary

The adiabatic temperature-pressure coefficients for 15 to 30 atmospheres are reported between 20 and 50° for benzene and toluene and between 20 and 40° for carbon tetrachloride, chloroform and *n*-heptane. From these are calculated, using thermal expansion coefficients derived from the "International Critical Tables," the corresponding specific heats. Since the calculated probable errors of these determinations are always below 0.1% and since it is not necessary to apply correction factors to the observed temperature and pressure differences, it is believed that they fix

¹¹ Shiba. *Sci. Papers Inst. Phys. Chem. Res. (Tokyo)*, **16**, 205 (1931).

the specific heats of the various liquids to better than 0.5%. The specific heats measured by previous investigators, although their mutual discordance makes a comparison difficult, are in fair agreement with those here reported.

SOLID CADMIUM AMALGAMS. AN X-RAY PROOF OF THE COMPOUND Cd_3Hg

BY NELSON W. TAYLOR

RECEIVED MARCH 7, 1932

PUBLISHED JULY 6, 1932

The possible existence of a compound between cadmium and mercury has been a question of interest for many years. The evidence has been conflicting. If the thermodynamic activity of cadmium is defined as unity for the pure liquid, it is found for liquid cadmium amalgams that the ratio of activity to mole fraction for cadmium is less than unity over the whole concentration range. The same is true of mercury when the activity of pure liquid mercury is taken as unity. Hildebrand, Foster and Beebe¹ found that the vapor pressures of mercury over liquid cadmium amalgams at 323° were less than corresponded to the mole fraction; and Richards and Forbes,² who measured concentration cells of cadmium amalgams at room temperature, obtained electromotive force values too large. Both of these criteria indicate an affinity between the two components, which should be manifested in complex or compound formation.³

On the other hand, microscopic or thermal analyses of solid alloys of cadmium with mercury have hitherto not brought to light any compound. The constitution diagram, based largely on the work of Bijl and of Mehl and Barrett,⁴ shows three solid solutions but no compounds. The stability of any compound which may exist should certainly be greater in the solid than in the liquid state. As the evidence from electromotive force and vapor pressure data is quite trustworthy it was a matter of considerable interest to make an x-ray study of certain amalgam compositions which had not been thoroughly investigated.

R. F. Mehl⁵ made x-ray patterns of ten alloys of Cd-Hg and reported that those containing more than 60 weight per cent. (73 atomic per cent.)

of cadmium showed an hexagonal close-packed lattice of axial ratio 1.89, while those containing 23 to 50 weight per cent. (64 atomic per cent.) of cadmium were face-centered tetragonal, with axial ratio 0.52. Since McKeehan and Coffi⁶ and a number of subsequent workers had shown that pure mercury possessed a rhombohedral lattice, $a = 3.00$, $\alpha = 70^\circ 32'$, R. F. Mehl and C. S. Barrett examined the structure of the solid solutions terminal to pure mercury and found that up to 3.5 atomic per cent. of cadmium, the rhombohedral structure persisted. Their work extended the range of face-centered tetragonal solid solutions down to 12 atomic per cent. of cadmium. The range from 3.5 to 12 was two-phase.

Experimental Part

In order to test the possibility of a new crystal phase in the immediate vicinity of a possible compound Cd_3Hg (75 atomic per cent. of cadmium) three alloys were prepared containing 70, 75 and 80.8 atomic per cent. of cadmium, respectively. These alloys were weighed from pure metals, sealed in Pyrex tubes which were then evacuated; they were melted and held as liquids at $285\text{--}295^\circ$ for four hours. They were then cooled quickly to avoid segregation, and the solids tempered at 145 to 149° for twenty-eight hours. The following day filings were made and these filings sealed up and evacuated as before, and tempered at $145\text{--}149^\circ$ for forty-four hours. This treatment avoids oxidation or volatilization and ensures the formation of the most stable crystal phase at the annealing temperature.⁷

Powder x-ray diagrams of these three alloys, each mixed with a small quantity of finely ground sodium chloride were made using a Siegbahn type metal x-ray tube⁸ with copper target, and a new type of camera developed by the writer.⁹ On account of the rather high absorption coefficient of mercury for CuK radiation about seven hours exposure was required. Mehl, using a larger camera with the more penetrating MoK radiation, required about twenty-four hours for his exposures. A film was also made on filings of pure cadmium mixed with sodium chloride.

The lines on the films forming the sodium chloride pattern were easily identified. Using the known lattice constant $a = 5.628 \text{ \AA.}$ for sodium chloride, the true angles of reflection 2θ were calculated¹⁰ from the Bragg equation

$$N\lambda = 2d \sin \theta$$

and a plot was made for each film of observed 2θ versus correction (difference between true and observed 2θ). These calibration curves were then used in getting the correct 2θ values for all the lines due to the alloys

⁶ McKeehan and Coffi, *Phys. Rev.*, **19**, 444 (1922).

⁷ The alloys were kindly prepared by Dr. B. E. Lauer.

106.70	.6437	.6453	211	m
108.05	.6549	.6590	204	w
113.35	.6982	.7017	212	m

Values of $\sin^2 \theta$ (calcd.) for the CuK_α lines are obtained from the quadratic equation for an hexagonal lattice

$$\begin{aligned}\sin^2 \theta &= 0.0895 (h^2 + hk + k^2) + 0.0188 l^2 \\ &= \frac{\lambda^2}{3a^2} (h^2 + hk + k^2) + \frac{\lambda^2}{4c^2} l^2\end{aligned}$$

using $\lambda = 1.539 \text{ \AA.}$, $a = 2.97 \text{ \AA.}$, $c = 5.61 \text{ \AA.}$, $c/a = 1.89$. The good agreement (average deviation = 0.3%) of calculated and observed values of $\sin^2 \theta$ shows that these lattice constants a and c are correct within 0.2%.

Since the wave lengths of CuK_α and CuK_β lines are 1.539 and 1.388 \AA. , the ratio of $\sin^2 \theta$ for these two lines reflected from a given plane is $(1.539)^2 / (1.388)^2 = 1.229$. The CuK_β lines may be readily identified by use of this constant. Thus for the 104 plane, $0.3905/1.229 = 0.3177$. Observed $\sin^2 \theta = 0.3184$.

The values of $\sin^2 \theta$ (calcd.) for the CuK_α lines were obtained from the relation

$$\sin^2 \theta = 0.0893(h^2 + hk + k^2) + 0.01846(l^2)$$

Setting $\lambda^2/3a^2 = 0.0893$ and $\lambda^2/4c^2 = 0.01846$ gives $a = 2.963 \pm 0.005 \text{ \AA.}$, $c = 5.645 \pm 0.008 \text{ \AA.}$, $c/a = 1.91$.

It may be seen that the 80.8 atomic per cent. cadmium amalgam has the same hexagonal close-packed structure as pure cadmium, with a slightly greater axial ratio. For the solid solution $c/a = 1.91$, for pure cadmium $c/a = 1.89$. This conclusion checks the results of Mehl, and also of C. v.

Simson,¹¹ who found the hexagonal structure in an amalgam containing 82 atomic per cent. cadmium.

The Tetragonal Solid Solution.—An excellent pattern of the face centered tetragonal solid solution is given by C. v. Simson for an amalgam containing 50 atomic per cent. cadmium. She tabulates values of the line position 1 on the film for a camera of radius 2.47 cm. From this one may calculate θ in the Bragg equation $n\lambda = 2d \sin \theta$. Using $\lambda = 1.539 \text{ \AA.}$ for

¹¹ Simson, *Z. physik. Chem.*, **109**, 197 (1924).

$\text{CuK}\alpha$, I have computed the corresponding values of $\sin^2 \theta$ and listed them together with the indices hkl . Table III contains this material.

Values of $\sin^2 \theta$ (calcd.) are obtained from the quadratic equation for a tetragonal lattice

$$\sin^2 \theta (\text{calcd.}) = 0.01917(h^2 + k^2) + 0.07124 l^2$$

Setting $\lambda^2/4a^2 = 0.01917$ and $\lambda^2/4c^2 = 0.07124$ give

$$a = 5.558 \pm 0.006 \text{ \AA.}, c = 2.883 \pm 0.003 \text{ \AA.}, c/a = 0.519$$

The agreement between observed and calculated values of $\sin^2 \theta$ is satisfactory so that one may have confidence in the lattice constants a and c . Mehl's lattice constants for the tetragonal solid solution are $a = 5.570 \text{ \AA.}$, $c = 2.896 \text{ \AA.}$, $c/a = 0.520$. These values are based on averages of a number of patterns representing alloys of different composition.

Amalgams Containing 70 and 75% Cadmium. New Structure.—Table IV presents $\sin^2 \theta$ values from films No. 93 and No. 92, which were made from the 70 and 75% amalgams, respectively. The fifth column gives the average or in some cases the best value, giving consideration to the intensities of the lines. The last two columns give calculated values of $\sin^2 \theta$ and the corresponding indices of the reflecting planes.

The agreement between observed and calculated value of $\sin^2 \theta$ is satisfactory. For the CuK_α lines, $\sin^2 \theta$ (calcd.) = $0.002168(h^2 + k^2) + 0.00405l^2$. The lattice is body-centered tetragonal with the constants $a = 16.53 \text{ \AA.} \pm 0.3\%$, $c = 12.09 \pm 0.3\% \text{ \AA.}$, axial ratio $c/a = 0.732$. Attempts were made to derive a structure with smaller lattice constants but without success. The high order of the reflections may possibly be a factor in giving lines of low intensity.

The patterns of films 92 and 93 are practically identical. The lines on No. 92 (75% Cd) are more intense because of the lower mercury content,

mercury being a very good absorber for CuK radiation. This accounts also for certain very weak lines on film No. 92 not appearing on No. 93 or being too faint to measure accurately. A few lines possibly belong to the hexagonal or tetragonal solid solution lattices (*cf.* Tables II and III) but this is not necessarily the case. They may be merely coincidences. If the period of tempering was not quite long enough, traces of the hexagonal or of the other tetragonal solid phase might persist. However, the great abundance of lines which are not to be ascribed to these structures show that a new crystal phase is present. The range of stability of this structure includes 70 and 75 atomic per cent. cadmium and may be a slightly wider range but does not reach 80.8% (at 147°), for the alloy of this composition annealed at the same temperature ($145\text{--}149^\circ$) as the 70 and 75% alloys shows only an hexagonal pattern. Mehl examined an alloy of 60.1 weight per cent. cadmium (73 atomic per cent. Cd) which had been tempered for 120 hours at 170° . His pattern shows lines of the hexagonal lattice only. The discrepancy between his results and mine may lie in the tempering conditions. Annealing the alloy at the lower temperature would favor compound formation. It is noteworthy that whereas according to Bijl's¹² melting point diagram, a 73 atomic per cent. of cadmium alloy should be inhomogeneous, Mehl found only the pattern of the hexagonal (α) solid solution and no tetragonal (ω). The Bijl diagram is in need of revision in this composition region, especially with regard to solid-solid equilibria.

There are other cases known where certain solid phases do not appear if the annealing temperature is too high. Thus alloys of copper with gold show two compounds, AuCu and AuCu₃ if annealed below about 400° , but these phases disappear in fifteen minutes if annealed at $400\text{--}420^\circ$ and quenched in water.¹³ A comparison of the lattice constants of the new structure with those of the body-centered tetragonal solid solution (50 atomic per cent. cadmium) is instructive. For the 50% Cd alloy

$$\begin{aligned}a_1 &= 3.932 \text{ \AA.}, \text{ Mehl; } a_1 = 3.930, \text{ Simson} \\c_1 &= 2.896 \text{ \AA.}, \text{ Mehl; } c_1 = 2.883, \text{ Simson} \\c_1/a_1 &= 0.74\end{aligned}$$

These values are computed from the constants of the face-centered lattice by dividing the length of the a axis by $\sqrt{2}$. For the 70 and 75% Cd alloys

$$\begin{aligned}a_2 &= 16.53 \text{ \AA.} \\c_2 &= 12.09 \text{ \AA.} \\c_2/a_2 &= 0.73\end{aligned}$$

$$\text{Thus, } a_2/a_1 = 2.97 \sqrt{2} \text{ and } c_2/c_1 = 2.96 \sqrt{2}$$

Each side of the new unit cell is roughly $3 \sqrt{2}$ times that of the smaller unit. The volume of the new cell is $54 \sqrt{2}$ larger than that of the smaller

¹² Bijl, Ref. 4.

¹³ G. Borelius, C. H. Johanssen and J. O. Linde, *Ann. Physik*, **86**, 291 (1928).

cell. Since the latter contains 2 atoms, the new cell must contain 152 atoms. The observed density for the 75% Cd alloy is 10.12 g. per cc. Taking a mean atomic weight of 134.5, the number of atoms per unit cell is computed to be $150.4 \pm 1\%$. Such a cell containing 152 atoms would have 38 Cd_3Hg in the case of the 75% Cd alloy. The complexity of the atomic arrangement in the cell is probably the reason why long annealing at not too high a temperature is necessary to bring about proper orientation and distribution of the atoms.

Alloy systems furnish other examples of large cells. Thus the γ -structure in Cu-Sn alloys has a lattice constant $a = 17.91 \text{ \AA}$. and contains 416 atoms per unit cell.¹⁴ It is possible that the large complex cell found in the Cd-Hg series is an example of a "superstructure" described by Westgren.

Summary

x-Ray examination of solid cadmium amalgams, which had been annealed *in vacuo* at 147° for seventy-two hours, has demonstrated the existence of a new crystal phase, body-centered tetragonal, with lattice constants $a = 16.53 \text{ \AA}$., $c = 12.09 \text{ \AA}$., axial ratio $c/a = 0.73$. The lattice constants are probably correct to 0.3%. The structure evidently contains 152 atoms or 38 molecules of Cd_3Hg . Its composition range includes 70 and 75 atomic per cent. cadmium, and may be slightly wider. It may be regarded as Cd_3Hg or as a solid solution of Hg in Cd_3Hg . The structure is apparently derived from the ω type of solid solutions which characterize alloys poorer in cadmium (down to 12 atomic per cent.).

Confirmation of the hexagonal close-packed structures of pure cadmium and of an 80.8 atomic per cent. of cadmium amalgam has also been obtained.

The bearing of these results on the thermodynamic behavior of cadmium amalgams has been noted.

A SERIES OF SIMPLE BASIC INDICATORS. I. THE ACIDITY FUNCTIONS OF MIXTURES OF SULFURIC AND PERCHLORIC ACIDS WITH WATER¹

BY LOUIS P. HAMMETT AND ALDEN J. DEYRUP²

RECEIVED MARCH 9, 1932

PUBLISHED JULY 6, 1932

Recent work, especially that of Hantzsch and of Hall and Conant, has demonstrated that we have to deal in ordinary chemical systems with a range of acidity much wider than is comprised in the field of dilute aqueous solutions. It has not however given us any single experimental criterion of acidity or any general method of measuring it. When, for instance, the acidity of a solution is determined by means of a simple basic indicator, the thing measured really is the tendency of the acids present, under the conditions prevailing, to transfer hydrogen ion to a neutral organic molecule, the indicator base, converting it to a positive ion. It has been pointed out³ that such a measure of acidity is not in general the same as that given by an acid indicator, and that neither is a measure of the theoretical concept of hydrogen ion activity.⁴

The "acidity in terms of a basic indicator" is, nevertheless, a most significant quantity, certainly for the equilibrium in any reaction in which hydrogen ion is added to a neutral molecule, and probably for the interpretation of cases of acid catalysis in which the first step is addition of hydrogen ion to a neutral substrate. We have now given it a definite formulation in terms of an acidity function, H_0 , and have developed a series of indicators by means of which this function can be measured for any solution whose acidity lies between that of dilute aqueous solutions and that of 100% sulfuric acid.

The possibility of measuring such an acidity function, of applying it to other properties of a solution than the indicator effects which serve to measure it and of determining the relative basicities of indicators by the "step method" which we have used, all depend upon one fundamental assumption. This is that the relative strength of two bases of the same charge type is independent of the medium in which they are compared. The approximate validity of this rule is evidenced by a number of in-

¹ This article is based upon part of a dissertation submitted by Alden J. Deyrup to the Faculty of Pure Science of Columbia University in partial fulfillment of the requirements for the degree of Doctor of Philosophy, March, 1932.

² Gottsberger Fellow, 1931-1932.

³ Hammett, *THIS JOURNAL*, **50**, 2666 (1928).

⁴ This conclusion is emphasized by the demonstration by Taylor, *J. Phys. Chem.*, **31**, 1478 (1927), and by Guggenheim, *ibid.*, **33**, 842 (1929); **34**, 1540, 1758 (1930), of the theoretical as well as the practical impossibility of the determination of individual ion activities.

vestigations;⁵ we shall discuss its precision later in the light of our own results.

We define a simple basic indicator as a non-ionized or neutral substance capable of adding one hydrogen ion per molecule without any complicating further reactions⁶ and in such a way that a color change is determined by the extent of the reaction.⁷ We further define the strength of such an indicator or of any other monoacid base by the function

$$pK' = -\log \frac{a_H + a_B}{a_{BH^+}} = -\log \frac{c_H + c_B}{c_{BH^+}} - \log \frac{f_H + f_B}{f_{BH^+}} \quad (1)$$

where a is activity, c is concentration and f is activity coefficient, and refer activities in all solvents to the same reference standard, a dilute aqueous solution. In such a solution therefore

$$\log \frac{f_H + f_B}{f_{BH^+}} = 0$$

and $pK' = -\log \frac{c_{OH^+} + c_B}{c_{BH^+}}$

If now we determine the ionization ratios of two such bases B and C in any given solution whatsoever

$$pK'_B - pK'_C = -\log \frac{c_B c_{CH^+}}{c_{BH^+} c_C} - \log \frac{f_B f_{CH^+}}{f_{BH^+} f_C} \quad (2)$$

The first term on the right is measurable colorimetrically if the bases are indicators; our fundamental assumption is equivalent to the statement that the activity coefficient term is zero and that the activity coefficient ratio f_B/f_{BH^+} in a given solution is the same for all bases. From this determination of the ionization ratios we therefore calculate the relative strengths of the two bases by the equation

$$pK'_B - pK'_C = -\log \frac{c_B c_{CH^+}}{c_{BH^+} c_C} \quad (3)$$

If we have a series of simple basic indicators covering any range of acidities whatever, we may by a stepwise application of this procedure, using any convenient solutions, obtain the base strength relative to water of the whole series. We can thus determine the basicities of those substances, too weakly basic for direct measurement in dilute aqueous solutions, which we must use for the study of strongly acid solutions.

Chem.*, **116**, 135 (1925); Mizutani, *ibid.*, **116**, 350; **118**, 318, 327 (1925); Ebert, *Ber.*, **58B**, 175 (1925); Hall, *THIS JOURNAL*, **52**, 5115 (1930); Halford, *ibid.*, **53**, 2939, 2944 (1931); Brönsted, *Ber.*, **61**, 2049 (1928).

⁶ A mobile tautomerism of either base or ion is not a complication in this sense. See A. A. Noyes, *THIS JOURNAL*, **32**, 815 (1910).

⁷ In the same way a simple acid indicator may be defined in terms of the addition of one hydrogen ion to a singly charged anion. Other types exist but offer less promise of usefulness.

We define the acidity function H_0 by the equation

$$H_0 = \log \frac{c_B}{c_{BH^+}} + pK'_B \quad (4)$$

It may be interpreted as a measure of the extent to which a base of zero strength (pK') reacts with hydrogen ion in the solution in question, or of the strength of a base which is half converted to the corresponding ion in that solution. In its equivalent form

$$H_0 = -\log a_{H^+} \frac{f_B}{f_{BH^+}} \quad (5)$$

the equation shows that the value of H_0 is definite and independent of the particular indicator used to measure it to the extent that our fundamental assumption that the ratio f_B/f_{BH^+} is the same for different bases in a given solution is exact. In dilute aqueous solution H_0 becomes equal to the P_H ; in acetic acid it is theoretically equal to the $(P_H)^{HAc}$ of Hall and Conant,⁸ but differs by an additive constant from the value actually given by their scale. The quantity $a_{H^+} f_B/f_{BH^+}$ is of the type which Guggenheim⁹ has shown to have an operational or physical meaning.

It is clear that there is a whole series of acidity functions, and we propose that they be distinguished by a subscript representing the sign of the base in the conjugate acid-base system¹⁰ used for their determination. Thus in terms of the simple acid indicator whose color change is determined by the reaction

the acidity function H_- is determined by the equations

$$H_- = \log \frac{c_{A'}}{c_{HA}} + pK_{HA} \quad (6)$$

$$pK_{HA} = -\log \frac{a_{H^+} + a_{A'}}{a_{HA}} \quad (7)$$

Similarly the acidity functions H_+ and H_{++} are defined by the extent of the indicator reactions

respectively.

The number of substances known to give reversible color changes with strong acids is enormous¹¹ and it is not difficult to find others. These can be used for the measurement of acidity with changing medium only if it

⁸ See the first criterion of selection of a scale of acidity given in the footnote, THIS JOURNAL, 49, 3059 (1927).

¹¹ The following papers contain extensive lists of examples: Baeyer and Villiger, *Ber.*, 35, 1189 (1902); Kaufmann and Beisswenger, *ibid.*, 36, 561 (1903); Hofmann and Kirmreuther, *ibid.*, 42, 4856 (1909); Hofmann, Metzler and Lecher, *ibid.*, 43, 178, 183 (1910); Hofmann, Roth, Höbold and Metzler, *ibid.*, 43, 2629 (1910); Fischer and Gross, *J. prakt. Chem.*, [2] 84, 377 (1911).

can be shown that they are simple indicators and only if the ionization type can be established. It cannot be too strongly emphasized that the indiscriminate application to solvent systems in general of substances, even such as are satisfactory indicators in dilute aqueous solution, which change color with acids and bases can only lead to confusion.

Fortunately there is among Hantzsch's many contributions to the study of strongly acid solutions an extensive cryoscopic and conductivity study of sulfuric acid as an electrolytic solvent.¹² His results demonstrate that interionic effects are not of great magnitude, and that the type of ionization of an electrolyte dissolved in sulfuric acid may therefore be determined by freezing point measurements. Our cryoscopic results, which will be published in a separate paper, are in qualitative agreement with his but deviate quantitatively in the sense of indicating even smaller interionic effects than do his.

It follows that any substance which is neutral or slightly basic in water, which has a different color in anhydrous sulfuric acid, and which gives a freezing point depression per mole in the latter medium the same as that of other 1:1 electrolytes and approximately twice that of a non-electrolyte, may safely be considered to act as a simple basic indicator at any acidity between that of water and that of pure sulfuric acid. Such a substance does not owe its indicator properties to the addition of a molecule of acid instead of a hydrogen ion. Nor is its indicator function complicated by the dissociation of a molecule of water, as seems to be the case with triphenylcarbinol,¹³ for which the color must have a specific dependence upon the activity of water in the solution being studied. Nor is there the overlapping addition of more than one hydrogen ion, which made the successful interpretation of the indicator properties of crystal violet by Conant and Werner so complex experimentally and theoretically.^{13,14}

We have selected the fifteen substances described and numbered in Table I as indicators for the range of acidities under investigation. With all but four the conclusion that they are simple basic indicators in this range rests upon our own cryoscopic measurements, which show that they act as strong 1:1 electrolytes in sulfuric acid. For number 1, *p*-nitraniline, we draw the same conclusion from the freezing point work of Oddo and Scandola.¹⁵ Number 4, *p*-nitrodiphenylamine, which is decomposed by

¹⁴ Safranine, suggested as an indicator for strongly acid solutions by Frey and Elöd, *Ber.*, **64B**, 2556 (1931), is clearly of the same type.

¹⁵ Oddo and Scandola, *Z. physik. Chem.*, **66**, 138 (1909).

100% sulfuric acid, is stable in less concentrated acid and recoverable from it unchanged upon dilution; in structure and reactions it is similar to other nitraniline derivatives. The benzophenone derivatives, 11 and 12, are apparently sulfonated very rapidly in 100% acid, but are recoverable unchanged from less concentrated sulfuric acid; they are assumed to be 1:1 electrolytes in sulfuric acid because benzophenone itself has been found to be a 1:1 strong electrolyte in that solvent.¹⁶

TABLE I
PROPERTIES OF INDICATORS

No.	Name	Color ^a Base ion	H ₂ SO ₄ -H ₂ O mixtures	pK' from HClO ₄ -H ₂ O mixtures	Formic acid
1	<i>p</i> -Nitraniline	y-c	(+1.40)	(+1.40)
2	<i>o</i> -Nitraniline	y-c	+0.16	+0.10	(+0.13)
3	<i>p</i> -Chloro- <i>o</i> -nitraniline	y-c	-0.56	- .62	- .64
4	<i>p</i> -Nitrodiphenylamine	y-c	-2.09	-2.21
5	2,4-Dichloro-6-nitroaniline	y-c	-2.93	-2.89	-3.01
6	<i>p</i> -Nitroazobenzene	c-y	-3.06	-3.06	-2.99
7	2,6-Dinitro-4-methylaniline	y-c	-4.03
8	2,4-Dinitroaniline	y-c	-4.09	-4.14
9	N,N-Dimethyl-2,4,6-trinitroaniline	y-c	-4.40
10	Benzalacetophenone	c-y	-5.32
11	β -Benzoylnaphthalene	c-y	-5.63
12	<i>p</i> -Benzoyldiphenyl	c-y	-5.90
13	6-Bromo-2,4-dinitroaniline	y-c	-6.30
14	Anthraquinone	c-y	-7.86
15	2,4,6-Trinitroaniline	y-c	-9.0

^a This refers to the visual effect at the dilutions used in indicator work. c = colorless, y = yellow.

In the course of this selection we have rejected as unsuitable (in some cases possibly with insufficient study) the following substances which give color changes with strong acids: triphenylcarbinol and its simple derivatives because of the evidence previously cited that they are not simple indicators; dibenzalacetone because Hantzsch¹⁶ found it to give a freezing point depression in sulfuric acid twice that of a 1:1 electrolyte; phenolphthalein, cresolphthalein, thymolphthalein, alizarin, *p*-nitroanisole, nitrofluorene, anisal-cinnamal-acetone, anisalacetophenone, piperonalacetophenone, cinnamalacetophenone, because our own experiments showed them to give greater freezing point depressions in sulfuric acid than do 1:1 electrolytes or because they are evidently decomposed by the acid; the sulfonephthaleins and all other sulfonic acid derivatives because of the improbability of their being simple bases; aminoazobenzene, dimethylaminoazobenzene, benzene-azo-diphenylamine and other amino-azo compounds, polyaminotriphenylmethane dyes, phenanthraquinone, 1-amino-

¹⁶ Oddo and Casalino, *Gazz. chim. ital.*, **47**, II, 232 (1917); Hantzsch, *Ber.*, **55**, 953 (1922).

and 2-aminoanthraquinone, because they have a second ionization step and second color change in the range investigated; xanthone and 2,4,6,2',4',6'-hexanitrodiphenylamine, because of low solubility.

In addition to a proper selection of indicators, any precise indicator work with changing medium must consider the fact that the absorption of light by a colored substance in solution depends to some extent upon the medium in which it is dissolved, even in cases where the inert nature of the solvent makes chemical reaction in the ordinary sense very improbable. From the numerous previous investigations¹⁷ of this "medium effect" and our own experiments the following general conclusions may be drawn: (1) that its magnitude is specific with regard to the colored substance and the change of solvent; (2) that it is not directly dependent on the charge of the colored substance, the color intensity of neutral molecules being changed as well as that of ions; (3) that its magnitude has not exceeded a factor of two in any case investigated.

In theory, therefore, we should make colorimetric comparisons in a constant medium; in practice it is more convenient to do this indirectly, making the direct comparison with a solution either in water or in 96% sulfuric acid. For the case of an indicator which is non-ionized and colored in water and colorless at high acidity, we define "the stoichiometric color intensity relative to water," I_w , of a solution A by the equation

$$I_w = \frac{C_w \cdot L_w}{C_a \cdot L_a} \quad (8)$$

where C_a and C_w are the stoichiometric concentrations of indicator in solution A and in water, respectively, and L_a and L_w are the lengths of a column of solution A and of a column of water containing these concentrations of indicator at colorimetric balance.¹⁸

We define "the specific color intensity of the colored form relative to water," S_w , by the equation

$$S_w = \frac{[B]_w \cdot L_w}{[B]_a \cdot L_a} \quad (9)$$

where $[B]_w$ is the concentration of the colored base in water, $[B]_a$ its concentration in solution A. From these equations and from

$$C_w = [B]_w \text{ since } [BH^+]_w = 0 \\ \text{and } C_a = [B]_a + [BH^+]_a$$

we obtain

$$\frac{[BH^+]_a}{[B]_a} = \frac{S_w}{I_w} - 1 \quad (10)$$

¹⁸ This is an expression of Lambert's law and Beer's law. See von Halban and Siedentopf, *Z. physik. Chem.*, **100**, 208 (1922); von Halban and Ebert, *ibid.*, **112**, 321 (1924).

A determination of the ionization ratio $[BH^+]/[B]$ and the acidity, H_0 , in a given solution must be made by determining I_w , and by then decreasing the acidity with as little change in medium properties as possible until the indicator is completely in the non-ionized colored form. Then $[BH^+] = 0$ and $S_w = I_w$.

If the color change is in the reverse sense (base colorless, cation colored) a similar equation and process are used

$$\frac{[BH^+]_a}{[B]_a} = \frac{I_h}{S_h - I_h} \quad (11)$$

where I_h = stoichiometric color intensity relative to a medium H, for instance 96% sulfuric acid, in which the indicator is completely converted to the colored form, and S_h = specific color intensity of the colored form relative to the medium H.

The present article describes the standardization of the series of indicators by the use of mixtures of water with sulfuric acid and with perchloric acid, together with some corollaries of the incidental determination of the values of the acidity function, H_0 , in these mixtures. These are particularly convenient solutions for the intercomparison of indicators by the step method; within the precision which our fundamental assumption allows, the values of basicity thus obtained will hold for other media. A following article shows that the indicator series thus standardized may indeed be successfully used in the investigation of solutions in the anhydrous solvent formic acid.

Materials and Procedure

Sulfuric Acid.—Chemically pure concentrated sulfuric acid was tested for clarity in the colorimeter (several samples had to be rejected because of a faint brownish tint). It was standardized to $\pm 0.1\%$ by titration with recently prepared 0.1 molar sodium hydroxide solution standardized with potassium acid phthalate from the Bureau of Standards. The value thus obtained was found to check with a gravimetric determination by precipitation of barium sulfate within 0.1%. It was kept in a tightly stoppered bottle, and was again standardized when nearly exhausted to make certain that it had not changed.

Commercial c. p. fuming acid could not be used to make up acid of concentrations greater than 96% because of its color. Decolorization with nitric acid or sodium persulfate left traces of oxidizing substances which destroyed the indicators. Colorless samples obtained from one manufacturer also destroyed indicators. We finally distilled sulfur trioxide from 30% fuming acid directly into 96% acid in an all-glass apparatus.

The various concentrations of acid required were made up by direct weighing of concentrated acid and water. Densities used in calculating indicator concentrations were taken from the "International Critical Tables." In the range of composition between 98 and 100% acid, where the acidity changes so rapidly with water content that volumetric analysis is not sufficiently accurate, solutions were prepared by addition of weighed amounts of water to acid of maximum freezing point.

In the range from 97 to 100% acid, the acidity-composition curves were determined both with the acid described above and with a sample purified by distillation in a plati-

num still. The latter was found to contain no detectable amount of platinum and less than 0.0002 molar sulfur dioxide. The curves were congruent within experimental error.

Perchloric Acid.—C. p. 70% acid was standardized against 0.1 molar sodium hydroxide. It was restandardized at the end of the series of experiments to make certain that it had not changed. Dilutions were made in the same way as with sulfuric acid.

Indicators.—These are listed by number from Table I. Except where otherwise noted they were obtained from well-known dealers. Melting points were determined by the capillary-tube method with a thermometer calibrated at the Bureau of Standards, and have been corrected for stem exposure. The tests of purity indicated by the letters A and B are explained later.

Recryst. from alcohol. 15. Recryst. from acetic acid.

Procedure.—For the experiments in sulfuric acid–water mixtures, a solution of known concentration of the indicator in 96% acid was placed in a short buret rigidly clamped and a definite number of drops were allowed to fall into a portion of the solution under investigation, and then a definite number into the liquid to be used as reference standard. A similar procedure was used for the perchloric acid series. For both series the composition of the acid–water mixture was corrected for the effect of the added indicator solution.

The solutions, immediately after addition of the indicator, were brought to $25 \pm 3^\circ$, transferred to the colorimeter cups, and compared. The reference standard was water²⁷ for those indicators whose acid form is colorless, and 96% sulfuric acid or 70% per-

²⁷ With the two most strongly basic indicators, 1 and 2, the water reference solution was made slightly alkaline to prevent ionization of the indicator.

chloric acid for those having colored ions and colorless molecules. From these comparisons the color intensity, I_w or I_h , was calculated by equation 8.

Precision of Measurements.—A series of experiments showed that the method used in adding the indicator is as precise as the colorimetric measurement. The temperature control was found to be within the same precision with all of the indicators used. Absorption of moisture from the air during the colorimetric measurement was found to be negligible except in the range from 97 to 100% sulfuric acid. In this range the cell shown in Fig. 1 was used. Its optically plane ends are fused on. The length of the enclosed column was determined by measurement with a scale, and was checked by colorimetric comparison of two solutions of a dye of known concentration ratio.

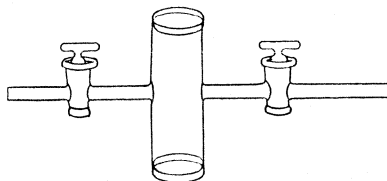

Fig. 1.

The scales of the Klett-Beaver colorimeter,²⁸ readable to 0.1 mm. were calibrated and found correct to 0.2 mm. In every determination of color intensity the mean of nine independent settings of the instrument was used. The average deviation of the result varies, according to the indicator, from 2 to 5%, at concentrations greater than about 10^{-5} molar. Below this the precision of matching drops off rapidly as the color of a 50-mm. column of liquid becomes very faint.²⁹ By dilution experiments in a constant medium it was found that within the precision of the color balance: Beer's law applies to the colored form of all the indicators used; the optical system of the colorimeter is accurate; the concentrations of indicator used, never greater than 0.005 molar, do not change the acidity of the sulfuric acid-water mixtures.

The colorimetric purity of the indicators was established in most cases by one or both of the following methods.

A. Constant Specific Color Intensity.—Recrystallization or other purification until the specific color intensity in water or in 96% sulfuric acid was unaffected by a repetition.

B. Congruent Intensity Curves.—The purification process was repeated until repetition produced no change in the intensity composition curves. This test should be very sensitive to an impurity of different base strength or charge type.

Discussion of Results

Table II contains the values of I_w for the series of indicators in sulfuric acid-water mixtures, and Table III those for perchloric acid-water mixtures.³⁰ The values for the sulfuric acid series are plotted in Figs. 2 and 3.

²⁸ Beaver, *J. Optical Soc. Am.*, **18**, 41 (1929).

²⁹ This is in accord with Weber's law of optical sensitivity. Peddie, "Colour Vision," London, 1922, p. 43.

³⁰ We did not consider it safe to work with solutions of organic compounds in perchloric acid of greater strength than this because of the explosion danger. Even in the range of acidities studied two indicators of our series were found inapplicable to perchloric acid solutions. *p*-Nitrodiphenylamine reacts with the formation of a violet color and a brown flocculent precipitate. Benzalacetophenone appears to be perfectly stable in solutions containing less than 65% acid; above this a fairly rapid decolorization takes place which is not reversed on dilution with water to a composition of 60% acid.

The shape of these curves is obviously due to the super-position of two effects: the steep part of the curve to changing ionization ratio, C_{BH^+}/C_B ; the gradual change preceding or following the steep part to the effect of the changing medium on the color intensity of the colored form (*S*). Comparison of the curves of different indicators shows that the value of *S* may be expected to change only to a small extent over the range in which the ionization ratio is measurable. We have, therefore, assumed it constant over this range for each indicator, and have set its value equal to the value of *I* at the point on the curve marked by the circle (Figs. 2 and 3), deter-

mined on a sufficiently large scale plot.³¹ The values of S for each indicator and for both solvent series are given in the tables. That the medium

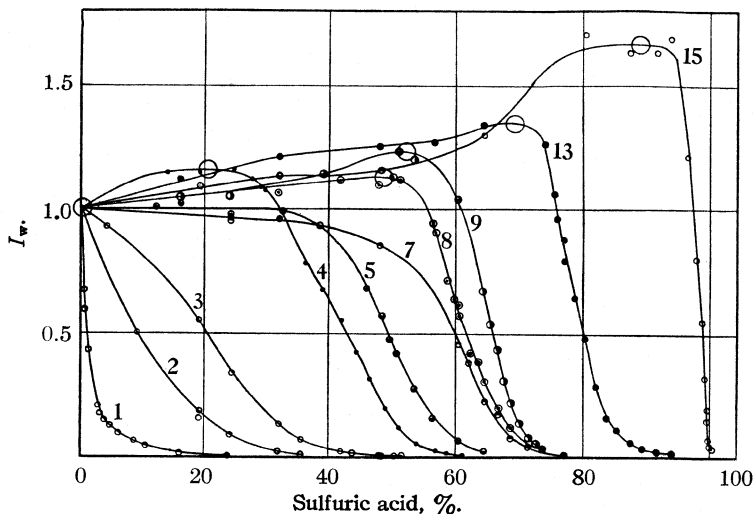

Fig. 2.

effect of the two acids is quite different is shown by the differences of the values of S for a given indicator. From these values the quantities $\log (C_{BH^+}/C_B)$ given in the tables are

calculated by equation 10 or 11. The results for the sulfuric acid series are plotted against the weight per cent. of acid in Fig. 4.

By equation 3 these curves should be parallel and the constant difference in ordinates between the curves of two indicators should equal the difference in base strengths in pK' units. The degree of parallelism is very satisfactory except in the range from 65 to 80%. As measured by the curve for picramide (15) in Fig. 1, this is the region in which the medium effect is greatest, and in which

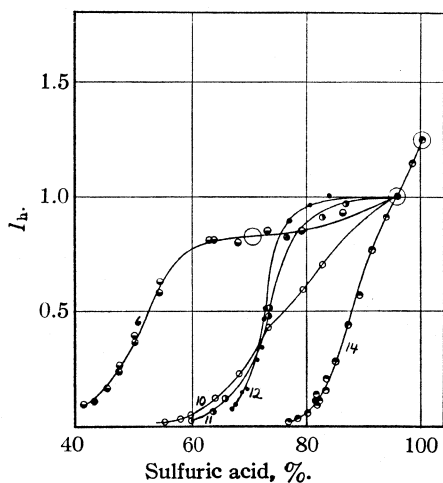

Fig. 3.

therefore the error in the determination of S may be expected to be greatest.

³¹ In the case of anthraquinone, S was taken as the relative color intensity in 100% sulfuric acid, although a definite maximum in the intensity curve is not evident, since anthraquinone has been found to be completely ionized in this medium.

It seems reasonable therefore to suppose that this failure of parallelism is due to variation of S rather than to inapplicability of our fundamental assumption embodied in equation 3.

By the step method the relative values of pK' thus obtained were all referred to that of p -nitraniline, for which a provisional value of $+1.40$ was adopted.³² The values for the sulfuric acid and the perchloric acid series are contained in Table I. There are also included the values obtained by a similar comparison in solutions of sodium formate and of benzene sulfonic acid in anhydrous formic acid, taken from a following paper. We thus have three independent determinations of the pK' values

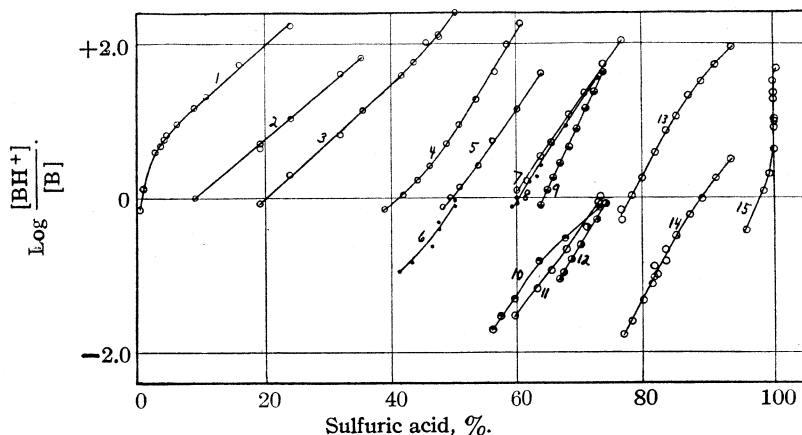

Fig. 4.

of a number of our indicators. The excellent agreement between the three sets of values is the best possible justification of the assumptions made in calculating them, and is sufficient demonstration of the possibility of measuring by means of properly chosen indicators an acidity function which is independent of the indicator used for measuring it, and of using in one solvent system an indicator series calibrated in another.

That the agreement is so much better than might be expected from

³² This was obtained by averaging the values in the literature for the observed pK' of p -nitraniline together with the calculated values obtained by adding the difference in pK' of o - and p -nitraniline read from Fig. 4 to the observed values for o -nitraniline. The error may be ± 0.5 unit, since the existing values for these constants have been obtained in fairly concentrated electrolyte solutions and are not very concordant. The observed values are: 2.03, Löwenherz, *Z. physik. Chem.*, **25**, 385 (1898); 1.8, Reinders, *THIS JOURNAL*, **52**, 5124 (1930); 1.0, Farmer and Warth, *J. Chem. Soc.*, **85**, 1713 (1904); Kuhn and Wassermann, *Helv. chim. acta*, **11**, 3 (1928). Those calculated from the pK' of o -nitraniline are: 1.3, Löwenherz, *loc. cit.*; Goldschmidt and Ingebrechtsen, *Z. physik. Chem.*, **48**, 435 (1904); 0.94, Farmer and Warth, *loc. cit.*; Kuhn and Wasserman, *loc. cit.*

previous work³³ may perhaps be due to some extent to the choice of media. Nevertheless, the deforming action upon the molecules of the indicator of the two acid-water mixtures is quite different, as is shown by the differences in the S values for a given indicator. And with formic acid we are dealing with anhydrous solutions of low total ion concentration, even though in a good ionic solvent; with the aqueous mixtures we have extremely large ionic concentrations. There is, however, good reason to expect that the agreement of these colorimetric values should be better than is the case with existing results from electrometric or conductivity data. The relative ionizations of two indicators may be compared in what is practically a single medium, because the concentration of the indicator is too small to affect the medium properties. In the electrometric and conductivity data

³³ According to Halford, THIS JOURNAL, 53, 2944 (1931), the difference between the pK' values for two bases may vary by as much as one unit from solvent to solvent.

the substance whose basicity is being measured changes the nature of the medium to an extent which may be large and specific in solvents of low dielectric constant.³⁴

The values of the acidity function, H_0 , have been calculated for each indicator for the various sulfuric and perchloric acid mixtures in which it has been used. They are included in Tables II and III, and are plotted in Fig. 5. The numbered horizontal lines in this figure represent the range of

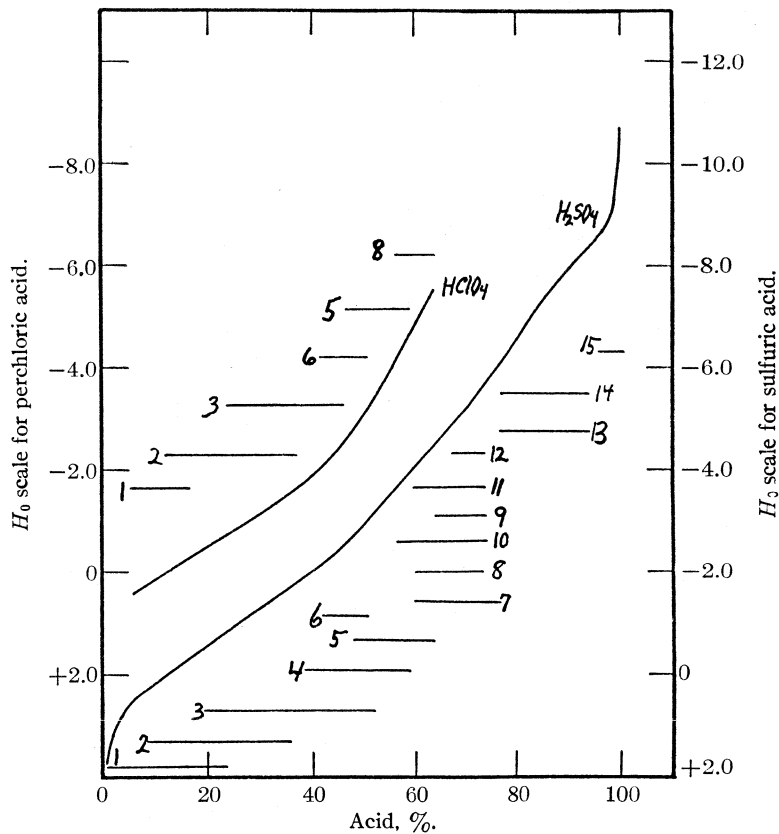

Fig. 5.

solutions in which the corresponding indicator could be employed. The curves for the two acids are nearly coincident, which is somewhat surprising (even though the equivalent weights are nearly the same in this range of acidity) especially because of the difference in the medium effects upon specific color intensity.

Except in the immediate neighborhood of pure water and pure acid, where rapid change is to be expected on a logarithmic plot, the curve is

³⁴ See Conant and Werner, *THIS JOURNAL*, **52**, 4436 (1930).

strikingly free from sudden changes of direction. This is true even in the region of the composition $\text{H}_2\text{SO}_4\cdot\text{H}_2\text{O}$, and is another reason for thinking that the lack of parallelism of the curves in Fig. 4 in the region from 65 to 80% acid is due to changing S values instead of to differences in the ratio $f_{\text{BH}^+}/f_{\text{B}}$ for different indicators, for large specific effects upon activity coefficients are to be expected only in a region where there is a large change in all activity coefficients. This can, of course, be checked by the use of some other medium in this range of acidity.

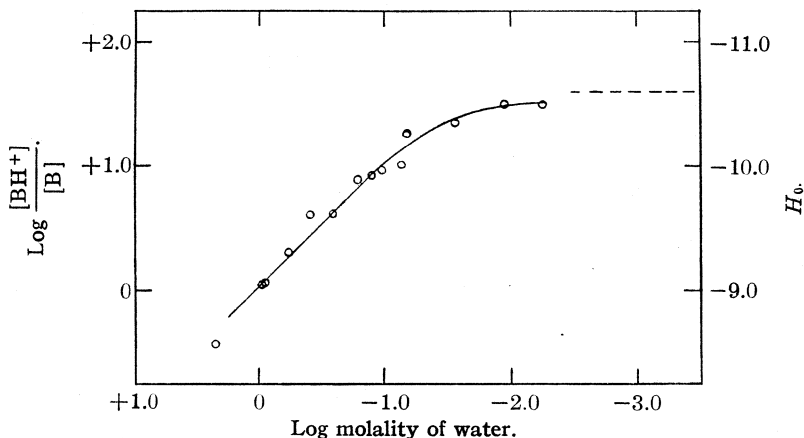

Fig. 6.

The data in the neighborhood of 100% sulfuric acid are plotted in Fig. 6 against the logarithm of the stoichiometric molal concentration of water. From this the acidity of pure sulfuric acid and the concentration of HSO_4^- in the pure solvent may be calculated. It may be shown that

$$\log \frac{C_{\text{BH}^+}}{C_{\text{B}}} + \log (x + c_w) = K - \log \frac{f_{\text{BH}^+} \cdot f_{\text{HSO}_4^-}}{f_{\text{B}} \cdot a_{\text{H}_2\text{SO}_4}}$$

where x is the concentration of HSO_4^- produced by self-ionization of the solvent, c_w is the stoichiometric concentration of water, and $(x + c_w)$ must equal the total concentration of HSO_4^- since water is a strong electrolyte in sulfuric acid.³⁵

At high values of c_w the slope of the curve should be unity, as it is, if the activity coefficients are constant. As c_w approaches zero, $\log (C_{\text{BH}^+}/C_{\text{B}})$ should approach asymptotically a limiting value, which is the case. From the limiting value the acidity function, H_0 , for pure sulfuric acid is -10.60 , 17.6 units more acid than pure water. From the values of the ionization ratio and of c_w in the region where x is negligible, K may be calculated; and from this, again on the assumption of constant activity coefficients, the concentration of HSO_4^- in pure sulfuric acid. The value, 0.027 molal,

³⁵ Hantzsch, *Z. physik. Chem.*, **61**, 257 (1907).

is in agreement with cryoscopic and conductivity evidence of the high self-ionization of sulfuric acid.

Some Kinetic Applications

There are two chief ways in which such a series of indicators as this may be expected to be useful. One is the determination of the strengths of bases and of acids too weak and too strong, respectively, to permit measurement in aqueous solutions; some examples of this are given in the following paper on formic acid solutions. The other is in the interpretation of re-

action velocity data. For a preliminary survey we may use the considerable amount of data on reaction velocities in sulfuric acid-water mixtures, which are summarized in Table IV. In the light of our determination of the acidity of these solutions the reactions may all be considered to be acid catalyzed, since they are reactions whose velocity increases with increase in acidity.³⁶

An exact parallelism between the reaction velocity and the acidity can only be expected if the velocity is proportional to the concentration of the ion formed by the addition of one hydrogen ion to one molecule of the neutral substrate, if the ratio of the concentration of this ion to the total concentration of substrate is small, and if there is no further ionization by addition of another hydrogen ion. If these conditions are fulfilled, the equation

$$H_0 + \log k = \text{constant}$$

where k is the velocity constant, should hold.

From the fact that the equation does hold in three of these cases, the decomposition of malic acid, the condensation of *o*-benzoylbenzoic acid and the Beckmann transformation of acetophenone oxime, it may be concluded that the necessary conditions are fulfilled for these reactions. The significance for studies of acid catalysis of measurements of acidity with basic indicators is thus demonstrated.³⁷

We wish to acknowledge assistance in this investigation made possible by the generosity of Mr. and Mrs. Reginald Auchincloss.

Summary

It is shown that a significant measure of differences in acidity in one solvent or between solvents may be obtained by means of a properly chosen series of indicators of the same charge type.

The conditions both experimental and in principle for the precise measurement of acidity by indicators are defined.

A series of simple basic indicators is developed by means of which any acidity lying in the range between that of dilute aqueous solutions and that of pure sulfuric acid and in any solvent may be determined.

The acidities of mixtures of sulfuric acid and water from 0 to 100% acid and of perchloric acid and water from 0 to 70% acid are determined and some applications of the results discussed.

³⁶ This may be considered a more specific statement of Wiig's conclusion (*loc. cit.*) on the basis of Taylor's theory of negative catalysis, *J. Phys. Chem.*, **27**, 322 (1923), that the substrate forms an addition compound with the sulfuric acid, and that water inhibits the reaction by decreasing the concentration of this compound.

³⁷ We justify this preliminary comparison of reaction velocities determined at one temperature with acidities determined at another by the probability that both relative reaction velocity and relative acidity are little influenced by temperature. Whitford (*loc. cit.*) found the temperature coefficient of the reaction in the malic acid case independent of the composition of the solution.

Because of a parallelism between the acidity and the rates of certain reactions in strong sulfuric acid-water mixtures, these reactions are characterized as acid-catalyzed; the "inhibition" produced by water is ascribed to its basic character.

THE KINETICS OF THE THIOCYANATE-BROMINATED FATTY ACID REACTIONS

BY VICTOR K. LA MER AND JOSEPH GREENSPAN

RECEIVED MARCH 11, 1932

PUBLISHED JULY 6, 1932

In their study of the kinetics of the replacement of bromine in brominated propionic ions by thiosulfate ion, La Mer and Kamner¹ found a greater velocity constant when the bromine was in the beta position than when it was in the alpha position, whereas the customary greater reactivity of the alpha position over the beta position was exhibited when the uncharged fatty acid esters were used instead of the sodium salts. This reversal in reactivity was predicted on the basis of the effect of electrostatic repulsions between the ions of the same sign upon the frequency of collisions.²

The analogous reactions in which thiocyanate ion³ is employed as the replacing ion instead of thiosulfate ion appeared to be well adapted for extending the study, particularly since the analytical method for the determination of thiocyanate published recently by Pagel and Ames⁴ possesses the advantages of precision and speed over the tedious method employed by Holmberg.

In Table I are given two typical runs for the reaction

in the presence of sodium as cation. The k values are the bimolecular constants; the units, liters per mole per minute; $T = 25.00 \pm 0.05^\circ$. The concentration of CNS^- in an aliquot at any time, t , was determined

9753	40	.0139	15251	25	.000441	21696	25	.00156

Titration of the solutions initially neutral showed that both the α - and β -bromopropionate-thiocyanate solutions had become acid (approximately P_H 3) whereas the bromoacetate-thiocyanate solutions still remained neutral. This clearly demonstrated the occurrence of side or consecutive reactions. In one run (No. 18 above), SCN^- was found to be regenerated, indicating either an hydrolysis of the resultant thiocyno compound

with consequent increase in acidity of the solution, or an interference of secondary products with the analytical determination of SCN^- .

Ostwald,⁵ using conductivity methods, showed that the reaction

was 90% complete in five days (room temperature) at a concentration of 1 mole in 1024 liters. In a recent paper, Fredga⁶ demonstrated that the α - and β -thiocyanopropionic acids were also unstable in aqueous solution, undergoing hydration to the corresponding thiocarbamine acids, which might interfere with the analytical method. The increasing acidity of the solution can be explained by the direct hydrolysis of the brominated acids, the monomolecular constants for the α and β cases being of the order of 10^{-5} and 10^{-4} , respectively.⁷

Holmberg's³ studies involved the reaction $CH_2ICOO^- + SCN^- \xrightarrow{K^+} CH_2SCNCOO^- + I^-$ for concentrations as dilute as 0.0125 M in the iodoacetic salt. The iodo derivative reacts about 50% faster than does the corresponding bromo derivative,⁸ so that measurements could be completed within forty-eight hours. Within this period Holmberg obtained no drift in k , whereas we observed a perceptible drift over this same time interval

⁵ Ostwald, *Z. physik. Chem.*, **3**, 179-181 (1889).

⁶ Fredga, *J. prakt. Chem.*, **231** (N. F.), 110-128 (1929).

⁷ Ref. 1, p. 2844.

⁸ See Ref. 2, p. 203.

(Table I). We attribute this difference to the more precise analytical method used by us. In but one measurement extending over fifty hours did Holmberg⁹ observe a drift; this he attributes to the formation of the thiocarbamine acid

TABLE III

Na α -bromopropionate			Na β -Bromopropionate		
$a = 0.05215$ m./l. NaSCN			$a = 0.05223$ m./l. NaSCN		
$b = 0.03528$ m./l.			$b = 0.03017$ m./l.		
t	% Conv.	k	t	% Conv.	k
1297	6	0.000899	1342	20	0.00326

Since interference from end-products will be at a minimum during the first few hours of reaction, we may conclude from Table III that the β -ion reacts about 3.4 times more rapidly than the α -bromopropionate ion, a result in good accord with that obtained for the thiosulfate reaction.¹

Summary

Side and consecutive reactions obscure the kinetics of the halogen replacement by thiocyanate ion in the halogenated fatty acids when the elapsed time exceeds 1500 minutes. The greater reactivity of halogen in the beta position in an ion has been confirmed for the thiocyanate ion replacement reaction.

TRANSFERENCE NUMBERS OF AQUEOUS SOLUTIONS OF POTASSIUM CHLORIDE, SODIUM CHLORIDE, LITHIUM CHLORIDE AND HYDROCHLORIC ACID AT 25° BY THE MOVING BOUNDARY METHOD¹

BY L. G. LONGSWORTH

RECEIVED MARCH 17, 1932

PUBLISHED JULY 6, 1932

Introduction

In the paper following this one, the conductance and transference data for aqueous solutions of some binary electrolytes will be interpreted from the standpoint of the modern theories of solutions. The transference data obtained for that study were determined by the moving boundary method. The experimental work involved in their measurement is the subject of this paper. An equation which is useful for interpolation and extrapolation to zero concentration is also given.

¹ A portion of the work here reported was completed while the author was a National Research Council Fellow.

Apparatus

The moving boundary cell used in making the measurements is shown in Fig. 1. It is similar to the one described in an earlier paper² in that either rising or falling boundaries may be formed by the shearing mechanism devised by MacInnes and Brighton.³ It has two measuring tubes, A and B, of different cross section, in either of which boundaries may be formed. The lower glass plate C is also provided with a cylindrical recess in which a small disk of metal may be inserted, the recess being placed directly beneath a graduated tube. With this addition boundaries of the type described by Cady and

Longworth⁴ may be made. Since these boundaries are formed automatically under the action of the electric current, thus requiring no shearing mechanism, they will henceforth be termed "autogenic" boundaries. Tube D carries the electrical connection from the metallic disk.

In this new apparatus the electrode chamber E is entirely immersed in the thermostat liquid. This is necessary in order to avoid volume changes due to thermal expansion and contraction which, if allowed to take place, would cause mass displacements of the boundary in the measuring tube.

An important procedure that has not been sufficiently described in previous papers on the moving boundary method as carried out in this Laboratory is the accurate calibration of the graduated tubes. The most recent practice is given below.

The tubes are of Pyrex and are graduated in the manner recommended by MacInnes, Cowperthwaite and Huang.⁵ The calibration was made before the tubes were cemented into the supporting framework of the cell. After the graduation marks were etched on a tube a small glass stopcock with a capillary tip was sealed onto it. The tube and stopcock were then very carefully cleaned. Redistilled mercury

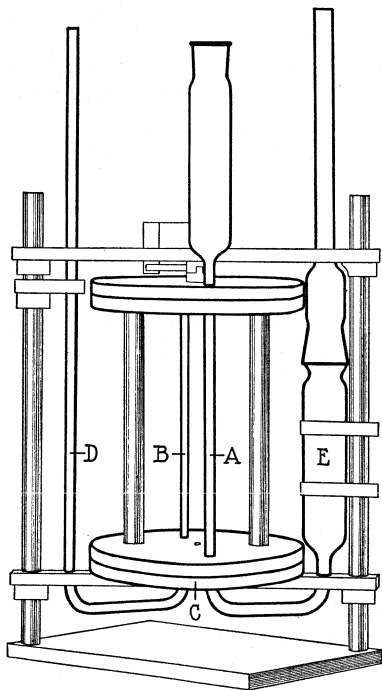

Fig. 1.—The moving boundary cell.

was drawn from a weighing bottle into the tube until the mercury meniscus roughly coincided with a graduation on the tube. The exact position of the meniscus with respect to the adjacent graduation was determined to the nearest 0.002 millimeter (by a device which will be described immediately) the bottle with remaining mercury weighed, and the meniscus then roughly adjusted to another graduation and the distance from meniscus to graduation again determined. The device for locating the meniscus with respect to a graduation was constructed as follows. A Brown and Sharpe micrometer head which could be read to 0.002 millimeter was adapted to a sliding support which carried the graduated tube, this in turn being clamped to the stage of a microscope with its optical axis in a horizontal position. The tube was thus held in a vertical position

² Longworth, *THIS JOURNAL*, **52**, 1897 (1930).

³ MacInnes and Brighton, *ibid.*, **47**, 994 (1925).

⁴ Cady and Longworth, *ibid.*, **51**, 1656 (1929).

⁵ MacInnes, Cowperthwaite and Huang, *ibid.*, **49**, 1710 (1927).

and could be moved perpendicularly. A magnification of 40 diameters was employed. With this arrangement it was not necessary to bring the mercury meniscus exactly in line with a graduation, which is an advantage as it is difficult to carry out with tubes of small diameter. In this manner accurate calibrations can be made quite readily. The following figures are the results of five determinations on the volume in milliliters between the first and last graduations of one of the tubes: 1.2114, 1.2112, 1.2108, 1.2110, 1.2108. The mean of these values is 1.2110₄ with a probable error of the mean of 0.00008 ml. The calibration of a tube includes, of course, a determination of the volumes between successive graduations.

Tubes A and B of Fig. 1 have average cross sectional areas of about 0.12 and 0.08 square centimeters, respectively. A third tube, of 0.05 square centimeter area, in a similar cell was also used in some of the measurements.

The constant current regulator and other auxiliary apparatus were the same as described in previous papers.² The regulation was accurate to about 0.01%.

Materials.—A good grade of potassium chloride was recrystallized twice from conductivity water, dried and fused. The sodium chloride was precipitated from a saturated solution with pure hydrogen chloride gas, dried and fused *in vacuo*. The best obtainable grade of hydrochloric acid was diluted to constant boiling strength and distilled, the end fractions being rejected. The concentration of this constant boiling acid was interpolated from the data of Foulk and Hollingsworth.⁶ The author is indebted to Dr. Shedlovsky for the purification of lithium chloride and preparation of the solutions of this salt. This procedure is described in connection with the conductance measurements on this salt. Solutions were usually prepared by direct weighing of both solute (or concentrated stock solution) and solvent, the concentration being converted to a volume formal basis by means of the density data taken from the "International Critical Tables." Solutions of sodium chloride above 0.02 *N*, however, were prepared in carefully calibrated flasks. All concentrations are expressed in gram equivalents per liter of solution at 25°.

An excellent grade of sodium and potassium salts of tetra-iodofluorescein, which served as indicators in many of the determinations, was furnished by the Eastman Kodak Co. These salts were further purified in this Laboratory by several recrystallizations. The solutions of the indicator electrolytes, the concentrations of which do not need to be known with great accuracy, were prepared in volumetric flasks. The metallic cadmium employed was of "C. P." grade and on qualitative analysis proved to be free from impurities which would yield on solution ions faster than cadmium.

Experimental Procedure

A large proportion of the data was obtained by the Cady and Longworth method using a cadmium disk anode as mentioned above. Where applicable this is the simplest procedure and gives results of high precision. However, the $\text{CdCl}_2\text{--HCl}$ and $\text{CdCl}_2\text{--KCl}$ boundaries become invisible below 0.01 *N* and the $\text{CdCl}_2\text{--NaCl}$ boundary cannot be detected much below 0.02 *N*. $\text{CdCl}_2\text{--LiCl}$ boundaries were obtained only at 0.05 *N* and above, and even at 0.05 *N* they were diffuse and difficult to locate accurately except at relatively high current densities. Lithium iodate proved to be the most satisfactory indicator for the lithium chloride solutions. To study solutions of sodium chloride and potassium chloride at concentrations lower than those mentioned, the corresponding salts

⁶ Foulk and Hollingsworth, *THIS JOURNAL*, **45**, 1220 (1923).

of tetra-iodofluorescein served as indicators, though in special cases other indicators were also used. MacInnes and Brighton's³ shearing mechanism was used for forming these boundaries. With the tetra-iodofluorescein as indicator boundaries were sharp and readily visible at concentrations considerably below 0.001 *N*. However, as will be shown later, the data obtained on the most dilute solutions are of lower precision due to a large and somewhat ambiguous solvent correction, which was, however, kept at a minimum.

The upper limit of concentration of solutions for which accurate transference numbers have been obtained is 0.2 *N*. At this and to an increasing extent at higher concentrations, the heat developed in the moving boundary cell gives rise to convection currents which tend to distort the boundary and cause mixing. In order to obtain accurate transference numbers at 0.2 *N* it was found necessary to employ the tube of smallest cross sectional area since the actual amount of heat developed is smaller and the area of tube surface exposed to the thermostat is relatively greater. In addition, at 0.2 *N* the volume correction for the processes behind the boundary is in many cases quite large. This correction, as will be shown below, is not an exact one, but has relatively little effect on the results, except in extreme cases.

In order to keep the volume correction as definite as possible one electrode is kept closed. In the case of the autogenic boundaries the anode side is necessarily the closed one. Using sheared boundaries the electrode chamber completely immersed in the thermostat is always the closed side of the system.

Among the advantages of the moving boundary method over the Hittorf method are the rapidity with which measurements can be made and the fact that the progress of the determination can be followed from the beginning. In contrast, a Hittorf determination in which, at best, two figures are obtained, requires several days and the success of a determination is in doubt until the final analyses are completed.

To show the number and relative accuracy of the data obtained in a single determination by the moving boundary method, the figures recorded in a quite typical experiment, lasting about ninety minutes, are given in Table I. It will be recalled that by this method the transference number *T* is obtained from the formula

$$T = \frac{VCF}{1000 It}$$

in which *V* is the volume in milliliters swept through by the boundary in *t* seconds when a current of *I* amperes is flowing. *C* is the concentration and *F* the faraday in coulombs.

Column 2 of the table gives the time required for the boundary to move through the volume between the etch marks spaced by the distance

in centimeters given in Column 1. Column 3 contains the factor $VCF/1000 I$, which gives, on division by the value of t in the preceding column, a value of T_+ (Column 4) corresponding to the total volume through which the boundary has moved in that time. The values in Column 4 thus constitute a running check on the progress of the experiment.

Mean 0.3894

In Column 5 there are fifteen combinations of readings in which the boundary has traveled eight or more centimeters, and in Column 6 the corresponding times in seconds. Hence, by calculating a value of T_+ (Column 8) for each of these combinations from the data of Columns 6 and 7, errors in individual observations are minimized. The probable error of the mean of this typical experiment is 0.00003, corresponding to an error of 0.3 second. This is, of course, merely an indication of the accuracy of the time observation. Errors may also arise from determinations of the volumes, the current and the concentration. The accuracy of all these measurements is within 0.02%. Uncertainties in the necessary corrections to be described below may also introduce small errors.

Experimental Results and Computations

The results of individual determinations on solutions of the four electrolytes each at a series of concentrations are given in Tables II to V. In general, more than one potential gradient was employed at each concentration, but over a considerable range of voltage no variation in the observed transference number resulted. As will be shown in the following sections these data are subject to corrections, (a) for volume changes

behind the boundary, and (b) for the conductance of the solvent. The magnitudes of these corrections are also given in the tables. Where results are given in the tables for both anion and cation boundaries at the

same concentration, a mean value of T_+ has been taken, and is recorded under the heading T_+ final.

(a) **The Volume Correction.**—G. N. Lewis⁷ has shown that the observed transference number must be corrected for a displacement of the boundary due to volume changes behind the boundary. This correction is most readily applied by means of the equation

$$T = T_{\text{obs.}} + \frac{C\Delta V}{1000}$$

where ΔV is this volume change in milliliters per faraday equivalent and C is the concentration. For the cation boundaries the volume change, ΔV_+ , is

$$\Delta V_+ = \frac{1}{2} \bar{V}_{\text{CdCl}_2} - T_+ \bar{V}_{\text{XCl}} - \frac{1}{2} V_{\text{Cd}}$$

in which the \bar{V} 's are partial molal volumes and V is an atomic volume. The subscripts indicate the salt involved and X may stand for H, K, Na or Li. For the anion boundaries a silver-silver chloride cathode was employed and the volume change, ΔV_- , is

$$\Delta V_- = V_{\text{Ag}} + T_+ \bar{V}_{\text{XCl}} - V_{\text{AgCl}}$$

In a recent paper E. R. Smith⁸ has found experimentally the value of ΔV_- in this reaction, using a potassium chloride solution, and has obtained adequate agreement with the computation as given. This important paper also includes a detailed treatment of the theory of the volume changes affecting the boundary velocity.

The partial molal volumes, which were computed from data in the "International Critical Tables" according to the directions of Lewis and Randall⁹ are expressed by the following formulas.

⁷ Lewis, *THIS JOURNAL*, **32**, 862 (1910).

⁸ Smith, *Bur. Standards J. Research*, **8**, 457 (1932).

⁹ Lewis and Randall, "Thermodynamics," McGraw-Hill Book Co., Inc., New York, p. 36.

$$\begin{aligned}
 \bar{V}_{\text{LiCl}} &= 17.06 + 2.13 \sqrt{m} \\
 \bar{V}_{\text{KCl}} &= 26.65 + 3.21 \sqrt{m} \\
 \bar{V}_{\text{NaCl}} &= 22.85 - 5.32 (0.8105)^m (1 - 0.2101 m) \\
 \bar{V}_{\text{HCl}} &= 18.07 + 1.27 \sqrt{m} \\
 \bar{V}_{\text{CdCl}_2} &= 23.24 + 8.82 \sqrt{m}
 \end{aligned}$$

These empirical expressions are based on the linear variation of the apparent molecular volume, ϕ , with the square root of the molality, m , except that in the case of sodium chloride the function given for that salt represents the data somewhat better than the simple square root relation, and is derived from the equation

$$\phi = 22.85 - 5.32 (0.8105)^m$$

The three constants of this equation were determined graphically by a method given by Running.¹⁰ It is interesting to note that this function, unlike the square root relation, may be used to compute the partial molal volume of the solute in the hypothetical solution in which no water is present ($m = \infty$),¹¹ as well as in the infinitely dilute solution ($m = 0$).

The functions given here were developed before the author had noted the appearance of the recent papers by Masson and others,¹² who show the wide validity of the linear variation of ϕ with the square root of the volume formal concentration. Otherwise their formulas could have been directly adapted to the computation of the necessary volume corrections.

In using these equations¹³ in computing the corrections recorded in

¹⁰ Running, "Empirical Formulas," John Wiley and Sons, Inc., New York, 1917, p. 28.

¹¹ A. F. Scott, *J. Phys. Chem.*, **35**, 1410 (1931).

¹² Masson, *Phil. Mag.*, **8**, 218 (1929); Redlich, *Naturwissenschaften*, **19**, 251 (1931); Geffcken, *ibid.*, **19**, 321 (1931); *Z. physik. Chem.*, [A] **155**, 1 (1931); Redlich and Rosenfeld, *ibid.*, [A] **155**, 65 (1931).

¹³ Since the partial molal volumes are functions of the concentration and as the concentration distribution in the neighborhood of the electrode is far from uniform, it is evident that the correction as computed above is an approximation. However, the entire correction is small at moderate concentrations so that the error involved in this case cannot be large. In the case of the autogenic boundaries the diffusion layer is well defined and the concentration distribution resulting from pure diffusion and ionic migration is not destroyed by gravity currents as may be the case with the electrode arrangement used with sheared boundaries. Hence in the case of the autogenic boundaries it is theoretically possible to obtain a better estimate of this correction in the following manner. A passage of one faraday of electricity will cause the boundary to move from $X = 0$ (the face of the electrode, of say metallic cadmium) to a point in the tube X_1 . The region from $X = 0$ to $X = X_1$ will contain one equivalent of cadmium chloride whose concentration distribution may be computed from formulas developed by Sand [*Phil. Mag.*, **6**, 1, 45 (1901)] and by Miller and Rosebrugh [*J. Phys. Chem.*, **14**, 816 (1912)]. Thus, since C_{CdCl_2} is known as a function of X , and \bar{V}_{CdCl_2} as a function of C_{CdCl_2} , \bar{V}_{CdCl_2} may be expressed as a function of the distance. The definite integral

$$\frac{1}{X_1} \int_0^{X_1} \bar{V}_{\text{CdCl}_2} dX$$

will then give the average value of the partial molal volume of the cadmium chloride and

Tables II to V the approximation was made that over the range studied, the concentration could be replaced by the molality, m . For the atomic and molecular volumes the following values were used

$$V_{\text{Ag}} = 10.3$$

$$V_{\text{Cd}} = 13.0$$

$$V_{\text{AgCl}} = 25.8$$

(b) **The Solvent Correction.**—Although the necessity for the correction for the conductance of the solvent has been generally recognized in the case of conductivity measurements, apparently no previous investigator has considered the application of such a correction to transference data. Other workers have either considered the data of insufficient accuracy to warrant the application of the correction or have thought that it would be negligible even at the lowest concentrations which they studied. However, with the precision attained by the moving boundary method, such a correction is imperative. Moreover, a solvent correction should be applied to the results of transference measurements made by all of the available methods. Fortunately it has but little effect on the final results except in the most dilute solutions. In that region, however, it may be the factor determining the accuracy of the data.

The necessity for a solvent correction was impressed on the author as a result of the following observations. If anion and cation boundaries are observed independently for the same solution, the value of $(1 - T_-)$ obtained from an anion boundary, T_- being the anion transference number, should exactly equal the cation transference number, T_+ . At concentrations above 0.02 N such was found to be accurately the case. As the concentration was decreased, however, the two independently observed values were found to diverge. This is illustrated in Fig. 2, where the observed transference data on the lower concentrations of potassium chloride have been plotted, for convenience, against the cube root of the concentration. Curve A gives values of $(1 - T_-)$ in which T_- is here the observed anion transference number which has been corrected for the volume changes behind the boundary, but not for solvent conductance. Curve B gives corresponding values of the directly determined cation transference number, T_+ , to as low a concentration as the boundaries were visible. Curves A and B should coincide and would do so except that at these low concentrations the conducting impurities in the solvent are carrying an appreciable fraction of the total current. Curve C in the figure is a plot of the values of $(1 - T_-)$ and T_+ after being corrected for the solvent conductance according to considerations discussed below.

An expression by which the observed transference number can be corrected for the solvent conductance may be derived as follows. The this is the value which should be used in computing the volume correction. The computation of the volume correction in this manner, however, is very laborious. The volume corrections actually used are based on a value of C_{CdCl_2} the same as C_{XCl} , that is, an approximate mean, in all probability sufficiently accurate for the purpose.

current I flowing in a linear conductor is equal to the total flux of electricity through a given cross section per unit time. For a solution of a uni-univalent electrolyte at concentration C , V_+ will represent the actual work-

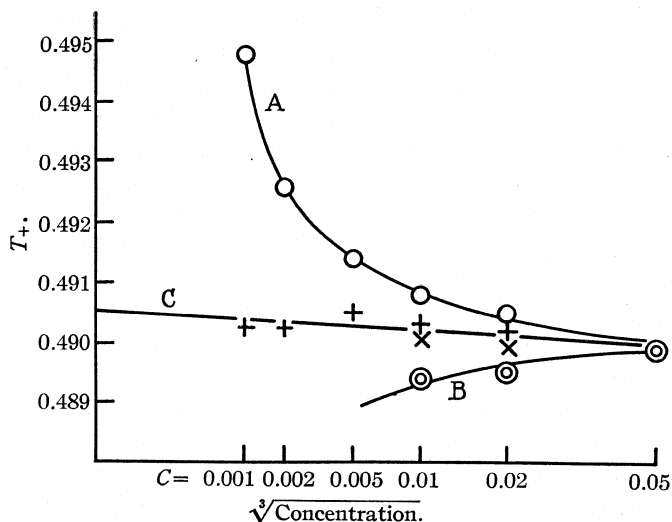

Fig. 2.—Effect of solvent correction on observed transference numbers for potassium chloride solutions: \circ , $1 - T_-$ (observed); $+$, $1 - T_-$ (corrected); \odot , T_+ (observed); \times , T_+ (corrected).

ing velocity of the entire cation constituent and V_- that of the anion constituent. The total current flowing in a tube of uniform cross section A is

$$I = \frac{CFA}{1000} (V_+ + V_-) + \frac{FA}{1000} \sum C_i V_i$$

The last term provides for the current carried by impurities in the solvent, whose unknown concentrations and velocities are C_i and V_i , respectively. On multiplying this equation through by $V_+/(V_+ + V_-)$ and rearranging

$$\frac{V_+}{V_+ + V_-} = T_+ = \frac{CFA V_+}{1000 I} + \frac{FA}{1000 I} \cdot T_+ \sum C_i V_i$$

is obtained. Since the mobility, U_i , of an ion constituent is the ratio of the velocity, V_i , to the field strength, E , this equation may be written

$$T_+ = \frac{CFA V_+}{1000 I} + \frac{FEA}{1000 I} T_+ \sum C_i U_i$$

However, the ratio I/EA is the specific conductance of the solution, K_{solution} , and $(F/1000) \sum C_i U_i$ is the specific conductance of the solvent, K_{solvent} , which may be measured independently. If the assumption be made that introduction of the solute into the solution does not alter the concentration and mobilities of the impurities in the solvent, this equation becomes

$$T_+ = T_+ (\text{obs.}) + T_+ \frac{K_{\text{solvent}}}{K_{\text{solution}}}$$

for the cation transference number and there is a corresponding expression for the anion transference number.

A determination of the solvent correction in the manner outlined above leads to a value for that correction which is necessarily too small, since the potential gradient in the indicator region is greater than that in the region ahead of the boundary, with the result that this region will be progressively contaminated with impurities forced across the boundary. It was thought that with the data on potassium chloride which were available a better estimate of this correction could be obtained by assigning to the solvent a conductance which, when the corresponding correction was applied to the data, would bring the two curves of Fig. 2 very nearly into coincidence. The solvent conductance as determined in this manner was but slightly higher than the value experimentally measured, and the data, when thus corrected, give Curve C of Fig. 2.

In order to reduce the solvent correction to as low a value as possible the following procedure was devised. The solutions of sodium chloride and potassium chloride below 0.02 normal, on which anion boundaries were observed, were swept out with carbon dioxide-free nitrogen¹⁴ before introduction into the moving boundary cell. This procedure materially improved the quality of the solvent but by no means eliminated the correction since after introduction into the cell a small portion of the solution must necessarily come in contact with the air of the laboratory. Moreover, the solvent contains minute amounts of ionic impurities other than carbonic acid and may also acquire additional impurities from contact with the lubricant used in the assemblage of the cell.¹⁵ The solvent conductance was therefore determined by direct current measurement in the moving boundary cell after the water had been subjected to the same treatment as the solutions being observed. The values for all solvent conductances are recorded in Tables II to V.

Disturbing and Restoring Effects at the Boundary.—A characteristic of the moving boundary method which largely determines the upper limit of concentration at which accurate measurements can be made is the presence of heat and diffusion effects at the boundary. There is, however, a mechanism operating to oppose such disturbances. This is a restoring effect due to the change of the potential gradient at the boundary. This effect has been studied and described by MacInnes and Cowperthwaite.¹⁶ A large difference in the densities of the two solutions meeting at the boundary appears to reinforce this restoring effect. Ob-

¹⁴ Shedlovsky, *THIS JOURNAL*, **54**, 1411 (1932).

¹⁵ A lubricant which was found to be quite satisfactory was prepared by melting together five parts of vaseline and one part of beeswax. Both ingredients were extracted several times with hot conductivity water before they were mixed.

¹⁶ MacInnes and Cowperthwaite, *Proc. Natl. Acad. Sci.*, **15**, 18 (1929).

viously, to obtain correct transference numbers the restoring effect must be stronger than all the disturbing influences. The indications that this latter condition is fulfilled are (a) the boundaries appear flat and sharp, (b) at constant current they move with constant velocity, (c) the observed transference numbers are, within wide limits, independent of the current density, and (d) independent observations on cation and anion boundaries for the same solution give consistent results. With the exception of condition (d) for hydrochloric acid solutions, as will be explained below, the experiments reported in this paper fulfilled all of these requirements.

Measurements on Solutions of Hydrochloric Acid.—Due to the high mobility of the hydrogen ion the heat effects were more difficult to eliminate in the measurements on hydrochloric acid than in corresponding determinations with solutions of the other electrolytes. In addition any uncertainty as to the values for these salts was eliminated by check measurements on cation and anion boundaries. Such checks were difficult to obtain with hydrochloric acid solutions, since at the high current densities necessary to bring out sharp HIO_3/HCl boundaries, for example, the heat effects are apparently large enough to produce appreciable mixing. It was therefore considered desirable to make confirmatory determinations of the cation transference numbers using indicators other than cadmium chloride. A comparison of the results with the different indicators is made in Table VI. Results, using cadmium chloride as indicator, with three sizes of tube, are also included.

TABLE VI
A COMPARISON OF RESULTS ON HYDROCHLORIC ACID

^a Autogenic boundaries.

From the data in this table it is seen that there is a slight increase in the apparent transference number at 0.1 *N* as the tube size is diminished from 0.12 to 0.08 and but little change on further decrease of tube size. Furthermore, the data of Table VI indicate such a slight dependence on the nature of the indicator ion as to be within the limits of error in the determinations. The data obtained in the smallest tube, with cadmium chloride as indicator, though possibly not quite as accurate as the corresponding data for potassium, sodium and lithium chlorides, are probably correct within 0.05%.¹⁷

¹⁷ The value of T_+ for 0.1 *N* HCl reported in this paper is 0.1% higher than the

Discussion of Results

A comparison between some of the data for potassium chloride given in Table II and that recently obtained by MacInnes and Dole,¹⁸ using the Hittorf method, has already been made by those authors, and showed excellent agreement of the results obtained by the two methods. The earlier work on potassium chloride by Smith and MacInnes¹⁹ and MacInnes and Brighton³ gave results slightly higher at 0.1 *N* than those given in this paper, but agreeing within the limit of error at 0.2 *N*. These researches were, however, carried out before the constant current apparatus was used. After that device was installed, Dr. Cowperthwaite obtained anion and cation results (not published) at 0.1 *N* with falling boundaries agreeing perfectly with those reported here.

In the case of lithium chloride, the recent careful measurements of Jones and Bradshaw²⁰ using the Hittorf method are given in Table VII together with values obtained by the moving boundary method on the same salt.

TABLE VII
VALUES OF T_+ FOR LiCl AT 25° AS DETERMINED BY THE HITTORF AND MOVING
BOUNDARY METHOD

T_+ , Jones and Bradshaw	.333	.331	.326	.320

A difficulty with the e. m. f. method is that, since the transference numbers change with the concentration, the experimental data must be fitted to empirical or semi-empirical equations. The difference between the transference numbers obtained from the same data using different equations is shown in the figures just given and indicates that the computed transference numbers are very sensitive to the form of the equation chosen. As can be seen the values in Table VII are roughly the mean of the results by the two

Transference Numbers as a Function of the Concentration.—For purposes of interpolation and for extrapolation to zero concentration it is desirable to express the measured transference numbers as a function of the concentration. Dole²² has recently shown how the Onsager²³ equations for ion conductances may be combined to give an expression for the transference number as a function of the concentration. This expression must be valid in the limiting region of zero concentration if the ion conductance equations are valid and the recent precise conductance measurements of Shedlovsky²⁴ indicate the accuracy of these limiting laws. Hence a plot of any function which may be derived for transference data must go into the axis of zero concentration with the slope required by the Onsager equations.

For the ions of uni-univalent electrolytes at 25° in water

$$\lambda = \lambda^0 - (\alpha\lambda^0 + \beta) \sqrt{C}$$

In this expression λ is the equivalent conductance of the ion at concentration C , λ^0 the equivalent conductance at zero concentration, and α and β are numerically equal to 0.2274 and 29.90, respectively. The cation transference number, on the basis of this expression, is

$$T_+ = \frac{\lambda_+}{\lambda_+ + \lambda_-} = \frac{\lambda_+^0 - (\alpha\lambda_+^0 + \beta) \sqrt{C}}{\lambda_+^0 + \lambda_-^0 - [\alpha(\lambda_+^0 + \lambda_-^0) + 2\beta] \sqrt{C}} \quad (1)$$

Since $T_+^0 = \lambda_+^0/(\lambda_+^0 + \lambda_-^0)$ and setting, for abbreviation

$$\begin{aligned} \Lambda' &= \lambda_+^0 + \lambda_-^0 - [\alpha(\lambda_+^0 + \lambda_-^0) + 2\beta] \sqrt{C} \\ &= \Lambda_0 - (\alpha\Lambda_0 + 2\beta) \sqrt{C} \end{aligned}$$

Equation (1) may be rearranged to give

$$T_+ = T_+^0 - \frac{(1 - 2T_+^0)}{\Lambda'} \beta \sqrt{C} \quad (2)$$

This limiting expression for the transference number states that a plot of T_+ against \sqrt{C} should go into the axis of zero concentration with the slope

$$\left(\frac{dT_+}{d\sqrt{C}} \right)_{C=0} = \frac{2T_+^0 - 1}{\Lambda_0} \beta$$

The limiting slope is thus seen to be proportional to the deviation of T_+^0 from 0.5 and inversely proportional to the limiting conductance, Λ_0 , of the electrolyte.

Equation (2) is not valid in the concentration range where the measurements have been made. However, the striking success of the Shedlovsky methods of calculation. MacInnes and Beattie did not use graphical methods in their computation as Jones and Bradshaw imply. Both methods of calculation are analytical, the difference being in the form of function used.

²² Dole, *J. Phys. Chem.*, **35**, 3647 (1931).

²³ Onsager, *Physik. Z.*, **27**, 388 (1926); **28**, 277 (1927).

²⁴ Shedlovsky, *THIS JOURNAL*, **54**, 1405, 1411 (1932).

method of treating conductance data suggested the possibility of a similar treatment of transference data. Solution of Equation (2) for T_+^0 gives

$$T_+^0 = \frac{T_+ \Delta' + \beta \sqrt{C}}{\Delta' + 2\beta \sqrt{C}}$$

Values of T_+^0 were computed from each pair of observed values for T_+ and C . These computed values of T_+^0 —plotted as $T_+^{0'}$ —were found to vary

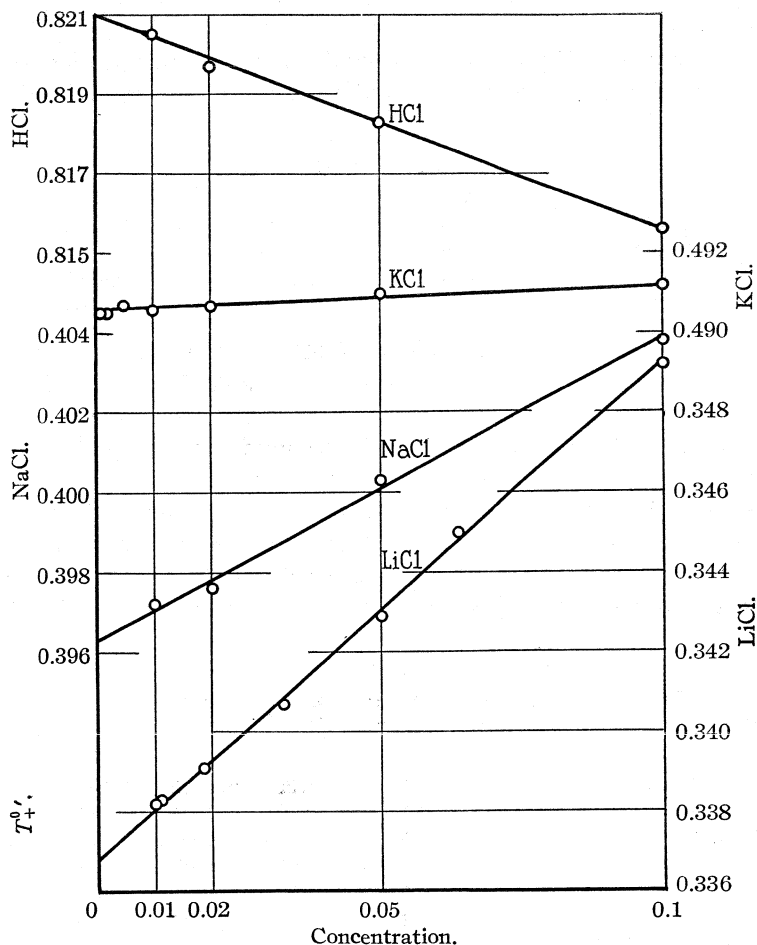

Fig. 3.—Test of Equation (4) and the evaluation of the constants T_+^0 and A .

linearly with the concentration as shown in Fig. 3 up to a concentration of 0.1 normal. Thus $T_+^{0'}$ is a linear function of the concentration

$$T_+^{0'} = T_+^0 + AC = \frac{T_+ \Delta' + \beta \sqrt{C}}{\Delta' + 2\beta \sqrt{C}} \quad (3)$$

Solution of (3) for T_+ gives

$$T_+ = T_+^0 - \frac{1 - 2T_+^0}{\Lambda'} \beta \sqrt{C} + AC \left(1 + \frac{2\beta \sqrt{C}}{\Lambda'} \right) \quad (4)$$

an expression for T_+ which has the theoretical limiting slope. A simple interpolation formula which appears to be valid to much higher concentrations than Equation (4) has been proposed and tested by Jones and Dole.²⁵ Their formula, however, does not in general extrapolate to infinite dilution with the correct limiting slope.

The constants of Equation (4) as obtained from a plot similar to Fig. 3 are given in Table VIII together with the values of Λ_0 given by Shedlovsky.

TABLE VIII
CONSTANTS OF EQUATION (4)

	T_+^0	A	Λ_0
LiCl	0.3368	0.125	115.00
NaCl	.3963	.076	126.42
KCl	.4906	.006	149.82
HCl	.8210	-.054	426.04

Values of T_+ computed by means of (4) and the data of Table VIII are compared with the observed values in Table IX. The deviations between observed and computed values are neither systematic nor large and Equation (4) can therefore safely be used for interpolation to 0.1 normal and for extrapolation to lower concentrations. Values computed by means of Equation (4) for round concentrations except the values for 0.2 N are summarized in Table X. In cases where the last figure appears in smaller type, that figure may be in error ± 3 units, except for the data on potassium chloride below 0.005 N , where the error may be slightly greater.

²⁵ Jones and Dole, *THIS JOURNAL*, **51**, 1073 (1929).

The results are presented graphically in Fig. 4. In this figure the circles represent the experimental points and the smooth curves are the values computed from Equation (4) and the constants of Table VIII.

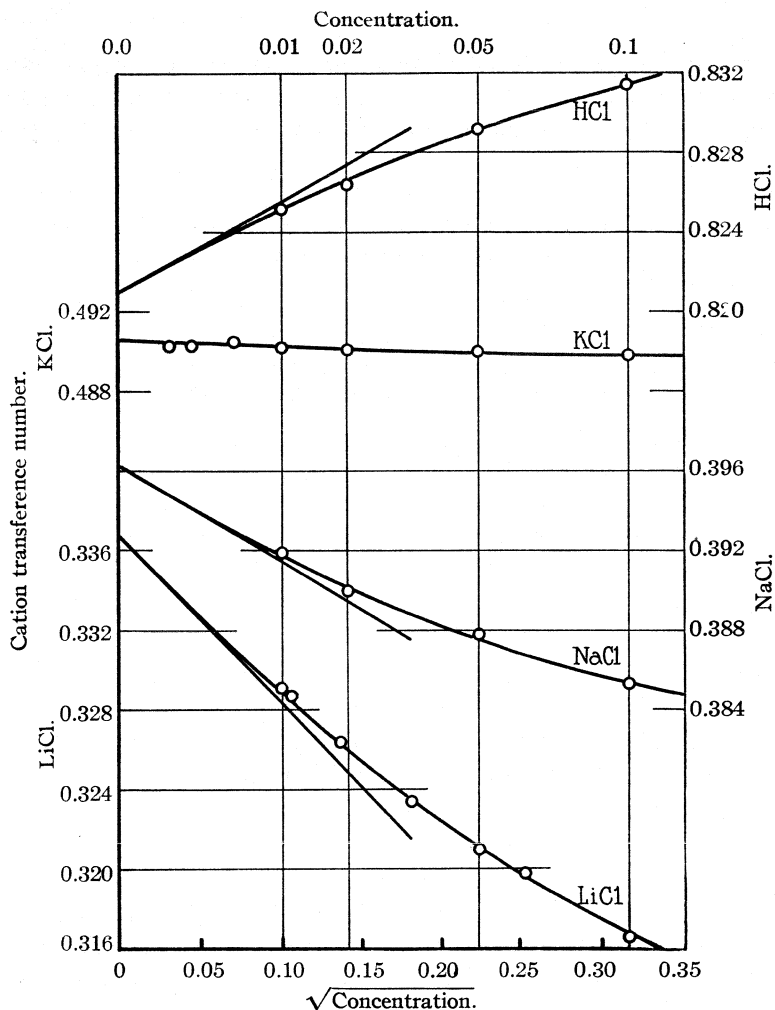

Fig. 4.—Graphical presentation of data showing approach to theoretical limiting slope. Circles represent experimental points; smooth curve represents values computed by Equation (4).

The curves through the experimental points are evidently approaching the limiting slopes which are represented in the figure by the straight full lines. In the case of potassium chloride the limiting slope and the curve given by Equation (4) are nearly coincident up to a concentration of several hundredths normal.

In conclusion the author would like to express his sincere appreciation to Dr. D. A. MacInnes for many suggestions during the course of this work and for valuable criticism during the preparation of this paper.

Summary

Measurements of the transference numbers at 25° of aqueous solutions of potassium chloride, sodium chloride, lithium chloride and hydrochloric acid by the moving boundary method have been made. The results are given in Table X.

TABLE X

TRANSFERENCE NUMBERS AT 25° OF POTASSIUM CHLORIDE, SODIUM CHLORIDE, LITHIUM CHLORIDE AND HYDROCHLORIC ACID

A correction for the conductance of the solvent, neglected by previous workers, has been found to be important when dilute solutions are measured.

An equation connecting the transference numbers with the concentration, which is useful for interpolation, and which gives a correct extrapolation to infinite dilution, is given.

THE LIMITING EQUIVALENT CONDUCTANCES OF SEVERAL UNIVALENT IONS IN WATER AT 25°

BY DUNCAN A. MACINNES, THEODORE SHEDLOVSKY AND LEWIS G. LONGSWORTH

RECEIVED MARCH 17, 1932

Published JULY 6, 1932

Data on the conductances of aqueous solutions of a number of binary electrolytes at concentrations ranging from 3×10^{-5} to 0.1 *N* are given in recent papers from this Laboratory,¹ and an article preceding this one describes the accurate determination of the transference numbers of four chlorides in the range 0.01 to 0.1 *N*.² With these data at hand we have been able to arrive at some definite conclusions concerning the equivalent conductances of ion constituents, and the values of the limiting ion mobilities.

Table I contains the assembled data on the equivalent conductances, Λ , of four chlorides and the corresponding transference numbers of the

chloride ion, T_{Cl} . These transference numbers are the directly determined values with the exception of those for lithium chloride, which have been brought to round concentrations by very short interpolations. From these data the equivalent conductances of the chloride ion constituents have been computed, and the results have been tabulated in the fourth column of the table.

.10	95.83	.6832	65.47	65.48

If values of λ_{Cl} for the four chlorides at equivalent concentrations are compared it will be seen that they are very nearly the same at 0.01 and 0.02 *N* but show definite deviations from each other at 0.05 and 0.1 *N*. This is not in accord with the observations of Lewis³ and MacInnes,⁴ who found from less accurate data that the chloride ion conductance appeared to be independent of its univalent co-ion up to a concentration of 0.1 *N*.

The data in Table I may be used to discover how the conductance of the chloride ion constituent changes with the concentration. Shedlovsky⁵ has proposed an empirical extension of Onsager's equation for the change of the equivalent conductance of a uni-univalent electrolyte with the concentration, *C*, having the form

³ G. N. Lewis, *THIS JOURNAL*, **34**, 1631 (1912).

⁴ MacInnes, *ibid.*, **43**, 1217 (1921).

⁵ Shedlovsky, *ibid.*, **54**, 1405 (1932).

$$\Lambda_0 = \frac{\Lambda + \beta \sqrt{C}}{1 - \alpha \sqrt{C}} - BC \quad (1)$$

With a few exceptions this equation has been found to hold with high accuracy for uni-univalent electrolytes up to 0.1 *N*.

In Onsager's equation

$$\alpha = \frac{5.78 \times 10^{-5}}{(DT)^{3/2}} \text{ and } \beta = \frac{58.0 \sqrt{2}}{\eta(DT)^{3/2}}$$

in which *D* is the dielectric constant, *T* the absolute temperature, and η the viscosity. The numerical coefficients depend upon universal constants. The extension of Onsager's equation consists of the term *BC* in which *B* is an empirical constant. For the equivalent conductance of an ion constituent $\lambda = T\Lambda$ the corresponding equation is

$$\lambda_0 = \frac{\lambda + 1/2 \beta \sqrt{C}}{1 - \alpha \sqrt{C}} - bC \quad (2)$$

in which λ_0 is the limiting equivalent conductance of the ion species and *b* is an empirical constant.

To use Equation (2) it is convenient to compute values of

$$\frac{\lambda + 1/2 \beta \sqrt{C}}{1 - \alpha \sqrt{C}} = \lambda'_0 \quad (3)$$

and plot them against *C*. Figure 1 shows values of λ'_0 for the chloride ion constituent plotted in this way. The result is a straight line for

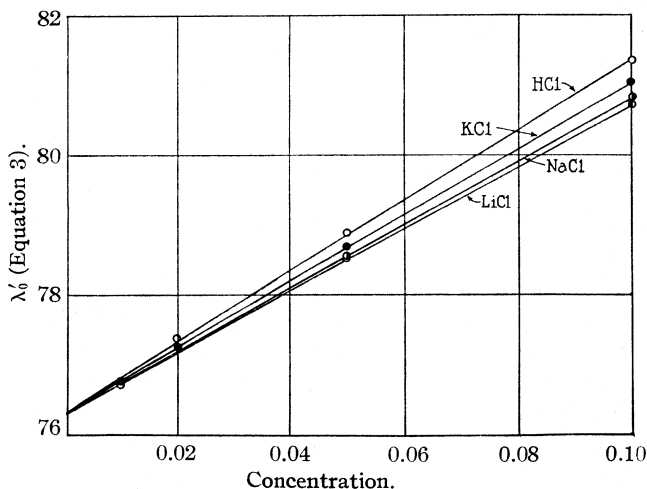

Fig. 1.

the λ'_0 values from each of the electrolytes. The four lines converge and meet at a point at zero concentration. Equation (2) thus provides a method for obtaining the limiting conductance of the chloride ion, $\lambda_{0\text{Cl}}$.

The most probable values of that constant and of b for each electrolyte were found by applying the method of least squares to the equation

$$\lambda'_0 = \lambda_0 + bC$$

The resulting constants are given in Table II.

TABLE II

COMPUTED VALUES OF THE LIMITING CONDUCTANCE AT 25° OF THE CHLORIDE ION

Substance	b	λ_0 for Cl ion
KCl	47.30	76.31
NaCl	45.00	76.32
LiCl	44.09	76.34
HCl	49.50	76.32

Average 76.32

It will be observed that the values for the limiting chloride ion conductance thus obtained are, within about 0.02%, the same from all four chlorides. The close agreement of the data with Equation (1) is best shown by comparing in Table I the observed and computed values of λ_{Cl} , the latter having been obtained by using in that equation the appropriate values of the constants in Table II. The comparatively large difference between the computed and measured values for 0.05 N for lithium chloride possibly indicates that the behavior of this substance may be influenced by some secondary effect, particularly as the conductance values of this salt deviate from Shedlovsky's equation at a lower concentration than is observed for the other electrolytes under consideration. However, the agreement shows that Equation (2) for the chloride ion constituent holds as well as Equation (1) has been found to do for complete uni-univalent electrolytes.

A check on the mean value of λ_{0Cl} in Table II is given by the limiting conductance value for potassium chloride, $\Lambda_0 = 149.82$, obtained by Shedlovsky from his measurements on the most dilute solutions, and the limiting value of the transference number, $T_{0Cl} = 0.5094$, of that salt, as given by Longworth in the paper preceding this one. The product of these two figures yields $\lambda_{0Cl} = 76.32$, agreeing exactly with the average value by the other method. Using the data from say 3×10^{-5} to 0.001 N an accurate extrapolation may be made of the conductance data by simply plotting the equivalent conductance values against the square root of the concentration. This does not involve the extension of the Onsager equation. The very close agreements just shown may be in some measure fortuitous, particularly as the transference numbers at the lower concentrations are not known to this high degree of accuracy.

It will be noted that the value $\lambda_{0Cl} = 76.32$ differs quite widely from that generally accepted for this constant. Noyes and Falk⁶ give $\lambda_{0Cl} = 75.8$

⁶ Noyes and Falk, THIS JOURNAL, 34, 454 (1912).

and the figures in the "International Critical Tables"⁷ yield 75.1 if the value at 18° and the temperature coefficient there given are used. It is important to note that *the new value of the constant is not dependent on any one transference number as were the older figures, the same value within a very narrow range being obtained from data on four electrolytes and four series of determinations of transference numbers.*

From the $\lambda_{0\text{Cl}}$ value just given and the limiting conductances, Λ_0 , from the recent papers by Shedlovsky and MacInnes and Shedlovsky,¹ the limiting ion conductances of a number of ions may be computed from Kohlrausch's law of independent ion mobilities. The results, which are collected in Table III, are all on the basis that a "dema1" solution of potassium chloride, containing 7.47896 g. of potassium chloride and 1000 g. of water (weighed in air) has a specific conductance value of 0.012852₄ at 25°.⁸

TABLE III
LIMITING ION CONDUCTANCES AT 25°

	Cations		Anions
K ⁺	73.50	Cl ⁻	76.32
Na ⁺	50.10	NO ₃ ⁻	71.42
H ⁺	349.72	CH ₃ COO ⁻	40.87
Ag ⁺	61.90		
Li ⁺	38.68		

These constants will be added to from time to time as the work in this Laboratory proceeds. A more elaborate theoretical discussion of the results will also be given along with further data, some of which are already at hand.

Summary

A table is given of the limiting conductance at 25° of eight ion species, based on transference and conductance values obtained in this Laboratory. The extrapolations have been made with an extension of Onsager's equation, which reduces to that equation in the limit. Closely agreeing values of the limiting chloride ion conductance have been found from the use of conductance and transference data on four different chlorides.

ACTIVITY COEFFICIENTS OF SULFURIC ACID IN ANHYDROUS ACETIC ACID

BY VICTOR K. LA MER AND W. C. EICHELBERGER¹

RECEIVED MARCH 30, 1932

PUBLISHED JULY 6, 1932

In a recent paper Hutchison and Chandlee² have reported measurements on the cell without transfer

corresponding to the process $\text{H}_2(\text{g}) + \text{Hg}_2\text{SO}_4(\text{s}) = \text{H}_2\text{SO}_4(\text{m}) + 2\text{Hg}(\text{l})$ (2 faradays) at 25° for molalities of sulfuric acid ranging from $m = 0.8715$ to $m = 0.0025$. These measurements are particularly valuable for, as the authors point out, they are not burdened with the uncertainties of liquid junction potentials, and the logical objections to individual ion activities which are inherent in data obtained from cells with transference, a criticism that may be raised against previous e. m. f. measurements in glacial acetic acid.

In this paper we shall present a modified interpretation of their data and show that they conform to the Debye-Hückel theory over a wider concentration range than does the original interpretation.

To evaluate E° , for the computation of the mean activity coefficients of sulfuric acid, Hutchison and Chandlee consider sulfuric acid as a ternary electrolyte ($\nu = 3$) dissociating into 2 H^+ and SO_4^- ions, and employ a two parameter equation; namely, the simple form of the Debye-Hückel theory (first approximation of the Poisson-Boltzmann equation) in combination with the linear term added by Hückel to account for changes in the dielectric constant, as a control on the extrapolation to infinite dilution. Since the dielectric constants of conducting solutions are not susceptible to experimental measurement and in aqueous solutions where the various attempts at measurement have led to widely different and often absurd results,³ the arbitrary parameter B involved in the Hückel extension cannot be regarded at the present time other than as a purely empirical correction term, we shall therefore restrict our computations to the region where the better theoretically founded parameter " a ," corresponding to the distance of closest approach of the ions, involved in the original form of the theory suffices as an explanation.

Our treatment differs in that we shall consider sulfuric acid when dissolved in glacial acetic acid as a binary electrolyte ($\nu = 2$) dissociating into H^+ and HSO_4^- ions. Owing to the high degree of acidity of glacial acetic acid, any secondary dissociation of the HSO_4^- ion into SO_4^{--} and

¹ National Research Council Fellow.

² Hutchison and Chandlee, *THIS JOURNAL*, 53, 2881 (1931).

³ Harned, *ibid.*, 48, 326 (1926).

H^+ ions would be completely repressed. In addition we shall take into account the higher terms, (III) and (V), of the Gronwall, La Mer and Sandved⁴ solution of the Poisson-Boltzmann equation which were neglected in Hutchison and Chandlee's treatment, namely

$$\begin{aligned}
 -\log_{10} f = & 19.63 \left(\frac{z^2}{a}\right) \frac{x}{1+x} - 320.7 \left(\frac{z^2}{a}\right)^3 \cdot 10^3 \left[\frac{1}{2} X_3(x) - 2Y_3(x)\right] \\
 & \text{(I)} \qquad \qquad \qquad \text{III} \\
 & -26,200 \left(\frac{z^2}{a}\right)^5 \cdot 10^5 \left[\frac{1}{2} X_5(x) - 4Y_5(x)\right] \qquad \qquad \text{(2)} \\
 & \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \qquad \text{V}
 \end{aligned}$$

In Table I are given the observed e. m. f.'s, E , corresponding to the molalities m . The other quantities are defined as follows

$$\begin{aligned}
 E^{\circ'} &= E + \frac{\nu RT}{nF} \log m = E + 0.05915 \log m \\
 &= E^{\circ} - 0.05915 \log f
 \end{aligned} \qquad (3)$$

$$\kappa = \sqrt{\frac{4\pi N e^2}{1000 kTD}} \sum n_i z_i^2 = 1.1734 \times 10^8 \sqrt{c} \qquad (4)$$

when we substitute D (acetic acid) = 6.165 and the numerical values of the universal constants. It is important to emphasize that the assump-

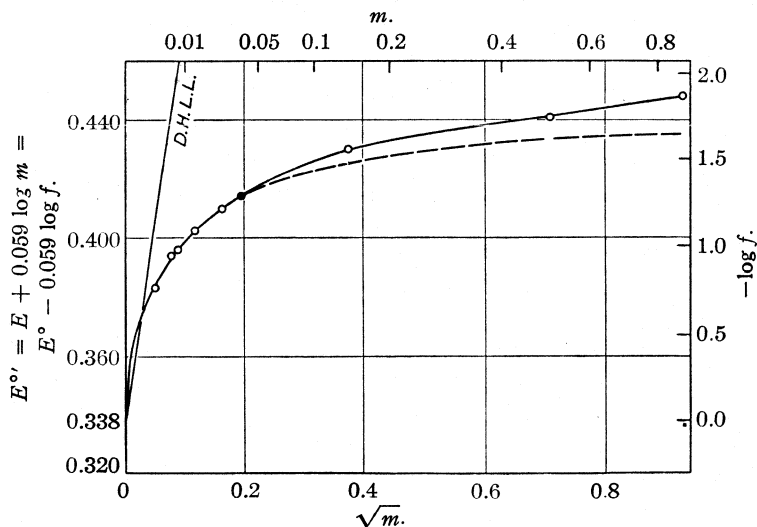

Fig. 1.—Heavy curve—Experimental: $E^{\circ'} = E + 0.05915 \log m$.
Dotted curve—Theory: Gronwall, La Mer and Sandved; " a " = 11 Å.;
 $E^{\circ'} = E^{\circ} - 0.05915 \log f = 0.338 + 0.05915 [\text{Eq. (2)}]$.

tion that $\nu = 2$ leads to an entirely different set of values for $E^{\circ'}$ and consequently for E° than those employed by Hutchison and Chandlee. Similarly, their values of κ are reduced by the factor $\sqrt{3}$ and the limiting

⁴ Gronwall, La Mer and Sandved, *Physik. Z.*, **29**, 358 (1928).

slope of $\log f$ against \sqrt{m} by the factor $2\sqrt{3}$ by this assumption. Another advantage is that we can employ the symmetrical solution of the Poisson-Boltzmann equation as given by Gronwall, La Mer and Sandved⁴ and not be obliged to carry out the tedious computations involved in the unsymmetrical case.⁵

TABLE I
COMPUTATION OF $E^{\circ'}$ FOR $\nu = 2$

No.	m	E	$E^{\circ'}$	c	\sqrt{c}	$10^{-8} \kappa$
1	0.002461	.537	0.3827	0.002567	0.05067	0.0595
2	.006053	.525	.3938	.006315	.07947	.0933
3	.007730	.521	.3961	.008063	.08979	.1054
4	.01377	.512	.4019	.01436	.1198	.1406
5	.02662	.5035	.4104	.02773	.1665	.1954
6	.03796	.498	.4140	.03954	.1988	.2333
7	.1437	.480	.4302	.1490	.3860	.4529
8	.5014	.459	.4413	.5133	.7164	.8406
9	.8715	.452	.4485	.8770	.9365	1.0989

Table II gives the computations for " a " = 11 Å., which value of " a " gives the most constant and therefore the most acceptable value of E° .⁶

The computed values of E° for this and other values of " a " are plotted in Fig. 2. It is noteworthy that a one-parameter function yields a value of E° which is constant to within the limits of experimental error (± 0.001 volt) for the six determinations extending over the concentration range $m = 0.0025$ to $m = 0.038$, whereas under the assumption $\nu = 3$ two parameters are required to account for these data. A small empirical correction term of the order of $0.02 m$ is sufficient to account for the deviation of the last three points from $E^{\circ} = 0.338$.

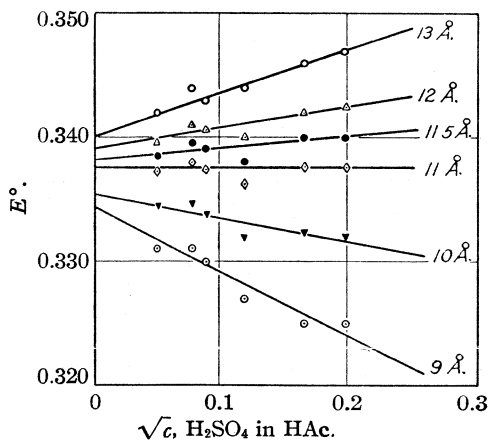

Fig. 2.

From recent measurements on the solubility of univalent salts in glacial acetic acid, Seward and Hamblet⁷ have shown that " a " is equal to 8.5 to 9.5 Å. and that it is unnecessary in dilute solution to introduce a term for change of dielectric constant, which is in agreement with our conclusions.

⁵ La Mer, Gronwall and Greiff, *J. Phys. Chem.*, **35**, 2245 (1931).

⁶ For details concerning this computation see La Mer and Parks, *THIS JOURNAL*, **53**, 2040 (1931); Cowperthwaite and La Mer, *ibid.*, **53**, 4333 (1931).

Summary

The e. m. f. measurements of Hutchison and Chandlee on the activity coefficient of sulfuric acid in glacial acetic acid can be accounted for on the basis of the Gronwall, La Mer and Sandved extension of the Debye-Hückel theory on the assumption that sulfuric acid behaves as a binary electrolyte in this solvent with an " a " value equal to 11 Å., for the concentration range $m = 0.0025$ to 0.038 .

$E^\circ = 0.338$ volt for the cell H_2, H_2SO_4 in glacial acetic acid, Hg_2SO_4, Hg .

MOLECULAR ROTATION IN THE SOLID STATE. THE VARIATION OF THE CRYSTAL STRUCTURE OF AMMONIUM NITRATE WITH TEMPERATURE

By S. B. HENDRICKS, E. POSNJAK AND F. C. KRACEK

RECEIVED APRIL 4, 1932

PUBLISHED JULY 6, 1932

The phenomenon of molecular rotation in the solid state, first recognized by L. Pauling,¹ is proving of wide occurrence. In sodium nitrate² the picking up of rotational energy by the nitrate groups takes place over an extended temperature interval and is accompanied by *gradual* changes in such properties as coherent scattering of x-rays, heat capacity and specific volume. Pauling interpreted the *gradual* transitions shown by methane, hydrogen bromide, hydrogen iodide and the ammonium halides as accompanying molecular rotation. He also suggested that the *polymorphic* transitions shown by nitrogen ($35.4^\circ K.$), oxygen ($43.75^\circ K.$) and hydrogen chloride ($93.36^\circ K.$) are accompanied by the excitation of molecular rotation.

The several gradual transitions shown by hydrogen bromide and hydro-

gen iodide³ were supposed by Pauling to be connected with incipient rotation about various directions in the crystals. x-Ray powder diffraction photographs, recently obtained, from the various crystalline modifications of these compounds are not readily interpretable.⁴ They are, however, in no sense incompatible with the concept of molecular rotation.

We have been fortunate in discovering in ammonium nitrate formal proof for the concept of molecular rotation in the solid state and evidence for the setting in of the rotation at a *polymorphic* transition point. The structures of the many modifications of ammonium nitrate have been studied in detail.

I. The Polymorphism of Ammonium Nitrate

Ammonium nitrate has one high pressure and five low pressure crystalline modifications. The inversion temperatures, the volume changes, and the latent heats of inversion have been determined,⁵ the most probable values of these constants are given in the following tabulation.

Phase reaction	Temp., °C.	Volume change, cc./g.	Heat of inversion, cal./g.	Authors
I \longleftrightarrow II	125.2	0.013	11.9	Early and Lowry, Bellati and Finazzi, Bellati and Romanese, Behn
II \longleftrightarrow III	84.2	-.008	5.3	Early and Lowry, Bellati and Romanese, Behn
III \longleftrightarrow IV	32.3	.0221	4.99	Cohen and Kooy, Cohen and Heldeman
IV \longleftrightarrow V	-18	-.016 -.018	1.6	Behn
II \longleftrightarrow IV	45 to 51	Bowen, Behn

Three series of measurements of the relative dilatation of ammonium nitrate have been published, by Bellati and Romanese, Bellati and Finazzi, and U. Behn. These series are not in mutual agreement because of errors in the elimination of the expansion of the dilatometer liquid. We have recalculated the results employing the accurate values of specific volumes at 32.0 and 32.5° for modifications IV and III by Cohen and Kooy, and the density 1.725 *ca.* 18° (Behn, Retgers).⁶ The recalculated results are represented in Fig. 1.

(London)*, **A80**, 444 (1908); Cohen and Kooy, *Z. physik. Chem.*, **109**, 81 (1924); Cohen and Helderman, *ibid.*, **113**, 145 (1924); N. L. Bowen, *J. Phys. Chem.*, **30**, 721 (1926).

⁶ Other values quoted in the literature are largely accidental; thus Schröder is quoted as having determined $\rho = 1.737$, the actually measured values being 1.681 and 1.791. Many other determinations are vitiated by lack of physical homogeneity of the salt used.

The crystallographic observations on the various modifications indicate that ammonium nitrate is (I) cubic (optically isotropic) above 125° , (II) tetragonal (Wallerant) or trigonal (Lehmann, Gossner) between 125 and 84° , (III) orthorhombic (Lehman) or monoclinic pseudo-tetragonal (Wallerant) between 84 and 32° , (IV) orthorhombic pseudo-tetragonal (Wallerant) or orthorhombic pseudo-trigonal (Lehmann) between 32 and -18° , and (V) tetragonal below -18° . Only the room temperature orthorhombic modification (IV) has been measured crystallographically, with the result that two mutually incompatible sets of axial ratios have been published,

- (a) 0.5834:1:0.736 (Retgers, Wallerant, based on measurements by Marignac)
- (b) 0.9092:1:1.0553 (Gossner)

The latter set of axial ratios (b) agrees with our structural determinations.

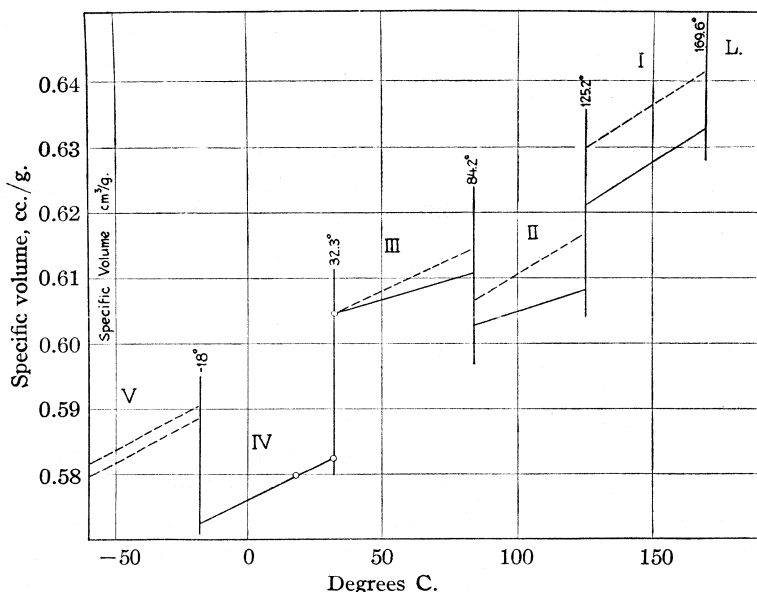

Fig. 1.—The specific volumes of the various modifications of ammonium nitrate. Circles represent the accurate values by Cohen and Kooy, and by Retgers. Full lines from relative expansion curves by Bellati and Romanese and Finazzi; broken lines, from relative expansion curves by Behn.

Bowen (1926) agrees with Wallerant that the 84 to 125° modification (II) is tetragonal, optically uniaxial and positive. He describes the 32 to 84° modification (III) as orthorhombic or monoclinic (optically biaxial), optic axial angle ($2V$) nearly 90° , with a moderately high birefringence, in comparison with the orthorhombic room temperature (IV) modification which has a very high birefringence, optic axial angle $2V$ about 35° .

We have studied the behavior of ammonium nitrate with the petro-

graphic microscope equipped with a heating stage. For reading the temperatures the stage is provided with a gold palladium-platinum rhodium thermocouple. The samples were prepared in the usual way, by melting a small quantity of the salt on an ordinary microscope slide, a cover-glass being then pressed down lightly to obtain a thin section. The lag in the inversions was clearly noticeable; the greatest lag is observed with the $\text{IV} \rightleftharpoons \text{III}$ inversion, which started at 36 to 40° with rising temperature, and 28 to 25° with falling temperature. When both phases are initially present, the lag is very much less; the boundary can then be seen to move quite rapidly at 33° in one direction and at 31 to 32° in the other. On raising the temperature to the $\text{III} \rightleftharpoons \text{II}$ inversion, the transformation starts quite promptly at about 85°. If the cooling is begun now before the temperature of the salt reaches 125°, modification II reverts to III directly, starting usually near 80°, but sometimes not until a temperature of 70 or even 65° is reached. If, on the other hand, the temperature is allowed to rise above the $\text{II} \rightleftharpoons \text{I}$ inversion near 125°, then, on subsequent cooling, the form II does not invert directly back to III as above, but it persists down to 48 or 45°, when it changes apparently to form IV, as also described by Bowen (*op. cit.*, p. 723). If the slide is very thin, and the salt well dried, the transformation is very like a single crystal to single crystal transition, taking place very rapidly, with barely a noticeable change in orientation and birefringence. If the slide is a little thicker than before, or the salt not too thoroughly dried, the transformation proceeds by recrystallization. If the temperature is allowed to decrease further, no other transformation occurs, either with the thin or the thick preparations, down to 0°. On heating now, the thin slides always revert back to form II at about 50 to 52°, again very rapidly, with a hardly noticeable change in birefringence. This metastable inversion can be carried back and forth in the thin films almost indefinitely, the metastable condition persisting for many hours; it is, however, rapidly destroyed by moisture. In the thicker slides the metastable inversion can sometimes also be reversed a number of times, but usually after three or four reversals the stable modification III appears. Sometimes this happens following the metastable inversion on cooling, as observed by Bowen, but often also on heating, and then only after the metastable inversion on heating has taken place. The difference in behavior of the very thin and the thicker slides at the metastable inversion is striking, as is likewise the reluctance of the preparations, when in the metastable condition, to assume the stable form.

II. The Crystal Structure of Ammonium Nitrate as a Function of Temperature

The Modification Stable between 125 and 169.5° (Melting Point, Cubic I).—x-Ray powder diffraction photographs were made with

MoK $\alpha_1\alpha_2$ radiation of a revolving sample of ammonium nitrate at 155°. The sample was obtained by cooling a melt. Photographs were also made with CuK $\alpha_1\alpha_2$ radiation of samples at 130–140°. In these cases the ammonium nitrate was ground finely and placed in small glass tubes which were rotated throughout the time of exposure. On account of the high rate of crystal growth it was necessary to change the sample every hour. The data obtained from these photographs are summarized in Table I.

TABLE I
POWDER PHOTOGRAPHIC DATA FROM CUBIC AMMONIUM NITRATE (I)
155° MoK $\alpha_1\alpha_2$ radiation (NaCl reference)
 $\sin^2 \theta = 0.00648 (h^2 + k^2 + l^2)$ $a_0 = 4.40 \text{ \AA.}$

Plane	$\sin^2 \theta$ (obs.)	$\sin^2 \theta$ (calcd.)	Int. obs.
(100)	0.00640	0.00648	v. s.
(110)	.01295	.01296	v. s.
(111)	.01955	.01944	w.
(200)	.0259	.0259	m.
(210)	.0321	.0324	v. w.
(211)	.0386	.0389	v. w.
(220)	.0522	.0518	v. w.
(300)(221)	.0588	.0583	w.
(310)	.0648	.0648	v. w.

The lattice required by these data is a simple cubic one. The unit of structure has $a_0 = 4.40 \text{ \AA.}$ at 155°. The density calculated on the basis of such a unit containing $1\text{NH}_4\text{NO}_3$ is 1.55 g./cc. in agreement with the experimentally observed value 1.57 g./cc.

The only possible atomic positions are:

$$\begin{array}{ll} \text{(a)} \ 000 & \text{(b)} \ \frac{1}{2}\frac{1}{2}\frac{1}{2} \\ \text{(3a)} \ \frac{1}{2}\frac{1}{2}0; \frac{1}{2}0\frac{1}{2}; 0\frac{1}{2}\frac{1}{2} & \text{(3b)} \ \frac{1}{2}00; 0\frac{1}{2}0; 00\frac{1}{2} \end{array}$$

Combinations of these positions lead to calculated intensities entirely out of agreement with the observed intensities. Moreover, but we must remark secondarily, such arrangements do not give nitrate groups. It is thus impossible, if the geometrical concepts of crystal symmetry are to be retained, for the oxygen atoms to be in fixed positions.

Several possible escapes from this conclusion might be considered.

(1) *Is the Symmetry Less than Cubic?*—The powder diffraction data would require the crystal axes to be approximately orthogonal and of equal lengths. The instance of $\text{LiCl} \cdot \text{H}_2\text{O}$ might be recalled as an illustration. H. Ott⁷ from powder photographic data concluded that the structure of $\text{LiCl} \cdot \text{H}_2\text{O}$ was based upon a simple cubic lattice and that the unit of structure contains $1\text{LiCl} \cdot \text{H}_2\text{O}$. Since it is not possible to have three dissimilar atoms in such a unit he suggested that two of the atoms were associated, this pseudo atom being the one defined by the geometrical criteria. These observations, however, were inconsistent with the high birefringence and

⁷ Ott, *Z. Krist.*, **63**, 231 (1926).

uniaxial character of $\text{LiCl} \cdot \text{H}_2\text{O}$. A closer examination⁸ of the structure showed it to be tetragonal with an axial ratio of approximately unity. If the symmetry of ammonium nitrate were less than cubic and the unit of structure contained $1\text{NH}_4\text{NO}_3$, the birefringence would necessarily be high, as it is observed to be in the four modifications of ammonium nitrate stable below 125° , since the molecular birefringence of the nitrate group is high. It is thus improbable that the symmetry is less than cubic.

(2) *Is the Unit of Structure Larger?*—This would be possible if the atoms in question, oxygen atoms, had negligible F values in comparison with the other atoms in the compound. In ammonium nitrate the oxygen atoms are in no sense negligible, and there is no evidence for reflections other than the ones listed in Table I.

(3) *Molecular Rotation.*—Randomness in positions of the oxygen atoms may be interpreted as evidence for rotation of the nitrate groups. In order to calculate intensities of reflection it is necessary, on the basis of such data, to assume certain types of distributions. Several distributions were tried. The centers of the ammonium groups can be taken at 000, of the NO_3 groups at $\frac{1}{2}\frac{1}{2}\frac{1}{2}$. Structure factors are listed in Table II calculated on the basis of the following assumptions: (1) the centers of the oxygen atoms are assumed to be randomly arranged on a sphere of 1.25 Å. radius about $\frac{1}{2}\frac{1}{2}\frac{1}{2}$, all positions of the oxygen atoms being considered equally probable; (2) the nitrate groups are assumed to be rotating with constant angular velocity in three orthogonal planes. In each case, the values of the structure factors, which are only approximate, lead to calculated intensities on the basis of assumed F curves, which are still not in good agreement with

TABLE II
STRUCTURE FACTORS FOR VARIOUS PLANES OF CUBIC AMMONIUM NITRATE (I)

Plane	$\sqrt{S} = A \ (B = 0)$		(1)	(2)	No. of planes in form	Intensity observed

(310)	1	+1	+0.2	-0.3	24	v. w.

(1) Calculated for the nitrate groups rotating with constant angular velocities in three orthogonal planes normal to the cubic axes.

(2) These calculations are based upon the assumption that the nitrate groups are rotating with approximately spherical symmetry.

⁸ S. B. Hendricks, *Z. Krist.*, **66**, 298 (1927).

the observed intensities. This lack of agreement is merely indicative of over-simplification in the assumed models. It is quite probable that the nitrate groups do not rotate with constant angular velocities and that they do not generate any simple geometrical figure. In any case, however, it should be pointed out that all reflections beyond (110) are characteristically weak. Either of the above cases qualitatively requires this. It can be seen that if the oxygen atoms approach such arrangements they will contribute partially out of phase for all reflections.

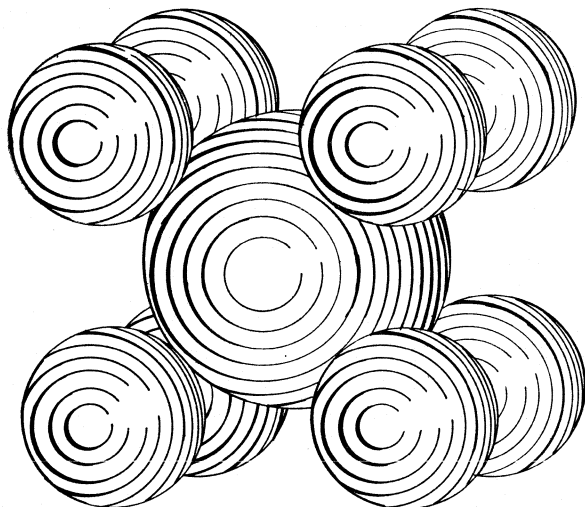

Fig. 2a.—Cubic ammonium nitrate (I). The small spheres represent ammonium groups, the large sphere a nitrate group rotating with spherical symmetry. $a_0 = 4.40 \text{ \AA.}$ (155°).

One factor of importance to geometrical crystallography is brought into clear relief by this structure of ammonium nitrate. It would seem that the unit of structure is the smallest element that *statistically* has the symmetry of the crystal. If this is true the figure generated by a rotating nitrate group must have at least the symmetry of the point group T-23. The minimum symmetry might be that of any cubic point group, the actual that of a sphere.

The unit of structure with the rotating nitrate group represented as a spherical shell is shown in Fig. 2a. In Fig. 2b the nitrate group is represented as rotating in three orthogonal planes. If the angular velocity were constant, the symmetry of the generated figure would be that of the point group $O_h-4/m \bar{3} 2/m$. The minimum separation of points $\frac{1}{2}\frac{1}{2}\frac{1}{2}$ is 4.40 \AA. , a_0 . If the nitrogen to oxygen distances within the nitrate group are 1.25 \AA. , the oxygen ions would, in either case, approach within 1.90 \AA. of one

another at some time if the nitrate groups were rotating independently in phase. This value is improbably small.⁹

Finally, it is interesting to note that ammonium chloride is soluble to the extent of *ca.* 8% by weight in cubic ammonium nitrate¹⁰ and is not soluble, in detectable amounts, in the other crystalline modifications. If it is assumed that the ionic radius of NH_4^+ is 1.46 Å., the apparent radius of NO_3^- is 2.35 Å., in comparison with *ca.* 1.90 Å., the radius of Cl^- with a coördination number of eight. On this basis solid solution would be expected with the nitrate group acting as a structural unit (rotating).

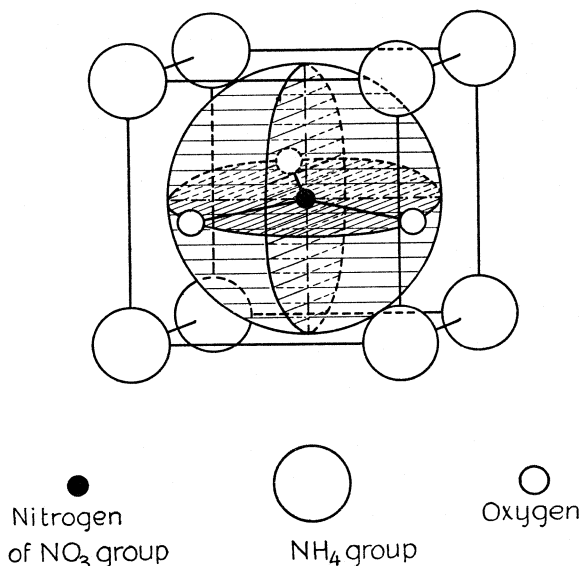

Fig. 2b.—Cubic ammonium nitrate (I). The structure is shown with the nitrate groups rotating in three orthogonal planes normal to the cubic axes. $a_0 = 4.40$ Å. (155°).

The Modification Stable between 125 and 84.2° (Tetragonal, II).—

A number of powder photographs were made, with $\text{CuK}\alpha$ and $\text{MoK}\alpha$ radiation, from revolving samples of ammonium nitrate at $100 \pm 10^\circ$. The samples were prepared and photographed as for the cubic modification. Some of the results obtained are summarized in Table III.

The data require a tetragonal unit of structure with $a = b = 5.74$ Å., $c = 5.00$ Å.

$$\text{CuK } \alpha_1 \sin^2 \theta = 0.0181 (h^2 + k^2) + 0.0236 l^2$$

$$\text{MoK } \alpha_1 \sin^2 \theta = 0.00380 (h^2 + k^2) + 0.00501 l^2$$

The density calculated on the basis of such a unit containing $2\text{NH}_4\text{NO}_3$ is 1.60 g./cc. in agreement with the observed value 1.64.

TABLE III
POWDER PHOTOGRAPHIC DATA FROM TETRAGONAL AMMONIUM NITRATE (II)
 $100 \pm 10^\circ$

MoK $\alpha_1\alpha_2$ radiation				MoK $\alpha_1\alpha_2$ radiation			
Plane	Int.	$\text{Sin}^2 \theta$ calcd.	$\text{Sin}^2 \theta$ obs.	Plane	Int.	$\text{Sin}^2 \theta$ calcd.	$\text{Sin}^2 \theta$ obs.
(100)	a	0.00380	...	(201)	1	0.02021	0.0202
(001)	3	.00501	0.0047	(102)	a	.02384	...
(110)	7	.00760	.0074	(121)	3	.02401	.0238
(101)	a	.00881	...	(112)	1	.02764	.0280
(111)	10	.01261	.0125	(220)	2	.03040	.0303
(200)	6	.01520	.0150	(221)	0.5	.0354	.0361
(120)	3+	.01900	.0187	(113)	0.5+	.0527	.0539
(002)	a	.02004	...	(132)	0.5+	.0580	.0583

The presence of reflections from (001), (120), (111) and (112) and the assumptions that the nitrate group has approximately the same configuration as found in other nitrates and that two such groups, irrespective of orientation, must be separated by at least 2.6 Å. eliminate all space groups save

$$P4mm, P4bm, P4, P\bar{4}2_1m, P\bar{4}, C\bar{4}2m$$

If it is assumed that the separation of the ammonium groups and of the ammonium and nitrate groups must be greater than 2.5 Å., that is, $\frac{1}{2}c$, the most general projection of the atomic arrangement on (001) is

If it is assumed that the closest oxygen to oxygen distances in the nitrate groups are about 2.2 Å., then the intensities, as listed in Table IV, of ($h\bar{k}0$) require $x = 0.14$, $y = 0.36$, the values probably being accurate to ± 0.03 . This might correspond to positions $u, \frac{1}{2} - u, v$, etc., with $u = 0.14$, arrangements derivable from space groups $P\bar{4}2_1m$, and $P4bm$. The paucity of the data does not permit the evaluation of the three or four parameters determining the atomic arrangement in the c direction. It might be stated, however, that an arrangement derivable from space group $P4 - (C_4^1)$ seems to be required by the data.

TABLE IV
CALCULATED INTENSITIES FOR SOME ($h\bar{k}0$) OF TETRAGONAL AMMONIUM NITRATE (II)

Plane	Obs. int.	Intensity calculated			
		$x = 0.31$ $y = 0$	$x = 0.33$ $y = 0.08$	$x = 0.35$ $y = 0.12$	$x = 0.36$ $y = 0.14$
(100)	a	1.7	0.7	0.1	0.0
(110)	7	1.6	1.8	2.0	1.8
(200)	6	6.7	5.5	4.5	4.0
(120)	3+	1.6	2.4	2.7	2.8
(210)					
(220)	2	0.2	1.1	1.9	2.1
(300)	a	1.2	0.3	0.0	0.0
(310)	a	0	0.1	0.3	0.4
(130)					

The projection of the atomic arrangement on (001), which is only approximate since x and y might be appreciably different from 0.14 and 0.36, respectively, is shown as Fig. 3. The nitrate groups probably are not rotating in this modification of ammonium nitrate.

It was very difficult to obtain reliable intensity measurements since the particle size increased rapidly at 100° . In particular on some films reflections from (110) and (220) were weak or absent. The absence of these reflections would be compatible with an entirely different type of structure that we have previously described in a letter to the Editor of *Nature*.¹¹ We are not certain at this time that these data are to be explained by crystal orientation.

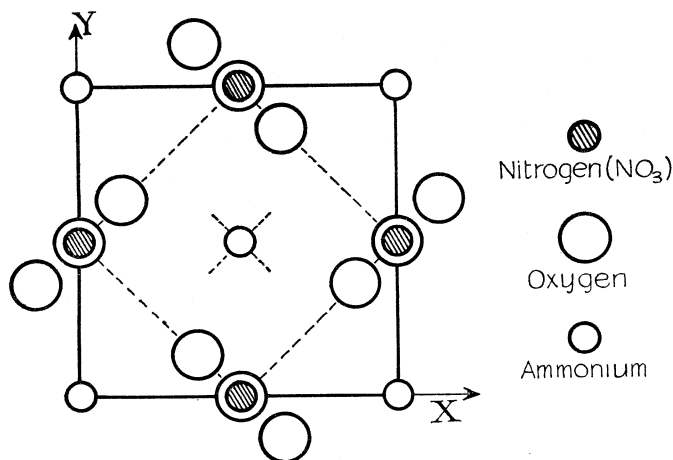

Fig. 3.—Tetragonal ammonium nitrate (II). Projection on (001).

In the microscopic work it was observed that the tetragonal modification II inverts directly to III, when it had originally been formed from III. On the other hand, if it had been formed from I by cooling from above 125° , it inverts metastably at 50° apparently to (IV) (orthorhombic room-temperature modification). It was also observed that the character of the metastable inversion depends on the specific experimental conditions of the sample, sometimes proceeding by distinct recrystallization with a high change in birefringence, at other times apparently as a single crystal transformation with practically no change in birefringence. This behavior might be due, partly or wholly, to the orientation of the crystals on the slide. The supposition suggests itself, however, that the character of the phases II and IV depends upon the previous thermal history of the salt such that II' and IV' closely similar to, but not identical with, II and IV, are formed under suitable conditions. Structures can be suggested

¹¹ F. C. Kracek, S. B. Hendricks and E. Posnjak, *Nature*, **128**, 410 (1931).

for hypothetical II' and IV' that would have optical properties identical with or closely similar to II and IV; these are not described since we have been unable to prove the existence of the hypothetical II' and IV'.

The Modification Stable between 84.2 and 32.3° (Orthorhombic III).—Single crystals of this modification were prepared by slowly cooling saturated solutions of ammonium nitrate in absolute alcohol from 50 to 35°. The crystals were usually long needles often showing well-developed side faces. In all cases the angles between the only four developed side faces were 90°0'. Photographs were made with a crystal rotating about its needle axis and about axes normal to the needle axis. Weissenberg photographs were made of the equatorial zone in the former case. The room in which the photographs were made was maintained at a temperature greater than 35°. CuK radiation was used in all instances.

The Weissenberg photographs show two planes of symmetry at 90° to one another. Since the crystals are biaxial it follows that the symmetry is probably orthorhombic. This modification has previously been said to be monoclinic, by Wallerant.

The dimension of the unit of structure along the needle axis as determined from the layer line separations on the rotation photographs is

$$c = 5.80 \pm 0.05 \text{ \AA.}$$

The other two dimensions of the unit of structure were determined from equatorial zone Weissenberg photographs about the c axis. They are

$$a = 7.06 \text{ \AA.}$$

$$b = 7.66 \text{ \AA.}$$

These values are not particularly accurate since all reflections from (100) and (010) were quite weak and high orders were missing. The density calculated on the basis of such a unit of structure containing $4\text{NH}_4\text{NO}_3$ is 1.68 g./cc. in comparison with the observed value, 1.66.

The data obtained from Weissenberg and rotating crystal photographs are in part summarized in Tables V and VI. Planes of the type $(0kl)$ with k odd and $(h0l)$ with $(h + l)$ odd are observed to be characteristically absent in odd orders. All space groups requiring planes of other types to be absent are eliminated by the presence of observed reflections. These absences are consistent with the requirements of space group $Pbnm$ (V_h^{16}). It should be borne in mind that there is no indication that the crystals are orthorhombic bipyramidal, and even if they were, space groups $Pmmm$, $Pmbm$ and $Pnmm$ could not be eliminated. The final justification for selecting space group $Pbnm$ is that it leads to calculated intensities in agreement with the observed ones.

Possible atomic positions from $Pbnm$ (V_h^{16}) are, in general

$$(a) \quad xyz; \bar{x}, \bar{y}, z + \frac{1}{2}; \bar{x} + \frac{1}{2}, y + \frac{1}{2}, \bar{z} + \frac{1}{2}; x + \frac{1}{2}, \bar{y} + \frac{1}{2}, \bar{z} \\ \bar{x}\bar{y}z; x, y, \bar{z} + \frac{1}{2}; x + \frac{1}{2}, \bar{y} + \frac{1}{2}, z + \frac{1}{2}; \bar{x} + \frac{1}{2}, y + \frac{1}{2}, z$$

on the reflection planes

$$(b) \quad uv\frac{1}{2}; \bar{u}\bar{v}\frac{3}{2}; \bar{u} + \frac{1}{2}, v + \frac{1}{2}, \frac{1}{2}; u + \frac{1}{2}, \bar{v} + \frac{1}{2}, \frac{3}{2}$$

without degrees of freedom, at symmetry centers

$$(c) \quad 000; 00\frac{1}{2}; \frac{1}{2}\frac{1}{2}0; \frac{1}{2}\frac{1}{2}\frac{1}{2}$$

$$(d) \quad \frac{1}{2}00; \frac{1}{2}0\frac{1}{2}; 0\frac{1}{2}0; 0\frac{1}{2}\frac{1}{2}$$

If it is assumed that NO_3 groups are present in the structure, then the observations that the maximum axis of the optical ellipsoid is parallel to c and that the intensities of reflection from (001) are second order m , and fourth order $m. s.$, require the ammonium ions to be on the reflection planes (b) and the oxygen ions to be at (a) and (b). The intensities of reflections from the two orders of (001) are compatible with $z = 0.06$, a value to be expected if the nitrate groups are stationary with a configuration similar to that found in other nitrates.

The parameters to be determined are

x, y for oxygen in the general positions

u_1, v_1 , for oxygen on the reflection planes

u_2, v_2 , for ammonium groups on the reflection planes

u_3, v_3 , for nitrogen atoms, of NO_3 group, on the reflection planes.

In this place only an outline of the method used in the parameter determination can be given. In the first approximation the effect of the nitrogen atoms of the nitrate groups on the intensities of reflection can be neglected. The remaining six parameters, which in both instances can be evaluated owing to unusual combinations of data, are separable into two groups of three each. Since structure factors for even order reflections from (hkl) are of the type

$$A = 8F_0 \cos 2\pi n(hx) \cos 2\pi n(ky) \cos 2\pi n(lz) + 4 \sum_{r=1}^3 F_r \cos 2\pi n(hu_r) \cos 2\pi n(kv_r) \cos 2\pi n(l/4)$$

the observed absence or low intensities of reflections from (400) and (402) require x to be ± 0.07 ; $(\frac{1}{4} \pm 0.07)$; $(\frac{1}{2} \pm 0.07)$ since $\cos 2\pi(4x)$ must be approximately zero.

The high value of the optic axial angle ($2V \text{ ca. } 90^\circ$) clearly indicates that the planes of the nitrate groups are not approximately parallel to (010) or (100). This and the assumption that the $\text{NH}_4\text{-O}$ distances must be greater than 2.5 \AA. greatly facilitate the determination of the other two parameters in the a direction. In particular the observations

(400)a

(200)v. s.

(101)m. s.

(600)a

(402)a

(202)s

(303)m. s.

limit u_1, u_2 and x to the following combinations

$$u_1 = -0.32$$

$$u_1 = -0.18$$

$$u_1 = -0.32$$

$$u_1 = -0.18$$

$$u_2 = 0.18$$

$$u_2 = 0.18$$

$$u_2 = 0.32$$

$$u_2 = 0.32$$

$$x = -0.43$$

$$x = -0.07$$

$$x = -0.43$$

$$x = -0.07$$

If it is now assumed that the nitrate groups have approximately the same configurations as found in other nitrates, then the above parameter limitations require $v_1 = y \pm 0.22$. The values of the two remaining parameters

y and v_2 can be determined from the intensities of reflections ($0kl$) and (hkl) in combination with the above values. The final values are

$$\begin{array}{lll} u_1 = -0.19 & x = -0.07 & v_3 = -0.19 \\ u_2 = 0.30 & v_1 = -0.05 & y = -0.27 \\ u_3 = -0.09 & v_2 = 0.52 & z = 0.06 \end{array}$$

These values are probably accurate to ± 0.03 .

F curves described in the next section. The agreement is only moderate but since the calculated intensities are sensitive to slight changes in parameter values no particular significance can be attached to the discrepancies observed.

The atomic arrangement is illustrated in Fig. 4, which is a projection on (001). The structure is hardly as simple as that of aragonite¹² or potassium nitrate¹³ in which the planes of the NO_3 groups are parallel to one of the pinacoids.

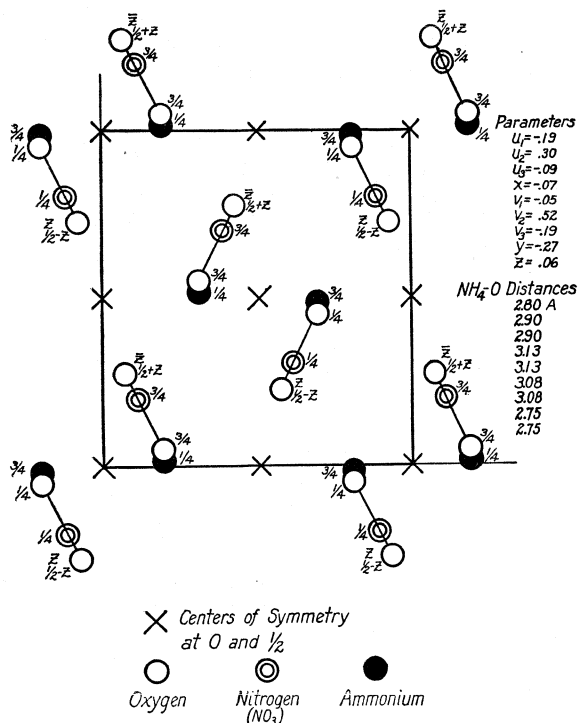

Fig. 4.—Orthorhombic ammonium nitrate (III) stable between 32.3 and 84.2°. Projection on (001) with distances above projection plane indicated.

An ammonium ion is approximately equidistant from nine oxygen ions. With the above parameter values these distances are: 2.75, 2.75, 2.80, 2.90, 2.90, 3.08, 3.08, 3.13, 3.13 Å. Each oxygen ion is approximately equidistant from three NH_4 groups.

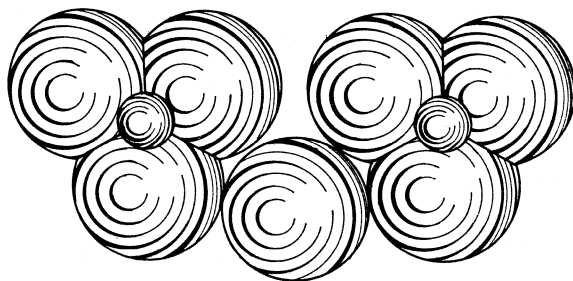

An element of the structure in the c direction is shown as Fig. 5. This element is also to be found in the orthorhombic modification stable at room temperature. The dimension determined by it is 5.7–5.8 Å. This dimen-

¹² W. L. Bragg, *Proc. Roy. Soc. (London)*, **A105**, 16 (1924).

¹³ D. A. Edwards, *Z. Krist.*, **80**, 154 (1931).

sion is further found as $d_{(100)}$ for the tetragonal modification although it apparently is not determined by the same structural element.

The Modification Stable between 32.3 and -18° (Orthorhombic IV).— The modification of ammonium nitrate stable at room temperatures has been described as orthorhombic bipyramidal. Single crystals were obtained by slowly cooling to 5° a 95% alcohol solution saturated at 25° . The crystals showed characteristic elongation and were plastic, as also were crystals of the other orthorhombic modification.¹⁴ Weissenberg and rotating crystal photographs were made with CuK radiation and some rotating crystal photographs were made with MoK α radiations. These data are in part listed in Tables VII and VIII.

$$C = 5.80 \text{ \AA}$$

Fig. 5.—A structural element along the c axis in orthorhombic ammonium nitrate (III), stable between 32.3 and 84.2° , along the a axis in the room temperature modification (IV) (-18 to 32° , orthorhombic), and possibly along the a (?) axis of the form (V) stable below -18° . In this, and in Fig. 6, the ammonium group is represented as a sphere, the nitrate group as three oxygen spheres around a central nitrogen atom.

The value of b determined from the spacings of high orders of (010) on Weissenberg photographs is

$$b = 5.45 \text{ \AA}.$$

The values of a and c were determined approximately from the layer line separation on a rotating crystal photograph around the long direction of the crystal and from Weissenberg data, respectively. These approximate values are $a = 5.74$, $c = 4.96 \text{ \AA}$. The measured and crystallographically determined axial ratios are:

$$\begin{array}{ll} \text{Measured:} & c:b:a = 0.909:1:1.053 \\ \text{Crystallographic:} & a:b:c = 0.909:1:1.0553 \end{array}$$

¹⁴ Compare W. L. Bond, *Phil. Mag.*, [6] **41**, 1 (1921).

Assuming that b is most accurately measured and that the crystallographic axial ratios are correct, the dimensions of the unit of structure are:

$$a = 5.75 \text{ \AA.}$$

$$b = 5.45 \text{ \AA.}$$

$$c = 4.96 \text{ \AA.}$$

The density calculated on the basis of such a unit of structure containing $2\text{NH}_4\text{NO}_3$ is 1.70 g./cc. in agreement with the observed value, 1.72.

If it is assumed that the crystallographically assigned symmetry is correct and that nitrate groups similar to those found in other compounds must be preserved, then all space groups save $Pmma$ and $Pm\bar{m}n$ are eliminated. The observed presence of reflections from (001), (110), (103) and (012) cannot be accounted for by $Pmma$. A satisfactory structure can be derived from $Pm\bar{m}n(V_h^{18})$. The possible atomic positions are

N of NO_3	(a)	$00u; \frac{1}{2}\frac{1}{2}\bar{u}$
O of NO_3	(a)	$00w; \frac{1}{2}\frac{1}{2}\bar{w}$
N of NH_4	(b)	$0\frac{1}{2}v; \frac{1}{2}0\bar{v}$
O of NO_3	(e)	$0\bar{x}y; 0xy; \frac{1}{2}, \frac{1}{2} - x, \bar{y}; \frac{1}{2}, \frac{1}{2} + x, \bar{y}$
or	(f)	$x0y; \bar{x}0y; \frac{1}{2} - x, \frac{1}{2}, \bar{y}; \frac{1}{2} + x, \frac{1}{2}, \bar{y}$

An atomic arrangement with oxygen atoms at (e) is eliminated by the normal decline in the intensities of reflection from $(0k0)$ ($0k_{\text{even}}l$) and $(0k_{\text{odd}}l)$. There are five parameters to be determined, four in the c direction and one in the a direction.

The observation that $(420) ca. = (220)$ and $(600) ca. = (400)$ requires $x = 0.18$ to 0.20 . Its value is taken as 0.19 ± 0.01 . If it is assumed that the oxygen atoms of the nitrate groups are at the corners of equilateral triangles with the nitrogen to oxygen distance 1.25 \AA. , then

$$w = u + 0.25 \qquad y = u - 0.125$$

Two parameters defining the relative positions of the NO_3 and NH_4 groups remain to be determined.

It is assumed that F_{NH_4} for CuK radiation is approximately the same as determined for MoK radiation diffracted from NH_4Cl ,¹⁵ that for oxygen the same as F_0 for oxygen in nickel oxide (CuK radiation),¹⁶ and that for $F_{\text{N of NO}_3} = 0.35 F_0$ independent of $\sin \theta/\lambda$. Allowing wide variations from these assumptions the observations

$$\begin{aligned} (220) \text{ m. w.} &> (311)a \\ &> (101)a \end{aligned}$$

and the observed intensities of reflections from $(00l)$ and $(0kl)$ require

$$u = 0.03 \pm 0.01 \qquad v = 0.57 \pm 0.03$$

It is not considered justifiable to attempt a closer restriction of the parameter values. The agreement between observed and calculated intensities of reflections is shown in Tables VII and VIII.

¹⁵ R. W. G. Wyckoff and A. H. Armstrong, *Z. Krist.*, **72**, 319 (1929).

¹⁶ R. W. G. Wyckoff, *Phys. Rev.*, **35**, 583 (1930).

The structure is partially illustrated in Fig. 6. The structural element shown in Fig. 5 is here repeated in the *a* rather than in the *c* direction, the corresponding dimension being 5.75 Å. An ammonium ion is approximately equidistant from six oxygen ions of nitrate groups in the

plane of the nitrate groups and from six other oxygen ions at a slightly greater distance, three each in planes $\frac{1}{2}b$ above and below it. The distances for the parameter values listed above are: 2.96, 2.96, 2.93, 2.93, 3.14, 3.14, 3.07, 3.07, 3.33, 3.33, 3.33, 3.33 Å. The structure indicates weaker binding normal to the planes of the nitrate groups than in the planes. The slippage accounting for the plasticity of the crystals is, as would be expected, parallel to the plane of the nitrate groups.

The Modification Stable below -18° (Hexagonal? V).—

Wallerant observed this modification to be uniaxial positive and suggested that the symmetry was tetragonal. Crenshaw and Ritter have recently¹⁷ measured the heat capacities from -90 to 0° . They observed a pronounced maximum in the neighborhood of -60° , the transition being similar in character to that exhibited by certain other ammonium salts. Transitions of this type were

interpreted by Pauling as accompanying initiation of molecular rotation. In the case of ammonium chloride x-ray powder diffraction photographs of

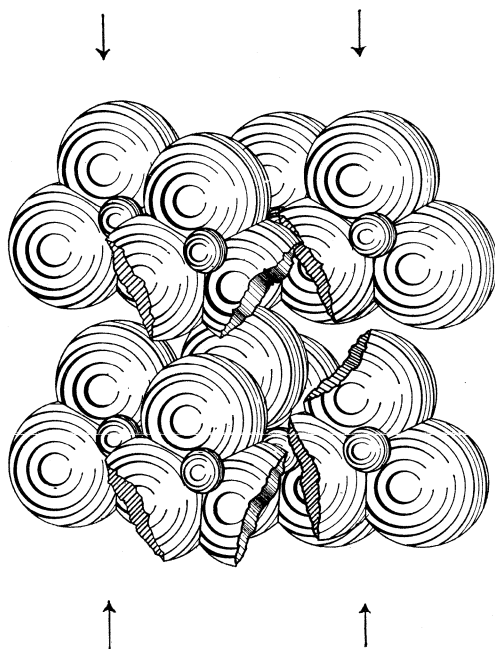

Fig. 6.—Orthorhombic ammonium nitrate (IV) stable between -18 and 32.3° , showing the nitrate groups surrounding an ammonium group.

¹⁷ Crenshaw and Ritter, *Z. physik. Chem.*, **B16**, 143 (1932).

samples below and above the transition region showed no essential changes other than those due to expansion of the lattice.¹⁸ As we have previously pointed out, these results are not inconsistent with the concept of molecular rotation.²

The transition $V \rightleftharpoons IV$ (-18°) was not recorded by Crenshaw and Ritter. There is, however, no possible ambiguity about the existence of this phase transformation. We have observed it under the microscope, by thermal analysis, and with a dilatometer. The x-ray powder diffraction patterns give final evidence of a change in phase. Although this transition is sluggish, and often is delayed so that it occurs on heating in the neighborhood of -5° , it nevertheless seems as if it should have been observed in the heat capacity measurements.

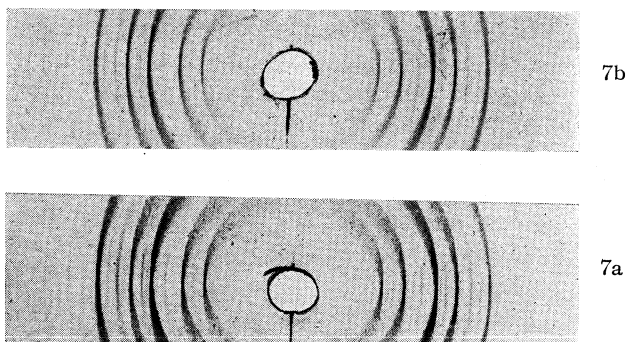

Fig. 7.—(a) A powder diffraction pattern of hexagonal ammonium nitrate (V) at -33° . CuK α radiation. (b) Same as (a), at -78° .

We have made x-ray powder diffraction photographs with CuK radiation of samples of ammonium nitrate at -33° (liquid ammonia) and -78° (solid carbon dioxide). Two such photographs are reproduced as Fig. 7. The photographs, with the exception of a displacement of the pattern due to thermal expansion, are the same within the limits of observation (fine lines will probably not show in the reproduced photographs). The ammonium group is probably rotating at -33° , and in the four modifications stable at higher temperatures and atmospheric pressure. This comment is speculative in that x-ray diffraction characteristics are not sufficient to afford an answer to the question.

Data obtained from photographs of ammonium nitrate at -78° are listed in Table IX. There apparently is one diffraction maximum very close to the central image; however, it was not definitely proved that this actually is a part of the diffraction pattern. The positions of the maxima, including the innermost, are given by

¹⁸ Simon and Simson, *Naturwissenschaften*, **38**, 880 (1926).

$$\sin^2 \theta = 0.0242 (h^2 + hk + k^2) + 0.00234 l^2$$

for CuK α_1 radiation. This corresponds to a hexagonal lattice having $a = 5.72$, $c = 15.9$ Å. The density calculated on the basis of a unit of structure containing $6\text{NH}_4\text{NO}_3$ is 1.76 g./cc. in agreement with 1.74, the determined value. It is to be emphasized that this integral number, 6, of NH_4NO_3 , in the unit of structure would be most unusual if the lattice dimensions were obtained from a spurious agreement between observed and calculated $\sin^2 \theta$ values.

The value of a_0 (5.72 Å.) is approximately the same as a_0 (5.75 Å.) of the room temperature modification, c_0 (5.80 Å.) of the second orthorhombic modification, and a_0 (5.74 Å.) of the tetragonal form. It is possible that it coincides with the direction of characteristic elongation, as is the case for the two orthorhombic modifications. This, the positive optical character, and the value of maximum index of refraction, clearly show that the planes of the nitrate groups are approximately parallel to the c axis. The intensities of reflections from the various orders of (001) are most unusual; (001) w. or a., (002)a., (003)a., (004)m. s., (005)a., (007)a., (008)w. w. We were unable to see the manner in which such an intensity distribution could be obtained in a hexagonal lattice with the atomic arrangement restricted as mentioned above. The, at least, pseudo-uniaxial character and hexagonal lattice require the nitrate groups to be approximately repeated in one or two groups of three planes containing the optic axis at angles of 20° . If in such a case the nitrate groups were not distributed according to hexagonal symmetry along the c axis, the crystals would

nevertheless be approximately uniaxial. For these reasons we would consider it quite possible that the symmetry may be orthorhombic, monoclinic or triclinic.

Summary

The structures of three of the six crystalline modifications of ammonium nitrate have been determined and data, leading to partial structure determinations, have been obtained from two other forms. The nitrate groups are rotating in at least three orthogonal directions in the cubic (I) form which is stable between 125.2 and 169.5°; $a_0 = 4.40$ Å., $1\text{NH}_4\text{NO}_3$ in the unit of structure. The structural characteristics of the other modifications examined are:

Tetragonal (II) (125.2 – 84.2°) $a = b = 5.75$ Å., $c = 5.00$ Å., $2\text{NH}_4\text{NO}_3$ in the unit of structure. 2NH_4 at 00; $\frac{1}{2}\frac{1}{2}$; 2N of NO_3 at $0\frac{1}{2}$, $\frac{1}{2}0$; 2 oxygen at $0\frac{1}{2}$, $\frac{1}{2}0$; 4 oxygen at xy , $\bar{x}\bar{y}$, $\bar{y}x$, $y\bar{x}$, with $x = 0.14$, $y = 0.36$. The arrangement in the c direction was not determined.

Orthorhombic (III) (84.2 – 32.3°) $a = 7.06$ Å., $b = 7.66$ Å., $c = 5.80$ Å., $4\text{NH}_4\text{NO}_3$ in the unit of structure. Space group $Pbnm(V_h^{16})$, 8 oxygens in general positions with $x = -0.07$, $y = -0.27$, $z = 0.06$, 4 oxygen on reflection planes with $u_1 = -0.19$, $v_1 = -0.05$, 4NH_4 on reflection planes with $u_2 = 0.30$, $v_2 = 0.52$, 4 nitrogen on reflection planes with $u_3 = -0.09$, $v_3 = -0.19$. The parameter values are probably accurate to ± 0.03 .

Orthorhombic (IV) (32.3° to -18°) $a = 5.75$ Å., $b = 5.45$ Å., $c = 4.96$ Å., with $2\text{NH}_4\text{NO}_3$ in the unit of structure. Space group $Pmmn(V_h^{18})$ with 4 oxygen at $x0y$; $\bar{x}0y$; $\frac{1}{2} - x, \frac{1}{2}, \bar{y}$; $\frac{1}{2} + x, \frac{1}{2}, \bar{y}$, with $x = 0.19$, $y = -0.095$, oxygen and 2 nitrogen at $00u$, $\frac{1}{2}\frac{1}{2}\bar{u}$, with parameter 0.28 and 0.03, respectively, and 2NH_4 at $0\frac{1}{2}v$; $\frac{1}{2}0\bar{v}$ with $v = 0.57$.

The form (V) stable below -18° gives a powder diffraction pattern in agreement with a hexagonal unit of structure having $a = 5.75$ Å., $c = 15.9$ Å. containing $6\text{NH}_4\text{NO}_3$. The data indicate that the true lattice might be only pseudo-hexagonal. Diffraction patterns of samples at -33 and -78° are identical save for displacement due to expansion, despite the existence of a gradual transition at *ca.* -60° .

THE QUANTUM YIELD IN THE PHOTOCHEMICAL DECOMPOSITION OF GASEOUS HYDRAZINE

BY RALPH R. WENNER AND ARNOLD O. BECKMAN

RECEIVED APRIL 4, 1932

PUBLISHED JULY 6, 1932

Introduction

The photochemical decomposition of gaseous hydrazine by the total radiation from a quartz mercury arc and the photosensitized decomposition by excited mercury atoms have been studied by Elgin and Taylor.¹ The products of the decomposition were identified as ammonia, hydrogen and nitrogen. A minimum quantum yield of thirteen molecules of hydrazine decomposed per quantum absorbed was obtained for the photosensitized decomposition by comparing the rate of decomposition of the hydrazine with the rate of formation of water from hydrogen and oxygen under similar conditions. No determination was made of the quantum yield for the purely photochemical decomposition.

The present investigation is concerned with the determination of the quantum yields in the photochemical decomposition of gaseous hydrazine by monochromatic radiation of wave length 1990 Å.

Experimental Method

Preparation of Anhydrous Hydrazine.—The anhydrous hydrazine was prepared by the dehydration of hydrazine hydrate with fused potassium hydroxide. Hydrazine hydrate, obtained from the Eastman Kodak Company, was refluxed for three hours in an atmosphere of hydrogen with fused potassium hydroxide in an all-Pyrex glass apparatus. The hydrazine was then distilled in a stream of hydrogen at a pressure of 30 to 100 millimeters of mercury. The distillate was refluxed with more potassium hydroxide and again distilled. This process was repeated three times. Analysis of the distillate by the iodate method² indicated a purity of 98.9%.

Barium monoxide is recommended by Hale and Shetterly³ for the dehydration of hydrazine hydrate. It was found in the present work that even the best available barium monoxide was less satisfactory than the fused potassium hydroxide which was used.

The product from the above operations was given a final distillation from potassium hydroxide in a stream of nitrogen. Three fractions were collected and sealed off in tubes containing fused potassium hydroxide. Each tube contained an internal thin-walled tip which could be broken by means of a glass-encased magnetically operated hammer after the tube had been sealed to the vacuum system and the system evacuated. The middle fraction of the anhydrous hydrazine was introduced into the system in this manner without exposure to the atmosphere after the final distillation. The hydrazine was distilled *in vacuo* at room temperature into a series of smaller similar tubes (containing fused potassium hydroxide) which were stored in the dark and attached to the vacuum system as needed.

Apparatus.—A diagram of the apparatus is shown in Fig. 1. Anhydrous liquid hydrazine (prepared as described above) was stored in contact with fused potassium hydroxide in the reservoir B, which was attached to the vacuum system. The vacuum system consisted essentially of a fused quartz reaction cell L in which the hydrazine was irradiated, a McLeod gage (attached at E) for reading the total pressure of nitrogen and hydrogen produced by the decomposition, a quartz fiber gage H for analyzing the nitrogen-hydrogen mixture, and several mercury cut-offs and freezing-out traps. The system was evacuated by a mercury vapor pump through the cut-off A. The quartz fiber gage H consisted of a single fiber of elliptical cross section and was fitted with an electromagnetic starting device.⁴ Some trouble was experienced initially from room vibrations but this difficulty was eliminated by mounting the gage on a very massive support which rested upon several layers of hair felt. The use of the quartz fiber gage as a means for analyzing nitrogen-hydrogen mixtures has been shown to give satisfactory results.⁵

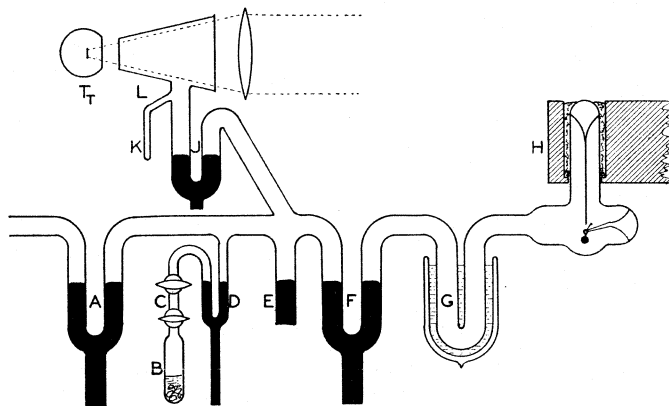

Fig. 1.—Diagram of apparatus.

Monochromatic radiation of wave length 1990 \AA . was obtained by the use of a condensed aluminum spark and a Bausch and Lomb ultraviolet monochromator in the manner previously described.⁶ The beam of monochromatic light emerging from the monochromator passed through two converging cylindrical quartz lenses, through the plane fused quartz windows of the reaction cell L and onto the receiving vane of a sensitive vacuum thermopile T_t (transmission thermopile). The reaction cell was constructed with the front window at an angle of 45° with the axis of the cell so that a fraction of the incident radiation was reflected at right angles onto the receiving vane of a similar thermopile T_r (reflection thermopile). The thermopiles were connected to two Leeds and Northrup high-sensitivity galvanometers which were set up in conjunction with an automatic recording device so that continuous records were made of the deflections of both galvanometers. From these continuous records the amount of radiant energy absorbed by the reaction mixture could be determined for each run with an accuracy which was independent of fluctuations in the intensity of the radiation or of changes in the absorption of the mixture during the run.

The vanes of the thermopiles were large enough to cover completely the converged beams. The thermoelectric system of each thermopile consisted of six junctions

⁵ Beckman and Dickinson, *THIS JOURNAL*, **50**, 1870 (1928).

⁶ Beckman and Dickinson, *ibid.*, **52**, 124 (1930).

of bismuth and bismuth-tin alloy (95% Bi, 5% Sn) in series, three junctions attached to each vane. The thermopiles were mounted in glass containers with plane fused quartz windows attached with wax. The thermopile vessels were continuously evacuated during the runs so that constant sensitivity was secured. Liquid-air traps prevented the access of mercury vapor into the thermopile vessels.

The continuous recording device consisted of a flat carriage which carried a 25×31 cm. sheet of photograph paper and was moved vertically at a constant speed by means of a screw which was driven by a synchronous motor. Two beams of light from a strongly illuminated vertical slit were reflected from the two galvanometer mirrors and focused upon the photographic paper by means of two one-diopter spherical lenses placed directly in front of the galvanometer mirrors. A 50-diopter cylindrical lens which extended horizontally across the width of the paper changed the narrow lines of light thus formed into two intense circular spots of light less than half a millimeter in diameter. The apparatus was adjusted so that the zero positions of the two spots of light were near the two edges of the paper with the deflections toward the opposite edges. This arrangement permitted the utilization of the full width of the paper for each beam, as no confusion resulted from the crossing of the two beams. To avoid the error caused by shrinkage on expansion of the paper during development, drying, etc., the coordinate system was printed upon the paper immediately after removal from the recorder by making a contact print through a coordinate screen made by ruling fine transparent coordinate lines through an opaque silver coating on a glass plate.

The thermopiles, galvanometers and leads were carefully shielded, thereby obtaining complete freedom from electrical disturbances caused by the spark. The galvanometer deflections were found to be exactly proportional to the galvanometer current throughout the range used in these experiments. The thermopiles were of the compensated type, to avoid difficulties occasioned by shifting zero positions. It was found that the zero positions were quite constant and the error introduced from this source was negligible.

Calibration.—The determination of the number of quanta absorbed by the reaction mixtures required the following data: (1) the calibration of the transmission thermopile T_t , (2) the transmission factors for $\lambda 1990 \text{ \AA.}$ of the rear window of the reaction cell and the window of the thermopile T_t , and (3) the ratio of the galvanometer deflections for thermopiles T_r and T_t with the cell evacuated. To calibrate thermopile T_t , carbon lamps calibrated by the Bureau of Standards were used. A brass plate with a hole of known area was placed in front of the thermopile window in such a way that light from the standard lamp passing through the hole was entirely intercepted by the receiving vane. The intensity of radiation at the hole was known from the calibration of the standard lamp. The transmission of the thermopile window for this radiation had been determined by previous experiments to be 0.914. By dividing the product of the intensity of radiation, the area of the hole and the transmission of the window by the scale deflection, the number of ergs per second required for unit deflection was obtained. A number of determinations at various lamp currents using two standard lamps gave consistent results with the average value 1.230 ergs per second per unit of deflection.

The transmissions for $\lambda 1990 \text{ \AA.}$ of the rear window of the cell and the window of thermopile T_t were obtained before the cell was assembled, with the aid of the continuous recording device. With both thermopiles in place, a piece of thin quartz plate was placed in the position later taken by the front window of the cell and a record of the galvanometer deflections was taken with the spark in operation. The rear window of the cell was then placed in front of thermopile T_t in the position it would ultimately occupy when the cell was in place, and another record of the galvanometer deflections taken. The transmission of the window was then found from a comparison of the two records. Five such determinations gave a mean value of 0.720 for the transmission of the rear

cell window. For convenience, to prevent dismantling thermopile T_1 , a duplicate window from the same stock of quartz was substituted for the actual thermopile window in determining the transmission of the latter. The mean value of five determinations of the transmission of the thermopile window was 0.653.

The ratio of the galvanometer deflections for the two thermopiles with the cell evacuated was checked several times during the course of the investigation. For runs 1 to 9 the ratio was 3.15 and for runs 10 to 22 the ratio was 2.86, the different values being due to a change in the apparatus between runs 9 and 10.

Procedure.—The procedure was as follows in a typical quantum yield determination. With the system evacuated, cut-offs A and F closed, cut-offs D and J opened, and with the mercury in the McLeod gage connection E as high as possible, the desired amount of hydrazine was admitted through the doser C. Cut-off D was then closed and a mixture of ether and solid carbon dioxide was applied to the trap K to freeze the hydrazine. The system was then evacuated to remove any traces of non-condensable gas which might be present. Cut-off J was then closed and the freezing mixture removed from the trap K, allowing the hydrazine to vaporize. The freezing mixture was again applied, cut-off J opened and the system again evacuated. This process was repeated a third time. With cut-off J closed and the freezing mixture removed, the pressure of the hydrazine was measured by the difference in mercury levels in the cut-off J. A sheet of photographic paper was put into the recorder and the galvanometer switches were closed. The hydrazine was then irradiated for a definite time, usually fifteen minutes, after which liquid air was applied to the trap K, cut-offs A and D were closed, cut-off F was opened and the connection made with the McLeod gage. (Liquid air was kept on the trap G throughout the run to keep mercury vapor out of the quartz fiber gage H.) Cut-off J was then opened allowing the non-condensable gases to flow into the McLeod and quartz-fiber gages on which readings were taken. The coördinate system was printed upon the photographic paper and the paper was developed.

It was found that when gaseous hydrazine stood in the reaction cell there was a slow development of non-condensable gas even in the dark, presumably due to some slow wall reaction, since the rate of pressure development was greatest when the cell was new or freshly cleaned and decreased after the cell had been in use for some time. To correct for this effect, the system was evacuated after the above readings were taken, cut-off J closed, the liquid air removed from the trap K and the hydrazine allowed to stand in the reaction cell for the same length of time as during the run. Liquid air was then applied at K, cut-off J opened and the pressure of the non-condensable gas read on the McLeod gage, all mercury levels being at the same levels as before. This pressure correction was always small, amounting to only 1 or 2% of the total pressure of non-condensable gas. The pressures were so small that satisfactory quartz

fiber readings for a composition correction could not be made. However, experiments extended over longer time intervals indicated that the non-condensable gas produced in the dark was of nearly the same composition as the non-condensable gas produced photochemically, so no appreciable error was introduced by neglecting entirely any slight changes in composition which might have been produced by the very small amounts of products of the dark reaction.

Experimental Results

The products of the decomposition have been identified by Elgin and Taylor as ammonia, hydrogen and nitrogen. The presence of ammonia was confirmed in the present investigation by the Nessler test. This test was made after irradiation by freezing the undecomposed hydrazine with ether-carbon dioxide mixture. The ammonia was then frozen in a side tube by applying liquid air. This tube was sealed off from the apparatus and the tip broken under ammonia-free water. Upon adding Nessler's reagent to the solution, a distinct reddish brown color developed proving the presence of ammonia. Blank tests without irradiation proved the absence of ammonia in the hydrazine.

The results of the quantum yield determinations are given in Tables I and II in which the runs are arranged for convenience in order of decreasing hydrazine pressure. In Table I are given the data from which may be calculated the number of molecules of hydrazine decomposed during each run. In the second column is given the initial pressure of hydrazine in the cell, which is also the pressure throughout the entire run since in none of the runs was more than 0.1% of the hydrazine decomposed. The temperature of the system is given in the third column and the total pressure of the non-condensable products in the fourth column. From the latter value must be subtracted the correction pressure for the dark reaction, given in the next column, to obtain the true pressure of the hydrogen plus nitrogen produced by the photochemical decomposition. In the sixth column is given the value for X_{H_2} , the mole fraction of hydrogen in the non-condensable gas as determined by the quartz fiber gage. In the last column is given the number of molecules of hydrazine decomposed, calculated from the equation

$$N_{N_2H_4} = \frac{4 \bar{N} P_{H_2 + N_2} V}{760 RT} (3/4 - X_{H_2}) \quad (1)$$

where \bar{N} is the Avogadro number and R has the value of 82.1 cc. atm. per degree. V is the effective volume of the system determined experimentally by air expansion with liquid air on traps G and K exactly as in the measurement of the non-condensable gas pressures. For runs 1 to 9 the volume was 137.2 cc. and for runs 10 to 22 the volume was 141.9 cc. The above equation may be obtained from the perfect gas law and the consideration

that the number of gram atoms of hydrogen and nitrogen in the products (NH_3 , H_2 and N_2) must equal the number of gram atoms of hydrogen and nitrogen in the decomposed N_2H_4 .

In Table II are given the data from which may be calculated the number of quanta of radiation absorbed during each run. The duration of the irradiation in seconds is given in column 2. In columns 3 and 4 are given the mean values D_t and D_r of the galvanometer deflections for the transmitted (thermopile T_t) and the reflected (thermopile T_r) beams, obtained from the continuous photographic record. In column 5 is given the total number of quanta of radiation of wave length 1990 Å. which entered the reaction mixture during the run, computed from the relation

$$Q_E = \frac{1.230 \beta D_r t}{\alpha_1 \alpha_2 hc/\lambda} = 2.65 \times 10^{11} \beta D_r t \quad (2)$$

the factor 1.230 being the number of ergs per second of radiation falling on the vane of thermopile T_t for unit deflection. β is the ratio of the galvanometer deflections for thermopile T_r to the deflections for thermopile T_t with the reaction cell evacuated, and t is the time of irradiation. α_1 and α_2 are the transmission factors of the rear cell window and the window of thermopile T_t for radiation λ 1990 Å. and have the values 0.720 and

0.653, respectively. In column 6 is given the total number of quanta which left the reaction mixture, as computed from the relation

$$Q_L = \frac{1.230 D_t t}{\alpha_1 \alpha_2 hc/\lambda} = 2.65 \times 10^{11} D_t t \quad (3)$$

By subtracting the value in column 6 from that in column 5 there is obtained the value given in column 7, namely, the total number of quanta absorbed by the reaction mixture during the run. Finally by dividing the value in column 7, Table I, by the corresponding value in column 7, Table II, the photochemical yield, Y , recorded in column 8, is obtained. This value represents the number of molecules of hydrazine decomposed per quantum absorbed of radiation of wave length 1990 Å.

Before discussing the relation between quantum yield and the pressure of hydrazine, attention should be called to the fact that the calculated values of Y are greatly affected by small errors in the determination of X_{H_2} , as will be seen from Equation 1. Thus, with a value $X_{H_2} = 0.60$, an error of 0.01 in X_{H_2} will cause an error of about 7% in the value of Y . To avoid the use of this equation, attempts were made to measure the ammonia pressures directly, as was done at higher pressures by Elgin and Taylor by freezing the hydrazine with ether-carbon dioxide mixture. It was found, however, that it was impossible to measure ammonia pressure

accurately at very low pressures. Since the values of X_{H_2} are known with considerable accuracy, it was felt that the direct measurement of the ammonia pressure would introduce greater errors than are introduced by the use of Equation 1.

It will be seen from column 8, Table II, that despite random variations, there is a definite increase in the quantum yield with increasing pressure of hydrazine, the values of Y ranging from about unity at the lower pressures to a value of 1.7 at the higher pressures. The quantum yield at pressures higher than 14 mm. could not be studied at room temperature since this pressure is the saturation pressure of hydrazine. At pressures lower than 2 mm. the light absorption was so small that neither the amount of radiation absorbed nor the amount of products formed could be measured satisfactorily.

The values of X , the mole fraction of hydrogen in the non-condensable gas, which are recorded in column 6 of Table I, also show a variation with the hydrazine pressure, a mole fraction $X = 0.58$ being obtained at the higher pressures and a mole fraction $X = 0.64$ at the lower pressures.

Discussion

The results of the present investigation are not in agreement with the conclusions of Elgin and Taylor¹ that the photochemical decomposition of hydrazine proceeds according to the stoichiometric relation

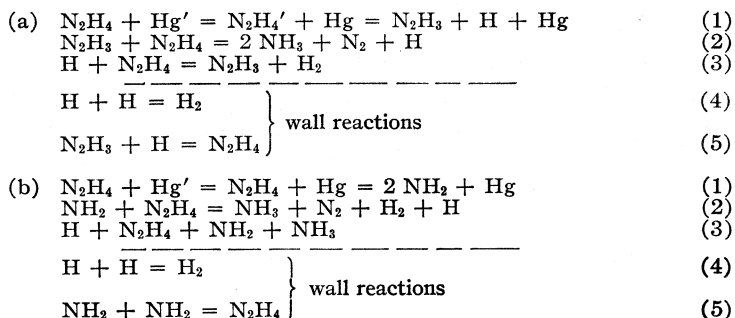

with the subsequent decomposition of the ammonia. If this conclusion is correct, then the mole fraction X of hydrogen in the non-condensable gas must be exactly 0.50 at the start of the decomposition before an appreciable amount of ammonia has decomposed. In the present experiments less than 0.1% of the hydrazine was decomposed in any run and it was found that the mole fraction of hydrogen varied from 0.58 at the higher hydrazine pressures to 0.64 at the lower pressures. These values do not agree with the analyses of the non-condensable gas reported by the previous investigators (Ref. 1, Table I) which showed approximately 50 mole per cent. of hydrogen even when more than one-fourth of the hydrazine was decomposed. The authors state that the analysis was accomplished by burning the hydrogen with copper oxide and that from five to six hours were required for the completion of an analysis, due to the slow diffusion of the gases. Under such conditions it is conceivable that the observed percentage of hydrogen may be too low on account of incomplete combustion. Indeed, it may be mentioned that if X is computed from their recorded values of ammonia and non-condensable gas pressures, using the stoichiometric relation

$$X = \frac{2}{3} - \frac{p_{NH_3}}{6 p_{H_2 + N_2}}$$

a minimum value of $X = 0.57$ is obtained. Therefore, since the initial value of X is not 0.50, but since, as our experiments show, the value of X is a function of the hydrazine pressure, it appears that the photochemical decomposition of hydrazine does not follow the simple stoichiometric equation given above but must proceed in at least two different ways, one of which yields low values of X and is favored at high pressures while the other yields higher values of X and is favored at low pressures.

Elgin and Taylor¹ have discussed at some length possible mechanisms for the decomposition of hydrazine. They found that the results of their investigations of the photosensitized decomposition could be explained by either of the following mechanisms

It will be seen that each of these mechanisms will account for a high quantum yield (their observed minimum quantum yield = 13 molecules N_2H_4 decomposed per quantum absorbed) and for the failure of hydrogen to retard the rate of the decomposition. The failure of hydrogen to retard the rate of decomposition was observed for both the photochemical and photosensitized decompositions but is of particular interest only for the latter case where hydrogen atoms are known to be formed by collisions between excited mercury atoms and hydrogen molecules. Although the above mechanisms were formulated on the basis of the results of their investigation of the photosensitized decomposition, the authors state "there is no reason to believe that the purely photochemical decomposition proceeds by another mechanism." It is clear, however, that the new experimental data disclosed in the present article show that the purely photochemical decomposition cannot be explained by either of the above mechanisms for the following reasons. (1) The low quantum yield for the photochemical decomposition does not indicate a chain mechanism. (2) The observed mole fraction of hydrogen in the products is greater than given by the above mechanisms.

In the photochemical decomposition of gaseous hydrazine produced by the absorption of radiation of wave length 1990 Å. the primary step undoubtedly involves the splitting of the molecules into substituent parts,

since this radiation lies well within the region of continuous absorption.^{1,7} Whether the splitting occurs at a N-H bond or at the N-N bond has not yet been established. Although Imanishi has concluded that the absorption of 5.5 volt radiation (2244 Å.) causes a rupture of the N-N bond, his conclusions are merely conjectures and are without experimental support. If one assumes that the primary dissociation results in the splitting of a hydrogen atom from the hydrazine molecule, a mechanism can be readily set up which will account for the experimental facts.

The steps in the mechanism are as follows

This mechanism assumes that collisions between N_2H_3 and N_2H_4 molecules do not result in chemical reaction. The N_2H_3 molecules can react with themselves in two competing reactions, namely, a homogeneous bimolecular reaction resulting in the formation of ammonia and a wall reaction resulting in the regeneration of hydrazine.

It may be seen that this mechanism is in substantial agreement with the experimental data. The quantum yield lies within the range one to two. The mole fraction of hydrogen in the non-condensable gases lies between the limits one-half and two-thirds. Further, the quantum yield increases and the mole fraction of hydrogen decreases with increasing hydrazine pressure, since increasing pressure favors reaction 3 in comparison with reaction 4.

Upon the basis of the above mechanism a definite relationship should exist between the quantum yield Y and the mole fraction of hydrogen X ; namely

$$Y = \frac{4X - 3}{X - 1}$$

A comparison of the observed quantum yields with the quantum yields calculated from this equation using the observed mole-fractions of hydrogen is given in Table III. The fact that the calculated values are slightly higher than the observed values except at the higher pressures suggests the possible occurrence of other wall reactions such as

which would have the effect of lowering the quantum yields with decreasing pressure.

On the basis of the above mechanism, it is evident that the value of Y depends upon the manner in which the N_2H_3 molecules divide themselves between the homogeneous and heterogeneous reactions. If α represents

the fraction of N₂H₃ molecules which react on the walls according to Equation 4, then $\alpha = 2 - Y$. From the observed values of Y it follows that from 0 to 70% the N₂H₃ molecules react homogeneously to form ammonia and 100 to 30% react upon the wall with the partial regeneration of hydrazine.

Summary

The quantum yields for the photochemical decomposition of gaseous hydrazine by monochromatic radiation of wave length 1990 Å. have been investigated over the pressure range 2 to 14 millimeters of mercury. It was found that the quantum yields range from 1.0 (molecules of N₂H₄ decomposed per quantum of radiation absorbed) at the lower pressure to 1.7 at the higher pressure.

The products of the decomposition were found to be ammonia, nitrogen and hydrogen, in agreement with the results of previous investigators, but the relative proportions of these substances are in disagreement with the earlier data. It was found that the composition of the products is a function of the hydrazine pressure, with more hydrogen formed at the low hydrazine pressures than at the high pressures.

It is shown that the mechanisms which have been previously proposed for the photosensitized decomposition of hydrazine are not applicable to the photochemical decomposition. A possible mechanism for the latter is suggested which is consistent with the experimental data.

VAPOR PRESSURES, EVAPORATION, CONDENSATION AND ADSORPTION

BY IRVING LANGMUIR

RECEIVED APRIL 6, 1932

PUBLISHED JULY 6, 1932

The adsorption of gases or vapors on solids is due to the time lag between the condensation and the evaporation of the molecules from the surface. The relation between the pressure and the amount of gas adsorbed thus depends primarily upon the laws of condensation and of evaporation. In an earlier paper¹ several different relationships for condensation and evaporation were chosen to illustrate some simple typical examples of adsorption phenomena.

In Case I, which was there considered as "simple adsorption," it was postulated that the forces acting between adjacent adsorbed atoms or molecules² are negligible, so that the average life of each adsorbed atom (adatom) is independent of the presence of others on the surface. If Θ represents the fraction of the surface covered by adatoms, the rate of evaporation ν is thus equal to $\nu_1\Theta$, where ν_1 is the rate of evaporation from a completely covered surface. It was also assumed, for the sake of simplicity, that atoms condense only on that part of the surface which is bare, so that the rate of condensation was taken to be $\alpha_0\mu(1 - \Theta)$, where μ , the rate at which incident atoms strike the surface per unit area is given by

$$\mu = (2\pi mkT)^{-1/2} p = 2.653 \times 10^{19} p(MT)^{-1/2} \quad (1)$$

p being the pressure in baryes, k the Boltzmann constant, 1.371×10^{-16} erg. deg.⁻¹, m the mass of an atom in the gas and M the atomic or molecular weight of the gas on the basis of O = 16.

The factor $\alpha_0(1 - \Theta)$ is the fraction of the incident atoms which condense, α_0 being a numerical factor not exceeding unity, which measures the efficiency of the condensation on a *bare surface*.

For a steady state the rates of condensation and evaporation are equal. Equating them and solving for Θ we have

$$\Theta = \frac{\alpha_0\mu}{\nu_1 + \alpha_0\mu} \quad (2)$$

The average life of τ of an adsorbed atom on the surface is

$$\tau = \sigma_1/\nu_1 \quad (3)$$

where σ_1 is the number of adsorbed atoms per unit area for a saturated surface, $\Theta = 1$. Thus equation (2) may also be written

¹ I. Langmuir, *THIS JOURNAL*, 40, 1361 to 1403 (1918).

² The word molecule properly includes the atom. However, in the applications of the theories developed in this paper, we shall deal principally with adsorption of atoms such as cesium and therefore for brevity shall use the word atom. In most cases the statements will be valid if atom is replaced by molecule.

$$\theta = \frac{\alpha_0 T \mu}{\sigma_1 + \alpha_0 T \mu} \quad (4)$$

This equation has been found to apply, with reasonable accuracy, to a surprisingly large number of cases of adsorption on plane surfaces. Considering the nature of the simplifying assumption made in its derivation, it should, of course, not be looked upon as a general equation of the "adsorption isotherm."

Several recent quantitative studies of adsorption phenomena in this Laboratory have given, as expected, data on evaporation and condensation which are very different from those indicated by Eqs. (2) or (4). It therefore seems desirable to present a more up-to-date analysis of the factors determining the rates of evaporation and condensation and to derive equations giving the amount of adsorbed gas, taking into account the effect of the forces acting between adjacent adsorbed atoms.

The evaporation of adsorbed atoms or adatoms from a surface must be governed by laws very similar to those that apply to homogeneous solids and liquids.

Vapor Pressures of Liquids.—The vapor pressures of solids and liquids or their rates of evaporation in vacuum depend principally upon the heats of evaporation since at least approximate values of the latent heats can be calculated from the boiling points by such rules as Trouton's rule. In general the vapor pressure is given with considerable accuracy over a wide range of temperature by an equation of the type

$$p = AT^\gamma e^{-b/T} \quad (5)$$

which is analogous to the Richardson equation for electron emission.

The curve obtained by plotting $\ln p$ against $1/T$ is a straight line if $\gamma = 0$. If γ differs from zero the line must be curved, but because of the very rapid increase of p with T , the range of temperature over which p can be observed is usually so limited that the curvature is extremely small, if not wholly imperceptible. For example, by measurements of electron emission it has not been possible to decide whether $\gamma = 0.5$ or 2.

Thus within a limited range extending symmetrically above and below a mean temperature T_M , we can always replace Eq. (5) by

$$p = A_0 e^{-b_0/T} \quad (6)$$

by so choosing A_0 and b_0 that the two equations give at $T = T_M$ not only the same value of p but the same slope dp/dT . Under these conditions we have

$$A_0 = AT_M^\gamma e^\gamma \text{ and } b_0 = b + \gamma T_M \quad (7)$$

The slope of the $(\ln p)$ vs. $(1/T)$ curve from Eq. (6) is constant, $S_0 = -b_0$, while that obtained from Eq. (5) is variable and at any point has the value

$$S = S_0 + \gamma(T - T_M) \quad (8)$$

A series expansion of the equation obtained by dividing Eq. (5) by Eq. (6) shows that

$$\ln \frac{p}{p_0} = (\gamma/2) \left(\frac{T - T_M}{T_M} \right)^2 \quad (9)$$

where p and p_0 are the values of p given by Eqs. (5) and (6), respectively, after choosing the constants in accord with Eq. (7).

The temperature change $\Delta T = T - T_M$ needed to cause a 5% change in p is

$$\Delta T = 0.05 T^2/b_0$$

With $T = 800$ and $b_0 = 32,000$, which are typical experimental data such as we shall have occasion to use in studies of cesium films on tungsten, it is thus necessary to know the filament temperatures within 1° in order to get p within 5%.

By Eq. (9) we see that Eqs. (5) and (6) give values of p agreeing within 5% as long as $(T - T_M)/T_M$ is numerically less than $0.32 \gamma^{-1/2}$. With $\gamma = 2$ and $T_M = 800$ there is thus a range of temperature extending about 180° on each side of T_M in which Eqs. (5) and (6) are experimentally indistinguishable if temperatures can only be measured within 1° . Over this total range of 360° , p increases more than 10^8 -fold.

According to the Clapeyron equation and the laws of ideal gases, λ , the latent heat of evaporation per atom, at constant pressure is

$$\lambda = -k \frac{d \ln p}{d(1/T)} = kb_0 = k(b + \gamma T) \quad (10)$$

The exponent γ is thus a measure of the temperature coefficient of λ and the constant A may be regarded as the integration constant of the Clapeyron equation.

Le Chatelier pointed out long ago³ that the integration constants of the Clapeyron equation for reactions of the same type have approximately the same numerical value.

Trouton's rule states that L , the latent heat in calories per gram molecule, is proportional to the boiling point T_B . The value of the ratio L/T_B from data on ordinary liquids is usually given as 20.7. Examination of Eq. (6) shows that Trouton's rule follows from this equation at once if A_0 is a universal constant. Placing $p = 10^6$ baryes (1 atmosphere) and $b_0/T = 20.7/R = 10.4$, we obtain $A_0 = 3.4 \times 10^{10}$ baryes.

When Trouton's rule is applied to substances having very low or very high boiling points, it is soon seen that L/T_B varies considerably and in general is higher for substances having higher boiling points.

Hildebrand⁴ has reasoned that different substances should be compared, not at their boiling points, T_B , but at temperatures T_0 at which the liquids have the same vapor concentration.

³ See H. S. Taylor, "Treatise on Physical Chemistry," Van Nostrand Co., N. Y., 1924, Vol. II, p. 1135.

⁴ J. H. Hildebrand, *THIS JOURNAL*, **37**, 970 (1915); **40**, 45 (1918).

Replacing p by its value nkT , in terms of the atomic concentration n , and putting $\lambda = kb_0$, Eq. (6) becomes

$$n = (A_0/kT)e^{-\lambda/kT} \quad (11)$$

Hildebrand's rule states that if, for each of a series of substances, we chose a temperature T_0 which gives the vapor of that substance an arbitrary concentration n_0 (the same for all), then the ratio λ/T_0 is the same for all the substances. By Eq. (11) this must mean that A_0/kT_0 is also the same for all the substances. Thus instead of A_0 being constant, as it should be by Trouton's rule, Hildebrand's rule requires that A_0 shall be proportional to T_0 , so that in Eq. (6) we can replace A_0 by CT_0 where C is a universal constant. We may now get rid of T_0 , a troublesome arbitrary factor, by transforming the equation by means of Eq. (7), obtaining ($\gamma = 1$)

$$p = A_1 T e^{-b_1/T} \quad (12)$$

where A_1 is a universal constant having the value C/ϵ and

$$b_1 = b_0 - T_0 \quad (13)$$

This conclusion from Hildebrand's rule is not strictly in accord with the Clapeyron equation since by Eq. (10) b_1 must have the value

$$b_1 = b_0 - T = (\lambda/k) - T \quad (14)$$

The errors made by replacing T by T_0 are, however, far less than those due to other causes of variability of the "universal constant" A_1 . The experimental evidence in support of Hildebrand's rule is thus equally good evidence that the constant A_1 in Eq. (12) is approximately the same for all substances. This formulation of Hildebrand's rule has the advantage that it does not involve any arbitrarily selected standard concentration such as that needed to define T_0 .

When a liquid or solid is in equilibrium with its vapor, evaporation and condensation go on simultaneously. In general every incident atom condenses, so that $\alpha = 1$ and the rate of condensation μ is given by Eq. (1); this must also equal the rate of evaporation ν_1 . The average life τ of the atoms on the surface, as given by Eq. (3), can thus be expressed by

$$\tau = (2\pi mkT)^{1/2} \sigma_1/p \quad (15)$$

The velocity constant K of a monomolecular reaction varies with temperature according to the equation

$$K = K_0 e^{-b/T} \quad (16)$$

Dushman⁵ calls attention to the fact that K_0 has the dimensions of a frequency. The constant b may also be related to a frequency ν_b by the Einstein equation $b = h\nu_b/k$. Dushman makes the hypothesis that these two frequencies are the same, $K_0 = \nu_b$. Let us generalize this hypothesis by assuming that

$$K_0 = \beta \nu_b \quad (17)$$

where β is a numerical factor which Dushman takes equal to unity.

⁵ S. Dushman, THIS JOURNAL, 43, 397 (1921).

The average life τ of a reacting molecule is $\tau = 1/K$. We may thus apply Eq. (16) to evaporation by identifying this average life with that of an atom on the surface of an evaporating substance. From Eqs. (16) and (17) we obtain

$$\tau = (h/\beta b k) e^{b/T}$$

or

$$\tau = 4.8 \times 10^{-11} (1/\beta b) e^{b/T} \text{ seconds} \quad (18)$$

Elimination of τ from Eqs. (15) and (18) gives⁶

$$p = (\beta b \sigma_1 k/h)(2\pi m k T)^{1/2} e^{-b/T} \quad (19)$$

The value of σ_1 depends primarily on the atomic volume but also on the arrangement of the atoms of the solid or liquid. For a crystal having a body-centered cubic lattice, such as tungsten, the crystal faces having closest packing of the atoms are the dodecahedral faces (110) and for these

$$\sigma_1 = 0.897 (\rho/m)^{2/3} = 6.43 \times 10^{15} (\rho/M)^{2/3} \quad (20)$$

where ρ is the density of the solid. The shortest distance δ_0 between atoms is

$$\delta_0 = 1.091 (m/\rho)^{1/3} = 1.289 \times 10^{-8} (M/\rho)^{1/3} \quad (20a)$$

With a close-packed lattice (face-centered) the octahedral faces contain most atoms per unit area and σ_1 is given by an equation like (20) having a coefficient 0.916 instead of 0.897. The coefficient for the expression for δ_0 is 1.122 instead of 1.091. Even for liquids we may use Eq. (20) with sufficient accuracy.

By substituting this value of σ_1 in Eq. (19) and by introducing numerical values of the constants, we obtain as a general equation for vapor pressure

$$p = 5.1 \times 10^6 \beta b \rho^{2/3} M^{-1/6} T^{1/2} e^{-b/T} \quad (21)$$

where

$$b = b_0 - (1/2T) \quad (22)$$

We now have three equations, (6), (12) and (21), which should give p in terms of b . Let us test them by the data on vapor pressures in "International Critical Tables" (I. C. T.), Volume III. In most cases the tables contain the constants B and A_c in the equation

$$\log_{10} p_{\text{mm.}} = 0.05223 A_c/T + B \quad (23)$$

together with the range in temperature over which this relation is known to hold. Comparing this equation with Eqs. (6), (12), (21) and (7) we find that

$$\log A_0 = B + 3.125 \quad (24)$$

$$\log A_1 = B - \log T_M + 2.690 \quad (25)$$

$$\log \beta = B - \log (b \rho^{2/3} M^{-1/6}) - (1/2) \log T_M - 3.80 \quad (26)$$

$$b_0 = -0.1203 A_c \quad (27)$$

⁶ This equation, with $\beta = 1$, has already been tested by Dushman and Langmuir. See Dushman's chapter in H. S. Taylor's "Treatise on Physical Chemistry," D. Van Nostrand Co., New York, 1924 ed., Vol. II, pp. 1041-1042.

In the case of substances for which B is not given in I. C. T., we may calculate B from two fairly widely separated values of vapor pressure (in mm.) by the equation

$$B = (T_1 \log p_1 - T_2 \log p_2)/(T_1 - T_2) \quad (28)$$

Table I contains values of B and b_0 for eighteen chemical elements, selecting those for which the vapor pressure data are probably of greatest accuracy. The second column gives T_M , the mid-point of the temperature range covered by the data which were used in calculating the values of B and b_0 in the third and fourth columns. All these data were obtained from I. C. T. except in the case of rubidium and cesium. The positive ion method⁷ developed in this Laboratory is believed by the writer to be far more accurate than other published data for these two elements.

If Trouton's rule is valid, the values of A_0 , and therefore by Eq. (24) the values of B , should be the same for all substances. At the bottom of the table the average value of B is given and also the "standard deviation" (S. D.) of the individual values from the mean, *viz.*, the root-mean-square deviation. The average value of $\log A_0$ is therefore 10.65 with a S. D. of 1.19.

The fifth column gives the $\log A_1$ calculated from B by Eq. (25). These data serve as a test of Hildebrand's rule. The S. D. from the average value is only 0.52, which is less than half of that observed with Trouton's rule.

⁷ Langmuir and Kingdon, *Proc. Roy. Soc. (London)*, [A] **107**, 61 (1925); Killian, *Phys. Rev.*, **27**, 578 (1926).

The data of the sixth column, which serve as a test for the validity of Eq. (21), show that the average value of $\log \beta$ is -0.88 and the individual values have an S. D. of 0.46 . Thus if we place $\beta = 0.13$ in Eq. (21) we have an expression for vapor pressure which is more accurate than Eq. (12). By Dushman's hypothesis β should be unity; the observed value is of about the same order of magnitude although distinctly less than unity.

In some preliminary tests of Eq. (21), $\log \beta$ was calculated from Eq. (26), by using approximate values of b from Trouton's rule placing $b = 11.5 T_B$. This gives a term $(3/2) \log T_M$ instead of $(1/2) \log T_M$. The resulting equation was found to agree with the experimental data much better than does Eq. (21). Furthermore, it was observed that the factor $\rho^{2/3} M^{-1/6}$ did not contribute materially to this accuracy. It was therefore decided to test also the empirical equation

$$p = A_{1.5} T^{3/2} e^{-b/T} \quad (29)$$

where

$$b = b_0 - (3/2)T = (\lambda/k) - (3/2)T \quad (30)$$

to see if $A_{1.5}$ is not more nearly constant than A_1 or β . The data in the seventh column⁸ were thus calculated, in accord with Eqs. (7) and (23), from

$$\log A_{1.5} = B - (3/2) \log T_M + 2.473 \quad (31)$$

It is seen in fact that the S. D. of $\log A_{1.5}$ is now only 0.22 , which is only about one-third as great as the S. D. for $\log A_1$ and less than one-half that of $\log \beta$. The average value corresponds to

$$A_{1.5} = 2.5 \times 10^6 \text{ baryes deg.}^{-3/2} \quad (32)$$

The data on the vapor pressures of liquid chemical compounds in I. C. T., Vol. 3, pp. 213-214, are in agreement with these conclusions. Certain "associated" substances, such as H_2O and NH_3 give values A_1 and $A_{1.5}$ about ten times above normal. The following ten liquids, for which accurate data are available, give $\log A_{1.5} = 6.50 \pm 0.16$: HCl , HBr , HI , CCl_4 , CS_2 , $SiCl_4$, $SnCl_4$, C_2H_6 , C_4H_{10} , C_6H_6 (benzene). The data for fused salts are similar, although naturally less reliable. Thus the seven salts: $PbCl_2$, $HgCl_2$, $LiCl$, $NaCl$, KCl , KI , LiF , give $\log A_{1.5} = 6.43 \pm 0.47$, the mean value of T_M being $1340^\circ K$.

We may thus conclude that Eq. (29) with the value of $A_{1.5}$ given by Eq. (32) is the most accurate of the expressions we have tested, giving the vapor pressures of liquids usually within about 40%, if the value of b_0 is known.⁹

⁸ In forming the average, the value for W was discarded as this metal was in the solid state. The data for C are said in I. C. T. to apply to liquid carbon.

⁹ These deviations from Eq. (29) are of course not to be regarded as errors. Any rigorous calculation of vapor pressures must involve either knowledge of specific heats and chemical constants or a detailed knowledge of the constitution of the liquid and gas phase such as we may hope to obtain from spectroscopic data, etc. This knowledge is so seldom available that it is a matter of considerable practical importance to have an empirical equation like Eq. (29) which is so generally applicable.

Vapor Pressures of Solids.—If the latent heat of fusion L_F is known, the vapor pressure of a solid below the melting point T_F may be calculated from that of the liquid above this temperature. Thus we have

$$P_S = A_S T^\gamma \exp. (-L_S/RT) \text{ and } p_L = A_L T^\gamma \exp. (-L_L/RT)$$

Equating $p_S = p_L$ at T_F and noting that $L_S - L_L = L_F$ we have

$$A_S = A_L \exp. (L_F/RT_F) \quad (33)$$

The heats of fusion of twenty-one metallic elements are given in I. C. T., Vol. II, p. 458. The ratio L_F/T_F , which we shall call f , is approximately constant, the average value for all these elements (except Sb, which gives 5.3) being 2.34 calories per g. atom per degree, while the S. D. of the individual values is ± 0.72 . For the non-metallic elements (I. C. T., Vol. V, p. 131), taking L_F as the heat of fusion per gram molecule, we find that the ratio $f = L_F/T_F$ is about 2.3 for A, O₂, H₂, N₂ and P₄, but rises to about 9.7 for Cl₂ and Br₂.

Among compounds such as HCl, CCl₄, C₆H₆, NaCl, which have rather compact molecules, f has values ranging from 3 to 8, but for organic substances consisting of large molecules such as stearic acid and tristearine, f rises to large values (40 and 124, respectively), increasing roughly in proportion to the number of atoms in the molecule.¹⁰

Equation (33), after putting $R = 2$ calories, thus becomes

$$\log A_S = \log A_L + 0.218 f \quad (34)$$

We may thus apply Eq. (29) to the vapor pressures of solids if we increase the value of $A_{1.5}$ in accord with Eq. (34). For solid elementary substances or those having relatively rigid molecules, we may put $f = 2.3$ and thus the value of $A_{1.5}$ instead of being given by Eq. (32) should be

$$(\text{for solids}) A_{1.5} = 8 \times 10^6 \text{ baryes deg.}^{-2/3} \quad (35)$$

Chlorine and bromine having less rigid molecules give values of $f = 9.7$ so that by Eq. (34) the value of $A_{1.5}$ for these substances in solid form is about 150 times as great as for ordinary liquids. This agrees well with the

¹⁰ These large values of f are understandable when we consider that a large part of the heat of fusion of such substances must represent an *internal* heat of fusion of the molecules themselves which would increase roughly in proportion to the size of the molecule. Thus in solid tristearine the three hydrocarbon chains are undoubtedly rigidly arranged within the solid lattice so that the molecule itself is solid. But when the substance melts, the molecule also melts.

With such large molecules it is probable that the *molecules of the vapor* may also exist in two states in which they are internally solid or liquid; however, the transition will probably occur in a temperature range far below the melting point of the solid phase. In this range the specific heat of the vapor would have abnormally high values.

From this point of view the large increase in A observed with some solids is due to the fact that the molecules "melt" during the evaporation process so that the vapor molecules have an internal mobility not possessed by those in the solid. If the molecules evaporated as solid molecules, f would have a normal value but the heat of sublimation L_S would no longer be equal to the sum $L_L + L_F$.

data of I. C. T. on the vapor pressures of these solids. For example, for solid chlorine B is given as 9.95, while for liquid chlorine (see Table I) it is 7.59. For organic substances such as tristearine ($f = 124$) according to Eq. (34) $A_{1.5}$ must rise to the enormous value of 10^{33} .

We may thus conclude that $A_{1.5}$ in Eq. (29) may be regarded approximately as a universal constant as applied to liquids and as another constant when applied to solids having rigid molecules; but for other solids the values of $A_{1.5}$ may increase to very much larger values.

Evaporation of Adsorbed Atoms.—The average life τ of an atom on the surface of an evaporating liquid or solid was given by Eq. (15) in terms of σ_1 and p . Disregarding for the present solids with non-rigid molecules, we may consider that p can be expressed in accord with Eq. (29) as a function of T and b . In this way a general expression for τ can be derived

$$\tau = (2\pi mk)^{1/2} (A_{1.5} T)^{-1} \sigma_1 e^{b/T} \quad (36)$$

or if we put $A_{1.5} = 8 \times 10^6$ by Eq. (35)

$$\tau = 4.7 \times 10^{-27} M^{1/2} \sigma_1 T^{-1} e^{b/T} \quad (37)$$

The atoms of solids and liquids as well as gases have kinetic energies corresponding approximately to $(3/2)kT$, so that their average velocity v may be taken to be $1.45 \times 10^4 (T/M)^{1/2}$. It is of interest to know δ , the average total distance measured along its path, which the surface atom travels in the time τ , so that we may estimate the number of oscillations that occur during its life τ . Putting $\delta = v\tau$ and combining with Eqs. (37), (20) and (20a), we thus obtain

$$\delta/\delta_0 = 34(\rho/M) T^{-1/2} e^{b/T} \quad (38)$$

where b is given by Eq. (30).

It should be noted that the coefficient of $e^{b/T}$ is of the order of magnitude of unity. Thus at very high temperatures or for very small values of b (b/T small), δ becomes approximately equal to δ_0 , so that the atoms evaporate in the time necessary to perform one oscillation. Under such conditions we may hardly consider that an impinging molecule condenses and reëvaporates.

We need to examine a little more closely the meaning of τ and σ_1 . The life τ may be called the *evaporation life*; a diffusion of a surface atom into the interior of a liquid should not be regarded as a termination of its life. More rigorously τ may be defined by stating that dt/τ is the probability that a given surface atom will evaporate in the time dt .

We have seen that Eq. (29), with the appropriate values of $A_{1.5}$, is applicable with reasonable accuracy to the evaporation of atoms or molecules from surfaces of such widely different types as those of liquid helium, phosphorus, mercury or carbon.

The life of any atom on the surface thus depends essentially on the value of b , in accord with Eqs. (36) and (37). In general, with homogeneous

bodies, the heat of evaporation ($\lambda = kb_0$) is the same for all the atoms. If there are on the surface atoms of more than one kind which differ in composition or in their geometrical relation to one another, the values of b for different atoms may vary. This should not affect the validity of Eq. (36); it would merely give a separate value of τ for each atom dependent upon the b for that atom. Since it is very unlikely that the validity of this equation requires that the evaporating atoms shall be similar to those in contact with them on the surface, we are justified in applying Eqs. (36) and (37) to adsorbed films.

Adjacent adsorbed atoms may exert strong forces on one another, but this will produce its effect on τ , in accord with Eq. (36), by the change in the value of b . However, if the surface is homogeneous, we may take the same value of b for all the adsorbed atoms, although b will vary with the surface concentration σ because of the forces between adatoms. In the following discussions we postulate homogeneous surfaces, but in a later section shall treat the case of heterogeneous surfaces where b varies from atom to atom, not because of the interactions of adatoms, but because of non-uniform forces exerted by the underlying surface.

Consider now a homogeneous surface on which there is an adsorbed film containing σ atoms per unit area, the value of τ being the same for all atoms. The rate of evaporation (atoms cm.⁻² sec.⁻¹) is proportional to the probability per sec. ($1/\tau$) for the evaporation of each atom, so that

$$\nu = \sigma/\tau = \sigma_1\Theta/\tau \quad (39)$$

Taking the value of τ from Eq. (36) we have

$$\nu/\Theta = A_{1.5}(2\pi mk)^{-1/2}T\epsilon^{-b/T} \quad (40)$$

or, after inserting numerical values including $A_{1.5} = 8 \times 10^6$ from Eq. (35) and transforming by Eq. (7), we have

$$\nu/\Theta = 5.7 \times 10^{26} M^{-1/2} T \epsilon^{-b/T} \quad (41)$$

where

$$b = b_0 - (1/2)T \quad (42)$$

In deriving these equations for the evaporation of adatoms we have not needed to assume that Θ is small or that the interactions between the adatoms are negligible. These relations should thus be applicable to concentrated as well as to dilute adsorbed films. Since, however, b is in general a function of Θ , it does not follow from Eq. (40) that ν is proportional to Θ , except at such low values of Θ that b is close to the limiting value that it must approach as Θ becomes zero.

It is frequently of interest to know the relation between Θ and the gas pressure p in equilibrium with an adsorbed film. Since the rates of condensation and evaporation are then equal we may put

$$\nu = \alpha\mu \quad (43)$$

By combining Eqs. (40), (43) and (1) we obtain the useful result.

$$p = (\Theta/\alpha)A_{1.5}T^{3/2}\epsilon^{-b/T} \quad (44)$$

which becomes identical with Eq. (29) if $\Theta = 1$ and $\alpha = 1$. After inserting numerical values according to Eq. (35) and transforming by Eq. (7), this becomes

$$\Theta = 2.8 \times 10^{-8} \alpha p T_M^{-2} / r_e b / T \quad (45)$$

Comparison with Experimental Data

In studies of the electron emission of thoriated tungsten filaments,¹¹ the rate of evaporation of adsorbed thorium atoms over the temperature range from 2055 to 2450°K. and at an average value $\Theta = 0.5$ was found to be given by

$$\log \nu = 31.43 - 44,500/T$$

By Eq. (41), putting $M = 232$, $T_M = 2250$ and $\Theta = 0.5$, we obtain

$$\log \nu = 28.62 - b/2.3T$$

The difference of 2.8 between 31.43 and 28.62 is far greater than the S. D. of 0.2 in $\log A_{1.5}$ which we found in Table I. This does not necessarily indicate, however, that the accuracy of Eq. (41) as applied to evaporation of adsorbed substances is not comparable with that of Eq. (29) for vapor pressures. If we put

$$\log \nu = 29 - 39,000/T$$

we find that these values of $\log \nu$ agree, with a S. D. of 0.12, with those experimentally determined. This S. D. is certainly within the possible experimental error.

Measurements¹² of the rates of evaporation of adsorbed oxygen atoms from a tungsten surface have given the data in Table II.

TABLE II
THE RATES OF EVAPORATION OF OXYGEN ATOMS FROM A TUNGSTEN SURFACE

T	$t_{1/2}$, min.	$\log (\nu/\Theta)_{\text{obs.}}$	$\log (\nu/\Theta)_{\text{calcd.}}$	Diff.
1856	27.5	11.77	11.82	-0.05
1978	2.00	12.91	(12.91)	(0.0)
2070	0.292	13.75	13.64	+0.11

The time in minutes required to evaporate half of the adsorbed oxygen is shown in the second column. The *ratios* of these values are far more accurate than the absolute values. Converting these times to seconds and dividing by $\ln 2$ we get τ , and then we may calculate $\nu/\Theta = \sigma_1/\tau$ according to Eq. (39). Since oxygen atoms or ions are smaller than tungsten atoms and are held by extremely strong forces, we may take σ_1 to be the same as for the tungsten atoms on the surface, $\sigma_1 = 1.42 \times 10^{15}$. This gives the values under $(\nu/\Theta)_{\text{obs.}}$ in the table. In these experiments Θ varied in a range between 0.3 and 0.1.

Putting $M = 16$ and $T_M = 2000$ in Eq. (41) and choosing b so that the value of ν/Θ at 1978° agrees with that observed, we obtain

$$\log (\nu/\Theta) = 29.45 - 32,720/T \quad (46)$$

¹¹ Langmuir, *Phys. Rev.*, **22**, 357 (1923). See Table VI and Eq. (41) on p. 391.

¹² Langmuir and Villars. *THIS JOURNAL*, **53**, 495 (1931).

and from this equation the values of $\log (\nu/\theta)_{\text{calcd.}}$ were calculated. Table II shows that the agreement is within the probable experimental error, as the S. D. corresponding to the differences is only 0.07. The value of b_0 by Eqs. (42) and (46) is 76,400, and the heat of evaporation per gram atom b_0R is 152 kg. cal., which is to be compared with 162 obtained¹² from the temperature coefficient of $t_{1/2}$.

The adsorption of oxygen on tungsten calls into play powerful chemical forces which are often regarded as very different in type from those involved in the evaporation of such substances as are listed in Table I. It is therefore of particular interest to find that Eq. (40) applies so well to a case of this kind.

Forces Acting on Adatoms.—There are two types of forces to be considered: those exerted by the underlying atoms, and those acting between the adatoms.

The underlying atoms always exert attractive forces but these may have an enormous range of intensities. If the surface is covered with adatoms having a heat of evaporation $\lambda = kb_0$, the energy per unit area which must be expended to remove them is $\sigma_1 kb_0$. If the effective range of the forces is 10^{-8} cm., the force per unit area which must be exerted to pull them off is thus $10^8 \sigma_1 kb_0$. With an oxygen film on tungsten $b_0 = 76,000$ and $\sigma_1 = 1.4 \times 10^{15}$, so that this force corresponds to 10^{12} baryes or 10^6 atmospheres.

The smallest forces that are likely to occur are those involved when helium atoms or hydrogen molecules strike a chemically saturated surface such as that of tungsten covered by adsorbed oxygen. In such cases¹³ there is no appreciable adsorption and the incident atoms remain on the surface for a time so short that they do not even reach thermal equilibrium, so that the accommodation coefficient is much less than unity (0.1 to 0.2).

The stability of an adsorbed film depends primarily on the magnitude of b_0 and on the pressure in the gas phase. The condition under which an approximately complete monatomic film is in equilibrium at the pressure p can be found by putting $\Theta = 1$ in Eq. (45)

$$\alpha p e^{b_0/T} > 3.6 \times 10^7 T_M^{3/2} \quad (47)$$

We shall see later in most cases that $\alpha = 1$ except when Θ approaches closely to unity. Thus under high vacuum conditions when $p = 1$ barye, the surface will be completely covered only when b_0/T exceeds 25.9 or 28.6 at values of T_M of 300 or 2000°, respectively. At atmospheric pressure ($p = 10^6$), the corresponding values of b_0/T are 12.1 and 15.2. From these data we find, for example, that an oxygen film in presence of 1 barye of oxygen should cover a tungsten surface ($b_0 = 76,000$) up to about 2600°K.; this conclusion is in accord with experiments.¹⁴ A filament at room

¹³ Blodgett and Langmuir, *Phys. Rev.*, **40**, 78 (1932).

¹⁴ Langmuir, *THIS JOURNAL*, **38**, 2271 (1916).

temperature in presence of gas at 1 barye would be covered if b_0 exceeds 7000.

When b_0/T is so large that the first layer of adatoms is nearly complete, it is possible that a second layer may form; let Θ_2 be the fraction of the surface covered by this second layer.

The conditions under which Θ_2 becomes comparable with unity are given, as before, by Eq. (47) if we replace b_0 by b' which measures the heat of evaporation of atoms from the second layer. There are now two important cases to consider according as b' is less than or is greater than b_0 .

Case I, $b' < b_0$.—There will be a range of temperature in which the film will be a complete monatomic film. For example, with a gas pressure of 1 barye and a temperature range in the neighborhood of $T_M = 600^\circ$, Eq. (47) shows that a complete film forms if b/T exceeds about 27. The temperature T_1 at which the first layer becomes complete is thus $T_1 = b_0/27$, whereas the second layer becomes complete at $T_2 = b'/27$. If $b_0 = 20,000$ and $b' = 15,000$, we have $T_1 = 740$ and $T_2 = 555^\circ$. By Eq. (45) we calculate that at 740° where the first layer is complete, $\Theta_2 = 0.0012$. The temperature coefficients are so great that above 740° the value of Θ in the first layer decreases to 0.14 at 800° and 0.01 at 900° ; in the second layer Θ_2 increases to 0.019 at 650° , 0.13 at 600° and 1.0 at 555° .

Thus even when b' is as great as $0.75 b_0$, the monatomic character of the adsorbed film is very striking, and there is a range of about 100° in which the film is complete.

Let us consider some typical cases in which $b' < b_0$.

The forces between tungsten atoms in solid tungsten (roughly measured by $b_0 = 108,000$ as given in Table I) are comparable in magnitude with those holding the atoms in the most stable of chemical compounds. These forces at a clean tungsten surface are very much unsaturated, each atom having only 6, instead of 8, neighbors. Although in other solids the forces are less intense than in tungsten, comparison with Table I shows that b_0 for typical solids will be at least as great as 10,000.

When gas molecules such as H_2 , N_2 or O_2 , or even inert gas atoms He or A, are brought into contact with the clean surface of solid bodies, attractive forces must usually come into play which are much larger than those holding these gas molecules on surfaces of their own liquid phases. Such attraction would result merely from the polarization of the molecules produced by their deformation in a strong field of force,¹⁵ but these "molecular" forces will never rise to very high values.

At sufficiently low temperatures in presence of gas the surfaces of solids must become completely covered with adsorbed films. Additional gas

¹⁵ A discussion of the nature and magnitude of such forces was given in a paper "Forces Near the Surfaces of Molecules," I. Langmuir, *Chem. Rev.*, **6**, 451 (1929); see particularly pp. 457-462.

molecules striking such surfaces are acted on only by the weak forces exerted by the adsorbed molecules and not the strong forces characteristic of the solid and therefore in all such cases $b' < b_0$.

An estimate of the magnitude of b_0 involved in typical molecular adsorption on non-metallic surfaces may be made from measurements¹⁶ of the adsorption of gases on plane surfaces of glass and mica at the temperature of liquid air.

The amount of gas adsorbed by a given surface was found to vary with the pressure p in accord with the equation

$$q = abp/(1 + ap) \quad (48)$$

where a and b are constants at any given temperature. The parameter a has the dimensions of the reciprocal of a pressure and its value does not depend upon the amount of surface exposed nor upon the units used in measuring q and b . Comparison of Eq. (48) with Eq. (4) shows that they are of the same form and that

$$ap = \alpha_0 \tau \mu / \sigma_1$$

Combining with Eqs. (43), (39) and (44)

$$1/a = p/\Theta = (1/\alpha) A_{1.5} T^{3/2} e^{-b/T} \quad (49)$$

where b is given by Eq. (30).

For argon, oxygen and nitrogen at 90°K. in contact with dry glass the values of a were found to be 0.051, 0.079 and 0.088 (baryes)⁻¹. The adsorption of these gases on mica gave 0.065, 0.080 and 0.156. From Eqs. (49), (35) and (30), putting $\alpha = 1$, we obtain values of b_0 that average 1950 with a S. D. of only ± 27 .

Table I shows that the average b_0 for the evaporation of these gases is 800. Thus the heat of evaporation of these adsorbed molecules from glass or mica surfaces is about 2.4 times as great as from the corresponding liquid phases.

In the experiments referred to, pressures from 1 to 100 baryes were used. At somewhat higher pressures or lower temperatures the adsorbed films approached saturation ($\Theta = 1$). The forces tending to hold molecules in a second layer are probably not appreciably greater than those that would act in the liquid phases of these gases. It is true that the adsorbed molecules in the first layer are not wholly in the condition of normal molecules in the liquid phase; they are polarized by deformation in a strong field of force. But surely the forces they exert on molecules in the second layer are much closer to the forces characteristic of gas molecules than they are to the forces exerted by the underlying solid upon the molecules in the first layer.

Transmission of Polarization through Molecular Layers.—The forces acting between successive layers of molecules may be characterized

¹⁶ Langmuir, *THIS JOURNAL*, **40**, 1361 (1918). See particularly Eq. (31) and the Tables on pp. 1390–1391.

by a series of values of b such as b_0, b', b'' . These must rapidly approach a limiting value b_∞ which would be the same as for a condensed phase of the adsorbed material. Almost the whole of the transition from b_0 to b_∞ must occur between b_0 and b' .

The experiments of de Boer¹⁷ on the adsorption of iodine vapor on solid films of calcium fluoride enable us to estimate the magnitude of these transmitted effects. His experimental results, in terms of our nomenclature, may be summarized by the equation

$$\log [-\log(p/1.1 p_0)] = -4.3 \times 10^{-16} \sigma_1 n + 0.43 \quad (50)$$

where n is the number of layers of molecules of I_2 , each layer containing σ_1 molecules per sq. cm.; p is the pressure of iodine vapor in equilibrium with the film at a given temperature (*ca.* 20°), while p_0 is the vapor pressure of solid iodine at the same temperature. In the experiments p/p_0 was varied only between 0.1 and 0.95.

De Boer and Zwikker¹⁸ have calculated that in a series of layers of polarizable molecules the polarization in the $(n + 1)^{\text{st}}$ layer is K_1 times that in the n th, where K_1 is a constant numerical factor less than unity, but which is proportional to the polarizability α of the molecules. From this they obtain an expression for the vapor pressure, which we may put in the form

$$p = K_3 p_0 \exp. (K_2 K_1^n) \quad (51)$$

Although de Boer does not give the numerical value of K_1 , comparison of Eqs. (50) and (51) shows that

$$\log K_1 = -4.3 \times 10^{-16} \sigma_1; K_2 = -6.2; K_3 = 1.1 \quad (52)$$

Assuming that the arrangement of atoms in the CaF_2 film (produced by evaporation) is like that of octahedral faces of a fluorite crystal, de Boer calculates that the number of fluorine ions per sq. cm. is 7.75×10^{14} . He considers that this number of iodine atoms per unit area are adsorbed. Applying Eq. (20) to molecular iodine we obtain $\sigma_1 = 4.56 \times 10^{14}$ molecules cm.^{-2} .

Harris, Mack and Blake¹⁹ have shown that iodine crystals belong to the orthorhombic system and that the atoms are grouped in pairs as molecules. The distances between the centers of the two atoms in a molecule is 2.79 Å., while the shortest distance between the centers of atoms which are not in the same molecule is 3.51 Å. The unit cell of dimensions $a = 4.795$ Å., $b = 7.255$ Å. and $c = 9.780$ Å., contains four molecules whose centers are at the corners and at the centers of the faces.

From these data we find that in crystal faces parallel to two axes the values of σ_1 are: for ab 5.75, for bc 2.82 and for ca 4.26 (unit = 10^{14} mole-

¹⁷ J. H. de Boer, *Z. physik. Chem.*, [B] **13**, 134 (1931); *Proc. Acad. Amsterdam*, **31**, 906 (1928); see particularly the equation at top of p. 152.

¹⁸ J. H. de Boer and C. Zwikker, *Z. physik. Chem.*, [B] **3**, 407 (1929).

¹⁹ P. M. Harris, E. Mack and F. C. Blake, *THIS JOURNAL*, **50**, 1583 (1928).

cules cm.^{-2}). The 111 faces contain $\sigma_1 = 4.35 \times 10^{14}$ molecules. It is evident that if one molecule is located above each fluorine ion ($\sigma_1 = 7.75 \times 10^{14}$) the molecules are very much crowded so that repulsive forces (neglected by de Boer) must be of very great importance. These facts invalidate the particular structure assumed by de Boer, in which *atoms* are considered to be arranged in vertical columns over the fluorine ions. Although the molecules in the first layer are probably attached to the fluorine ions, those in the next few layers are thus probably arranged as irregularly as those of liquids, with a tendency to assume a more stable crystalline form at greater distances from the disturbing CaF_2 surface. In any case, however, the exponential decrease in polarization as the number of layers increases should be approximately true, except in the case of the first and second layers.

If we take $\sigma_1 = 5.75 \times 10^{14}$ as the most probable value (after the first layer), we find from the expression for K_1 in Eq. (52)

$$K_1 = 0.57$$

If $\sigma_1 = 4.56 \times 10^{14}$ as given by Eq. (20), the value of K_1 would be 0.64.

In calculating the coefficient 4.3×10^{-16} in Eq. (50) de Boer assumed that the surface of the CaF_2 film was the same as that of the glass on which it was deposited. If the actual surface was 50% larger, this would decrease K_1 from 0.57 to 0.43.

Roughly speaking, therefore, the polarization of any layer of molecules is about one-half of that in the next lower layer. Langmuir,²⁰ by a study of the dissociation constants of the chlorine-substituted fatty acids, found that the polarizing forces along an aliphatic hydrocarbon chain deformed near one end decrease in the ratio 2.1:1 (or $K_1 = 0.37$) for each successive carbon atom.

Comparing Eqs. (51) and (6) and using the values $K_1 = 0.5$, $K_2 = -6.2$, $K_3 = 1.1$, and $T = 293$ we see that

$$b_n = b_s - 29 + 1800(0.5)^n \quad (53)$$

where b_s is the value of b_0 for solid I_2 , which is 7570 according to the data of I. C. T. The term -29 is the contribution of the factor K_3 . The disturbance in the regular arrangement of molecules which results from the underlying CaF_2 film raises the limiting vapor pressure for thick layers by 10% ($K_3 = 1.1$), but this is equivalent to a change of b of only 29 out of 7570 or only 0.4%. When we consider that the difference between the liquid and solid state alters b_0 from 5370 to 7570 (see Table I), we realize how insignificant these disturbances are, and how little we should be justified in assuming a value for σ_1 which is appreciably different from that characteristic of solid iodine.

The term $1800(0.5)^n$ in Eq. (53) results from the polarization transmitted from layer to layer. Thus the polarization of the second layer

²⁰ See reference (15), particularly p. 467.

increases the value by 450 which is only 6% of the value of b_0 for solid iodine.

The exponential factor $(0.5)^n$ is certainly not applicable to the first layer of molecules for these are exposed directly to the powerful polarizing forces of the ions with which they are in contact. We have already seen that glass surfaces (far less effective than CaF_2) raise the value of b_0 for the first layer of nitrogen molecules 2.4-fold, although the polarizability α of N_2 is small compared to that of I_2 . If a similar factor can be applied to iodine, the value of b_0 for the first layer on CaF_2 would be about 13,000; compared to this, the effect of the polarization in the second layer is almost wholly negligible.

When, however, the vapor in contact with an adsorbed film is nearly saturated, even these weak polarizing forces naturally produce marked effects. Substituting the values of K_1 , K_2 and K_3 in Eq. (51), we calculate that the values of p/p_0 for the successive layers are (for $n > 2$).

n	p/p_0	n	p/p_0
1.01	0.0005	2.0	0.235
1.1	.006	3	.504
1.2	.014	4	.744
1.4	.038	5	.906
1.6	.082	6	1.00

For values of n less than 2, where the exponential relation cannot hold, we have assumed a linear relation between b and n . In the exponent of Eq. (51), $-6.2(0.5)^n$ has been replaced by $1.55(3 - n)$, which gives the same value (1.55) for $n = 2$ and gives a value twice as great as this for the evaporation of isolated molecules from the second layer.²¹ The values of p/p_0 obtained by Eq. (51), in the range below $n = 2$, were then multiplied by $\Theta_2 = n - 1$ in accordance with the occurrence of the factor Θ in Eq. (44).

Over the range of pressures p/p_0 from 0.1 to 0.95 covered by de Boer's experiments, n varied only from 1.6 to 5.5. At pressures less than 0.01 p_0 the second layer of molecules rapidly disappears, and the film becomes monomolecular. If b_0 has any such value as 13,000, this monomolecular film would be stable in presence of an iodine pressure as low as $10^{-8} p_0$; the average life τ of the molecules in the first layer would be 2000 sec., while that of isolated molecules in the second layer ($b' = 8440$) would be only 4×10^{-4} seconds.

These conclusions, while only approximate, help us to form a clear conception of the relative magnitudes of the factors determining the character of typical adsorbed films. The reasons for the nearly universal

²¹ A similar assumption has been found to be approximately true for cesium films on tungsten and is in accord with de Boer's calculation that the mutual repulsion of the dipoles in a complete layer decreases the heat of evaporation (due to dipoles) to one-half of that for single dipoles; see *Proc. Amsterdam Acad.*, **31**, 909 (1928).

monomolecular character of adsorbed films become apparent, but at the same time we are led to understand that under rather special conditions multimolecular layers may form.

Case II, $b' > b_0$.—Liquid mercury (or cadmium) does not wet a glass surface. We may infer that the forces between mercury atoms in liquid mercury are greater than those between a glass surface and mercury atoms in contact with it. Thus the heat of evaporation (kb_0) of adsorbed mercury atoms on glass is less than the heat of evaporation (kb') of atoms from a second or third layer of mercury atoms on glass.

It has been proved experimentally²² that isolated cadmium atoms evaporate from a glass surface at room temperature enormously more rapidly than do atoms in contact with other cadmium atoms. When cadmium vapor at low pressure strikes a glass surface at -40° , nearly all the atoms reëvaporate before they come in contact with other cadmium atoms. If, however, small groups of atoms are formed by raising the pressure of the vapor or by further lowering of the temperature, then these serve as nuclei for the formation of crystals from which there is no appreciable evaporation at room temperature.

Under such conditions the only uniform adsorbed films that can occur are those that cover an extremely small fraction of the surface ($\theta \ll 1$); with higher surface concentrations nuclei are formed and the condensed film is discontinuous. Strong lateral attractive forces between adatoms may also cause these colloidal or granular condensed films to form.

The cases where $b' > b_0$ are to be found particularly where the adsorbate is a substance having a large heat of evaporation (low vapor pressure) and is the type of substance that would be difficultly soluble or miscible with the substance of the adsorbent. Thus since molten metals are not generally miscible with non-metallic liquids, we understand the behavior of mercury and cadmium toward glass.

Such effects may be greatly enhanced by covering the surface of the adsorbent with a monomolecular oil film such as that of a fatty acid. For example, glass surfaces in contact with saturated cesium vapor show marked electrical conductivity because of adsorbed cesium; but a monomolecular oil film on the glass tends to cause the cesium to condense in separated particles and eliminates the conductivity. The hydrocarbon surface is covered with chemically saturated hydrogen atoms from which cesium atoms evaporate far more readily than from cesium metal. A similar phenomenon is responsible for the injurious effect of traces of oily substances on the operation of mercury condensation pumps.

In our present study of evaporation and condensation of adsorbed films, we shall confine ourselves to cases where $b' < b_0$.

Forces Acting between Adatoms.—From measurements of the rate of

²² Langmuir, *Proc. Nat. Acad. Sci.*, **3**, 141–147 (1917).

evaporation of cesium adatoms on oxygen-covered tungsten, Becker²³ has concluded that the heat of evaporation decreases as θ increases, and from kinetic theory considerations deduces an equation similar to Eq. (40) in which b is a linear function of θ .

Dr. John Bradshaw Taylor has recently²⁴ completed an extensive series of accurate measurements of the rates of evaporation of atoms (ν_a), of ions (ν_p) and electrons (ν_e) as functions of T from surfaces of pure tungsten on which are adsorbed known numbers (σ) of cesium atoms per unit area. These data afford an opportunity of studying in detail the electrical properties of adsorbed films and the forces acting between adatoms.

The values of ν/θ at 800°K. were found to increase about 10^{10} -fold as θ increases from 0 to 1, indicating very strong repulsive forces between adatoms. The following analysis enables us to determine these forces quantitatively.

Equation of State of Adsorbed Films.—The Gibbs equation for the adsorption isotherm is readily expressed²⁵ in the form

$$\frac{dF}{d \ln \mu_a} = \sigma kT \quad (54)$$

where μ_a is given by Eq. (1) and F is the spreading force of the adsorbed film (dynes cm.⁻¹). This equation is thermodynamically rigorous if the ideal gas laws apply in the gaseous phase, the surface is homogeneous and is in equilibrium with the vapor. Variations in surface mobility of the adatoms cannot affect the value of F if equilibrium prevails, but they may determine the time of relaxation, *i. e.*, the time required for restoration of equilibrium after a disturbance.

If ν_a can be expressed as a function of θ , then by Eqs. (43) and (54) the spreading force is

$$F = kT \int \sigma d \ln (\nu_a/\alpha) \quad (55)$$

The effect of forces acting between molecules on the equation of state of gases can be calculated by the virial equation²⁶

$$pV = RT + \frac{1}{3} \Sigma (rf)$$

where f is the repulsive force that acts between two molecules when their distance apart is r ; the summation is to be extended over all pairs of molecules in a gram molecule of gas. In the van der Waals equation

²³ J. A. Becker, *Trans. Am. Electrochem. Soc.*, **55**, 153–173 (1929).

²⁴ A brief preliminary description of the method used in obtaining these data and of the conclusions drawn from them has been published: Langmuir, *THIS JOURNAL*, **54**, 1252 (1932). The derivation of the equations there given is contained in the present paper.

²⁶ See Jeans, "Dynamical Theory of Gases," University Press, Cambridge, England.

$$(p + a/V^2)(V - b) = RT$$

the presence of the factor $V - b$ can be deduced by considering the virial of short range repulsive forces which act when molecules come into contact. The term a/V^2 corresponds to the attractive forces of relatively long range.

In an entirely analogous manner the virial may be used to calculate an equation of state for adatoms. In this case

$$FA = RT + \frac{1}{2} \Sigma (rf) \quad (56)$$

where A is the area which contains a gram atom and the summation extends over all the pairs of adatoms in area A .

The two-dimensional van der Waals equation, considering that the long range forces are now repulsive instead of attractive, takes the form

$$(F - a/A^2)(A - A_1) = RT \quad (57)$$

The ordinary derivation of this equation considers only first-order effects as the surface concentration increases; the value of A_1 is then found to be *one-half* the area actually covered by a gram atom of adatoms. Langmuir²⁷ has tested this equation with experimental data of N. K. Adam on oil films at high surface concentrations and finds that A_1 corresponds to a close packed film in which the molecules unquestionably completely cover the surface. Dr. Lewi Tonks has made a theoretical analysis for the case of adatoms at high concentrations and finds in fact that the value of A_1 should then correspond to the actual area covered instead of one-half that area.

In carrying out the summation in Eq. (56), we may select arbitrarily any atom P as typical and form the sum $\Sigma_1(rf)$ for all the pairs which include the atom P . Since f must decrease very rapidly as r increases, this sum $\Sigma_1(rf)$ is independent of the area over which the summation extends as long as it greatly exceeds molecular dimensions. To form the summation indicated in Eq. (56) we must thus select each atom in turn as a P -atom, finding

$$\Sigma (rf) = (1/2)\sigma A \Sigma_1(rf)$$

where the factor $1/2$ has been introduced in order that we shall not count each pair twice. Substituting this value in Eq. (56) and noting that $A\sigma = R/k$ we obtain

$$F = \sigma kT + (1/4)\sigma \Sigma_1(rf) \quad (58)$$

In order to bring out the relationship between Eqs. (58) and (57) we may rewrite the latter in the form

$$F = \sigma kT / (1 - \sigma/\sigma_1) + a'\sigma^2 \quad (59)$$

and this may be further modified to

$$F = \sigma kT + \sigma^2 kT / (\sigma_1 - \sigma) + a'\sigma^2 \quad (60)$$

By considering the origins of the terms in Eq. (60) and comparing these with the corresponding terms in Eq. (58), we see that the virial term in the

²⁷ Langmuir, "Third Colloid Symposium Monograph," 1925, p. 72.

latter can be split into two parts: one, $\sigma^2 kT/(\sigma_1 - \sigma)$, corresponds to the short-range forces acting when atoms are in contact, and the other, $a'\sigma^2$, to the long-range repulsive forces. The actual form of the $a'\sigma^2$ term has, however, been based on approximations which will not be sufficiently good for our needs and therefore we may write in place of Eq. (59)

$$F = \sigma_1 kT\Theta/(1 - \Theta) + F' \quad (61)$$

where

$$F' = 0.25 \sigma \Sigma_1(rf_2) \quad (62)$$

f_2 being the *long range* repulsive force at distance r .

Ordinarily in gas theory the force function $f(r)$ is not definitely known and it falls off with such a high power of the distance that structural properties of the molecules cannot be neglected. Therefore the virial method has not been particularly successful in gas theory. In the theory of electrolytics, however, where the forces decrease less rapidly, the virial proves very useful.²⁸

The attractive forces holding adsorbed molecules on surfaces are ordinarily far stronger than those acting among the adsorbed molecules and thus the adsorbed molecules will usually be highly polarized so that they become dipoles having parallel orientations. In general, therefore, we should expect repulsive forces rather than attractive forces to be active between the adsorbed molecules.

In the case of cesium films we have very direct proof that the adatoms act as dipoles. Adsorption of alkali metal atoms occurs strongly only when the electron affinity of the adsorbent metal exceeds the ionizing potential of the alkali, so the act of adsorption probably involves a transfer of the valence electron to the underlying metal. The force holding the atom may thus be regarded as the attraction of the cesium ion and the negative charge induced in the metallic surface (image force). The positive charge on the adatoms manifests itself by changing the contact potential (by as much as 3.0 volts²⁹ and by a corresponding increase in the electron emission.

The measurements of Langmuir and Kingdon³⁰ have shown that for a given temperature the electron emission has a maximum at a particular value of Θ . With the surface in this condition the emission is given by $I = AT^2\epsilon^{-b/T}$ with $A = 3.26$ amp. cm.⁻² deg.⁻² and $b = 15,820$, whereas for a pure tungsten surface the constants are $A = 120$, $b = 53,650$. A comparison of these data gives for the contact potential of the optimum cesium surface against pure tungsten $3.26 - 0.31 (T/1000)$ volts or 3.01 volts at 800°K.

³⁰ Langmuir and Kingdon, *Proc. Roy. Soc., (London)*, **A107**, 61 (1925).

Taylor's experiments have shown that at low temperatures and high cesium pressures, the surface concentration approaches a definite limiting value of 4.8×10^{14} atoms per cm.² of apparent surface (πld) corresponding to $\Theta = 1$. In the preliminary treatment of the filament it was heated for a considerable time to 2800°K. so that appreciable etching by evaporation occurred. Under these conditions the dodecahedral forces (110) are developed.³¹ The true surface on which adsorption takes place must therefore exceed the apparent surface. Tonks³² has shown, on the assumption that the crystal grains have random orientation, that the lowest possible value for the surface excess for dodecahedral faces is 0.225. The number of tungsten atoms per sq. cm. in a dodecahedral face is 1.425×10^{15} .

Simon and Vohsen³³ have found that cesium crystallizes in a body-centered cubic lattice with a lattice constant 6.05 Å. at liquid air temperature (about 6.17 Å. at room temperature). Tungsten has the same type of lattice but the constant is 3.15 Å. Thus if cesium atoms arrange themselves on the face of a dodecahedral tungsten crystal so that there is one cesium atom for every four tungsten atoms, the surface lattice is identical in type and in spacing (within 2%) with that occurring in a similar face of a cesium crystal. Since the strongest forces exerted on the adatoms are those originating from the underlying tungsten atoms, we may therefore, with considerable confidence, take for $\Theta = 1$

$$\sigma_1 = 3.563 \times 10^{14} \text{ atoms cm.}^{-2} \quad (63)$$

for the true surface density of a complete monatomic cesium film on tungsten. Comparing this with the apparent surface density 4.8×10^{14} we conclude that the ratio of the true to the apparent surface is 1.347 as compared to 1.225 for the *minimum value* of this ratio calculated by Tonks.

Taylor's data show that the optimum electron emission occurs at $\Theta = 0.67$ corresponding to $\sigma = 2.4 \times 10^{14}$.

Simon and Vohsen's data give 5.34 Å. as the shortest distance between the atoms in metallic cesium. A sphere of this diameter, having unit positive charge, in contact with an ideal plane conducting surface, produces an external electric field equivalent to that of a dipole (without neighboring conductor) having a moment $M = 25.4 \times 10^{-18}$.

If a conducting surface is covered with σ such ions per unit area, each having a dipole moment M , the contact potential V_c against a bare surface of the same material would be

$$V_c = 2\pi M\sigma \text{ (c. g. s. u.)} = 1885 M\sigma \text{ volts} \quad (64)$$

Placing $\sigma = 2.4 \times 10^{14}$ and $M = 25.4 \times 10^{-18}$ we obtain $V_c = 11.6$ volts, which is 3.84 times the 3.01 volts observed for the surface of optimum emission.

³¹ Langmuir, *Phys. Rev.*, **22**, 374 (1923).

³² Tonks, *ibid.*, **38**, 1030 (1931).

³³ Simon and Vohsen, *Z. physik. Chem.*, **133**, 165-187 (1928).

It is evident that the strong field (10^8 volts per cm.) in the double layer draws electrons from the tungsten to a plane which lies only 0.69 \AA. below that of the centers of the adatoms. The actual dipole moment per atom in a film of optimum emission is thus only $M = 6.1 \times 10^{-18}$.

Assuming that M is independent of surface concentration Langmuir has calculated³⁴ that the logarithm of the electron emission of a metal partly covered by adatoms of an electropositive metal should be a linear function of Θ . Becker²³ has determined the electron emission from monatomic barium films on tungsten at 1100°K. The curve of $\log_{10} (i/i_w)$ against Θ gives a maximum at $\Theta = 1$ of 11.3 while the initial slope is 25. We may interpret this as indicating that for low values of Θ , M is 2.2 times as great as for a film giving the optimum emission. Becker implies that the curve for cesium on tungsten is closely similar. If we may thus use the factor 2.2, we conclude that for very dilute cesium films $M = 14.6 \times 10^{-18}$, which is 0.57 of that which we estimated for cesium ions on an idealized plane conductor. The decrease in M as Θ increases is to be attributed to the depolarizing effect of the field produced by the adatoms.

Let us now calculate by the virial method the equation of state of adsorbed cesium atoms. Although the electric field produced by an ion on a conducting surface is the same as that of a dipole (without the presence of the conductor), the force acting between adions is not equal to that between the two dipoles, for we must consider only the force on the real ion and not that on its image. The force acting between two adions separated by the distance r , being half that between dipoles is thus

$$f = (3/2) M^2/r^4 \quad (65)$$

and the potential energy in electron volts is

$$Ve = (1/2)M^2/r^3 \text{ or } V = 3.14 \times 10^{11} M^2/r^3 \text{ volts} \quad (66)$$

The effect of the repulsive forces between adatoms is to decrease the concentration of other atoms in the neighborhood of a given atom in accord with the Boltzmann equation

$$\sigma = \sigma'_e - Ve/kT \quad (67)$$

where e/k has the value 11,600 degrees per volt. To form an estimate of the magnitude of this effect, let us imagine for simplicity that the elementary spaces which can hold adatoms are arranged in an hexagonal lattice (honeycomb structure). With $\sigma_1 = 3.563 \times 10^{14}$ this gives $r_1 = 5.69 \text{ \AA.}$ for the shortest distance between atoms. At this distance for $M = 14.6 \times 10^{-18}$ we find by Eq. (66) that $V = 0.365$ volt and thus by Eq. (67) at $T = 800$ the probability that one of the six available spaces adjacent to a given atom will be occupied is only 0.005 as great as that for the distant spaces. The next ring contains 12 spaces, half of which are at a distance 9.9 \AA. and

³⁴ Langmuir, *Phys. Rev.*, **22**, 364 (1923). A fuller discussion is given by W. Schottky and H. Rothe, "Handbuch Exptl. Physik," XIII, [2] 1928, pp. 160-167.

the other half at 11.8 Å. from the central atom. For these $V = 0.069$ and 0.041 volt and the corresponding probabilities are 0.37 and 0.55.

Since these nearest 18 spaces tend to be far less densely populated than an average space, the distribution of the atoms will be much more uniform than if there were no forces acting and will approximate to a regular lattice arrangement. Let us therefore at first calculate the virial term $\Sigma_1(rf)$ in Eq. (62) on the assumption that the atoms are in an hexagonal lattice,³⁵ the shortest distance r_1 between them being given by

$$r_1 = (4/3)^{1/2} \sigma^{-1/2} = 5.69 \times 10^{-8} / \Theta^{1/2} \text{ cm.} \quad (68)$$

Using the value of f from Eq. (65) we see that

$$\Sigma_1(rf) = (3/2) M^2 \Sigma_1(1/r^3) \quad (69)$$

By adding the values of $1/r^3$ for the separate atoms in an hexagonal surface lattice, using an accurate empirical integration process for the more distant atoms, it was found that

$$\Sigma_1(1/r^3) = 11.044/r_1^3 \quad (70)$$

Combining Eqs. (61), (62), (69), (70) and (68)

$$F = \sigma_1 k T \Theta / (1 - \Theta) + 3.338 \sigma^{3/2} M^2 \quad (71)$$

This gives the equation of state on the assumption that the adatoms are arranged in a plane hexagonal lattice. This should be a fairly good approximation at higher values of Θ . The last term must quite accurately represent the virial contribution of all the adatoms which are at distances as great as r_1 . The atoms nearer than this must, however, often contribute materially to the virial. We may take these into account as follows.

At distances much less than r_1 the concentration is determined largely by the potential energy of the adatoms in accord with Eq. (67).

The contribution to $\Sigma_1(1/r^3)$ furnished by the atoms that lie within a circular ring is thus

$$\Sigma_1(1/r^3) = \int_{r_0}^{r_2} 2\pi r \, dr (1/r^3) \sigma_2 \exp. (-Ve/kT) \quad (72)$$

where r_2 and r_0 are the outer and inner radii of the ring, σ_2 is the surface concentration of atoms at $r = r_2$ and Ve is the change in potential energy when an atom is moved from r_2 to r .

At distances greater than about r_1 , given by Eq. (68), V remains constant because the forces from the separate atoms must on the average balance one another. If we choose a suitable value for r_2 , somewhat less than r_1 , we may thus put in accord with Eq. (66).

$$Ve/kT = (M^2/2kT)(r^{-3} - r_2^{-3}) \quad (73)$$

For values of r greater than r_2 we may take $V = 0$ and may replace the actual discontinuous distribution of adatoms by an equivalent continuous

³⁵ It should be noted that this hypothetical lattice is not related to that of the underlying tungsten atoms, but varies continuously in lattice constant as Θ changes. It expresses merely the fact that the repulsive forces are effective in establishing a far more uniform distribution than if the adatoms were in random positions.

distribution. Thus the contribution to $\Sigma_1(1/r^3)$ resulting from adatoms beyond r_2 is

$$\Sigma_1(1/r^3) = \int_{r_2}^{\infty} 2\pi r \, dr (1/r^3) \sigma_2 = 2\pi\sigma_2/r_2 \quad (74)$$

Since we have already found that the contribution of the more distant atoms is given by Eq. (70), we may compare these two expressions to determine the appropriate value of r_2 . Since σ_2 may be identified with σ , we thus find from Eqs. (70), (74) and (68)

$$r_2 = 2\pi\sigma r_1^3/11.044 = (2\pi/11.044)(4/3)^{3/4}\sigma^{-1/2} = 0.7059\sigma^{-1/2} \quad (75)$$

With this value of r_2 , we can now derive an improved expression for F by merely adding to Eq. (71) a term

$$F'' = (3/8)\sigma M^2 \Sigma_1(1/r^3) \quad (76)$$

in accord with Eqs. (62) and (69), the sum $\Sigma_1(1/r^3)$ being given by Eq. (72). To integrate Eq. (72) we may substitute

$$u^3 = M^2/2kTr^3 \quad (77)$$

and obtain

$$\left. \begin{aligned} F'' &= (3\pi/4)(2kT)^{1/2} M^{4/3} \sigma^2 I \\ \text{or} \quad F'' &= 1.531 \times 10^{-5} \sigma^2 T^{1/2} M^{4/3} I \end{aligned} \right\} \quad (78)$$

where the integral I is

$$I = \exp. (u_2^3) \int_{u_2}^{u_0} dx \exp. (-x^3) \quad (79)$$

The values of u_2 and u_0 are found by Eq. (77) from the corresponding values of r_2 and r_0 . The former is given by Eq. (75), while r_0 may be obtained from this same equation by replacing σ by σ_1 . Thus, after introducing the numerical value of k , we have

$$\left. \begin{aligned} u_0 &= 2.181 \times 10^5 M^{2/3} T^{-1/3} (\sigma_1)^{1/2} \\ \text{and} \quad u_2 &= 2.181 \times 10^5 M^{2/3} T^{-1/3} (\sigma_1)^{1/2} \Theta^{1/2} \end{aligned} \right\} \quad (80)$$

The spreading force F' due to the long range forces between adatoms, as defined by Eq. (62), can be obtained by adding F'' from Eq. (78) to the last term of Eq. (71) giving

$$F' = 3.338 \sigma^{1/2} M^2 + 1.531 \times 10^{-5} \sigma^2 T^{1/2} M^{4/3} I \quad (81)$$

The complete equation of state of the adsorbed film is then given by Eq. (61) after inserting this expression for F' .

Calculation of F' from Experimental Data on ν_a .—Differentiation of Eq. (61) gives

$$dF = \sigma_1 k T d\Theta / (1 - \Theta)^2 + dF' \quad (82)$$

Taylor's experiments have shown that for cesium films $\alpha = 1$ and therefore by Eq. (43) we may identify ν_a with μ_a . Thus integration of Eq. (54) gives

$$\ln \nu_a = \frac{1}{\sigma_1 k T} \int \frac{dF}{\Theta} \quad (83)$$

Introducing the value of dF from Eq. (82) and integrating

$$\ln \nu_a = \ln [\Theta/(1 - \Theta)] + 1/(1 - \Theta) + (1/\sigma_1 kT) \int dF'/\Theta \quad (84)$$

Taylor's experimental data on ν_a can be expressed in the form

$$\ln [\nu_a(1 - \Theta)/\Theta] - 1/(1 - \Theta) = A - B/T \quad (85)$$

where A and B are functions of Θ only. The data give

$$A = 61.0 + 4.8\Theta - 2.4\Theta^2 \quad (86)$$

For values of Θ up to 0.6 the values of B can be represented within the experimental error (about 0.3%) by the empirical equation

$$B = 32,380/(1 + 0.714\Theta) \quad (87)$$

Beyond $\Theta = 0.6$ the experimental values of B gradually become somewhat larger than those given by Eq. (87), but this deviation is only 2% at $\Theta = 0.8$ and 4% at $\Theta = 0.9$.

By eliminating ν_a from Eqs. (84) and (85) we obtain

$$\int (1/\Theta) dF' = \sigma_1 kT(A - B/T) \quad (88)$$

Differentiation with respect to Θ and multiplication by Θ gives

$$\frac{dF'}{d\Theta} = \sigma_1 k\Theta \left(T \frac{dA}{d\Theta} - \frac{dB}{d\Theta} \right) \quad (89)$$

By integration we obtain an expression for F'

$$F' = \sigma_1 k \left[T \int \Theta (dA/d\Theta) d\Theta - \int \Theta (dB/d\Theta) d\Theta \right] \quad (90)$$

Inserting the values of A and B from Eqs. (86) and (87) and placing $\sigma_1 k = 0.04884$ in accord with Eq. (63), we get from Taylor's data

$$F' = (0.1172\Theta^2 - 0.078\Theta^3) T + 2215 [\ln(1 + \beta\Theta) - \beta\Theta/(1 + \beta\Theta)] \quad (91)$$

where $\beta = 0.714$, the coefficient in the denominator in Eq. (87). The integration constant was so chosen as to make $F' = 0$ at $\Theta = 0$. This expression gives that part of the spreading force (in dynes cm.⁻¹) which is due to the dipole repulsion of the cesium atoms.

Values of F' calculated by Eq. (91) for $T = 800$ are given in the third column of Table III. The second column gives the total spreading force F obtained from F by Eq. (61).

Calculation of Dipole Moment M .—By equating the theoretical and the experimental expressions for F' , given by Eqs. (81) and (91), an equation is obtained which may be solved for M . By inserting the value of σ_1 from Eq. (63), Eq. (81) may be written

$$F' = 8.00 x^3 \Theta^{3/2} + 1.943 x^2 T^{1/2} \Theta^2 I \quad (92)$$

where

$$x = 10^{12} M^{2/3} \quad (93)$$

The values of F' for any particular values of Θ and T are first calculated from Eq. (91) and these are inserted in Eq. (92). These cubic equations in x may be readily solved by Horner's method. A difficulty arises from the fact that the integral I , according to Eqs. (79) and (80), is itself a function

of x . However, by a series of rapidly converging approximations, it is found possible without much labor to evaluate the integral with sufficient accuracy to get x to 3 or 4 significant figures. This procedure is facilitated by the fact that the term in Eq. (81) which contains I is small compared to the other term. (Ratio is 0.4 at $\theta = 0.1$, 0.18 at $\theta = 0.3$, 0.09 at $\theta = 0.7$.)

TABLE III

CESIUM FILMS ON TUNGSTEN³⁶

Spreading force F , dipole moment M , contact potential V and depolarizing field E , all calculated from ν_a at $T = 800^\circ\text{K}$.

1 θ	2 F , dynes cm. ⁻¹	3 F' , dynes cm. ⁻¹	4 I	5 $10^{18} M$ c. g. s. (e. s.)	6 V , volts	7 $10^{-6} E$ volt cm. ⁻¹
0.0	0	0	0.893	16.16	0	0
.1	10.35	6.01	.315	13.01	0.874	10.4
.2	31.9	22.1	.237	11.17	1.500	22.2
.3	62.6	45.9	.200	9.94	2.003	34.6
.4	101.4	75.4	.180	9.01	2.420	47.0
.5	148.2	109.1	.163	8.28	2.780	59.2
.6	204.3	145.7	.148	7.67	3.089	71.1
.7	271.9	180.7	.130	7.10	3.328	81.6
.8	366.9	210.6	.102	6.54	3.515	90.4
.9	586.9	235.2	.048	6.06	3.663	96.8

The values of I and M obtained in this way are given in the fourth and fifth columns of Table III. The contact potential V of the cesium covered surface against a pure tungsten surface, as calculated from M by Eq. (64), is given in the sixth column.

Depolarizing Field.—Every adatom on the surface is acted on by the electric field produced by all the neighboring adatoms. A dipole of moment M on a surface, with its axis normal to the surface, produces a field of intensity M/r^3 at a point on the surface whose distance from the dipole is r . To obtain the total field E acting on a given adatom we must sum the contributions of all neighboring adatoms

$$E = M \Sigma_1 (r^{-3})$$

By eliminating f between Eqs. (62) and (65) we find that

$$F' = (3/8)\sigma M^2 \Sigma_1 (r^{-3})$$

and therefore

$$E = (8/3\sigma_1)F'/\theta M = 2.245 \times 10^{-12} F'/\theta M \text{ volts cm.}^{-1} \quad (94)$$

The last column in Table III contains values of E (in millions of volts cm.⁻¹) calculated by this equation. The magnitude of these fields seems adequate to cause the marked decrease in M that occurs as θ increases.

Electron Emission ν_e .—Consider a plane tungsten surface part of which is bare while the rest is covered by an adsorbed film of cesium con-

³⁶ The values of θ in the 1st column refer to the cesium on the homogeneous part of the surface (see later section). These were obtained from the observed values $\theta_{\text{obs.}}$ by the equation $\theta = \theta_{\text{obs.}} - 0.005$.

taining σ atoms cm.^{-2} . Under equilibrium conditions at temperature T the concentration of electrons over the surface is governed by the Boltzmann equation and therefore if there is no appreciable reflection of low velocity electrons from the surface we have

$$\nu_e/\nu_w = \exp. (Ve/kT) \quad (95)$$

where ν_e and ν_w are, respectively, the rates of evaporation of electrons from the cesium covered and from the bare tungsten surfaces, V being the contact difference of potential between these surfaces.

The electron emission from pure tungsten according to Dushman is given by

$$I = 60.2 T^2 e^{-b/T} \text{ amp. cm.}^{-2}$$

where $b = 52,400$ was obtained by experiments in the range of temperatures from 1400 to 2400°K. The coefficient 60.2 was calculated by the Sackur-Tetrode relation. At the time of Dushman's derivation the electron-spin was not known to exist. If this is taken into account³⁷ the coefficient should be 120.4. This change of coefficient requires a change of b from 52,400 to 53,650 if the values of I and of dI/dT are to keep their same values at $T = 1800^\circ\text{K}$. At 1400 and at 2400° the values of I obtained by the new equation differ by less than 20% from those given by the original equation, although over this range of temperature the emission increases 2×10^7 -fold. These differences are probably within the experimental error. Since our present interest lies in the range of temperature down to 600°, where the difference between the two equations amounts to a factor of about 4, it seems better to adopt the equation which is in accord with modern theory.

The revised equation can be expressed

$$\nu_w = 4\pi m (kT)^2 h^{-3} \exp. (-V_w e/kT) \quad (96)$$

where $V_w e/k = 53,650$ and V_w , the electron affinity of pure tungsten, has the value

$$V_w = 4.622 \text{ volts} \quad (97)$$

Within the range from 600 to 1000° the values of ν_w from Eq. (96) are very closely given by

$$\ln \nu_w = 63.44 - 55,250/T \quad (98)$$

Combining this with Eq. (95) we get

$$\ln \nu_e = 63.44 - e/kT(4.760 - V) \quad (99)$$

By inserting the values of V from Table III for any particular value of Θ (and T), the electron emission ν_e can be calculated from data on ν_a . Since these values are derived on the assumption of equilibrium, they correspond to the electron emission at zero accelerating field.

Positive Ion Emission ν_p .—In an enclosure containing cesium vapor,

³⁷ See Fowler's "Statistical Mechanics," University Press, Cambridge, England.

under conditions of equilibrium, the law of mass action requires that the concentrations n_e , n_p and n_a of electrons, ions and atoms fulfil the condition

$$K_n = n_e n_p / n_a \quad (100)$$

Using the third law of thermodynamics, the equilibrium constant K_n is found³⁸ to be

$$K_n = \frac{\omega_e \omega_p}{\omega_a} \frac{(2\pi m_e kT)^{3/2}}{h^3} \exp. (-V_i e / kT) \quad (101)$$

where V_i , the ionizing potential, is

$$V_i = 3.874 \text{ volts}$$

for cesium. The statistical weights ω have the values $\omega_e = \omega_a = 2$ and $\omega_p = 1$. The concentrations n are related to the corresponding ν according to the kinetic theory by

$$\nu = n(kT/2\pi m)^{1/2} \quad (102)$$

We may thus place

$$K_\nu = \nu_e \nu_p / \nu_a = 2\pi m (kT)^2 h^{-3} \exp. (-V_i e / kT) \quad (103)$$

Combining this equation with Eqs. (96) and (95) we get

$$\ln (2\nu_p) = \ln \nu_a + (e/kT)(V_w - V_i - V) \quad (104)$$

Using the values of V in Table III we see that the rate of ion evaporation ν_p (for zero accelerating field) can be calculated wholly from atom evaporation data.

Comparison with Experiment.—The values of M and V in Table III have been calculated from the data on ν_a given by Eq. (85) taking $T = 800^\circ$. The values obtained by similar calculations using $T = 600$ or $T = 1000$ are practically identical with those at 800° (within about 0.02 volt for V). This shows that the temperature coefficient of F' is adequately represented by the last term in Eq. (92) which originates from the changing distribution of the adatoms in accord with the Boltzmann equation. At low temperatures the distribution is governed mainly by the repulsive forces which tend to bring about a regular lattice arrangement, but at high temperatures thermal movements cause some of the atoms to approach closer to one another than corresponds to this lattice. We see by Eq. (90) that the temperature coefficient of F' is associated with a dependence of A on Θ .

The value of A from the experiments, as given by Eq. (86), is of the same order of magnitude as that given by Eq. (41) which we obtained from our general vapor pressure equations. Thus inserting $T = 800$ and $M = 133$ in Eq. (41) and comparing with Eq. (85) (neglecting the terms containing $1 - \Theta$) we find $A = 65.8$ in place of the values given by Eq. (86). This equation gives $A = 65.8$ at $\Theta = 0.66$.

In our derivation of Eqs. (40) and (41) b was assumed to be independent

³⁸ Fowler, "Statistical Mechanics," 1929, p. 281.

of temperature. The variation of the adatom distribution with temperature, due to the Boltzmann effect, must cause slight changes in the heat of evaporation, at constant Θ , and corresponding changes in b . This is indistinguishable in its effect from a dependence of A upon Θ and therefore in the present case with strong forces between the adatoms we should not expect A to be strictly constant.

In his experiments Taylor has determined ν_e and ν_p as functions of T , Θ and the accelerating field. At high fields, such as are obtained with 40 to 200 volts on the cylinder (field of 3000 to 15,000 volts cm.⁻¹ at filament), the variation is approximately in accord with Schottky's theory, but at lower fields the variation is far greater than given by this theory.³⁹ By plotting the logarithms of ν_e or ν_p against the cylinder potential, a rapid change of slope (kink) occurs as the field changes from retarding to accelerating. The values of ν_e at this kink are about one-half to one-seventh of those obtained with accelerating fields of 3000 volts cm.⁻¹. These are presumably the values that correspond to the thermodynamic equilibrium implied in Eqs. (99) and (104). As a matter of fact, the experimentally determined values of ν_e and ν_p at the kink agree very satisfactorily with those calculated by these equations (from data on ν_a) up to values of $\Theta = 0.5$. The observed values of ν_e for $\Theta > 0.5$ fall below those calculated. A full report of Taylor's experiments, soon to be published, will contain a more detailed comparison of the experimental and theoretical results.

The agreement obtained seems sufficient to justify the belief that the foregoing analysis of the effects of dipole forces between adatoms on plane surfaces is substantially correct, except for very concentrated films.

General Characteristics of Atom Evaporation from Cesium Films.—

The observed variation of ν with Θ as expressed in Eqs. (85), (86) and (87) is very different from that of the adsorption isotherm of Eq. (2). The occurrence of Θ in the denominator of the B term in Eq. (85) causes an increase of ν with Θ of the exponential type.

This characteristic of the evaporation is illustrated in another way in Fig. 1 which shows the rate of decrease in Θ by evaporation when a filament is maintained at constant temperature in a space free from cesium vapor (bulb in liquid air). Within any narrow range in values of Θ the rate of evaporation ν_a is approximately proportional to an exponential function of Θ so that we can put

$$\nu_a = Ke^{H\Theta}$$

where H varies only slowly with Θ . To construct a given curve, for example that for 700°, having a time scale covering one-half hour, we are interested only in values of ν_a from 10^{10} to 10^{12} which occur for values of Θ between 0.23 and 0.40. In this range H varies only from 34 to 30.

³⁹ K. T. Compton and I. Langmuir, *Rev. Modern Phys.*, **2**, 123-242 (1930); see especially pp. 146-157.

Since $\sigma_1(d\theta/dt) = \nu_a$, we can calculate the time interval required to pass from θ_2 to θ_1 by integration, treating H as constant in this range; thus

$$t = \frac{\sigma_1}{H} \left(\frac{1}{\nu_1} - \frac{1}{\nu_2} \right) \quad (105)$$

where ν_1 and ν_2 are the values of ν_a corresponding to θ_1 and θ_2 . The four full-line curves in Fig. 1 have been prepared in this way.

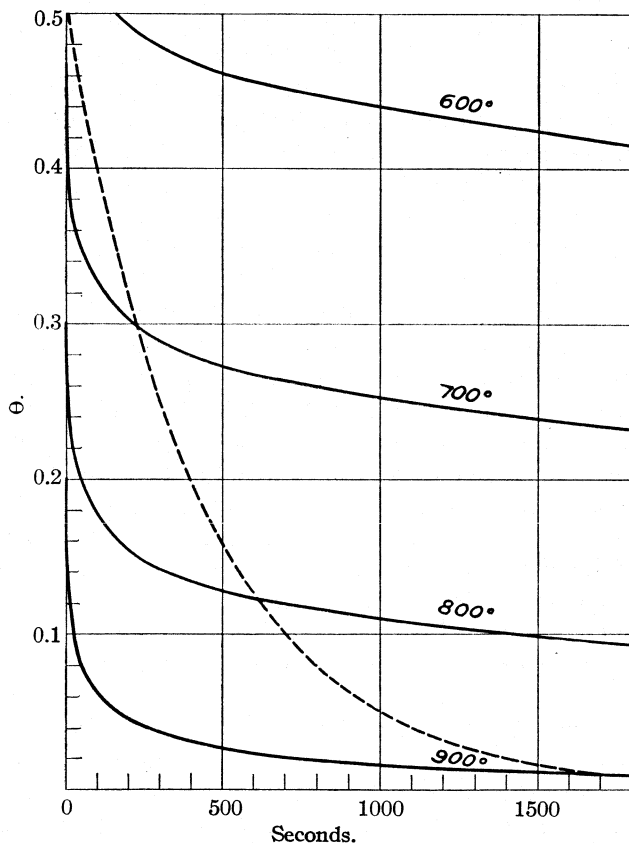

Fig. 1.—Evaporation of cerium films from tungsten at various temperatures. The dotted line is an exponential curve.

The dotted line curve gives for comparison an ordinary exponential curve $y = be^{-ax}$, which corresponds to evaporation on the assumption that the rate is proportional to θ , *i. e.*, that there are no repulsive forces between adatoms. A striking feature of the evaporation from cesium films on tungsten is the fact that θ decreases almost instantly from $\theta = 1$ down to a certain value and then tends to approach a limiting value. Thus at 700°, θ falls to 0.4 in 10 sec., to 0.25 in 1080 sec., but would take 10.5 hours to fall

to 0.15 and 80 hours to reach 0.1. Similar effects are observable with oxygen films on tungsten and point to the presence of strong repulsive forces between adatoms.

Homogeneity of the Tungsten Surface.—In this paper we have so far tacitly assumed that the tungsten surface is homogeneous in the sense that the life τ of any adatom is independent of its position on the surface. The variation of τ with Θ has been taken to be evidence of forces between adatoms.

In the author's 1918 paper on adsorption⁴⁰ the second and third typical cases that were considered were based on the assumed presence of more than one kind of elementary space. The surface may be considered as divided into infinitesimal fractions $d\beta$, each element having its own characteristic evaporation rate ν_1 if saturated with adatoms. Thus ν_1 expressed as a function of β gives a "law of distribution" of the evaporation rate ν_1 over the surface. If there are no forces acting between adatoms, Eq. (2) can be applied to each element $d\beta$ and thus by integration it was found for the whole surface that

$$\sigma = \sigma_1\Theta = \int_0^1 (\nu_1 + \alpha_0\mu)^{-1} \alpha_0\mu d\beta \quad (106)$$

The practical importance of *active areas* in determining the catalytic properties of surfaces (even plane surfaces) was pointed out in a later paper.⁴¹ Within recent years many experimental and theoretical studies have been made of active spots, especially by H. S. Taylor and his collaborators.

It is evident from Eq. (106) that by assuming a heterogeneous tungsten surface, that is, by properly choosing the function $\nu_1(\beta)$, any observed law of variation of ν_a with Θ , such as that expressed by Eqs. (85), (86) and (87), can be accounted for without the necessity of postulating forces between adatoms. However, in this case M would be zero and thus the electron emission ν_e would not vary with Θ . The fact that the observed values of ν_e and ν_p agree with those calculated by Eqs. (99) and (104) from the values of M in Eq. (81) proves conclusively that the tungsten surface is essentially homogeneous.

Active Spots on Tungsten Surface.—The foregoing conclusion is justified by Taylor's experimental data on ν_a for values of Θ greater than about 0.05. In our first detailed analysis of the data obtained with still more dilute cesium films, it was found that the observed values of ν_a were considerably less than those calculated by Eqs. (85), (86) and (87). Since the equation of state of the two-dimensional gas film should approach more nearly to the ideal gas law $F = \sigma kT$ at low concentrations, it appeared to

⁴⁰ Langmuir, *THIS JOURNAL*, **40**, 1361 (1918), see particularly p. 1371.

⁴¹ Langmuir, *Trans. Faraday Soc.*, **17**, 607 (1921), see especially pp. 617 and 618. This paper was reprinted in *Gen. Elec. Rev.*, **25**, 445 (1922).

be impossible to account for these deviations on assumption that the tungsten surface was wholly homogeneous.

It was found that this difficulty disappeared entirely if it was assumed that about 0.50% of the tungsten surface holds cesium so much more firmly than the rest, that this *active surface* becomes saturated before more than 0.5% of the remaining surface is occupied. The total surface concentration may thus be divided into two parts

$$\sigma = \sigma_a + \sigma_n = \sigma_1(\Theta_a + \Theta_n) \quad (107)$$

where the subscripts refer to the *active* and to the *normal* parts of the surface. Evidently when the active surface becomes saturated, so that $\Theta_a = 0.005$, we may put

$$\Theta_n = \Theta_{\text{obs.}} - 0.005 \quad (108)$$

If ν_a is calculated by Eqs. (85), (86) and (87), using Θ_n instead of $\Theta_{\text{obs.}}$, the values are found to agree with those found by Taylor's experiments down to values of $\Theta_{\text{obs.}}$ as low as 0.01. The reason for the discrepancies that remain at still lower values of Θ are then explainable as due to a lack of complete saturation on the active surface. In this way, by Eq. (107), subtracting the calculated values of Θ_n from $\Theta_{\text{obs.}}$, we can obtain Θ_a from experiments carried out with known values of T and μ . In an analysis of Taylor's data (to be published) it will be shown that

$$\ln [\mu(0.005 - \Theta_a)/\Theta_a] = 65.8 - 44,440/T \quad (109)$$

expresses quite accurately the variation of Θ_a with T and μ .

The degree of saturation of the active surface, $\Theta' = \Theta_a/0.005$, thus approaches unity as μ increases or T decreases. Comparison of Eq. (109) with Eqs. (85), (86) and (87) shows that B is independent of Θ' . The experiments show strikingly that the evaporation from the active surface resembles that illustrated by the dotted curve in Fig. 1 instead of the full line curves. A moderate increase of temperature causes practically all of the adatoms to evaporate from the active surface.

This constancy of B proves that repulsive forces do not act between the adatoms on the active surface. This must mean that the active areas consist of isolated elementary spaces, each capable of holding one adatom. It is probable that these active spots are located at points where the spacing of the tungsten atoms is abnormal and is particularly favorable for holding cesium atoms. Such positions may occur close to grain boundaries where the tungsten lattice must be disturbed. The filaments in Taylor's experiments had a very fine-grained crystalline structure which had been considerably etched by heating to 2800°K.

It is probable that the extent of the active area can be made to vary by heat treatment of the filament, but that the properties of the normal part of the surface are uninfluenced by such treatment.

If we solve Eq. (2) for ν_1 we find

$$\nu_1 = \mu(1 - \Theta)/\Theta \quad (110)$$

Since the rate of evaporation ν_1 for a saturated surface varies with temperature in such a way that $\ln \nu_1$ is a linear function of $1/T$, we thus see that Eq. (109) is of a form that is directly derivable from Eq. (2).

It seems probable that the cases in which Eq. (2) is applicable to adsorption on plane surfaces are those in which the elementary spaces available for adsorption are isolated from one another. Only in such cases does it seem reasonable that the average life of adatoms shall be independent of Θ and that the rate of condensation shall be proportional to $\Theta_s - \Theta$, where Θ_s corresponds to saturation of these spaces. In general, therefore, when Eq. (2) applies we should expect Θ_s to be considerably less than unity. This was observed in the case of adsorption of gases on glass and mica.¹

Effect of Oxygen.—The foregoing theories of the nature of cesium films on tungsten aid in understanding the effects observed when the tungsten is partly covered by adsorbed oxygen before bringing into contact with cesium vapor. The oxygen decreases the rate of evaporation of cesium atoms so greatly that the filament can be heated about 250° higher before losing its cesium film. This is now explainable as the result of attractive forces between the negative dipoles of the oxygen adatoms and the positive cesium dipoles. The cesium atoms thus form clusters about every oxygen adatom and will also cover the oxygen atoms. The effect of the oxygen will also be to increase the dipole moment of the cesium adatoms. The presence of minute amounts of oxygen should manifest itself by producing active spots which can be investigated by the methods outlined above.

It is our plan to investigate experimentally these effects of traces of oxygen.

Summary

The vapor pressures of liquids can be expressed (in baryes) by

$$p = AT^\gamma \exp. (-b/T)$$

where A , γ and b are constants. Trouton's rule is equivalent to postulating that $\gamma = 0$ and $A =$ a universal constant. Vapor pressure data of "International Critical Tables" give $\log A = 10.65$ with a standard deviation (S. D.) of 1.19. Hildebrand's rule is equivalent to taking $\gamma = 1$ and A is then a universal constant for which $\log A = 7.83$ with S. D. = 0.52. A rule which agrees still better with the data is obtained by putting $\gamma = 1.5$ and then it is found that $\log A_{1.5} = 6.37$ with a S. D. = 0.22, which is less than half as great as that for Hildebrand's rule.

The vapor pressures of solids whose vapors have rigid molecules are also given by this equation with $\gamma = 1.5$ and $\log A = 6.9$. Much larger values of A are obtained for solids if the molecules possess internal degrees of freedom. The concept is advanced that such molecules in the vapor phase at higher temperatures may possess high internal mobility (as though

liquid) while at lower temperatures they may become rigid (as though solid). Such effects probably do not exist with molecules of vapors of liquids.

These vapor pressure equations may be applied to adsorption phenomena. The rate of evaporation of atoms or molecules from monatomic films on surfaces is thus given by

$$\nu = A_{1.6}(2\pi mk)^{-1/2} \Theta T \exp. (-b/T)$$

This is found to agree reasonably well with experimental data on thorium, oxygen and cesium films on tungsten.

The conditions are discussed which lead to the formation of monatomic and of polyatomic adsorbed films. It is emphasized that the latter can occur on plane surfaces only under rather unusual conditions.

In general adsorbed molecules on plane homogeneous surfaces are acted upon by strong forces originating from the underlying solid. The resulting polarization causes the adsorbed molecules to repel one another as dipoles, with forces varying in proportion to M^2r^{-4} , where M is the dipole moment and r the distance. Attractive forces predominate only if two kinds of adsorbed molecules are present which become polarized in opposite senses, as for example cesium and oxygen on tungsten (or salt-like substances on metals, such as mercurous sulfate on mercury).

The equation of state of the two-dimensional gas constituting the adsorbed film is worked out for molecules which repel as dipoles by means of the Clausius virial. By use of Gibbs' equation for the adsorption isotherm the rate of evaporation ν can be worked out in terms of Θ , T and M . The equations are found to be of the form required by experimental data on cesium films on tungsten. Thus the experimental data furnish values of M as a function of Θ .

The Boltzmann equation and the Saha equation then permit the calculation of the rates of evaporation of electrons (ν_e) and of ions (ν_p) from $M(\Theta)$ and T , yielding results in agreement with experiment. The results indicate that the tungsten surface is essentially homogeneous except for about 0.5% of the surface which holds cesium atoms much more firmly than the rest.

THE BEHAVIOR OF GERMANIUM TETRACHLORIDE AND RELATED CHLORIDES, ESPECIALLY ARSENIOS CHLORIDE, WITH CONCENTRATED HYDROCHLORIC ACID¹

BY ELTON R. ALLISON AND JOHN H. MÜLLER

RECEIVED APRIL 20, 1932

PUBLISHED JULY 6, 1932

Procedures for the separation of germanium from arsenic have followed two general methods: the distillation of germanium tetrachloride from a hydrochloric acid solution of germanium dioxide under conditions which keep arsenic in the pentavalent state of oxidation, and the precipitation of arsenic as sulfide under conditions which prevent the precipitation of germanium sulfide. The method proposed by Dennis and Johnson,² using a current of chlorine and a special still head, is the most efficient distillation process. Abrahams and Müller³ have recently described a method for the sulfide separation which is particularly valuable for analytical purposes.

The purpose of this investigation was to study an extraction method for the removal of arsenious chloride from germanic chloride. Friedrich⁴ first noticed that germanium tetrachloride was immiscible with and unaffected by concentrated sulfuric acid. Dennis and Hance⁵ observed that concentrated nitric acid attacked germanium tetrachloride, although somewhat slowly. The effect of concentrated hydrochloric acid on germanium tetrachloride has not been studied, while it is known that arsenious chloride has a high solubility in this acid.⁶

Preliminary experiments showed that concentrated sulfuric acid was not suitable for the extraction of arsenious chloride from germanic chloride because of the low solubility of arsenious chloride in the acid. Germanium tetrachloride was found to be practically insoluble in concentrated hydrochloric acid. The distribution of arsenious chloride between concentrated hydrochloric acid and germanium tetrachloride was investigated and the extraction of arsenious chloride from germanic chloride by means of concentrated hydrochloric acid studied as a purification method.

¹ This paper is based on a thesis submitted by Elton R. Allison to the Graduate School of the University of Pennsylvania in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

Experimental Part

The apparent solubility of germanium tetrachloride and of arsenious chloride in hydrochloric acid of various concentrations was determined in order to learn the concentration of acid most suitable for extraction purposes. The term "apparent solubility" is used advisedly since it cannot be said that no hydrolytic decomposition of the chlorides takes place on dissolving.

Materials.—Germanium tetrachloride was prepared from the mineral germanite. The mineral was decomposed by concentrated nitric acid. This served to remove the great bulk of copper, iron and sulfur, leaving a siliceous residue small in bulk and rich in germanium dioxide. The residue was treated with concentrated hydrochloric acid and germanium tetrachloride distilled and collected under iced water. Hydrolysis of the chloride gave the dioxide, which was contaminated with arsenic. This was removed by the sulfide method. The pure germanium sulfide obtained was hydrolytically converted to the dioxide⁷ and the latter reconverted to the tetrachloride. No attempt was made to remove hydrogen chloride from the product since it was to be used in experiments in which it would be shaken with hydrochloric acid. The other materials were Baker's c. p. Analyzed Chemicals. Arsenic-free sulfuric and hydrochloric acids were used at all times when the avoidance of traces of this element was desired.

Methods of Analysis.—Determinations of germanium and separations of germanium from arsenic were made according to the method of Abrahams and Müller.³

Arsenic was determined as magnesium pyroarsenate according to the method of McNabb.⁸

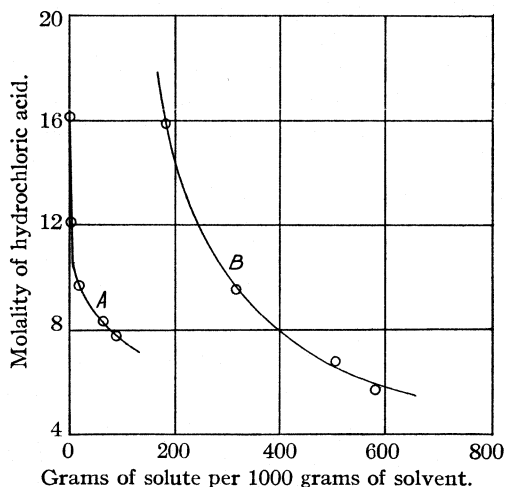

Fig. 1.—Curve A, germanium tetrachloride; Curve B, arsenious chloride.

The solubility of both chlorides increases as more dilute acid is used as

⁷ Müller and Eisner, *Ind. Eng. Chem., Anal. Ed.*, **4**, 134 (1932).

⁸ McNabb, *THIS JOURNAL*, **49**, 1451 (1927).

Experimental Procedure.—Concentrated hydrochloric acid of known strength, and various solutions of the carefully diluted acid, were placed in 50-cc. sealing bottles and an excess of germanic chloride added to each one. The bottles were sealed and suspended in a thermostat maintained at $25 \pm 0.02^\circ$. The bottles were shaken manually several times a day. After two weeks samples of the clear upper layers were taken for analysis.

solvent. Germanic chloride is almost insoluble in the most concentrated acid used, while arsenious chloride has a very high solubility in the same solvent. The diluted acid, which dissolves almost one hundred times as much germanium tetrachloride as the concentrated acid, dissolves only about twice as much arsenious chloride as the concentrated acid. This is clearly shown in Fig. 1. Concentrated hydrochloric acid is thus most suitable for the extraction of arsenious chloride from germanium tetrachloride.

Since germanium tetrachloride proved to be so slightly soluble in concentrated hydrochloric acid it seemed possible that it would be precipitated from an aqueous germanium dioxide solution on saturation with hydrogen chloride. The production of liquid germanic chloride without distillation in the reversal of the hydrolysis reaction

has not been reported. The experiment is also of interest as a further test of the solubility of germanic chloride in concentrated hydrochloric acid. A solution of germanium dioxide was chilled in crushed ice and saturated with hydrogen chloride. Germanium tetrachloride was produced, separated from the hydrochloric acid by means of a separatory funnel, and identified by its boiling point. The hydrochloric acid was analyzed for its germanium content. It contained only 0.348 g. of germanium tetrachloride per 1000 g. of solvent, which compares favorably with values obtained later for the solubility of germanium tetrachloride in concentrated hydrochloric acid at 0° (see Table IV).

The Distribution of Arsenious Chloride between Germanium Tetrachloride and Concentrated Hydrochloric Acid

Apparatus.—On account of the high vapor pressures of the liquids involved it was necessary to work at a low temperature. A jacketed

separatory funnel was obtained for use as the vessel in which equilibrium conditions were attained. The outer jacket could be packed with crushed ice, keeping the inner compartment at 0°. The inner compartment was cylindrical in shape and set off center, causing one side to nearly touch the wall of the outer jacket. In this way the ice did not prevent vision into the inner compartment.

Experimental Procedure.—Approximately 10 cc. of arsenious chloride, 50 cc. of germanium tetrachloride and 75 cc. of concentrated hydrochloric acid were placed in the apparatus. The acid used contained 36.63% hydrogen chloride. The apparatus was shaken for two minutes and then allowed to stand for three minutes. This was repeated for an hour and a half, then the apparatus was allowed to stand for half an hour to give complete settling of the germanium tetrachloride layer. Samples of the upper hydrochloric acid layer were sealed in thin-walled glass bulbs for accurate weighing. It was not necessary to weigh samples of the germanium tetrachloride layer. Portions were run under cold water and allowed to hydrolyze. Pellets of pure sodium hydroxide were added slowly until the solution reacted alkaline to phenolphthalein. Warming caused rapid solution of the germanium dioxide which had resulted from the hydrolysis of the chloride. The solutions thus obtained were analyzed for both arsenic and germanium.

After the first set of samples had been taken the hydrochloric acid layer was siphoned out of the apparatus and replaced by fresh acid. Repetition of the shaking and sampling procedure gave a second set of samples in which the amounts of arsenious chloride present in the two layers were necessarily smaller. In the same way a third set of samples was obtained. This made possible the determination and comparison of values for the distribution coefficient obtained with varying amounts of arsenious chloride distributed.

Results of the analyses and the values of the distribution coefficient are given in Table III. Variation of the distribution coefficient is expressed graphically in Fig. 2. Experiments 4A and 4B were carried out under a different procedure. Germanium tetrachloride, arsenious chloride and concentrated hydrochloric acid were placed together and sealed in large bulbs. These were fastened to a mechanical shaker placed in a

TABLE III
DISTRIBUTION COEFFICIENT AT 0°

	Molality of AsCl ₃ in HCl layer, M_1	Molality of AsCl ₃ in GeCl ₄ layer, M_2	$K = M_1/M_2$
1	0.3298	0.3571	0.9235
2	.1707	.1617	1.056
3	.08012	.06489	1.235

4B	.2356	.2475	.9519

cold room regulated at 0° , with a maximum variation of 5° . After five days the bulbs were taken off the shaker and kept in crushed ice, still in the cold room, for an additional twenty-four hours. This gave a final equilibrium temperature of 0° . Samples of the two layers were taken as in the previous experiments.

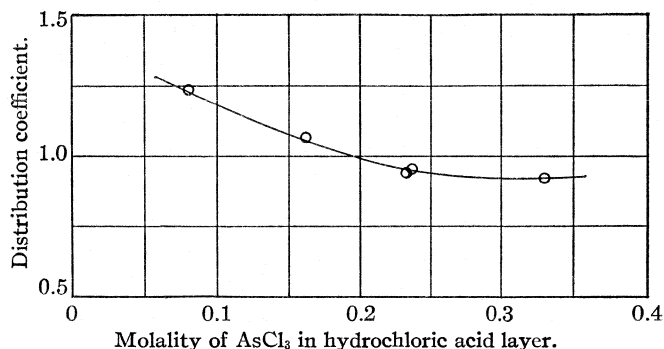

Fig. 2.—Variation of the distribution coefficient with the amount of arsenious chloride distributed between concentrated hydrochloric acid and germanium tetrachloride at 0° .

The values of the distribution coefficient vary inversely with the amounts of arsenious chloride distributed between the two layers. The rate of extraction, removal of arsenious chloride from germanic chloride, increases as the extraction proceeds, although the coefficient is small in all cases. The fact that the values obtained in experiments 4A and 4B, in which six days were allowed for the attainment of equilibrium, fall in the proper relation to the other values, is an indication that equilibrium conditions had been reached in all experiments. This is clearly shown in Fig. 2.

The concentration of germanium tetrachloride in the concentrated hydrochloric acid layers was determined. The results are given in Table IV. The solubility of germanic chloride in concentrated hydrochloric acid at 0° is shown to be considerably less than at 25° (compare No. 1, Table I).

Purification Experiment

The coefficient for the distribution of arsenious chloride between concentrated hydrochloric acid and germanium tetrachloride is so small that a sample of germanic chloride containing arsenious chloride must be shaken with several portions of acid in order to remove the arsenic completely. This can be done without loss of much germanium since the solubility of the chloride in concentrated hydrochloric acid at 25° is

sufficiently low to allow the use of a liter of acid with an accompanying loss of only 1 g. of germanium tetrachloride. At 0° the solubility is less than half as much. A purification experiment was made using the apparatus shown in Fig. 3. Impure germanic chloride and concentrated hydrochloric acid are shaken together in chamber A, allowed to separate into two layers, and the lower germanic chloride layer then run into chamber B. The acid layer is poured out of the apparatus and the germanic chloride run back into A from B, after proper adjustment of the three-way stopcock at C. Fresh acid is now added. The process involves inversion of the appa-

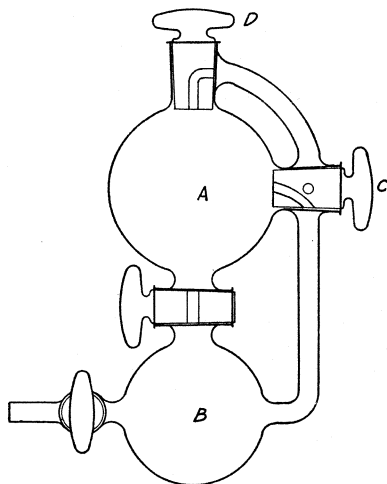

Fig. 3.—Extraction apparatus.

ratus and removal of the stopper at D while the acid is being poured out.

Approximately 35 cc. of germanic chloride containing 1.16% of arsenious chloride was treated with 70 cc. of chilled acid. The same amount of acid was used for the second extraction and 100 cc. in each of the successive treatments, each extraction requiring about five minutes. After the eighth extraction the acid no longer gave a test for arsenic and no arsenic could be detected in the germanium tetrachloride. On the basis of the small amount of arsenic required to discolor germanium sulfide,³ and since the last portion of acid used gave a pure germanium sulfide precipitate when treated with hydrogen sulfide, it was calculated that the germanium tetrachloride layer could not have contained more than one part of arsenious chloride for each two million parts of germanium tetrachloride.

Experiments with the Chlorides of Antimony, Tin and Titanium.—A study of the behavior of chlorides of elements closely related to germanium and arsenic, with concentrated hydrochloric acid in the presence of germanium tetrachloride, is interesting. Antimony pentachloride, stannic chloride and titanium tetrachloride were chosen. These are known to be soluble in concentrated hydrochloric acid.

Approximately 25 cc. of germanic chloride was placed in the jacketed

separatory funnel and 1 cc. of antimony pentachloride added. This caused a slight turbidity which disappeared on treatment with 100 cc. of chilled acid. The apparatus was kept cold, shaken for fifteen minutes, and allowed to stand for thirty minutes. Portions of the germanic chloride layer were drawn off under cold water and the resulting solutions tested with hydrogen sulfide. No antimony could be detected. Similar experiments in which germanic chloride had been contaminated with stannic chloride and titanium tetrachloride resulted in the complete removal of these substances from germanium tetrachloride by a single extraction with concentrated hydrochloric acid.

Discussion of Results

The insolubility of germanium tetrachloride in concentrated hydrochloric acid is a characteristic difference in behavior from that of the tetrachlorides of titanium, tin and lead. These compounds are soluble in concentrated hydrochloric acid with formation of complex chloro acids of the type H_2MeCl_6 . The corresponding germanium chloro acid has not been prepared. This behavior of germanic chloride is not only an interesting distinction from the anhydrous chlorides of its type, but also likens germanic chloride to the similarly inactive tetrachloride of carbon. The complete removal of the chlorides of antimony, tin and titanium from germanic chloride in one treatment with concentrated hydrochloric acid is an interesting distinction from the behavior of arsenic. This can only be well explained by the assumption of a definite formation of the chloro acids of these elements, which must be insoluble in the germanium tetrachloride layer.

Sufficient data for the calculation of the constant for the distribution of arsenious chloride between concentrated hydrochloric acid and germanic chloride are not available. The constant could only be calculated provided the concentration of simple arsenious chloride molecules in each layer were known. The values for the coefficient reported here were calculated from the total concentration of arsenic found in each layer. At present there is no information available regarding the ionization or possible association of arsenious chloride dissolved in germanium tetrachloride or concentrated hydrochloric acid. The actual conditions existing in these systems may be the subject of further investigation.

If proper apparatus for the preparation of large quantities of pure germanium tetrachloride by the distillation method is not available, the method of extracting arsenious chloride by means of cold concentrated hydrochloric acid may be conveniently used.

Summary

1. Arsenious chloride can be removed completely from germanium tetrachloride by extraction with concentrated hydrochloric acid.

2. The apparent solubility of germanium tetrachloride, and of arsenious chloride, in hydrochloric acid of various concentrations, has been determined. Germanium tetrachloride is practically insoluble in concentrated hydrochloric acid.

3. The distribution of arsenious chloride between concentrated hydrochloric acid and germanium tetrachloride has been studied.

4. The chlorides of antimony, tin and titanium may be removed from germanium tetrachloride by a single extraction with concentrated hydrochloric acid.

THE PHOTOLYSIS OF HYDROGEN PEROXIDE IN AQUEOUS SOLUTION

BY LAWRENCE JOSEPH HEIDT

RECEIVED APRIL 26, 1932

PUBLISHED JULY 6, 1932

Quantum yields of the photolysis of hydrogen peroxide in aqueous solution as reported in the literature vary from 4 to 500. Rice and Kilpatrick¹ have suggested that dust-free solutions from which all surface effects have been eliminated should give a quantum yield of unity. Allmand and Style² found that the quantum yield decreases from 500 to 20 as the intensity of light increases.

Investigations of the photolysis prior to 1929 have been reviewed and discussed by Kistiakowsky³ and by Griffith and McKeown.⁴ Kornfeld⁵ suggests the dissociation $\text{H}_2\text{O}_2 \longrightarrow \text{H}^+ + \text{OOH}^-$ in explaining her results.

Urey, Dawsey and Rice⁶ favor the photolysis $\text{H}_2\text{O}_2 \xrightarrow{h\nu} \text{H}_2\text{O} + (\text{O})$. In the present investigation a quantitative study of the photolysis in monochromatic light was made to ascertain whether secondary effects can be eliminated to such an extent that the photolysis can be further studied profitably from a theoretical standpoint.

Materials.—General Chemical Co. superoxol (Code B, At 1788) was purified by distillation in an all-Pyrex still, at a pressure of 25 mm. in the presence of an excess of c. p., silver sulfate. The receiving flask at 0° was of

quartz. Conductivity water for dilution was made by redistillation of distilled water first in a tin and then in an all quartz still. Sulfuric acid was made by dissolving in a quartz flask at 0° the white crystals of acid from 30% reagent quality fuming sulfuric acid in conductivity water. Solutions of the above purified materials were kept in covered quartz flasks. Potassium permanganate, C. P., was not subjected to further purification.

Purification of materials and all experiments were carried out in a laboratory comparatively free from dust. It had no windows and was isolated from chemical fumes. The laboratory air was filtered. All cells and glassware were cleaned with chromic acid and thoroughly rinsed with conductivity water.

Experimental Procedure

The light source, monochromator and radiometric procedure have been described.⁷

Absolute energy measurements were determined by reference to U. S. Bureau of Standards lamp C 44. They were checked against determinations of the decomposition of uranyl oxalate in the same cell using the data of Leighton and Forbes.⁸

A two compartment (9 cm. \times 1 cm. \times 1 cm.) rectangular quartz cell, all seams fused, was used as the reaction vessel. It was placed flush against the exit slit (0.6 mm. \times 20.0 mm.) so that all the light from this slit was intercepted by the front windows of either compartment. Special precautions were taken to have the center of the beam pass through the center of the reaction compartment; otherwise results were erratic and gave higher values of the quantum yield, particularly if the beam grazed a side wall. Photolyses were carried out at 313 m μ and $28 \pm 2^\circ$ in only one compartment at a time, thus eliminating corrections for the dark reaction taking place under otherwise identical conditions in the other compartment. The dark reaction, however, was generally negligible.

Analyses were carried out volumetrically using 0.02 *N* potassium permanganate standardized against sodium oxalate and oxalic acid. An excess of sulfuric acid was always present. Extra care was taken to prevent surfaces in contact with the hydrogen peroxide from rubbing together, and to add the titer always at the same rate; otherwise, analyses were not reproducible.

The "*P_H*" of the solutions was determined by the use of a glass electrode apparatus⁹ kindly furnished by Dr. Hazel. The values should be considered only as qualitative until the reliability of the glass electrode for solutions of this type is further established.

⁹ Hazel and Sorum, *ibid.*, **53**, 49 (1931).

Data and Discussion

Results of the photolyses are summarized in the table. Concentration of hydrogen peroxide is expressed in moles per liter. Data for one photolysis for each series are shown and check determinations of the quantum yield, Φ , are given in parentheses. The average quantum yield, Φ av., of the series is given in the last column. In series A, where the original peroxide containing an inhibitor was not purified, a strong blue fluorescence was noted throughout the solution.

TABLE I

Series	[H ₂ O ₂]	[H ₂ SO ₄]	"P _H "	<i>I</i> / <i>I</i> ₀	Time of photolysis in sec. $\times 10^{-3}$	Quanta absorbed $\times 10^{-19}$	Molecules decomposed $\times 10^{-19}$	Φ	Φ av.
A	1.77	0.0	3.0	89	7.2	7.9	14.2	1.8 (1.7 0.9)	1.5
B	2.36	0.0	3.6	91	7.2	7.0	8.0	1.1 (1.1 1.1)	1.1
C	4.20	0.0	2.5	98	7.2	3.5	6.8	2.0 (3.1 2.1)	2.4
D	3.70	1.3	-1.0	96	14.4	8.2	15.6	1.9 (1.9 1.3)	1.7
E	3.72	4.1	-1.8	95	14.4	5.6	11.2	2.0 (1.3 2.1 1.8)	1.8
F	4.48	1.3	-1.5	98	10.8	6.6	6.4	1.0 (1.6 2.0 2.1)	1.7

It is evident from the table that a quantum yield approaching unity has been obtained, substantiating the predictions of Rice and Kilpatrick¹ for dust-free solutions and those of Griffith and McKeown⁴ for radiation of high intensity. The intensity per square millimeter was of the order of 1000 times that of Allmand and Style^{2b} in their experiments with filters. The data also show, almost within the limits of experimental error, that Φ tends to increase with the concentration of hydrogen peroxide and to decrease with the addition of sulfuric acid. Results obtained a year later independently by Mr. Harrison Holmes and the author are in general agreement with the above.

Calculations based on the data of the table show that the extinction coefficient, $\epsilon(1/cd \log I_0/I$ where c is expressed in moles per liter and d in cm.), tends to decrease with an increase in [H₂O₂] and in [H₂SO₄]. The reaction cell used in these experiments was irregular but the thickness was approximately 1 cm. and relative values of ϵ are accurate to 5%.

Using the method of Forbes, Heidt and Boissonnas¹⁰ for measuring extinction coefficients, the following was obtained. In a given cell for 2.36 molar H₂O₂, $\epsilon_{313 \text{ m}\mu} = 0.44$; for 2.36 molar H₂O₂ in 2.6 molar H₂SO₄, $\epsilon_{313 \text{ m}\mu} = 0.41$ and on adding a slight excess of sodium hydroxide to 2.36 molar H₂O₂, $\epsilon_{313 \text{ m}\mu} = 1.14$. All measurements were taken before any noticeable decomposition had taken place. From this it appears that some chemical individual derived from hydrogen peroxide, possibly the ion OOH⁻, has an extinction coefficient for λ 313 m μ greater than that of the peroxide. To draw definite conclusions, it is planned to make a detailed study of the dependence of ϵ on [H₂O₂] and [H⁺]. In later experiments

¹⁰ Forbes, Heidt and Boissonnas, THIS JOURNAL, 54, 960 (1932).

with an improved cell $\epsilon_{313 \text{ m}\mu}$ was found to be 0.38 for molar hydrogen peroxide. This is in good agreement with the value 0.39 obtained by Allmand and Style.^{2a}

The author desires to express his appreciation to Professor Farrington Daniels for his help and guidance in this investigation, and to the Research Committee of the University of Wisconsin for substantial aid.

Summary

1. A quantum yield approaching unity as the concentration of hydrogen peroxide is decreased has been obtained for its photolysis in aqueous solution at $28 \pm 2^\circ$ using light of high intensity at $313 \text{ m}\mu$ from a monochromator.

THE OPTICAL CRYSTALLOGRAPHIC DESCRIPTION OF THE PHENYLOSAZONES AND OTHER DERIVATIVES OF CERTAIN SUGARS¹

BY VINCENT H. MORRIS

RECEIVED APRIL 27, 1932

PUBLISHED JULY 6, 1932

Introduction

The identification of sugars which have been isolated from plants or plant products is a constantly recurring problem. The usual method of attack consists of preparing insoluble derivatives of the sugars in more or less pure crystalline form and identifying these derivatives through their melting points, optical rotation, microscopic observation of crystal form, etc. Since the presence of very small quantities of impurities is sufficient to make melting points misleading, as well as to influence the crystal form, positive identification through these characteristics is sometimes difficult. In searching for some other means, that suggested by Wright,² based on the optical properties of the crystalline derivatives, seemed to offer promise of being such a valuable tool in the identification of sugars that a study of certain derivatives of some of the more common sugars was undertaken.

Materials.—The sugars investigated were glucose, fructose, mannose, galactose, arabinose, xylose and maltose. The derivatives used were the phenylosazones of five of these and the following additional compounds:

¹ This study was carried out under the direction of Dr. H. C. Sampson and Dr. W. G. McCaughey, Departments of Botany and Mineralogy, respectively, The Ohio State University, and presented in partial fulfilment of the requirements of the degree of Doctor of Philosophy to the Faculty of the Graduate School of The Ohio State University. Original manuscript received October 23, 1931.

² Wright, *THIS JOURNAL*, **38**, 1647 (1916).

potassium hydrogen saccharate, fructose methylphenylosazone, mannose phenylhydrazone, mucic acid, arabinose diphenylhydrazone and cadmium bromide xylonate. The phenylosazones, potassium hydrogen saccharate and mannose hydrazone were prepared according to Morrow,³ mucic acid and arabinose diphenylhydrazone according to Van der Haar,⁴ fructose methylphenylosazone according to Neuberg,⁵ and cadmium bromide xylonate according to Bertrand and Thomas.⁶

Methods.—The immersion method of examination used by mineralogists and petrographers for many years was employed. The light used in measuring refractive indices and extinction angles was obtained by passing light from a 400-watt Mazda C bulb through two Corning glass ray filters, G584J and G34. These filters transmit light from 540 μ to 640 μ with a maximum at 580 μ .

The phenylosazones and several of the other derivatives were obtained as such minute crystals that it was necessary to use an oil immersion objective in measuring the refractive indices.⁷ The size of the crystals, together with the unusually high degree of dispersion shown by the crystals themselves and also by the methylene iodide solutions used in measuring the high indices, made this determination unusually difficult. The indices between 1.70 and 1.80 are accordingly accurate only to about ± 0.005 , while those above 1.80 are accurate to ± 0.01 . The indices below 1.70 are probably all correct within ± 0.002 .

The optical axial angle was estimated from the curvature of the isogyre of an optic axis interference figure or by actual measurement of the distance between the axes, using a micrometer eyepiece. Since, with the equipment available and the type of material under examination, these methods only give approximations, the angles are reported as large, medium or small.

The optical crystallographic data are given in Table I. A determinative table for identification of five of the sugars by optical examination of their phenylosazones is given in Table II.

One $n =$ liquid (130° with elongation), others higher	galactose
Two n 's less and one much greater, elongation \neq	glucose

WOOSTER, OHIO

NOTES

The Existence of the High-Temperature Form of Cristobalite at Room Temperature and the Crystallinity of Opal

BY J. W. GREIG

There has appeared recently an interesting letter from Levin and Ott¹ announcing that they have established, by means of x-rays, the existence of the high-temperature modification of cristobalite in a number of opals. So far as I am aware, the high-temperature modification of cristobalite has not before been shown to occur in nature at atmospheric temperatures. In my opinion, however, this form has, contrary to their statement, been shown to be present at room temperature in certain artificial products.

In the course of experimental determinations of points on the liquidus of silica, in systems of silica with other oxides, carried out at this Laboratory, study of the charges frequently shows that some of the cristobalite crystals embedded in the glass are sensibly isotropic, often in contrast to other birefringent ones in the same melt. This has been observed repeatedly by microscopists doing this work here and was explained by Andersen as due to some of the crystals of cristobalite failing to invert during cooling and so persisting in the high-temperature cubic modification.²

In connection with a study of the decomposition of cyanite, $\text{Al}_2\text{O}_3 \cdot \text{SiO}_2$, at high temperatures to give mullite, $3\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$, and silica, I have investigated the question of the form in which the silica was present in the product of decomposition.³ When first formed the products of the decomposition are so fine-grained that some question remains as to the nature of the silica, but with continued heating at high temperature it collects

¹ Levin and Ott, *THIS JOURNAL*, **54**, 828 (1932).

² O. Andersen, *Am. J. Sci.*, **39**, 418 (1915).

³ J. W. Greig, *J. Am. Ceram. Soc.*, **8**, 478-481 (1925); *Am. J. Sci.*, **11**, 21-25 (1926).

into larger particles and is then definitely cristobalite. On cooling through the inversion temperature the cristobalite remains, as indicated by thermal studies, for the most part in the high-temperature form.

Although they do not explicitly say so, Levin and Ott have evidently based their opinion, that the high-temperature form of cristobalite has not before been shown to exist at room temperature, on the fact that Sosman, in his monograph on silica,⁴ mentions only two reports to that effect and discusses both unfavorably. It is to be noted that the experiments described in these reports are of a somewhat different nature from those mentioned in the preceding paragraphs. In both these cases the cristobalite was already in the low-temperature form and supposedly free from any enclosing solid medium. As will appear later, this is probably an important difference. Sosman's remarks, quoted from p. 133, follow.

"Endell stated in 1912 that he had found the low-to-high inversion of cristobalite to be reversible with difficulty, and that rapid cooling after the crystals had been heated to above 220° left them in the isotropic high-form, from which the change" [to the low-temperature birefringent form] "at atmospheric temperature was a matter of some hours" (phrase in brackets mine).

"Schwarz has also stated that cristobalite after being heated about 15 minutes at 250° and then quickly cooled remains isotropic.

"These statements are in such direct contradiction to the numerous observations of all other investigators that it can hardly be admitted without further evidence that the phenomena observed were really due to a delayed inversion. It is easy to be mistaken on this point because cristobalite after passing through the inversion is very fine grained, and its birefringence, furthermore, is small, so that it may give a false appearance of being isotropic."

One must agree with Sosman that more evidence is needed before one can accept their conclusions as established, for their reported results are not in accord with general experience with cristobalite. The two forms of cristobalite are distinguishable by other properties than birefringence, yet no one, so far as I am aware, has since reported the same result, although many experimenters have studied cristobalite since 1912. It must, however, be noted that Sosman's suggested explanation cannot account for Endell's reported observations. It could indeed explain only the first part and would put anyone accepting it in a difficult position in respect to the second part. If one accepts it he must, to explain the reappearance at room temperature of the normal birefringent aspect, assume further that in this aggregate of cristobalite, already in the low-temperature form, individual crystals grew markedly in a few hours at room temperature.

⁴ R. B. Sosman, "The Properties of Silica," American Chemical Society Monograph 37, 1927.

It is appropriate here to mention two additional sets of observations, so far unpublished, indicating that under certain conditions the high-temperature form of cristobalite may be brought to room temperature without inverting. The first of these is a confirmation of Andersen's opinion. I have examined literally hundreds of charges, similar to those described by Andersen, in which well-formed cristobalite crystals occur distributed in glass. It is quite normal to find, using crossed nicols, that sensibly isotropic cristobalite crystals as well as birefringent cristobalite crystals occur together in the same preparation. Since the inversion from the high-temperature to the low-temperature form is accompanied by a considerable decrease in volume, the high-temperature isotropic form should have the lower index of refraction. It should thus be possible, by this property, to differentiate them readily, if they were embedded in a medium with an intermediate index of refraction. In order to apply this test I have prepared suitable glasses with indices of refraction lower than those of the low-temperature form (*i. e.*, $n < 1.485$), and, by holding these at a temperature immediately under that of the cristobalite liquidus, have grown excellent faceted crystals of cristobalite in them. The cristobalite crystals in these glasses after cooling to room temperature were of both the isotropic and the birefringent kinds. The isotropic crystals had always a low index of refraction (not far from that of a glass $n = 1.46_6$), and were thus definitely differentiated from those that had inverted and that had therefore a higher index of refraction than the glass. Reëxamination of some of these preparations after they had stood for over three years at room temperature showed that sensibly isotropic crystals with this low index of refraction were still present. It is accordingly concluded that in these glasses cristobalite in the high-temperature form may be cooled to room temperature without inverting and will there remain in that form for an indefinite time.

In the case of certain silicate liquids it is extremely difficult to prevent the crystallization of cristobalite during cooling. When such liquids are chilled the cristobalite appears as small crystals thickly distributed throughout so that the quenched products vary, depending on the size and number of the crystals, from faintly opalescent to porcelain-like.⁵ I have made heating and cooling curves on several such porcelain-like "glasses" using a differential apparatus sufficiently sensitive to detect the heat absorption or evolution accompanying the inversion of a fraction of the cristobalite present, yet these curves showed no trace of such heat effect. The cristobalite in them did not invert sharply on cooling through the inversion temperature.

In the cases that I have described, from my own experience, in which high-temperature cristobalite was cooled through the inversion tem-

⁵ J. W. Greig, *Am. J. Sci.*, **13**, 40-44 (1927).

perature without inverting, the crystals were small and embedded in some solid medium: in one case intergrown with mullite crystals, in the other cases embedded in a siliceous glass. In the glasses with an index of refraction < 1.485 mentioned above the glass immediately surrounding the crystals with the low index of refraction is, at room temperature, invariably birefringent, showing that it is strained. The relation of the vibration directions of the fast and slow rays in the strained glass to the enclosed crystal, together with the localization of the strain, indicate that the strain is due to a contraction of the crystal that is being resisted by the glass. The glass and crystal are therefore adhering. This strain fades out on heating but on cooling reappears, becoming evident at a temperature somewhat above that of the inversion, and increasing as the temperature is lowered. The glass surrounding the crystals that have inverted to the low-temperature form, on the other hand, is not strained, and in some cases it is even possible by careful microscopic work to see that a crack surrounds the crystal. The inversion and the breaking free of the crystal from the restraint of the glass are thus associated. Such crystals invert to the high-temperature form on heating and back again on cooling, as may readily be seen by watching them under the microscope during the process. It is probable, in view of the strong contrast between the behavior of the crystals mechanically attached to the surrounding glass and that of free crystals, whether surrounded by the glass as these are, or prepared by some other method and entirely separate, that the solid embedding medium exercises an important restraint on the inversion of the attached crystals.

Since the appearance of the letter by Levin and Ott, Dr. E. Posnjak has obtained an x-ray spectrogram, corresponding closely to that given by the high-temperature form of cristobalite, from a translucent amber-colored "resin opal" from Queretaro, Mexico. Dr. H. E. Merwin and I have examined this material under the microscope. It is then resolved into two parts, a matrix $n = 1.41$ and, thickly distributed through it, small particles of considerably higher index of refraction. In all likelihood these particles are the crystals giving rise to the x-ray pattern. If, as seems most probable, they are indeed the high-temperature form of cristobalite, they are probably another example of small crystals of cristobalite embedded in a medium failing to invert on cooling through the inversion temperature, for, on the basis of our present very limited knowledge, this is considered more probable than that the high-temperature form of cristobalite would crystallize in the temperature range in which the low-temperature form is the more stable.

The Preservation and Determination of Sodium Sulfocyanate

By JOSEPH GREENSPAN

Several recent improvements in the analytical determination of thiocyanates by oxidation with iodine in appropriate alkaline buffers permit of a more precise investigation of the kinetics of reactions involving thiocyanate ion.¹ In searching the literature for means of preventing mold formation in standard aqueous solutions of sodium thiocyanate, we were struck by the paucity of information regarding this salt.² We have found the following methods satisfactory.

Preservation.—The commercial c. p. salt was recrystallized from 95% alcohol. The addition of one drop of toluene per 100 cc. of approximately 0.02 *M* solutions completely prevented mold growth and loss of titer for a period of at least three weeks, whereas mold growth developed in the absence of toluene. Titration after two weeks of standing with toluene preservative gave a value of 0.01982 *M*; after three weeks, 0.01982 *M*.

Analytical.—The ammonia-ammonium salt buffer recommended by Pagel and Koch³ developed iodine absorption after standing for several days, giving titer values of 13.38, 17.68, 15.92 cc. against the calculated 20.83, 20.64, 20.54 cc., respectively, although accurately concordant results were obtained with fresh buffer, giving 18.71, 20.43 cc. *vs.* calculated 18.67, 20.46 cc. The authors mention that traces of nickel, cobalt and manganese produce erratic results. Our solutions were kept in Non-Sol bottles.

Schwicker's⁴ ammonium borate buffer method, as modified by Pagel and Ames,⁵ yielded a black precipitate, presumably an iodide of nitrogen, which disappeared upon subsequent acidification. This method was therefore rejected in favor of that employing a borax buffer,⁵ which yielded accurate and consistent values, 40.51, 40.53 cc. *vs.* calculated 40.49, 40.51 cc.

The Equilibrium of Para and Ortho Hydrogen

By ROY W. HARKNESS AND W. EDWARDS DEMING

Investigators in several laboratories are studying the transition of para to ortho hydrogen. In most of this work it is desirable to know the equilibrium ratio at different temperatures. There appears to be no accessible tabulation of this ratio, and it seems desirable to publish a table calculated

from Dennison's¹ equation, covering the range 20 to 273°K. Between these temperatures the equilibrium mixture changes from 99.82% para to 25.13%. In the accompanying table we give the ratio of para to ortho hydrogen and the percentage amount of para hydrogen at a sufficient number of temperatures for ordinary purposes. In the liquid air range values are given at every degree.

RATIO AND PERCENTAGE OF PARA HYDROGEN IN AN EQUILIBRIUM MIXTURE AT VARIOUS TEMPERATURES, CALCULATED FROM THE EQUATION

T, °K.	Ratio para:ortho	Para hydrogen, %	T, °K.	Ratio para:ortho	Para hydrogen, %	T, °K.	Ratio para:ortho	Para hydrogen, %
20	544.8	99.82	76	1.046	51.13	95	0.6801	40.48
21	363.5	99.73	77	1.017	50.41	100	.6262	38.51
22	251.6	99.60	78	0.9894	49.73	105	.5829	36.82
23	179.8	99.45	79	.9626	49.05	110	.5456	35.30
24	132.2	99.25	80	.9377	48.39	115	.5152	34.00
25	99.57	99.01	81	.9140	47.75	120	.4897	32.87
30	32.07	96.98	82	.8916	47.13	130	.4498	31.03
35	14.28	93.45	83	.8702	46.53	140	.4208	29.62
40	7.780	88.61	84	.8500	45.95	150	.3994	28.54
45	4.853	82.91	85	.8307	45.37	160	.3835	27.72
50	3.327	76.89	86	.8123	44.82	170	.3715	27.09
55	2.443	70.96	87	.7981	44.39	190	.3555	26.23
60	1.890	65.39	88	.7781	43.76	210	.3463	25.72
65	1.521	60.33	89	.7621	43.25	230	.3409	25.42
70	1.264	55.83	90	.7469	42.75	250	.3377	25.24
75	1.077	51.86	91	.7323	42.27	273	.3357	25.13

The ratio of para to ortho hydrogen, as given by Dennison, is

$$\frac{1 + 5e^{-6x} + 9e^{-20x} + 13e^{-42x} + \dots}{9e^{-2x} + 21e^{-12x} + 48e^{-30x} + \dots}$$

wherein $x = h^2/8\pi^2 JkT$. We have adopted the following values, in C. G. S. units: $h = 6.547 \times 10^{-27}$, $k = 1.371 \times 10^{-16}$, $J = 0.466 \times 10^{-40}$, so that $xT = 84.977$. J is the moment of inertia of the hydrogen molecule, and the value $(0.466 \pm 0.001) 10^{-40}$ was estimated by Birge and Jeppesen.² Increasing J by 0.001×10^{-40} lowers the calculated percentage of para hydrogen 0.13 per cent. in the central portion of the curve and much less at the end portions. The series in the numerator and denominator converge rapidly over the temperature range used; the expression written above contains all the terms needed for the accuracy of the accompanying table.

Eucken and Hiller³ published six values of the ratio para : ortho hydrogen, at $T = 21.2, 28.3, 42.5, 60.0, 85, 170$, which agree with the entries in our table except at their two highest temperatures, $T = 85$ and 170° .

² R. T. Birge and C. R. Jeppesen, *Nature*, **125**, 463 (1930).

³ Eucken and Hiller, *Z. physik. Chem.*, **B4**, 142 (1929).

At $T = 85^\circ$ they give 48.0%, whereas we find 45.4; at $T = 170^\circ$ they give 25.3, whereas we find 27.1. They presumably calculated their values

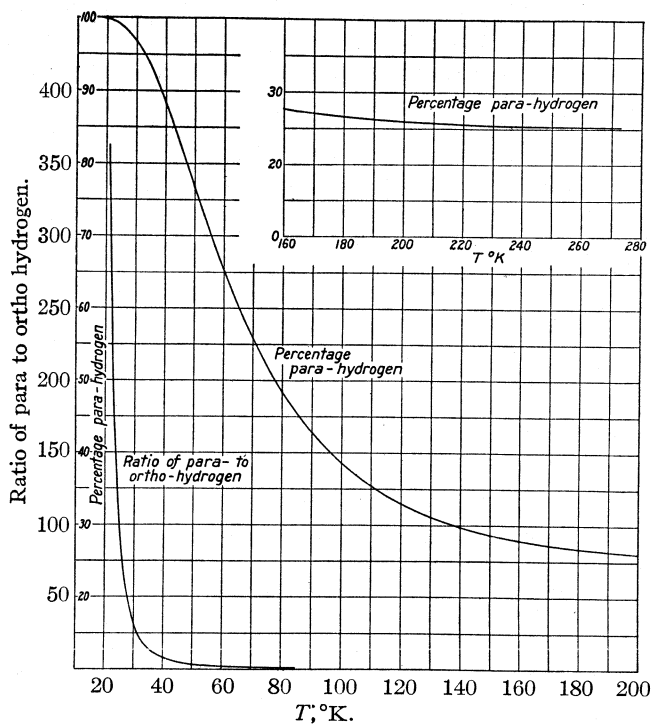

Fig. 1.

from Dennison's equation. We know of no explanation for this discrepancy. They used 0.467×10^{-40} for J , so it is not to be found there.

IODIMETRIC TITRATION OF SEMICARBAZIDE¹

BY PAUL D. BARTLETT

RECEIVED JANUARY 23, 1932

PUBLISHED JULY 6, 1932

The reaction of compounds containing the carbonyl group with nitrogen bases such as phenylhydrazine, semicarbazide and hydroxylamine, is one of the most general reactions of organic chemistry. A convenient and exact titration method for one of these nitrogen reagents therefore opens an important type reaction to quantitative study. Perhaps the most favorable case of this reaction for investigation is the formation of semicarbazones

This is so because the semicarbazones crystallize well and are conveniently water-soluble, also because semicarbazide is not rapidly autoxidized. The present paper describes a titration method for semicarbazide which has been applied to the study of rates and equilibria in semicarbazone formation.^{1a}

Dilute aqueous semicarbazide has been found to react quantitatively with iodine in the proportion of four atoms of iodine to one molecule of semicarbazide. The reaction, which is attended by effervescence except at high dilution, is probably as follows

In this reaction semicarbazide is analogous to phenylhydrazine,² which reacts with iodine in the same proportion, and behaves differently from hydroxylamine, whose iodine equivalent varies with the concentration.³

Phenylhydrazine is inconvenient for reaction velocity studies because it and some of the phenylhydrazones are readily oxidized by the air. Just as semicarbazide is more stable in air than phenylhydrazine, so it is less rapidly attacked by iodine. Phenylhydrazine hydrochloride can be titrated with iodine, but the reaction between iodine and semicarbazide hydrochloride is very slow. Some rough tests were therefore made of the rate of this reaction in buffer solutions of different *P_H* values, in order to determine the necessary conditions for quantitative reaction within the time of a titration.

Reaction Rate as a Function of *P_H*.—Small samples of iodine and semi-

carbazine hydrochloride were added in equivalent amounts to 20 cc. of 0.5 *M* buffer solutions diluted to 70 cc., kept in a thermostat at $25.00 \pm 0.01^\circ$. Titrations were made with thiosulfate at short intervals. In all cases it was provisionally assumed that throughout the reaction one molecule of semicarbazide had disappeared for each four atoms of iodine which had reacted. The reciprocal of the semicarbazide concentration, calculated on this basis, increased linearly with time, showing that the reaction rate is controlled by a bimolecular step. Consistent results are obtained by the formulation

$$-dx/dt = kx \cdot 2x = 2kx^2$$

where *t* is the time in minutes, *x* is the concentration of semicarbazide and 2*x* is the concentration of iodine in moles per liter. The values of *k* are computed from the experimental data by the integrated form

$$2k = \frac{1}{t} \left[\frac{1}{x} - \frac{1}{x_0} \right]$$

*x*₀ being the initial concentration of the semicarbazide.

Table I gives the experimental data and the values of *k* for these runs at 25° . In these, *x*₀ is 0.000238, so that 1/*x*₀ is 4200. The iodine solution used was 0.0336 *N* (0.0168 *M*). The figures in the column headed "Iodine" refer to the amount of iodine found in the reacting solution at the time of titration, expressed in cc. of stock solution.

TABLE I

RATE OF REACTION OF IODINE WITH SEMICARBAZIDE AT $25.00 \pm .01^\circ$					
<i>P_H</i>	Minutes	Iodine	1/ <i>x</i>	(1/ <i>x</i> - 1/ <i>x</i> ₀)	<i>k</i>
1.48	0.93	1.63	5610	1410	750
	3.23	1.01	9055	4855	750
	4.25	0.89	10300	6100	720
	6.02	.70	13065	8865	730
2.02	0.30	1.68	5450	1250	2080
	.98	1.17	7810	3610	1840
	1.47	0.86	10640	6440	2190
	1.95	.70	13060	8860	2270
2.45	0.37	1.11	8240	4040	5410
	.63	0.86	10640	6440	5100
	1.25	.50	18300	14100	5640
	1.68	.39	23450	19250	5720
3.01	0.16	0.75	12200	8000	25000
	.27	.52	17600	13400	24800

At *P_H* 3 the reaction has become almost too fast to measure, but the rates can be followed in solutions of higher *P_H* values by measurements at 0° . In these runs (summarized in Table II) *x*₀ = 0.000184 and 1/*x*₀ = 5435.

TABLE II

RATE OF REACTION OF IODINE WITH SEMICARBAZIDE AT $0.1 \pm 0.1^\circ$

	1.88	.50	24810	19375	5150
5.01	0.18	.68	18250	12815	35600
	.44	.38	32700	27265	31000
7.08	.10	.25	49600	44400	180000
	.15	.23	54000	48800	248000

The chemical interpretation of a measurable first step followed by an immediate second step may be as follows

The dependence of the reaction rate upon the P_H would also be explained if, according to this picture, it is the free, non-ionized form of semicarbazide which reacts. We should then expect the rate constant to be proportional to the fraction of the semicarbazide which is present in the non-ionized form at the P_H of the reaction. This is shown to be true up to P_H 5 by dividing each value of k by that fraction, which we define as

$$F = \frac{(\text{H}_2\text{NCONHNH}_2)}{(\text{NH}_2\text{CONHNH}_2) + (\text{H}_2\text{NCONHNH}_3^+)}$$

Substituting the values for the semicarbazide positive ion (see below) $pK_A = 3.68$ at 25° and 4.40 at 0° , in the equation

$$pK_A - P_H = \log \frac{(\text{H}_2\text{NCONHNH}_3^+)}{(\text{H}_2\text{NCONHNH}_2)} = \log (1/F - 1)$$

we find values of F as shown in Table III.

Within the accuracy of the rate determinations, the corrected velocity constant k/F is independent of P_H up to P_H 5. This constancy through a set of buffer solutions involving different acids at different concentrations demonstrates the absence at these P_H values of any considerable catalysis by either acidic or basic substances in the buffers. On the other hand, rough as the measurements at P_H 7 are, they show clearly that there is an increase of about five-fold over the value of k/F in the other buffers at 0° . This is probably due to an independent hypiodite reaction, analogous to the replacement of amide hydrogen by halogen, and yielding the same product as Step 1.

TABLE III
 VELOCITY CONSTANTS REFERRED TO FREE SEMICARBAZIDE

Temp.	P_H	$(pK_A - P_H)$	$(1/F - 1)$	$1/F$	k	k/F

	3.57	0.83	6.76	7.76	5270	41000
	5.01	— .61	0.246	1.25	33300	42000
	7.08	-2.68	.002	1.00	214000	214000
Average at 0° (omitting P_H 7.08)						39000

Conditions of Titration.—This acceleration makes the reaction an acceptable titration method at P_H 7. Using the procedure described below, 99.9% of the semicarbazide present reacts with iodine in three seconds.

Experiments on the rate of reaction of iodine with semicarbazones will be described in a later communication.^{1a} In no case is this reaction rapid enough to be a significant source of error when titrating semicarbazide in the presence of semicarbazones.

On the basis of this study, the following procedure is employed in titrating semicarbazide with iodine. To 20 cc. of a 0.5 *M* phosphate buffer of P_H 7 (or, in the case of reactions taking place in acid solutions, the calculated amount of di-sodium phosphate to bring the P_H of the resulting solution to 7) enough 0.02 *M* iodine is added from a buret to provide a 2.5-cc. excess. A sample of the reacting solution is then added from a pipet and the excess of iodine is titrated back with thiosulfate.

Basicity of Semicarbazide.—The basicity of semicarbazide, expressed in terms of the acid dissociation constant K_A of the ion $H_2NCONHNH_3^+$, was determined at 24° (room temperature) and at 0° by potentiometric titration of semicarbazide hydrochloride with standard sodium hydroxide. The value of pK_A , the negative logarithm of K_A , was taken as equal to the P_H at the point of half neutralization on the curves shown in Fig. 1. The semicarbazide hydrochloride was tenth normal, and the ionic strength at the midpoint was 0.079. The values found for pK_A were 3.66 at 24° and 4.40 at 0°. Such values, of course, involve the magnitude of the activity coefficient of the semicarbazide positive ion (γ) and are therefore not the same at all ionic strengths. The quantity determined experimentally is

$$pK_A = P_H - \log \frac{(H_2NCONHNH_2)}{(H_2NCONHNH_3^+)} = pK - \log \gamma$$

If the approximate limiting equation held for the relation between γ and ionic strength at high dilutions

$$-\log \gamma = 0.5 \sqrt{\mu}$$

the value of $-\log \gamma$ at $\mu = 0.079$ would be 0.14, and the value of pK (infinite dilution) would be 3.52 at 24° and 4.26 at 0° . The experimentally determined values for pK_A were used in all the calculations, since semicarbazide was worked with in solutions of $\mu = 0.08$ and higher. pK_A at 25° was computed from its values at room temperature and 0° by applying the integrated form of the van't Hoff formula. This yields the value 3.68 for pK_A at 25° and $\mu = 0.079$.

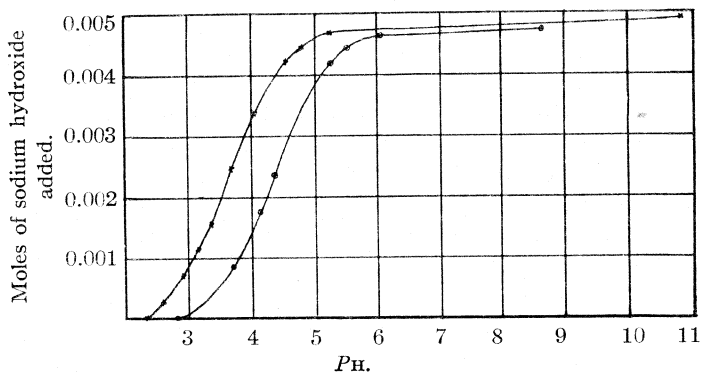

Fig. 1.—Titration of semicarbazide with sodium hydroxide: Crosses, 24° , Circles, 0° .

Two determinations of the basicity of semicarbazide are reported in the literature. Wood⁴ reported K_B at 40.2° to be 2.6×10^{-11} , from studies of the hydrolysis of methyl acetate. Veley,⁵ using methyl orange and a colorimeter, reported this constant to be 9.1×10^{-9} at 15° . The pK_A values corresponding to these are 2.90 and 6.25, respectively. Thus Wood's catalytic constant is in reasonable agreement with the present potentiometric results, while the work of Veley is not substantiated.

Experimental

The iodine-potassium iodide solution was standardized against weighed potassium bromate by comparing both with the thiosulfate solution on the same day. The iodine was 0.03365 *N*.

Semicarbazide hydrochloride from the Eastman Kodak Co. was recrystallized from alcohol-water. Its tenth normal solution was standardized by potentiometric titration with standard sodium hydroxide.

In the potentiometric titrations, a saturated calomel half-cell was used which had been standardized at the beginning of the run against a tenth normal calomel half-cell, whose single potential of 0.3377 volt at 24° was

⁴ Wood, *J. Chem. Soc.*, **83**, 568-578 (1903).

⁵ Veley, *ibid.*, **93**, 652-666 (1908).

in turn checked by measuring its e. m. f. against a $M/20$ solution of potassium hydrogen phthalate of assumed P_H 3.974.⁶

The buffer solutions were composed approximately as follows

P_H	Acid	Concentration	Salt	Concentration
1.48	H_3PO_4	0.295	Mono-sodium	0.205
2.02	H_3PO_4	.155	Mono-sodium	.345
2.45	H_3PO_4	.425	Mono-sodium	.075
3.01	Citric	.25	Mono-sodium	.25
3.57	Citric	.08	Mono-sodium	.42
5.01	Acetic	.17	Sodium	.33
7.08	NaH_2PO_4	.06	Di-sodium	.14

In measuring the rates of reaction at 25° , the following procedure was used. In each of a series of Erlenmeyer flasks were put 20 cc. of the appropriate buffer solution, 50 cc. of distilled water, and 5 cc. of a prepared iodine solution containing 2.18 cc. of the standard iodine. This was the amount calculated to react with 2.02 cc. of 0.00909 M semicarbazide hydrochloride, which was added to the flask from a pipet when the flasks had come to temperature in the thermostat. The several samples were thus identical and the excess iodine in the different flasks was titrated after suitable lengths of time. The time was measured to 0.01 minute with a stop watch.

In measuring the rate at 0° a similar procedure was used except that the total concentration of diluted reacting solution was in this case 100 cc., and the volumes of semicarbazide hydrochloride and of iodine solutions were, respectively, 2.02 and 2.39 cc. The reaction mixtures were kept in an ice-bath.

Summary

1. Semicarbazide reacts quantitatively, one molecule with four atoms of iodine.
2. The reaction is bimolecular; its rate is proportional to the non-ionized fraction of the semicarbazide up to P_H 5, but is considerably accelerated at P_H 7.
3. At P_H 7 the reaction is rapid enough to provide a suitable titration method for semicarbazide.
4. The basicity of semicarbazide has been determined by potentiometric titration at 0 and at 24° .

THE BEHAVIOR OF ALIPHATIC DIAZO COMPOUNDS WITH DERIVATIVES OF METALS. I. MERCURI-ORGANIC DERIVATIVES AND MERCURIC SALTS WITH DIAZOMETHANE. (NOTE ON THE REACTION OF MERCURIC CHLORIDE WITH DIPHENYLDIAZOMETHANE)¹

BY LESLIE HELLERMAN AND MINETTE D. NEWMAN

RECEIVED JANUARY 29, 1932

PUBLISHED JULY 6, 1932

Some years ago we were investigating the methylation with diazomethane of certain hydroxylated aromatic mercury derivatives,² as an aid to the elucidation of their structures. There was encountered, in the course of those studies, an interesting new reaction which seemed to involve essentially a transformation of the type represented by the equation

The investigation of this reaction has recently been resumed by us and has included observations of the action of diazomethane and its derivatives upon a variety of simple mercuri-organic compounds and mercuric salts. Some of the results of the studies are recorded in this paper and certain theoretical implications set forth.

When *p*-tolylmercuric chloride, suspended in ether, is suitably treated with a molecular equivalent of diazomethane³ a gas (nitrogen) is evolved and slightly soluble mercury di-*p*-tolyl remains suspended in the ether and may be separated from the latter by filtration; upon evaporation of the ether, there is obtained a third product, the hitherto unknown substance, bis-chloromethyl mercury.

Thus diazomethane plays here the role of a peculiar type of "bridging" reagent which, itself, participates in the establishment of a new carbon-to-mercury bond. Its behavior, in this instance, bears a striking resemblance to its reactions⁴ and those of some of its derivatives⁵ with certain acid chlorides. Reference will be made to this further on. The assumption, implied in equation (2), that the unsymmetrical substance, chloromethyl *p*-tolyl mercury, is first formed and that this disproportionates to yield two

¹ This paper was presented before the Division of Organic Chemistry at the Buffalo Meeting of the American Chemical Society, September, 1930.

³ See the Experimental Part for details.

⁴ For references see Malkin and Nierenstein, *THIS JOURNAL*, **52**, 1504 (1930); Bradley and Robinson, *ibid.*, **52**, 1558 (1930).

⁵ Staudinger and co-workers, *Ber.*, **49**, 1940, 1959, 1976 (1916).

symmetrical mercuri-bis compounds is supported by the work presently to be described. That this unsymmetrical derivative, if formed first, would very readily undergo disproportionation, seems to us entirely likely in view of the relatively great disparity in the apparent electron affinities of the groups carried by the mercury atom, that of the *p*-tolyl group presumably being high with respect to that of the chloromethyl group.⁶

From the interaction of phenylmercuric chloride and diazomethane there was obtained a liquid product ($\text{C}_6\text{H}_5\text{HgCH}_2\text{Cl}$?). After some time the product began slowly to deposit crystals of mercury diphenyl. This behavior suggested disproportionation, a change that would again be accompanied by the formation of bis-chloromethyl mercury.⁷ The residual oil, separated from the precipitated mercury diphenyl, yielded, when treated with hot alcoholic hydrogen chloride, the beautifully crystalline new substance, chloromethylmercuric chloride, ClCH_2HgCl .

This was also obtained when bis-chloromethyl mercury, one of the products from the interaction of diazomethane and *p*-tolylmercuric chloride or mercuric chloride (equation 8), was similarly treated.⁸

These results encouraged us to attempt, by means of the interaction of diazomethane and a suitable mercury compound, the direct preparation of a relatively stable unsymmetrical derivative, disproportionation of which would take place but slowly. For this purpose, benzylmercuric chloride was selected, on the supposition that the desired stability in the product might be attained if the chloromethyl group were "balanced" against a group which, like itself, appears to possess relatively low electron affinity.⁹

⁶ A large number of unsymmetrical mercury compounds, RHgR' , were prepared by Kharasch and Marker, *THIS JOURNAL*, **48**, 3130 (1926), by the use of the classical method whereby an organomagnesium halide is treated with an appropriate organomercuric halide. Careful control of the experimental conditions was found by them to be essential because of the tendency of these substances to undergo disproportionation. The results obtained from the decomposition of the unsymmetrical derivatives with alcoholic hydrogen chloride were used by these investigators in the construction of a table of organic groups in the order of their increasing "relative electronegativities" (apparent degrees of "affinity" or "attraction" of the organic groups for their assumed bonding electron pairs).

⁷ Compare equation (2).

⁸ Two reactions resulted when bis-chloromethyl mercury was treated with mercuric chloride: (1) the anticipated cleavage reaction in which the substance was converted to chloromethylmercuric chloride; and (2) an oxidation-reduction resulting in the formation of much *calomel*. For a discussion of the reactions of mercuri-bis compounds with mercuric halides consult Whitmore, "Organic Compounds of Mercury," The Chemical Catalog Company, New York, 1921, p. 65.

⁹ "Groups" that have marked attractions for their bonding doublet pairs (for example, C_6H_5 or Cl) often appear to induce a lowering of the apparent electron affinity of methyl carbon atoms upon which they are substituted. This principle cannot be

As a matter of fact, benzyl chloromethyl mercury, the liquid product (obtained in practically quantitative yield) from the action of diazomethane upon benzylmercuric chloride, showed little apparent tendency to disproportionate while standing for a period of several weeks. The identity of the product was demonstrated by means of (a) analysis, (b) evidence of homogeneity after an attempted fractionation with ether, and (c) its behavior during decomposition with hydrogen chloride on the one hand and mercuric chloride on the other.

It seems worthy of emphasis that a completely unsymmetrical breakdown in benzyl chloromethyl mercury resulted from the action upon it of alcoholic hydrogen chloride. The only mercury compound produced as a result of this process was chloromethylmercuric chloride. This was obtained directly in a high state of purity and in good yield. In the reaction mixtures from several independent experiments benzylmercuric chloride was sought but could not be detected. The change may, therefore, be represented by the following equation.¹⁰

Of especial interest in connection with the foregoing are the reactions of mercuric salts with aliphatic diazo compounds. It had already been incidentally observed¹¹ that diazomethane *reduces* mercuric chloride. However, employment of the experimental procedure developed in this work has demonstrated that the course of the reaction may be very different. From mercuric chloride with one molecular equivalent of diazomethane, there was obtained in high yield chloromethylmercuric chloride.

The same salt with two equivalents of the diazo compound yielded the expected symmetrical derivative, bis-chloromethyl mercury.

It has already been stated that chloromethylmercuric chloride is obtained as a product when bis-chloromethyl mercury is decomposed by either hydrogen chloride or mercuric chloride. Both compounds are physiologically active; for example, in minute quantities they act upon the skin causing a "dermatitis." This may be severe in the case of individuals who are very susceptible to the action of mercurials. The di-chloromethyl compound is a powerful vesicating agent and causes painful blisters.

elaborated here. It is illustrated by certain aspects of the chemical behavior of such compounds as benzyl-, benzohydril- and triphenylmethylmagnesium halides, highly phenylated hydrocarbons, phenylated or halogenated acetic acids, etc.

¹⁰ When mercuric chloride was substituted for hydrogen chloride in this reaction, there was produced the expected *mixture* of chlorides. On the basis of the result of the hydrogen chloride reaction it would be concluded, following Kharasch's reasoning (see Ref. 6), that the group, ClCH_2- , is less "electronegative" than the benzyl group.

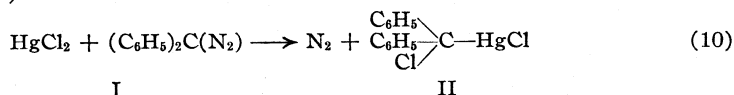

¹¹ Meerwein and Burneleit, *Ber.*, **61B**, 1843 (1928).

torily exist; but the concomitant destruction of the electrical neutrality of the diazo molecule would cause the diazo group to be "lost" together with the electron pair with which it is bound to the carbon atom (*i. e.*, as N_2) and the latter would again complete its octet by attracting Cl^- with the elaboration of the final product (IV).

An analogous interpretation for the reactions of acid chlorides^{4,5} with diazo compounds should be of service. Here the carboxyl carbon atom is the *relatively* oxidized atom that would "share" an electron pair with the diazo carbon atom in the first stage of the reaction. Such reactions seem to be closely allied to the changes involved in the decomposition of diazo compounds with acids, in which hydrogen ions presumably share the "exposed" doublet pairs.

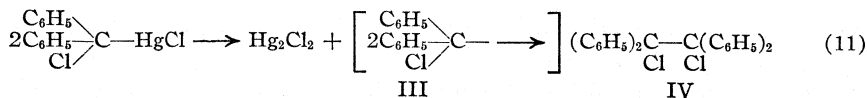

Staudinger has demonstrated that chloro-ketonic derivatives may be formed when certain acid chlorides react with aliphatic diazo compounds in which the diazo carbon atoms are *fully substituted* (*i. e.*, carry no hydrogen atoms). In the following section preliminary results are presented that indicate that a diazo compound of that type may also react with mercuric chloride. The applicability of the concept of "electron-sharing" as tentatively suggested in the foregoing is thus strengthened.

Mercuric Chloride with Diphenyldiazomethane.—When mercuric chloride is treated with diphenyldiazomethane (I), under the conditions used, nitrogen is evolved and there is obtained, as the main product, a white amorphous solid which is not appreciably soluble in dry ether. This solid has the mercury content calculated for chlorodiphenylmethylmercuric chloride (II).

Upon exposure to moist air, it is converted chiefly to benzophenone and calomel. Hydrogen chloride is also formed. Of preëminent interest is its behavior when shaken with moist ether. Calomel is produced *quantitatively* and, at the same time, organic material dissolves in the ether, which is abruptly colored yellow. This indicates cleavage at the carbon-to-mercury bond, a property to be anticipated for a substance of the type assumed.¹⁶ From the ethereal solution, after spontaneous evaporation of the solvent (during which the yellow color vanishes), there is obtained chiefly a white crystalline substance. The properties of the latter indicate that it is 1,2-dichlorotetraphenylethane. The following equation depicts the assumed course of the decomposition.

¹⁶ Triphenylmethylmercuric bromide, $(\text{C}_6\text{H}_5)_3\text{CHgBr}$, would be a similar substance of much theoretical interest. It is not produced when triphenylmethylmagnesium bromide is treated with mercuric bromide. Instead, the mercuric salt is reduced; triphenylmethyl bromide is a product of the reaction (unpublished results of the authors).

Work is being continued upon the preparation and properties of unstable metallic derivatives of this type (II) and upon the probable elaboration from them of free radicals (III). Enough has been accomplished here to indicate that the new reaction type considered in this paper is applicable also to *derivatives* of diazomethane and that the mechanism suggested [equation (9)] for the course of such reactions is not inconsistent with the experimental results.

Experimental Part

For the addition of diazomethane to the various mercury compounds treated, a simple standard type of apparatus was found useful. The reaction vessel, set up in a good hood, was a three-necked flask of convenient volume fitted with (a) a short return condenser ("closed" with a calcium chloride tube), (b) a mercury-sealed stirrer and (c) the delivery end of a condenser which in turn was sealed to the outlet tube of a suitable distilling flask to be used for the generation of diazomethane. The distilling flask was equipped with a dropping funnel.

The Interaction of Mercuric Chloride and Diazomethane in Equimolecular Proportions: Chloromethylmercuric Chloride, ClCH_2HgCl .—Pure mercuric chloride, 13.6 g. (0.05 mole), and 200 cc. of ether (c.p.) were mixed in the reaction flask which was placed in an ice-bath. The mixture was well stirred mechanically. In the distilling flask a molecular equivalent (2.1 g.) of diazomethane¹⁷ was prepared in the usual manner by the slow addition of 12.0 cc. of nitrosomethylurethan to a mixture of 60 cc. of ether and 18 cc. of a 25% solution of potassium hydroxide in methyl alcohol. The ethereal diazomethane was distilled during its preparation directly into the reaction vessel at such a rate that the mercuric chloride was always in excess and the reaction mixture remained colorless. The reaction took place rapidly with the evolution of nitrogen. At the end of the operation the product had crystallized partially. It was obtained in almost pure form and in practically quantitative yield after the solvent had been allowed to evaporate spontaneously. Recrystallization of the product from 95% ethanol yielded micaceous scales of the pure substance; m. p. 131° (corr.). The substance is slightly soluble in water. It is appreciably hydrolyzed in its aqueous solution. It is decomposed in the presence of concentrated sodium hydroxide with the formation of metallic mercury.

Anal. Subs., 0.2776 g.: required 16.25 cc. of NH_4CNS (1.00 cc. \approx 0.01196 g. Hg). Calcd. for $\text{CH}_2\text{Cl}_2\text{Hg}$: Hg, 70.3. Found: Hg, 70.0. Subs., 0.4287, 0.4945 g.: AgCl , 0.4384, 0.4976. Calcd. for $\text{CH}_2\text{Cl}_2\text{Hg}$: Cl, 24.8. Found: Cl, 25.3, 24.9.

Analytical Methods. (1) **Mercury.**—The convenient thiocyanate method gave excellent results when used in conjunction with the treatment (somewhat modified) recommended by Kharasch and Flenner (cited by Hillebrand and Lundell)¹⁸ for mercury compounds containing halogens.

(2) **Halogens.**—In a long-necked flask fitted with a condenser (preferably with a ground-glass seal) the substance, suspended in anhydrous ethanol, is decomposed by

¹⁷ The directions given in Houben-Weyl, "Die Methoden der organischen Chemie," Georg Thieme, Leipzig, 1923, Vol. III, p. 124, were found reliable; it was considered that 1 cc. of ethyl-N-methyl-N-nitrosocarbamate (nitrosomethylurethan) produced 0.18 g. of diazomethane.

¹⁸ Hillebrand and Lundell, "Applied Inorganic Analysis," Wiley, New York, 1929.

the addition of pieces of pure sodium. Water is then added and the alcohol removed by distillation. The residual solution is filtered and neutralized with nitric acid. Halogen is determined in the usual manner.

Mercuric Chloride with Diazomethane in Excess: Bis-Chloromethyl Mercury, $(\text{ClCH}_2)_2\text{Hg}$.—In the standard apparatus and under conditions of temperature, stirring, etc., identical with those set forth in the preceding section, mercuric chloride in ethereal solution and suspension was treated with two molecular equivalents and a 10% excess of diazomethane. At the end of the operation, the solution of the product was colored yellow (excess diazomethane). It was filtered from a trace of calomel and the filtrate evaporated as completely as possible in a rapid stream of calcium chloride-dried air. A slightly colored oil remained; its weight was that expected, assuming that bis-chloromethyl mercury had been formed quantitatively. The crude product was assayed (calcd.: Hg, 67.0. Found: Hg, 63.6, 63.4). After several days the oil crystallized, when manipulated; the crystals consisted of rods and plates. Although they were quite soluble in various organic solvents, it was found possible to effect the purification of a quantity sufficient for analysis by means of recrystallization from ether. A second recrystallization from isopropyl ether yielded material with the same melting point. The latter property was evidently materially affected by the presence of small amounts of impurities; m. p. 37–40° (rather indefinite). The molten substance re-solidified upon cooling. The physiological properties are touched upon in the first part of the paper.

Anal. Calcd. for $\text{C}_2\text{H}_4\text{Cl}_2\text{Hg}$: Hg, 66.98. Found: Hg, 66.83, 66.97.

Bis-Chloromethyl Mercury with Mercuric Chloride.—Of the bridged compound, 2 g. was heated with a mixture of 15 cc. of ethanol and 2 g. of mercuric chloride just below the boiling point of the solvent for one-half hour. The compound dissolved; a solid product precipitated. The mixture was filtered while hot. The residue consisted of 0.91 g. of calomel, which was identified by its physical and chemical properties. When the filtrate was cooled there were obtained characteristic spangles of chloromethylmercuric chloride. The product was pure; it melted at 128° (uncorr.) and did not depress the melting point of known chloromethylmercuric chloride.

Bis-Chloromethyl Mercury with Hydrogen Chloride.—Some of the substance was heated for ten minutes with a freshly prepared, concentrated solution of hydrogen chloride in ethanol at the boiling point of the solvent. Crystals did not appear until the reaction mixture had been permitted to stand at room temperature for a week. After most of the solvent had evaporated spontaneously, the characteristic scales that had been formed were collected and washed with alcohol. They were in all respects identical with chloromethylmercuric chloride; m. p. 129° and "mixed m. p." 129°. This was the only mercury compound that could be isolated from the reaction mixture.

The Interaction of Diazomethane and *p*-Tolylmercuric Chloride.—*p*-Tolylmercuric chloride, 16.4 g. (0.05 mole), suspended in 100 cc. of pure ether, was treated at 0° with 2.4 g. of diazomethane (0.055 mole) in a manner entirely similar to that described in the foregoing except that the ethereal diazomethane was added rather rapidly. There was no difficulty in controlling the action, which was slow but increased in rate when the temperature was raised somewhat. After the evolution of nitrogen had entirely ceased (two hours) the suspended solid was collected on a filter and washed *well* with ether. The product contained no chlorine; it was identified as mercury di-*p*-tolyl (7.1 g.) by its solubility behavior and its melting point (233–236°). It depressed the melting point of a sample of *p*-tolylmercuric chloride and did not depress that of authentic mercury di-*p*-tolyl ("mixed m. p." 236°).

The ether filtrate from the solid product was evaporated in a stream of dry air. A slightly colored viscous oil remained which resembled in appearance and properties

crude *bis*-chloromethyl mercury. Possibly some chloromethyl *p*-tolyl mercury was present. The oil was treated with concentrated alcoholic hydrogen chloride according to the directions of the preceding section. The results of this experiment were analogous to those noted for the corresponding decomposition of known *bis*-chloromethyl mercury. But one substance containing mercury was isolated. The product, obtained in excellent yield, was identical in all respects with samples of chloromethylmercuric chloride which had been prepared during the course of this investigation from other sources. It melted at 131° (corr.). For analysis it was recrystallized from ethanol and dried over phosphoric anhydride and paraffin.

Anal. Calcd. for $\text{CH}_2\text{Cl}_2\text{Hg}$: Hg, 70.3. Found: Hg, 69.7, 70.2.

The Interaction of Diazomethane and Phenylmercuric Chloride.—Phenylmercuric chloride was treated with diazomethane according to the general procedure. During the action, the evolution of gas proceeded evenly and the mercurial gradually “dissolved”; the action ceased abruptly and the reaction mixture became yellow immediately after one molecular equivalent of the diazo compound had been added. The solution thus obtained was cooled (5°) and concentrated in a stream of dry air. A colorless oil remained. Upon standing some needle-like crystals were deposited from the oil and the amount soon became very appreciable. Those were collected and washed with ether; they were found to be slightly impure mercury diphenyl. They were identified (a) by means of comparison with authentic mercury diphenyl and (b) by the observation that their decomposition in the presence of alcoholic mercuric chloride yielded only pure phenylmercuric chloride (m. p. 252°, “mixed m. p.” 252°).

The residual oil (filtrate from the mercury diphenyl) was mixed with alcoholic hydrogen chloride and the mixture heated for fifteen minutes. When the mixture was cooled there crystallized pure chloromethylmercuric chloride, identified by comparison with authentic material (see above).

The Interaction of Diazomethane and Benzylmercuric Chloride: Benzyl Chloromethyl Mercury, $\text{C}_6\text{H}_5\text{CH}_2\text{HgCH}_2\text{Cl}$.—Benzylmercuric chloride, 8.18 g., was suspended in 200 cc. of ether (c. p.). To the mixture, cooled to 0° and stirred well, was added 1.05 g. of diazomethane (a 5% excess) in ether solution. The general procedure, as described in preceding experiments, was employed. The reaction proceeded slowly with the evolution of nitrogen; the gas ceased to be evolved after one equivalent of the diazo compound had been added and at this stage all of the suspended solid had “dissolved.” Ether and excess diazomethane were next removed in a blast of clean, dry air and an oil, colored faintly yellow, remained. Crystallization of the product could not be effected. The initial unpleasant odor of the product vanished after the oil had been brought to constant weight (at room temperature) in a vacuum desiccator (over chipped paraffin and phosphoric anhydride). The yield of the product was quantitative. Its analysis indicated that it was either an equimolecular mixture of mercury dibenzyl and mercury di-chloromethyl or the unsymmetrical compound, benzyl chloromethyl mercury. That the latter alternative is correct was rather convincingly demonstrated by the experiments to be described.

Anal. Calcd. for $\text{C}_6\text{H}_5\text{ClHg}$: Hg, 58.8. Found: Hg, 58.4, 58.8.

Decomposition with Hydrogen Chloride.—Benzyl chloromethyl mercury, 22.4 g., was treated with 125 cc. of alcoholic hydrogen chloride on a water-bath for fifteen minutes. The odor of toluene became evident almost at once. To the solution, which had been freed from a suspended trace of mercury by means of filtration, was added water; a large amount of solid was precipitated. The solid was collected and directly (without being washed) dried in a vacuum desiccator over paraffin and phosphoric anhydride. It consisted of 14.8 g. of practically pure chloromethylmercuric chloride (m. p. 129–131°; m. p. of a mixture with authentic material, 129–131°). The filtrate

contained more of the same substance. The product was recrystallized from ethanol; m. p., unchanged. No other mercury compound could be isolated from the reaction mixture. The decomposition of benzyl chloromethyl mercury by hydrogen chloride took thus the course depicted by equation (6).

Decomposition with Mercuric Chloride.—The decomposition of benzyl chloromethyl mercury with hot alcoholic mercuric chloride resulted in the production of a substantial amount of calomel together with a mixture of benzylmercuric chloride and chloromethylmercuric chloride. The nature of the mixture was indicated by its melting point behavior before and after a partial fractionation with alcohol; the products were compared with the pure individual chlorides.

An Attempt at Fractionation.—Some benzyl chloromethyl mercury (about 8 g.) was well agitated with a little ether until about one-third had dissolved. The extract was separated from residual oil (R) by decantation and the two fractions freed from ether and brought to constant weight in the manner already described. The two fractions were found to be identical in their chemical behavior (decomposition reactions, etc.); their mercury contents were identical.

Anal. Calcd. for C_6H_5ClHg : Hg, 58.8. Found: (first fraction, R) Hg, 58.6; (second fraction) Hg, 58.6.

It had been observed that occasionally freshly prepared benzyl chloromethyl mercury contained in suspension a trace of mercury, from which it could be separated by filtration. As the unsymmetrical compound stood the formation of mercury continued; heat or exposure to light accelerated the process. The nature of this oxidation-reduction change was not studied in detail; such behavior is not unusual for compounds of this type. The fractions described above were permitted to stand for several weeks, after which they were separated from precipitated mercury. They were then assayed for chlorine and, as was expected, the chlorine contents were somewhat high.

Anal. Calcd. for C_6H_5ClHg : Cl, 10.4. Found: (first fraction, R) Cl, 11.0; (second fraction) Cl, 10.8.

Diazomethane and Mercuric Iodide: Bis-iodomethyl Mercury, $(ICH_2)_2Hg(?)$.—Of red mercuric iodide (c. p.), one-twentieth mole was treated with one-tenth mole of diazomethane, the procedure being entirely similar to the general method already described. A vigorous action ensued and nitrogen was evolved. However, much solid remained undissolved. Some of it was probably yellow mercuric iodide. When the action had ceased, the ether solution was still deeply colored (yellow diazomethane). The solution was separated from undissolved yellowish material (S) and the removal of ether and diazomethane effected as usual. During the evaporation, some well-formed long needles crystallized; m. p. 80–84°. The solid (S) possessed a disagreeable odor; when heated with various alcohols or ethers it became gummy and but little dissolved in the solvents. Nevertheless, some indefinite crystalline matter precipitated when methyl alcohol, ether or isopropyl ether extracts were cooled. After repeated recrystallizations of this from isopropyl ether, there was obtained a pure substance as fine, white, silky plates; m. p. 82–84°. The total yield amounted to but a few grams. In another preparation in which mercuric iodide was treated with one molecular equivalent of diazomethane, diazomethane again remained in excess and the final results were similar to those described, except that less of the pure product was obtained.

Anal. Calcd. for $C_2H_4I_2Hg$: Hg, 41.6. Found: Hg, 41.6, 41.7.

Diazomethane with Mercuric Cyanide.—Of powdered mercuric cyanide, 6.32 g. (one-fortieth mole) suspended in ether was treated with diazomethane (one-fortieth mole). No action took place, although the mixture was finally boiled (refluxed) for some time. There was recovered 6.20 g. of the mercuric salt.

Diphenyldiazomethane and Mercuric Chloride.—To pure, dry mercuric chloride, one-twentieth mole, in 150 cc. of anhydrous ether, cooled to 0° and stirred mechanically, was added during one hour a molecular equivalent of diphenyldiazomethane¹⁹ (dissolved in a little ether). Care was taken to exclude moisture. The pink color of the diazo compound vanished, a gas was evolved and a pale yellow product, insoluble in the ether, appeared. The product was rapidly brought upon a Buchner funnel, washed thoroughly with anhydrous ether and dried at room temperature for twelve hours in a vacuum over phosphoric anhydride and chipped paraffin. When the preparation was carried out as described, the ether filtrates contained but little dissolved material. An analysis indicated that the product might be chlorodiphenylmethylmercuric chloride, $\text{Cl}(\text{C}_6\text{H}_5)_2\text{C}\cdot\text{HgCl}$.

Anal. Calcd. for $\text{C}_{13}\text{H}_{10}\text{HgCl}_2$: Hg, 46.9. Found: Hg, 47.5.

When some of the product was exposed to moist air, it was hydrolyzed and decomposed rather rapidly with the evolution of hydrogen chloride. All of the mercury in the initial compound was recovered as *calomel*, insoluble in ether, when the decomposed material was extracted with that solvent. When the ether was allowed to evaporate spontaneously there remained a colorless oil that crystallized in prismatic plates when "seeded" with benzophenone. That the material was chiefly benzophenone was indicated by its melting point and conversion to benzophenone oxime. Air oxidation was probably a factor here; further data are required for an accurate description of the nature of the change. Calomel is also one of the products when the compound is decomposed thermally in the presence of xylene.

Some of the supposed chlorodiphenylmethylmercuric chloride was covered with anhydrous ether. When a drop of water was added and the mixture shaken, the ether became *pronouncedly yellow* and a white solid remained undissolved. That the latter was calomel was proved by its properties (ammonia test, etc.) and an assay of its mercury content. The formation of calomel was shown to be quantitative. Samples were decomposed as described; the residues of calomel were collected in Gooch crucibles, washed well with ether, alcohol and water and dried to constant weight over phosphorus pentoxide.

Anal. Subs., 0.2994, 0.2978: Hg_2Cl_2 , 0.1656, 0.1635. Calcd. for $\text{C}_{13}\text{H}_{10}\text{Cl}(\text{HgCl})$: (HgCl), 55.2. Found: (HgCl), 55.3, 54.9.

From the yellow ether filtrates (from the calomel) the solvent was permitted to evaporate spontaneously. The residue consisted of a portion very soluble in ether and a less soluble part. The former portion contained benzophenone. The less ether-soluble material consisted of large, white, thick, rhomboidal plates. These were purified by means of crystallization and recrystallization from a mixture of benzene and isopropyl ether (1:3). They melted and decomposed at 183° with the evolution of hydrogen chloride. The physical and chemical properties of this product and its analysis indicated that it was 1,2-dichlorotetraphenylethane.²⁰

Anal. Subs., 0.2449: CO_2 , 0.6943; H_2O , 0.1092. Calcd. for $\text{C}_{26}\text{H}_{20}\text{Cl}_2$: C, 77.4; H, 4.96. Found: C, 77.3; H, 4.98.

Summary

1. It is shown that, under appropriate conditions, diazomethane reacts with a variety of mercuric salts and mercuri-organic derivatives with the formation of interesting new products. For example, from mercuric chloride, mercuric iodide and benzylmercuric chloride there are obtained, respectively, bis-chloromethyl mercury (and chloromethylmercuric chlo-

¹⁹ Staudinger, Anthes and Pfenninger, *Ber.*, **49**, 1932 (1916).

²⁰ Schmidlin and Escher, *ibid.*, **43**, 1153 (1910).

ride), bis-iodomethyl mercury and benzyl chloromethyl mercury. The primary product of the interaction of diazomethane and *p*-tolylmercuric chloride undergoes disproportionation, yielding mercury di-*p*-tolyl and bis-chloromethyl mercury; that from phenylmercuric chloride behaves analogously.

2. There are described the reactions with alcoholic hydrogen chloride and those with mercuric chloride of bridged mercury compounds prepared in this work. With the former reagent benzyl chloromethyl mercury yields toluene and chloromethylmercuric chloride and no benzylmercuric chloride.

3. Aliphatic diazo compounds react also with some other types of mercury compounds and with certain salts and organic derivatives of metals other than mercury. Mercuric chloride and *diphenyldiazomethane* interact forming, apparently, diphenylchloromethylmercuric chloride. The latter displays interesting decomposition reactions.

4. Certain theoretical implications of the results of the investigation are discussed.

AN OPTICAL METHOD FOR THE STUDY OF REVERSIBLE ORGANIC OXIDATION-REDUCTION SYSTEMS.

I. PARA-BENZOQUINONES¹

BY W. H. HUNTER AND D. E. KVALNES

RECEIVED FEBRUARY 5, 1932

PUBLISHED JULY 6, 1932

Introduction

Extensive studies have been made on the reduction potentials of reversible organic oxidation-reduction systems.² In one of these investigations, Conant and Fieser^{2h,k} determined the oxidation-reduction potentials of a number of systems composed of a quinone and its hydroquinone referred to the solid, dissolved and gaseous states.

¹ (a) The work described in this paper constituted part of a thesis submitted to the Graduate Faculty of the University of Minnesota by Donovan E. Kvalnes in partial fulfilment of the requirements for the degree of Doctor of Philosophy, July, 1931. This paper was prepared by the junior author after the death of Dr. W. H. Hunter.—L. I. Smith. (b) Presented at the spring meeting of the American Chemical Society, New Orleans, 1932.

² (a) Granger and Nelson, *THIS JOURNAL*, **43**, 1401 (1921); (b) Clark, *J. Wash. Acad. Sci.*, **10**, 225 (1920); (c) Clark, *Science*, **54**, 557 (1921); (d) Biilmann, *Ann. chim.*, **15**, 109 (1921); (e) Conant, Kohn, Fieser and Kurtz, *THIS JOURNAL*, **44**, 1382 (1922); (f) La Mer and Baker, *ibid.*, **44**, 1954 (1922); (g) Conant and Fieser, *ibid.*, **44**, 2480 (1922); (h) Conant and Fieser, *ibid.*, **45**, 2194 (1923); (i) Biilmann, *Trans. Faraday Soc.*, 676 (1923); (j) Conant and Fieser, *THIS JOURNAL*, **46**, 1858 (1924); (k) Conant, *ibid.*, **49**, 293 (1927); (l) Fieser, *ibid.*, **51**, 3101 (1929).

They found that in general the order of the potentials is alcoholic solution > aqueous solution > solid state > gaseous state; that the introduction of methyl groups progressively and regularly decreases the potentials; that in all but the gaseous state the introduction of chlorine into the quinone first raises and then lowers the potential.

In a few cases the potentials of the corresponding chloro and bromo quinones have been determined.^{2f,g,i} These results, together with the data of Conant and Fieser^{2j} on derivatives of naphtho and anthraquinones and the data of Clark³ on oxidation-reduction indicators show that the effect of the introduction of chlorine and bromine is identical within the limits of the significance of the data.

Since the potential of a quinone-hydroquinone combination depends upon the state of the system, *i. e.*, whether solid, dissolved or gaseous, the question arises as to which is the preferred state in which to study the result of substitution of the parent compound. Conant^{2k} believes that the gaseous state is the one to be selected, with a dilute solution as second choice, in order to eliminate secondary effects such as solubilities or the affinity of the quinone and hydroquinone molecules for each other.

Since there is no general agreement among the potentials of a series of quinones, determined in different states, and since potential measurements have been used as evidence in problems of chemical constitution, it seemed advisable to attack this question of oxidizing strength by some method other than an electrochemical one. This has been accomplished in the following manner.

If one mole of a hydroquinone (H_2Q) is in solution with one mole of some quinone (Q'), an equilibrium will eventually result, as shown by the equation

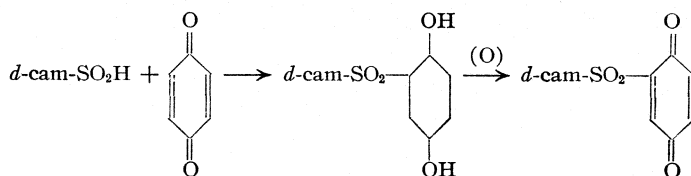

The same equilibrium may be reached by starting with one mole each of Q and H_2Q' . If the H_2Q - Q pair were an optically active hydroquinone and quinone, it would be possible to measure the concentration of each substance involved in the equilibrium. This would afford a means of grading the oxidizing strength of a series of hydroquinone-quinone pairs, represented by $H_2Q'-Q'$, against a given optically active pair, $H_2Q^*-Q^*$, used as a standard. If the $H_2Q'-Q'$ pair were a stronger oxidizing agent than the standard pair, and if a mole each of H_2Q^* and Q' were used at the start, then at equilibrium there would be proportionately more Q^* present than H_2Q^* . The reverse would be true if the $Q'-H_2Q'$ pair were a weaker oxidizing agent than the standard pair.

By this method of determining the concentrations, the equilibrium can in no way be affected. However, for accurate measurements it would be necessary to employ an optically active quinone and hydroquinone with a

³ Clark, *Chem. Reviews*, **2**, 127 (1925).

relatively large difference in specific rotations, since the actual rotation would be a summation of the rotations due to each in the equilibrium mixture. A search of the literature failed to show any optically active compounds fulfilling these requirements and, therefore, the first part of this work dealt with the preparation of a series of such compounds.⁴

Optically Active Quinones and Hydroquinones.—The optically active hydroquinones were prepared by treating a quinone with *d*-camphorsulfonic acid, to give the *d*-camphorsulfone of the hydroquinone, according to the method of O. Hinsberg.⁵ A few of the corresponding optically active quinones were made by oxidation of the respective hydroquinones.

The specific rotations of the hydroquinones are given in Table I.

TABLE I
ROTATIONS OF OPTICALLY ACTIVE HYDROQUINONES

<i>d</i> -Camphorsulfone of	$[\alpha]_{5461}^{27}$ in benzene
Hydroquinone	+46.5°
2,6-Dibromohydroquinone	37.9
2,6-Dichlorohydroquinone	35.4
2,5-Dibromohydroquinone	19.6
2,5-Dichlorohydroquinone	29.9
2,5-Dimethylhydroquinone	24.2

With regard to this table, it will be noted that the unsubstituted hydroquinone has the highest rotation, while the introduction of methyl groups or halogen atoms causes a lowering of the rotation. The position of substitution is of importance since the 2,6-dihalogen derivatives have higher rotations than have the corresponding 2,5-dihalogen compounds. This is much more marked in the case of the bromo than in the chloro compound.

The rotations of the quinones are given in Table II.

TABLE II
ROTATIONS OF OPTICALLY ACTIVE QUINONES

<i>d</i> -Camphor sulfone of	$[\alpha]_{5461}^{27}$ in benzene
Benzoquinone	+305.5
α -Naphthoquinone	237
<i>p</i> -Xyloquinone	223

⁴ While this research was in progress, a paper by Hill and Adams [THIS JOURNAL 53, 3453 (1931)] appeared, in which an optically active quinone was prepared and resolved, although the corresponding hydroquinone was not resolved.

⁵ Hinsberg, *Ber.*, 27, 3259 (1894); *ibid.*, 28, 1315 (1895); *ibid.*, 29, 2025 (1896).

The unsubstituted quinone has the highest rotation. Two methyl groups, in the 2,5-positions, have a greater lowering effect than a condensed ring. The rotations of the quinones are much greater than those of the corresponding hydroquinones. This would be expected due to the change of the benzenoid to the quinoid structure, since unsaturation has a marked effect on rotations.

Choice of a Standard.—The hydroquinone–quinone pair chosen as a standard was the *d*-camphorsulfone of 2,5-dimethylhydroquinone and the corresponding quinone. These two compounds are fairly easy to obtain in a pure condition and have a large difference in specific rotations. Benzene was selected as a solvent because it is a non-polar liquid and, therefore, larger specific rotations are secured.⁶

Soon after the addition of a quinone to the H_2Q^* , there are present in the solution two hydroquinones and two quinones

Furthermore, there is the possibility of the formation of the following four quinhydrones: (H_2Q^*-Q') , $(H_2Q^*-Q^*)$, $(H_2Q'-Q')$, $(H_2Q'-Q^*)$. If one of these is formed more readily than the others, the point of equilibrium will not be the same as it would if there were no quinhydrones present. However, it is impossible to determine the exact amounts or the specific rotations of the quinhydrones.

It is not possible to measure the effect of an optically inactive quinone on the rotation of the optically active hydroquinone, and *vice versa*, because of immediate oxidation and reduction to form new compounds according to the equation above. However, by adding definite amounts of the H_2Q^* to the Q^* and determining the resulting rotation, it is possible to ascertain whether or not there is any effect on the individual rotations of the two compounds due to association or quinhydrone formation. If the resultant rotation is the sum of the individual rotations, observed under the same conditions, then no association has occurred.

Twenty-five cc. of benzene containing 0.0855 g. of H_2Q^* and 0.0850 g. of Q^* gave 98.8% of the calculated rotation, and gave 100% of the calculated value when diluted to 50 cc. Accordingly, subsequent measurements were carried out with solutions sufficiently dilute to obviate association.

General Procedure

A weighed amount of a given quinone was added to a weighed sample of H_2Q^* . Enough benzene was added to dissolve the two compounds and the solution was allowed to stand for several hours. It was then diluted to a definite volume and the rotation was determined. Rotations were again observed after various periods of time. The rotation of the solution rose slowly to a definite value, remained constant at this point for several hours

⁶ Rule and McLean, *J. Chem. Soc.*, 674 (1931).

to a day and then dropped, often quite abruptly. The equilibria were established after lengths of time varying from a few hours to two days. Several determinations were carried out at different concentrations, and the equilibrium constants thus calculated served to check the separate runs.

Because the equilibrium points are not rapidly reached, it was necessary to determine whether or not the rotations of the optically active compounds change with time. The optically active hydroquinone showed no change in rotation even after several days. However, the rotation of the optically active quinone dropped slowly during the same period of time. Although this introduces an error into the determinations, it is a small one. Moreover, since the observed equilibrium points, using various quinones, are reached in approximately the same length of time, this error does not affect the comparative results.

Calculation of Conversions.—If a quinone Q' be added to H_2Q^* , in equimolecular amounts, the following equilibrium will be reached

If the concentrations of H_2Q^* and Q' , at the start, be represented by 1, and the concentrations of Q^* and H_2Q' at equilibrium be represented by β , then the concentrations of H_2Q^* and Q' at equilibrium will each be $(1-\beta)$. The equilibrium constant for the reaction is given by the equation $K = \beta^2/(1-\beta)^2$. To calculate β it is necessary to know the actual rotation of H_2Q^* at the start (A), the actual rotation of Q^* , if all the H_2Q^* were changed to Q^* , (B), and the observed rotation (C). These values must be calculated for definite concentrations in a given solvent. At equilibrium, the contribution of H_2Q^* to the observed rotation will be $A(1-\beta)$ and the contribution of Q^* will be $B\beta$. The observed value for the rotation of the solution (C) will be the sum of the above two values. $C = A(1-\beta) + B\beta$; from which $\beta = (C - A)/(B - A)$. β will be a measure of the oxidizing strength of the system H_2Q' and Q' referred to the standard system, H_2Q^* and Q^* , in the solvent used. The conversion β_0 of any quinone Q' , will be defined as the percentage change at equilibrium of H_2Q^* into Q^* when equimolecular amounts of H_2Q^* and Q' are used. Thus, if the system chlorohydroquinone-chloroquinone is a stronger oxidizing agent than the system hydroquinone-benzoquinone, referred to the standard system, chloroquinone will have a higher conversion, (β_0), than benzoquinone. The calculation of the benzoquinone equivalent may be illustrated as follows. The conversion value for 2,6-dichloroquinone is 51.2; that is, one mole of 2,6-dichloroquinone added to one mole of H_2Q^* would cause 51.2% of the latter to be oxidized to Q^* . It is possible to calculate how many moles of benzoquinone it is necessary to add to one mole of H_2Q^* to cause 51.2% of the latter to be oxidized to Q^* , knowing the equilibrium constant for benzoquinone to be 0.114.

$$\frac{(\beta_0)^2}{(1 - \beta_0)(X_0 - \beta_0)} = 0.114$$

X_0 will be the number of moles of benzoquinone which would be required to cause a conversion equal to β_0 , obtained by using only one mole of the quinone in question. X_0 may be called the *benzoquinone equivalent*. Thus 5.2 moles of benzoquinone are necessary to give the same β as is given by one mole of 2,6-dichloroquinone.

Results

Table III gives a list of quinones, with their equilibrium constants, conversions, (β_0), and benzoquinone equivalents, (X_0), in relation to the standard system. For the purposes of comparison, the potentials in the solid, dissolved and gaseous states for the same quinones are given. The latter were determined by Conant and Fieser^{2h,k} unless otherwise noted.

TABLE III
CONVERSIONS OF QUINONE-HYDROQUINONE SYSTEMS

Quinone	K (av.)	β_0	X_0	E_s	Normal reduction potentials E_0				E_g

Since conversions and benzoquinone equivalents do not yield to ready comparison with the potentials determined electrochemically, a series of potentials, (E^*), has been calculated from the equilibrium constants given in Table III. This has been accomplished by use of the equation $E = (RT/nF) \log_e K$ in which T is 300. A system which has the same oxidizing strength as the optically active standard system will have a value of E^* equal to zero. Weaker oxidizing systems will have negative values of E^* and stronger oxidizing systems will have positive values of E^* . It is convenient to change the E^* values to a series in which the benzoquinone-hydroquinone system is represented by zero. This series is given in Table IV under the heading ΔE^* .

⁷ La Mer and Baker^{2f} give the following: chloroquinone, 0.7125; bromoquinone, 0.7151; whereas Biilmann²ⁱ gives: chloroquinone, 0.7124 and bromoquinone, 0.7120; 2,5-dichloroquinone, 0.7230 and 2,5-dibromoquinone, 0.7228.

In order to calculate the potentials for a system in benzene from the E_g values determined by Conant it would be necessary to know the vapor pressures of the components of the system and their solubilities in benzene. As yet these data are not available. An interesting series of potentials could be calculated if the E_g value of benzoquinone, 0.570, were arbitrarily chosen as the potential of benzoquinone in benzene. To this could be added the ΔE^* values. Since these potentials might be misleading, an alternative procedure has been used. The E_g value of benzoquinone has been set equal to zero and ΔE_g values calculated accordingly. These results are given in Table IV.

TABLE IV
RELATIVE POTENTIALS OF QUINONE-HYDROQUINONE SYSTEMS IN BENZENE

Discussion

The results indicate that this method gives a quantitative evaluation of the oxidizing strength of a series of hydroquinone-quinone systems, compared to a standard system. Certain generalizations are apparent from the data in Table III. A methyl group lowers and a halogen raises the conversion value of the parent compound. Furthermore, a methyl group is more effective than a halogen atom. In general, the successive introduction of like groups causes the conversion values to change consistently in the same direction, the first group always being more effective than the succeeding ones. The position of the groups is of importance since the 2,5-dihalogenated quinones have much higher conversion values than anticipated, even higher than those of the tetrasubstituted quinones. A similar difference due to position was pointed out in the consideration of the rotations of the optically active halogenated hydroquinones, shown in Table I. In both cases this difference is far more marked in the brominated compounds than in the chlorinated compounds. The introduction of bromine gives systems which are stronger oxidizing agents than are the analogous chlorinated systems. The difference between the two is quite uniform except in the abnormal 2,5-dihalogenated quinones.

Comparison with Electrochemical Data.—The relative order of the

potentials of *p*-xyloquinone, toluquinone, benzoquinone and chloroquinone is the same whether the potentials are determined for the solid, dissolved or gaseous state. Thus benzoquinone has a higher potential than has *p*-xyloquinone, in all three states.^{2h,k,8} The results obtained in this research also show the same relative order for these four quinones.

However, for the polyhalogenated quinones there is no agreement among the potentials for the three states. The potentials of the tri- and tetrachloroquinones, in the solid state and in solution, are lower than that of benzoquinone. In the gaseous state the potentials of the polychloro compounds are higher than that of benzoquinone. Our results are well in accord with those obtained by Conant for the gaseous state, as can be seen by Table III.

The introduction of two methyl groups into benzoquinone causes a decided drop in both E_g and β_0 . The successive introduction of a chlorine atom causes an increase in E_g and β_0 , the first chlorine being more effective than the second, and it in turn more effective than the next. Two methyl groups decrease E_g and β_0 to a greater extent than two chloro groups increase them. It would be unwarranted to predict close agreement between the ΔE^* and ΔE_g values, given in Table IV, though values of the same order of magnitude would be expected. Conant did not determine the E_g value of 2,5-dichloroquinone or of any bromoquinones.

Electrochemical studies of analogous chloro and bromo compounds give potentials differing by less than the experimental error. Our method, however, shows that these compounds differ decidedly in oxidizing strength.

The electrochemical results for alcoholic solutions cannot be checked by this method because the optically active quinones do not give reproducible rotations in alcohol. In some cases the rotations are so abnormal as to indicate possible reaction between the quinone and the alcohol. The present method is further limited because a quinone-hydroquinone pair that is weaker in oxidizing strength than is the 2,5-dimethylhydroquinone-quinone pair cannot be measured accurately, due to the low rotations resulting. To overcome this difficulty a new standard pair for a different range must be obtained.

The junior author is continuing the investigation of this field.

Experimental

Experimental Determination of Conversions.—An extensive study of the system hydroquinone-benzoquinone, in the presence of the standard pair, was first carried out. A number of runs at several different concentrations were made to obtain the equilibrium constant. All determi-

⁸ Information obtained from absorption spectra of molecular compounds involving these four quinones also indicates the same relative order (unpublished work by W. H. Hunter and E. H. Northey).

nations were made at 27°. A weighed quantity of benzoquinone was added to a weighed sample of H_2Q^* , together with enough benzene to dissolve the two compounds. In a few minutes a green precipitate formed. After letting the solution stand for about two hours, enough benzene was added to dissolve the precipitate, and the whole was diluted to a definite volume. Benzoquinone was the only quinone used that resulted in a precipitation of a quinhydrone. Because of this quinhydrone formation it was possible to arrive at the equilibrium point much sooner than in any other case.

 $\beta_0 = 25.2$ for benzoquinone.Average of K 's .114

The equilibrium was now approached from the other side. Hydroquinone was added to an equimolecular amount of Q^* . The hydroquinone was dissolved in warm benzene and cooled before it was added to Q^* , since hydroquinone dissolves very slowly in benzene. No quinhydrone formed in this experiment. The rotation slowly dropped during the first twenty-four hours and then remained constant for about twenty hours before it began to drop again. From the rotation at equilibrium it was determined that 74.9% of the optically active quinone had been converted into the H_2Q^* . This value agrees very well with the conversion value (β_0) of 25.2%.

Below are given the results of a typical determination, using an equimolecular mixture of 2,6-dichloroquinone and H_2Q^* .

0.1228 g. of H_2Q^* 0.0618 g. of 2,6-dichloroquinone
$$\frac{0.1228}{0.1240} \times 0.24 = 0.238^\circ = A = \text{rotation due to } H_2Q^* \text{ in 25 cc. benzene, 2-dec. tube}$$

$$\frac{0.1228}{0.1042} \times \frac{350}{352} \times 1.82 = 2.180^\circ = B = \text{rotation if all of } H_2Q^* \text{ were changed to } Q^*,$$

in 25 cc. benzene, 2-dec. tube.

The two compounds were dissolved in 25 cc. of benzene and allowed to stand for thirteen hours before being diluted to 50 cc.

Preparation of Materials

The common derivatives of benzoquinone were prepared by the ordinary methods. Zinc *d*-camphorsulfinate was made according to the method of Smiles and Hilditch.¹⁰

***d*-Camphorsulfones of Hydroquinones.**—The quinone, dissolved in alcohol, was added slowly to an excess of zinc *d*-camphorsulfinate, dissolved in dilute acid. The reaction was very rapid in the case of benzoquinone and the halogenated quinones and the yellow color of the quinone disappeared very rapidly. On standing for a few hours or by concentration *in vacuo* precipitation took place or an oil settled out. In the latter case several days was sometimes necessary to effect crystallization. The sulfones are quite soluble in all the common organic solvents. Recrystallization is accomplished from dilute alcohol. The *d*-camphorsulfone of 2,5-dimethylhydroquinone when dissolved in alcohol is easily precipitated, by the addition of water, to give a cotton-like mass. The hydroquinones are soluble in alkali and are reprecipitated by the addition of acids, but are not obtained in a pure state. The hydroquinones give no color with ferric chloride but reduce an ammoniacal silver nitrate solution. By dissolving a small amount of any one of these hydroquinones, together with a little benzoquinone, in ether a small amount of a purple quinhydrone remains on evaporation of the solvent. The hydroquinones are white and odorless. The yields are practically quantitative.

Hydroquinone *d*-Camphorsulfone. Melting point 159–160°, $[\alpha]_{5461}^{27} + 46.55$, $c = 0.3366$ in benzene, $\alpha = 0.47^\circ$, $l = 3$.

Anal. Calcd. for C₁₆H₂₀O₅S: C, 59.26; H, 6.17. Found: C, 59.25; H, 6.7.

Diacetate of Hydroquinone *d*-Camphorsulfone.—This was obtained by treating the hydroquinone with acetic anhydride. It was recrystallized from aqueous alcohol. It is soluble in organic solvents and insoluble in water or alkali; m. p. 119–122°. The rotation of the diacetate is slightly lower than that of the hydroquinone, $[\alpha]_{5461}^{27} + 17.5$, $c = 0.5448$ in abs. alc., $\alpha = 0.18^\circ$, $l = 2$.

Anal. Calcd. for C₂₀H₂₄O₇S: C, 58.8; H, 5.9. Found: C, 58.7; H, 5.9.

2,5-Dichlorohydroquinone *d*-Camphorsulfone.—M. p. 169–173°, $[\alpha]_{5461}^{27} + 29.99$, $c = 0.3398$ in benzene, $\alpha = 0.305^\circ$, $l = 3$.

Anal. Calcd. for C₁₆H₁₈O₅Cl₂S: C, 48.86; H, 4.6. Found: C, 49.0; H, 4.6.

2,6-Dichlorohydroquinone *d*-Camphorsulfone.—M. p. 104–106°, $[\alpha]_{5461}^{27} + 35.4^\circ$, $c = 0.3716$ in benzene, $\alpha = 0.395^\circ$, $l = 3$.

Anal. Calcd. for C₁₆H₁₈O₅Cl₂S: C, 48.86; H, 4.6. Found: C, 48.91; H, 4.6.

2,5-Dibromohydroquinone *d*-Camphorsulfone.—M. p. 172–173°, $[\alpha]_{5461}^{27} + 19.6^\circ$, $c = 0.5260$ in benzene, $\alpha = 0.31^\circ$, $l = 3$.

Anal. Calcd. for C₁₆H₁₈O₅Br₂S: C, 39.83; H, 3.74. Found: C, 39.55; H, 4.0.

⁹ The results for *p*-xyloquinone are not as reliable as for the other quinones since the observed rotations were close to that due to the unchanged optically active hydroquinone added.

¹⁰ Smiles and Hilditch, *J. Chem. Soc.*, **91**, 519 (1907).

2,6-Dibromohydroquinone *d*-Camphorsulfone.—M. p. 108–112°, $[\alpha]_{5461}^{27} + 37.9^\circ$, $c = 0.3568$ in benzene, $\alpha = 0.395^\circ$, $l = 3$.

Anal. Calcd. for $C_{16}H_{18}O_5Br_2S$: C, 39.83; H, 3.74. Found: C, 40.7; H, 4.4.

2,5-Dimethylhydroquinone *d*-Camphorsulfone.—M. p. 176–177°, $[\alpha]_{5461}^{27} + 24.22$, $c = 0.4960$ in benzene, $\alpha = 0.24^\circ$, $l = 2$.

Anal. Calcd. for $C_{18}H_{24}O_5S$: C, 61.36; H, 6.82. Found: C, 61.12; H, 6.84.

Diacetate of 2,5-Dimethylhydroquinone *d*-Camphorsulfone.—M. p. 103–106°, $[\alpha]_{5461}^{27} + 21.7^\circ$, $c = 0.4758$ in benzene, $\alpha = 0.31^\circ$, $l = 3$.

Anal. Calcd. for $C_{22}H_{28}O_7S$: C, 60.55; H, 6.42. Found: C, 60.50; H, 6.47.

The *d*-Camphorsulfones of Quinones.—The *d*-camphorsulfones of benzoquinone and *p*-xyloquinone were prepared by oxidation of the corresponding hydroquinones. The latter were dissolved in ether and an excess of either lead dioxide or silver oxide was added. The mixture was stirred from three to ten minutes and was then filtered. The residue was well washed with dry ether. The combined ether filtrates were concentrated, using a water pump. The yellow quinones crystallized from the concentrated solutions. The quinones were filtered off and washed with a little cold ether. The yields ranged from 30 to 80%.

The optically active quinones are yellow, crystalline compounds, quite soluble in alcohol, benzene, chloroform, acetic acid and acetone. They are less soluble in ether and are insoluble in water. They are not volatile with steam and do not have an odor. The values for their specific rotations are considerably higher than those of the corresponding hydroquinones. In the case of the *d*-camphorsulfone of benzoquinone the rotation in alcohol is very little higher than that of the hydroquinone, but in benzene solution there is a considerable difference in their rotations.

Benzoquinone *d*-Camphorsulfone.—M. p. 135–136°, $[\alpha]_{5461}^{27} + 305^\circ$, $c = 0.5696$ in benzene, $\alpha = 3.48^\circ$, $l = 2$.

Anal. Calcd. for $C_{16}H_{18}O_5S$: C, 59.63; H, 5.6. Found: C, 59.73; H, 5.7.

***p*-Xyloquinone *d*-Camphorsulfone.**—M. p. 148–151°, $[\alpha]_{5461}^{27} + 223^\circ$, $c = 0.4168$ in benzene, $\alpha = 1.86^\circ$, $l = 2$.

Anal. Calcd. for $C_{18}H_{22}O_5S$: C, 61.7; H, 6.3. Found: C, 61.7; H, 6.7.

α -Naphthoquinone *d*-Camphorsulfone.— α -Naphthoquinone was added to *d*-camphorsulfinic acid. The expected hydroquinone was impure due to partial oxidation to the quinone. This impure product was oxidized in the usual manner to give the optically active quinone, m. p. 144–148°, $[\alpha]_{5461}^{27} + 237.3^\circ$, $c = 0.3224$ in benzene, $\alpha = 1.53^\circ$, $l = 2$.

Anal. Calcd. for $C_{20}H_{20}O_5S$: C, 64.5; H, 5.4. Found: C, 64.0; H, 5.6.

Attempted Preparation of Hydroquinone *d*-Bromocamphorsulfone.—It was supposed that the *d*-bromocamphorsulfone of hydroquinone would have a higher rotation than has the unbrominated compound. However, it was found that the zinc-absolute alcohol reduction of *d*-bromocamphorsulfonyl chloride gave zinc *d*-camphorsulfinate instead of the desired zinc *d*-bromocamphorsulfinate.

Summary

1. A number of optically active quinones and hydroquinones have been prepared.
2. The effect of substitution on their rotations has been determined.
3. The oxidizing strength of a number of hydroquinone-quinone pairs has been measured by use of a standard optically active hydroquinone-quinone pair.

4. The effect of substitution on the oxidizing power of a hydroquinone-quinone system has been shown.

5. The results thus obtained have been compared with the electrochemical data in the form of oxidation-reduction potentials.

A QUANTITATIVE STUDY OF SEMICARBAZONE FORMATION

BY JAMES B. CONANT AND PAUL D. BARTLETT

RECEIVED FEBRUARY 10, 1932

PUBLISHED JULY 6, 1932

The interaction between ketones or aldehydes and such substances as phenylhydrazine and hydroxylamine has been the subject of numerous investigations in which the rate of the reaction has been measured. Most of these studies, however, were carried out before the use of the hydrogen electrode had enabled the chemist to define with precision the acidity of his solutions.¹ In recent years it has become apparent that in all these reactions one is dealing with a reversible reaction in which the acidity of the medium plays an important role in determining both the rate of the reaction and the final equilibrium which is reached. The early work of Acree and of Lapworth considered the influence of these factors to the extent that was possible at that time. The recent work of Ölander on the formation of acetoxime is the most complete study of this type of reaction from the modern viewpoint. This work will be referred to again in connection with our own measurements.

We have undertaken to study semicarbazone formation by a variety of carbonyl compounds in aqueous buffer solutions. Our results show the conditions which control the equilibrium in this reaction and the factors which influence the rate of the process. It seems probable that the fundamental principles which we believe we have elucidated can be applied to other similar reactions such as phenylhydrazone and oxime formation; these reactions, therefore, will be briefly discussed in the appropriate place in this paper. We shall first present our own results which are concerned with the equilibrium, then the kinetic study and finally a discussion of the influence of the structure of the carbonyl compound on both the composition of the equilibrium mixture and the rate at which this equilibrium is reached.

I. Equilibrium Measurements

The reaction between a carbonyl compound AO and a carbonyl reagent such as semicarbazide, phenylhydrazine or hydroxylamine BNH_2 is a reversible reaction; it is convenient to regard this reaction as an hydrolysis of the condensation product and write the reaction:

The reagent, BNH_2 , is a base whose conjugate acid is BNH_3^+ and the condensation product is similarly related to the acid $\text{A}=\text{NBH}^+$. We may write for the two acid-base equilibria the following equations in which the concentrations are denoted by the square brackets; these are the limiting laws holding in very dilute solution, and the relationships we shall derive with their use are subject to this same limitation. The probable error introduced by assuming their validity in solutions containing considerable salt will be discussed later.

$$K_R = \frac{[\text{BNH}_2] [\text{H}^+]}{[\text{BNH}_3^+]} \quad (1)$$

$$K_C = \frac{[\text{ANB}] [\text{H}^+]}{[\text{ANBH}^+]} \quad (2)$$

For the reversible formation of the condensation product $\text{A} = \text{NB}$ we may define a constant which corresponds to the equilibrium in a solution so strongly acid that no appreciable quantity of the reagent or condensation product is uncombined with a proton. This is the limiting hydrolysis in acid solutions

$$K_{\infty A} = \frac{[\text{AO}] [\text{BNH}_3^+]}{[\text{ANBH}^+]} \quad (3)$$

If there are no appreciable quantities of intermediate compounds (such as the hypothetical direct addition product of the reagent and carbonyl compound) we may write for the hydrolysis of the condensation product in a solution of any acidity the equation (where K is a constant only at constant acidity).

$$K = \frac{[\text{AO}] ([\text{BNH}_3^+] + [\text{BNH}_2])}{[\text{ANB}] + [\text{ANBH}^+]} \quad (4)$$

Substituting values of $[\text{BNH}_2]$ and $[\text{ANB}]$ from equations 1 and 2 into 4, we find the following relation between K , $K_{\infty A}$, K_R and K_C (equation 5)

$$K = K_{\infty A} \frac{[\text{H}^+] + K_R}{[\text{H}^+] + K_C} \quad (5)$$

When $[\text{H}^+]$ is small compared to K_R and K_C , we have the limiting value of K for the case where the solution is so weakly acid that no appreciable quantity of the reagent or condensation product is combined with a proton. This limiting value will be denoted as $K_{\infty B}$

$$K_{\infty B} = K_{\infty A} \frac{K_R}{K_C} \quad (6)$$

It is clear that the ratio of the equilibrium constants in very acid and basic solutions is a function of the difference in acid strength of the ions BNH_3^+

and ANBH^+ . Expressed logarithmically $pK_{\infty B} - pK_{\infty A} = pK_R - pK_C$. It is interesting to note that when the hydrolysis constant (K) is midway between its limiting values, $[\text{H}^+] = K_C$ or $pH = pK_C$; that the inflection of the $pH:K$ curve must occur at this point can be shown by differentiation of equation 5.

The data we have obtained on the equilibrium involving the hydrolysis of acetone semicarbazone illustrates the application of the equations we have just developed. The data are summarized in Table I and shown graphically in Fig. 1. The experimental procedure consisted in dissolving the semicarbazone in an aqueous buffer solution containing in some cases a definite quantity of acetone to suppress the hydrolysis, and removing samples from time to time and titrating with iodine at a pH of about 7 obtained by using a concentrated phosphate buffer solution. This method of determining semi-

carbazine has recently been published.² The chief sources of error in the determination of the hydrolysis constant are the slowness with which final equilibrium is reached and the appreciable decomposition of semicarbazide into hydrazine and hydrazodicarbamide. This decomposition slowly displaces the equilibrium in such a way as to increase the iodine equivalent of the solution. The two sources of error thus work in opposite directions, and where the rate of hydrolysis was such that equilibrium was reached in a few hours, the results are more reliable than in those cases where several days were required. Several samples were always taken from the reaction mixture and titrated at successive times sufficiently far apart to ensure equilibrium being reached.

In the case of acetone semicarbazone the limiting hydrolysis on the weakly acid side is sufficient so that the value of $K_{\infty B}$ can be measured experimentally and is clearly the value of K obtained at P_H values of 4, 5 and 7 (0.0032–0.0034). With this value and the dissociation constant of semicarbazide $K_R = 0.000219$, one can obtain the value of K_C from each value of K by combining equations 5 and 6 to yield 7. The values thus

$$K_C = \frac{[H^+]}{\frac{K_{\infty B}}{K K_R} ([H^+] + K_R) - 1} \quad (7)$$

obtained (last column of Table I) were satisfactory except with the two citrate buffer solutions, in which case impossible negative values were obtained. The curve in Fig. 1 is drawn with the constants $K_R = 0.000219$, $K_{\infty B} = 0.0032$ and $K_C = 0.0463$ which yield $K_{\infty A} = 0.69$. The agreement is all that can be expected considering the experimental difficulties and the uncertainties involved in applying equations developed for very dilute solutions to those containing considerable salt.³ It will be noted that the acid limit of hydrolysis is very nearly reached in 1.2 *M* hydrochloric acid, so that with acetone semicarbazone the whole curve can be realized experimentally.

In the case of the semicarbazones of aromatic aldehydes the hydrolysis is so slight in the more basic solutions that no direct measure of $K_{\infty B}$ is possible. Portions of the $P_H : K$ curve lying in the more acid regions can be estimated from values of K obtained at different P_H values. Since two unknown constants, K_C and $K_{\infty A}$ (or $K_{\infty B}$ if one desires), are involved, the best curve through the experimental points can be obtained by a trial and error graphical method. It was found more convenient, however,

² Paul D. Bartlett, *THIS JOURNAL*, **54**, 2853 (1932).

³ The buffer solutions employed (see Table VIII) varied in ionic strength from 0.045 to 1.28; the value of K_R taken corresponds to an ionic strength of 0.08. The errors introduced by the effect of changing ionic strength and individual ion effects on the values of K_R , K , K_C and $K_{\infty B}$ have been neglected. It is doubtful in the present case whether the equilibrium measurements are of sufficient precision to warrant a consideration of these factors.

to determine the most probable values of the two constants by an application of the method of least squares.

The observational equations were in the form $aK_{\infty A} + bK_C = q$ and by the theory of normal equations the most probable values of the two constants were obtained by solving the equations

$$\Sigma(aa) K_A + \Sigma(ab) K_C = \Sigma(aq) \text{ and } \Sigma(ab) K_{\infty A} + \Sigma(bb) K_C = \Sigma(bq)$$

The values thus calculated are given in Table II for the semicarbazones of furfural, acetaldehyde and benzaldehyde. In the case of the first compound, equilibrium was approached from the side of the aldehyde and semicarbazide; with the other two the same procedure was used as with acetone semicarbazone. In Table II are recorded the observed values of K (the hydrolysis constant) at the different P_H values and the value of K calculated with the aid of K_C and $K_{\infty A}$ determined as just described. A comparison of the observed and calculated values of K shows that equation 4 is a satisfactory formulation of the hydrolysis equilibrium in these cases. It is evident that the limit of acid hydrolysis ($K_{\infty A}$) should be nearly reached at a P_H value of 0. With furfural semicarbazone, however, absurd values of K , some 200 times too large, were obtained with a 1.2 M solution of hydrochloric acid. It seems that some side reactions were involved in this strong acid solution.

Pyruvic Acid Semicarbazone.—In the case of pyruvic acid we have an interesting example of a carbonyl compound which also enters into an acid-base equilibrium, so that the behavior of its semicarbazone would be expected to differ from that of a semicarbazone of an ordinary ketone or aldehyde. The limiting basic hydrolysis equilibrium is one between neutral semicarbazide, the negative ion of pyruvic acid and the negative ion of the semicarbazone.

The results are included in Table II, the value of K_A for pyruvic acid being taken as 0.0056.⁴ It seems most reasonable to attribute the value of K_C to the compound HPNBH^+ , regarding the uncharged form of pyruvic acid semicarbazone as the molecular form $\text{CH}_3\text{C}(\text{COOH})=\text{NNHCONH}_2$, and not an "inner-salt" form. The hydrolysis of pyruvic acid semicarbazone increases with acidity more slowly than the hydrolysis of the other semicarbazones. This is due to the tendency of the semicarbazone $\text{CH}_3\text{C}(\text{COO}^-)=\text{NNHCONH}_2$ to take on a hydrogen ion at the carboxyl group, which occurs in approximately the same P_H range as the taking of a hydrogen ion by the free semicarbazide. In their effects upon hydrolysis constant these two changes work against each other. Therefore pyruvic acid is well adapted for regenerating ketones and aldehydes from their semicarbazones and similar derivatives, working either in acid solutions (as with 10% neutralized pyruvic acid) or with the sodium salt of pyruvic acid in neutral solution. The low limiting value of the hydrolysis constant which is more like that of an aldehyde semicarbazone than a ketone semicarbazone is, of course, of fundamental importance in this connection. Such a use of pyruvic acid has been suggested by Grassi, and by Sidgwick.^{1g,5}

We may now consider briefly the equilibria which are concerned with the hydrolysis (or formation) of oximes and phenylhydrazones. If we may make the same assumption as in the case of semicarbazone formation that there are no appreciable quantities of intermediates in the equilibrium mixture, the equations developed above should apply directly to the hydrolysis of these other condensation products. The only adequate data available to test this point seem to be those of Ölander on the equilibria in acetoxime formation in buffer solutions from P_H 1.22 to 5.27. We have calculated from Ölander's values of $1/K$ (since he expressed his equilibrium constant in the inverse form from our equation), the most probable values of K_C and $K_{\infty A}$ taking his value of K_R for hydroxylamine as 8.05×10^{-7} . The following table (Table III) shows that except at the extreme end of his range, the agreement between $1/K$ calculated, and observed, is excellent, showing the applicability of equation 5 to the hydrolysis of oximes.

The acid dissociation constant of the acetoxime ion $(\text{CH}_3)_2\text{C}=\text{NH}^+\text{OH}$ by this computation is 0.012 or $pK_C = 1.92$; from the values in the litera-

TABLE III
 HYDROLYSIS OF ACETOXIME AT 20.0° (DATA OF ÖLANDER)

P_H	Equilibrium constant		Deviation, %	P_H	Equilibrium constant		Deviation, %
	$1/K$ obs.	$1/K$ calcd.			$1/K$ obs.	$1/K$ calcd.	
1.22	54.1	85	+57	3.15	1428	1286	-10
1.70	103.0	114	+11	3.41	2500	2273	-9.1
1.74	106.8	118	+10.5	3.50	3060	2780	-9.1
2.15	203.4	192.6	-5.3	3.80	5120	5453	+6.5
2.18	215.2	201.3	-6.5	4.25	16250	15207	-6.4
2.58	475.5	396.9	-16.5	4.86	55700	57729	+3.6
2.65	560	455.1	-18.9	5.27	71000	139088	+96

The calculated values of K were obtained using equation 5 and the values: $K_{\infty A} = 14 \times 10^{-3}$; $K_R = 8.05 \times 10^{-7}$; $K_C = 12 \times 10^{-3}$.

ture it appears⁶ that K_B (the old basic dissociation constant) is about 6×10^{-13} ; this corresponds to pK for the acid ion of 1.78 in good agreement with our value. It is clear from an inspection of the values given in Table IIa for the dissociation constant of the acid ion of the semicarbazone (pK_C) that they differ not more than half a pK unit from a mean value of 1.1. It is not certain that this variation really represents differences in the acid-base equilibria of the condensation product as some of the errors of the equilibrium measurements are reflected in these constants. The acetoxime ion appears to be a weaker acid than the corresponding semicarbazone ion by about one pK unit (*i. e.*, acetoxime is a somewhat stronger base); however, the closeness in the two acid constants shows that the acid dissociation of the ion $R_2C=NH^+B$ is not very dependent on the nature of B .

It is interesting to compare the common carbonyl reagents in regard to the hydrolysis of their condensation products with acetone, and the effect of changing hydrogen-ion concentration on the equilibrium. In Table IV are collected values for $pK_{\infty B}$ for acetoxime (Ölander's data), acetone phenylhydrazone (some preliminary unpublished data) and acetone semicarbazone, the values of pK for the acid dissociation constant of the reagent BNH_3^+ (pK_R) and for the condensation product (pK_C); the value of $pK_{\infty A}$ was calculated by equation 6. If one assumes that pK_C for a phenylhydrazone is the same as for a semicarbazone, $pK_{\infty A}$ for phenylhydrazine would be -1.1.

TABLE IV

A COMPARISON OF THE CONSTANTS INVOLVED IN THE EQUILIBRIUM BETWEEN ACETONE AND THREE COMMON CARBONYL REAGENTS

Reagent	pK_R	pK_C	$pK_R - pK_C$	$pK_{\infty B}$ (at 25°)	$pK_{\infty A}$
Hydroxylamine	6.09 (at 20°)	1.92	4.2	6.03	1.8
Phenylhydrazine	5.21 (at 15°)	2.76	...
Semicarbazide	3.66 (at 25°)	1.33	2.3	2.49	0.16

⁶ Scudder, "Electrical Conductivity and Ionization Constants of Organic Compounds," New York, 1914.

It is clear from the values of $pK_{\infty B}$ and $pK_{\infty A}$ that the oximes are much less hydrolyzed than the phenylhydrazones or the semicarbazones and that the difference between the classes of compounds is more pronounced in weakly acid solutions than in strongly acid solutions.

The hydrolysis constant of acetone semicarbazone was determined at P_H 7 at 0° —the value of $K_{\infty B}$ thus obtained was 0.00073 as compared with 0.00324 at 25° . A substitution of these values in the usual integrated form of the Van't Hoff equation yields $\Delta H_{298} = +9700$ cal. for the hydrolysis of acetone semicarbazone to acetone and free semicarbazide in very dilute aqueous solution. ΔF_{298} for the same process is $-1365 \log 0.00324 = +3400$ cal., from which $T\Delta S$ equals 6300 cal. or $\Delta S = 21.1$ E. U.

II. Kinetic Measurements

It has been known for some time that the rate of reaction of ketones and aldehydes with reagents of the type BNH_2 is a function of the acidity of the medium. Acree and Johnson showed that oxime formation was catalyzed by acids and Barrett and Lapworth, working on the formation of acetone and acetaldehyde oximes, found an optimum concentration of acid, above and below which the velocity decreased sharply. Ölander investigated this phenomenon with more care and put forward a hypothesis, accounting for it as purely an effect of hydrogen ion activity. The work of Brönsted has shown that in many reactions it is not solely the hydrogen ion (H_2OH^+) which is the catalyst but that other acids present in the solution⁷ may be effective in increasing the rate of the reaction. In general with those reactions which are subject to acid catalysis, the rate is proportional to the concentration of each species of acid present and a constant characteristic for the acid in question. These catalytic constants roughly parallel the acid dissociation constants of the acid, and for this reason if one is using a series of buffer solutions of about the same concentrations true acid catalysis may be overlooked and erroneously believed to be merely hydrogen ion catalysis. To determine whether or not the rates were solely a function of the P_H of the buffer solution or whether catalytic effects were at work, we measured the rate of formation of furfural semicarbazone in an acetate buffer of constant P_H but varying concentration of acetic acid and acetate ions.

Measurement of Velocity Constants.—It has been customary, apparently, in studies of this type of bimolecular reaction, to introduce the two reactants in exactly equal concentrations. This simplifies the mathematical treatment if the reaction is irreversible, but for reversible reactions it makes the treatment unnecessarily difficult. The logarithmic integration of the differential equation for such a process is not suitable for exact

⁷ Brönsted, *Chem. Rev.*, 5, 231-338 (1928); Brönsted and Guggenheim, *THIS JOURNAL*, 49, 2554 (1927).

computation in those cases where the reaction is almost irreversible. However, by maintaining a difference in concentration of the two reactants, it is possible to determine the velocity constants in both directions in a reversible reaction, from a single run and by a single equation with which it is easy to compute. There are three constants which must be known: the difference in concentration of the two reactants (called c in these formulations), the equilibrium constant K and either the initial concentration of a reactant or its concentration at equilibrium (one of these can be derived from the other). These are expressed by x_0 and x_e , respectively.

For a reversible bimolecular reaction in which a single molecule of product is formed by combination of one molecule of each reactant, where the concentrations of the reactants are x and $(x + c)$, respectively, and the equilibrium constant for the reverse reaction $K = k_1/k_2 =$ the ratio of the backward to the forward rate

$$-dx/dt = k_2x(x + c) - k_1(x_0 - x)$$

where x_0 is the initial concentration of x ; or

$$k_2dt = \frac{-dx}{x(x + c) - K(x_0 - x)}$$

The integrated equation takes on the final form

$$k_2t = \frac{2.303}{(2x_e + c + K)} \log \frac{x + (x_e + c + K)}{x - x_e} + C$$

Since the quantities in parentheses are all made up of constants known or measured in the course of the reaction, this equation reduces for a special run to a very simple form in which, especially with a calculating machine, the values of x can be rapidly and easily substituted. It is equally easy to determine k_1 directly from the original equation, or to find it as the product Kk_2 .

The integration constant is evaluated if desired by taking x_0 as one of the values of x . In certain cases in this work, x_0 is known with certainty (for example, in all runs at room temperature when the P_{H} is 7 or less) and in these cases the integration constant is incorporated in the logarithmic formula. At 0° , where the coefficients of expansion were not allowed for in calculating the molarity, and in the alkaline buffers, where addition of semicarbazide was followed by some immediate decomposition by dissolved air, the first determined value of x was sometimes more reliable than the calculated x_0 . In these cases the integration constant was not determined, but was canceled out in taking the differences of the logarithms.

It will be seen that this equation reduces to the equation for an irreversible reaction in the special case where x_e and K are equal to zero, for it becomes

$$k_2t = \frac{2.302}{c} \log \frac{x + c}{x} + C$$

This form was used for reactions in which x_e and K were too small to affect the value of the logarithm.

The concentration of reactants was usually chosen which would give not more than 80% reaction in five minutes. The usual velocity run included five titrations, covering about 80% reaction. Whenever there was a measurable equilibrium, the reversible-reaction formula was used in calculating the constants.

The most careful measurements were those in which the sampling was done at one-minute intervals. The 250-cc. glass-stoppered flask containing 200 cc. of buffer solution and 5 cc. of standard furfural solution (previously added from a pipet) and the bottle of standard semicarbazide hydrochloride were brought to temperature in the thermostat. Just before starting the run, the flask was removed and dried, and its stopper, on the inside of which a small inverted weighing bottle was sealed with de Khotinsky cement, was removed and inverted; 5 cc. of the semicarbazide hydrochloride solution was pipetted into the little bottle and at the moment of starting the run the stopper was inserted into the flask and the whole vigorously shaken, resulting in practically instantaneous mixing, as the timing was begun. The flask was replaced in the thermostat, and samples were taken at the stated intervals and added to successive flasks containing a measured amount of iodine, and enough disodium phosphate to bring the P_H of the mixture to 7. Immediately after addition of a reaction sample, the excess of iodine was destroyed by thiosulfate from a pipet. After the five minutes, the excess thiosulfate in each flask was titrated with iodine.

TABLE V

RATE OF FORMATION OF FURFURAL SEMICARBAZONE IN ACETATE BUFFERS OF VARYING CONCENTRATION BUT CONSTANT IONIC STRENGTH

P_H , 4.4; Temp., 25.0 \pm 0.01°; μ , 0.694

Total concn. of acetate ion plus acetic acid, moles per liter	0.0302	0.0477	0.0691	0.1257	0.742 ^a	0.742 ^a
Constant of rate of semicarbazone formation k_2	22.5	31.5	40.4	55.6	102.9	108.4

^a The ionic strength here was 0.74.

The ionic strength of the solutions dilute in acetate was made up by the addition of potassium chloride. The ratio of acetate ion to acetic acid throughout was 1.7. Two experiments at a molarity of 0.069 with an ionic strength of 0.069 gave values of k_2 of 36.6 and 37.9, showing that a large change of ionic strength had little effect on the rate. To illustrate the method of measuring k_2 , some typical data are given in Table Va.

The results summarized in Table V clearly show that at essentially constant P_H (and ionic strength) the rate of furfural semicarbazone formation may be increased five-fold by a change in concentration of the acetate

ion and acetic acid. The increase in rate with increase in concentration is nearly linear up to a molarity of about 0.13; in higher concentrations the increase of concentration produces a less effect. From these results it seemed probable that we were dealing with a reaction between the free semicarbazide (BNH_2) and the carbonyl compound, the reaction being subject to acid catalysis by the acetic acid molecules; as will be shown later, we could obtain no evidence that the reaction was subject to basic catalysis in aqueous solutions. Further evidence was obtained by studying the rate of formation of acetone semicarbazone at 0° in acetate and phosphate buffer solutions. The results are shown graphically in Fig. 2. Since the hydrolysis constant of acetone semicarbazone is high, k_2 was determined indirectly by measurements of the equilibrium constant and of the velocity of hydrolysis of the semicarbazone.

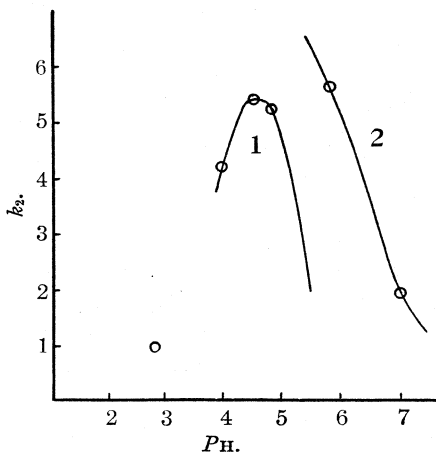

Fig. 2.—Velocity of condensation of acetone and semicarbazide at 0° in 0.045 M buffer solutions; curve 1, acetate buffers; curve 2, phosphate buffers.

A test of the applicability of Brönsted's theory to semicarbazone formation is afforded by the results shown in Fig. 2. From the relationship $pK - pH = \log ([\text{BNH}_3^+]/[\text{BNH}_2])$ and the value of pK at 0° for semicarbazide acid ion (4.40),² the fraction of total semicarbazide present as free base may be calculated. The reaction velocity constant referred to free semicarbazide (k_2°) is obviously the ob-

served velocity constant (k_2) divided by this fraction; this value is given in the fourth column of Table VI.

TABLE VI
SUMMARY OF DETERMINATIONS OF CONDENSATION VELOCITY OF ACETONE AND SEMI-CARBAZIDE AT $0.1 \pm 0.1^\circ$

P_H	C_A	k_2	k_2°	$k_A = k_2^\circ/C_A$	
2.84	0.0226	1.13	42.2	...	Citric acid buffer
4.00	.0363	4.25	14.9	410	Acetic acid buffers
4.52	.0233	5.43	9.55	406	
4.84	.0157	5.30	7.05	450	
5.84	.0350	5.70	5.90	169	Phosphate buffers
7.00	.0146	2.02	2.02	138	

In the second column of the same table is given the molar concentration of acid in each of the buffers; according to Brönsted's theory the value of k_2° should be proportional to this concentration since in general $k_2^\circ = \Sigma C_A k_A$ where C_A and k_A are the concentrations and specific catalytic constants for all the species of acids involved. The last column in Table VI shows that the value of k_A for acetic acid is $420 \pm 5\%$ and for $H_2PO_4^-$, $150 \pm 10\%$. These facts show clearly that the formation of acetone semicarbazone is a reaction involving acetone and free semicarbazide subject to acid catalysis. (No attempt was made to calculate a value for the citric acid buffer since it is difficult to identify the molecular species of acid present in this case.)

Since in general the specific catalytic constants of a series of acids parallel the dissociation constants,⁷ it is evident that as one passes from a set of buffers composed of the monobasic phosphate ion to one composed of acetic acid and then to those containing still stronger acids the value of k_A would increase. Furthermore, in a given set of buffers C_A , the concentration of the acid component, increases with decreasing P_H values. These two effects by themselves would cause an increase in the rate of semicarbazone formation with increasing acidity. However, this effect is counteracted by increasing removal of free semicarbazide by the formation of the ion $NH_2CONHNH_3^+$ as soon as one approaches a P_H value near the pK value of the semicarbazide ion. The result of these two opposing factors would obviously lead to a maximum in the P_H versus k_2 curve for semicarbazone formation. It would be clearly accidental, however, if such a curve were a smooth continuous curve; indeed, it is not as shown by Fig. 2. It would be easy, however, to assume that there was such a smooth curve showing a maximum if a limited number of buffer solutions of approximately the same concentration were employed. This is shown by the results we obtained early in the work using furfural at 25° . These measurements are summarized in Fig. 3; the values of k_2 and K were measured directly as explained above. There is a maximum value

of k_2 at P_H 3.13, but the curve is not regular. Ölander obtained a similar maximum in studying acetoxime formation but explained it by an entirely different mechanism. As his measurements were made before Brönsted's work had shown the importance of general acid catalysis, he made no experiments to determine whether or not the P_H value of the solution alone determined the rate. We believe that these results of Ölander's indicate that oxime formation like semicarbazone formation is a reaction between the free base and the carbonyl compound catalyzed by the acid component of the buffer.

The temperature coefficient of the reaction between acetone and semicarbazide was determined at P_H 7 (phosphate buffer molarity of 0.049) by measuring the rate at $0.1 \pm 0.1^\circ$, and $25.00 \pm 0.01^\circ$. The values for k_2 were 2.02 ± 0.06 and 2.95 ± 0.06 , respectively; these values in the usual Arrhenius equation yield a value for the heat of activation of 2500 cal. \pm 240 cal. This, combined with the value of ΔH for the hydrolysis of acetone semicarbazone given above (9700), gives the heat of activation of the hydrolysis reaction as 12,200 cal.

This latter value is about what one might expect for a reaction of this sort, but the very small heat of activation of semicarbazone formation is very unusual. The facts concerning acid catalysis, however, show that the rate of the reaction is dependent on the concentration of three substances, namely, the carbonyl compound, the reagent and the acid. It seems probable that in reality we have a bimolecular reaction between one of the reactants and a complex of the other two. The low temperature coefficient of the reaction would be accounted for by the fact that the equilibrium involving the complex would be shifted toward dissociation by increased temperature. This shift would diminish the concentration of the reactant in the rate-determining step and lower the velocity. This effect would offset to a considerable extent the usual increase in rate of a reaction with increase in temperature. According to this view, then, the value of the heat of activation of the reaction in question does not correspond to any real reaction but is complicated by including the heat of dissociation of a complex.

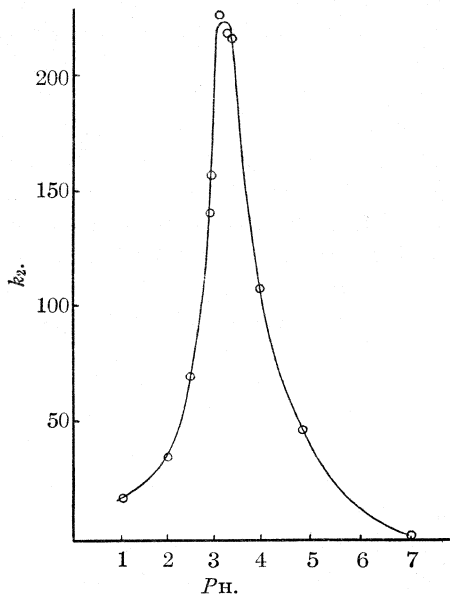

Fig. 3.—Condensation velocity of furfural and semicarbazide in 0.5 *M* phosphate, citrate and acetate buffers.

We have not been able to obtain any clear evidence of basic catalysis of semicarbazone formation. For study in a borate buffer of P_H 9.11 and a dibasic-tribasic phosphate buffer of P_H 11.01, the most reactive carbonyl compound, acetaldehyde, was chosen. This aldehyde, which condenses with semicarbazide with a velocity constant of about 360 in a 0.1 M phosphate buffer at P_H 7, showed a constant of 9.2 in the P_H 9 buffer and a constant of 1.42 at P_H 11. Evidently the rate at neutrality was almost entirely due to catalysis by the $H_2PO_4^-$ ion. Certainly there is no basic catalysis evident by the $PO_4^{=}$ ion in 0.25 M solution. To avoid using acetaldehyde, with its tendency to polymerize in strongly basic solutions, cyclohexanone was condensed with semicarbazide in the P_H 11 buffer, and in 0.1 N and 1 N sodium hydroxide solution, carrying the P_H almost up to 14. The constants, which were not very satisfactory for the slower reactions, were: at $P_H = 11.0$, $k_2 = 0.27 \pm 0.06$; 0.1 N NaOH, $k_2 = 0.22 \pm 0.03$; 1 N NaOH, $k_2 = 1.61 \pm 0.05$. There appears to be about a five-fold increase in velocity on passing from 0.1 N sodium hydroxide to 1 N , which is perhaps too large a difference to be caused by a solvent effect; but since the velocity in normal sodium hydroxide is less than one-twentieth of that in our P_H 7 buffer (with 0.03 M monobasic sodium phosphate functioning as an acid catalyst), it would appear that, if there is any basic catalysis of semicarbazone formation, it is exceedingly small in aqueous solutions.

On the other hand, the accelerating effect of strong alkali on oxime formation appears well-established. It was first noticed by Auwers in 1889 and is commonly used in the preparation of the slowly forming oximes of highly substituted ketones. According to the work of Barrett and Lapworth^{1b} the velocity of formation of acetoxime increases linearly with the quantity of alkali present, up to an alkali concentration of about 0.025 N , which was as high as their experiments were carried. Acree and Johnson put forward the hypothesis that this accelerating effect of alkali on oxime formation was due to formation of the negative ion of hydroxylamine, which had a greater reactivity than the neutral form. If such is the case, we should expect the accelerating effect of alkali on the formation of semicarbazones to be much less pronounced than in the case of oximes, or perhaps not to appear at all in ordinary aqueous solutions, since free semicarbazide shows no acid ionization.

III. The Effect of the Structure of the Carbonyl Compound on the Equilibrium and the Rate

From the work reported in the two previous sections of this paper it is clear that a comparison of rates and equilibria with a variety of carbonyl compounds and the same nitrogen base should be made (a) under conditions where all the nitrogen base and all the condensation product are in

the free-base form, and (b) with a definite concentration of a known catalyst present. This concentration of catalyst should not much exceed $0.1 M$ and should not be more than about 100 times the concentration of the reactants. These conditions will be fulfilled for semicarbazone formation if we choose a phosphate buffer of concentration $0.1 M$ or $0.2 M$ and with a value of P_H 7, since the concentration of the catalyst (primary phosphate ion) in a $0.2 M$ buffer of this P_H is only $0.06 M$, and since here more than 0.999 of the semicarbazide is in the form of the free base.

In addition to the methods outlined above for measuring equilibrium and rate constants, another method was introduced for convenient determination of the rate of hydrolysis of a semicarbazone. This method is applicable in certain cases only, and depends upon the stability of the semicarbazone toward iodine. If iodine does not attack a semicarbazone directly, hydrolysis may be carried on in a solution containing iodine, and the continuous removal of the semicarbazide by the iodine makes the hydrolysis kinetically irreversible and easily subject to treatment by the simple monomolecular formula.

The constancy of the values of k calculated from any such hydrolysis run where only a slight excess of iodine is present constitutes a sufficient criterion of the stability of the semicarbazone; for if iodine participates in the rate-controlling reaction, the "monomolecular constants" will decrease with time, and be proportional to the concentration of iodine remaining.

The logarithm of the semicarbazone concentration was plotted against the time for the several semicarbazones measured. The method was applied only to those semicarbazones for which such a plot resulted in a straight line; these were acetone, acetaldehyde and cyclohexanone semicarbazones. With the last two, the rate of hydrolysis could be measured more accurately than the rate of formation, so that this was a very useful method in these cases.

An account of the determination of the hydrolysis velocity of acetone semicarbazone will illustrate the method. The dry semicarbazone was weighed and a solution of it in water made up to be about $0.01 M$. This was kept overnight and then for a few hours in the thermostat; 5-cc. portions of this solution were then introduced into flasks containing 7 cc. of iodine and 20 cc. of a $0.2 M$ phosphate buffer of P_H 7.02. The time from addition of this sample to the iodine, to reaching the end-point with thiosulfate was taken with a stop watch. At any time a new point on any part of the curve could be taken. In another run 50 cc. of $0.1 M$ buffer (P_H 7.08) was used instead of 20 cc. of the $0.2 M$ buffer. This made a buffer concentration of 0.0794 instead of 0.125 and a semicarbazone concentration of 0.00082 instead of 0.001568. The two values for k_1 found are 0.0214 and 0.0152. Corrected to a concentration of catalyst of $0.06 M$ (buffer concentration of exactly $0.1 M$) these yield the constants 0.017 and 0.019.

The average of these values, divided by the rate of formation of acetone semicarbazone at the same concentration of buffer, $(2.95/0.049 \times 0.100 = 6.0)$, gives a value for the equilibrium constant of 0.0030 as compared with 0.00324 from the measurements of equilibrium as a function of P_H (Table I).

In preparing to study the other semicarbazones, blanks were run in each case to test for any reaction between iodine and the ketone or aldehyde itself. In all these cases it was found that there was no reaction rapid enough to be a source of error. Acetaldehyde, for example, reacted forty times more slowly with iodine at P_H 7 than the semicarbazone.

The final results of the comparative study of eight different aldehydes and ketones are given in Table VII.

TABLE VII
COMPARISON OF EQUILIBRIA AND RATES OF SEMICARBAZONE FORMATION OF A VARIETY OF KETONES AND ALDEHYDES

At $25 \pm 0.01^\circ$ in $0.07 M Na_2HPO_4 + 0.03 M NaH_2PO_4$

Semicarbazone of:	$K_{\infty B} \times 10^5$ Hydrolysis constant of semicarbazone	$pK_{\infty B}$	Velocity constants formation = k	hydrolysis $k_1 \times 10^5$
Acetaldehyde	2.9	4.5	(361)	1040
Benzaldehyde	(0.30)	5.5	2.05	(0.62)
Furfural	(0.76)	5.1	0.73	(0.55)
Trimethylacetaldehyde	1.85	4.7	20	(37)
Pyruvic acid	0.51	5.3	7.37	(3.8)
Acetone	324	2.5	6.02	1800
Cyclohexanone	214	2.7	(36)	7600
Pinacolone	1260	1.9	0.068	(86)

In this table the figures which were not determined directly, but were computed from other data at hand, are enclosed in parentheses. The values of $K_{\infty B}$ for benzaldehyde and furfural were calculated by equations 5 and 6 from values of K at different P_H values. Values of k_2 for acetaldehyde and cyclohexanone were calculated from $K_{\infty B}$ and k_1 and the reverse procedure was used in calculating k_1 for the four bracketed values.

A consideration of Table VII brings out a number of points of interest. In the first place it is clear that there is no apparent relation between the speed of formation of the semicarbazone and its stability as measured by the hydrolysis constant $K_{\infty B}$. Thus the rates of formation of the semicarbazones of benzaldehyde, pyruvic acid, trimethylacetaldehyde and acetone are within a power of ten but the hydrolysis constants show a divergence of a thousand-fold between the extremes, and the most rapidly reacting of the four (trimethylacetaldehyde) is about in the middle of the series from the point of view of the extent of hydrolysis of the semicarbazones. Considering first the relation between structure and rate of semicarbazone formation, acetaldehyde is found at the top of the list, with its

trimethyl substitution product about a tenth as reactive, but some ten times more reactive than benzaldehyde or furfural. The latter is the least reactive of all the aldehydes and differs from acetaldehyde by nearly a thousand-fold. Of the ketones, cyclohexanone is the most reactive, as would have been expected from previous work, acetone and pyruvic acid essentially equal and about a sixth as rapid in semicarbazone formation as the cyclic ketone. The large drop in reactivity caused by substitution of three methyl groups (0.068 for pinacolone compared with 6.0 for acetone) is in accord with a large variety of qualitative and quantitative facts of organic chemistry. It is interesting that the change in reactivity produced by the substitution of three methyl groups in the alpha position is much less in the case of the aldehyde than with the ketone ($361/20 = 18$, compared with $6.0/0.06 = 100$). A comparison of benzaldehyde, furfural, acetone and trimethylacetaldehyde gives very little support to the idea that the rate of carbonyl reactions is determined solely by so-called "steric effects." If the comparison is sufficiently restricted, however, as, for example, between acetaldehyde and its trimethyl derivative, the concept of steric hindrance is in accord with the facts.

Turning now to the equilibrium constants, we find all the ketones (except pyruvic acid) falling into one class and the aldehydes into another. Within the ketone class the variation in $K_{\infty B}$ is only three-fold, the most highly substituted ketone being the most completely hydrolyzed. The variation among the aldehydes in $K_{\infty B}$ is ten-fold, but the difference between the least hydrolyzed ketone semicarbazone (always excepting pyruvic acid) and the most hydrolyzed aldehyde semicarbazone is 100-fold. Pyruvic acid behaves like an aldehyde in respect to the hydrolysis constant of the semicarbazone. It would appear that the carbonyl compounds, as far as the energy relationships are concerned, show a rather simple relationship between structure and semicarbazone formation, the equilibrium constant being determined by the same sort of factors which determine the dissociation constants of acids. For convenience these factors may be termed the polarity or negativity of the attached groups.

Using the dissociation constants of the acid XCOOH , as a measure of the negativity of the group X, we have the following series, the groups being arranged in order of decreasing negativity (the values of pK_A for the acids are given in parentheses): COOH (2.8), H (3.7), C_6H_5 (4.2), CH_3 (4.7), $(\text{CH}_3)_3\text{C}$ (5.0). Now turning to a comparison of the extent of hydrolysis of the semicarbazones formed from carbonyl compounds of the type XCOCH_3 , we find the following order for the group X (the values of $pK_{\infty B}$ are given in parentheses): COOH (5.3), H (4.5), CH_3 (2.5), $(\text{CH}_3)_3\text{C}$ (1.9). The two series coincide not only qualitatively but semi-quantitatively, the most hydrolyzed semicarbazone corresponding to the weakest negative group. If we compare the values of pK_B for semicar-

bazones derived from compounds of the type $XCHO$, we find that the value for benzaldehyde is greater than for acetaldehyde, as would be predicted, but that trimethylacetaldehyde is out of place. This discrepancy we do not feel is serious in view of the uncertainty of the interpretation of small differences in pK values.

We are aware that some of our conclusions in regard to the relation between structure and rate of reaction are contradictory to earlier measurements which have been much quoted. It would take far too much space to discuss all the earlier work but with the exceptions previously noted we feel that the previous work is unreliable because of the then unknown factors affecting both equilibrium and rates and a failure to distinguish between equilibria and rates in the measurements themselves. Furthermore, we have devised a few qualitative experiments which demonstrate the correctness of some of the conclusions summarized in Table VII.

A comparison of semicarbazone formation of cyclohexanone and furfural is of interest. The differences in rate are in favor of the former by a factor of about 50; the hydrolysis of the aldehyde semicarbazone, however, is only $1/300$ of that of the ketone. As a result, if one mole of semicarbazide and one mole each of cyclohexanone and furfural are allowed to react, practically the entire *final* product is furfural semicarbazone. Because of the differences in the rates of reaction, however, the *initial* product in such an experiment is almost wholly cyclohexanone semicarbazone. The effects of differences of rate and equilibrium constants on the nature of the product can be shown very simply by allowing semicarbazide to react with a mixture of cyclohexanone and furfural in alcoholic solution and isolating the semicarbazone after a few seconds and after a few hours. Because of the solubility of cyclohexanone semicarbazone in water, it is necessary to precipitate the product by pouring a sample of the mixture into a saturated ammonium sulfate solution in which the cyclohexanone semicarbazone is almost insoluble. In such an experiment starting with 0.01 mole each of semicarbazide hydrochloride, furfural, and cyclohexanone and 0.05 mole of potassium acetate in 50% alcohol, a sample precipitated after twenty seconds yielded a product melting at 165° (identified as cyclohexanone semicarbazone by mixed melting point); after two and one-half hours a similar precipitate melted at 190° and was identified as furfural semicarbazone. In a comparison of acetone and furfural, it is impossible to isolate the ketone semicarbazone by precipitation as it is too soluble. The delayed precipitation of furfural semicarbazone from a reaction mixture containing one mole of acetone (and saturated with furfural semicarbazone) was however striking proof of the correctness of the results shown in Table VII, where k_2 for acetone is nearly ten times greater than that of furfural. Two exactly parallel experiments were performed using an aqueous solution of semicarbazide hydrochloride (0.01 mole) and potassium acetate (0.05 mole) in

20 cc. of water saturated with furfural semicarbazone. In one flask a mixture of 0.01 mole each of acetone and furfural was introduced, in the other 0.01 mole of furfural alone. In the first flask the precipitate after one minute was 0.25 g., in the other 1.20; the filtrate from these precipitates yielded, after standing for twelve hours, 1.00 g. and 0.20 g. of additional furfural semicarbazone.

TABLE VIII

COMPOSITION OF BUFFER SOLUTIONS				
P_H	Acid	Concentration	Salt	Concentration
-0.01	HCl	1.284

The buffers of other P_H 's in the neighborhood of 3, not listed here, were prepared from these buffers by adding different amounts of acid or base, account being taken of the changes in concentration in the values reported for μ .

Summary

A quantitative study has been made of the factors affecting the equilibria and rates of semicarbazone formation. The extent of hydrolysis of a given semicarbazone is a function of the acidity of the solution, which may be expressed by an equation which has been derived. The results obtained correspond to this equation. The formation of semicarbazones has been found to be subject to general acid catalysis and a fairly satisfactory formulation has been developed in terms of the effect of acidity on the amount of semicarbazide reacting and acid catalysis. The equilibria and rates of semicarbazone formation for a variety of ketones and aldehydes have been measured under strictly comparable conditions. Certain relations between structure and equilibria and rates of semicarbazone formation have been pointed out.

A CONTRIBUTION TO THE CHEMISTRY OF DIHYDRORETENE¹

BY GUST. KOMPPA AND HARALD P. FOGELBERG

RECEIVED FEBRUARY 18, 1932

PUBLISHED JULY 6, 1932

Introduction and Historical

Retene is a hydrocarbon, 1-methyl-7-isopropylphenanthrene, derived from pine tar. The hydrogenated derivatives of retene are of interest especially because of their relationship to resin acids and in view of their occurrence with retene in pine tar and pine oils.

Dihydroretene may be obtained as a well-characterized, crystalline material by carefully reducing retene with sodium and amyl alcohol. Virtanen,² who first isolated dihydroretene by this method, found that the compound, unlike retene, formed no picrate and that it yielded retenequinone on chromic acid oxidation.

It is well known that phenanthrene is more closely related to diphenyl in its chemical behavior than to naphthalene. This property is clearly evident in a series of reactions of phenanthrene in which the double bond of the 9,10 position, the "bridge," appears almost olefinic in nature. It is to be expected that the middle ring of the retene molecule should have the same character as that of phenanthrene. A ring system obtained by saturating the "bridge" double bond of retene should in many respects bear a close relationship to the mother substance, although it is to be expected that the aromatic character of the other two benzene nuclei should be enhanced.

Monosubstitution derivatives of retene have been prepared by halogenation, carboxylation and sulfonation.³ Of these, the last mentioned are the best characterized. Komppa and Wahlforss⁴ isolated two monosulfonic acids and from them prepared a series of well-characterized derivatives. These sulfonic acids, designated as A-retenesulfonic acid and B-retenesulfonic acid, are colorless, crystalline substances free of water of crystallization and possess sharp melting points.⁵ In view of these

³ Additional derivatives of retene have recently been reported by Bogert and Hasselström, *THIS JOURNAL*, **53**, 3462 (1931), and by Fieser and Young, *ibid.*, **53**, 4120 (1931). (Abstractors' note.)

⁴ Komppa and Wahlforss, *ibid.*, **52**, 5009 (1930).

⁵ Fieser and Young suggest that the A- and B-substituents occupy the 2- and 6-positions, respectively, in retene. In this connection they state: "While no promising

circumstances it seemed desirable to study similar reactions of dihydroretene.

Results and Discussion

The sulfonation of dihydroretene gave, in good yields, two monosulfonic acids. Sulfonation at 66° resulted in the formation of a monosulfonic acid which was characterized by its difficultly soluble alkali salts. The acid, purified by means of its barium salt, when recrystallized from ether melted at 147–148°. Sulfonation at 200° resulted in the formation of a second monosulfonic acid which, when regenerated from its ethyl ester and recrystallized from benzene, melted at 106–107°. The sulfonic acid group could be eliminated from the former much more easily than from the latter. Dihydroretene could readily be regenerated from the sulfonic acid melting at 147–148° by heating with water at 200°. On the other hand, the products obtained by treating the sulfonic acid melting at 106–107° either with water or with concentrated hydrochloric acid, could not be definitely identified as dihydroretene.

Fusion of the alkali salts of the two monosulfonic acids with potassium hydroxide gave, in very low yields, two phenols. They were found to be identical with the retenols obtained from retene by Komppa and Wahlforss.⁴ This was established by preparing the acetyl and benzoyl derivatives of the phenols obtained from both hydrocarbons. This result indicated that dehydrogenation had occurred and implied that the sulfonic acid groups in the sulfonic acids of retene and dihydroretene were in analogous positions. In order to obtain further evidence the ethyl esters of A- and B-retenesulfonic acids were prepared and oxidized with chromic acid to the ethyl esters of retenequinonesulfonic acid. The ethyl esters of the two dihydroretenesulfonic acids were similarly oxidized. The quinonesulfonic ester thus obtained from the dihydroretenesulfonic acid melting at 147–148° was identified, by melting point and the mixed melting point test as well as other characteristics, as the ethyl ester of A-retenequinonesulfonic acid. On the other hand, the properties of the quinonesulfonic acid ester obtained from the dihydroretenesulfonic acid melting at 106–107° corresponded to those of the ester of B-retenequinonesulfonic acid. This shows, consequently, that in the sulfonation of dihydroretene the substituents enter positions analogous to those in A- and B-retenesulfonic acid. The new sulfonic acids were, therefore, designated as A-dihydroretenesulfonic acid and B-dihydroretenesulfonic acid. The addition of two hydrogen atoms has, therefore, apparently not changed the behavior of the retene nucleus toward substitution reactions.

method of degradation was discovered, we believe that, from certain properties of the compounds in the two series, the two retenols may be assigned structures which, if not definitely proved, are highly probable." (Abstractors' note.)

The acid chloride as well as the methyl and ethyl esters of both dihydroretenesulfonic acids were prepared. The acid chloride of A-dihydroretenesulfonic acid was reduced to the corresponding sulfinic acid and to the mercaptan.

During the course of this research it was found necessary to prepare a number of derivatives of retene. The description of the preparation of these compounds constitutes the last portion of the Experimental Part.

The following is a comparison of the derivatives of dihydroretene prepared in this investigation with the corresponding derivatives of retene.

Substituent	TABLE I Dihydroretene derivatives, °C.		Retene derivatives, °C.

Frey⁶ obtained a mixture of diphenyl ketone and potassium phenanthrenesulfonate by boiling the potassium salt of phenanthrenequinone-sulfonic acid with aqueous potassium hydroxide. In order to determine whether the corresponding reaction occurred with retene derivatives, the potassium salts of A- and B-retenequinonesulfonic acids were boiled with aqueous potassium hydroxide. Potassium retenesulfonate, however, could not be identified among the products of the reaction. A mixture containing the potassium salt of a retene ketone monosulfonic acid was obtained from A-retenequinonesulfonic acid while retene ketone was the principal product from B-retenequinonesulfonic acid.

From the highest boiling fractions of pine tar (from *Pinus Sylvestris*) used as a raw material in this investigation, there was isolated a small amount of another, apparently new, hydrocarbon, possessing the formula C₂₄H₂₀.

Experimental Part

The retene used in these experiments was obtained from that fraction of pine tar boiling at about 360°. Besides retene, a small quantity (less than 1 g. from 500 g. of

⁶ Werner, *Ann.*, **321**, 345 (1902).

crude retene) of another hydrocarbon was isolated from this crude material in the course of recrystallization from petroleum ether. This substance crystallized from benzene in shining silver scales melting at 297–298° (uncorr.). This hydrocarbon was quite difficultly soluble in most solvents and appeared to be sulfonated by hot concentrated sulfuric acid. Analysis indicated the formula $C_{24}H_{20}$ for this hydrocarbon.

Anal. Calcd. for $C_{24}H_{20}$: C, 93.46; H, 6.54; mol. wt. 308.16. Found: C, 93.68, 93.83; H, 6.52, 6.35; mol. wt. (Rast),⁷ 306, 311.

Dihydroretene.—This compound was prepared essentially according to the method described by Virtanen.² The total yield of dihydroretene, m. p. 64–65°, amounted to 62.7% of the theoretical.

Dihydroretene Derivatives A-Series

A-Dihydroretenesulfonic Acid.—To 20 g. of dihydroretene heated on an oil-bath to 66–68° was added, with vigorous stirring, 20 g. of sulfuric acid (sp. gr. 1.84). The sulfonation was completed in fifteen minutes. The sulfonation mixture was then poured into 200 cc. of hot water and thoroughly agitated. Under these conditions the sirupy mass dissolved, forming a quite clear bright yellow solution. The ammonium salt of A-dihydroretenesulfonic acid precipitated immediately upon the addition of an excess of concentrated ammonium hydroxide. After standing overnight the salt was filtered off, washed with cold water and dried at 110°. The dried product was extracted with petroleum ether (b. p. 80–100°) in a Soxhlet extractor; yield 19.5 g. (69.1%).

The ammonium salt (10 g.) was dissolved in 150 cc. of a mixture of equal parts of pyridine and water. The solution was filtered and a warm aqueous solution of barium chloride was stirred in. The barium salt of the sulfonic acid which precipitated was filtered off, washed repeatedly with hot water and dried.

Of the barium salt obtained in this way, 11.5 g. was warmed and stirred with 80 cc. of glacial acetic acid until a homogeneous thin paste was obtained. Then 45 cc. of sulfuric acid (2 *N*) was gradually added and the mixture was heated nearly to boiling for ten minutes. Warm water (35 cc.) was then added and the solution filtered through a hot water funnel. The quite clear yellowish filtrate was concentrated *in vacuo* to about 75 cc. and 10 cc. of dilute sulfuric acid (1:1) added. On cooling the liquid solidified to a stiff white paste which could easily be filtered by suction. The shining scales of the sulfonic acid thus obtained were spread out on a porous plate. The acetic acid could be removed, almost completely, by allowing the product to stand over concentrated sodium hydroxide solution in a vacuum desiccator; yield, 7.6 g. The acid was obtained in the form of strongly refracting crystals melting at 147–148° by recrystallization from ether. The acid was titrated in aqueous alcohol solution with *N*/10 aqueous sodium hydroxide: calcd. for $0.1701 \text{ g. of } C_{19}H_{19}SO_3H + 2H_2O$: 4.83 cc.; found: 4.85 cc.

The acid lost its water of crystallization on standing over sulfuric acid in a vacuum desiccator.

Salts.—A number of salts of A-dihydroretenesulfonic acid were prepared and analyzed.

Methyl Ester.—Prepared by boiling the potassium salt with dimethyl sulfate for four minutes. Recrystallization from methyl alcohol gave slightly yellowish scales, m. p. 98–99°.

Anal. Calcd. for $C_{19}H_{19}SO_3$: C, 69.04; H, 6.71. Found: C, 68.81; H, 6.70.

Ethyl Ester.—Prepared by boiling the potassium salt with diethyl sulfate. Recrystallization from ethyl alcohol gave fine scales, m. p. 72.5–73.5°.

Anal. Calcd. for $C_{20}H_{24}SO_3$: C, 69.71; H, 7.03. Found: C, 69.18, 69.52; H, 7.06, 6.81.

Ca ^a		Crystalline powder	150	.005	Ca, 5.98	6.05
Cu ^b	2H ₂ O	Light green blue scales	150 ^c	.011	Cu, 9.16	8.84

^a Prepared from the free acid and the metallic hydroxide. ^b Prepared from the free acid and the metallic carbonate. ^c Lost its water of crystallization at 110°.

^d Grams of anhydrous salt per 100 g. of water at 17°.

To a solution of two grams of the ethyl ester in 50 cc. of glacial acetic acid gently heated on a water-bath was slowly added a warm solution of three grams of chromic acid in 30 cc. of glacial acetic acid. The solution was heated for forty-five minutes, allowed to cool and poured into cold water. The precipitate which formed was filtered off and dried on a porous plate; yield, 0.95 g. (44.0%).

Recrystallization from glacial acetic acid gave small light orange colored needles, m. p. 183–184°. These crystals exhibit complete identity in physical properties and appearance with the product obtained from the oxidation of ethyl A-retenesulfonate. A mixed melting point test of the two oxidation products showed no depression of the melting point. The substance was difficultly combustible.

Anal. Calcd. for C₂₀H₁₀SO₅: C, 64.48; H, 5.42. Found: C, 64.57, 63.24, 62.85; H, 6.00, 5.96, 6.66.

Chloride.—Prepared by treating potassium A-dihydroretenesulfonate with phosphorus pentachloride in the presence of a small amount of phosphorus oxychloride. The reaction was completed by warming for a short while on a water-bath. After cooling the reaction product was poured into ice water, extracted with ether and the ether solution was washed with water. Evaporation of the ether gave a yellow oil which quickly solidified; yield, 1.8 g. (95.3%). Recrystallization from benzine (b. p. 80–100°) gave thin star-shaped prisms, m. p. 91–92°.

In some cases a second modification of the chloride was obtained. This crystallized from benzine as dense granules which, despite repeated recrystallization, did not melt above 82–83°. Analysis gave values which agreed with those calculated for C₁₉H₁₉SO₂Cl. Both chlorides gave an amide, m. p. 193–194°, with ammonium hydroxide.

Anal. (Carius). Calcd. for C₁₉H₁₉SO₂Cl: Cl, 10.60; S, 9.58. Found: Cl, 10.41; S, 9.82.

Amide.—Prepared from the chloride of A-dihydroretenesulfonic acid and ammonium hydroxide; yield, 46.6%; colorless scales, m. p. 193–194°.

Anal. Calcd. for C₁₈H₂₁SO₂N: N, 4.44. Found: N, 4.49.

Anilide.—Prepared by boiling the chloride of A-dihydroretenesulfonic acid with aniline; yield, 51.3%. The anilide crystallized from alcohol in shining plates, m. p. 112–114°.

Anal. Calcd. for C₂₄H₂₆SO₂N: N, 3.58. Found: N, 3.40.

A-Dihydroretenesulfonic Acid.—The chloride of A-dihydroretenesulfonic acid (2 g.) was dissolved in 10 g. of toluene and 2 cc. of water added. The mixture was warmed and shaken on a water-bath while 3 g. of zinc dust was gradually added. A vigorous reaction began and the mass thickened to a stiff paste. Heating and stirring was continued, however, for a short while. After cooling, the mixture of the zinc salt

of the sulfonic acid and unchanged zinc dust was filtered off, washed with a little toluene, and dried. The residue was boiled with a solution of sodium carbonate in aqueous alcohol (1:1) and filtered. On cooling the sodium sulfinate crystallized in shining colorless scales; yield, 1.1 g. (57.1%). The salt is difficultly soluble in water.

Anal. Calcd. for $C_{18}H_{19}SO_2Na$: Na, 7.14. Found: Na, 7.13.

The sulfonic acid was freed from its sodium salt by concd. hydrochloric acid. Crystallization from aqueous alcohol gave white scales, m. p. 123–130°. The acid was titrated with *N*/10 sodium hydroxide: calcd. for 0.1110 g. of $C_{18}H_{19}SO_2H$: 3.70 cc.; found, 3.35 cc.

A-Dihydroretene Mercaptan.—The chloride of A-dihydroretenesulfonic acid was first reduced with zinc dust, giving the zinc sulfinate. This was further reduced in the cold with zinc dust in the presence of concd. hydrochloric acid. The mercaptan was obtained in the form of fine, light yellow scales, m. p. 185–188°; yield, 10.4%. As the substance seemed to be quite unstable, it was converted directly to the benzoyl derivative by means of benzoyl chloride in the presence of pyridine. In this way lemon yellow crystalline granules were obtained, m. p. 170–172°.

Anal. Calcd. for $C_{26}H_{24}SO$: C, 80.59; H, 6.50. Found: C, 80.74; H, 6.68.

Attempted Preparation of A-Dihydroretenol.—All attempts to replace the sulfonic acid group of potassium A-dihydroretenesulfonate, by means of alkali fusions, with the hydroxy group resulted in the formation of A-retenol. The yields were uniformly low; 15.6% from a fusion carried out in the usual manner. The retenol crystallized from xylene in the form of small glistening plates, m. p. 200–202°. With picric acid the picrate, m. p. 150–151°, was obtained in the form of ruby red needles.

Dihydroretene Derivatives, B-Series

B-Dihydroretenesulfonic Acid.—To 10 g. of dihydroretene heated on an oil-bath to 200° was added, with vigorous stirring, 10 g. of sulfuric acid (sp. gr. 1.84). The sulfonation was completed in five minutes. The sulfonation mixture was poured into 150 cc. of hot water and a slight excess of concentrated ammonium hydroxide was added to the hot solution. After standing overnight, 1.6 g. of a crystalline salt precipitated out. This was filtered off and the cloudy filtrate was extracted with ether. The clear aqueous solution was heated on a water-bath to remove the ether and then treated with a solution of 10 g. of potassium hydroxide in 30 cc. of water. When cooled, the potassium B-dihydroretenesulfonate crystallized in shining plates; yield, 5.78 g. (36.7%).

The first precipitate obtained with ammonium hydroxide was found to be mostly ammonium B-retenesulfonate.

Potassium B-dihydroretenesulfonate (5 g.) was dissolved in two liters of hot water and acidified with hydrochloric acid. An excess of barium chloride was added and the mixture was boiled for a few minutes. The precipitated barium B-dihydroretenesulfonate was filtered off, washed repeatedly with hot water and boiled for several hours with the calculated quantity of very dilute sulfuric acid. The barium sulfate was filtered off and the clear filtrate was concentrated, first on a water-bath and then *in vacuo* over sulfuric acid. This product, purified by recrystallization from benzene, gave slightly brownish colored scales, m. p. 105–106°, which, air dried, contained two molecules of water; both were lost when dried over sulfuric acid.

The free sulfonic acid was also obtained as nearly colorless scales, m. p. 106–107°, by saponifying the ethyl ester. The acid was titrated with *N*/10 potassium hydroxide: calcd. for 0.11 g. of $C_{18}H_{19}SO_3H + 2H_2O$: 3.12 cc.; found, 3.12 cc.

Salts.—A number of salts of B-dihydroretenesulfonic acid were prepared and analyzed.

TABLE III

Salt	H ₂ O of crystallization	Crystallized as	Dried at °C.	Solubility ^e	Analysis, anhydrous salt, %	
					Calcd.	Found
K ^a	H ₂ O	Shiny scales	150 ^d	0.248	K, 11.04	10.75

					(Kjeldahl)	
Ba ^b	H ₂ O	Crystalline powder	130	0.026	Ba, 17.89	17.79
Ca ^b	6H ₂ O	Shiny scales	150	0.031	Ca, 5.98	5.82
Cu ^c	5.5H ₂ O	Green-blue needles	150	0.038	Cu, 9.16	8.86

^a Prepared from the free acid and potassium carbonate. ^b Prepared from the free acid and the metallic hydroxide. ^c Prepared from the ammonium salt and copper chloride. ^d Lost its water of crystallization at 110°. ^e Grams of anhydrous salt per 100 g. of water at 17°.

Methyl Ester.—Prepared by boiling the dried potassium salt with dimethyl sulfate. yield, 50.3%. Recrystallization from methyl alcohol gave small scales, m. p. 85–86°;

Anal. Calcd. for C₁₀H₂₂SO₃: C, 69.04; H, 6.71. Found: C, 68.72; H, 6.71.

Ethyl Ester.—Prepared by boiling the dried potassium salt with diethyl sulfate; yield, 82.3%. Recrystallization from ethyl alcohol gave long, colorless prisms, m. p. 78–79°.

Anal. Calcd. for C₂₀H₂₄SO₃: C, 69.71; H, 7.03. Found: C, 69.53; H, 7.10.

The ethyl ester was oxidized by chromic acid in a manner similar to that used for the oxidation of the corresponding A-derivative. Orange colored needles were obtained, m. p. 169–171°; yield, 58.5%. The crystals exhibited complete identity in physical properties and appearance with the ethyl B-retenequinonesulfonate obtained by oxidizing ethyl B-retenesulfonate. A mixed melting point test of the two oxidation products showed no depression of the melting point. The substance was difficultly combustible.

Anal. Calcd. for C₂₀H₂₀SO₅: C, 64.48; H, 5.42. Found: C, 64.10, 64.18; H, 5.40, 5.56.

Chloride.—Prepared by treating anhydrous potassium B-dihydroretenesulfonate with phosphorus pentachloride in the presence of phosphorus oxychloride, as in the case of the corresponding A-derivative; yield, 74.1%. Recrystallization from benzine gave yellowish, symmetrical crystals, m. p. 112–113°.

Anal. (Carius). Calcd. for C₁₈H₁₉SO₂Cl: Cl, 10.60; S, 9.58. Found: Cl, 10.72; S, 9.93.

Amide.—Obtained as small scales, m. p. 189–190°, from the chloride and ammonium hydroxide.

Anal. Calcd. for C₁₈H₂₁SO₂N: N, 4.44. Found: N, 4.10.

Anilide.—Prepared in a manner similar to that used for the preparation of the corresponding A-derivative. The anilide crystallized from alcohol in shining scales, m. p. 196–197°.

Anal. Calcd. for C₂₄H₂₅SO₂N: N, 3.58. Found: N, 3.58.

Attempted Preparation of B-Dihydroretenol.—All attempts to replace the sulfonic acid group of potassium B-dihydroretenesulfonate, by means of alkali fusions, with the hydroxy group resulted in the formation of B-retenol. The yields were uniformly low, 8.5% from a fusion carried out in the usual manner. After two crystallizations from alcohol-water, slightly yellowish scales of B-retenol, m. p. 158–159°, were obtained. The B-retenol was identified by means of its acetyl and benzoyl derivatives.

Retene Derivatives, A-Series

Ethyl A-Retenesulfonate.—Prepared from ammonium A-retenesulfonate and diethyl sulfate; yield, 61.7%; small, colorless leaflets, m. p. 137.5–138.5°.

Anal. Calcd. for $C_{20}H_{22}SO_3$: C, 70.12; H, 6.48. Found: C, 69.91; H, 6.52.

A-Retenesulfonyl Chloride.—Prepared from ammonium A-retenesulfonate, phosphorus pentachloride and phosphorus oxychloride; yield, 78.6%. Recrystallization from ether gave light yellow scales, m. p. 135–136°.

Anal. (Carius). Calcd. for $C_{18}H_{17}SO_2Cl$: Cl, 10.66; S, 9.64. Found: Cl, 10.52; S, 9.40.

Ethyl A-Retenequinonesulfonate.—Ethyl A-retenesulfonate was oxidized by chromic acid in a manner similar to that used for the oxidation of the corresponding dihydro derivative; yield, 39.4%. When crystallized from glacial acetic acid, small light orange yellow needles, m. p. 183–184°, were obtained. This substance, as was stated previously was identical with the product obtained by oxidizing ethyl A-dihydroretenesulfonate.

Action of Aqueous Potassium Hydroxide on Potassium A-Retenequinonesulfonate.—Potassium A-retenequinonesulfonate (6.8 g.) obtained from A-retenesulfonic acid, was boiled for three hours with about 120 cc. of a 50% solution of potassium hydroxide. The product was cooled and filtered. The residue was washed with water and dried on a porous plate. The light yellow product (5.5 g.) was separated by repeated recrystallization from aqueous alcohol into two fractions.

Fraction 1.—The more easily soluble portion, canary yellow in color, comprised about three-fifths of the original material. Analysis gave values which agreed with those calculated for potassium retene ketone sulfonate. Calcd. for $C_{17}H_{15}O_4SK$: C, 57.58; H, 4.27; K, 11.04. Found: C, 57.53; H, 4.56; K, 10.92. Esterification with diethyl sulfate resulted in the formation of small needles, m. p. 130°, insufficient in quantity for an analysis.

Fraction 2.—The more difficultly soluble portion consisted of an apparently crystalline light yellow powder. Analysis gave no conclusive evidence as to the composition of this product. After fusion with potassium hydroxide an acid which crystallized from benzene in the form of small scales melting at 160° was obtained. Analysis gave values which agreed with those calculated for methyl isopropyl diphenylmonocarboxylic acid. Calcd. for $C_{17}H_{18}O_2$: C, 80.27; H, 7.14. Found: C, 80.00; H, 7.16. The acid was titrated with *N*/10 potassium hydroxide: calcd. for 0.0637 g. $C_{16}H_{17}COOH$, 2.51 cc.; found, 2.30 cc.

A-Methoxyretene ($CH_3OC_{18}H_{17}$).—Prepared by heating an alcoholic solution of A-retenol and dimethyl sulfate in the presence of sodium hydroxide; yield, 63.1%. Crystallization from alcohol gave colorless needles melting at 147–148°.

Anal. Calcd. for $C_{19}H_{20}O$: C, 86.31; H, 7.63. Found: C, 86.29; H, 7.78.

A-Benzoxyretene ($C_6H_5COOC_{18}H_{17}$).—Prepared from A-retenol and benzoyl chloride in pyridine solution; yield, 57.4%. When crystallized from alcohol the benzoyl derivative was obtained in the form of tufts of needles, moderately soluble in ether and melting at 177–178°.

Anal. Calcd. for $C_{25}H_{22}O_2$: C, 84.70; H, 6.26. Found: C, 84.84; H, 6.34.

Retene Derivatives, B-Series

Ethyl B-Retenesulfonate.—Prepared from ammonium B-retenesulfonate and diethyl sulfate; yield, 87.1%. Crystallization from alcohol gave small pointed scales, m. p. 114–115°.

Anal. Calcd. for $C_{20}H_{22}SO_3$: C, 70.12; H, 6.48. Found: C, 69.93; H, 6.54.

Ethyl B-Retenequinonesulfonate.—Ethyl B-retenesulfonate was oxidized in glacial acetic acid solution with chromic acid. Recrystallization of the oxidation product from glacial acetic acid gave small, orange colored needles, identical with those obtained by the oxidation of ethyl B-dihydroretenesulfonate, but distinctly darker than those obtained from the corresponding A-derivative.

Action of Aqueous Potassium Hydroxide on Potassium B-Retenequinonesulfonate.—A mixture of 7.6 g. of potassium B-retenequinonesulfonate and 40 cc. of 50% aqueous potassium hydroxide was refluxed for forty-five minutes. After cooling, the insoluble part was filtered off, washed with water and dried on a porous plate. Crystallization from alcohol gave sulfur-yellow flat prisms, m. p. 88–89°. Analysis gave values which agreed with those calculated for retene ketone, $C_{17}H_{16}O$; yield, 3 g. (62.2%). Calcd. for $C_{17}H_{16}O$: C, 86.39; H, 6.83. Found: C, 86.59; H, 6.60. For further identification the substance was reduced in alcohol solution by means of zinc dust in the presence of ammonium hydroxide. The retenefluorenyl alcohol thus obtained as pointed colorless scales, m. p. 132–133°, was analyzed. Calcd. for $C_{17}H_{18}O$: C, 85.66; H, 7.62. Found: C, 86.03; H, 7.41.

B-Benzoxypyrene ($C_{26}H_{18}O$).—Prepared from B-retene and benzoyl chloride in pyridine solution; yield, 58.8%. Crystallization from alcohol gave well-developed plates, m. p. 112°.

Anal. Calcd. for $C_{26}H_{18}O$: C, 84.70; H, 6.26. Found: C, 84.72; H, 6.38.

Summary

The stability and aromatic character of dihydroretene as well as the similarity to retene in behavior has been studied.

Sulfonation gave two well-defined sulfonic acids which were isolated by means of their potassium salts. These were used in the preparation of a number of derivatives. In general they exhibited marked similarity in mode of preparation and in properties with the previously known A- and B-retenesulfonic acids. Oxidation of the ethyl esters of the A- and B-dihydroretenesulfonic acids resulted in the formation of the corresponding ethyl A- and B-retenequinonesulfonates. This showed that the sulfonic acid group had entered similar positions in the two hydrocarbons. Attempts to replace the sulfonic acid group of A- and B-dihydroretenesulfonic acid by the hydroxy group resulted in simultaneous dehydrogenation and consequent formation of the corresponding retenols.

For the purpose of comparison a number of additional derivatives of retene were prepared. The action of boiling aqueous potassium hydroxide on the potassium retenequinonesulfonates was studied. Retene ketone was obtained in good yield from potassium B-retenequinonesulfonate.

A new crystalline hydrocarbon, $C_{24}H_{20}$, m. p. 297–298° (uncorr.), occurring in small quantities with retene in the highest boiling fractions of pine tar, was isolated.

Although honey's chief characteristic does not appear to be the quantity of mineral matter which it contains, yet two reasons suggest themselves why there is need for more information on its inorganic constituents than is now available. One centers around the newer emphasis placed by students of nutrition on the value of manganese and copper in the diet, the other around the present practice in merchandizing this saccharine food which reaches the consumer in its natural state, that is not refined by any manufacturing processes.

It is not required that honey be sold in interstate commerce on the basis of floral source. This is a matter which is left to the discretion of the several states. Rather it must bear a grade in which color, appearance and freedom from generally recognized disagreeable flavors are given predominant consideration. To that end there have been adopted such color designations as *white*, modified when necessary to indicate lighter tints by the words *water* or *extra*; *amber*, likewise qualified to differentiate the lesser pigmented members of this group by the terms *extra light* or *light*; whereas the adjective *dark* is reserved for the most heavily pigmented honeys.

Although it is perhaps suspected by those conversant with the chemistry of honey that, as between a deeply pigmented product and one less so, the mineral content of the former will in general exceed that of the latter, yet no published reference to this situation has apparently been made heretofore. Be that as it may, however, color and quality often bear an inverse relationship to each other in the lay mind. For this reason it seemed worth while to seek quantitative data in support or contradiction of this circumstance for it would follow, on *a priori* grounds at least, that a deeply pigmented honey ought to be deemed superior to one of light color from the standpoint of nutritive value if the mineral content of the former should prove to be higher. On making an analysis of the ash of twenty-two floral nectar and honey-dew honeys which had been selected at random from widely separated localities in this country in order to reduce any suggestion of accidental results, such was actually found to be the case. This observation in itself is not presented as novel, rather the fact that iron, copper and manganese appear to predominate in the mineral matter of dark honeys.¹

¹ A line of demarcation has been arbitrarily drawn between the *white* honeys, typified by those from clover or alfalfa and probably indicative of the layman's conception of a light colored product, and the *light amber* honeys as representing the dark

A search of the literature of the past three decades reveals that, although data on the total mineral content of honey are plentiful, yet comparatively few are available with respect to the aforementioned elements.²⁻⁸ Gottfried² has already called attention to the probable existence of a relationship between the manganese content and the albuminoids of honey. Lindow and his colleagues⁶ in this country and Svoboda in Czechoslovakia are probably among the first to report the presence of copper in this food though unfortunately their records do not reveal a description of the material under examination. Fehlmann³ found silica in several Swiss honeys and advanced the opinion that its presence there was purely adventitious. Sundberg and Lundgren⁷ also reported it as present in the honeys of Swedish origin which they examined. An inspection of their data shows that there is apparently a progression in the silica content of their samples with an increasing depth of color. Existing data for iron^{3,4,7,8} with the probable exception of those of Elser⁴ and his Swedish contemporaries,⁷ do not lend themselves very well to a similar analysis.

Experimental

Material.—With four exceptions (marked by an asterisk in Table I) all samples were obtained in the comb and extracted in the laboratory. As for the others, there was no apparent reason for assuming that they had been extracted in the apiary under conditions leading to the introduction of extraneous metal or mineral matter.

Ashing of Samples.—Weighed amounts of honey in approximately 75-g. portions were first evaporated in large platinum dishes on a hot-plate until substantially all of the water had been driven off. The resulting honey solids were then carbonized over an open flame, after which they were reduced to an ash in an electrically heated muffle furnace whose temperature was kept at a dull redness. The top and sides of the furnace were lined with sheet platinum for the purpose of preventing contamination of the contents of the dishes.

Inasmuch as the determinations of silica were to be made macrochemically it was, therefore, desirable to obtain fairly large mineral residues, and this was only possible by ashing more material than is the usual practice. To that end three to eighteen portions of each honey, depending upon the material available, were separately incinerated, the weight of the respective residues being noted. It was found that the average deviations in the determination of the ash by this mode of procedure lay between ± 0.0008 and $\pm 0.006\%$ for the entire series.

Determination of Silica.—Silica was determined in the usual way, that is, treatment of the ash with 10 cc. of hydrochloric acid (1 + 1), evaporation of the whole to dryness and the addition to the residue of 5 cc. of 1 *N* hydrochloric acid and a like volume of

ones, this group herein being headed by those in which Spanish needle is the predominant floral source.

water, and finally digestion of the mixture for thirty minutes on a water-bath, solution of the soluble constituents in hot water and filtration. The combined filtrates and washings from all the ash portions of each sample were evaporated to dryness, after which the residue was treated as before, the filtrate this time being made up exactly to 100 cc. The silica was volatilized as the tetrafluoride. After corrections were made for the blank on the reagents, a practice which was followed throughout this investigation, the silica content was calculated on the basis of mg. per kilo of honey and per cent. of the ash.

Determination of Iron.—Iron analyses were made colorimetrically by the ferric thiocyanate procedure⁹ with application of the technique of Kennedy,¹⁰ who suggested that the reaction product be extracted with amyl alcohol. Aliquots for analysis were chosen to fit the needs of the individual honeys, sample weights lying between 6 and 24 g. representing the limits employed for the whole series. The volume of standard solution which was used for comparison contained 0.04 mg. of iron. Data obtained in the determination of this and the succeeding elements are reported on the same basis as is the silica content.

Determination of Copper.—The Elvehjem and Lindow modification¹¹ of the potassium thiocyanate-pyridine procedure¹² was used for the determination of copper.

TABLE I

ASH, SILICA, IRON, COPPER AND MANGANESE CONTENT OF LIGHT AND DARK HONEYS

Predominating floral source	Origin	Silica		Iron		Copper		Manganese	
		Ash, %	mg. per kg.	% of ash	mg. per kg.	% of ash	mg. per kg.	% of ash	mg. per kg.

The range of sample weights used lay between 23 and 124 g. Their copper content was checked by means of a colorimeter against a reference solution containing 0.02 mg. of this element.

Determination of Manganese.—Manganese determinations were made by the periodate method of Willard and Greathouse¹³ with certain modifications in procedure as suggested by Peterson and colleagues.^{14,15} The method in question rests upon the comparison of color intensities of the permanganate ion. Aliquot portions of the several ash solutions, representing not less than 35 g. nor more than 228 g. of sample, were taken for comparison with a standard potassium permanganate solution, the volume of the latter being determined by the individual needs of the sample, but in every instance containing 0.05 mg. of manganese or a multiple thereof up to 0.2 mg.

Discussion

It is evident that the ash content and degree of pigmentation apparently bear some relationship to each other, for the dark honeys were found to contain more mineral matter than the light colored ones. Quantitative relationships with respect to these two major color differences cannot be set up, of course, because of the fact that honey is seldom derived exclusively from the nectar of one species of flower. But even with this limitation the general conclusion finds corroboration in the data of Browne¹⁶ which, when subjected to a similar analysis, also reveal the fact that the light colored honeys which he examined contained less mineral matter than did the dark ones. This correlation of data cannot be extended beyond this point for analyses were not made to include manganese and copper since the clinical advantages of the presence of these elements in the diet were unknown at that time. A parallel is found, however, when more recent data, reported by foreign investigators, are reinterpreted. The data of Sundberg and Lundgren,⁷ for example, although limited to seven samples, show the same trend in the silica, iron and manganese content of dark honeys in contrast to lesser pigmented ones. Similarly, this condition obtains in the iron and manganese data of Elser,⁴ who examined honeys grown in Switzerland.

It is also significant that this preponderance of total mineral matter in the dark colored honeys is reflected both in the average and in the maximum quantities of the constituent elements thereof (Table II). The order of magnitude of the minima is also larger except for the silica content and probably, too, the iron, yet in the latter case comparisons appear hardly valid because of the unequal number of analyses in both groups.

It is indeed an interesting observation that buckwheat honey, which in the competition for consumer preference and price is often handicapped

^a Per cent., other constituents in terms of mgs. per kg.

by its dark color and a not so delicate flavor, should contain, in comparison with clover and alfalfa honeys, strikingly more manganese and copper.

An explanation for the conditions which are noted above may conceivably be found in the suggestion that the characteristics and flavor of honey are influenced to a marked degree by nectar and pollen. They, in turn, may very well vary in composition and quality according as the plant which produced them is affected by such growth factors as the meteorological conditions prevailing in its habitat and the nature and fertility of the soil, as it possesses some peculiar ability to utilize nutrient materials or thrives because of some unique mineral requirements.

These studies on honey pigmentation will be continued in the hope of ascertaining whether or not any relationship exists between pollen and mineral content, particularly manganese. The observation of Famintzin and Przybytik¹⁷ that the ash of the pollen of the pine, *Pinus sylvestris*, contains this element will be made the point of departure in extending this search to the pollens of those plant species which serve as sources of honey.

Summary

Data have been presented in support of the hypothesis that there apparently exists in honey a relationship between the degree of pigmentation and the quantity of mineral matter, notably manganese and copper, which it contains.

THE CONSTITUTION OF STÄDELER'S TYROSINE SULFONIC ACID

BY FREDERICK R. CONKLIN¹ AND TREAT B. JOHNSON

RECEIVED FEBRUARY 24, 1932

PUBLISHED JULY 6, 1932

When proteins are nitrated, or halogenated, one definite point of attack in the molecule is the phenol nucleus of the aromatic amino acid tyrosine combined in the protein. Oswald² isolated from the hydrolysis products of several iodinated proteins the amino acid diiodotyrosine, which was shown to be identical with the iodine derivative obtained by direct iodination of tyrosine, and whose constitution was established by Wheeler and Johns.³ Inouye's⁴ observation that one of the hydrolytic products of nitrated silk fibroin is mono-nitrotyrosine was confirmed by the work of Johnson, who also established the constitution⁵ of this tyrosine derivative.

Regarding the nature of the products of hydrolysis of sulfonated proteins we have very little knowledge outside of the data contributed by the early work of Müller⁶ and Loew.⁷ The sulfonic acids resulting from treatment of proteins with sulfuric acid are usually obtained as amorphous substances with a varying content of sulfur, and it has been assumed that the change brought about by the action of this reagent involves a substitution in the aromatic nucleus of the amino acids, phenylalanine and tyrosine. No sulfonic acid derivative of either of these two amino acids has been identified, however, among the products formed by hydrolysis. In addition, while both of these amino acids have been shown to interact with sulfuric acid with formation of definite sulfonic acids,⁸ the constitution of these respective substitution products has not been established with certainty.

We have now repeated the experiments of Städeler, who investigated the action of sulfuric acid on tyrosine in 1860, and have developed a practical method for preparing a definite mono-sulfonic derivative of this amino acid. It is easily obtained in excellent yield, and in a crystalline condition, and this acid obtained by our method is undoubtedly identical with the tyrosine-sulfonic acid originally described by Städeler. We did not obtain

any evidence of the formation of a disulfonic acid derivative of tyrosine corresponding in structure to dinitrotyrosine or diiodotyrosine.

Of the two mono-sulfonic acid derivatives theoretically possible of formation by the action of sulfuric acid on tyrosine, namely, 2- and 3-sulfotyrosines, we now conclude that the acid described by Städeler is to be represented structurally by formula I. This was established by the fact that it interacts smoothly with nitric acid to form 3,5-dinitrotyrosine II with complete substitution of the sulfonic acid group by a nitro radical.

While it would be of interest to establish the presence of this acid I among the products of hydrolysis of a sulfonated protein, we have not made any serious attempts to accomplish such a separation. We are more especially interested at present in the possibility of utilizing tyrosine-3-sulfonic acid as the source of new types of pressor-bases, and for preparing other aromatic derivatives of immediate biochemical interest. The study of this compound is being continued.

Experimental Part

Preparation and Properties of Tyrosine-3-sulfonic Acid.⁹—

Ten grams of pure crystallized tyrosine is thoroughly mixed with 32.5 g. (six mols) of cold concentrated sulfuric acid. The sulfonation starts immediately on adding tyrosine to the acid and the temperature of the mixture rises quickly to 55°. After the mixture is prepared, it is heated in an oil-bath at a temperature of 95–100° for one hour, and with constant stirring to insure uniformity of reaction. The acid solution is then cooled and poured into 800 cc. of cold water and the sulfuric acid removed quantitatively as barium sulfate by addition of barium hydroxide. After separation of the barium sulfate by filtration, the filtrate and washings are combined and finally concentrated under reduced pressure to a volume of about 70 cc. and this then allowed to stand in an ice chest. A portion of the tyrosine sulfonic acid will crystallize in the form of colorless fine needles. These were separated and the solution concentrated further to 30 cc. in volume and another crop of the pure sulfonic amino acid obtained. The total yield of the sulfonic acid obtainable by crystallization is about 90% of the theoretical. If crystallization is hurried by quick chilling of the solution the tyrosine sulfonic acid always separates in an amorphous condition. Tyrosine sulfonic acid exhibits the characteristic property of forming supersaturated solutions when dissolved in water and consequently the purification of the acid by crystallization is very slow.

Anal. Calcd. for $\text{C}_9\text{H}_{11}\text{O}_6\text{NS}$: N, 5.36; S, 12.25. Found: N, 5.33; S, 12.50.

Tyrosine-3-sulfonic acid shows no definite melting point but chars and decomposes

⁹ The authors are indebted to the Cheney Brothers, Silk Manufacturers of South Manchester, Connecticut, for the supply of silk fibroin which was used in our research for the preparation of tyrosine.

rapidly when heated above 280°. It is insoluble in cold water, gives an opaque solution when digested with a large volume of boiling water, and also dissolves in warm methyl alcohol. The acid separates from methyl alcohol in an amorphous form when the solvent is evaporated, and it also separates from its aqueous solution in a similar form if the crystallization is hurried. The acid gives a deep violet coloration with ferric chloride solution, and also reacts with Millon's reagent to give a characteristic pink color. The barium, sodium and potassium salts are all amorphous substances which are very soluble in water. Attempts to bring about a reaction with potassium cyanate and phenyl isocyanate were unsuccessful. In other words, the characteristic reactivity of the tyrosine molecule is completely changed by introduction of the sulfonic acid group. The basicity of the α -amino radical is masked by the presence in the molecule of the three negative groupings—OH, SO₃H and COOH.

The Formation of 3,5-Dinitrotyrosine II from Tyrosine-3-sulfonic Acid.—Twenty-two grams of concentrated sulfuric acid is mixed with 3 g. of concentrated nitric acid and the liquid cooled to 5°. Three grams of tyrosine-3-sulfonic acid is then added to this mixed acid in small portions with constant shaking over a period of twenty minutes. The sulfonic acid dissolves completely, giving a light orange-colored solution and the temperature rises to about 25°. After completion of the nitration the acid mixture is poured into 800 cc. of cold water and the sulfuric acid quantitatively removed as barium sulfate. The resulting solution is then made strongly alkaline by addition of ammonia and concentrated to a volume of about 10 cc. under reduced pressure. A brick-red crystalline precipitate of an ammonium salt is obtained which is decomposed by washing with dilute hydrochloric acid. This treatment gave a crystalline substance which was identified as the hydrochloride of 3,5-dinitrotyrosine. It crystallized from hot water in beautiful yellow plates melting with effervescence at 230°. It did not respond to a test for sulfur. The yield of purified acid was about 1.0 g. The identity of this compound was established by comparison with a sample of the hydrochloride of 3,5-dinitrotyrosine prepared by Johnson and Kohmann⁵ in 1915. There was no change in melting point when a mixture of the two salts was heated in a capillary tube. It is of interest to note here the stability of this nitration product of tyrosine. The 3,5-dinitrotyrosine hydrochloride prepared by Johnson and Kohmann actually showed no change in melting point after storage in the laboratory for sixteen years.

Anal. Calcd. for C₉H₉O₇N₃·HCl: N, 13.60; Cl, 11.54. Found: N, 13.55; Cl, 11.60.

This formation of dinitrotyrosine is another outstanding example of the easy replacement during nitration of a sulfonic acid group by the nitro radical. This interchange of sulfonic and nitro groups has been observed previously by several investigators.¹⁰

While tyrosine-3-sulfonic acid interacts smoothly with nitric acid with replacement of the sulfonic radical by a nitro group, an attempt to bring about a corresponding conversion into 3,5-dibromotyrosine¹¹ by the action of bromine was unsuccessful. This technique of establishing structure of aromatic compounds has been applied with success in other cases by several workers.¹²

¹² Datta and Bhoomik, *THIS JOURNAL*, **43**, 303 (1921); Sakellarios, *Ber.*, **55**, 2845 (1922); Sudborough, *J. Chem. Soc.*, **111**, 41 (1910); Elgersma, *Rec. trav. chim.*, **48**, 759 (1929); Suter, *THIS JOURNAL*, **53**, 1112 (1931).

An attempt was also made to establish the constitution of tyrosine-3-sulfonic acid by conversion into a cinnamic acid derivative through deamination by digestion with methyl iodide and potassium hydroxide. This transformation is not accomplished without complete degradation of the greater part of the sulfonic acid. We did succeed in obtaining a small quantity of the desired cinnamic acid derivative, $\text{HO}_3\text{S}(\text{OH})\text{C}_6\text{H}_3\text{CH}=\text{CHCOOH}$ in the form of its potassium salt, but the quantity formed was so small that this method of operating proved of no practical utility. This potassium salt was purified by crystallization from water. It reacted with concentrated sulfuric acid to give a red colored solution, but did not give color reactions when treated with ferric chloride solution or Millon's reagent. It had no definite melting point.

Anal. Calcd. for $\text{C}_{10}\text{H}_9\text{O}_6\text{SK}$: S, 10.80. Found: S, 10.66, 10.9.

Summary

1. When tyrosine is allowed to react with sulfuric acid at 95–100° it is converted smoothly into tyrosine-3-sulfonic acid.
2. The structure of this acid is established by the fact that it is converted into 3,5-dinitrotyrosine by the action of nitric acid.

NEW HAVEN, CONNECTICUT

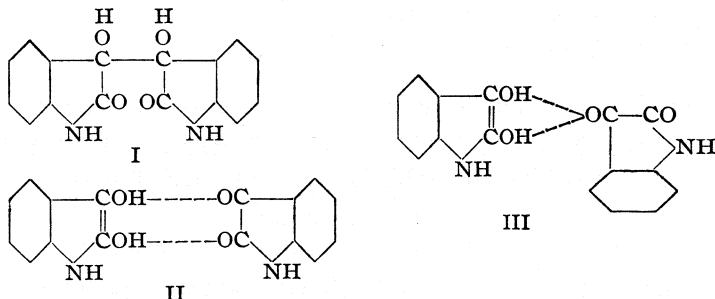

[CONTRIBUTION FROM THE DEPARTMENT OF CHEMISTRY OF THE COLLEGE OF THE OZARKS] SOME OBSERVATIONS CONCERNING THE STRUCTURE OF ISATIDE

By WARD C. SUMPTER

RECEIVED FEBRUARY 29, 1932

PUBLISHED JULY 6, 1932

The isatin pinacol formula for isatide, I, proposed by Kohn¹ and by Lefèvre,² has been disputed by Heller.³ Heller regards isatide as being a quinhydrone type of compound, II or III.

Isatide is best prepared by condensing isatin with dioxindole in alcoholic solution in the presence of piperidine. The condensation of a substituted dioxindole with isatin and of a substituted isatin with dioxindole should give rise to two different isatides if the quinhydrone formulation is correct.

¹ Kohn, *Ber.*, **49**, 2514 (1916); Kohn and Klein, *Monatsh.*, **33**, 929 (1912); Kohn and Ostersetzer, *ibid.*, **37**, 25 (1916).

² Lefèvre, *Bull. soc. chim.*, **19**, 113 (1916).

³ Heller, *Ber.*, **49**, 1406 (1916); Heller and Lauth, *ibid.*, **62**, 343 (1929).

Wahl and Faivret⁴ obtained a 5-methylisatide by condensing dioxindole with 5-methylisatin. The condensation of 5-methyldioxindole with isatin gives the same 5-methylisatide. This fact precludes acceptance of the quinhydrone formulation and strongly supports the symmetrical isatin pinacol formula.

Experimental

5-Methylisatide. A. From 5-methylisatin and dioxindole, Method of Wahl and Faivret.—Ten drops of piperidine was added to a solution of 1.9 g. of dioxindole and 2 g. of 5-methylisatin in 50 cc. of 95% ethyl alcohol and the whole heated on the water-bath under a reflux condenser for one hour. After cooling the precipitate was filtered off and washed repeatedly with small portions of alcohol. The straw colored powder so obtained could not be crystallized from any of the usual organic solvents. The yield was 3.1 g. or 81% of the theoretical. The substance softened at about 220° and melted with decomposition at 228–230°. Wahl and Faivret reported 229–230°.

B. From Isatin and 5-Methyldioxindole.—The procedure was identical with that described above. The substance softened at about 220° and melted with decomposition at 227–230°. A mixture of this substance with the 5-methylisatide prepared from dioxindole and 5-methylisatin melted with decomposition at 227–230°. The yield was 3 g. or 79% of the theoretical.

The writer is indebted to the Dow Chemical Co. for the gift of a generous supply of indigo from which the isatin and dioxindole used in this work were prepared.

Summary

The condensation of 5-methyldioxindole with isatin yields the same 5-methylisatide obtained by Wahl and Faivret from 5-methylisatin and dioxindole. In the light of this fact the unsymmetrical quinhydrone formulation for isatide is untenable. The isatin pinacol formula is probably correct.

THE NUMBER OF STRUCTURAL ISOMERS OF CERTAIN HOMOLOGS OF METHANE AND METHANOL

BY DOUGLASS PERRY

RECEIVED MARCH 4, 1932

PUBLISHED JULY 6, 1932

A very ingenious general method for determining the number of structurally isomeric paraffin hydrocarbons has been published recently.¹ The purpose of this article is to extend the results previously given by applying this method to the computation of the number of structural isomers of hydrocarbons of the methane series of carbon contents ranging from twenty to forty, inclusive, and of hexacontane.

In order to calculate the number of structural isomers of a given paraffin hydrocarbon by the method referred to above, it is first necessary to know

¹ Henze and Blair, *THIS JOURNAL*, **53**, 3077 (1931).

the numbers of all structurally isomeric alcohols of the methanol series of carbon content not exceeding one-half that of the hydrocarbon. Table I represents the number of structurally isomeric saturated monohydric alcohols containing from twenty to thirty carbon atoms per molecule, computed according to the method of Henze and Blair,² and augments the values listed by them.

TABLE I
THE NUMBER OF STRUCTURALLY ISOMERIC HOMOLOGS OF METHANOL

Carbon content	Primary	Secondary	Tertiary	Total
21	5,622,109	5,806,256	3,287,448	14,715,813
22	14,715,813	15,256,265	8,677,074	38,649,152
23	38,649,152	40,210,657	22,962,118	101,821,927
24	101,821,927	106,273,050	60,915,508	269,010,485
25	269,010,485	281,593,237	161,962,845	712,566,567
26	712,566,567	747,890,675	431,536,102	1,891,993,344
27	1,891,993,344	1,990,689,459	1,152,022,025	5,034,704,828
28	5,034,704,828	5,309,397,294	3,081,015,684	13,425,117,806
29	13,425,117,806	14,187,485,959	8,253,947,104	35,866,550,869
30	35,866,550,869	37,977,600,390	22,147,214,029	95,991,365,288

The inverse ratios of consecutive numbers in the last column are very nearly constant, but always slightly increasing, and possess ever diminishing first differences. Assuming that the numbers in the last column are in geometric progression, and extrapolating the value of the average common ratio over the carbon content interval from 30 to 35, the number of structurally isomeric alcohols of the formula $C_{35}H_{71}OH$ can be estimated as: $T_{35} = (2.688)^5 T_{30} = 1.35 \times 10^{13}$. Taking the average common ratio over the carbon content interval from 30 to 40 as 2.695, by a similar computation the corresponding value for $C_{40}H_{81}OH$ is 1.94×10^{15} .

Table II contains the number of structurally isomeric hydrocarbons of the methane series, and supplements the results previously found.³ The

TABLE II
THE NUMBER OF STRUCTURALLY ISOMERIC PARAFFINS

Carbon content	Number of isomers	Carbon content	Number of isomers
19	148,284	31	10,660,307,791
21	910,726	32	27,711,252,769
22	2,278,658	33	72,214,088,660
23	5,731,580	34	188,626,236,139
24	14,490,245	35	493,782,952,902
26	93,839,412	36	1,295,297,588,128
27	240,215,803	37	3,404,490,780,161
28	617,105,614	38	8,964,747,474,595
29	1,590,372,121	39	23,647,478,933,969
		60	22,158,734,535,770,411,074,184

² Henze and Blair, *THIS JOURNAL*, **53**, 3042 (1931).

³ Ref. 2, p. 3084.

number of isomers of $C_{19}H_{40}$ was found to be in error, and the correct value is here given. As in the case of the alcohols, the numbers of structurally isomeric hydrocarbons also form an approximate geometric progression. Here again the inverse ratios of successive numbers are always slightly increasing, and have decreasing first differences. The extrapolated average inverse ratio of consecutive numbers over the carbon content interval from 60 to 70 is 2.72, and hence the value for $C_{70}H_{142}$ is approximately 4.91×10^{26} .

Several corrections are to be noted in the original papers by Henze and Blair. On line 2, p. 3045, for " $(n-1)6$ an integer," read $(n-1)/6$ an integer. In the discussion of the number of hydrocarbons of even carbon content of group A, p. 3080, line 19, the factor $1/2$ should be inserted to make the formula read correctly. This remark also applies to the formula for hydrocarbons of odd carbon content resulting from joining alkyls of $(N+1)/2$ and $(N-1)/2$ carbon atoms through an intermediate carbon atom, p. 3080, line 36. In group B, type b, Case 2, page 3082, line 23, it might be well to mention explicitly that j and k cannot interchange values, which may be expressed by requiring that j always exceed k . For completeness, it may be added that in the formula for compounds of odd carbon content of Group A, it is implied that the definition of T_0 is unity. These corrections apply to the references noted, but were correctly applied in the computations of the authors.

MOLECULAR REARRANGEMENT IN THE HYDROLYSIS OF CHLOROTOLUENES WITH ALKALI

By V. E. MEHARG AND IVEY ALLEN, JR.

RECEIVED MARCH 8, 1932

PUBLISHED JULY 6, 1932

It is known that molecular rearrangement takes place when ortho or para chlorobenzene sulfonic acid is fused with potash, both compounds yielding resorcinol by this treatment.¹ It now appears that such a rearrangement may be general with halogen substituted benzenes carrying aliphatic side chains. We have carried out a number of experiments on the hydrolysis of substituted chlorobenzenes carrying normal aliphatic side chains and have been singularly unsuccessful in obtaining pure products. This was particularly apparent in the case of the products obtained from the hydrolysis of ortho and para chloro substituted derivatives of ethylbenzene, normal butylbenzene, and normal amylbenzene. These compounds are not adequately described in the literature and the phenols derived from them have been described² but there are no quantitative methods for purifying

¹ Beilstein, 4th ed., Vol. VI, p. 796.

² Coulthard, Marshall and Pyman, *J. Chem. Soc.*, 280 (1930).

them in the presence of their isomers. The para substituted phenols in general have higher melting points than the corresponding ortho and meta derivatives but usually are very close to the meta derivatives in boiling point and many other properties. The fact that in some cases where we expected to obtain the para compounds the product, when purified by careful fractional distillation, distilled at almost exactly the correct point and yet failed to crystallize on cooling led us to believe that the meta isomer might be present as an impurity. A comparison of the properties of the product derived from *p*-ethylchlorobenzene with a sample of *p*-ethylphenol from another source seemed to confirm this explanation.

As a final check on the above we have carried out the hydrolysis of *o*- and *p*-chlorotoluenes in sodium hydroxide at temperatures above 300° and found *m*-cresol to be present in the product from each. The hydrolyses were carried out in a manner similar to that used by Meyer and Bergius³ for the hydrolysis of chlorobenzene. These authors state that *p*-cresol is easily obtained from chlorotoluene, but do not state which chlorotoluene. In our experiments the purified phenolic portion from the *o*-chlorotoluene showed a *m*-cresol content of 25.3% and that from the para 38.2%. There was some slight evidence that all three cresols were present in each case but our method of analysis was not sufficiently accurate to detect small amounts of ortho and para. A slightly modified Raschig nitration method⁴ was used for the meta determinations. This has been checked thoroughly in this and other laboratories and can be relied upon with certainty to give results accurate to 2% of the true value under our conditions.

Experimental

Hydrolysis of Chlorotoluenes.—The autoclave was 61 cm. long by 7 cm. inside diameter, and was fitted with a thermocouple well and flexible connections to a pressure gage and relief valve. It was made of carbon steel and the capacity was about 2.2 liters. It was heated electrically and was mounted on a shaking machine. The *o*- and *p*-chlorotoluenes used were obtained from the Eastman Kodak Company and were not given any further purification before use. The para compound had a freezing point of 7.1°. The melting point is given in the literature as 6.5–7.5°.

One hundred twenty-six grams (one mole) of *o*-chlorotoluene, 1332 g. (5 moles) of 15% sodium hydroxide, and 10 g. of freshly reduced copper powder were heated together for two hours at 315–320°. The shaking machine was run intermittently (five minutes on, ten minutes off). About two hours was required to raise the reaction mixture to the required temperature and a somewhat longer time for it to cool. When cold the contents were removed from the autoclave and extracted with ether. The water layer was then acidified and again extracted. The yield of crude alkali-soluble material was 60 g. *p*-Chlorotoluene treated in the same manner yielded 63 g. of crude product.

The greater part of the products from each of the runs described above was fractionated through a column of good efficiency built to handle small amounts of material. The data from the distillations and analyses were:

³ Meyer and Bergius, *Ber.*, **47**, 3155 (1914).

⁴ *Z. angew. Chem.*, **31**, 759 (1900).

	From <i>o</i> -chlorotoluene	From <i>p</i> -chlorotoluene
Still charge	32.9 g.	40.0 g.
Fraction 197–202°	9.7 g.	26.8 g.
Fraction 202–235°	0.4 g.	0.5 g.
Total distillate 182–235°	25.9 g.	30.2 g.
Meta cresol in 197–202° cut	67.5%	43.1%

When these results are calculated back to the total crude yields (parts of which were used for another purpose) we find that *o*-chlorotoluene yielded 55.4% of pure mixed phenols, calculated as cresol, and 25.3% of this material was *m*-cresol. The corresponding figures for *p*-chlorotoluene are 55.5 and 38.2%. No trace of phenol was found in either product.

Preparation and Hydrolysis of Ethylchlorobenzenes.—The products obtained from the chlorination of ethylbenzene were carefully fractionated and two fractions separated, one boiling chiefly at 180°, the other at 185°. Tohl and Eberhard⁵ give the boiling point for *p*-ethylchlorobenzene as 180–182°. The fraction boiling at 180° yielded on oxidation with alkaline permanganate an acid which melted at 130–132°. *o*-Chlorobenzoic melts at 137°. The meta and para acids both melt much higher so the material boiling at 180° is *o*-ethylchlorobenzene. Both fractions were hydrolyzed in a manner similar to that used for the chlorotoluenes and the products purified in the same manner. Since the higher boiling fraction was not identified and might therefore contain some of the meta compound, its hydrolysis products will not be discussed at length. That which was obtained from several runs on the ortho was combined before purification and on distillation, cuts were taken as follows: 168–205°, 20.7 g.; 205–211° (205°), 45.5 g.; 211–218°, 7.8 g.; 218–222° (219°), 112.2 g.; 222–245°, 5.2 g. The total still charge was 224.5 g. Temperatures in parentheses are points at which the larger portions distilled. Boiling points given in the literature for ethylphenols are:⁶ ortho, 206.5–207°; meta, 217°; and para, 218°. The lower boiling constituent is undoubtedly the ortho compound and the fraction boiling at 218–222° is probably a mixture of meta and para with meta largely in excess. It did not crystallize when seeded with crystalline *p*-ethylphenol from another source. The refractive index (n_D) was 1.5294 at 25°; *p*-ethyl gives 1.5288 for the supercooled liquid. A phenylurethan was prepared by the method of Fromm and Eckard⁷ and it melted at 133–137°. The phenylurethan from *p*-ethylphenol melts at 120° and that from the meta at 138.8°.⁸

Summary

Ortho and para chlorotoluenes when hydrolyzed with sodium hydroxide undergo partial molecular rearrangement, yielding a mixture of products containing *m*-cresol.

Results on the hydrolysis of *o*-ethylchlorobenzene indicate that the rearrangement is general.

THE ALKALOIDS OF ARGEMONE MEXICANA

BY ALFREDO C. SANTOS AND PACIFICA ADKILEN

RECEIVED MARCH 10, 1932

PUBLISHED JULY 6, 1932

Many years ago Schlotterbeck¹ has shown that *Argemone mexicana*,² which is more familiarly known as mexican or prickly poppy, does not contain morphine. He isolated two alkaloids from this plant and on the basis of precipitation and color reactions he concluded that one of them was berberine. He identified the other alkaloid as protopine because of its melting point (204°) and color reactions.

Since then many alkaloids of the berberine type have been reported in the literature. According to Feist³ palmatine gives also an acetone compound and responds to other reactions which Gordin⁴ used for the identification of berberine. It appears, therefore, that the identification of berberine can no longer be done by precipitation and color reactions alone. In view of the foregoing reasons and of the fact that Schlotterbeck did not analyze his alkaloids, the present authors deemed it necessary to reinvestigate this plant.

By a method of isolation described in the experimental part, two alkaloids have been isolated from *Argemone mexicana*. One is a quaternary and the other is a tertiary base. The former was converted by reduction into a colorless tertiary base melting at 173–174° which by analysis and mixed melting point proved to be identical with tetrahydroberberine. The second base crystallized from a mixture of chloroform and methanol in nice monoclinic prisms melting at 207°. It responded to all the color reactions of protopine and on the basis of elementary analysis and mixed melting point with authentic material kindly furnished by E. Merck, Darmstadt, it was recognized as protopine.

Therefore, the assumption of Schlotterbeck that *Argemone mexicana* contains berberine and protopine proved to be correct.

Experimental

The material used consisted of whole plants collected at San Juan, La Union, and carefully deprived of the seeds; 568 g. of the air-dried powdered material was extracted until free from alkaloids with alcohol acidified with acetic acid. The alcohol was recovered from the alcoholic extract, the residue taken up with acidified water and filtered. The filtrate was first shaken out with ether in acid solution to remove neutral and indifferent substances, then rendered alkaline with potassium hydroxide and

¹ Schlotterbeck, THIS JOURNAL, **24**, 238 (1902).

² A native of tropical America. Introduced into the Philippines and known locally as *diluariu*, *kachumba* and *kasubang-aso*.

⁴ Gordin, *ibid.*, **240**, 146 (1902).

shaken out again with ether. The aqueous portion (A) was acidified with hydrochloric acid and set aside. On spontaneous evaporation of the ether a partly crystalline and sirupy residue remained. It was dissolved in diluted hydrochloric acid; rendered alkaline with potassium hydroxide and shaken out again with ether, this process being repeated many times until a white residue was left. This was dissolved in a little chloroform and an equal amount of methanol added. After three weeks' standing clusters of nice monoclinic prisms melting at 207° ⁵ separated. The melting point of a mixture of an equal amount of these crystals and protopine (m. p. 207°) furnished by E. Merck, Darmstadt, was 207° . The crystals gave the following color reactions: (1) with sulfuric acid, deep blue-violet; (2) with Froehde's reagent, violet-green changing to deep blue and finally becoming green; (3) with Mandelin's reagent, violet, then bluish-green, and finally blue; (4) with concentrated nitric acid, colorless in the cold, turning yellow on heating. The microanalysis gave values agreeing fairly with the values calculated for protopine.

Anal. Subs., 2.371 mg.: CO_2 , 5.893 mg.; H_2O , 1.261 mg. Calcd. for $\text{C}_{20}\text{H}_{19}\text{O}_3\text{N}$: C, 67.95; H, 5.48. Found: C, 67.78; H, 5.95.

Tetrahydroberberine.—The yellow aqueous acid solution (A) that had been set aside in the isolation of protopine was reduced with zinc dust and sulfuric acid until the solution became almost colorless and filtered. The filtrate was cooled rapidly, treated with ammonia water until the precipitated zinc hydroxide redissolved and shaken out with ether. The ethereal solution was repeatedly shaken with dilute potassium hydroxide, washed with a little water and dried. On concentrating the ether crystals melting at $173\text{--}174^{\circ}$ ⁶ separated. The melting point of a mixture of these crystals with tetrahydroberberine (m. p. $173\text{--}174^{\circ}$) was $173\text{--}174^{\circ}$.

Microanalysis. Subs., 2.720 mg.: CO_2 , 7.089 mg.; H_2O , 1.509 mg. Subs., 2.609 mg.: AgI, 3.558 (Zeisel-Pregl-Friedrich). Calcd. for $\text{C}_{20}\text{H}_{21}\text{O}_4\text{N}$: C, 70.74; H, 6.24; OCH_3 , 18.29. Found: C, 71.08; H, 6.21; OCH_3 , 18.01.

Summary

The alkaloids of *Argemone mexicana* have been correctly identified as berberine and protopine.

MANILA, P. I.

⁵ The melting point of pure protopine is reported at 207° by W. H. Perkin, Jr., *J. Chem. Soc.*, 109, 1023 (1916), and by P. W. Danckwortt, *Arch. Pharm.*, 250, 615 (1912).

⁶ Späth and Polgar, *Monatsh.*, 52, 117 (1929), reported that pure tetrahydroberberine melts at $173\text{--}174^{\circ}$.

THE REACTION BETWEEN DIETHYLAMINE AND ETHYLENE OXIDE

BY W. H. HORNE AND R. L. SHRINER

RECEIVED MARCH 10, 1932

PUBLISHED JULY 6, 1932

β -Diethylaminoethanol is an important intermediate in the preparation of alkylamino esters. The reaction between diethylamine and ethylene oxide should furnish a method of preparation which would be superior to the reduction of diethylaminoacetic ester¹ or the action of diethylamine on ethylene chlorohydrin² because of the greater ease in the isolation of the product. The starting materials are now available commercially and inexpensive. The purposes of the present investigation were (1) to determine the optimum conditions for the preparation of β -diethylaminoethanol and (2) to separate and identify some of the higher boiling compounds which are always formed in reactions involving ethylene oxide.

In 1863, just four years after he had first prepared ethylene oxide,³ Wurtz noted its reaction with ammonia.⁴ Since that time the action of ethylene oxide on ammonia,⁵ primary, secondary and tertiary amines,⁶ hydrazines,⁷ amides and imides⁸ has been investigated. Substituted ethylene oxides^{8,9} have also been shown to react with ammonia and amines to yield various amino alcohols. These investigations were carried out before ethylene oxide was readily available, so no complete study of the combination of diethylamine and ethylene oxide has been published. Quite different experimental conditions were used by the previous investigators and no general procedures were described.

It was found that pure dry diethylamine did not react with ethylene oxide but in the presence of water or alcohol the reaction would take place. A study was made of the effect of various solvents and the data obtained are summarized in Table I of the Experimental Part. It is evident that methyl and ethyl alcohols afford a smooth, rapid absorption of ethylene

oxide resulting in a good yield of β -diethylaminoethanol. Methyl alcohol was easier to separate by fractional distillation and hence is the best solvent. There was no evidence that the ethylene oxide reacted with the solvent under the conditions used.

A series of experiments was carried out to determine the best temperature for the reaction. If diethylamine containing a little water and liquid ethylene oxide are mixed at room temperature in a closed vessel the combination takes place slowly at first, but as the mixture warms up it finally proceeds with explosive violence.¹⁰ It seems probable that an addition compound is first formed similar to that between Grignard reagents and ethylene oxide¹¹ which must be subsequently rearranged. It was found that a temperature range of 45–60° permitted a smooth, rapid absorption of gaseous ethylene oxide. Below 45° the absorption was slow and above 60° the reaction also slowed down due to the diminished solubility of the ethylene oxide in the amine. By carrying out the reaction at 45–60° the addition compound is rearranged as fast as it is formed, thus avoiding a violent reaction. It is interesting to note that this temperature range is the same as that used to rearrange the Grignard addition compounds.

The results of variations in the mole ratio of reactants are also given in Table I. It is evident that the best yield was obtained with a ratio of about 1.3 moles of ethylene oxide to one mole of diethylamine (Run 9). The very slightly higher yield in Run 10 does not justify the use of the additional half mole of ethylene oxide. From Table II it will be noted that as the amount of ethylene oxide was increased the amount of unreacted diethylamine decreased but the percentage of material boiling above β -diethylaminoethanol was increased. These high boiling fractions from several runs were combined and carefully fractionated and two of the fractions definitely identified as the mono- β -diethylaminoethyl ether of ethylene glycol (II) and mono- β -diethylaminoethyl ether of diethylene glycol (III). Analyses and molecular refractivities of the two highest boiling fractions indicated that they are the mono- β -diethylaminoethyl ethers of triethylene glycol (IV) and tetraethylene glycol (V), respectively. These compounds represent the progressive addition of ethylene oxide and are of considerable theoretical interest, since they constitute further examples of bifunctional reactions discussed by Carothers in connection with chain polymerization.¹² They are evidently formed according to the reactions shown.

Compounds II, III, IV and V represent very low molecular weight chain molecules with different functional groups on the ends of the chain. Cyclic

¹⁰ Staudinger [*Ber.*, **62**, 2395 (1929)] has also recorded the explosive polymerization of ethylene oxide.

Experimental Part

The results of the experiments carried out to determine the optimum conditions for the preparation of β -diethylaminoethanol are summarized in the two tables.

The best procedure for the production of β -diethylaminoethanol (Run 9) was the following.

β -Diethylaminoethanol.—Forty grams of diethylamine was dissolved in 40 g. of methyl alcohol as solvent. The mixture was warmed to 45–60° and a fairly rapid stream of ethylene oxide passed through the reaction mixture. The flow of ethylene oxide was adjusted to keep the heat of the reaction from raising the temperature of the mixture above 60°. The maximum rate of addition was achieved in this manner. After two hours, 32 g. (8 g. excess) of ethylene oxide had been added. By fractional distillation *in vacuo* 48 g. of β -diethylaminoethanol (74.9% of the theoretical) was obtained. The residues in the flask (about 15 g.) from several runs were combined and fractionated as described below.

The product of the reaction was identified as β -diethylaminoethanol by means of its chemical and physical properties. It was found to contain hydrogen replaceable by metallic sodium, and to produce a distinctly alkaline aqueous solution. It was soluble in water, ether, benzene, petroleum ether and acetone. Its hydrochloride salt was precipitated from ether solution. This salt is very hygroscopic. Physical Properties: colorless, hygroscopic liquid, which turns yellow on standing; b. p. 163° at 760 mm. and 42–44° at 8 mm.; n_D^{25} 1.4400; d_4^{25} 0.8601; M_D calcd., 35.02; found, 35.81.

Anal. Calcd. for $C_6H_{15}ON$: N, 11.95. Found: N, 11.40.

To establish further the identity of the compound the *p*-nitrophenyl urethan was prepared by mixing β -diethylaminoethanol with *p*-nitrophenyl isocyanate in benzene solution. Evaporation of the benzene left the urethan, which was recrystallized from carbon tetrachloride as yellow crystals, m. p. 59–60° (corr.).

Anal. Calcd. for $C_{13}H_{19}O_4N_3$: N, 14.95. Found: N, 14.66.

The hydrochloride salt of this urethan was obtained by dissolving the urethan in dry acetone and precipitating as yellow crystals with dry hydrogen chloride. This derivative was recrystallized from 95% alcohol as fine yellow crystals, decomp. 200–210°.

Anal. Calcd. for $C_{13}H_{20}O_4N_3Cl$: Cl, 11.17. Found: Cl, 11.12.

Fractionation of the High Boiling Residues.—The residues from the distillation of ten runs from the preparation of β -diethylaminoethanol were combined and fractionally distilled *in vacuo* with the following results.

Fraction	Temp. at 7 mm., °C.	Vol. (approx.), cc.
1	80–90	4
2	90–95	15
3	95–100	25
4	100–120	15
5	120–130	30
6 (Residue)	Above 130	10
		<hr/>
		Total 99

Fractions 2 and 3 were combined and redistilled, yielding about 27 cc. of material boiling between 92 and 95° (Fraction A). Fraction 5 was redistilled and about 22 cc. of material was obtained between 123 and 128° (Fraction B). In this way these two

fractions represented the two chief components of the mixture. The residue was a dark brown viscous material from which no definite product could be isolated.

Identification of Fraction A as the Mono-(β -diethylaminoethyl) Ether of Ethylene Glycol.—Fraction A was a colorless hygroscopic liquid with an odor similar to that of β -diethylaminoethanol. It reacted with sodium and was soluble in water, benzene, alcohol, ether and acetone. The aqueous solution was alkaline. Its hydrochloride was precipitated from ether by dry hydrogen chloride and found to be very hygroscopic. Physical properties: b. p. 92–95° at 7 mm.; n_D^{25} 1.4457; d_4^{25} 0.9399; M_D , calcd., 44.52; found, 45.65.

Anal. Calcd. for $C_8H_{19}O_2N$: N, 8.70. Found: N, 8.77.

To further establish the identity of this compound the *p*-nitrophenyl urethan hydrochloride was obtained by treating fraction A with *p*-nitrophenyl isocyanate in benzene solution. Addition of dry hydrogen chloride gave an orange oil which was crystallized from 95% alcohol and washed with acetone; light yellow crystals, m. p. 152–153° (corr.).

Anal. Calcd. for $C_{15}H_{24}O_5N_3Cl$. Cl, 9.81. Found: Cl, 9.77.

Identification of Fraction B as the Mono-(β -diethylaminoethyl) Ether of Diethylene Glycol.—Fraction B was also a light yellow, hygroscopic, viscous liquid. It reacted with metallic sodium, and produced a distinctly alkaline aqueous solution. It was soluble in water, ether, acetone and benzene. Its hydrochloride salt was precipitated from ether and found to be hygroscopic. Physical properties: b. p. 123–128° at 7 mm.; n_D^{25} 1.4534; d_4^{25} 0.9763; M_D , calcd., 55.00; found, 56.80.

Anal. Calcd. for $C_{10}H_{23}O_3N$: N, 6.83. Found: N, 6.71.

The *p*-nitrobenzoate was obtained by treatment with *p*-nitrobenzoyl chloride. The product was obtained as light yellow crystals from 95% alcohol; m. p. 121.5–122° (corr.).

Anal. Calcd. for $C_{17}H_{25}O_5N_2$: N, 7.91. Found: N, 8.09.

Attempts to prepare derivatives of fractions A and B with the following reagents failed: with α -naphthyl isocyanate and methyl-*p*-toluenesulfonate, viscous, non-crystallizing products were obtained; with chloroplatinic acid and picric acid no insoluble products were produced.

Conversion of β -Diethylaminoethanol into Mono-(β -diethylaminoethyl) Ether of Ethylene Glycol.—Twelve grams of β -diethylaminoethanol was dissolved in 10 g. of methyl alcohol and ethylene oxide passed into the solution which was kept at 50°. In thirty minutes 14 g. of ethylene oxide was absorbed. The solvent was distilled and the residual oil fractionated. About 7 g. of unreacted β -diethylaminoethanol was recovered and 4 g. of material boiling 92–95° at 7 mm. was obtained. This last fraction agreed in its properties with the mono-(β -diethylaminoethyl) ether of ethylene glycol.

Separation of Fraction 6.—After a considerable number of the residues constituting fraction 6 above had been obtained, they were combined and carefully fractionated *in vacuo* using a column packed with carborundum. After repeated distillation two fractions were obtained; C, boiling between 164–172° at 7 mm.; and D, boiling 190–200° at 7 mm.

Identification of Fraction C as the Mono-(β -diethylaminoethyl) Ether of Triethylene Glycol.—Fraction C was a yellow, very viscous hygroscopic liquid. It was soluble in water, ether, alcohol and acetone but was less soluble in benzene than fraction B. Physical properties: b. p. 164–172 at 7 mm., n_D^{25} 1.4570, d_4^{25} 1.0237, M_D calcd. 65.48, found 66.31.

Anal. Calcd. for $C_{12}H_{27}O_4N$: N, 5.61. Found: N, 5.65.

Identification of Fraction D as the Mono-(β -diethylaminoethyl) Ether of Tetraethylene Glycol.—Fraction D was a dark yellow viscous hygroscopic liquid.

It was soluble in water, ether, alcohol, acetone but slightly soluble in benzene and insoluble in petroleum ether. Physical properties: b. p. 190–200° at 7 mm., n_D^{25} 1.4622, d_{25}^{25} 1.0510, M_D calcd. 75.96, found, 74.92.

Anal. Calcd. for $C_{14}H_{31}O_3N$: N, 4.77. Found: N, 4.72.

No solid derivatives of Fractions C and D could be obtained.

Summary

1. β -Diethylaminoethanol may be prepared conveniently by the combination of diethylamine with ethylene oxide in methyl alcohol solution at a temperature range of 45–60°.

2. The above reaction also produces chain molecules corresponding to the addition of two, three, four and five molecules of ethylene oxide to one of diethylamine. The mono-(β -diethylaminoethyl) ethers of ethylene glycol, diethylene glycol, triethylene glycol and tetraethylene glycol have been isolated and characterized.

THE TOXICITY TO GOLDFISH OF CERTAIN ORGANIC THIOCYANATES AND ISOTHIOCYANATES¹

BY NATHAN L. DRAKE AND RUTH L. BUSBEY

RECEIVED MARCH 10, 1932

PUBLISHED JULY 6, 1932

There appear in the literature several scattered references to investigations concerned with the possible value of thiocyanates and isothiocyanates as insecticides.

Moore² reported that, molecule for molecule, allyl isothiocyanate is more toxic against house flies (*Musca domestica* L.) than chloropicrin. Later, allyl isothiocyanate was found by Tattersfield and Roberts³ to be the most toxic to wireworms (*Agriotes*) of all compounds tested by them. Probably two or more species were used in the tests. More recently, Neifert and co-workers⁴ in tests with fumigants against the rice weevil (*Calendra oryzae* L.) and the flour beetle (*Tribolium confusum* Duv.) and the granary weevil (*Calendra granaria* L.) found that methyl and ethyl thiocyanates, and allyl isothiocyanates were more effective than carbon bisulfide.

In another investigation of possible fumigants, Roark and Cotton⁵ found

⁵ Roark and Cotton, "Tests of Various Aliphatic Compounds as Fumigants," Tech. Bull. 162 of the U. S. Dept. of Agriculture, March, 1930.

ethyl thiocyanate and ethyl and allyl isothiocyanates very effective against the rice weevil (*Calendra oryzae* L.); in fact, these substances were shown to be about as effective as the now widely used ethylene oxide.

A number of patents covering insecticides and fungicides which contain as the active constituent aliphatic or aromatic thiocyanates have been issued.⁶ Most of the compounds mentioned in these patents are aromatic thiocyanates, or aromatic hydrocarbons with the thiocyanate group substituted for hydrogen in an alkyl side chain. Only the last two references mention specifically pure aliphatic thiocyanates. None of the patents relate to isothiocyanates.

The present paper is the report of a study, according to the method of Gersdorff,⁷ of the toxicity to goldfish of a number of other thiocyanates and isothiocyanates. It has been found that compounds and plant extracts highly toxic to fish are more likely to have value as insecticides than materials which are non-toxic to fish. This study has been made in the hope of finding additional thio- and isothiocyanates which may prove to be valuable insecticides.

Preparation of Materials

n-Amyl and isoamyl isothiocyanates were prepared from the corresponding amines by the method of Slotta and Dressler.⁸ The boiling points of the products used in the toxicity tests were 193.5–196.5°, and 190–192°, respectively (uncorr.).⁹ *Tert*-amyl isothiocyanate was made in the same way through the amine, the latter having been prepared by the Hofmann reaction from dimethylethylacetamide. During the degradation of the amide, a considerable amount of a by-product melting at 224.5–225.5° was formed. Analysis proved this compound to be the symmetrical tertiary diamylurea. The tertiary-amyl isothiocyanate used in the tests boiled at 164–167°.¹⁰

⁷ Gersdorff, *THIS JOURNAL*, **52**, 3440 (1930).

⁸ Slotta and Dressler, *Ber.*, **63**, 889 (1930).

⁹ The boiling point of *n*-amyl isothiocyanate is given in Beilstein, 4th ed., Vol. IV, p. 176, as 193.4° (corr.). Isoamyl isothiocyanate is not described in the literature.

¹⁰ The boiling point reported in the literature is 166° at 770 mm. Beilstein 4th ed., Vol. IV, p. 179.

Benzoyl isothiocyanate was prepared from benzoyl chloride by the method described by Dixon and Taylor.¹¹ The fraction used boiled at 128–131° at 15 mm. pressure.

Phenyl thiocyanate was synthesized from aniline by means of the diazo reaction. The product boiled at 230–234°.¹²

p-Thiocyanogeno-*N*-dimethylaniline, melting at 71–73°, was also tested.¹³

Benzyl thiocyanate was made by the reaction between potassium thiocyanate and benzyl chloride. The substance used melted at 41–43°.¹⁴

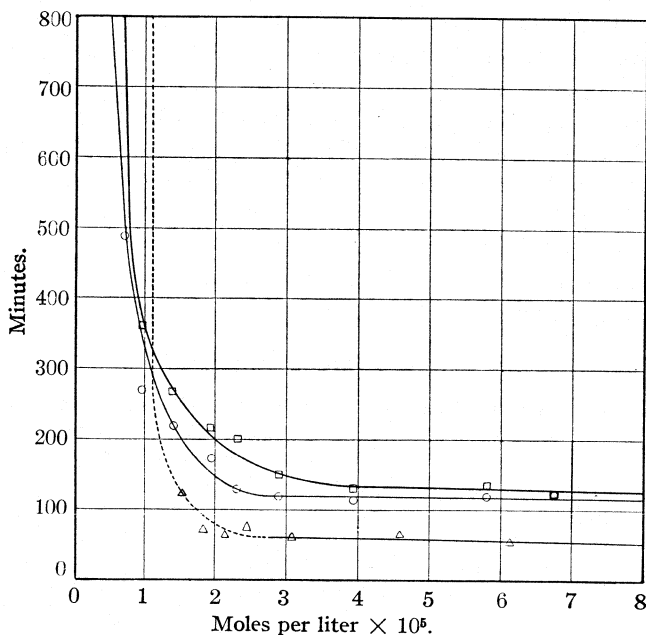

Fig. 1.—Survival time curves: ○, *n*-amyl isothiocyanate; □, isoamyl isothiocyanate; △, benzoyl isothiocyanate.

The Toxicity Tests

The acetone solutions of the substances to be tested were prepared at such concentrations that suitable aliquots could be taken for the tests without causing the proportion of acetone in the test jar to exceed 1 part in 1000 parts of water. Gersdorff⁷ has shown that this concentration has no effect on goldfish.

¹¹ *J. Chem. Soc.*, **93**, 684 (1908). Dixon and Taylor found the boiling point of benzoyl isothiocyanate to be 119° at 10 mm.

¹² This product was kindly prepared by Mr. R. J. Busbey. The boiling point recorded in the literature for phenyl thiocyanate is 232–233°. Beilstein, 4th ed., Vol. VI, p. 312.

¹³ Supplied by Dr. R. C. Roark of the Insecticide Division. This compound has been used in a commercial fly spray.

¹⁴ Beilstein, 4th ed., Vol. IV, p. 460, records 36–38° for the melting point of this substance.

The time of addition of the solution to the test jars and the time of death of the fish were recorded. The survival times were then calculated. When an individual survival time differed widely from the others for the same concentration, the following test was applied¹⁵ to see whether the result should be discarded in calculating the mean survival time. The mean survival time and the average deviation were calculated, omitting the doubtful observation. The difference between the doubtful observation and the mean was then found, and if this difference was equal to, or more than four times the average deviation, the questionable observation was rejected.

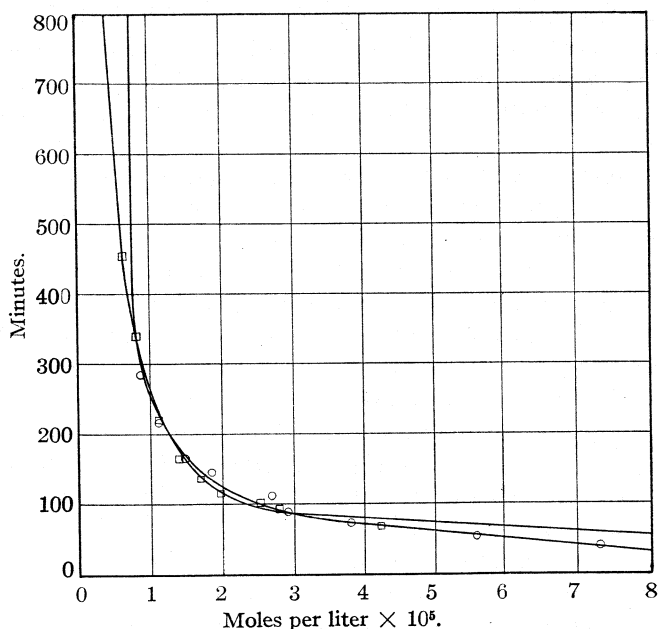

Fig. 2.—Survival time curves: ○, phenyl thiocyanate; □, *p*-thiocyanogeno-N-dimethylaniline.

As a general rule, six fish were used at each concentration, and after the mean survival time at different concentrations had been determined, the results were combined in the form of two graphs, shown in Figs. 1 and 2. Here are plotted survival times against concentration. The dotted portion of curve 3 of Fig. 1 is of questionable accuracy.

Discussion of Results

Examination of the curves reveals that except at the very low concentrations, the two amyl isothiocyanates are the least toxic. The other

¹⁵ J. S. Stevens, "Theory of Measurements," D. Van Nostrand, New York, 1916, p. 71.

three compounds possess very nearly equal toxicity at high concentrations, but the toxicity of the benzoyl isothiocyanate falls off more rapidly than that of the other two substances after the curve begins to break from the horizontal. The curves of phenyl thiocyanate and of *p*-thiocyanogeno-*N*-dimethylaniline are very similar throughout their lengths, and the same holds true for the two amyl isothiocyanates. This result is to be expected, since the members of these two pairs are very similar chemically.

Isoamyl isothiocyanate is slightly less toxic than the corresponding *n*-amyl compound at all concentrations tested. Tertiary amyl isothiocyanate in concentrations of 2.90×10^{-5} mole/liter and 3.87×10^{-5} mole/liter had no effect on goldfish even though the fish were left in the solution overnight. As it was thought that possibly this isothiocyanate had decomposed on standing, a new sample was prepared and tested immediately. At concentrations of 3.88×10^{-5} and 3.48×10^{-5} mole/liter goldfish were unaffected.

The lack of toxicity of the tertiary amyl isothiocyanate and the decrease in toxicity in passing from *n*-amyl to isoamyl isothiocyanate are contrary to what one would expect judging from the work of Roark and Cotton.⁵ Their fumigation tests indicated that among a group of isomers those with highly branched carbon chains were most effective. It is possible that this effect was the result of the higher vapor pressure of the branched chain isomers, since of a group of isomers the one with the most highly¹⁶ branched chain invariably has the lowest boiling point.

In solutions containing 3.36, 5.60 and 7.38×10^{-5} mole/liter of benzyl thiocyanate goldfish showed no signs of distress after four hours. Tests with this substance were therefore discontinued, and no survival time curve for benzyl thiocyanate is given.

At the higher concentrations benzoyl isothiocyanate was much more toxic than the amyl compounds. Its toxicity diminished more rapidly, however, after the curve began to bend from the horizontal. At high concentrations of benzoyl isothiocyanate the survival times were nearly equal, but below concentrations of slightly less than 2×10^{-5} mole/liter erratic results were obtained. Repetition of the tests in this region gave results which differed widely, and when the concentration was diminished only a little more, all toxic effect disappeared. A large number of fish were used in obtaining each point in the vicinity of this break in the curve. The doubtful region is represented by a dotted line in Fig. 2.

The peculiar behavior of this substance is probably due to the fact that it is easily hydrolyzed in aqueous solution. In the more dilute solutions the odor of benzoyl isothiocyanate soon disappeared, but in the concentrated solutions a layer of undissolved isothiocyanate remained on top of the water and dissolved gradually. The odor of the substance per-

¹⁶ Compared to the less highly branched isomers.

sisted for a long time in these solutions. It seems quite likely, therefore, that in the very dilute solutions the isothiocyanate decomposed too quickly to have any effect on the fish, while in the concentrated solutions the undissolved layers served as a reserve which kept benzoyl isothiocyanate in solution long enough to kill the goldfish. The fish which were killed by this compound bled from their gills, sometimes severely, and even those which did not die appeared inflamed about the gills.

At the higher concentrations, the toxicity of phenyl thiocyanate was very close to that of benzoyl isothiocyanate. Its decrease in toxicity became appreciable at a higher concentration than did that of benzoyl isothiocyanate, but the curve of Fig. 2 is regular, and results can be duplicated throughout its length. Phenyl thiocyanate is quite stable toward water. The goldfish were intensely irritated very quickly by this compound. They swam about violently, and often tried to jump out of the water.

p-Thiocyanogeno-*N*-dimethylaniline was very similar to phenyl thiocyanate in toxicity at all concentrations tested. It did not seem to irritate the fish as much as phenyl thiocyanate.

Summary

The toxicity to goldfish of certain organic thiocyanates and isothiocyanates has been determined at several concentrations, and the results are presented in the form of survival-time curves.

TWO CONSTITUENTS OF PAROSELA BARBATA (OERST.) RYDB.¹

By JOSEPH R. SPIES AND NATHAN L. DRAKE

RECEIVED MARCH 11, 1932

PUBLISHED JULY 6, 1932

Two constituents have been isolated from the leaves and stems of *Parosela barbata* (Oerst.) Rydb. in connection with the examination of certain plants reported to contain fish poisons.

The first, a white crystalline solid melting at 84–84.5°, was shown to be montanyl alcohol. This compound is assigned the formula $C_{29}H_{60}O$ by Damoy,² who obtained the alcohol from beeswax. Gascard and Damoy³ report the melting point of montanyl alcohol as 84°. Damoy² gives the melting point of its acetate as 68–68.2° and that of its iodide as 64–64.2°.

On the other hand, Fargher and Probert⁴ report montanyl alcohol ob-

¹ Collected by Dr. H. Pittier in Caracas, Venezuela, and identified by Dr. S. F. Blake, Bureau of Plant Industry, Washington, D. C.

² Damoy, *J. Pharm. Chim.*, **29**, 225–236 (1924).

³ Gascard and Damoy, *Compt. rend.*, **177**, 1442–1443 (1923).

⁴ Fargher and Probert, *J. Textile Inst.*, **15**, 337–346T (1924).

tained from the wax of American cotton as $C_{28}H_{58}O$ with a melting point of 83.5° and the melting point of its acetate as $67-67.5^\circ$.

The material isolated in this investigation was purified by repeated recrystallizations from chloroform until the melting point showed no further rise. The alcohol crystallizes from chloroform or benzene in colorless, diamond-shaped plates. It is very slightly soluble in cold solvents but is very soluble in warm chloroform or benzene. The highest yield of fairly pure substance was 0.075% of the plant and our total supply consisted of about 3.0 g.

Molecular weight determinations by the method of Landsberger⁵ with chloroform as solvent gave values of 415, 412 and 385. By the method of Karl Rast⁶ values of 410 and 387 were obtained.

The acetate of the material melted at $68-69^\circ$ and the iodide melted at $64-64.5^\circ$. The phenylurethan was prepared and found to have a melting point of 96° . This derivative does not seem to have been prepared by previous workers.

It is not possible to distinguish positively between two compounds possessing formulas of $C_{28}H_{58}O$ or $C_{29}H_{60}O$ by means of carbon and hydrogen analysis due to the small difference in carbon and hydrogen content. There is, however, a difference of 0.62% in the iodine content of the two corresponding iodides; and analyses gave values which varied only 0.04 and 0.11% from the value calculated for $C_{29}H_{59}I$. This is in agreement with the formula for montanyl alcohol determined by Damoy.

The second constituent, a yellow oil, was obtained by steam distillation of the substance remaining after evaporation of the methyl alcohol mother liquor of the montanyl alcohol. The yield amounted to 0.6% of the plant material.

The oil boiled between 95 and 110° at 4-5 mm. pressure. Its density and refractive index were: d_{20}^{20} 0.947, and n_D^{20} 1.497. It possessed a peculiar sickening odor and was insoluble in water, but readily soluble in organic solvents. It added bromine readily and decolorized neutral permanganate solution but did not reduce Fehling's solution.

At a concentration of 1:10,000 at 27° it killed goldfish in an average of 117 minutes.⁷ Four fish were used to obtain this value. The toxicity tests were carried out by the method described by Gersdorff.⁸

Experimental

Isolation of Montanyl Alcohol.—720 g. of the ground plant was extracted for two and a half hours in a Soxhlet extractor with benzene. The benzene was then dis-

⁵ Landsberger, *Ber.*, **31**, 458 (1898).

⁶ Karl Rast, *ibid.*, **55**, 1051 (1922).

⁷ For toxicity of the acetone extract of the entire plant, see Drake and Spies, *J. Ec. Entomol.*, **25**, No. 1, 129-133 (1932).

tilled off and the residue dissolved in boiling methyl alcohol and filtered on a hot water funnel. On cooling a gelatinous, green, pasty mass separated, which was filtered off with suction. This solid was stirred up with cold ether, which removed much of the color. The ether was filtered off, the solid dissolved in warm chloroform and the solution decolorized with charcoal. The chloroform solution was allowed to cool slowly and to stand for some time, whereupon it deposited a crystalline material which was further purified by repeated recrystallizations from the same solvent. A brownish color may persist even after this treatment, but it can be removed by a crystallization from methyl alcohol, followed by recrystallization from chloroform again; yield, 0.55 g. of substance melting at 82.5°. Recrystallization from chloroform to constant melting point gave a product melting at 84–84.5°.

Anal. Subs., 2.948, 2.919 mg.: CO₂, 8.813, 8.772; H₂O, 3.759, 3.687. Calcd. for C₂₈H₅₈O: C, 81.86; H, 14.24. Calcd. for C₂₈H₆₀O: C, 81.98; H, 14.25. Found: C, 81.53, 81.96; H, 14.17, 14.04.

Acetylation of Montanyl Alcohol.—0.15 g. of montanyl alcohol was treated with 2 cc.⁹ of acetic anhydride containing a trace of sulfuric acid and kept on a boiling water-bath for one hour. Methyl alcohol was then added cautiously, and after destruction of the excess acetic anhydride the acetate crystallized from the methyl acetate–methyl alcohol mixture. The ester was recrystallized once more from methyl alcohol and melted at 68–69°.

Anal. Subs., 3.659, 3.262 mg.: CO₂, 10.680, 9.498; H₂O, 4.315, 3.901. Calcd. for C₃₀H₆₀O₂: C, 79.56; H, 13.36. Calcd. for C₃₁H₆₂O₂: C, 79.75; H, 13.39. Found: C, 79.60, 79.40; H, 13.10, 13.29.

Preparation of Montanyl Iodide.—0.09 g. of montanyl alcohol was treated with 0.025 g. of red phosphorus and 0.3 g. of iodine and the whole kept at a temperature of 80–90° for three and a half hours. The mixture was then extracted with warm chloroform and the chloroform solution washed with a dilute aqueous solution of sodium bisulfite. It was then washed with water and finally dried over calcium chloride. The chloroform was evaporated off and the solid residue recrystallized to constant melting point from ether. It melted at 64–64.5°.

Anal. Subs., 4.999, 3.205 mg.: CO₂, 11.856, 7.623; H₂O, 4.976, 3.207. Calcd. for C₂₈H₅₇I: C, 64.57; H, 11.04. Calcd. for C₂₉H₅₉I: C, 65.12; H, 11.13. Found: C, 64.67, 64.86; H, 11.06, 11.12. Subs., 6.907, 7.222 mg.: AgI, 3.052, 3.182. Calcd. for C₂₈H₅₇I: I, 24.39. Calcd. for C₂₉H₅₉I: I, 23.77. Found: I, 23.88, 23.81.

Preparation of the Phenylurethan of Montanyl Alcohol.—0.04 g. of montanyl alcohol and two drops of phenyl isocyanate were refluxed for half an hour in benzene solution. The crystals which separated on cooling were recrystallized once from benzene. The compound melted at 96°.

Anal. Subs., 2.874, 3.080 mg.: CO₂, 8.385, 8.971; H₂O, 3.136, 3.319. Calcd. for C₃₅H₆₃O₂N: C, 79.32; H, 11.99. Calcd. for C₃₆H₆₅O₂N: C, 79.48; H, 12.05. Found: C, 79.38, 79.41; H, 12.12, 11.97.

Summary

1. Montanyl alcohol has been isolated from *Parosela barbata* and identified by means of several of its derivatives.
2. The phenylurethan of montanyl alcohol has been prepared.
3. The formula of montanyl alcohol suggested by Damoy has been confirmed.

⁹ This was sufficient to effect complete solution at 100°.

4. An oil possessing some toxicity to goldfish has been isolated and described.

COLLEGE PARK, MARYLAND

A REACTION BETWEEN DIETHYL ETHER AND PHOSPHORUS PENTACHLORIDE

BY WALTER S. GUTHMANN¹

RECEIVED MARCH 11, 1932

PUBLISHED JULY 6, 1932

In the course of some work on molecular rearrangements in the triphenylmethylhydroxylamine series, it was found necessary to reflux ether solutions of the materials being studied with phosphorus pentachloride for several days. At the end of this time water was added to the reaction mixture, and a very considerable and unexpected evolution of acetaldehyde was observed. This led to the investigation reported here.

Liebermann and Landshoff² report the formation of a crystalline compound of the probable formula $C_8H_{14}O_2P_3Cl_{15}$, when ether is treated with phosphorus pentachloride, and show that it is not a direct addition product with the formula $(C_4H_{10}O)_2 \cdot 3PCl_5$. No mention is made, however, of the evolution of acetaldehyde upon addition of water to the above compound.

Reactions of phosphorus pentachloride with aliphatic-aromatic ethers have been reported.³ In these cases only the aromatic portion of the molecule is oxidized.

It has been found that halogens, at ordinary temperatures, will react with ether to form α -halogen ethyl ethers which are easily hydrolyzed by water:⁴

It is well known that phosphorus pentachloride may be used as a chlorinating agent, and this fact might well account for the reaction described below, except that some organic phosphorus derivatives are formed at the

¹ A portion of the dissertation submitted to the graduate faculty of the University of Chicago, by W. S. Guthmann, in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

² Liebermann and Landshoff, *Ber.*, **13**, 690 (1880).

³ Henri, *ibid.*, **2**, 710 (1869); Colson, *Compt. rend.*, **99**, 975 (1884).

⁴ Richter, "Organic Chemistry," P. Blakiston's Son and Co., Philadelphia, 1922, Vol. I, p. 129.

⁵ Since this paper was written, Henze and Murchison [THIS JOURNAL, **53**, 4077 (1931)], have reported the preparation of α -chloroethyl *n*-alkyl ethers by saturating equimolar quantities of paraldehyde, and the alcohol which contains the desired alkyl group, with hydrogen chloride, in the cold. The products hydrolyze very readily to re-form the original materials; on long standing they polymerize and leave a dark tarry residue.

same time (see experimental part). We might accept the point of view of Bergmann and Bondi,⁶ who advance evidence that one of the five chlorine atoms in phosphorus pentachloride is differently and less firmly linked than the others, which causes this compound to react as Cl-PCl_4 ; this would account for a C-P linkage in the product of reaction of phosphorus pentachloride with an organic compound.

The ultimate reaction product of phosphorus pentachloride with ether is an oil, not completely miscible with ether, and perfectly stable, at room temperatures, in the absence of moisture. All attempts to crystallize it have failed. On treatment with water the oil yields acetaldehyde, hydrochloric, phosphoric and phosphorous acids, and an unidentified organic residue which contains trivalent phosphorus. In view of the fact that the oil is most probably a mixture, no elementary analysis has been attempted. It is possible that this reaction provides an additional method for the preparation of the type of phosphoric and phosphorous esters prepared by Milobdendzki and Sachnowski⁷ and by Arbuzov and Arbuzuva.⁸

Further work in this field should yield valuable information on organic phosphorus compounds, and conceivably serve to develop a method for the determination of the relative ease of oxidation of the groups in mixed ethers.

Experimental Part

A mixture of pulverized phosphorus pentachloride (7 g.) and ether (30 cc.), carefully dried and purified, was boiled under reflux⁹ on the steam-bath for forty-eight hours, the reaction mixture being protected from moisture by means of a calcium chloride tube. At the end of this time a clear, almost colorless, mobile solution resulted. The reaction flask was well cooled and agitated while water (75 cc.) was slowly added to its contents. After separation from the aqueous layer, the ether layer was repeatedly washed with water. The washings were added to the original aqueous part. The presence of some organic phosphorous compound in the ether layer was shown as follows: the solution was dried over calcium chloride (or potassium carbonate), the solvent evaporated, and the residue oxidized with concentrated nitric acid; addition of molybdic acid then gave a precipitate, although no such precipitate was obtained prior to the oxidation.¹⁰

⁶ Bergmann and Bondi, *Ber.*, **64B**, 1455-80 (1931).

⁷ Milobdendzki and Sachnowski, *Chem. Polski*, **15**, 34 (1917); *cf. Chem. Abs.*, **13**, 2865 (1919).

⁸ Arbuzov and Arbuzuva, *J. Russ. Phys.-Chem. Soc.*, **62**, 1533 (1930); *cf. Chem. Abs.*, **25**, 2414 (1931).

⁹ The flasks used here were of 150-cc. capacity, and were joined to the condenser by means of a ground-glass joint in such a way that the condensed liquid washed the solid material (which otherwise tends to cake on the walls just above the surface of the reaction mixture) back into the bottom of the flask. These flasks also have the great advantage that contamination of the reaction mixture from stoppers is prevented.

¹⁰ Evaporation of the ether, prior to the hydrolysis, left an oil which did not crystallize on standing. Hydrolysis of this oil yielded the same products that were obtained from the ethereal solution.

The aqueous portion was fractionated; the fraction boiling below 35° contained all the acetaldehyde, which was identified by one of its many color reactions, and also by the preparation of the aldehyde semicarbazone¹¹ (melting point 162°). A mixture of the latter material with acetaldehyde semicarbazone from a known source had the same melting point (162°).

The distillation of the aqueous layer was continued until the volume of the material in the flask was reduced one-half; this residue was used for the following tests. (1) A portion allowed to stand exposed to air acquired a brown coloration, but no other change in properties was noted. (2) The presence of phosphate ion was shown by the molybdic acid reaction and confirmed by the precipitation of magnesium ammonium phosphate. When bromine was added to the filtrate obtained in the molybdic acid test, the yellow liquid became colorless, and some of the phosphorus was oxidized to phosphate ion, as was shown by the formation of more precipitate, an excess of molybdic acid having previously been used. (3) Ferric chloride was added to another portion, and the resulting mixture was made slightly alkaline and filtered. Addition of molybdic acid to a portion of the filtrate now gave no precipitate; but when another portion of the filtrate was oxidized with bromine or with concentrated nitric acid, the test for phosphate ion was positive.

The phosphate-free solution mentioned above has strong reducing properties when alkaline. It also gives the various tests for phosphorous acid, and we have the following indications of an organo-phosphorus compound: when the neutralized solution was evaporated a brown sirup resulted, encrusted with sodium chloride (formed in the neutralization of the hydrochloric acid originally present). This brown sirup was further heated, and first gave phosphine (identified in the usual way), and later became charred with the production of a distinct carbylamine odor, although no nitrogen was present. The residue which remained after the heating, when extracted with water, gave the usual phosphate tests; much carbon remained.

I wish to take this opportunity to express my sincere gratitude to Professor Stieglitz for his kind help and guidance.

Summary

1. A new reaction of diethyl ether and phosphorus pentachloride is described.
2. Organo-phosphorus compounds are formed in the course of the reaction. These are easily hydrolyzed by water alone.
3. The products of hydrolysis of the compounds mentioned in (2) include acetaldehyde, hydrogen chloride, phosphoric and phosphorous acids, and some unidentified stable organo-phosphorus compounds.

RESEARCHES ON PYRIMIDINES. CXXIX. THE SYNTHESIS OF
2-THIO-OROTIC ACIDBY TREAT B. JOHNSON AND ELMER F. SCHROEDER¹

RECEIVED MARCH 12, 1932

PUBLISHED JULY 6, 1932

The two sulfur analogs of uracil-4-carboxylic acid (orotic acid)² and uracil-5-carboxylic acid,³ respectively, have been described in the chemical literature. The pyrimidine acid represented by formula II was synthesized

by Johnson and Ambler⁴ in 1911, and the isomeric acid I by Bachstetz⁵ in 1930. Both of these pyrimidines have a biochemical interest, and the presence of sulfur in the molecule increases greatly the possible application of these two compounds for future synthetic operations.

Bachstetz's method of preparing 2-thio-orotic acid involves the condensation of thiourea with ethyl oxaloacetate to form the ethyl ester of 2-thio-orotic acid, which is then converted into the acid I by saponification. In other words, practically the same technique is employed here for its preparation as was originally applied by Müller for the synthesis of the ethyl ester of uracil-4-carboxylic acid. Neither condensation reaction is productive of pyrimidines in good yield, that reported by Bachstetz for 2-thio-orotic acid averaging, for example, less than 21% of the theoretical.

In the progress of our researches on pyrimidines we have sought for an improved method of preparing 2-thio-orotic acid, and find that it can be prepared easily by application of a Cannizzaro reaction to the corresponding pyrimidine aldehyde, 2-thiouracil-4-aldehyde. This aldehyde and also the corresponding uracil-4-aldehyde have been described previously in papers by Johnson and Cretcher⁶ and by Johnson and Schroeder.⁷ Both pyrimidines undergo smoothly a Cannizzaro transformation, giving practically quantitative yields of the corresponding pyrimidine acids and primary alcohols as is expressed below

1. 2-Thiouracil-4-aldehyde \longrightarrow 2-thio-orotic acid and 2-thio-4-hydroxymethyluracil.
2. Uracil-4-aldehyde \longrightarrow orotic acid and 4-hydroxymethyluracil.

These transformations (1 and 2) not only illustrate the importance of our original pyrimidine aldehyde syntheses, but they also introduce

workers in this field to a method for synthesizing primary alcohol derivatives of uracil, which is an improvement over the method previously developed in this Laboratory. Both 2-thio-orotic acid and the corresponding 2-thio-4-hydroxymethyluracil can be converted quantitatively into orotic acid and 4-hydroxymethyluracil, respectively, by desulfurization.

In his last publication on the chemistry of 2-thio-orotic acid, Bachstetz discusses the behavior of the sodium salt of this acid toward benzyl chloride, and describes the reaction product, melting at 264° , as a N-benzyl derivative. It has been our experience that the sodium salt of 2-thio-orotic acid and also 2-thio-4-hydroxymethyluracil interact with alkyl halides to form smoothly alkyl derivatives with the substituent group attached to sulfur. Several representatives of this type of derivative have been prepared by us, and we have observed that they undergo hydrolysis by acids, in every case examined, with formation of mercaptans and the corresponding sulfur-free pyrimidines. In other words, no abnormality in behavior is revealed in this series of compounds.

Experimental Part

The Application of Cannizzaro's Reaction to 2-Thiouracil-4-aldehyde.^{6,7} The Preparation of 2-Thio-orotic Acid and 2-Thio-4-hydroxymethyluracil.—Five grams of 2-thiouracil-4-aldehyde is dissolved in a solution of 5 g. of potassium hydroxide and 12 cc. of water, previously cooled to room temperature. The aldehyde dissolves readily with rise in temperature to give a clear bright red solution. The reaction is practically complete after standing at room temperature for forty-eight hours.

The reaction mixture is then acidified with dilute hydrochloric acid and the precipitate, consisting of both reaction products, is separated by filtration, suspended in 50 cc. of water and redissolved by addition of a small amount of sodium hydroxide solution. On acidifying this solution with acetic acid the 2-thio-4-hydroxymethyluracil is precipitated in crystalline condition, and the separation is usually complete within half an hour. This alcohol is easily purified by crystallization from hot water, and separates on cooling in the form of colorless needles. The yield was 1.8 g. This pyrimidine is moderately soluble in hot alcohol, easily soluble in concentrated sulfuric acid and hot acetic acid, and insoluble in ether, benzene, ligroin and acetone. It melts with decomposition at 259° .

Anal. Calcd. for $C_6H_6O_2N_2S$: N, 17.72. Found: N, 17.66, 17.70.

The filtrate from the acetic acid precipitation is then made strongly acid with hydrochloric acid when the 2-thio-orotic acid is precipitated as a yellow powder. The yield was 2.4 g. This pyrimidine was purified by repeated reprecipitations from alkaline solution with hydrochloric acid. It does not show a sharp melting point and decomposes with strong effervescence when heated at $338-339^{\circ}$. The acid described by Bachstetz⁵ showed a similar behavior, melting at the same temperature. This pyrimidine is very insoluble in cold water, alcohol and ether, but is moderately soluble in hot water.

Anal. Calcd. for $C_6H_4O_3N_2S$: N, 16.28. Found: N, 16.30, 16.43.

Conversion of 2-Thio-orotic Acid into Orotic Acid.—The desulfurization of 2-thio-orotic acid is accomplished quantitatively by oxidation with chromic acid. Two grams of the sulfo acid is slowly added to an oxidizing mixture consisting of 5 g. of sodium dichromate, 5 cc. of sulfuric acid and 25 cc. of water. Considerable heat is evolved during the addition. After standing for a short time, the reaction mixture is heated to

boiling for about one minute. On cooling, the sulfur-free orotic acid separates out as a yellowish solid. It is decolorized with norite and recrystallized from hot water. The purified product melted at 345° . A mixed melting point with known orotic acid showed no depression; yield, 1.9 g.

The desulfurization may also be accomplished by heating for a short time with alkaline 3% hydrogen peroxide. Two grams of 2-thio-orotic acid is covered with 25 cc. of 3% hydrogen peroxide and sufficient sodium hydroxide solution is added to dissolve the acid. The solution is heated under a gentle boil for three minutes. On cooling and acidifying with hydrochloric acid, the orotic acid separates out as a colorless solid. The yield was 1.8 g. Attempts to desulfurize 2-thio-orotic acid with monochloroacetic acid were not successful.

Conversion of 2-Thio-4-hydroxymethyluracil into 4-Hydroxymethyluracil.—Two grams of 2-thio-4-hydroxymethyluracil is suspended in a solution of two grams of monochloroacetic acid in 25 cc. of water. The pyrimidine readily goes into solution on warming. The solution is heated under a reflux condenser for five hours, remaining perfectly clear during this period. On cooling, 4-hydroxymethyluracil separates out in the form of colorless elongated prisms or plates. It may be purified by recrystallization from a small quantity of hot water; yield, 1.5 g. The product darkened at 248° and then melted sharply at $255\text{--}256^{\circ}$. It gave no test for sulfur. It was easily soluble in hot water, acetic acid, methyl and ethyl alcohol, and insoluble in ether and benzene.

Anal. Calcd. for $C_4H_6O_2N_2$: N, 19.72. Found: N, 19.52, 19.65.

4-Hydroxymethyluracil was first prepared by Johnson and Chernoff⁸ by way of the intermediate, 4-ethoxymethyluracil. The product which they obtained did not melt sharply, showing signs of decomposition at 240° then melting at 254° .

Application of the Cannizzaro Reaction to Uracil-4-aldehyde.—Uracil-4-aldehyde undergoes a Cannizzaro reaction when allowed to stand in aqueous potassium hydroxide solution to give orotic acid and 4-hydroxymethyluracil. Five grams of the aldehyde, prepared according to the method of Johnson and Schroeder⁷ is dissolved in a solution of 8 g. of potassium hydroxide and 18 cc. of water, and allowed to stand at room temperature for forty-eight hours. The solution assumes a deep yellow color and partially solidifies. At the end of the reaction 25 cc. of water is added and the solution then acidified with concentrated hydrochloric acid, cooled in ice water, and the yellowish precipitated mixture of alcohol and acid filtered off by suction.

The separation of the two reaction products depends on the much greater solubility of the pyrimidine alcohol in hot water. The precipitate obtained as described above is transferred to a beaker, covered with 50 cc. of water and heated nearly to boiling ($85\text{--}90^{\circ}$). Practically the whole of the pyrimidine alcohol goes into solution, while if the heating is not continued too long, only negligible amounts of orotic acid dissolve. The mixture is rapidly filtered hot, and the extraction of the solid residue is repeated in the same way, using 25 cc. of water. The crude yellow residue of orotic acid is purified with norite and recrystallized from hot water, from which it separates in colorless rhombic blocks; yield, 2.0 g. It melted at 345° . A mixed melting point with known orotic acid showed no depression.

The alcohol, 4-hydroxymethyluracil, is obtained on concentrating and cooling the extraction liquors. It is purified with norite and recrystallized from a small quantity of hot water, separating in the form of colorless elongated prisms or plates, melting at $255\text{--}256^{\circ}$. A mixed melting point with the product previously described, obtained by desulfurization of 2-thio-4-hydroxymethyluracil, showed no depression, melting at 255° ; yield, 1.6 g.

⁸ Johnson and Chernoff, *THIS JOURNAL*, **36**, 1742 (1914).

2-Ethylmercapto-4-hydroxymethyluracil (A) and 2-Benzylmercapto-4-hydroxymethyluracil (B).—These two pyrimidines are easily prepared by alkylation of the sodium salt of 2-thio-4-hydroxymethyluracil with ethyl iodide and benzyl chloride, respectively, in alcohol solution. Practically quantitative yields of the mercapto pyrimidines are obtained. The pyrimidine (A) melts at 168°. It is easily soluble in alcohol, acetone and acetic acid, and slightly soluble in ether and benzene. When digested with hydrochloric acid ethyl mercaptan is evolved and 4-hydroxymethyluracil is formed, melting at 255°.

Anal. Calcd. for $C_7H_{10}O_2N_2S$: N, 15.05. Found: N, 15.14, 15.08.

The benzyl derivative (B) crystallizes from hot water in the form of needles melting at 156°. This pyrimidine is easily soluble in alcohol, acetone and acetic acid, and insoluble in ether and benzene. When digested with hydrochloric acid benzyl mercaptan and 4-hydroxymethyluracil are formed.

Anal. Calcd. for $C_{12}H_{12}O_2N_2S$: N, 11.29. Found: N, 11.18, 11.22.

2-Benzylmercapto-orotic Acid (A). 2-Ethylmercapto-orotic Acid (B) and 2-Methylmercapto-orotic Acid (C).—(A) This pyrimidine was prepared by the following modification of the method employed by Bachstet. Two grams of thio-orotic acid was dissolved in a solution of 1.3 g. of potassium hydroxide (two mols) in 24 cc. of an 80% alcohol-water mixture, and refluxed for three hours with 1.5 g. of benzyl chloride (one mol). At the end of this time the reaction mixture was diluted with 200 cc. of water and acidified with hydrochloric acid. The white solid separating out was recrystallized from a large quantity of hot water and came out in the form of small colorless prisms melting at 265° (corr.). Bachstet reports a melting point of 264° (corr.). The yield was 1.8 g. The product was difficultly soluble in alcohol and ether.

The structure of this compound is erroneously reported by Bachstet to be that of a N-benzyl-2-thio-orotic acid, the benzyl group being linked to one of the nitrogen atoms in the pyrimidine cycle. That the benzyl group is in fact linked to sulfur is shown by the ready conversion of the compound in question to orotic acid, with loss of benzyl mercaptan. A small amount of 2-benzylmercapto-orotic acid is dissolved in concentrated hydrochloric acid and refluxed for six hours. A strong mercaptan-like odor appears. On evaporating the solution to dryness and extracting the residue with hot water, a good yield of orotic acid is obtained.

(B) This pyrimidine is prepared by the action of ethyl bromide on the sodium salt of thio-orotic acid in alcohol solution. The pyrimidine is easily purified by recrystallization from hot water and separates on cooling in the form of colorless prisms melting at 248°. It is easily soluble in hot water and alcohol and insoluble in ether and benzene. When the pyrimidine was digested with hydrochloric acid ethyl mercaptan and orotic acid were formed quantitatively.

Anal. Calcd. for $C_7H_8O_3N_2S$: N, 14.00. Found: N, 13.92.

(C) This pyrimidine crystallizes from hot water in the form of prisms melting at 255°. It is converted quantitatively into orotic acid with evolution of methyl mercaptan when digested with hydrochloric acid.

Anal. Calcd. for $C_6H_6O_3N_2S$: N, 15.05. Found: N, 15.09.

Summary

1. The pyrimidine aldehyde, 2-thiouracil-4-aldehyde and uracil-4-aldehyde react normally toward alkali and undergo the Cannizzaro reaction, giving equivalent amounts of the corresponding pyrimidine acid and alcohol.

2. 2-Thio-orotic acid is desulfurized by the action of chromic acid, or with hydrogen peroxide in alkaline solution to give orotic acid quantitatively. The acid is not desulfurized by the action of chloroacetic acid.

3. 2-Thio-4-hydroxymethyluracil is desulfurized and converted quantitatively into 4-hydroxymethyluracil by digestion with chloroacetic acid in aqueous solution.

4. 2-Thio-orotic acid and 2-thio-4-hydroxymethyluracil interact with alkyl halides in alkaline solution to give alkyl derivatives with substitution on the sulfur atom.

5. The investigation of these compounds is being continued.

SUBSTITUTED PHENYLDIHALOARSINES

BY F. F. Blicke, L. D. Powers and G. L. Webster

RECEIVED MARCH 12, 1932

PUBLISHED JULY 6, 1932

A number of substituted phenyldihaloarsines, not described hitherto, have been prepared in the hope that they might be used for the preparation of certain types of arsenicals under investigation in this Laboratory. Since many of them have been found to be unsuitable for our purpose, a brief description of them is published at this time.

Considerable difficulty was experienced in the preparation of many of the dihaloarsines in pure form. The following was found to be a very satisfactory general procedure: preparation of the arylarsonic acid, conversion of the acid into the corresponding aryldichloroarsine, purification of the latter by recrystallization from acetic acid or absolute ether, hydrolysis of the chloride into the arylarsine oxide and treatment of the latter at ordinary temperature with the desired halogen acid.

Arylarsine oxides are sometimes contaminated by small quantities of the arylarsonic acid and as a result of this contamination the preparation of the aryldihaloarsine is often very troublesome. Since the pure oxides usually possess rather indefinite melting points, the detection of the arsonic acid by means of a melting point determination cannot be relied upon. However, since the arylarsonic acid and concentrated hydriodic acid yield the corresponding aryldi-iodoarsine and free iodine, it is merely necessary to add a cubic centimeter of hydriodic acid to a fraction of a gram of the solid oxide in order to determine the presence or absence of the arsonic acid. If the oxide is pure, the mixture assumes the yellow color of the aryldi-iodoarsine; if even a slight amount of arsonic acid is present, the latter is detected by a deep red color due to the free iodine.

Experimental Part

 TABLE I
 SUBSTITUTED PHENYLDICHLOROARSINES

	M. p., °C.	Formulas	Chlorine analyses ^a	
			Calcd.	Found
3-Nitro	53-54 ^b	C ₆ H ₄ O ₂ NAsCl ₂	26.47	26.36
4-Benzoyl	118-120	C ₁₃ H ₉ OAsCl ₂	21.69	21.65
4-(4'-Phenoxy)-benzoyl	83-85	C ₁₉ H ₁₃ O ₂ AsCl ₂	16.92	16.61

^a All halogen analyses were made by the use of the Thompson-Oakdale method, *THIS JOURNAL*, **52**, 1195 (1930). Oxidation was effected with chromic acid.

^b Michaelis and Loesner [*Ber.*, **27**, 269 (1894)] reported the melting point to be 46-47°.

 TABLE II
 SUBSTITUTED PHENYLDIBROMOARSINES

	M. p., °C.	Formulas	Bromine analyses	
			Calcd.	Found
2-Nitro	52-54	C ₆ H ₄ O ₂ NAsBr ₂	44.79	44.91

SALTS OF PHENOLPHTHALEIN

BY WILLIAM M. DEHN

RECEIVED MARCH 14, 1932

PUBLISHED JULY 6, 1932

The problem of constitution of the salts¹ of phenolphthalein has engaged the interest of many chemists since 1871, the date of discovery by Baeyer² of free phenolphthalein, which later he showed³ possesses the lactone structure. The exact constitution of its salts, the reddening and fading effects produced by a variety of influences, and the correlations of chemical and color changes in solutions have been the chief problems giving rise to different opinions.

It is usually suggested that the color changes of phenolphthalein are in accordance with equilibrium of the following forms⁴

However, since the solid colorless mono-, di- and tri-basic salts all yield by dehydration corresponding red salts, it seems probable that more than one colored quinoid form and colorless carbinol forms are involved in equilibria both of the solid salts and in their solutions. Furthermore, no structures depict water of crystallization, which is always present in the colorless salts and in some of the red salts, and it seems certain that equilibria of such water molecules are involved in solutions, at least in saturated solutions, as well as in the dry salts. Then, too, it must be remembered, whereas isomerization, neutralization, hydrolysis, hydration and de-

¹ Only a few salts have hitherto been prepared, namely, salts of sodium, potassium, calcium and silver, and these possess different colors. The dry hydrated salts of sodium and potassium are colorless and their anhydrous salts are red. The silver salt is red. Red and green salts of calcium were described by Meyer and Posner, *Ber.* **44**, 1954 (1911). See experimental part of this paper.

² Baeyer, *Ber.*, **4**, 659 (1871).

³ Baeyer, *Ann.*, **202**, 36 (1880).

⁴ Apparently Berthsen was the first to use the quinoid formula in connection with phenolphthalein, *Chem.-Ztg.*, **16**, 1956 (1892). Also see Dehnst, *ibid.*, **17**, 654 (1893); Friedländer, *Ber.*, **26**, 172 (1893); Armstrong, *Proc. Roy. Soc. (London)*, **55** (1893). For opinions of the non-existence of the quinoid form for phenolphthalein, see Hjelt, *Chem.-Ztg.*, **18**, 3 (1894); Herzig and Meyer, *Ber.*, **29**, 138 (1896); Bistrzyski and Nencki, *ibid.*, **29**, 131 (1896); Schestakov and Nocken, *ibid.*, **47**, 331 (1914); Oddo, *ibid.*, **47**, 967 (1914); Consonno and Apostolo, *Gazz. chim. ital.*, **51**, [1] 50 (1921).

hydration are all probably involved, there are at least eight color-changing *first causes*.⁵

Experimental

Methods of Formation of Salts of Phenolphthalein.—Owing to the great solubilities of salts of phenolphthalein in organic solvents, the insolubility of most inorganic bases and the capacity of phenolphthalein to form a series of salts with the same base, a variety of methods must be employed to obtain the different salts. The following methods were effective. (a) A metal, such as sodium, was dissolved in an alcohol, phenol, or ketone, and the resulting sodium compound was treated in the presence of the excess of the solvent, with the calculated quantity of phenolphthalein. On standing, the salt usually crystallized out. Promotion of formation of the red salts was influenced by the absence of water in the solvent. If the white hydrated salt was desired, usually a little water was added. The white salts were filtered off, washed with a little alcohol or methyl ethyl ketone, and dried in the desiccator. Whether or not an alkali alcoholate, etc., was first formed, the added water always was found to have formed the hydrated salts, free from combined alcohol, phenol or ketone.

(b) Solid hydrates were added to solutions of the phenolphthalein. These solids were gradually replaced by the solid salts. For the alkali metals, an organic solvent was used; for the alkali-earth metals, water was used. The latter salts could be formed very slowly in ordinary alcohol.

(c) The sodium or better the ammonium salt of phenolphthalein was treated with the acetate of the metal. When the heat of formation of the latter is less than that of the alkali acetate, the new salt of phenolphthalein can be formed.

(d) An ammoniacal solution of the base was treated with an ammoniacal or with an alcohol solution of phenolphthalein.

Ammonium Salt.—Anhydrous ammonia was passed into a mixture of methyl

⁵ **COLORING.** *By acids*, such as HCl, HClO₄, etc., Meyer and Hantzsch, *Ber.*, **40**, 3482 (1907); Hofmann and Keimreuter, *ibid.*, **42**, 4856 (1909). *By alkalies*. Baeyer, *loc. cit.* *By water*. All colorless salts dissolve in water to give colored solutions. *By heat*. Herzig and Meyer, *Ber.*, **28**, 3258 (1895); **29**, 138 (1896); Green and Perkin, *J. Chem. Soc.*, **85**, 398 (1904). *By certain salts*, such as AlCl₃, SnCl₄, etc., Meyer and Hantzsch.⁴ *By alcohol*, Meyer and Marx, *Ber.*, **40**, 3603 (1907). They prepared red alkali salts in absolute alcohol. *By pressure*. Oddo and Vassallo, *Gazz. chim. ital.*, **42**, 209 (1912). *By friction*. All white salts prepared in this paper were reddened by rubbing with a glass rod.

BLANCHING. *By acids*. Green and Perkin observed that neutralization by acetic acid of strongly alkaline solution in potassium hydroxide yielded unstable colorless C₂₀H₁₈O₅K. *By more alkali*. News*, **55**, 133, 143 (1887); McCoy, *loc. cit.*; Schmatolla, *Ber.*, **35**, 1905 (1904); Jones and Allen, *Am. Chem. J.*, **18**, 377 (1896), explain the phenomena on the basis of suppression of the hydroxyl ions. Hildebrand, *THIS JOURNAL*, **30**, 1914 (1908), concludes that the alcohol unites with the phenolphthalein. Wegscheider, *Z. physik. Chem.*, **100**, 532 (1922), concurs in this opinion. Since red salts can be prepared in absolute alcohol and since colorless salts can be prepared in ordinary alcohol, it is evident that the concentration of water contained therein makes the difference.

ethyl ketone and phenolphthalein until the latter dissolved. On evaporating spontaneously in a desiccator over sulfuric acid, white crystals were obtained.

Anal. Calcd. for $C_{20}H_{14}O_4 \cdot NH_4OH$: NH_4OH , 9.51. Found (loss on heating to 130°): NH_4OH , 9.92.

White Monopotassium Phenolphthalein.⁶—Prepared in methyl ethyl ketone from equivalent quantities of potassium hydroxide and phenolphthalein, glistening white rectangular plates and prisms, with truncated corners and beveled ends, were obtained.

Anal. Calcd. for $C_{20}H_{14}O_4 \cdot KOH \cdot 2H_2O$: H_2O , 13.17; K, 9.55. Found: H_2O , 13.12; K, 9.35.

This compound was also prepared from potassium cyanide. When its mixture with phenolphthalein in methyl ethyl ketone was permitted to stand for days, no precipitate formed. When a little water was added, an immediate voluminous precipitate of the above salt was obtained. Here either the cyanide was first added to phenolphthalein and the product was then hydrolyzed or the cyanide was first hydrolyzed and the potassium hydroxide then added.

Red Monopotassium Phenolphthalein.—A hot concentrated solution of equivalent quantities of potassium hydroxide and phenolphthalein in 95% alcohol was treated with a little ether and then was permitted to stand. After a few minutes there were formed rosetts of red needles and long rectangular leaflets which were blanched by ether and re-reddened by ordinary alcohol.

Anal. Calcd. for $C_{20}H_{14}O_4 \cdot KOH \cdot H_2O$: water, 9.18; K, 9.96. Found: water, 9.11; K, 10.01.

Red Disodium Salts.—The sodium hydroxide was prepared by Cornog's⁷ or by Kuster's⁸ method. For example, the necessary weight of sodium was dissolved in amyl alcohol and this mixture was treated with the calculated weight of phenolphthalein. On adding anhydrous ether to this deep red solution, little or no precipitate formed but the solution became indigo-violet by transmitted light. On adding water to this ether solution in quantities necessary for forming the hydrated salt, a voluminous red precipitate was obtained.

Anal. Calcd. for $C_{20}H_{12}O_4Na_2 \cdot 2H_2O$: H_2O , 9.05; Na, 11.55. Found: H_2O , 9.76; Na, 11.30.

Contact with atmospheric moisture slowly changed this color through lighter reds to white.

Red Calcium Salt.—This was prepared by Meyer and Posner by quite an involved method. It is easily prepared by treating freshly ignited marble with phenolphthalein in the presence of a little water. Its composition was given as $C_{20}H_{12}O_4Ca \cdot 2.5H_2O$; its more probable composition is $C_{20}H_{14}O_6Ca \cdot 2H_2O$, whose structural relations can be in-

⁶ Kober and co-workers obtained the colorless monopotassium salt containing 1 mole of water and 1 mole of C_2H_5OH . When the sodium and the potassium salts were prepared by the author in the higher alcohols by their treatment with the metal, and proper equilibrium was established with the traces of water, the above salts free from alcohol of crystallization were always obtained.

Oddo and Vassallo⁸ obtained the red monopotassium salt from (absolute) alcohol. Bassett and Halton claim to have disproved the formation of the red salt, because they obtained the white salt of Kober when they used (ordinary) alcohol. These apparent contradictions can be understood because the experiments of this paper point out the modifying influence of traces of water in various solvents.

⁷ Cornog, *THIS JOURNAL*, **43**, 2573 (1921).

⁸ Kuster, *Z. anal. Chem.*, **41**, 474 (1904).

dicated as $\text{HOCaCOOCC}_6\text{H}_4\text{C}(\text{C}_6\text{H}_4\text{OH})=\text{C}_6\text{H}_4=\text{O}\cdot 2\text{H}_2\text{O}$, and whose anhydrous salt, as $\text{O}(\text{CaOCC}_6\text{H}_4\text{C}(\text{C}_6\text{H}_4\text{OH})=\text{C}_6\text{H}_4=\text{O})_2$.

The first formula involves the elimination of the phenol hydroxyl, an assumption which is disproved by the evolution of phenol itself at high temperatures. Furthermore, the analyses confirm the latter formulas:

Calcd. for $\text{C}_{20}\text{H}_{12}\text{O}_4\text{Ca}\cdot 2\frac{1}{2}\text{H}_2\text{O}$	Ca, 9.98; $2.5\text{H}_2\text{O}$, 11.22
Calcd. for $2(\text{C}_{20}\text{H}_{14}\text{O}_5\text{Ca}\cdot 2\text{H}_2\text{O})$	Ca, 9.77; $5\text{H}_2\text{O}$, 10.98
Calcd. for $\text{C}_{20}\text{H}_{12}\text{O}_4\text{Ca}$	Ca, 11.25
Calcd. for $\text{C}_{40}\text{H}_{26}\text{O}_9\text{Ca}_2$	Ca, 10.97
Found by M and P in the hydrated salt	Ca, 10.1; water, 11.3
Found by M and P in the anhydrous salt	Ca, 11.5; and 11.6
Found by the author in the hydrated salt	Ca, 9.61
Found by the author in the anhydrous salt	Ca, 10.74

White Calcium Salt.—Equivalent quantities of freshly ignited marble and phenolphthalein were placed in ordinary 95% alcohol. At first a very red solution and a red solid were formed. After shaking often during days and weeks, the red solution became pink and the red solid was replaced by a fluffy, white solid. By shaking and letting stand for a few seconds, the solution with suspended white solid could be decanted from the heavier red solid, filtered, washed with alcohol, dried and analyzed.

Anal. Calcd. for $\text{C}_{20}\text{H}_{16}\text{O}_6\text{Ca}\cdot 2\text{H}_2\text{O}$: H_2O , 14.72. Found: H_2O , 14.50. Calcd. for $\text{C}_{40}\text{H}_{26}\text{O}_9\text{Ca}_2$ (see above): Ca, 10.97. Found: Ca, 10.96.

When dehydrated, this white salt became deep red at 110° and brown-black at 150° ; both forms became bright red in moist air. Because the green anhydrous salt of Meyer and Posner becomes red on standing in the air and green again on heating, apparently the two anhydrous salts are two different compounds. However, when the green salt is pulverized in the absence of moisture, it becomes red, hence the green color is merely a fluorescent property of large red crystals.

Piperidine Phenolphthalein.—Upon mixing equivalent quantities of piperidine and phenolphthalein in methyl ethyl ketone or in alcohol, heating was observed; on cooling, white needles were obtained. After filtering and drying, they were found to give off slowly the odor of piperidine. On heating to 110° or higher, the material remained white.

Anal. Calcd. for $\text{C}_{20}\text{H}_{14}\text{O}_4\cdot \text{C}_6\text{H}_{11}\text{N}$: loss in weight, 21.10. Found: 20.95.

Because this additive compound contains no carbinol hydroxyl, it gives no color on being heated. With water it yields a red solution because of preliminary hydration, followed by dehydration.

Summary

1. A number of new salts of phenolphthalein have been prepared and studied. They are always additive compounds of phenolphthalein and the base. Usually two or more molecules of crystal water are also present.

2. It has been demonstrated that most hydrated salts are colorless and become colored by loss of water. Loss of water can be effected by heat, pressure, friction or certain solvents and such loss of water is probably a dehydration from the carbinol form to the quinoid form. The colors of dehydrated salts, containing either chromogenic or non-chromogenic metals, differ widely.

3. The probable cause of color of phenolphthalein salts is the quinoid chromophore. Hydration and dehydration are important influences effecting changes in color. Isomerization, neutralization, addition, hydrolysis and ionization attend phenolphthalein phenomena, but precede or are incidental to the transforming of colorless carbinol forms to the colored quinoid form.

THE PREPARATION AND PROPERTIES OF SOME SUBSTITUTED 2-METHYLTHIOPHENES

BY ALVIN F. SHEPARD

RECEIVED MARCH 14, 1932

PUBLISHED JULY 6, 1932

In order to identify certain thiophene homologs in pyrolysis products, 2-methyl-5-ethylthiophene, 2-methyl-4-ethylthiophene and 2,3-dimethylthiophene were prepared for comparison. The preparation and properties of these compounds are reported here since these thiophene homologs were either unknown or imperfectly described.

2-Methyl-5-ethylthiophene was obtained in 40% yield by a modified Wolff reduction which consisted of heating the semicarbazide of 2-methyl-5-acetothienone with moist powdered potassium hydroxide. Steinkopf¹ has prepared this substituted thiophene in 10% yield by a Clemmensen reduction of 2-methyl-5-acetothienone, but he obtained insufficient material for determination of its physical properties.

The other two thiophene homologs were synthesized by the action of phosphorus sulfides on the proper substituted levulinic acids. While 2,3-dimethylthiophene has been prepared by Paal and Püschel² and by Grünewald,³ it is noteworthy that our specimen had a boiling point about 3° higher than reported by them. This observation was checked on a purer

The freezing points were measured with a toluene thermometer and are reliable to $\pm 1^\circ$. Molecular weights were determined cryoscopically in benzene. The indophenin tests were made by adding a drop of the substituted thiophene to a solution of isatin in sulfuric acid containing a trace of nitric acid, and the color reported is the one which developed after the mixtures had stood for five to fifteen minutes.

Experimental Part

2-Methyl-5-ethylthiophene.—2-Methyl-5-acetothienone semicarbazide was prepared by the method of Steinkopf. It melted at 224.5° (with decompn.); Steinkopf gives 225° . Fifty grams of the finely powdered potassium hydroxide and 35 g. of the semicarbazide were placed in a 500-cc. distilling flask, 5 cc. of water was added and the whole mass was thoroughly mixed. The flask was then heated with a free flame as long as liquid distilled over. The product from three runs was combined, steam distilled once to separate a small amount of yellow solid which accompanied the methylethylthiophene, dried and fractionated over sodium. The yield of pure material having the constants indicated in the table was 40%. This thiophene homolog has a very characteristic and pleasant odor, similar to that of *p*-ethyltoluene.

2-Methyl-4-ethylthiophene.— α -Ethyllevulinic acid was obtained by the procedure of Fittig and Young,⁴ and boiled from 161 – 166° (uncorr.) at 20 mm. Its semicarbazone had m. p. 171 – 172° with slight gas evolution; Gault and Solomon⁵ give 171 – 172° . The acid was converted to the sodium salt, which was dried over phosphorus pentoxide at 100° . The sodium salt was powdered, thoroughly mixed with twice its weight of sand, and the mixture was distilled from a retort heated with a free flame. The resulting distillate was washed with cold sodium hydroxide solution and fractionated over

⁴ Fittig and Young, *Ann.*, **216**, 39 (1883).

⁵ Gault and Solomon, *Ann. chim.*, [10] **2**, 205 (1924).

sodium, which separated a small amount of material boiling below 140°. The purified 2-methyl-4-ethylthiophene was obtained in 20% yield (based on ethyllevulinic acid).

2,3-Dimethylthiophene.— β -Methyllevulinic acid was obtained by the excellent method of Pauly, Gilmour and Will,⁶ and boiled from 130–132° (uncorr.) at 10 mm. On heating 30-g. portions of this acid with 35-g. portions of powdered phosphorus pentasulfide, a vigorous reaction took place and the product was distilled out as soon as the reaction slowed down. The crude product was worked up as before. The purified 2,3-dimethylthiophene was obtained in 20% yield.

As a check on the high boiling point observed, a specimen of 5-chloromercuri-2,3-dimethylthiophene was purified by crystallization until it melted with slight decomposition at 218.5–219.5 (corr.). Steinkopf⁷ gives the melting point of this compound as 213–214° (with decomposition). The 2,3-dimethylthiophene was recovered quantitatively from this mercury compound by heating with hydrochloric acid, and the specimen thus obtained boiled entirely in the range 140.2–141.2° (corr.). The constants of both specimens are given in the table.

Summary

The preparation and physical properties of 2,3-dimethylthiophene, 2-methyl-4-ethylthiophene and 2,5-methylethylthiophene are presented.

NATURAL AND SYNTHETIC RUBBER. IX. THE PRODUCTS OF DESTRUCTIVE DISTILLATION OF EBONITE

BY THOMAS MIDGLEY, JR., ALBERT L. HENNE AND ALVIN F. SHEPARD

RECEIVED MARCH 14, 1932

PUBLISHED JULY 6, 1932

Introduction

It has been shown that there is a definite relationship¹ between the rubber molecule and its pyrolysis products, and consequently the thermal decomposition of ebonite has been undertaken to throw light on the nature of the rubber sulfur complex.

It was relatively simple to correlate the pyrolysis products of raw rubber with the formula of the parent molecule, as the rubber formula had been previously established by oxidation. However, the formula of ebonite is still unknown, and cannot be arrived at by ordinary methods, because ebonite is amorphous, insoluble, non-volatile, completely saturated, and inert toward chemical agents. A correlation of its pyrolysis products may thus be the only way of establishing its formula.

The pyrolysis products of ebonite, the decomposition products of a mixture of rubber and sulfur, and the interaction of sulfur and the pyrolysis

¹ Midgley and Henne, *THIS JOURNAL*, **51**, 1215 (1931).

products of raw rubber have been investigated to establish a basis from which the formula of ebonite may be derived.

The present paper presents the study of the products obtained when ebonite is destructively distilled.

Procedure.—Thirty-six kilograms of ebonite were destructively distilled in the manner reported previously. The volatile products were progressively condensed by means of warm water ice water and solid carbon dioxide. The non-condensed gases were washed through a copper sulfate solution to eliminate hydrogen sulfide, and finally led through another condenser cooled with carbon dioxide. The condensed products were subjected to fractional distillation, and from the various cuts thus obtained the thiophene homologs were separated by mercuration.

Results.—The amount of hydrogen sulfide liberated during pyrolysis accounted for approximately one-half of the sulfur originally present in the ebonite. As a consequence, the oils obtained were of a highly unsaturated character. An examination of the oils boiling below 170° established the presence of mercaptans, sulfides, thiophene homologs and *m*-xylene. The examination failed to detect disulfides. The oils boiling above 170° were rich in sulfur; they were not further investigated. The limited stability of a portion of the sulfur compounds precluded their separation, and hence the determination of their constitution. The thiophenes and the hydrocarbons were stable enough to be successfully investigated, and it was thus possible to isolate and identify 2-methylthiophene, 2,3-dimethylthiophene, 2,4-dimethylthiophene, 2,5-methylethylthiophene and *m*-xylene. At the same time it was shown that benzene, toluene, thiophene, 2,5-dimethylthiophene, 2,3-methylethylthiophene or trimethylthiophenes were not present in significant quantities. Similarly, the absence of other isomers of the thiophene homologs was established. The yields were: thiophenes, 1%; xylene, 0.1%, of the total quantity of ebonite used.

Experimental Part

The ebonite used in this investigation was prepared by the Inland Manufacturing Company of Dayton, Ohio, through the kindness of Dr. A. H. Flower, to whom we here wish to express our thanks. The following mix was used: first latex crepe, 100, sulfur, 32, diphenylguanidine, 2, "Kadox," 2, stearic acid, 2. The mix was cured for eight hours at 148°; analysis showed 0.1% free sulfur at the end of this time.²

² The effect of the ingredients other than sulfur and rubber in the ebonite may be discounted, as shown by the following experiments. A small batch of ebonite, prepared from a crepe rubber-sulfur mix containing 32% sulfur and no accelerators, was destructively distilled. In the distillate, 2-methylthiophene, 2,3-dimethylthiophene and *m*-xylene were positively identified. Thiophene, benzene, toluene, 3-methylthiophene and *p*-ethyltoluene were absent, while 2,4-dimethylthiophene and 2-ethyl-5-methylthiophene appeared to be present, although they were not positively identified. An ebonite was also prepared from sodium-rubber containing 32% sulfur and no accelera-

Thirty-six kilograms of this ebonite were cracked as previously described. The vapors were progressively condensed at 100, 0 and -80° . The condensate obtained at -80° was chiefly hydrogen sulfide and quite free of hydrocarbons boiling below 30° . A rough estimate of the amount of hydrogen sulfide liberated was made by passing the cracked gases through copper sulfate solutions. Table I summarizes the results.

TABLE I

	Liquid	H ₂ S	Water	Coke	Uncondensed gases and loss
Yield on ebonite, %.....	59	13	4	6	18

The liquid was topped to 200° . The higher boiling materials contained 14.2% sulfur; they were not further investigated. The distillate below 200° (3600 g. or 10% of the original liquid) was systematically fractionated. After three runs, the material boiling below 120° was repeatedly washed with alkali to remove mercaptans completely, and the fractionation was resumed and carried out to its practical limit. Table II shows the results of the final fractionation together with the physical properties and sulfur content of the fractions. Double bond determinations were made only on the fractions containing little sulfur.

140-142	39	20	.916	1.491		16.8

tors. The pyrolysis products of this sodium rubber ebonite were also quite similar to those from crepe rubber ebonite. The mercuration treatment allowed the recovery of small amounts of thiophene homologs, similar in their indophenin reactions to those obtained from the crepe rubber ebonite.

175-180	100	20	.919	1.495		

Each of the three main fractions, b. p. 109-111°, 138-140° and 160-160.5°, was a complex mixture. Distillation from aniline separated these mixtures roughly into hydrocarbon-rich fractions and sulfur-rich fractions, but since this was insufficient, chemical methods were preferred.

Mercaptans and Disulfides.—A mercaptan concentrate was isolated by steam distilling the alkali washings of the ebonite fraction boiling below 120°. It weighed only 8 g. and boiled chiefly from 66-80°. It had the characteristic mercaptan odor and gave typical mercaptan reactions with iodine, alcoholic lead acetate, sodium plumbite and mercuric oxide. The ebonite fractions boiling from 100-180° contained mere traces of mercaptans.

Disulfides were absent from the ebonite fractions boiling below 170°; this was shown by the failure to form mercaptans on reduction with zinc and glacial acetic acid.³

Thiophenes and Aromatic Hydrocarbons.—Thiophene and its lower homologs are very readily mercurated.⁴ Thiophene is quantitatively extracted from benzene⁵ by a boiling solution of mercuric acetate in dilute acetic acid; it forms a di-mercuri compound, and is readily regenerated from this compound by boiling hydrochloric acid. The various ebonite fractions were refluxed for thirty minutes or more with Dimroth's reagent (40 g. mercuric oxide), 40 cc. glacial acetic acid and 200 cc. water) and subjected to steam distillation. This operation removed unreacted aromatic and saturated hydrocarbons and left behind a complex mixture, from which the thiophenes were regenerated in a fair state of purity by boiling hydrobromic acid. The mercuric acetate treatment always caused the loss of the olefins and of up to 70% of the sulfur compounds. In order to show that this loss of sulfur derivatives was not due to the preferential destruction of some definite thiophene homolog, the mercuration and regeneration of thiophene, 2-methylthiophene, and of 3-methylthiophene were checked. None was appreciably oxidized; all were completely regenerated from their mercury compounds by hydrobromic acid. This check was regarded as important because Volhard reports that 2,5-dichloromercuri-3-methylthiophene is very difficult to split with acids.

Other Sulfur Compounds.—Many unsuccessful attempts were made to isolate by

³ Faragher, Morrell and Monroe, *Ind. Eng. Chem.*, **19**, 1281 (1927).

⁴ Volhard, *Ann.*, **267**, 172 (1892); Steinkopf and Bauermeister, *ibid.*, **403**, 50-72 (1914); (a) Steinkopf, *ibid.*, **413**, 310-333 (1917); (b) **424**, 23-61 (1921); (c) **428**, 138 (1922).

⁵ Dimroth, *Ber.*, **32**, 759 (1899).

other methods the sulfur compounds lost in the mercuration procedure. Significant are the following observations.

Fractions containing these sulfur compounds react with mercurous nitrate monohydrate, a reagent used by Faragher, Morrell and Monroe³ for the quantitative removal of sulfides from thiophene and hydrocarbons.

Diethyl sulfide may be recovered from its mixture with a hydrocarbon and thiophene by shaking with a solution of mercuric acetate and steam distilling the mercuric acetate solution but no sulfur compound is recoverable from the 109–113° cuts in this way.

The ebonite distillates did not react appreciably with dimethyl sulfate, a reagent which reacts with dimethyl sulfide on gentle warming.

The early experiments with aniline fractionation showed that in the case of the large fractions boiling at 107–113°, 136–142° and 159–165°, the sulfur compounds lost had physical properties not widely different from the thiophenes with which they were associated.

A proposed explanation is that the lost sulfur compounds represent members of an homologous series of dihydrothiophenes.

Tests for Individual Compounds.—The mercuration procedure was systematically applied to all the ebonite distillates boiling in the range 60–165°. Unless otherwise stated, all mercury derivatives were prepared and purified exactly according to the directions of Steinkopf.^{4b}

Thiophene and Benzene.—One drop of oil was recovered from the mercury compounds obtained from the ebonite fractions boiling from 66–88°. This drop did not give the indophenin reaction; thiophene was therefore absent. The steam distillate from the mercury compounds was treated with bromine water and steam distilled; 1 cc. of an oil was obtained. Nitration to dinitrobenzene was attempted but none could be isolated.

2-Methylthiophene.—The product isolated boiled at 111.5–112.5° (741 mm.), and had d_4^{20} 1.017, n_D^{20} 1.5132, molecular refraction observed 29.0, theoretical 30.1. It gave the green indophenin reaction characteristic of 2-methylthiophene. The following derivatives were prepared: 5-chloromercuri-2-methylthiophene, m. p. 204°, alone and in a mixture with authentic material; 2-methylthiophene-5-mercurithiocyanate, m. p. 200–201° (decomp.); tribromo-2-methylthiophene, m. p. 83°. Steinkopf gives the melting points of the first two derivatives as 204° and 202–204° (decomp.), respectively. Gattermann, Kaiser and Meyer⁶ give a melting point of 86° for tribromo-2-methylthiophene and state that a mixture of the 2- and the 3-isomers is inseparable by crystallization and melts at 74°. Comparison of the relative amounts of alcohol-insoluble material formed on mercuring the thiophene from ebonite and synthetic 3-methylthiophene indicated⁷ that less than 10% of 3-methylthiophene could have been present in the ebonite product.

Toluene.—The steam distillate containing the toluene was brominated at 0° with bromine water and steam distilled to separate the unreacted constituents from olefin bromides. After washing with sulfuric acid the product boiled at 109.5–111.5° and had n_D^{20} 1.4812. A saturated compound was present with the toluene since the material was not completely soluble in 10% oleum. Nitration gave dinitrotoluene of m. p. 69–70° alone and in a mixture with authentic material. A check experiment showed that no significant amount of toluene could have been mercured and thus lost in the procedure of separation.

⁶ Gattermann, Kaiser and Meyer, *Ber.*, 18, 3009 (1885).

⁷ Later experiments have shown that 3-methylthiophene is readily formed by the interaction of isoprene and boiling sulfur.

Dimethylthiophenes.—The thioxene mixture as isolated boiled at 139.5–141.5° (745 mm.) corr. and had n_D^{20} 1.5137 and d_4^{20} 0.984. Mercuration with mercuric chloride according to Steinkopf's procedure yielded a product completely soluble in benzene or alcohol. This shows the absence of 3,4-dimethyl- or 3-ethylthiophene; Steinkopf states that these isomers form di-mercuri compounds insoluble in these or other low-boiling solvents. The boiling point of the mixture is too high to be compatible with the presence of any significant quantity of 2-ethylthiophene (b. p. 132–134° corr.).⁸

Fractional crystallization of the mercury chloride compounds of the ebonite thioxenes from benzene permitted the isolation of 50% of the mercury compounds as 5-chloromercuri-2,3-dimethylthiophene, m. p. 217.5–218.5° (decomp.) alone and in a mixture with authentic material. This substance was converted to 2,3-dimethylthiophene-5-mercurithiocyanate, which shrunk and blackened at about 198° and did not melt up to 240°. Steinkopf states that this compound darkens at 200–202° and does not melt below 240°. Further confirmation of the presence of 2,3-dimethylthiophene was obtained by permanganate oxidation of the original thioxene mixture. A mixture of mono- and dicarboxylic acids resulted and the mono acid was steam distilled out from a very concentrated solution. Recrystallized twice from water it melted at 140–141° and its melting point was raised by mixture with the acid of m. p. 143° obtained similarly from the oxidation of synthetic 2,3-dimethylthiophene. The dicarboxylic acids gave the fluorescein reaction strongly.

Anal. of monocarboxylic acid: (a) from synthetic 2,3-dimethylthiophene; C, 50.8, 50.9; H, 4.1, 4.2. Calcd. for $C_8H_6O_2S$: C, 50.7; H, 4.3. (b) From ebonite thioxene: molecular weight by alkali titration, 141.5; calcd. for $C_8H_6O_2S$, 142.

The other mercury compounds occurring with 5-chloromercuri-2,3-dimethylthiophene were much more soluble in all solvents, melted mostly at 135–150°, and could not be purified satisfactorily by crystallization. Steinkopf has noted a considerable difference in the rates at which the substituted thiophenes mercurate, and a separation of 2,4-dimethylthiophene derivatives was accomplished by the application of this principle. The above-mentioned mixture of mercury compounds was converted to the thioxenes with hydrogen bromide and the thioxenes were remercurated. After five minutes the mercury compound formed was separated from the mercuration mixture and reconverted to the thioxenes. The mercuration was then repeated, and after two minutes the formed mercury compound was again removed. The final amount of this mercury compound corresponded to 10% of the original mixture of mercury compounds obtained from the ebonite thioxenes. Crystallized from benzene, it melted at 168–169° in a bath preheated to 165°; on slower heating it sintered together somewhat above 170° but did not melt. The mercuric chloride addition product of oxodihydromercuri-2,3-dimethylthiophene is stated by Steinkopf to melt at 167–168° on rapid heating; slow heating causes only a gradual sintering together. From this compound were prepared 5-chloromercuri-2,4-dimethylthiophene, m. p. 137.5–138.5°; 2,4-dimethylthiophene-mercurithiocyanate, m. p. 175–177° (sinters at 173°); and 5,5'-mercuri-bis-2,4-dimethylthiophene, m. p. 160–161° (with sintering). Steinkopf gives the melting points of these substances as 138–139°, 173–175° (sinters at 171°) and 160–161° (with sintering), respectively. The presence of 2,4-dimethylthiophene in the ebonite distillates is thus proved.

An attempt was made to isolate 2,5-dimethylthiophene by a similar method based on the principle that the compound mercurates much more slowly than the 2,3- and 2,4-isomers. None was found.

***m*-Xylene.**—The xylene fraction was separated from olefins in the same way as the toluene. The product had b. p. 138–139° (746 mm.) (corr.), d_4^{20} 0.852 and n_D^{20} 1.4895. Sulfonation with oleum left about 10% of saturated hydrocarbon. According to

⁸ Meyer and Kreis, *Ber.*, 17, 1560 (1884).

Timmermans⁹ *m*-xylene has b. p. 139.3° (760 mm.) and d_4^{20} 0.8641. Ten drops of the xylene fraction was added to 10 cc. of concentrated sulfuric acid and 5 cc. of fuming nitric acid; the mixture was boiled for two minutes, then poured on ice and diluted with water. The precipitate was filtered off, washed with water and then with 15 cc. of cold 50% alcohol. The dried product showed m. p. 177–179°; after one crystallization from 50% alcohol it melted at 181–182° alone and in a mixture with authentic material. This proves the presence of *m*-xylene, substantially free of isomers.

2-Methyl-5-ethylthiophene.—The product first recovered from the mercuration procedure still contained unsaturated compounds and had d_4^{20} 0.957. To eliminate the unsaturated material the procedure of mercuration and regeneration was repeated. The product thus obtained boiled at 159.8–161.3° (chiefly 160.1–160.6°), had a freezing point –74.2°, d_4^{20} 0.958, n_D^{20} 1.5048 and a mol. wt., as determined by the freezing point depression in benzene, of 124.2, 126.5.

Anal. Calcd. for $C_7H_{10}S$: S, 25.42. Found: S, 24.05, 24.10, 23.90.

A specimen was prepared from the mercury acetate compound crystallized from glacial acetic acid; this preparation boiled at 159.5–160.6°, had a freezing point of –69.4°, d_4^{20} 0.9644, n_D^{20} 1.5063, and contained 25.28, 25.31% S. Presumably the earlier preparation still contained a small amount of hydrocarbon.

Synthetic 2-methyl-5-ethylthiophene boils at 159.8–160.4° and has¹⁰ the freezing point –68.4°, d_4^{20} 0.9663 and n_D^{20} 1.5073. The freezing point of the product from ebonite (f. p. –74.2°) was raised by admixture with the synthetic material. It is noteworthy that this 2,5-disubstituted thiophene mercures more slowly than the other compounds heretofore described, a behavior which parallels that reported by Steinkopf for 2,5-dimethylthiophene. Both synthetic 2-methyl-5-ethylthiophene and the product from ebonite (f. p. –74.2°) gave an intense red-brown color when added to a solution of isatin in commercial sulfuric acid. Dr. W. R. Brode has very kindly compared the absorption spectra of both these colorations with a spectrophotometer, and has found no difference whatever in the spectra.

It is evident that the material from ebonite is 2-methyl-5-ethylthiophene, reasonably free from isomers.

A trimethylthiophene, especially the 2,3,5-isomer, might be expected to mercurate with extreme difficulty, and these compounds were sought in the steam distillate from the mercuration. Youtz and Perkins¹¹ state that 2,3,5-trimethylthiophene dissolves in sulfuric acid and is reprecipitated apparently unchanged on dilution. Schulze¹² has recovered thiophene and its homologs by diluting with water and steam distilling the sulfuric acid washings of various aromatic hydrocarbons obtained from coal tar. Accordingly, the steam distillate from the mercuration of the ebonite fractions boiling in the neighborhood of 160° was carefully washed, cold, with 2 volumes of concd. sulfuric acid. The sulfuric acid extract was drawn off and ice and water were added to it, which caused the separation of an oil. The oil was removed, steam distilled, and then distilled over sodium. There was thus recovered 2 g. of a product of b. p. 158–168° which had n_D^{30} 1.484. A measurement of the depressions of the freezing point of 2-methyl-2-ethylthiophene caused by the addition of this material and of *n*-nonane was made. This measurement showed that at least 50% of the material recovered by sulfuric acid treatment was 2-methyl-5-ethylthiophene, which fact, in view of the low refractive index of the material, shows the practical absence of trimethylthiophenes.

⁹ Timmermans, *J. chim. phys.*, **27**, 2 (1930).

¹⁰ The preparation and physical properties of the synthetic specimen are described in a separate paper now submitted for publication in THIS JOURNAL.

¹¹ Youtz and Perkins, THIS JOURNAL, **51**, 3511–3516 (1929).

¹² Schulze, *Ber.*, **18**, 497 (1885).

Aromatic hydrocarbons were present only in insignificant amount in the ebonite fractions boiling from 156–165°, since less than 1 g. of hydrocarbon (b. p. 160–163°, n_D^{30} 1.472) was recovered from the sulfuric acid washing of the steam distillates.

TABLE III

AMOUNTS OF PRODUCTS RECOVERED BY PYROLYSIS OF 36,000 G. OF EBONITE

Compound	Recovered, g.	Compound	Recovered, g.
Benzene	<0.5	2,4-Dimethylthiophene	10
2-Methylthiophene	10	<i>m</i> -Xylene	50
Toluene	1	Aromatic hydrocarbon, b. p.	
2,3-Dimethylthiophene	50	ca. 160°	< 1
		2-Methyl-5-ethylthiophene	240

Summary

The following compounds have been identified in the products obtained from ebonite by destructive distillation: 2-methylthiophene, 2,3-dimethylthiophene, 2,4-dimethylthiophene, 2,5-methylethylthiophene and *m*-xylene. These results will be used to derive the structural formula of ebonite.

THE PREPARATION OF BENZOYLACETIC ESTER AND SOME OF ITS HOMOLOGS

BY JOHN B. DORSCH AND S. M. MCELVAIN

RECEIVED MARCH 14, 1932

PUBLISHED JULY 6, 1932

Although benzoylactic ester was first prepared by Baeyer¹ by the hydration of phenylpropionic ester, this method has certain disadvantages that reduce its preparative value.² The most satisfactory methods that may be found in the literature are two developed by Claisen. One of these involves the direct condensation of ethyl benzoate with ethyl acetate in the presence of sodium ethoxide,³ and although a 33% yield of product is claimed, the actual weight of benzoylactic ester reported as having been obtained shows the yield to be only 26% of the theoretical. In the other method benzoylactic ester is obtained by the partial hydrolysis of benzoyl-acetoacetic ester.⁴ Recently, failures to duplicate the yield claimed in Claisen's first method and modifications of the second method have been reported by Shriner and Schmidt.⁵

A number of the homologs of benzoylactic ester have been prepared

by Perkin and co-workers⁶ by the alkylation of this ester with an alkyl iodide in alcoholic solution in presence of sodium ethoxide. Although no yields are reported the idea is conveyed that the procedure is quite satisfactory. Experiences with the alkylation of benzoylacetic ester in this Laboratory by Perkin's method as well as with one using metallic sodium in the absence of alcohol⁷ have been far from gratifying. Besides being obtained in quite low yields, the product was a mixture of the alkylated and unalkylated benzoylacetic esters.

This paper reports the results of a study of the preparation of benzoylacetic ester and its homologs, ethyl α -benzoylpropionate, ethyl α -benzoylbutyrate and ethyl α -benzoylvalerate. These esters were prepared by the hydrolysis of the imino ether hydrochlorides derived from the corresponding α -benzoyl alkyl cyanides. These latter compounds were obtained by the condensation of ethyl benzoate with the alkyl cyanide by means of sodium ethoxide. The steps in the preparation may be illustrated thus

The yields of the benzoyl alkyl cyanides varied from 53–60%, while the yields of the esters from the cyanides were 64–74%. The over-all yields of each of the keto esters from ethyl benzoate was 35–44% of the theoretical.

An interesting variation in the behavior of the benzoyl alkyl cyanides was noted in their conversion into the esters. When the intermediate imino ether hydrochlorides were treated with alcohol containing the theoretical amount of water for their hydrolysis, benzoylacetic ester was obtained from benzoyl methyl cyanide with no side product, but from α -benzoyl ethyl cyanide a considerable amount of benzoyl propionamide was isolated along with the keto ester. From α -benzoyl propyl cyanide and α -benzoyl butyl cyanide practically the entire yield in each case was the corresponding amide. This amide formation could be considerably reduced, but not completely prevented, if about three times the required amount of water, containing a small amount of hydrochloric acid, was used for the hydrolysis.

A study also was made of the direct condensation of ethyl benzoate with ethyl acetate and certain of its homologs in the presence of sodium ethoxide. Not only was it possible in the case of benzoylacetic ester to duplicate the yields reported by Claisen and Lowman,³ but by certain modifications the yield was raised to 37% of theory. With such a yield the direct condensa-

⁶ Perkin and co-workers, *J. Chem. Soc.*, **45**, 179 (1884); **49**, 160 (1886); **95**, 2047 (1909).

⁷ Cf. Folkers and Adkins, *THIS JOURNAL*, **53**, 1416 (1931).

tion procedure is to be preferred over the method involving the intermediate benzoyl methyl cyanide. The yields of the higher homologs by direct condensation were, however, much lower, being in the cases of ethyl α -benzoylpropionate and ethyl α -benzoylbutyrate 19 and 4%, respectively. The procedure through the α -benzoyl cyanides seems to be the most satisfactory method of preparation of these higher homologs not only because of the yield but on account of the high purity of the product which it affords due to the fact that the unalkylated and dialkylated products are necessarily absent.

Experimental

Materials Used.—The esters and cyanides which were used were dried over and distilled from phosphorus pentoxide. Sodium ethoxide was prepared by two previously described procedures.⁸

α -Benzoylalkyl Cyanides.—In a 3-necked 1-liter flask fitted with a mercury-seal stirrer, a long-stem dropping funnel and a reflux condenser were placed 150 g. (1 mole) of ethyl benzoate and 68 g. (1 mole) of sodium ethoxide. The mixture was warmed by an oil-bath to about 80° and stirred until it became a homogeneous gelatinous mass. Then 1.25 moles of the alkyl cyanide was added slowly under the surface of this mass from the dropping funnel over a period of two hours. The temperature of the oil-bath was then raised to and maintained at 110–120°, in the case of methyl and ethyl cyanide, for ten hours with continuous stirring. When propyl and butyl cyanides were used it was found advantageous at this point to replace the reflux condenser with a short (18-cm.) Vigreux column, raise the temperature of the oil-bath to 140–160° and to allow the alcohol formed in the condensation to distil out slowly from the reaction mixture.

The reaction mixture was then cooled to about 0° in an ice-bath, treated with 400 cc. of ice water and 100 cc. of ether and shaken until the solid material had dissolved. The aqueous layer was then separated from the ether layer and acidified with dilute sulfuric acid. The precipitated benzoyl alkyl cyanide together with a small amount of benzoic acid was taken up in ether and the resulting ethereal solution washed with a saturated sodium bicarbonate solution to remove the benzoic acid. After drying over anhydrous sodium sulfate, the ether was removed by distillation. Benzoyl methyl

Butyl ^c		139–140 (3 mm.)	59	7.48	7.47

^a Haller, *Compt. rend.*, **104**, 1448 (1887), reports this compound as melting at 80.5°.

^b Walther and Schickler, *J. prakt. Chem.*, [2] **55**, 306 (1897), obtained by the above procedure a small amount of α -benzoyl ethyl cyanide which they isolated as the phenylhydrazone, m. p. 100–104°. They could not obtain any satisfactory results with the higher cyanides. Meyer, *J. prakt. Chem.*, **147**, 190 (1889), reports this compound as a liquid but gives no physical constants. ^c These compounds do not appear to have been described previously in the literature.

⁸ McElvain, *THIS JOURNAL*, **51**, 3128 (1929); Houben-Weyl, Vol. II, 1922, p. 578.

cyanide is a solid and was purified by recrystallization from naphtha (b. p. 90–125°). The higher homologs are liquids and were purified by distillation under diminished pressure.

α -Benzoyl Esters and Amides.—A solution of 50 g. of the benzoyl alkyl cyanide in 250 cc. of absolute alcohol was cooled to 0° and saturated with dry hydrogen chloride. After standing at room temperature for about twelve hours, the excess alcohol and hydrogen chloride were removed under diminished pressure. Then 100 cc. of absolute alcohol containing three times the theoretical quantity of water necessary for the hydrolysis of the imino ether hydrochloride and 3 cc. of concentrated hydrochloric acid were added to the residue and the resultant solution heated for thirty minutes on a steam-bath. The solution was then cooled and poured into 800 cc. of cold water. The ester layer which separated was taken up in ether and separated from the water layer. In certain cases a small amount of the solid amide remained insoluble in both the ether and water layers and was removed by filtration. The ether extract of the α -benzoyl esters was dried over sodium sulfate and after removal of the ether the ester was distilled under diminished pressure. It is advisable to use as low pressures as possible for these distillations in order to minimize the formation of the dehydro compounds. The boiling points and yields of these esters are summarized in Table II.

If only the theoretical quantity of water were employed for the hydrolysis of the imino ether hydrochlorides instead of three times the required amount as described above, the yield of benzoylactic ester was unaffected but the yields of the higher homologs were considerably reduced. In each of these latter cases a sufficient amount of the corresponding amide was obtained to compensate for the reduction in the yield of the ester. These amides, which are summarized in Table II, were characterized by hydrolysis into the phenyl alkyl ketones.

^a Haller, *Bull. soc. chim.*, [2] 48, 23 (1887), reports the preparation of benzoyl-acetic ester from benzoyl methyl cyanide. ^b Cf. Hope and Perkin, *J. Chem. Soc.*, 45, 179 (1884); 47, 241 (1885); 49, 156–160 (1886); 95, 2045 (1909). ^c Not previously described in the literature.

Direct Condensation of Ethyl Benzoate with Ethyl Acetate and its Homologs.—A mixture of 136 g. (2 moles) of sodium ethoxide and 300 g. (2 moles) of ethyl benzoate was placed in a 1-liter 3-necked flask fitted with a mercury-seal stirrer, a dropping funnel extending below the surface of the liquid, and a reflux condenser carrying a calcium chloride tube in the upper end. This mixture was stirred and heated in an oil-bath to 70–80° until the mass became a fairly homogeneous paste. Then 176 g. (2 moles) of ethyl acetate was added slowly from the dropping funnel over a period of about two

hours. The temperature of the oil-bath was then raised to 90° and the reaction mixture held at this temperature with continuous stirring for another two hours.⁹

The reaction mixture was then cooled and treated with a cold solution of 150 cc. of glacial acetic acid in 300 cc. of water and the ester layer taken up in ether. The ether extract was washed free of acid with sodium bicarbonate and, after removal of the ether, fractionated under diminished pressure. The yield of ester boiling over a 5° range amounted to 144 g. (37% of calcd.).

When the above procedure was followed using equivalent quantities of ethyl propionate and ethyl butyrate instead of ethyl acetate the yields of the corresponding keto-esters dropped to about 19 and 4% of the theoretical, respectively.

Summary

A method of preparation of a number of α -benzoyl alkyl cyanides and their conversion into the corresponding α -benzoyl substituted esters are described. The properties of the amides corresponding to certain of these esters are recorded.

A satisfactory method for the preparation of benzoylacetate ester by the direct condensation of ethyl benzoate with ethyl acetate is given.

⁹ Claisen and Lowman³ recommend mixing the reactants and heating for fifteen hours. It was found in the present work that this longer period of heating was not only unnecessary but somewhat disadvantageous since invariably 5-10% lower yields were obtained when this procedure was employed.

ESTERS OF ORTHOFORMIC ACID

By PETER P. T. SAH AND TSU SHENG MA

RECEIVED MARCH 14, 1932

PUBLISHED JULY 6, 1932

The discovery of the first orthoformic ester was connected with the famous Williamson synthesis.¹ The product from sodium ethoxide and chloroform was really an ether with three ethoxy groups attached to the same carbon atom. The reaction was further studied by a number of investigators,² notably Deutsch,³ who synthesized five members of the homologous series (methyl, ethyl, *n*-propyl, *i*-butyl and *i*-amyl) and determined roughly their boiling points and densities. Pinner,⁴ allowing various alcohols to react on form-imino-ether-hydrochlorides, succeeded not only in confirming Deutsch's work but also isolating a number of mixed ortho-

formates. Of these, little was known regarding their physical properties except their boiling points.

By allowing metallic sodium to react with a mixture of chloroform and various alcohols, we have prepared seven tri-alkyl orthoformates in a very pure condition and determined carefully their simple physical constants.

Experimental

Preparation of Tri-alkyl Orthoformates.—Into a one-liter round-bottomed flask, with a reflux condenser, containing 150 g. of dry chloroform and 500 cc. of absolute alcohol (methyl, ethyl, *n*-propyl, *i*-propyl, *n*-butyl, *i*-butyl and *i*-amyl), 69 g. of metallic sodium cut into sticks was introduced gradually in the course of two hours. For methyl and ethyl derivatives, the reactants were well cooled in ice water. The higher homologs showed retardation of reaction and initial heating was necessary. When the reaction was over, the flask was allowed to cool at room temperature for four hours. The

sodium chloride was filtered off. The clear filtrate was fractionated at atmospheric pressure. The lower fractions consisted of unreacted chloroform and alcohol and could be used over again. The higher constant boiling fraction was collected and redistilled three times. The product was considered to be pure; yield, 30%. The simple physical constants were then determined.

Tri-alkyl orthoformates are colorless liquids with a faint characteristic odor, insoluble in water but soluble in all organic solvents. They could be distilled at atmospheric pressure without any decomposition.

Summary

1. Seven simple tri-alkyl orthoformates have been synthesized from chloroform and sodium alkoxides. Among these, the *i*-propyl and *n*-butyl ortho-esters are new compounds. The rest have been mentioned in the literature, but their simple physical constants are for the first time accurately determined.

STEREOCHEMISTRY OF DIPHENYL. XXIII.¹ OPTICALLY ACTIVE 2,5-DIMETHOXY-2'-NITRO-6'- CARBOXYDIPHENYL AND THE MUTAROTATION OF ITS SALTS

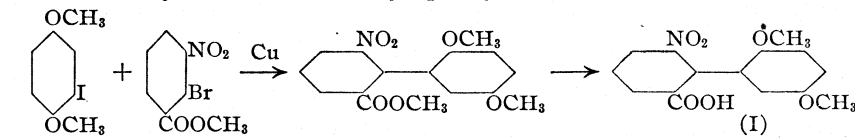

By H. C. YUAN² AND ROGER ADAMS

RECEIVED MARCH 17, 1932

PUBLISHED JULY 6, 1932

On the assumption that the size of the 2,2',6,6' groups is the primary factor in preventing free rotation of the aryl groups in substituted diphenyls, the relative rates of racemization of various derivatives should lead to conclusions concerning the relative size of groups. Since the tetra-substituted derivatives, except in very few instances, present molecules which cannot be racemized at all or only with great difficulty, the 2,2',6-trisubstituted diphenyls offer the most promising field for this study.

In the present investigation a compound was selected containing one group, the methoxyl, which from previously published and unpublished results, was known to be small. The specific compound prepared was 2,5-dimethoxy-2'-nitro-6'-carboxydiphenyl (I).

¹ The last five papers in this series are as follows: (a) Hill and Adams, *THIS JOURNAL*, **53**, 3453 (1931); (b) Bock and Adams, *ibid.*, **53**, 3519 (1931); (c) Woodruff and Adams, *ibid.*, **54**, 1977 (1932); (d) Roll and Adams, *ibid.*, **54**, 2494 (1932); (e) White and Adams, *ibid.*, **54**, 2104 (1932).

² This communication is an abstract of a portion of a thesis submitted by H. C. Yuan in partial fulfillment of the requirements for the Degree of Doctor of Philosophy in Chemistry at the University of Illinois.

This acid was converted into a brucine salt in alcohol solution and the solid salt obtained by evaporation. It was then dissolved in hot water and in the course of a few days three-fourths of the total weight of the salt in solution was deposited in the form of a light yellow homogeneous crystalline compound. Upon evaporation of the filtrate, only the same salt could be obtained. It was thus obvious that, if a racemic acid were in hand at the beginning, the second salt during the period of crystallization or of the concentration of the liquors, was gradually converted to the less soluble form which, in turn, precipitated.

The brucine salt thus obtained showed a very interesting phenomenon. When dissolved in an organic solvent such as chloroform, a specific rotation was at first obtained, $[\alpha]_D^{25} - 167^\circ$, which, over a period of time, changed gradually to a final value, $[\alpha]_D^{25} + 3.2^\circ$, and then remained constant. This obviously presents a new example of mutarotation.³ The resulting product was presumably an equal mixture of the salts from the *l*-brucine *d*-acid and the *l*-brucine *l*-acid, since the solid salt obtained from such a solution by precipitation with petroleum ether gave an inactive acid on decomposition with cold hydrochloric acid. If the original acid in chloroform or alcohol was mixed with a molecular quantity of brucine in the same solvent and made up to a known volume, rotations identical with the mutarotation values of the solid brucine salt in chloroform or alcohol were obtained. It was noticeable, however, that the final constant rotation did not appear at once but only after some minutes, especially in the case of dry chloroform.

The solid brucine salt was decomposed by ice-cold hydrochloric acid and the active acid thus obtained proved to be the *l*-modification. It racemized with unusual ease. At room temperature the time necessary to reach zero rotation was between sixty and seventy minutes, though at 0° the racemization was much slower. The half-life period was 10.8 min. at 28° and 274 min. at 0° . The *l*-modification showed the same melting point as the racemic acid, due, in all probability, to its conversion to the racemic acid before melting.

The sodium salts of all the previously studied optically active 2,2',6,6'-substituted diphenyls, of which two of the groups were carboxyls, racemized in aqueous solution more readily than the free acid racemized in organic solvents. This was assumed to be due to ionization and the smaller size of the COO^- group, though the electrical characteristics of the ion might well be a factor in such experiments. Curiously enough, the sodium salt of 2,5-dimethoxy-2'-nitro-6'-carboxydiphenyl in water racemized less readily

³ Meisenheimer, who found a somewhat similar phenomenon in 8,8'-dicarboxy-dinaphthyl, its monoethyl ester and 8-carboxydinaphthyl, prefers to speak of it as racemization. Meisenheimer and Beitswenger, *Ber.*, **65**, 32 (1932). See also Kuhn and Albrecht, *Ann.*, **455**, 272 (1927); **458**, 221 (1927); Kuhn, *Ber.*, **65**, 49 (1932); also Read and McMath, *J. Chem. Soc.*, 1572 (1925).

than the free acid in organic solvents. The sodium salt in absolute alcohol, however, racemized more readily than the free acid in the same solvent.

The cinchonine salt of 2,5 - dimethoxy - 2' - nitro - 6' - carboxydiphenyl showed similar characteristics to the brucine salt. It mutarotated from $[\alpha]_D^{23} -135^\circ$ to $[\alpha]_D^{23} +57^\circ$. On the other hand, the strychnine salt showed no change of rotation in solution. This may have been due to a similar solubility of the two diastereoisomeric strychnine salts.

The rates of mutarotation of the salts, racemization of the acids, the half-life periods and the extrapolated maximum rotations are shown in the figures and table.

^a In this experiment $l = 1$. ^b A solution of 0.5 g. of metallic sodium in 500 cc. of absolute alcohol was used for this purpose.

From the rotation values at different time intervals, the constant K of the rate of mutarotation can be calculated by the formula

$$K = \frac{1}{t} \log \frac{\alpha_0 - \alpha_t}{\alpha_t - \alpha_t}$$

where α_t is time in minutes, α_0 the initial rotation, α_t the final rotation, α_t rotation at time t . The half-life period is calculated from the equation $T = (1/K) \log 2$.

If the assigned values of the relative size of the groups on the basis of x-ray data are approximately correct, the compound described in this investigation should be more stable than actually found.⁴ Neither the 2'-carboxyl nor the 6'-nitro group should collide with the 2-hydrogen atom, but the interference on the other side of the molecule would be (assuming the value of the methoxyl the same as the hydroxyl), NO_2 , $1.92 \text{ \AA.} + \text{OCH}_3$, $1.54 \text{ \AA.} = 3.46 \text{ \AA.} - 2.90 \text{ \AA.} = 0.56 \text{ \AA.}$; COOH , $1.56 \text{ \AA.} + \text{OCH}_3$,

⁴ Stanley and Adams, *THIS JOURNAL*, **52**, 1200 (1930).

$1.54 \text{ \AA.} = 3.10 \text{ \AA.} - 2.90 \text{ \AA.} = 0.20 \text{ \AA.}$ Under these conditions the compound should be more stable to racemization if proper conclusions can be drawn from the data on compounds previously studied. It follows, therefore, that the methoxyl has a smaller value than originally assigned to it. A proposed value is 1.45 \AA. , which would lead to a slight interference between the methoxyl and carboxyl, the latter being the smaller of the nitro and carboxyl groups: $\text{COOH}, 1.56 \text{ \AA.} + 1.45 \text{ \AA.} = 3.01 \text{ \AA.} - 2.90 \text{ \AA.} = 0.11 \text{ \AA.}$ This value is slightly larger than that for the fluorine atom which has been directly determined by x-rays and therefore represents probably a fairly correct value.

The 2,5-dimethoxy-2'-nitro-6'-carboxydiphenyl was prepared by condensation with copper of 1-nitro-2-bromo-3-carbomethoxybenzene and 2-iodo-1,4-dimethoxybenzene followed by saponification of the product.

The combination of nitro, carboxyl and hydrogen with another grouping in the 2,2',6,6'-positions is an ideal one for further study since the relative racemization rates can be studied in a reasonably quantitative way. A series of compounds containing the nitro, carboxyl, hydrogen and the halogens, F, Cl and Br and other groups are being prepared and the results will soon be ready for publication. From these compounds conclusions concerning the relative size of the F, Cl, Br, OCH_3 , CH_3 , carboxyl and nitro groups will be possible. The combination of nitro, carboxyl, methoxyl and hydrogen also offers the possibility of determining whether the presence of substituting groups in other positions in the molecule will affect the rate of racemization of molecules in which the 2,2',6,6' groups remain the same.

Experimental

2,5-Dimethoxy-2'-nitro-6'-carboxydiphenyl.—In a 200-cc., three-necked flask fitted with a mechanical stirrer and an air condenser were placed 40 g. of 1-iodo-2,5-dimethoxybenzene⁵ and 15 g. of 1-nitro-2-bromo-3-carbomethoxybenzene. Then the flask was gradually heated in a metal bath to 260° , at which temperature the decomposition of the iodo compound to give off iodine vapor was noticed. In small portions, 30 g. of copper bronze was now introduced. Each addition of copper resulted in a rise of temperature sufficient to cause the temporary boiling of the reaction mixture. The addition of all of the copper required about fifty minutes, and during this period the bath temperature was maintained at $260\text{--}270^\circ$. After all of the copper was added, the bath temperature was raised to 300° to reflux the reaction mixture for twenty minutes. The flask was removed from the bath and cooled. The products were then extracted with 200 cc. of ether. From the ether, by evaporation, a dark oily residue resulted which was transferred to a 500-cc. flask and refluxed with 200 cc. of 5% aqueous sodium hydroxide for four hours. The unsaponifiable oil was separated from the water solution and the water layer was shaken with two 50-cc. portions of ether to remove some tarry substance which was present. The solution was then acidified with dilute hydrochloric acid. An oily substance separated out immediately and solidified upon standing or cooling. It was a mixture of dinitrodiphenic acid and 2,5-dimethoxy-2'-nitro-6'-carboxydiphenyl and weighed 16 g. The crude product was then dissolved in 60 cc. of warm

⁵ Kauffmann and Fritz, *Ber.*, **41**, 4413 (1908).

glacial acetic acid and treated with some norite. Upon standing for several hours, 1.5 g. of white crystalline substance was obtained which proved to be 2,2'-dinitro-6,6'-diphenic acid. The mother liquor was diluted with an equal amount of water and decanted from the tarry substance which separated. Another 60 cc. of water was added and the solution was heated to bring all the precipitate to solution. Light yellow long crystals were obtained after standing at room temperature overnight. About half a gram of the same product could be obtained from the tar by extraction with 250 cc. of boiling water. They were combined and recrystallized twice from 20% alcohol. The yield was 5 g.

The 2,5-dimethoxy-2'-nitro-6'-carboxydiphenyl forms lemon-yellow leaflets. It melts at 141–142°. It is very soluble in the common organic solvents except carbon tetrachloride, petroleum ether and slightly soluble in chloroform and hot water.

Anal. Calcd. for $C_{15}H_{11}NO_6$: Neut. equiv., 303.1; N, 4.62. Found: Neut. equiv., 305.8; N (Micro Dumas), 4.80.

Alkaloid Salts of 2,5-Dimethoxy-2'-nitro-6'-carboxydiphenyl. (Brucine Salt).—A solution of 0.933 g. of 2,5-dimethoxy-2'-nitro-6'-carboxydiphenyl in 10 cc. of alcohol was treated with a solution of 1.292 g. of brucine in 20 cc. of alcohol. No salt was obtained upon cooling, or upon dilution with water or with ethyl acetate. It was then evaporated to dryness and a granular residue was left. The residue was dissolved in 240 cc. of boiling water. Upon standing at room temperature overnight, 1.4 g. of the brucine salt was obtained as slightly yellow short needles. By concentrating the mother liquor to 100 cc., 0.3 g. more of salt was obtained. A third portion of 0.4 g. was obtained by evaporating the mother liquor to dryness at room temperature. Different portions of the salts were identical. Each fraction had the same melting point, 158–160°, the same maximum specific rotation, the same mutarotation. It had one mole of water of crystallization.

Anal. Calcd. for $C_{38}H_{39}N_3O_{10} \cdot H_2O$: H_2O , 2.52; N (anhydrous salt), 6.03. Found: H_2O , 2.26; N, 6.16.

Mutarotation Experiments.⁶ (See Fig. 1 and Table I).—Racemic acid was dissolved in chloroform and neutralized with a molecular equivalent of brucine in chloroform. A similar experiment was performed in alcohol. In both instances the constant rotation was, within experimental error, the same as the mutarotation value of the isolated salt dissolved in the same solvent. In these experiments the final reading was not reached immediately.⁷ This may have been due to the slowness in salt formation in the organic solvent. It was not due to the fact that the mixture at the equilibrium point consisted of unequal quantities of *l-l* and *l-d* salts because the salt at this point was precipitated completely by addition of petroleum ether and, upon decomposition in the manner found suitable for obtaining active acid from the *l-l* salt, gave only inactive acid.

0.1673 g. of the racemic acid and 0.2130 g. of anhydrous brucine made up to 50 cc. with chloroform gave an initial rotation (four minutes after preparation) $\alpha_D -0.13$; $l = 2$, $[\alpha]_D^{25} -8.6^\circ$. After eighty minutes $[\alpha]_D +0.05^\circ$; $[\alpha]_D^{25} +3.3^\circ$. A second experiment required even a longer time for equilibrium to be reached.

0.9330 g. of the racemic acid and 1.2920 g. of anhydrous brucine made up to 45 cc. with absolute alcohol gave an initial rotation (fourteen minutes after preparation) $\alpha_D +2.6^\circ$, $[\alpha]_D^{26} 2.6^\circ$, but it required another hour before $\alpha_D +0.30$; $[\alpha]_D^{26} +3.0^\circ$.

⁶ The numerous intermediate α_D readings are not recorded but the values found are shown in the curves in the charts.

⁷ Mills and Elliot, *J. Chem. Soc.*, 1291 (1928), observed the same phenomenon in *N*-benzenesulfonyl-8-nitro-1-naphthylglycine.

The brucine salt could be dehydrated in the usual way and gave a rotation comparable to that of the hydrated form.

0.0951 g. of salt heated at 100° for five hours made up to 15 cc. with chloroform at 25° (two minutes after preparation) gave $\alpha_D -2.05^\circ$; $l = 2$, $[\alpha]_D^{25} -162^\circ$. By extrapolation this corresponds to $[\alpha]_D^{25} -195^\circ$ for hydrated salt, which is within experimental error of the found value.

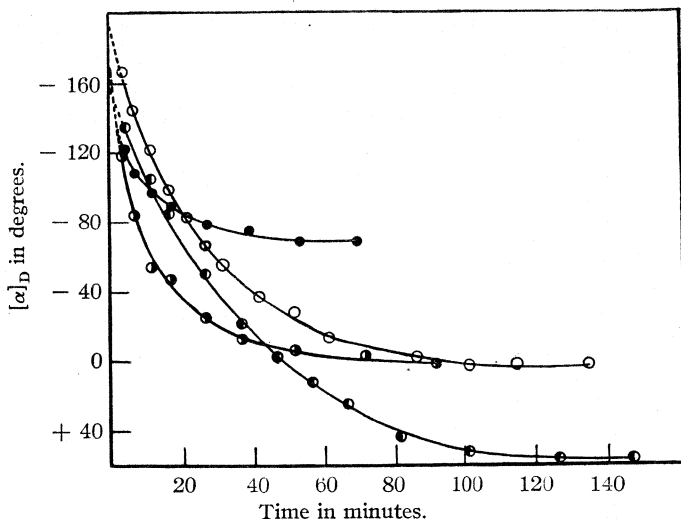

Fig. 1.—Mutarotation curves of brucine and cinchonine salts of 2,5-dimethoxy-2'-nitro-6'-carboxydiphenyl in various solvents. The dotted lines indicate values by extrapolation: \circ , brucine salt in chloroform at 25° ; \bullet , brucine salt in ethanol at 25° ; \bullet , brucine salt in pyridine at 25° ; \bullet , cinchonine salt in chloroform at 23° .

Attempts were made to isolate the other *l*-brucine *d*-acid salt by extracting the filtrate from the *l*-brucine *l*-acid salt which had crystallized out of aqueous solution. The ice-cold filtrate was extracted with ice-cold chloroform and the chloroform solution run immediately into a large volume of petroleum ether. All the brucine salt precipitated but gave a rotation corresponding to the equilibrium rotation value $[\alpha]_D^{25} +3.0^\circ$ in spite of the fact that the whole operation of extraction and precipitation took less than five minutes.

Cinchonine Salt.—A solution of 0.6035 g. of 2,5-dimethoxy-2'-nitro-6'-carboxydiphenyl in 10 cc. of methanol was treated with 0.5864 g. of cinchonine in 30 cc. of boiling methanol. After standing at room temperature overnight, 0.42 g. of the cinchonine salt crystallized out as light yellow small needles. From the mother liquor after two days in the ice box, a second portion of the salt separated which weighed 0.35 g. The filtrate from this material upon evaporation gave a further quantity of salt. The different portions of the salt had the same melting point, $198\text{--}204^\circ$ and mutarotated at the same rate.

Anal. Calcd. for $C_{24}H_{20}N_2O_7$: N, 7.03. Found: N (micro Dumas), 7.21.

Strychnine Salt.—A solution of 0.4819 g. of 2,5-dimethoxy-2'-nitro-6'-carboxydiphenyl in 8 cc. of absolute alcohol was mixed with 0.5314 g. of strychnine in 45 cc. of

boiling alcohol. No crystals were obtained after long standing. The solution was evaporated to dryness and the granular residue was dissolved in 85 cc. of boiling water. Upon standing at room temperature for several hours, 0.38 g. of the strychnine salt crystallized out as compact plates. Two more portions were obtained by further concentration of the solution. They had the same melting point, 220–223° with decomposition, and the same specific rotation. Unlike the other salts, it showed no mutarotation.

A solution of 0.0715 g. made up to 10 cc. with chloroform at 23° gave a rotation $\alpha_D -0.33^\circ$; $l = 2$, $[\alpha]_D^{23} -23.1$.

Anal. Calcd. for $C_{33}H_{35}N_3O_8$: N, 6.59. Found: N (micro Dumas), 6.75.

The acid obtained from the strychnine salt by the procedure described under the brucine salt was inactive.

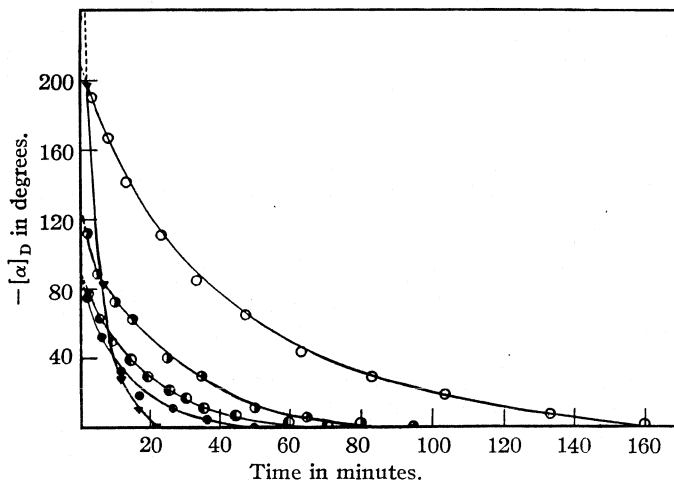

Fig. 2.—Racemization curves of *l*-2,5-dimethoxy-2'-nitro-6'-carboxydiphenyl and its sodium salt. The dotted lines indicate values by extrapolation: ○, *l*-acid in ethanol at 28°; ○●, *l*-acid in acetone at 26°; ●, *l*-acid in acetic acid at 26°; ○, sodium salt in water at 26°; ▼, sodium salt in ethanol at 26°.

***l*-2,5-Dimethoxy-2'-nitro-6'-carboxydiphenyl.**—A suspension of 1 g. of the brucine salt in ice-cold 100 cc. 6 *N* hydrochloric acid surrounded with ice-salt mixture was stirred vigorously for a half hour. Then it was left in the ice box overnight. The next morning, finely divided 2,5-dimethoxy-2'-nitro-6'-carboxydiphenyl, which is darker yellow than the salt, had settled to the bottom. The acid was then filtered by suction and washed thoroughly with ice-cold water until the filtrate showed negative tests for both brucine and chloride. The dried acid weighed 0.41 g. It melted at 141–142°.

Racemization Experiments.⁶—See Fig. 2 and Table I.

Summary

1. 2,5-Dimethoxy-2'-nitro-6'-carboxydiphenyl was prepared by condensation of 1-iodo-2,5-dimethoxybenzene and 1-nitro-2-bromo-3-carbomethoxybenzene with copper, and saponification of the product.

2. The acid readily forms brucine and cinchonine salts. Only one salt

with each alkaloid could be isolated. Each of the salts mutarotated to equilibrium values which were equal mixtures of the two diastereoisomeric salts. Strychnine gave a salt which showed no mutarotation and yielded no active acid.

3. By careful decomposition with hydrochloric acid, the *l*-acid was isolated. It racemized rapidly in organic solvents. The sodium salt racemized much more rapidly in absolute alcohol than in water.

STEREOCHEMISTRY OF DIPHENYL. XXIV.¹ PREPARATION AND PROPERTIES OF 2,2'-DIFLUORO-3,3'- DICARBOXY-6,6'-DIMETHOXYDIPHENYL

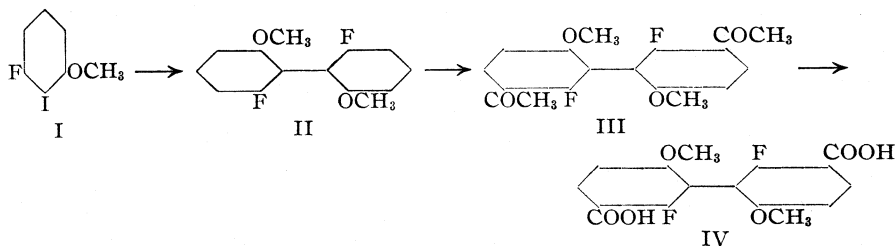

BY B. C. BECKER² AND ROGER ADAMS

RECEIVED MARCH 17, 1932

PUBLISHED JULY 6, 1932

The small size of the fluorine atom and, as shown in the previous paper, the similarly small size of the methoxyl group,^{1c} made particularly interesting a study of the properties of properly substituted 2,2',6,6'-tetrafluoro-, 2,2',6,6'-tetramethoxy- and 2,6-difluoro-2,6'-dimethoxydiphenyls. On the assumption that the methoxyl is about the same size as the fluorine and calculating the interference possibilities as previously described,³ none of these three compounds should be capable of resolution.

A representative of the last type has been prepared and is described in this communication. The compound is 2,2'-difluoro-3,3'-dicarboxy-6,6'-dimethoxydiphenyl (IV).

It was prepared (1) by the condensation with copper of 1-fluoro-2-iodo-3-methoxybenzene to 2,2'-difluoro-6,6'-dimethoxydiphenyl (II), (2) by in-

² This communication is a portion of a thesis submitted by B. C. Becker in partial fulfillment of the requirements for the degree of Doctor of Philosophy in Chemistry at the University of Illinois.

³ Stanley and Adams, *THIS JOURNAL*, **52**, 1200 (1930).

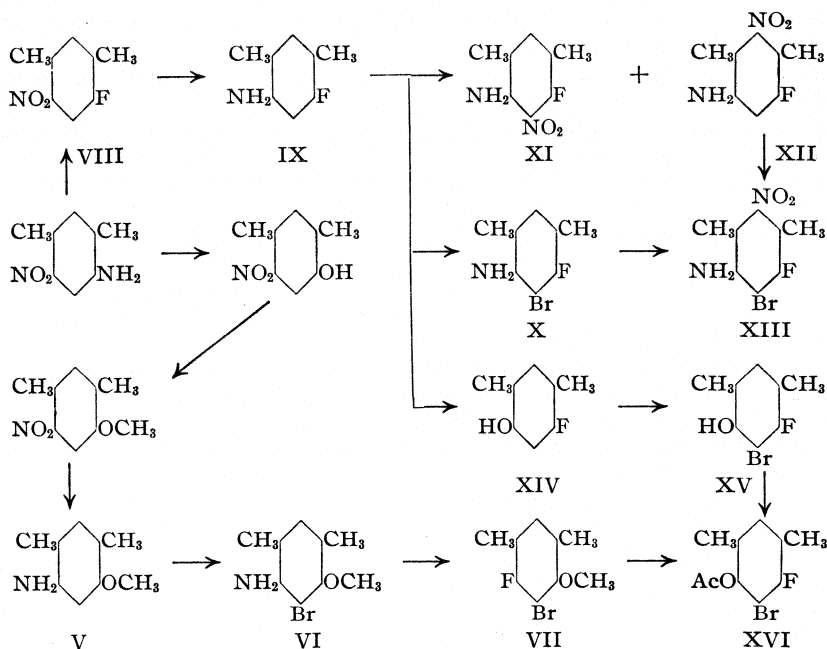

roduction of two aceto groups by means of aluminum chloride and acetyl chloride to 2,2'-difluoro-3,3'-diaceto-6,6'-dimethoxydiphenyl (III), (3) by oxidation of the diaceto derivative by means of sodium hypochlorite to 2,2'-difluoro-3,3'-dicarboxy-6,6'-dimethoxydiphenyl (IV). The various alkaloid salts—brucine, strychnine, morphine, cinchonine and quinine—were all prepared. In no instance was more than a single salt obtained and none of these showed mutarotation even at low temperatures or gave an active acid on decomposition. It appears then that this is truly a representative of a 2,2',6,6'-tetrasubstituted diphenyl in which the ortho substituents do not interfere sufficiently to allow resolution.

Before the above compound was prepared, a number of proper intermediate compounds were synthesized, but all attempts to convert them to the corresponding diphenyls were unsuccessful. These will be described briefly. It was found impossible to obtain 1-fluoro-2-nitro-3-methoxybenzene from 1-fluoro-3-methoxybenzene by nitrating according to the procedure found successful for nitrating 1-fluoro-3-hydroxybenzene.

1-Fluoro-2,4-dimethyl-5-methoxy-6-bromobenzene (VII) was prepared by bromination of 1-amino-2,4-dimethyl-5-methoxybenzene (V) and replacement of the amino group in the 1-amino-2,4-dimethyl-5-methoxy-6-bromobenzene (VI) by fluorine. From the product (VII) attempts to fill the last position in the ring with a nitro or aceto group, to form the Grignard reagent, or to carry out an Ullmann reaction were all unsuccessful.

1-Fluoro-2,4-dimethyl-5-nitrobenzene (VIII) was prepared from the corresponding amino compound by introduction of a fluorine in place of the amino group. It was converted by reduction to 1-fluoro-2,4-dimethyl-5-aminobenzene (IX), which was brominated to 1-fluoro-2,4-dimethyl-5-amino-6-bromobenzene (X). 1-Fluoro-2,4-dimethyl-5-aminobenzene (IX) was nitrated in sulfuric acid to a mixture of the 1-fluoro-2,4-dimethyl-5-amino-6-nitrobenzene (XI) and 1-fluoro-2,4-dimethyl-5-amino-3-nitrobenzene (XII). The 1-fluoro-2,4-dimethyl-5-amino-3-nitrobenzene (XII) was then brominated to 1-fluoro-2,4-dimethyl-3-nitro-5-amino-6-bromobenzene (XIII), identical with the product obtained by nitration of 1-fluoro-2,4-dimethyl-5-amino-6-bromobenzene (X). Attempts to replace the amino group in 1-fluoro-2,4-dimethyl-3-nitro-5-amino-6-bromobenzene (XIII) by hydroxyl or methoxyl were unsuccessful, though no difficulty was encountered in replacing the amino group by chlorine.

1-Fluoro-2,4-dimethyl-5-aminobenzene (IX) was diazotized and converted to 1-fluoro-2,4-dimethyl-5-hydroxybenzene (XIV) which was brominated to 1-fluoro-2,4-dimethyl-5-hydroxy-6-bromobenzene (XV). This product gave an acetyl derivative (XVI), identical with that obtained by demethylating and acetylating 1-fluoro-2,4-dimethyl-5-methoxy-6-bromobenzene (VII).

Experimental⁴

1-Fluoro-2-iodo-3-methoxybenzene.⁵—This product has been described by Hodgson and Nixon. In this investigation it was prepared by the same series of reactions, 3-nitroaniline \rightarrow 1-fluoro-3-nitrobenzene \rightarrow 1-fluoro-3-aminobenzene \rightarrow 1-fluoro-3-hydroxybenzene \rightarrow 1-fluoro-2-nitro-3-hydroxybenzene \rightarrow 1-fluoro-2-nitro-3-methoxybenzene \rightarrow 1-fluoro-2-amino-3-methoxybenzene \rightarrow 1-fluoro-2-iodo-3-methoxybenzene. Since the previous authors give no details, a comment or two on each step may be serviceable to others.

3-Nitroaniline was converted into the corresponding diazonium fluoborate in the usual way. The yield was 79%. The product, light brown crystals in crude form, could be purified by dissolving in methyl alcohol and precipitating with ethyl ether. White crystals were formed which decomposed at 170–175° after darkening at 145°.

The fluoborate was decomposed as slowly as possible by careful heating *in vacuo*, then by heating thoroughly to drive over all the product. After alkali washing and steam distillation, a 50% yield of 1-fluoro-3-nitrobenzene of b. p. 197–202° at 750 mm. was obtained.

1-Fluoro-3-nitrobenzene was reduced in the usual way with iron powder and water in the presence of a little hydrochloric acid. The mixture after neutralization was steam-distilled; yield, 85%, b. p. 185° at 755 mm.

1-Fluoro-3-aminobenzene was converted to the corresponding phenol by following

⁴ The melting points reported in this investigation are uncorrected.

⁵ Hodgson and Nixon, *J. Chem. Soc.*, 880 (1928); *ibid.*, 981 (1931); Swarts, *Bull. acad. roy. Belg.*, 241 (1913); Schiemann and Pillarsky, *Ber.*, 62, 3035 (1929). The literature constants are as follows: 1-fluoro-3-nitrobenzene, b. p. 200° at 756 mm., m. p. 3.6°; 1-fluoro-3-aminobenzene, b. p. 186° at 753 mm.; 1-fluoro-3-hydroxybenzene, b. p. 177.8° at 760 mm., m. p. 13.7°; 1-fluoro-2-iodo-3-methoxybenzene, b. p. 240° at 756 mm.

the directions of Hodgson and Nixon used for 3-chloro-1-hydroxybenzene;⁶ yield, 76%, b. p. 174° at 753 mm.

1-Fluoro-2-nitro-3-hydroxybenzene was obtained in 50% yield; orange yellow needles, m. p. 39°.

1-Fluoro-2-nitro-3-methoxybenzene was prepared by methylating in dry xylene solution with anhydrous potassium carbonate and dimethyl sulfate. Addition of water and then distillation of most of the xylene gave a product, readily purified from methyl alcohol and then petroleum ether; yield, 80% of white crystals, m. p. 43°.

1-Fluoro-2-amino-3-methoxybenzene was prepared by reduction of a methyl alcoholic solution of the nitro compound with concentrated hydrochloric acid and stannous chloride. It was then made alkaline, steam distilled and extracted with ether. The hydrochloride was precipitated with hydrogen chloride after drying the ether solution; yield of amine hydrochloride 81%.

1-Fluoro-2-iodo-3-methoxybenzene was made from the amine hydrochloride by diazotizing and treating with potassium iodide. The product was extracted with ether and washed with sodium bisulfite; yield, 65%, b. p. 115–125° at 3–6 mm.

2,2'-Difluoro-6,6'-dimethoxydiphenyl.—A mixture of 25 g. (0.1 mole) of 1-fluoro-2-iodo-3-methoxybenzene and 25 g. of copper bronze was placed in a small Pyrex flask fitted with a short air condenser and heated in a metal bath at 180–200° for one hour or until the odor of the iodo compound was no longer detectable. The coupling took place much more rapidly at 210–220° but the yield was slightly less. After the flask had cooled sufficiently, the contents were extracted with 40-cc. portions of hot ethyl alcohol. The alcohol was filtered and allowed to cool. Yellow-white crystals of difluorodimethoxydiphenyl were deposited. Evaporation of the mother liquor gave additional crystals which were more yellow. The total yield of crude product was 10 g. (80%). After recrystallization from petroleum ether and again from ethyl alcohol, there remained 8 g. (65%). By several more recrystallizations from ethyl alcohol, pure white 2,2'-difluoro-6,6'-dimethoxydiphenyl was obtained. It melted at 135–136°.

Anal. (Micro). Calcd. for $C_{14}H_{12}F_2O_2$: C, 67.2; H, 4.84. Found: C, 67.23; H, 4.85.

2,2'-Difluoro-3,3'-diaceto-6,6'-dimethoxydiphenyl.—In a three-necked flask fitted with a mercury-sealed stirrer, a lead to a water trap, and a stopper, 5 g. (0.02 mole) of difluorodimethoxydiphenyl was dissolved in a mixture of 75 cc. of dry carbon disulfide and 25 cc. of acetyl chloride. The solution was cooled in a salt-ice mixture and three 5-g. portions of powdered anhydrous aluminum chloride were introduced at ten-minute intervals. The stirring was continued after the ice-bath had been removed until the contents of the flask had reached room temperature. The carbon disulfide top layer was then decanted from the viscous lower layer which was washed with a fresh portion of carbon disulfide. The lower layer containing the aluminum chloride was slowly poured onto 250 g. of cracked ice. The diacetodifluorodimethoxydiphenyl readily formed a solid mass suspended in the water solution of the aluminum chloride. The solid was filtered and washed repeatedly with water to remove all of the inorganic salts. The yield of the crude material was quantitative (6.7 g.) but was reduced to 90% after recrystallization from methyl alcohol. The diacetodiphenyl formed white crystals melting at 138–139.5°.

Anal. Calcd. for $C_{18}H_{16}F_2O_4$: C, 64.65; H, 4.83. Found: C, 64.92; H, 4.78.

2,2'-Difluoro-3,3'-dicarboxy-6,6'-dimethoxydiphenyl.—The difluorodimethoxydiphenyl was oxidized to the difluorodicarboxydimethoxydiphenyl by means of sodium hypochlorite, according to the general procedure of VanArendonk and Cupery.⁷

⁶ Hodgson, English Patent, 200,714 (1923).

⁷ VanArendonk and Cupery, *THIS JOURNAL*, **53**, 3184 (1931).

A solution of 6.7 g. (0.02 mole) of difluorodiacetodimethoxydiphenyl in 250 cc. of methyl alcohol was made alkaline with 20 cc. of 20% sodium hydroxide. This solution was kept cold while alkaline sodium hypochlorite was added slowly. (The sodium hypochlorite was prepared from two 100-cc. portions of 20% sodium hydroxide by passing in chlorine gas in the cold until the reaction to litmus was neutral. A liberal excess (20–30 cc.) of sodium hydroxide was then added to make the solution markedly basic.) Keeping the solutions alkaline and cold (under 30°) was important in preventing ring chlorination. As the sodium hypochlorite solution was added, a cloudiness was produced which disappeared as the diphenic acid was formed from the ω -chlorinated aceto derivative. Before acidifying, the excess hypochlorite was destroyed by bubbling in sulfur dioxide or by adding sodium bisulfite until the solution no longer reacted to starch-iodide paper when acidified. Upon acidification the acid was precipitated as a solid, which was filtered off. Additional acid was obtained from the filtrate by making it alkaline, evaporating the methyl alcohol, and reacidifying. The yield was 5.7 g. (84%). The crude acid was purified by dissolving in sodium hydroxide solution, boiling with norite, and reprecipitating. It could also be crystallized from methyl alcohol; m. p. 285–289° with decomposition. For analysis the acid was dried at 110° for twelve hours.

Anal. Calcd. for $C_{16}H_{12}F_2O_6$: neut. equiv., 169; C, 56.8; H, 3.58. Found: neut. equiv., 173.5; C, 56.9; H, 3.71.

Alkaloid Salts of 2,2'-Difluoro-6,6'-dimethoxy-3,3'-dicarboxydiphenyl

Brucine Salt.—When 0.58 g. of anhydrous brucine dissolved in 30 cc. of ethyl alcohol was added to 0.50 g. of the diphenic acid in 80 cc. of ethyl alcohol, a white amorphous precipitate was formed. This weighed 0.86 g. or 80% of the calculated total weight of salt formed. There was no loss of weight on heating to 110° *in vacuo*, hence no solvation.

Rotation. 0.0205 g. made up to 5.4 cc. with pyridine gave $\alpha_D -0.26^\circ$; $l = 1$; $[\alpha]_D^{25} -68.5^\circ$.

The monobrucine salt was also prepared in ethyl acetate in a similar manner. A distinctly crystalline product formed to the amount of 70% in the first fraction. The weight of the residual material brought the total to 82%. The crystalline fraction 0.0226 g. made up to 10 cc. with pyridine gave $\alpha_D 0.31^\circ$; $l = 2$; $[\alpha]_D^{25} -68.7^\circ$. The residual fraction gave $[\alpha]_D^{25} -61.4^\circ$. The first fraction was washed with warm dry ethyl acetate and dried.

Rotation. 0.0205 g. made up to 10 cc. with pyridine gave $\alpha_D -0.27^\circ$; $l = 2$; $[\alpha]_D^{25} -65.8^\circ$.

Anal. (Micro). Calcd. for $C_{39}H_{35}F_2N_2O_{10}$: N, 3.83. Found: N, 3.92.

Decomposition of the salt was carried out at 0–5°. A solution of 0.1 g. of the monobrucine salt in 30 cc. of chloroform was shaken with 100 cc. of ice water to which 2 cc. of concentrated hydrochloric acid had been added. The free diphenic acid was insoluble in both layers and was precipitated as fast as it was formed. After fifteen minutes of shaking the suspension was filtered and the free acid was dried over calcium chloride in a vacuum desiccator. The weight was 0.041 g. (calcd. 0.046). The acid was essentially pure, m. p. 280°, and was used without recrystallization. It gave no rotation in pyridine.

An attempt was made to determine if the newly formed salt showed any evidence of mutarotation. Into a 1-dm. rotation tube enclosed in case for cooling or heating, 0.0394 g. of anhydrous brucine dissolved in 7 cc. of pyridine was introduced. Rotation was taken at 25° and again at 0°, $\alpha_D -0.70^\circ$ and -0.71° ; $[\alpha]_D^{25} -124^\circ$ and $[\alpha]_D^0 -128^\circ$. Then, still at 0°, 0.0388 g. (0.005 g. excess) of the diphenic acid was introduced, mixed thoroughly, and a rotation was taken within a period of five minutes: $\alpha_D -0.535^\circ$;

$[\alpha]_D^0 -51.2^\circ$. Rotation, three hours later: $\alpha_D -0.535^\circ$; $[\alpha]_D^0 -51.2^\circ$. The tube and its contents were then permitted to warm to room temperature: $\alpha_D -0.663^\circ$; $[\alpha]_D^{25} -63.4^\circ$. (This checks the rotation of the crystalline monobrucine salt.) After twenty-four hours at room temperature the solution was again cooled to 0° . Rotation: $\alpha_D -0.540^\circ$; $[\alpha]_D^0 -51.7^\circ$.

No success was encountered in attempting to prepare the dibrucine salt.

Morphine Salt.—The monobasic morphine salt was formed in dry ethyl acetate by the addition of 0.285 g. (0.001 mole) of morphine in 40 cc. of ethyl acetate to 0.338 g. of the diphenic acid in 80 cc. of ethyl acetate. The first fraction separated immediately and amounted to 0.25 g. or 40% of the total weight of salt; the second precipitate was obtained by partial evaporation and cooling, and weighed 0.128 g. (20%). The third fraction, formed on further evaporation, was 14%; and the residue recovered on evaporation to dryness was 10%. The specific rotations of these crude fractions, in 95% ethyl alcohol ($l = 2$) were, respectively, -63.5 , -59.5 , -64.3 and -26° . The low value for the residue was undoubtedly the result of impurities. The first two fractions (0.30 g.) were dissolved in absolute ethyl alcohol, filtered and cooled in carbon dioxide snow. A white precipitate was formed, weighing 0.17 g. and having a coarsely granular appearance under the microscope. A sample of this was dissolved in 95% ethyl alcohol at $0-10^\circ$ and cooled immediately to 0° .

Rotation. 0.0243 g. made up to 10 cc. with ethyl alcohol at 0° gave $\alpha_D -0.20^\circ$; $l = 1$; $[\alpha]_D^0 -82.3^\circ$.

The solution in the rotation tube was allowed to come to room temperature 25° : $\alpha_D -0.145^\circ$; $[\alpha]_D^{25} -59.7^\circ$. (This checked the rotation of crude fractions.) The solution was further allowed to stand at $25-30^\circ$ for twenty hours and then cooled again to 0° : $\alpha_D -0.19^\circ$; $[\alpha]_D^0 -78.2^\circ$. Analysis of the recrystallized material showed it to be the desired morphine salt.

Anal. (Micro). Calcd. for $C_{38}H_{31}F_2NO_9$: N, 2.25. Found: N, 2.4.

Quinine Salt.—A solution of 0.324 g. of quinine (0.001 mole) in 30 cc. of absolute ethanol was added to 0.338 g. of the diphenic acid dissolved in 30 cc. of absolute alcohol. Evaporation to half volume gave a yellow precipitate weighing 0.05 g. The second fraction, which was a very light yellow amorphous precipitate, weighed 0.26 g. The third or residual fraction was obtained by evaporation to dryness. It was quite yellow and weighed 0.217 g. The total recovered material amounted to 80% of the calculated value. These three fractions gave, respectively, the specific rotations in chloroform at 27° : -69.4 , -83.4 and -75.4° . The intermediate fraction, 0.0736 g., made up to 10 cc. with chloroform gave $\alpha_D 1.23$; $l = 2$; $[\alpha]_D^{27} -83.4^\circ$. This fraction was analyzed.

Anal. (Micro). Calcd. for $C_{38}H_{38}F_2N_2O_8$: N, 4.23. Found: N, 4.21..

Strychnine Salt.—A solution of 0.334 g. (0.001 mole) of strychnine in 50 cc. of absolute ethanol was added to 0.338 g. of the diphenic acid dissolved in absolute alcohol. The solution was filtered, evaporated to 40 cc., and cooled with carbon dioxide snow. A precipitate formed and was filtered off. However, on warming to room temperature this material melted and became viscous and sticky. On being placed in a desiccator, it finally hardened to a glassy solid which could be pulverized to a white amorphous powder; weight, 0.101 g.

Rotation. 0.0705 g. made up to 10 cc. with chloroform gave $\alpha_D -0.15^\circ$; $l = 2$; $[\alpha]_D^{25} -10.6^\circ$.

The second fraction of the strychnine salt was obtained by evaporating the ethyl alcohol to about 10 cc. and then adding 70 cc. of ethyl acetate. A white amorphous powder was precipitated. This was filtered off, washed with warm dry ethyl acetate and dried; weight, 0.422 g. (63%). On heating this salt shrank at $180-205^\circ$ and foamed without darkening at $205-220^\circ$.

Rotation. 0.0627 g. made up to 10 cc. with chloroform gave $\alpha_D -0.15$; $l = 2$; $[\alpha]_D^{25} -12^\circ$.

Analysis of the intermediate fraction showed it to be the desired salt. The residue soluble in ethyl acetate was negligible—the amount recovered being too small for a determination of the specific rotation.

Anal. (Micro). Calcd. for $C_{37}H_{34}F_2N_2O_8$: N, 4.16. Found: N, 4.25.

The intermediate fraction of strychnine salt, 0.2 g., was shaken with 50 cc. of 6 *N* hydrochloric acid at -15° . After two hours, the 6 *N* acid was replaced by a fresh 50-cc. portion—the free diphenic acid was filtered off, resuspended in cold hydrochloric acid, and placed in the refrigerator overnight. The free acid was then filtered off, washed free of hydrochloric acid, and dried at room temperature in a vacuum desiccator; weight, 0.093 g. (calcd. 0.101 g.); m. p. 275° . It showed no rotation.

Cinchonine Salt.—A solution of 0.294 g. (0.001 mole) of cinchonine in 30 cc. of absolute ethyl alcohol was added to 0.338 g. of the diphenic acid dissolved in 30 cc. of absolute alcohol. The solution was filtered, evaporated to 15 cc. and 50 cc. of ethyl acetate was added. A precipitate was formed, weighing 0.43 g.

Rotation. 0.0654 g. made up to 10 cc. with 95% ethyl alcohol gave $\alpha_D +1.08^\circ$; $l = 2$; $[\alpha]_D^{25} 82.7^\circ$.

The filtrate was evaporated to dryness to give a yellow amorphous material weighing 0.189 g.

Rotation. 0.0490 g. made up to 10 cc. with 95% ethyl alcohol gave $\alpha_D 0.75^\circ$; $l = 2$; $[\alpha]_D^{25} 76.5^\circ$.

Another run of 0.294 g. of cinchonine and 0.338 g. of acid in 60 cc. of absolute alcohol gave three fractions on the slow evaporation of the alcohol. Of these, the intermediate fraction, weighing 0.114 g. was white and amorphous.

Rotation. 0.0436 g. made up to 10 cc. with ethyl alcohol gave $\alpha_D 0.733^\circ$; $l = 2$; $[\alpha]_D^{25} 84.1^\circ$. Analysis of this fraction showed it to be the desired monochinchonine salt.

Anal. (Micro). Calcd. for $C_{35}H_{34}F_2N_2O_7$: N, 4.43. Found: N, 4.30.

1-Fluoro-3-methoxybenzene.—A solution of 123 g. (1 mole) of 1-amino-3-methoxybenzene in a mixture of 280 cc. of concentrated hydrochloric acid, and 500 g. of ice was diazotized at $0-5^\circ$ by the addition of 69 g. of sodium nitrite in 160 cc. of water. The diazotized mixture was filtered if necessary and a minimum of 170 cc. of fluoboric acid solution was added. The precipitated diazonium fluoborate of 1-amino-3-methoxybenzene was filtered off and washed successively with 10–20 cc. of fluoboric acid solution, 70 cc. of ethyl alcohol, and 70 cc. of ethyl ether. The weight of dry diazonium salt was 170 g. (76%). This was quite unstable as compared with the corresponding 3-nitrodiazonium salt and unless it was kept very dry, it decomposed spontaneously over a period of twenty-four to forty-eight hours.

The diazonium salt was decomposed immediately without purification in a dry flask connected through a condenser and wash bottle to a water aspirator. Heat was applied to one part of the flask to start the decomposition; and the reaction was allowed to proceed spontaneously. Sometimes cooling was necessary if decomposition was too rapid. Finally, when the reaction subsided, the flask was heated strongly while the system was evacuated. The distillate and the water in the wash bottles were mixed, neutralized with sodium carbonate, filtered and extracted with ethyl ether. The 1-fluoro-3-methoxybenzene (b. p. 158° at 743 mm.) was a colorless mobile liquid of characteristic anisole-like odor. The yield was 53 g. (42%); $d_4^{20} 1.107$, $n_D^{20} 1.4892$.

Anal. (Micro). Calcd. for C_7H_7FO : C, 66.6; H, 5.60. Found: C, 66.77; H, 5.52.

1-Fluoro-2-nitro-3-methoxybenzene.—Attempts to prepare 1-fluoro-2-nitro-3-methoxybenzene by sulfonation and nitration of 1-fluoro-3-methoxybenzene as de-

scribed for the preparation of 1-fluoro-2-nitro-3-hydroxybenzene from 1-fluoro-2-nitro-3-hydroxybenzene were unsuccessful.

1-Amino-2,4-dimethyl-5-methoxy-6-bromobenzene Hydrobromide.—To a solution of 50 g. (0.33 mole) of 1-amino-2,4-dimethyl-5-methoxybenzene⁸ in 250 cc. of glacial acetic acid, was added slowly 53 g. of bromine in 25 cc. of acetic acid. On cooling the mixture, fine white crystals of the brominated amine hydrobromide were precipitated. The precipitate was filtered and washed with 25–50 cc. of glacial acetic acid. The salt was dried at 110°. The yield depended upon the volume of acetic acid used; the pure product usually weighed about 78 g. (75%); m. p. 187° with decomposition. By evaporation of the acetic acid filtrate, the remaining impure material could be obtained. (Acetyl derivative of the free base, from dilute alcohol, m. p. 147–148°.) A small amount of the acetyl derivative was always formed when recrystallizing the amine hydrobromide from glacial acetic acid.

Anal. Calcd. for $C_9H_{13}Br_2NO$: Br (ionizable), 25.71. Found: Br, 25.69.

1-Fluoro-2,4-dimethyl-5-methoxy-6-bromobenzene.—A solution was made of 31.1 g. (0.1 mole) of the 1-amino-2,4-dimethyl-5-methoxy-5-bromobenzene hydrobromide in 10 cc. of concentrated hydrochloric acid and 25 cc. of water. The mixture was cooled to 0–5° and diazotized slowly with 6.9 g. of sodium nitrite in 15 cc. of water. After being allowed to stand for fifteen minutes, the solution was filtered and 17–25 cc. of cold fluoboric acid solution was added. The diazonium fluoborate was precipitated, filtered off, and washed successively with 5 cc. of fluoboric acid solution, 10 cc. of ethyl alcohol and 10 cc. of ethyl ether. The dry salt weighed 23 g. (70%). It was a pale yellow solid, quite soluble in water and fairly stable when dry. The decomposition temperature was about 105°. The desired fluoro compound was obtained from this diazonium salt by dry distillation in a flask connected to a condenser and wash bottles. The flask was gently heated to start the decomposition. If the reaction became so rapid as to tend to build up an internal pressure, the flask was externally cooled with tap water. After the diazonium salt was decomposed, the fluoro compound remaining in the flask was distilled under reduced pressure. The product weighed 12.2 g. (52%) based on the original amine hydrobromide. 1-Fluoro-2,4-dimethyl-5-methoxy-6-bromobenzene is a heavy colorless liquid of faint odor; b. p. 125° at 15 mm., n_D^{20} 1.5302, d_4^{20} 1.4350.

Anal. (Parr bomb). Calcd. for $C_9H_{10}BrFO$: Br, 34.3. Found: Br, 33.9.

Attempts to nitrate the molecule and replace the last vacant position were unsuccessful.

The Ullmann reaction with copper or zinc was unsatisfactory and the Grignard reagent could not be formed.

With aluminum chloride and acetic anhydride in carbon disulfide no reaction took place at low temperature, but heated to the boiling point of the reaction mixture, 1-fluoro-2,4-dimethyl-5-acetoxy-6-bromobenzene (described below) was formed.

1-Fluoro-2,4-dimethyl-5-nitrobenzene.—To 135 cc. of cold concentrated sulfuric acid 24.2 g. (0.2 mole) of 1-amino-2,4-dimethylbenzene was slowly added. The mixture was stirred until all of the amine sulfate dissolved and it was then cooled to 0–10° and 20 g. or 14.5 cc. (10% excess) of nitric acid (sp. gr. 1.42) was added. After standing for fifteen minutes, the solution was diluted with 400 g. of ice. The nitrated 1-amino-2,4-dimethylbenzene sulfate⁹ precipitated but was not isolated.

The suspension was immediately diazotized by the addition of 13.8 g. of sodium nitrite in 30 cc. of water. After the diazotization mixture had stood for fifteen minutes,

⁹ Nölting and Collin, *Ber.*, 17, 265 (1884).

34–40 cc. of cold fluoboric acid was added. The precipitated diazonium fluoborate was filtered off, washed with ethyl alcohol and ether and dried. The weight was 28.2 g. (53% based on 1-amino-2,4-dimethylbenzene used). The dry diazonium fluoborate was quite stable; its decomposition temperature was 130°.

The salt was placed in a distilling flask connected to a condenser and wash bottles and decomposed as described for the other fluoborates. The product boiled at 133° at 30 mm.; 234° at 750 mm. The yield was 9.5 g. (53% based on the diazonium salt). The 1-fluoro-2,4-dimethyl-5-nitrobenzene was a pale yellow, heavy liquid; d_{20}^{20} 1.230, n_D^{20} 1.532.

Anal. (Micro). Calcd. for $C_8H_8FNO_2$: N, 8.28. Found: N, 8.10.

1-Fluoro-2,4-dimethyl-5-aminobenzene.—A mixture of 17.0 g. (0.1 mole) of 1-fluoro-2,4-dimethyl-5-aminobenzene, 25 g. of iron powder, 25 cc. of water and 5 cc. of dilute hydrochloric acid was placed in a 500-cc. flask fitted with a reflux condenser, and heated with shaking until the water refluxed from the heat of reaction. The reduction was completed by heating on the steam-bath for an hour, with the occasional addition of 1–2 cc. of dilute hydrochloric acid. The contents of the flask were neutralized with a few cubic centimeters of 20% sodium hydroxide solution and the 1-fluoro-2,4-dimethyl-5-aminobenzene steam distilled. The product separated from the steam distillate in white plates which turned pink or brown on contact with the air. It was purified by recrystallization from petroleum ether and then sublimation to give white plates melting at 57–58° (acetyl derivative from dilute alcohol, m. p. 133–134°).

Anal. (Micro). Calcd. for $C_8H_{10}FN$: N, 10.07. Found: N, 9.74.

1-Fluoro-2,4-dimethyl-5-amino-6-bromobenzene.—By addition of one mole equivalent of bromine to an acetic acid solution of 1-fluoro-2,4-dimethyl-5-aminobenzene, the hydrobromide of the 1-fluoro-2,4-dimethyl-5-amino-6-bromobenzene separated. The salt was readily recrystallized from glacial acetic acid. It decomposed without melting at 220°. The free base was purified by recrystallization from methyl alcohol and was obtained in white crystals melting at 56° (acetyl derivative from dilute alcohol, m. p. 170–171°).

Anal. (Volhard). Hydrobromide salt: Calcd. for $C_8H_{10}Br_2FN$: Br (ionized), 26.74. Found: Br, 26.85.

Nitration of 1-Fluoro-2,4-dimethyl-5-aminobenzene: 1-Fluoro-2,4-dimethyl-5-amino-3-nitrobenzene and 1-Fluoro-2,4-dimethyl-5-amino-6-nitrobenzene.—When 1-fluoro-2,4-dimethyl-5-aminobenzene was nitrated in concentrated sulfuric acid, two products were obtained. These were separated by their difference in solubility in petroleum ether. The less soluble nitration product, which was formed in smaller amounts, could be recrystallized from petroleum ether to give orange red crystals which melted at 88–89° (acetyl derivative from alcohol, m. p. 148–149°). This was identified by bromination in acetic acid to give 1-fluoro-2,4-dimethyl-3-nitro-5-amino-6-bromobenzene which was identical (m. p. 106°) with the product prepared by brominating first and then nitrating, as described in the next paragraph.

Anal. Calcd. for $C_8H_9FN_2O_2$: N, 15.2. Found: N, 15.29.

The more soluble part was recrystallized several times from petroleum ether to give a dark red compound melting at 72–74° (acetyl derivative from alcohol, m. p. 193–194°). Analysis of the amine indicated that it was an isomeric mononitro derivative, 1-fluoro-2,4-dimethyl-5-amino-6-nitrobenzene.

Anal. Calcd. for $C_8H_9FN_2O_2$: N, 15.2. Found: N, 14.76. The analysis of the acetyl derivative, which could be obtained in a purer form, confirmed this formula.

Anal. Calcd. for $C_{10}H_{11}FN_2O_3$: N, 12.38. Found: N, 12.34.

1-Fluoro-2,4-dimethyl-3-nitro-5-amino-6-bromobenzene.—To a solution of 10.9 g. (0.05 mole) of 1-fluoro-2,4-dimethyl-5-amino-6-bromobenzene in 25 cc. of cold concentrated sulfuric acid was added 1.4 cc. of nitric acid (sp. gr. 1.42) in 25 cc. of concentrated sulfuric acid. After standing for thirty minutes in the cold, the nitration mixture was poured onto 150 g. of cracked ice. The free amine precipitated, and was purified by recrystallization from petroleum ether giving a bright yellow solid, m. p. 105.5–106°.

Anal. (Micro). Calcd. for $C_8H_8BrFN_2O_2$: N, 10.65. Found: N, 10.72.

The attempts to replace the amino groups through the diazonium salt by hydroxyl or methoxyl were unsuccessful, though a chlorine could thus be introduced readily.

1-Fluoro-2,4-dimethyl-3-nitro-5-chloro-6-bromobenzene.—A solution of 1.3 g. (0.005 mole) of 1-fluoro-2,4-dimethyl-3-nitro-5-amino-6-bromobenzene in 12 cc. of cold hydrochloric acid was diazotized with 0.35 g. of sodium nitrite in 5 cc. of water. A solution of cuprous chloride in concentrated hydrochloric acid was then added and the 1-fluoro-2,4-dimethyl-3-nitro-5-chloro-6-bromobenzene precipitated. By purification from ethyl alcohol, white crystals were obtained, m. p. 113.5–114°.

Anal. (Parr bomb). Calcd. for $C_8H_6BrClFNO_2$: Cl + Br, 40.85. Found: Cl + Br, 40.7.

1-Fluoro-2,4-dimethyl-5-hydroxybenzene.—A solution of 2.8 g. (0.02 mole) of 1-fluoro-2,4-dimethyl-5-aminobenzene in 6 cc. of concentrated sulfuric acid and 12 g. of ice was diazotized with 1.4 g. of sodium nitrite in 6 cc. of water. The diazonium salt was decomposed to the phenol by dropping its solution slowly into a boiling mixture of 10 cc. of concentrated sulfuric acid and 7 cc. of water. The 1-fluoro-2,4-dimethyl-5-hydroxybenzene was steam distilled and extracted from the distillate with ethyl ether. The yield was 2.4 g. (85%). The phenol was purified by sublimation to give a white solid melting at 44–45°.

Anal. Calcd. for C_8H_9FO : C, 68.54; H, 6.48. Found: C, 68.41; H, 6.44.

1-Fluoro-2,4-dimethyl-5-hydroxy-6-bromobenzene.—The product was obtained by bromination of 1-fluoro-2,4-dimethyl-5-hydroxybenzene in glacial acetic acid. The product obtained by dilution of the reaction mixture was recrystallized from ethyl alcohol, m. p. 65–68°. This product was identical with that obtained by demethylation and simultaneous acetylation of the corresponding methyl ether previously described. It was purified from 50% ethyl alcohol, m. p. 75–76°.

Anal. (Micro) of the phenol and the acetyl derivative. Calcd. for C_8H_8BrFO : Br, 36.5. Found: Br, 36.7. Calcd. for $C_{10}H_{10}BrFO_2$: Br, 30.6. Found: Br, 30.8.

An attempt to nitrate the 1-fluoro-2,4-dimethyl-5-hydroxy-6-bromobenzene was unsuccessful.

Summary

1. 2,2'-Difluoro-3,3'-dicarboxy-6,6'-dimethoxydiphenyl has been synthesized. 1-Fluoro-2-iodo-3-methoxybenzene was condensed with copper to 2,2'-difluoro-6,6'-dimethoxydiphenyl. By means of acetyl chloride and aluminum chloride, 2,2'-difluoro-3,3'-diaceto-6,6'-dimethyldiphenyl was produced and this substance oxidized by sodium hypochlorite to 2,2'-difluoro-3,3'-dicarboxy-6,6'-dimethoxydiphenyl.

2. The alkaloidal salts showed no mutarotation. Only one form could be obtained of each and no active acids could be obtained by decomposition.

A STUDY OF SOME PARA-ALKYLPHENOLSULFONIC ACIDS

BY C. M. SUTER AND EUGENE W. MOFFETT

RECEIVED MARCH 19, 1932

PUBLISHED JULY 6, 1932

The purpose of this investigation was to prepare some sodium *p*-alkylphenolsulfonates and to determine their activity as antiseptics. It was thought that the presence of a sulfo group would confer the properties of increased solubility and decreased toxicity upon a phenol without seriously diminishing its bactericidal power. Since phenol-*o*-sulfonic acid has been shown¹ to be more active than its isomers and *p*-cresol-*o*-sulfonic acid more effective than phenol-*o*-sulfonic acid, it seemed reasonable to assume that the higher *p*-alkylphenol-*o*-sulfonic acids would be the most useful compounds of this type.

The four *p*-alkylphenols, *n*-propyl- to *n*-hexyl-, were sulfonated and the solubilities in water of the sodium salts of the resulting *o*-sulfonic acids were determined. The values obtained are listed in column four of Table I. It is interesting to note the alternation in the solubilities with the increase in the length of the alkyl group.

Determination of the phenol coefficients² indicated that only the *n*-propyl and *n*-butyl compounds have a detectable disinfectant action, the values for these being 1.8 and 2.4, respectively. A saturated solution of each of the other sulfonates gave no indication of bactericidal activity.

Experimental

***p*-Alkylphenols.**—These were made by a recently³ used procedure involving the Fries reaction for the preparation of the *p*-hydroxyphenyl alkyl ketones and their reduction by the Clemmensen method to the alkylphenols. Part of the necessary phenyl esters were made from acyl chlorides and phenol and part of them by a method similar to one recently⁴ reported.

Sodium *p*-Alkylphenol Sulfonates.—The sulfonation of *p*-butylphenol is described here. The other preparations were carried out in a similar manner.

A mixture of 40 g. of *p*-butylphenol and 30 cc. of concentrated sulfuric acid was heated on the steam-bath for an hour and poured into a saturated solution of sodium

TABLE I

chloride. The precipitate of the sodium salt was twice recrystallized from hot water. The yield of pure product was 44 g. or 66% of the theoretical. The analytical data and yields of the four sulfonates are included in Table I.

The sulfur analyses were made by the Parr bomb method. The solubility determinations consisted of weighing the residues obtained by evaporation of the water from 25-cc. portions of saturated solutions of the various salts.

Summary

Four new *p*-alkylphenol-*o*-sulfonic acids have been made and the solubilities of their sodium salts in water determined. Of the compounds studied only the *n*-propyl- and *n*-butylphenolsulfonates have a measurable antiseptic action.

THE MECHANISM OF THE PRODUCTION OF THIOL ACIDS (R SH) AND SULFONIC ACIDS (R SO₃H) FROM DITHIO ACIDS (R S S R). III. THE ACTION OF COPPER SALTS^{1,2}

BY PAUL W. PREISLER AND DORIS B. PREISLER

RECEIVED MARCH 21, 1932

PUBLISHED JULY 6, 1932

Dithio acids (R S S R) have been shown to be simultaneously converted into thiol acids (R SH) and sulfonic acids (R SO₃H) by the action of Ag⁺,^{3,4} BrHg⁺,⁵ and Hg⁺⁺,^{6,7} the final result may be expressed by the equation

in which the formation of R SH and R SO₃H appears to be accelerated by reactants which remove the R SH by precipitation (Ag⁺, Hg⁺⁺) or by formation of un-ionized complexes (BrHg⁺).

The reaction between cupric salts and dithio acids has been studied by a quantitative method in which the corresponding sulfonic acid barium salt and the di-cuprous derivative of the thiol acid were isolated and identified. Of several possible reactions, the most probable is expressed by the equation

¹ Presented at the Meeting of the American Chemical Society in Buffalo, N. Y., September, 1931.

This presents an interesting example of oxidation and reduction in which two substances in higher states of oxidation are both reduced at the expense of a further oxidation of part of one of the reactants. Reactions of this kind may be the cause of lower yields when copper salts are used in the isolation of R SH and R S S R compounds.

Experimental

Because of the ease of the isolation of the products, dithiodihydracrylic acid was selected for study of the reaction of dithio acids with copper sulfate and copper perchlorate. The quantity of di-cuprous compound that was isolated depended upon the acidity, the temperature, the concentrations and the presence of oxygen. Conditions were adjusted so as to obtain a high yield of products, since complete reaction apparently did not take place within reasonable time under the conditions studied. The maximum yield obtained was approximately 57% of the original dithio acid as a di-cuprous derivative.

Isolation of the Di-cuprous Thiol Derivative.—(CuSO_4 reaction): 100 cc. of 0.2 *M* CuSO_4 , 0.0025 *N* in H_2SO_4 , and 325 cc. of water were placed in a flask fitted with a reflux condenser and heated in a boiling water-bath. Nitrogen, purified by passing over hot copper, was continuously passed through the solution to remove oxygen.

Fifty cc. of 0.1000 *N* di-sodium dithiodihydracrylate was added and the mixture heated for five hours. The light yellow precipitate was filtered off on a sintered glass crucible, washed with water containing a little sulfuric acid and then with acetone; amount of precipitate isolated (average of six experiments), 0.661 g., representing 57% of the original dithiodihydracrylic acid.

Analysis of the Di-cuprous Derivative.—Thiol determination: 0.30 to 0.45 g. of the precipitate was dissolved in excess potassium iodide and hydrochloric acid and titrated² with 0.1000 *N* potassium iodate: found, SH (average of six experiments), 14.26%; theoretical, 14.30%.

Copper determination: A 0.15 to 0.20 g. sample was dissolved in bromine water. After the removal of the excess of bromine by evaporation on the steam-bath, 3 g. of potassium iodide was added and the solution titrated with 0.1000 *N* sodium thiosulfate; found, Cu (average of six experiments), 54.3%; theoretical, 55.0%.

Isolation of the Di-cuprous Thiol Derivative.—($\text{Cu}(\text{ClO}_4)_2$ reaction): Sulfonic acid could not be isolated successfully from the sulfate solutions so similar experiments were carried out with perchlorate solutions: 150 cc. of 0.1 *M* copper perchlorate, 0.01 *N* in perchloric acid and 300 cc. of water were heated in a boiling water-bath, nitrogen was passed through, and 40.00 cc. of 0.1000 *N* di-sodium dithiodihydracrylate was added. The mixture was allowed to react for eight hours, after which the precipitate was filtered off. Amount of precipitate obtained (average of six experiments), 0.439 g., representing 47% of the original dithiodihydracrylic acid. To establish the identity of the compound, analyses for copper content, using 0.17 to 0.23 g. samples, were made: found (average of six experiments), 54.9%; theoretical, 55.0%.

Isolation of the Barium Salt of the Sulfonic Acid.—To the filtrate from the di-cuprous thiol compound was added 15 cc. of *N* barium perchlorate and then the mixture was saturated with hydrogen sulfide. After warming to coagulate, the copper sulfide (and a little barium sulfate) was filtered off and the filtrate was evaporated to about 10 cc. on the steam-bath. The solution was neutralized with *N* sodium hydroxide and one drop excess *N* perchloric acid was added; the white or gray precipitate which

formed was removed by centrifugalization. This precipitate is, perhaps, due to a decomposition of the dithiodihydracrylic acid present, since this gives a similar precipitate and a small amount of sulfonic acid when treated in a like manner. The solution and washings were evaporated to 50 cc., 150 cc. of 95% ethyl alcohol was added and the mixture warmed, whereupon precipitation of the barium sulfonate took place. This concentration of alcohol prevents the precipitation of the barium salt of the dithio acid. The mixture was cooled to about 7° and the crystalline precipitate filtered off on a sintered glass crucible. Isolated (average of five experiments) 0.284 g. of anhydrous Ba(OOCCH₂CH₂SO₃), representing approximately 24.5% of the original dithio acid.

Analysis of the Barium Sulfonate.—A 0.1 to 0.18 g. sample of the precipitate was placed in a platinum dish and dried at 180° to obtain the anhydrous salt and then quickly weighed. The material was ignited in a muffle, treated with a few drops of sulfuric acid and again ignited. Found, Ba (average of five experiments), 46.8%. Theoretical, 47.5%.

Discussion

The action of copper salts in causing the formation of sulfonic acids and thiol acids from dithio acids is probably due to reduction of the Cu⁺⁺ to Cu⁺ with subsequent precipitation of the di-cuprous derivative. The reduction of Cu⁺⁺ may result from the reaction with the R SH formed when water reacts with the dithio acid according to

Cupric ion is then reduced as follows

Cuprous ion then reacts with the R SH present forming the insoluble di-cuprous derivative similar to the reaction with Ag⁺,⁴

The sum of the properly substituted equations gives

This series of reactions would require the conversion of 37.5% of the original dithio acid into sulfonic acid or a sulfonic acid—thiol derivative ratio of 0.60. The ratio calculated from the best experimental values is

0.52 and indicates that some Cu^{++} reduction is perhaps caused by material other than the $-\text{SH}$ of the R SH .

The possibility of the occurrence of this series of reactions or any of its steps must be considered when isolating (as from biological material) R SH compounds (in the presence of oxidizing agents) or R S S R by means of cupric or cuprous salts, since sulfonic acids may result which cannot be easily reconverted into the original acids. Such reactions may also take part in the oxidation of R SH and R S S R when copper salts are used as catalysts.

The reaction is of chemical interest as an example of the interaction of two substances in higher states of oxidation to produce more reactive reducing substances and some of a more fully oxidized, unreactive product. The mechanism will be more fully discussed in a subsequent publication on the production of $\text{R SO}_3\text{H}$ from R S S R by oxidizing agents.

THE PREPARATION OF DI- AND ISOMERIC TETRACHLORODIOXANES

BY C. L. BUTLER AND LEONARD H. CRETCHER

RECEIVED MARCH 23, 1932

PUBLISHED JULY 6, 1932

Dichlorodioxane was recently prepared by Böeseken, Tellegen and Henriques¹ for use as an intermediate in the preparation of stereoisomeric 1,4,5,8-naphthodioxanes. A convenient means of determining the structure of the dichloro derivative was found in the easy hydrolysis of the substance in boiling water. As the aqueous solution of the hydrolysis product yielded quantitatively one molecular equivalent of glyoxal-*p*-nitrophenylosazone on treatment with *p*-nitrophenylhydrazine, it was concluded that the chlorine atoms were in vicinal positions. The hydrolysis apparently proceeded according to equation I. In the present paper, this work was confirmed and the evidence in support of equation I

was completed by the identification of glycol, as dibenzoate, among the hydrolysis products. As far as the present authors are aware, no other experiments on the chlorination of dioxane have been made. Van Alphen²

¹ Böeseken, Tellegen and Henriques, *Proc. Roy. Soc. Amsterdam*, **34**, 631 (1931); *Rec. trav. chim.*, **50**, 909 (1931).

² Van Alphen, *ibid.*, **49**, 1040 (1930).

attempted to brominate the substance by warming the bromine addition compound, $C_4H_8O_2Br_2$, but could isolate only ethylene bromide and aqueous hydrobromic acid from the reaction product.

Dioxane is now a commercial product, but its chemistry has been incompletely studied. It was thought by the present authors, therefore, that further investigation of its chlorinated derivatives would be of interest. The present paper consists of a report on the preparation and chemistry of dichloro- and of several isomeric tetrachlorodioxanes.

It is well known that glyoxal is a highly reactive substance and a useful reagent in many syntheses. As the usual method of preparation³ is inconvenient, it appeared to be worth while to investigate the use in glyoxal condensations of solutions prepared by hydrolyzing dichlorodioxane. Employing this source of glyoxal, the *p*-nitrophenylosazone was prepared in quantitative yield by reaction with *p*-nitrophenylhydrazine; the diurea condensation product glycoluril,⁴ was isolated in 70% yield; and from the latter hydantoin was prepared in 67% yield. Thus it is apparent that dichlorodioxane is a practical source of glyoxal for reactions of this type.

Dichlorodioxane.—This substance was prepared according to Böeseken, Tellegen and Henriques;¹ 208 g. of dioxane yielded 233 g. of pure dichlorodioxane boiling at 88–89° at 16–17 mm.; yield, allowing for 15 g. of recovered dioxane, 67.7%.

Glycol Dibenzoate.—1.6 g. of dichlorodioxane was decomposed by warming in 25 cc. of boiling water. A clear solution was obtained after about ten minutes' heating. The reaction mixture was cooled, made alkaline with sodium hydroxide and treated with benzoyl chloride in the usual way. The alkali-insoluble ester was extracted with ether and recrystallized from methyl alcohol. It melted at 70–72° on rapid heating.

Glyoxal-*p*-nitrophenylosazone.—1.6 g. of dichlorodioxane was decomposed as described above. An abundant red precipitate, which was formed on addition of an aqueous solution of 4 g. of *p*-nitrophenylhydrazine hydrochloride to the cooled hydrolysis product, was filtered and washed with water and alcohol; yield, 3.2 g. of pure product melting at 306°, or 97% of the theoretical.

Glycoluril.—1.6 g. (1 mol) of dichlorodioxane was decomposed in 25 cc. of boiling water and the resulting acidic solution of glyoxal was mixed with an aqueous solution of 1.3 g. (2 mols) of urea. The mixture was warmed to the boiling point and then set aside. White crystals of glycoluril soon began to separate from the solution. After standing for several hours these were filtered, washed and dried. The yield was 1.0 g., or 70% of the theoretical; 15.6 g. of dichlorodioxane when treated similarly gave 8.7 g. of glycoluril, or 61.3% of the theoretical. The substance did not melt below 330°.

Hydantoin.—Nine grams of glycoluril was mixed with 36 g. of 25% hydrochloric acid and the mixture evaporated on a hot water bath until it weighed only 21 g.³ Hydantoin crystallized from the solution on cooling in the ice box. A further quantity was obtained on evaporation of the mother liquor. The product was recrystallized from water. The yield of purified hydantoin melting at 214° was 4.3 g., or 67% of the theoretical.

³ Siemonsen, *Ann.*, **333**, 111 (1904).

⁴ Schiff, *ibid.*, **189**, 157 (1877); Bottinger, *Ber.*, **10**, 1923 (1877); Widman, *ibid.*, **19**, 2477 (1886); Biltz, *ibid.*, **40**, 4808 (1907); see also Pauly and Sauter, *ibid.*, **63B**, 2063 (1930).

The previous authors¹ also prepared diethoxydioxane by reaction of the dichloro compound with sodium ethylate. The method was improved in the present work by the substitution of absolute alcohol for sodium ethylate as reagent.

An attempted bromination gave the same negative results as were obtained by Van Alphen.²

Diethoxydioxane.—15.6 g. of dichlorodioxane was warmed on a water-bath for two and one-half hours with 30 cc. of absolute alcohol. Most of the hydrogen chloride and the excess of alcohol were removed by evaporation. The residue was taken up in ether, and the ether solution was washed with sodium bicarbonate solution and with water. The ether layer was dried with anhydrous sodium sulfate. The ether was evaporated off and the residue on distillation at 14 mm. gave 12.3 g. of diethoxydioxane boiling at 95–98°, or 71% of the theoretical yield.

Attempted Bromination of Dioxane.—Ninety grams of dioxane was kept gently refluxing and during six hours 335 g. of bromine was dropped into the liquid. The mixture was warmed for seven hours longer. On distillation of the reaction product 100 g. of liquid came over under 105°. The distillate collected in two layers, which were separated in a separatory funnel. The heavy layer was washed with water and dried with calcium chloride; 65.5 g. of ethylene dibromide boiling at 128–131° was obtained. The top layer consisted of aqueous hydrobromic acid. The residual tar could not be distilled.

2,3-Dichlorodioxane is theoretically capable of existence in *cis*- and *trans*- modifications. The facts that Böeseken, Tellegen and Henriques¹ were able to prepare stereoisomeric 1,4,5,8-naphthodioxanes and that chlorination of dioxane to the dichloro stage yields a uniform product, are interesting in this connection. Thus, although this substance is a constant boiling liquid, it may contain both of the possible isomers, because, on reaction with glycol, it yields two crystalline 1,4,5,8-naphthodioxanes.

The further chlorination of dioxane was next undertaken. It was hoped that the reaction would yield symmetrical tetrachlorodioxane, as this substance would give two molecular equivalents of glyoxal if its hydrolysis proceeded in a manner similar to the decomposition shown in equation I. However, the reaction product was found to consist of a mixture of tetrachlorodioxanes.

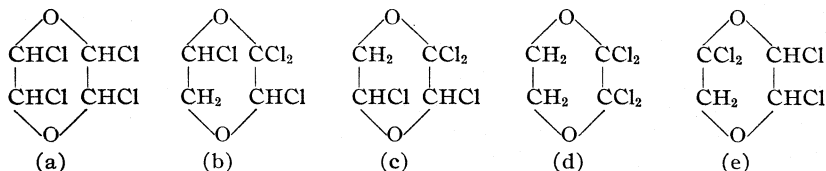

Preparation of Isomeric Tetrachlorodioxanes.—Two hundred grams of dioxane was chlorinated for twelve hours at 90°, as described previously.¹ Chlorine was then passed into the crude dichlorodioxane for twelve hours longer at 135–140°, heat being supplied by an oil-bath. Some crystalline material separated on cooling the reaction product. After standing for forty-eight hours in the ice box, the mixture was filtered, the crystals were set aside and the liquid was repeatedly fractionated at 11–12 mm.

As the distillations were continued, the top fractions yielded further small amounts of crystalline material. The lowest liquid fraction, 10 g. boiling below 90°, was not further investigated. The fractions between 95 and 100° also deposited crystals as the separation progressed, leaving a liquid fraction which on redistillation had a constant boiling point of 93–95°; yield, 57 g. The crystalline material from the low-boiling fractions was recrystallized from a mixture of ether and petroleum ether of boiling range 30–40°. The yield was 35 g. of white crystals melting at 57–58°. Several small

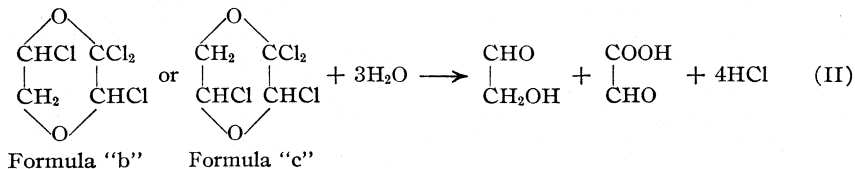

fractions (total weight 46 g.) of boiling point up to 120° were also obtained. The mixture of crystals from the crude reaction product and from the top fractions of the distilled liquid on recrystallization from ether yielded white needles melting at 143–144° in a yield of 22 g. and smaller flat crystals melting at 59–60°. The yield of the latter was 10 g.

The four main fractions on analysis gave the correct value for tetrachlorodioxane. The structures of the compounds were determined by hydrolysis in boiling water and identification of the hydrolysis products in the form of their nitrophenylhydrazine derivatives.

Because the first stage of the chlorination was carried out under conditions which yield the known 2,3-dichlorodioxane, at least two of the chlorine atoms in the tetrasubstituted derivatives are in vicinal positions. The structural possibilities for the four compounds isolated are limited by this condition to those shown.

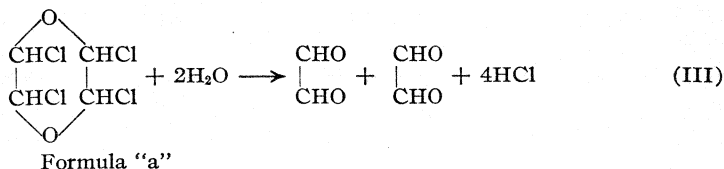

Tetrachlorodioxanes, b. p. 93–95° at 11–12 mm. and m. p. 57–58°, on decomposition with boiling water and subsequent treatment with *p*-nitrophenylhydrazine each yielded one molecular equivalent of glyoxylic acid *p*-nitrophenylhydrazone and one of glyoxal-*p*-nitrophenylosazone. The formation of glyoxylic acid on hydrolysis, together with the analytical data, indicates that these substances are tetrachlorodioxanes with three chlorine atoms on one side of the molecule and one on the other. They may be the structural isomers shown, formulas “b” and “c,” or stereoisomers of either of these. The side of the molecule bearing the single chlorine atom should on hydrolysis yield glycolic aldehyde. The glyoxal-*p*-nitrophenylosazone obtained in the experiments is explained by the ease with which glycolic aldehyde is converted into this substance on treatment with *p*-nitrophenylhydrazine in acid solution.⁵ The breakdown of these tetrachlorodioxanes is shown in Equation II.

Tetrachlorodioxanes, m. p. 59–60° and m. p. 143–144°, gave two molecular equivalents of glyoxal-*p*-nitrophenylosazone when solutions obtained by decomposing them with boiling water were treated with *p*-nitrophenyl-

⁵ Wohl and Neuberg, *Ber.*, **33**, 3107 (1900).

hydrazine. They are therefore symmetrically substituted tetrachlorodioxanes and are two of five possible geometric isomers of formula "a." Their breakdown is shown in equation III.

Analyses of the Isomeric Tetrachlorodioxanes.—Calcd. for $\text{C}_4\text{H}_4\text{O}_2\text{Cl}_4$: Cl, 62.8. Found: liquid b. p. 93–95° at 11–12 mm., Cl, 62.1, d_4^{15} 1.5735; n_D^{25} 1.4956; crystals m. p. 57–58°, Cl, 63.1; crystals m. p. 59–60°, Cl, 63.1°, crystals m. p. 143–144°, Cl, 62.8.

Structure of the Isomeric Tetrachlorodioxanes.—Approximately 1.0-g. samples were heated under a reflux condenser with 50 cc. of water until clear solutions were obtained. The solutions were filtered and treated with 4.25 equivalents of *p*-nitrophenylhydrazine in dilute hydrochloric acid solution. A summary of the reaction products is shown in Table I.

^a This substance was identified by the facts that it darkened at about 180° and decomposed at about 200°,⁶ and that it was soluble in dilute alkali to a beautiful deep red solution.

Formula "d" requires the formation of one molecule of oxalic acid and one of glycol, and formula "e" one of glycolic acid and one of glyoxal on hydrolysis. As neither of these sets of results agrees with the actual laboratory findings, these structures may be ruled out as applying to this work.

As a convenient source of glyoxal the tetrachlorodioxanes did not prove to be particularly suitable, mainly because of the low yields of symmetrically substituted compounds which give glyoxal on hydrolysis. All the compounds prepared had an odor resembling phosgene, which was more pronounced in the unsymmetrical tetrachloro derivatives. The liquid ap-

⁶ Dakin and Dudley, *J. Biol. Chem.*, **15**, 136 (1913).

peared to be less stable than the other isomers, as it developed a strong odor of hydrochloric acid and lost about 3% of its chlorine on keeping for two weeks. The chlorine atoms in all these substances are quite reactive, and hence it is possible that further study will show interesting uses to which they might be put.

Some interesting information as to the relative stability toward hydrolysis of the di- and the isomeric tetra-substituted chloro derivatives of dioxane is available as a result of these studies. While dichlorodioxane is completely broken up by warming for ten or fifteen minutes in boiling water, two and one-half to three hours of heating were required to decompose the symmetrical tetrachloro derivatives which have quite similar structures. The unsymmetrical tetrachlorodioxanes were found to be even more stable, as five to six hours heating was required for their complete decomposition.

The yields of the various products obtained from 200 g. of dioxane are shown in Table II. That they are not higher is probably due in part to the many fractional distillations required to complete the separations.

THE INTERACTION OF DIARYLARSYL IODIDES, DIARYLSTIBYL IODIDES AND PHENYLDIHALOARSINES WITH THE PIPERIDINE SALT OF N-PENTAMETHYLENE-DITHIOCARBAMIC ACID¹

BY F. F. BLICKE AND U. O. OAKDALE²

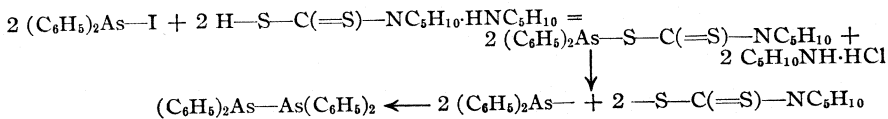

RECEIVED APRIL 1, 1932

PUBLISHED JULY 6, 1932

N-Pentamethylene-S-triarylmethyldithiourethans are formed almost instantly and quantitatively from the interaction, at ordinary temperature, of a triarylmethyl halide and the piperidine salt of N-pentamethylenedithiocarbamic acid. These urethans are of interest because of the fact that they dissociate spontaneously, in solution, with the formation of triarylmethyls.³

In view of the great reactivity of the halogen in diarylarsyl and diarylstibyl iodides it seemed probable that these halides, too, might react with the piperidine salt of N-pentamethylenedithiocarbamic acid similarly to the triarylmethyl halides. It was found that piperidine hydriodide was precipitated almost immediately upon the addition of diphenylarsyl iodide, dissolved in benzene, to the piperidine salt of the dithiocarbamic acid. A colorless, crystalline compound was isolated from the benzene solution which, according to the results obtained from an analysis and molecular weight determination, was N-pentamethylene-S-diphenylarsyldithiourethan.

Di- α -naphthylarsyl iodide, biphenylenearsyl iodide, 6-iodophenoxarsine, diphenylstibyl iodide and di-*p*-tolylstibyl iodide reacted with the piperidine salt in a manner entirely analogous to that described.

In the event that N-pentamethylene-S-diphenylarsyldithiourethan behaved similarly to the triarylmethyl analogs it should yield spontaneously, in solution, diphenylarsyl which would then polymerize, partly or com-

¹ This paper represents the second part of a dissertation to be submitted to the Graduate School by Mr. Oakdale in partial fulfillment of the requirements for the degree of Doctor of Philosophy in the University of Michigan.

pletely, to tetraphenyldiarsyl. This compound, as well as other tetra-aryldiarsyls, absorbs with great rapidity an amount of oxygen which corresponds to that required for the formation of a peroxide.⁴ Tetraphenyldistibyl reacts with oxygen in a similar manner.⁵

In one series of experiments the reactivity of the dithiourethans toward oxygen was tested by the use of the original reaction mixture. A number of sealed tubes were prepared; each tube contained the iodide, the required amount of the piperidine salt of N-pentamethylenedithiocarbamic acid and bromobenzene. After twenty-four hours the tubes were broken in an absorption apparatus and the contents exposed to oxygen, with continuous agitation, for two hours. No absorption of oxygen was noticed in any instance. Absorption experiments were repeated with the isolated dithiourethans with negative results.

Phenyldichloro- and phenyldi-iodoarsine react readily with two molecular equivalents of the piperidine salt of the dithiocarbamic acid from phenylarsylene N-pentamethylenedithiocarbamate, $C_6H_5As[S-C(=S)-NC_5H_{10}]_2$. Other alkyl- and aryldihaloarsines would, undoubtedly, react in an analogous manner. Many alkyl- and aryldihaloarsines are liquids or low melting solids, hence, it is difficult if not impossible to identify small amounts of these substances. No entirely satisfactory derivatives have been described hitherto which can be used for identification purposes; the dithiocarbamate, however, which can be obtained in sufficient amount from one drop of either of the above mentioned halides, seems to be especially suitable for this purpose because of the ease of its preparation,⁶ the high molecular weight, sharp melting point and the low loss of material on recrystallization.

Experimental Part

N-Pentamethylene-S-diphenylarsyldithiourethan.—Two hundredths of a mole of diphenylarsyl iodide, dissolved in the smallest possible amount of warm benzene, was added to 0.02 mole of the piperidine salt of *n*-pentamethylenedithiocarbamic acid,⁷ dissolved in warm benzene. Piperidine hydriodide precipitated immediately. The mixture was protected from moisture and after twelve hours the piperidine salt was removed by filtration and about 30 cc. of petroleum ether (30–60°) was added to the filtrate in order to precipitate a small quantity of piperidine hydriodide which had remained in solution. The hydriodide weighed 4.0 g.; the calculated amount is 4.2 g. To the benzene-petroleum ether solution there was added 150 cc. of petroleum ether whereupon the N-pentamethylene compound precipitated in crystalline form. The yield of the

⁵ Blicke and Oakdale, *ibid.*, **53**, 1025 (1931).

⁶ In order to obtain the reagent it is merely necessary to add piperidine to a solution of carbon disulfide in absolute ether; the piperidine salt of the dithiourethan precipitates immediately.

⁷ Cahours, *Ann. chim. phys.*, [3] **38**, 88 (1853); Ladenburg and Roth, *Ber.*, **17**, 514 (1884).

latter was 5.2 g. It was washed thoroughly with water to remove traces of piperidine hydriodide, dried and recrystallized from acetic acid or ethyl acetate.

Neither the original reaction mixture^a nor the pure, isolated dithiourethan absorbed oxygen.

The molecular weight was determined in boiling benzene by the Menzies method. Calcd. mol. wt., 389; found, 386.

Dissolved in acetone the compound decolorized potassium permanganate, as well as iodine, instantly.

Diphenylchloroarsine was formed when the benzene solution of the compound was treated with hydrogen chloride at ordinary temperature.

A few drops of sulfuric acid were added to an acetic acid solution of the material and the mixture boiled for a few minutes. Diphenylarsinic acid was obtained as a reaction product.

Di- α -naphthylarsyl iodide, biphenylenearsyl iodide, 6-iodophenoxarsine, diphenylstibyl iodide and di-*p*-tolylstibyl iodide reacted in a similar manner with the piperidine salt of the dithiocarbamic acid.

Phenylarsylene N-Pentamethylenedithiocarbamate, C₆H₅As[S—C(=S)—NC₅H₁₀]₂.—The following experiment illustrates the serviceability of the piperidine salt of the dithiocarbamic acid as a reagent for the identification of a very small quantity of phenyldi-iodoarsine. To one drop (0.0306 g.) of the latter compound there was added 0.127 g. (five times the calcd. amount), of the piperidine salt dissolved in about 3 cc. of dry benzene. The mixture was protected from moisture and after twelve hours the benzene was allowed to evaporate. The crystalline residue was washed with water until the piperidine hydriodide and excess piperidine salt of the dithiocarbamic acid had

^a As a control experiment the reaction mixture obtained from 1.61 g. (0.005 mole) of triphenylmethyl bromide and 0.005 mole of the piperidine salt of the dithiocarbamic acid, dissolved in bromobenzene, was placed in the absorption apparatus and shaken vigorously. Previously, absorption experiments in the case of N-pentamethylene-S-triarylmethyldithiourethans had been carried out only with the isolated urethan. After one hour the reaction mixture had absorbed 60 cc. of oxygen and after two and one-half hours over 100 cc. had been absorbed. An absorption in excess of 56 cc., the required amount of gas for peroxide formation, is to be expected because of the union of the sulfur radical, formed during the dissociation of the dithiourethan, with oxygen. The formation of sulfur dioxide, or other volatile product, during the absorption naturally render the absorption procedure only a semi-quantitative one. Two-tenths of a gram of pure triphenylmethyl peroxide was isolated from the mixture.

been removed completely. The crude product weighed 0.022 g. One-half of the material was recrystallized from ethyl acetate; m. p. 173–174°.

Phenyldichloroarsine reacts in an analogous manner.

Anal. Calcd. for $C_{18}H_{25}S_4N_2As$: As, 15.87; S, 27.15. Found: As, 15.76; S, 26.92.

Summary

Diarylarsyl and diarylstibyl iodides react readily with the piperidine salt of N-pentamethylenedithiocarbamic acid to form N-pentamethylene-S-diarylarsyl- and N-pentamethylene-S-diarylstibyl dithiourethans. Unlike the triarylmethyl analogs these substances do not undergo spontaneous decomposition in solution to form compounds of the type $R_2As-AsR_2$ and $R_2Sb-SbR_2$. Phenyldihaloarsines and the piperidine salt of the dithiourethan interact to yield a dithiocarbamate. Because of the advantageous properties of this substance the piperidine salt of the dithiocarbamic acid is suggested as a reagent for the identification of small quantities of alkyl- and aryldihaloarsines.

[CONTRIBUTION FROM THE INSECTICIDE DIVISION, BUREAU OF CHEMISTRY AND SOILS] ROTENONE. XXII. SOME NEW DATA IN CONFIRMATION OF THE STRUCTURE OF ROTENONE

BY L. E. SMITH AND F. B. LAFORGE

RECEIVED APRIL 6, 1932

PUBLISHED JULY 6, 1932

The complete formula for rotenone having been established on the basis of its principal reactions as I,¹ reference should be made to several other typical reactions not explained in previous articles.

¹ LaForge and Haller, *THIS JOURNAL*, **54**, 810 (1932).

The derritols are converted into anhydroderritols with loss of one molecule of water. The reaction mechanism proposed by Butenandt for this transformation has proved to be correct, and anhydroderritol therefore corresponds to the formula III.² The reaction is, however, best accomplished by boiling the compounds in xylene solution with phosphorus pentoxide rather than by distillation as recommended by Butenandt. The anhydroderritols all contain a free phenolic hydroxyl group in position 6 and can be acetylated to monoacetyl compounds which do not give the ferric chloride reaction. They are insoluble in alkali, a property which is in agreement with the fact that all phenols of the rotenone series with only one hydroxyl group in the 6 position, are alkali insoluble.¹

All these relations serve as further confirmation of formula III for derritol.

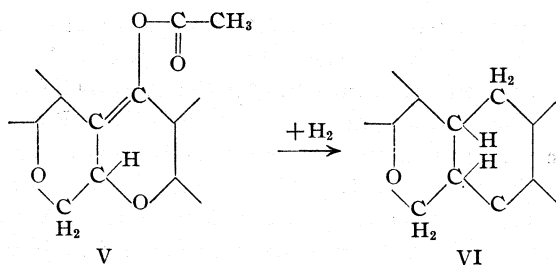

As previously reported, dehydrodihydrorotenonic acid is easily acetylated in position 4 to a monoacetyl compound. From analogy it could be predicted that dihydrorotenonic acid would yield a corresponding monoacetyl derivative. Contrary to expectations, however, treatment of dihydrorotenonic acid with acetic anhydride and sodium acetate resulted in the formation of a diacetyl derivative.

Rotenone, dihydrorotenone and isorotenone on treatment with acetic anhydride yielded monoacetyl compounds.

These results might have been very disturbing in the speculations on the structure of rotenone, had they been observed before the rotenone formula had been established. They are, however, easily explained on the assumption that rotenone and rotenonic acid react to form enol acetates, V. This theory has been proved definitely by the fact that on catalytic hydrogenation acetyldihydrotrotenone is easily converted into dihydrodesoxyrotenone, VI, with simultaneous loss of the acetyl group.³ The enol acetates

² Butenandt, *Ann.*, **464**, 253 (1929).

³ Roll and Adams, *THIS JOURNAL*, 53, 8469 (1931).

of rotenone and dihydrorotenone give promise of being of practical importance owing to their comparative stability toward oxidation. Comparative toxicity tests are being made on these compounds. The structure of rotenonone will be discussed in a future communication.

Experimental

The Anhydroderritols.—Two grams of substance was dissolved in 75 cc. of xylene and 4 g. of phosphorus pentoxide was added in small portions to the boiling solution. The solution was then decanted from the viscous residue and evaporated to dryness on the steam-bath. The crude product crystallized on cooling. The yield in all cases was about 1.5 g.

Anhydro-	Recrystal- lized from	M. p. °C.	Ferric chloride test	Formula	C	Calcd. H	Analyses, % C	Found H

									21.46

Diacetyldihydrorotenonic Acid.—One gram of dihydrorotenonic acid, 0.3 g. of anhydrous sodium acetate and 16 cc. of acetic anhydride were refluxed for one hour, and the solution then evaporated to dryness on the steam-bath. The product was washed with water and then recrystallized from dilute ethyl alcohol. The substance melted at 115–116°. It was again recrystallized from petroleum ether (b. p. 80–100°) and it

then melted at 119°; yield, 0.8 g. Calcd. for $C_{27}H_{30}O_8$: C, 67.22; H, 6.22; $2CH_3O$, 12.86; $2CH_3CO$, 17.84. Found: C, 67.62, 67.23; H, 5.91, 6.15; CH_3O , 13.17, 12.87; CH_3CO , 17.79.

This same compound was obtained when 2 g. of dihydrorotenonic acid dissolved in 5 cc. of pyridine was treated in the cold with 1 g. of acetyl chloride. After standing at room temperature for three days, water was added and the mixture extracted with ether. The ether extract was extracted twice with water, twice with 10% hydrochloric acid and once with 10% potassium carbonate solution. After drying over anhydrous sodium sulfate the ether was evaporated and the product recrystallized from petroleum ether, m. p. 119°. When the substances obtained by the two methods were mixed, the melting point was not depressed.

The Acetylrotenones.—One gram of substance, 0.3 g. of anhydrous sodium acetate and 16 g. of acetic anhydride were refluxed for one hour, and the solution was then evaporated to dryness on the steam-bath. After washing with water the products were recrystallized. The compounds can also be prepared by the pyridine-acetyl chloride method as in the case of diacetyldihydrorotenonic acid. Acetylisorotenone is distinctly yellow in color whereas the corresponding rotenone and dihydrorotenone derivatives are only very slightly colored.

	Re-crystal- lized from	M. p., °C.	Formula	Analyses

Dihydrodesoxyrotenone from Acetyldihydrorotenone.—Four-tenths gram of acetyldihydrorotenone in acetic acid solution was reduced with hydrogen under 50 pounds pressure with 0.2 g. of platinum oxide catalyst. The substance crystallized when the acetic acid solution was diluted with water. It was filtered off, dissolved in ether, and the ether solution was extracted with 5% potassium hydroxide. The ether solution was then dried over anhydrous sodium sulfate and evaporated to dryness. The product was recrystallized from methyl alcohol; m. p. 168°, yield 0.3 g. When mixed with dihydrodesoxyrotenone there was no depression of melting point.

*Anal.*⁴ Calcd. for $C_{23}H_{26}O_5$: C, 72.28; H, 6.86. Found: C, 72.23, 72.08; H, 6.97, 7.05.

Summary

Anhydroderritols were prepared from derritol, isoderritol and dihydroderritol by the action of phosphorus pentoxide on the xylene solution of the corresponding derritols.

The methyl derritols do not yield anhydrides.

The anhydroderritols are alkali insoluble but give ferric chloride color reactions and can be acetylated.

The mechanism of the formation of the anhydroderritols proposed by Butenandt has proved to be correct. These reactions serve as a confirmation of the derritol formula as previously proposed. Dihydrorotenonic acid gives a diacetyl derivative. Rotenone, isorotenone and dihydrorotenone give monoacetyl compounds. These acetyl compounds belong to

⁴ These analyses were made by Mr. J. R. Spies of this division.

the class of enol acetates and one of the acetyl groups in dihydrorotenonic acid is of this type.

Dihydrorotenone monoacetate is reduced by catalytic hydrogen to dihydrodesoxyrotenone.

DEGUELIN. IV. THE STRUCTURE OF DEGUELIN AND TEPHROSIN

By E. P. CLARK

RECEIVED MAY 3, 1932

PUBLISHED JULY 6, 1932

On the basis of information now available it may be stated with a considerable degree of assurance that the structure of deguelin is represented by formula I.

I. Deguelin, $C_{28}H_{22}O_6$

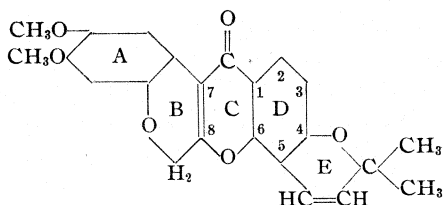

This statement is based upon facts concerning reactions of deguelin previously published together with certain new information which will be presented at this time and also upon the important observation previously made relative to relationships existing between deguelin and rotenone.

As the reactions principally involved in establishing that portion of the structure of deguelin represented by rings A, B, C and D have been recorded¹ and an interpretation of these reactions has been made in establishing the same structures in toxicarol,² it will be necessary only to refer to these facts briefly.

Deguelin, like rotenone and toxicarol, contains two hydrogen atoms which are readily removed by mild oxidation. In their place a double bond is introduced into the molecule, and the oxidation product, dehydrodeguelin (formula II), undergoes reactions which establish the fact that the position of the new double bond is between the carbon atoms common to rings B and C (designated in the formula as carbon atoms 7 and 8). The facts supporting the last statement are as follows: first, permanganate oxidation of dehydrodeguelin yields three products, namely, 2-hydroxy-4,5-dimethoxybenzoic acid, risic acid (2-carboxy-4,5-dimethoxyphenoxyacetic

¹ Clark, *THIS JOURNAL*, (a) **53**, 313 (1931); (b) **53**, 2369 (1931); (c) **53**, 3431 (1931); (d) **53**, 2007 (1931).

² Clark, *ibid.*, **54**, 2537 (1932).

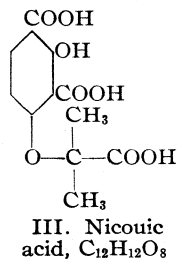

II. Dehydrodeguelin, $C_{23}H_{20}O_6$

acid) and a new tricarboxylic acid, $C_{12}H_{12}O_8$, which has been designated as nicouic acid. Second, hydrolysis of dehydrodeguelin with alcoholic potassium hydroxide yields deguelic acid, $C_{23}H_{24}O_8$, which upon oxidation with potassium permanganate gives risic acid. If, however, the oxidizing agent is alkaline hydrogen peroxide, derric acid (2-carboxymethyl-4,5-dimethoxyphenoxyacetic acid) is formed. Disregarding for the moment nicouic acid, the interpretation of these facts is the same as was presented in developing that portion of the structure of toxicarol which is identical with rings A, B and C in the deguelin formula presented above.² It follows, therefore, that deguelin, having no free hydroxyl as is the case with toxicarol, undoubtedly possesses the structure represented by rings A, B, C and D. There then remain only the elements C_5H_6O to be accounted for.

Available information concerning this grouping is purely of an analytical character, but the evidence is fairly conclusive that the structure represented by ring E in formulas I and II is correct.

Deguelin has been shown to be optically inactive^{1a} and it also possesses a double bond capable of reduction to a dihydro derivative. Except for the configurations of carbon atoms 7 and 8 which are assumed to be racemized in the process of preparing deguelin, as was also suggested as being the case with toxicarol,² formula I satisfies the two conditions just mentioned. It has further been shown that permanganate oxidation of dehydrodeguelin yields besides 2-hydroxy-4,5-dimethoxybenzoic and risic acids, nicouic acid, to which reference was made above.

Nicouic acid is a tricarboxylic acid, as shown by combustion, titration and the methoxyl content of its methyl ester. It decomposes at its melting point with the evolution of gas and at the same time gives as one of its decomposition products α -hydroxyisobutyric acid. It also gives the fluorescein reaction for resorcinol,³ and it may be decomposed in boiling aniline solution to give resorcinol. When considered in conjunction with the structure of that portion of the dehydrodeguelin molecule represented by rings A, B and C in formula II and also the manner in which permanganate attacks the molecule, these facts indicate that nicouic acid has the structure represented by III.

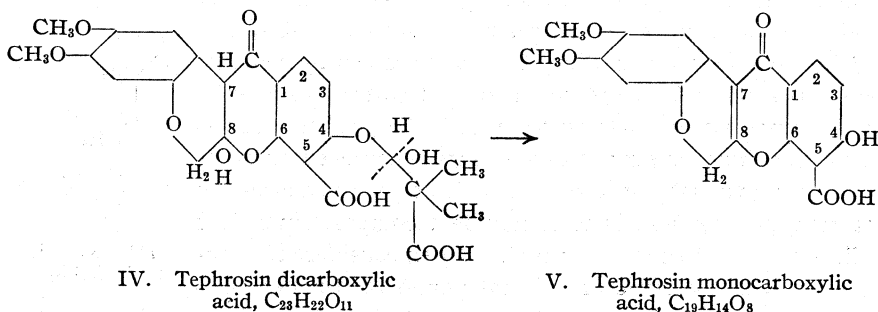

³ Mulliken, "Identification of Pure Organic Compounds," 1905, Vol. I, p. 110.

Further evidence bearing upon the nature of ring E has been obtained through another source. It has been shown that tephrosin, $C_{23}H_{22}O_7$, is a hydroxydeguelin^{4,5} and that the hydroxyl group replaces one of the easily oxidizable hydrogen atoms attached to carbon atoms 7 or 8 in deguelin. It has also been shown that tephrosin is oxidized by potassium permanganate to a dicarboxylic acid, $C_{23}H_{22}O_{11}$ (IV),⁴ in which process the ring containing the double bond (ring D) is split and four atoms of oxygen are added. No loss of carbon or hydrogen occurs.

Tephrosin dicarboxylic acid, when dissolved in hot diphenyl ether and then heated a short time to the boiling point of the solvent, loses the elements $C_4H_8O_3$ and yields a phenolic monocarboxylic acid, $C_{19}H_{14}O_8$ (V), to which the name tephrosin monocarboxylic acid has been given. In this process the hydrogen atom and the hydroxyl group attached to carbon atoms 7 and 8 are removed as water with the generation of a double bond, so that tephrosin monocarboxylic acid belongs to the dehydro series of derivatives. This fact is shown not only by the insolubility of the product, a characteristic of dehydro derivatives of the rotenone group of fish poisons, but also because of its composition and its ability, when treated with alcoholic potassium hydroxide solution, to undergo hydrolysis with the formation of a new carboxyl and phenolic hydroxyl group (deguelic or derrissic acid reaction).

The remaining portion of the $C_4H_8O_3$, namely, $C_4H_6O_2$, which is lost by tephrosin dicarboxylic acid, consists of α -hydroxyisobutyric acid. Evidence of this was obtained by isolating the α -hydroxyisobutyric acid as a decomposition product of the reaction. Because α -hydroxyisobutyric acid is removed from the original acid with the simultaneous generation of a hydroxyl group in ring D, demonstrated by a positive ferric chloride test and the formation of an acetyl derivative, it is obvious that the process is one of hydrolysis and may be represented as follows

⁴ Clark, *THIS JOURNAL*, **53**, 729 (1931).

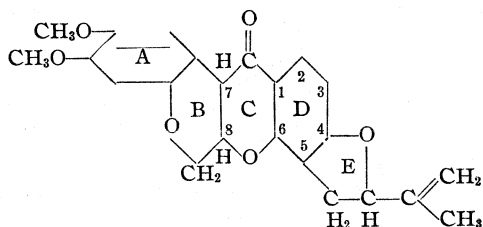

⁵ Besides acetic anhydride or a mixture of acetic and sulfuric acids other dehydrating agents convert tephrosin into dehydrodeguelin. An acetyl derivative of tephrosin has also been prepared (see experimental part).

The reaction is important, however, aside from showing the nature of the C_4 group, in that tephrosin monocarboxylic acid undergoes the Dakin reaction, yielding risic acid, and therefore restricts the possible positions of the hydroxyl group in tephrosin monocarboxylic acid and consequently the oxygen linkage of ring E in deguelin and tephrosin. The Dakin reaction has been discussed recently in connection with its application to the structure of toxicarol,² and from that discussion it follows that the hydroxyl group in ring D of tephrosin monocarboxylic acid is either at position 2 or 4.

From the facts presented relative to nicouic and tephrosin dicarboxylic acids it follows that the grouping C_6H_6O in deguelin and tephrosin consists of an optically inactive unsaturated pyran ring, which can be represented only as indicated by ring E.

In the data thus far presented only two facts bear upon the attachment of ring E to ring D. This of course refers to the application of the Dakin reaction to tephrosin monocarboxylic acid and the evidence that nicouic acid is a resorcinol derivative. However, another approach to this problem is available as a result of the observation that dihydrodehydrodeguelin and dihydrodeguelic acid are respectively identical with dehydro- β -dihydrorotenone and dehydrodihydroxy- β -dihydrorotenonic acid.^{1b}

It has recently been demonstrated by LaForge and Haller⁶ that rotenone may be represented by formula VI, and in the course of this work it was

VI. Rotenone

shown that rotenonic acid is formed from rotenone by opening the furan ring (E) by hydrogenation.

Haller⁷ also found that in attempting to isomerize rotenonic acid to isorotenonic acid with glacial acetic and sulfuric acids, ring closure occurred in a measure analogous to the formation of a saturated lactone from an unsaturated acid and yielded an alkali-insoluble compound which he designated as β -dihydrorotenone. Mild oxidation of this compound removed the readily oxidizable hydrogen atoms on carbon atoms 7 and 8 in formula VI and yielded dehydro- β -dihydrorotenone. Hydrolysis of the dehydro- β -dihydrorotenone with alcoholic alkali yielded what was called dehydrodi-

⁶ LaForge and Haller, *THIS JOURNAL*, **54**, 810 (1932).

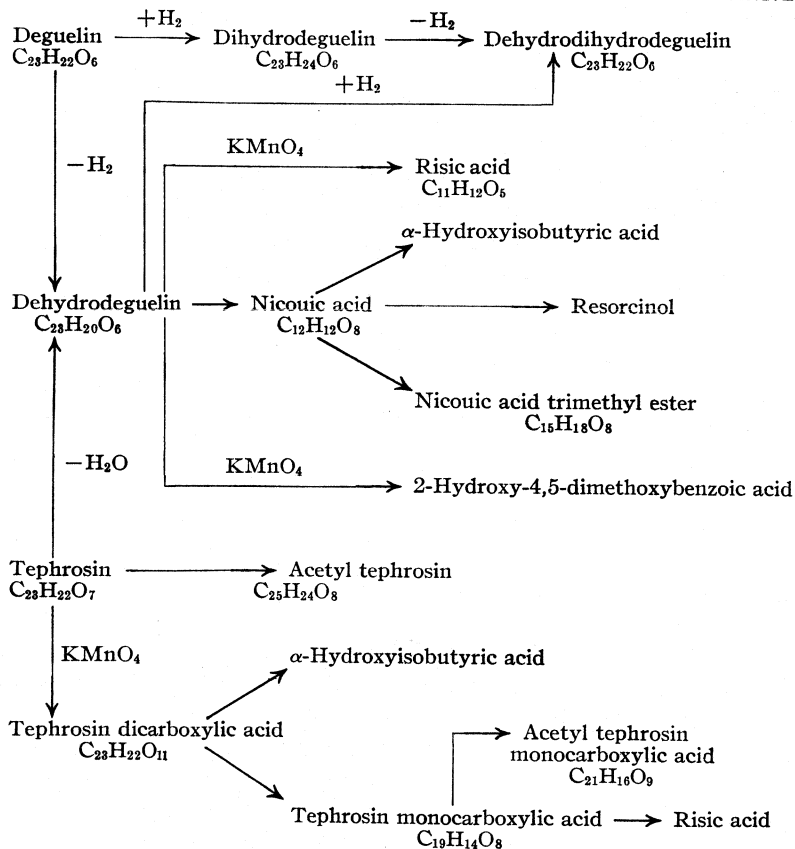

⁷ Haller, *ibid.*, **53**, 733 (1931).

hydroxy- β -dihydrorotenonic acid. These β -dihydrorotenone compounds, as stated before, were the same as dehydrodihydrodeguelin and dihydrodeguelic acid, respectively. From the way in which the β -dihydrorotenone derivatives were prepared it follows that no shift of points of attachment of ring E to ring D in rotenone occurred, and therefore ring E in deguelin and tephrosin is attached to ring D as indicated in formula I.

The relationships existing between the β -dihydrorotenone and deguelin derivatives are also verification of that portion of the structure of deguelin represented by rings A, B, C and D which was developed upon evidence relating to independent reactions of deguelin and its derivatives.

The reactions involved in the foregoing discussion which have been presented for the first time are summarized in the accompanying chart.

NEW REACTIONS OF DEGUELIN AND TEPHROSIN AND SOME OF THEIR DERIVATIVES

Experimental

Dihydrodeguelin.—A solution of 5 g. of deguelin in 150 cc. of hot acetic acid was reduced at atmospheric pressure and 75° with hydrogen and the platinum catalyst of

Voorhees and Adams.⁸ The catalyst was removed, and the solution was concentrated *in vacuo* to a sirup, which was dissolved in 35 cc. of methanol and allowed to crystallize. Three and six-tenths grams of colorless crystals separated which melted at 153–155°. This material when recrystallized from various solvents gave products which appeared to be uniform but which did not melt sharply. The melting points of the various preparations also differed from each other over the range from 153° to 163°, and combustion analysis gave carbon and hydrogen results which, while uniform, were too high to warrant the assumption that the material was pure.

A portion of the reduced material dissolved in ethyl acetate was then treated for two hours with hydrogen and the platinum catalyst at a pressure of 375 pounds. The resulting product obtained as outlined above was recrystallized by dissolving it in the necessary quantity of chloroform and adding an excess of methanol. It melted sharply at 173–174° and gave satisfactory analysis.

Anal. Calcd. for $C_{28}H_{24}O_6$: C, 69.67; H, 6.10; OCH_3 , 15.66. Found: C, 69.31; H, 6.08; OCH_3 , 15.6.

To further identify the compound as dihydrodeguelin it was oxidized to dehydrodihydrodeguelin with potassium ferricyanide in the manner in which dehydrodeguelin was prepared from deguelin.^{1a} The product was shown to be the material expected by comparison with an authentic sample of dehydrodihydrodeguelin.

Risic Acid by Permanganate Oxidation of Dehydrodeguelin.—The mother liquors from which the 2-hydroxy-4,5-dimethoxybenzoic acid was obtained by oxidizing 50 g. of dehydrodeguelin with permanganate¹⁰ were thoroughly extracted with ether. The extract was dried with sodium sulfate and concentrated to a volume of approximately 50 cc. As the operation proceeded a small quantity (150–160 mg.) of risic acid separated. It was purified according to the directions previously recorded⁹ and then was shown to be pure risic acid by comparison with an authentic sample of this material.

Nicouic Acid.—After removing the risic acid from the above ether extract, the mother liquors were concentrated to a sirup and dissolved in 150 cc. of boiling chloroform. Upon standing, 8.2 g. of nicouic acid separated as groups of irregularly shaped salmon-colored rods and plates. Upon spontaneous evaporation the mother liquors left a mass of highly colored sticky crystals. These were dissolved in a large excess of boiling 5% potassium hydroxide solution and treated with small quantities of 30% hydrogen peroxide until the color of the liquid became light yellow. The solution was then acidified with sulfuric acid, filtered through norit and extracted with ether. The purified acid was recovered from the ethereal solution as outlined above. The yield was 2 g., making in all 10.2 g. of **nicouic acid** from 50 g. of dehydrodeguelin.

For analysis the acid was purified by treatment with hydrogen peroxide as outlined above and then recrystallized once from boiling chloroform. Thus obtained it consisted of colorless rods which melted at 196° with decomposition. They showed inclined extinction (crossed nicols), double refraction was extremely strong and only partial bi-axial interference figures were shown in convergent polarized light; α , 1.455; β , indeterminate and $\gamma > 1.740$.¹⁰

It gave a wine red color with ferric chloride and when it was condensed with phthalic anhydride a yellow-green fluorescent solution (fluorescein) was obtained showing that the acid was a resorcinol derivative.³

Anal. Calcd. for $C_{12}H_{12}O_8$: mol. wt., 284.2; C, 50.69; H, 4.26. Found: mol. wt., titration calcd. as a tricarboxylic acid, 291; C, 50.23; H, 4.44.

⁸ Voorhees and Adams, *THIS JOURNAL*, **44**, 1397 (1922).

⁹ Clark, *ibid.*, **54**, 1600 (1932).

¹⁰ The optical data here recorded were determined by Geo. L. Keenan of the Food and Drug Administration, U. S. Department of Agriculture.

Nicouic Acid Methyl Ester.—A solution of 1 g. of nicouic acid in 25 cc. of 5% methanolic hydrochloric acid solution was refluxed for two hours and then allowed to stand at room temperature overnight. The liquid was then poured into crushed ice, and after the ice had melted, the liquid was extracted with ether. The ethereal solution was thoroughly washed with water and then dried. The extract was freed from ether and dissolved in methanol and sufficient water was added to cause a slight turbidity. Crystallization soon began, yielding colorless plates which melted at about 90°. The yield was 280 mg. The material was recrystallized from dilute methanol until its melting point rose to 120–121°.

Anal. Calcd. for $C_{18}H_{18}O_8$: C, 55.20; H, 5.56; OCH_3 (3), 28.5. Found: C, 55.12; H, 5.81; OCH_3 , 27.5.

α -Hydroxyisobutyric Acid from Nicouic Acid.—Approximately 0.1 g. of nicouic acid was carefully heated in a large test-tube until the material melted and the resultant effervescence subsided. The test-tube was then connected to a high vacuum, and the melt was subjected to distillation as long as any material condensed on the cool portion of the tube.

During the entire process of heating and distilling, a sublimate of long, beautiful crystals collected on the cool portion of the test-tube. This was α -hydroxyisobutyric acid. After purification by sublimation it melted at 79° and when mixed with an authentic sample of α -hydroxyisobutyric acid the melting point was not depressed.

Another product of the decomposition of nicouic acid by this treatment was a water-soluble acid which gave a deep blue color reaction with ferric chloride and melted at 162°. As this material has not been completely investigated it will not be reported upon at this time.

Resorcinol from Nicouic Acid.—A solution of 1 g. of nicouic acid in 4 cc. of aniline was heated to its boiling point and maintained at this temperature until gas was no longer evolved.

The resultant liquid was then mixed with 25 cc. of water, and the mixture was steam distilled until the aniline was completely removed. The residual aqueous solution was cooled in ice, filtered through a little norit, treated with approximately 2 g. of sodium bicarbonate and extracted with ether. The ethereal solution was dried, evaporated to dryness and dissolved in chloroform. After standing for some time the solution crystallized. The product was resorcinol, melting point 110°. The identification consisted of comparing the product with a known sample of resorcinol as to melting point, mixed melting point and optical properties, all of which were in agreement. The crystals were also nitrated according to the directions of Mulliken,³ and the product was shown by comparison with an authentic sample to be trinitroresorcinol.

Acetyl Tephrosin.—A solution of 2 g. of tephrosin in a mixture of 12 cc. of pyridine and 12 cc. of acetic anhydride was allowed to stand at room temperature for two days. Two volumes of methanol were then added to the reaction mixture and, after the resulting liquid was cooled, water was added until a slight turbidity was produced. Crystallization began at once, and yielded 1.85 g. of acetyl tephrosin. Upon recrystallization from dilute methanol it melted at 200°. When mixed with pure tephrosin (melting point 198°), the melting point was depressed (165–175°).

Anal. Calcd. for $C_{28}H_{24}O_8$: C, 66.35; H, 5.35; OCH_3 (2), 13.72. Found: C, 66.36; H, 5.42; OCH_3 , 14.2.

Tephrosin Monocarboxylic Acid.—A mixture of 0.5 g. of tephrosin dicarboxylic acid and 5 cc. of diphenyl ether was heated to its boiling point for approximately one-half minute. During the process the liquid rapidly acquired a bright yellow color as a result of dehydro formation. The solution was then cooled and quickly diluted with three volumes of methanol, causing crystallization to take place immediately. The product

(250 mg.) consisted of bright yellow rods whose melting point was 269° with decomposition.

For analysis, 250 mg. of the acid was dissolved in the necessary quantity of alkali, the solution was diluted with water to 2 liters and then acidified with acetic acid. The material separated as pale yellow hair-like crystals which began to sinter and darken at 250° and melted with decomposition at $268-269^{\circ}$. A saturated alcoholic solution of the material gave a pink color with ferric chloride.

Anal. Calcd. for $C_{19}H_{14}O_8$: mol. wt., 370.2; C, 61.61; H, 3.81; OCH_3 (2), 16.76. Found: mol. wt., acid titration, 370; C, 61.71; H, 3.95; OCH_3 , 16.8.

α -Hydroxyisobutyric Acid from Tephrosin Dicarboxylic Acid.—The methanol-diphenyl ether mother liquor from the experiment above was diluted with water, made strongly alkaline and extracted with ether. The aqueous solution was then acidified and again extracted with ether. This extract was dried, the ether was removed and the residue, contained in a test-tube, was gently heated under reduced pressure. A very small quantity of α -hydroxyisobutyric acid sublimed upon the cool portion of the tube. There was, however, a sufficient quantity to identify it by its melting point and its characteristic property of subliming at approximately 50° .

Acetyl Tephrosin Monocarboxylic Acid.—A solution of 0.2 g. of tephrosin monocarboxylic acid in a mixture of 2 cc. of acetic anhydride and 2 cc. of pyridine was allowed to stand at room temperature for two days. During the process 0.2 g. of the acetyl derivative separated. It was dissolved in the necessary quantity of boiling butanol, and this solution was diluted with 5 volumes of ethanol. In a short time the material separated as aggregates of small extremely thin yellow rods, which when rapidly heated began to melt at approximately 230° and decomposed at $250-255^{\circ}$. It gave no color reaction with ferric chloride.

Anal. Calcd. for $C_{21}H_{16}O_9$: C, 61.16; H, 3.91; OCH_3 (2), 15.06. Found: C, 60.75; H, 4.07; OCH_3 , 15.7.

Risic Acid from Tephrosin Monocarboxylic Acid.—A solution of 0.5 g. of tephrosin monocarboxylic acid in 10 cc. of 10% potassium hydroxide solution was treated with 3 cc. of 30% hydrogen peroxide, according to the directions for the preparation of derric acid.^{1b} When the reaction was completed the solution was diluted to 50 cc. and acidified with sulfuric acid. Two hundred and fifty mg. of risic acid (melting point, 256°) separated and was identified by comparison with an authentic sample of the acid.

Tephrosic Acid from Tephrosin Monocarboxylic Acid.—Tephrosic acid was prepared by hydrolyzing tephrosin monocarboxylic acid with 10% alcoholic potassium hydroxide, according to the directions recorded for the preparation of deguelic acid.^{1a} Acidification of the resultant solution caused the separation of tephrosic acid as beautiful colorless crystals which melted at 196° . Their solution gave a brownish pink color with ferric chloride but because of lack of material¹¹ the study of this compound has not been concluded. A complete description of its properties, therefore, cannot be presented at this time. For the purpose at hand, however, the fact that the compound is formed is sufficient evidence to indicate that tephrosin monocarboxylic acid is a dehydro derivative.

Summary

Evidence has been presented to indicate that deguelin may be represented by formula I in the text.

¹¹ Our last shipment of cubé roots, upon which we depend for tephrosin and its derivatives, was unusual in that its rotenone content was very high (11%) and the deguelin obtained from the rotenone mother liquors was almost chemically pure. The extract, however, contained no tephrosin. It is therefore necessary to await a satisfactory supply of cubé root from South America before completing the study of tephrosic acid.

It has also been shown that tephrosin is a hydroxydeguelin and that the hydroxyl group in tephrosin occupies the position of one of the hydrogen atoms attached to either carbon atom 7 or 8 in the deguelin formula.

NOTES

The Decomposition of *n*-Valerolactone

BY RALPH W. THOMAS AND H. A. SCHUETTE

Proof has already been presented¹ in support of the statement that *n*-valerolactone will not withstand distillation at atmospheric pressure—reports to the contrary notwithstanding—since it undergoes partial decomposition as it approaches its boiling point. The nature of this decomposition has now been traced to the formation, in the main, of a polymerization product, and an explanation has been found for the discrepancies in the vapor pressure curves of this compound when obtained by two different methods of procedure, a dynamic² and a static.³ How the former conclusion has been arrived at is summarized in this communication.

In order to fix a point of departure in the study of this problem, the assumption was made that the decomposition in question is accompanied by the evolution of carbon dioxide and the formation of a butene (2:3 or 1:2). The set-up in which the decomposition studies were carried out closely simulated the conditions which obtain in the determination of pressure-temperature relationships. To that end the lactone was heated under thermostatically controlled conditions in a 2.5-cc. bulbous glass decomposition chamber to which had been sealed an 8-mm. delivery tube provided with a short upright side arm which was later to serve the dual purpose of introducing or removing samples and as an aid in sweeping out the air from the apparatus with nitrogen. At a distance of about 25 mm. from this side arm, the tube was bent at an angle of 45°; beyond that, as a precautionary measure against loss of material during heating, it took the form of a spiral condenser. A delivery tube leading from the latter to an inverted, mercury-filled buret completed the system.

That the reaction herein involved is not wholly due to a decarboxylation with the formation of a butene was shown by the fact that a 3.16-g. sample yielded only about 1 cc. of gas on heating for 530 hours at $202 \pm 0.5^\circ$, which is four degrees below the alleged boiling point of this compound at atmospheric pressure. Although this gas was found to contain some carbon dioxide, yet no evidence could be secured that ethylenic hydrocarbons had been formed in the decomposition. A repetition of the

¹ Schuette and Thomas, *THIS JOURNAL*, **52**, 2028 (1930).

² Ramsay and Young, *J. Chem. Soc.*, **47**, 42 (1885).

³ Smith and Menzies, *THIS JOURNAL*, **32**, 1412 (1910).

experiment during the course of which, at three time intervals, samples were removed for ultimate analysis showed that the residue, except for change in color, had altered only slightly during a 773-hour heating, having changed from C = 59.58 and H = 8.17 to C = 59.32 and H = 7.74. For these reasons it appears quite probable that the main course of the reaction is such as to favor the formation of a polymerization product. Further support for this conclusion may be found in the fact that the observed vapor pressures¹ when measured by a dynamic method² were lower than the calculated at any given temperature above that at which this compound begins to decompose. This is to be expected were a polymerization takes place.

The static method³ of measuring pressure-temperature relationships which was employed is very susceptible to the influence of gaseous decomposition products even though their quantity may be small. An immediate effect of this characteristic is to be found in the higher values which were obtained by this method of measurement. The foregoing observations account, it seems, for the discrepancies which were previously noted in vapor pressure measurements by two different methods of approach.

Preparation and Properties of the Normal Barium Salt of *l*-Cystine.¹

BY CLIFFORD J. B. THOR AND ROSS AIKEN GORTNER

Several normal metallic salts of cystine have already been described. In 1900, Embden² prepared the normal copper salt and employed it in the isolation of the amino acid. A little later, Neuberg and Mayer³ prepared the corresponding salts of silver, mercury, lead and cadmium as well as of copper. Recently, Toennies and Lavine⁴ have succeeded in obtaining the lithium, sodium and potassium salts of cystine in crystalline form.

In the course of a study of the alkaline decomposition of cystine, which will be presented in a separate paper, it was observed while adding crystalline barium hydrate to a hot aqueous suspension of *l*-cystine that most of the cystine went into solution at a certain stage and that immediately thereafter a pale yellow precipitate separated out. By filtering off this pre-

¹ Published as Paper No. 1079, Journal Series, Minnesota Agricultural Experiment Station. Abstracted from a thesis submitted by Clifford J. B. Thor to the Faculty of the Graduate School of the University of Minnesota in partial fulfilment of the requirements for the degree of Doctor of Philosophy, December, 1931.

² Embden, *Z. physiol. Chem.*, **32**, 94 (1901).

³ Neuberg and Mayer, *ibid.*, **44**, 498 (1905).

⁴ Toennies and Lavine, *J. Biol. Chem.*, **90**, 203 (1931).

precipitate at once, washing it with a small amount of water, then with alcohol and ether and finally drying at 105° , a product was obtained (Preparation I) which analyzed fairly well for the normal barium salt of cystine.

Since no mention of this substance could be found in the literature and since it is involved in studies dealing with the decomposition of cystine by alkalis, it was thought desirable to prepare the salt in pure form and to determine its more important properties.

Method of Preparation.—A very satisfactory method consists in mixing equivalent amounts of aqueous $\text{Ba}(\text{OH})_2$ and cystine in the cold and precipitating the resulting salt with alcohol. More exactly, 16 g. of $\text{Ba}(\text{OH})_2 \cdot 8\text{H}_2\text{O}$ was dissolved in 250 cc. of boiled distilled water and cooled to 0° . Then 12 g. of the *l*-cystine was added and the mixture shaken in a stoppered Erlenmeyer flask until only very little undissolved material remained. The cold mixture was filtered through a Buchner funnel and after washing with distilled water the slight residue was discarded. The combined filtrate and washings, amounting to about 300 cc., were treated with 1600 cc. of 95% ethyl alcohol, which caused abundant precipitation of a white granular material. After thorough shaking, this mixture was placed in a refrigerator at -15° overnight. In the morning, the precipitate was filtered off with suction, washed with 600 cc. of 95% ethyl alcohol, then with ether and finally dried in an air oven at 100° . The yield was 18.1 g., which is 96.5% of the theoretical calculated from the cystine taken.

Properties.—The above product (Preparation II) was a perfectly white, finely divided powder which under the microscope showed no clearly defined crystalline form.

Anal. Calcd. for $\text{C}_6\text{H}_{10}\text{O}_4\text{N}_2\text{S}_2\text{Ba}$: N, 7.46; S, 17.07; Ba, 36.57. Found: N (Prepn. I), 7.32, (Prepn. II), 7.31; S (I), 16.20, (II) 16.65; Ba (I), 35.78; (II) 36.42.

A saturated solution of the salt was prepared by shaking 4 g. with 50 cc. of distilled water, allowing it to stand overnight at 25° , and filtering to remove excess salt. The saturated solution was very faintly yellow in color but seemed to be perfectly stable under the conditions of observation. Forty cc. of this solution was diluted to 200 cc. with water and aliquots were taken for nitrogen, sulfur and barium analyses to determine solubility, as indicated. This new salt of cystine then is water soluble at 25° to the extent of 6.15 g. per 100 cc. of saturated solution.

SOLUBILITY OF THE NORMAL BARIUM SALT OF *l*-CYSTINE IN WATER AT 25°

Basis of calculation.....	Nitrogen content	Sulfur content	Barium content	
Barium salt in 100 cc. of				
satd. soln.....	6.14	6.17	6.14	Av. 6.15

When placed in a 1-decimeter tube, the saturated solution gave a saccharimeter reading of -11.0° at 25° and on dilution to five times its volume with water a proportionate value of -2.2° . Calculated on the basis of concentration of the barium salt, this gives a specific rotation of -61.9° ; or calculated for cystine contained in the salt, of -96.9° . The latter agrees quite well with similar figures reported by Toennies and Lavine⁴ for the lithium, sodium and potassium salts of cystine. Free cystine was isolated from some of the salt and 0.2 g. of this dissolved in 25 cc. of normal hydrochloric acid at 25° , when placed in a 1-decimeter tube, gave a reading of -4.6° saccharimeter units. The corresponding specific rotation of -199.1° as compared with -204.2° for the original cystine indicates that racemization had not occurred to any considerable extent during the formation of the barium salt. Hence, it is safe to conclude that Preparation II consisted almost entirely of the barium salt of *l*-cystine.

If the saturated aqueous solution of the substance is diluted sufficiently with water,

hydrolysis takes place and a portion of the cystine precipitates out in the form of hexagonal plates. That hydrolysis had not taken place in preparing the saturated solution is clearly shown by the very close agreement between solubilities calculated from contents of nitrogen and sulfur on the one hand and barium on the other.

When the dry salt was heated in a melting point tube it showed no signs of decomposition or fusion up to about 250°; then it began to brown very gradually but without sintering.

When a portion of the salt equivalent to 2.5 g. of cystine was refluxed with 50 cc. of distilled water for twelve hours, nitrogen and sulfur analyses made after the removal of free hydrogen sulfide and ammonia indicated that decomposition to the extent of approximately 50% had taken place.

In its property of being water soluble, the barium salt of *l*-cystine resembles the alkali salts and differs from the heavy metal salts so far described. This characteristic as well as its ease of preparation and the ease of determination of its metallic constituent should make the barium salt useful in further studies on the mechanism of the alkaline decomposition of cystine. It might also find use in the preparation of derivatives of cystine, particularly in cases where the reaction requires anhydrous conditions.

The Structure of the Bromination Product of Ortho-Nitrotoluene

BY DAVID L. YABROFF

Wachendorff¹ obtained a dibromo product upon the bromination of *o*-nitrotoluene which he called a dibromonitrotoluene. He made the observation, however, that this product was soluble in alkali. Greiff² showed that the compound was a dibromo-anthranilic acid and suggested that it might be the *p-m*-dibromo-anthranilic acid obtained by Hübner³ upon the nitration and reduction of *p-m*-dibromobenzoic acid since both of the products melted at 225°.

If an intramolecular oxidation and reduction of the nitrotoluene occurs before the bromination, we should expect 3,5-dibromo-2-aminobenzoic acid as the final product. If bromination occurs before the oxidation-reduction process, we should expect 4,6-dibromo-2-aminobenzoic acid to be formed. These two compounds may be readily distinguished by allowing them to react for twenty-four hours in a dilute alcoholic solution with bromine water in the presence of a mineral acid. Under these conditions^{4,5} all positions ortho or para to the amino group which are not already substituted are brominated, and at the same time bromine is substituted for the carboxyl group. This may be represented as

⁵ Flürscheim and Holmes, *J. Chem. Soc.*, 448 (1928).

In one case we would obtain tribromoaniline, in the other case pentabromoaniline. The product actually obtained by this treatment was tribromoaniline—m. p. 119°, mixed m. p. 120°; bromine analysis (Carius),⁶ found 72.3, 72.2%; calcd. for $\text{C}_6\text{H}_2\text{NH}_2\text{Br}_3$: 72.7.

These results indicate that the oxidation-reduction process of the nitrotoluene occurs first and the anthranilic acid formed is then brominated, giving rise to the 3,5-dibromo-2-aminobenzoic acid. Wheeler and Oates⁷ obtained this compound (m. p. 232°) by the direct bromination of anthranilic acid.

⁶ These analyses were carried out by Mr. Leslie H. Bayley.

The Isomeric Desoxybenzanisoin

BY JOHANNES S. BUCK AND WALTER S. IDE

In a recent paper¹ S. S. Jenkins criticizes some of our work,² being apparently unable to reproduce certain of our results. The Friedel and Crafts reaction which is in question goes unusually well, and we have repeated the other two questioned preparations, with results identical to those which we reported previously.

We desire to correct Jenkins' statement that, with regard to the reduction of benzanisoin to *p*-methoxybenzyl phenyl ketone, we reported none of the isomeric ketone. On the contrary we specifically stated³ that isomeric ketones might be present but that no serious attempt to isolate these was made. Jenkins neglects to mention that we proved the structure of our compounds by the Beckmann reaction. His work

¹ Jenkins, *THIS JOURNAL*, **54**, 1155 (1932).

² Buck and Ide, *ibid.*, **53**, 1536 (1931).

³ Ref. 2, p. 1538.

has not contradicted any of our conclusions as to the structures of the compounds obtained by us.

In view of the difficulties which have arisen, we submit descriptions of the methods of preparation in question at greater length. The preparations have been checked, and we reaffirm our earlier statements.

Benzyl *p*-Methoxyphenyl Ketone.—15.5 g. of phenylacetyl chloride⁴ and 13.0 g. of anisole (calcd. 10.8) were dissolved in 100 cc. of carbon bisulfide (Baker c. p.), in a flask fitted with a reflux condenser and a wide tube for adding the aluminum chloride; 15.0 g. of powdered aluminum chloride (Baker, anhydrous, c. p.) was then added in portions over thirty minutes. The bisulfide refluxes gently during the addition, and hydrogen chloride is evolved. The mixture becomes deep crimson in color and a dark crimson oil sinks to the bottom. After standing at room temperature for a further ninety minutes, 150 g. of crushed ice was added and then 20 cc. of concd. hydrochloric acid. The bisulfide layer was separated and washed twice with dilute hydrochloric acid (further bisulfide being added if the product starts to separate). The bisulfide was then evaporated on the steam-bath, 100 cc. of water added and steam bubbled through for ten minutes. On cooling the product solidified, and was then filtered off, washed with water, drained and dissolved in hot alcohol. On standing the ketone crystallized out. The melting point was 72°, raised to 74–75° on recrystallization. On three consecutive runs the yields were 19.4, 18.3 and 19.0 g., average, 84%. A further quantity (about 1.5 g.) may be obtained on diluting the liquors. Washing with alkali is unnecessary.

***p*-Methoxybenzyl Phenyl Ketone.**—50.0 g. of benzanisoin was dissolved in 200 cc. of 96% alcohol, in a flask fitted with a reflux condenser; 50.0 g. of mossy tin and 50.0 cc. of concd. hydrochloric acid were added, together with 0.5 g. of copper sulfate. The mixture was refluxed on the steam-bath for twelve to fifteen hours, a little (0.5 g.) copper sulfate being added occasionally as the reaction slowed down. After the first six hours, an additional 50 cc. of concd. hydrochloric acid was added to the mixture. When the reaction was complete, the mixture was filtered hot, the product rapidly crystallizing out on cooling. After standing, it was filtered off and washed with water, and then with cold alcohol; yield (unrecrystallized) 87%. Recrystallized from alcohol, the product melted at 91–92° and weighed 37.7 g. (82%). The melting point is raised to 94° after two further recrystallizations. The writers were unable to obtain a pure specimen of benzyl *p*-methoxyphenyl ketone from the liquors of this preparation.

Oximes of *p*-Methoxybenzyl Phenyl Ketone.—14.4 g. of *p*-methoxybenzyl phenyl ketone was dissolved in 100 cc. alcohol (96%) and hydroxylamine acetate solution (from 8.0 g. hydroxylamine hydrochloride and 13.0 g. potassium acetate) added. The reaction mixture was kept at 40–50° for two hours, when crystals commenced to separate. The mixture was then put in a cold place (0°) overnight and the crystals which formed were filtered off next day. After one recrystallization from alcohol the melting point was 132°. The liquors, after evaporation under reduced pressure, deposited a product, which, recrystallized several times from alcohol, melted at 95–96° (previously reported as 94°). The yield of the *anti* oxime (m. p. 132°) is about 10 g. and that of the *syn* oxime about 2 g., the relative amounts varying somewhat in different preparations.

Erratum.—In the paper in question,² p. 1540, line 19, for "Ketone E" read "Benzoin 5."

COMMUNICATIONS TO THE EDITOR

3-FURALDEHYDE (3-FURFURAL)

Sir:

"Furfural" or 2-furaldehyde was first obtained one hundred years ago [Döbereiner, *Ann.*, **3**, 141 (1832)]. Its isomer, 3-furaldehyde or 3-furfural, has now been synthesized by the following sequence of reactions: malic acid \rightarrow coumalic acid \rightarrow methyl coumalate \rightarrow methyl bromocoumalate \rightarrow 2,4-furandicarboxylic acid \rightarrow 3-furancarboxylic acid \rightarrow 3-furoyl chloride \rightarrow 3-furaldehyde.

The odor of 3-furaldehyde is more remindful of benzaldehyde than is 2-furaldehyde. Some physical constants are: b. p. 144° (732 mm.); n_D^{20} 1.4945; sp. gr. $\frac{20}{20}$ 1.111. The phenylhydrazone melts at 149.5° .

3-Furaldehyde responds to the usual aldehyde tests but *unlike* 2-furaldehyde it gives no color test with aniline acetate. We have also noted that 2,4-dimethyl-3-furfural gives no aniline acetate test. The new aldehyde appears to be more highly resistant to auto-oxidation than might have been predicted, and is more stable than its isomer.

THE VELOCITY OF DISSOCIATION OF NITROGEN TETROXIDE BY THE
METHOD OF SOUND WAVES

Sir:

In a communication from this Laboratory [Kistiakowsky and Richards, *THIS JOURNAL*, **52**, 4661 (1930)] it has been demonstrated that with an experimental accuracy of 0.5%, no change in the velocity of sound in nitrogen tetroxide is detected at 25° with frequencies between 9 and 80 k.c. The lower limit thus set for the velocity of dissociation ($k = 5 \times 10^4$) according to the reasoning of Einstein [*Sitz. Akad.*, 380 (1920)] closely approximates the value ($k = \text{about } 1 \times 10^5$) which is obtained from the kinetic theory of gases as the maximum reasonable upper limit. Brass and Tolman [*THIS JOURNAL*, **54**, 1003 (1932)] by another method have recently obtained positive evidence of the rate of dissociation, and assign to the velocity constant at 25° an order of magnitude ($k = 2.2 \text{ to } 8.4 \times 10^4$) which accords with these conclusions.

It is now possible to obtain more specific information concerning this reaction by the acoustical method. Apparatus of special design has permitted the study of the velocity of sound in nitrogen tetroxide between 1.0 and 30° and from 130 to 760 mm. pressure at frequencies between 9 and 93 k.c. At 260 mm. pressure and 30° a further study has been made

between 90 and 500 k.c. In both cases the reproducibility of the measurements has proved to be 0.05%. A wall-correction has been evaluated and applied.

The correspondence between measured velocities at zero frequency and those calculated from Einstein's equations is excellent at 260 mm., and indicates that the assumptions underlying the theoretical reasoning may be applied with confidence to the interpretation of these measurements. Since the absorption coefficient is not found to increase noticeably even at 500 k.c., similar reasoning appears legitimate over the entire frequency range which has been studied. Granting this, a straightforward picture of the kinetics of dissociation emerges. The velocity constant at 25° and 260 mm. is approximately 4.8×10^4 , and the activation energy of dissociation approximates closely to the heat of dissociation of nitrogen tetroxide. It may be assumed, therefore, that the velocity of association of nitrogen dioxide has little if any temperature coefficient. The velocity of dissociation decreases with decreasing pressure. These conclusions are independent of unavoidable uncertainties concerning the heat capacities of the dioxide and tetroxide molecules, the exact value of the heat of dissociation, and the exact absolute values of the velocity of sound in nitrogen tetroxide at zero frequency.

Recent evidence that the vibrational specific heat terms in carbon dioxide may become inactive at high frequencies of sound [Kneser, *Ann. Physik*, [V] 11, 777 (1931)] has suggested the possibility that a similar effect may appear in nitrogen tetroxide, and has caused a delay of some months in the publication of the conclusions outlined above. It is hoped that the temperature coefficient of the divergence between high and low frequency velocities of sound will provide a means to differentiate between this effect and that discussed by Einstein. When an experimental distinction between the two has been established, the measurements on nitrogen tetroxide will be submitted in detail for publication.

THE INVERSION OF CRISTOBALITE

Sir:

Supplementing the foregoing note by Dr. J. W. Greig (p. 2846), I may be permitted to quote from a letter received recently from Dr. K. Endell, one of the observers referred to in my discussion of the inversion of cristobalite. Dr. Endell says (in translation): "It appears to me very improbable that this inversion can be delayed. My early observations are probably not entirely conclusive. In recent years I have tested hundreds

of silica brick, and also ceramic bodies which contain cristobalite, for their thermal dilatation upon heating and cooling. The result has invariably been that upon cooling the volume contraction associated with the alpha-beta cristobalite inversion takes place without a time lag. The cases observed by Greig in glass and by Levin and Ott in opals are not known to me. As you correctly state, however, this is different from the delay of the inversion by quenching."

Dr. Olaf Andersen and I have tried several ways of quenching free cristobalite from a temperature above its high-low inversion point, but it has always inverted without delay. The inhibition of the inversion in crystals embedded in a glassy matrix, as observed by Greig and by Levin and Ott, deserves further study for the light it may throw on the atomic mechanism of such inversions.

NEW BOOKS

Von Davy und Döbereiner bis Deacon, ein halbes Jahrhundert Grenzflächenkatalyse. (From Davy and Döbereiner to Deacon; A Half Century of Contact Catalysis.)

By ALWIN MITTASCH, Director of the Oppau Research Laboratories of the I. G. Farbenindustrie A.-G., and ERICH THEIS. Verlag Chemie G. m. b. H., Corneliusstrasse 3, Berlin W 10, Germany, 1932. 278 pp. 14 Figures and 16 Portrait Inserts. 17 × 23.5 cm. Price, Mk. 18.50.

In the study of a phenomenon such as catalysis, which is still the object of intensive investigation and which makes its appearance in every branch of chemistry, it is important to attain an historical perspective. This will be greatly facilitated by the present volume which is an historical study of the earlier stages in the development of our knowledge of heterogeneous catalysis. It presents meticulously and sympathetically the work of scores of investigators; for instance, the discoveries of Davy, Thénard, Döbereiner and Schönbein, and the theoretical contributions of Berzelius, Liebig and the less widely known Bellani, Mercer and Playfair.

In addition, there are special chapters on the beginnings of the sulfuric acid contact process, and of the processes for the catalytic synthesis and oxidation of ammonia.

The authors have also succeeded, by means of many footnotes and excellent portraits, in maintaining that connection between personalities and ideas which is so advantageous in an historical treatise.

ARTHUR B. LAMB

Lehrbuch der Radioaktivität. (Textbook on Radioactivity.) By GEORG V. HEVESY and FRITZ PANETH. Second, fully revised edition. Verlag von Johann Ambrosius Barth, Salomonstrasse 18 B, Leipzig C 1, Germany, 1931. xii + 287 pp. 50 figs. 16 × 23.5 cm. Price, RM. 19.80; bound, RM. 21.60.

The first German edition of this excellent little text appeared in 1923. Three years later, the Oxford Press brought out an English translation by R. W. Lawson of an enlargement of the first edition, which amounted almost to a second edition in itself. As a textbook of radioactivity for college use, this work has proved so acceptable that the present second edition is sure to find a ready welcome.

A complete revision has been effected with the addition of much new material. The newest phases of radioactivity and nuclear chemistry and physics are discussed, such as the relation between alpha, beta and gamma radiation and the structure of the nucleus, the nature of cosmic rays, and the ultra-gamma radiation produced by bombarding certain lighter nuclei with alpha particles. The application of wave mechanics to the escape of particles from the nucleus through an energy barrier is well presented. The chapters on isotopy, on radioactive substances as indicators, on packing effect and the deviation of atomic masses from whole numbers are especially well done, as well as the chapter on the importance of radioactivity in geology and in cosmic chemistry and physics.

The reviewer's impression is strengthened by the second edition that this work is much too scholarly and broad in its scope to be regarded merely as an elementary text. The need for literature references especially in the newest fields will be keenly felt by many readers. Such addition in a succeeding volume appears to be all that is lacking to raise this otherwise splendid work to the dignity of an elementary treatise.

S. C. LIND

Katalyse vom Standpunkt der chemischen Kinetik. (Catalysis from the Point of View of Chemical Kinetics.) By GEORG-MARIA SCHWAB, Lecturer in Chemistry at the University of Munich. Verlag von Julius Springer, Linkstrasse 23-24, Berlin W 9, Germany, 1931. viii + 249 pp. 39 figs. 16 × 24 cm. Price, RM. 18.60; bound, RM. 19.80.

The last decade witnessed a rapid progress of the kinetic theory of catalysis and the appearance of a book by G.-M. Schwab dealing with this subject is very timely.

In a rather limited space the author succeeds in giving a good review of the stand of knowledge (at the end of 1930) concerning the following subjects: homogeneous catalysis of simple and chain reactions in gases; homogeneous catalysis by intermediary products and by ions in solutions; solvent action; heterogeneous gaseous reactions and the theory of ad-

sorption of gases; colloid catalysis and enzyme action. The author has succeeded very well in creating as clear a presentation as could be expected in a rapidly developing branch of science. At the same time, the book is sufficiently complete to acquaint the reader with all significant developments of the theory and with the more essential experimental contributions.

Some rather insignificant mistakes have been noticed. Thus on p. 21 the author counts translation among degrees of freedom active in unimolecular decompositions; on pp. 201–202 the length of edges of a crystal is considered to be proportional to the square of the surface area of the crystal. On p. 168 the proof of the (quite correct) assertion that the catalytic action of a solid surface is due not entirely and not principally to a condensation of the reactants is not convincing. The reviewer cannot agree with the statement (pp. 141–142) that the “semi-thermodynamic” derivation of the Langmuir adsorption isotherm by Volmer is to be preferred to the original treatment, since the Volmer argument assumes complete freedom of motion of the adsorbate on the surface, something which may be seriously doubted in many cases important in catalysis and an assumption unessential to the purely kinetic elementary treatment of the problem.

In conclusion the reviewer would like to recommend this book to all those who are interested in catalysis and who have already some knowledge of the general kinetic theory of reaction velocities.

G. B. KISTIAKOWSKY

Electrical Phenomena in Gases. By KARL KELCHNER DARROW, Ph.D., Research Physicist, Bell Telephone Laboratories. The Williams and Wilkins Company, Mt. Royal and Guilford Aves., Baltimore, Maryland, 1932. xvii + 492 pp. 91 figs. 15.5 × 23.5 cm. Price, \$8.00.

This is the second book by the author on recent developments in modern physics; the first, “An Introduction to Contemporary Physics,” was published in 1926 by Van Nostrand.

The second book is the only one on this subject published in this country and brings up to date the information concerning the electrical phenomena in gases. The book is written by a physicist from a physicist's point of view. The style, which is excellent and original, is characteristic of the man and so quite human. The subject matter is well chosen from a mass of material published over years. The bibliography is very extensive and well chosen but necessarily not complete. Complicated and not well understood experiments and phenomena are presented in a clear and well-digested form. The context is largely descriptive of carefully selected typical experiments with an evaluation of the results together with numerous suggestions as to the next step or experiment to be done in the

respective fields. Mathematical equations and theoretical developments are reduced to a minimum.

The author and subject index on this broad and much worked subject is very useful and is to be commended. However, it is much to be regretted that the table of contents consists only of listing the titles of the chapters. While these titles may be well chosen, they cannot and do not represent the wealth of subjects or subject matter discussed in the respective chapters. An explanation of the origin and functions of the various elements and factors concerned in a conducting gas in an electric discharge such as electrons, ions, normal and excited atoms and molecules, photons, radiation, visible and invisible, electric potential, field strength, excitation, ionization and collision phenomena play the major roles in this treatise.

The first four chapters deal with elementary processes in a very rarefied atmosphere and may be attributed to single electrons, single ions or single atoms. The next five chapters by contrast deal with phenomena at higher pressures up to atmospheric where an ion is forced to make many collisions with a resulting current drift superimposed upon the random velocities of the electrons, atoms and excited molecules. These chapters are largely concerned with the phenomena of mobility, diffusion, recombination and attachment, self-amplified ionization and breakdown in the gaseous system. The last three chapters are concerned with the glow and arc discharges. Elaborate and painstaking efforts to bring about order and understanding out of chaotic complex phenomena are much in evidence, unfortunately, however, without entire success, leaving much to be desired until the arc is better understood. The exploring electrode method of investigation is described. The results are interpreted in the form of "space charge," "sheaths" and "plasma," these terms being the added technology employed within the last decade.

The publishers are to be commended on the general appearance and the clarity of type and figures of this volume which should add considerably to the pleasure of the reader.

C. H. KUNSMAN

Chemische Bindung als elektrostatische Erscheinung. (Chemical Combination as an Electrostatic Phenomenon.) By A. E. VAN ARKEL AND J. H. DE BOER. Authorized German translation by Li Klemm and Wilhelm Klemm. With a Word of Accompaniment by Wilhelm Biltz. Verlag von S. Hirzel, Königstrasse 2, Leipzig C 1, Germany, 1931. xx + 320 pp. 71 figs. 15 × 23 cm. Price, RM. 15; bound, RM. 17.

It is not without reason that this book has three prefaces and an eight-page "glossary of the most important concepts," for, as expressed in the "Geleitwort:" "I believe I am making no subjective statement when I

assert that never before in the history of chemistry has the chemist encountered questions of equal theoretical difficulty. Not difficulties of the formal mathematical sort, the mathematician will gladly undertake to overcome those for us, but *conceptual* difficulties." And it is typical of the state of the subject that after ten chapters of fairly successful explanation of chemical combination in purely electrostatic terms, the authors should begin the last chapter with the confession: "So long as we have to do with combination between *unlike* atoms, we reach in very many cases a satisfactory representation by assuming that the atoms bear opposite electric charges, *i. e.*, have thus become ions. As has previously been shown, we can derive from this an essential part of the properties of compounds.

"This conception of valence force is however not suitable for *all* cases; in particular it leaves us completely in the lurch when it is a question of combinations between *like* atoms."

The key to the paradox is perhaps to be found in the proof on p. 55 that changing the exponent of distance in the expression for the Born repulsion force from 10 to 9 makes only a little over one per cent. difference in the lattice energy. As, in the calculus, second differentials need be considered only when first differentials vanish; so, in valence theory, Coulomb's law forces, when present, may swamp the other terms in the expression for the energy of combination. Since, however, the energies of formation of symmetrical diatomic molecules are of the same order as those of unsymmetrical molecules, there must be many cases in which only the present roughness of our measurements makes a neglect of homopolar energy terms tolerable.

The book is a translation of a compilation of articles which appeared in 1929 in the *Chemisch Weekblad*. At a time when the chemical pendulum has swung so far away from Berzelius, such a volume is of value in attaining a proper mental balance.

ELLIOT Q. ADAMS

Kolloidchemische Technologie. Ein Handbuch kolloidchemischer Betrachtungsweise in der chemischen Industrie und Technik. (Colloid-Chemical Technology.) Edited by Dr. RAPH. ED. LIESEGANG, Frankfurt A.M. Second, completely revised edition. Verlag von Theodor Steinkopff, Residenzstrasse 32, Dresden-Blasewitz, Germany, 1932. viii + 1085 pp. 376 figs. 18.5 × 26.5 cm. Price, RM. 68; bound, RM. 72.

The present edition of this book does not differ materially in content or organization from the first edition, which preceded it by only four years. In general, the various topics are treated by the same co-authors who contributed to the first edition, but new chapters relating to lipoids, sugar, insecticides and fertilizer have been added. The "theoretical part,"

which filled about a quarter of the first edition, is now limited to two short chapters, and on this account the new edition is not much larger than the previous one. Most of the chapters have been brought up to date by the addition of such new material as is warranted by recent progress, though it is probably not to be expected that industrial practice has changed very much in such a short time. In the chapter on the textile industry, no mention is found of the excellent work published from the British laboratories devoted to wool and cotton, and only a single reference to work done since 1926. By contrast, the chapter on "artificial silk" has been brought up to date in the most thorough manner, and this may be said also of nearly all the chapters. The attractive typographical style of the previous edition has been retained, and the material has been thoroughly indexed.

E. B. MILLARD

Organic Syntheses. Collective Volume I, being a Revised Edition of Annual Volumes I-IX. HENRY GILMAN, Editor-in-Chief, ROGER ADAMS, W. H. CAROTHERS, H. T. CLARKE, J. B. CONANT, C. S. MARVEL, C. R. NOLLER, F. C. WHITMORE, C. F. H. ALLEN, Secretary. John Wiley and Sons, Inc., 440 Fourth Ave., New York, 1932. ix + 564 pp. 15.5 × 23.5 cm. Price, \$6.00.

In the preface to the "Collective Volume" the reasons for collecting the material contained in the first nine volumes of "Organic Syntheses" are stated in the following terms: "There are several objectives for this Collective Volume, the realization of which, it is hoped, will extend the usefulness of the series. First, it is convenient to have a large number of preparations in a single volume. Second, new and improved directions are included to replace or supplement earlier preparations. The new directions are for adipic acid, benzilic acid, cyclohexylcarbinol, dibenzoylmethane, *d*-glutamic acid, glycine *dl*-methylethylacetic acid, pentaerythritol and *n*-propylbenzene. Third, a large number of relatively minor but significant corrections have been made, and many suggestions have been incorporated for improving specific preparations. Fourth, the large number of preparations contained in a collective volume makes it more practicable to have several useful indexes."

The editors manifestly have spared no effort to make the volume as useful as possible. Besides arranging all preparations in alphabetical order, they have supplied the volume with five indexes, including one in which preparations are listed with respect to the type of reaction that is employed, and another in which they are classified with respect to the type of compound that is formed.

The publishers have done their part in making an attractive volume, and the edition is so free from typographical errors that the reviewer takes some pride in having discovered "glucol" on page 286.

E. P. KOHLER

Esercizi Numerici di Chimica Organica. (Numerical Exercises in Organic Chemistry.)

By Professor GUIDO BARGELLINI, University of Rome. Editrice Studium, Piazza S. Agostino 20-a, Rome, Italy, 1931. 242 pp. 13.5 × 19.5 cm. Price, 25 lire.

This book consists of three parts. The first of these sets forth the methods of determining molecular formulas from analytical data. The second part presents fifty problems, detailed solutions of which make up the third part. Each problem describes a compound by giving analytical data from which one may calculate the empirical formula and the molecular weight. Characteristic reactions and properties follow and from these it is possible to identify the compound.

The problems deal with a wide variety of important types of organic compounds and require the student to possess and to use a large amount of information on the subject. There is enough of the puzzle element involved to make the exercises fascinating, and there can be no doubt that the author has hit upon an excellent scheme for impelling students to think.

Although this book is novel in type, problems of a similar sort have been rather widely used in this country in connection with courses in qualitative organic analysis. However, no collection of such problems has as yet been published in English and for this reason this book should be welcomed by all teachers of organic chemistry.

REYNOLD C. FUSON

Principles of Soil Microbiology. By SELMAN A. WAKSMAN. Second edition, thoroughly revised. The Williams and Wilkins Company, Mt. Royal and Guilford Aves., Baltimore, Md., 1932. xxviii + 894 pp. 15.5 × 23.5 cm. Price, \$10.00.

In reviewing a Second Edition it is always difficult to know to what extent criticism of the book as a whole is permissible. The author of this book, in his preface, states that a number of chapters have been entirely rewritten, others combined and additional ones added. Accordingly it is probably justifiable to reexamine it as a whole. The verdict rather depends upon the attitude taken up in considering the subject. Viewed as an encyclopedic account of soil micro-organisms, their activities and interrelationship, the author's achievement is undoubtedly a brilliant one. If, however, it is to be regarded as a readable textbook, the verdict is somewhat less certain—the success of the book as such is jeopardized by the shapelessness and turgidity of some of the material presented, and the inclusion of much material not directly relevant. In other words, it lacks at times the forcefulness and strength of simplicity; its readability could be much enhanced by the ruthless use of a big blue pencil. Further, it is not at times as critical as one might wish—for example, in the discussion as to the number of organisms in the soil great prominence is given to the results of Richter, which are at variance with the generally accepted

views of many investigators in that field. As examples of the sort of material which might well have been omitted, one might mention the mathematical treatment of plate counts given on pp. 22-24. No one unacquainted with the theory of statistics could apply the data there presented, since the technical terms employed are not adequately defined, and no one wishing such knowledge would seek it in this type of book. Again, such formulas as are given on pp. 421-424, 426 and 427 for the degradation of amino acids are of very doubtful value. The table on page 597, if really necessary, might more properly have been included in the chapter on the decomposition of proteins. It is doubtful whether those sections dealing with the classification of bacteria, fungi and protozoa on pages 138, 178, 229 and 315 should really find a place in a text of this sort.

A certain amount of repetition is no doubt unavoidable in a book of this nature, and numerous instances of this can be found. The optimum P_H for the growth of fungi seems an irresistible subject. Repetition is also rather noticeable in those chapters dealing with the decomposition of plant materials, and particularly in Chapters XVI and XXIV.

The new chapters dealing with the microbiology of stable and artificial manures, of peat-bogs and forest soil, considerably enhance the value of the book. The author has stressed admirably the interrelationship of the synthetic activities of the organisms with the degradative processes carried out by them in obtaining energy. The last few chapters of the book are perhaps the most convincing; the author appears to be more at home in general discussion and broad generalization than in the more routine presentation of facts and observations.

There is no doubt that this book is of immense value to workers in soil microbiology and allied fields, and an adequate testimonial to the breadth of knowledge and vision of the author. While the publisher's statement that it is recognized as the "bible of that particular field of human enquiry" is perhaps a little generous, nevertheless it is clearly the key-book in English on soil microbiology.

THE CALCULATION OF PARTIAL MOLAL QUANTITIES

BY T. F. YOUNG AND O. G. VOGEL

RECEIVED JANUARY 25, 1932

PUBLISHED AUGUST 5, 1932

For many applications of thermodynamics to chemical and physical problems it is necessary to employ the partial derivative, with respect to the amount of some substance present, of an extensive¹ quantity G , such as the volume, entropy, heat capacity, etc. The role of such quantities in the thermodynamics of mixtures has been discussed by Lewis.² The partial derivative of G with respect to the number of moles, n_1 , of the constituent designated as number one is termed by Lewis and Randall³ the "partial molal" property of that constituent. They represent it by the symbol \bar{G}_1 , thus

$$\bar{G}_1 \equiv \left(\frac{\partial G}{\partial n_1} \right)_{n_2, n_3, \dots, P, T}$$

The subscripts indicate that the number of moles of each of the constituents other than number one are held or "considered held" constant, and likewise that the pressure, P , and the temperature, T , are considered constant; in other words, P , T and the amounts of each of the constituents are selected as independent variables.

Several methods for the calculation of partial molal quantities have been discussed by Lewis and Randall. They have described two methods which involve certain intensive properties rather than the extensive ones embodied in the fundamental definition of \bar{G} . More recently, Sosnick⁴ and Randall and Rossini⁵ have suggested other similar procedures which are very useful.

As pointed out by these authors, appropriate changes of variables are frequently very convenient. They permit the use of curves with finite

slopes in critical regions, or curves which follow closely, simple empirical equations. Plots of small deviations from such equations can often be manipulated with less effort or more accuracy than the plot of the complete function. A change of variables sometimes aids also in the utilization of data already available in a particular form.

To facilitate changes of variables, two tables have been prepared in this Laboratory which exhibit the relations between a number of common intensive properties, various composition terms, and the corresponding partial molal quantities. These tables are useful aids in the selection and manipulation of convenient functions.

The mathematical methods employed in the construction of the tables are simple and well known. A single illustration will suffice: \bar{G}_1 is to be obtained from a plot of $y = G/(n_1 + n_2)$ against N_1 , the mole fraction of constituent number one. For example, G might represent volume, and y the volume of one mole of solution.

$$(\partial y)_{n_2, P, T} = \frac{(\partial G)_{n_2, P, T}}{(n_1 + n_2)} - \frac{G}{(n_1 + n_2)^2} (\partial n_1)_{n_2, P, T} \quad (1)$$

$$(\partial G)_{n_2, P, T} = (n_1 + n_2) (\partial y)_{n_2, P, T} + y (\partial n_1)_{n_2, P, T} \quad (2)$$

$$\text{The mole fraction } N_1 = \frac{n_1}{n_1 + n_2}$$

$$(\partial N_1)_{n_2, P, T} = \frac{1}{(n_1 + n_2)} (\partial n_1)_{n_2, P, T} - \frac{n_1 (\partial n_1)_{n_2, P, T}}{(n_1 + n_2)^2} \quad (3)$$

$$(\partial n_1)_{n_2, P, T} = \frac{n_1 + n_2}{N_2} (\partial N_1)_{n_2, P, T} \quad (4)$$

$$\bar{G}_1 = N_2 \left(\frac{\partial y}{\partial N_1} \right)_{n_2, P, T} + y = N_2 \left(\frac{\partial y}{\partial N_1} \right)_{P, T} + y \quad (5)$$

The subscript n_2 may be omitted since the value of dy/dN_1 is obviously independent of the way in which N_1 is varied at constant pressure and temperature. This formula corresponds to the one in Table I

$$\bar{G}_1 = N_2 S + y - C \quad (6)$$

for the special case in which $C = 0$. S represents the slope of the curve.

Symbols

W_1 and W_2 = mass of one mole of constituents 1 and 2, respectively

n_1 and n_2 = numbers of moles of constituents 1 and 2, respectively

N_1 and N_2 = mole fractions of constituents 1 and 2

$r_1 = n_1/n_2$; $r_2 = n_2/n_1 = m W_1/1000$

m = moles of constituent 2 (solute) per 1000 g. of constituent 1 (solvent)

G = any extensive property of the mixture consisting of n_1 moles of constituent 1 and n_2 moles of 2

G_1 and G_2 = molal properties of pure constituents 1 and 2

$\Phi = (G - n_1 G_1)/n_2$, apparent molal property of constituent 2

$G = G/(n_1 + n_2)$

$\Delta = G - (N_1 G_1 + N_2 G_2)$

$G_w = G/(n_1W_1 + n_2W_2)$, specific property (*i. e.*, specific heat, etc.)

$$\bar{G}_1 = \left(\frac{\partial G}{\partial n_1} \right)_{n_2}; \bar{G}_2 = \left(\frac{\partial G}{\partial n_2} \right)_{n_1}$$

C = any constant

k = any exponent

y = the quantity plotted as ordinate

x = the quantity plotted as abscissa

S = the slope of the curve = dy/dx

The units of quantity chosen for the formulas placed above the double lines are purely arbitrary and may be varied at will. Thus W'_1 may represent any desirable amount of constituent 1, and W'_2 a convenient quantity of constituent 2. Then n'_1 and n'_2 will represent the numbers of such units and r'_2 the ratio of the numbers of units of constituent 2 to the number of units of constituent 1. Except for the addition of primes to each symbol, the same formulas will represent the partial derivatives for the quantities corresponding to W'_1 and W'_2 . For example if W'_1 represents one gram, \bar{G}'_1 represents a partial specific property and must be multiplied by the molal weight of the first constituent to yield a partial molal quantity.

It is sometimes convenient to plot such quantities as heat capacity *per gram* against *mole* (rather than weight) fraction. Below the double lines in the tables are a few formulas arranged for direct calculation of partial molal properties from such typical pairs of dissimilar units.

Some of these formulas have already been used or suggested. 1-*E* is the relation recommended by Sosnick.⁴ It is especially useful in those cases in which Δ is very small. 1-*C* is the basis of the method of intercepts used by Lewis and Randall,³ 6-*D* was also used by Lewis and Randall, and 4-*D* without the constant, was employed by Randall and Rossini.

The list presented is, of course, not complete but contains the formulas which seem to us most likely to be useful. If special problems require other relations, those presented here are sufficiently varied to act as guides in the selection of other formulas which might be of value.

Summary

Formulas have been prepared to facilitate changes of variables in the calculation of partial molal properties of the constituents of solutions. These are presented in tables.

THE RELATIVE HEAT CONTENTS OF THE CONSTITUENTS OF AQUEOUS SODIUM CHLORIDE SOLUTIONS

BY T. F. YOUNG AND O. G. VOGEL

RECEIVED JANUARY 25, 1932

PUBLISHED AUGUST 5, 1932

The complete evaluation of activity coefficients from freezing point measurements is dependent upon the determination of relative partial molal heat contents. The data available for their evaluation are neither as extensive nor as accurate as desirable. In this paper are presented an examination of previously published data for aqueous sodium chloride solutions at 25°, a few new experimental determinations, a convenient method for utilizing a combination of heat of solution and heat of dilution data, and finally the results of new calculations.

The data first employed for the evaluation of relative partial molal heat contents of sodium chloride were those of Randall and Bisson.¹ They measured a series of heats of dilution from about 6.1 *m* to 0.41 *m* and the heat of solution of sodium chloride in sufficient water to produce compositions between 0.13 *m* and 0.54 *m*. Later Wüst and Lange² measured heats of solution between 0.43 *m* and 5.6 *m* and with a few heats of dilution extended their data to about 6.1 *m*. More recently Lipsett, Johnson and Maass³ determined many heats of solution at both 20 and 25°. They made one dilution between 0.173 *m* and 0.0284 *m*.

Because the work of Randall and Bisson and that of Wüst and Lange were not extended to sufficiently dilute solutions, a change in sign of the heat of dilution was not revealed. Later Lipsett, Johnson and Maass, and Lange and Messner,⁴ observed that heat was evolved by the dilution of a very dilute solution of sodium chloride at 25°. Several years earlier Pratt⁵ had observed similar behavior of several electrolytes. His curves for sodium chloride exhibit evidence of the reversal phenomenon.

Examination and Treatment of Previous Data.—For comparison, the three series of heat of solution data were represented by separate plots. The *experimental* values reported in the first paper of Lipsett, Johnson

¹ Randall and Bisson, *THIS JOURNAL*, **42**, 347 (1920).

⁴ (a) Lange and Messner, *Naturwissenschaften*, **15**, 521 (1927); (b) *Z. Elektrochem.*, **33**, 431 (1927).

⁵ Pratt, *J. Franklin Inst.*, **185**, 663 (1918); cf. Thomsen, "Thermochemistry," Longmans, Green and Co., London, 1908, p. 178. Thomsen reported evolution of heat for the dilution of his 0.28 *m* solution, but the results of modern workers indicate that the opposite effect should have been observed.

and Maass were multiplied by 0.9995 to correct them in accordance with the second report of these authors and to convert them to 15° calories.

The experiments of Wüst and Lange and of Lipsett, Johnson and Maass were first compared. The difference between the two series was nearly constant. Since absolute values are not required for the determination of relative partial molal properties, one curve was superimposed upon the other and adjusted until the two appeared to be as nearly coincident as the data would permit. Appropriate constants, one of which was entirely arbitrary, were then added to the data in each series so that they could be represented on one plot. Curve 1 (indicated only) of Fig. 1 exhibits the satisfactory agreement of the relative values obtained from the two series.

+, Wüst and Lange; O, Lipsett, Johnson and Maass; ●, $\int S dm^{1/2}$.

Fig. 1.—Curve 1 (indicated) represents experimental determinations of the heat absorbed during the solution of one mole of sodium chloride, plus an arbitrary constant; the data are those of Lipsett, Johnson and Maass plus a convenient constant, -1100, and those of Wüst and Lange, -1108. Curve 2, $\phi H - \phi H^0$ as determined by integration of the S curve, Fig. 2, plotted with the data of Lipsett, Johnson and Maass -924 and those of Wüst and Lange -932.

The heat of solution data calculated by Randall and Bisson were very different from the others, but that portion of their curve corresponding to the composition range in which they actually made solution experiments

is in good agreement with the measurements of Wüst and Lange. These data will be discussed after the significance and use of the curve has been considered.

The heat absorbed during the solution of one mole of sodium chloride, ΔH , differs from the apparent molal heat content, ϕH , by the heat content of one mole of solid sodium chloride, H_2

$$\phi H = \Delta H + H_2 \quad (1)$$

Curve 1, Fig. 1, therefore represents the apparent molal heat content plus a constant, C .

The \sqrt{m} was chosen as abscissa in Fig. 1, so that the slope of the curve would approach a finite value as m approaches zero. Investigations of the solubilities of salts in very dilute aqueous solutions of other salts have demonstrated that the activity coefficients, γ , of many strong electrolytes are nearly linear functions of \sqrt{m} in very dilute solutions, and that $d\gamma/d\sqrt{m}$ approaches a finite limit as m approaches zero. For this to be true at more than one temperature $d(\phi H)/d\sqrt{m}$ must approach either zero or a finite value. Randall and Rossini's⁶ heat capacity measurements of sodium chloride solutions have established that this slope has a temperature coefficient and cannot in general be zero.

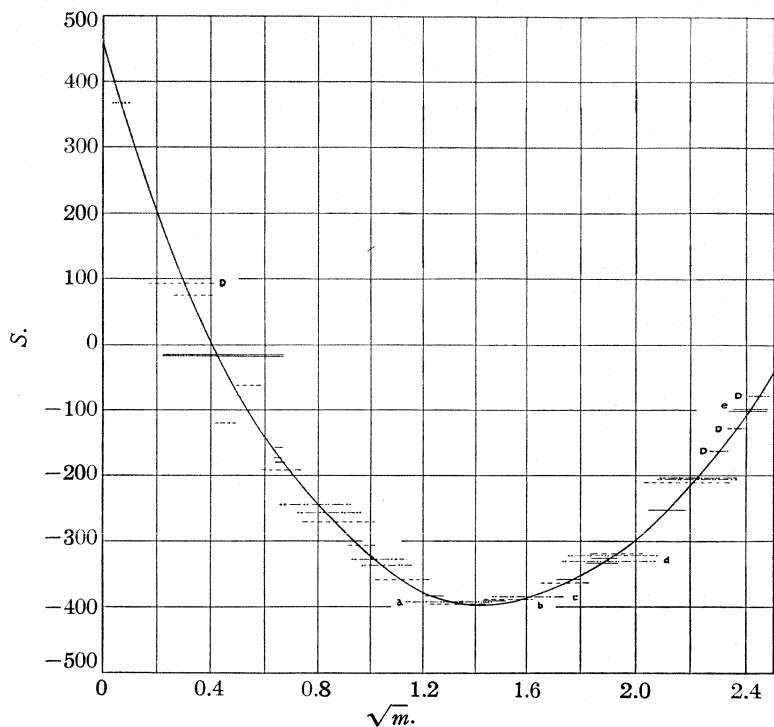

The Derivative Curve.—Customary graphical methods of differentiation are not convenient for the precise manipulation of both heat of solution and heat of dilution data. Figure 2 illustrates the method employed for determination of the slope, $S \equiv d(\phi H)/d\sqrt{m}$, of Curve 1, Fig. 1. Between any two values of \sqrt{m} , the average of the slope is $\Delta(\phi H)/\Delta\sqrt{m}$. The value of $\Delta(\phi H)$ may be calculated directly from the heat of dilution of one mole of sodium chloride or from the difference in two heats of solution. The average values of the slope, S , are equal to the slopes of chords between corresponding points of Curve 1, Fig. 1.

Average values of S were determined from all of the data in the two series represented on Curve 1 and from one dilution experiment of Lange and Messner. These were plotted as lines drawn between corresponding values of \sqrt{m} . The true derivative curve should pass through each chord so that the two areas enclosed between the curve, the chord and imaginary vertical lines drawn through the ends of the chord, are equal.

Comparison of chords revealed the source of differences between the data reported by Randall and Bisson and by subsequent workers. The chords calculated from Randall and Bisson's measurements fell erratically on both sides of the curve, Fig. 2. The errors of several dilution experiments accumulated and affected the estimated form of their heat of solution curve. As a result, heat of solution data tabulated by those authors for large values of m are in error whereas actual solution measurements and

⁶ Randall and Rossini, *THIS JOURNAL*, **51**, 323 (1929).

the corresponding tabulations for dilute solutions agree well with the data of Wüst and Lange.

·····, Wüst and Lange; ·····, Lange and Messner; ----, Lipsett, Johnson and Maass; ———, Young and Vogel.

Fig. 2.—The curve represents $S = d(\phi H)/d\sqrt{m}$. Each horizontal line represents an experimental determination of $\Delta(\phi H)/\Delta\sqrt{m}$ through the range indicated by the terminal abscissas of the line. The data of Lange and Messner and of Young and Vogel were obtained from dilution experiments. Most of the chords calculated from the work of Wüst and Lange and of Lipsett, Johnson and Maass represent differences in heats of solution. The few obtained from dilution measurements are distinguished by a symbol, D. Two chords of Wüst and Lange were omitted from the plot because they were nearly coincident with others designated, respectively, a and c. Similarly, chords of Young and Vogel were omitted because of proximity to those marked a, b, c and e. Two were omitted at d.

Since chords calculated from the early work of Randall and Bisson could not aid in locating the derivative curve, they were not added to the plot, Fig. 2. This somewhat arbitrary procedure required further justification. Furthermore in certain regions of the graph additional chords were desirable. Because heats of dilution yield directly the desired average slopes, they were determined experimentally.

Experimental Procedure

The calorimeter is illustrated in Fig. 3. A silvered Dewar flask, D, of about one liter capacity was cemented with litharge and glycerin to a metal ring, R, to which was bolted the calorimeter cap, F. This cap was provided with five vertical tubes, one for each of the following: a stirrer, S; a heater, H; a thermel, T; a bulb, B; and a bulb crushing device, C. Each tube was equipped with a tight-fitting rubber tube, cotton packing moistened with oil, or with an oil seal. Corrosion was prevented by a coating of paraffin on various metal parts.

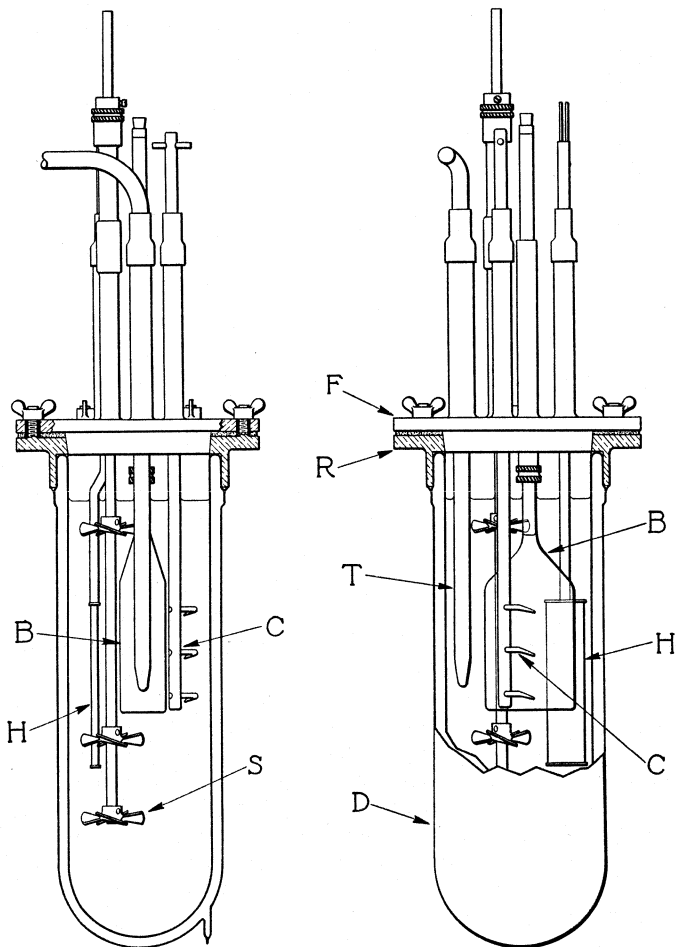

Fig. 3.—The calorimeter.

The bulbs were very thin-walled Pyrex glass vessels of 75–85 cc. capacity. During each dilution experiment, a bulb was broken by the manual rotation of the crushing device. The heat produced by the mixing process was measured several times. When there was water both inside and outside the bulb, about 0.07 calorie was produced. This corresponds to a temperature rise of about 0.00009°.

The stirrer was driven at about 500 revolutions per minute by a synchronous motor. Before each dilution the temperature of the liquid in the calorimeter was allowed to become practically constant. The equilibrium attained was about 0.2° above the surroundings.

The core of the calorimeter heater was a mica strip wound with constantan wire. It was enclosed in a tight-fitting metal sheath separated from the core by thin sheets of mica.

Current was supplied by a large storage battery. For several minutes before it was used, it was permitted to discharge through a coil, the resistance of which was nearly equal to that of the heater. During a customary three-minute heating interval the current, of about 0.04 ampere, varied but a few hundredths of one per cent.

Current was determined during each heating period from a measurement of the potential drop across a standard 0.1-ohm resistance. The length of the period was measured by a stop watch which had been compared with an accurate clock.

One or more heating periods (usually two) followed each mixing process. When a steady cooling rate had been established after the final period, current was again allowed to flow through the heater and was measured as before. With the potentiometer and standard 1 and 10,000 ohm resistances, the potential drop across the heater was also determined. These measurements revealed a variation, throughout the whole work, of only about 0.03% in the resistance of the heater.

Two copper-constantan thermels were constructed in accordance with many of the recommendations of White.⁷ Because they were used principally for the determination of the ratio of successive temperature changes, great care in calibration and in several details of construction was not essential. Comparison with a mercury thermometer calibrated by the Bureau of Standards was sufficient for the determination of the temperature of the calorimeter contents. One of the thermels which contained twenty-four pairs of wires produced a galvanometer deflection somewhat greater than one centimeter per microvolt. The precision of reading was about 0.02 microvolt, corresponding to approximately 0.00002° . One end of the thermel dipped into the calorimeter, the other into a silvered Dewar bulb which was placed near the calorimeter in a thermostat.

The thermostat was controlled by a large mercury regulator. Its precision was investigated with a thermel, one end of which was immersed as usual in its Dewar bulb. The other end was exposed directly to the thermostat. No fluctuations greater than two thousandths of a degree were detected over periods of many minutes. Inside the calorimeter, fluctuations were very much smaller.

The e. m. f. produced by the thermel was determined each minute during the periods preceding the breaking of the bulb and before and after each heating interval. These values were plotted as functions of time and the appropriate linear portions of the plot were extrapolated to lines representing, respectively, the instant of breaking the bulb, and the center of each electrical heating period. From the plot, the e. m. f. change produced by each operation was ascertained. More elaborate methods for the estimation of thermal leakage were not justified.

The electrical energy required for an increase of one volt in the thermel e. m. f. was computed for each heating interval. There was no significant variation in successive values of this ratio. The heat of mixing was computed by multiplying this ratio, calories/volt, by the change in thermel e. m. f. produced by the mixing process.

Materials.—Concentrated solutions were prepared from fused sodium chloride and distilled water. They were analyzed gravimetrically, some by silver chloride precipitation, others by sodium chloride residue methods. In the latter determinations

⁷ White, *THIS JOURNAL*, **36**, 2292 (1914).

high temperatures were used in accordance with the observations of Richards and Hall.⁸ Dilute solutions were prepared by the dilution of a stock solution about 5.5 molal.

Experimental Results and Calculations

The small temperature changes produced precluded any attempt with available equipment to obtain a precision much better than one or two in a hundred. The dilution of solutions about 0.45 molal produced lowerings of only about 0.0002°. Nevertheless the average deviation from the mean of three such experiments represented an error in temperature measurement of only about 0.00002°. The precision of the experiments with concentrated solutions was limited by analytical methods. Because of the rapid variation of the slope, S , with concentration, an error of 0.1% in the analysis of a 6.1 m solution of sodium chloride would correspond to an error of about 1% in the measured value of the chord.

The experimental results are in Table I. The first and second columns exhibit the initial and final values of the molality. The third column shows the temperature of the calorimeter contents before mixing and the fourth the approximate rise in temperature due to the mixing operation. The fifth contains $\Delta(\phi H)$, which is the heat (15° calorie) which would be absorbed per mole of sodium chloride in an isothermal dilution process at the temperature stated in the third column. In the sixth column is the value of $\Delta(\phi H)$ calculated for 25°. The last column contains the chord for use in the determination of the S curve.

⁸ Richards and Hall, *THIS JOURNAL*, **51**, 709 (1929).

The value of $\Delta(\phi H)$ at 25° (column 6) was calculated from the corresponding quantity at the temperature of observation by means of the apparent molal heat capacity, ϕC , which is the temperature coefficient of ϕH .

$$\phi C = d(\phi H)/dT \quad \Delta(\phi C) = d(\Delta(\phi H))/dT \quad (2)$$

For the purpose of the calculation,⁹ a plot was prepared of ϕC versus \sqrt{m} . The data of Randall and Rossini were supplemented by ϕC data calculated from differences in the heats of solution determined by Lipsett, Johnson and Maass for 20 and 25° . Though these values of ϕC were merely averages for the five degree interval, they were sufficient for a satisfactory extension of the 25° curve.

Final Construction of Differential Curve.—After the new data had been added to the plot, a preliminary curve was carefully drawn in accordance with all of the chords. The curve was then tested and slightly readjusted as follows: the first derivative of the preliminary S curve was determined at numerous values of \sqrt{m} . For this purpose the tangentometer described by E. v. Harbou¹⁰ was used. From a plot of S' the next higher derivative, S'' , was estimated. When S'' may be considered constant over the range covered by any chord, the following equation may be used for the calculation of the difference between P , a point on the curve directly above the center of any chord, and \bar{P} , the ordinate of the chord itself.

$$P - \bar{P} = -(S''/24)(\Delta\sqrt{m})^2 \quad (3)$$

Values of P were calculated for all of the chords and were plotted on a large graph. Since each chord was represented by a point, all of the data could be placed, without conflict, upon a single sheet of paper, and it was less difficult to draw the S curve with due regard to all of the data than on the original chord plot. The new diagram served as a convenient aid for testing and improving the fundamental chord plot.

Further confirmation of Fig. 2 in the region between $\sqrt{m} = 0.4$ and 1.5 was obtained from the work of Richards and Rowe, who determined a few heats of dilution at approximately 15 and 20° . Chords for 25° , calculated from their 20° data by means of values of ϕC , read from a curve similar to that discussed above,¹¹ are in satisfactory agreement with the data represented in Fig. 2.

The position of the S curve in the neighborhood of $\sqrt{m} = 0.05$ was largely determined by a measurement made by Lange and Messner. Except for the portion to the left of that chord, the curve seems to be sufficiently precise for application to thermodynamic problems.

⁹ Cf. Rossini, *Bur. Standards J. Research*, **7**, 47 (1931).

¹⁰ Harbou, *Z. angew. math. Mechanik*, **10**, No. 6 (1930).

¹¹ This curve, determined from the measurements of Lipsett, Johnson and Maass, represented average values of ϕC between 20 and 25° .

Extrapolation into the region of great dilution is, of course, uncertain.¹² However, an error as large as 200 in the estimated average value of S between $\sqrt{m} = 0$ and 0.05 would introduce an error of only 10 cal./mole into calculations of ϕH .

Column 2 of Table II contains values of S read from the large plot. The curve between $\sqrt{m} = 0$ and 0.4 is well represented by the following empirical equation¹³

$$S = 461.3 - 1427.6\sqrt{m} + 704.2m \quad (4)$$

TABLE II				
\sqrt{m}	S	$\phi H - \phi H^\circ$	\bar{L}_1	\bar{L}_2

2.45	-76	-480	10.1	-573

In the third column of Table II are values of the differences between ϕH , the apparent molal heat content, and ϕH° , the limit approached by

¹² For a summary of the important investigations of this problem by Lange and his co-workers, see Lange and Robinson, *Chemical Reviews*, **9**, 89 (1931). See also Robinson, *THIS JOURNAL*, **54**, 1311 (1932). At the time this paper was written the precise data of Robinson had not been published. Chords calculated from his measurements are in good agreement with Fig. 2 and contribute greatly to the reliability of extrapolation.

¹³ According to the theory of Debye and Hückel $dS/d\sqrt{m}$ is related to ionic size [see Bjerrum, *Trans. Faraday Soc.*, **23**, 445 (1927), Equation 4]. From the second derivative, with respect to \sqrt{m} , of Bjerrum's equation 4, an expression was easily obtained for the limit of $dS/d\sqrt{m}$ as $\sqrt{m} \rightarrow 0$. This was equated to a numerical value derived from equation (4). According to the resulting relation, the mean effective ionic diameter is 4.7×10^{-8} cm. This is the expected order of magnitude in spite of certain approximations in Bjerrum's equation. If theory can be used as a guide, our extrapolation is probably not far from correct.

ϕH as \sqrt{m} approaches 0. These tabulated values of $\phi H - \phi H^\circ$ were obtained from the equation

$$\phi H - \phi H^\circ = \int_0^{\sqrt{m}} S d\sqrt{m} \quad (5)$$

For $\sqrt{m} < 0.4$ this becomes

$$\phi H - \phi H^\circ = 461.3 m^{1/2} - 713.8 m + 235 m^{3/2} \quad (6)$$

Mechanical integration was employed for the determination of values of $\phi H - \phi H^\circ$ which were not calculated from equation 6.

The Integral Curve.—A plot of $\phi H - \phi H^\circ$ was constructed and compared with the curve representing the heat of solution data of Lipsett, Johnson and Maass. The latter curve, according to Equation 1, represents $\phi H - H_2$. The difference in the ordinates of the two curves is therefore $\phi H^\circ - H_2$, which is the heat absorbed during the solution of one mole of sodium chloride in an infinite amount of water. One curve was placed over the other and shifted until the two were as nearly coincident as possible. From the amount of the shift, $\phi H - H_2$ was determined as 924. In a similar manner Wüst and Lange's data yielded 932.

From each of the two series of experimental data, values of $\phi H - \phi H^\circ$ were calculated by subtraction of these respective constants. They were compared on Curve 2, Fig. 1, with the direct results of the integration of the S curve.

The Relative Heat Contents.—According to Lewis and Randall's convention¹⁴ the difference between \bar{H} , the partial molal heat content of any constituent and \bar{H}° , the partial molal heat content of that substance in its reference state, is termed the "Relative Heat Content."

When the infinitely dilute solution is chosen as the reference state of both constituents, the relative heat content of the solvent, \bar{L}_1 , and of the solute, \bar{L}_2 , may be calculated from the following equations, 7 and 8. These are easily obtained from formulas 4-D of each of the tables in the preceding paper.

$$\bar{L}_1 = \bar{H}_1 - \bar{H}^\circ_1 = -\frac{m^{1/2}S}{2(55.51)} \quad (7)$$

$$\bar{L}_2 = \bar{H}_2 - \bar{H}^\circ_2 = \phi H - \phi H^\circ + \frac{m^{1/2}S}{2} \quad (8)$$

Combinations of these with equations 4 and 6 give 9 and 10, valid for values of the \sqrt{m} less than 0.4.

$$\bar{L}_1 = -4.16 m^{1/2} + 12.86 m^2 - 6.34 m^{5/2} \quad (9)$$

$$\bar{L}_2 = 692 m^{1/2} - 1428 m + 587 m^{3/2} \quad (10)$$

The new determinations of \bar{L}_1 and \bar{L}_2 are exhibited in Table II.¹⁵ Those corresponding to values of $\sqrt{m} < 0.4$ were computed from equations 9

¹⁴ Lewis and Randall, "Thermodynamics," McGraw-Hill Book Company, New York, 1923, pp. 351 and 354.

¹⁵ For similar tables of properties of dilute solutions of sodium chloride at 18° see Rossini, *Bur. Standards J. Research*, **6**, 791 (1931).

and 10. The others are the results of substitution in equations 7 and 8 of the data listed in Columns 2 and 3.

Lewis and Randall's¹⁶ calculations of the activity coefficients of sodium chloride depended upon the classic \bar{L}_1 data of Randall and Bisson. The data of Table II, together with the new heat capacity data of Randall and Rossini and of Lipsett, Johnson and Maass, were employed in a recalculation of activity coefficients. In spite of important differences between the above and the original values of \bar{L}_1 the results of the new calculations differ so little from the original ones that we refrain from giving them.

It seems probable however that work now being performed at other temperatures will introduce more important corrections. Some preliminary measurements¹⁷ indicate that the variation of $\phi H - \phi H^\circ$ between 25 and 0° is much larger than is indicated by heat capacity data at 25°.

Summary

Data applicable to the calculation of the relative heat contents of the constituents of aqueous sodium chloride solutions have been assembled. They have been critically examined by a method convenient for their inter-comparison and for differentiation. The collected information has been supplemented by new measurements.

From all of the available data, the relative partial molal heat contents have been calculated for 25°. Activity coefficients calculated with the aid of these values are not very different from those originally calculated by Lewis and Randall.

THE SYSTEM CALCIUM CHLORIDE-MAGNESIUM CHLORIDE-WATER¹ AT 0, -15 AND -30°

BY C. F. PRUTTON AND O. F. TOWER

RECEIVED FEBRUARY 3, 1932

PUBLISHED AUGUST 5, 1932

Introduction

Sodium, calcium and magnesium chlorides occur together in sea water, most salt brines and salt deposits, and provide a commercial source of the above chlorides. In connection with the separation of these chlorides, data on the quaternary system calcium chloride-magnesium chloride-sodium chloride-water are of importance.

¹ Presented by C. F. Prutton in partial fulfilment of the requirements for the degree of Doctor of Philosophy at Western Reserve University, 1928.

This work is a study in the ternary system calcium chloride-magnesium chloride-water, undertaken as a preliminary study to the quaternary system. The only data available on this ternary system is that of Lee and Egerton,² who give the 25° isotherm, and Smith and Prutton³ who verified the existence of tachydrate— $\text{CaCl}_2 \cdot 2\text{MgCl}_2 \cdot 12\text{H}_2\text{O}$ —and also found a second double salt at higher temperatures— $2\text{CaCl}_2 \cdot \text{MgCl}_2 \cdot 6\text{H}_2\text{O}$. The data of Van't Hoff, Kenrick and Dawson⁴ were obtained in solutions saturated with sodium chloride. The occurrence of this second double salt suggested the possibility of still other double salts at temperatures below those investigated. The exact freezing points of solutions of calcium and magnesium chlorides are of interest in refrigeration where some use is made of the mixed chlorides for refrigerating brines.

Experimental

A. Materials Used.—Pure calcium chloride was obtained by dissolving c. p. calcium carbonate in c. p. hydrochloric (1 to 1) acid and precipitation of any magnesium present by boiling this solution with an excess of calcium oxide made by ignition of part of the calcium carbonate. The filtered solution was neutralized, concentrated by evaporation, and then cooled to 20° for about one day. Large crystals of the hexahydrate of calcium chloride separated. This crystallization was repeated six times.

Magnesium chloride was prepared by the solution of distilled magnesium metal (American Magnesium Corporation) in (1 to 2) c. p. hydrochloric acid. The slight excess acidity in solution was neutralized with c. p. magnesium oxide. The solution was filtered, concentrated and cooled to obtain crystals of the hexahydrate of magnesium chloride. The crystals were recrystallized twice from distilled water.

Both chlorides met with all tests on these salts as specified by Murray⁵ for chemically pure reagents.

B. Method.—Solubilities were determined by the usual saturation method; samples of the saturated solutions and of the residues were taken for analysis. The residue method of Schreinemakers⁶ was used to identify the solid phase present. All isothermal invariant points were approached from both sides of the equilibrium, and it was found that eight hours' agitation, in all cases, was sufficient time for equilibrium to be reached.

The cryostat used was a modification of that of Sinozaki and Hara.⁷

Liquid ammonia was used as the cooling agent for temperatures down

to -30° and liquid air for the lower temperatures. The cryostat bath was a four-liter Pyrex thermos silvered vacuum flask, 15 cm. in diameter and about 25 cm. deep. This was filled with a 50% ethyl alcohol-water mixture.

Temperature control of the bath could be automatically maintained at $\pm 0.1^{\circ}$ for about twelve hours. With this variation in bath temperature, the temperature inside the solubility tube was maintained within $\pm 0.03^{\circ}$ of the desired temperature.

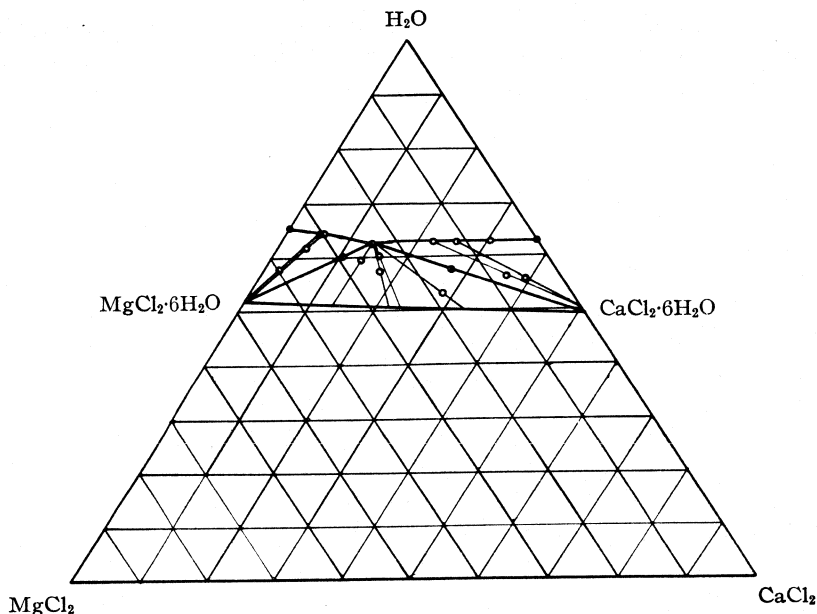

Fig. 1.— 0° isotherms. System: $\text{CaCl}_2\text{--MgCl}_2\text{--H}_2\text{O}$.

The solubility tube was a large Pyrex test-tube (6×22 cm.) similar to that used by the Earl of Berkeley.⁸ This tube was immersed in the cryostat bath to a depth of about 18 cm. and contained sufficient solution and crystals to fill the tube to a depth of about 7 cm.

Temperatures were measured by a multiple (six) junction copper-constantan thermocouple, inside the solubility tube, using a Leeds-Northrup portable potentiometer pyrometer. The uniformity of the wire used in the couple was checked and the couple calibrated in place; at the ice point, the freezing points of mercury and carbon tetrachloride, and the vaporizing temperature of solid carbon dioxide.

In the solutions and residues, calcium and total chloride were determined volumetrically, and the amounts of the two chlorides present cal-

⁸ Earl of Berkeley, *Trans. Roy. Soc. (London)*, **A203**, 189-215 (1904).

culated. The method of Blasdale⁹ was used for precipitation of calcium oxalate and the precipitated calcium oxalate titrated by the well-known method using standard potassium permanganate. Mohr's method was used for the volumetric determination of total chlorides.

The octahydrate of magnesium chloride obtained as the solid phase in the above solubility determinations is evidently the stable alpha form of this salt reported by Van't Hoff and Meyerhoffer,¹⁰ as the solubility of the octahydrate in water at -15° agrees closely with the value reported by these workers.

There was no evidence of the metastable beta form of magnesium chloride octahydrate as reported by Van't Hoff and Meyerhoffer.

Magnesium chloride hexahydrate will not change to the octahydrate at -15° even when agitated for twenty-four hours with the solution.

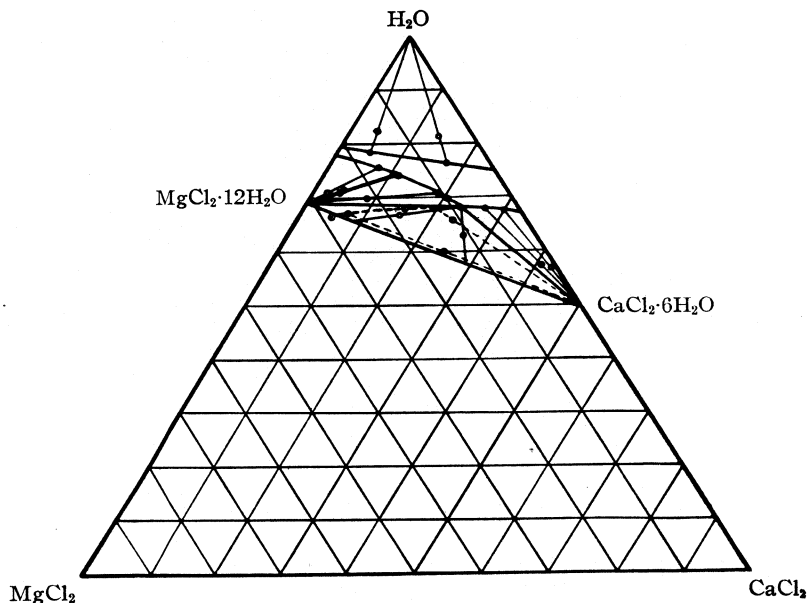

¹⁰ Van't Hoff and Meyerhoffer, *Z. physik. Chem.*, **27**, 75 (1898).

Fig. 2a.— -15° isotherms, showing metastable equilibria.

This transition takes place rapidly when the solution is "seeded" with octahydrate crystals obtained by freezing a solution containing about 30% magnesium chloride at -30° or lower and then raising the temperature to -15° .

Fig. 3.—30 isotherms. System: $\text{CaCl}_2\text{-MgCl}_2\text{-H}_2\text{O}$.

Determination of Monovariant Points.—The following monovariant points were determined. Temperatures were determined by the thermometric method and compositions by the saturation method.

Phases in equilibrium	Temperature, °C.	Composition
1. $\text{MgCl}_2\cdot 6\text{H}_2\text{O}$ $\text{MgCl}_2\cdot 8\text{H}_2\text{O}\alpha$ $\text{CaCl}_2\cdot 6\text{H}_2\text{O}$ Satd. soln.	— 6.7	26.40 MgCl_2 9.90 CaCl_2
2. $\text{MgCl}_2\cdot 12\text{H}_2\text{O}$ $\text{MgCl}_2\cdot 8\text{H}_2\text{O}\alpha$ $\text{CaCl}_2\cdot 6\text{H}_2\text{O}$ Satd. soln.	—20.7	23.23 MgCl_2 10.56 CaCl_2
3. $\text{CaCl}_2\cdot 6\text{H}_2\text{O}$ $\text{MgCl}_2\cdot 12\text{H}_2\text{O}$ Ice Satd. soln.	—52.2	2.93 MgCl_2 27.40 CaCl_2

Figure 4 shows the completed ternary diagram plotted on triangular coordinates.

The curves for temperatures above 0° , from data of Van't Hoff, are shown by broken lines, as these results were obtained in solutions saturated with sodium chloride.

Points B, C and F are the monovariant points at -6.7 , -20.7 and -52.2° , respectively. Points A, D, E and point between B and C, are isothermal monovariant points at 0 , -24.0 , -30 and -15° , respectively.

The light lines with arrows in the various areas indicate the direction in which the composition of a solution changes, on progressive cooling, due to separation of crystals of the stable solid phase in the given area.

Arrows on heavy lines between phase areas indicate how the solution changes when two solids separate from solutions on cooling.

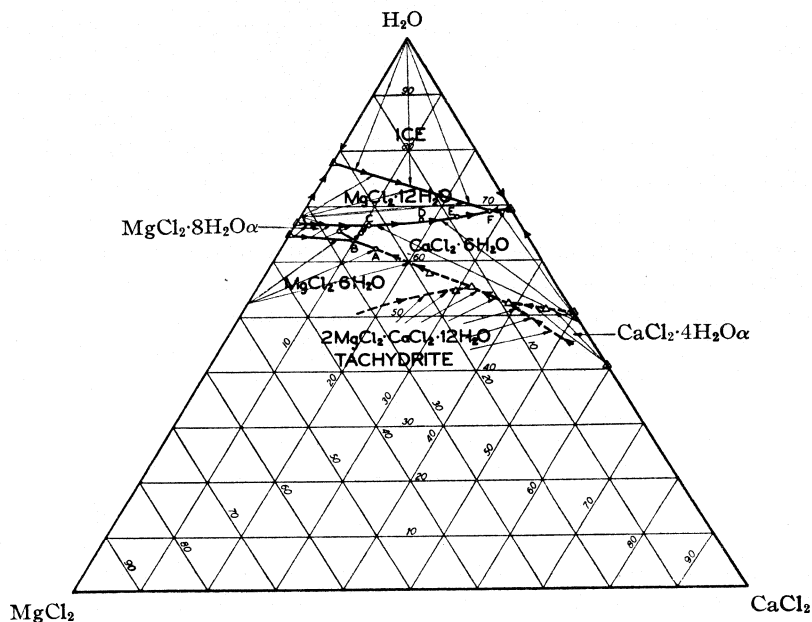

Fig. 4.—Crystallization paths. System: $\text{CaCl}_2\text{--MgCl}_2\text{--H}_2\text{O}$.

Summary

1. The solubility relations of the ternary system, calcium chloride-magnesium chloride-water, at 0, -15° and -30° have been determined.
2. There is no evidence of double salt formation in this system at the temperatures studied.
3. Temperatures and compositions of ternary monovariant points have been determined.
4. The existence of $\text{MgCl}_2\cdot 8\text{H}_2\text{O}\beta$ reported by Van't Hoff and Meyerhoffer, was not detected.

THE IONIZATION OF ORGANIC ACIDS

BY HUGH M. SMALLWOOD

RECEIVED FEBRUARY 4, 1932

PUBLISHED AUGUST 5, 1932

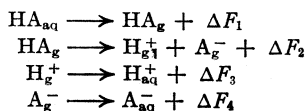

The physical interpretation of the effects of substituent groups upon the acid strength of organic compounds has been the subject of much discussion. Ostwald¹ began the attack on the problem by classifying the various groups as positive or negative according to whether they caused a decrease or an increase in acidity. Since then numerous papers have dealt with the subject in a more quantitative manner, but the treatments have been empirical throughout, in that they have established relationships between the ionization constants of various acids without attempting any numerical correlation of the effect of a particular substituent with the properties of that substituent.

As a result of the recent activity in the measurement of dipole moments, it is natural to suppose that the extent of ionization of an organic acid is affected by the dipoles present in the molecule. This possibility has been considered qualitatively by Wolf,² and Langmuir,³ and, in a more general way, by Briegleb.⁴ The first named author suggested that the acid properties of the carboxyl group are due to the influence of the dipole associated with the carbon-carbonyl oxygen bond. Langmuir pointed out that the dipole associated with the carbon-chlorine bond in mono-chloroacetic acid should facilitate the ionization of the molecule. Briegleb concluded that it is not possible to give a quantitative treatment of the subject, due to the inability of calculating the various free energies of hydration, and of allowing for the effect of association. Although these difficulties would undoubtedly prevent the development of a complete theory, it is possible to give an approximate treatment of the effect of dipole moments upon ionization. Such a treatment may be obtained as follows.

The ionization constant of a weak acid is a measure of the free energy change in the reaction

For purposes of calculation it is simpler to carry out this process in the following manner

¹ W. Ostwald, *J. prakt. Chem.*, **31**, 300 (1885); *Z. physik. Chem.*, **3**, 170, 241, 369 (1889).

² K. L. Wolf, *ibid.*, **3B**, 128 (1929).

³ I. Langmuir, *Chem. Rev.*, **6**, 465 (1929).

⁴ G. Briegleb, *Z. physik. Chem.*, **10B**, 205 (1931).

Then

$$\Delta F = \Delta F_1 + \Delta F_2 + \Delta F_3 + \Delta F_4 = -RT \ln K_a \quad (1)$$

where K_a is the ionization constant of the acid HA and the free energy changes are defined by the various reactions. Of these four free energy terms the second is important for the present purpose. It is, of course, equal to $\Delta E + p\Delta V - T\Delta S$, where the symbols have their usual significance. ΔE , the energy change accompanying the removal of a proton from the neutral HA molecule, is made up of four parts: first, the work of altering the electron distribution from that corresponding to the mainly non-polar binding, present in the neutral molecule, to a distribution corresponding to two ions, H^+ and A^- , situated at a distance equal to their equilibrium separation in the undistorted molecule; second, the work against the Coulomb attraction necessary to remove the H^+ to infinity; third, the change in the polarization energy of the anion due to the removal of H^+ ; and, finally, the work of removal of H^+ from the electric field due to any dipoles in the anion. Of these four contributions to the free energy of ionization, the last is the only one of immediate interest. In general, it is small in comparison with the other energy terms, but it may be brought into prominence, and the difficulties of calculating the other terms may be avoided by comparing the ionization constants of two acids differing mainly in the group moments present in their anions. Let the other member of such a pair be represented by HA' . The corresponding $\Delta F'$'s will be designated by the same subscripts as have been used for HA, but with the addition of primes. Then, if the anions are sufficiently similar, it may be supposed that $\Delta F_2 - \Delta F'_2$ will equal the difference between the work of removal of H^+ from the dipole field of A^- and the work of removal from that of A'^- , say $\epsilon - \epsilon'$. Similarly, if the two compounds are not too different, it may be expected that $\Delta F_1 = \Delta F'_1$ and $\Delta F_4 = \Delta F'_4$. Of course $\Delta F_3 = \Delta F'_3$ for all acids. Since

$$\Delta F' = \Delta F'_1 + \Delta F'_2 + \Delta F'_3 + \Delta F'_4 = -RT \ln K'_a \quad (2)$$

one obtains by subtracting (2) from (1)

$$\Delta F - \Delta F' = \epsilon - \epsilon' = -RT \ln \frac{K_a}{K'_a} \quad (3)$$

The work of removal ϵ is $-e\Phi$, where e is the charge on the hydrogen ion, and Φ is the potential due to the group moments of the anion calculated at the point occupied by the hydrogen nucleus in the undissociated molecule. Similarly, $\epsilon' = -e\Phi'$. By substitution

$$\log \frac{K_a}{K'_a} = \frac{e(\Phi - \Phi')}{2.3kT} \quad (4)$$

The dielectric constant of water, the medium in which the dissociation actually takes place, does not appear in this equation because the energy terms affected by this quantity occur in the free energies of hydration, which have been assumed to cancel. This is not true of some analogous calculations by Bjerrum,⁵ in which the dielectric

⁵ N. Bjerrum, *Z. Physik. Chem.*, **106**, 219 (1923).

constant of water does appear. The latter calculations evaluate the ratio of the first and second ionization constants of some dibasic acids, taking account of the energy necessary to remove the second hydrogen ion from the field of the negative charge left by the first ionization, the whole process being assumed to take place in the solvent. This discrepancy between Bjerrum's work and the present treatment is only apparent, since in his case a cyclic process could not lead to cancellation of the free energies of hydration, due to the difference in charge of the two anions compared (HA^- and A^-). The inclusion of this change in the free energies of hydration involves the introduction of the dielectric constant of water.

It might also be pointed out that the present treatment avoids the difficulty of allowing for the association of the neutral acid molecules in solution, by means of the assumption that the extent of the association of the unsubstituted acid is practically the same as that of the substituted.

Equation (4) will first be applied to the rather extreme case of formic acid and methyl alcohol. It is necessary to assume detailed models of the molecules under discussion: that used for formic acid is shown in Fig. 1,

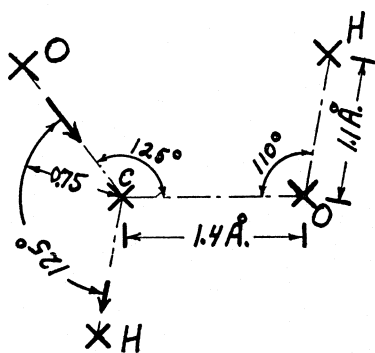

Fig. 1.—Model of formic acid.

together with the necessary dimensions. The potential at the hydrogen nucleus is made up of one contribution from the $\text{C}=\text{O}$ group moment and one from the CH group moment, the potential of a dipole of strength μ being given by the relation

$$\Phi = \frac{\mu}{r^2} \cos \angle (\mu, r) \quad (5)$$

where r is the radius vector from the dipole to the point at which the potential is calculated. The $\text{C}-\text{O}$ group moment is neglected, since it is present with the same orientation in both molecules. Φ' , the analogous quantity for methyl alcohol, is due to three CH moments. Here, however, it may be supposed that the methyl group can rotate about the $\text{C}-\text{O}$ bond. Formic acid is presumably a plane molecule, since the strong interaction between the OH and CO moments completely prevents rotation at ordinary temperatures.⁶ To take into account the rotation of the methyl group it is necessary to average Φ' over the azimuthal angle about the CO bond.

This averaging is effected as follows: a set of coördinates is so chosen that (1) the X -axis coincides with the axis of rotation in the molecule, and (2) the group moment, whose potential is to be averaged, is contained in the XY plane. Then

$$\begin{aligned} \bar{\Phi} &= \frac{1}{\pi} \int_0^\pi \Phi d\varphi \\ &= \frac{A}{\pi} \int_0^\pi \frac{d\varphi}{(p^2 - q^2 \cos \varphi)^{3/2}} + \frac{B}{\pi} \int_0^\pi \frac{\cos \varphi d\varphi}{(p^2 - q^2 \cos \varphi)^{3/2}} \end{aligned} \quad (6)$$

⁶ L. Meyer, *Z. physik. Chem.*, **8B**, 27 (1930).

where φ is the azimuth about the axis of rotation, and

$$\left. \begin{aligned} A &= \xi(x_H - x_m) - \eta y_m; B = \eta y_H \\ p^2 &= (x_H - x_m)^2 + y_H^2 + y_m^2; q^2 = 2 y_H y_m \end{aligned} \right\} \quad (7)$$

In equation (7) ξ and η are, respectively, the x and y components of the group moment; x_H, y_H the coördinates of the ionizing hydrogen nucleus; and x_m, y_m those of the group moment. Evaluation of the integrals⁷ leads to the expression

$$\bar{\Phi} = \frac{2}{(p^2 + q^2)^{1/2}\pi} \left\{ \frac{1}{p^2 - q^2} \left[A + \frac{Bp^2}{q^2} \right] E - \frac{BK}{q^2} \right\} \quad (8)$$

where K and E are, respectively, the complete elliptic integrals of the first and second kinds for the modulus

$$k = \left(\frac{2q^2}{p^2 + q^2} \right)^{1/2} \quad (9)$$

The values of the group moments used for these calculations, together with the necessary molecular dimensions, have been summarized in Table I. In addition to these, the following values have been used. The angle between the oxygen valence bonds has been assumed to equal 110° , the aliphatic carbon bonds to possess tetrahedral symmetry, the benzene nucleus to be a regular plane hexagon. Group moments have been assumed to lie along the valence bonds and to be situated at a point 0.75 \AA. from the carbon nucleus (0.6 \AA. from the oxygen nucleus in OH). A moment whose positive end is farthest from the carbon nucleus (from the oxygen nucleus in OH) is written + and *vice versa*. The magnitudes of the group moments have been obtained from the resultant moment of the corresponding mono-benzene derivative, as listed by Smyth,⁸ with the assumption that $\mu_{CH} = +0.5$. Reasons for the use of these values will be presented in a future article. The group moments of the nitro and cyano groups have been located 0.4 \AA. beyond the N and 0.75 \AA. beyond the C nuclei, respectively.

TABLE I

Group	Internuclear distance, Ångström units	Electric moment $\times 10^{18}$	Group	Internuclear distance, Ångström units	Electric moment $\times 10^{18}$

CI	...	-0.8			

Application of equations (4) and (8) to formic acid and methyl alcohol leads to a calculated value of the ionization constant of the latter compound of the order of magnitude 10^{-17} . This quantity has not been measured, but it is safe to assume that this calculated value is too high, since smaller ionization constants have been measured. The discrepancy is due to the neglect of the resonance energy of the carboxyl ion, recently pointed out by

⁷ Cf. Bierens de Haan, "Nouvelles Tables d'Intégrales Définies," Leiden, 1867, Table 67, p. 102, equation (3) and (4). Equation 4, as given by de Haan, is incorrect. The correct value for this integral has been used in the present calculations.

⁸ C. P. Smyth, "Dielectric Constant and Molecular Structure," The Chemical Catalog Co., New York, 1931, pp. 195 and 203.

Pauling.⁹ According to his estimations, this effect should increase the strength of formic acid to about 10^{13} times that of methyl alcohol. Taking into account both the dipole repulsion and the resonance energy, the expected value for the ionization constant of methyl alcohol is $\sim 10^{-30}$, an entirely reasonable figure. It may be concluded that the acid properties of the carboxyl group are due in part to the substitution of a repelling carbonyl group moment for two attracting CH dipoles, and in part to the resonance energy of the carboxyl ion, the two effects being of approximately the same importance.

A more satisfactory test of the present treatment may be obtained from a study of the substituted acetic, propionic and benzoic acids and the substituted phenols. The calculations are entirely analogous to the previous case, and need not be given in detail. It has seemed best to compare the calculated change in energy of ionization, $(\Delta E - \Delta E')_{\text{calcd.}} = -e(\Phi - \Phi')$, with the experimental values, $(\Delta E - \Delta E')_{\text{obs.}} = 2.3RT \log K_a/K'_a$. These quantities, expressed in kilocalories per mole, are listed in Table II for most of the substituted acids for which data are available and which are amenable to treatment. The list is greatly diminished by the fact that the present method of calculation is limited to molecules in which there is only one effective possibility of rotation between the substituent group moments and the ionizing hydrogen. Further limitations will be mentioned below. Inspection of Table II shows that there is good agreement in some cases and definite disagreement in others. The causes of these discrepancies are, in most cases, apparent.

The first of such departures is found for the poly substituted acetic acids. These deviations must be ascribed to alterations of the magnitudes and directions of the group moments due to the intense interaction of the substituents. The data necessary to show that this is the case are available, if it be assumed that the effects of distortion and induction in di- and trichloroacetic acids are the same as in methylene chloride and in chloroform, respectively. Using the valence angles deduced from the x-ray measurements of Bewilogua¹⁰ and group moments calculated from the molecular moments listed by Smyth,¹¹ together with the assumption that the CH moment equals 0.5×10^{-18} , one obtains the figures listed in the last column of Table II. These are seen to be in good agreement with the experimental values.

Further discrepancies are apparent in the compounds containing nitro groups. These are most probably caused by the use of a single resultant moment for this substituent. Taking the complexity of the nitro group into account would improve the agreement but, in the absence of data

^a Calculated from ionization constants at 25° listed by H. Scudder, "The Electrical Conductivity and Ionization Constants of Organic Compounds," D. Van Nostrand Co., New York, 1914.

^b Corrected for interaction of group moments.

^c Calculated assuming rotation to be completely frozen out.

indicating the magnitudes of the N=O and C—N moments, it has not seemed worth while to attempt a more detailed calculation for these compounds. The agreement shown by *o*-C₆H₄NO₂COOH is probably fortuitous, the effect of hindered rotation (discussed below) counterbalancing the effect of using a resultant moment for the nitro group.

The most serious discrepancy is shown by the ortho halobenzoic acids, for which compounds the calculations indicate that the substituent halogen should cause a decrease in acid strength. This is undoubtedly due to a hindered rotation of the carboxyl group. If it be assumed that the rotation is entirely frozen, the ionizing hydrogen being as far from the substituent as possible, the figures listed in the last column of Table II are obtained.

Finally, it should be pointed out that there is a pronounced tendency for the calculated values to be higher than the observed. In all probability

this is due to the neglect of the change in polarization energy of the anion upon substitution (the third part of ΔE , p. 3049). This cannot be allowed for numerically, since the electric intensities are so great that polarizabilities calculated from refractive indices no longer have any meaning. It is, however, worth noting that this divergence is roughly proportional to the polarizabilities of the substituent groups.

The only definite discrepancy that has not been accounted for is shown by cyanoacetic acid. Judging from the other results, this departure is too large to be explained by the omission of the polarization energy of the anion. The experimental value for *p*-bromobenzoic acid is enclosed in parentheses because it is of a lower order of accuracy than the other figures.

It has been shown empirically by a number of authors, in particular by Derick,¹² that the change in free energy of ionization upon substitution is an additive property of the nature and relative position of the substituent. This rule is explained by the present treatment as follows. According to the assumptions used above, the change in free energy equals the change in energy of removal of the hydrogen ion. The latter quantity is proportional to the electrostatic potential of the group moment of the substituent, and since the potential is an additive quantity the change in the free energy of ionization must also be additive. As an illustration of this rule, it might be mentioned that $\Delta E - \Delta E'$ for picric acid (compared with phenol) is equal to the energy difference for *p*-C₆H₄NO₂OH plus twice that for *o*-C₆H₄NO₂OH.

Numerous papers have dealt with the effect of removing the substituent along the straight chain of an aliphatic acid. According to equation (5) the effect of the substituent should vary with the inverse square of the distance, provided the angle between the group moment and the radius vector to the ionizing hydrogen remains the same. In general, this will not be the case, and it is this angle which is most important in determining the magnitude of the effect. The large number of rotations, which take place to a more or less limited extent in a straight chain, precludes applying the present calculations to any aliphatic acids except those substituted in the alpha position.

Finally, it is desirable to consider briefly the assumptions underlying equations (4) and (8). First, the cancellation of the free energies of hydration, to within 1-2 k. cal., seems probable upon recalling that these quantities are dependent in part upon the orientation of the water dipoles in the field of the negative charge, if any, and in the field due to the dipoles of the particle; and in part to dispersion attraction. The first effect cannot be altered greatly by substitution since the domain of the —COO⁻ group is not affected. The increase in diameter of the anion occurs in a region relatively

¹² Derick, *THIS JOURNAL*, **33**, 1167 (1911); **34**, 74 (1912); Derick and Kamm, *ibid.*, **39**, 38 (1917); Derick and Hess, *ibid.*, **40**, 537 (1918).

far from the location of the charge and therefore in a region where this effect is least.¹³ The orientation in the dipole field and the dispersion attraction probably differ for the substituted and unsubstituted acids. They should, however, affect by the same amount the free energy of hydration of the anion and that of the undissociated molecule so that they cancel upon adding ΔF_1 to ΔF_4 .

It is necessary to consider in more detail the assumptions made concerning the extent of rotation about valence bonds. It has been assumed that there is no rotation in the carboxyl group, or in the ortho halobenzoic acids, but that in all the other compounds treated the acid group rotates freely with respect to the rest of the molecule. These suppositions may be justified qualitatively as follows. Whether or not rotation takes place depends on the accompanying change in the internal energy of the molecule. This energy is made up of (1) dipole attractions or repulsions, (2) changes in polarization, due to changes in dipole fields, (3) steric repulsions.¹⁴ Only the first of these terms can be calculated, at present; even here the accuracy is probably not very great due to the close approach of the group moments. The direction and extent of the other two terms may at least be estimated, the first from the polarizabilities of the groups between the rotating dipoles, and the second from internuclear distances. Upon applying the calculation of the dipole energy to the carboxyl group, it is found that this term is very large. Since steric hindrance and polarization should be negligible for this group, it is almost certain that rotation is frozen out, as was indicated by Meyer.⁶ In the mono-halo-acetic acids the dipole energy is again large, but here one would expect appreciable change in the polarization energy. The dipole term favors that position of the molecule in which the ionizing hydrogen is as near as possible to the substituent. The polarization energy has the opposite effect. In the configuration corresponding to minimum dipole energy there must be considerable steric hindrance. The net effect cannot be predicted with any certainty, but it seems most probable that rotation is nearly free. In any case the assumption of free rotation is not critical for these compounds, since here Φ does not change greatly upon rotation.

This is not true, however, of the ortho phenols and the ortho benzoic acids, where Φ changes sign as φ goes from 0 to π . In both of these classes of compounds there is a relatively small dipole energy tending to hold the ionizing hydrogen near to the substituent. No steric hindrance is to be expected in *o*-C₆H₄ClOH, but the polarization energy, due to the easily deformable aromatic C-C bonds, should be enough to counteract the dipole energy, so that rotation about the C-O bond may be expected to take place.

¹³ T. J. Webb, *THIS JOURNAL*, **48**, 2589 (1926).

¹⁴ The change in dispersion energy is negligible for the compounds under consideration. Cf. H. A. Stuart, *Phys. Rev.*, **38**, 1372 (1931).

The ortho halobenzoic acids differ from the phenols in that the position of minimum dipole energy for the former compounds involves so great a steric hindrance that the configuration becomes extremely improbable. Rather than attempt a discussion based on partially restricted rotation, it has seemed best to include values based on the extreme assumption of no rotation, but with the ionizing hydrogen fixed at the farthest point from the substituent. Interactions between the substituent and the acid group in the meta and para compounds are too slight to affect the rotation.

Extremely interesting information on the gradual loosening of a restricted rotation might be obtained by comparing the ionizations of ortho substituted benzoic acids with that of benzoic acid over as wide a temperature range as possible. Similar studies on phenols might also be of value in this connection, but here it would probably be necessary to go to lower temperatures. From the present discussion it is to be expected that at sufficiently low temperatures the ionization of $o\text{-C}_6\text{H}_4\text{ClOH}$ will approach that of phenol, and that at high enough temperatures that of $o\text{-C}_6\text{H}_4\text{ClCOOH}$ will approach that of benzoic acid. It is not possible to calculate the temperatures at which these changes should take place; it may be that they are beyond the experimental range. By choosing the substituent groups suitably, however, it should be possible to find compounds in which the free energies of ionization, relative to the unsubstituted acid, change profoundly with the temperature.

Indications of the expected change are definitely shown by the few compounds for which Scudder gives data at more than one temperature. These data are listed in Table III, the $(\Delta E')$'s being obtained from the ionization constants of benzoic acid at the appropriate temperatures. It is apparent that the strengthening effect of the substituent in the ortho compounds decreases with increasing temperature, while the effect of the substituent in the meta position is essentially independent of the temperature. This is in entire accord with the predictions of the present treatment: in the ortho compounds there is sufficient steric hindrance to hold the ionizing hydrogen in a region where the substituent's group moment repels the H^+ and so causes an increase in acidity. As the temperature increases the amplitude of oscillation about the bond between the COOH and $\text{C}_6\text{H}_4\text{X}$ groups increases, with the result that the H^+ spends more and more time in regions of decreased repulsion or even of attraction. At sufficiently high temperatures it is to be expected that $o\text{-C}_6\text{H}_4\text{ClCOOH}$ will be weaker than benzoic acid. No such effect is found or expected in the meta acids since in these compounds the steric effects, if any, should be essentially the same as in the unsubstituted acid. The five compounds listed in Table III are by no means enough to establish the present interpretation, but it may be considered that they bring to it definite confirmatory evidence.

TABLE III

<i>t</i> , °C.	$(\Delta E - \Delta E')_{\text{obs.}}$ K. cal./Mole.		50°	90°
	0°	25°		
<i>o</i> -C ₆ H ₄ ClCOOH	...	1.8	1.6	1.4
<i>o</i> -C ₆ H ₄ ICOOH	...	1.8	1.6	1.4
<i>o</i> -C ₆ H ₄ NO ₂ COOH	3.0	2.7	2.5	2.2
<i>m</i> -C ₆ H ₄ ICOOH	...	0.5	...	0.4
<i>m</i> -C ₆ H ₄ NO ₂ COOH	0.9	1.0	1.0	1.1

Two further inferences may be drawn from this treatment of acidity. In the first place, it has not been necessary to take into account any transmission of the dipole forces through the electronic structure between the ionizing hydrogen and the polar substituent. This amounts to neglect of the alteration of the induced moments in this region. That the permanent moments predominate is to be expected, since they are, as a general rule, considerably larger than the induced moments. Second, the strengthening effect of unsaturation is due, not to a specific property of the double or triple bond, but to the removal of CH dipoles which, in the saturated acid, are so oriented as to attract the hydrogen ion and thus hinder ionization.

From the foregoing discussion it may be concluded that the change in ionization of an organic acid caused by substitution may be accounted for numerically, at least in the absence of disturbing effects, by assuming as its cause the change in electrostatic repulsion or attraction between the hydrogen ion and the dipoles of the anion of the acid.

In conclusion it is a pleasure to express my indebtedness to Professor K. F. Herzfeld and to Professor J. B. Conant for valuable suggestions in the preparation of this manuscript.

Summary

It has been shown that the changes in ionization of organic acids upon substitution of polar groups are, to a large extent, determined by the magnitude and orientation of the electric moments associated with the substituent groups.

TAUTOMERISM OF HYDROXYTRIARYLCARBINOLS. III¹BY LEIGH C. ANDERSON AND M. B. GEIGER¹

RECEIVED FEBRUARY 8, 1932

PUBLISHED AUGUST 5, 1932

Previous papers from this Laboratory² have shown that a marked change in absorption spectra occurs on changing from the colorless benzenoid *p*-hydroxytriphenylcarbinols to the corresponding colored carbinols. These spectroscopic data were interpreted as constituting further evidence for the existence of a quinonoid tautomer (II) of the corresponding benzenoid carbinol (I). The fact that the colorless carbinol possesses a benzenoid structure has not been doubted, and the structure of the corresponding fuchsone (III) has never been called in question. Explanations for the

existence of the colored carbinol, however, have implied the suggestion that it is a hydrate of the fuchsone,³ or that it is a mixture of the benzenoid carbinol with small amounts of the highly colored fuchsone as impurity. Chemical evidence by Gomberg and co-workers⁴ has definitely shown that the colored carbinol is not an impure benzenoid carbinol.

This work was undertaken in order to obtain further data concerning this class of compounds with the hope that certain effects that were observed in previous work in regard to the position and height of the absorption bands might now be explained.

¹ The material in this and the succeeding paper comprises a portion of a thesis presented by M. B. Geiger to the Graduate School of the University of Michigan in partial fulfilment of the requirements for the degree of Doctor of Philosophy, 1931.

² (a) Anderson and Gomberg, *THIS JOURNAL*, **50**, 203 (1928); (b) Anderson, *ibid.*, **51**, 1889 (1929).

³ (a) Auwers and Schröter, *Ber.*, **36**, 3247 (1903); (b) Orndorff, Gibbs, McNulty and Shapiro, *THIS JOURNAL*, **49**, 1546 (1927). In the latter article the statement is made that "Gomberg has shown that fuchsone readily takes up water to form the quinoid hydrate." The word hydrate in this connection is ambiguous and was not used by Gomberg. He states in the article from which the above inference was drawn [*THIS JOURNAL*, **35**, 1037 (1913)] "nor does either of the two molecules contain water of crystallization."

⁴ Gomberg, *THIS JOURNAL*, **35**, 1035 (1913); Gomberg and Van Stone, *ibid.*, **38**, 1577 (1916).

In Figs. 1, 2, 3 and 4, respectively, are given the curves for the quantitative spectra of the methane, colorless carbinol (except for the 3-chloro-), colored carbinol, and the fuchsone of each of the following: 3-chloro-4-hydroxy-, 3-bromo-4-hydroxy-, 3,5-dichloro-4-hydroxy- and 3,5-dibromo-4-hydroxy-triphenylcarbinol. The methanes and colorless carbinols are undoubtedly benzenoid in constitution while the fuchsones contain a quinonoid nucleus.

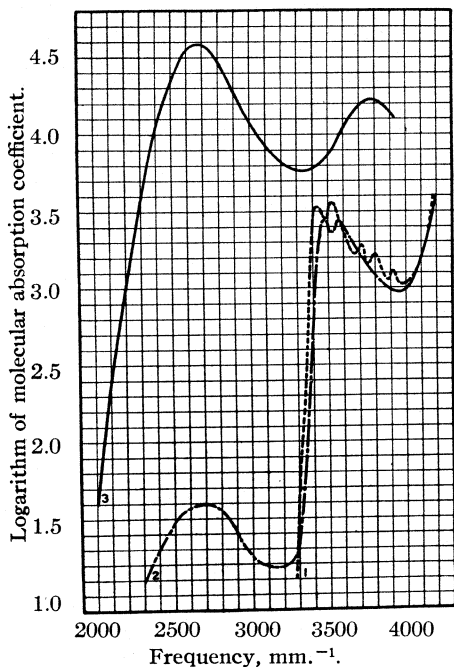

Fig. 1.—3-Chloro-4-hydroxytriphenylcarbinol: 1, methane; 2, carbinol, colored; 3, fuchsone.

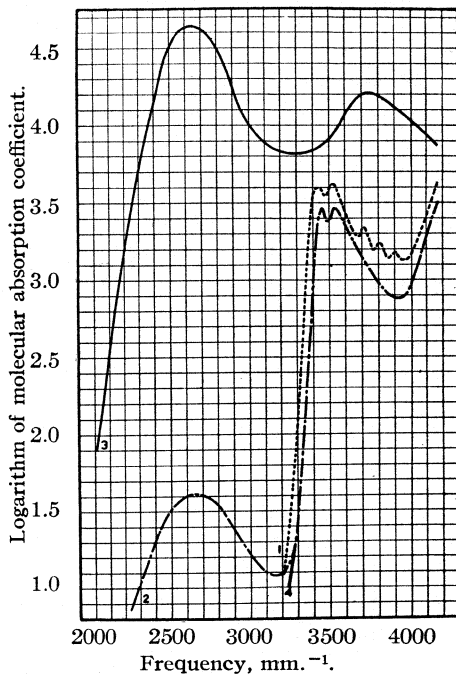

Fig. 2.—3-Bromo-4-hydroxytriphenylcarbinol: 1, methane; 2, carbinol, colored; 3, fuchsone; 4, carbinol, colorless.

The similarity of the curves for the corresponding derivatives in each of the groups is very striking. All of the fuchsones have an intense absorption band on the edge of the visible region of the spectrum and another band in the ultraviolet. The methanes have no absorption in the visible region but have a series of bands in the ultraviolet between frequencies 3400 and 4000 mm^{-1} . The benzenoid carbinols show no absorption in the visible region of the spectrum, and their ultraviolet absorption consists of a number of fine bands very similar to those of the methanes. The colored carbinols have spectra resembling both the fuchsones and the benzenoid carbinols in that they have an absorption band in the visible region of the spectrum and the ultraviolet absorption is practically identical with the ultraviolet absorption of the colorless carbinol.

The progressive substitution of one chlorine atom, one bromine atom, two chlorine atoms and two bromine atoms for the hydrogens in the ortho positions to the nuclear hydroxyl group in the 4-hydroxytriphenylcarbinol compounds causes a shift in the intense absorption band for the fuchsones toward the longer wave lengths. A similar change is noted for the band in the visible for the colored carbinols and for the two most persistent bands in the ultraviolet for the methanes, colorless carbinols and colored carbinols.

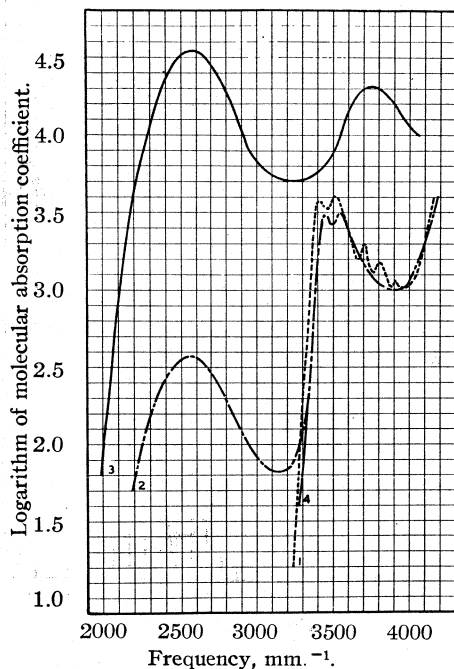

Fig. 3.—3,5-dichloro-4-hydroxytriphenylcarbinol: 1, methane; 2, carbinol, colored; 3, fuchsones; 4, carbinol, colorless.

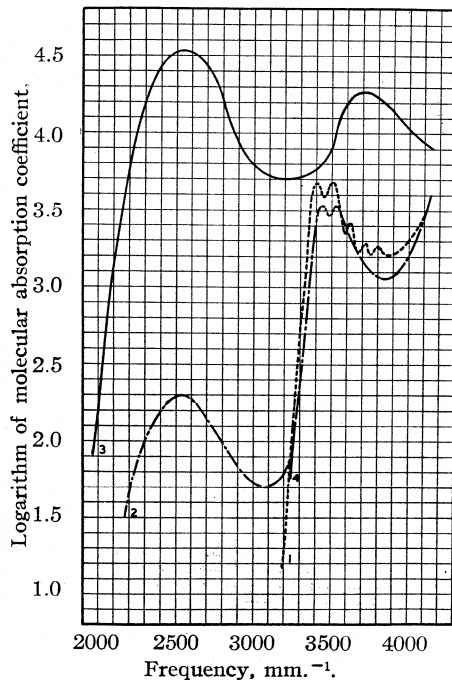

Fig. 4.—3,5-Dibromo-4-hydroxytriphenylcarbinol: 1, methane; 2, carbinol, colored; 3, fuchsones; 4, carbinol, colorless.

The height of the quinonoid band⁵ for the various fuchsones is approximately the same. In all cases which have been observed the quinonoid band for the colored carbinols is much lower than the quinonoid band for the fuchsones; Table I lists the heights of the quinonoid bands of the fuchsones and the colored carbinols expressed as logarithms of the molecular absorption coefficients. If the colored carbinol were a hydrate of the corresponding fuchsones such a variation would not be expected. The curve for the hydrate calculated on the basis of fuchsones should be 93.5%

⁵ The band which occurs in the edge of the visible and near ultraviolet in the spectra of these fuchsones and colored carbinols will be called, for convenience of description, the quinonoid band.

TABLE I
HEIGHTS OF THE QUINONOID BANDS

3-X,5-X ₀ ,4-hydroxy- triphenylcarbinol	^a		^b		^c		^d		^e	
	X H	X ₀ H	X H	X ₀ Cl	X H	X ₀ Br	X Cl	X ₀ Cl	X Br	X ₀ Br
Fuchsones		4.48		4.58		4.64		4.54		4.53
Colored carbinols		2.52		1.59		1.61		2.57		2.30

as high as the curve for the fuchsones. The difference which has been found in the height of the bands is, therefore, much more than would be accounted for by the effect of a molecule of water in so heavy a molecule as the fuchsones, even assuming that it were a hydrate and that it would all remain hydrated in so dilute an ether solution.

It has been found that the colored carbinols with symmetrical substitution in the nucleus (a, d, e, Table I) have quinonoid bands whose heights are of the same order of magnitude. The height of the quinonoid bands for the colored carbinols with unsymmetrical substitution (b and c, Table I) is even lower than the band for those with symmetrical substitution, but when compared with each other, they are of the same order of magnitude.

Figure 5 gives the position of the peaks or frequencies of maximum absorption of the bands for the colored carbinols (Q) and the fuchsones (F) of the different carbinols studied in this investigation and also includes those described in the papers previously referred to. It will be noted that in the case of some of the carbinols the frequency of maximum absorption of the quinonoid band for the colored carbinol as compared to the frequency of maximum absorption of the quinonoid band for the corresponding fuchsones is shifted toward the shorter wave lengths while in other cases it is shifted toward the longer wave lengths. The displacement of the peaks for the colored carbinols and the corresponding fuchsones is greater than the experimental error of determining the position of these peaks for the compounds indicated as a, c, d, f, g, h and i while for b and e the displacement is less than the experimental error. In a, h and i the peak for the fuchsones compared to that of the corresponding carbinol is displaced toward the shorter wave lengths, while in all the other groups the displacement is toward the longer wave lengths. These data allow an interesting observation to be made. When the groups in the ortho position to the nuclear hydroxyl are the same (a, h and i) the displacement of the peak for the quinonoid band of the colored carbinol compared to that of the fuchsones is toward the longer wave lengths. If the groups in the ortho position to the nuclear hydroxyl are not alike, then the displacement is in the opposite sense. It does not seem likely that this relation is due to chance, since no inconsistencies have been observed in any of the compounds studied.

The fact that the position of the quinonoid band for the colored carbinol and the quinonoid band for the corresponding fuchsones is not at the same

frequency is a positive indication that the colored carbinol is not the colorless carbinol with small amounts of fuchsone as impurity. The two effects, namely, the displacement of the quinonoid band for the colored carbinol as compared to that of the fuchsone and the lowering of the quinonoid absorption band of the colored form of 4-hydroxytriphenylcarbinol by a

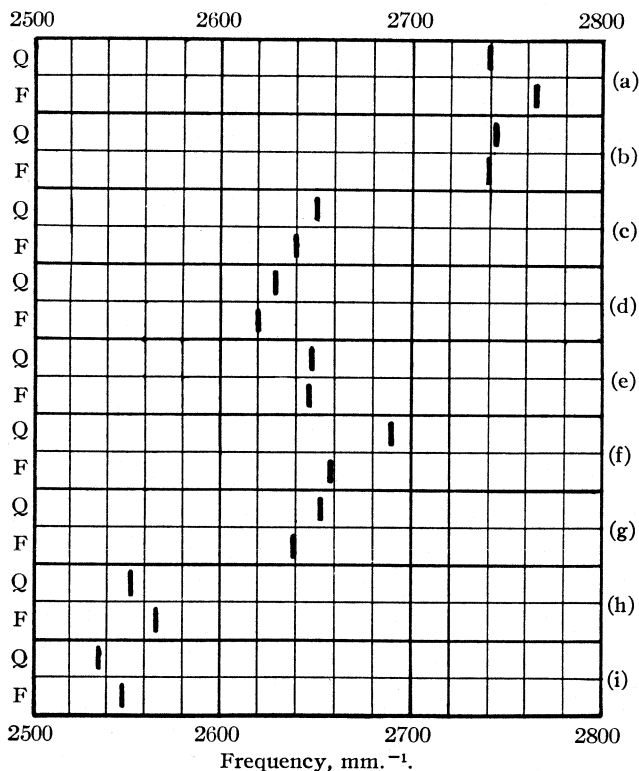

Fig. 5.—Q = colored carbinol; F = fuchsone: (a) 4-hydroxytriphenylcarbinol; (b) 3-methyl-4-hydroxytriphenylcarbinol; (c) 3-methyl-5-chloro-4-hydroxytriphenylcarbinol; (d) 3-methyl-5-bromo-4-hydroxytriphenylcarbinol; (e) 3-methoxy-4-hydroxytriphenylcarbinol; (f) 3-chloro-4-hydroxytriphenylcarbinol; (g) 3-bromo-4-hydroxytriphenylcarbinol; (h) 3,5-dichloro-4-hydroxytriphenylcarbinol; (i) 3,5-dibromo-4-hydroxytriphenylcarbinol.

definite amount, both of which phenomena occur when one and two of the hydrogens adjacent to the nuclear hydroxyl group are replaced, appear to be evidence in favor of the hypothesis that the ring in which the substitution has been made has a very direct influence upon the nature of the electron transition which produces this band and also upon the probability of the occurrence of this transition.

Experimental

The apparatus and the methods used for obtaining the quantitative absorption spectra as well as the methods employed for determining the frequencies of maximum absorption have been described.²

The four fuchsones studied in this investigation were each prepared according to the method of Gomberg and Van Stone.⁴ They were all carefully crystallized from ether which showed no selective absorption between 2300 and 7500 Å. The four colored carbinols were prepared by adding hot water to a solution of the corresponding fuchsone in glacial acetic acid until the concentration of the acetic acid in the solution had been reduced to 60%. After allowing the mixture to cool the crystals were filtered off and dried in a vacuum desiccator over soda lime. Each of the three colorless carbinols was prepared by dissolving the corresponding fuchsone in normal alkali and treating the clear, cold solution with ammonium chloride. The precipitate was filtered off and crystallized from optically clear ether and hexane. The four methanes that were studied were prepared by reducing the corresponding fuchsone with zinc dust and glacial acetic acid. Each of them was crystallized from optically clear hexane. The melting points of the compounds prepared as described above are as follows (degrees centigrade):

	Methane	Colorless Carbinol	Colored Carbinol	Fuchsone
3-Chloro-4-hydroxytriphenyl	73		124-125	161
3-Bromo-4-hydroxytriphenyl	79	108.5-109	105-105.5	139.5
3,5-Dichloro-4-hydroxytriphenyl	105	132	133-134	216
3,5-Dibromo-4-hydroxytriphenyl	130	136	136-137	233

Summary

1. Curves have been prepared which show the quantitative absorption spectra of the methane, colored carbinol and fuchsone of each of the following compounds: 3-chloro-4-hydroxytriphenylcarbinol, 3-bromo-4-hydroxytriphenylcarbinol, 3,5-dichloro-4-hydroxytriphenylcarbinol and 3,5-dibromo-4-hydroxytriphenylcarbinol together with the curves for the colorless carbinols of the last three compounds.

2. Symmetrical or unsymmetrical substitution in the ortho positions to the nuclear hydroxyl group of 4-hydroxytriphenylcarbinol has been shown to have a definite effect upon the height of the quinonoid band for the colored carbinol; symmetrical substitution producing a greater absorption.

3. The direction of the displacement of the quinonoid band for the colored carbinol, in reference to the position for the quinonoid band for the corresponding fuchsone of the 4-hydroxytriphenylcarbinol series has also been found to be dependent upon the groups substituted in the ortho positions to the nuclear hydroxyl. If the two groups are the same the displacement is in one direction, while if they are different, the displacement is in the opposite direction.

THE TAUTOMERISM OF QUINONEOXIME AND PARA-NITROSOPHENOL

BY LEIGH C. ANDERSON AND M. B. GEIGER

RECEIVED FEBRUARY 8, 1932

PUBLISHED AUGUST 5, 1932

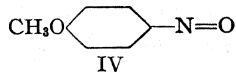

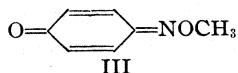

The chemical reactions and the methods of preparation of quinoneoxime (I) indicate that it is in tautomeric equilibrium with *p*-nitrosophenol (II); the relative amounts of the two substances present being dependent upon the solvent and conditions which are employed.

It has been generally accepted that the methyl ethers of tautomeric substances do not undergo tautomerization and that in many instances each can be obtained pure. A comparison of the physical properties of a solution of the tautomeric mixture of non-methylated substances with solutions of each of the corresponding methyl ether isomers has been used in investigations of compounds such as isatin, acetoacetic ester, etc., to determine the extent to which each of the tautomeric forms occurs in the equilibrium mixture. This procedure has been followed in the present investigation in the case of the mixture of quinoneoxime and *p*-nitrosophenol. Ether has been chosen as the solvent because it is optically

clear in the visible and ultraviolet regions, it is chemically inert toward solutes and also because all the compounds included in this work are monomolecular in this solvent. Sluiter¹ has shown that *p*-nitrosophenol, which is polymolecular in most solvents, is monomolecular in ether regardless of the concentration of the solution.

The methyl ethers of quinoneoxime (III) and of *p*-nitrosophenol (IV) have been described in the literature. A comparison of the quantita-

tive absorption spectrum of the tautomeric mixture of quinoneoxime and *p*-nitrosophenol with that of each of the ethers should indicate which form is present to the greater extent. These curves are presented in Fig. 1. The similarity in the curves for quinoneoxime methyl ether and the tautomeric mixture is obvious. The absorption curve for *p*-nitrosoanisole differs from the curves of the other solutions in that it shows no indication of fine bands in the edge of the visible region and the band in the ultraviolet is much narrower.

The similarity of the curves for the tautomeric mixture and quinoneoxime methyl ether leaves no doubt that the mixture in ether solution is mainly in the quinoneoxime form. On the assumption that the curves for pure quinoneoxime and pure *p*-nitrosophenol should be similar each to the curve for the corresponding methyl ether, it is possible from Fig. 1 to make an estimate of the composition of the mixture. A comparison of the

Fig. 1.—1, Tautomeric mixture of quinoneoxime and *p*-nitrosophenol; 2, *p*-nitrosoanisole; 3, quinoneoxime methyl ether.

¹ Sluiter, *Rec. trav. chim.*, **25**, 8 (1906).

quantitative absorption curves which are given in Fig. 2 for hydroquinone and its mono- and dimethyl ethers indicates that in these compounds the principal effect produced upon methylation is a displacement of the absorption toward the shorter wave lengths.

An examination of the curves in Fig. 1 shows that between frequencies 2000 and 2500 mm^{-1} the *p*-nitrosophenol tautomer should have little influence on the height of the curve of the mixture; and since curve 1 is about 70% as high as curve 3 within this region, the mixture should contain approximately 70% quinoxneoime and 30% *p*-nitrosophenol. Using

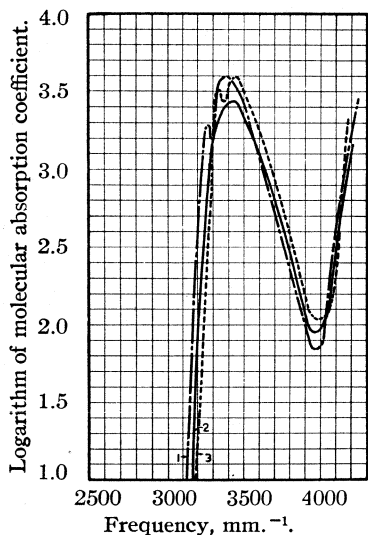

Fig. 2.—1, Hydroquinone; 2, hydroquinone monomethyl ether; 3, hydroquinone dimethyl ether.

values corresponding to such a mixture of methyl ethers and extending the calculations out to the regions where both compounds influence the absorption curve of the mixture, the values indicated by the circles in Fig. 1 are obtained. It will be seen that the agreement is very good except near the top of the absorption band in the ultraviolet. The disagreement within this region probably indicates that our assumption of the close similarity of the curves of the methyl ethers to the corresponding hydroxy compounds does not hold within these limits. Studies of solutions of this tautomeric mixture in other solvents are being carried on.

The curves for the quantitative absorption spectra for quinone, quinonechlorimine and quinonedichlorodiimine are shown in Fig. 3, and the curves for quinone and quinonedioxime are shown in Fig. 4.

In the latter figure a curve has been included for the absorption spectrum that we should expect to obtain from a sample of pure quinoneoxime. That portion of the curve has been omitted where the previously made assumptions do not seem to apply. The frequencies of maximum absorption for the bands in the visible which are indicated in Fig. 4 and in the table are the same as those found for quinoneoxime in the tautomeric mixture. The compounds in Fig. 3 are the derivatives of quinone in which the ketonic oxygen has been replaced by the $=\text{NCl}$ group, and the compounds in Fig. 4 are the derivatives of quinone in which the ketonic oxygen has been replaced by the $=\text{NOH}$ group.

The progressive changes which are noted on the successive substitution of the $=\text{NCl}$ group for a $=\text{O}$ group in quinone are the shifting of the ultraviolet band toward the visible and a shifting of the bands in the visible

region toward the ultraviolet. In quinonedichlorodiimine we find only one intense band. The ultraviolet band as we pass through the series successively persists over a greater dilution being least for quinone and greatest for quinonedichlorodiimine. In Fig. 4, similar changes are noted for the $=\text{NOH}$ compounds. The curves for quinonechlorimine and the calculated one for quinoneoxime are very similar to each other, as are also the curves for quinonedioxime and quinonedichlorodiimine.

The quantitative absorption curves for the reduction products of each: quinone, quinoneimine and quinonediimine, namely, the curves for hydroquinone, *p*-aminophenol and *p*-phenylenediamine, are given in Fig. 5.² The solvent used was absolute ether. *p*-Aminophenol and *p*-phenylenediamine may be considered as derived from hydroquinone by

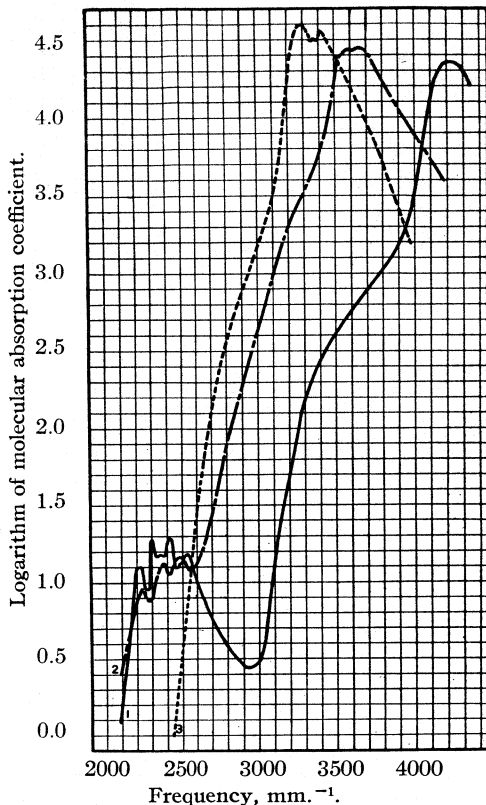

Fig. 3.—1, Quinone; 2, quinone chlorimine; 3, quinonedichlorodiimine.

the replacement of the hydroxyl groups of hydroquinone with amino groups. The regular changes in absorption curves which accompany these replacements are, first, a shifting of the absorption toward the visible region and, second, a decrease in its persistence.

The question of the structure of quinone and its derivatives has received considerable attention in the past. The assignment of the di-

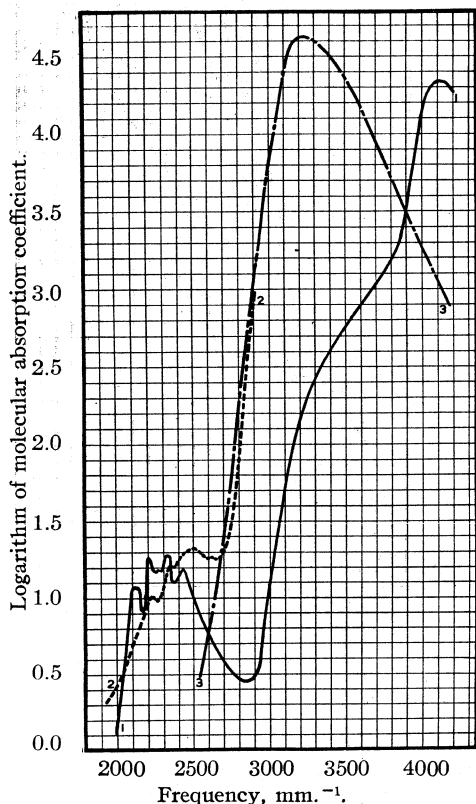

Fig. 4.—1, Quinone; 2, quinoneoxime (calcd.); 3, quinonedioxime.

ketonic formula to quinone has been favored by evidence obtained by Garner and Sugden³ from parachor measurements, by Pascal⁴ from magnetic susceptibility measurements and by Light⁵ from absorption spectra data. The most recent data which favor the peroxidic formula were presented by Binder⁶ from heats of combustion. If the quinone derivatives are better represented by the peroxidic structure, then the general location and the height of the absorption bands of these derivatives should resemble those of hydroquinone and its derivatives, since under such an assumption, they would all contain a benzenoid nucleus. That there is, however, no such resemblance is evident from a comparison of the curves in Figs. 2 and 5 with those in Figs. 3 and 4. The compounds of known benzenoid structure of Figs. 2 and 5 have no absorption

in or adjacent to the visible region of the spectrum and the absorption band in the ultraviolet is only about one-tenth as persistent as the ultraviolet band for the quinone derivatives. Our conclusion, therefore, is that the diketonic structure best explains the data obtained from the absorption spectra.

Experimental

The instruments and methods used for obtaining the quantitative absorption curves and points of maximum absorption have been described.⁷ In the purification of all the compounds except quinone, *p*-aminophenol and *p*-phenylenediamine the final recrystallization was carried out from a solvent which showed no selective absorption between 2300 and 7500 Å. The material which on solution in ether produced the tautomeric mixture of quinoneoxime and *p*-nitrosophenol was prepared by the action of nitrous acid on phenol. The product was first crystallized from water using charcoal for decolorizing, and finally from ether; m. p. 128–129°.

***p*-Nitrosoanisole.**—*p*-Nitrosoanisole was reduced to the corresponding hydroxylamine and this compound was oxidized to the nitroso derivative by the method described by Rising.⁸ The product was purified by distillation with steam and was crystallized from hexane; m. p. 22.5°.

Quinoneoxime methyl ether was obtained by the methylation of quinoneoxime with diazomethane.⁹ It was crystallized from hexane; m. p. 82°.

***p*-Quinone** was prepared by the oxidation of hydroquinone with chromic acid. The crude product was purified by several successive sublimations; m. p. 116°.

Quinonechlorimine was obtained by the action of sodium hypochlorite on the hydrochloride of *p*-aminophenol.¹⁰ The material was crystallized from hexane; m. p. 87°.

Quinonedichlorodiimine resulted from the oxidation of *p*-phenylenediamine hydrochloride with sodium hypochlorite.¹⁰ The product was crystallized from hexane; m. p. 128° with decomposition.

Quinonedioxime was prepared by the action of hydroxylamine hydrochloride on quinoneoxime.¹¹ The material was crystallized from ether; m. p. 242° with decomposition.

Hydroquinone.—Kahlbaum's product was crystallized from water using charcoal for decolorizing; m. p. 169°.

Kahlbaum hydroquinone monomethyl ether was crystallized from hexane; m. p. 55.5°.

The **dimethyl ether of hydroquinone** was obtained by crystallizing an Eastman product from 95% alcohol; m. p. 56°.

Eastman ***p*-aminophenol** was purified by sublimation at 180° under reduced pressure (2 mm.); m. p. 184° with decomposition.

Eastman's *p*-phenylenediamine was sublimed at 200° under reduced pressure (2 mm.); the pure white product melted at 140°.

Summary

1. The quantitative absorption curves for ether solutions of *p*-nitrosoanisole, the methyl ether of quinoneoxime and of quinoneoxime have been determined. The spectroscopic results indicate that quinoneoxime and *p*-nitrosophenol are in tautomeric equilibrium in ether solutions in the ratio of approximately seven parts of the former to three parts of the latter.

2. The quantitative absorption spectra of ether solutions of quinone, quinoneoxime, quinonedioxime, quinonechlorimine and quinonedichlorodiimine together with the curve for the tautomeric mixture of quinoneoxime, and *p*-nitrosophenol have been obtained. The conclusion is drawn from these data that the diketonic or quinonoid formula represents the correct structure for quinone and the quinone derivatives.

3. The quantitative absorption curves for the ether solutions of hydroquinone, *p*-aminophenol, *p*-phenylenediamine, hydroquinone monomethyl ether and hydroquinone dimethyl ether have been obtained.

4. The frequencies of maximum absorption for all the compounds studied in this investigation have been ascertained and these values are presented in a table.

REACTIONS IN LIQUID HYDROGEN SULFIDE. IX. REACTIONS BETWEEN PERSULFIDES OF HYDROGEN AND ORGANIC COMPOUNDS

BY WALTER BERNARD KING¹ AND JOHN A. WILKINSON

RECEIVED FEBRUARY 23, 1932

PUBLISHED AUGUST 5, 1932

The persulfides of hydrogen bear the same relationship to liquid hydrogen sulfide as does hydrogen peroxide to water. Since hydrogen sulfide dissolves organic bodies very readily, more readily than does water, one would expect that the hydrogen persulfides would react with organic compounds more readily than does hydrogen peroxide but in a similar manner.

Up until the work of Bloch and Höhn,² Schenck and Falcke³ and Brunner and Vuillenmuir⁴ the properties of the hydrogen persulfides were either little known or the data given were incorrect.

The reactions of hydrogen peroxide on organic compounds were in-

¹ This work is from a portion of a thesis presented to the Graduate Faculty of Iowa State College in partial fulfilment of the requirements for the degree of Doctor of Philosophy.

² Bloch and Höhn, *Ber.*, **41**, 1961–1980 (1908).

³ Schenck and Falcke, *ibid.*, **41**, 2600 (1908).

⁴ Brunner and Vuillenmuir, *Schweiz. Med. Wochschr.*, **46**, 436 (1908).

vestigated by Fenton⁵ and Walton and Jones,⁶ who showed that in the presence of ferrous salts the following reactions took place with hydrogen peroxide. Glycolic acid is changed to glyoxylic acid, tartaric acid to dihydroxymalic acid, primary amines to aldehydes, piperidine to glutaric acid, benzene to phenol, benzonitrile to benzamide, azo compounds to azoxy compounds and phenol to dihydroxyphenol or quinone.

It will be noticed that all of the above reactions are of an oxidizing nature, either removing hydrogen or adding oxygen. Walton and Jones⁶ also showed that substances which will catalyze reactions of hydrogen peroxide in water solution will catalyze similar reactions in organic solvents.

In endeavoring to duplicate similar reactions with persulfides, alkaline solutions cannot be used because alkalies will decompose the persulfides very rapidly. Catalysts such as ferrous salts cannot be used because the persulfides are decomposed by them. Walton and Parsons⁷ showed that the persulfides are decomposed by many oxides and inorganic salts. It was found, however, that solutions of the persulfides in organic solvents without catalysts could be used in bringing about similar reactions.

Experimental

Preparation of the Persulfides.—The persulfides were prepared by the method of Walton and Parsons⁷ by heating a mixture of sodium sulfide and sulfur and water for several hours on a water-bath. The flask containing the mixture was closed with a Bunsen valve to prevent the entrance of air. This made it unnecessary to pass hydrogen through the solution during the heating. The solution of the sodium persulfide thus formed was allowed to run beneath the surface of concentrated hydrochloric acid kept at a temperature of -10 to -4° . As soon as a brown film started to form on the surface of the acid, showing that the persulfides were beginning to decompose, a fresh supply of acid was used. An emulsion of the persulfides was first formed which settled after several hours to form a yellow liquid. This was washed with distilled water in a separatory funnel and dried over phosphorus pentoxide. The material thus obtained is a mixture of the di- and the trisulfides and these may be separated and purified by fractional distillation in quartz apparatus as described by Walton and Parsons. The yield of the trisulfide obtained in this way was about 10% of the total crude persulfides. The crude persulfide mixture and the pure trisulfide react in the same manner so that in most of the work only the crude material was used.

Reactions of Liquid Hydrogen Sulfide on Styrene and Amylene.—Ten grams of each of these two bodies were sealed in glass tubes with four cubic centimeters of liquid hydrogen sulfide at the temperature of an ether-solid carbon dioxide bath, and allowed to come to room temperature and stand for two weeks. In neither case was any reaction apparent. When the hydrogen sulfide was allowed to evaporate, the styrene and amylene were recovered unchanged. This shows the stability of these two unsaturated bodies toward liquid hydrogen sulfide and indicates that any reduction or oxidation brought about by the persulfides could not be due to the hydrogen sulfide formed by the decomposition of the persulfide.

⁶ Walton and Jones, *THIS JOURNAL*, **38**, 1956 (1916).

⁷ Walton and Parsons, *ibid.*, **43**, 2546 (1921).

Reaction of Hydrogen Persulfides with Styrene.—To find the effect of the persulfides on a double bond between two carbon atoms styrene was treated with some of the crude persulfide. Twenty grams of the crude sulfide was added to forty grams of styrene dissolved in 180 cc. of benzene. The mixture became warm and was colored first yellow and then green and finally became milky. After standing for a few hours the mixture was refluxed at the temperature of boiling benzene for six hours. Upon cooling, crystals of sulfur were precipitated, leaving a clear yellow solution. Ammonia gas was passed through the solution for five minutes and a heavy orange precipitate was formed. This was filtered off and discarded and the benzene removed from the filtrate by vacuum distillation. The liquid residue, weighing 42 g., was purified by dissolving in ether and passing ammonia gas into this solution until no more sulfur precipitated. The sulfur was filtered out and the ether evaporated, leaving a clear light yellow liquid. This was heated in a water-bath under a pressure of 30 mm. to remove any unchanged styrene. The ether solution could be changed into a wine colored one by passing ammonia gas into it but no sulfur could be precipitated. The yellow color would return to the solution if either air or illuminating gas was passed into the solution to remove the ammonia. A similar product may be made by adding pure styrene to the persulfide without the addition of a solvent providing the temperature is kept below 40°. An analysis of the liquid for the sulfur content showed 37.44 and 37.40% while the calcd. for the compound $\text{C}_6\text{H}_5\text{—CH—CH}_2$ is 38.12% and for the compound $\text{C}_6\text{H}_5\text{—CH—CH}_2$ is 23.55%. Bloch,

Höhn and Bugge⁸ reported a similar compound but their analysis for the percentage of sulfur was much lower (29.8). This is probably due to the use of $(\text{NH}_4)_2\text{S}$ in dissolving out the excess of sulfur instead of precipitating it with ammonia gas. Undoubtedly some of their compound was decomposed and part of the sulfur they removed came not from free sulfur but from the chemically combined sulfur.

The material could not be distilled as it decomposes to give styrene and sulfur. It does not add bromine and is stable toward hypochlorites and alkalis. Concentrated nitric acid oxidizes it completely to water, carbon dioxide and sulfuric acid. A molecular weight determination gave a value of 252, showing that some polymerization had occurred. The persulfide in this reaction has acted as an oxidizing agent, adding sulfur at the double bond. There was no evidence of there being any reducing action to form ethylbenzene.

Reaction of the Persulfides with Amylene.—As another compound containing a double bond between two carbon atoms amylene, the unsymmetrical methylethylethylene, was used. Both the pure trisulfide and the crude mixture of the persulfides gave the same reaction with the body.

Ten grams of the pure trisulfide was added to 50 cc. of amylene. No reaction took place at first but after a few hours standing a compound with an odor similar to a mercaptan was formed. After a week the crystals of sulfur which had formed were filtered off and the greenish yellow liquid was heated in a water-bath under a vacuum but nothing was distilled over. When the liquid was treated with ether, sulfur was precipitated in a large amount. On passing ammonia gas into the ether solution a colloidal orange precipitate formed which after standing for several days settled to a clear liquid with a strong odor of a mercaptan. After removing the ether the light yellow liquid did not add bromine, and was stable toward hypochlorites, alkalis and dilute acids. An analysis of this liquid for the per cent. of sulfur showed 45.38 and 44.84 while the theoretical for the compound $\text{C}_6\text{H}_{10}\text{S}$ is 31.37% and for $\text{C}_6\text{H}_{10}\text{S}_2$ is 47.76%. The boiling point of the liquid is 132–135° under a pressure of 8 mm. although different preparations of the liquid vary

⁸ Bloch, Höhn and Bugge, *J. prakt. Chem.*, **82**, 473–485 (1908).

some from this. The liquid is probably not entirely pure but contains some of both the mono- and di-sulfur compound. Here again the action of persulfides is one of oxidation or addition of sulfur at the double bond.

Reaction of the Persulfides with Azobenzene.—As hydrogen peroxide forms azoxybenzene from azobenzene the similar reaction between the persulfides and azobenzene should give a thioazoxybenzene. When benzene solutions of the persulfides and the azobenzene were mixed, no reaction was apparent for an hour. After standing for three hours and then refluxing at the temperature of boiling benzene for twenty minutes and cooling, crystals of sulfur were deposited. The sulfur was filtered out and the benzene removed by distillation. The solid residue was purified by recrystallizing several times from 95% ethyl alcohol. The crystals thus obtained melted at 126° and a mixed melting point determination showed it to be hydrazobenzene. No sulfur was added at the double bond as in the case of the peroxide on azobenzene.

Reaction of the Persulfides with Benzenediazonium Chloride.—In order to observe the effect of the persulfides on a triple bond between two nitrogen atoms the compound benzene diazonium chloride was used. If the dry material is added to the liquid persulfide at room temperature the reaction is of explosive violence. If the solid is cooled and the sulfide added slowly the reaction is somewhat slower and by dissolving in either carbon disulfide or benzene it becomes quite mild. From a carbon disulfide solution a large amount of hydrogen chloride is liberated, a red liquid forms, and a buff colored solid with the odor of a mercaptan remains. This solid is explosive on heating, showing that some of the diazonium compound still remains unacted upon. The difficulty in studying this reaction is in finding some medium which will dissolve both the persulfide and the diazonium chloride. The former dissolves quite readily in organic solvents but the latter being of the nature of a salt is insoluble in such solvents. This reaction is being studied further.

Conclusions

1. While liquid hydrogen sulfide does not react with either styrene or amylene the persulfides do react, adding the group —S—S— at the double bond. This reaction is essentially one of oxidation similar to the action of hydrogen peroxide.
2. The persulfides form hydrazobenzene from azobenzene, which is essentially a reducing reaction and differs from the reaction with hydrogen peroxide.
3. With diazonium chloride the reaction with the persulfides is so vigorous that it takes place with explosive violence unless it can be regulated by the use of a solvent such as carbon disulfide.

AN ESTIMATION OF SOME SPECTRAL PROPERTIES OF ELEMENT 87

BY HERMAN YAGODA*

RECEIVED MARCH 4, 1932

PUBLISHED AUGUST 5, 1932

Evidence for the existence of minute quantities of element 87 in several alkali-bearing minerals has recently been secured by Allison and his collaborators¹ using the magneto-optic method of analysis, and also by Papish and Wainer² through x-ray analysis of a concentrate from the mineral samarskite. The latter investigators have questioned the evidence adduced from the magneto-optic analyses, claiming that the minima attributed to the missing alkali element are also given by certain complex ions, as SnCl_3^+ and ReCl^+ . More refined measurements of the position of the minima by McGhee and Lawrenz³ and by Allison and his collaborators⁴ reveal that a conflict between the points used to identify element 87 and those given by the complex ions is not probable.

The delicacy of spectroscopic analysis is well known, and the fact that two homologs of element 87, rubidium and cesium, were first discovered in that way by R. Bunsen and G. Kirchhoff suggests that the spectroscopic method of analysis may also prove useful in establishing the existence of the element in question. The several investigators^{2,5} who have approached this problem placed little weight on the negative results obtained from their spectroscopic analyses, claiming that the spectral lines of the principal series are located in the far-red end of the spectrum where visual and photographic sensitivity are very poor. It is true that by extrapolating a wave length-atomic number function through potassium, rubidium and cesium, a value for the first transition is obtained that locates the line in the red end of the spectrum, but such an extrapolation, as will soon be shown, is not justified. Furthermore, in the practical detection of traces of potassium, rubidium and cesium, the second transition of the series is used for the identification of the element, as the respective lines reside in the violet region of the spectrum where photographic sensitivity is close to its maximum value.

The present writer has shown that the $1^2\text{S}-3^2\text{P}_2$ transition has an approximate wave length of 4260 Å. This value was obtained through the use of an empirical observation that the quantum defect of a given elec-

tronic level (Q) in a sequence of homologous elements is approximately a linear function of the total quantum number (n) of the valence electron.⁶ Data are lacking by which this figure can be directly compared, but its validity can be partially tested by the ionization potential predicted by the same method, as the latter can be calculated from several independent considerations.

It is generally known that in the periodic classification of the elements the properties of the members of the second and fourth periods exhibit anomalous behavior when the properties of a given group of elements are considered. The question arises whether members in the seventh period, and element 87 in particular, are also exceptions to the rule governing the properties of the group. The writer has been interested in this problem for some time, as it is of practical importance in developing a method for the concentration of the missing element.⁷ The chief evidence available for the solution of this problem resides in the measurements of the optical spectrum of radium and its analysis into terms by Hicks.⁸ When the spectral properties of RaII are compared with those of the other alkaline earths, it is observed that the wave lengths of the first two transitions are anomalous with respect to the similar lines of calcium, strontium and barium, and that both the ionization potential and the doublet separation of the first transition exhibit marked departures from the relations connecting the respective properties of the other alkaline earth elements. Such an exceptional behavior might be expected from the intrusion of the rare-earth elements in the sixth period. In formulating a relationship between the ionic potential and the ionization potential, Cartledge⁹ has shown that for ions of only slightly larger size than cesium and barium, unusual behaviors can be expected owing to the great polarizing effect of the valence electron upon the ion. It is highly probable that the spectroscopic properties of element 87 will not follow the same trend as the triad, potassium, rubidium and cesium, and that any theoretical or empirical method which permits the correct prediction of the known properties of the singly ionized radium atom may also furnish a correct guide to the unknown properties of the neutral eka-caesium atom.

Table I represents a summary of the different methods employed in the estimation of the probable ionization potential of element 87. The first value was calculated from deductions made by Fermi¹⁰ concerning the

¹⁰ Fermi, *Z. Physik*, **49**, 550 (1928).

quantum defects of the S levels of the elements as a function of their atomic number (N). Since Q is known, the value of the normal term can be calculated from the relationship

$$\nu = RZ_0^2/(n - Q)^2$$

where ν represents the wave number of the level, R the Rydberg constant and Z_0 the mean effective nuclear charge for the outer portion of the electronic orbit. For the element in question, $\nu = (109,680 \times 1^2)/(7 - 5.22)^2 = 34,600$, and the ionization potential, $V = \nu/8106 = 4.27$ volts.

Cartledge⁹ has shown that V can be calculated from the ionic potential (φ); this leads to a value of 4.55 volts. In a private communication Cartledge states: "This extrapolation value is in error, both on account of the disturbances introduced by the abnormally great polarizability of the seventh-period ions, and because of the uncertainty of the radius of the Ra^{++} ion."¹¹ From the several estimates of the radius, Cartledge finds that a probable value of the ionization potential resides between 4.2 and 4.4 volts.

The ratio of corresponding alkali and alkaline earth terms is nearly a constant for all the family members. The logarithm of this ratio plotted against n gives a smooth curve which can be extrapolated for the particular value of Eka-CsI/RaII with a fair degree of accuracy; for the 1^2S term this ratio is equal to 0.399. The value of 4.05 volts published by Bainbridge¹² was probably obtained by a similar calculation.

Hume-Rothery¹³ has recently demonstrated from considerations of the interatomic distance between atoms in metallic crystals that n^2V is a linear

TABLE I
IONIZATION POTENTIAL AND 1^2S TERM OF ELEMENT 87

Method	V	1^2S in ν	Quantity directly estimated

N , which is in very good agreement with the theoretic deduction, but that for the singly ionized atoms of the alkaline earth elements much better agreement with the observed data is obtained by using the relationship

$$\log n^2V = 0.6188 \log N + 1.4667$$

In both families, however, the first members, lithium and beryllium, show marked departures from these relationships, and when the above equation is extrapolated for V of RaII a value of 9.53 volts is obtained, whereas the constant calculated from the spectrum of the element is equal to 10.32 volts. The value of 3.89 volts estimated for element 87 from the relationship

$$n^2V = 9.836 N^{2/3} - 2.580$$

is probably also too low.

The atomic volume of eka-caesium can be estimated from the observation made by Hicks¹⁵ that in the alkali family the atomic volume (v) is expressed by the product of a constant k , and an integer s characteristic of the element. At 20° , $v = 11.5 \times 7 = 80.5$ cc. For the alkalis, the present writer has found that the ionization potential is connected with the atomic volume by the relationship $Vv^{1/4} = K$, where K is equal to 11.3 at 20° . These relationships indicate that the ionization potential of the element is 3.77 volts. However, lithium is a marked exception to both generalizations, hence the validity of the estimates for v and V for eka-caesium is also questionable. The lowest value of the ionization potential is that published by Loring;¹⁴ this was secured by extrapolation of the 1^2S levels through all the alkalis.

In the alkaline earth spectra V diminishes progressively from beryllium to barium, but the value for radium is anomalous, being greater than that of barium. Therefore, the ionization potential of eka-caesium will probably also be greater than that of cesium. Of the values calculated, those numerically less than 3.88 volts (which is the ionization potential of cesium) have but little significance. The average of the estimates above 3.88 volts is 4.11 ± 0.2 volts. The particular value of V calculated from the quantum defect rule, 4.06 volts, is in good agreement with the average value.

Doublet Separations.—Each transition of the principal series spectra of the alkali atoms consists of two members of which the line of shorter wave length is the more intense, and in which the distance between the lines increases progressively from lithium to cesium. The separation of the lines in the first and second doublets is an important criterion in the spectro-

¹⁵ Hicks, *Proc. Roy. Soc. (London)*, **83**, 226 (1910). Recently, W. Biltz has shown that the atomic volumes of the elements at the absolute zero (v_0) are expressed by the relationship, $v_0 = 11.3 n/Z_0$, where Z_0 is the periodic group number of the element. In many cases Hicks' integers (s) are identical to n ; *Z. physik. Chem.*, Bodenstein Festband, 198 (1931); also, W. Biltz and K. Meisel, *Z. anorg. Chem.*, **198**, 191 (1931).

scopic identification of the alkali element in question. Bell¹⁶ has demonstrated that for the known alkali atoms the doublet separations are expressed by the following equations:

$$2^2P_j: \log \Delta\nu = 2.1515 \log N - 0.9997; \text{ when } N = 87, \Delta\nu = 1490$$

$$3^2P_j: \log \Delta\nu = 2.160 \log N - 1.500; \text{ when } N = 87, \Delta\nu = 490$$

In view of the unusual relationships existent in the seventh period, I have thought it desirable to test similar equations on the alkaline earth family in order to judge how well they predicted the doublet separations of the singly ionized radium spectrum.

$$2^2P_j: \log \Delta\nu = 1.925 \log N - 0.134; \text{ when } N = 88, \Delta\nu = 4040$$

$$3^2P_j: \text{data are available only for the BeII and MgII spectra}$$

The observed doublet separation in the case of radium is 4857.2ν . The above expressions, therefore, need modification in order to account for members of the seventh period. When corrective terms are introduced into Bell's expressions, their general precision is lost, but the range of extrapolation is improved.

$$\text{Alkaline earth II spectra, } 2^2P_j: \log \Delta\nu = 1.537 \log (N - n^2) + 1.228; \text{ when } N = 88 \\ \Delta\nu = 4710$$

$$\text{Alkali I spectra, } 2^2P_j: \log \Delta\nu = 1.543 \log (N - n^2) + 0.771; \text{ when } N = 87, \Delta\nu = 1620$$

By extrapolating the ratio of the doublet separations of corresponding alkali and alkaline earth atoms a value of 1660ν is obtained for the 2^2P_j separation of element 87. Bainbridge¹² finds that this value is equal to $1675 \pm 50\nu$. It would seem then, that the separation of the first doublet is in the region of 1650ν .

However, a much larger value is obtained by applying the Landé relationship¹⁷

$$\Delta\nu = \frac{R\alpha^2 Z_0^2 Z_i^2}{(n^*)^3 l(l+1)} \left[1 + \frac{5}{8} (\alpha Z_i)^2 + \frac{53}{128} (\alpha Z_i)^4 + \dots \right]$$

Here α represents the fine structure constant $2\pi e^2/hc$, n^* and l the effective and azimuthal quantum numbers, and Z_i the effective nuclear charge for the inner portion of the electronic orbit. For the first transition of the singly ionized radium spectrum, $Z_i = 83.6$, $n^* = 2.784$, $Z_0 = 2$, $l = 1$ and $\alpha = 0.007284$.¹⁸ These quantities lead to a value of 4860ν , which is in excellent agreement with the observed doublet separation. In order that the Landé formula be applicable to the spectrum of element 87, n^* and Z_i for the 2^2P_2 and 3^2P_2 levels must be known. The mean value of n^* for the 2^2P_2 level is 2.365 .¹⁹ Landé has shown that Z_i differs only by a small

¹⁶ H. Bell, *Phil. Mag.*, [6] **36**, 337 (1918). The coefficients of the following two equations have been reevaluated to fit more recent measurements of the doublet separations.

¹⁷ Landé, *Z. Physik*, **25**, 46 (1924).

¹⁸ Birge, *Phys. Rev. Supplement*, **1**, 1 (1929).

¹⁹ This number was obtained by calculation from the mean of the two estimates available for the 2^2P_2 level of eka-caesium, viz., Bainbridge¹² finds $19,670\nu$, and from the quantum defect rule⁶ $19,540\nu$.

quantity from the atomic number of the atom. The screening constant (σ) is larger for an alkali atom than for the corresponding alkaline earth atom, the ratio of the two being 1.45 for the heavy atoms; also σ for RaII is less than that of BaII. The screening constant for the neutral eka-caesium atom should therefore be smaller than that of the neutral caesium atom, and be about 1.45 times as large as that of the singly ionized radium atom. A value of 6.4 satisfies these conditions; hence $Z_i = 80.6$, and $\Delta\nu$ for 2^2P_2 is equal to 1810ν . Assuming that Z_i for the second doublet is approximately the same as for the first, and that the value of 3^2P_2 is 9416ν ,⁶ then the displacement of the doublet in the violet region, as given by the Landé formula, is 600ν .

Now, the ratio of the displacements of the first and second doublets in the spectra of the neutral alkali atoms is nearly a constant for the group, and in the case of element 87 the ratio is probably 3.07. Dividing the average displacement of the first doublet, as found by the empirical relationships, by this figure gives as the displacement of the second doublet $1650/3.07 = 538\nu$. It can be assumed, then, that the distance between the two lines characterizing the doublet in the violet region is approximately $570 \pm 30\nu$. The average displacement for the first doublet is $1690 \pm 100\nu$.

Of the two lines constituting the doublet, the line of shorter wave length is the more intense. From the sum rule of Burger and Dorgelo²⁰ it may be expected that in the first doublet the major line will be twice as intense as the component of longer wave length; and from the empirical relationship formulated by Sambursky²¹ it may be conjectured that in the second doublet the major line will be 8–9 times more intense than its satellite.

By correlating the limit of spectroscopic detection with the sensitivity of the recording device for the wave length and intensity of the light emitted on the return of electrons from the several energy levels to the alkali ions when the salts are dissociated in a flame at 2000°K ., it can be deduced that about 10^{-5} g. of eka-caesium will be sufficient for the visual observation of the most persistent line in the red end of the spectrum²² and that it will also suffice to record a photographic image of the *raie ultime* in the violet region. Experiments on the spectrophotographic detection of minute traces of potassium, rubidium and caesium in the presence of large amounts of the other elements reveal that the simultaneous

²⁰ Burger and Dorgelo, *Z. Physik*, **23**, 258 (1924).

²¹ Sambursky, *ibid.*, **49**, 731 (1928).

²² The wave length of the most persistent line in the red has been estimated at 7460 \AA .; Bainbridge¹² assigns to it a value of 7600 \AA . H. Deslandres, *Compt. rend.*, **191**, 169 (1930), has observed that the constant $d = 1062.5\nu$ enters into the wave number relationships of the *raies ultimes* of the elements. Using a multiple of 13 (selected with the aid of the measured spectrum of radium) for element 87, a value of 7240 \AA . is obtained for this line.

presence of the other ions in the flame does not appreciably affect the photographic sensitivity for the *raies ultimes* of the alkalis, and that, in particular, a thousand-fold concentration of sodium does not interfere with the spectrophotographic detection of 10^{-5} g. of potassium, rubidium or cesium.²³

Allison states that the concentration of element 87, in the several minerals investigated, varies between 1 part in 10^{10} and 10^8 parts of the mineral.⁴ From the above deductions, it may be concluded that in order to secure spectroscopic evidence for the existence of element 87 a concentrate from 1–100 kg. of ore will be necessary, the quantity depending upon the nature of the mineral.

Summary

The ionization potential and the doublet separations of the principal series spectrum of element 87 have been evaluated by several independent methods. The values are not very concordant, but it may be assumed for purposes of further investigation that the ionization potential is approximately 4.11 ± 0.2 volts. In the spectrophotographic detection of the element, an intense line of approximate wave length $4260 \pm 100 \text{ \AA}$. is to be expected, followed by a much weaker line, of longer wave length, separated from the intense line by $550 \pm 50\mu$.

²³ These experiments were performed in the Chemistry Laboratories of the Washington Square College, New York University, during the summer of 1931.

NON-METALLIC CATALYSTS FOR HYDROGENATION AND DEHYDROGENATION. II. THE CATALYTIC PROPERTIES OF CHROMIUM OXIDE

BY WILBUR A. LAZIER AND J. V. VAUGHEN

RECEIVED MARCH 8, 1932

PUBLISHED AUGUST 5, 1932

In the first report on the specificity of oxide hydrogenation catalysts¹ it was pointed out that a number of difficultly reducible oxides catalyze the hydrogenation of carbon monoxide and other compounds containing the carbonyl group, but are quite inert toward activating ethylene and its homologs for hydrogenation. A continuation of this line of investigation has led to the discovery that amorphous chromium oxide constitutes an exception to the rule governing the behavior of oxide catalysts generally. In fact, the high activity of specially prepared samples of chromium oxide as catalysts for the hydrogenation of ethylene prompted a further study of the catalytic properties of this oxide and the effect of variations in the

¹ Vaughen and Lazier, *THIS JOURNAL*, 53, 3719 (1931).

method of preparation, composition, physical condition and heat treatment.

Sabatier² lists chromium oxide as a catalyst of mediocre activity for the dehydrogenation and dehydration of alcohol, with the latter reaction predominating. Several other investigators have tested it alone and with zinc oxide as a catalyst for the synthesis of methanol.³

Hydrogenation of Ethylene and other Alkenes.—Attention was directed to the unique behavior of chromium oxide during a series of experiments in which hydrogenation occurred when a mixture of ethylene and hydrogen was passed over zinc oxide–chromium oxide catalysts of the type employed for methanol synthesis.⁴ These catalysts were prepared by the thermal decomposition of zinc ammonium chromate containing a slight excess of chromic acid. The hydrogenating activity was at first attributed to the possible presence of small amounts of some contaminating oxide capable of yielding a metal on reduction with hydrogen. The same result, however, was obtained with chromium oxide prepared by the ignition of carefully purified ammonium bichromate. Chromium oxide was also prepared by precipitation in order to eliminate the reducing action of the ignition process as a factor in the development of catalytic activity. The use of a catalyst prepared by reducing chromic acid with methanol, followed by precipitation with ammonium hydroxide, led to the fullest manifestation of catalytic activity. These and subsequent experiments have fully established the fact that capacity for catalyzing the hydrogenation of simple alkenes is an inherent property of amorphous chromium oxide.

Extensive use has been made of the hydrogenation reaction as a control method for the investigation of the influence of variables of catalyst preparation and treatment on the catalytic activity. Comparison has been made of the relative efficiency of catalysts prepared from various salts by the use of several different precipitating agents. The effect of heating the catalysts in oxidizing and reducing atmospheres has been investigated. A résumé of representative results on the hydrogenation of ethylene is presented in Table I. In every case a 20-cc. sample of catalyst was heated to 400° in a slow current of hydrogen and held at this temperature while a 7-liter sample of an equimolar hydrogen–ethylene gas mixture was passed over the catalyst in an hour.

The first five runs shown are for chromium oxides prepared by igniting ammonium bichromate. This familiar exothermic reaction, resulting in

^a A second run with same charge of catalyst gave almost double this contraction. ^b Contraction of gas volume only took place at beginning of run. ^c By condensation and fractional distillation exit gas contained 81.8% ethane. ^d Exit gas passed through dry-ice trap gave no liquid condensate.

the formation of a fluffy oxide having a tea-leaf appearance, has given products exhibiting erratic catalytic behavior. As indicated in the table, a variation of from 2 to 80% conversion may be obtained with successive preparations. Ignitions carried out in air, nitrogen and hydrogen have proved that the catalytic activity is not greatly influenced by the nature of the atmosphere in which the ignition is conducted. It is instead a function of the heat treatment. It has been possible to duplicate the results shown for Runs 1 and 2 by giving careful attention to the size of the mass undergoing decomposition at any one time. Ignition in deep layers permits a greater mass heat effect which results in lowered activity. A product of good activity is obtained, however, by igniting the bichromate in thin layers, which facilitates rapid dissipation of the heat. Close inspection of the ignited material reveals a non-homogeneity represented by the presence of particles of different color. It is believed that the dark colored part is the only fraction that is catalytically active. The product obtained by ignition in deep layers is much brighter green than that prepared in thin layers. It does not exhibit the glow phenomenon when heated whereas the active material glows feebly when heated to 500°.

When ammonium bichromate is heated in a vacuum at 200–250°, it slowly darkens and gradually evolves water, ammonia and nitrogen. After four or five hours there remains a glistening black residue which contains no ammonia and is slightly paramagnetic. This oxide was found to be stable at temperatures up to 400°. When further heated it suddenly glows, leaving a light green residue. Reaction tests showed that the unglowed sample was moderately active (Run 3) while samples that had been heated above the glow point were without activity (Runs 4 and 5). Ignition of chromium oxalate or nitrate at moderate temperatures yielded catalysts that were inactive for ethylene hydrogenation. This fact is especially interesting in view of the frequency with which both of these methods have been suggested and used for the preparation of active catalysts of other compositions.

The reduction of chromic acid with alcohol followed by precipitation with ammonium hydroxide is a well-known step in the separation of chromium from certain other elements. When this method was applied to the preparation of chromium oxide catalysts, the precipitates formed were different in character from those obtained under similar conditions from trivalent salts. The precipitates from reduced chromates were of a chalky blue-green color and had a powdery texture after washing and drying, whereas the hydrated oxides prepared from the trivalent salts were dark green and dried to glassy gel-like masses. Evidence will be presented later to show that the difference observed is at least partly due to a higher state of oxidation in the case of the reduced chromate catalysts. As indicated by the results of Runs 9 and 10 on the one hand and Runs 12

and 13 on the other, there is little to choose between these two sources of raw material for catalyst preparation. Both yield very active catalysts. Experience has shown, however, that the freshly precipitated gel-like products are less susceptible to the glow phenomenon. Catalysts 12, 13 and 14 prepared by use of alkalis other than ammonium hydroxide had uniformly poorer activities than those prepared with ammonium hydroxide, indicating the detrimental effect of alkali metal compounds as impurities. The reaction between ammonium chromate and a trivalent chromium salt yields a product that contains ammonia, is highly susceptible to the glow phenomenon, and consequently has a low activity for the hydrogenation of ethylene (Run 6).

Precipitation of chromium nitrate with ammonium hydroxide as represented by Catalyst 11 is perhaps the most convenient and reliable method for preparing an active chromium oxide catalyst. This catalyst was used for determining the lower temperature limits of the hydrogenation reaction. Hydrated chromium oxide becomes active at 350–370°. At higher temperatures hydrogenation is rapid, resulting in a temperature rise of about 40° in the catalyst bed. Catalyst 11 was also used for the hydrogenation of propylene and octylene. Under the conditions of Run 13, the conversion of propylene to propane was 43%. In carrying out the hydrogenation of the higher boiling compound, a hydrogen stream containing 2% of normal octylene vapor was passed over the catalyst at the usual space velocity. The iodine number of the recovered condensate indicated a conversion of 95% to saturated products. These results reveal the general applicability of the reaction.

Oxidation and Reduction Reactions of the Catalyst.—In the course of preparing samples for the hydrogenation tests it was early observed that the blue-green chromium hydroxides were reducible. A sample of Catalyst 9 dried at 400° in nitrogen evolved water copiously when the gas was changed to pure hydrogen. This reduction was accompanied by a change in color from the original blue-green to a greenish brown. Careful treatment with air led to a black product which could be reduced again. The reduced oxide was pyrophoric and very active for hydrogenation. On the other hand, if the oxidation was carried out with oxygen at 500°, subsequent reduction yielded a bright green product that was catalytically inactive and apparently no longer susceptible to further oxidation or reduction. The hydrated chromium oxide gels prepared from chromic salts appeared to be unaltered by heating in air or hydrogen.

In order to obtain more accurate data on the reduction reactions observed, the hydrogen consumption of weighed analyzed samples was determined in apparatus designed especially for the study of oxide reductions.⁵ At 400° Catalyst 9 (*ex-sulfate*) consumed about 0.75 mole of hydrogen

⁵ Taylor and Starkweather, *THIS JOURNAL*, **52**, 2314 (1930).

per gram atom of chromium whereas only 0.5 mole is theoretically required to reduce CrO_2 to Cr_2O_3 . However, the catalyst contained sulfate equivalent to 3.8 weight per cent. of sulfur. That this sulfate was reduced at least in part to sulfide was evidenced by the formation of hydrogen sulfide during the reduction. The hydrogen consumption was in excess of that necessary for complete reduction of the sulfate, which shows that this was not the only reduction taking place. Catalysts 10 and 11 prepared as the hydroxides from chromium chloride and nitrate, respectively, required for reduction only 0.2 mole of hydrogen per gram atom of chromium. The reduction data cannot be interpreted accurately on account of the fact that it was practically impossible to wash the chromium hydroxide samples completely free from salts. In an attempt to determine the initial state of oxidation, several of these samples were evacuated at high temperatures with a Toepler pump and in every case the evolved gases contained, in addition to oxygen, acidic components corresponding to the salts used in preparing the catalysts. The reduction data are sufficiently accurate however to establish the wide difference in oxidation level of the products from the alcohol-reduced compounds and those from commercial trivalent salts.

x-Ray Analysis.—Dr. A. W. Kenney of this Laboratory has obtained Debye-Scherrer diffraction patterns of several catalysts tested for ethylene hydrogenation. Exposures were made on catalysts before and after use and in the glowed and unglowed condition. Catalysts 1, 6 and 7, all of which were prepared by ignition processes and were catalytically inactive, gave the characteristic pattern of a well-defined crystalline chromium sesquioxide.⁶ Catalyst 2, which was prepared by a more gentle heat treatment and was found to be active, yielded a diagram indicating dilution of the crystalline oxide with amorphous material. None of the precipitated catalysts, whether prepared from reduced chromic acid or from chromic salts, yielded diffraction patterns when exposed to x-rays, demonstrating the amorphous character of these materials. Catalyst 9 was unchanged in this respect after having been employed for hydrogenation, but Catalyst 11 contained a trace of crystalline oxide after only one hour of use. Glowing of any of the amorphous catalysts resulted in the formation of products having the typical diffraction pattern of chromium sesquioxide. Oxidations and reductions carried out under conditions leading to the formation of the light green reduction product were also found to develop the crystalline state.

Dehydrogenation and Dehydration of Ethanol.—The effect of the glow phenomenon on the catalytic characteristics of chromium oxide is further illustrated by results obtained in a series of experiments on the catalytic decomposition of alcohol. Ethanol vapor was passed over small samples of Catalysts 11 and 11A under the conditions indicated in Table II. Run 2 was made with a sample that had been heated in air to 600° before

⁶ Davey, *Phys. Rev.*, [2] **21**, 716 (1923).

use while Runs 3-5 were made consecutively on a sample of a duplicate catalyst. During the interval between Runs 4 and 5, the catalyst was heated in hydrogen to 530°, at which temperature it glowed with an observed rise in temperature of about 100°. The data presented in the table represent the performances of the respective catalysts during the first hour of use.

TABLE II
DECOMPOSITION OF ETHANOL

Run	Catalyst	Catalyst vol., cc.	Alcohol flow, cc./hr.	Temp., °C.	Gas evolution, liters/hr.	H ₂	Gas composition, C ₂ H ₄	% C ₂ H ₆
1	No. 11	3	60	375	2.62	42.8	48.6	3.1
2	No. 11 (heated to 600°)	3	62	375	1.51	57.5	35.4	..
3	No. 11A	5	60	415	5.40	40.4	50.6	3.9
4	No. 11A	5	60	430	6.20	42.6	48.7	4.5
5	No. 11A (glowed)	5	55	430	3.38	66.4	29.1	1.8
6	ZnO	3	90	380	6.20	69.3	25.8	0.0

Although the activity of the catalyst is impaired by glowing, it is not destroyed to as great an extent for dehydrogenation as for the hydrogenation of ethylene. This fact is also evident in the last column of the table. The difference in total dehydrogenation and dehydration activity for Runs 4 and 5 as measured by gas evolution is only about 45%, whereas the decrease in saturated hydrocarbon formation is about 78%. Catalyst 11 had an activity for alcohol decomposition equal to 42% of that of zinc oxide (*ex-oxalate*) at 375°, whereas Sabatier's⁷ chromium oxide was 70% as active as his zinc oxide. Sabatier also reported a dehydration-dehydrogenation ratio of 10 compared with 1.1 obtained in this work. Both researches⁸ are in accord, however, in finding that heat treating the catalyst shifts the ratio in the direction of a greater proportion of dehydrogenation. As in the case of zinc oxide,⁹ a shift in the temperature of decomposition of alcohol over chromium oxide has little effect on the ratio of dehydration to dehydrogenation.

Dehydrogenation of Cyclohexane.—The fact that amorphous chromium oxide is capable of catalyzing the hydrogenation of ethylene suggested a test of its activity in the dehydrogenation of hydrocarbons. Cyclohexane was chosen for the experiment because the position of the equilibrium in the temperature range required is favorable while that of the dehydrogenation of ethane is unfavorable. Cyclohexane was passed over 3-cc. samples of Catalyst 11 at the rates of flow indicated in Table III. Glowing was induced in the catalyst used for Run 4 by heating the unglowed oxide to 510°. Several other oxides were employed as controls.

TABLE III
 DEHYDROGENATION OF CYCLOHEXANE

Run	Catalyst	C ₆ H ₁₂ flow, cc./hr.	Temp., °C.	Gas evolution, liter/hr.	Benzene in condensate, %
1	Glass wool	60	420-500	0.00	0.08
2	No. 11	57	410	1.50	1.56
3	No. 11	78	430	2.24	3.12
4	No. 11 (glowed)	110	410	0.00	..
5	ZnO	80	410-480	.16	0.33
6	SiO ₂ gel	80	410	.00	.0
7	Al ₂ O ₃	80	410	.00	.0

While cyclohexane is apparently stable at temperatures up to 500° in the absence of an active surface, as shown by the results obtained with glass wool, the compound is dehydrogenated by unglowed chromium oxide. Zinc oxide and glowed chromium oxide, on the other hand, are relatively inactive as catalysts for the reaction even at much higher temperatures. Alumina and silica gel are also non-catalysts for the reaction in the temperature range studied.

Other Reactions Catalyzed by Chromium Oxide.—Several chromium oxide catalysts have been tested for the high pressure synthesis of methanol in the course of a comprehensive survey of the subject. The results given in Table IV were obtained with gaseous mixtures containing about 58% hydrogen, 35% carbon monoxide and 1 to 2% each of nitrogen, carbon dioxide and methane. The yields are reported on the basis of a 100-cc. catalyst sample, although a lesser quantity was used in some of the experiments.

^a Yields are expressed as cc. per 100 cc. of catalyst per hour.

In general the activity of chromium oxide catalysts for this reaction is low as compared with certain other single oxides. Zinc oxide, for example, when prepared by igniting the oxalate,¹⁰ gives a yield of 70 cc. of pure methanol per 100 cc. of catalyst per hour when used under the first set of

¹⁰ Lazier, U. S. Patent 1,746,781, Feb. 11, 1930.

conditions of Run 2. Chromium oxide gel is the most efficient chromium oxide catalyst. When removed from the reaction vessel, this catalyst was unchanged in appearance, whereas Catalysts 1, 5 and 6 had assumed the bright green color characteristic of a glowed chromium oxide. Although none of the samples was heated above the temperatures indicated, the poorer showing made by each of the last-named samples is in all probability due to the type of sintering which results in crystallization and in the case of ethylene hydrogenation causes a much larger decrease in catalytic activity.

Like many other oxides, chromium oxide, particularly in the hydrated form, is an active catalyst for the conversion of water gas and steam to hydrogen and carbon dioxide. The reaction takes place at temperatures up to 500° without carbon deposition. The work of Beekley¹¹ indicates that preservation of the activity of the catalyst is contingent upon prevention of the glow phenomenon, although no indication is given as to whether the sensitivity in this case corresponds with that observed for hydrocarbon hydrogenation or for alcohol synthesis and decomposition.

Observations on the Glow Phenomenon.—The large number of tests incident to the investigation of the catalytic properties of chromium oxide have furnished an excellent opportunity for observing the glow phenomenon as it affects this particular oxide. It has been found that the transformation is not associated with any one source of the oxide or method of preparation but with all amorphous catalysts. The phenomenon is not dependent on a gel structure as ordinarily manifested by the outward appearance of a precipitate, since the powdery chromium oxides obtained from reduced chromates glow even more readily than those of a gel-like character. Amorphous chromium oxide glows when strongly heated regardless of the nature of the atmosphere which happens to surround it. If the nature of the gas affects the temperature of glowing, as is sometimes the case, it is because a reaction such as reduction of a higher oxide or oxidation of adsorbed hydrogen is initiated on the surface which produces heat effects that accelerate what would otherwise be a spontaneous transformation. No specific state of oxidation appears to be necessary since glowing has been experienced with both oxidized and reduced samples. The glow may take place without evolution or adsorption of gases but water is copiously evolved. In case the unglowed oxide is in a higher state of oxidation than Cr_2O_3 , oxygen is eliminated in the process, leaving a residue of Cr_2O_3 .

Discussion

The outstanding fact uncovered by the experimental work is that chromium oxide is inherently capable of bringing about the hydrogenation of the alkene bond, a distinction which sets it apart from all of the other hydrogenating-dehydrogenating oxides so far studied. On account of the several

¹¹ Beekley, U. S. Patent 1,789,538, Jan. 20, 1931.

methods used for the production of active catalysts and the precautions taken in the purification of the starting materials, it is not reasonable to attribute the results obtained to the presence of an impurity. Assuming that in order to obtain hydrogenation, activation of both hydrogen and the compound to be hydrogenated is necessary, it is apparent that chromium oxide differs from the other oxides in that it is *capable of activating hydrocarbons*, for many oxides are capable of catalyzing the hydrogenation of carbonyl groups in processes which must also require hydrogen activation. A practical application of this concept is found in the reported use of chromium oxide as a major component of catalysts for the destructive hydrogenation of coal and petroleum,¹² and it is possible that such a catalyst might also be useful for other reactions of the unsaturated hydrocarbons.

Equilibrium considerations and the necessity of avoiding the glow phenomenon have precluded an attempt to investigate the reverse reaction of dehydrogenation of simple saturated hydrocarbons. It can be assumed, however, that the cyclic hydrocarbons should behave in a manner analogous to the alicyclic series; in fact, the same differences between zinc and chromium oxides observed in ethylene hydrogenation were found to hold for the dehydrogenation of cyclohexane. The same forces are apparently at play in these two cases. This is another instance in support of the proposal that the mechanism of hydrogenation and dehydrogenation is the same.

Another important point established by the experimental work is the discovery that the capacity of chromium oxide for hydrogenation and dehydrogenation of hydrocarbons is linked to the amorphous form alone. x-Ray data are readily applicable to the detection of crystalline material, but they cannot be applied with equal facility to the detection of amorphous compounds when crystalline material is also present. In spite of this limitation of the experimental method, it has been shown that any treatment leading to glowing and the consequent development of crystalline material in the oxide resulted in a serious and usually total loss of activity toward hydrocarbons. The same factors however caused relatively minor effects on the activity toward oxygenated compounds as illustrated by the results on methanol synthesis and dehydrogenation of ethanol. The amorphous state is not in general a prerequisite for catalytic activity since the hydrogenating oxides previously studied were all crystalline in character.

The high-temperature loss of capacity for hydrocarbon activation appears to contribute to a further understanding of the mechanism of the glow phenomenon. Weiser¹³ believes that "there is little doubt but that the glow is due to a very sudden decrease in the large surface of the oxides

¹² See especially British Patent 251,264 filed April 14, 1926, and 311,251 filed December 5, 1927.

¹³ Weiser, "The Hydrous Oxides," McGraw-Hill Book Co., New York, 1926, p. 79.

prepared by precipitation" while Böhm¹⁴ and Blanc¹⁵ have reached the conclusion as a result of x-ray studies and thermal analyses that the transformation is only a change from the amorphous to crystalline state. Measurement of catalytic activity should provide a sensitive test for any substantial decrease in surface. The effect of the glow phenomenon on activity toward hydrocarbon activation, if taken alone, would be exactly what to expect if Weiser's explanation is the correct one. Our x-ray findings confirm those of Böhm, and the results on alcohol decomposition and methanol synthesis indicate no greater loss of active surface than may be readily obtained by mildly sintering a crystalline oxide catalyst. While it is believed that the catalytic observations reported have a significant bearing on the mechanism of the glow phenomenon, it is inadvisable in the present state of our knowledge to attempt a more elaborate interpretation of the results obtained.

The preparation of an oxide capable of glowing by partial ignition of ammonium bichromate throws some light on the mechanism of the decomposition of this salt. It is of interest to note that the heat evolved is due only in part to the oxidation of ammonia. The remainder is furnished by the glow phenomenon. It is evident that the arrangement of oxygen and chromium atoms in ammonium chromates is as unstable as in the precipitated trivalent oxides. Mellor¹⁶ states that chromium oxide prepared by igniting ammonium bichromate is amorphous. In view of our experimental results, this statement holds good only for the oxide prepared at low temperatures in a vacuum.

The theoretical treatment of contact reactions is usually based on the concept of a crystalline catalyst in which the surface presents a definite pattern which is held responsible for the direction of the reaction. In an extension of these ideas the authors¹⁷ explained the non-activity of oxides for hydrogenation of alkenes by assuming that the residual valences of the metal atoms of the surface which ordinarily function as hydrogenation centers were dissipated in metallic oxides by the surrounding oxygen atoms. The present case of amorphous chromium oxide cannot be treated in the same way, since as far as we know there is no regular arrangement of atoms in the surface of amorphous materials.

The dehydrogenation of cyclohexane over *amorphous* chromium oxide constitutes a formidable obstacle to Balandin's theory¹⁸ requiring a surface lattice of a certain configuration. The theory further requires that before catalysis can occur the permissible spacing of the atoms must be within

¹⁴ Böhm, *Z. anorg. allgem. chem.*, **149**, 217 (1925).

¹⁵ Louis Blanc, *Ann. chim.*, [10] **6**, 182 (1926).

¹⁸ Balandin, *Z. physik. Chem.*, **B2**, 289 (1929).

narrow limits the symmetry of the active points of the catalyst coinciding with the symmetry of the adsorbate. Unlike the hydrated chromium oxide catalyst, zinc oxide is crystalline, and the arrangement of the zinc atoms is similar to that of metallic zinc, but the spacings between zinc atoms in the oxide are wider than in the case of the metal. In zinc oxide the interatomic distance is about 3.25 Å. as compared with 2.8 set by Balandin as the upper limit for an active hydrogenation catalyst.

A discussion of the relationship of the physical, chemical and catalytic properties of chromium oxide should not be concluded without reference to the possible role played by water. Most of the active preparations studied were highly hydrated, the water being so tightly held that it was not removed in appreciable quantities at the relatively high temperatures of the catalytic tests. The catalyst prepared by the controlled ignition of ammonium bichromate was no exception, since this oxide was found to retain a portion of the water formed by the oxidation of ammonia during ignition. On the other hand, the glow phenomenon results in an effective and probably non-reversible expulsion of water which must of itself alter the chemical nature of the surface. The changes in catalytic properties of chromium oxide resulting from the glow phenomenon cannot be definitely associated either with the chemical changes caused by dehydration or the physical changes manifested by x-ray analysis.

Experimental Part

Catalyst Preparation.—On account of the large number of catalysts prepared and tested it will be impossible to give the complete details of preparation of each. In presenting this section care has been taken to set forth only such information as, in the present state of our information, is regarded necessary to obtain reproducible results. Catalysts 1 and 2 were prepared by igniting c. p. ammonium bichromate. The salt was freed from traces of iron by dissolving in strong ammonia solution, allowing to stand at 40–50° and removing the iron hydroxide sludge by filtration. For Catalyst 1, 100 g. of the dry salt was placed in a 650-cc. loosely covered casserole and heated in a muffle furnace at 400° for thirty minutes, no effort being made to control the rate of decomposition or temperature of the mass. In preparing Catalyst 2, 1-g. portions of the salt were warmed over a flame until ignition was initiated. Catalysts 3 and 4 were prepared by slowly heating 15-g. samples of ammonium bichromate in an oil-bath under the vacuum produced by a Cenco Hyvac pump. In the first case decomposition was observed to set in at about 200° and the sample was not heated above 245°. For the second preparation, the temperature was raised to 500° after four hours of heating at the lower temperature. A second change in the character of the product was evident at about 485°. In the preparation of Catalysts 5 and 6 chromium nitrate and oxalate, respectively, were heated for four hours in a muffle furnace controlled at 400°. The following procedure was employed for the preparation of Catalysts 8 and 9. A hot solution containing 150 g. of ammonium bichromate dissolved in 500 cc. of water was poured slowly into a boiling solution of 200 cc. of sulfuric acid (or such a volume of concentrated hydrochloric acid as is equivalent to the sulfuric acid indicated) and 150 cc. of methanol in 500 cc. of water. The reduction product was diluted with 5 volumes of water, cooled to room temperature and precipitated by the addition of a slight excess of ammonium hydroxide.

Catalysts 10-14 inclusive were prepared by the addition at room temperature of the appropriate alkali precipitating agents to 0.04 molar solutions of c. p. trivalent chromium salts. All precipitated catalysts were washed five to ten times by decantation with a volume of water at least equal to the mother liquor. In one case a dialyzed sample was found to give the same catalytic results as an undialyzed sample. Catalyst 5 was prepared by adding an equivalent of ammonium chromate to chromium nitrate, the other conditions being the same as for the precipitated hydroxides. All of the precipitated catalysts were dried at 110°, and suitable physical form was obtained by breaking up the filter cake and collecting the 8-14 mesh material. These products were subject to a 20% shrinkage when heated in place in the reaction apparatus but no allowance was made for this in measuring the catalyst charges. Catalysts prepared by ignition processes were granulated by briquetting. The samples of zinc oxide and alumina used for reference catalysts were prepared by ignition of zinc oxalate and aluminum hydroxide, respectively.

Apparatus and Experimental Method.—The apparatus used for the hydrogenation of alkenes was the same as that described for this purpose in the earlier paper.¹⁹ In every case the catalyst sample was heated to the reaction temperature in a slow stream of hydrogen. All oxidations or reductions on samples to be tested for this reaction were made in place by by-passing the gasometers. The furnace temperature was controlled by a Republic pyrometer while the temperature of the interior of the catalyst bed was simultaneously recorded by a Leeds and Northrup controller-recorder.

Gas analyses were made on a Fisher Universal Gas-Analyzing Apparatus. The necessity of burning only a small aliquot of samples containing a high ethane content often led to somewhat discordant results, necessitating repeated analyses. In view of Lenher's discovery²⁰ that a trace of oxygen is able to initiate a polymerization of ethylene to higher alkenes, it was desirable to determine whether any saturated hydrocarbon other than ethane was formed. In two representative experiments on the hydrogenation of ethylene, analyses of the effluent gases were made by Dr. D. F. Babcock in the Podbielniak fractional-distillation apparatus.²¹ These data were in very good agreement with those obtained by the combustion method and proved conclusively the absence of saturated hydrocarbons other than ethane. In the preparation of Table I, the ethylene conversions were calculated from the inlet gas compositions and contractions observed on passage over the catalysts. The analyses for ethane served to confirm the conclusions reached in this way. In some cases, particularly in connection with the dehydrogenation experiments, the gas analyses reported do not equal 100% for the reason that negligible amounts of nitrogen, carbon dioxide or carbon monoxide initially present in the apparatus or formed as side reactions are not included in the tabulated data.

The experiments reported on the dehydrogenation of ethanol and cyclohexane were carried out in apparatus patterned after that of Adkins and Nissen.²² The accuracy, efficiency and convenience of this apparatus have been improved by so many alterations and additions over a period of six years' use in this Laboratory that it is thought worth while to describe the improved set-up in some detail. The added features are (1) automatic regulation of the mercury head of the feed device, (2) provision for refilling without disassembling, (3) semi-automatic control of the gasometer pressure and volume and (4) provision for gas sampling at constant pressure and without interrupting the progress of the experiment. By mounting the reaction tube and furnace in a vertical position, channeling of the catalyst bed due to shrinkage is prevented. With a 46-cm. reaction

²² Adkins and Nissen, *THIS JOURNAL*, **46**, 140 (1924).

A Y-tube is provided at the head of the reaction vessel to permit the passage of hydrogen over the catalyst during its pretreatment. The catalyst is held in place in the reaction tube with plugs of glass wool, the lower plug being supported by a button on the thermocouple well, through which a thermocouple reaches the interior of the catalyst bed. Another thermocouple is placed at the catalyst level against the outside of the tube. Temperature control and records are obtained as outlined for the ethylene hydrogenation apparatus.

The liquid products are condensed in the water-cooled trap E, and the gaseous products pass into the gasometer F. Water is drawn out of the gasometer by suction on bottle G, and the rate of withdrawal is controlled by the manometer H and solenoid valve I. The collecting system used in this work was capable of receiving a gas evolution of about 20–25 liters per hour, with a deviation from atmospheric pressure of only a few millimeters. At definite intervals the exit gas was sampled by turning stopcock 9, which permitted gas to displace the water in sample bottle J into the gasometer F. Saturated salt solution was used as the retaining liquid, and a little of it was left in the sample bottle when sampling in order to displace dissolved gases from the condensed alcohol. Small quantities of benzene in cyclohexane were determined by use of the refractometer.

The apparatus assembly used for methanol synthesis was essentially the same as that described by Lewis and Frolich.²³ The average duration of operation at each set of conditions was four hours, the same charge of catalyst being used at a number of different temperatures.

Materials.—Ethylene and hydrogen of 98–99% purity were procured from commercial storage cylinders. Propylene was prepared by the catalytic dehydration of isopropanol over an alumina catalyst. Absolute ethanol was used for the dehydrogenation tests. The cyclohexane and octylene were Eastman Nos. 702 and 1821. The synthetic water gas used for methanol synthesis was prepared by mixing cylinder hydrogen with carbon monoxide prepared by blowing carbon dioxide over heated coke.

In addition to references already made, the authors also acknowledge the assistance and helpful criticism of Drs. G. B. Taylor and H. G. Tanner of the Experimental Station staff.

Summary

Amorphous chromium oxide has been found to be an active catalyst for the hydrogenation of ethylene, propylene and octylene and for the dehydrogenation of cyclohexane, differing in this respect from any other hydrogenating oxide tested. Experiments on a variety of catalyst preparations bear out the conclusion that this behavior is not associated with any particular impurity, source of materials or method of preparation but is inherently associated with the amorphous state of chromium oxide. Any treatment leading to glowing with consequent development of crystalline material in the oxide greatly impairs or destroys activity for the hydrocarbon reactions. Activity for methanol synthesis or dehydrogenation of ethanol is less affected by such treatment.

Chromium oxide is quite active for alcohol decomposition, giving about 50% each of dehydration and dehydrogenation. Heat treatment causes a shift in the ratio in the direction of a greater proportion of dehydrogenation.

²³ Lewis and Frolich, *Ind. Eng. Chem.*, **20**, 285 (1928).

A number of observations on the glow phenomenon have been recorded, the most interesting and important fact uncovered being that the glow phenomenon, which invariably results in the crystallization of the chromium oxide, also results in the loss of capacity of the catalyst for activating hydrocarbons. The bearing of these experimental results on current theories of catalysis is discussed.

THE THEORY OF THE GLASS ELECTRODE. II. THE GLASS AS A WATER ELECTRODE

BY MALCOLM DOLE

RECEIVED MARCH 14, 1932

PUBLISHED AUGUST 5, 1932

Introduction

The inability of the glass electrode to function as a perfect hydrogen electrode in alkaline solutions has recently been explained¹ on the assumption that sodium or other positive ions as well as hydrogen ions may have an appreciable mobility across the aqueous solution glass boundary. This theory, however, fails to account for the interesting errors of the glass electrode in very acid solutions recently discovered by MacInnes and Belcher and by Buchböck² inasmuch as the current carried by the sodium ion across the boundary becomes less and less as the hydrogen-ion concentration increases and the hydrogen ion carries more and more current. Since

¹ Dole, *THIS JOURNAL*, **53**, 4260 (1931). The author wishes to publish the following corrections to this paper. On page 4271 a statement was made concerning the work of Lengyel which is, perhaps, a bit misleading in that Lengyel's experimental procedure was not fully described. Lengyel considered his quartz membranes as condensers, but since he used his electrometer as a null point instrument, the relative capacity of the quartz membrane and of the condenser did not matter; it is only on attempting to measure the potential difference directly by the electrometer deflections that the capacity of the electrometer must be considered in relation to the capacity of the quartz membrane.

The author also wishes to emphasize further concerning his theory of the glass electrode that the experimental equation is highly empirical in that the slope and intercept have to be found from the data; they cannot be calculated. The theoretical significance of the equation rests in the analogy between the empirical equation and one derived on the basis of liquid junction theory (after making several hypothetical assumptions). Hence in reading the author's second paper on the theory of the glass electrode this should be borne in mind.

A misunderstanding has arisen over the mention of the name of Dr. MacInnes in reference 1 of the author's first paper. Dr. MacInnes does not subscribe to the author's theory as given in this paper; Dr. MacInnes' own theory of the glass electrode appeared in a paper previously published with Belcher, *THIS JOURNAL*, **53**, 3315 (1931).

² Buchböck, *Z. physik. Chem.*, [A] **156**, 232-236 (1931); MacInnes and Belcher, *THIS JOURNAL*, **53**, 3315 (1931).

the migration of the sodium ion becomes negligible at a hydrogen-ion concentration of 1×10^{-8} , it can be readily seen that a different explanation is necessary for the acid solution errors. There have been certain theories proposed to account for these results, but they have not proved to be entirely satisfactory. Hence this investigation was undertaken in order to obtain more experimental data and to obtain an explanation for the behavior of the glass electrode in acid solutions which will be thermodynamically sound and which will agree quantitatively with the data.

Experimental

The apparatus and experimental technique were identical with that already described.^{1,3} The glass electrode was carefully compared with the hydrogen electrode in pure solutions of hydrochloric acid and sulfuric acid. A comparison at approximately constant chloride-ion activity was carried out by adding 2 *N* hydrochloric acid to 4.4 *N* lithium chloride. Experiments were performed to find out if varying the positive ion affected the errors; *e. g.*, sodium sulfate, aluminum sulfate, lithium chloride, sodium chloride and aluminum chloride solutions were used in the comparison. These experiments likewise enabled a comparison to be made of the relative effect of the chloride and sulfate ions in causing the acid solution errors. Finally some experiments in ethanol solutions were performed to test any possible effect due to a change in the concentration of the solvent water. These experiments were carried out by adding absolute ethyl alcohol to an aqueous solution of hydrochloric acid at a *P_H* of about one and comparing the glass electrode with the hydrogen electrode as the concentration of the water was changed. The comparison in the approximately 98% ethanol was performed in a separate experiment. A comparison of the glass and hydrogen electrodes was also made in an ethanol solution of sodium iodide over a considerable *P_H* range by adding aqueous sodium hydroxide to the solution.⁴

All the *P_H* values of the tables were calculated neglecting the liquid junction potential between the saturated potassium chloride solution of the salt bridge and the solution under investigation. The data which are

³ Since the first paper was submitted for publication, a paper by MacInnes and Belcher has appeared² in which it is stated that the potentials of the glass electrode in alkaline solution are not reproducible and that different potentials are obtained depending on the direction of the titration, *e. g.*, whether the *P_H* is changed by adding base to acid or acid to base. These results are contrary to those found by the author, who obtained reproducible results in sodium and lithium alkaline solutions and who obtained the same results irrespective of the manner in which the *P_H* was changed. The anomalous results of MacInnes and Belcher may be attributed to the fact that in their titrations the sodium-ion concentration was not held constant, as it was in the author's experiments. On adding sodium hydroxide to hydrochloric or acetic acid, the sodium-ion concentration is continually increasing and is indefinite, and on adding the acid to the base the sodium-ion concentration would decrease continually; hence one would expect to get different results depending on the direction of *P_H* change when the experiments are carried out in this way, since in alkaline solutions the potentials are functions of the sodium-ion concentration.

⁴ The hydrogen-platinum electrodes apparently behaved reversibly in sodium iodide-ethanol solutions although in the neighborhood of the neutralization point they drifted slowly in the direction of higher *P_H* values. No reproducible results were obtained in barium iodide-ethanol solutions; hence these results are not given.

collected in Tables I to IV are not as reliable as the errors in alkaline solutions for they were not so reproducible nor so reversible. A study of the

data for the 4.4 *N* lithium chloride solution indicates this fact. The errors are plotted against the *P_H* in Figs. 1 and 3 and against the concentration of the alcohol in Fig. 2.

Interpretation of the Results

A possible explanation of the errors of the glass electrode in acid solution may be based on the assumption that negative ions are carrying the current across the glass aqueous solution boundary instead of the positive ions. It will be remembered that the errors of the glass electrode in alkaline solutions depended to a large extent upon the particular positive ions present and not at all upon the negative ions. Since the errors of the glass electrode in acid solutions are of opposite sign to those in the alkaline solutions, it might reasonably be assumed that the acid solution errors are due to the negative ions since these ions are charged oppositely to the positive ions. It would be very difficult to see why positive ions could cause any errors in acid solutions; hence if these errors are to be due to ions, they must be due to negative ions. If this were true, the errors in acid solution should be a function of the concentration and nature of negative ions present just as the alkaline solution errors are functions of the con-

centration and nature of the positive ions. A glance at the data, however, indicates that this is not the case. The difference between the chlorides and sulfates is slight in contrast to the large difference, for example, between the sodium and barium errors in alkaline solutions. Furthermore, a large increase in chloride-ion concentration causes no appreciable increase in the error as the results for 4.4 *N* lithium chloride solutions prove.

It is also interesting to note that the presence of the triply charged aluminum ion has no effect upon the errors, which indicates that the errors are not caused by any adsorption phenomenon. Because of all of these facts we must reject the hypothesis that the acid solution errors are caused by negative ions. Another possible explanation of the errors is that recently advanced by MacInnes and Belcher.² These authors have modified the Horovitzian ionic exchange theory¹ by stipulating that in acid solutions sodium ions in the glass are replaced by hydrogen ions of the solution, thereby diminishing the concentration difference of hydrogen ions between the glass and the outside solution and accordingly

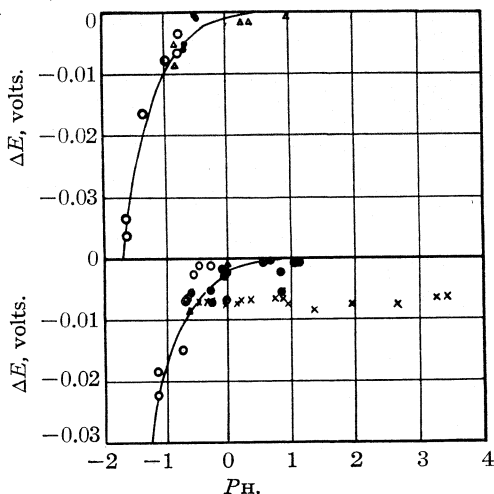

Fig. 1.—Errors of the glass electrode in acid solutions. Top curve: sulfate solutions; circles, H_2SO_4 ; triangles, $\text{Al}_2(\text{SO}_4)_3 + \text{H}_2\text{SO}_4$; solid circles, $\text{Na}_2\text{SO}_4 + \text{H}_2\text{SO}_4$. Bottom curve: chloride solutions; circles, HCl ; triangles, $\text{AlCl}_3 + \text{HCl}$; solid circles, $\text{NaCl} + \text{HCl}$; crosses, $\text{LiCl} + \text{HCl}$; note the constant error in the lithium solutions as the P_H is changed.

the potential. However, by increasing the hydrogen-ion concentration of the glass the potential difference between the glass and the *inside* solution will be increased and it is easy to show mathematically that the resulting increase will just balance the decrease in potential between the glass and the *outside* solution, and no error will result. In other words, as long as the current through the glass membrane is carried solely by hydrogen ions it does not matter at all what the hydrogen-ion concentration in the glass is. An additional theoretical objection to the theory of MacInnes and Belcher is that ionic exchange should occur at all but one P_H since there can only be one concentration of hydrogen ions for a given solution where the free energy of transfer of hydrogen ions will just balance the free energy of transfer of sodium ions (the criterion of zero exchange).⁵ A practical objec-

⁵ In a rapid titration complete thermodynamic equilibrium will never be set up unless the concentration of the aqueous solution happens to be at the concentration which

tion to the ionic exchange theory is that the glass electrode error remains constant at -7.0 millivolts in the $4.4\ N$ lithium chloride solution over the large P_H range $+4$ to -0.5 . Neither of the above theories gives any clue to the explanation of this interesting fact. Nor do they explain why the glass electrode fails to function properly in alcohol solutions.

Since neither the concentration nor the nature of the negative or positive ions had any appreciable influence upon the errors of the glass electrode in acid solutions and since the errors also were not a direct function of the hydrogen-ion concentration, it occurred to the author that possibly the change in activity of the water was causing the error. This idea was strengthened further by a study of the alcohol solutions. Such an error

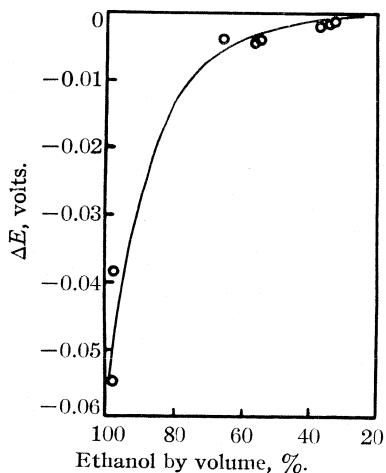

Fig. 2.—Errors of the glass electrode in ethanol-water mixtures.

could be caused by a transfer of water molecules through the glass by the hydrogen ions as they migrated from one solution to the other. A platinum hydrogen electrode transports, of course, no water when it transfers hydrogen ions from one solution to another; hence if water is transferred through an activity difference by the glass electrode, it is obvious that an additional potential will be introduced which will cause the glass electrode potentials to deviate from those given by a perfect hydrogen electrode. This may be easily demonstrated mathematically provided the assumption is made that as the activity of the water is decreased the number of water molecules carried through the glass per

hydrogen ion remains unchanged. If S is the number of moles of water carried across the boundary by one equivalent of hydrogen ions, a_{H_2O} the activity of the water (taken as unity in the reference solution inside the glass electrode), a_H the activity of the hydrogen ion, then the equation for the net potential across the glass membrane is⁶

$$E_t = \frac{RT}{F} \ln \frac{a'_H}{a_H} + S \frac{RT}{F} \ln a'_{H_2O} \quad (1)$$

it would have if equilibrium were allowed to take place. With the concentration of the glass at an approximately fixed value, it is obvious that there can be only one concentration of the aqueous solution that will agree with the equilibrium condition. Hence ionic exchange should occur at all but one P_H according to the theory of MacInnes and Belcher. But the glass electrode agrees with the hydrogen electrode over a billion-fold change of hydrogen-ion concentration without any apparent error.

⁶ See Taylor, *J. Phys. Chem.*, **31**, 1480 (1927).

If the glass electrode acted as a perfect hydrogen electrode, the equation would be

$$E_2 = \frac{RT}{F} \ln \frac{a'_H}{a''_H} \quad (2)$$

Subtracting E_2 from E_1 an equation for the error of the glass electrode in acid solutions is obtained, namely

$$\Delta E = E_1 - E_2 = S \frac{RT}{F} \ln a'_{H_2O} \quad (3)$$

This equation agrees qualitatively with all the facts observed; it shows that the error is independent of the nature and concentration of any ions present including the hydrogen ion and that the error depends only upon the activity difference of the water between the two solutions.

If the activity of the water is diminished, the error will be negative in sign as is actually observed. But it is possible to test equation (3) quantitatively. From data given in the "International Critical Tables" and elsewhere the vapor pressure of the water and therefore the activity in the solutions of hydrochloric and sulfuric acids in the alcohol solutions (assuming that the vapor pressure of the water in the alcohol water mixtures is the same as in the acid mixture actually used), and in the 4.4 *N* lithium chloride solution may readily be determined.⁷

If the activity of the water in the reference solution inside the glass be taken as unity, and if a'_{H_2O} is the activity of the water in the solution under investigation, then by plotting $-\log a'_{H_2O}$ against the error of the glass electrode a straight line should be obtained with slope equal to $0.059 S$ and with intercept on the abscissa equal to zero if equation (3) is valid. The data necessary for such a graph are collected in Table V, and are plotted in Fig. 4.

From a study of the data and the graph it is evident that the potentials of the glass electrode agree within the rather large experimental error with the supposition that as the hydrogen ion migrates through the glass it

carries just one molecule of water along with it (the slope of the line turns out to be equal to 0.059 and S equal to one). The agreement is best for the 4.4 *N* lithium chloride solution; this is perhaps because the error in this solution was the most carefully determined error. In the alcohol, hydrochloric acid and sulfuric acid solutions there is the possibility that alcohol or acid molecules might be transported through the glass; this would cause the error to be lower than theoretically calculated. The agreement between the data and the theoretically calculated values, however, indicates that it is water that is carried through the glass in preference to any other neutral molecule. At constant P_H , therefore, the glass electrode would function as a true water electrode. As far as the author is aware this is the only known example of such an interesting phenomenon.

The errors of the glass electrode in alkaline ethanol solutions of sodium iodide are what might be expected from the behavior of the glass electrode in water. An orienting experiment carried out in a solution of barium iodide indicated that quite analogously with aqueous solutions the barium ion causes considerably less error than does the sodium ion in ethanol solutions. The magnitude of the errors, however, is greater than the errors in water, and due to the complex situation, the errors are rather unexplainable on a quantitative basis.

Conclusions

It is now possible to obtain a complete equation for the glass electrode over practically the entire P_{H} range by combining equation 3 with equation 15 of the author's previous¹ paper, and including in the final equation the usual equation for the hydrogen electrode. The equation is

$$E = \frac{RT}{F} \ln \frac{a_{\text{H}}'}{a_{\text{H}}''} + \frac{RT}{F} \ln \frac{B/a_{\text{H}}^{(n-1)'} + a_{\text{H}}'}{a_{\text{H}}''} + \frac{RT}{F} \ln a_{\text{H}_2\text{O}}' \quad (4)$$

In equation (4) B and n are constants to be chosen from the data; equation 4 also contains the implication that the reference solution inside the glass electrode will not cause any deviation from the correct hydrogen electrode function on the inside surface of the glass electrode.

The question now arises, can a glass electrode be used to measure the hydrogen-ion activity in non-aqueous solvents? The answer is that it surely will not give the correct potentials if the reference solution inside the glass is an aqueous solution. Furthermore, since MacInnes and Belcher have shown rather conclusively² that glass of the type used in this research contains water, it is exceedingly doubtful if the glass electrode will function at all correctly and reproducibly in any solvent but water.⁸ It is somewhat possible that glasses might be made which would allow waterless hydrogen ions or protons⁹ to migrate; in this case the glass electrode could be used in non-aqueous solutions provided only protons migrated through the glass.

The rôle of the glass electrode as a water electrode reduces the analogy between glass and quartz membranes which was apparent at the time of

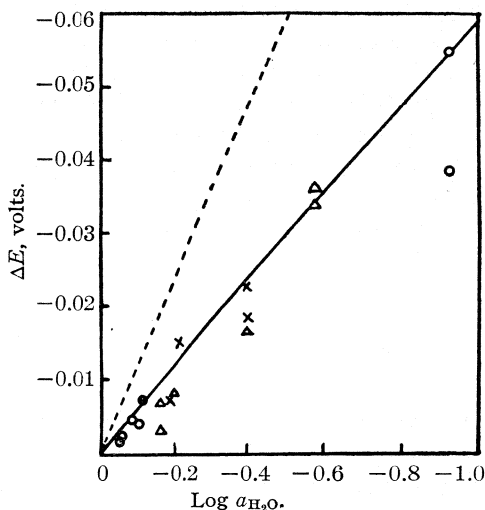

Fig. 4.—The errors of the glass electrode as a function of the activity of the water: circles, ethanol-water mixtures; crosses, HCl solutions; triangles, H_2SO_4 solutions; solid circles, 4.4 N LiCl. The solid line is theoretically calculated on the assumption that the hydrogen ion carries one molecule of water through the glass; the dotted line on the assumption of two water molecules per hydrogen ion. The exact proportionality between the potentials and the logarithm of the water activity shows that the glass may be considered as a water electrode.

⁸ Professor Norris F. Hall has informed me that the glass electrode cannot be used in solutions of glacial acetic acid.

⁹ The theoretical treatment of this paper indicates that the hydrogen ions do not migrate through the glass as protons as suggested by MacInnes and Belcher.²

writing of the author's last paper. Lengyel¹⁰ conceives of glass electrodes of low electrical resistance as being explainable on purely thermodynamic grounds, but as the resistance of the glass is increased surface effects become more and more pronounced until with quartz membranes surface effects will predominate and a theory of adsorption of ions on the surface will serve to explain the potentials. However, this assumption has not been verified yet in any quantitative fashion. It would be interesting to see whether the quartz membranes will act as a water electrode similarly to the glass membranes. If they should also act as water electrodes, the adsorption theory would have to be abandoned inasmuch as it would be difficult to explain how a neutral molecule on adsorption could affect the potential.

Since the above paper was written, Lengyel has published further work on the quartz electrode¹¹ in which he has discovered errors of the quartz electrode in acid solutions similar to the glass electrode acid solution errors. He tried to explain these results on the basis of a consideration of the negative ions, but finds such an explanation inadequate. The author is unable to explain Lengyel's results quantitatively on the assumption that the quartz electrode acts as a water electrode although qualitatively the theory and the data are not irreconcilable.

Summary

1. The glass electrode is directly compared with the hydrogen electrode in acid solutions of sodium chloride and sulfate, lithium chloride, aluminum chloride and sulfate, hydrochloric acid, sulfuric acid and in acid ethanol water mixtures. A comparison was also made over a wide *PH* range in a solution of sodium iodide dissolved in ethanol.
2. The errors of the glass electrode in acid solutions are not a direct function of the nature or concentration of any ion present. This statement includes the hydrogen ion.
3. The errors in alcoholic solutions are similar to the errors in acid solutions.
4. Previous theories to explain these errors are reviewed and rejected.
5. It is found that the acid solution errors are a function of the activity of the water; reduction of the activity of the water makes the error more negative in accordance with the equation

$$\Delta E = \frac{RT}{F} \ln a_{\text{H}_2\text{O}}$$

Because of this the glass electrode can be shown to act as a perfect *water electrode* at constant *PH* (within the experimental uncertainties).

6. The mathematical analysis of the results indicates that as the hydrogen ion migrates through the glass it carries exactly one molecule of water

¹¹ Lengyel, *ibid.*, **A159**, 145 (1932); Lengyel and Mátrai, *ibid.*, **A159**, 393 (1932).

along with it. In other words, the hydrogen ion or proton is hydrated in the glass.

7. The results indicate that the glass electrode when made of the glass used in this research may not be used to measure the hydrogen ion activity of non-aqueous solutions.

8. By combining the equation for the glass electrode in acid solutions with the equation for the glass electrode in alkaline solutions given in the author's last paper, an equation for the glass electrode over an extensive P_H range is obtained.

THE RELATION BETWEEN THE TWO CONSTANTS OF THE ARRHENIUS EQUATION

BY MILTON J. POLISSAR

RECEIVED MARCH 23, 1932

PUBLISHED AUGUST 5, 1932

Introduction.—The rate constants of both first order and second order reactions can be represented by the following empirical equations

$$K = Se^{-Q/RT}; \log K = B - Q/4.58T \quad (1)$$

The simple collision hypothesis of gaseous bimolecular reactions yields the following equation for the second order rate constant

$$K = Ze^{-Q'/RT}; \log K = \log Z - Q'/4.58T \quad (2)$$

Z is proportional to the square root of the absolute temperature and is equal to the number of collisions between the reacting molecules, in moles per liter per second, when the concentration of each of the two reactants is one mole per liter. Q' is the heat of activation and for reactions measured at or near room temperature it is smaller than Q by about 300 calories. Equation 2 is the mathematical equivalent of the statement that all collisions between two reactant molecules in which the energy of impact is equal to or larger than the heat of activation will result in chemical decomposition.¹

Several investigators tested the applicability of Equation 2 to second order rate constants in liquid solutions. In their calculations of the value of Z they assumed that the gas-kinetic formula may be relied upon to give the right order of magnitude for the number of collisions between the solute molecules. They found that the observed values of the tested rate constants were much smaller than those calculated by means of this formula.²

¹ Cf. Hinshelwood, "The Kinetics of Chemical Change in Gaseous Systems," Oxford University Press, Oxford, 1929, pp. 100, 105.

² (a) Christiansen, *Z. physik. Chem.*, **113**, 35 (1924). (b) Norrish and Smith, *J. Chem. Soc.*, 129 (1928). (c) Moelwyn-Hughes and Hinshelwood, *ibid.*, 230 (1932).

In a recent paper Moelwyn-Hughes³ listed a number of reactions in solution whose rate constants satisfy Equation 2. He also added several cases to the list of those reactions whose observed rate constants are much below the theoretical value. He was the first on record to make the observation that what he calls "normal" reactions are characterized by a heat of activation equal to about 21,000 calories, and that in other reactions the ratio between the calculated and the observed rates is the larger, the smaller the heat of activation. He tested several possible explanations of this parallelism and found them untenable, thus leaving the problem unsolved.

The object of the present contribution is to suggest an explanation of Moelwyn-Hughes' rule. It should be emphasized at this point that this explanation does not represent an attempt to reconcile the exceptions with the simple collision hypothesis. On the contrary, in the following discussion the point of view is taken that this hypothesis is too narrow to account for all known bimolecular reactions; attention is next called to the well-known fact that our restricted facilities for measuring rates in solution enable us to study only a fraction of all possible bimolecular reactions; finally, it is shown that all reactions suitable for investigation must satisfy the generalization announced by Moelwyn-Hughes.

The Present Status of the Simple Collision Hypothesis.—Hinshelwood¹ summarized in 1929 the then available data on gaseous bimolecular reactions. In six cases the observed rates agreed with those calculated by means of the simple collision hypothesis. In the seventh (the decomposition of ozone) the observed rate is higher than the calculated one. A few years ago it would have been difficult to explain a case in which the reaction takes place faster than the molecules can be activated by collisions. However, the modern theory of unimolecular reactions offers a simple explanation in the assumption that energy distributed among a large number of internal degrees of freedom can be converted into energy of activation.⁴ Finally, the reaction between nitrogen pentoxide and ozone is a bimolecular one, and the observed rate of reaction is about 90,000 times as great as that allowed by the simple collision hypothesis. According to Hinshelwood, this may indicate a chain mechanism, but it may also be connected with the many degrees of freedom possessed by the complex $\text{N}_2\text{O}_5\cdot\text{O}_3$.

No gaseous bimolecular reaction is known in which the observed rate is much smaller than that calculated by means of Equation 2.^{4a} However, it was shown that the rates of reaction between triethylamine and ethyl iodide

³ (a) Moelwyn-Hughes, *Chem. Rev.*, **10**, 241 (1932); (b) *Nature*, **129**, 316 (1932).

⁴ Ref. 1, p. 152.

^{4a} Just before this paper was sent to print the author's attention was called to the case of polymerization of ethylene in the gaseous phase. This is a bimolecular reaction, and its observed rate is one two-thousandth of that calculated [Pease, *THIS JOURNAL*, **53**, 613 (1931)].

and between acetic anhydride and ethyl alcohol in the gas phase are not much higher than the rates in non-polar solvents.^{2c} The two reactions are bimolecular in solution, and it is very probable that they are of the same order in the gas phase. If their heats of activation are the same in the gas phase as in solution, then it follows from the available data that the rates calculated by means of Equation 2 are more than 100,000 times as large as the observed rates.

To summarize the evidence on the experimental side in the case of gaseous reactions, Equation 2 predicts correctly the rates of six known reactions; it gives too low values for two reactions and too high values for the last two reactions.

Equation 2 is derived on the assumption that all collisions in which the energy requirement is satisfied result in decomposition. Evidence from the field of unimolecular reactions throws some doubt on this assumption. The theory of unimolecular reactions is based on the fundamental assumption that the activated molecules are in thermal equilibrium with the unactivated ones. It follows that the average life of an activated molecule, with respect to decomposition, must be much larger than the average duration between two successive collisions. On the other hand, the time of contact between two colliding molecules is small in comparison with the duration between two successive collisions. It is not clear, then, why we must assume that in a bimolecular reaction all, or at least a large portion, of the activated collision complexes will undergo chemical decomposition during their relatively short life period. It seems more plausible that practically all complexes will separate into the original components and that only a small fraction will suffer decomposition.

On the Number of Collisions in Condensed Systems.—We can define with mathematical exactitude what we mean by a collision between two perfectly elastic and perfectly rigid spheres. With the use of statistical mechanics we can calculate the number of such collisions in a perfect hypothetical gas consisting of such ideal particles. If we pass to the case of a real gas, we lose some of the precision, but we are still in a position to calculate the number of collisions with an accuracy satisfactory enough for a kinetic interpretation of reaction rates. The introduction of an inert solvent gas in ordinary quantities does not call for a fundamental change in the collision formula. Unimportant corrections must be made to allow for the fact that the free space is reduced by the solvent particles and that intermolecular forces acquire an importance.

Let us suppose, however, that a sufficient quantity of the solvent gas is introduced to pack the space solidly with molecules. Under such conditions each of the solute molecules is in continuous contact with several solvent molecules. A definite portion of the solute molecules of the first kind are in continuous contact with molecules of the second kind. Evi-

dently, neither our usual definition of "collision" nor our usual formula for the number of collisions can be employed without making some fundamental changes in them. The mere application of the free-space correction factor is insufficient, since molecules having ordinary dimensions cannot move in such "free" space.

There is good evidence of the fact that molecules in the liquid phase are fairly closely packed. Thus, if we calculate the molecular diameters of molecules in the liquid phase on the assumption of close packing, we obtain values which are in fair agreement with those obtained by other methods.⁵ It follows from what has been said that the application of the gas-kinetic formula to the case of solutions may be incorrect not only in degree but also in kind.⁶

It was shown that on the empirical side the universal applicability of Equation 2 to gaseous bimolecular reactions is far from established; on the theoretical side there is no *a priori* reason why the rate of a reaction cannot be much smaller than that predicted by this equation; furthermore, this equation cannot even be relied upon to give the maximum limit for the rate of a bimolecular reaction at least in the case of molecules with a large number of internal degrees of freedom; finally, it was shown that the application of this equation in the case of liquid solutions is objection-

⁵ Jeans, "The Dynamical Theory of Gases," Cambridge University Press, Cambridge, 1925, p. 332.

⁶ The question may be raised as to the nature of the process whereby molecules in a closely packed system change neighbors and position. The answer will probably be supplied by the statistical theory of fluctuations. As long as the molecules are not solidly packed, there is room for fluctuation in density. The fluctuation in a system consisting of a large number of molecules is very small. However, in a system consisting of from ten to fifty molecules the fluctuation may be violent enough to allow individual molecules a frequent change of neighbors and of position.

It should be pointed out that in a closely packed system bimolecular reactions call for second order rate equations, without the introduction of the idea of collisions. Thus, if we assume that in a dilute solution of substances A and B each molecule of solute A is in contact with eight other molecules most of the time, we arrive at the following formula for the concentration of the AB complex, in moles per liter

$$n_{AB} = 8s_2C_A C_B/n$$

where n is the number of moles of solution per liter (in a very dilute solution it is equal to the number of moles of solvent per liter); C_B/n is the molal fraction of B; s_2 is a statistical factor depending on the relative affinity between molecules A and the other molecules in solution; it is nearly equal to unity when the molecules of B and of the solvent are similar; it is much larger than unity if A and B are oppositely charged ions, and it is much smaller than unity if they are ions carrying charges of the same sign.

If k_2 is the probability that complex AB will undergo decomposition in the course of one second, then the rate of reaction is given by the equation

$$r_2 = 8k_2s_2C_A C_B/n$$

Similarly, the rate of a termolecular reaction is given by the following equation

$$r_3 = 56k_3s_3C_A C_B C_C/n^2$$

able because of the fact that "collisions" in solution are of a nature entirely different from that of collisions in the gas phase. One should not therefore be surprised to find a large number of cases which are not in agreement with Equation 2.

The *ad hoc* nature of the simple collision hypothesis was clearly recognized in the earlier discussions.⁷ However, in a series of recent papers there is shown a definite tendency to assume that conformity with Equation 2 is the normal rule, and elaborate *ad hoc* explanations are offered to reconcile the "exceptions" with the rule.^{2c,3,8} While one may criticize this tendency, there is no doubt that Moelwyn-Hughes' generalization regarding the parallelism between the heat of activation and the deviation from Equation 2 is well grounded. An explanation of this relation is offered in the following section.

The Relation between the Values of B and Q for Investigated Bimolecular Reactions in Liquid Solutions.—The study of reactions in solution is confined to a small range of temperatures. For this reason the value of $\log Z$ does not vary much from one reaction to another and is approximately equal to 11. Equation 2 can therefore be replaced by

$$\log K = 11 - Q'/4.58T \quad (3)$$

Moelwyn-Hughes' generalization is equivalent to the statement that the value of B in Equation 1 is much smaller than 11 for those reactions in which the value of Q is much smaller than 21,000 calories. It is also equivalent to an empirical generalization made by Holzschildt,⁹ who found a linear relationship between B and Q .

If we search for the relation between the values of B and Q which is characteristic of all reactions having measurable speeds at ordinary temperatures, we shall find the solution in Equation 1. Thus, if a reaction is to have a value of $\log K$ which is not much different from some measurable value $\log K_1$, at a temperature T which is not far removed from some average temperature T_1 , then the two Arrhenius parameters of this reaction must satisfy approximately the equation

$$\log K_1 = B - Q/4.58T_1 \quad (4)$$

The B and Q values of all reactions investigated by ordinary methods must satisfy approximately such a linear equation. An inspection of Equation 4 will show that if the pair of values ($B = 11$, $Q = 21,000$) forms an approximate solution, then in other solutions $B \ll 11$ if $Q \ll 21,000$.

Figure 1 will be used to illustrate the relation developed in this section. It is a $\log K$ vs. $1/T$ plot for seven reactions measured by direct methods and

⁷ Ref. 1, p. 100.

⁸ For the extension of the simple collision hypothesis to the case of first order reactions in solution see Moelwyn-Hughes, *J. Chem. Soc.*, 95 (1932); Moelwyn-Hughes and Rolfe, *ibid.*, 241 (1932).

⁹ Holzschildt, *Z. anorg. allgem. Chem.*, 200, 82 (1931).

drawn in to show broadly the region within which the great majority of measurements of reaction rates in solution had been carried out.

It is evident that all reactions suitable for direct investigation have the common characteristic that their Arrhenius lines cross the small rectangle. An inspection of Fig. 1 will show that for such reactions small values of Q must be coupled with small values of B . Thus, reaction 9 cannot be studied by ordinary methods, since its rates at ordinary temperatures are too high.¹⁰

While it is true that reactions whose Arrhenius lines are far removed from the rectangle cannot be measured directly, it would be erroneous to assume that they cannot be measured at all. Thus, the data for the three broken lines in Fig. 1 were obtained by indirect methods. Line 10 (the reaction between ethyl bromide and diethyl sulfide) was obtained from a study of the reverse reaction and the reaction isochore.^{3a} The position of line 9 (the catalytic decomposition of ethylene iodide in the presence of atomic iodine) was estimated from the kinetics of the decomposition in the presence of iodine and the degree of dissociation of molecular iodine.¹¹ Finally, the data for line 8 (the reaction between hypiodous and arsenious acids) were obtained from measurements of the rate of reaction between iodine and arsenious acid, in the presence of hydriodic acid.¹² It is hardly necessary to add that the usefulness of the three reactions as examples of cases investigated by indirect methods is independent of the fact that the kinetic interpretations given by the three authors may be tentative.

Summary

A critical examination of the simple collision hypothesis leads to the conclusion that the latter is too narrow to account for all known bimolecular reactions.

Attention is called to the fact that the application of the gas-collision formula to the case of liquid solutions may be incorrect not only in degree but also in kind.

A simple explanation is offered of the linear relationship between the two Arrhenius constants of bimolecular reactions in solution.

BERKELEY, CALIFORNIA

¹⁰ If all the lines were to pass through a point P inside the rectangle, their B - Q value would have to satisfy Equation 4, with K_1 and T_1 equal to the coordinates of point P . Since the lines pass near that point but not through it, the pairs of values satisfy only approximately a common linear equation. Point P was not selected arbitrarily; its coordinates were chosen in such a way as to give the equation of Holtschmidt's line when substituted in (4). Allowance had to be made for the fact that Holtschmidt used the minute, and not the second, as the unit of time.

THE IONIC ACTIVITY COEFFICIENT PRODUCT AND DISSOCIATION OF WATER IN BARIUM CHLORIDE SOLUTIONS AT 25°

BY HERBERT S. HARNED AND C. MORGAN MASON¹

RECEIVED MARCH 24, 1932

PUBLISHED AUGUST 5, 1932

The equilibrium constant, K , of the dissociation of water is given by

$$K = \frac{\gamma_H \gamma_{OH}}{a_{H_2O}} m_H m_{OH} \quad (1)$$

where the " γ 's" and " m 's" are the activity coefficients and molal concentrations of the ions denoted by subscripts, and a_{H_2O} is the activity of the water. The quantities $\gamma_H \gamma_{OH} / a_{H_2O}$ and, subsequently, $m_H m_{OH}$ have been evaluated from suitable electromotive force measurements for the cases of aqueous cesium,² potassium, sodium³ and lithium chloride⁴ solutions and potassium and sodium bromide⁵ solutions in earlier investigations. The present study is concerned with the evaluation of these important quantities in aqueous solutions of barium chloride by two methods which involve somewhat different cells and computations.

The Determination of the Ionic Activity Coefficient and Dissociation of Water in Aqueous Barium Chloride Solutions by Method I.—The electromotive forces at 25° of the cells

are given by the equation

$$E = 0.08873 \log \frac{\gamma_{(m_1+m_2)}}{\gamma_{m_0}} \frac{\sqrt[3]{m_1^2(m_1+m_2)}}{m_0} + 0.05915 \log \frac{p_{m_0}}{p_{m+m_2}} \quad (2)$$

$\gamma_{m_1+m_2}$ is the activity coefficient of barium hydroxide, $\sqrt[3]{\gamma_{Ba} \gamma_{OH}^2}$, in the solution of barium chloride, and γ_{m_0} is the same quantity at a concentration m_0 in the aqueous solution on the right of the cell which we have employed as reference and kept at a constant concentration of 0.05 M . p_{m_0} and $p_{m_1+m_2}$ are the vapor pressures of water in the reference solution and in the hydroxide-chloride solutions, respectively. From previous results,⁶ we know that γ_{m_0} equals 0.527, and, consequently, from measurements of the above cells we may determine $\gamma_{(m_1+m_2)}$ if we evaluate the term in equation (2) which contains the ratio of the vapor pressures.

The technique employed in these measurements has been described by

¹ This paper was constructed from material forming part of a dissertation presented to the Graduate School of Yale University in partial fulfillment of the requirements for the degree of Doctor of Philosophy, 1932.

⁶ Harned and Mason, *THIS JOURNAL*, **54**, 1439 (1932).

Harned and Mason. It is desirable to record the electromotive forces for cells containing barium hydroxide at the same concentration on both sides. Since the solutions were boiled *in vacuo*, it was necessary to apply a small correction in order to accomplish this result. A concentration of m_0 and m_1 equal to 0.05 was found to be convenient.

Table I contains the experimental results and the computed values of the vapor pressure ratios as well as the values of $\gamma_{m_1 + m_2}$. The second and third columns contain the observed electromotive forces and those read from a smooth curve drawn through them, respectively. The consistency of the results is thus seen to be good considering the difficulties of measurement of cells of this type. The fourth column contains the ratios of the vapor pressure of pure water to that of a barium chloride solution of concentration ($m_2 + 0.05$) which we employed to compute γ . These were computed from the activity coefficients of barium chloride by the method described by Harned.⁷ The activity coefficients employed in evaluating the constants of Harned's equation were obtained from the electromotive force measurements of Lucasse.⁸ The equation

$$\log \gamma = -\beta m \alpha' + \alpha m \quad (3)$$

was found to give satisfactory agreement with the observed activity coefficients when α , α' and β were taken to be 0.435, 0.381 and 0.835, respectively, and, consequently, the vapor pressure ratios may be obtained by the equation

$$\ln \frac{p_0}{p_m} = \frac{m}{55.5} \left[\nu + \frac{2.303 \alpha \nu m}{2} - \frac{2.303 \nu \beta \alpha'}{\alpha^2 + 1} m \alpha' \right] \quad (4)$$

By rearrangement of equation (2) we obtain

$$\log \gamma_{m_1 + m_2} = \frac{E}{0.08873} + \log \gamma_0 m_0 - \frac{1}{3} \log m_0^2 (m_0 + m_2) - \frac{2}{3} \log \frac{p_0}{p_{(m_0 + m_2)}} \quad (5)$$

by means of which the values of $\gamma_{(m_1 + m_2)}$ given in the fifth and sixth columns of Table I were computed. We note at this juncture that the values of $p_{m_0 + m_2}$ are those of pure aqueous barium chloride solutions at the concentration ($m_0 + m_2$). These have been used in place of the vapor pressures of the solutions containing m_0 barium hydroxide and m barium chloride. This procedure causes no large error since the last term on the right of equation (5) is small at low concentrations, and since at high concentrations there is present many times more barium chloride than hydroxide.

In Fig. 1, the values of the activity coefficient of barium hydroxide in barium chloride solutions as well as in pure aqueous solution have been

plotted against the square root of the ionic strength. We note that the values of γ in the salt solutions are higher than in the pure aqueous solutions.

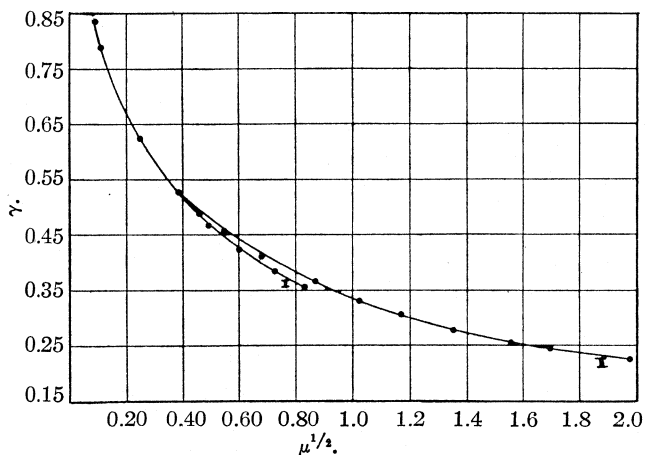

Fig. 1.—The activity coefficient of barium hydroxide in water and in aqueous barium chloride solutions: I, water; II, barium chloride solutions.

To obtain $\gamma_H\gamma_{OH}/a_{H_2O}$ in the barium chloride solution by this method, it is necessary to know both the activity coefficient of hydrochloric acid at zero concentration, and the activity coefficient of barium hydroxide at zero concentration in a barium chloride solution of m molal concentration. Further, the activity coefficient of barium chloride in aqueous solution at a concentration m , and the activity of water in this solution are required. Thus, all the necessary quantities will be known in the same solution and from them $\gamma_{Ba}\gamma_{OH}^2/a_{H_2O}^2$, $\gamma_H\gamma_{Cl}$ and $\gamma_{Ba}\gamma_{Cl}^2$ may be computed. From these quantities $\gamma_H\gamma_{OH}/a_{H_2O}$ may be readily computed by the equation

$$K_\gamma = \frac{\gamma_H\gamma_{OH}}{a_{H_2O}} = \sqrt{\frac{\gamma_{Ba}\gamma_{OH}^2\gamma_H^2\gamma_{Cl}^2}{a_{H_2O}^2\gamma_{Ba}\gamma_{Cl}^2}} \quad (6)$$

The evaluation of $\gamma_{Ba}\gamma_{OH}^2/a_{H_2O}^2$, to be denoted $\gamma''_{Ba(OH)_2}$ and $\gamma_H\gamma_{Cl}$, in the pure barium chloride solutions was carried out by a graphical method which is illustrated by Figs. 2 and 3. The results are given in Table II.

(1) $\gamma''_{Ba(OH)_2}$ in aqueous solution. (2) $\gamma''_{Ba(OH)_2}$ (0.05) in barium chloride solutions. (3) $\gamma''_{Ba(OH)_2}$ (0.00) in barium chloride solutions. (4) γ_{HCl} in aqueous solutions. (5) γ_{HCl} (0.01) in barium chloride solutions. (6) γ_{HCl} (0.00) in barium chloride solutions.

^a Extrapolated points.

In Fig. 2, the values of $\log \gamma''$ are plotted against the concentration of barium hydroxide. The curve represents the activity coefficient of the hydroxide in aqueous solution and was obtained from the values in the second column of Table II and the points represented by the filled in circles are those taken from the third column. To extrapolate these latter results to zero hydroxide concentration, use was made of the law of the linear variation of the logarithm of the activity coefficient which states that at con-

stant total ionic strength $\log \gamma$ varies linearly with the concentration of the substance whose activity coefficient is γ . Thus, by drawing straight lines from the curve through the point at the same total concentration of electrolyte, the extrapolation may be effected. Unfortunately, the saturated solution of barium hydroxide is at too low a concentration to accomplish this at all ionic strengths. Consequently, we have resorted to the expedient

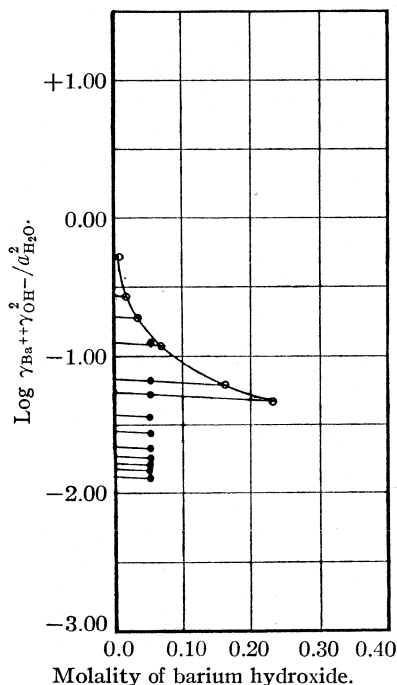

Fig. 2.—Plots of $\log \gamma''$ against m_1 at constant total ionic strength.

of drawing a system of parallel lines from the point to the ordinate, and reading from the curve the results given in the fourth column of the table. Figure 3 shows an exactly similar plot of the $\log \gamma_{\text{HCl}}$ against the concentration of the acid. The curve is drawn through the points taken from the computations and data of Randall and Young⁹ given in the fifth column of the table. The points near the ordinate through which the straight lines at constant ionic strength are drawn represent the activity coefficients of hydrochloric acid in barium chloride solutions determined by Harned and Robinson¹⁰ and given in the sixth column. In this case, the parallel nature of such plots is very apparent. The extrapolated values of γ_{HCl} are given in the seventh column. The values of the activity coefficient of barium chloride in aqueous solution given in the eighth column were those computed from the amalgam cell measurements of Lucasse.¹¹

The last column contains K_γ computed from the results in the fourth, seventh and eighth columns by equation (6).

The Evaluation of K_γ by the Second Method.—The electromotive forces of the cells at 25°

are given by the equation

$$E = E_0 - 0.05915 \log \gamma_{\text{H}} \gamma_{\text{Cl}} m_{\text{H}} m_{\text{Cl}} \quad (7)$$

and the dissociation constant, K_w , of water is

$$K_w = \frac{\gamma_{\text{H}} \gamma_{\text{OH}} m_{\text{H}} m_{\text{OH}}}{a_{\text{H}_2\text{O}}} \quad (8)$$

⁹ Randall and Young, *THIS JOURNAL*, 50, 989 (1928).

¹⁰ Harned and Robinson, *ibid.*, 50, 3157 (1928).

¹¹ Lucasse, *ibid.*, 47, 743 (1925).

By eliminating m_H from these equations, rearranging terms, and substituting 0.2224 for the normal potential of hydrochloric acid, E_0 ,¹² we obtain

$$\left[E - 0.2224 + 0.05915 \log \frac{m}{m_0} \right] = -0.05915 \log K_w a_{H_2O} - 0.05915 \log \frac{\gamma_H \gamma_{Cl}}{\gamma_H \gamma_{OH}} \quad (9)$$

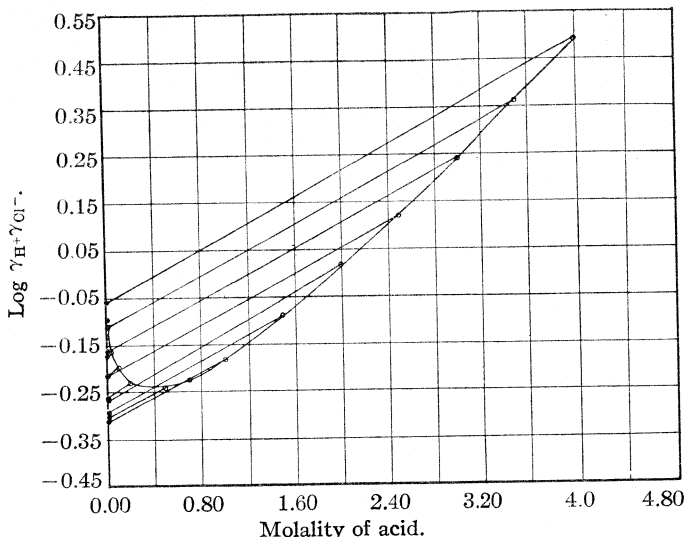

Fig. 3.—Plots of $\log \gamma_H \gamma_{Cl}$ against the acid molality in barium chloride solutions of a constant total ionic strength.

The actual measurements of the cells are given in Table III. The number of cells at the concentrations designated in the first three columns which were measured is given in column four and the difference in millivolts in column five. Column six contains the mean values of the electromotive forces and column seven the value of the left side of equation (9).

In order to obtain results at convenient concentrations, the values of the left side of equation (9) were plotted against μ as shown in Fig. 4. Since a_{H_2O} , $\gamma_H \gamma_{Cl}$ and $\gamma_H \gamma_{OH}$ equal unity at zero ionic strength, the value of the ordinate at zero μ equals $-0.05915 \log K_w$. Since the present results were not carried out at sufficiently low concentrations to obtain an accurate extrapolation, we have drawn the curve to 0.8280, corresponding to a value of K_w equal to 1.005×10^{-14} .¹³

The second column of Table IV contains the values of $E - E_0 + 0.05915$

¹² Roberts, *THIS JOURNAL*, **52**, 3877 (1930); Harned and Schupp, Jr., *ibid.*, **52**, 3892 (1930); Harned and Ehlers, *ibid.*, **54**, 1350 (1932).

¹³ This value, which was obtained by Lewis and Randall [*"Thermodynamics,"* McGraw-Hill Book Co., Inc., New York, 1923, p. 434] is very close to the value recently obtained in this Laboratory and will be employed until the more recent results can be published.

(1) Method I. (2) Method II.

$\log (m/m_0)$ read from the plot of Fig. 4. K_γ may now be readily calculated as can be seen by rearranging (9) as follows

$$\log K_\gamma = \log \frac{\gamma_H \gamma_{OH}}{a_{H_2O}} = \frac{E - E_0 + 0.05915 \log (m/m_0)}{0.05915} + \log K + \log \gamma_H \gamma_{Cl} \quad (9a)$$

$\gamma_H \gamma_{Cl}$ is the activity coefficient product of hydrochloric acid in the barium chloride solutions or the square of γ_{HCl} given in the seventh column of Table II. The values of K_γ thus obtained are given in the fourth column

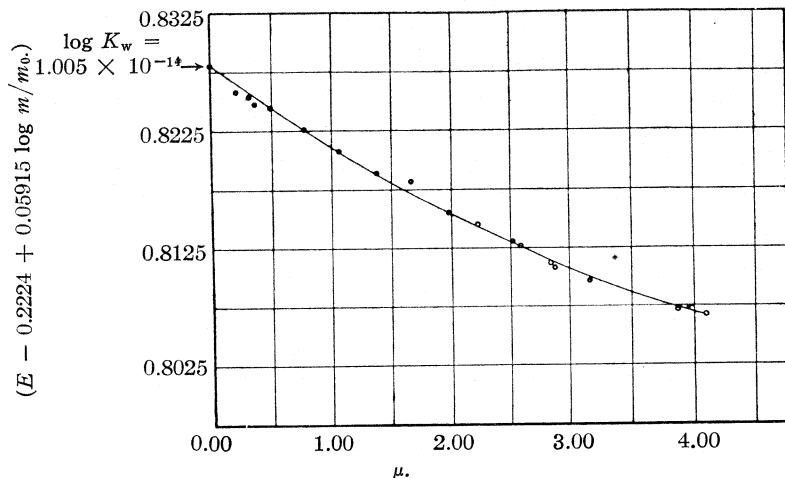

Fig. 4.—Plot of the values of the left side of equation (9) against ionic strength.

of Table IV. In the third column the values of K_γ obtained by the first method are given for purposes of comparison. Both series of values are

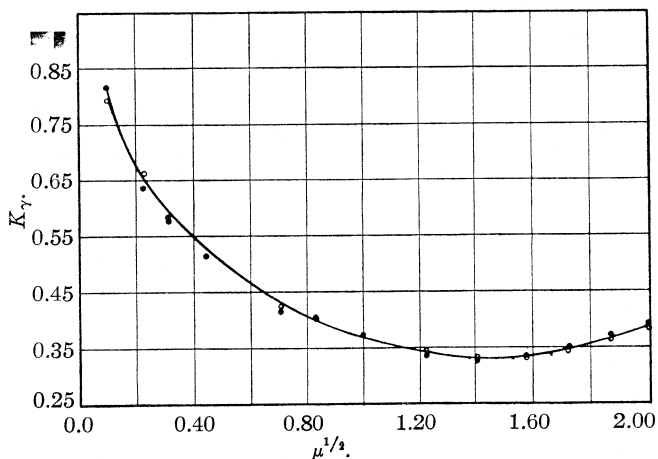

Fig. 5.—Plot of the ionic activity coefficient product, of water, K_γ , in barium chloride solutions: ●, method I; ○, method II.

plotted against $\mu^{1/2}$ in Fig. 5. The agreement is excellent when we consider the difficulties involved in measuring cells containing barium amalgam.

The fifth and sixth columns of Table IV contain the values of $m_w = m_H = m_{OH}$ computed by equation (8). The next two columns contain the values of $\gamma_H \gamma_{OH}$ computed by multiplying K_γ by a_{H_2O} , and the last two columns γ or $\sqrt{\gamma_H \gamma_{OH}}$. The values of γ obtained by the two methods rarely differ by more than 1% or $\pm 0.5\%$ from their mean.

Summary

1. Measurements of the electromotive forces of the cells

have been made, and the activity coefficient of barium hydroxide in aqueous barium chloride solutions has been computed.

2. From these and other suitable results previously determined, the ionic activity coefficient of water in barium chloride solutions has been computed.

3. The cells

have been measured and the ionic activity coefficient of water has been computed from the results, and compared with the values obtained from the amalgam cells.

4. The dissociation of water in barium chloride solutions increases, passes through a maximum and then decreases with increasing ionic strength, a behavior similar to that observed in solutions of the alkaline halides. The maximum dissociation occurs at 1.5μ .

INTEGRAL HEATS OF DILUTION AND RELATIVE PARTIAL MOLAL HEAT CONTENTS OF AQUEOUS SODIUM BROMIDE AND POTASSIUM BROMIDE SOLUTIONS AT TWENTY-FIVE DEGREES*

BY H. HAMMERSCHMID AND A. L. ROBINSON

RECEIVED APRIL 1, 1932

PUBLISHED AUGUST 5, 1932

Introduction

The measurement of heats of dilution of strong electrolytes at concentrations low enough to permit an unambiguous extrapolation of the results to infinite dilution makes possible a combination of such measurements with data obtained at higher concentrations to calculate the relative partial molal heat contents of the components of the solutions. These are the partial molal heat contents referred to the molal heat contents of

* Communication Number 37 on Thermochemical Investigations by E. Lange and co-workers.

the reference state, the infinitely dilute solution.¹ A knowledge of the partial molal heat contents and the partial molal specific heats of the components of solutions is necessary for the calculation of thermochemical and thermodynamic properties of solutions, such as heats of reaction and their temperature coefficients, temperature coefficients of activity coefficients and partial molal free energies, temperature coefficients of solubility and ionic entropies.

Measurements are presented here of the heats of dilution of aqueous sodium bromide and potassium bromide solutions from 0.1 *M* to infinite dilution at 25° and these measurements are combined with data of Wüst and Lange² to calculate relative partial molal heat contents from infinite dilution to saturation.

Experimental

A differential adiabatic calorimeter, developed by Lange and co-workers, already described³ was employed. All details of manipulation and calculation were the same as in previous investigations.

The potassium bromide was a guaranteed preparation of de Haën, several times recrystallized. For the sodium bromide measurements two different 0.1 *M* stock solutions were used; one was a solution prepared by Dr. W. Geffken for density determinations and kindly furnished by him, which contained sodium bromide prepared from pure sodium carbonate,⁴ and solution two was made from a Kahlbaum preparation that had been recrystallized twice. Both solutions were standardized by titration with two different silver nitrate solutions using phenosafranine as an indicator.⁵

The first two columns of Table I give the initial and final concentrations of a dilution, respectively. The third column of the table gives the heat effects of individual measurements (negative values of ΔH indicate heat evolved) in this concentration interval calculated per mole of salt, and the fourth column gives the average of the individual measurements and the probable error, exclusive of any systematic errors. The reproducibility of the measurements is better than two per cent.

Discussion

The data of Table I are plotted against the square root of the molality (weight and volume concentrations differ inappreciably in this concen-

The integral heat of dilution⁷ is related to the relative partial molal heat contents of solute and solvent by $-\Delta H_{\text{int.}} = \bar{L}_2 + n_1 \bar{L}_1$, where n_1 moles of water are associated with one mole of salt at a given concentration. Values for \bar{L}_1 and \bar{L}_2 are most readily obtained from heat of dilution data by the method of Rossini,⁷ using the slopes of the curves of Fig. 2. Figure 3 shows a plot of \bar{L}_1 and \bar{L}_2 for sodium bromide and potassium bromide

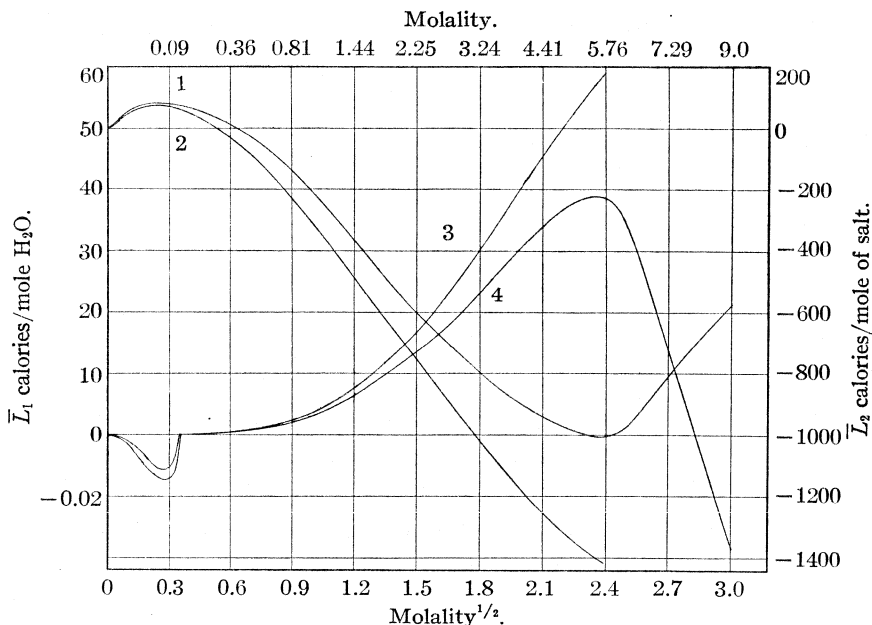

Fig. 3.—Relative partial molal heat contents at 25°. $\bar{L}_1 = \bar{H}_1 - \bar{H}_1^\circ$. $\bar{L}_2 = \bar{H}_2 - \bar{H}_2^\circ$. Curve 1, \bar{L}_2 NaBr; Curve 2, \bar{L}_2 KBr; Curve 3, \bar{L}_1 KBr; Curve 4, \bar{L}_1 NaBr.

solutions so obtained and the values of Table III are interpolated from these curves. L_s is the relative molal heat content of the solid salt (referred to the standard state of infinite dilution) and is calculated from the data of Wüst and Lange on integral heats of solution; L_s for sodium bromide is for the anhydrous salt, although the saturated solution at 25° is of course in equilibrium with $\text{NaBr} \cdot 2\text{H}_2\text{O}$.

Rossini⁸ has shown that at 25° up to concentrations of 2.5 *M* the partial molal specific heats of sodium bromide solutions are represented by $\bar{c}_{p_2} = -24.3 + 20.4 m^{1/2}$ for the sodium bromide and $\bar{c}_{p_1} = -0.123 m^{3/2}$ for the water and for potassium bromide solutions $\bar{c}_{p_2} = -29.5 + 16.2 m^{1/2}$ and $\bar{c}_{p_1} = -0.097 m^{3/2}$. These values can probably be used up to saturation

⁷ This is the negative of the function $\phi_h - \phi_h^\circ$ used by Rossini [*Bur. Stand. J. Res.*, **6**, 791 (1931)] and called by him the relative apparent molal heat content of the solute.

The experimental portion of this work was kindly supported by the Notgemeinschaft der Deutschen Wissenschaft, the Kaiser Wilhelm Institute for Physics and the Munich Universitätsgesellschaft.

Summary

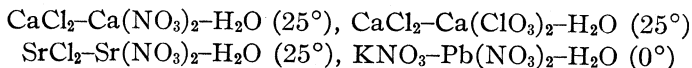

The heats of dilution of aqueous sodium bromide and potassium bromide solutions have been measured at 25° from 0.1 *M* to 0.0002 *M* and extrapolated to infinite dilution. These measurements have been combined with the data of Wüst and Lange, which extend to saturation concentrations, to obtain values for the integral heats of dilution and relative partial molal heat contents of solvent and solute for the entire concentration range.

RECEIVED APRIL 6, 1932

PUBLISHED AUGUST 5, 1932

The chemical literature abounds with references² to double and complex salts of the type RX--R'X where R and R' are two different simple or complex radicals and the common radical, X, is Cl^- , $(\text{CN})^-$, $(\text{NO}_2)^-$, Br^- , $(\text{NO}_3)^-$, $(\text{SO}_4)^-$, etc. Much fewer and more isolated are records of salts of the type RX--RX' . It was with the hope of discovering additional compounds of this type that the present work was begun. The systems chosen for study were selected because of the interest centering in the question of whether complex compounds are formed in solutions of very soluble, highly ionized alkaline earth salts containing anions both of which are strongly negative in character. Recent measurements of migration numbers in similar solutions,³ but of the type $\text{RX} + \text{R'X} + \text{H}_2\text{O}$, indicate that rather extensive complex ion formation takes place. The study of the system $\text{KNO}_3\text{--Pb}(\text{NO}_3)_2\text{--H}_2\text{O}$ (type RX--R'X) was undertaken for reasons mentioned later in connection with the isotherms.

Experimental Details

The systems at 25° were run in a water thermostat of the Freas type, the temperature being kept constant at $25.0 \pm 0.01^\circ$. "Non-Sol" glass bottles, containing the salt solutions, were rotated in the thermostat. The temperature of the 0° thermostat was kept constant to $\pm 0.05^\circ$ by means of felt insulation and an ice-water mixture.

In all the systems the various mixtures of salts and water were made by starting with a bottle containing only one salt and water and in each subsequent run more of the second salt was added to the solution and solid left from the previous run. In the systems $\text{CaCl}_2\text{--Ca}(\text{NO}_3)_2\text{--H}_2\text{O}$ and $\text{CaCl}_2\text{--Ca}(\text{ClO}_3)_2\text{--H}_2\text{O}$ it was frequently necessary to add the dehydrated salts, since, as will be seen from the isotherms, certain mixtures of the hydrated salts will dissolve completely in their own water of hydration. Two days of rotation in the bath was found by experience to be the minimum length of time necessary to bring the solution and the crystalline residues to equilibrium. In establishing the composition of the new double salt in the system $\text{CaCl}_2\text{--Ca}(\text{NO}_3)_2\text{--H}_2\text{O}$, the bottles containing the saturated solutions in contact with the double salt were kept in the

¹ The greater portion of the experimental work for this paper was conducted at Columbia University and was submitted there in partial fulfillment of the requirements for the degree of Doctor of Philosophy. The remainder of the work was carried out at the Washington Square College of New York University.

thermostat for over six months and then re-rotated to ensure equilibrium conditions. It was found by experiment that exactly the same points of equilibrium were reached whether the solutions in contact with the solids were heated to 25° in the bath or whether solutions saturated at a higher temperature were cooled to 25° while turning in the bath. The latter method was found to be quicker, since the dehydrated salts were brought into solution much more readily. In all cases the bottles were re-opened, after they had reached the temperature of the bath, and inoculated with the crystal variety that was thought to be the one which would exist in stable equilibrium with the solution at that temperature.

After the mixtures had come to equilibrium and while still in the bath, samples of the liquid were withdrawn by means of a pipet provided with a folded filter paper at its lower end. When the solutions were viscous, suction, approaching within 2–3 mm. of complete vacuum, was necessary to suck up a sufficient amount of the solution. The latter was immediately deposited in a specific gravity bottle, brought to 25°, and weighed. At the same time about 10–15 g. of the crystals from the same bottle were weighed as quickly as possible to prevent evaporation or absorption of moisture. The weighed samples were diluted in a volumetric flask and aliquots taken for analysis. In the case of the $\text{Pb}(\text{NO}_3)_2\text{--KNO}_3\text{--H}_2\text{O}$ system the samples were not diluted, but were weighed and then dried. The $\text{Pb}(\text{NO}_3)_2$ and KNO_3 were determined by a method used by Glasstone and Saunders.⁴ In the $\text{SrCl}_2\text{--Sr}(\text{NO}_3)_2\text{--H}_2\text{O}$ system, strontium was determined as carbonate, and chlorine, volumetrically, by Mohr's method. The nitrate was determined by difference. The method used in the $\text{CaCl}_2\text{--Ca}(\text{NO}_3)_2\text{--H}_2\text{O}$ and $\text{CaCl}_2\text{--Ca}(\text{ClO}_3)_2\text{--H}_2\text{O}$ systems was as follows: calcium was first precipitated as the oxalate and then determined volumetrically with potassium permanganate. Chlorine was determined volumetrically and the nitrate or chlorate radical by difference. The composition of the solid phases in equilibrium with saturated solutions was determined by the indirect⁵ or "residue" method. Results of the analyses are plotted as weight percentages on the triangular diagrams.

The salts used were prepared or purified as follows.

$\text{CaCl}_2\cdot 6\text{H}_2\text{O}$ was at first obtained by three successive recrystallizations of c. p. $\text{CaCl}_2\cdot 6\text{H}_2\text{O}$. This method resulted in the loss of about one-quarter to one-half of the material, due to the extreme solubility and the deliquescent character of the crystals. Later the salt was obtained pure by a more economical method due to Morgan⁶ in which the salt is melted in its own water of crystallization and then recrystallized. CaCl_2 was prepared from the pure hexahydrate by heating in a Freas electrically heated air oven to 110° for several days. A test run, covering a period of nine hours, showed that during this interval no hydrolysis of the CaCl_2 had occurred. The salt was kept in a vacuum desiccator. $\text{Ca}(\text{NO}_3)_2\cdot 4\text{H}_2\text{O}$ was prepared by triple recrystallization of c. p. crystals. Later an improved method similar to that given under $\text{CaCl}_2\cdot 6\text{H}_2\text{O}$ was used. $\text{Ca}(\text{NO}_3)_2$ was made by heating the purified hydrated salt in an air oven as under CaCl_2 . During the process of dehydration tufts of anhydrous $\text{Ca}(\text{NO}_3)_2$ grew up out of the liquefied salt; these were easily removed and the process amounted to a recrystallization as well as a dehydration. The anhydrous salt was tested as was the CaCl_2 and then stored in vacuum desiccators. $\text{Ca}(\text{ClO}_3)_2\cdot 2\text{H}_2\text{O}$.—This salt as purchasable is an imported product and the small quantity kept in stock by a large retailer of chemicals was found to be so impure as to make many crystallizations, with consequent losses, necessary. It was thought best to prepare the salt in large enough quantity in the laboratory and for this purpose a new method of preparation was devised. Previous methods,

although they furnished valuable ideas for the new method, were either not considered to yield a pure enough product or were considered too dangerous to work with. The method devised is as follows.

Eight hundred and fifty grams of c. p. barium chlorate crystals is dissolved in two liters of distilled water. About a liter of boiling hot solution of ammonium sulfate, containing enough salt to precipitate almost all the barium, is added, with stirring, to the barium chlorate solution. The remaining barium ion is precipitated with a dilute solution of ammonium carbonate. Complete removal of the barium is tested for with the sulfate test. The precipitated sulfate and carbonate are allowed to settle and the solution of ammonium chlorate removed by filtration. To the solution is added, with stirring, a calcined lime paste containing sufficient chemically pure lime to release all the ammonia and a slight excess. The mixture is then boiled until no more ammonia is driven off. After cooling and filtering, the slight excess of lime is neutralized by means of chloric acid using phenolphthalein as indicator. The resulting solution containing calcium chlorate is boiled down until a drop crystallizes. The crystals obtained by recrystallization contain no impurities except a trace of chloride ion which is not detrimental to the work in hand. $\text{SrCl}_2 \cdot 6\text{H}_2\text{O}$, $\text{Sr}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$, $\text{Pb}(\text{NO}_3)_2$ and KNO_3 were obtained by recrystallizing the so-called chemically pure crystals of the salts from distilled water.

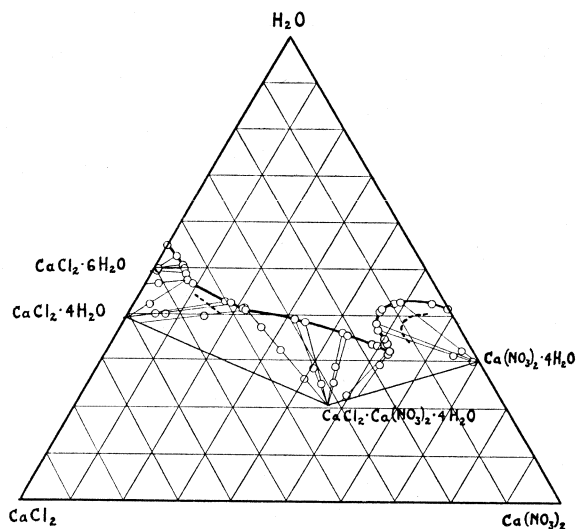

Fig. 1.—The system CaCl_2 – $\text{Ca}(\text{NO}_3)_2$ – H_2O at 25° .

Experimental Results

The System CaCl_2 – $\text{Ca}(\text{NO}_3)_2$ – H_2O at 25° (Fig. 1 and Table I).—It will be seen from Fig. 1 that the solid phase in equilibrium with saturated solutions along the first branch of the curve, beginning at the left, is $\text{CaCl}_2 \cdot 6\text{H}_2\text{O}$. Along the next branch, the crystals in equilibrium with the saturated solution are $\text{CaCl}_2 \cdot 4\text{H}_2\text{O}$. They are the alpha modification of the tetrahydrate. At 20.55% $\text{Ca}(\text{NO}_3)_2$, three phases, namely, double salt, $\text{CaCl}_2 \cdot 4\text{H}_2\text{O}$, and saturated solution, exist together. Then follows the curve

for solutions saturated with double salt $(\text{CaCl}_2 \cdot \text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O})$ and the right branch of the solubility curve passes through solutions saturated with $\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$.

44.92	0.00	1.453			$\text{CaCl}_2 \cdot 6\text{H}_2\text{O}$

An interesting property of this system is that crystals of $\text{CaCl}_2 \cdot 6\text{H}_2\text{O}$ and $\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$, when brought together, often yielded a completely liquid mixture. That this must be so can be seen from Fig. 1. A line joining the points marked $\text{CaCl}_2 \cdot 6\text{H}_2\text{O}$ and $\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$ represents all possible mixtures of the solid salts, and this line would cut the ternary solubility curve in two places and for a considerable space run through the field of

unsaturated solutions. Mixtures of the two salts along this part of the line will liquefy with the formation of unsaturated solutions.

Below the portions of the ternary solubility curve in equilibrium with $\text{CaCl}_2 \cdot 4\text{H}_2\text{O}$ and $\text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$ will be found the incomplete solubility curves (broken lines) in this system at 30° as found by Barbaudy.⁷ Because of the extreme viscosity of the saturated solutions formed, he obtained no further data. However, the slope of the curves agrees with the slope at 25° and it is therefore very likely that the double salt exists also at 30° and possibly over an even greater range of concentrations.

According to Fig. 1, a solution containing the two salts in approximately the ratio of 60 g. of $\text{Ca}(\text{NO}_3)_2$ to 40 g. of CaCl_2 should upon isothermal evaporation at 25° yield only crystals of the double salt. Furthermore, the double salt, if brought into contact with water at this temperature, will not be decomposed but will continue to dissolve until a saturated solution is formed. The solubility, as estimated from the diagram, is 168 ± 3 g. of anhydrous salt per 100 g. of water.

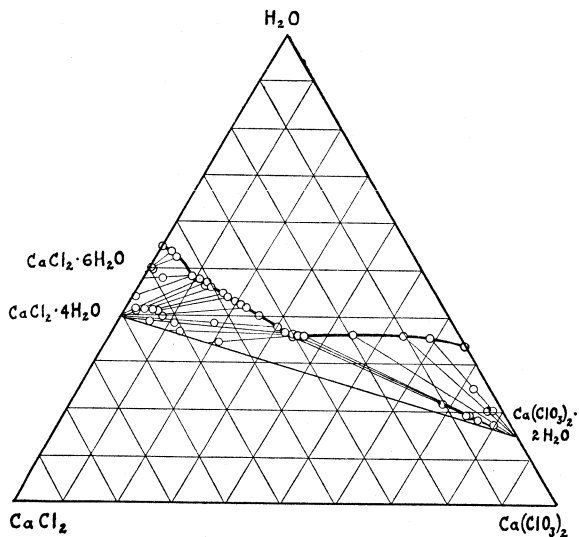

Fig. 2.—The system CaCl_2 - $\text{Ca}(\text{ClO}_3)_2$ - H_2O at 25° .

The System CaCl_2 - $\text{Ca}(\text{ClO}_3)_2$ - H_2O at 25° (Fig. 2 and Table II).—The solubility curve of this system has three branches and shows the absence of any double salt at this temperature. The first branch is in equilibrium with $\text{CaCl}_2 \cdot 6\text{H}_2\text{O}$. The middle branch of the curve represents solutions in equilibrium with $\text{CaCl}_2 \cdot 4\text{H}_2\text{O}$ and the right branch those in equilibrium with $\text{Ca}(\text{ClO}_3)_2 \cdot 2\text{H}_2\text{O}$.

The System $\text{SrCl}_2\text{--Sr}(\text{NO}_3)_2\text{--H}_2\text{O}$ at 25° (Fig. 3 and Table III).—The solubility curve in this system is again one with three branches, a simple dehydration occurring as in the previous system. No double salt is formed. The left branch of the curve represents solutions in equilibrium with $\text{SrCl}_2 \cdot 6\text{H}_2\text{O}$. The central portion represents solutions in equilibrium with anhydrous $\text{Sr}(\text{NO}_3)_2$, and the right branch those in equilibrium with $\text{Sr}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$.

The System $\text{KNO}_3\text{--Pb}(\text{NO}_3)_2\text{--H}_2\text{O}$ at 0° (Fig. 4 and Table IV).—After the work on the alkaline earth systems was well under way, the system $\text{KNO}_3\text{--Pb}(\text{NO}_3)_2\text{--H}_2\text{O}$ was brought to the attention of the author. Glasstone and Saunders⁴ have determined the isotherms at 25, 50 and 100° . Their reason for investigating the system was their belief in the existence of

a complex compound of lead nitrate and potassium nitrate in water solution. Several previous investigations had shown that the solubility of

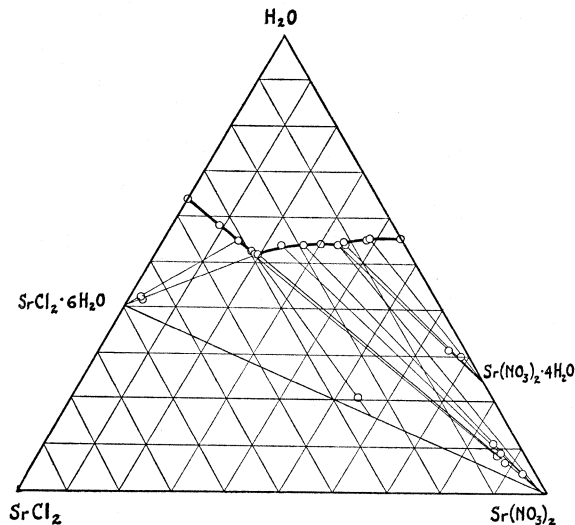

Fig. 3.—The system $\text{SrCl}_2\text{--Sr}(\text{NO}_3)_2\text{--H}_2\text{O}$ at 25° .

lead nitrate in water was markedly increased by the addition of potassium nitrate. The increase was attributed to the formation of double molecules

in solution, and cryoscopic measurements by Leblanc and Noyes⁸ seemed to support this view. They found that mixtures of potassium nitrate and lead nitrate did not depress the freezing point of water as low as would

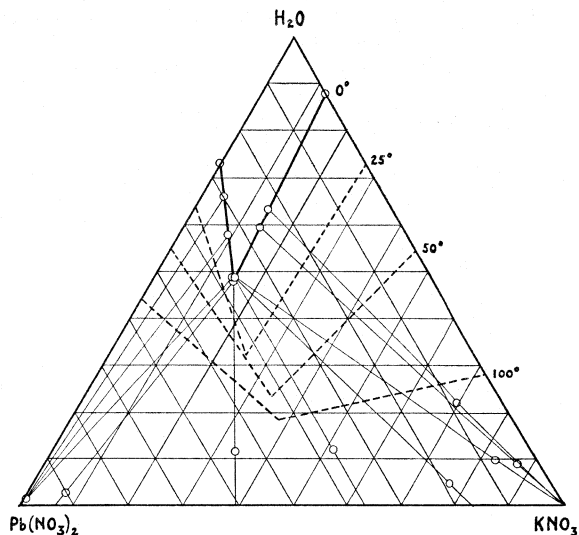

Fig. 4.—The system $\text{KNO}_3\text{--Pb}(\text{NO}_3)_2\text{--H}_2\text{O}$ at 0° (broken curves show results obtained by Glasstone and Saunders).

be expected taking into consideration the common ion effect. Lewis⁹ concluded from electromotive force measurements that complexes must be formed upon adding the aforementioned salts to water, for he found a

⁹ Lewis, Dissertation, Breslau, 1908.

diminution of lead ion concentration whenever potassium nitrate was added to a solution of lead nitrate. Although Glasstone and Saunders found no stable double salt in the system at 25, 50 and 100°, the character of their isothermal solubility curves (see dotted curves, Fig. 4) showed distinctly that the solubility influence exerted by potassium nitrate upon lead nitrate was the more decided, the lower the temperature, *i. e.*, the complex, if such exists, is more stable at lower temperatures. Later work, by Glasstone and Riggs,¹⁰ indicated that a double salt, $2\text{KNO}_3 \cdot \text{Pb}(\text{NO}_3)_2$, separated as a solid solution along with $2\text{KNO}_3 \cdot \text{Ba}(\text{NO}_3)_2$ from solutions in the quarternary system $\text{KNO}_3\text{--Pb}(\text{NO}_3)_2\text{--Ba}(\text{NO}_3)_2\text{--H}_2\text{O}$ at 25°.

These considerations led the author to believe that a solubility determination at 0° over the whole range of concentrations would establish the existence of an addition compound of the two salts. The system was therefore investigated and the results are given in Table IV and Fig. 4. The solubility curve is composed of only two branches and no double salts are formed. Along the left branch will be found solutions in equilibrium with lead nitrate and along the right branch those in equilibrium with potassium nitrate. It will be noted that the relative increase in solubility of lead nitrate upon addition of potassium nitrate is greatest at 0°. The same may be said about the effect of the presence of lead nitrate upon the solubility of potassium nitrate. Although these are strong indications of the formation of complexes in the solution, a definite compound was not isolable. A number of additional experiments were carried out at -10° with mixtures of lead nitrate, potassium nitrate and water calculated to yield the complex if it exists. No solid phase, different from those already observed at 0°, was found.

The author wishes to take this opportunity to thank Professor James Kendall of the University of Edinburgh for the many valuable suggestions made during the course of the work.

Summary

1. The solubility relations have been determined in the following ternary systems: (I) $\text{CaCl}_2\text{--Ca}(\text{NO}_3)_2\text{--H}_2\text{O}$ at 25°, (II) $\text{CaCl}_2\text{--Ca}(\text{ClO}_3)_2\text{--H}_2\text{O}$ at 25°, (III) $\text{SrCl}_2\text{--Sr}(\text{NO}_3)_2\text{--H}_2\text{O}$ at 25°, (IV) $\text{KNO}_3\text{--Pb}(\text{NO}_3)_2\text{--H}_2\text{O}$ at 0°.
2. The existence of a new, stable double salt whose empirical formula is $\text{CaCl}_2 \cdot \text{Ca}(\text{NO}_3)_2 \cdot 4\text{H}_2\text{O}$ has been established.
3. A new method for the preparation of pure $\text{Ca}(\text{ClO}_3)_2 \cdot 2\text{H}_2\text{O}$ is described.

THE CONDITIONS FOR PRODUCING TEMPERATURES BELOW 1° ABSOLUTE BY DEMAGNETIZATION OF $\text{Gd}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$. TEMPERATURE-MAGNETIC FIELD ISENTROPICS

BY W. F. GIAUQUE AND C. W. CLARK

RECEIVED APRIL 8, 1932

PUBLISHED AUGUST 5, 1932

Several years ago one of us¹ devised a method for producing temperatures below those which it has been found possible to obtain by means of liquid helium.

Briefly, the method in its simplest form consists in: (a) magnetizing a suitable paramagnetic substance; (b) absorbing the resulting heat by means of thermal conduction to liquid helium; (c) thermal isolation of the working substance from the helium bath; (d) reversible adiabatic demagnetization with consequent lowering of the temperature.

A few remarks on progress may be of interest here. From the beginning of this problem seven years ago, it has been planned not merely to produce a low temperature but rather to make such temperatures as can be obtained available for experimental work. This has meant the acquisition of apparatus on a scale which has necessitated very slow progress.

The principal requirements are a magnet to produce considerable and very homogeneous fields throughout a large volume and liquefaction cycles of considerable capacity for hydrogen and helium, the liquid hydrogen being required for precooling the helium gas.

A specially built hydrogen compressor with a delivery of 50 cubic feet per minute has been obtained. A very satisfactory hydrogen liquefaction cycle has been constructed. The capacity is about 15 liters of liquid per hour and this can be increased to about 25 liters per hour when a suitable vacuum pump can be obtained for more effective evaporation of the liquid air used for precooling the hydrogen. Storage facilities for 2000 cubic feet of pure hydrogen have been provided.

A helium compressor with a delivery of 25 cubic feet per minute has also been installed and storage facilities for 2000 cubic feet of helium are available. A purification system for removing oil and air or other gases from the helium cycle has been built and it is hoped that the liquefier can be completed in the near future. Acquisition of vacuum pumps permitting recovery of hydrogen evaporated at reduced pressures in the helium cycle and for the reduction of the temperature of liquid helium by reduced pressure is not possible at present.

An iron-free solenoid magnet with oil-cooled conductors and necessary accessories has been placed in operation. A very homogeneous field is obtained in the central portion of a three-foot cylinder with six inches inside diameter. The magnet has been constructed to take 1000 k. v. a., producing a field of over twenty thousand gauss. At present 100 k. v. a. are available, giving a field of about 8000 gauss. The design of the magnet and helium cycle has been carried out by D. P. MacDougall and one of us. G. F. Nelson has been responsible for mechanical construction of apparatus.

The object of the work reported in this paper was to supply information which would determine the magnetic field requirements and thus provide a sound basis for the design of the magnet referred to above.

Gadolinium sulfate octahydrate is a suitable working substance and a full discussion of its magnetic susceptibility with references to the excellent experimental work of Kamerlingh Onnes, Perrier, Oosterhuis and Woltjer has been given previously.^{1b,c} Before the temperature effect produced by the demagnetization of gadolinium sulfate could be determined, it was necessary to know the heat capacity of this substance. It would be preferable to have these data at the temperatures of liquid helium. However, rather than delay until this is possible, it was decided to utilize results at liquid hydrogen temperatures with a Debye heat capacity extrapolation since only approximate results are necessary for our present purpose. Later the heat capacity will be investigated accurately in the liquid helium temperature range. Since no previous measurements have been made on the heat capacity of rare earth compounds at low temperatures it was thought desirable to cover the range to room temperature.

Purity of the Gadolinium Sulfate.—The gadolinium sulfate was obtained from the Welsbach Company, Gloucester, New Jersey, and the analysis furnished by them was Gd 98.5%, Sa 0.5%, Tb 1.0%. These impurities are sufficiently like gadolinium as to introduce a negligible error. A difference of several per cent. in the respective heat capacities would introduce an error of only a few hundredths of one per cent. The average atomic weight of the mixture is but 0.02% lower than that of gadolinium, so the difference may be neglected; 275.804 g. or 0.36926 mole was used in the measurements, the molecular weight of $\text{Gd}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$ being taken as 746.90.

Heat Capacity Measurements.—The apparatus and calorimetric method were similar to those used in many of the previous low temperature investigations² in this Laboratory.

The calorimeter was of copper on which was wound a gold resistance thermometer-heater. The resistance was 365 ohms at 290°K. with a

² (a) Gibson and Giauque, *THIS JOURNAL*, **45**, 93 (1923); (b) Giauque and Johnston, *ibid.*, **51**, 2300 (1929).

dR/dT of about 1 ohm per degree from 40 to 290°K. Twelve radial vanes improved the distribution of heat, which was also facilitated by helium gas in the spaces between the gadolinium sulfate crystals. A massive electrically-heated hollow cylinder constructed of copper and lead surrounded the calorimeter and provided a practically constant temperature environment during measurements. The apparatus was enclosed in an evacuated container.

The resistance thermometer was calibrated by means of the standard copper-constantan thermocouple number 16 which was compared with the hydrogen gas thermometer by Giauque, Buffington and Schulze.³ The thermocouple was attached to the calorimeter during the heat capacity measurements. All low temperatures were produced by liquid air or by liquid hydrogen. The results are given in Table I.

³ Giauque, Buffington and Schulze, *THIS JOURNAL*, **49**, 2343 (1927).

The data are not as accurate as the various low temperature calorimetric investigations made with similar apparatus in this Laboratory within recent years. During the course of the measurements it was found that the thermometer-heater wound on the exterior of the cylindrical calorimeter had an unusually large thermal head with respect to the calorimeter. This greatly increased the usually small correction for radiation to the protective cylinder during heat input and also made it somewhat difficult to obtain equilibrium for the temperature measurements. Following the completion of the measurements the calorimeter was destroyed in order to learn the reason for the difficulty. It was found that the lacquer used on the closely wound thermometer-heater had not adhered to the calorimeter as in previous cases. However, the experimental results are sufficiently accurate and a smooth curve through the points is believed to represent the heat capacity to about 1% at 250°K. and about 0.5% at 100°K.

Since the completion of these measurements, S. Freed⁴ has carried out a magnetic investigation on the electronic levels existing in $\text{Sa}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$. In this connection he has desired to compare the heat capacities of gadolinium and samarium sulfates. We have suggested that the accuracy required in this matter makes it desirable to have the present measurements repeated. We have accordingly given the gadolinium sulfate to Dr. J. E. Ahlberg, who is collaborating with Dr. Freed in this investigation, which should lead to results of increased accuracy. Moreover, for the purposes of comparison some accuracy is gained by measuring both substances in the same calorimeter.

The Entropy of Gadolinium Sulfate Octahydrate at Low Temperatures.—At the temperatures of liquid hydrogen the heat capacity has decreased to such an extent that it seems plausible that the degrees of freedom ordinarily assumed to be represented by the Einstein function are not appreciably active. It is further assumed that the remaining vibrational heat capacity can be represented by the Debye equation. Error resulting from this will be in such a direction as to make the conditions for producing low temperatures more favorable than calculations based on these assumptions will indicate.

Adopting a $\beta\nu = 110$ for $1/2$ mole of gadolinium sulfate, the Nernst-Lindemann limiting expression for the Debye equation gives

$$C = \frac{12}{5} \frac{\pi^4 R}{(\beta\nu)^3} T^3 = 3.5 \times 10^{-4} T^3 \quad (1)$$

The arbitrariness in selecting $1/2$ mole for determining $\beta\nu$ is of little consequence near the T^3 region. The Debye entropy for the T^3 region is given by

$$S_v = \frac{1}{3} \frac{12\pi^4 R}{5(\beta\nu)^3} T^3 = \frac{3.5 \times 10^{-4}}{3} T^3 \quad (2)$$

⁴ Freed, *THIS JOURNAL*, **52**, 2702 (1930).

The entropy due to the distribution of the gadolinium ions in the eight states associated with the seven additively coupled electron spins of this ion has been previously considered.^{1c}

The expression for the decrease in entropy which accompanies the application of a magnetic field is given by

$$\Delta S_{\frac{7}{2} \rightarrow 0} = R \left[\ln \sum \cosh \frac{gjM_{\frac{7}{2}} \cos \theta}{RT} - \ln 4 - \frac{gjM_{\frac{7}{2}}}{RT} \frac{\sum \cos \theta \sinh \frac{gjM_{\frac{7}{2}} \cos \theta}{RT}}{\sum \cosh \frac{gjM_{\frac{7}{2}} \cos \theta}{RT}} + 0 \right] \quad (3)$$

Since the gadolinium ion is an ⁸S state, $g = 2$ is the ratio of magnetic to mechanical moment. $j = S = 7 \times \frac{1}{2}$, the total momentum. M is the molal unit Bohr magneton value. $M = 5567$ ergs/gauss. The summations require four values of $\cos \theta$, namely, 1, $\frac{5}{7}$, $\frac{3}{7}$ and $\frac{1}{7}$. The negative values ordinarily used in addition to these are included by the use of hyperbolic functions.

The above expression assumes that the eight spatial orientations of the magnetic moment are equally probable in the absence of a magnetic field. This cannot be quite true but the magnetic susceptibility data extending to 1.3°K. indicate that the states differ but little in energy.^{1c} Further magnetic susceptibility measurements and heat capacity determinations near 1°K. are needed to increase our information concerning the separation of the octet levels. However, the most promising method of obtaining this information appears to be the study of absorption spectra of the solid.

The measurements of Freed and Spedding⁵ and more recent work by Spedding⁶ and by Spedding and Nutting⁷ include observations on $\text{GdCl}_3 \cdot 6\text{H}_2\text{O}$ which has the same crystal structure and very nearly the same absorption spectrum as $\text{Gd}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$. It would be expected that the two substances have quite similar characteristics. Dr. Spedding informs us that preliminary results indicate disturbances in the ideal separation of the Zeeman components amounting to two or three-tenths of a reciprocal centimeter. Energies of this magnitude become of importance below 1°K. Spedding and Nutting⁷ have recently pointed out that the hexagonal crystals $\text{Gd}(\text{BrO}_3)_3 \cdot 9\text{H}_2\text{O}$ and $\text{Gd}(\text{C}_2\text{H}_5\text{SO}_4)_3 \cdot 9\text{H}_2\text{O}$ have energy levels which are affected by the crystal forces only to about one-half the extent of the monoclinic crystals $\text{Gd}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$, $\text{GdCl}_3 \cdot 6\text{H}_2\text{O}$ and $\text{GdBr}_3 \cdot 6\text{H}_2\text{O}$. It is evident that the greater symmetry will produce conditions favorable to maximum magnetic cooling effect. Moreover, it is well known from the many investigations of Kamerlingh Onnes and his collaborators that greater dilution of the paramagnetic atoms by diamagnetic ones permits an increased perfection of magnetic behavior. For these reasons it appears

⁵ Freed and Spedding, *THIS JOURNAL*, **52**, 3747 (1930).

⁶ Spedding, *Phys. Rev.*, **38**, 2080 (1931).

⁷ Spedding and Nutting, *ibid.*, **38**, 2294 (1931).

that $\text{Gd}(\text{C}_2\text{H}_5\text{SO}_4)_3 \cdot 9\text{H}_2\text{O}$, the magnetic susceptibility of which has been investigated to low temperatures by Jackson and Kamerlingh Onnes,⁸ will prove superior to $\text{Gd}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$ as a working substance. It is also evident that best results will eventually be obtained by placing the crystal axis in proper relationship with the magnetic field.

For our present purposes which are purely for determining the order of magnitude in connection with the design of apparatus it will be possible to neglect the effect of the splitting of the energy levels mentioned above. However, as a result of the ideal conditions assumed, the calculated reduction in temperature for a given change in field is greater than will be found experimentally. In fact it may be shown that effects of the order of magnitude found in $\text{Gd}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$ by Spedding will produce a considerable effect below 1°K . and an appreciable effect extending to several degrees absolute. Nevertheless the figures to be presented in Table IV show the order of magnitude of the ideal limit for a magnetic cooling process utilizing a gadolinium compound. It is possible that a well-diluted crystal with cubic symmetry may make a reasonably close approach to such a limit even below 1°K .

Another consideration that may be of importance is the perfection of the crystals used. Dr. Spedding states that strained crystals give absorption lines which have been broadened to an extent that may lead to an appreciable effect on the magnetic and thermal properties at one or two degrees absolute.

The calculations were made in the following manner. The total entropy, excluding the effect of nuclear spin, and at zero field strength, was taken as $S_T = R \ln 8 + (3.5/3) \times 10^{-4} T^3$. Let ΔS_M be the change (reduction) in entropy caused by the application of the field \mathcal{H} at temperature T . Then the total entropy for a given situation is

$$S_{T,\mathcal{H}} = R \ln 8 + \Delta S_M + \frac{3.5 \times 10^{-4}}{3} T^3$$

This must remain constant during a reversible adiabatic change.

Values of ΔS_M were calculated from equation 3 and represented on a large graph. The calculated values have been given in Table II as a function of $(gjM/R) \cdot (\mathcal{H}/T)$. Table II is for the most part a repetition of the similar values given previously.^{1c} However, a correction of the previous values on the basis of 1 calorie (15°) equals 4.185×10^7 joules instead of the value 4.182×10^7 has been made. The table is included to facilitate appreciation of the relatively large amount of entropy under the control of obtainable magnetic fields compared to the small amount concerned in ordinary vibration.

For comparison several values of the vibrational entropy calculated from the expression $S_V = (3.5 \times 10^{-4}/3)T^3$ are given in Table III.

⁸ Jackson and Kamerlingh Onnes, *Comm. Phys. Lab. Leiden*, No. 168a.

TABLE II

THEORETICAL ENTROPY OF MAGNETIZATION OF $1/2 \text{ Gd}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$ AS A FUNCTION OF $gjM\hbar/RT$

$4.687 \times 10^{-4} \hbar/T$ gauss/deg.	$-\Delta S_M$ cal./deg.	$4.687 \times 10^{-4} \hbar/T$ gauss/deg.	$-\Delta S_M$ cal./deg.
0.1	0.004	2.8	1.673
.2	.017	4.2	2.396
.4	.068	6.3	3.064
.7	.196	7.0	3.220
1.4	.663	∞	4.132
2.1	1.195		

TABLE III

VIBRATIONAL ENTROPY OF $1/2 \text{ Gd}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$

$T, ^\circ\text{K.}$	$S, \text{ cal./deg.}$	$T, ^\circ\text{K.}$	$S, \text{ cal./deg.}$
1	0.000117	6	0.0252
2	.000934	7	.0400
3	.00315	8	.0598
4	.00747	9	.0851
5	.0146	10	.117

For example, when a field of 12,000 gauss is applied at a temperature of 10°K.

$$S = R \ln 8 - 0.1275 + 0.1167 = R \ln 8 - 0.0108$$

Then at 0.5°K.

$$R \ln 8 - 0.0108 = R \ln 8 + \Delta S_M + 0.0000146$$

From this ΔS_M is found to be -0.0108 E. U., which corresponds to a value of $gjM\hbar/RT = 0.160$ and $\hbar = 171$ gauss.

This means that $\text{Gd}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$ should cool from 10 to 0.5°K. when the magnetic field is reduced from 12,000 gauss to 171 gauss. As may be seen from Table IV, the particular isentropic which was considered above shows that the temperature will fall from 4 to 0.5°K. when the field is reduced from 1780 gauss to 171 gauss.

The results for a number of isentropics are summarized in Table IV.

TABLE IV

TEMPERATURE-MAGNETIC FIELD ISENTROPICS FOR $\text{Gd}_2(\text{SO}_4)_3 \cdot \text{H}_2\text{O}$
Each column represents a line of constant entropy

$T, ^\circ\text{K.}$	Gauss						
10	20000	15000	12000	11400	11100	10100	7800
9	17000	12300	9320	8650	8260	7220	4180
8	14300	10100	6990	6320	5960	4860	0
7	12100	8180	5180	4530	4120	2790	
6	10000	6550	3710	3060	2620	0	
5	8130	5160	2590	1920	1430		
4	6410	3960	1780	1060	0		
3	4750	2880	1170	448			
2	10000	3150	1890	709	0		
1	4970	1570	940	342			
0.5	2430	786	470	171			

The possibilities shown by the tabulated data need little comment. As mentioned above, the amount of entropy under the control of the magnetic field is large compared to the amount concerned in vibration. For this reason conditions appear favorable to the production of extremely low temperatures even if several members of the magnetic octet are rendered inactive at such temperatures by energy differences comparable with kT . It is evident that the cooling effect available is not only sufficient for producing very low temperatures in the gadolinium sulfate octahydrate itself, but is also sufficient to cool simultaneously other materials in addition.

Summary

The heat capacity of $\text{Gd}_2(\text{SO}_4)_3 \cdot 8\text{H}_2\text{O}$ has been measured from 14 to 290°K . Extrapolation of the heat capacity results combined with the entropy of magnetization previously given has been used to determine the conditions for producing temperatures below 1°K . by reversible adiabatic demagnetization of gadolinium sulfate octahydrate.

The magnetic field-temperature isentropics have been tabulated. The data indicate that the demagnetization of gadolinium sulfate at the temperatures of liquid helium not only provides enough cooling effect to produce temperatures considerably below 1° absolute, but that in addition other substances may be cooled by gadolinium sulfate for investigation of their properties.

THE CONDUCTIVITY OF SOLUTIONS OF GERMANIC OXIDE¹

BY CHARLES E. GULEZIAN AND JOHN H. MÜLLER

RECEIVED APRIL 12, 1932

PUBLISHED AUGUST 5, 1932

There are known to exist several modifications of germanium dioxide, the physical and chemical properties of which differ very definitely.² The ordinary form—the so-called “hydrolyzed” oxide—is soluble in water and is obtained by the hydrolysis of the tetrachloride. When solutions of this modification are evaporated to dryness, ignition of the residue gives varying yields of a very insoluble variety—the amount depending on the conditions under which the evaporation is carried out and on the temperature at which the residue is ignited. Only traces of this insoluble form can be obtained by directly igniting large quantities of the “hydrolyzed” oxide, whereas repeated evaporations and ignitions of the “evaporated” oxide bring about complete conversion of the soluble to the insoluble

¹ From a thesis presented by C. E. Gulezian in partial fulfillment of the requirements for the degree of Doctor of Philosophy.

² Müller and Blank, *THIS JOURNAL*, **46**, 2358 (1924).

variety.³ Finally, a very soluble, transparent and "glassy" form results on quickly cooling melted germanic oxide obtained from any other variety. This form is amorphous and a true glass, as is indicated by the absence of lines in its x-ray spectrograph and the lack of a sharp break in its heating or cooling curves. Recently, R. Schwarz and E. Huf,⁴ from a study of the properties of this oxide both in the solid condition and in solution, conclude that there are three true modifications—two crystalline and one amorphous. The "evaporated" oxide, according to their data, is homogeneous and not a separate variety.

This observed allotropy of germanium dioxide should, therefore, be taken into consideration in any study of the solutions of this substance. Roth and O. Schwartz,⁵ in their study of the physical properties of this oxide in solution, give the earliest data on its conductivity. Their work, however, covers only solutions of the above-named "hydrolyzed" oxide, for the specific conductivity of which they obtained values showing very wide differences, depending on whether the solution of the oxide was prepared in the hot or cold. Furthermore, their lowest value for the primary dissociation constant of germanic acid, 1.2×10^{-7} , calculated from their conductivity data, is approximately fifty times the value given by Pugh,⁶ 2.5×10^{-9} , and obtained from a potentiometric determination of the hydrogen-ion concentration in solutions containing sodium acid germanate. R. Schwarz and Huf,⁴ working with solutions of the fused or "glassy" oxide, found 0.5×10^{-7} for this constant, which, though less than the value of Roth and Schwartz, is still about twenty times that of Pugh. The present study was undertaken in order to determine the conductivity of this substance in solution under different conditions with special reference to the influence, if any, of polymorphism on the conductivity, and also to determine the more probable of the above-mentioned values for the dissociation constant of the acid formed when the oxide is dissolved in water.

Preparation of Pure Germanium Dioxide

As will be seen from the experimental data to be given later, solutions of pure germanic oxide have an extremely low conductivity, which makes it imperative that the solid be prepared in such a way that it will be absolutely free of foreign ions capable of contributing to conductance. Considerable difficulty was experienced at first in getting concordant results with what was thought to be very pure oxide. When the sample was re-purified, such difficulties were overcome; and since, in an investigation such as this, the most important single factor affecting the final results seems to be the purity of the material used, considerable information will be given concerning its source and method of purification.

"Hydrolyzed" Germanic Oxide (Lot 1).—The original sample of oxide used in this investigation was obtained from germanite. The mineral was decomposed with nitric acid and the undissolved residue containing germanic oxide, siliceous gangue, etc., heated with concentrated hydrochloric acid, the crude germanium tetrachloride distilling out in the usual manner. The tetrachloride was then redistilled and the product hydrolyzed to oxide—most of which was deposited as the difficultly soluble solid. The acid filtrate from this hydrolytic decomposition was purposely discarded in order to eliminate rapidly most of the arsenic. This yield of solid oxide was then dissolved in water and the remaining traces of arsenic removed by rendering the solution faintly acid and adding hydrogen sulfide. The snow-white disulfide was then precipitated in the filtrate in the presence of 6 *N* sulfuric acid and the solid hydrolyzed to oxide by boiling with water in the absence of air. This residue of oxide was once more converted to chloride and the final transformation to oxide effected by collecting the chloride under ice water and warming. The solid so obtained was washed with cold water and then repeatedly moistened and ignited at 950° until no test for chloride ion was observed on dissolving two gram samples in water.

(Lot 2).—The solutions prepared from Lot 1 and used in all the preliminary experiments were combined and concentrated by slow evaporation to about one liter. The germanium was distilled out as chloride in a current of pure hydrogen chloride and the chloride collected, this time, not under water, but under ice cold, concentrated hydrochloric acid.

The advantages of this method will be discussed fully in a forthcoming contribution by Mr. E. R. Allison of this Laboratory. The lower layer of chloride was then run, drop by drop, from the ice-jacketed separatory funnel in which it had been collected into a large platinum dish containing about 300 cc. of conductivity water heated to 45–50° and kept in constant agitation. No solid oxide separated out at first—even after the addition of about forty grams of chloride. Then the apparently clear dispersion of chloride and water gave way to a very finely divided and heavy precipitate of germanium dioxide. The solid appeared uniform in structure, the absence of cakes or lumps of the oxide being especially noticeable. The precipitated oxide was filtered, washed with cold water and warmed with about 50 cc. of conductivity water. After a second filtration, the residue remaining on the filter was washed until apparently clear of chloride ion. This entire behavior was strikingly different from that observed when the chloride is hydrolyzed according to the usual method of adding it in bulk to water and gradually warming. The small amount of chloride lost by volatilization in the method described is more than compensated for by the improved condition of the oxide obtained, which makes subsequent purification much less difficult. Even though the wash water gave a negative test for chloride ion, large samples of the solid when dissolved in water gave good positive tests. The removal of the final traces of hydrogen chloride was effected only by ignition of the moistened oxide at temperatures above 900°. Only about five or six such ignitions are required when the oxide is obtained in the manner described, whereas at least twice as many are necessary when it is prepared by the other method.

(Lot 3).—A third yield of "hydrolyzed" oxide was prepared indirectly through the sulfide. Pure oxide solutions obtained from Lot 2 were made 6 *N* with hydrochloric acid and the sulfide precipitated with hydrogen sulfide obtained from liquid hydrogen sulfide. The filtered disulfide was washed with 6 *N* acid saturated with hydrogen sulfide, then with hydrogen sulfide water and finally with conductivity water. After drying in a desiccator over soda lime for three days, the sulfide was changed to chloride by Winkler's method⁷ with the use of pure mercuric chloride. The distillate collected in a cooled receiver was redistilled and the portion boiling below 84° collected, as before,

⁷ Winkler, *J. prakt. Chem.*, **36**, 188 (1887).

under pure concentrated hydrochloric acid. The subsequent transformation to oxide and purification of the latter were carried out exactly as in the preparation of Lot 2.

"Glassy" Germanic Oxide.—"Hydrolyzed" oxide from Lot 2 or 3 was placed in a platinum boat and the temperature raised to about 1250° in an electrically heated platinum resistance furnace. After removal from the furnace and quick cooling in the air, the sample was dissolved, without grinding, in conductivity water.

Germanic Oxide from the Sulfide.—About six grams of "hydrolyzed" oxide was dissolved in conductivity water and precipitated as sulfide from 6 *N* sulfuric acid solution. After thorough washing of the sulfide—as previously indicated—until visible peptization occurred, it was transformed into oxide in a quartz flask by the hydrolytic method.⁸ Superheated steam was passed through the liquid until the escaping vapors gave no test for hydrogen sulfide. Evaporation of the liquid to dryness in a platinum dish and ignition at 950° for eight hours gave a residue of oxide, 2-g. samples of which in conductivity water showed no visible test for sulfate ion.

Germanic Oxide Crystallized at 1050° .—"Hydrolyzed" oxide was melted as above, but instead of removing and cooling the melt quickly, the sample was cooled slowly in the furnace to $1050 \pm 5^{\circ}$, and kept at this temperature for about five hours. When removed and broken up, observation of the solid under an ordinary microscope indicated the presence of a mass of large well-formed crystals. As the oxide obtained in this way dissolved much more slowly than the other samples, it was finely powdered in a quartz mortar before addition to water.

Insoluble Germanic Oxide.—The material was a 10-g. sample prepared in a previous investigation.³ It was repeatedly treated with boiling conductivity water in order to remove all traces of soluble matter—the boiling being carried out in a quartz flask. A re-determination of the solubility of the material thus obtained showed that 2.3 milligrams dissolved per liter at 25° .

Conductivity Measurements

Apparatus and Reagents.—The usual Kohlrausch set-up was used with a thousand cycle microphone hummer as the source of alternating current. The slide was a Gray instrument with the scale divided into a thousand divisions. The variable resistance was a Leeds and Northrop instrument accurate to 0.1%—as checked against L. and N. standard resistances. A variable air condenser was placed in parallel with the resistance box to compensate for capacitance in the conductivity cell. All readings, except those on conductivity water, were taken with the end-coils of the slide wire in the circuit, thereby greatly increasing the accuracy of the bridge reading.

The thermostat was maintained at $25.00 \pm 0.02^{\circ}$, the temperature being read with a calibrated thermometer.

All glassware was thoroughly cleaned and steamed before use, and all measuring apparatus calibrated. The heating of all germanic oxide solutions used in the measurements was carried out either in platinum dishes or quartz vessels.

The conductivity cell was made of Pyrex glass with the exception of a ground-glass stopper and the supporting tubes through which the electrodes were sealed. The electrodes were about three centimeters in diameter and about four millimeters apart. The cell constant, 0.02564, was checked frequently during the determinations and the change found to be inappreciable.

The potassium chloride was a sample of Kahlbaum's best grade recrystallized from conductivity water and heated to 300° for two to three hours just before use. The solutions necessary for the determination of the cell constant were prepared according to the data given in the "International Critical Tables."⁹

⁸ Müller and Eisner, *Ind. Eng. Chem., Anal. Ed.*, **4**, 134 (1932).

⁹ "International Critical Tables," Vol. VI, p. 230, Table I.

The specific conductivity of the water used was in all cases below 1.0×10^{-6} mho per cm. The water was kept in well steamed and seasoned Pyrex flasks which were always kept filled with water until immediately before use, all samples of water being used within ten hours after collection.

Preliminary Experiments.—(a) In this and in all the other preliminary experiments, the conductivity measurements were made at 30° with samples of the oxide taken from Lot 1. Solutions of the “hydrolyzed” oxide of the same concentration (2.276 g. per liter) were prepared at 0° and at 100° . The specific conductivity was approximately the same for solutions made at both temperatures—between 6.5 and 8.0×10^{-6} mhos per cm. At the same concentration—but at 18° —Roth and Schwartz⁵ obtained a value of about 17×10^{-6} mhos per cm. for the solution prepared in the cold and of about 35×10^{-6} mhos per cm. for that prepared in the hot (the temperatures at which the solutions were prepared not being stated in either case). Our experiments were easily duplicated and indicated that extremes of temperature in the preparation of such solutions had very little, if any, effect on the conductivity. After being kept in Pyrex flasks for several days, the solutions were found to be quite stable, only very slight changes in conductivity being observed.

(b) Samples of a similar solution of “hydrolyzed” oxide were then sealed up in previously cleaned and steamed quartz bulbs of 25-cc. capacity, and heated continuously for seven days in a boiling water-bath. A bulb was removed every twenty-four hours and the conductivity of its contents determined. Throughout the entire period, no changes over 1% were observed. The same experiment was carried out for solutions of the “glassy” form—the original solution in this case being prepared at 0° . Water blanks were also prepared and kept in the same bath throughout the run. After an initial slight increase—equal to that in the case of the water in the blanks—the values observed were constant over a period of five days. Solutions kept thus for four days at temperatures of 0, 30 and 65° also showed a similar stability.

(c) The sample of oxide used in the preparation of all these solutions had been ignited at 950° in order to remove traces of hydrogen chloride. It was thought that, perhaps, on heating, the germanic oxide had undergone some change in its physical condition that was responsible for its low conductivity when placed in solution. Attempts were then made to remove the hydrogen chloride from the hydrolyzed oxide at lower temperatures. The material was repeatedly extracted with boiling conductivity water; it was moistened and ignited at various temperatures up to 700° ; superheated steam was passed over it at temperatures up to 500° ; it was moistened several times and heated *in vacuo* at 500° ; but, no matter what method was used, the residues when dissolved in conductivity water still gave good positive tests for chlorine. All attempts to obtain chloride-free germanic oxide at temperatures much below 900° were then given up. That such a high temperature is required to remove all the hydrogen chloride is quite remarkable. It may be that the last traces leave only with the last traces of water, which Dennis, Tressler and Hance¹⁰ have shown to be completely removed only on heating to 950° . It is, perhaps, due to this fact also that Roth and Schwartz obtained the results which they report, since they state that, in purifying the oxide, the final step consisted in heating to a “dull-red” heat—which is considerably below 900° . R. Schwarz and Huf¹¹ report more than 0.1% of chlorine in the oxide ignited at 600° , and succeeded in eliminating all the chlorine at 800° .

(d) The conductivity of solutions of the “evaporated” oxide was then studied in order to determine whether it differed from that of the hydrolyzed modification. Solutions of the hydrolyzed oxide were evaporated in electrically heated platinum dishes.

¹⁰ Dennis, Tressler and Hance, *THIS JOURNAL*, **45**, 2033 (1923)

¹¹ Ref. 4, p. 196.

The results of four such experiments indicated a drop in specific conductivity from 24 to approximately 7.5×10^{-6} mhos per cm. Enough of this "evaporated" oxide was then obtained to heat one-gram portions to various temperatures in order to change some of it to the insoluble form and then to determine the influence of such heat treatment on the conductivity of the unchanged solid. In each case, the insoluble oxide was rapidly filtered off with suction and the conductivity of the filtrates determined. The concentration of the solutions obtained was found—as in all previous cases—by evaporating accurately measured 50.0-cc. portions to dryness in a small quartz beaker and igniting in the same vessel to constant weight. Table I summarizes the observations made.

TABLE I

THE CONDUCTIVITY OF IGNITED SAMPLES OF "EVAPORATED" GERMANIC OXIDE

Nature of sample	$k \times 10^6$ mhos/cm.	Concn. g./liter	$k \times 10^6$ mhos/cm. (for 4.8 g./liter)
Hydrolyzed oxide	24.54	4.792	24.58
Evaporated oxide	7.94	4.786	7.96
Evaporated oxide (to 380°)	7.72	5.464	6.78
Evaporated oxide (to 700°)	5.13	4.948	4.98
Evaporated oxide (to 850°)	4.67	5.058	4.43
Evaporated oxide (to 1250°)	3.85	4.796	3.85

In the last column are shown values for the specific conductivities of all the solutions at the same concentration—calculated on the assumption that, between such small limits, a straight line relationship exists between concentration and specific conductivity.

Either one of two explanations was thought capable of accounting for these results: (1) the portion of the oxide not transformed to the insoluble variety may be so changed as a result of the increasingly high temperatures to which it is subjected that on subsequent solution it is hydrated in a continually different manner, or (2) there may have been present in the hydrolyzed oxide an impurity removable by evaporation and ignition—the impurity being completely driven out on heating to the melting point (approx. 1100°).

(e) It was then decided to repurify the oxide used. This was done as described above for the preparation of Lot 2 of the hydrolyzed oxide. The evaporations of this especially pure material were carried out in a quartz flask closed to the air and immersed in a thermostat kept at about 60°. The evaporation was aided by passing air through a purifying train containing silver nitrate solution, concentrated sulfuric acid, concentrated sodium hydroxide, solid sodium hydroxide and blowing it across the surface of the evaporating liquid. The air was introduced through quartz tubes sealed into a tightly fitting quartz stopper, while the escaping air and water vapor passed out through a small indentation on the side of the stopper. Under these conditions the changes observed in the specific conductivity when the "evaporated" oxide was redissolved in water were very small—about 2 to 3% of the original values, which, as shown in Table II, were themselves extremely low. Successive evaporations had, likewise, little or no effect on the conductivity.

Final Determinations.—These determinations were made on solutions of the oxide prepared from Lot 2 or 3. They were all obtained by boiling a weighed sample in a quartz flask with conductivity water until a clear solution was formed, cooling the solution to room temperature and determining the specific conductivity at 25°. The concentration was then determined accurately, as described above, on a carefully measured

volume of the solution—the sample being taken at 25°. Table II gives a summary of these observations.

TABLE II
THE SPECIFIC CONDUCTIVITY OF GERMANIC OXIDE AT 25°

	Source of sample	Concn., g./liter	$k \times 10^6$ (mhos/cm.)	$k \times 10^6$ mhos/cm. (for water)
1	Hydrolyzed (Lot 2)	4.720	2.91	0.96
2	Hydrolyzed (Lot 2)	4.720	2.99	.93
3	Hydrolyzed (Lot 3)	4.720	2.74	.92
4	Glassy (Lot 2)	4.658	2.78	.89
5	1050° (Lot 2)	5.520	5.41	1.00
6	From sulfide (Lot 3)	4.845	4.57	0.90

Table III shows the calculated values for the degree of dissociation, the equivalent conductivity and the primary dissociation constant of germanic acid as obtained from each of the observations recorded in Table II.

TABLE III
THE DEGREE OF DISSOCIATION, EQUIVALENT CONDUCTIVITY AND PRIMARY DISSOCIATION CONSTANT OF GERMANIC ACID

	Concn., mole/liter	$k \times 10^6$ mhos/cm.	$k \times 10^6$ mhos/cm. (corr.)	$\alpha \times 10^4$	Λ	$K_1 \times 10^9$
1	0.04513	2.91	2.73	1.59	0.0606	1.14
2	.04513	2.99	2.87	1.67	.0636	1.26
3	.04513	2.74	2.61	1.52	.0578	1.04
4	.04453	2.78	2.65	1.56	.0595	1.09
5	.05277	5.41	5.34	2.66	.101	3.73
6	.04632	4.57	4.50	2.55	.0970	3.00

In the case of each of the above solutions, dilutions were made and the specific conductivities determined at each concentration. The dissociation constants calculated decreased for all the solutions with decreasing concentration and remained fairly constant within the range 0.95 and 1.1×10^{-9} .

The only added electrolyte in all these solutions was the germanic oxide, which in the presence of water forms germanic acid. The specific conductivity of the water used was close to the value 0.85×10^{-6} mho per cm. found by Kendall¹² for "equilibrium water," and therefore we can make the assumption that the entire conductivity of the water was due to carbonic acid. In view of the very low conductivities observed, it is impossible to ignore the mutual effect of the two acids, carbonic and germanic, on their dissociation. A correction must be applied for this effect, and in making the above calculations this correction was determined by the method of Walker and Cormack.¹³ Column 3 of the last table gives the corrected value for each of the specific conductivities recorded. The value of Λ_∞ for germanic acid which is needed in these calculations was

¹² Kendall, *THIS JOURNAL*, **38**, 1480 (1916).

¹³ Walker and Cormack, *J. Chem. Soc.*, **77**, 5 (1900).

taken as 381.2, and was obtained by adding the mobilities of the hydrogen ion and the bigermanate ion. The value for the hydrogen ion, 349.9 at 25°, was taken from the "International Critical Tables,"⁹ while the value for the bigermanate ion, 31.3, was obtained from measurements on the conductivity of sodium bigermanate—the data for which are given in the following paper. The dissociation constant of carbonic acid at this temperature was taken as 3.5×10^{-7} , and the concentration of carbon dioxide in equilibrium water at this temperature as 1.4×10^{-5} mols per liter.¹²

In order to complete the study of the conductivity of solutions of the allotropes of germanic oxide, several experiments were carried out with the insoluble variety—obtained as already described. The purified sample was boiled repeatedly with conductivity water in a quartz flask. The specific conductivity of solutions thus boiled in the presence of the solid for varying lengths of time up to four hours showed no appreciable increase over the value for the conductivity water used in preparing the solutions. This is to be expected in view of the very low solubility of the α modification and the extremely low conductivity of even saturated solutions of the soluble varieties.

Discussion

The results obtained indicate that solutions of germanic oxide are quite stable, at least over a period of a week at the concentrations studied. Extremes of temperature do not seem to bring about any changes in the fundamental equilibria set up when the oxide is first dissolved in water, no matter whether an amorphous or crystalline variety is involved in the equilibria. Furthermore, the fact that at similar concentrations, solutions of the "evaporated" and "hydrolyzed" oxides have similar conductivities lends support to the conclusion of R. Schwarz and Huf that they are not distinct modifications, in spite of the observed differences in density and in their behavior on ignition. On the other hand, it is difficult to explain the fact that solutions of the "glassy" and "hydrolyzed" forms give practically the same conductivity—since it has been shown^{3,4} from x-ray spectrographic data that the one is amorphous and the other crystalline. It may be that the low values for these two varieties are due entirely or in large part to electrically charged colloidal particles, whereas, in the cases of the oxide obtained from the sulfide and that crystallized at 1050°, the amount of colloid in solution is relatively small. The higher conductivities observed in the solutions of the latter two samples would then be due almost entirely to dissociated germanic acid. In other words, all solutions of germanic oxide—no matter from what source—contain both molecularly and colloiddally dispersed material with the one or the other in greater amount depending on the source and manner of preparing the solutions. This would explain the small differences in conductivity observed for the

different samples and would be in agreement with the conclusion to which Schwarz and Huf arrived on the basis of their data concerning anomalies in the solubility of the oxide.

In any event, the very low conductivities observed in all the cases indicate a very high degree of purity for all the samples, and should serve to place a definite upper limit for the value to be assigned to the primary dissociation constant of germanic acid. Both the high and low values agree very well with the average value of Pugh, *i. e.*, 2.5×10^{-9} ; and when it is considered that Pugh's average was obtained from the three values 1.75, 3.2 and 2.1×10^{-9} , the agreement of our values with his seems to be quite satisfactory. However, in view of the very low conductivities measured, it was thought advisable to determine the value of the constant by other and independent methods. These are discussed in a subsequent paper.

Summary

1. The importance of exceptionally pure germanic oxide in conductivity work has been discussed and a description given of the method used to obtain such material.
2. The conductivity of solutions of the oxide from various sources has been measured and the values in all cases found to be much lower than those already in the literature.
3. In contrast to the work of Roth and O. Schwartz, the conductivity of these solutions was found to be practically unaffected by changes in temperature—either during their preparation or after.
4. Small differences in conductivity of solutions of the several varieties were observed and the possible cause for such differences discussed.
5. The dissociation constant of germanic acid was calculated from the conductivity data obtained, and found, at different concentrations, to lie between 1.0 and 3.0×10^{-9} . These values were in close agreement with those of Pugh.

THE CONDUCTIVITY AND DEGREE OF HYDROLYSIS OF SODIUM BIGERMANATE AND THE PRIMARY DISSOCIATION CONSTANT OF GERMANIC ACID¹

BY CHARLES E. GULEZIAN AND JOHN H. MÜLLER

RECEIVED APRIL 12, 1932

PUBLISHED AUGUST 5, 1932

The values obtained by the present authors for the conductivity of solutions of germanic oxide of a high degree of purity² tend to show that the probable value for the dissociation constant of germanic acid is approximately 1.0×10^{-9} , a value which is far removed from the values 1.2×10^{-7} and 0.5×10^{-7} obtained by Roth and O. Schwartz³ and R. Schwarz and Huf⁴ from similar conductivity measurements. Pugh,⁵ whose value for the constant, 2.5×10^{-9} , is in good agreement with our own, attributes the very high value of Roth and Schwartz to the low grade of conductivity water used in their investigation. The specific conductivity of their water was $1.5\text{--}1.7 \times 10^{-6}$ mhos per cm. at 18° , while that of the water used by Schwarz and Huf was $1.8\text{--}2.0 \times 10^{-6}$ mhos per cm. at 20° ; but, even though these values are much higher than that desirable for accurate measurements at these temperatures, they do not, alone, seem to be a sufficient explanation of the very wide discrepancy. The low conductivities found by us cannot be ascribed to colloidal dispersion because samples of the oxide which were definitely crystalline gave similar results. Furthermore, no matter from what source the germanic oxide was obtained, the results were always of the same order of magnitude. It seems, therefore, that either the results of other authors are subject to correction or that there exists in our own observations an undetected source of error of considerable magnitude. To remove the doubt that thus exists concerning the value for this constant, it was determined by two other methods, one conductimetric and the other colorimetric.

Outline of Conductimetric Method.—In order to secure some information concerning the behavior of germanic oxide in solution, conductimetric titrations were carried out. The titrations were performed in a closed conductivity cell, the air in which had been passed into it after purification through a line containing silver nitrate, concentrated sulfuric acid and solid sodium hydroxide. The carbonate-free caustic soda was prepared by

Cornog's method.⁶ Curves for several titrations are shown in Fig. 1. Curve A shows the results obtained when 25.0 cc. of 0.04453 *M* germanic oxide solution was titrated with 0.09287 *M* sodium hydroxide; curve B is for the titration of 25.0 cc. of 0.04632 *M* germanic oxide with the same caustic solution, while curve C gives the changes in specific conductivity when 100.0 cc. of 0.004453 *M* sodium hydroxide was titrated with 0.04453 *M* germanic oxide solution. In all these and similar cases, a definite break was obtained at a point corresponding to one equivalent of each substance.

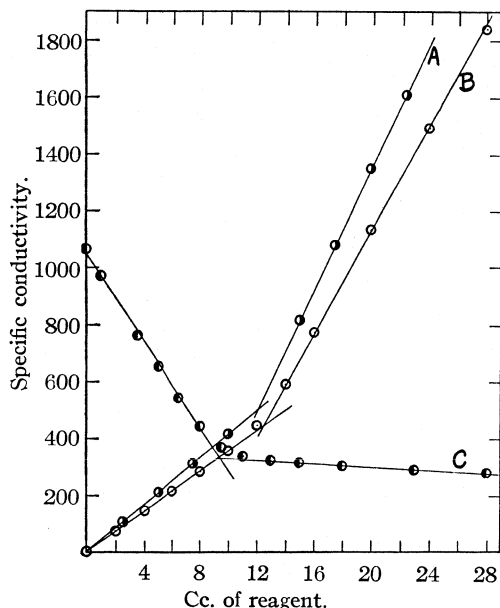

Fig. 1.—The conductimetric titration of germanic acid.

The further addition of sodium hydroxide produced no change in the direction of the curve irrespective of the nature or source of the oxide in solution. Germanic acid, therefore, can behave toward sodium hydroxide as a monobasic acid with the formation of the salt sodium acid germanate (analogous to sodium bicarbonate), evidence for the existence of which has already been given by Pugh. Pugh has also shown that the salt sodium metagermanate, Na_2GeO_3 , is hydrolyzed to an extent of 95% or more at concentrations approximately equal to those in our solutions, so that the addition of sodium hydroxide to sodium bigermanate produces

no appreciable formation of the normal meta salt. Obviously, accurate measurements of the concentration of germanic acid by conductimetric titrations is impossible due to the occurrence of considerable hydrolysis of the acid salt at the equivalent point—the evidence for this being especially noticeable in Curve C, Fig. 1; but the extent of this hydrolysis can be measured conductimetrically and from the degree of hydrolysis of the salt the dissociation constant of the parent acid can easily be calculated.

The conductimetric method for the determination of the degree of hydrolysis of a salt was originally described by Walker⁷ for salts of weak bases. Bredig⁸ also applied the method to the determination of the dis-

⁸ Bredig, *ibid.*, **13**, 321 (1894).

sociation constants of a number of weak organic bases; while, since then, it has been used to determine the degrees of hydrolysis of salts of weak acids as well as of weak bases. Examples of the application of the method for salts of weak acids are obtained in the work on cacodylic acid,⁹ acetic acid,¹⁰ cyanamide¹¹ and on certain oximes.¹²

In the present case, we have the reaction

taking place in a water solution of this salt. Direct measurement of the conductivity of the salt is, therefore, a measurement of the combined conductivity of the unhydrolyzed salt and of the sodium hydroxide formed. The conductivity of the free acid formed—exceedingly small as it is, even when present in water by itself at much higher concentrations—is here negligible, because of the very large excess of bigermanate ions from the salt. If, now, a buffer solution is formed having a considerable quantity of germanic acid present, hydrolysis of the salt can be prevented almost completely. The acid, again, will not contribute to the conductance of the solution, while complete dissociation of the salt can still be assumed. Measurement of the conductivity of such a solution will give a much more accurate value for the equivalent conductivity of the unhydrolyzed salt. From a knowledge of the equivalent conductivities in the two cases, it is possible to calculate the degree of hydrolysis from the expression.

$$\Lambda = x\Lambda'' + (1 - x)\Lambda'$$

where x is the degree of hydrolysis, and Λ , Λ' and Λ'' are the equivalent conductivities, at the same concentrations, of the hydrolyzed salt, the unhydrolyzed salt and sodium hydroxide, respectively. The value, Λ'' , for the sodium hydroxide used at any concentration is assumed to be that which would be obtained if the salt were completely hydrolyzed.

Experimental

The salt, sodium bigermanate, has never been isolated. Attempts to do so proved unsuccessful. It was, therefore, prepared in solution by adding exactly equivalent amounts of carbonate-free sodium hydroxide to known amounts of germanic oxide in solution. The figures in Table I show the method of preparation and composition of the various solutions used.

Twenty-five cubic centimeter portions of each of these solutions were transferred to the conductivity cell, dilutions made and the specific conductivity determined at each dilution. The apparatus was the same

The Mobility of the Bigermanate Ion.—When plotted against \sqrt{c} , the values for the equivalent conductivities for the salt in these four solutions give the results shown in Fig. 2. The points on curve A are for solution (1)—of the hydrolyzed salt. They fall on a smooth curve which rises very rapidly with dilution, indicating increasingly larger amounts of hydrolysis with decreasing concentration. The curve for the 1:1 buffer—curve C in the figure—shows that, in such a solution, hydrolysis is not completely repressed, since it becomes quite appreciable at low concentrations. Curve B is drawn through the points corresponding to the 3:1 buffer (Table V). The points for the 2:1 buffer, as shown, lie sufficiently close to this curve to warrant the conclusion that, in the case of the 3:1 buffer,

hydrolysis has been reduced almost to a minimum. As expected, curve B is asymptotic to curve A, since, in the more concentrated range, hydrolysis of the salt in water alone is very slight.

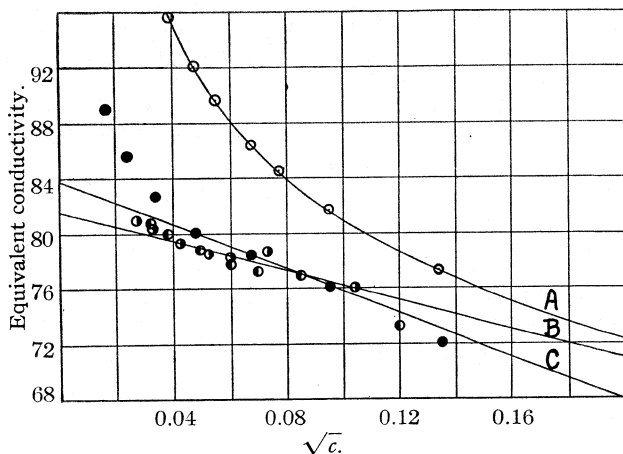

Fig. 2.—The equivalent conductivity of sodium bigermanate at 25°: ○, the salt in water alone; ●, 1:1 acid-salt ratio; ◐, 2:1 acid-salt ratio; ◑, 3:1 acid-salt ratio.

Extrapolation of curve B to zero concentration of salt then gives Λ_{∞} for sodium bigermanate. This was done on a large scale plot and the value found to be 81.75. This value can then be inserted in the theoretical equation of Onsager¹³ for strong electrolytes of the uni-univalent type

$$\Lambda = \Lambda_{\infty} - \alpha\sqrt{2\mu}$$

where μ is the ionic strength (equal here to the concentration of the salt in moles per liter) and α a constant varying with the electrolyte and equal at 25° to $0.1605 \Lambda_{\infty} + 42.28$. Evaluating this constant and introducing it as well as Λ_{∞} into the above equation we get

$$\Lambda = 81.75 - 78.3\sqrt{\mu}$$

The experimental slope obtained from the curve was found on the large scale plot to be 79.2, which checks very favorably with the value indicated for α in the above equation. We can, therefore, use the experimental curve and the extrapolated value of Λ_{∞} for the salt to calculate the mobility of the bigermanate ion.

The mobility of the sodium ion at 25° was taken as 50.5, as calculated from the value at 18° and the temperature coefficient given in the "I. C. T."¹⁴ Subtracting it from Λ_{∞} for the salt, we obtain 31.25 for the value of the bigermanate ion at 25°. This is considerably less than the corresponding

value for the bicarbonate ion, 46.6, calculated from Kendall's value¹⁵ for Λ_{∞} for sodium bicarbonate.

The Dissociation Constant of Germanic Acid.—In order to carry out the required calculations, it is necessary to have values for the equivalent conductivities of the hydrolyzed and unhydrolyzed salt as well as of sodium hydroxide at the same concentration. Inasmuch as the experimental concentrations for the different solutions from which the curves were drawn were not the same, the concentrations chosen for these calculations were those corresponding to the points on curve A for the hydrolyzed salt. The values for Λ' (for the unhydrolyzed salt) at these concentrations were then obtained by interpolation from curve B. Likewise, the values for sodium hydroxide were found by interpolation from a large scale plot of the values given for this substance in the "I. C. T."¹⁶ In Table VI are shown the necessary values used in the calculations together with the values for Λ' calculated from the Onsager equation. Table VII gives the calculated values for the degree of hydrolysis and the hydrolysis constant of the salt and the dissociation constant of germanic acid.

TABLE VI

\sqrt{c}	Λ	Λ'_{curve}	$\Lambda'_{\text{calcd.}}$	Λ''

Colorimetric Determination of the Dissociation Constant.—Buffer solutions were prepared, as before, containing germanic acid and sodium bigermanate, except that, before the final dilution, the indicator thymol blue was added to the solution. Determinations were carried out with two different samples of indicator of ordinary purity (Hynson, Westcott and Dunning) with no differences in the results. The indicator stock solution was prepared according to the directions given by Clark.²⁰ Throughout the measurements the concentration of the indicator in the buffers and comparison solutions was kept at 2×10^{-5} mole per liter; while the fully transformed acid and basic forms of the indicator were prepared as described by Kolthoff²¹ for the alkaline range of thymol blue. A Gillespie colorimeter was used to determine the acid-base ratio of the indicator in the buffer solutions. From this value and the relationship $[H^+] = K_{\text{Ind.}} \text{ acid/base}$ are obtained the hydrogen-ion concentrations in the various solutions. As the ratios of the salt to the free acid are known for each buffer, simple calculation with the aid of the mass action law gives the dissociation constant of the acid. The observations and calculated results are shown in Table VIII. The values in the third column for the dissociation constants of thymol blue at different ionic strengths were obtained by interpolation from a large scale plot of corrected values for this indicator which were very kindly supplied by Dr. Martin Kilpatrick, Jr.

TABLE VIII

	Concn. of salt	Buffer ratio (acid/salt)	$K \times 10^9$ (T. B.)	Ind. ratio (acid/base)	$[H^+] \times 10^9$	$K_1 \times 10^9$

Discussion

The values found for K_1 by the conductimetric method decrease with ionic concentration, as is to be expected on the basis of our present concepts on electrolytic solutions. The reverse seems to be the case for the values obtained colorimetrically. This apparent discrepancy is probably due to the fact that in the solutions studied by the latter method—with the exception of the one numbered 6—the buffer ratio is getting larger from solution to solution, even though the salt concentration is decreasing. In the case of two solutions—for example, 3 and 6—in which the ratio of molecular acid to dissociated salt is the same, the hydrogen-ion concentra-

²¹ Kolthoff, "The Colorimetric and Potentiometric Determination of pH ," John Wiley and Sons, New York, 1931, p. 45.

tion as well as the dissociation constant of the acid are found to decrease with decreasing ionic strength. On comparing the values 0.55×10^{-9} obtained colorimetrically with the value 0.89×10^{-9} obtained conductimetrically on a similar 3 : 1 buffer at approximately the same ionic strength, the agreement is found to be fair. The magnitude of the values is, again, of the same order, while the results themselves agree very well with the values close to 1.0×10^{-9} obtained previously by us from conductimetric measurements on solutions of the free acid. The colorimetric method is, of course, limited in its accuracy, but it serves as a very good check on the values obtained by the other and more accurate methods. The fact that the hydrogen-ion concentrations in the buffer solutions studied lie within the range of applicability of this indicator is good indication that the dissociation constants of thymol blue and germanic acid are of the same order of magnitude.

Three methods, independent of each other, were thus used and all gave values in good agreement. The average value of all the determinations—about 1.5×10^{-9} —though somewhat smaller than the value 2.5×10^{-9} reported by Pugh from potentiometric measurements, points rather definitely to the conclusion that values in the neighborhood of 1.0×10^{-7} are considerably in error. We attribute our lower values to a higher degree of purity of the germanic oxide used.

Acknowledgment.—Grateful acknowledgment is made by C. E. Gulezian to the George Leib Harrison Foundation for the fellowship grant which made it possible to carry out this investigation.

Summary

1. Conductimetric titrations of germanic acid with sodium hydroxide have been carried out and indicate the existence in solution of the salt sodium bigermanate.
2. The degree of hydrolysis of this salt at different concentrations has been measured by a conductimetric method, and the dissociation constant of germanic acid calculated from the observations made.
3. The mobility of the bigermanate ion was determined and found to be 31.3 at 25°.
4. Thymol blue was used, in buffer solutions, for the colorimetric determination of the dissociation constant of germanic acid.
5. The average value—approximately 1.5×10^{-9} at 25°—found for the constant by the use of three different methods was compared with the values of other investigators and found to agree with that of Pugh.

MOLECULAR AND ACTIVATED ADSORPTION OF CARBON MONOXIDE ON MANGANOUS OXIDE SURFACES

BY ARTHUR TANDY WILLIAMSON

RECEIVED APRIL 16, 1932

PUBLISHED AUGUST 5, 1932

During the course of a thorough experimental study of the adsorption of hydrogen on oxides of manganese,¹ an orientation experiment indicated that carbon monoxide behaved in the same general way as hydrogen. The purpose of this communication is to report the results of a comprehensive investigation leading from the earlier observation, and to compare the results obtained with the two gases.

The general theory underlying the experimental work has been given by Taylor,² whose paper should be consulted for a comprehensive background. Experimental studies of the adsorption of carbon monoxide on various oxides have been carried out by many,³ although none of these workers chose the particular surfaces used in this investigation.

Experimental

The preparation of the catalysts and the apparatus was described in the earlier paper.¹ The carbon monoxide used for these investigations was prepared by dropping formic acid into concentrated sulfuric, passing the resulting gas through copper gauze held at 300°, ascarite and phosphorus pentoxide.

Low Temperature Adsorption.—Isothermal adsorption was measured at the temperature of liquid air and again at -78.5° . The results are given in the following tables, which show the amount of carbon monoxide adsorbed in cubic centimeters per gram of catalyst, and which give the resulting equilibrium pressures in millimeters of mercury. All gas volumes were reduced to standard conditions. The general procedure consisted in the preliminary evacuation of the catalyst at 450° and the immersion of the catalyst tube in the desired thermostating medium for several hours to facilitate the attainment of temperature equilibrium. Successive portions of carbon monoxide were then added, readings of the equilibrium pressure being made after each addition. When several points had been obtained desorption was carried out in the same way. The reversibility of an isotherm is shown by the fidelity with which adsorption and desorption points fall on a common curve. In all cases low temperature adsorption was instantaneous.

¹ Taylor and Williamson, *THIS JOURNAL*, **53**, 2168 (1931).

In addition to the thermostating agents described in a previous paper, use has been made of liquid air, whose temperature could be read continuously by an oxygen vapor pressure thermometer.⁴ It was found that an isotherm could be completed in such a bath with a total temperature drift of less than 0.5°.

TABLE I
ISOTHERMS ON 51.3 GRAMS OF $\text{MnO}-\text{Cr}_2\text{O}_3$

Temp., P	85.0°K. V ads./m.	P	85.0°K. V ads./m.	P	194.5°K. V ads./m.
0	0.0	32	18.0	0	0.00
1	8.8	58	19.2	6	2.63
2	10.4	87	20.5	20	3.65
3	12.2	118	21.6	62	4.52
4	13.2	91	20.8	132	5.18
5	14.2	68	19.9	227	5.70
8	15.3	47	18.9	332	6.10
17	16.5			177	5.48
				75	4.72
				23	3.82

The isotherm obtained in this manner is difficult to extrapolate to pressures less than 1 mm. If, however, we plot the function P/V against P we obtain a curve which becomes a straight line of the general form $y = mx + b$ below 40 or 50 mm. Disregarding P/V values where P is less than 5 mm. (due to the hypersensitivity of the function in this region), we obtain a straight line which enables us to calculate the equilibrium pressure corresponding to any adsorbed quantity in the low pressure region. In such a manner the values obtained for the pressure given by the adsorption of 3.0 cc. per gram of catalyst were 0.36 mm. and 9.0 mm. at temperatures of 85.0 and 194.5°K., respectively. Substituting these values in the equation

$$\ln P_2/P_1 = \frac{\lambda}{R} \left[\frac{1}{T_1} - \frac{1}{T_2} \right]$$

we obtain $\lambda \cong 980$ cal. This low value is in accord with the idea that this type of adsorption is caused by van der Waals forces.

For the adsorption of 0.1 cc. per gram we obtain pressures of 0.05 mm. and 77 mm. at 83.0 and 194.5°K., respectively. This leads to the following value for the heat of adsorption, $\lambda \cong 2100$ cal.

Due to such complications as capillary condensation of the adsorbate, which is easily condensable in this temperature region, the values given for the heat of adsorption should be accepted only in so far as they give the correct order of magnitude required by non-specific adsorption.

Inspection of the low temperature isotherms of $\text{MnO}-\text{Cr}_2\text{O}_3$ yields the following values for isobaric adsorption at 150 mm. pressure: at 85.0°K.

⁴ Stock, *Ber.*, 39, 2066 (1906).

				296	.325
				141	.166

V ads./m. = 22.5; at 194.5°K. V ads./m. = 5.3. Assuming that the amount adsorbed decreases exponentially with temperature we can show that it will have decreased to less than 2.4 cc. per gram at 306°. The importance of this result will be clear after the high temperature measurements have been presented.

High Temperature Adsorption.—Attempts were made to obtain an isotherm at 218° on MnO-Cr₂O₃, for at this temperature the adsorption should be largely activated. This prediction was realized in part, for large quantities were adsorbed at speeds which were rapid but finite, the amount reaching the following high value.

<i>V</i> ads.	<i>V</i> ads./m.	<i>P</i>
343.5	6.70	172

However, it was impossible to obtain true equilibrium values, for after the rate had died down to a certain point it drifted steadily for weeks without any marked diminution in magnitude. The reason for this drift with carbon monoxide became apparent when a similar experiment was made at 306°. Once more the rate dropped from its initially high value to one which showed no signs of approaching zero. After five weeks' contact the adsorption reached the following value.

V_T^5	V_{DS}	<i>V</i> ads.	<i>V</i> ads./m.	<i>P</i>
276.0	4.3	271.7	5.29	90

The temperature was then raised to 450° and the gas was removed from the catalyst chamber by the Sprengel pump for measurement and analysis. The results are tabulated below.

⁵ These abbreviations have the following meanings: V_T = total volume of gas in the catalyst tube; V_{DS} = volume required to fill the "dead space"; V ads. = the difference of the above two, *i. e.*, the amount adsorbed. V ads./m. = adsorption per gram of catalyst.

TABLE III

ADSORPTION OF CO ON $\text{MnO}-\text{Cr}_2\text{O}_3$ AT 306°

Carbon monoxide introduced, 276.0 cc. Gas recovered by Sprengel pump, 273.4 cc.

Sample no.	CO	Analysis of recovered gas	
		CO_2	% CO_2
1	33.2	8.4	20.2
2	18.7	6.3	25.2
3	38.2	14.3	27.2
4	36.4	16.5	31.2
5	41.1	18.0	30.5
6	23.1	19.2	45.4
	<hr/> 190.7	<hr/> 82.7	<hr/> 30.3

There are two ways in which the carbon dioxide may be formed; by the reaction $2\text{CO} \rightarrow \text{C} + \text{CO}_2$ or by actual reduction of the catalytic surface. Since the total volume of the recovered gases was practically equal to the amount of carbon monoxide originally introduced, it is evident that the former mechanism is excluded. We are, therefore, forced to the conclusion that reduction of the catalyst has taken place. It is to be observed that the proportion of carbon dioxide increases as the desorption advances.

The reduced catalyst was next reconditioned by oxidizing it in air at 300° and reducing with hydrogen at the same temperature. It was pumped off thoroughly at 450° . The influence of the time factor on reduction of the stable oxides was then studied by adsorbing a fairly large quantity of carbon monoxide at 306° and cleaning the surface with the Sprengel pump as rapidly as possible.

TABLE IV

ADSORPTION OF CO ON $\text{MnO}-\text{Cr}_2\text{O}_3$ AT 306°

Time of adsorption = two hours

V_T	V_{DS}	$V_{ads.}$	$V_{ads./m.}$	P
172.5	6.4	166.1	3.22	134
		Analysis of recovered gas		
		CO	CO_2	% CO_2
1.	Desorption at 306° , 12 hours	115.9	0.9	0.8
2.	Desorption at 450° , 8 hours	41.2	16.2	28.2
		<hr/> 157.1	<hr/> 17.1	<hr/> 9.8
Carbon monoxide introduced				172.5
Gas recovered				174.2

The marked rise in the yield of carbon dioxide with the rise in temperature shows that this is the main factor in the reduction of the catalyst, and that an activated adsorbate does not necessarily yield a reduced surface unless the temperature is high enough. Since the 57.3-cc. sample collected at the higher temperature did not yield as high a proportion of carbon dioxide as did the similar final portion collected after the five-week run, we

may conclude that reduction of the catalyst will take place at 306°, but only at a rate which is very small compared with the velocity of activated adsorption. Both rates are increased tremendously by raising the temperature.

On MnO an attempt was made to measure an isotherm at 444°, but the same difficulties intervened. After three weeks of contact the following values were obtained.

TABLE V
CO ON MnO AT 444°

V_T	V_{DS}	$V_{ads.}$	$V_{ads./m.}$	P
41.3	17.2	24.1	0.60	447
Analysis of desorbed gas				
	CO	CO ₂	% CO ₂	
	7.9	29.1	78.6	
Carbon monoxide introduced				41.3
Gas recovered				37.0

The reduction is startlingly evident. Furthermore, the apparent decrease of 4.3 cc. in the total volume is significant, for the quantities of gas admitted normally agree with the amounts collected by the Sprengel pump within $\pm 1\%$. In this case there is a drop of some 10%, so the reaction $2\text{CO} \rightarrow \text{C} + \text{CO}_2$ may have been proceeding simultaneously with the ordinary surface reduction by the carbon monoxide.

Rates of Adsorption.—In the investigation of the adsorption of hydrogen on these catalysts it was easy to separate the two types because adsorption of the molecular sort was relatively very small, and was negligible in the temperature range where the activated adsorption was occurring with a measurable velocity. With carbon monoxide the van der Waals forces are larger, so the molecular adsorption overlaps the activated form at all temperatures suitable for rate measurement. For this reason it was impossible to measure the activation energy required to adsorb carbon monoxide in the activated form.

General

Although the order given in this paper would indicate that the low temperature measurements were the first to be made, this was so only with the unpromoted MnO. On the mixed oxide surface all the high temperature measurements were completed before the isotherms at -78.5 and -190° were investigated. This is very important in the light of a suggestion⁶ recently made which attempts to explain activated adsorption as a slow chemical reaction which removes impurities from the surface, thereby leaving a larger area available for adsorption purposes.

The experimental facts actually obtained are not in accordance with

⁶ Allmand and Chaplin, *Trans. Faraday Soc.*, **28**, 223 (1932).

such a theory, for the early attempts to obtain an isotherm at 218° led to an adsorption value of 6.70 cc. per gram of $\text{MnO-Cr}_2\text{O}_3$. Later, when the isotherm at -78.5° was measured it was found that the quantity adsorbed per gram at the same pressure (172 mm.) was about 5.4 cc., a marked decrease instead of a very large increase. Additional evidence against the theory has been given in Table IV, where it was shown that of 166.1 cc. of gas adsorbed in the activated form not more than 17.1 cc. could be attributed to a combination with the surface to give carbon dioxide, and that the maximum possible "molecular" adsorption would be 2.4 cc. per gram, or 127 cc. in all.

In the experiments with hydrogen reported in the earlier paper,¹ high temperature runs on both catalysts were completed before the molecular adsorption was measured, and in that case the activated adsorbate was far greater in magnitude than any of the low temperature molecular values.

In conclusion the writer wishes to thank Professor Hugh S. Taylor for his interest in the prosecution of this work, and for his part in the planning of the experimental procedure leading to the results given above.

Summary

1. The adsorption of carbon monoxide on MnO and $\text{MnO-Cr}_2\text{O}_3$ has been measured between -190 and $+444^{\circ}$.
2. The adsorption takes place in two forms: a molecular form at low temperatures with zero energy of activation and a heat of adsorption of 1000–2000 calories and an activated form which becomes evident above 0° . The former is easily pumped off, the latter is very difficult to recover.
3. Unlike hydrogen, the activated carbon monoxide adsorbate causes partial reduction of the catalyst. It has been found, however, that this reduction is slow compared with the velocity of activated adsorption, and as much as 90% of the activated adsorbate has been recovered unchanged.
4. Overlapping of the two types prevented measurement of the velocity of adsorption, so it is impossible to give any values for the activation energy of the high temperature process.
5. These oxides do not catalyze the reaction $2\text{CO} \longrightarrow \text{C} + \text{CO}_2$ to any measurable extent below 300° , although evidence points to its possible occurrence on MnO at 444° .

THE PHOTOLYSIS OF THE ALIPHATIC ALDEHYDES. I. PROPIONALDEHYDE

BY PHILIP A. LEIGHTON AND FRANCIS E. BLACET

RECEIVED APRIL 20, 1932

PUBLISHED AUGUST 5, 1932

The application of atomic mechanics to the processes following upon the absorption of light has met with some success in the case of diatomic molecules, in elucidating the nature of photochemical activation and reaction mechanism. In applying to polyatomic molecules some of the principles of photochemical activation and reaction mechanism which have arisen from the study of diatomic molecules, one of the most promising fields is offered by the aliphatic aldehydes, which, starting with formaldehyde, are only a step more complicated than a diatomic molecule of the oxygen type.

The absorption spectra of the aldehydes in the region 2500–3500 Å. have been studied by Victor Henri and his collaborators¹ who have shown that in every case the three typical regions of absorption; bands with fine structure, diffuse bands or predissociation, and continuous absorption, are found as one goes from long to short wave lengths. The different regions merge into each other, and the first two are overlaid with a faint continuous absorption.

The work of a number of observers² has shown that the simpler aldehydes are all decomposed by the absorption of light in this region. The reaction proceeds principally in two ways: first, a direct decomposition into carbon monoxide and the corresponding hydrocarbon, $\text{RHC}\text{O} = \text{RH} + \text{CO}$; and second, a polymerization into complex solid products. Attempts to detect the presence of other gases, such as hydrogen, carbon dioxide, oxygen or water vapor in the products of decomposition have shown that they are either totally absent or, if present, are found in only very small amounts.

An investigation by J. H. C. Smith and Victor Henri³ into the kinetics of the reactions has shown in the case of acetaldehyde that the governing rate of the decomposition is unimolecular, while the governing rate of the polymerization is bimolecular.

It is a matter of interest, in view of recent interpretations of the phenome-

non of predissociation,⁴ to correlate, as far as is possible, the spectroscopic data with the photochemical reactions produced. In particular the influence of wave length changes on the two reactions should be investigated. Several approximate measurements of the influence of wave length have been made. De Hemptinne,¹ working on benzaldehyde, found that the decomposition into benzene and carbon monoxide did not occur at wave lengths longer than the limit of the diffuse spectrum. Kirkbride and Norrish² have recently made similar tests on formaldehyde, and have reached the same conclusion regarding its decomposition. Smith³ studied the effect of wave length on both the decomposition and polymerization of acetaldehyde vapor. He found that polymerization was effected by light throughout the absorption region, but that the decomposition proceeded rapidly only in the region of continuous absorption.

Since these measurements were all made with the use of light filters, which can give only an approximate separation of the different regions, and since none involved an accurate measurement of quantum yields, the authors have undertaken a series of quantitative measurements in monochromatic light on a number of the aldehydes. The present paper describes the experimental method, and the results on propionaldehyde. In a subsequent paper, a study on acetaldehyde will be reported, and a correlation between spectroscopic and photochemical data proposed.

2. Apparatus and Method

(a) **Monochromator.**—The ultraviolet radiation was obtained from a high pressure quartz mercury arc of the type perfected by Forbes, Harrison, P. A. Leighton and W. G. Leighton.⁵ These arcs give very constant and intense illumination. The one employed in this research has been used frequently for runs of over twelve hours duration without appreciable fluctuation of intensity although no adjustments of any kind were made during this time.

Monochromatic light was obtained by means of a fused quartz prism and lenses, as shown diagrammatically in Fig. 1. Section A outlines the box, drawn to scale, which housed the arc and monochromator. Light from the arc entered the collimating slit S and, after passing through the prism and lenses, had its various components focused along the dotted line F. The entire box A was movable so that any desired line of the mercury spectrum could be brought to a focus upon the second slit S'. This was facilitated by pivoting the box beneath the lens L'. The pivot pin fitted in a channel which was in direct line with S'. This made it certain that the light entering section B was always traveling in the same direction.

The equilateral prism *P* was of fused silica 6.5 cm. high and 9.5 cm. on a side. The lenses *L* and *L'* were of the same material and 7.5 cm. in diameter. Their focal lengths were approximately 21 cm. for yellow light. *L* was placed 20 cm. from the slit *S*. The monochromator had a curved collimator slit, 1.5 mm. by 30 mm. in size, which gave a rectilinear image.

Section B, Fig. 1, was a thermostatically controlled box containing, primarily, the absorption tube *R* and the thermopile *T*. The slit *S'* was of adjustable knife edges, 3 cm. high. It was maintained at 1 mm. in width in this work. A black screen was placed in front of *R*. The opening in this was made sufficiently small so that no light could enter directly into the walls of the tube.

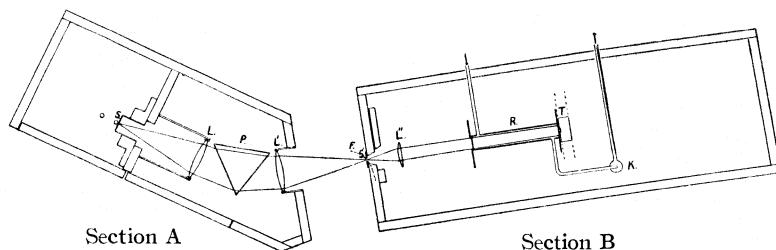

Fig. 1.—Diagram showing the path of monochromatic light.

(b) **The Gas Train.**—It was found that the common stopcock lubricants cause polymerization of propionaldehyde vapor. Mercury, on the other hand, in the absence of oxygen has no effect on the aldehydes. Accordingly, a gas train was constructed in which the aldehyde vapor at no time came in contact with any material except mercury, Pyrex glass and fused silica. Figure 2 is a diagrammatic sketch of this arrangement. *A* was a storage bulb for the substance being investigated. *B* and *C*, with the vertical tubes above, were mercury gas traps. *R* represents the absorption chamber. *K* was a liquid air trap. That part of the diagram designated by *M*, *N*, *O*, *O'*, *Q*, *U*, *Y* and *W* was a gage for measuring small changes in pressure during an exposure.

The operation of the traps *B* and *C* is obvious, except that in order to open them it was necessary to have the mercury standing at the same level in the two arms of the U-tube, as vacuum was being applied to the flask. This was accomplished by using liquid air to reduce the vapor pressure either in *A* or *R* as might be required. The right-hand vertical tube of trap *C* led to a Toepler pump and the gas analysis apparatus.

The absorption chamber *R* was 20 cm. long and 3 cm. in diameter. It was made entirely of fused quartz and was connected to the rest of the apparatus by means of Pyrex-to-silica graded seals. The ends were of plain quartz fused in place. An attempt was made to use a glass tube with quartz windows sealed on with chicle cement. This plan was abandoned, however, when it was found that propionaldehyde vapor condenses rapidly to a liquid upon coming in contact with this cement.

(c) **The Pressure Gage.**—In order to measure the small changes in pressure during photolysis, the differential pressure gage diagrammed in Fig. 2 was employed. This was an adaptation of the type described by Pearson.⁶ *M* was an evacuated bulb, having two sealed-in tungsten electrical contacts. The tip of the upper one of these was accurately centered in the bulb. A dry cell and relay completed the circuit. A condenser was used across the relay terminals to prevent sparking.

N was a tube of uniform bore and 13.1 mm. diameter. *O* was a uniform capillary tube having a volume of 0.867 cu. mm. per linear mm. This was mounted upon a milli-

⁶ Pearson, *Z. physik. Chem.*, **A156**, 86 (1931).

meter scale. O' was a 300-cc. bulb, which acted as an air cushion and permitted a sensitive adjustment of the mercury height in the capillary O.

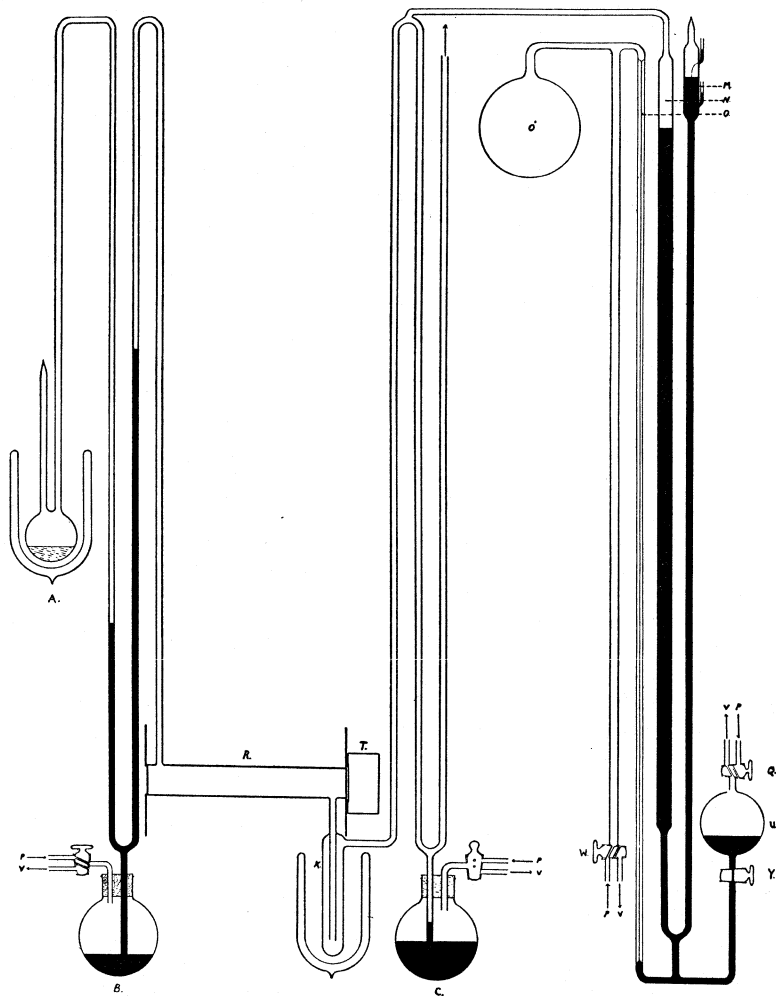

Fig. 2.—Diagram of the essential features of the gas train and the pressure gage.

At the beginning of a run, mercury was brought to a convenient height in the capillary by operating the two-way stopcock W, which was open to the atmosphere and also connected to the vacuum line. Mercury was then brought just to the point of electrical contact in M by the proper manipulation of stopcocks Q and Y. Following this, Y was closed, leaving a definite amount of mercury in the system, MNO. In these adjustments the mercury in N automatically came to a certain level, depending upon the pressure in the absorption tube R.

With the traps B and C closed (but their stopcocks open to the atmosphere), the volume of gas in RKN was fixed. (Volume change in the small columns of the traps

due to fluctuating atmospheric pressure was negligible with respect to the total volume of the gas.) Any change in pressure in the system due to a reaction in R caused a variation of the mercury level in N. Let it be supposed that there was a slight increase in pressure in the system. Since the space above the mercury in M was evacuated, the system MN acted in the same manner as a barometer and there was a definite completion of the relay circuit. Now by applying vacuum at W, the mercury level in O was raised, drawing mercury from M until the level there was again just at the point of "make and break." Since the level in M was back then to the original point, the extra mercury drawn into O came from N. From the change in height of the column in the capillary and from the volume ratio per unit length of the tubes N and O, the pressure change in the system RKN was calculated. One mm. change of the mercury height in O was equivalent to 0.00642 mm. pressure change in the reaction system.

In practice, pressure gage readings were taken at frequent intervals during an exposure. These values were plotted against time and from the curve obtained in this way the total pressure change in the system during an exposure was obtained with a certainty of ± 0.01 mm.

The temperature of the system RKN was controlled to within 0.1 of a degree. The volume, which varied with the pressure, could always be calculated. The total pressure in the system was obtained from a metric scale placed between the two arms of the Y tube of trap C. This was permissible since the tube leading to the Toepler pump was always highly evacuated during an exposure.

(d) **Energy Measurements.**—The thermopile used in this work was made by one of us. It contained twenty bismuth to silver "hot" junctions with blackened tin foil radiators. It was of the line type, having an exposed sensitive surface 3.0 mm. wide and 30.50 mm. high. A thin crystal quartz window protected the junctions from air currents and dust. As indicated in Fig. 1, the thermopile could be moved horizontally across the rear window of the absorption tube R. This movement was effected by means of a machined screw with 1 mm. pitch. A high sensitivity galvanometer (Leeds-Northrup, type 2285-X) was used with the thermopile. This was mounted in a heavy Julius suspension and at the center of curvature of a millimeter scale five meters away.

This thermopile-galvanometer system was calibrated in the manner previously described.⁷ In addition to the sensitivity of the thermopile as a whole, the integrating ability of aliquot portions of its length was tested in the manner described by W. G. Leighton and G. S. Forbes.⁵ The mean deviation in sensitivity along the sensitive surface was found to be $\pm 4\%$. Corrections were found for only the first and last thermopile readings, and since these readings were always of small magnitude (being taken on the edge of the beam), the corrections could be neglected without appreciable error. The sensitive surface of the thermopile was sufficiently long to extend slightly above and below the widest portion of the light beam coming through the absorption tube. Since the thermopile slit was 3 mm. in width, the total emergent energy, ΣB , was integrated by moving the thermopile across the back of the absorption tube in steps of 3 mm. each.

(e) **Calibration of the Absorption Tube.**—In order to obtain the amount of energy absorbed by a gas in the reaction chamber, it was not sufficient to calculate the difference between the total radiation passing through the tube when it was full and when it was empty. A certain fraction, x , of the light entering the tube was lost through the walls because of imperfections in the optical train. This loss was due principally to the fact that a line source, instead of a point source, of radiation was used.

⁷ Leighton and Forbes, *THIS JOURNAL*, 51, 3549 (1929).

It can be shown that this fraction x is given for each wave length by the expression

$$x = 1 - \frac{J_t}{b^2 J_0} \quad (1)$$

in which J_0 is the energy incident on the front window of the cell, J_t is the energy emerging from the rear window, and b is the fraction of incident monochromatic light transmitted by a single quartz window in air. The values for b may be obtained from indices of refraction of the various wave lengths and the application of Fresnel's law. Experimentally, for each of the strong lines of the mercury arc, J_t was obtained in the manner which has been described and J_0 was ascertained by removing the quartz reaction tube and placing the thermopile and its track up so that its window was in the same plane as was previously occupied by the front window of the tube. By integrating the beam which came through the black screen, which was now immediately in front of the thermopile, the correct value of J_0 was secured. Once determined for an experimental set-up, x becomes a constant in the calculation of quantum efficiencies (see equation 2).

(f) **Method of Analysis.**—The method of microanalysis employed has been described in detail elsewhere.⁸ In spite of the fact that liquid air was used to condense the surplus aldehyde vapor, a small amount of this substance was always present in the gaseous decomposition products. In order to remove it, a solid potassium hydroxide bead was introduced into the gas by the method previously described. This reagent caused rapid polymerization of the aldehyde to a resin-like substance which adhered to the bead and was removed with it from the gas sample.

The amount of carbon monoxide produced in decomposition was taken as an index of the number of molecules of aldehyde which decomposed. Solid silver oxide was used to absorb the carbon monoxide. A complete description of the use of this absorbent will be given in another article. The volumes of gas used for analysis varied between 50 and 100 cu. mm. Check determinations were made in all cases, and for eighteen consecutive samples from different exposures, the average deviation from the mean per cent. of carbon monoxide for each sample was 0.26% absolute.

In the study of the mechanism of decomposition, it is important to know whether or not hydrogen is produced and, if so, to what extent. The principal hydrocarbon found in the decomposition of propionaldehyde is ethane. If hydrogen is formed there should be an equivalent amount of butane formed also. Since these hydrocarbons are solids at liquid air temperatures, an attempt was made to separate the carbon monoxide and hydrogen from the ethane and butane by thoroughly cooling the trap K (Fig. 2) and pumping off the carbon monoxide and hydrogen in a minimum number of operations of the Toepler pump. Although some of the hydro-

⁸ Blacet and Leighton, *Ind. Eng. Chem., Anal. Ed.*, **3**, 266 (1931).

carbons came over in the pumping, there was a sufficient enrichment of the hydrogen content so that an analysis for it could readily be made. The carbon monoxide was first removed and then the residue was analyzed by explosion for hydrogen and ethane, the assumption being made that the butane remained in the liquid air trap.

It is well known that silver oxide reacts with both hydrogen and carbon monoxide and, theoretically, its use as an absorbent introduced an error in the percentages of these gases found to be present. However, dry silver oxide reacts much more slowly with hydrogen than it does with carbon monoxide. By means of a series of experiments with known mixtures of these gases, it was found that in the time necessary to remove all the carbon monoxide in a sample containing 90% CO and 10% H₂, not more than 2.5% of the total amount of hydrogen could be absorbed. Since 10% H₂ is above the maximum amount experimentally found in photolysis (see Table II), it may be reasoned that 0.25% absolute represents the maximum error due to this cause.

(g) **Calculations.**— L_0 , the amount of light which entered the absorption tube per second, is given by the equation

$$L_0 = \Sigma B_I \times \frac{1}{b} \times \frac{1}{1-x} \quad (2)$$

and L_t , the energy reaching the rear window per second, by

$$L_t = \Sigma B_L \times \frac{1}{b} \quad (3)$$

ΣB_I is the total ergs per sec. emerging from the rear window of the empty tube and ΣB_L is this summation when the tube contains the absorbing gas. In the calculation of each of these quantities a factor was introduced which corrected for the difference in transmission of the quartz thermopile window for the wave length used as compared to its transmission for the mean wave length of the light from the carbon filament standard lamps.

It can be shown that Q and Q' , the fraction of L_0 absorbed by the original vapor at the beginning and at the end of an exposure, are given respectively by the expressions^{9,7}

$$Q = (1-L)(1+rL) \frac{\log L - \log I}{\log L} \quad (4)$$

and

$$Q' = y(1-L)(1+rL') \frac{\log L - \log I'}{\log L'} \quad (5)$$

in which $L = L_t/L_0$, $I = 1-x$, L' is the fraction of L_0 reaching the rear window at the end of an exposure, r is the fraction of light striking the rear window which is reflected back into the reaction system, and y is the fraction of the original gas remaining in the reaction chamber. In the evaluation of y , the assumption was made that in polymerization a trimer

⁹ Luther and Weigert, *Z. physik. Chem.*, **53**, 408 (1905).

was formed which remained in the gaseous state. The error introduced because of this assumption cannot be large, for in all cases y was only slightly less than 1.0.

In this research it was found that L and L' were equal, within about 1%, for all runs. Since this is within the limits of experimental errors

$$Q' = yQ \quad (6)$$

and from previous study⁷ the average fraction of the light entering the tube absorbed during a run

$$Q_m = \sqrt{QQ'} = Q \sqrt{y} \quad (7)$$

The total quanta absorbed is given by

$$\text{Quanta} = \frac{L_0 S Q_m}{h\nu}$$

in which S represents the time in seconds and $h\nu$, of course, the energy per quantum. Φ_d , the quantum efficiency of decomposition, was taken as the ratio of the molecules decomposed to the total quanta absorbed (*i. e.*, $\Phi_d = \text{molecules decomposed}/\text{quanta absorbed}$).

It was impossible to determine the polymerization products of photolysis (see experimental results); therefore, in order to obtain some basis for the comparison of the amounts of polymerization at different wave lengths or pressures, a quantum yield of apparent polymerization was adopted. This value was obtained by calculating the decrease in molecular concentration during an exposure which was due to polymerization and dividing this by the number of quanta absorbed. The total molecular change in the system was secured from the pressure gage readings. Each decomposing molecule caused an increase of one molecule in the system. Therefore, molecules apparently polymerized = molecules decomposed - (\neq total molecular change). From this was calculated the quantum efficiency of *apparent polymerization*.

$$\Phi_p = \frac{\text{molecules apparently polymerized}}{\text{total quanta absorbed}}$$

3. Experimental Results

In the study of propionaldehyde, five lines of the mercury arc, ranging from 2537 to 3130 Å., were used for monochromatic radiation (Table I). As shown in Fig. 3, these lines cover fairly uniformly the region of maximum absorption which is attributed to the carbonyl group. In this graph, the average value of Q_m at 200 mm. pressure is plotted against the wave length of light employed.

The variations of both the decomposition and apparent polymerization quantum yields (Φ_d and Φ_p , respectively) with wave length, are given in Fig. 4. The points shown in each case are the average of two or more values obtained with an approximately constant pressure of 200 mm. in the reaction system.

TABLE I
 EXPERIMENTAL DATA FOR QUANTUM YIELDS

λ , Å.	Pressure, mm.	L_0 , erg./sec.	Quanta absorbed $\times 10^{18}$	Molecules decomposed $\times 10^{18}$	Mol. appar. polymerized $\times 10^{18}$	Φ_d	Φ_p

	192	8485	12.87	6.40	9.80	.497	.763
	74	27500	27.56	14.90	7.32	.540	.266
	36	11620	13.40	7.57	1.80	.565	.134
	13	12340	7.53	4.16	0.26	.552	.034

At two different wave lengths (2654 and 3130 Å.) the variations of quantum yields with pressure were determined. In Fig. 5, it may be observed that Φ_d at both wave lengths has a nearly constant value over the pressure range of 13 to 200 mm. Polymerization, on the other hand, increases steadily over this range.

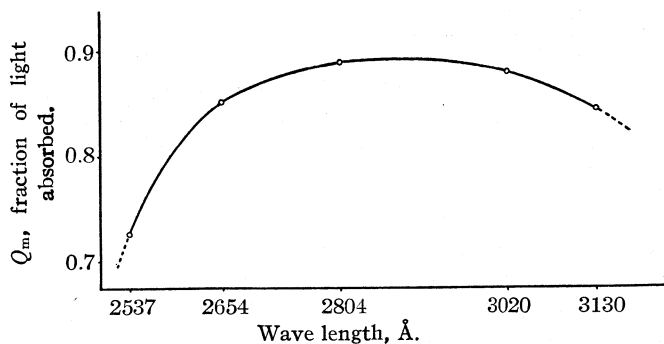

Fig. 3.—Fraction of light absorbed, Q_m vs. wave length, at 200 mm. pressure.

A constant temperature of 30° was used for all determinations of quantum efficiencies.

TABLE II
 HYDROGEN FROM PROPIONALDEHYDE DECOMPOSITION

λ , Å.	Pressure, mm.	Analysis	Vol. CO, cu. mm.	Vol. H ₂ , cu. mm.	H ₂ , %	Average % H ₂	% C ₂ H ₅ CHO molecules yielding H
2537	196	1	328.2	14.1	4.6	4.4	8.8
		2	328.2	13.0	4.2		
2654	89	1	384.8	28.0	7.3	8.8	17.6
		2	384.8	39.6	10.3		
3130	14	1	569.2	23.6	4.1	4.2	8.4
		2	569.2	24.5	4.3		

The presence of hydrogen in the decomposition products was confirmed for three different wave lengths as shown in Table II. In calculating the percentage of decomposing propionaldehyde molecules which produced hydrogen, it was assumed that only one hydrogen atom was expelled from each molecule. As shown by Table II, at a pressure of 14 mm. where the polymerization reaction has practically ceased, the amount of hydrogen produced is still comparable with that at higher pressures. Accordingly, it is assumed that the hydrogen production accompanies the decomposition reaction only.

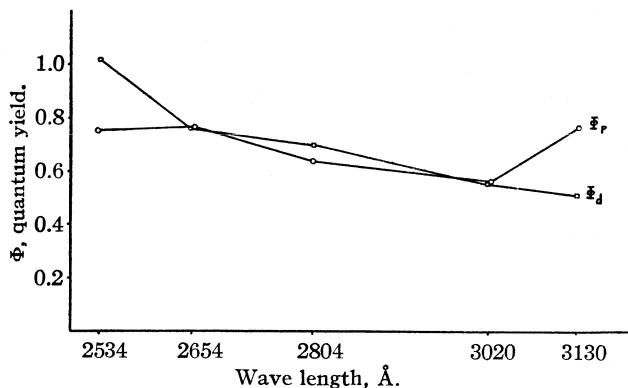

Fig. 4.—Variations of decomposition (Φ_d) and apparent polymerization (Φ_p) quantum yields with wave length, at 200 mm. pressure.

The fluorescence of propionaldehyde vapor could only be studied qualitatively because of the varying intensity of the mercury lines. However, marked fluorescence was present when the vapor was exposed to all wave lengths down to and including the $\lambda 2654$ Å. line. It apparently decreased in intensity with decreasing wave length, and when the aldehyde was exposed to the $\lambda 2537$ Å. line it was absent.

The only evidence obtained in regard to the nature of the polymerization products was (1) a very slight cloudiness which appeared on the walls of the quartz absorption tube; and (2) the percentage of light absorption did not

decrease appreciably during an exposure. These observations indicate either that a mixture of different polymers is formed or that if a single substance is the product, it has a high vapor pressure at 30°.

4. Discussion

Upon examination of the curves in Figs. 4 and 5, it is observed that the quantum yield of decomposition, Φ_d , increases with decreasing wave length, from a value of 0.51 at $\lambda 3130$ to 1.02 at $\lambda 2537$, with a sharp rise between $\lambda 2654$ and 2537. The apparent quantum yield of polymerization, Φ_p , shows variable behavior with changing wave length. Between $\lambda 3130$ and 3020 it drops rapidly, then rises at about the same rate as the decomposition to $\lambda 2654$, while between $\lambda 2654$ and 2537 it does not change.

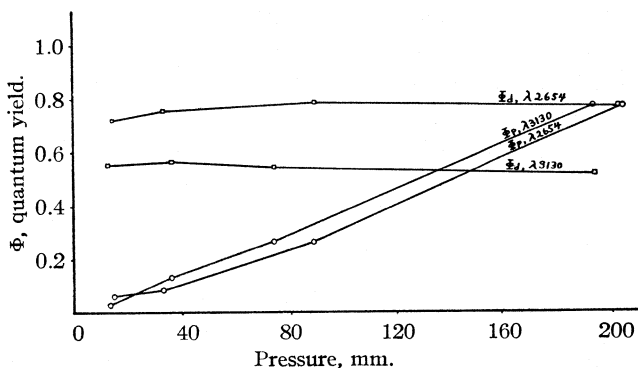

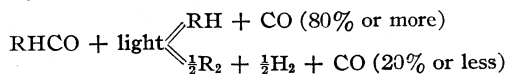

Fig. 5.—The effect of the variation of pressure upon decomposition (Φ_d) and polymerization (Φ_p) quantum yields.

The variations in quantum efficiencies with pressure (Fig. 5) are of especial interest. At two widely different wave lengths, decomposition appears to be a unimolecular process, the quantum yield being independent not only of the pressure but also of the amount of polymerization. The polymerization quantum yield, on the other hand, is zero at zero pressure and increases in direct proportion to the pressure. This suggests that the governing rate of the polymerization is bimolecular, in agreement with the findings of J. H. C. Smith for acetaldehyde.³ It should be emphasized that the decomposition quantum yields represent the true values, since they maintain their constancy at low pressures, where the rate of polymerization has approached zero.

All of the evidence earlier quoted, together with that found in this Laboratory, indicates that in the decomposition of the aldehydes the principal reactions may be represented by

In their study of the absorption spectra of the aldehydes, Henri and Schou¹⁰ have found that with increase in molecular weight it becomes more and more difficult to analyze the spectral structure. For propionaldehyde they were able to detect discontinuous absorption only between 3400 and 3250 Å. The bands were faint, very diffuse, close together and became more and more indistinguishable toward shorter wave lengths, merging apparently into a continuum in the neighborhood of 3250 Å.

Herzberg⁴ has reviewed the work of Henri and Schou on formaldehyde and on the basis of theoretical reasoning has suggested that the primary product of predissociation is represented thus

The application of this to the higher aldehydes gives two possibilities

Although studies of the energies of dissociation of the C—H and C—C bonds result in values of 90,000 to 110,000 calories for the former and 70,000 to 90,000 calories for the latter,¹¹ all measurements agree that the C—C bond energy is about 15,000 to 20,000 calories less than that of the C—H bond. Hence it may be assumed that in the higher aldehydes the C—C bond is broken and the decomposition occurs principally according to the second equation above.

In this regard, it is interesting to observe that, if the dissociation of formaldehyde by light involves the breaking of a C—H bond, while the dissociation of acetaldehyde involves a C—C bond, by the theory of Herzberg the long wave length limit of predissociation in each case should set an upper limit for the energy of dissociation of these bonds. The predissociation limits and corresponding energies in each case are:

	Bond	λ	Upper limit of diss. energy	Thermal bond energy ¹²
Formaldehyde	C—H	2750 Å.	103,000 cals.	98,500
Acetaldehyde	C—C	3200 Å.	89,000 cals.	87,600

With regard to the secondary reaction, the simplest course of the decomposition would be represented by

¹² L. Pauling, personal communication.

Experimental findings on the relative amounts of RH and of H_2 produced would indicate that the probability of reaction 2 occurring is of the order of five to ten times that of reactions 3 and 4. Since the rate of all these reactions is dependent only on the amount of dissociation, the quantum yield of decomposition should be independent of the pressure, as it is.¹³ A recombination, as by reaction 5, is indicated by the low decomposition quantum yields at wave lengths between 3020 and 2654 Å.

It is difficult to reconcile the existence of polymerization at all wave lengths, as well as the observation of fluorescence down to 2654 Å., with a pure dissociation spectrum, as is indicated by the continuous absorption below 3250 Å. It is possible that banded absorption, with the production of activated molecules, extends to much shorter wave lengths than 3250 Å., and is not observable because of the fineness of the bands and the overlaid continuum. The reactions produced by absorption in this banded, overlaid continuum region would be, in addition to the decomposition reactions

This postulate explains the high polymerization yield at 3130 Å., the existence of fluorescence, and the effects of pressure on polymerization. The drop in polymerization rate between 3130 and 3020 Å. would then be due to a weakening of the bands and a strengthening of the continuum between these two wave lengths. The same postulate does not explain the increase in polymerization quantum yield at still shorter wave lengths. Since the mechanism in reactions 1 to 4 permits of no chain formation, a maximum value of unity is placed on the quantum yield of decomposition. At 2537 Å. the decomposition yield has reached this maximum value, and fluorescence has disappeared, yet polymerization is still produced with an apparent quantum yield of 0.75.

This may only be explained by assuming that the free radicals resulting from the primary dissociation (reaction 1) can produce polymerization in other aldehyde molecules, possibly through the formation of intermediate addition compounds, before combining to give the final decomposition products. Until more evidence is available the authors wish to refrain from undue speculation in this direction.

¹³ In view of the number of vibrational degrees of freedom and consequent close spacing of the vibrational energy levels in these molecules, together with the finite width of the energy levels when the total vibrational energy is equal to the energy of dissociation, it may be assumed that in the bimolecular association reactions (4 and 5, above) the product molecule may temporarily accommodate any value of energy. These molecules will, therefore, be sufficiently long-lived to make the rates of association, except at pressures lower than were used here, independent of the concentration of the third body, X. See Kassel, *THIS JOURNAL*, **53**, 2143 (1931), and Pease, *ibid.*, **54**, 1876 (1932).

The marked rise in decomposition at 2537 Å. cannot be due to activation of mercury vapor in the absorption tube, for spectrum photographs show that with the type of high pressure arc used in this study the 2537 Å. resonance line is completely reversed, only the wings and the continuum to the long wave length side, which are not absorbed by cold mercury vapor, being present.

The authors wish to acknowledge their indebtedness to Dr. J. H. C. Smith for many helpful suggestions made during the course of this work.

Summary

1. The first of a series of articles on the photochemical reactions of the aliphatic aldehydes has been presented. The apparatus and method of study has been described and the experimental results given for propionaldehyde.

2. In the region investigated, $\lambda 2537$ Å. to $\lambda 3130$ Å., photochemical decomposition and polymerization are independent reactions. The quantum yield of decomposition is independent of pressure, while the quantum yield of apparent polymerization is directly proportional to the pressure.

3. The variation of the quantum yields of both reactions with wave length has been studied.

4. The principal products of decomposition were found to be carbon monoxide and ethane. A small amount of hydrogen also was formed in decomposition.

5. Fluorescence was produced by exposure to all wave lengths down to and including $\lambda 2654$ Å.

6. Mechanisms for both photochemical reactions have been proposed.

DISTRIBUTION OF ACIDS BETWEEN WATER AND SEVERAL IMMISCIBLE SOLVENTS

BY RAYMOND C. ARCHIBALD

RECEIVED APRIL 25, 1932

PUBLISHED AUGUST 5, 1932

Part I. Monocarboxylic Acids

The distribution ratios at 25° of the six straight-chain members of the saturated monocarboxylic acid series from formic acid to caproic acid have been determined between water and the following solvents: ethyl methyl ketone, tertiary amyl alcohol, secondary butyl alcohol, normal butyl alcohol and normal amyl alcohol. Data have also been included from the literature for ratios between ethyl ether and water¹ and between isopropyl

¹ W. U. Behrens, *Z. anal. Chem.*, **69**, 97 (1926).

ether and water.² Since the distribution ratios change slightly with the concentration of the acid, the values of the ratios for ethyl ether have been estimated for an acid concentration of about 0.001 *M* in the water layer. The values for isopropyl ether and water were obtained by using weighted means from the three papers cited for an average acid concentration of both layers of about 0.05 *M*. These values of the distribution ratios in water and ethyl ether, and in water and isopropyl ether are included in the table and plot of the original data. The exact concentrations in the ether layers cannot be calculated because the volumes after mixing are not given. Note: The value given for butyric acid by Werkman in his first paper is undoubtedly in error.

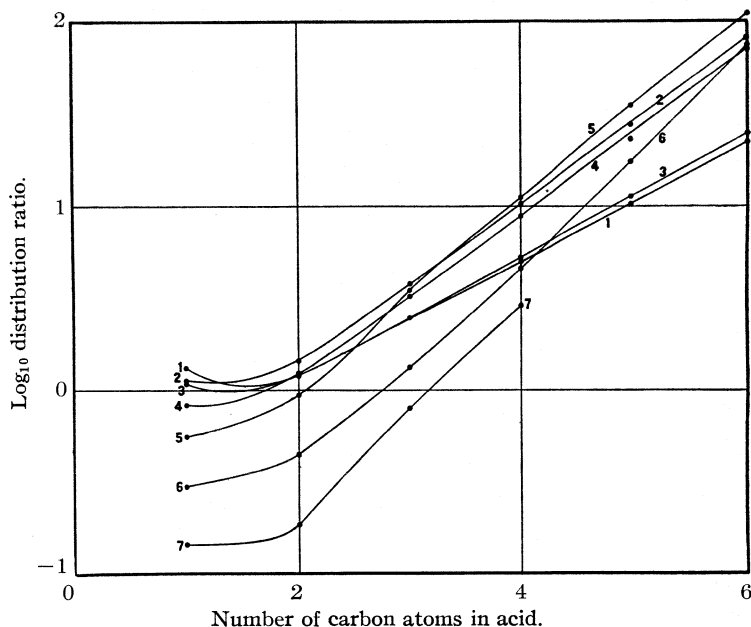

Fig. 1.—Distribution of monocarboxylic acids: 1, ethyl methyl ketone; 2, tertiary amyl alcohol; 3, secondary butyl alcohol; 4, normal butyl alcohol; 5, normal amyl alcohol; 6, ethyl ether; 7, isopropyl ether. Ratios are: moles per liter in solvent layer/moles per liter in water layer.

The plot, Fig. 1, shows the logarithm of the distribution ratio at the concentration given in Table I, or in cases where two concentrations are given, the logarithm of the average distribution ratio.

Experimental

Industrial solvents were obtained from Shell Chemical Company, Sharples Solvents Corporation, Commercial Solvents Corporation, Carbide

elsewhere.³ Blank titrations were made on all solvents in equilibrium with distilled water at 25°. These titrations showed no appreciable acid in either the water or any of the solvents. The acids used were high grade commercial C. P. products.

The solvent, water and acid were mixed in a flask and allowed to remain, with frequent shaking, in a thermostat at $25.00 \pm .01^\circ$ for several hours. Samples of each layer were pipetted out and titrated in duplicate against standardized 0.1 *N* sodium hydroxide with phenolphthalein indicator. These samples were 25 cc. in all cases except the higher concentrations of formic, acetic and butyric acids, for which 10-cc. samples were used. The values in Table I were obtained from the average of the duplicate titrations. The close check of the duplicate titrations showed that equilibrium had been attained.

Discussion

This work was undertaken for its bearing on the possibility of separating sterols from vitamins by forming some ester of the sterol, such as the gluconate, which might be slightly soluble in water, and fractionating the mixture in a column which gives multiple distribution between two immiscible solvents. The construction and use of this column will be pub-

³ Evans, Cornish, Lepkovsky, Archibald and Feskov, *Ind. Eng. Chem., Anal. Ed.*, **2**, 339 (1930).

lished later in a paper from this Laboratory dealing with the isolation of the fat-soluble vitamins.

This work is also of interest in connection with the Dakin process for separating amino acids.⁴ This process consists in extracting a water solution of the mixed amino acids with normal butyl alcohol or other solvent. The strongly ionized amino acids remain in the water layer, while the slightly ionized acids are extracted. A similar process is also being used in this Laboratory in an attempt to isolate some of the water-soluble vitamins.

Part II. Inorganic Acids

This part of the paper will consider the distribution of hydrochloric, nitric, sulfuric and perchloric acid between water and some of the non-

⁴ H. Dakin, *Biochem. J.*, **12**, 290 (1918).

aqueous solvents used in Part I. Distributions of these acids were determined in three concentrations, the average concentration for both layers being about 0.05, 0.25 and 1.25 *N*. The layers were approximately equal in volume.

The experimental method is identical with that used for the monocarboxylic acids; 25-cc. samples were used in the two lower concentrations and 10-cc. samples in the highest.

The data on hydrochloric acid in aniline are due to Sidgwick, Pickford and Wilsdon.⁵

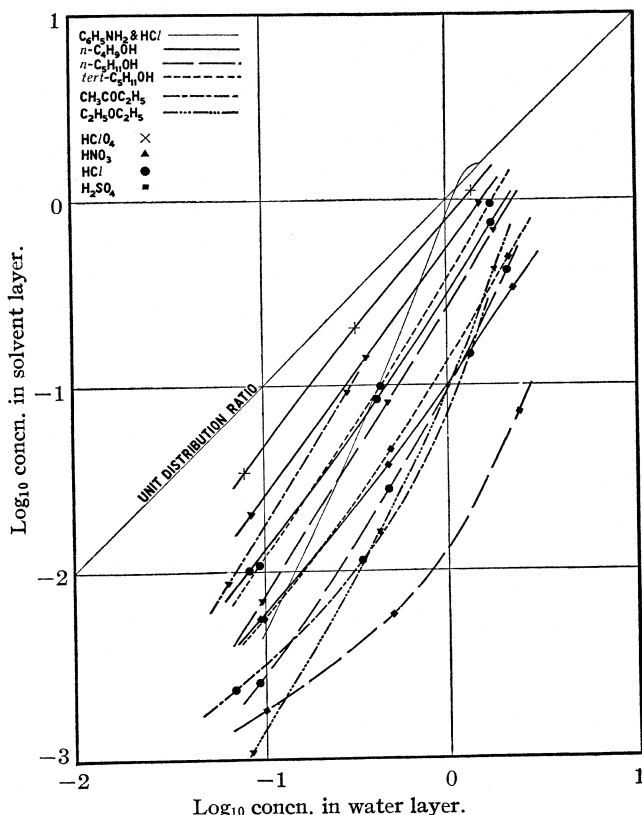

Fig. 2.—Distribution of inorganic acids. Concentrations are in equivalents per liter, except aniline values where hydrochloric acid is in moles per 1000 g. of solution.

Table II shows the acid concentration in the water layer, and in the solvent layer in equilibrium with it. All measurements are at $25.00 \pm .01^\circ$.

In Fig. 2 the logarithm of the acid concentration in the aqueous layer is plotted against the logarithm of the acid concentration in the solvent layer.

Discussion

The tendency is for the curves to approach the line denoting unit distribution ratio as the acid concentration is increased. They reach this line at the point where complete miscibility between the two layers occurs, which in the case of nitric acid in ethyl methyl ketone and water is within the range of concentrations studied. The curves may cross this line before the point of complete miscibility, returning to it later, as in the case of aniline and hydrochloric acid.

The curve for hydrochloric acid in aniline and water has a slope of about 2 over most of its length. That is, the concentration of the hydrochloric acid in the aniline layer varies approximately as the square of the acid concentration in the water layer. From this fact it may be assumed that the hydrochloric acid is practically un-ionized in the aniline layer. This condition is approximated also in the curve representing nitric acid in ethyl ether and water. The other curves, however, apparently show more tendency for the acids to be ionized in the non-aqueous layers.

Distribution measurements were also attempted for hydrochloric acid between ethyl ether and water. However, due to the extreme insolubility of hydrochloric acid in ether at all the concentrations studied, it was impossible to make any accurate measurements without a much more refined procedure.

In any one solvent the order of the curves from the line of unit distribution ratio is HClO_4 , HNO_3 , HCl , H_2SO_4 , which follows the Hofmeister series for the precipitation of proteins, the sulfate ion being the most efficient. The series is also the same as that found by Randall and Failey⁶ for the salting-out effect, rather than the strength of acids series⁷ which gives the order HNO_3 , HCl , H_2SO_4 , HClO_4 , where perchloric is the strongest acid.

An attempt was made to measure the distribution of hydrochloric acid between propylene oxide and water, but due to the rapid reaction of propylene oxide with hydrochloric acid⁸ even in cold dilute aqueous solution, these measurements were impossible. Propylene oxide is more reactive than propylene glycol and consequently much more reactive than ethers such as ethyl ether. This extreme reactivity is probably due to the fact that the oxygen atom is one member of a three-membered ring, and this makes propylene oxide more suitable as a reagent than a solvent.

The purpose of this research was to determine quantitatively which acid would be most suitable for acidifying a water solution, one component of

which was to be extracted out with one of the solvents mentioned above. Since it was necessary to extract with very large amounts of solvent, many times it was imperative that the acid be very insoluble in the solvent in order that the solution remain acid until the end of the extraction process.

Acknowledgment.—The author acknowledges his indebtedness to Dr. Herbert M. Evans and to Dr. R. E. Cornish of this Department for their valuable assistance and advice.

Summary

Distribution ratios of six fatty acids and four inorganic acids were measured between water and several solvents which are not miscible with water. A short discussion of the results is given.

THE KINETICS OF GAS EXPLOSIONS. III. THE INFLUENCE OF HYDROGEN ON THE THERMAL DECOMPOSITION OF OZONE SENSITIZED BY BROMINE VAPOR, AND THE TERMINATION OF THE EXPLOSION TEMPERATURE¹

BY W. FEITKNECHT² AND BERNARD LEWIS³

RECEIVED APRIL 25, 1932

PUBLISHED AUGUST 5, 1932

In a previous paper⁴ it was shown that inert gases exert a small influence on the rate of decomposition of ozone in the presence of bromine as long as the ozone pressure is low. At higher pressures the rate is slowed down and the explosion pressure limit of ozone is increased considerably. The efficiency of inert gases in increasing the explosion limit decreases with increasing molecular weight.

The influence of hydrogen was not included in the previous investigations. It seemed of special interest, as hydrogen increases considerably the photochemical rate of decomposition of ozone with the simultaneous formation of water.⁵ Belton, Griffith and McKeown⁶ found a similar influence of hydrogen on the thermal decomposition of ozone, whereas Schumacher⁷ states that hydrogen has only a slight effect on the thermal

decomposition. It has been found by one of us⁸ that ozone is indeed extremely stable in the presence of hydrogen at room temperatures. However, at higher temperatures (80 to 90°), the influence of hydrogen is so great that under certain conditions the ozone may be made to explode violently. The thermal decomposition of ozone sensitized by bromine vapor, at temperatures (<15°) at which the solid oxide of bromine is formed, is unaffected by hydrogen.⁹

The present experiments with ozone-bromine mixtures and hydrogen were carried out in the same way as those with similar mixtures and inert gases described previously.⁴ The experimental temperature employed was 25°. The rate of the non-explosive reaction was of the same order as that for corresponding mixtures with other inert gases, and the reaction went to about 70% completion in ten minutes. This strongly indicated that no water was formed, for water in very small amounts (<0.1 mm.) poisons the walls and decreases the rate of decomposition of ozone materially.⁴

A more direct method was employed to detect water formation, if any. A mixture, the original composition of which was 50 mm. ozone, 20 mm. hydrogen and 0.5 mm. bromine, was cooled down to -65° after 87% of the ozone had decomposed. The vessel was evacuated removing all gases except water (if formed) and then warmed up again to 25°. No pressure increase could be detected, although the manometer employed read easily to less than 0.1 mm., indicating that less than 0.5% of the hydrogen could have been transformed to water.

These results do not conflict with the chain mechanism suggested by the authors, for the explanation of the decomposition of ozone sensitized by bromine in which the oxygen atom is an important link, for according to the experiments of Harteck and Kopsch,¹⁰ oxygen atoms do not react readily with hydrogen molecules. The results indicate that the second carrier in the proposed chain, namely, an energy-rich oxygen molecule, also does not react with hydrogen to form water at the temperature of these experiments.

Whenever the ozone concentration was above the explosion limit, the hydrogen was burned to water in the explosion. If the vessel was then evacuated in the usual way, it proved to be very inactive in the next experiment. It was shown previously⁴ that the direct introduction of a small amount of water vapor affected the vessel in a similar way. The vessel could be reactivated only after prolonged evacuation accompanied by heating and subjecting the vessel to sparking with a high-tension coil. This was in striking contrast to the unaltered activity

¹⁰ Harteck and Kopsch, *ibid.*, **12B**, 327 (1931).

of the vessel after a non-explosive reaction, a further proof that in the latter case no water is formed.

The explosion limit of ozone (sensitized by bromine) was found to be greatly increased by hydrogen. It was nearly twice as high as for a similar mixture in which the hydrogen is replaced by helium. Hydrogen, therefore, fits well into the order in which inert gases increase the explosion limit—namely, argon, oxygen, nitrogen, helium and hydrogen.

The final pressure after an explosion was always considerably lower than the pressure calculated on the assumption that all the hydrogen had oxidized to water and all the ozone had decomposed to oxygen. On alternately raising and lowering the temperature of the products, the deviation in pressure from Gay-Lussac's law was such as to indicate that some liquid had condensed on the wall of the vessel at 25°. The experiments could be reproduced very well. The difference between the calculated and observed pressures increased with increasing amounts of bromine and hydrogen but were affected little by changes in the ozone pressure, as can be seen from Table I.

TABLE I

PRESSURE CHANGES IN EXPLOSIONS OF OZONE-BROMINE-HYDROGEN MIXTURES AT 25°

In the first column, the first numbers represent the experimental series, and the numbers after the dash the experiment in the series.

These results can only be due to the formation of hydrogen bromide in the explosion,¹¹ forming afterward with water a solution with low vapor pressure. To prove this the products of several successive explosions were condensed in a side tube and analyzed. The solution proved to be fairly concentrated in hydrogen bromide.

¹¹ If any hydrogen bromide were formed in the non-explosive reaction it would have reacted with ozone immediately to give water, oxygen and bromine (see Lewis and Feitknecht, *THIS JOURNAL*, **53**, 3565 (1931); *ibid.*, **54**, 1784 (1932)).

The excellent reproducibility and the way in which the amount of hydrogen bromide formed depends upon the initial pressures of bromine, hydrogen and ozone, suggest that the following equilibrium is established in the explosion.

If the amounts of hydrogen bromide and water formed were known, the equilibrium constants calculated from these data could be compared with the equilibrium constants of this reaction at different temperatures derived from independent sources, and an estimate could be obtained of the temperature reached in these low-pressure explosions.

Determination of the Explosion Temperature from the Equilibrium Attained.—Owing to the condensation of hydrogen bromide and water in the lead tube, the use of a simple manometric method of determining the equilibrium was precluded.

TABLE II

ESTIMATED COMPOSITIONS OF MIXTURES IN MM. AFTER EXPLOSION AND EXPERIMENTAL EQUILIBRIUM CONSTANTS OF REACTION (1)

75-11	13.0	18.0	83.5	4	118.5	106.1	4.6	1.95×10^3	3.5×10^2

The total amount of hydrogen bromide formed in the explosion (Table II, Column 5) could be estimated by a method of trial and error. First a value is assumed and, together with the original pressures of hydrogen, bromine and oxygen (Table I), the total amounts of water, bromine and oxygen are calculated (Columns 2, 3 and 4). Thus the total pressure, $P_{\text{calcd.}}$ in Column 6, is known. Column 7 contains the observed pressure. $P_{\text{calcd.}} - P_{\text{obs.}}$ equals the amount of water and hydrogen bromide condensed out; and since Columns 2 + 5 give the total amount of these products formed, Column 8 represents the pressure of water and hydrogen bromide in the gas phase. Several such values in Column 8 are calculated for different assumed values of hydrogen bromide in Column 5. These vapor pressures are compared with the data of Wrewsky, Sawaritzky and Scharloff¹² on the vapor pressure and composition of the vapor above solutions of hydrogen bromide in water. It turns out that in experiments with 10 millimeters and more of hydrogen and bromine the mixture must correspond approximately to the one having the smallest vapor pressure, or one in which the composition of the liquid and gas phases is identical—in other words, to a mixture with approximately 20 mole per cent. of hydrogen bromide. The final values of hydrogen bromide thus

¹² Wrewsky, Sawaritzky and Scharloff, *Z. physik. Chem.*, **112**, 97 (1924).

estimated are given in Column 5, Table II, and the corresponding vapor pressure of hydrogen bromide plus water at 25° in Column 8. For experiments 75-8 and 75-11 the values in Column 8 are about 1 mm. lower than those which would correspond to the minimum vapor pressure of the hydrogen bromide-water solution. This is partly due to the errors which may accumulate by the addition and subtraction of several somewhat uncertain values and to the solution of a small amount of bromine in these particular experiments with higher bromine concentrations. In general the error in the hydrogen bromide values given is about ± 0.5 mm. This is sufficiently accurate for our purpose as it introduces an error of only about $\pm 4.5\%$ in the final explosion temperature.

By substituting the pressures of water, bromine, hydrogen bromide and oxygen in atmospheres in the formula

$$K = \frac{[\text{H}_2\text{O}]^2 [\text{Br}_2]^2}{[\text{HBr}]^4 [\text{O}_2]} \quad (2)$$

the experimental equilibrium constant K can be determined for the different experiments. There is not much variation of the constants in Column 9, Table II. The differences observed are attributable to differences in the temperatures at which the equilibria are frozen out in the different experiments. However, the error in the estimation of hydrogen bromide would introduce about the same differences, so that it is not possible to draw definite conclusions on this point. These K 's are calculated for the gas pressure at the temperature 298° K. It will be seen later that the temperature at which the equilibrium is established is approximately 5.5 times higher. The K 's should therefore be corrected for the pressures existing at this temperature, and from formula (2) it follows that they should be divided by 5.5. The corrected constants are given in the last column of Table II.

There are two methods by which the equilibrium constant K of formula (2) can be approximately calculated theoretically.

1. By using the Nernst formula:¹³

$$\log K = -\frac{Q}{4.57 T} + \Sigma v \log T + \Sigma v C \quad (3)$$

On introducing the values given by Nernst for the conventional constants C and Σv and the value of Q as the difference between the heats of formation of $2\text{H}_2\text{O}$ and 4HBr (that is, $-115,600 + 48,400 = -67,200$), equation 3 becomes

$$\log K = +\frac{14,700}{T} - 1.75 \log T - 0.6 \quad (4)$$

The values for K thus calculated are given in the fifth column of Table III as K_1 , for temperatures between 1500 and 2000° A.

¹³ Nernst, "Die theoret. u. experimentellen Grundlagen des neuen Wärmesatzes," 1918, p. 112.

TABLE III
CALCULATED EQUILIBRIUM CONSTANTS OF REACTION (1) AT DIFFERENT TEMPERATURES

T, °A.	K_{HBr}	$K_{\text{H}_2\text{O}}$	$K_2 = \frac{(K_{\text{HBr}})^2}{K_{\text{H}_2\text{O}}}$	K_1
1500	3.66×10^{-5}	5.02×10^{-12}	2.67×10^2	4.36×10^3
1600	6.10×10^{-5}	6.34×10^{-11}	5.87×10^1	9.60×10^2
1700	9.9×10^{-5}	5.7×10^{-10}	1.72×10^1	2.45×10^2
1800	1.51×10^{-4}	4.26×10^{-9}	0.53×10^1	7.41×10^1
1900	2.19×10^{-4}	2.4×10^{-8}	$.20 \times 10^1$	2.51×10^1
2000	3.11×10^{-4}	1.17×10^{-7}	.83	0.93×10^1

2. The second method is derived from the fact that

$$K = \frac{[\text{H}_2\text{O}]^2 [\text{Br}_2]^2}{[\text{HBr}]^4 [\text{O}_2]} = \frac{K_{\text{HBr}}^2}{K_{\text{H}_2\text{O}}} \quad (5)$$

K can therefore be calculated from the constants of the hydrogen bromide and water equilibria, namely

Vogel von Falckenstein¹⁴ has shown experimentally that the hydrogen bromide equilibrium follows the formula of Nernst¹⁵ fairly well, namely

$$\log K_{\text{HBr}} = -\frac{5223}{T} + 0.553 \log T - 2.72 \quad (8)$$

The K for the water equilibrium was calculated from the formula given by Lewis and Friauf¹⁶

$$\begin{aligned} \log K_a = & + \frac{57,295}{4.57T} - 0.848 \log T - 1.474 \times 10^{-4} T + 7.78 \times 10^{-8} T^2 \\ & - 8.72 \times 10^{-12} T^3 + 0.0616 \end{aligned} \quad (9)$$

It should be mentioned that K_a calculated from this formula is $K_a = [\text{H}_2\text{O}]/[\text{H}_2] [\text{O}_2]^{1/2}$, while the $K_{\text{H}_2\text{O}}$ to be used in (5) is

$$K_{\text{H}_2\text{O}} = \frac{[\text{H}_2]^2 [\text{O}_2]}{[\text{H}_2\text{O}]^2}$$

Therefore

$$K_{\text{H}_2\text{O}} = 1/K_a^2 \quad (10)$$

Columns 2 and 3, Table III, contain these values of K_{HBr} and $K_{\text{H}_2\text{O}}$ and Column 4 contains K_2 , the desired constant by the second method—namely, $K_2 = K_{\text{HBr}}^2/K_{\text{H}_2\text{O}}$.

It is seen that K_1 is roughly one order of magnitude larger than K_2 , corresponding to an average temperature difference of 200°. This is roughly of the same order as the uncertainty in temperature arising from the uncertainty in the value of the hydrogen bromide formed.

Comparing K_1 and K_2 with the $K_{\text{corr.}}$ of Table II, one observes that the equilibrium constants found correspond to a temperature of about 1600 ± 100°A. This temperature is probably not the maximum explosion

¹⁴ Von Falckenstein, *Z. physik. Chem.*, **68**, 270 (1909); **72**, 113 (1910).

¹⁶ Lewis and Friauf, *THIS JOURNAL*, **52**, 3905 (1930).

temperature which is possible in the mixtures considered because the experiments were not carried out adiabatically, but is indicative of the temperature at which the equilibria found were frozen out.

Summary

The influence of hydrogen on the thermal decomposition of ozone sensitized by bromine vapor has been investigated. In the non-explosive reaction it is found that hydrogen behaves only as an inert gas retarding the reaction to about the same degree as other inert gases do. No water is formed, indicating that hydrogen does not react readily at room temperature with the oxygen atoms and energy-rich oxygen molecules assumed to play a role in the decomposition of ozone. The explosion pressure limit of ozone is greatly increased by hydrogen, which fits well into the order in which inert gases increase the explosion limit—namely, argon, oxygen, nitrogen, helium and hydrogen. During the explosion the hydrogen is burned to water and the following equilibrium is established

The concentrations of the products are determined and the equilibrium constants calculated. These are compared with the equilibrium constants at different temperatures derived from two independent sources. The temperature at which the equilibria are established is found to be $1600 \pm 100^\circ$ Absolute.

STERIC HINDRANCE AND COLLISION DIAMETERS¹

BY HENRY EYRING

RECEIVED APRIL 25, 1932

PUBLISHED AUGUST 5, 1932

Introduction

A large part of chemistry is interpretable in terms of potential energy diagrams. Stable compounds are configurations of low potential energy which are separated from configurations of still lower energy by energy ridges of approximately 20 kg. cal. or more per mole. If the ridge is much lower than this the rate at which molecules accumulate sufficient energy to pass over the barrier, even at ordinary temperatures, make it impossible to isolate any but the molecular species of lowest energy. Energy barriers are sometimes lowered by two molecules colliding, making a complex from which a new species emerges—a bimolecular reaction. A rearrangement or splitting inside a single molecule is a unimolecular

¹ Presented except for minor changes September 2, 1931, as part of the symposium on the Kinetics of Chemical Reactions at the Buffalo meeting of the American Chemical Society, by Henry Eyring and J. C. Slater.

reaction. Every bimolecular reaction has a unimolecular stage, *i. e.*, the rearrangement inside the complex.

Spectroscopy gives the information from which potential energy curves for diatomic molecules can be constructed. A convenient way of doing this is to use Morse curves.²

Quantum mechanics and the Pauli principle give approximate values for the potential energy of a complex configuration of atoms in terms of the potential energies that would exist between pairs of electrons if the other electrons were not present. Thus for reactions involving three and four valence electrons it is possible to construct potential energy functions such that the minimum energy which permits molecules to approach near enough to exchange partners can be calculated.³

Calculation of Potential Energy of Molecules.—In a recent paper by Slater,⁴ the method of calculating energy terms in complex atomic spectra has been extended to molecules. For a definite way of drawing the valence bonds in molecules perturbation theory gives

$$E = Q + \Sigma\alpha_p - \frac{1}{2}\Sigma\alpha_u \quad (1)$$

Here Q is the sum of all coulombic interactions plus the sum of the energies due to mutual polarization of atom pairs (van der Waals forces) plus terms arising from permanent dipoles. $\Sigma\alpha_p$ is the sum of the resonance attraction between the pairs forming shared electron bonds. $\frac{1}{2}\Sigma\alpha_u$ is the sum of the resonance repulsions between all pairs where there is not a bond and can be evaluated in exactly the same way as the terms, α_p , that is, as half the interchange bond that exists between the electrons when paired. In these considerations it is immaterial how the valence electrons are distributed among the various atoms, that is, whether we are considering monovalent or polyvalent atoms. Electron pair bonds within atoms are the same things as closed shells, and are formed inside all atoms showing less than the highest spin valence. For purposes of calculations these bonds need not be considered different in kind from those between neighboring atoms. The interchange integrals for these internal bonds correspond to half the difference between definite terms of successive multiplicities in the atom, and are known from atomic spectra.

Equation (1) is a general result, as may be seen in the following way. Consider any system of molecules, such that all valence electrons are bound in definite electron pairs. Then an approximate wave function can be set up, corresponding to this way of drawing the electron bonds. And the energy value connected with this wave function is just analogous to the expression (1).

² Morse, *Phys. Rev.*, **34**, 57 (1929).

³ Eyring and Polanyi, *Z. physik. Chem.*, **B12**, 279 (1931); Eyring, *THIS JOURNAL*, **53**, 2537 (1931).

⁴ Slater, *Phys. Rev.*, **38**, 1109 (1931).

The way of setting up a wave function corresponding to definite bonds is interesting. Suppose the $2n$ valence electrons are distributed among $2n$ states whose wave functions have the dependence on coördinates given by a, b, c, d, \dots , and suppose the bonds are situated between states as indicated by the lines, $a-b, c-d, e-f, \dots$, etc., where more than one electronic function can belong to the same atom. Now to specify a state of the system completely we must give not only the dependence on coördinates but also on spin. Thus if α represents a spin directed along a fixed axis, β a spin in the opposite direction, such a state is given by assigning to each function a, b, \dots , a definite spin, as is given by the symbol $(a\alpha) (b\beta) (c\alpha) (d\beta) (e\alpha) \dots$. To get the actual wave function, we must form an antisymmetric function of the electrons, in a manner which has been described elsewhere. This state which we have symbolized above does not correspond to valence binding; we require rather a linear combination of such states. This linear combination is of the following nature. In each state concerned in it, the two electrons in a pair, as a and b , have opposite spins, but in some the spins are arranged $\alpha\beta$, in others $\beta\alpha$. There are, in other words, just 2^n different states consistent with this condition, and all of them are added together to get the required linear combination. The coefficient multiplying the functions for each state is $+1$ if an even number of interchanges of spins is required to get back to the original function and -1 if an odd number of interchanges is required.

We should consider the relation of this procedure to the case of a chemical reaction. Suppose after a reaction the eigenfunction a is paired with c instead of b , and that b simultaneously becomes paired with d . Then a different function representing the new arrangement of bonds is easily found. If by a reaction the bonds change adiabatically from the one state to the other, the perturbation theory gives us a two-rowed secular determinant the lowest root of which gives the energy during reaction. This equation for the energy has the form

$$E = Q + \Sigma \alpha_p - \frac{1}{2} \Sigma \alpha_u + \frac{\sqrt{1/2((\alpha_1 + \alpha_2 - \beta_1 - \beta_2)^2 + (\alpha_1 + \alpha_2 - \gamma_1 - \gamma_2)^2 + (\beta_1 + \beta_2 - \gamma_1 - \gamma_2)^2)}}{2} \quad (2)$$

The quantities not under the radical sign have the significance given the same symbols in equation (1). These quantities outside of the radical do not include the bonds between the four electrons which interchange partners during the reaction. α_1 and α_2 are the bonds between these latter electrons before reaction, β_1 and β_2 the bonds after the reaction and γ_1 and γ_2 bonds which have an appreciable value for configurations intermediate between the initial and final states. These quantities are explained in more detail for equation (3) which is a special case of (2). Equation (2) should be used for reactions involving steric hindrance. Let us now consider the potential arising from the collision of two molecules.

Kinetic Theory Diameters

We shall content ourselves here with an illustrative example. For four monovalent atoms we have the expression for the potential energy

$$E = A_1 + A_2 + B_1 + B_2 + C_1 + C_2 + \sqrt{1/2((\alpha_1 + \alpha_2 - \beta_1 - \beta_2)^2 + (\alpha_1 + \alpha_2 - \gamma_1 - \gamma_2)^2 + (\beta_1 + \beta_2 - \gamma_1 - \gamma_2)^2)} \quad (3)$$

Greek letters are for interchange binding. The italic letters are for the types of binding which are independent of spin, coulombic plus van der Waals, etc. Figure 1 represents molecule WX colliding with molecule ZY. The sum written on the line joining the symbols for two atoms is the total energy required to separate these atoms if the other two atoms were far away. If WX is at a considerable distance from YZ the radical in (3) can be expanded considering

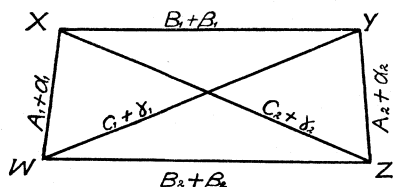

Fig. 1.—Potential terms which determine the total potential of colliding molecules.

$\alpha_1 + \alpha_2$ large compared with $\beta_1 + \beta_2$ and $\gamma_1 + \gamma_2$.

This gives

$$E = A_1 + A_2 + B_1 + B_2 + C_1 + C_2 + \alpha_1 + \alpha_2 - 1/2(\beta_1 + \beta_2 + \gamma_1 + \gamma_2) \quad (4)$$

i. e., interchange attraction between the electrons whose spins are anti-parallel and a repulsive interchange potential with a coefficient of $1/2$ between all other pairs where there is no chemical bond. Equation (4) may equally well be regarded as a special case of (1). In an ordinary collision there is practically no distortion of the two molecules so that $(A_1 + A_2 + \alpha_1 + \alpha_2)$ stays constant throughout the process. The collision potential is thus

$$E = B_1 + B_2 + C_1 + C_2 - 1/2(\beta_1 + \beta_2 + \gamma_1 + \gamma_2) \quad (5)$$

As an example we will consider the collision of two H_2 molecules. Sugiura's⁵ evaluation of Heitler and London's⁶ potential energy for an H_2 molecule is used for evaluating the quantities in (5). The curve $f(r)$ in Fig. 2 gives the interchange potential between two H atoms as a function of the distance. This serves to determine β_1 , β_2 , γ_1 and γ_2 . The coulombic parts of B_1 , B_2 , C_1 and C_2 are determined similarly from the curve $F(r)$. The polarization or van der Waals potential is likewise independent of the spin and can be calculated as the sum of four parts to be added to the coulombic terms. We use $101/r^6$ in kg. cal. for the van der Waals potential between each pair of atoms. r is to be expressed in Ångströms. This is the value London selects.⁷ Eizenschitz and London's⁸ theoretical value is $91.5/r^6$. This latter value for the van der Waals poten-

⁸ Eizenschitz and London, *ibid.*, **60**, 491 (1930).

tial would make the theoretical curve agree more closely with the Lennard-Jones curve for large distances between hydrogen molecules but also makes the difference slightly larger when the molecules come closer together.

The resulting total potential energies for various orientations of the H_2 molecules are given as curves I and III of Fig. 3. These are to be compared with the Lennard-Jones⁹ empirical potential energy curve II for the collision of two hydrogen molecules. His curve was obtained by choosing the constants A and B and the powers of r in the equation for the potential $E = Ar^{-13/3} - Br^{-4}$ so as to lead to the experimental second virial

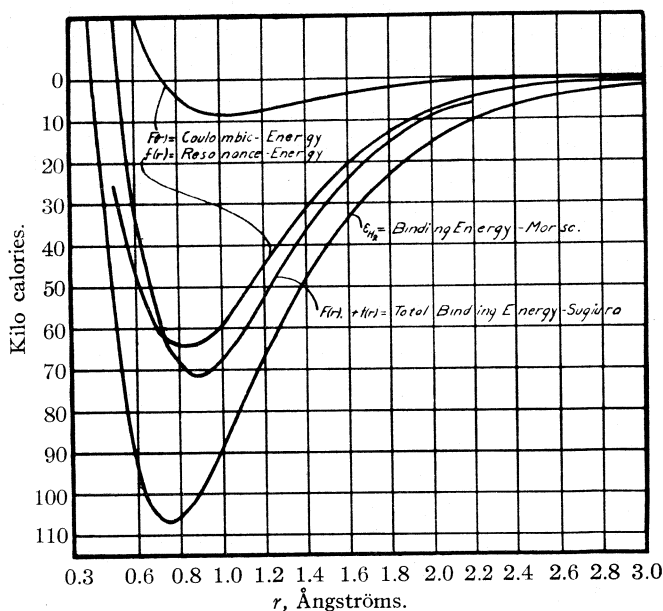

Fig. 2.—Potential energy of the H_2 molecule.

coefficient. The values given are $A = 2.473 \times 10^5$ and $B = 5.65$. In all three curves the abscissa is the distance between the centers of gravity of the colliding molecules. The ordinate is the potential energy referred to zero energy for infinite abscissas. Curve I is for a collision between two molecules colliding with axes parallel to each other but perpendicular to the line joining the centers of gravity of the molecules. As long as the two molecular axes remain perpendicular to the line joining centers of gravity the energy does not change perceptibly (at these large distances) with rotation of one of the molecules about this line. Curve III, however, gives the potential energy for the extreme case in which both molecular axes have turned in such a way that they coincide with the line joining molecular centers of gravity. This gives a much greater repulsion for a

⁹ Fowler, "Statistical Mechanics," Cambridge Univ. Press, 1929, Chapt. X.

fixed distance between centers of gravity since it brings two of the colliding atoms much closer together. For comparison with II a weighted average of all configurations should be taken. Both geometrical and energy considerations tend to weight the low lying configurations. The weighted curve of course varies with the temperature but would not differ greatly from I at the temperature for which II represents experiment. The theoretical minimum is 0.05 kg. cal. deeper than the minimum of curve II calculated from experiment. The fact that an oscillator always has a half quanta of energy decreases the discrepancy. Even if the value $91.5/r^6$ is used for calculating van der Waals forces the theoretical minimum is still 0.038 deeper than the minimum of the Lennard-Jones curve. The general agreement is fairly satisfactory and it is probably too early to decide which method of obtaining the potential curve is the better.

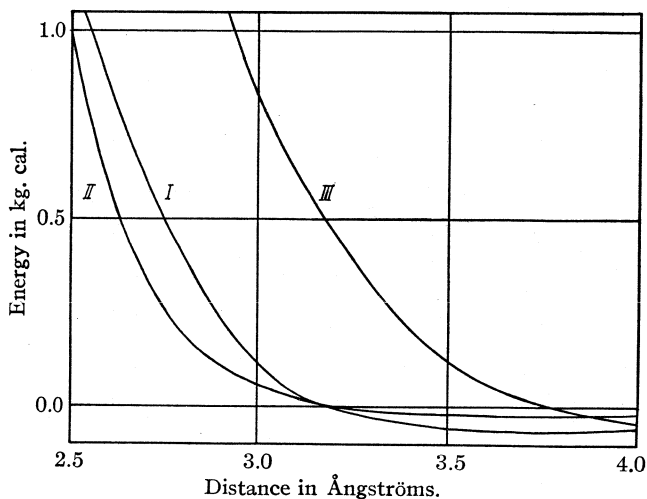

Fig. 3.—Potential energy curve for the collision of two hydrogen molecules.

Cremer and Polanyi¹⁰ have calculated the equilibrium distance between H_2 molecules in the crystal lattice using essentially the method used here for the liquid. They were interested in ascertaining the applicability of the Morse curve for this purpose and so used ϵ_{H_2} of Fig. 2 rather than $f(r)$ for calculating β_1 , β_2 , γ_1 and γ_2 . They neglected coulombic binding. This led to a calculated equilibrium distance between H_2 molecules of 5 Ångströms as compared with an experimental 4 Ångströms. Using the same assumptions in the case of HCl, HBr and HI the agreement was much better, probably indicating that the Morse curve is more satisfactory in these cases. Since the Morse curves are correct in the

¹⁰ Cremer and Polanyi, *Z. physik. Chem.*, [A] Bodenstein Festband, 720 (1931).

neighborhood of the minimum they are probably better for calculating activation energies than for calculating kinetic theory diameters.

Eisenschitz and London⁸ have given potential energy curves at large distances for the attraction of two hydrogen atoms in a singlet state and the repulsion in a triplet state. It is of considerable interest in addition to know how two hydrogen atoms interact when they are each bound to another atom since it is this interaction which largely determines the physical properties of the hydrocarbons as well as the properties of hydrogen itself. In Fig. 4 we have drawn the corresponding experimental and theoretical curves. The ordinate of curve I is the van der Waals force,

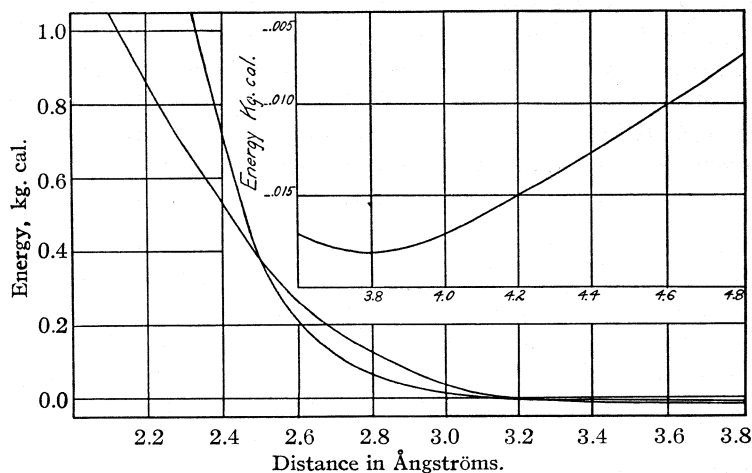

Fig. 4.—Potential energy between widely separated saturated hydrogen atoms.

$101/r^6$, plus the theoretical coulombic integral minus one-half the interchange integral. The ordinate of curve II is one quarter the Lennard-Jones potential between two H_2 molecules plotted, however, against an abscissa which instead of being the distance between centers of gravity of the molecules is the corresponding distance between two H atoms one from each molecule for configurations in which all four such distances are equal. This way of choosing the abscissa is justified by the remarks previously made in connection with Curve I, Fig. 3, that as long as the two molecular axes remain perpendicular to the line joining centers of gravity the energy does not change perceptibly with rotation of one of the molecules about this line. Thus, the statistical curve given by Lennard-Jones gives substantially the potential energy for the configuration assumed. The upper right-hand corner of Fig. 4 simply gives a continuation of Curve I on a larger scale. We shall find such a curve useful in discussing the physical and chemical properties of the hydrocarbons.

All the physical properties of a gas such as the kinetic theory diameter heat of vaporization, compressibility, coefficient of expansion, Sutherland constant and specific heats are deducible from a correct potential energy surface. Conversely these physical properties may be used for determining constants in an equation for the potential energy which in turn gives the activation energy. This fact is of importance in the many cases where the complete quantum mechanical calculations of the energy integrals are excessively difficult to obtain.

The method used for considering the collision of H_2 molecules may be extended to collisions between polyatomic molecules using Morse curves for the energy between atom pairs, x-ray data for the position of the atoms inside the molecules and substituting in Equation 1. The repulsive potential is simply the sum of one-half the interchange integrals between all pairs of atoms one from each molecule. The coulombic and van der Waals forces are all attractive. The van der Waals forces are calculable either by the method of Slater and Kirkwood¹¹ or of London.⁷

Steric Hindrance

We may now consider another application of Equations (1) and (2). Since all the interchange integrals are presumably negative the potential energy terms, $-1/2 \sum \alpha u$, increase as unpaired electrons approach each other and are largely responsible for steric hindrance. This repulsion becomes appreciable at kinetic theory diameters as we have just seen and increases exponentially upon closer approach. Permanent dipoles localized in bonds give additional steric effects. The electric moments are known in many cases so that this term is roughly calculable. The other source of attractive potential, van der Waals potential and the coulombic energy are readily calculable.

That the interchange forces are an important factor in steric hindrance is shown in a recent paper by Stuart.¹² He examined the experimental data for heats of combustion of substituted benzene isomers differing only in the relative position of certain radicals. After theoretically calculating the polarization and dipole potentials there is left in many cases a positive potential energy which must be attributed to the repulsive interchange energy between neighboring unpaired electrons. To calculate the energy from potential energy curves for diatomic molecules one must know what fraction of the total energy is coulombic. The coulombic part is 10% of the total in the case of H_2 ,¹³ for Li_2 it is 22%¹⁴ and for Na_2 ¹⁵ it is 28.3%. It must be estimated in other cases. The rest of the potential energy is

interchange binding except for the small fraction due to polarization. The percentage of coulombic binding for a particular molecule from the minimum out to almost complete dissociation is constant to about 1% in the cases where it is known.

It is of some interest to estimate the magnitude of steric effects in a typical case. Quantum theoretical considerations¹⁶ lead to the conclusion that the two strongest eigenfunction bonds in an oxygen atom will make an angle of 90° with each other. This angle will be modified by the positive interchange energy $-\alpha/2$ between H atoms, by the negative coulombic energy, the negative van der Waals energy, and the positive energy due to the two dipoles. In addition to these factors there is a new one to consider for directed valences. If one considers the Heitler-London coulombic and interchange integrals for a bond formed from a directed P eigenfunction and a spherically symmetrical one, it is found that the bond energy, E , depends in the following way on the angle, θ , between the axis through the atoms and the axis of the directed eigenfunction.

$$E = L \cos^2 \theta + M \sin^2 \theta$$

Thus for $\theta = 0$ we have $E = L$, the heat of dissociation of the strongest possible bond. Lacking precise information we shall assume $M = L/5$. We can then construct Table I for the energy terms between the two H atoms in H₂O for angles of 90, 110 and 120° between the OH bonds. The distance O to H is taken as 0.98 Ångströms and the value L for an OH bond is taken as 104 kg. cal.

TABLE I

Angle between bonds	Distance H to H	$-\alpha/2$	A	P	$0.8 L \sin^2 \theta$
90°	1.385	16.1	-5.7	-14.3	0
110°	1.606	10.2	-3.6	-5.9	29
120°	1.697	8.2	-2.9	-4.2	43

Column 2 of Table I gives the distance between two H atoms corresponding to the angle between the OH bonds given in Column 1. Column 3 gives the interchange repulsive energy; Column 4 the coulombic attraction; Column 5 the van der Waals attraction; Column 6 the positive potential due to distortion of the valence bond. The potential energies of Columns 3, 4 and 5 are zero when the H atoms are very far apart, whereas Column 6 depends only on the angle between the OH bonds. The van der Waals potential given in Column 5 is certainly much too large. All the energies are in kg. cal. The fact that the two OH bonds are polar will tend to increase the angle between the bonds. In spite of the approximateness of our calculations it is clear that steric effects are not to be neglected in H₂O. Also an angle differing greatly from 90° would be

¹⁶ Slater, *Phys. Rev.*, **37**, 481 (1931); Pauling, *THIS JOURNAL*, **53**, 1367 (1931).

surprising because of the rapidity with which directed valence falls off with θ . Equation 5 is, however, only valid for small values of θ . The methods suggested for calculating the potential energy upon collision of complicated molecules suffice also to calculate steric hindrance in complicated cases. Collision potentials and steric hindrance are really two aspects of the same problem. Kinetic theory diameters are a convenient measure of the distance at which steric hindrance starts to be important.

With alcohols and ethers the angle between the oxygen bonds should be still further increased by the larger steric effects and this is what electric moments indicate.¹⁷ A carbon to oxygen bond involves two directed eigenfunctions. If the axis of the carbon eigenfunction makes an angle, θ_1 , with the line joining the atoms and the axis of the oxygen eigenfunction an angle, θ_2 , with this same line, the bond varies with the angles approximately in the following fashion.

$$L \cos^2 \theta_1 \cos^2 \theta_2 + M (\sin^2 \theta_1 \cos^2 \theta_2 + \cos^2 \theta_1 \sin^2 \theta_2) + N \cos^2 \theta_1 \cos^2 \theta_2 \quad (6)$$

The significance of L , M and N is made clear by substituting the value 0 and $\pi/2$ for θ_1 and θ_2 in various ways. In (6) many terms have been neglected, some of which are probably almost as large as the last term and it is only approximately true for small values of θ_1 and θ_2 . Equation 6 is readily obtained by considering the interchange and coulombic integrals for a bond formed from two directed eigenfunctions. According to the views of Slater¹⁶ and Pauling¹⁶ each of the four valences of the carbon atom in the saturated hydrocarbons is approximately three-quarters a directed P valence, the remaining s valence is spherically symmetric. This introduces no difficulty in applying (6) to the directed part of the eigenfunction.

We shall now consider rotation about a single bond. Using the potential energy between two saturated H atoms given in Curve 2, Fig. 4, we can readily calculate the sum of the nine potentials between the hydrogen atoms on the two methyl groups in ethane. In Fig. 5 the sum of these nine potentials is plotted against angular displacement. Zero angle corresponds to the hydrogen atoms of one methyl group just eclipsing the hydrogen atoms of the other group as viewed along the C-C axis. Such an eclipse occurs three times in a revolution and accounts for the periodic nature of the potential. It is assumed that tetrahedral angles are preserved; that the C-C distance is 1.54 Å., and that the C-H distance in a methyl group is 1.13 Å. The distance between two H atoms on adjacent carbons is then given by the expression $d = (7.53 - 2.27 \cos \varphi)^{1/2}$, where φ measures the angular displacement of the two H atoms viewed along the C-C axis. If Curve II, Fig. 4, instead of I is used for estimating the potential between H atoms the ordinates in Fig. 5 are all approximately

¹⁷ Smyth, *Chem. Rev.*, **6**, 549 (1929).

cut in two. The true potential curve will probably lie between these extremes. A detailed consideration of the physical properties of hydrocarbons will enable us to come to more precise conclusions and this is being done.

If one uses for the potential between saturated hydrogen atoms a repulsion corresponding to 35% of the Morse curve, which amounts to assuming that it is 10% coulombic and 90% interchange, and then adds to this a van der Waals potential, $101/r^6$, a somewhat larger potential is found than those given in Fig. 4. For some other atoms such assumptions lead to fairly good results. A systematic investigation of such potentials is being carried out.

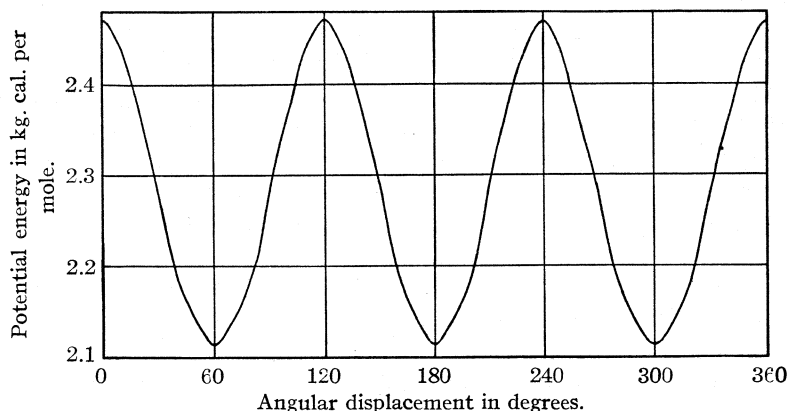

Fig. 5.—The dependence of the potential energy of the ethane molecule on rotation about the C—C bond.

As a final illustration of steric effects we will consider for hydrocarbons how the strength of a C—H bond is affected by successive substitution of CH_3 radicals for the other three hydrogen atoms in methane. Two hydrogen atoms in methane are at a distance from each other of 1.84 Ångströms. From Fig. 2 we find that half the theoretical interchange integral for this distance is -5.8 kg. cal. and the coulombic integral is -1.9 kg. cal. These values are probably each about 10% too low, since the corresponding integrals are about (but not more than) twenty-five per cent. too low when the atoms are 0.76 Ångströms apart and approach the correct values as the distance increases. The van der Waals attraction between hydrogen atoms cannot be satisfactorily estimated at such small distances with an expression of the type $101/r^6$ since this gives a fantastically large figure for the van der Waals attraction at 0.76 Å. for which the upper limit is the difference between the true heat of dissociation and that calculated by Sugiura. The van der Waals attraction is then considerably less than $101/1.84^6 = 2.62$ kg. cal. Ten per cent. of the sum of the interchange

plus coulombic integral, which is -1.4 kg. cal., cannot be far from correct. Using these figures we get for the total potential $5.8 - 1.9 - 1.4 = 2.5$ kg. cal.

When a hydrogen atom in methane is replaced by a methyl radical, there is a corresponding change in the repulsion on any one of the remaining hydrogen atoms. The repulsion due to the hydrogens on the methyl group depends on the angular displacement of the methyl group about the C—C bond and is just one-third of the ordinate in Fig. 5. We must still estimate the repulsive potential due to the carbon atom in the methyl radical. For this purpose we shall assume a Morse potential curve with the following constants, $\omega = 2920$; $r_0 = 1.13$; $D = 92$. ω is the vibration frequency in wave numbers for the lowest level; r_0 is the normal distance in Ångströms between atoms and D is the heat of dissociation in kg. cal. If the C—C distance is taken as 1.54 Ångströms, then the distance from a carbon atom to a hydrogen atom on an adjacent carbon is 2.19 Å. The Morse curve gives 24.5 kg. cal. for the potential energy at this distance. If we assume this is eighty per cent. interchange binding and twenty per cent. coulombic plus van der Waals, the net repulsion is $[(0.80/2) - 0.20] 24.5 = 4.9$ kg. cal. This estimate is probably low since proper account has not been taken of the repulsion of three of the electrons on the carbon atom. As a final result then we find for the difference in the repulsive potential of a methyl group and a hydrogen atom on a single hydrogen atom the value $4.9 + (2 \times 1/3) - 2.5 = 3.1$, which is probably low rather than high. If the CH bond is assumed to have a strength of 120 kg. cal. everything else being the same, we obtain instead of 3.1 kg. cal., the value 5.6 kg. cal. We shall use the value 3.1 kg. cal. Thus, if we neglect changes in the bonds themselves, we should expect it to be hardest to remove a hydrogen from a carbon in methane, 3.1 kg. cal. easier to remove a hydrogen from ethane, 6.2 easier to remove a hydrogen atom from the central carbon in propane and 9.3 kg. cal. easier to remove a hydrogen from a carbon in which the other three bonds are methyl radicals.

The experiments of Bonhoeffer and Harteck¹⁸ show that while hydrogen atoms will dehydrogenate other hydrocarbons, the reaction $H + CH_4 = H_2 + CH_3$ does not go. Since during a reaction of hydrogen with ethane the approaching H atom is much farther away from the methyl radical from which it does not remove a hydrogen than is the hydrogen removed, it is necessary to suppose that the principal effect of this methyl group is to weaken the bond of carbon to the attached hydrogen. The repulsion of the methyl group for the approaching hydrogen atom is negligible. The difference in rates observed is thus to be attributed to a stronger C—H bond in methane and not just to a higher activation energy. Ex-

¹⁸ Bonhoeffer and Harteck, *Z. physik. Chem.*, [A] **139**, 64 (1929).

periments of von Hartel and Polanyi¹⁹ show that sodium atoms more readily detach halogen atoms from ethyl than from methyl radicals. Here again we see the effect of the repulsive potential of methyl radicals. From this point of view the heat of combustion might be supposed greater for branched than for the corresponding straight chain hydrocarbons. However, the net heat effect is greatly complicated by attraction between groups slightly farther apart than those we have just found repel.²⁰ Isopentane evolves 5 kg. cal. more heat upon combustion than normal pentane but with some of the longer chains this effect is lessened and even reversed so that for comparison of heats of combustion a more detailed treatment is necessary.

I wish to thank Professor J. C. Slater for many helpful discussions.

Summary

The method of calculating the potentials between saturated molecules or groups of atoms is indicated and the potential energy curve for two colliding H_2 molecules is calculated and compared with experiment. The agreement is good. A potential energy curve for the collision of two saturated hydrogen atoms is given and used in constructing a potential for the rotation of the two methyl groups in ethane about the C—C axis. Viewed along the C—C axis the greatest potential occurs at eclipse of the far hydrogen atom by the near ones. The lowest potential corresponds to a position half way between two eclipses. The calculated change in potential is 0.36 kg. cal. The true value probably lies between 0.36 kg. cal. and half this amount. A similar calculation indicates that a hydrogen in ethane is at a potential at least 3.1 kg. cal. higher than a hydrogen in methane due to the greater repulsion of a methyl group than of a hydrogen atom. This fact explains the increase in reactivity of a hydrogen attached to carbon as the three neighboring hydrogens are replaced by methyl groups.

THE ABSORPTION SPECTRA OF THE CHROMIUM AMMINE HYDRATES¹

BY ROBERT IRVING COLMAR AND FREDERICK WILLIAM SCHWARTZ

RECEIVED APRIL 29, 1932

PUBLISHED AUGUST 5, 1932

Introduction

The aquo ammino chromic salts have been regarded by Werner² as indicating the close relationship between chromic ammine complexes and chromic salt hydrates. Schwarz³ mentions the interesting colors exhibited by these compounds, noting that the color changes from yellow through red to violet as ammonia molecules are replaced by water molecules in hexammine chromic salts. Shibata, together with his co-workers,^{4,5} and Luther and Nikolopoulos⁶ have published absorption spectra observations on several of the aquo ammino chromic salts though data for the complete series were not obtained. These investigators agreed that the substitution of a water molecule for an ammonia molecule in these amines causes the visible absorption band (of the compound in solution) to shift in the direction of increasing wave length. Since their data were not precise enough to furnish an estimate of the magnitude of this shift, this research was undertaken to obtain the desired information.

Preparation of Compounds.—The compounds used in this investigation were prepared by standard methods described in the literature.⁷

Apparatus.—The absorption spectra measurements were obtained by the use of a Nutting Polarization Photometer in conjunction with a Constant Deviation Spectrometer. Both instruments were made by Wm. Gaertner and Co. For a description and method of operation of this

spectrophotometer, Wagner's book⁸ may be consulted. The absorption cells consisted of various lengths (about 1.5 cm. diameter) of hollow cylinders with polished ends over which were slipped circular end-plates. Measurements were taken at room temperature, no form of temperature control being employed.

Molecular extinction coefficients were calculated from the formulas

$$\text{Molecular extinction coefficient} \equiv \text{M. E. C.} = -\log_{10} T / cd$$

where T was the transmission of a tube of solution, of concentration c molar, and a length of d centimeters. The value of T was obtained from the equation

$$T = \frac{\sin^2 x}{\sin^2 x^0}$$

where x was the value of the photometer disk angle necessary to produce a balance in the photometric field when the solution being measured was in the path of the light beam of the photometer and x^0 was the value of the photometer disk angle when no absorption cell was in place.

Precision of Measurements.—The average deviation of the mean of the M. E. C. was kept at about ± 1 unit throughout the visible spectrum by varying the number of observations. In the violet part of the spectrum, ten readings at each point were taken because of poor visibility and low illumination; otherwise, five readings were satisfactory. By using copper sulfate and potassium chromate solutions, which are accepted spectrophotometric standards, recognition of constant or residual errors was possible. From a consideration of the results obtained by comparing observations on these solutions with those furnished by the Bureau of Standards, the author believes that the precision measure of the M. E. C. is 5%, which is a good value for this type of measurement.

Results

By plotting the molecular extinction coefficient versus wave number (see Tables I and II; also Figs. 1 and 2) for each solution, a value of the wave number at which the extinction coefficient is a maximum, is obtained. These maximum values of the M. E. C. are plotted *versus* molecules of water replacing molecules of ammonia in the complex (see Fig. 3). On examining these curves, the following generalizations may be noted.

- (1) On substituting a water molecule for an ammonia molecule in either a chromium or cobalt complex (up to four substitutions) the wave number at which maximum absorption of light occurs is decreased 610 mm.^{-1} (Fig. 3).
- (2) On substituting a water molecule for an ammonia molecule in a chromium complex, the value of the molecular extinction coefficient at the maximum of the absorption band is decreased successively 4.9 units (Fig. 4).
- (3) In the cobalt complexes an anomaly to the previous rule for

chromium complexes exists, for a decrease in the molecular extinction coefficient takes place on the substitution of the first molecule of water for ammonia but an *increase* is noted for the second entering water molecule. However, the shift in wave number (as in Rule 1) holds true (Fig. 4).

(4) Referring to Fig. 3 it will be noted that the lines for chromium salts and cobalt salts are parallel. This would seem to indicate that the substitution of a cobalt atom for a chromium atom in a complex as in $[\text{Cr}(\text{NH}_3)_6]\text{Cl}_3$ to $[\text{Co}(\text{NH}_3)_6]\text{Cl}_3$ or in $[\text{Cr}(\text{NH}_3)_5(\text{H}_2\text{O})]\text{Cl}_3$ to $[\text{Co}(\text{NH}_3)_5(\text{H}_2\text{O})]\text{Cl}_3$ causes the wave number at which maximum absorption of light occurs to decrease 510 mm^{-1} . In order to verify this assumption $[\text{Cr}(\text{NH}_3)_5(\text{Cl})]\text{Cl}_2$ and $[\text{Co}(\text{NH}_3)_5(\text{Cl})]\text{Cl}_2$ were prepared and their absorption spectra studied. The difference between their wave numbers at maximum absorption was 500 mm^{-1} , a value not much different from that predicted by the above generalization. (5) The molecular extinction coefficients at maximum absorption for all cobalt compounds have higher values than those of the corresponding chromium compounds (Fig. 4). (6) The substitution of chlorine for an ammonia molecule decreases the wave number at maximum absorption 1970 mm^{-1} .

Discussion

Shibata⁴ believes that in solution the following equilibrium is rapidly established

the chloro-pentammino salt being formed almost exclusively. As the reason for this belief he points out that, according to his measurements, the absorption spectra of the aquo and chloro compounds are nearly identical. The author finds that this is not the case, since aquo-pentammino-cobaltic chloride has a wave number at maximum absorption of 20,570, while chloro-pentammino-cobaltic chloride has a wave number of 19,200, a difference quite beyond the possibility of experimental error.

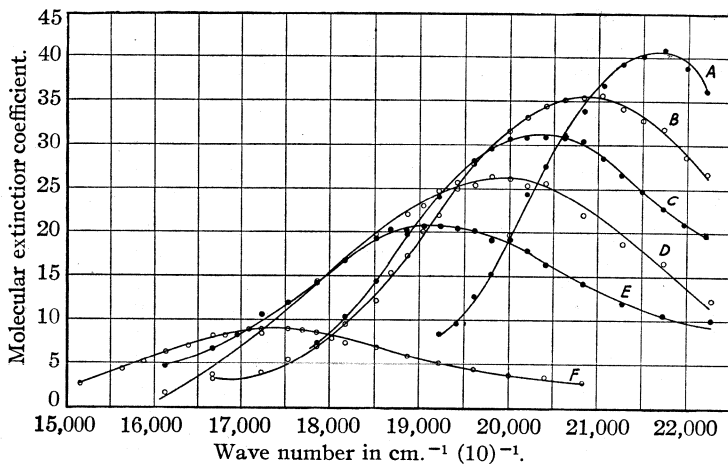

Fig. 1.—Absorption spectra of the chromium ammine hydrates: Curve A, hexamino-chromic chloride; B, aquo-pentammino-chromic chloride; C, diaquo-tetrammino-chromic chloride; D, triaquo-triammino-chromic chloride; E, tetraquo-diammino-chromic chloride; F, hexaquo-chromic chloride.

A similar difference is observed for the corresponding chromium salts. It is therefore believed that the absorption spectra furnish no evidence for such an hydrolysis (in freshly prepared solutions). However, the author has noticed that aquo-pentammino-chromic chloride changes into chloro-pentammino-chromic chloride in about a week, even if stored in the dark and over phosphorus pentoxide. It is therefore extremely likely that if a considerable interval elapsed between the preparation of the salts and their optical examination, erroneous results would be obtained.

Physical Theory.—From the fact that changes of the central atom produce variations in molecular extinction coefficients and wave numbers, it is evident that at least some (if not the greater part) of the color must be due to the central atom, or, strictly speaking, the central ion. This idea

furnishes a starting point in formulating a theory to explain the observed regularities.

For a basis the following principle, having wide application in spectroscopy, has been applied. If a molecule contains a number of energy absorbing units, capable of absorbing quanta denoted by $h\nu_1$, $h\nu_2$, $h\nu_3$, etc., then absorption of radiation energy, whose frequency is ν_1 , ν_2 , ν_3 and $\nu_1 + \nu_2 + \nu_3 + \dots$, etc., may occur.

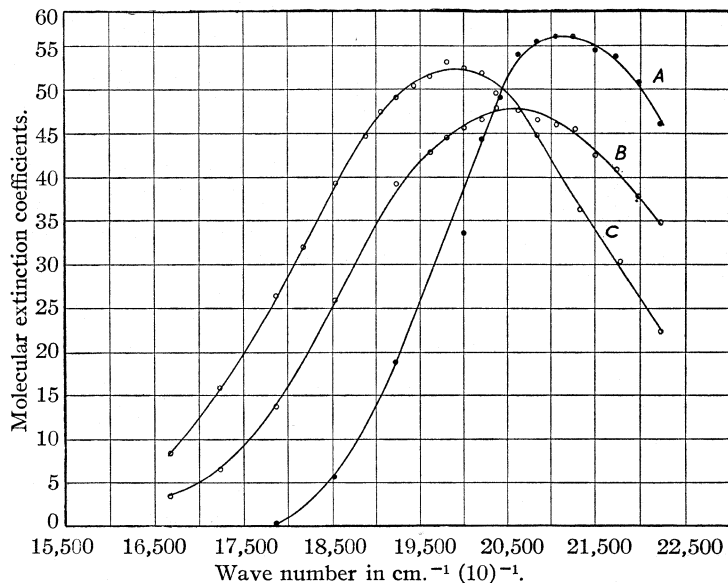

Fig. 2.—The absorption spectra of the cobaltic ammine hydrates: Curve A, hexammino-cobaltic chloride; B, aquo-pentammino-cobaltic chloride; C, diaquo-tetrammino-cobaltic chloride.

In any molecular group there may be a number of possibilities; these have been enumerated by Taylor:⁹ (1) electronic transitions within individual atoms; (2) vibrations of the atoms within chemical groups; (3) rotation or quasi-rotation of the group as a whole.

Thus part of the light absorption capacity is attributed to the chromic ion or the cobaltic ion, because of an electronic transition within these ions. Another part is attributed to the internal vibrations of the atoms and ions making up the complex. Here, because of the great number of degrees of freedom possible in the system, many modes of vibration are possible, though it seems reasonable to expect that one or two modes will predominate.

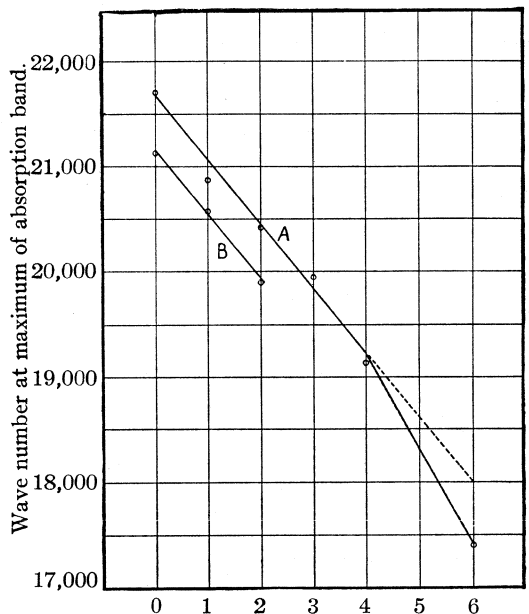

The vibrational frequency (which is proportional to wave number) must be proportional to some function of the binding forces between the

⁹ Taylor, *Trans. Faraday Soc.*, **25**, 860 (1929).

vibrating bodies and inversely proportional to some function of their masses.

The rotational frequencies are small, compared with electronic and vibrational frequencies, and are therefore neglected.

From the foregoing considerations, the absorption spectra of these complexes should show a strong absorption line (corresponding to $\nu_1 + \nu_2 + \nu_3 + \dots$, etc.) surrounded by fine line structure (since there is a series of vibrational levels); instead a continuous band is observed. A number of reasons may be advanced for this, one of the most important being that given by Sidgwick,¹⁰ who states "the broadening of the absorption lines of an ion in solution is due to the electric fields of neighboring atoms, which break up each line into components, whose separation depends on the strength of the field (Stark effect); as the ions present are thus affected in various degrees, the result is to spread the sharp lines into a band." The rotational frequencies must also contribute to the blurring of the lines as well as the collisions of the absorbing bodies in solution.

Molecules of water replacing ammonia in complex.

Fig. 3.—Curve A, chromic ammine hydrates; Curve B, cobaltic ammine hydrates.

Consider the compounds

Since (1) and (3) have the same central ion, their electronic term must be the same and the shift in frequency, which is $1830 (10)^{10}$ [the product of the velocity of light in centimeters and the difference between the wave numbers at maximum absorption of compounds (1) and (3)], is due to a change in the vibrational spectral terms. Since the masses of the ammonia and water molecules are approximately the same (17 and 18), it seems reasonable to attribute the change in vibrational frequency to a loosening of the binding forces which connect the ammonia and water groups to the central ion. This effect should be observed in an x-ray crystal analysis

¹⁰ Sidgwick, "The Electronic Theory of Valency," The Clarendon Press, Oxford, England, 1927.

of these compounds. The hexammino salt should have the most compact structure, while the substitution of ammonia for water should loosen the crystal structure. The effect also should parallel the shifts in frequency: an anomaly should be observed for the hexaquo salt. Other evidence which supports this point of view comes from considerations of the chemical stability. The hexammine salts are the most stable, with the stability decreasing as water is substituted for ammonia, which is what would be expected from the binding forces becoming weaker.

The vibrational frequencies are affected by change of mass also, since the substitution of chlorine for ammonia causes a shift in frequency of 5910 units while a change of water for ammonia causes a shift in frequency of 1830 units. This also is to be expected on the basis of the theory.

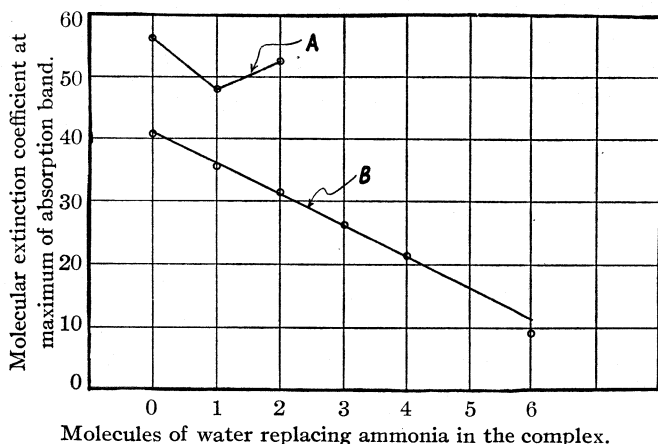

Fig. 4.—Curve A, cobaltic ammine hydrates; Curve B, chromium ammine hydrates.

Considering Compounds (1) and (2), the generalizations previously mentioned state that a decrease of 1530 units is to be expected on changing from Cr to Co. Since this difference of 1530 is constant for all compounds whose only difference is the central ion and the shift in frequency (1830) due to the substitution of water for ammonia remains the same for cobalt compounds, the only way to account for this is to assume that the vibrational terms for these compounds are the same or always differ by a constant amount. This attributes all change of color in these compounds to differences in the electronic terms. Since this electronic transition is a property of the central ion only, all complexes of cobalt and chromium, whose only difference in structure is a change of central ion, should show this same constant difference.

The explanation of the decrease in the value of the molecular extinction coefficients at the wave number of maximum absorption with the number of

substitutions of water for ammonia is related to the probability of electronic transitions within the group.

Acknowledgment.—This investigation was under the co-direction of Dr. Frederick William Schwartz, Professor of Inorganic Chemistry, and Dr. Robert Alexander Patterson, Professor of Physics, at the Rensselaer Polytechnic Institute. The author is deeply grateful to these men and others, who, by their interest and aid, contributed to the advancement of this research.

Summary

1. The visible absorption spectra of some chromamines and cobaltamines have been measured.
2. Certain empirical generalizations have been deduced from these measurements.
3. A theory has been put forth to account for the light absorption of complex compounds.
4. As a test of the theory, a prediction of the x-ray crystal analysis of a series of chromamines has been recorded.

THE PRECISION WITH WHICH THE CONCENTRATIONS OF SOLUTIONS OF HYDROCHLORIC ACID AND SODIUM HYDROXIDE MAY BE DETERMINED WITH THE IMMERSION REFRACTOMETER

BY E. ROGER WASHBURN AND ALLEN L. OLSEN

RECEIVED MAY 4, 1932

PUBLISHED AUGUST 5, 1932

The refractive index of solutions varies with the concentration. A curve may be prepared showing this variation and then if the refractive index of an unknown solution is determined, the concentration may be read from the curve, or calculated from the equation of the curve. In order to make an accurate determination, it is necessary that the solution contain no measurable amount of impurity and that the temperature at which the reading is taken be the same as that for which the curve and equation were determined. Since refractive index may be easily and accurately determined, it has been suggested¹ that the refractometer be used as a means of determining the concentrations of various standard solutions used in analytical chemistry.

The results of previous work on concentration-refractive index relation-

¹ H. H. Willard, *Ind. Eng. Chem., Anal. Ed.*, **2**, 201 (1930); C. A. Clemens, *J. Ind. Eng. Chem.*, **13**, 813 (1921); B. Wagner, *Z. angew. Chem.*, **33**, 249 (1920).

ships are recorded in standard reference works.² A study of the original articles from which these tables have been compiled reveals the need for further work designed to determine the limits of precision within which the concentration of solutions may be measured by a study of the refractive index and precautions which must be taken in order to attain this accuracy. The usefulness of the method will be increased by the formulation of equations by which the normality may be calculated from refractive index.

Apparatus.—A Bausch and Lomb immersion refractometer, with a range of 1.32540 to 1.36639, was used in this investigation. A rectangular tank, provided by the makers of the instrument, was used to contain the cups of liquids during the time required to take the readings.

By siphoning water from an electrically heated, hand-controlled water-bath of thirty gallon capacity, we were able to maintain the temperature of the dipping tank to within $\pm 0.05^\circ$ of the desired temperature during the time required to make the measurements. The temperatures in the bath and in the dipping tank were measured with calibrated thermometers graduated to 0.10° . The siphoned water in the refractometer tank was stirred with air, and the field was well illuminated with artificial light.

The pipets, burets and volumetric flasks used in preparing and standardizing the solutions were calibrated at 25.0° .

Solutions.—The water that was used in all of the experimental procedures was redistilled from an alkaline permanganate solution contained in a copper boiler fitted with a block tin condenser.

Hydrochloric Acid.—The hydrochloric acid solutions used in the major part of this study were prepared from freshly distilled samples of Grasselli c. p. quality acid. Some solutions were prepared by direct dilution of different samples of commercial c. p. acid. No significant differences were noted between the refractive indices of solutions of equal normality prepared from the two sources. The actual normality of each prepared solution was established by at least one of the following methods, gravimetric determination of silver chloride, the use of constant boiling hydrochloric acid prepared according to the method of Foulk and Hollingsworth³ as a primary standard in making up the samples, or by quantitative dilution of a solution, the normality of which had been established by one of these procedures. The method used in each case is indicated in the table of results. All normalities were determined at 25.00° .

Sodium Hydroxide.—The sodium hydroxide solutions were prepared by the dilution of a saturated aqueous solution of Mallinckrodt reagent quality sodium hydroxide. Analysis⁴ indicated that these solutions contained less than 0.5% sodium carbonate in terms of the sodium hydroxide content. The concentrations of the solutions of sodium hydroxide were determined by titration with hydrochloric acid which had been standardized by means of chloride analysis. Methyl orange was used as the indicator. Some of the test solutions were prepared by dilution of standard solutions and from the proportions used the concentrations were calculated. The solutions of sodium hydroxide

were kept in bottles which had been coated with a rubber preparation designed to be resistant to alkali.⁵ A few tests were run on solutions prepared by simply dissolving ordinary c. p. sodium hydroxide and U. S. P. X sodium hydroxide in water. The source of the different test solutions is indicated in the tables of results.

Measurement of Refractive Index.—Immersion refractometers are graduated in arbitrary scale divisions which may be converted into refractive indices by means of an equation or by conversion tables provided with the instrument. Since not all instruments have the same arbitrary scale, it is important to be sure that the conversion tables fit the instrument which is used. Our instrument was adjusted at each temperature to give the correct value for water. The uniformity of the scale and accuracy of the instrument were checked by measurement of the refractive indices of sodium chloride solutions. The results obtained, throughout the range of the instrument, checked accepted⁶ values within ± 0.00003 at 25.0° .

In view of the fact that a 1° change in temperature is equivalent to about 0.3 of a scale division or 0.00012 in refractive index for water, it is evident that temperature variations must be small. The variation which we allowed ($\pm 0.05^\circ$) is equivalent to about 0.015 scale division, which is less than the usual experimental error in reading the instrument. It was found necessary to wait several minutes after the refractometer was immersed in the solution for temperature equilibrium to be reached so that a sharp field and constant readings could be obtained.

That it is necessary to guard against evaporation from the liquid in the refractometer cups and that paraffined corks will effectively cut down evaporation are shown by the data in Table I. These readings were taken at 25.00° with an approximately 4 *N* solution of hydrochloric acid.

TABLE I

•	Open cups		Stoppered with paraffined corks	
	Elapsed time, min.	Scale reading	Elapsed time, min.	Scale reading
	0	99.56	0	99.56
	24	99.58	20	99.58
	69	99.57	62	99.55
	108	99.63	103	99.55
	221	100.03	254	99.57
	994	101.62	917	99.68
	1283	102.90	1263	99.68

The holes at each end of the rack in the dipping tank were not used as it was found that unequal illumination in these positions caused variable results.

The dipping prism of the refractometer is fastened in a mounting made

⁶ "International Critical Tables," The McGraw-Hill Book Co., Inc., New York Vol. VII, p. 73.

of an acid-resisting alloy. It was found that this dissolved slowly when in contact with concentrated solutions of hydrochloric acid and resulted in variable scale readings. The mounting was coated with a thin layer of paraffin which successfully prevented the corrosion and resulted in practically constant readings over a period of several hours.

Experimental Results

The refractive indices of a number of solutions of hydrochloric acid ranging in normality from 0 to 4, and of solutions of sodium hydroxide ranging in normality from 0 to 3, were determined at 20.00, 25.00 and 30.00°. The normalities of the solutions at 20.00 and 30.00° were calculated from the values measured at 25.00° making use of the densities and compositions listed in the "International Critical Tables."

From these results equations for each of the materials at each temperature were determined by substituting normalities and the corresponding refractive indices in the following general equation for a parabola:

$$N = A + B (\text{ref. index soln.} - \text{ref. index water}) + C (\text{ref. index soln.} - \text{ref. index water})^2$$

N represents the normality of the chosen solution. Since with pure water N is zero, A is also zero, so an equation for the curve may be formulated by solving two simultaneous equations for B and C . A fourth or D term to be multiplied by the cube of the difference in refractive indices was not used because it was found that for the range of concentrations studied the agreement between the results calculated without the D term and the actual normality was within the experimental error of the method. Slightly different values for these constants resulted from using different combinations of solutions. Several combinations were used and from the constants obtained those given in the equations in Tables II and III were chosen as seeming to represent closely the relation between normality and refractive index for the system studied.

Test solutions were then prepared and the normalities calculated from refractive indices were compared with those obtained by standard methods. Since the agreement in these examples is in no sense different from that found with the original solutions studied, the results are listed together in the same tables.

In the case of hydrochloric acid, the greatest difference between the calculated normalities and the actual normalities is ± 0.005 . This amounts to an error of $\pm 5.0\%$ with a 0.1 N solution, but to only 0.5% for a 1.0 N solution or 0.13% for a 4 N solution. The average difference, however, is only ± 0.002 , which would be a percentage error of ± 1.0 , ± 0.1 and ± 0.05 for 0.1 N , 1.0 N and 4.0 N , respectively.

The greatest difference between the calculated values and those obtained by analysis for sodium hydroxide is about ± 0.003 in normality

The percentage error would be ± 3 , ± 0.3 and ± 0.1 for concentrations of 0.1, 1 and 3 normal, respectively. The average difference is ± 0.001 , which, when applied to the three concentrations, would be a percentage error of ± 1 , ± 0.1 and ± 0.03 .

The differences between the calculated and the observed normalities of hydrochloric acid and sodium hydroxide are found to fall within the limits of precision which one would calculate from the slopes of curves plotted from the values in Tables II and III and from the accuracy with which one may read the refractometer. One unit in the fifth decimal place in refractive index (0.00001) corresponds to about 0.0012 in normality for hydrochloric acid and to about 0.0009 in normality for sodium hydroxide. The makers of the instrument state that an ordinary worker is able to read scale divisions with a precision of ± 0.2 and with a little practice to a ± 0.1 . One-tenth of a scale division is equivalent to 0.00004 in refractive index. Therefore

$$\begin{aligned}\pm 0.2 \text{ in scale readings} &= \pm 0.0096 \text{ in } N \text{ for HCl} \\ &\quad \pm 0.0072 \text{ in } N \text{ for NaOH} \\ \pm 0.1 \text{ in scale readings} &= \pm 0.0048 \text{ in } N \text{ for HCl} \\ &\quad \pm 0.0036 \text{ in } N \text{ for NaOH}\end{aligned}$$

Summary

The refractive indices for hydrochloric acid solutions up to 4 N and for sodium hydroxide solutions up to 3 N have been determined at 20.00, 25.00, 30.00°.

Equations relating normalities to refractive indices for these solutions have been formulated.

Several precautions which must be taken in order to obtain precision results with the immersion refractometer have been studied.

The limits of precision with which one may expect to determine the concentrations of these solutions by this method have been determined.

THE USE OF A SULFATE-HYDROSULFATE BUFFERED SOLUTION FOR THE PRECIPITATION OF ZINC SULFIDE

By C. E. P. JEFFREYS AND ERNEST H. SWIFT

RECEIVED MAY 5, 1932

PUBLISHED AUGUST 5, 1932

It has been realized for over half a century that there are advantages in precipitating zinc sulfide from an acid solution rather than one which is neutral or alkaline; specifically, certain separations can be made by proper adjustment of the hydrogen-ion concentration and the precipitate usually separates in a form which is more readily handled. Because of these effects many early workers¹ recommended the use of various organic acids for acidifying the solution and thereby obtained, somewhat uncertainly, the effect of a buffered solution considerably prior to the development of the modern theory and use of such solutions.

Somewhat more recently the use of sulfuric acid solutions was studied by Weiss,² who recommended that the precipitation be made from a solution 0.01 *N* in sulfuric acid by means of a very rapid stream of hydrogen sulfide, but he apparently provided no means for controlling the increase in hydrogen ion concentration taking place during the precipitation; by Waring,³ who once more recommended the use of formic acid; by Funk⁴ who studied the effect of various organic acids on the precipitation and on the separation of zinc from various other elements; while Glixelli⁵ made a comprehensive study of the effect of the nature of the solution on the forms and apparent solubility of the precipitate, also on the time factor which enters in establishing the precipitation equilibrium.

In the excellent work of Fales and Ware⁶ the limits of the hydrogen-ion concentration between which quantitative precipitation could be effectively made were first precisely determined and means provided for controlling the acidity within these limits. They found that 0.01 *N* sulfuric acid solutions were near the limiting hydrogen-ion concentration above which precipitation is incomplete. Therefore they rejected sulfuric acid solutions in favor of formic acid-formate buffered solutions, and found that for such solutions the hydrogen-ion concentration most favorable for quantitative precipitation of zinc sulfide was 10^{-2} to 10^{-3} . They seem not to have

investigated the possibility of using sulfate and hydrosulfate as a buffer for controlling the acidity during the precipitation.

Lundell, Hoffman and Bright⁷ have recently recommended the precipitation of zinc sulfide from a 0.01 *N* sulfuric acid solution and state that the best precipitation is obtained from a sulfuric acid-sulfate solution. They do not present any discussion or experimental data in support of this recommendation.

This paper presents the results of a study of the use of sulfate-hydrosulfate mixtures as buffer solutions, of the precipitation of zinc as zinc sulfide from such solutions, and of the separation of zinc under such conditions from nickel, cobalt, iron, manganese, chromium and aluminum.

There are certain advantages in using sulfate-hydrosulfate buffered solutions for this particular precipitation. The second ionization constant of sulfuric acid having been determined⁸ as 1.15×10^{-2} , and the optimum hydrogen-ion concentration for the precipitation of zinc sulfide from sulfate solutions having been found to be about 10^{-2} , it would seem that the required ratio of sulfate to hydrosulfate should be about one, the most favorable ratio for effective buffer action. As compared with this, Fales and Ware had to use an acid-to-salt ratio of 84:1, with the formic acid concentration 4.7 formal, in order to obtain an initial *PH* of 1.86, a value at which, in our experiments, quantitative precipitation was obtained. This *PH* was experimentally obtained in the sulfate-hydrosulfate solution by using an acid-to-salt ratio of 20.7:66, with the total concentration of sulfate and hydrosulfate 0.347 formal. In addition, Fales and Ware recommended the use of considerable ammonium citrate and 6.25 g. of ammonium sulfate in 200 ml. of solution. It is stated that: "ammonium citrate is used for the purpose of forming complexes with interfering metals," thus assisting in holding in solution such elements as iron and manganese. We find that from a sulfate-hydrosulfate solution of the proper *PH*, such an agent is not needed. The ammonium sulfate was added as a "salting-out agent." In our experiments the need of adding an additional salting-out agent was not apparent, as quantitative precipitation was obtained, and as the form of the precipitate left nothing to be desired as to ease of filtration and washing. It is believed that under the conditions of our experiments, the hydrogen-ion concentration is the predominant factor governing the form as well as the solubility of the precipitate. It should also be mentioned that when using this precipitation of zinc as a means of effecting a qualitative separation it is a decided advantage not to have to add organic matter to the solution, for, especially in a group analysis, such material as citrates may cause difficulties in subsequent operations.

⁷ Lundell, Hoffman and Bright, "Chemical Analysis of Iron and Steel," John Wiley and Sons, 1931, p. 388.

⁸ Sherrill and Noyes, *THIS JOURNAL*, **48**, 1873 (1926).

This study was originally undertaken in order to devise a suitable method for the qualitative separation of zinc from nickel and cobalt which would be more quantitative than those commonly employed in qualitative systems, such as, for example, the treatment of the mixed sulfides with dilute hydrochloric acid or the use of sodium hydroxide and peroxide. We wish to express our obligation to Mr. W. H. Pickering and to Mr. D. F. Bender for a large number of preliminary experiments in which the limiting conditions were determined and in which the effect of such modifications as carrying out the precipitation at elevated temperatures under considerable pressure of hydrogen sulfide was studied.

Materials

Preparation and Standardization of a Zinc Sulfate Solution.—A c. p. grade of zinc sulfate was recrystallized once from distilled water and once from conductivity water. The solution, saturated at 70°, was cooled in an ice-bath and the crystals collected by suction filtration. A stock solution containing approximately 40 mg. per ml. was made, and a working solution containing 10 mg. per ml. was prepared from it by dilution. This latter solution was standardized by precipitating the zinc as sulfide from sulfate-hydrosulfate solutions at such a *PH* that the precipitation was quantitative, *i. e.*, initial *PH*'s of 2.18 and 1.86. The zinc sulfide was then converted to sulfate and weighed as such. The values thus obtained were 257.0 mg. per 25 ml. and 257.3 mg. per 25 ml. Some difficulty was experienced in igniting the zinc sulfate samples to constant weight. Fales and Ware, after igniting the paper and precipitate, added concentrated sulfuric acid and heated to constant weight in an air-bath. With their particular arrangement they mention no difficulty. Scott⁹ directs that the zinc sulfate be ignited to dull red heat. It was found difficult to drive off all the sulfuric acid on an air-bath, and very difficult to ignite with a Bunsen burner without decomposing some of the sulfate. However, constant weight was easily obtained by fuming off the excess acid on an air-bath and heating the precipitate to 500 ± 20° for one hour (an electric furnace with a temperature indicator and control was used). Lundell, Hoffman and Bright⁷ recommend igniting to zinc oxide at 900°, and indicate that in this case also the temperature of ignition must be fairly closely controlled. Our experiments confirmed this and indicate that either method is capable of consistent results with careful control of the temperature of ignition.

The Gases Used.—Hydrogen gas for the hydrogen electrode was taken from a cylinder. Using standard buffer solutions it was found that with this hydrogen constant and reproducible e. m. f. values were obtained which agreed with the accepted values for these solutions. Hydrogen sulfide, also from a cylinder, was used after passing it through a bottle of distilled water. Carbon dioxide was obtained from a cylinder.

Buffer Solutions.—The buffer solutions were made by weighing out the proper quantity of c. p. sodium sulfate decahydrate, and adding the required amount of either standard sulfuric acid or a weighed quantity of c. p. sodium hydrosulfate.

Sulfates of Other Metals.—The best available c. p. grade sulfates of cobalt, iron, nickel and manganese were used without further purification. Qualitative tests showed that the cobalt contained no nickel, and the nickel no cobalt. The source of the chromium and aluminum were c. p. grades of potassium aluminum sulfate and potassium chromium sulfate.

⁹ Wilfred W. Scott, "Standard Methods of Chemical Analysis," 4th ed., D. Van Nostrand Co., 1927, p. 599.

The Experiments

***PH* Measurements on the Buffer Solutions.**—The buffer solution was made up in a 500-ml. Erlenmeyer flask, and 25 ml. of zinc sulfate solution containing 257 mg. of zinc was added with a pipet. The total volume in all experiments was 250 ml. The *PH* of the solution was measured by means of a Hildebrand type bubbling electrode, and a saturated calomel half-cell. The electrodes and assembly for the hydrogen-ion concentration measurements were checked against a standard acetate solution, and also against a *M*/20 potassium acid phthalate solution. A sample of Bureau of Standards potassium acid phthalate was used for checking an electrode, then with the same electrode a solution prepared from a c. p. brand of potassium acid phthalate was measured. The e. m. f.'s agreed to within one millivolt. This latter solution was then used for checking the electrode from time to time during the course of the work.

Precipitation of the Zinc Sulfide.—The method of precipitation closely followed that given by Fales and Ware.¹⁰ The solution from which the zinc was to be precipitated was heated to 60°, hydrogen sulfide bubbled through rapidly and the heating continued until the temperature reached 90–95°. As the solution cooled, hydrogen sulfide was also bubbled through it until the precipitate began to settle rapidly, and finally the solution was saturated when cold. Twenty-five to forty minutes were usually required before rapid settling was obtained. The precipitation was found to be quantitative in forty minutes when carried out in this way in solutions of the proper acidity.

The mixtures were allowed to stand until the supernatant liquid was entirely clear. Some solutions were filtered after standing for three hours, and others were allowed to stand overnight; no difference was detected as to ease of filtering or completeness of precipitation. The precipitate was of a dense, granular form, which filtered rapidly and did not cling tightly to the glass of the flask as is the case with zinc sulfide precipitated from less acid or alkaline solutions.

***PH* Measurements on the Filtrate.**—The filtration was made through a dry paper, the filtrate freed of hydrogen sulfide by bubbling carbon dioxide through it, and the *PH* measured after removing the carbon dioxide by passing hydrogen through. A blank was run on a solution made up as was the solution in Expt. 3 of Table I. Instead of precipitating the zinc in this case, an amount of sulfuric acid was added corresponding to the acid liberated on precipitating 257 mg. of zinc. The *PH* change was from 1.86 to 1.68, which corresponds closely with the change observed in the experiments shown in the tables.

The Solubility of Zinc Sulfide in Sulfate-Hydrosulfate Solutions.—In Table I are given the results of a group of experiments in which the

¹⁰ Ref. 6, p. 493.

solubility of zinc sulfide with various ratios of hydrosulfate to sulfate and various P_H values was studied. Column 2 gives the ratios of $\text{NaHSO}_4/\text{Na}_2\text{SO}_4$ initially in the solution, columns 3 and 4 the initial and final P_H values, respectively, and column 5 the milligrams of zinc remaining in solution after the precipitation with hydrogen sulfide. The values in the last column were obtained in the following way. After making the final P_H measurement, ammonia was slowly added to the filtrate until it remained just acid to litmus, and again hydrogen sulfide was passed in to precipitate any zinc which had remained in the filtrate. The size of the precipitate thus obtained was compared with that obtained on precipitating known quantities of zinc under the same conditions. Fales and Ware⁶ estimated the unprecipitated zinc by weighing the precipitate obtained and calculating the difference from the amount taken. The method here used is a more direct way of estimating the small amounts of zinc remaining in solution, and is sufficiently accurate for estimating the quantities involved. Confirmatory experiments showed that under these conditions 0.1 mg. of zinc would give a detectable opalescence on treatment with hydrogen sulfide. A blank was run to prove that no free sulfur would be obtained under the same conditions. This possibility was minimized by the fact that the solution had been freed from oxygen by being saturated with carbon dioxide, and contact with air thereafter prevented so far as possible.

TABLE I

THE SOLUBILITY OF ZINC SULFIDE IN SULFATE-HYDROSULFATE SOLUTIONS OF VARIOUS HYDROGEN-ION CONCENTRATIONS

Volume, 250 ml.		Zinc taken, 257 mg.		
Expt.	Initial ratio $\text{NaHSO}_4/\text{Na}_2\text{SO}_4$ in millimoles	P_H initial	P_H final	Zinc found in the filtrate, mg.
1	8.3/66	2.18	1.83	0.0
2	12.4/66	2.08	1.78	Trace
3	20.7/66	1.86	1.66	0.20
4	22.8/66	1.78	1.62	Trace ^a
5	24.9/66	1.77	1.62	0.1-0.2

12	45.0/66	1.49	1.39	0.8-1.0
13	58.0/66	1.38	1.29	1.5
14	70.5/66	1.31	1.22	4.0
15	87.2/66	1.19	1.14	6.0

^a Filtered after standing for three hours. ^b Filtered after standing overnight.

From the above experiments it may be concluded that from these solutions precipitation will be complete to less than 0.25 mg. at a P_H of 1.6 or

at a hydrogen-ion concentration as high as 2.5×10^{-2} . Less than 1 mg. remains in solution at a *PH* of 1.54 or hydrogen-ion concentration of 2.9×10^{-2} . It would seem that the conditions of Expt. 4, where the ratio of $\text{NaHSO}_4/\text{Na}_2\text{SO}_4$ is about one-third and the initial *PH* 1.78, are best adapted for securing the desired completeness of precipitation of zinc and for holding other elements in solution. At the same initial *PH* the solubility of the zinc sulfide in these solutions is about the same or even a little less than in the formic acid-formate solutions of Fales and Ware, in spite of the fact that in our experiments 257 mg. of zinc is precipitated as compared to about 162 in theirs, with consequently more acid liberated due to the precipitation. If desired the buffer action could be made considerably more effective and the change in hydrogen-ion concentration during precipitation made much smaller by increasing the concentrations of sulfate and hydrosulfate in the solution. This effect is shown in the last three experiments of Table I, where with a higher concentration of hydrosulfate the change during precipitation is less than 0.1 of a *PH* unit. We have considered it desirable, in order to minimize difficulty in washing the precipitate and to avoid the use of excessive quantities of buffer material, to keep the buffer concentrations at the lowest values which would adequately control the acidity. It should be pointed out that due to the high concentration of electrolyte in these solutions, the evaluation of the activities of the various ions is subject to considerable uncertainty, while a simple calculation of the hydrogen-ion concentration from the formal salt/acid ratios may lead to results considerably divergent from the experimental values. Because of this a series of experiments was made to show the effect of dilution on the *PH* of such a solution. The results are given in Table II.

TABLE II
THE EFFECT OF DILUTION ON THE *PH* OF SULFATE-HYDROSULFATE SOLUTIONS

Experiment	1	2	3	4	5
NaHSO_4 [moles/liter]	0.1	0.05	0.025	0.01	0.0025
Na_2SO_4 [moles/liter]	0.5	0.25	0.125	0.05	0.0125
<i>PH</i>	1.78	1.48	2.17	2.43	2.82

The decrease in acidity in the more dilute solutions is due to the fact that the fraction of the hydrosulfate ionized into hydrogen and sulfate ions becomes large at these concentrations; the increase in the more concentrated solutions would be predicted because of the effect of the high salt concentrations on the activities of the various ions. It is thus seen that if, in order to control more closely the acidity, a higher concentration of the buffer is used, the initial ratio of hydrosulfate to sulfate should be adjusted accordingly, thus with the sodium sulfate concentration 0.25 formal, a $\text{NaHSO}_4/\text{Na}_2\text{SO}_4$ ratio of one-third is required to produce an initial *PH* of 1.78; with the sodium sulfate concentration 0.5 formal this ratio has to

be reduced to one-fifth. The effect of the use of ammonium sulfate was tested in two additional experiments which were duplicates of Expt. 4 except that ammonium sulfate and sulfuric acid were used to adjust the initial hydrosulfate-to-sulfate ratio to the value 22.8/66. No difference could be detected in either the rate or completeness of the precipitation or the nature of the precipitate. This indicates that neither the hydrogen-ion activity nor the salt effect had been greatly changed, and that where desirable ammonium sulfate can be substituted for the sodium salt.

Effect of Chloride Ion on the Precipitation of Zinc Sulfide.—In the following table is gathered a group of experiments in which the solution contained in addition to the buffer mixture 132 milli-equivalents of potassium chloride.

TABLE III

THE EFFECT OF CHLORIDE ION ON THE SOLUBILITY OF ZINC SULFIDE				
Potassium chloride added, 132 milli-equivalents. Zinc taken, 257 mg. Volume, 250 ml.				
Expt.	Initial ratio NaHSO ₄ /Na ₂ SO ₄ in millimoles	Initial <i>P_H</i>	Final <i>P_H</i>	Zinc found in the filtrate, mg.
16	20.7/66	1.73	1.51	1.5
17	27.0/66	1.62	1.46	2.0
18	37.3/66	1.43	1.37	2.0

The presence of a high concentration of chloride ion lengthens the induction period in the beginning of precipitation, apparently slows down the precipitation and, with the same *P_H*, increases the solubility of zinc sulfide by three or four times. This is shown by comparing the results in Table III with those obtained at corresponding *P_H* values in Table II. It should be noted also that the presence of the potassium chloride increases the acidity in solutions where the initial hydrosulfate and sulfate ratios and concentrations are the same; for example, compare Expt. 16, Table III, with Expt. 3, Table I.

The Separation of Zinc from Cobalt, Nickel, Iron, Manganese, Chromium and Aluminum.—The following table gives a group of experiments showing the efficiency of the separation of zinc from the common metals most likely to be found with it after an ammonium sulfide precipitation.

The cobalt brought down with the zinc precipitate in Expt. 19 was determined by the method of Engle and Gustavson,¹¹ after dissolving the precipitate with hydrochloric acid. In Expt. 20 the precipitate was dissolved in acid, the solution made just alkaline, and sodium peroxide added. The black cobaltic oxide was easily detectable. The nickel in the zinc sulfide precipitate was estimated by dissolving the precipitate, making the solution barely basic with ammonia, and adding dimethylglyoxime. The quantity of glyoxime precipitate was estimated by comparison with precipitates obtained with known quantities of nickel under the same condi-

24	Ni			0.3-0.4	
25	Mn	1.81	1.65	0.1	
26	Mn			0.1	
27	Fe	1.82	1.65	0.5-0.6	
28	Fe			0.5-0.6	
29	Al			<0.25	
30	Cr			0	

tions. Manganese was estimated by adding sodium bismuthate to the nitric acid solution obtained by dissolving the precipitate, then making comparisons of the color developed with that obtained on oxidizing known amounts of manganese. Iron was determined by comparison with standards to which potassium thiocyanate had been added. The precipitates from Expts. 29 and 30 were dissolved in hot 6 *N* hydrochloric acid and the solutions then made just basic to methyl red with ammonia. No chromium hydroxide and a bare trace of aluminum hydroxide formed. This precipitate was compared with standards.

From the results shown in Table IV it is seen that the separations are satisfactory in all cases except with cobalt. Even in a solution whose initial P_H was 1.35, too high in acid for complete precipitation of zinc, cobalt is still co-precipitated. In Expt. 21 where 100 mg. of zinc is precipitated from a solution containing 400 mg. of cobalt, the zinc sulfide precipitate came down quite white for several minutes, then the precipitate darkened rapidly and finally was almost black in color.

This effect appears to be similar to the induced precipitation of zinc sulfide by copper sulfide in more concentrated acid solutions which has been studied recently by Kolthoff and Pearson.¹² This effect they designate "post-precipitation" and attribute it to an induced precipitation of the zinc sulfide from a supersaturated solution, the induction being caused by adsorption of hydrogen sulfide on the copper sulfide. Under the conditions of certain of their experiments this adsorption became effective in promoting the precipitation of the zinc sulfide only after quantitative precipitation of the copper sulfide had taken place. That the effect obtained

¹² Kolthoff and Pearson, *J. Phys. Chem.*, **36**, 549 (1932).

here is a case of either promoted or of co-precipitation is shown by Expt. 22. This solution, which was identical with that in Expt. 21, but contained 500 mg. of cobalt alone, was saturated with hydrogen sulfide in the usual way, except that the gas was bubbled through for more than an hour; then the flask was closed and allowed to stand for three days. No cobalt sulfide precipitated. Fales and Ware report that cobalt cannot be separated from zinc by hydrogen sulfide precipitation from formic acid-formate solutions. It is of interest to mention that when a few milligrams of cobalt are precipitated with zinc sulfide, as in experiment No. 19, the resulting precipitate is colored green. This phenomenon was noted in a large number of experiments.

Method Recommended for the Precipitation of Zinc Sulfide, and the Separation of Zinc from Nickel, Iron, Manganese, Chromium and Aluminum.—As a result of the above experiments the following procedure is recommended. To a chloride-free solution of the zinc as sulfate in a 500-ml. flask add sodium (or ammonium) sulfate and hydrosulfate (or sulfuric acid) until the hydrosulfate to sulfate ratio is approximately 1:3 with the total concentration of sulfate and hydrosulfate about 0.35 formal.¹³ Dilute the solution to 250 ml., heat it to 60°, rapidly bubble hydrogen sulfide through it and continue heating until the solution reaches 90–95°. Continue the passage of hydrogen sulfide until the precipitate settles rapidly, cool the mixture, again saturate it with the gas, close the flask and allow it to stand until the supernatant liquid is clear. Filter the mixture through a quantitative paper filter and wash the precipitate with 0.01 *N* sulfuric acid saturated with hydrogen sulfide.

If a gravimetric determination is desired, the precipitate is dried and ignited at as low a temperature as possible, care being taken to avoid the formation of zinc oxide. The cold residue is moistened with concentrated sulfuric acid and the excess fumed off on an air-bath. If carbonaceous material remains it is burned off by carefully heating with a Bunsen flame. Again the residue is moistened with sulfuric acid, the excess fumed off on the air-bath, and the precipitate either heated to 500° and weighed as zinc sulfate, or heated to 900° and weighed as zinc oxide. It is recommended that the temperature of the ignition be controlled to $\pm 20^\circ$.

¹³ Solutions containing zinc sulfate and an unknown excess of sulfuric acid can be neutralized with standard sodium hydroxide, preferably using methyl red as indicator, then the proper amounts of sulfate and hydrosulfate added. With aluminum present methyl orange should be used as the indicator; before neutralizing the solution ferric salts should be reduced with sulfur dioxide and the excess expelled; in neutralizing highly colored solutions containing large amounts of cobalt or nickel the formation of the first permanent precipitate can be used satisfactorily. With large amounts of the elements, especially of aluminum, account should be taken of the approximate amount of sulfate associated with them. Volatile acids can be removed by gentle fuming with sulfuric acid.

Summary

The precipitation of zinc sulfide from sulfate-hydrosulfate solutions has been studied. The precipitation was found to be complete to less than 0.25 mg. out of 257 mg. at a hydrogen-ion concentration as high as 2.5×10^{-2} . Nickel, iron, manganese, chromium and aluminum may be separated quantitatively from zinc by this sulfide precipitation, but cobalt cannot be so separated. High chloride-ion concentration increases the solubility of the zinc sulfide. A procedure is outlined for the quantitative precipitation of zinc and its separation from the other metals. Methods of igniting the precipitate have been studied. The temperature should be closely controlled at 500° when igniting the zinc sulfate, and at 900° when igniting the sulfate to oxide.

THE DIRECT PREPARATION OF HYDROGEN PEROXIDE IN A HIGH CONCENTRATION

By JAMES H. WALTON AND GEORGE W. FILSON

RECEIVED MAY 6, 1932

PUBLISHED AUGUST 5, 1932

The fact that hydrazobenzene is readily autoxidized with the formation of hydrogen peroxide has been pointed out by Manchot and Herzog.¹ In an investigation carried out in this Laboratory it was found that in an alcoholic solution the reaction is practically quantitative according to the equation

As would be expected a small amount of the alcohol is oxidized by the hydrogen peroxide. The reaction takes place very readily in either ethanol or propanol. By dissolving hydrazobenzene in alcohol and bubbling oxygen through the solution it is possible to follow the speed of reaction by measuring colorimetrically the increasing color of the solution caused by the formation of the azobenzene. The reaction apparently takes place between the dissolved oxygen and the hydrazobenzene, so that in studying the speed of the reaction it is necessary to bubble the oxygen through the solution fast enough to keep the solution saturated. The reaction is bimolecular as evidenced by the following data taken from a series of experiments.

Temp., 30°; 1% solution of hydrazobenzene in 95% C₂H₅OH

<i>t</i> , min.	<i>a</i> - <i>x</i>	<i>x</i>	<i>k</i> × 10 ⁴
0	33.1		
16	20.6	12.5	11.4

¹ Manchot and Herzog, *Ann.*, **316**, 331 (1901).

t , min.	$a - x$	x	$k \times 10^4$
26	17.0	16.1	11.0
36	14.5	18.6	10.8
46	12.2	20.9	11.3
62	10.8	22.3	10.1
105	6.6	26.5	11.5
		Av.	11.0

In the experiment recorded the oxygen was released at the bottom of a Nessler tube containing 50 cc. of solution, through a delivery tube with an opening of about 1 mm. In another experiment with a delivery tube opening of 2 mm. bore the value of $k \times 10^4$ was 10.6, when the oxygen was passed through a group of five small jets of 0.5 mm. each, the constant was 9.7. Oxygen was bubbled through these delivery tubes without regard to the absolute rate, the object being to keep a rapid stream of bubbles flowing from each jet. The fact that the constants agree shows that the reaction is taking place in solution and not at the gas-liquid interface. The reaction when carried out in a tube covered with tin foil gave a constant of 10.2 showing that diffused light has no appreciable effect. In absolute ethyl alcohol the constant had a value of 3.4×10^{-4} while in isopropyl alcohol the speed of oxidation was somewhat slower, 4.2×10^{-5} .

Autoxidation in Benzene Solution.—In an effort to isolate an intermediate product of the peroxide type, the hydrazobenzene was oxidized in benzene solution. The concentration of the oxygen in the solution was increased by placing it in a bomb, lowering the temperature to 0° and increasing the oxygen pressure to about 370 pounds per square inch. No intermediate compound could be detected. However, drops of liquid separated from the benzene solution, which when analyzed were found to be hydrogen peroxide of a purity of about 94%. The total yield of hydrogen peroxide was determined and it was found that from a given weight of hydrazobenzene it was possible to obtain about 97% of the theoretical yield of hydrogen peroxide.

This quantitative yield of highly concentrated hydrogen peroxide from hydrazobenzene suggests the possibility of production of the peroxide on a large scale. Its attractive feature, of course, lies in the fact that the azobenzene formed in the reaction can be changed to hydrazobenzene and thus used continuously. The problem is the subject of further investigation.

ELECTRIC MOMENT AND MOLECULAR STRUCTURE. IX. THE OXYGEN AND SULFUR VALENCE ANGLES

BY C. P. SMYTH AND W. S. WALLS

RECEIVED MAY 7, 1932

PUBLISHED AUGUST 5, 1932

A previous paper¹ has described the determination of the carbon valence angle in benzyl derivatives as the angle between two component dipole moments, the resultant of which is the moment of the molecule as a whole. Since the dipoles are so far removed from one another by interposition of the benzene ring that they apparently do not affect one another's moments appreciably, a very satisfactory result was obtained. The present paper attempts to determine the oxygen and sulfur valence angles by application of the same method to ethers and sulfides, although the treatment is complicated by the considerable moments between the carbons and the oxygen or sulfur atoms. At the same time it appears desirable to consider the moments of certain newly determined heterocyclic compounds together with those of closely related compounds in the literature.

Preparation of Materials

Benzene and heptane were prepared as previously described.¹ The other materials, except as noted, were obtained from the Eastman Kodak Company. The densities and refractive indices determined for the liquids are given as criteria of purity.

***p*-Bromoanisole.**—Material (m. p. 12–13°) was dried with anhydrous calcium chloride and twice fractionally distilled under reduced pressure; b. p. 101.9–102.1° (18 mm.); n_D^{20} 1.56422; n_D^{25} 1.56212; d_4^{25} 1.4902; d_4^{50} 1.4597.

***p*-Bromophenetole.**—Material (m. p. 2–4°) was dried with anhydrous calcium chloride and twice fractionally distilled under reduced pressure; b. p. 109.2–109.5° (17 mm.); n_D^{20} 1.55168; n_D^{25} 1.54950; d_4^{25} 1.4071; d_4^{50} 1.3768.

***p*-Bromodiphenyl Ether.**—Material (b. p. 167–168° (15 mm.)) was dried with anhydrous sodium sulfate and fractionally distilled under reduced pressure; b. p. 171.6–171.7° (17 mm.); d_4^{25} 1.4155; d_4^{50} 1.3896.

4,4'-Dibromodiphenyl Ether.—Material (m. p. 57.5–58.5°) was twice fractionally crystallized from petroleum ether and dried in a vacuum desiccator; m. p. 58.8–58.9°.

4,4'-Dinitrodiphenyl Ether.—Material which had been recrystallized from alcohol, partially decolorized with norit, and finally crystallized from benzene, and had a m. p. 142–143°, was further purified by repeated treatments with "Darco" in benzene solution. After being twice fractionally crystallized from benzene and dried in an evacuated desiccator, it had only a very faint yellowish tinge, which could not be removed by further treatment with decolorizing materials; m. p. 144.4–144.7°.

4,4'-Dibromodiphenyl Sulfide.—Material, prepared by Mr. P. D. Hammond and kindly loaned for our measurements, had been purified by crystallization from glacial acetic acid and drying in a vacuum desiccator to remove acetic acid; m. p. 112.2–112.4°. This material was twice fractionally crystallized from a mixture of benzene and petroleum ether, washed with petroleum ether, and dried in a vacuum desiccator; m. p. 112.6–112.8°.

Divinyl Ether.—Material² loaned by Dr. W. L. Ruigh of the Laboratory for Pure Research of Merck and Company, Inc., was dried over sodium wire and fractionally distilled; b. p. $28.31 \pm 0.03^\circ$ (758.7 mm.); n_D^{20} 1.39892.

Furan.—Material obtained from the Miner Laboratories, Chicago, was purified by fractional distillation through a soda lime tower as described in "Organic Syntheses," Vol. VII, p. 40 (New York, John Wiley and Sons, Inc., 1927); b. p. 31.3° (757 mm.); n_D^{20} 1.42150; n_D^{25} 1.41852; d_4^{20} 0.9378; d_4^{25} 0.9313.

Tetrahydrofuran.—This was prepared under the direction of Dr. Wallace H. Carothers of E. I. du Pont de Nemours and Company by catalytic reduction of the above described furan in butyl alcohol solution. It was purified by fractional distillation through a 1.8-meter fractionating column, dried with anhydrous sodium sulfate, decanted and fractionally distilled; b. p. 64.0 – 64.1° (755 mm.); n_D^{20} 1.40550; n_D^{25} 1.40355; d_4^{20} 0.8966; d_4^{25} 0.8910; d_4^{50} 0.8631.

Experimental Results

The densities and dielectric constants of the solutions of the polar substances in the non-polar were measured with the apparatus and methods previously employed,^{1,3} a wave length of 1000 meters being used in the dielectric constant determinations. In Table I the first column gives the

^a Calculated from refractive indices and densities of solutions. ^b Measurements made at 20°.

Discussion of Results

It is interesting to note in Table II that the moments found for *p*-bromoanisole, *p*-bromophenetole and *p*-bromodiphenyl ether in benzene solution are $0.07\text{--}0.09 \times 10^{-18}$ lower than the values found in heptane solution, which is the reverse of the situation in the case of the ethylene halides treated in a previous paper.⁴ The differences are so small, however, that the conclusions to be drawn are not materially affected by using only the values obtained in benzene, which was a better solvent for the larger molecules and which was generally used in the measurements taken from the literature. The low values for 4,4'-dibromodiphenyl ether and the corresponding sulfide may be, at least, 0.2×10^{-18} too high because of neglect of the atomic polarization in the calculation. The P_2 - c_2 curve for tetrahydrofuran in benzene is very different from that in dioxane, but the value found for the moment in benzene is but slightly lower. Its use, rather than that of an average value, will not affect the conclusions to be drawn.

The values adopted for the moments and those taken from the literature⁵ for use in calculation or discussion are listed in Table III.

The method of calculating the oxygen valence angle θ is obvious from consideration of Fig. 1. The calculation is somewhat complicated by the presence of the dipoles in the directions of the C-O bonds and it is necessary to assume that these moments, as well as θ , are unaffected by the moments in the bonds of the para-substituted groups and *vice versa*. The validity of this assumption has been discussed in the previous paper dealing with the carbon valence angle, where it seems fully justified by the results. It may be a more inexact approximation in the case of the ethers and sulfides, where the C-O and C-S moments are immediately adjacent to the ring. Our ignorance of the absolute value of the small moment probably existing in the C-H bond causes no error in the calculations since it cancels out when a set of simultaneous equations for the moments involved in the diphenyl ethers is solved. This is apparent in the following calculation given as an example.

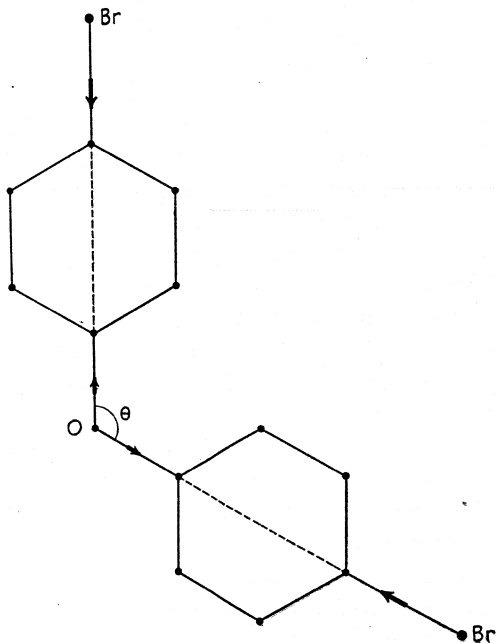

Fig. 1.—The 4,4'-dibromodiphenyl ether molecule.

⁶ Hunter and Partington, *J. Chem. Soc.*, 2062 (1931).

$$\text{C}_6\text{H}_5\text{Br} \quad m_{\text{C-H}} + m_{\text{C-Br}} = 1.50 \times 10^{-18} \quad (1)$$

$$(\text{C}_6\text{H}_5)_2\text{O} \quad 2(m_{\text{C-H}} + m_{\text{C-O}}) \cos \theta/2 = 1.05 \times 10^{-18} \quad (2)$$

$$(\text{p-BrC}_6\text{H}_4)_2\text{O} \quad 2(m_{\text{C-Br}} - m_{\text{C-O}}) \cos \theta/2 = 0.6 \times 10^{-18} \quad (3)$$

Adding (2) and (3) and substituting (1), we have

$$3.00 \cos \theta/2 = 1.65, \text{ whence } \theta = 113^\circ$$

In the cases of the monosubstituted ether and sulfide, the equation for the resolution of two unequal vectors has, of course, to be used. The angles calculated for oxygen and sulfur in the diphenyl ethers and sulfides by this method are given in Table IV.

TABLE IV
VALENCE ANGLES OF OXYGEN AND SULFUR

$(\text{p-BrC}_6\text{H}_4)_2\text{O}$	113°	$(\text{p-BrC}_6\text{H}_4)_2\text{S}$	146°
$\text{p-BrC}_6\text{H}_4\text{OC}_6\text{H}_5$	124°	$\text{p-ClC}_6\text{H}_4\text{SC}_6\text{H}_5$	147°
$(\text{p-O}_2\text{NC}_6\text{H}_4)_2\text{O}$	121°		

The angle calculated for $\text{p-BrC}_6\text{H}_4\text{OC}_6\text{H}_5$ is obtained by using the values of $(m_{\text{C-H}} + m_{\text{C-O}})$ and $(m_{\text{C-Br}} - m_{\text{C-O}})$ given by equations (2) and (3). The difference between the values of the angle for the monobromo and the dibromo ether is without significance. If the moment of the latter is taken as 0.4×10^{-18} , which may be more nearly correct than 0.6×10^{-18} , the angles calculated rise to 123 and 129° . The mean of these four rough values happens to be 122° , in excellent agreement with the value for $(\text{p-O}_2\text{NC}_6\text{H}_4)_2\text{O}$, which, being calculated from a large moment, is much more accurate than the others. If the presence of the nitro group increased the C-O moment by 0.15×10^{-18} , the value of θ would be lowered by only 3° , while, if the nitro group moment were increased at the same time, the lowering of the value calculated for θ would be less.

When $(\text{p-BrC}_6\text{H}_4)_2\text{S}$ is treated like the ether, a value of 98° is obtained for the sulfur valence angle, but, in the monochloro compound, the impossible value of -2 is obtained for $\cos \theta$. It, therefore, becomes necessary to suppose that $m_{\text{C-S}}$ is greater than $m_{\text{C-Br}}$, that is $(m_{\text{C-Br}} - m_{\text{C-S}})$ is negative. The large angles given in Table IV are then obtained, the negligible difference between the moment of $\text{C}_6\text{H}_5\text{Cl}$, and that of $\text{C}_6\text{H}_5\text{Br}$ being disregarded. If the moment of $(\text{p-BrC}_6\text{H}_4)_2\text{S}$ is taken as 0.5×10^{-18} instead of 0.6×10^{-18} , the angles calculated are 142 and 140° . The value calculated by Bergmann, Engel and Sándor⁷ from their determination for $\text{p-ClC}_6\text{H}_4\text{SC}_6\text{H}_5$, which is the one here used, is 142° . When the equations used in calculating are solved for $m_{\text{C-H}} + m_{\text{C-S}}$, the value 2.5×10^{-18} is obtained, which is surprisingly high in comparison with the approximate figure 1.1×10^{-18} for $m_{\text{C-H}} + m_{\text{C-O}}$. This high value is not, however, irreconcilable with the moments of other sulfur compounds. The moment of the hydrogen sulfide molecule is little more than half that of the water

⁷ Bergmann, Engel and Sándor, *Z. physik. Chem.*, [B] 10, 397 (1930).

molecule, but replacement of hydrogen by an alkyl group in the sulfur compound raises the moment, while the moment is lowered by a similar change in the case of the oxygen compound. This is evident in the results of Hunter and Partington,⁶ in Table III, which are in excellent agreement with values calculated by one of the writers.⁸ If the value of the moment of *p*-ClC₆H₄SC₆H₅ obtained by Bergmann, Engel and Sándor is correct and if, as has been assumed, the moment of the para-substituted group is approximately independent of the other moments in the molecule, the large value of about 146° must be accepted for the sulfur valence angle in these diphenyl sulfides.

As methyl and ethyl ethers, anisole, phenetole and diphenyl ether have moments of the same magnitude, it is natural to suppose that the valence angles and the R-O moments in all these compounds are much the same whether R is an alkyl or a phenyl group. However, the moments of the para-halogenated anisoles and phenetoles are much higher than that of *p*-bromodiphenyl ether and it is impossible to calculate their moments on the basis of these assumptions. Actually, the alkyl halides have moments from $0.3\text{--}0.5 \times 10^{-18}$ higher than the phenyl halides. If the R-O moment when R is an alkyl group is taken as 1.8×10^{-18} as compared to a value of 1.1×10^{-18} obtained for R-O from the phenyl ethers, oxygen valence angles lying between 130 and 140° are obtained for the anisoles, methyl ether and the hydroquinone ethers, the equation for rotating dipoles being used in these latter calculations, and still larger angles are obtained for the phenetoles and ethyl ether. A larger angle in the phenetoles gives a lower moment to the unsubstituted compound and a higher one to the substituted as observed. If the H-O moment in the phenols is taken as 2.4×10^{-18} , instead of 1.6×10^{-18} as used by Eucken and Meyer,⁹ the oxygen valence angles in the unsubstituted and in the *p*-chloro- and *p*-bromophenols are calculated as having values from 127 to 141°, the angle in *p*-nitrophenol being 152°. This H-O value gives a valence angle of 134° for water and, combined with the R-O value, 1.8×10^{-18} , an oxygen angle of 136° in the alcohols, the mutual inductive effects being neglected in both cases.

The difference between the phenyl R-O moment and the value assigned to that of the alkyl R-O is greater than would be expected. The experimental data on the anisoles and phenetoles are satisfactory, as evidenced, for example, by the identity of the value for *p*-bromoanisole obtained in the present investigation with that for *p*-chloroanisole obtained by Bergmann, Engel and Sándor.⁷ Impurities, which might be present in small quantities only, should tend to lower the apparent values of the moments and thus make the difference between these substances and the diphenyl

⁸ Smyth, THIS JOURNAL, **46**, 2151 (1924).

⁹ Eucken and Meyer, *Physik. Z.*, **30**, 397 (1929).

ethers appear less. The necessary neglect of the atomic polarization tends to make all the values a little high, but should not affect their comparison with one another or seriously alter the values of the angles calculated. It is evident that the moments of the substituted phenols are practically useless as a means of calculating the oxygen valence angle, possibly because of a shift to a quinoid structure. An example of this is probably found in *p*-nitroaniline, which has a moment, 7.1×10^{-18} ,¹⁰ larger than the sum of the nitro and the amino moments acting in the same direction. The transmission of a large inductive effect through the ring could account for these discrepancies in the molecules which have two unlike groups attached to the oxygen, perhaps causing the apparent difference between the phenyl and the alkyl R-O moments. The transmission of such large effects appears consistent with chemical behavior but difficult to reconcile with the mutual independence of simple dipoles in meta- and para-disubstituted benzenes as summarized in the treatment of the carbon valence angle.¹ If such transmission were to occur from the two like substituents in the *p,p'*-disubstituted diphenyl ether, the two transmitted effects would so cancel each other as greatly to reduce the error caused in the calculated valence angle. In view of the uncertainty as to the interpretation of the data for the anisoles and phenetoles, it may be concluded only that there is an indication of the possibility of an oxygen valence angle larger than that found in the diphenyl ethers. It is obvious that the values used for the H-O and alkyl R-O moments cannot be regarded as determinations of these quantities.

If, in diphenyl ether, the C-C nuclear separation in the ring is taken as 1.42 Å,¹¹ the C-O distance as 1.43 Å. and the C-H distance as 1.06 Å,¹² and the hydrogen nuclei are assumed to be surrounded by repulsive spheres of radius 1.20 Å., calculation shows that, if the two benzene rings lay in the same plane, the oxygen valence angle would be widened to 169°. Indeed, with the rings in the same plane and an oxygen angle of 114°, the protons in the ortho position would be coincident. As the most reliable determination of this angle in the diphenyl ethers gives approximately 121°, it appears probable that the two rings oscillate about positions of minimum potential energy in which their planes are perpendicular to that of the oxygen valence angle.

In diphenylene oxide, if the external valences of the benzene rings made 120° angles with the adjacent sides of the hexagon in the normal fashion, the five-membered ring would be so distended that the C-O-C distance would be 2.99 Å. even if the oxygen valence angle were widened to 180°.

¹⁰ Højendahl, *Physik. Z.*, **30**, 391 (1929).

¹¹ Lonsdale, *Proc. Roy. Soc. (London)*, **123**, 494 (1929); Wierl, *Ann. Physik*, [5] **8**, 521 (1931).

¹² Pauling, *Proc. Nat. Acad. Sci.*, **18**, 293 (1932).

As this is more than double the C-O distance of 1.43 Å., it is evident that the carbon valence angles in this ring must be reduced below 120°, while the oxygen angle must be widened probably to more than 130°. As the force required to stretch a bond is much greater than that required to bend it, tension in the ring should be reduced more by alteration of the angles than by change of the internuclear distances, although both presumably occur. An exact quantitative treatment of this and of similar moments is impossible because of our ignorance of the size of effects, such as the adjustment of angles to lessen the ring tension, the stretching of bonds, the effect of such stretching upon bond moments, the size of the C-H dipoles and the angles which they make with the other parts of the molecule, but it is evident that the moment is markedly lower than those of ethyl, vinyl and phenyl ethers, as would be expected from the widening of the oxygen angle. If the furan ring were regarded as containing two double bonds, the carbon valence angles in the ring should tend to be 125°,¹³ which would mean an even greater widening of the oxygen valence angle than in diphenylene oxide, perhaps to more than 140°, and a correspondingly lower moment, as observed. Since, however, the molar refraction MR_D , found for furan is 0.7 lower than the value calculated for it on the assumption of the occurrence of two double bonds in the ring, this simple explanation of the low moment is highly speculative.

The angle in a regular pentagon is 108°, but, in tetrahydrofuran, the fact that the C-O distance is about 1.43 Å. and the C-C about 1.54 Å. necessitates an alteration of the angles. It is impossible to say precisely what the oxygen angle is, but geometrical considerations indicate that it is probably not far from 100°, which causes the moment to be much higher than in the unsubstituted oxides previously discussed. As tetrahydrofuran is radically different in properties from furan, it may be that the disappearance of unsaturation also contributes to the increase in moment. This would accord with the assignment of a higher moment to the alkyl R-O. If the interatomic distances remain unchanged in the triangular ethylene oxide molecule, the oxygen valence angle is 65°, and the carbon angles in the ring 57.5°, which necessitates a higher moment than that of tetrahydrofuran, as observed, although the difference is less than would be expected. The very small moment, indistinguishable from zero, of dioxane indicates that the structure conforms to a symmetrically distorted hexagonal model with the four carbons in a plane and one oxygen above and the other below. The very small moment of thiophene shows a structure analogous to that of furan with a large sulfur valence angle of possibly 140° or more.

The heterocyclic compounds which have been discussed show the wide variation which the oxygen valence angle may be forced to undergo, from

¹³ This angle would result if the double bond were formed by the sharing of an edge between two regular tetrahedra. Cf. Slater, *Phys. Rev.*, **37**, 481 (1931).

65° to, perhaps, 140°. Because of the fact that the effects upon one another of the different moments in the molecule may not be wholly negligible, as well as because of the experimental error, the oxygen valence angle in the diphenyl ethers cannot positively be taken as 121°. However, the previously advanced reasons for deciding these effects to be small are sufficient to warrant the conclusion that the angle is correct to within $\pm 5^\circ$. It is evident that the 90° angle calculated by the wave mechanics¹⁴ may be much altered by the groups with which the oxygen combines.

Summary

The electric moments of para-substituted diphenyl ethers and a sulfide, an anisole, a phenetole and heterocyclic compounds have been determined and used, together with other moments taken from the literature, to study the angles between the valences in the oxygen and sulfur atoms.

The oxygen valence angle in the diphenyl ethers is found to be $121 \pm 5^\circ$. The results for the anisoles and phenetoles, which are more complex, do not give dependable values for the oxygen angle, although they may be explained in terms of an oxygen angle not far from 135°. Limited data give for the sulfur valence angle in the diphenyl sulfides a value of about 146°, which may be too high. The oxygen valence angles in various heterocyclic compounds calculated from the interatomic distances vary from 65 to about 140° and the moments are in excellent qualitative agreement with predictions based on the size of the angles. The behavior of thiophene is strictly analogous to that of the corresponding oxygen compound.

THE ACTION OF HYDRIODIC ACID ON STANNIC OXIDE

BY EARLE R. CALEY

RECEIVED MAY 5, 1932

PUBLISHED AUGUST 5, 1932

The recent note of Laubengayer and Brandt¹ on a method for the preparation of germanium tetraiodide by the action of hydriodic acid on germanium dioxide leads me to mention an analogous reaction that I first observed some months ago and to which I can find no reference in the chemical literature.

It is a well-known fact that stannic oxide, especially ignited stannic oxide, is very resistant toward the usual chemical reagents. It was found, however, that concentrated hydriodic acid acts readily on stannic oxide, converting the latter into stannic iodide. With constant boiling hydriodic acid the reaction commences at about 90–95° and takes place quite

¹ Laubengayer and Brandt, *THIS JOURNAL*, **54**, 621 (1932).

rapidly at the boiling point of the acid. The conversion is never quite complete with fixed amounts of the reactants in a closed system but successive additions of hydriodic acid to a heated reaction mixture will effect the complete transposition of the stannic oxide. With slightly diluted acid the reaction is slower and less complete, while dilute hydriodic acid has no effect. Stannic oxide prepared by different methods and ignited at various elevated temperatures gives the same reaction. Even the natural oxide, when powdered, reacts readily with concentrated hydriodic acid in the manner described.

The following experiments were performed to establish the course of the reaction.

A. On heating a weighed amount of stannic oxide with hydriodic acid, the increase in weight, after allowing for the amount of oxide not acted upon and after removal of the excess acid, was found to correspond closely to the calculated increment for the formation of stannic iodide alone. In a typical experiment 0.1553 g. of pure stannic oxide, prepared by igniting the metastannic acid derived from a specimen of Kahlbaum's pure tin, was placed in a weighed glass dish together with 3.0 cc. of pure constant boiling hydriodic acid. After heating the covered vessel for fifteen minutes on a steam-bath the dish was placed in a desiccator charged with calcium chloride, potassium hydroxide and metallic copper to remove water, excess acid and iodine formed by the oxidation of the hydriodic acid. Simple evaporation of the excess hydriodic acid by heating was found to be an impossible procedure for exact work, due to the volatility of the stannic iodide under these conditions. After reaching constant weight, the contents of the dish were found to weigh 0.5672 g. The tin iodide in the mixture was dissolved out with pure benzene, leaving a residue of unchanged stannic oxide weighing 0.0249 g. From these data it follows that 0.1304 g. of oxide was converted into 0.5423 g. of iodide. This agrees well with the calculated value of 5420 g. based upon the conversion of the stated amount of oxide into stannic iodide alone.

B. Analysis of the salt obtained by evaporation of the benzene extracts from experiments like the one just described indicated that stannic iodide was the sole compound present.

Anal. Sample taken, 0.4857 g.: SnO_2 found, 0.1175 g.; AgI found, 0.7283 g.; Sn, 19.06%; I, 81.06%; total, 100.12%. Another specimen was analyzed for tin by an alternative method: sample taken, 0.2594 g.; SnO_2 found, 0.0626 g.; Sn, 19.01%. Calculated for SnI_4 : Sn, 18.95%; I, 81.05%.

C. On heating the two reacting substances under an atmosphere of carbon dioxide no iodine was found to be liberated from the reaction, thus indicating absence of valence change.

D. The salt obtained from the reaction hydrolyzed slowly on the addition of water in accordance with the known behavior of stannic iodide.

On the basis of these experiments it follows that the reaction may be represented by the simple equation

This reaction is therefore quite analogous to the one between germanium dioxide and hydriodic acid and it differs from the general one between this acid and most higher metallic oxides.

In contrast to the chemical action of hydrobromic acid on germanium dioxide as recorded by Laubengayer and Brandt,¹ stannic oxide is apparently not affected by hot concentrated hydrobromic acid. Several experiments in which different specimens of stannic oxide were heated with many times their weight of constant boiling hydrobromic acid yielded no evidence of any action between the two substances. In a typical quantitative experiment, for example, 0.2170 g. of pure ignited stannic oxide treated with 10 cc. of hydrobromic acid at the steam-bath temperature for an hour left a residue of stannic oxide weighing 0.2169 g. after evaporation of the acid. There is, therefore, an interesting and distinct difference in the behavior of these two related oxides toward hydrobromic and hydriodic acids.

The formation of red stannic iodide in the manner described is a rather distinctive reaction for stannic oxide and can serve to differentiate readily this latter substance from other highly insoluble compounds encountered in qualitative analysis. It also suggests itself as a convenient means for identifying the natural oxide, cassiterite. If pure constant boiling hydriodic acid is employed in making the test, however, liberation of iodine is often so excessive that the reaction is obscured unless it is performed under a carbon dioxide atmosphere. It is much preferable for this purpose to use the concentrated acid that has been stabilized by the addition of 1-2% of hypophosphorous acid. A reagent of this composition behaves like the pure acid toward stannic oxide, can be kept without decomposition, and permits the performance of the test in air since liberation of iodine is slight even at the boiling point. In making the test it is sufficient to treat the powdered sample with a few cc. of the above reagent and boil the mixture gently in a test-tube for two or three minutes. In the presence of stannic oxide the orange-red stannic iodide is formed in the reaction mixture and on the cooler parts of the vessel it appears as a yellow to orange sublimate. With proper manipulation amounts of oxide as small as one milligram can be readily identified.

Summary

1. Concentrated hydriodic acid readily reacts with stannic oxide forming stannic iodide and water.
2. Concentrated hydrobromic acid does not react with stannic oxide under similar conditions.

3. The reaction described can be used as a qualitative test for natural or artificial stannic oxide.

AN EQUATION FOR THE REPRESENTATION OF HIGH-TEMPERATURE HEAT CONTENT DATA¹

BY CHAS. G. MAIER² AND K. K. KELLEY³

RECEIVED MAY 9, 1932

PUBLISHED AUGUST 5, 1932

High temperature heat content data have commonly been represented by the empirical equation

$$Q_{273.1}^T = \left[aT + \frac{b}{2} T^2 + \frac{c}{3} T^3 + \dots \right]_{273.1}^T \quad (1)$$

because the manipulation of such power series is easy and rapid. However, it is well known that this form of equation is not particularly satisfactory for the purpose. A reasonable number of terms often cannot be made to fit the data with sufficient accuracy; moreover, the resulting derived equation for specific heat

$$C_p = a + bT + cT^2 + \dots \quad (2)$$

may have a maximum in the temperature range under consideration due to the signs and magnitudes of the coefficients, but such a maximum does not correspond to known physical facts. These difficulties are most apparent where the specific heats are still far below the Dulong and Petit equipartition value of 6 calories per gram atom at 0°. Obviously, a better form of equation is desirable, but the choice is limited by several conditions: namely, (1) the equation selected should be usable in conjunction with conventionally accepted methods in thermodynamic calculations, (2) differentiation and integration under the conditions imposed by thermodynamic calculations should be analytic and reasonably easy to perform, and (3) derived values should be consistent with the available facts.

The Pacific Experiment Station of the United States Bureau of Mines is interested in the correlation of high temperature thermal data on metallurgically important elements and compounds, and has investigated several forms of equations for the representation of these data. It is apparent that at high temperatures specific heats of normally behaving substances

¹ Published by permission of the Director, U. S. Bureau of Mines. (Not subject to copyright.)

² Metallurgist, U. S. Bureau of Mines, Pacific Experiment Station, Berkeley, Calif.

³ Associate Physical Chemist, U. S. Bureau of Mines, Pacific Experiment Station, Berkeley, Calif.

in the solid or liquid state increase nearly linearly with the temperature, and that a subtractive term is needed which will be effective at temperatures lower than that where the equipartition value of specific heat is reached. Consequently, the following equations are proposed

$$C_p = a + bT - cT^{-2} \quad (3)$$

$$Q_{273.1}^T = \left[aT + \frac{b}{2} T^2 + cT^{-1} \right]_{273.1}^T \quad (4)$$

The conditions mentioned above are satisfied by equation (4), and trial on the data for several substances has shown that it gives a satisfactory representation, as may be seen from the following examples.

The data on zinc oxide recently were reviewed by Maier,⁴ who has represented the available figures by the expression

$$Q_0^t = 9.35t + 4.34 \times 10^{-3}t^2 - 1.574 \times 10^{-6}t^3$$

This equation is equivalent to

$$Q_{273.1}^T = [6.63T + 5.63 \times 10^{-3}T^2 - 1.574 \times 10^{-6}T^3]_{273.1}^T \quad (5)$$

based on the specific heat value 9.35 cal. per degree per gram formula weight at 0°, and the total heats obtained by White and Day⁵ for 700 and 1300°. If equation (5) is differentiated, the resulting C_p equation has a maximum at 920°, which is without physical significance. Using the same three data for determining the constants in equation (4), there is obtained

$$Q_{273.1}^T = 11.40T + 0.726 \times 10^{-3}T^2 + 1.824 \times 10^5T^{-1} - 3835 \quad (6)$$

The comparison of equations (5) and (6) with the actual experimental data on zinc oxide is shown in Table I.

TABLE I
HEAT CONTENT OF ZINC OXIDE ABOVE 0°

Temp., °C.	Observed heat content	Observer	Equa- tion (5)	Diff., %	Equa- tion (6)	Diff., %
98	984	Regnault	957	-2.7	988	+0.4
99	995	Magnus	967	-2.8	998	+ .3
259	2886	Magnus	2686	-6.9	2780	-3.7
550	6033	Magnus	6193	+2.7	6262	+3.8
700	8132	White and Day	8132	0.0	8132	0.0
900	10677	White and Day	10783	+1.0	10692	+ .1
1100	13306	White and Day	13443	+1.0	13320	+ .1
1300	16009	White and Day	16009	0.0	16009	.0

It is seen that White and Day's data are represented with great exactness and furthermore that the agreement with the less accurate lower temperature data is very much better with equation (6) than with equation (5).

⁴ Maier, U. S. Bureau of Mines Bulletin 324, "Zinc Smelting from a Chemical and Thermodynamic Viewpoint," pp. 18-20.

⁵ See Maier and Ralston, THIS JOURNAL, 48, 364 (1926).

The heat content of calcium silicate in the form of pseudowollastonite has been measured by White⁶ up to 1400°, and Parks and Kelley⁷ have measured specific heats at low temperatures on the same sample. A smooth curve through the results of the latter investigators gives $C_p, 273.1 = 20.06$ cal. per degree per gram formula weight, a value far removed from the equipartition figure of about 30. Using this datum and White's total heat figures at 700 and 1400°, the following expressions are obtained and a comparison is made in Table II.

$$Q_{273.1}^T = 12.82T + 14.90 \times 10^{-3}T^2 - 4.020 \times 10^{-6}T^3 - 4530 \quad (7)$$

$$Q_{273.1}^T = 25.48T + 2.066 \times 10^{-3}T^2 + 4.881 \times 10^5T^{-1} - 8900 \quad (8)$$

TABLE II
HEAT CONTENT OF CALCIUM SILICATE ABOVE 0°

Temp., °C.	White's data	Equation (7)	Diff., %	Equation (8)	Diff., %
100	2140	2120	-0.9	2700	+2.8
300	7125	6950	-2.5	7230	+1.5
500	12600	12430	-1.3	1.660	+0.5
700	18350	18350	0.0	18350	.0
900	24290	24530	+1.0	24250	-.2
1100	30390	30760	+1.2	30340	-.2
1300	36630	36870	+0.7	36610	-.1
1400	39800	39800	.0	39800	.0

Here, again, equation (8) is much more satisfactory than equation (7). At only one point, 100°, does equation (7) fit better, but this particular experimental value may be low, as the curve given by Parks and Kelley indicates.

The proposed equations are by no means perfect, but appear to be definitely better than the older forms; they require no additional data and are as easily handled as the ordinary power series expressions, in conjunction with which they readily may be used, if desired. Also, all the data investigated so far (which are for metals, oxides and silicates) are adequately represented by the three constant equations, there being no necessity for adding more terms, as is often the case when the power series expressions are used. It is preferable to obtain the constants in the manner indicated by solving simultaneously one specific heat equation, into which has been substituted the true specific heat at 273.1°K., and two total heat equations. This makes the resulting equations consistent with both the high temperature and low temperature thermal data. Where no true specific heat measurements exist, three total heat equations must be solved for the constants. No difficulty is encountered in writing heat of reaction and free energy equations, which are of the form

⁶ White, *Am. J. Sci.*, [4] **28**, 334 (1909); **47**, 1 (1919).

⁷ Parks and Kelley, *J. Phys. Chem.*, **30**, 1175 (1926).

$$\Delta H_T = \Delta H_0 + \Delta aT + \frac{\Delta b}{2} T^2 + \Delta cT^{-1} \quad (9)$$

$$\Delta F_T^\circ = \Delta H_0 - \Delta aT \ln T - \frac{\Delta b}{2} T^2 + \frac{\Delta c}{2} T^{-1} + IT \quad (10)$$

Summary

The equation $Q_{273.1}^T = \left[aT + \frac{b}{2} T^2 + cT^{-1} \right]_{273.1}^T$ is suggested for the representation of high temperature thermal data and is shown to be superior to the ordinary power series expression. The suggested equation is readily usable in all thermodynamic calculations, involves no additional labor and may be employed in conjunction with power series expressions, if desired.

APPARATUS FOR QUANTUM YIELDS OF GAS REACTIONS BY ACTINOMETRY

BY GEORGE S. FORBES, GEORGE B. KISTIAKOWSKY AND LAWRENCE J. HEIDT

RECEIVED MAY 12, 1932

PUBLISHED AUGUST 5, 1932

By proper use of actinometry it is possible to avoid most of the difficulties of radiometric procedures, also the disadvantage that radiometric errors can be estimated only by the original investigator and only before his apparatus is dismantled. When quantum yields are referred to a reproducible standard under identical conditions, systematic errors tend to cancel out. If, later, the given actinometer is restandardized, it is easy to recalculate all quantum yields previously referred to it.

In this Laboratory the quantum yields of uranyl oxalate have been determined within 5% over the range 435 to 254 $m\mu$,¹ also 278 to 208 $m\mu$,² thus providing the basis for an advance in actinometric procedure. We have constructed an apparatus (Figs. 1, 2) for quantitative study of photochemical gas reactions attended by pressure changes. It could easily be modified for studies of gas reactions without pressure change, or of liquid systems.

Light from a vertical mercury vapor lamp O (Fig. 1) was resolved by the conventional train between the quartz condenser, Q_c , and the exit slit, E, cut to fit the image of the spectral line furnishing the monochromatic radiation. A shutter was placed between O and Q_c . A small elliptical quartz lens of short focus, Q_e , lessened the divergence of the issuing beam.

Two quartz cells, each the frustum of a rectangular pyramid, had identical dimensions and a volume approximately 40 cc. All seams were fused. The gas cell, C_g , shown in detail in Fig. 2, had a capillary inlet, I. The acti-

¹ Leighton and Forbes, *THIS JOURNAL*, **52**, 3139 (1930).

² Brackett and Forbes, data to be published.

nometer cell, C_a , had instead a tubulure 4 mm. in internal diameter through which passed a small stirrer propelled by a windmill. Either cell enveloped the light beam diverging from E, just avoiding incidence of light upon the side walls. Each cell was encased in a copper jacket, J, having two rectangular openings, opposite the front and back windows. Copper ribbons

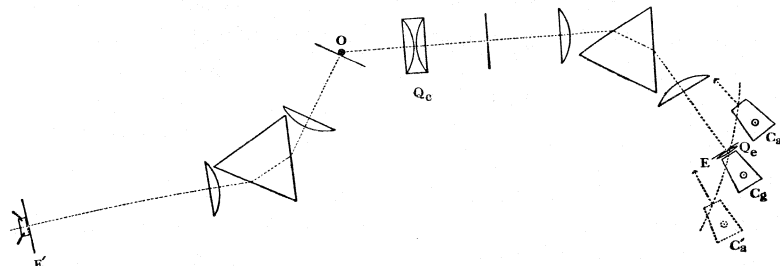

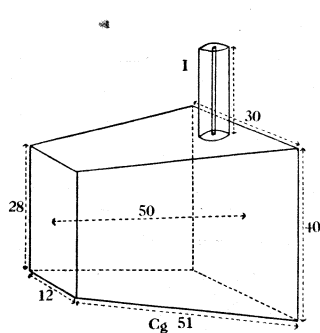

Fig. 1.

10 mm. wide soldered around the edges of these openings and cemented around the ends of the cells made the jackets water-tight. Thermal insulation was provided by cork sheets 6 mm. thick (1 mm. over the front wall). A cork cover insulated the rear window. Water from thermostats was circulated by pumps at a uniform rate through the jackets. The temperature of the issuing water remained constant within $\pm 0.05^\circ$.

Dimensions in mm.

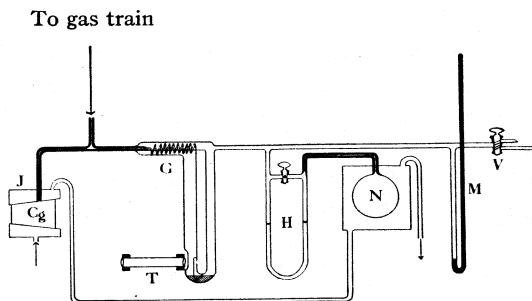

Fig. 2.

The apparatus to the right of O, Fig. 1, permits direct comparison of reaction rate in C_g with that in C_a by exposing the cells alternately behind E for measured times. Frequent shifting would average out lamp fluctuations, but this always is inconvenient, and would be unsuitable if the gas reaction involved induction periods or after effects. Therefore, we added a second monochromator in fixed position to the left of O. Its exit slit E' receives the image of the *same* spectral line as is incident upon E. By means of the thermopile behind E' and a high-sensitivity galvanometer,

scale deflections *proportional* to the energy flux emerging from either E' or E can be measured frequently during an experiment. Such readings make it possible to separate short-time variations in photochemical reaction rate from simultaneous fluctuations in the lamp.

As C_g must be rigidly mounted, it cannot be removed to allow substitution of C_a . Therefore the train from Q_c to E was solidly mounted upon a horizontal steel plate 3 mm. thick (not shown) which slid freely upon the upper surfaces of three heavy steel bars held parallel to each other. By means of a rigid steel arm suitably bent the plate was pivoted directly under O. To shift radiation from C_g (Fig. 1) to C_a , E was first detached from the plate (all cell windows covered) and the plate swung through the required angle. Next E was attached again to the plate in front of C_a , and the beam accurately centered by means of a screw mechanism operated through a milled head. Exposure of C_a in two positions C_a and C'_a as shown (Fig. 1) made it possible to average out any error due to uneven spatial distribution in the radiation of the lamp.

Pressure changes in C_g were measured in the customary fashion in terms of an artificial atmosphere, using as a null instrument a Bodenstein quartz spiral gage, G, Fig. 2. An offset near the free end of the pointer dipped in triacetin and damped out vibrations. Observing the end of the pointer through the telescope, T, pressure differences of 0.05 mm. of mercury were readily recognized by the excursions of the pointer from the fixed zero point. The gage was connected to the reaction cell by a Pyrex capillary and two graded seals; the combined volume of these was less than five per cent. that of the cell. The Pyrex jacket surrounding the gage communicated with a compensation cell, N, of appropriate volume, thermostated at the same temperature as C_g . All parts of the compensating system not thermostated were wrapped with heavy felt; otherwise drafts produced erratic changes in the apparent pressure within C_g . Differences in pressure between C_g and N could be read from the triacetin manometer H, and total pressures (by cathetometer) from the mercury manometer M.

If the reaction is free from complications, the second monochromator is dispensed with, and C_g and C_a are exposed alternately behind E for measured times Δt_g and Δt_a . Repeating, C_a is exposed on the other side of C_g . While C_a is being exposed, the dark reaction, if any, is studied in C_g . Assume the ratio of total quanta received by C_g and C_a , respectively, equal to $\Sigma \Delta t_g / \Sigma \Delta t_a$, after suitable corrections for difference in the reflections quartz-gas and quartz-water, also for any transmissions exceeding one per cent. Then the quantum yield of the gas reaction $\phi_g = \phi_a \Delta m_g - \Sigma \Delta t_a / \Delta m_a \Sigma \Delta t_g$ where Δm_g and Δm_a equal the moles transformed in C_g and C_a as measured by manometry and titration, respectively.

If the second monochromator is used, galvanometer deflections are frequently recorded during irradiations of C_g and C_a and plotted against the

corresponding times as ordinates. The cell C_a is exposed (using both positions) until the quantity of oxalic acid decomposed is measurable with the degree of precision desired. The area under the curve is divided into strips by ordinates at those times which mark the various stages of the experiments. The area of any strip is proportional to total quanta emerging from either exit slit during the corresponding time interval. Corrections for reflection and transmission are made as stated above. Let A_g be the area of the strip corresponding to a given exposure of C_g , and $(A_a + A'_a)$ the sum of the areas for the two exposures of C_a . Also let $\Sigma(h\nu)_g$ and $\Sigma(h\nu)_a$ be corrected total quanta absorbed, and Δm_g , Δm_a the moles transformed during the same time intervals. Then $\phi_g = \phi_a \Delta m_g \Sigma(h\nu)_a / \Delta m_a \Sigma(h\nu)_g = \phi_a \Delta m_g (A_a + A'_a) / \Delta m_a A_g$.

If the apparatus is carefully handled, the ratio $(A_a + A'_a) / \Delta m_a$ remains constant and reproducible within experimental error, and need not be rechecked for each refilling of the gas cell.

Summary

An apparatus and a method are described whereby the quantum yield of a photochemical gas reaction over any time interval during its progress may be stated in terms of the quantum yield of uranyl oxalate in monochromatic light of the same wave length with a probable error of five per cent.

CAMBRIDGE, MASSACHUSETTS

A NEW METHOD FOR THE DETERMINATION OF PROPIONIC ACID

By JAMES B. MCNAIR

RECEIVED MAY 12, 1932

PUBLISHED AUGUST 5, 1932

There is a need for a suitable method for the quantitative estimation of propionic acid in the presence of formic and acetic acids. This becomes of special importance in connection with the analysis of acids produced by fungi. The fact that oxalic acid is produced by the following method from propionic acid but is not formed from formic and acetic acids under the same circumstances serves as a basis for a new method for the determination of propionic acid.

Method.—To every 5.94 cc. of 0.1 *N* propionic acid, 1.5 g. of anhydrous sodium carbonate, 17.5 cc. of 3.12% potassium permanganate, and 27 cc. of distilled water are added in a 250-cc. Pyrex Erlenmeyer flask. This flask is capped by a small glass beaker and the entire Erlenmeyer covered by a large glass beaker and placed on a steam-bath for four hours. After that time the Erlenmeyer is removed from the steam-bath and 5 cc. of 95% alcohol added to eliminate the excess potassium permanganate. The manganese dioxide is separated by filtering the mixture through an alundum crucible under suction. The alundum crucible is placed in a

funnel, the stem of which passes through the neck of a bell jar into a beaker. The crucible is washed five times with distilled water before and after filtering the manganese dioxide. The filtrate is now acidified with glacial acetic acid and 3 g. of calcium acetate added and let steam overnight. The precipitate (calcium oxalate) is collected on an alundum crucible by filtration and washed with four fillings of distilled water. The crucible and contents are now placed in a 250-cc. beaker. Ten cc. of concentrated sulfuric acid is added just before the final titration with 0.04 *N* potassium permanganate. During the titration the acid liquid is kept at a temperature of 65 to 70° and the titration with potassium permanganate continued until the rose tint remains permanent for two minutes.

Two check experiments required for each 5.94 cc. of 0.1 *N* propionic acid 18.60 and 18.60 cc., an equivalent of 7.44 of 0.1 *N* potassium permanganate.

It was found that with the above amounts of material the formation of oxalic acid was not complete with less than three hours of heating on the steam-bath. When experiments were first begun with this method the excess potassium permanganate was oxidized with hydrogen peroxide formed by the addition of sodium peroxide. All glassware used in the experiment had been cleaned with dichromate sulfuric acid cleaning mixture.

Summary

A new method has been described for the determination of propionic acid. In this method propionic acid is oxidized to oxalic acid. Such a method is especially valuable in the determination of propionic acid in the presence of formic and acetic acids.

THE ELECTRON AFFINITY OF FREE RADICALS. IV. COMPOUNDS NOT AROMATIC HYDROCARBONS

BY H. E. BENT, M. DORFMAN AND W. F. BRUCE

RECEIVED MAY 14, 1932

PUBLISHED AUGUST 5, 1932

In the three previous papers of this series¹ values for the free energy change of the reaction of addition of sodium to eight organic free radicals have been reported and by combination with appropriate equations the electron affinities in the gaseous state calculated. These free radicals contained only phenyl, biphenyl or naphthyl groups attached to the trivalent carbon atom. The values of ΔF for the reaction²

¹ H. E. Bent *This Journal*, **52**, 1498 (1930); **53**, 1786 (1931); Bent and Dorfman, *ibid.*, **54**, 1393 (1932).

² The standard state is the metal in the case of the sodium and for the other species the activity is taken as equal to the mol fraction.

in which R represents the free radical, were found to fall within narrow limits ranging from -17.9 kg. cal. for triphenylmethyl to -20.6 kg. cal. for tri-*bi*-phenylmethyl and within these limits the effects produced by the various groups were additive. The electron affinity in the gaseous state for these compounds was calculated to be about 60 kg. cal.

That these compounds should all give nearly the same value of ΔF for this reaction is perhaps not very surprising in view of the fact that in each case an electron is being added to an "odd" molecule to complete an electron pair. In all of the compounds heretofore studied the central atom has been carbon and the three groups attached to this carbon have been aromatic in structure. It would seem very desirable to continue the study of this reaction, extending the work to compounds of non-aromatic structure.

Unfortunately the requirements of the problem greatly limit the number of compounds which may be studied. In the first place it is essential that the ethane be either largely dissociated into the free radical or else that the equilibrium constant for this dissociation be known. If neither of these conditions is satisfied, then the addition of sodium to the ethane involves not only the free energy change of the addition of sodium to the free radical but also the unknown free energy of dissociation of the ethane. Knowing the sum of these two values and either one, the other may be calculated. From the standpoint of this investigation it is necessary to know the free energy of dissociation of the ethane or else that this be nearly complete. The converse of this calculation, the determination of the dissociation of ethanes by measuring the equilibrium with sodium, is the subject of another investigation which will be reported later.

Another very obvious requirement of this investigation is that a true equilibrium be established free from side reactions. These conditions make it impossible to study a great many of those compounds which satisfy the first condition of being largely dissociated. In some cases the solubility is too small and in others the sodium reacts with some active part of the molecule.

The free radicals reported in this paper are diphenylanisylmethyl, trianisylmethyl, pentaphenylcyclopentadienyl, pentaphenylethyl, the oxygen free radical, 9-chloro-10-phenanthroanil and the nitrogen free radical α, α -diphenyl- β -trinitrophenylhydrazyl. These compounds are known to be largely dissociated.

Diphenylanisylmethyl showed a similar behavior to triphenylmethyl and gave approximately the same value for the electron affinity. Tri-*p*-anisylmethyl and pentaphenylcyclopentadienyl failed to yield sodium derivatives that had even a slight solubility in ether and possibly these free radicals were decomposed by sodium amalgams. 9-Chloro-10-phenanthroli formed a monosodium derivative with 1% sodium amalgam but the sodium

was held too firmly to be removed by mercury sufficiently to be detected analytically. The nitrogen free radical α,α -diphenyl- β -trinitrophenylhydrazine was undoubtedly decomposed in ether by saturated sodium amalgam, even nitrobenzene being decomposed by this treatment. Penta-phenylethane reacted with sodium in liquid ammonia but failed to yield a sodium derivative that could be extracted with ether.

Experimental

Diphenylanisylmethyl.—Diphenylanisylmethylcarbinol was obtained from the Eastman Kodak Co. in the form of a brown sirup. The melting point reported for the pure carbinol is 82° .³ 7.8 g. of the sirupy carbinol was dissolved in 35 cc. of absolute ether and a little calcium chloride added. The addition of hydrogen chloride gas produced a white precipitate of the chloride. Ether was added to make a total volume of 125 cc. which dissolved the precipitated chloride and none separated upon again treating with hydrogen chloride. After standing overnight and filtering, the solution was evaporated to 30 cc. and cooled to 0° . White crystals of the chloride separated. These were crystallized twice more from ether at 0° to yield 2.4 g. of chloride melting at 123° . The value previously reported is 122° .

Anal. Calcd. for $C_{20}H_{17}OCl$: Cl, 11.50. Found: Cl, 11.54, 11.31.

The apparatus and procedure used in making the equilibrium measurements have been previously described.¹

Table I gives the experimental data for the equilibrium measurements. The column headed $\log K_2$ gives the values of the equilibrium constant for equation (1). A dissociation constant for the sodium addition compound giving ions, of 10^{-4} has been assumed here as was done in the earlier papers of this series. The dissociation constant for the ethane has been taken as 10^{-2} based upon molecular weight determinations.⁴

The mean value of ΔF is -18.3 kg. cal., which is not very different from 17.9 kg. cal., the value found for triphenylmethyl.¹

^a Compound treated with 40% amalgam.

The equilibrium constants obtained agree with each other as well as for any of the preceding compounds studied. However, a decided difference was noted in the color change when adding mercury. With sodium tri-

³ Gomberg and Buchler, *THIS JOURNAL*, **45**, 217 (1923).

⁴ Ref. 3, p. 220.

phenylmethyl it was possible to see a partial disappearance of the red color upon shaking with a large quantity of mercury. The ether solutions of the other compounds studied were so dark that even a ten-fold dilution could not be noted and shaking with the quantities of mercury used produced no color change that could be detected.

The ether solution obtained by treating the diphenylanisyl chloride with saturated amalgam had a red color about the same as that of sodium triphenylmethyl. A small quantity of mercury changed this to a yellow, practically the same as that of the free radical solution obtained by treating the chloride in ether solution with mercury. This apparently indicated a nearly complete removal of sodium from the addition compound for even a fifty-fold dilution of the red solution gave a color distinctly red-orange. From Table I, however, it is seen that the equilibrium constant is the same within experimental error when 1.35 mols of mercury, removing about one-third of the sodium, and 5.05 mols of mercury, removing about two-thirds of the sodium, were used. This contradiction between the evidence furnished by the color of the solution as to the amount of sodium present and that furnished by analysis, was further studied.

To test the reversibility of the color change an ether solution of sodium diphenylanisylmethyl was prepared in the usual way and decanted into a two-tube system which was then sealed off. One of these contained saturated amalgam about 1%, and the other connected to it, mercury. The red solution changed to yellow upon pouring into the mercury tube and shaking, and the original color was restored upon pouring back and shaking in the amalgam tube. This was repeated ten times with the same result, even though according to the equilibrium measurements very little sodium would be removed in the mercury tube after the first few times.

It appeared possible that a derivative containing two atoms of sodium was being formed, the red color being due to small amounts of the disodium compound and this second sodium atom being readily removed by amalgams more concentrated than those ordinarily at equilibrium with the monosodium derivative. If so this derivative should be formed completely with 40% amalgam. To test this some of the chloride was first treated in the usual way with 1% amalgam in ether solution and then poured onto 40% sodium amalgam and shaken. No deepening of the color could be noted and after decanting and shaking with mercury in the last tube, the yellow color of the previous runs was noted. Usual analyses gave the same equilibrium constant within experimental error. In addition the ether phase was hydrolyzed with water and the sodium hydroxide formed titrated. The sum of the titrations of ether and mercury phases gave 0.0001247 mole, 0.0001238 mole of chloride having been used, which agrees well within experimental error and shows that the monosodium derivative was formed quantitatively.

It appears possible that a quantity of impurity in amounts too small to affect the analytical results might be present and this form a red sodium addition compound from which the sodium is easily removed by mercury. However, an additional crystallization of the chloride this time from benzene and petroleum ether gave the same red colored solution upon treatment with 1% amalgam.⁵

Tri-*p*-anisylmethyl.—Trianisylcarbinol was made according to the directions of Baeyer and Villiger.⁶ After the sulfuric acid addition product was decomposed with water, the product was extracted with ether. A large volume of ether is needed since some of the methane tends to precipitate at this stage as an asbestos-like gummy material. The distilled product was orange-red and fragrant. It was not crystallized before oxidation^{1,7} which was followed by conversion to the picrate. This was digested with hot chloroform for half an hour and filtered by suction. It was then shaken in a mechanical shaker with a large amount of dilute alkali. On extraction with ether, desiccation over calcium chloride and evaporation, an orange oil was obtained which solidified on seeding with some of the solid which formed on the lip of the flask. Some of the oily carbinol was dissolved in benzene, calcium chloride added and the solution saturated with hydrogen chloride. The solution became deep red and a red precipitate formed which later turned to a red oil below the benzene. The two liquid phases were decanted from the calcium chloride and boiled down to about 75 cc. On standing for several days some deep red rosetts together with some red gum separated slowly. The clear liquid was decanted, an equal volume of absolute ethyl ether added and the solution allowed to stand overnight at 0°. Large white plate-like crystals formed which were dissolved in 30 cc. of benzene. Where the solid came in contact with air it became brick-red. When the operations were carried out in an atmosphere of carbon dioxide no marked coloration occurred. The chloride after recrystallization was washed with absolute ether several times and dried under reduced pressure over potassium hydroxide. The compound melted at 158°; that previously reported⁸ at 154–156°.

Practically no information exists about the free radical. Wieland⁹ states that the free radical tri-*p*-anisylmethyl is obtained by the splitting in ligroin of an azo compound, but he gives no description of the free radical. There are no other references to it in the literature. We obtained an orange solution with some orange precipitate upon dissolving the chloride in ether and shaking with mercury. The color disappeared upon admitting air. With a more dilute solution, 0.02 g. of chloride in 100 cc. of ether, shaken with mercury an orange solution formed without a red precipitate.

A sample of the chloride in ether was shaken with saturated amalgam. The solution became orange. After shaking for almost an hour a brown

⁵ Another possible explanation, suggested by Dr. W. L. Gilliland, is that sodium diphenylanisylmethyl exists in two tautomeric forms, one red and the other yellow or much lighter, the red existing in small amounts the sodium of which is readily removed by mercury. One would have to postulate in addition that the equilibrium between these two forms is mobile while in contact with amalgam, but not over mercury. In order to shed further light on this peculiar behavior the trianisylmethyl was studied.

⁸ Ref. 6, p. 3031.

⁹ Wieland, *Ber.*, **55**, 1830 (1922).

suspension slowly formed and in several hours the orange color had completely disappeared.

It was thought that possibly the saturated amalgam was too strong a reducing agent and that the use of a very dilute amalgam would enable equilibrium measurements to be made.

0.614×10^{-4} mole of chloride in ether solution was shaken in a single tube carrying a stopcock with an amalgam the mole fraction of sodium in which was 0.743×10^{-4} which is about the mean concentration of the amalgams in equilibrium with diphenylanisylmethyl and its sodium derivative (see Table I). An orange colored solution together with some gray precipitate which may have been entirely sodium chloride was formed. After shaking overnight in the dark the amalgam phase was withdrawn through the stopcock and titrated. Water was then admitted to hydrolyze the ether phase and precipitate, and the mixture titrated. The orange colored solution did not change color upon adding water but was instantly decolorized by air.

To summarize the titration results

0.10×10^{-4}	mole of sodium in ether phase + ppt.
0.81	mole of sodium in amalgam after shaking
0.61	mole of sodium equivalent to Cl in original chloride
<hr/>	
1.52	mole of sodium sum
1.46	mole of sodium in original amalgam

Considering that the end-point was not very good in titrating the ether and precipitate, these two figures check quite well.

These figures indicate that the tri-*p*-anisylchloromethane reacts quantitatively with this dilute amalgam to form the free radical but that no appreciable amount of sodium adds to the free radical to form the sodium derivative. We prepared an amalgam the mole fraction of sodium in which was 6.04×10^{-4} , about eight times as strong as the preceding one. This was done in order to force more sodium into the ether phase. In this experiment an apparatus with two tubes, similar to those used in the equilibrium measurements was used, except that the first tube also had a stopcock. 0.878×10^{-4} mole of chloride was shaken in the first tube with the amalgam. The solution turned orange and remained so upon shaking overnight in the dark. The solution was decanted and filtered into the second tube and mercury added and this shaken overnight in the dark. The orange color did not lighten after shaking with mercury, or upon admitting water, but was decolorized in air. Both phases in the second tube and the amalgam and precipitate in the first tube were hydrolyzed and titrated with the following results. The amount of sodium in the original amalgam was 3.07×10^{-4} gram atom. The amount remaining at the conclusion of the experiment was 1.93×10^{-4} gram atom. About 0.08×10^{-4} gram atom was found in the precipitate formed in the first tube. 0.88

$\times 10^{-4}$ gram atom is the amount which should be required to convert the chloride into the free radical. These amounts add up to give 2.89×10^{-4} , nearly the amount of sodium introduced in the original amalgam. This agrees with the fact that no sodium was removed by the mercury and none found in the ether phase. One may conclude, therefore, that tri-*p*-anisylmethyl may be prepared from the chloride by treatment with either mercury or an amalgam whose mole fraction of sodium is from zero to 0.7×10^{-4} . Since no sodium addition compound has been prepared, it is not possible to give a value for the free energy change for the reaction. It may be somewhat less negative than for the compounds heretofore studied.

Pentaphenylcyclopentadienyl.—This free radical has been prepared by Ziegler and Schnell,¹⁰ who found it to be completely dissociated by freezing-point measurements.

In the preparation of methylene-bis-desoxybenzoin, it was found important that desoxybenzoin should be pure, and that alkali should not be added until the formalin had been well mixed with the solution. It is desirable to cool the solution to 0° during the slow addition of alkali. Under these conditions crystals began to appear almost at once and there was no oily phase. When the reaction was carried out at room temperature, however, and the alkali added rapidly, the gummy material described by Ziegler and Schnell was obtained. Heat is liberated when the ketone is added to the final Grignard solution at the boiling point of ether, and a considerable amount of tarry by-products appeared. But when the Grignard solution was cooled to 0° and the ketone added slowly, a good yield of carbinol was obtained. This was crystallized twice from acetic acid and converted into the chloride, which melted at 170° . The value previously reported is 167° .

A sample of the chloride in ether solution was treated with 1% amalgam in the usual system. A purple colored solution was formed at first. This is the color of the free radical in benzene described by Ziegler and was also obtained by shaking an ether solution of the chloride with mercury. After shaking with the amalgam a short while, a dirty green precipitate was formed and the purple color disappeared. The ether phase remaining contained no hydrolyzable sodium.

It was thought that possibly the sodium derivative was formed but was insoluble in ether and might be soluble in benzene. The experiment was repeated using very dry benzene in place of the ether. The same phenomena occurred again although the purple color persisted longer than when in ether solution. In order to learn whether or not a more dilute amalgam would give the free radical as in the case of tri-*p*-anisylmethyl another sample of the chloride in ether solution was treated with a very dilute amalgam the mole fraction of sodium in which was 0.743×10^{-4} . Here again the same phenomena were noted, the purple solution forming at first and then a green precipitate.

The analysis of the amalgam indicated that not more than one and one-half equivalents of sodium had reacted with the chloride, one equivalent

¹⁰ Ziegler and Schnell, *Ann.*, **445**, 274 (1925).

of this being required to form the free radical. Evidently the presence of sodium amalgam catalyzes the decomposition of the free radical.

Oxygen and Nitrogen Free Radicals.—We are indebted to Professor L. F. Fieser for the 9-chloro-10-phenanthrol used in these experiments. This material had been prepared by the method of Schmidt and Lumpp and melted at 122°. The previously recorded value is 121°. ¹¹

Goldschmidt and Steigerwald¹² prepared the free radical by oxidation with lead dioxide and found it to exist in the dissociated form in several solvents.

Upon treating the phenanthrol with sodium amalgam a reaction took place which should give the same compound as would be obtained by addition to the free radical. The solution remained colorless and on shaking with mercury no sodium was removed. Ninety per cent. of the calculated amount of sodium was found in the ether solution by titration. The original phenanthrol was recovered after the titration, and identified by a mixed melting point.

This experiment clearly indicates that an oxygen-free radical unites with sodium to form a compound which is much more stable than the corresponding carbon compound. One can place the free energy change for this reaction qualitatively by saying that it is more negative than in the case of carbon by at least 5 kg. cal.

One might expect from the foregoing experiment on the oxygen-free radical that a nitrogen-free radical would show a similar behavior but would hold to the sodium less firmly. The choice of largely dissociated nitrogen free radicals is, however, very limited. α,α -Diphenyl- β -trinitrophenylhydrazyl was synthesized by the method of Goldschmidt and Renn.¹³ However, treatment of the hydrazine with the sodium amalgam resulted in side reactions which prevented further study with this compound. Doubtless the nitro groups are responsible for the various reactions observed.

We are indebted to the Milton Fund of Harvard University for financial support in this investigation.

Summary

1. ΔF for the addition of sodium to diphenylanisylmethyl is the same as for the addition of sodium to triphenylmethyl.
2. ΔF for the addition of sodium to the oxygen free radical, 9-chloro-10-phenanthroxyl, is more negative than for carbon free radicals by at least 5 kg. cal.
3. The following compounds will give no sodium addition compound when treated with a one per cent. sodium amalgam, presumably due to the

THE HEAT CAPACITY OF SELENIUM FROM 100 TO 300°A.¹

BY THOS. DE VRIES AND L. FRANCIS DOBRY

RECEIVED MAY 16, 1932

PUBLISHED AUGUST 5, 1932

Previous work on the heat capacity of metallic selenium has been of a rather uncertain nature. None of the experimenters has stated the method of purification so as to have selenium free from tellurium, nor have they shown that their specimens were the metal and not some other form of selenium.

Some of the earliest work was done by Regnault.² He obtained the value 6.63 calories per mole at 98° and 5.93 at 20 to 98°. Bettendorf and Wüllner³ found 6.65 from 25 to 60°. Dewar⁴ gave the value 2.86 between liquid nitrogen and liquid hydrogen temperatures. In our investigation the selenium was carefully purified and annealed to the metallic form. The Nernst method was used to find the heat capacity.

Purification and Preparation of the Sample

A Mallinckrodt grade of selenium was dissolved in concentrated nitric acid. The selenium dioxide was then dissolved in dilute hydrochloric acid. The insoluble material was filtered out and the selenium precipitated with sulfur dioxide. The selenium came down in the red form and turned black upon drying. This was repeated twice. For the complete removal of tellurium, the method of Lenher and Kao⁵ was used, in which hydroxylamine hydrochloride was used as the reducing agent. This purification was also repeated twice. This gave a black form of selenium. The wet selenium was washed with alcohol and vacuum dried at room temperature. This amorphous selenium was then placed in a Pyrex glass tube, connected to a vacuum pump and heated. Large volumes of gas came off, and finally a tarry mass was formed. This was allowed to cool to a shiny black, brittle solid in an atmosphere of nitrogen.

The selenium was transferred to a soft glass cylinder and melted. In this was inserted two Pyrex thermocouple wells, and a spiral heating coil of No. 30 nichrome wire. (Approximate resistance was 11 ohms.) The entire assembly was then heated in an oil-bath to 210–215°, where it was kept for several hours. It was then allowed to cool slowly in a Dewar flask filled with oil of about 225°. At the end of eight hours the temperature of the oil was still about 50°, so it was assumed that only the metallic

form of selenium was present. This procedure, and the assumption that only the selenium metal was present after cooling, is substantiated by Saunders and Mellor in their publications.⁶ The soft glass was then broken away, leaving a selenium slug of 32 mm. outside diameter by 60 mm. long and weighing 189.14 g. No. 30 copper wires were silver soldered to the nichrome heating element, and copper-constantan thermocouples were fixed in the wells with paraffin.

The selenium slug was suspended by fine silk thread inside a copper jacket, 4.8 cm. in diameter and 13.2 cm. long, weighing 1260 g. The thermocouple and electric heater wires from the selenium were taken out through a copper tube fastened to the lid. The entire length of the jacket was wound with No. 30 D. S. C. manganin wire, which was firmly cemented on with bakelite varnish. To the inside of the jacket was fastened a copper-constantan thermocouple. These circuits were used to adjust the temperature of the jacket equal to that of the selenium sample.

The thermostat consisted of a long Pyrex glass cylinder, 6.3 cm. in diameter by 46 cm. deep. Into the upper end was ground a 250-cc. flask which served as a stopper, and from its neck was suspended the jacket containing the selenium. The joint was sealed with de Khotinsky cement. To the sides, 10 cm. from the top, were sealed three tubes. One was connected to a mercury vapor pump, another served as an outlet for the thermocouples and heating element wires. The third tube, filled with 2.54 cm. of dibutyl phthalate, served to contain the cold junctions of the thermocouples. This cylinder, or thermostat proper, was placed in a Dewar flask, 14 cm. in diameter and 32 cm. deep, so that it could be surrounded by a suitable cooling bath. The liquid level of the bath was at least 10 cm. higher than the upper end of the copper jacket.

Electrical Standards and Experimental Technique.—A carefully prepared manganin resistance, which was frequently calibrated against a standard resistance furnished by Leeds and Northrup, was used in series with the nichrome heating coil of the selenium sample. This prepared resistance had a value of 1.0751 ohms. If E_1 and E_2 represent the volts across the nichrome heating element in the selenium, and across the standard resistance, the number of calories produced per second in the selenium is given by

$$\frac{E_1 \times E_2}{1.0751 \times 4.181}$$

In order that the voltage across the heating coil could be read on the type K potentiometer, a resistance of 1100 ohms was placed in parallel with the heating coil, and a tap taken off at about the 100 ohm value. The ratio of the tapped resistance to the entire resistance was found to be 1 : 100.84.

The thermocouples were calibrated against a platinum resistance thermometer, recently calibrated by the Bureau of Standards. The e. m. f. values for copper-constantan thermocouples given by Southard and Andrews⁷ were used as a standard. The following were the observed corrections for the two-couple thermel used in the sample.

⁷ Southard and Andrews, *J. Franklin Inst.*, **207**, 323 (1929).

TABLE I
 THERMOCOUPLE CORRECTIONS

Temperature of bath, °A.	84.60	151.43	209.06
Observed e. m. f., mv.	10523	7734	4469
Calculated e. m. f., mv.	10623	7798	4497
Deviation, mv.	+100	+64	+28

These deviations lie on a smooth curve fitted by the equation

$$\Delta \text{mv.} = 3.51 (e/1000) + 0.616 (e/1000)^2$$

As thermostatic liquids in the large Pyrex Dewar flask, there were used liquid air, carbon dioxide snow and ether, carbon dioxide snow and chloroform or ice and water, depending on what temperature was desired. After a constant temperature was obtained in the slug, the apparatus was evacuated. A record of the temperature of the selenium was made until a constant change was observed. The heating current was then turned on for ten minutes, the time being measured with a stop watch to one-fifth of a second. While the current was on, the e. m. f. across the tapped resistance and the standard resistance were taken alternately every minute. At the end of ten minutes, the current was shut off, and the e. m. f. across the two-couple thermel was again taken, until a constant change of temperature was again observed. The method of Jaeger and Steinwehr³ was used to calculate the correction for heat lost and gained during the time that the selenium was heated and the temperature became constant. The correction amounted to about ten per cent. of the total temperature rise. These

corrections are included in the values of column two of Table II, in which the changes in observed microvolts are tabulated. The change in the thermocouple correction with change in temperature was also considered in calculating the temperatures, tabulated in column three of Table II. The values lie on a reasonably smooth curve, fitted by the equation

$$C_p = 2.69 + 0.0560 T - 2.66 \times 10^{-4} T^2 + 4.35 \times 10^{-7} T^3$$

The values in the last column of Table II have been calculated by the use of the above equation.

Summary

1. The heat capacity of metallic selenium was determined by the Nernst method. The selenium was carefully purified by the Lenher and Kao method.

2. The experimental values for the temperature range from 100 to 300°A. lie between 6.08 and 7.25. Values for this range have not been reported previously. The value calculated for 300°A. is approximately ten per cent. larger than that reported by Bettendorf and Wüllner.

NOTES

The Standardization of Weights

BY FRED C. EATON

The method of Richards¹ for calibrating a set of weights has one particularly attractive feature, the procedure used in calculating the corrections from the system of observation equations. The discussion which follows will show that this procedure gives values which are exactly the same as the values defined by the system of equations. In other words, they are identical with the values to be found by substituting in algebraic formulas like those of Kohlrausch.²

The Reasoning of Richards.—A study of what Richards has written will explain why some do not appreciate just how accurate the calculation is. His preliminary values are *consistent* by reason of two assumptions. First, there is the assumption that the first centigram weight, called the standard of comparison, has the mass of 0.01 g. Second, it is implicitly assumed that the small differences between the masses of the various combinations of weights have been correctly measured by the rider in terms of grams. These consistent values are then translated into other terms by a method depending upon the properties of small numbers in presence

¹ T. W. Richards, *THIS JOURNAL*, **22**, 144 (1900); *Z. physik. Chem.*, **33**, 605 (1900).

² F. Kohlrausch, "Lehrbuch der praktischen Physik," 11th edition, p. 62.

of large ones.³ This reasoning may well confuse those who study it carefully. Semon,⁴ for example, was guided by it in making his analysis.

A Different Interpretation.—That procedure of Richards will now be explained in a different way. Let the symbol (*A*) denote the actual number of grams in the mass of the weight whose face value is *A* grams. Moreover, let (0.01) denote the mass of the first centigram weight. Then, if [*A*] and [0.01] are the corrections for these weights, the relation between their masses is expressed by the equation

$$(A) = [A] + 100 A \{ (0.01) - [0.01] \}$$

The first step in calculating the corrections is to find from the equations a preliminary value for each weight. In doing this we shall make no assumption regarding the mass of the first centigram weight. The preliminary values in Table I are *defined* by assigning to (0.01) the value 0.⁵ Hence, it follows immediately from the preceding equation that

$$\text{Preliminary value of } (A) = [A] - 100 A [0.01]$$

TABLE I

$$(A) = A + [A] \quad (0.01) = 0.01 + [0.01] \quad \text{Standard: } (100) = 100.00158 \text{ g.}$$

(<i>A</i>)	Observation equations	Grams	Preliminary values [<i>A</i>] - 100 <i>A</i> [0.01]	Aliquot parts 100 <i>A</i> [0.01]	Corrections [<i>A</i>], milligrams
(0.01)	0.00000	+0.00007	+0.07
(0.01') = (0.01)		-0.00006	- .00006	+ .00007	+ .01
(0.01'') = (0.01)		- .00009	- .00009	+ .00007	+ .02
(0.02) = (0.01) + (0.01')		- .00004	- .00010	+ .00014	+ .04
(0.05) = Σ(0.05) ^a		- .00013	- .00038	+ .00035	- .03

(50) = Σ(50)		+ .00024	- .35049	+ .35173	+1.24
(100) = Σ(100)		- .00067	- .70189	+ .70347	+1.58

^a The meaning of this notation is shown by the following example: Σ(5) = (2) + (1'') + (1') + (1).

³ When α and β are quite small in comparison with N , then $N(N + \alpha)/(N + \beta) \simeq N + \alpha - \beta$.

⁴ W. L. Semon, *J. Chem. Ed.*, **2**, 132 (1925).

⁵ As we are giving a definition, this value may be chosen arbitrarily. The preliminary values of Richards would result from setting (0.01) = 0.01000.

This equation easily explains the rest of the procedure. Let the last term *define* what we mean by the aliquot part for (*A*). Then it is self-evident that, when the aliquot part for one weight is known, the aliquot parts for all the others can be found. Theoretically, if we know the correction for *any* one weight, we can quickly calculate the corrections for all the others. In practical work, however, the face value of the standard should not be less than that of the largest weight in the set.

This explanation of the procedure of Richards makes no assumption and requires the use of no approximation. Consequently that procedure gives values which are precisely the same as those defined by the system of equations, and the accuracy of those values depends solely on the errors made in measuring the small differences between the masses of the various combinations of weights.

Another convenient method of arranging the computation is shown in Table II. This arrangement has the advantage of using smaller numbers. A few additional remarks will make the procedure clear. In dealing with the first group we know the mass of the weight (100) and we define the preliminary values by assigning to (10) the value 0. When we come to the second group, we know the mass of the weight (10) and we define the preliminary values by assigning to (1) the value 0.

TABLE II

Observation equations	Grams	Preliminary values	Aliquot parts	Corrections, milligrams
(10) 	0.00000	-0.00003	-0.03
(10') = (10)	+0.00030	+ .00030	- .00003	+ .27
$\Sigma(10)$ = (10)	+ .00014	+ .00014	- .00003	+ .11

(1) 	0.00000	-0.00006	-0.06
(1') = (1)	+0.00013	+ .00013	- .00006	+ .07
(1'') = (1)	+ .00003	+ .00003	- .00006	- .03
(2) = (1) + (1')	+ .00002	+ .00015	- .00011	+ .04
(5) = $\Sigma(5)$	+ .00004	+ .00035	- .00028	+ .07
(10) = $\Sigma(10)$	- .00014	+ .00052	- .00055	- .03 ^a

^a This value has been taken from the corrections for the preceding group of weights.

Summary.—The procedure of Richards for calculating corrections from the system of observation equations has been discussed. It has been shown that this procedure gives values which are identical with those to be found by substituting in algebraic formulas like those of Kohlrausch.

Alkaline Persulfate as an Analytical Reagent

BY WILLIAM M. DEHN AND DONALD A. BALLARD

Though persulfate in acid¹ or neutral solutions² has frequently been applied as a qualitative reagent, its use in alkaline³ solution has been limited to the precipitation of cobaltic oxide. Using potassium persulfate in potassium hydroxide solution, instead of ammonium persulfate in sodium hydroxide solution as used by Pozzi-Escot, a more complete precipitation of Co_2O_3 can be made (1:1,000,000).

Comparable precipitations of black Ni_2O_3 can be made from nickelous solutions by treatment with alkaline persulfate. In the absence of cobalt, it is a characteristic test for nickel, since its black will cover up the colors of other metallic hydroxides. Also in the presence of metals whose hydroxides are soluble in fixed alkalies, it can give a separation of either nickel or cobalt or both of these metals. Conversely nickel or cobalt is a qualitative test for persulfate.

Cyanides.—Alkaline persulfate oxidized cyanides, ferricyanides, ferrocyanides, nitroprussides and thioazanes to cyanic acid, as indicated by the following test. To any one of these, add the reagent and heat to boiling. Acidify with hydrochloric acid and again make alkaline. Moist red litmus paper on the convex side of a watch glass covering the beaker turns blue, owing to the liberation of ammonia. Without persulfate, the litmus paper remains unaffected.

Thiosulfate, but not sulfite, or arsenite, is oxidized by the reagent. Sodium peroxide liberates oxygen. These and other reactions will be studied.

A Lubricant Insoluble in Organic Solvents

BY C. C. MELOCHE AND W. G. FREDRICK¹

In working with organic solvents it is occasionally necessary to lubricate a stopcock or ground-glass joint in such a manner as to maintain a vacuum or a gas-tight seal and at the same time withstand the solvent action of the liquid. Under such conditions lubricants containing petroleum grease or rubber are as a rule useless on account of their solubility in the solvent and inorganic lubricants are often unsuitable due to separation of a constituent, reaction with the solvent, solubility or freezing.

¹ Mallinckrodt Fellow in Chemistry, University of Michigan, 1930-1932.

A solution of dextrin in glycerin is occasionally recommended² as a lubricant under the special conditions mentioned. The insolubility of this material in many organic solvents, as well as the high viscosity and slightly adhesive quality, renders this mixture suitable where a gas-tight seal is needed but where the frequent turning of a stopcock is unnecessary. The writers have found that the addition of mannitol in proper amount imparts the correct lubricating quality and renders this lubricant practically indispensable in certain types of work. For general use the lubricant may be prepared as follows.

Mix thoroughly 25 g. of anhydrous glycerin, 7 g. of dextrin and 3.5 g. of chemically pure *d*-mannitol until a thick paste is obtained. Heat carefully with constant stirring until the solid material is dissolved and the solution just begins to boil. A small amount of water is lost. Cool the clear, colorless or sometimes slightly turbid liquid with occasional stirring to room temperature. The liquid becomes highly viscous and finally acquires a lustrous white or opalescent appearance due evidently to the separation of part of the mannitol in a finely divided state. This preparation has excellent lubricating qualities as well as the body and adhesiveness suitable for most purposes. To increase the viscosity add more dextrin. To increase the fluidity add more glycerin. To impart the physical property of a greasy paste add a little more mannitol. Chemically pure *d*-mannitol is recommended, since commercial mannitol will not always yield the desired result. This lubricant is best stored in an ointment jar or kept in a desiccator, but exposure to laboratory air is not harmful.

The action of a number of solvents on this lubricant was tested as follows. The stopper of a small Erlenmeyer flask was lubricated so as to give a thin uniform film on both ground glass surfaces when the stopper was inserted. The stopper was removed, both lubricated surfaces were drenched with the solvent to be tested, and the excess of the solvent shaken or blown off. The stopper was then replaced in the flask and rotated to test the lubricating action. After repeating the operations of drenching and testing a number of times alternately the relative effects of the various solvents could be easily observed.

Tested in the manner described, the following solvents had no detectable effect, or at most a very slight and negligible effect: acetic anhydride, acetophenone, benzaldehyde, benzene, bromobenzene, carbon bisulfide, carbon tetrachloride, chlorobenzene, tetrachloroethane, cyclohexane, ethyl acetate, ethyl acetoacetate, ethyl bromide, ethyl carbonate, ethylene dichloride, methyl acetate, methylaniline, nitrobenzene, nitromethane, petroleum ether, diphenyl ether, toluene, *o*-toluidine, turpentine, *o*-xylene.

The following solvents had a slight effect, not, however, sufficient to prevent the use of the lubricant provided the latter is renewed when

² Iredale, *Phil. Mag.*, **45**, 1097 (1923).

necessary: acetaldehyde, acetone, acetyl chloride, amyl acetate, amyl nitrate, benzoyl chloride, *n*-butyl ether, diethyl ether, methylene chloride.

The solvent or disintegrating action of the following was sufficient to prevent or greatly hinder the use of the lubricant: aniline, acetic acid, tertiary amyl alcohol, benzyl alcohol, *n*-butyl alcohol, tertiary butyl alcohol, ethyl alcohol, methyl alcohol, diethylamine, ethylene chlorohydrin, ethylene glycol, formic acid, propionic acid, pyridine, quinoline, water and solvents containing water. In general, therefore, water, alcohols, aliphatic acids and to a lesser extent certain amines and nitrogen containing heterocyclic compounds prevent the use of the lubricant.

Before lubricating a stopcock with this preparation, petroleum and rubber grease should be entirely removed by means of benzene or acetone and the stopcock should be thoroughly dried. After applying a thin film of the lubricant, a stopcock will remain gas tight even when frequently turned in the presence of solvents of the first group mentioned above. With a liquid-air trap in the line to remove any water vapor evolved, a stopcock lubricated as described will hold a good vacuum. In gas analytical operations where the presence of petroleum grease was thought to cause error by absorbing constituents such as ether vapor, the glycerin-dextrin-mannitol lubricant has been used with success. Water dissolves the lubricant readily and may therefore be used to remove it when desired.

The Probable Non-Existence of Normal Tribasic Aluminum Soaps Such as Aluminum Tripalmitate

BY JAMES W. MCBAIN AND WINIFRED L. MCCLATCHIE

Aluminum soaps are articles of commerce used in several industries; they are even listed in most catalogs of pure reagents, and they have frequently been employed in scientific work.¹ Nevertheless, after repeated purchases and attempts to prepare aluminum tripalmitate and other tribasic aluminum soaps, we have come to the conclusion that the product is a mechanical mixture from which an appreciable proportion of free fatty acid is at once dissolved by ether, leaving behind a monobasic or at most a dibasic soap such as a dipalmitate, even when prepared and extracted in the complete absence of moisture. For example, Kahlbaum's aluminum tripalmitate yielded 50% of its fatty acid content to ether dried over sodium. A sample of aluminum palmitate obtained from Eimer and Amend contained only one equivalent of fatty acid to three equivalents of aluminum.

Aluminum soaps are usually prepared from aqueous solution by pre-

¹ For example, in emulsions of water with other solvents, in studies of swelling, etc.

precipitating a soluble soap with aluminum salt. The precipitate is then taken to be the tribasic aluminum soap. Consideration of the elementary theory of aqueous solutions (compare, for example, aluminum sulfide) would lead one to expect a doubtful or negative result on account of the extensive hydrolysis of a salt of a weak fatty acid with a base at once so weak and insoluble as aluminum hydroxide.

Preparations of Oleates, Stearates, and Palmitates from Aqueous Solutions.—When aluminum sulfate solution was added in excess to an aqueous solution of a sodium or potassium soap, the P_H of the soap solution changed during precipitation from about 8.5 to about 4.5. The precipitates were washed with water, alcohol and ether or with acetone, and aluminum was determined by ignition as Al_2O_3 . They contained from 5.5 to 6.7% aluminum for palmitates and from 5.0 to 6.2% for stearates and oleates. This indicates a gross composition slightly nearer to dibasic rather than monobasic soap, which was confirmed by a determination of fatty acid present. Preparations made when the P_H was kept equal to 8.5 with sodium bicarbonate gave similar results. With P_H between 3 and 4.5 the product contained little more palmitic acid than corresponded to monopalmitate.

Preparation of Palmitates in Non-Aqueous Media.—Preparations made in 95% alcohol and in absolute methyl and ethyl alcohols gave results no nearer the tripalmitate. Diamyl ether, a good solvent for aluminum soap, was used with palmitic acid and freshly prepared aluminum hydroxide washed with alcohol and ether. The soap from this solution was no better. Similar procedures with chloroform left as much as 14% of aluminum in the soap even when the solution had become clear.

Finally, we turned to the reaction between aluminum ethoxide and palmitic acid and benzene which had been dried over sodium. Of 2.6 g. of Kahlbaum's ethoxide, 2.0 g. dissolved on refluxing with benzene. When the theoretical amount of Kahlbaum's best palmitic acid was added, the resulting solution was clear and fluid, but after evaporation to dryness a large amount of fatty acid or fatty anhydride was extracted at 40° by dry ether, yielding palmitic acid 92.2 and 93.5% and aluminum 5.10 and 5.15%. This corresponds closely to an anhydride or ethoxide of aluminum dipalmitate (there was no water present at any time for formation of $AlPal_2OH$).

Further experiments in the same direction have been made in the Department of Chemistry, University of Nevada, Reno, by S. Allan Lough and E. L. J. Randall. The Kahlbaum palmitic acid used was found to be 99.9% pure as determined by titration with standard alkali. The ethoxide by ignition indicated a content of 45.28% although only 40% was extracted with benzene, leaving the alumina behind. Another sample of benzene extract contained 88% of material removed from the

crude ethoxide after filtering through surgical absorbent cotton. After reaction with more than the theoretical amount of palmitic acid and extracting the dried (at 45°) product with ether, the aluminum content was 4.8% as compared with the 5.1% already quoted. In a final experiment with dried benzene which had dissolved 77% of the crude ethoxide the product was dried in four portions at 25, 45, 55 and 75°. The crude material contained between 2.85 and 3.00% of aluminum and after hydrolysis with sulfuric acid yielded fatty acid determined by titration in alcoholic potash corresponding to from 78.96 to 94.84% of palmitic acid. These four products after extraction with sodium-dried ether contained, respectively, 5.38 and 4.43, 5.36 and 5.34, 5.29 and 5.20, 5.24 and 5.33% of aluminum, whereas aluminum tripalmitate would contain only 3.400% of aluminum. These results again indicate that not more than the dibasic palmitate is attained even under these unusually favorable conditions.

Our conclusion is that aluminum soaps are commonly a mixture of uncombined free fatty acid with either a monobasic or a mixture of mono- and dibasic soaps. Normal tribasic aluminum soaps have never been prepared even in completely anhydrous media.

THE DETERMINATION OF IODINE IN BUTTERFAT

By H. A. A. AITKEN

RECEIVED DECEMBER 12, 1931

PUBLISHED AUGUST 5, 1932

The estimation of iodine in carbonaceous materials such as oil or butter is generally regarded as the most difficult of all estimations of minute amounts of iodine in natural products. The most recent method that has been described is that of McClendon, Remington, von Kolnitz and Rufe,¹ in which melted butter (as much as 500 g. in one sample) was sprayed from an atomizer into a silica tube and burnt with a current of oxygen in the presence of a catalyst. This process obviates the difficulty inherent in the much simpler method of combustion with alkali, namely, that the low iodine content of the material necessitates so large a sample being taken for analysis that the use of an excess of potash is out of the question. This leads to loss of iodine, and in addition there is a pronounced tendency for the products of saponification of the butter to froth up during combustion in an uncontrollable fashion.

However, in the micro-titration method devised by the author for the

¹ J. F. McClendon, Roe E. Remington, Harry von Kolnitz and Redding Rufe, *THIS JOURNAL*, 52, 541 (1930).

analysis of blood for iodine,² as little as 0.4 microgram of iodine in the sample suffices if the worker is content with a possible error of not more than 5%. When this method is applied to butter or butterfat (average iodine content about 20 microgram/kg.), a comparatively small sample of 25 g. will provide sufficient material for an analysis.

As a result it is possible to carry out a gentle combustion in the presence of an amount of caustic potash far in excess of that required to saponify the butter. Under these conditions, indeed, the process except in its final stages is better described as an alkali-fusion, the evolution of hydrocarbons from the melt taking place at a relatively low temperature. The iodide formed can be extracted readily and quantitatively from the resulting potassium carbonate and estimated immediately by titration. The method is a much more rapid one than the silica-tube method and probably gives more accurate results.

The procedure in actual practice is as follows: 25 g. of butter (or butterfat) is placed in a 20-cm. nickel basin and 20 cc. of 50% caustic potash is added, followed by 80 cc. of alcohol. All reagents and vessels used must be iodine-free. The butter is saponified by heating for an hour on the water-bath, and the contents of the basin are then evaporated gently to dryness on the sand-bath. The dry residue is now ignited

below red heat over a gas-ring. The arrangement used to avoid overheating is shown in Fig. 1. The basin is set in a shallow iron dish about 15 cm. in diameter and 3.8 cm. deep, the depth being such that an air space intervenes between the bottom of the basin and the iron dish. This eliminates the possibility of local overheating. A trial is made with the basin empty and shaded from direct light to determine how strong a flame can be used without bringing the bottom of the basin to a glow. At this temperature the contents of the basin are

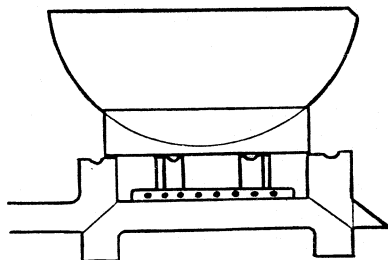

Fig. 1.

found to form a melt from which hydrocarbons are evolved over a period of about three hours, the volume of the melt at the same time steadily diminishing. The process is accelerated by occasionally stirring with a nickel spatula set in a wooden handle, and distributing the material over the heated surface of the basin.

When evolution of gases has ceased, combustion is continued for a further half hour or more until a gray layer of potassium carbonate remains in the basin. The basin is cooled and the layer of salt washed down with a small amount of water, evaporated to dryness, and again ignited for half an hour. The residue is now taken up with about 150 cc. of water and filtered hot with gentle suction using a 10-cm. Büchner funnel and a 250-cc. filter flask. A fast pipet (about 50-cc.) can be used to transfer the liquid from the basin to the filter; the pipet is rinsed into the empty basin and this liquid is used to wash the precipitate. The filtrate and washings, which should be almost colorless, are now transferred to a clean basin and evaporated to dryness. The residue is ignited as before for a further quarter of an hour and allowed to cool.

Just sufficient half-saturated potassium carbonate solution (about 8 cc.) is now added to produce a smooth paste when rubbed into the residue by means of two stout

² H. A. A. Aitken, *Biochem. J.*, **24**, 1456 (1930).

glass rods with flattened ends. Formation of the paste may be assisted by the addition of a few cc. of 90% alcohol. About 25 cc. of 95% alcohol is added and stirred thoroughly into the paste. The extract is decanted into a 100-cc. nickel crucible with the aid of a thin glass rod, the lip of the basin being smeared with vaseline. The extraction is repeated two or three times, a total volume of about 75 cc. of alcohol being employed. If the paste has been made too thin it is an advantage to use absolute alcohol for the extraction; if it becomes too stiff, 90% alcohol is used.

The alcoholic extract with the addition of a little water is gently evaporated to dryness on the sand-bath. The residue of salts is rinsed down with a thin stream of water from a wash bottle, only a few cc. being employed, and the resulting solution is decanted into a 25-cc. nickel crucible. The process is repeated two or three times, a total of about 18 cc. of water being used. The contents of the small crucible after addition of about 10 drops of saturated potassium carbonate are evaporated carefully to dryness on the sand-bath and ignited for about five minutes by placing the crucible in a slightly larger one containing a few chips of pipe-clay to prevent actual contact and heating the outer crucible in a large non-luminous flame.

The residue is carefully moistened with a few drops of saturated potassium carbonate solution so as to form a paste as before when rubbed with two small glass rods. The alcoholic extraction is then carried out, this time with successive small amounts of about half a cc. of alcohol. The extracts are decanted into a titration tube, a particle of pumice is dropped in to initiate the boiling, the tube is suitably supported on the sand-bath and the contents are evaporated to dryness. (The titration tube is a tapering tube such as can be made from a centrifuge test-tube. A platinum wire is sealed into the bottom to ensure regular boiling.)

To the tube which now contains a very small residue of salt is added about 1 cc. of water and the resulting solution is acidified by adding three drops of 1% sulfuric acid from a dropping bottle. Three drops of fresh saturated bromine water are added, the solution is evaporated to a volume of about 0.3 cc. and cooled; a minute crystal of potassium iodide is added, and then a small drop of fresh starch solution. The iodine liberated is titrated in good diffuse light with *N*/100 thiosulfate from a micrometer screw buret.³ If the sample taken contains rather more than 0.4 microgram of iodine, the yellow color of free iodine will be discernible on adding the iodide, and the solution should then be titrated until nearly colorless before adding the starch.

Duplicate analyses by the above method generally agree within 2 to 5% depending on whether the sample has a high or a low iodine content. The reliability of the method has also been checked by testing the recovery of added amounts of iodine. Three identical 25-g. samples of a butter containing 45 micrograms of iodine per kg. were taken and to each of two samples before saponification was added 2 cc. of a solution containing 0.55 microgram of iodine per cc. The three samples were then analyzed with the following result

- Sample 1 No iodine added. Contained 1.09 micrograms
- Sample 2 1.10 microgram added. Contained 2.16 micrograms
- Sample 3 1.10 microgram. Contained 2.16 micrograms

Thus 1.07 or 97% of the iodine added was recovered.

The following are some recent values obtained for butterfats from different places in Otago, New Zealand.

³ H. A. A. Aitken, *Biochem. J.*, **25**, 446 (1931).

Source.....	Dunedin	Highcliffe	Kokonga	Momona	Ranfurly

As pointed out by the American workers, analyses of butter are of questionable value in the mapping of iodine-efficiency areas on account of the increasing use of iodized dairy feeds and salt licks.

Summary

The iodine content of butterfat may be determined by igniting a relatively small sample with caustic potash, extracting the iodide from the resulting potassium carbonate with alcohol and estimating the iodine by micro-titration using a standard thiosulfate solution.

ALLYL LEVULINATE AND ITS DERIVATIVES¹

BY PETER P. T. SAH AND TSU-SHENG MA

RECEIVED JANUARY 11, 1932

PUBLISHED AUGUST 5, 1932

A number of alkyl levulinates² were recently synthesized and studied. Allyl levulinate, representing an unsaturated ester of levulinic acid, has not been reported in the literature. We have successfully prepared this new ester in a very pure condition by direct esterification of levulinic acid³ with allyl alcohol,⁴ using hydrogen chloride as the catalyst. Apparently at low temperature the extent of addition of hydrogen chloride on the ethylene linkage was too slight to affect the yield and the purity of the product. We have further allowed chlorine or bromine to add on the new ester and found the addition products to be identical in physical properties with those obtained by direct esterification of levulinic acid with β,γ -dichloropropyl or β,γ -dibromopropyl alcohol.

To characterize these three new esters, their corresponding semicarbazones and phenylhydrazones were prepared by the usual methods. They were carefully purified and their melting points determined. The experimental details are hereby communicated.

Experimental

Preparation of Allyl Levulinate.—Into a cooled solution of 100 g. of levulinic acid in 200 cc. of allyl alcohol, 15 g. of dry hydrogen chloride was passed. After refluxing, the unesterified alcohol was distilled off on an oil-bath kept at 103°. The residue was fractionated under reduced pressure. The fraction boiling most constantly from 133 to 136° at 40 mm. was collected and purified by vacuum distillation; yield, about 60%.

Freshly distilled in a vacuum, allyl levulinate was a colorless liquid with a faint odor, insoluble in water, but soluble in all organic solvents. Distilled at atmospheric pressure, it boiled with decomposition at 219–222°. The simple physical constants of the pure product were determined and tabulated (see Table I).

Anal. Calcd. for $C_8H_{12}O_3$: C, 61.50; H, 7.75. Found: C, 62.05; H, 8.01.

Addition of Halogens on Allyl Levulinate.—Into a cooled solution of allyl levulinate in carbon tetrachloride, the calculated amount of dry chlorine or bromine was slowly introduced. The solvent was recovered. The residue was fractionated under a reduced pressure of 40 mm. The constant boiling fraction (β,γ -dichloropropyl levulinate at 199–202° and β,γ -dibromopropyl levulinate at 208–210°) was collected and purified by vacuum distillation; yield, about 40% of the theoretical.

Freshly distilled in a vacuum, they were colorless liquids with a faint disagreeable odor, insoluble in water, slightly soluble in carbon disulfide or carbon tetrachloride, but soluble in other organic solvents. Distilled at atmospheric pressure, considerable decomposition took place. The simple physical constants of the pure product were carefully determined and tabulated (see Table I).

To prove the identity of the addition products, β,γ -dichloropropyl⁵ and β,γ -dibromopropyl⁶ alcohols were prepared and directly esterified with levulinic acid. The esters thus obtained were found to be identical in physical properties to the corresponding addition products from allyl levulinate. For the sake of comparison, the simple physical constants of pure β,γ -dichloropropyl and β,γ -dibromopropyl alcohols were also determined and tabulated (see Table I). The halogen contents of the halogenated esters were determined by Stepanow's method⁷ (see Table II).

TABLE I
SIMPLE PHYSICAL CONSTANTS OF REAGENTS AND PRODUCTS

Name	B. p., °C.	d_4^{20}	n_D^{20}	Molecular refraction			
				Gladstone-Dale Obs.	Calcd.	Lorentz-Lorenz Obs.	Calcd.
β,γ -Dichloropropyl alcohol	183–185	1.3607	1.4819	45.67	45.70	27.02	27.33
β,γ -Dibromopropyl alcohol	214–215	2.0739	1.5466	57.49	56.28	33.30	33.18
Allyl levulinate	133–136 (40 mm.)	1.0277	1.4413	67.03	67.27	40.14	40.42
β,γ -Dichloropropyl levulinate	199–202 (40 mm.)	1.2357	1.4652	85.46	84.73	50.82	50.71
β,γ -Dibromopropyl levulinate	208–210 (40 mm.)	1.6580	1.5035	95.94	95.31	56.37	56.57

Semicarbazones.^{2a}—These were conveniently prepared by shaking the new esters with the calculated amount of semicarbazide hydrochloride and potassium acetate in alcohol solution. They were snow white crystals, insoluble in water. After being dried, their melting points were determined. The semicarbazone of allyl levulinate melted at 126–127°; that of β,γ -dichloropropyl levulinate, at 104–106°; while that of the dibromo analog melted at 101–102°. The nitrogen content of the first was determined by Dumas' method.

Anal. Calcd. for $C_9H_{15}O_3N_3$: N, 19.72. Found: N, 19.59.

⁵ King and Pyman, *J. Chem. Soc.*, **105**, 1257 (1914).

⁶ Kohler, *Am. Chem. J.*, **42**, 381 (1909).

⁷ Stepanow, *Ber.*, **39**, 4056 (1906).

For the dihalogen derivatives, the halogen contents were determined by Stepanow's method (see Table II).

Phenylhydrazones.^{2a}—These were easily obtained by shaking the new esters with the calculated amount of phenylhydrazine in ethyl alcohol. The precipitation was instantaneous. The products, recrystallized from benzene and washed with ether, were snow-white crystals. The phenylhydrazone of allyl levulinate melted at 79–80°; that of the dichloro derivative, at 73–75°; and that of the dibromo analog, at 98–99°. The nitrogen content of the first was determined by Dumas' method.

Anal. Calcd. for $C_{14}H_{18}O_2N_2$: N, 11.39. Found: N, 11.6.

For the dihalogen derivatives, again Stepanow's method was used for the determination of their halogen contents (see Table II).

TABLE II
HALOGEN CONTENTS OF DERIVATIVES OF ALLYL LEVULINATE

Name	Formula	Subs., g.	AgNO ₃ used		Halogen, %	
			in cc. (0.1059 N)		Found	Calcd.

Semicarbazone of II	$C_9H_{14}O_2Br_2N_3$.3004	15.29	43.07	42.85	

Summary

1. Allyl levulinate, a new ester, was prepared by the direct esterification of levulinic acid with allyl alcohol in the presence of hydrogen chloride.

2. Direct chlorination or bromination of allyl levulinate yielded β,γ -dichloropropyl or β,γ -dibromopropyl levulinates, identical with the products obtained by the direct esterification of levulinic acid with β,γ -dichloropropyl or β,γ -dibromopropyl alcohol.

3. The simple constants of β,γ -dichloropropyl alcohol, β,γ -dibromopropyl alcohol, and the three new esters of levulinic acid were determined.

4. The three new esters were characterized by their corresponding semicarbazones and phenylhydrazones.

THE COMMON BASIS OF INTRAMOLECULAR REARRANGEMENTS¹

BY FRANK C. WHITMORE

RECEIVED JANUARY 12, 1932

PUBLISHED AUGUST 5, 1932

The failure of organic reactions to give yields approaching the theoretical is well known. Processes which deviate most from the theoretical involve either an apparent metathesis or the elimination of an inorganic molecule such as water, halide acid or nitrogen. These reactions are also the chief source of the rearrangements which have become so common in organic chemistry. In the years since Fittig discovered the pinacolone rearrangement,² countless other rearrangements have been found and many explanations have been evolved.³ These explanations have assumed intermediates including cyclopropane rings, ethylene oxide rings, olefins, univalent nitrogen, bivalent carbon, ordinary ions, bipolar ions and chelate compounds.

The purpose of this paper is to show that rearrangements and the peculiarities of organic "metathetical" reactions have a common mechanism based on the very nature of the "bonds" in organic compounds as contrasted to the ionic attachments in inorganic molecules. All the essentials of the mechanism proposed in this paper are old and are implicit in conceptions of atoms and molecules introduced during the last twenty years by G. N. Lewis, Arthur Michael, Julius Stieglitz, Lauder W. Jones, W. A. Noyes, Hans Meerwein, H. J. Lucas and Charles Prévost. In each

case circumstances limited the application of these conceptions. The time has arrived, however, when the multitude of explanations of organic rearrangements can be discarded and the fact must be realized that these interesting reactions are not merely freaks to be expected from certain complex compounds but are dependent on properties inherent in even the simplest organic molecules. As soon as this important fact is recognized, it will be possible to focus attention on the fundamental changes taking place in all rearrangements instead of considering each type of rearrangement as an isolated exception. Even such simple processes as the formation of tertiary butyl halides from isobutyl alcohol will be found to follow the same course as the pinacolone rearrangement.⁴

The first recognition of the true cause of an intramolecular rearrangement was achieved independently by Julius Stieglitz and Lauder W. Jones about 1913 in connection with the rearrangements of organic nitrogen compounds.⁵ Jones says of the Hofmann conversion of N-bromoamides to isocyanates and amines: "The present mode of viewing the rearrangement would speak of the potency of the carbon atom to lose negative electrons and of the nitrogen atom to acquire them, and would look upon the free valences of univalent nitrogen as the stage setting required to furnish a suitable environment in which the essential action may take place."

In considering the rearrangement of triphenylmethyl hydroxylamine and its relation to the Hofmann, Lossen and Curtius rearrangements, Stieglitz states, "In the formation of water, containing the stable negative hydroxyl, the oxime hydroxyl deprives the nitrogen atom of two electrons. . . ." In 1916, referring to the same types of rearrangements, he said, "In recent years the initial force leading to the rearrangements has been sharply defined, on the basis of the electron theory of valence, as residing in the instability of the charges on the radicals held by nitrogen . . . and to the great tendency of these radicals to go over into their stable forms . . . by absorption of electrons from neighboring atoms. . . ."⁶

The conception of bivalent carbon as an intermediate in rearrangements has been used by many including Nef, Tiffeneau, Lucas and, most recently, Hellerman,⁷ who combines the bivalent carbon assumption with a transfer

⁴ See pp. 3279, 3448.

⁵ Jones, *Am. Chem. J.*, **50**, 441 (1913); Stieglitz and Leech, *THIS JOURNAL*, **36**, 272 (1914); Stieglitz and Stagner, *ibid.*, **38**, 2047 (1916); *Cf. Am. Chem. J.*, **18**, 751 (1896); **29**, 49 (1903); *Proc. Natl. Acad. Sci.*, **1**, 207 (1915).

⁶ After this paper was presented at New Haven, a colleague of Dr. Stieglitz informed the author that similar conceptions had been applied to C—C rearrangements by Dr. Stieglitz in his advanced classes for several years. Since the meeting Dr. Stieglitz has kindly made available unpublished theses by R. B. Cooper, 1930, and G. W. Ayer, 1931, in which oxonium salts of pinacol are prepared and a mechanism for the rearrangement is proposed which is entirely analogous to that of the present paper. See also the Dohme Lecture by Dr. Stieglitz at Johns Hopkins University, February 19, 1932.

⁷ Hellerman, *THIS JOURNAL*, **50**, 1718 (1928).

of electrons. The bivalent carbon mechanism could not be applied to tertiary alcohols or related compounds. P. A. Krueger of this Laboratory has called attention to the fact that the assumption of bivalent carbon will not account for the facts even with a secondary alcohol like pinacolyl alcohol which gives tetramethylethylene and *unsym.*-methylisopropylethylene on dehydration, whereas the assumption of bivalent carbon would indicate tetramethylethylene and *tert.*-butylethylene as the products to be expected.

In recent years Meerwein and his co-workers have added materially to our knowledge of rearrangements and have shown that conditions which favor ionization also favor rearrangement in many cases. In certain cases they have proved that it is the positive ion which undergoes rearrangement rather than the molecule.⁸ The present study is an extension of this work but is not limited to cases in which ordinary ionization is possible.⁹

The English school of organic chemists, including Robinson, Ingold, Shoppee and their students, has long emphasized the dependence of various types of rearrangements on electron transfer within the molecule.¹⁰

The present study involves, then, a fusion and a simplification as well as a more general application of much that has gone before. Most organic molecules which give poor yields of "metathetical" products, or of products obtained by elimination of an inorganic molecule, or which give rearranged products, contain a portion which can be indicated electronically in one of the following ways

in which X is usually oxygen or halogen or other strongly electronegative atom and A, B and D are atoms like carbon and nitrogen which are neither strongly electronegative nor strongly electropositive. In the original compound, each atom has a completed octet of electrons and the linking is due to the shared electrons. These compounds are usually very stable and relatively inactive. They remain so only while all the octets are complete. System (1) is involved in such "two atom" rearrangements, as the pinacolic, the retropinacolic, the Hofmann, the Beckmann and many others, some of which have been named and some of which stand merely as isolated abnormalities of organic chemistry. System (2) is found in many types of allylic or triad rearrangements.

When a molecule containing System (1) is brought into a reaction which results in the *removal of X*¹¹ from its attachment to atom B, then, *regardless*

⁸ Cf. Lipp, *Ber.*, **65**, 242 (1932).

⁹ See p. 3441.

¹⁰ See "Annual Reports of the Chemical Society" since 1923.

¹¹ This point in the present hypothesis called forth much criticism from the referees. In some reactions the first step appears to be an actual ionization (Meerwein) but, more often, it involves the formation of an addition compound such as an oxonium salt which is then decomposed to form the final products. The entire process behaves more

The shift of the electron pair includes the atom or group which it holds.

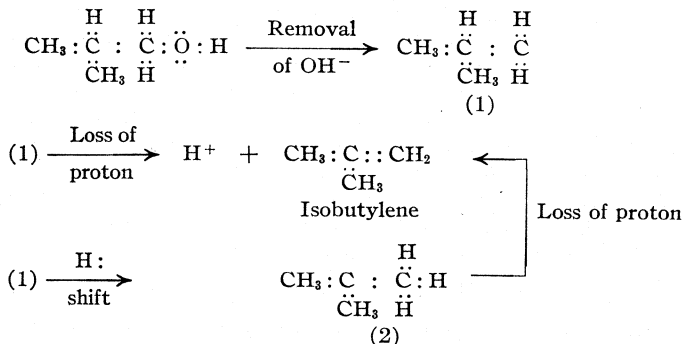

The new fragment can then recombine with the ion X or with a new negative ion Y from the reaction mixture. The result is an "abnormal" or rearranged product, the series of changes being

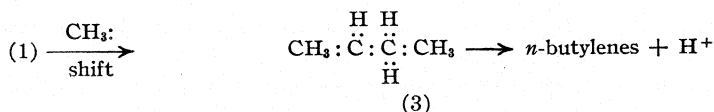

If atom B in the rearranged positive fragment has a hydrogen attached to it, the system may lose a proton. Depending on the other groups attached to A and B, the resulting unsaturated compound may or may not be identical with that obtained by the loss of a proton from the original fragment. It is important to note that the shift of electrons within the positive fragment and the stabilization by loss of a proton are *monomolecular* processes which may effectively compete with the *bimolecular* union of the original or the rearranged fragment with an ion from the reaction mixture. Thus the formation of considerable amounts of abnormal products is to be expected.

A study of these fundamental changes shows that processes in which a strongly electronegative atom or group is *removed* from an organic molecule during a reaction may readily give products other than those of simple metathetical or elimination reactions. Such a conclusion agrees with the facts. This simple mechanism fits all types of rearrangements which involve the transfer of an atom or group from one atom to an adjacent one. Its application is shown by the following examples.

The dehydration of isobutyl alcohol gives *normal* butylenes as well as the expected isobutylene.¹⁴

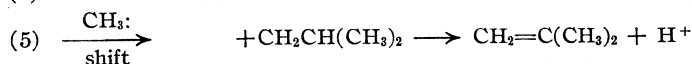

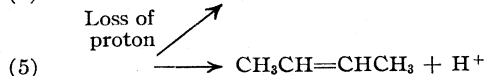

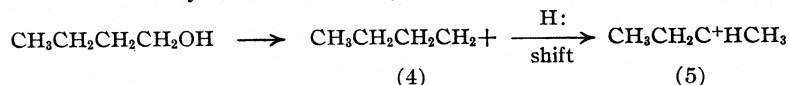

¹⁴ Nevole, *Bull. soc. chim.*, [2] **24**, 122 (1875); Le Bel and Greene, *ibid.*, [2] **29**, 306 (1878); *Am. Chem. J.*, **2**, 23 (1880); Konowalow, *Ber.*, **13**, 2395 (1880); *Bull. soc. chim.*, [2] **34**, 333 (1880); Faworski and Debout, *J. prakt. Chem.*, [2] **42**, 153 (1890); Wislicenus and Schmidt, *Ann.*, **313**, 210 (1900); Nef, *ibid.*, **318**, 211 (1901); Ipatiew, *Ber.*, **35**, 1061 (1902); **36**, 1997, 2011 (1903); Senderens, *Bull. soc. chim.*, [4] **1**, 693 (1907); *Ann. chim. phys.*, [8] **25**, 497 (1912); similar results have been obtained in this Laboratory by J. C. Mitchell using a phosphoric acid catalyst at 250°.

In a similar way isobutyl iodide reacts with lead oxide to give both isobutylene and butene-2.¹⁵

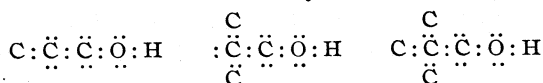

If instead of dehydrating isobutyl alcohol, it is treated with hydrobromic acid, the product is not pure isobutyl bromide but contains tertiary butyl bromide (Michael). Under the conditions, only fragments (1) and (2) are formed in effective amounts. In other words, only hydrogen rearranges. At higher temperatures and with dehydrating catalysts fragment (3) is formed in large amounts by the shift of a methyl.

The dehydration of *normal* butyl alcohol gives isobutylene and all three normal butylenes instead of only the expected butene-1.¹⁶ The probable steps in this process follow. For the sake of simplicity the atom in an open sextet is indicated by a + without any assumption as to its ionic properties.

Exactly similar changes take place during the dehydration of secondary butylcarbinol to give mainly trimethylethylene and small amounts of pentene-2 and *unsym.*-methylethylethylene.¹⁷

The tendency to rearrangement increases with the number of carbon atoms attached to "A" in the two atom system.

Thus compounds containing the last of these systems, the "neopentyl alcohol" system, give mainly rearrangement products in any reaction in which the hydroxyl is removed. They give esters of organic acids without rearrangement but all attempts to replace the hydroxyl by halogen lead to rearranged products.¹⁸ Thus neopentyl alcohol itself (tertiary butylcar-

¹⁵ Eltekow, *Ber.*, **13**, 2404 (1880).

¹⁶ Senderens, *Bull. soc. chim.*, [4] **1**, 692 (1907). Lucas was unable to obtain any isobutylene from butanol-1 or -2 (private communication).

¹⁷ Wischnegradsky, *Ann.*, **190**, 350 (1877); Étard, *Compt. rend.*, **86**, 488 (1878); Kondakow, *Ber.*, **25**, Ref. 570 (1892); Tissier, *Ann. chim. phys.*, [6] **29**, 326 (1893).

¹⁸ Beilstein, 4th ed., Vol. I, p. 152, Spl. Vol. I, p. 54; Edgar, Calingaert and Marker, *THIS JOURNAL*, **51**, 1487 (1929).

binol) gives tertiary amyl halides and olefins formed from the rearranged fragment. The alcohol of this type which has been most studied is pinacolyl alcohol (methyl-tertiary-butylcarbinol) which gives none of the expected tertiary butylethylene on dehydration but only the rearranged products, tetramethylethylene and *unsym.*-methylisopropylethylene. Attempts to convert pinacolyl alcohol to the corresponding halide also give only rearranged products.¹⁹

An even more surprising failure to give a "normal" dehydration is shown by isopropyl-tertiary-butylcarbinol²⁰ which gives none of the expected product, 2,2,4-trimethylpentene-3.²¹ In this case, the loss of a tertiary hydrogen to give an olefin is more difficult than the shift of a methyl group and its electron pair from the neopentyl system. A case in which the hydroxyl of the neopentyl alcohol system is tertiary and has no alpha hydrogens is presented by diphenyl-tertiary-butylcarbinol.²² This substance is dehydrated with extraordinary ease to give 2,2-diphenyl-3-methylbutene-3 with the shift of a methyl group. On the other hand, a purely aliphatic neopentyl alcohol with a tertiary hydroxyl, methylethyltertiarybutylcarbinol²³ gives the "normal" dehydration product, and a lesser amount of the rearranged product.

The rearrangement of borneol to camphene and the many similar rearrangements in the terpene and other series studied so brilliantly by Meerwein follow this same course.²⁴ In each case the open sextet left after removal of the hydroxyl or halogen is completed by the transfer of an electron pair from an adjacent carbon with the corresponding shift of a carbon-carbon linkage.

The pinacolone rearrangement and rearrangements of other types of glycols, iodohydrins and related compounds follow a similar course. The more reactive hydroxyl or halogen atom is removed in the course of the reaction, leaving an open sextet which is completed by a rearrangement. An interesting variant of this reaction is the conversion of isobutylene dibromide and trimethylethylene dibromide into isobutyraldehyde and methyl isopropyl ketone by merely heating with water.²⁵ In each case the

¹⁹ These results with neopentyl alcohol and pinacolyl alcohol have been entirely confirmed in this Laboratory, see p. 3431.

tertiary bromine is removed with its octet and a hydrogen with its electron pair shifts.

The conversion of aliphatic amines to alcohols by treatment with nitrous acid is unusually subject to side reactions.²⁶ Thus isobutylamine gives mainly tertiary butyl alcohol and isobutylene.²⁷ In this case the intermediate product loses a hydroxyl or other ion with a complete octet and a nitrogen molecule with its ten electrons, thus leaving a carbon with an open sextet which makes possible the usual rearrangement.²⁸ Interesting cases of this rearrangement are the conversion of cyclopropylamine into allyl alcohol by nitrous acid²⁹ and the Demjanow rearrangement³⁰ which has recently been shown by Fuson³¹ to take place with aliphatic as well as with alicyclic amines.

The rearrangements of Hofmann, Lossen, Curtius and Beckmann all involve the system

If *X* is removed with its octet in the course of the reaction, a rearrangement of *R:* takes place in the usual way.³²

The resulting product, depending on the groups involved and the conditions of the reaction, is an isocyanate, an amine, or a substituted amine. In certain types of compounds, *X* is sometimes removed with only a sextet of electrons (as positive halogen by hydrolysis) and the remaining fragment has a complete octet and consequently cannot rearrange. J. G. Aston of this Laboratory was the first to recognize that the shifting group in the Hofmann and related rearrangements cannot rearrange internally during its transfer from carbon to nitrogen because it has its full complement of electrons during this transfer. This prediction has been strikingly confirmed in the case of the amide of *tert.*-butylacetic acid.³³

Although rearrangement of compounds containing carbonyl groups and no group corresponding to the *X* in the systems discussed so far might be expected to follow a very different course, such may not be the case. The only difference is that an atom with an open sextet may be formed by

³² In the Curtius rearrangement of acid azides, triarylmethyl azides and benzyl azide, *X* is a pair of nitrogen atoms with ten electrons.

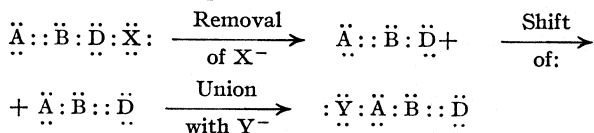

³³ See p. 3436.

the *addition* of a positive ion instead of by the *removal* of a negative ion. Thus the first step in the benzylic acid rearrangement becomes

The carbon with the open sextet then attracts the electron pair and phenyl group from the adjacent carbon. Addition of an hydroxyl ion to the rearranged fragment converts it to benzylic acid. A similar result is obtained in the conversion of trisubstituted acetaldehydes to ketones by concentrated sulfuric acid.³⁴ The initial addition product of the aldehyde with a proton undergoes rearrangement because of an open sextet and then loses a proton to give the enolic form of the ketone.

The rearrangements in triad systems which have been studied so intensively in recent years, especially by the English school of organic chemists, involve similar changes.³⁵ Thus

My sincere thanks are due my colleagues, J. G. Aston, P. A. Krueger and R. V. McGrew, for their help and criticisms in the development of this work. Special recognition is due Dr. McGrew for his help in the direction of the experimental studies on which the accompanying papers are based.³⁶

Summary

Many of the "abnormal" reactions of organic chemistry, including most intramolecular rearrangements, are correlated by the following simple assumptions.

1. A non-ionic attachment between an atom like carbon or nitrogen and an electronegative atom or group is *broken during the reaction*.
2. At the instant of removal of the electronegative group, it takes a completed octet of electrons with it.
3. The atom which had shared an electron pair with the electronegative group is thus left with only a sextet of electrons.
4. This deficiency of two electrons may induce a migration of an electron pair from an adjacent atom, thus giving rise to "abnormal" or rearranged products.

³⁴ Tiffeneau and Orékhoff, *Compt. rend.*, **182**, 67 (1926); Danilov, *Ber.*, **60**, 2390 (1927); Ramart-Lucas and Guerlain, *Bull. soc. chim.*, [4] **49**, 1860 (1931).

³⁵ For summaries and references see Prévost, *Compt. rend.*, **184**, 1460 (1927); Ingold and Burton, *J. Chem. Soc.*, 904 (1928); Ingold and Shoppee, *ibid.*, 1199 (1929); Ingold, *ibid.*, 2752 (1931).

³⁶ See pp. 3431-3454.

5. In the case of carbonyl compounds a carbon with an open sextet may be formed by the addition of a positive ion to the oxygen. In this case also the presence of the open sextet induces rearrangement.

6. The application of these simple principles is already proving helpful in experimental studies of "abnormal" reactions of simple aliphatic compounds.

ACYL DERIVATIVES OF ORTHO-AMINOPHENOL. I

BY C. B. POLLARD, C. E. SPARKS AND M. L. MOORE

RECEIVED MARCH 4, 1932

PUBLISHED AUGUST 5, 1932

When diacyl derivatives of *o*-aminophenol were prepared by the usual methods, it was found in many cases that the order of introduction of the two different acyl groups has no influence upon the formation of the diacyl, identical products being isolated from the two acylations. The position of the acyl groups can be determined by removing the groups attached to the oxygen by saponification with dilute alkali, and determining from the physical constants of the remaining monoacylated product the group attached to the nitrogen. The identical diacyls mentioned above were found to saponify to yield identical products, as would be expected.

The formation of identical rather than isomeric products on reversing the order of acylation indicated that during acylation a rearrangement must have occurred in one of the two cases. The formation of isomeric diacyls and the production of the same saponification product indicate that a rearrangement must have occurred during saponification. Some evidence has indicated that certain acyl groups have more power than others to bring about this migration, weight and acidity of the groups being considered to have the predominating influence in their obtaining a position in the more basic amino group.

Previous work on this subject by Ransom,¹ Ransom and Nelson,² Nelson and Rothrock,³ and Raiford and Clark⁴ is discussed in the literature.

The work of Pollard and Nelson,⁵ using phenylacetyl chloride as one of the acylating agents in each diacyl throughout a series of experiments, indicated that relative acidity and weight are not the controlling factors in this type of rearrangement.

⁴ Raiford and Clark, *ibid.*, **48**, 483 (1926).

⁵ Pollard and Nelson, *ibid.*, **53**, 996 (1931). A more extensive bibliography is given in this article.

To determine whether similar results would be obtained by using the hydrocinnamyl group as a constant was the purpose of this investigation. Hydrocinnamyl chloride was used as one of the acylating agents in the preparation of all diacyl derivatives of *o*-aminophenol in these experiments. This selection afforded a rather heavy group and one which is appreciably acidic in nature to check against the acetyl, propionyl, valeryl, isovaleryl, phenylacetyl and benzoyl groups.

When *o*-hydrocinnamylaminophenol was acylated with acetyl chloride, a diacyl melting at 79.5–81° was produced, while the acylation of *o*-acetylaminophenol with hydrocinnamyl chloride gave a diacyl melting at 124.5–126°. Saponification of each of these diacyls produced only *o*-hydrocinnamylaminophenol, indicating that in the latter case migration of the hydrocinnamyl group from the oxygen to the nitrogen must have occurred. Similar results were obtained with diacyls containing, respectively, the valeryl, isovaleryl and benzoyl groups. The saponification of these isomers involved rearrangements in which the hydrocinnamyl group replaced the lighter and less acidic valeryl and isovaleryl and the lighter and more acidic benzoyl group.

o-Hydrocinnamylaminophenol acylated with propionyl chloride gave a diacyl melting at 113.5–115.5°, while the acylation of *o*-propionylaminophenol with hydrocinnamyl chloride gave a diacyl melting at 102.5–104.5°. A mixture of these two products melted at 110–115°, indicating that each might be an equilibrium mixture of the two possible diacyls. However, each product gave only *o*-hydrocinnamylaminophenol on saponification.

Acylation of *o*-hydrocinnamylaminophenol with phenylacetyl chloride gave a diacyl melting at 90–92°, while acylation of *o*-phenylacetylaminophenol with hydrocinnamyl chloride gave a diacyl melting at 81–83°. A mixture of these two products melted at 67–70°, showing the two to be different. Saponification of each of these diacyls gave approximately 60% *o*-hydrocinnamylaminophenol and 40% *o*-phenylacetylaminophenol, showing that a partial rearrangement occurred.

Experimental

o-Hydrocinnamylaminophenol was prepared by the method of Groenvik⁶ using *o*-aminophenol and the acid chloride. Its properties are summarized below.

Formula	M. p., °C.	Yield, %	Analysis, N, %	
			Calcd.	Found
$\text{HOC}_6\text{H}_4\text{NHCOCH}_2\text{CH}_2\text{C}_6\text{H}_5$	131.5–132	70	5.81	5.65

The other monoacyls used, which have been described previously, were made by the same method.

***o*-Hydrocinnamylaminophenyl Acetate** ($\text{C}_6\text{H}_5\text{CH}_2\text{CH}_2\text{CONHC}_6\text{H}_4\text{OCOCH}_3$).—To 5 g. of *o*-hydrocinnamylaminophenol an excess of acetyl chloride was added. After the addition of a drop of sulfuric acid, the mixture was stirred and heated on the water-bath

⁶ Groenvik, *Bull. soc. chim.*, [2] 25, 173 (1876).

for three hours. A brown oil formed which was washed well with hot water and upon cooling in an ice bath solidified. This brown solid was dissolved in hot 90% alcohol and filtered. Repeated crystallizations from dilute alcohol gave light tan crystals melting at 79.5–81°.

About 1 g. of this compound was saponified in the equivalent quantity of 10% potassium hydroxide. After complete solution resulted, the solution was filtered and acidified with dilute hydrochloric acid. A flesh-colored precipitate formed which was filtered, washed and crystallized from dilute alcohol. These crystals melted at 129.5–131° and when mixed with *o*-hydrocinnamylaminophenol (m. p. 131.5–132°) melted at 130–131.5°, showing them to be the same.

***o*-Acetylaminophenyl Hydrocinnamate** ($\text{CH}_3\text{COHNC}_6\text{H}_5\text{OCOCH}_2\text{CH}_2\text{C}_6\text{H}_5$).—A slight excess of hydrocinnamyl chloride was added to 6 g. of *o*-acetylaminophenol. A drop of sulfuric acid was added, the mixture stirred and heated on the water-bath for two hours. A light brown oil formed which was washed well with hot water and cooled in an ice-bath. On standing the oil solidified. The solid was dissolved in hot alcohol and on cooling formed light pink flakes. These were recrystallized from dilute alcohol and then from toluene. These crystals melted at 124.5–126°.

10	81–83	45	3.90	4.05	60% $\text{C}_6\text{H}_5\text{CH}_2\text{CH}_2\text{CONHC}_6\text{H}_5\text{OH}$ 40% $\text{C}_6\text{H}_5\text{CH}_2\text{CONHC}_6\text{H}_5\text{OH}$
11	116.5–118.5	55	4.06	4.05	$\text{C}_6\text{H}_5\text{CH}_2\text{CH}_2\text{CONHC}_6\text{H}_5\text{OH}$
12	122.5–124.5	44	4.06	4.20	$\text{C}_6\text{H}_5\text{CH}_2\text{CH}_2\text{CONHC}_6\text{H}_5\text{OH}$

This diacyl was saponified in approximately the same manner as the preceding one and yielded *o*-hydrocinnamylaminophenol. A rearrangement must have occurred during saponification.

All diacyl derivatives of *o*-aminophenol were made by the method described above using the monoacyl, the acid chloride and a drop of sulfuric acid, which is a modification of the method of Jacobs, Heidelberger and Rolf.⁷ The properties of all of these diacyls are summarized in Table I.

The melting points in the cases of two pairs of isomers listed above as 5, 6, 11 and 12 might indicate the possibility that in each case they were identical substances in an impure state, but the facts that each substance appeared to be homogeneous and the melting points of the mixtures were decidedly lower lead to the conclusion that they were isomers.

Mixed melting point of 5 and 6	52-54°
Mixed melting point of 11 and 12	90-93°

Summary

A study of the diacyl derivatives of *o*-aminophenol, when one of the acyl groups was always the hydrocinnamyl radical, has been made. The hydrocinnamyl group was checked against the acetyl, propionyl, valeryl, isovaleryl, phenylacetyl and benzoyl groups.

In five cases out of six, isomers were obtained depending on the order of introduction of the acyl groups.

In five cases out of six, complete rearrangement occurred during saponification and one case showed partial rearrangement. When complete rearrangement did occur the nitrogen atom was shown to be attached to the heavier and more acidic group in four cases and to the heavier and less acidic in one case.

In the case where partial rearrangement occurred during saponification, the saponification products showed 60% of the nitrogen to be attached to the heavier and less acidic group and 40% to be attached to the lighter and more acidic group.

New mono and diacyl derivatives of *o*-aminophenol have been made and studied.

STUDIES OF ORGANIC LEAD COMPOUNDS. III. THE REACTION OF ORGANIC LEAD SALTS ON MERCURY AND LEAD ARYLS

BY PAUL R. AUSTIN¹

RECEIVED MARCH 7, 1932

PUBLISHED AUGUST 5, 1932

Various metallic and organo-metallic halides have been arylated by means of mercury derivatives² and it was thought that this reaction might be utilized in the synthesis of organic lead compounds as follows

Diphenyllead dichloride and diphenylmercury heated in pyridine gave a 21% yield of triphenyllead chloride. Phenylmercuric chloride was easier to isolate and a 57% yield was obtained. When the following reaction $(o-C_7H_7)_2PbCl_2 + (C_6H_5)_2Hg \longrightarrow (o-C_7H_7)_2(C_6H_5)PbCl + (C_6H_5)HgCl$, was carried out in an attempt to obtain mixed compounds, phenylmercuric chloride was obtained in a 38% yield, but the expected phenyldi-*o*-tolyllead chloride could not be isolated from the mixture of reaction products. A small amount of diphenyllead dichloride which was isolated indicated that a further reaction had taken place.

Triphenyllead chloride when refluxed with diphenyl- or dibenzylmercury in a variety of solvents did not react. A small amount of tetraphenyllead was formed in every case, but a study of the decomposition of trialkyl and triaryl lead halides on heating showed that the tetraphenyllead resulted from disproportionation according to the equation

a type of reaction which has been previously observed in the pyrolysis of triethyllead bromide³ and triphenyltin hydroxide.⁴ Triphenyllead chloride heated in butyl alcohol yielded about 10% of the expected compounds. Similar results were obtained when triethyllead chloride was heated in toluene or benzene. These yields suggested that the reaction might be reversible when carried out in organic solvents. This was found to be the case and tetraphenyllead and diphenyllead dichloride heated in butyl alcohol gave an 86% yield of triphenyllead chloride. Tetraethyllead and diethyllead dichloride heated in benzene gave a 39% yield of triethyllead chloride. Tetraphenyllead and di-*o*-tolyllead dihalides heated in benzene or toluene in an attempt to form a mixed aryl lead halide did not react.

⁴ Chambers and Scherer, *THIS JOURNAL*, **48**, 1056 (1926).

Experimental Part

Diphenyllead Dichloride and Diphenylmercury.—Four and five-tenths grams of diphenyllead dichloride and 3.5 g. of diphenylmercury in 75 cc. of pyridine were refluxed for ten hours. After cooling and filtering, the pyridine mother liquor was concentrated by distillation and then water was added to throw out the product. This was almost completely soluble in hot alcohol and on cooling gave 1.8 g. of crude phenylmercuric chloride which on recrystallization from alcohol melted at 250–252°. The product obtained on concentration of the alcohol mother liquor above was fractionated from alcohol or petroleum ether. One gram of triphenyllead chloride was obtained which after recrystallization from alcohol melted at 204–205°.

Di-*o*-tolyllead Dichloride and Diphenylmercury.—Di-*o*-tolyllead dichloride and diphenylmercury (4.6 g. and 3.5 g., respectively), in 200 cc. of alcohol were refluxed for six hours. The solution was concentrated and the reaction products separated by fractional crystallization first from alcohol and then from petroleum ether. There was obtained 1.2 g. of phenylmercuric chloride, m. p. 251–252°, and 0.5 g. of what was shown to be diphenyllead dichloride by halogen analysis and solubility behavior. Exhaustive fractionation of the remainder of the material failed to yield any other product which could be identified. The expected reaction product, phenyldi-*o*-tolyllead chloride, was prepared by a separate synthesis and its solubility and behavior on heating studied in order that it might not be overlooked.

Phenyldi-*o*-tolyllead Chloride.—This compound was prepared in a 70% yield from the bromide using the general procedure described for triphenyllead acetate.⁵ It was recrystallized from ligroin or aqueous alcohol and melted at 113–114°.

Anal. Calcd. for $C_6H_5(C_7H_7)_2PbCl$: Pb, 41.29; Cl, 7.07. Found: Pb, 41.54; Cl, 6.77.

A small amount of the compound was refluxed in benzene and in alcohol for six hours and in each case it was recovered unchanged.

Disproportionation of Triphenyllead Chloride.—Five grams of triphenyllead chloride in 100 cc. of butyl alcohol was refluxed for six hours. Filtration gave 0.2 g. of an organic material which was undoubtedly diphenyllead dichloride. The solution on cooling gave 4 g. of product. Extraction with three 50-cc. portions of alcohol left 0.3 g. of tetraphenyllead which after recrystallization from benzene melted at 222–223°.

Disproportionation of Triethyllead Chloride.—Thirty-three grams of triethyllead chloride in 100 cc. of toluene was refluxed for five hours. Filtration gave 3 g. of insoluble material which was shown by analysis to be largely lead chloride. Most of the toluene was distilled and was replaced by petroleum ether. From this there was recovered 21.8 g. of triethyllead chloride and concentration of the filtrate gave 3.5 g. of an oil which was undoubtedly tetraethyllead. It was distilled under diminished pressure in an atmosphere of carbon dioxide and the index of refraction and density corresponded closely to the known values.

Tetraphenyllead and Diphenyllead Dichloride.—Five and one-tenth grams of tetraphenyllead and 4.3 g. of diphenyllead dichloride were dissolved and suspended in 250 cc. of butyl alcohol. The mixture was refluxed for eighteen hours and then filtered. The crude product obtained from the filtrate was recrystallized from alcohol and gave 8.1 g. of triphenyllead chloride, m. p. 202°.

Tetraethyllead and Diethyllead Dichloride.—Sixteen grams of tetraethyllead and 17 g. of diethyllead dichloride were dissolved and suspended in 100 cc. of benzene and refluxed for five hours. The mixture was filtered and most of the benzene was removed from the filtrate by distillation and was then replaced by petroleum ether.

⁵ Austin, *THIS JOURNAL*, **53**, 3517 (1931).

The hot solution was clear and on cooling gave 13 g. of what was shown by halogen analysis and melting point to be triethyllead chloride.

The author is indebted to Professor C. S. Marvel for many helpful suggestions.

Summary

Diaryl lead dichlorides react in some cases with mercury diaryls to form the aryl mercuric chloride and a triaryl lead chloride.

Triaryl or alkyl lead halides disproportionate on heating to form a tetra-substituted lead derivative and a disubstituted lead dihalide. Diaryl or alkyl lead dihalides react with their corresponding tetraaryl or alkyl derivatives to form trisubstituted lead halides in good yields.

SUBSTITUTION PRODUCTS OF ALPHA-NAPHTHOYL-ORTHO-BENZOIC ACID

BY E. H. JOHNSON,¹ V. WEINMAYR² AND ROGER ADAMS

RECEIVED MARCH 18, 1932

PUBLISHED AUGUST 5, 1932

The formation of anthraquinone and its substitution products through the condensation of phthalic anhydride with benzene and its derivatives has found wide commercial application. Among the variations of this general procedure certain substituted anthraquinones, otherwise difficult to obtain, can be prepared by substituting the intermediate benzoyl-*o*-benzoic acids and subsequently closing the ring to the anthraquinone.

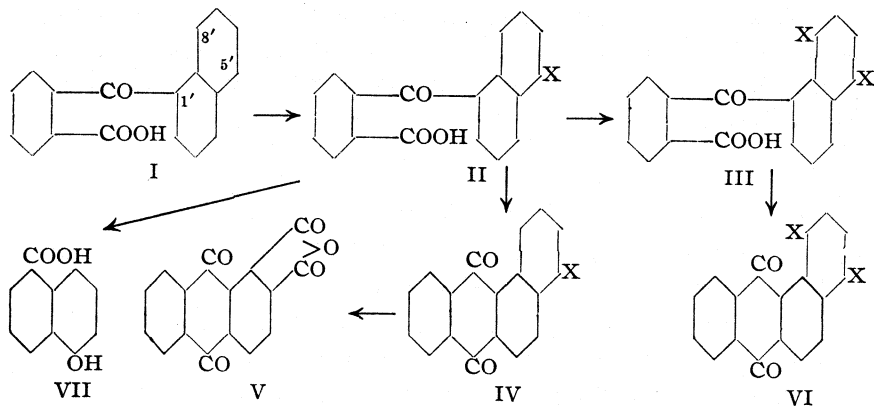

Benzanthraquinones have likewise been prepared from phthalic anhydride or substituted phthalic anhydrides with naphthalene or substituted naphthalenes,³ though more difficulties are encountered so far as isomers are concerned than appear in the benzene series. The substitution of the intermediate α -naphthoyl-*o*-benzoic acids with subsequent conversion to the benzantraquinones, however, has not been previously described. A number of such reactions are reported in this communication.

¹ This communication is an abstract of a thesis submitted by E. H. Johnson in partial fulfilment of the requirements for the degree of Doctor of Philosophy in Chemistry at the University of Illinois.

² Dr. V. Weinmayr, in the Laboratories of the Organic Chemicals Department, Dyestuffs Division of the du Pont Company, carried out the experiments on the chlorine derivatives.

α -Naphthoyl-*o*-benzoic acid (I) was readily chlorinated or brominated in glacial acetic acid either to a monochloro or monobromo (II) derivative. By further halogenation of the monohalogen products or by using two molecular equivalents of halogen with the α -naphthoyl-*o*-benzoic acid, dihalogen substitution products (III) resulted. With sulfuric acid as a solvent, the reaction proceeds rapidly toward the production of the dihalogen compound without stopping at the monohalogen state.

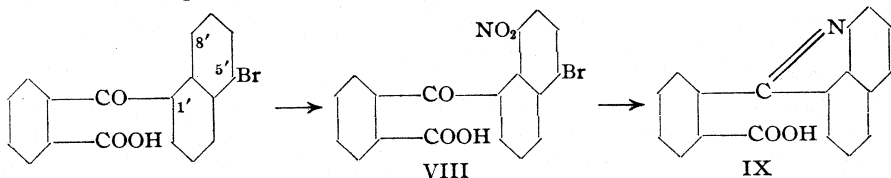

The position of the monosubstituted bromine compound was established. Upon oxidation with potassium permanganate of the bromo-1,2-benzanthraquinone (IV) obtained by ring closure of the bromo- α -naphthoyl-*o*-benzoic acid, anthraquinone-1,2-dicarboxylic acid anhydride (V) resulted which indicated that the bromine must be located in the original naphthalene nucleus. Its exact position was shown by fusing the bromo- α -naphthoyl-*o*-benzoic acid (II) with a mixture of sodium and potassium hydroxide at 200°. From the fusion 5-hydroxy-1-naphthoic acid (VII) was isolated and identified by its melting point and the melting point of its acetyl derivative, thus showing the original compound to be 5'-bromo-1'-naphthoyl-2-benzoic acid. It is fair to assume that the chlorine occupies the same position. The positions 5', 8' might be expected for the dihalogen compounds and by analogy to the structure of the nitro compounds discussed below these positions appear reasonably certain.

The monochloro- or bromo-1'-naphthoyl-2-benzoic acids were readily converted to the corresponding benzantraquinones (IV) by means of sulfuric acid with or without boric acid. The dihalogen compounds were, in a similar manner, converted to benzantraquinones (VI). A single dibromobenzanthraquinone was isolated, but from the dichloronaphthoyl-benzoic acid, two isomeric dichlorobenzanthraquinones were obtained. It would appear that during the dehydration, migration of the halogens must have occurred to some extent. As a consequence, the exact structure of these dihalogen benzantraquinones is not certain. It is probable,

however, that the dibromo and one of the dichloro compounds are 5', 8' disubstitution products.

The chloro- and bromo-1'-naphthoyl-2-benzoic acids were nitrated to mononitro derivatives (VIII). The 8'-position for this nitro group might be anticipated and subsequent experiments showed this to be the case. Upon reduction, the nitrobromo-1'-naphthoyl-2-benzoic acid gave a product, not an amine but obviously a secondary product (IX) acid in character with water eliminated. This could have formed only if the nitro were in the 8' position. This is a product analogous to that reported by

Scholl and Wolodkowitsch⁴ upon reduction of bz-1-nitro-1,2-benzanthraquinone.

The 5'-bromo-1'-naphthoyl-2-benzoic acid may also be nitrated in acetic anhydride. Under these conditions the product proved to be a dinitro- α -naphthoyl-*o*-benzoic acid. Bromine had been eliminated completely. It seems probable that the first nitro group was introduced in the 8'-position as in the mononitro monobromo compound, and since the bromine is eliminated, it is a natural conclusion that the second nitro has probably taken its place, leading to 5',8'-dinitro-1'-naphthoyl-2-benzoic acid.

Experimental

α -Naphthoyl-*o*-benzoic Acid.—This product was made by the procedure of Heller and Schulke⁵ as modified by Groggins and Newton.⁶ The only modification which was followed was in the purification. It was found that, in the laboratory at least, it could be crystallized readily from a large volume of toluene and purified much more readily than through the ammonium salt as previously recommended. The crude material obtained by following directions specified gave a product melting at 153–165° which, upon two recrystallizations from toluene gave a melting point of 173–173.5°. By evaporating the toluene mother liquors from the crystallizations there was no difficulty in recovering essentially all of the α -naphthoyl-*o*-benzoic acid present.

5'-Bromo-1'-naphthoyl-2-benzoic Acid (II).—To 100 g. of α -naphthoyl-*o*-benzoic acid in a 500-cc., round-bottomed flask fitted with a glass-jointed reflux condenser, were added 100 cc. of glacial acetic acid and 36 cc. (115 g.) of bromine and the mixture was refluxed for four hours. The reaction mixture was then cooled in an ice-salt bath until it had all solidified. On warming the flask to room temperature, a precipitate of 5'-bromo-1'-naphthoyl-2-benzoic acid was present. This was filtered out and dried; yield, 89.2 g. (69.5%). The compound was purified by two recrystallizations from toluene, m. p. 203–204°.

Anal. Calcd. for $C_{18}H_{11}O_3Br$: neut. equiv., 355; Br, 22.51. Found: neut. equiv., 350; Br, 22.35.

5',8'-Dibromo-1'-naphthoyl-2-benzoic Acid.—In a mortar 5 g. of pure α -naphthoyl-*o*-benzoic acid was ground with a trace of ferric chloride and a trace of iron powder and placed in a 125-cc. Erlenmeyer flask. Five cc. of bromine was allowed to drop slowly onto this mixture. After the bromine was all added, the reaction mixture was allowed to stand for three to four hours at room temperature and was then treated with dilute sodium hydroxide solution. All of the product dissolved in the boiling solution leaving a residue of ferric hydroxide. This was filtered off and on cooling a small amount of the sodium salt precipitated. The solution was acidified with dilute hydrochloric acid and a white precipitate was produced; yield, 4.5 g. (57.3%). The dibromo compound was purified by crystallization from toluene or glacial acetic acid. It formed fine white needles, m. p. 260–261°.

Anal. Calcd. for $C_{18}H_{10}O_3Br_2$: Br, 36.84. Found: Br, 36.72.

An alternate procedure is to dissolve 276 g. of α -naphthoyl-*o*-benzoic acid in 1370 g. of 93% sulfuric acid at 50°, and to add 160 g. of bromine slowly at this temperature, which is maintained for twenty-two hours longer. The temperature is then raised slowly to 70° to complete the reaction. The mass is now poured into 4 liters of ice water and the yellow precipitate is filtered and washed. The cake is extracted with dilute sodium hydroxide (to separate it from a considerable amount of ring-closed product) and the clear solution is run into ice and acid. The product is purified as described above and melts at 260–261°. The mixed melting point of the products made by the two methods was unchanged.

Anal. Calcd. for $C_{18}H_{10}O_3Br_2$: Br, 36.84. Found: Br, 36.68.

Proof of the Position of Bromine Atom in Bromo- α -naphthoyl-*o*-benzoic Acid

1. Oxidation⁷ of the Benzantraquinone from Bromo- α -naphthoyl-*o*-benzoic Acid.—A solution of 10 g. of monobromobenzantraquinone in 160 g. of concentrated sulfuric acid was poured into 400 cc. of water so that the product was precipitated in a finely divided form. This suspension was then heated to boiling and 75 g. of potassium permanganate was added in small portions. This was followed by solid oxalic acid until the black color was entirely gone. The hot solution was filtered, leaving a light yellow residue on the filter paper. More of this light colored solid precipitated when the hot filtrate had cooled. The precipitate from the hot filtration was treated with dilute aqueous ammonia, filtered, then acidified, when fine needles precipitated. This precipitate was then united with the one obtained from the cooling of the original oxidation solution and recrystallized twice from acetic anhydride (V). Light yellow needles were formed, m. p. 322–324°. This substance was shown to be anthraquinone-1,2-dicarboxylic acid anhydride by comparing it with an authentic sample prepared by oxidation of 1,2-benzantraquinone.⁷

2. 5-Hydroxy-1-naphthoic Acid by Fusion of Monobromo- α -naphthoyl-*o*-benzoic Acid with Potassium Hydroxide.—A mixture of 100 g. of sodium hydroxide, 100 g. of potassium hydroxide, and 25 g. of potassium nitrate was placed in a 500-cc., two-necked flask and heated until melting took place. A stirrer and condenser were placed in the center neck while a thermometer was placed in the side-neck. The stirrer was started and the flask was cooled to 200°. This temperature was maintained throughout the reaction. With continuous stirring 10 g. of bromo- α -naphthoyl-*o*-benzoic acid was added in small portions. When all had been added, the reaction mixture was stirred for fifteen minutes longer and then allowed to cool. The melt was dissolved in

⁷ General Method of Scholl and Schwinger, *Ber.*, **44**, 2992 (1911); Scholl and Graz, German Patent 241,624.

water and poured into a large volume of iced dilute hydrochloric acid. This solution was then extracted with ether. The ether extract was evaporated to a small volume and poured into a large volume of petroleum ether. A reddish-purple tar was precipitated. The liquid was decanted after standing, during which more tar appeared, was decanted again and then evaporated to dryness. The yellow residue thus obtained was dissolved in boiling water and treated with norite for a few minutes. The solution was filtered while hot and on cooling a white precipitate appeared. This was recrystallized twice from water to a constant m. p. of 236–237°. This is the melting point given in the literature for 5-hydroxy-1-naphthoic acid (VII).⁸

Some of this precipitate was then refluxed for two hours with acetic anhydride. The acetic anhydride was distilled off under reduced pressure and the resulting residue was recrystallized three times from water. It was a white solid, m. p. 198–201°. This is the melting point of the acetyl derivative of 5-hydroxy-1-naphthoic acid.⁸

5'-Chloro-1'-naphthoyl-2-benzoic Acid.—A solution of 414 g. of α -naphthoyl-*o*-benzoic acid in 500 g. of glacial acetic acid was treated at 114–118° with chlorine gas until it increased in weight by about 53 g. The red solution was poured onto a large amount of ice and water and the precipitate filtered. It weighed 440 g. (94.4%). White crystals, m. p. 179–180°, formed after purification from toluene.

Anal. Calcd. for $C_{18}H_{11}O_3Cl$: Cl, 11.42. Found: Cl, 11.35.

5',8'-Dichloro-1'-naphthoyl-2-benzoic Acid.—Into a solution of 276 g. of α -naphthoyl-*o*-benzoic acid in 1370 g. of 93% sulfuric acid at 30–70°, chlorine was passed until it had gained 87 g. in weight. The solution was then poured onto ice and water. The filtered mass was extracted with hot dilute sodium hydroxide, which left about 92 g. of chlorinated benzantraquinones. The alkaline solution was acidified and the product recrystallized from glacial acetic acid. White crystals of 5',8'-dichloro-1'-naphthoyl-2-benzoic acid, m. p. 242°, were obtained.

Anal. Calcd. for $C_{18}H_{10}O_3Cl_2$: Cl, 20.60. Found: Cl, 20.54.

The chlorination in glacial acetic acid gives the same dichloro compound as the chlorination in sulfuric acid but in much poorer yields.

Halogenated 1,2-Benzanthraquinones

Bz-4-bromo-1,2-benzanthraquinone (IV).—A solution of 20 g. of 5'-bromo-1'-naphthoyl-2-benzoic acid in 400 cc. of concentrated sulfuric acid was heated for exactly fifteen minutes at 115–117° and then was poured into a large volume of ice and water. The total reaction time was twenty minutes. A yellow precipitate was produced which was filtered off and treated with dilute sodium hydroxide solution to dissolve any unreacted material. The product was recrystallized from glacial acetic acid and gave greenish-yellow bulky needles, m. p. 231–232°; yield, 10.8 g.

Anal. Calcd. for $C_{18}H_9O_2Br$: Br, 23.71. Found: Br, 23.08, 23.39.

Bz-1,4-dibromo-1,2-benzanthraquinone (VI).—A solution of 4.8 g. of 5',8'-dibromo-1'-naphthoyl-2-benzoic acid in 30 cc. of concentrated sulfuric acid was heated at 122–124°, with or without 3 g. of boric acid, for twenty minutes. The sulfuric acid solution was immediately poured into a large volume of ice and water. A yellow precipitate was produced. This was filtered out, washed several times with water and then heated to the boiling point in 1300 cc. of dilute sodium hydroxide solution. Most of the yellow precipitate did not dissolve and after the solution cooled, it was filtered off; yield, 2.5 g. (54.3%). The product was purified by crystallization from benzene and gave a bright yellow solid, m. p. 265–266°.

Anal. Calcd. for $C_{18}H_8O_2Br_2$: Br, 38.44. Found: Br, 38.16.

⁸ Royle and Schedler, *J. Chem. Soc.*, 123, 1647 (1923).

Bz-4-chloro-1,2-benzanthraquinone.—A solution of 45 g. of 5'-chloro-1'-naphthoyl-2-benzoic acid in 450 g. of 100% sulfuric acid containing 45 g. of boric acid was heated to 115–120° and held for twenty minutes. The ring-closed mass was poured onto a large amount of ice and water. The yellow precipitate was filtered, washed and extracted with hot dilute caustic solution. The yield was 38 g. (90.5%). Upon crystallization from glacial acetic acid, bright yellow needles were formed which melted at 232°.

Anal. Calcd. for $C_{18}H_9OCl$: Cl, 12.13. Found: Cl, 12.10.

Bz-dichloro-1,2-benzanthraquinones.—Seventy grams of 5',8'-dichloro-1'-naphthoyl-2-benzoic acid melting at 242° was added to a solution of 70 g. of boric acid in 700 g. of 100% sulfuric acid, heated to 160° and held for thirty minutes at 160–165°. The solution was cooled quickly to 100°, then poured onto a large amount of ice and water. The yellow precipitate was filtered, washed and extracted with hot dilute caustic solution. The yield was 30 g. (45.2%) of product melting at 240–300°.

Twenty-eight grams of the dry ring-closed product was extracted twice with 80 cc. of hot chlorobenzene. On cooling the extract, fine yellow needles separated which were filtered and recrystallized from 100 cc. of toluene. The fraction (7 g.) melted at 237–238°.

Anal. Calcd. for $C_{18}H_8O_2Cl_2$: Cl, 21.70. Found: Cl, 21.47.

The residue insoluble in chlorobenzene was further extracted hot with 380 cc. of chlorobenzene and 55 cc. of nitrobenzene. The precipitate from these extractions was filtered and recrystallized from 250 cc. of chlorobenzene. Five grams of dark yellow needles was obtained melting at 304°.

Anal. Calcd. for $C_{18}H_8O_2Cl_2$: Cl, 21.70. Found: Cl, 21.57.

8'-Nitro-5'-bromo-1'-naphthoyl-2-benzoic Acid. (VII).—A solution of 97 g. of 5'-bromo-1'-naphthoyl-2-benzoic acid in 550 g. of 100% sulfuric acid was cooled to 10° and nitrated under agitation with 90 g. of a mixed acid containing 21% nitric acid and 69% sulfuric acid at 5–10°. After stirring for an hour, a test showed no nitric acid. Upon dilution with water the nitro compound precipitated (yield, 112 g.). It was purified by crystallization from hot nitrobenzene or *n*-butyl alcohol. The product consisted of white crystals, m. p. 228–230°.

Anal. Calcd. for $C_{18}H_9O_6NBr$: Br, 19.97; N, 3.50. Found: Br, 19.98; N, 3.51.

Reduction of 8'-Nitro-5'-bromo-1'-naphthoyl-2-benzoic Acid.—A solution of 4 g. of 8'-nitro-5'-bromo-1'-naphthoyl-2-benzoic acid in 100 cc. of acetic anhydride was reduced with 0.05 g. of platinum-oxide platinum black at 2.5 atm. pressure and a temperature of 80°. The catalyst was filtered and the acetic anhydride was distilled off under reduced pressure. A deep red tar remained in the flask which was washed with ether several times. An oil apparently dissolved in the ether leaving a brown solid. The solid was recrystallized twice from *n*-butyl alcohol to give a light brown amorphous product. It had no melting point, but merely turned black gradually.

Anal. Calcd. for $C_{18}H_{10}O_2NBr$: Br, 22.70. Found: Br, 22.18.

The same product is formed if iron and acid are used as a reducing agent.

8'-Nitro-5'-chloro-1'-naphthoyl-2-benzoic Acid.—A solution of 109 g. of 5'-chloro-1'-naphthoyl-2-benzoic acid in 600 g. of 100% sulfuric acid at 20–25° was cooled to 0–5° and nitrated with 110 g. of nitrating mixture containing 20% nitric acid and 69% sulfuric acid. The product was poured into water and ice; yield, 130 g. The compound is readily purified from chlorobenzene, m. p. 233–234°.

Anal. Calcd. for $C_{18}H_9O_6NCl$: Cl, 10.0; N, 3.94. Found: Cl, 10.78; N, 3.74.

5',8'-Dinitro-1'-naphthoyl-2-benzoic Acid.—Into a solution of 30 g. of 5'-bromo-1'-naphthoyl-2-benzoic acid in 160 cc. of acetic anhydride was dropped slowly with stirring 30 cc. of concentrated nitric acid. The temperature of the reaction was not allowed to go above 30°. The solution was stirred for eight hours after the nitric acid

had all been added, during which time an appreciable quantity of the yellow 5',8'-dinitro-1'-naphthoyl-2-benzoic acid precipitated and was filtered. The acetic anhydride filtrate was poured into a large volume of water and allowed to stand overnight to decompose the acetic anhydride. A yellow precipitate was produced which was filtered and dried at room temperature. The precipitate was then crystallized twice from boiling toluene; yield, 10 g. (32%) of yellow plates. If heated rapidly it melted sharply at 262–263° (decomp.).

Anal. Calcd. for $C_{18}H_{10}O_7N_2$: C, 59.0; H, 2.43. Found: C, 59.9; H, 2.52.

Summary

1. A study of the substitution of α -naphthoyl-*o*-benzoic acid has been made. By the action of chlorine or bromine, either the 5'- or 5',8'-disubstitution derivatives are obtained which may readily be dehydrated to the corresponding benzantraquinones.

2. Proof of the 5'-position of the monobromo derivative was established by oxidation of the bromobenzantraquinone to anthraquinone-1,2-dicarboxylic acid and by fusion of the bromo- α -naphthoyl-*o*-benzoic acid with sodium and potassium hydroxide to yield 1-hydroxy-5-naphthoic acid.

3. Nitration of 5'-chloro- or bromo-1'-naphthoyl-2-benzoic acid gave the 8'-nitro derivative, as shown by the fact that on reduction a ring structure was produced characteristic of 1-keto-8-aminonaphthalenes. Further nitration gave a halogen-free dinitro compound, probably 5',8'-dinitro-1'-naphthoyl-2-benzoic acid.

THE DEAMINATION OF ETHYL BETA-METHYLAMINOPROPIONATE

BY W. B. THOMAS AND S. M. McELVAIN

RECEIVED MARCH 22, 1932

PUBLISHED AUGUST 5, 1932

In an attempt to prepare β -carbethoxyethyl- β -carbethoxypropyl-methylamine (I), ethyl β -methylaminopropionate was treated with ethyl β -bromoisobutyrate. Instead of the desired compound the product which was obtained was β,β' -dicarbethoxydiethylmethylamine¹ (II) as shown by the fact that it was converted by sodium ethoxide into 1-methyl-3-carbethoxy-4-piperidone¹ (III).

¹ McElvain, *THIS JOURNAL*, 46, 1721 (1924).

benzoyl chloride was added from a dropping funnel at such a rate that the acetone did not reflux too vigorously. After this addition the acetone was refluxed and stirred for ten hours. The solid precipitate was then filtered off and the acetone removed by distillation. The residue was taken up in ether, washed with dilute hydrochloric acid and dilute sodium hydroxide and, after drying over anhydrous potassium carbonate, distilled. The yield of the benzoyl derivative was 86 g. (62%); b. p. 155–157° (3 mm.); n_D^{25} 1.51741; d_4^{25} 1.1076. Calcd. for $C_{13}H_{17}O_2N$: N, 5.96. Found: N, 6.31.

This benzoyl derivative was hydrolyzed by refluxing for eight hours with 20% hydrochloric acid. After cooling the precipitated benzoic acid was filtered off and any remaining in solution extracted with ether. The acid solution was evaporated to dryness and the residue esterified as previously described.⁵ The yield of ethyl β -methylaminopropionate from 48 g. of the benzoyl derivative was 18 g. (67%). It boiled at 60.5–61° (10 mm.); n_D^{25} 1.41990; d_4^{25} 0.9502. Calcd. for $C_6H_{13}O_2N$: N, 10.7. Found: N, 11.1. The secondary amino ester obtained by the above procedure differs quite materially in physical properties from the product previously described.⁵

Reaction of Ethyl β -Methylaminopropionate and Ethyl β -Bromoisobutyrate.—A mixture of 70.1 g. (2 mols) of ethyl β -methylaminopropionate and 52.2 g. (1 mol) of ethyl β -bromoisobutyrate was heated in an oil-bath at 130–140° for two hours. After this time the reaction mixture was cooled, diluted with ether and the ethereal solution separated by decantation from the semi-crystalline precipitate. From an alkaline solution of this precipitate methylamine was distilled out and characterized as methyl benzamide, m. p. 79–80°. After removal of the ether from the ethereal extract the residue was fractionated and the following fractions collected: (1) 9.5 g. below 50° (25 mm.), (2) 8.9 g. at 40–50° (4 mm.) and (3) 37.5 g. at 116–117° (4 mm.). Fraction (1) was mainly ethyl α -methylacrylate, (2) unchanged secondary amine and (3) was a tertiary amino ester which gave 6.25% N on analysis. (Calcd. for symmetrical ester (II), 6.06% and unsymmetrical ester (I), 5.72%.) This tertiary amino ester was condensed by sodium ethoxide to 1-methyl-3-carbethoxy-4-piperidone (III).

Reaction of Ethyl β -Methylaminopropionate with Ethyl α -Methylacrylate.—A mixture of 12.4 g. (1 mol) of the secondary amino ester and 10.8 g. (1 mol) of the unsaturated ester was heated in an oil-bath at 130–140° for three hours. After this time the reaction mixture was fractionated and the following fractions obtained (1) 8.9 g. of ethyl α -methylacrylate, (2) 4.9 g. of secondary amino ester and (3) 6 g. of a tertiary amino ester. A residue of polymerized methylacrylate remained. Fraction (3) was shown to be the β,β' -dicarbethoxydiethylmethylamine (II) by analysis (found, 6.12 N) and by the fact that sodium ethoxide condensed it to 1-methyl-3-carbethoxy-4-piperidone as above.

Preparation of β,β' -Dicarbethoxydiethylmethylamine (I) from Ethyl β -Methylaminopropionate.—(1) To 8.4 g. (1 mol) of the secondary amino ester was added 13.5 g. (1 mol) of its hydrobromide and the mixture heated in an oil-bath at 130–140° for three hours. After cooling, ether was added and the ethereal solution decanted from the precipitated hydrobromide. On distillation of the ethereal extract, 1.5 g. of unreacted secondary amino ester and 5 g. (34%) of the tertiary amino ester (II) was obtained. To the hydrobromide residue left after the ether decantation 30 cc. of 20% sodium hydroxide was added. Then about half of the alkaline solution was carefully distilled into standard acid and the methylamine determined; 0.99 g. (51%) was found.

(2) A 25-g. sample of the secondary amino ester when heated under a reflux condenser at 130–140° for four hours evolved 0.445 g. (14.8%) of methylamine. Fractionation of the remaining ester yielded 18.9 g. of unchanged secondary amino ester and 3.4 g. (15%) of the tertiary amine (II).

(3) A mixture of 7 g. of ethyl acrylate and 9.2 g. of the secondary amino ester

was heated under reflux in an oil-bath at 110–120° for two hours. Distillation of the reaction mixture yielded small amounts of unreacted acrylic and secondary amino esters and 11.6 g. (80%) of tertiary amino ester (II).

Summary

It has been found that when ethyl β -methylaminopropionate is allowed to react with either ethyl β -bromoisobutyrate or ethyl α -methylacrylate the product obtained is not the expected β -carbethoxyethyl- β -carbethoxypropylmethylamine, but is β,β' -dicarbethoxyethylmethylamine which is formed by the elimination of methyl amine (or its salt) from two molecules of the secondary amino ester.

RYE GERM OIL

BY ALBERT W. STOUT AND H. A. SCHUETTE

RECEIVED MARCH 25, 1932

PUBLISHED AUGUST 5, 1932

Little published information¹ on the composition of the oil in rye, *Secale cereale* L., is available. That which has found its way into the literature is of European origin and is not pertinent to the same type of product in each instance inasmuch as the whole kernel,^{1a,d,h} its bran,^{1b} its embryo^{1g} and its flour^{1c,h} and breads^{1h} baked therefrom have been used as the sources of the oil or "ether extract," under examination. The inevitable result of this diversity in selection of raw material has been a lack of correlation of data.² Furthermore, with one exception,^{1h} all of the reports in question are incomplete when viewed in the light of the newer trends in the technique of fatty oil analysis.

Unlike the embryo oils of other cereals such as corn and wheat, rye oil finds at present no important technical or alimentary use. The facts that it is apparently rich in the carotinoid pigments, that it contains a high percentage of lecithin-bearing unsaponifiable matter, and that the antimony trichloride test which is presumed to be indicative of the presence of vitamin A is positive, suggest the thought that the clinical advantages of

² This is particularly noticeable in the description of the color—it has been variously reported as being dark green to yellowish-brown—and other external characteristics of the oil and in the records of its simpler chemical constants. Iodine numbers, for example, have been reported as lying between 81.8 and 127.7; saponification numbers between 172.8 and 196.0; and the content of unsaponifiable matter to vary between 8.2 and 11.20%.

the presence of rye oil in the diet might profitably be investigated. There are, however, obvious needs both for a definition of the term rye oil and a better knowledge of the chemistry of the lipin which is elaborated in the embryo or germ of the kernel. Precedent and consistency, it seems, dictate that, apart from all the substances recoverable by solvent extraction from this cereal grain and its products, the term rye oil should be reserved for the constituent in question in the embryo.

A re-investigation of this oil appears then justified in view of the unsatisfactory state of our knowledge of its chemistry and the fact that no record appears to be extant on a domestic product which had been recovered exclusively from the embryo. A report of such a study is made the subject of this communication.

I. Preparation of Material

The oil in question was obtained by extracting with sulfur-free petroleum ether (b. p. 30–60°) rye embryo (oil content 11%) recovered by repeated sifting and air cleaning of so-called rye germ stock,³ a by-product in the milling of the grain. The last traces of solvent were removed by distillation at reduced pressures on a water-bath and in the presence of carbon dioxide. The oil was found to be of a deep golden-brown color. It possesses an odor suggestive of the grain itself and, in contradistinction to the report that rye oil is of a semi-solid consistency at 15°, ^{1h} was found still to be plastic at –60°.

II. Analysis of the Oil

(a) **Chemical and Physical Characteristics.**—The important chemical and physical constants (Table I) were determined by recognized procedures.⁴ In the determination of the thiocyanogen number of the fatty acids and the interpretation of this constant the procedure of Kaufmann was followed.⁵ Because of the presence of the relatively large quantities of unsaponifiable matter, this was first removed before the acids were subjected to analysis. Separation of the fatty acids into saturated and unsaturated groups was effected by the lead salt-ether^{6a} method, after which corrections were made for the small amount of unsaturated acids contaminating the former, when this procedure is used,^{6b} and for the unsaponifiable matter accompanying the insoluble acids.

³ Acknowledgment is made to the Messrs. Frank H. Blodgett, Inc., of Janesville, Wisconsin, who by gratuitously placing at our disposal some two hundred pounds of this material, made possible this investigation.

TABLE I
CHEMICAL AND PHYSICAL CHARACTERISTICS OF RYE GERM OIL

Specific gravity 20/20°	0.9229
Index of refraction, 20°	1.4779
Titer test, °C.	25.2
Iodine number ^a (Wijs)	139.91
Saponification number	176.81
Reichert-Meissl number	0.05
Polenske number	.3
Free fatty acids (per cent. oleic)	2.9
Acetyl number	20.19
Soluble acids (per cent. as butyric)	trace
Insoluble acids (Hehner number) ^b	84.45
Iodine number (Wijs) of insoluble fatty acids ^b	133.57
Thiocyanogen number of insoluble fatty acids ^b	85.05
Unsaturated acids (per cent.) corrected	77.46
Saturated fatty acids (per cent.) corrected	10.12
Iodine number of unsaturated acids (Wijs)	158.90
Saponification number of unsaturated acids	172.6
Unsaponifiable matter (per cent.)	7.28

^a The iodine number when determined by the Hanus method was found to be 134.0. This figure represents an average of four determinations. ^b Corrected for unsaponifiable matter.

(b) **Unsaturated Acids.**—Separation of the unsaturated acids was effected through the preparation of their bromo addition compounds and the fractional separation of the mixture into its components by the use, in turn, of diethyl and petroleum ethers.⁷ The presence of linolenic acid was indicated by the formation of an ethyl ether-insoluble precipitate in the cold (-10°). Analysis proved the latter to be the hexabromide of this acid. A considerable quantity of the tetrabromo derivative of linoleic acid (Br, 53.62%) separated from the cold petroleum ether solution. The bromine content (43.43%) of the dibromide fraction showed it to be a mixture of this compound and the tetrabromo derivative. Using the latter value and those expressing the bromine content of the oleic and linoleic derivatives, respectively, the percentage composition of the mixture was calculated.⁸

The composition of this fraction was also arrived at, and perhaps with greater accuracy of results since gravimetric separations are not involved, by the mode of procedure suggested by Kaufmann,⁵ a scheme of analysis in which the iodine (133.57) and thiocyanogen (85.05) numbers of the purified fatty acids become the point of departure in a mathematical calculation. Exact agreement was not obtained by these two different methods of approach, yet the order of magnitude of the quantities of each acid present is substantially the same (Table II).

⁸ Baughman and Jamieson, *THIS JOURNAL*, **42**, 157 (1920).

TABLE II
PERCENTAGE COMPOSITION OF THE UNSATURATED ACID FRACTION

Acid	Obs. ^a	In oil	Glycerides in oil	
			Obs. ^a	Calcd. ^b
Oleic	36.17		37.79	31.92
Linoleic	38.92		40.68	44.05
Linolenic	2.37		2.48	4.99

^a From bromine addition products. ^b From thiocyanogen number.

(c) **Saturated Acids.**—The methyl esters of the saturated acids were separated into five fractions (Table III) of boiling range 163 to 181° (5 mm). The average molecular weights of the respective fractions as calculated from saponification and iodine numbers—the latter serving as a basis for correcting each for the presence of unsaturated acids—indicated the presence of acids in the C₁₄ to C₁₈ group.

TABLE III
RESULTS OF ANALYSES OF METHYL ESTERS OF THE SATURATED FATTY ACIDS

Fraction	Wt., g.	Iodine no.	Sapon. no.	Mean mol. wt.	Myristic ester	Palmitic ester	Stearic ester
1	7.30	2.76	215.6	257.6	3.203	3.894	...
2	9.72	3.37	211.2	265.0	1.745	7.759	...
3	15.68	7.56	209.5	266.4	2.024	11.876	...
4	2.30	22.59	209.3	263.8	0.450	1.507	...
5	1.01	43.25	196.5	270.7	...	0.686	...
Res.	3.35					.432	0.598
Total					7.422	26.154	.598

These data lead to the following statement of the percentage composition of the saturated acid fraction.

TABLE IV
PERCENTAGE COMPOSITION OF THE SATURATED ACID FRACTION

Acid	Myristic	Palmitic	Stearic
In oil	2.21	7.73	0.17
Glycerides in oil	2.33	8.11	.18

(d) **Miscellaneous.**—The phosphorus content of both the oil itself and its unsaponifiable matter was determined in the usual manner after the organic matter, saturated with sodium hydroxide solution, had been destroyed by incinerating it. From the data so obtained the lecithin equivalent of a hypothetical di-oleyl derivative (C₄₄H₈₆O₉NP) was calculated. It was found to be 1.33% for the oil and 3.05% for its unsaponifiable matter. The former value is somewhat higher than the lecithin content (1.04%) of a purified rye oil reported by Alpers¹⁸ but less than that found by him (3.04%) in a crude oil. It compares very favorably with the lecithin content of a corn oil (1.49%) examined by Hopkins⁹ but is

⁹ Hopkins, THIS JOURNAL, 20, 948 (1898).

lower than that found in wheat germ oil (2.00%) by Frankforter and Harding.¹⁰

The deep golden-brown color of this oil suggests the presence of the carotinoid pigments. In view of the fact that vitamin A potency is now generally associated with carotene, and since the antimony chloride reaction¹¹ is presumed to indicate its presence, application of this test bid fair to lead to affirmative results.

When the oil itself was added to a chloroform solution of this salt, a strong blue coloration appeared. The unsaponifiable matter which had been extracted with ethyl ether gave a stronger reaction than did that recovered by treatment with petroleum ether, a condition which is probably due to the fact that the latter removes less coloring matter from the oil than does the former.

Summary

The more important physical and chemical characteristics and the approximate percentage composition of rye germ oil have been determined. It is a semi-drying oil which is characterized by the quantity of heavily pigmented unsaponifiable matter which it contains. Correlation of its constants with those obtained by others, with perhaps one exception,¹⁸ cannot satisfactorily be made because of the diversity of products which have been included under the name rye oil.

The percentage composition of this oil was found to be as follows: myristin, 2.33; palmitin, 8.11; stearin, 0.18; olein, 31.92; linolein, 44.05; linolenein, 4.99; unsaponifiable matter, 7.28; undetermined, 1.14.

MIXED BENZOINS. VIII. FURTHER DETERMINATIONS OF STRUCTURES. QUESTION OF ISOMERS

By JOHANNES S. BUCK AND WALTER S. IDE

RECEIVED MARCH 26, 1932

PUBLISHED AUGUST 5, 1932

The present paper deals mainly with the determination of the structure of a number of mixed benzoins, most of them new, in continuation of the authors' purpose to characterize a sufficiently large number of mixed benzoins to enable worth-while deductions to be made regarding the reactivity of aldehydes. The method used depends on the Beckmann transformation of the second type, previously used and described in Part IV.¹ The reaction appears to be trustworthy, as no results so far obtained contradict

¹ Buck and Ide, *THIS JOURNAL*, 53, 1912 (1931).

structures established in other ways. The transformation is considered as taking place in the Beckmann sense, between vicinal groups, and not in the Meisenheimer sense between *anti* groups. The method also enables the structure of the oximes of the benzoins to be deduced. The structures of the corresponding desoxy compounds have been determined by a method also previously described² (Beckmann transformation of the first type). In the present paper, the benzoins and their oximes together with the derived desoxybenzoins and their oximes and transformation products are described.

A point of considerable importance in the study of mixed benzoins is whether both of the possible isomers are formed by the condensation of two different aldehydes in the presence of potassium cyanide, or whether only one is formed. In an earlier paper³ the present authors reported that they had isolated two such isomers, using benzaldehyde and piperonal. The evidence was chiefly analytical. Tiffeneau and Lévy⁴ have failed to isolate the two isomers. The present authors, after many attempts, have also failed to repeat the isolation of the two isomers. It now seems probable that the compound melting at 110° was a side-product such as benzyl piperonylate or piperonyl benzoate, of the same synoptic formula, isolated by chance. Unfortunately, none of the compound is now available to settle the point.

Tiffeneau and Lévy⁴ believe that they have in two cases obtained evidence for the existence of pairs of isomeric benzoins. In work which was probably carried out simultaneously with Tiffeneau and Lévy's work, the present authors⁵ have twice commented upon the ability of benzoins to form addition compounds, and it seems to them that Tiffeneau and Lévy's results could be readily explained on the basis of addition compound formation rather than on the basis of the formation of isomers. Thus in the condensation of piperonal and anisaldehyde, Tiffeneau and Lévy obtain two substances, melting at 75 and at 110°. The first is admittedly a mixture and gives on potash fission a mixture of piperonylic and anisic acids. In the hands of the present authors this substance, on oxidation with Fehling's solution, gave a mixture of about equal amounts of piperil and methoxymethylenedioxybenzil, showing the presence of considerable amounts of piperoin in the preparation. The substance melting at 110° similarly gave on oxidation, piperil, methoxymethylenedioxybenzil and anil in the ratio 20:4:1 and is hence chiefly piperoin.

The other case is the condensation of benzaldehyde and *m*-methoxybenzaldehyde. The two products described by Tiffeneau and Lévy were

² Buck and Ide, *THIS JOURNAL*, **53**, 1536 (1931).

³ Buck and Ide, *ibid.*, **52**, 220 (1930).

⁴ Tiffeneau and Lévy, *Bull. soc. chim.*, [4] **49**, 725 (1931).

⁵ Buck and Ide, *THIS JOURNAL*, **53**, 2350, 2784 (1931).

regenerated from a semicarbazone preparation. Both on potash fission gave benzoic and *m*-methoxybenzoic acids and so are not entities. No analyses are given, and the main product, m. p. 80°, is admittedly not pure.

It is evident that, by potash fission, the same acids would be obtained either from a mixture or addition compound of two simple benzoin, or from a mixture or addition compound of the corresponding pair of isomeric mixed benzoin.

In view of the above considerations, it would appear that the claim to have obtained evidence of two pairs of isomeric mixed benzoin requires further substantiation. It seems to the present authors that the evidence is strongly in favor of addition compounds. Benzoin reactions are, however, very susceptible to variations in experimental conditions, and unless these are exactly specified, it is not at all certain that two different workers will always reproduce each other's results.

The present authors therefore consider that no case of the formation of a pair of isomeric mixed benzoin has been conclusively demonstrated, and they are inclined to the belief that only one isomer is formed. Experimental proof, for or against, will be difficult on account of the possible complexity of the reaction mixtures (*cf.* Lachman⁶) and the probability that, if both isomers are formed, one will be present only in small amount.

It is intended to investigate the question of isomeric mixed benzoin from another angle, by regenerating the benzoin from the corresponding benzil, where isomerism and addition compound formation are not involved.

Note on Nomenclature.—The system earlier suggested by Buck and Ide³ (depending on the termination -oin) is inadequate for the more highly substituted benzoin and derivatives. The authors therefore suggest using primes for the numbered substituents on the benzene ring next to the CO group (or in the case of oximes, the C=NOH group). This method has been followed in the present paper, using the full systematic name, however. In future, *o*-chlorobenzveratrin (old name) will be written 2-chloro-3',4'-dimethoxybenzoin, and so on.

Experimental

Benzoin.—The benzoin not previously described were prepared by dissolving 0.2 mole of each aldehyde in 100 cc. of alcohol; 10 g. of potassium cyanide, dissolved in 20 cc. of water, was then added and the solution refluxed on the steam-bath for one to one and one-half hours. The crystalline products are obtained from the reaction mixtures by treatment with solvents and exposure to cold (refrigerator). Steam distillation to remove unchanged aldehydes was not resorted to, on account of the pos-

sibilities of change in the reaction mixtures during the process. The benzoin, when crystallized from alcohol, are persistently yellow. Crystallization from acetic acid gives the benzoin in a pure white form. The results are given in Table I. Derived compounds, such as oximes, have the same letter as the parent benzoin.

Benzils.—The benzils were all prepared by dissolving the appropriate mixed benzoin in alcohol (usually 2.0 g. was taken) and oxidizing with a slight excess of Fehling's solution. The crude product was recrystallized from alcohol until pure.

TABLE II

BENZILS

	Benzil	M. p., °C.	Yield, %	Appearance	Analyses, %			
					Calcd.		Found	
					C	H	C	H

N	3,4-Methylenedioxybenzyl-4'-dimethylamino-	140	44	Glittering plates	72.05	6.05	72.17	6.27

Oximes of Desoxy Compounds.—The oximes were prepared by one of the methods given in Part IV¹ for the benzoin oximes. The figure in the last column of the table refers to the preparation. All the oximes are white, well-crystallized compounds. They have, in every case, the *anti*-benzyl configuration.

The amides were identified either by hydrolysis and the identification of the acid so produced (the basic fragment is always decomposed) or by synthesis. The amides are very stable and require many hours' refluxing with concentrated hydrochloric acid in order to hydrolyze them. Amides I, J and K gave on hydrolysis *o*-chlorophenylacetic acid, identified by comparison and mixed melting point determinations with an authentic specimen. Amide L on hydrolysis gave *m*-chlorophenylacetic acid, identical

with a specimen prepared as described below. Amide M on hydrolysis gave *p*-chlorophenylacetic acid, identical with a specimen prepared by the method of Petrenko-Kritschenko, *Ber.*, 25, 2239 (1892). Amide N was identified with a synthetic specimen prepared from homopiperonyl chloride and dimethyl-*p*-phenylenediamine hydrochloride, by the Schotten-Baumann method.

m-Chlorophenylacetic Acid. Azlactone.⁹—One-tenth mole of *m*-chlorobenzaldehyde, 0.1 mole of hippuric acid and 0.1 mole of freshly-fused, powdered, anhydrous sodium acetate are mixed with 0.3 mole of acetic anhydride and the mixture heated on a hot-plate, with constant stirring, until liquid. The flask is then at once transferred to a water-bath and heated for 105 minutes. After cooling, the magma is stirred with an equal volume of alcohol and left overnight. The crystals are then filtered off and washed with a little cold alcohol and then with hot water. The azlactone forms a mass of canary-yellow crystals. The yield is 63%. After recrystallization from alcohol the compound melts at 164°.

Anal. Calcd. for C₁₀H₁₀O₂NCl: C, 67.71; H, 3.55. Found: C, 67.93; H, 3.93.

m-Chlorophenylpyruvic Acid.—Fifteen grams of azlactone is refluxed (oil-bath) with 100 cc. of 10% sodium hydroxide solution for four hours. The mixture, after cooling, is saturated with sulfur dioxide (temperature below 40°), and the benzoic acid filtered off and washed with a little water. The filtrate and washings are then heated nearly to boiling and concentrated hydrochloric acid added cautiously, in small

⁹ Cf. Kropp and Decker, *Ber.*, 42, 1188 (1909).

portions, until excess is present. The mixture is gently boiled for a short time, then cooled and the *m*-chlorophenylpyruvic acid filtered off and washed with water. The yield is 8.1 g. (77%). Recrystallized from acetic acid, the compound forms white, tiny, felted needles, melting at 145°.

Anal. Calcd. for $C_9H_7O_2Cl$: C, 54.43; H, 3.55. Found: C, 54.60; H, 3.79.

***m*-Chlorophenylacetic Acid.**¹⁰—Six grams of the pyruvic acid, dissolved in a solution of 8.0 g. of sodium hydroxide in 25 cc. of water, together with 10 g. of ice, is treated with a solution of 7.5 g. of superoxol (30% H_2O_2) in 15 cc. of water. The addition is carried out slowly, with cooling and shaking. After standing for five hours the solution

TABLE VII

BECKMANN REACTION

The reaction was carried out as previously described, using benzene sulfone chloride and alkali.¹ The residues from oximes I and N were very small. In all the other cases a considerable residue remained after fractionation. The reaction mixtures were fairly clean, except in the cases of oximes L and M, where considerable tarry matter was formed. In no case was there more than a trace of isonitrile odor.

Oxime	Taken, g.	1st Fraction		Yield g.	%	2d Fraction		Yield g.	%
		Name, aldehyde				Name, nitrile			
I	17	<i>o</i> -Chlorobenz- ^a		6.0	88	3,4-Diethoxybenzo- ^c		8.0	87
J	12	<i>o</i> -Chlorobenz- ^a		3.7	73	3-Ethoxy-4-methoxybenzo- ^c		2.8	44
K	12	<i>o</i> -Chlorobenz- ^a		3.3	65	3-Methoxy-4-ethoxybenzo- ^d		3.8	60
L	6.7	<i>m</i> -Chlorobenz- ^a		1.6	52	<i>p</i> -Dimethylaminobenzo- ^e		2.0	62
M	6.0	<i>p</i> -Chlorobenz- ^a		1.4	38	Pipero- ^e		1.8	47
N	8.0	Piperonal ^b		3.1	77	<i>p</i> -Dimethylaminobenzo- ^e		2.5	63

^a Converted into the acid and identified by mixed melting point determinations with an authentic specimen. ^b Identified by mixed melting point determinations with the authentic aldehyde. ^c Identified by mixed melting point determinations with a specimen of nitrile prepared as described below. ^d Identified by mixed melting point determinations with a specimen of authentic nitrile prepared by the action of acetic anhydride on the corresponding oxime. Previously obtained by Keffler, *J. Chem. Soc.*, 119, 1476 (1921). ^e Identified by comparison with the authentic nitrile prepared as in Part IV.¹

¹⁰ Cf. Mauthner, *Ann.*, 370, 375 (1909).

is cautiously acidified with hydrochloric acid, and, while still warm, extracted with benzene. The extract is dried and the benzene evaporated. After recrystallization from aqueous alcohol, the acid forms large, pearly leaflets, melting at 74° . The yield is 3.0 g. (57%).

Anal. Calcd. for $C_8H_7O_2Cl$: C, 56.29; H, 4.13. Found: C, 56.00; H, 4.26.

3,4-Diethoxybenzaldoxime was prepared by the action of hydroxylamine acetate on the aldehyde. The oxime forms tiny needles melting at 98° .

Anal. Calcd. for $C_{11}H_{13}O_3N$: C, 63.12; H, 7.23. Found: C, 63.55; H, 7.33.

3,4-Diethoxybenzonitrile was prepared by refluxing the above oxime with acetic anhydride for two hours, and pouring the mixture into water. When recrystallized from aqueous alcohol, the nitrile forms long, flat prisms, melting at 68° .

Anal. Calcd. for $C_{11}H_{13}O_2N$: C, 69.07; H, 6.85. Found: C, 69.25; H, 7.00.

3-Ethoxy-4-methoxybenzaldoxime, prepared by means of hydroxylamine acetate, forms fine needles, melting at 98° .

Anal. Calcd. for $C_{10}H_{13}O_3N$: C, 61.50; H, 6.71. Found: C, 61.85; H, 6.86.

3-Ethoxy-4-methoxybenzonitrile was prepared from the above oxime by refluxing with acetic anhydride for two hours and pouring the reaction mixture into water. Recrystallized from aqueous alcohol it forms a mass of tiny needles melting at 70° .

Anal. Calcd. for $C_{10}H_{11}O_2N$: C, 67.76; H, 6.26. Found: C, 68.00; H, 6.30.

3-Methoxy-4-ethoxybenzaldoxime, prepared in the usual way by means of hydroxylamine acetate, forms tiny needles, melting at 100° .

Anal. Calcd. for $C_{10}H_{13}O_3N$: C, 61.50; H, 6.71. Found: C, 61.63; H, 6.65.

Summary

The structures of six mixed benzoin and their oximes, together with the corresponding desoxy compounds and their oximes, have been determined. The benzils and Beckmann transformation products are also described.

The question of the formation of pairs of isomeric mixed benzoin (by the potassium cyanide condensation) is discussed. It is considered that reported cases of the occurrence of such pairs of isomers require further substantiation.

THE CONDENSATION OF 3-NITRO-4-HALOGENO-PHENYLARSONIC ACIDS WITH ALIPHATIC AMINO COMPOUNDS AND PHENOLS

By W. D. MACLAY¹ AND CLIFF S. HAMILTON

RECEIVED MARCH 26, 1932

PUBLISHED AUGUST 5, 1932

Aromatic arsonic acid derivatives containing both primary and secondary amino groups have not been studied as extensively as those containing only a primary amino group; and arsonic acid derivatives containing more than one aromatic nucleus, the second substituted nucleus being attached to that containing the arsono group by the linkage of oxygen, have been studied hardly at all. A common method for synthesizing types of compounds such as these is through the substitution of nuclear halogen. It has long been known that this replacement could be brought about by the ordinary reagents employed in the aliphatic series, only when the attachment of the halogen was loosened by the presence of certain groups, such as nitro, cyano, carboxyl, arsono, etc. Gibson and others² successfully applied the method of Ullmann³ to condensation reactions of *o*-bromophenylarsonic acid with aromatic amines. In an analogous manner Etzelmiller and Hamilton⁴ condensed *o*-chlorophenylarsonic acid with aliphatic amines, aliphatic alcohols and phenol.

Boehringer and Soehne⁵ showed that 3-nitro-4-chlorophenylarsonic acid and glycine reacted in an alkaline solution to give 2-nitro-4-arsonophenylglycine. King⁶ condensed the same arsonic acid with piperidine in an alcoholic solution to form 3-nitro-4-piperidinophenylarsonic acid. Fourneau and Funke⁷ showed that 3-nitro-4-chlorophenylarsonic acid reacted with ethylenediamine and piperazine in the presence of anhydrous sodium acetate. This reaction has been further extended by Barber,⁸ who prepared a series of diphenylamine derivatives through the condensation of 3-nitro-4-chlorophenylarsonic acid with various substituted aromatic amines in aqueous alkaline solution. Thus, the reactivity of the halogen in 3-nitro-4-halogenophenylarsonic acids suggested the use of these compounds in condensation reactions with aliphatic amino compounds and substituted phenols leading to two series of arsenicals.

A series of condensation reactions was carried out with 3-nitro-4-halogenophenylarsonic acids and various aliphatic primary amines. The amines, iso- and *n*-amyl, iso- and *n*-butyl, *n*-propyl and ethanol, condensed with the arsonic acid in aqueous alkaline solution. The reaction worked equally well in an anhydrous mixture of potassium carbonate and *n*-amyl alcohol, but the ease of carrying out the condensation and purification of the reaction product favored the former method. Three hours at temperatures of 125–135° was found to be sufficient time for obtaining maximum yields in this type of condensation.

Glycine readily condensed with 3-nitro-4-halogenophenylarsonic acids in an anhydrous mixture of potassium carbonate, *n*-amyl alcohol and copper powder, to give good yields of 2-nitro-4-arsonophenylglycine.

The amino derivatives of the condensation products of the aliphatic primary amines with 3-nitro-4-halogenophenylarsonic acids were prepared in yields of 40–48% by the method of Jacobs, Heidelberger and Rolf.⁹

The free base, 2-amino-4-arsonophenylglycine, was not isolated when the corresponding nitro derivative was reduced. In every instance, 2-oxy-3-dihydroquinoxaline-7-arsonic acid,¹⁰ was obtained through the elimination of water.

A series of condensation reactions was also carried out with substituted phenols. These reactions took place only in an anhydrous medium. Phenol-, *p*-chlorophenol, *o*- and *p*-cresols and *p*-nitrophenol reacted with 3-nitro-4-bromophenylarsonic acid to form the corresponding phenyl ether derivatives. Under similar conditions, salicylic acid, *o*-nitrophenol, salicylic aldehyde and *p*-hydroxybenzaldehyde failed to condense.

The amino derivatives of these phenyl ethers were prepared by means of reduction with alkaline ferrous hydroxide. When 2-amino-4-arsono-2'-carboxyphenyl ether was heated above 200°, water was eliminated, leading to the formation of the corresponding lactam.

It was considered desirable to study the reaction of 3-nitro-4-bromophenylarsonic acid with aliphatic alcohols. The alcohols, iso- and *n*-amyl, and *n*-butyl, were included in this study. The general procedure was to heat a mixture of 10 g. of 3-nitro-4-bromophenylarsonic acid, 10 g. of anhydrous potassium carbonate, 0.2 g. of copper powder and 35 cc. of the alcohol containing either potassium or sodium, in amounts varying from 1 to 2.5 g., for ten hours at refluxing temperature, with stirring. In no case was a condensation product isolated. Condensation reactions with isoamyl alcohol invariably led to tarry formations from which nothing was isolated. With *n*-butyl alcohol, although the alcohol had been carefully dried and distilled, as high as 50% of the compound was hydrolyzed to 3-nitro-4-hydroxyphenylarsonic acid. The water present was

⁹ Jacobs, Heidelberger and Rolf, *THIS JOURNAL*, **40**, 1581 (1918).

¹⁰ Ewins, Newbery and Stickings, *J. Chem. Soc.*, 851 (1927).

possibly due to the formation of the double potassium salt of the arsonic acid group.

In beginning a study of the activity of the halogen in the para-position with respect to the arsonic acid group, a series of condensation reactions with aniline was carried out under varying experimental conditions. The halogenophenylarsonic acid employed in these reactions was *p*-bromophenylarsonic acid. The general procedure was to heat 10 g. of *p*-bromophenylarsonic acid, 10 g. of anhydrous potassium carbonate, 0.2 g. of catalyst and varying amounts of aniline and amyl alcohol, which was used as a solvent at different temperatures, in an Erlenmeyer flask fitted with a condenser with a ground-glass connection and mechanical stirrer. Only two catalysts, copper powder and cuprous iodide, were tried in this series of reactions while *n*-amyl alcohol was the only solvent employed. The temperatures varied from 90 to 220°, the time from ten to eighty hours and the amounts of aniline and amyl alcohol from 0 cc. to 30 cc. In some instances sealed tube reactions were employed. In no case was a substance isolated which would give the slightest qualitative test for nitrogen. In all cases from 40–80% of the original arsonic acid was recovered.

Incidentally, the halogen in *p*-bromophenylarsonic acid was not hydrolyzed when refluxed for forty-eight hours in 3 *N* sodium hydroxide solution.

Experimental¹¹

General Procedure for the Preparation of 3-Nitro-4-alkylaminophenylarsonic Acids.—Twelve grams of 3-nitro-4-chlorophenylarsonic acid, 40 cc. of 2 *N* sodium hydroxide, 6 cc. of the primary alkylamine and 25 cc. of water in a 200-cc. Erlenmeyer flask, fitted with a condenser, were heated in an oil-bath at 125–135° for three hours. On acidification to Congo red paper with 6 *N* hydrochloric acid, an orange colored oil separated which on cooling solidified to a yellow crystalline mass. This was redissolved in sodium carbonate solution, acidified to litmus paper and boiled with decolorizing carbon. The arsonic acid was again precipitated with hydrochloric acid and further purified by recrystallizing from dilute acetic acid. These compounds did not melt or decompose below 250°.

TABLE I

3-NITRO-4-ALKYLAMINOPHENYLARSONIC ACIDS

-Aminophenyl- arsonic acid	Yield, %	Formula	Arsenic analyses, %		
			Calcd.	Found	Found
3-Nitro-4-propyl-	68	C ₉ H ₁₃ O ₆ N ₂ As	24.67	24.60	24.58

¹² Boehringer and Soehne, German Patent 285,604.

glycine and 35 cc. of *n*-amyl alcohol in a 200-cc. Erlenmeyer flask fitted with a ground-glass connection was heated for seven hours in an oil-bath at 150°. The reaction mixture was agitated by means of a mechanical stirrer extending down through the condenser. The reaction mixture was cooled and the amyl alcohol removed by decantation. The mass remaining was dissolved in 75 cc. of hot water and acidified to Congo red paper with hydrochloric acid. A dark brown crystalline mass separated. This was further purified by reprecipitating from sodium carbonate solution and recrystallization from acetic acid. The arsonic acid separated from this solvent in the form of light yellow needles decomposing at 230–235°. The yield was 9.0 g. or 61% of the calculated amount.

2-Oxy-3-dihydroquinoxaline-7-arsonic Acid.¹⁰—When 2-nitro-4-arsonophenylglycine was reduced with alkaline ferrous hydroxide, a quinoxaline derivative was formed through the loss of water. The free base was not isolated, the ring compound separating from the filtrate when it was acidified to Congo red paper. Recrystallized from 75% methyl alcohol, 2-oxy-3-dihydroquinoxaline-7-arsonic acid separated in long white needles, yield 70%.

Anal. Calcd. for $C_8H_9O_4N_2As$: As, 27.57; N, 10.28. Found: As, 27.65, 27.59; N, 10.15.

The Condensation of 3-Nitro-4-bromophenylarsonic Acid with Phenols.—A mixture of 10 g. of 3-nitro-4-bromophenylarsonic acid, 10 g. of anhydrous potassium carbonate, a trace of copper powder, a small excess of an equivalent amount of the phenol and 35 cc. of *n*-amyl alcohol in a 200-cc. Erlenmeyer flask fitted with a ground-glass connection was heated for six to eight hours in an oil-bath at 140–150°, the reaction mixture being well stirred. The excess phenol and amyl alcohol were removed by steam distillation, and the resulting solution was treated with decolorizing carbon. On acidification to Congo red paper with dilute hydrochloric acid a brownish mass separated which was further purified through crystallization from acetic acid. These phenyl ether derivatives separated from this solvent in the form of a white crystalline mass. Phenol, *p*-chlorophenol, *p*-cresol, *o*-cresol and *p*-nitrophenol were condensed with the 3-nitro-4-bromophenylarsonic acid in this manner. The carboxyl derivatives were prepared through oxidation of the corresponding methyl derivatives with alkaline permanganate. They do not melt or decompose below 250°.

2-Amino-4-arsono-2'-carboxyphenyl Ether Lactam.—Three grams of 2-amino-4-arsono-2'-carboxyphenyl ether was placed in a hard-glass test-tube fitted with a suction apparatus. The tube was placed in an oil-bath at 200–210°. At this temperature water was eliminated. Heating was continued for twenty minutes, after which the reaction mixture was dissolved in dilute sodium hydroxide and treated with decolorizing carbon. After precipitation with hydrochloric acid, the lactam was further purified by recrystallizing from 150 cc. of 75% acetic acid. It separated from this solvent in white rectangular plates; yield 2 g. or 70%. It does not melt or decompose below 250°.

Anal. Calcd. for $C_{13}H_{10}O_5NaS$: As, 22.39; N, 4.18. Found: As, 22.41, 22.44; N, 4.06, 3.97.

4-Arsono-4'-methylphenyl Ether.—Twenty grams of 4-amino-4'-methylphenyl ether was dissolved in 24 cc. of hydrochloric acid (sp. gr. 1.18) and 400 cc. of water. This solution was diazotized at 0° with a solution of 7 g. of sodium nitrite in 50 cc. of water in the usual manner. After neutralizing the diazo solution to Congo red paper with 2 *N* sodium carbonate solution, it was added to a solution of sodium arsenate at 0°, which had been prepared by dissolving 30 g. of arsenious oxide in 300 cc. of 2 *N* sodium carbonate to which had been added a solution of 1 g. of copper sulfate dissolved in 25 cc. of water. After stirring for two hours, the reaction mixture was concentrated to 400 cc. on a steam-bath, treated with decolorizing carbon and the arsonic acid precipitated with hydrochloric acid. It was further purified through recrystallization from 75% acetic acid as white plates; yield, 47%. It did not melt or decompose below 250°.

Anal. Calcd. for $C_{13}H_{13}O_4As$: As, 24.35. Found: As, 24.32, 24.28.

4-Arsono-4'-carboxyphenyl Ether.—This compound was prepared by oxidizing the corresponding methyl derivative in alkaline permanganate solution; yield, 84%. It did not melt or decompose below 250°.

Anal. Calcd. for $C_{13}H_{11}O_6As$: As, 22.19. Found: As, 22.13, 22.11.

Summary

1. Condensation reactions with 3-nitro-4-halogenophenylarsonic acids and a series of aliphatic amino compounds, namely, iso- and *n*-amyl, iso- and *n*-butyl, *n*-propyl and ethanol amines, and glycine were successfully completed.

2. The corresponding amino derivatives of the above condensation products were prepared.

3. 3-Nitro-4-bromophenylarsonic acid was condensed with phenol and a series of substituted phenols, namely, *p*-chlorophenol, *o*- and *p*-cresols and *p*-nitrophenol, leading to a series of phenyl ether derivatives. The carboxyl derivatives were also prepared through the oxidation of the methyl derivatives.

4. The corresponding amino derivatives of the substituted phenol condensation products were synthesized. The lactam of 2-amino-4-arsono-2'-carboxyphenyl ether was obtained through the elimination of water from 2-amino-4-arsono-2'-carboxyphenyl ether. This resulted in the formation of a seven-membered ring compound.

5. A study was made of the effects of experimental conditions on the reaction of *p*-bromophenylarsonic acid with aniline.

HALOGEN DERIVATIVES OF MONOHYDROXYDIPHENYLMETHANE AND THEIR ANTIBACTERIAL ACTION

By EMIL KLARMANN, LOUIS W. GATES AND VLADIMIR A. SHTERNOV

RECEIVED MARCH 29, 1932

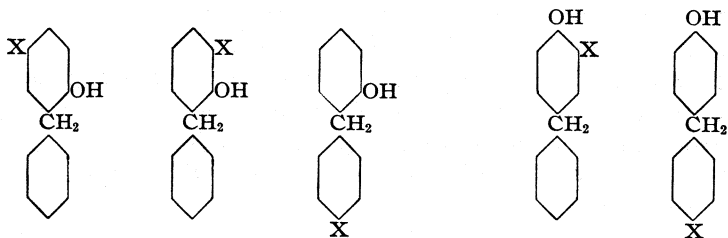

PUBLISHED AUGUST 5, 1932

It was shown in a recent communication that monosubstituted halogen derivatives of 2,4-dihydroxydiphenylmethane are potent bactericides for *Eberthella typhi* and *Staphylococcus pyogenes aureus*.¹ Distinct differences in antibacterial action were observed depending upon the position of the substituting halogen. Thus with both the chloro and the bromo derivatives, it was found that a greater germicidal efficacy toward both test microorganisms was obtained in the case of substitution in the nucleus bearing the two hydroxyl groups than in that of substitution in the other nucleus. While *E. typhi* appeared to be more susceptible to the action of the compounds of this group than *Staph. aureus* the differences in susceptibility were by no means indicative of bactericidal specificity.

Notes on the Preparation of Halogen Hydroxydiphenylmethane Derivatives.—In continuing our studies on related problems, we devoted

¹ Klarmann and Von Wowern, THIS JOURNAL, 51, 605 (1929).

our attention to the substitution by halogen of the 2- and 4- monohydroxydiphenylmethanes and of some of their alkyl derivatives, and to the antibacterial action of the compounds thus obtained. The two groups of compounds studied may be represented schematically by the following structural formulas (where X stands for the halogen)

Group I

Derived from 2-hydroxydiphenylmethane

Group II

Derived from 4-hydroxydiphenylmethane

In addition, a number of dihalogen substituted derivatives were prepared which may be regarded as combinations of the types within each group. The alkyl homologs studied contain the substituting alkyl radicals in the nucleus bearing the hydroxyl group.

The different compounds were obtained by condensation of a benzyl or halogen benzyl derivative with a phenol derivative substituted by halogen only or by halogen and alkyl groups. In the preparation of these substances advantage was taken of the following facts: condensation in the presence of "acid" agents, such as anhydrous zinc chloride, sulfuric acid, etc., leads predominantly to substitution in para-position to the phenolic hydroxyl group if the para-position is open, and to substitution in ortho-position if it is not; on the other hand, condensation according to Claisen leads primarily to substitution in ortho-position to the hydroxyl group.²

The 3-methyl-5-chloro-2-hydroxydiphenylmethane was obtained by benzylation of *o*-cresol according to Claisen and subsequent chlorination.

Benzylation of 4-chloro-*m*-cresol (6-chloro-3-hydroxy-1-methylbenzene) according to Claisen might yield two ortho-substituted derivatives, *viz.*, 5-chloro-4-methyl-2-hydroxydiphenylmethane or 5-chloro-6-methyl-2-hydroxydiphenylmethane; possibly a mixture of both is formed. We have made no attempt as yet to establish the position of the methyl group in this product which will be referred to hereafter as 5-chloro-4[6]-methyl-2-hydroxydiphenylmethane.

It is evident that some of the compounds under discussion should permit preparation by either method of condensation. This was actually found to be the case in a number of instances whereby additional evidence was obtained in support of the constitution attributed to the compounds studied.

² L. Claisen, *Ann.*, **442**, 210 (1925).

Action on Bacteria

(a) **Bactericidal Effects.**—The researches on the relation between the chemical constitution and the bactericidal action of organic compounds heretofore published point to the great usefulness of testing the effect of the chemicals upon as many microorganisms as possible. In the present investigation four bacterial species were used, *viz.*, two representatives of the Gram-positive and two of the Gram-negative microorganisms. Thus *Staphylococcus pyog. aureus* and *Streptococcus* (hemolytic strain) are representatives of the former, *Eberthella typhi* and *Eberthella paradysenteriae* (Flexner) of the latter class. This procedure appears desirable in view of the findings obtained with other related groups of organic compounds which seem to point distinctly to a class specificity for Gram-positive bacteria in a number of instances.³ The data reported in the present paper indicate that most of the compounds studied show a similarly specific action; while practically all the compounds under consideration may be regarded quite generally as potent germicides, several of them are many times more effective against *Staphylococcus* and *Streptococcus* than against the bacilli of typhoid and paradysentery. It is of interest that similar effects have been observed by several investigators in the case of the inhibitory action of certain basic dyes of high molecular weight, particularly in the triphenylmethane series.

Table I gives a list of the compounds studied, the minimum average concentrations which are capable of killing the four microorganisms at 37° in five, ten and fifteen minutes, respectively, and the "phenol coefficients" calculated from a comparison of this effect with that produced by phenol under the same experimental conditions.

Table I indicates that this series of compounds comprises some very powerful bactericides. The action upon the Gram-positive microbes appears to be generally considerably stronger than upon the Gram-negative. Within the two classes of germs, *E. typhi* is somewhat more resistant than *E. paradysenteriae*, and staphylococcus more so than streptococcus.

When considering the two groups of monohalogen compounds studied, *viz.*, those derived from 2-hydroxydiphenylmethane and those derived from 4-hydroxydiphenylmethane, one cannot say that generally one or the other group is distinguished by greater antibacterial potency. However, certain regularities of behavior toward the microbes are distinctly evident, such as: that the 5-halogen-2-hydroxydiphenylmethanes are more potent than the 3-halogen-4-hydroxydiphenylmethanes, or that the monobromo derivatives of both the 2- and the 4-hydroxydiphenylmethanes are less effective than the corresponding monochloro derivatives against the two Gram-negative microorganisms, but more so against the Gram-positive. The 4'-chloro-2-hydroxydiphenylmethane is less effective than the 4'-chloro-4-hydroxydi-

³ Klarmann, Gates and Shternov, *THIS JOURNAL*, **54**, 1204 (1932).

phenylmethane against the Gram-negative, but it is somewhat more effective against the Gram-positive germs. The 3-chloro-2-hydroxydiphenylmethane in which the halogen is in ortho-position to the hydroxyl group is considerably less effective than the corresponding 5-chloro derivative, *i. e.*, one in which the chlorine and the hydroxyl groups are in para-position to each other. The germicidal superiority of the para- over the ortho-halogen substituted compounds has been observed previously in the case of simple phenol derivatives,⁴ both *p*-chloro- and *p*-bromophenol being more effectively bactericidal for *E. typhi* and *Staph. pyog. aureus* than the corresponding ortho derivatives.

Little regularity is discernible in the antibacterial behavior of the di-halogen derivatives. They also appear to be strong germicides; however, in one instance no definite bacteriological data could be obtained, in some others the results will be of a somewhat limited significance as the relative insolubility of these compounds necessitated the use of comparatively large quantities of alcohol in the preparation of dilutions; the presence of alcohol in excessive proportions, as will be shown later, may affect the outcome of the experiment either by impairing or by promoting the antibacterial action of the solutions.

The introduction of alkyl groups into the nucleus of phenol and of simple phenol homologs is known to produce an increase of bactericidal potency. The presence of alkyl groups in the compounds of considerable molecular weight under discussion produces no uniform effect on the bactericidal action. The presence of one or two methyl groups increases the germicidal potency against staphylococci and streptococci, the dimethyl derivatives in particular showing extraordinarily high phenol coefficients. The presence of one methyl and one isopropyl group, however, does not have any such effect, the compound in question (5-chloro-6-methyl-3-isopropyl-2-hydroxydiphenylmethane) actually being the least effective in the series. The bactericidal action upon the typhoid and paradysentery germs generally is not intensified by the presence of alkyl groups in the nucleus bearing the hydroxyl group.

In order to obtain an idea of the effect of temperature several chloro derivatives were allowed to act upon *Staph. aureus* at 20°. Table II shows

TABLE II
GERMICIDAL ACTION UPON *Staph. Aureus* AT 20°

Derivatives of hydroxydiphenylmethane	5 min.	10 min.	15 min.	Phenol coeff.
5-Chloro-2-	1:10,000	1:10,000	1:12,000	200
4'-Chloro-4-	1:10,000	1:10,000	1:11,000	195
5-Chloro-4[6]-methyl-2-	1:20,000	1:20,000	1:20,000	380
5-Chloro-4,6-dimethyl-2-	1:40,000	1:40,000	1:40,000	810

⁴ Klarmann, Shternov and Von Wowern, *J. Bact.*, 17, 423 (1929).

that somewhat higher concentrations are necessary at the lower temperature to produce a germicidal effect; the numerical values of the phenol coefficients compare with those obtained at 37°.

(b) **Bacteriostatic Effects.**—The data given in Table I indicate the germ-killing action of the compounds prepared. To supplement our knowledge of the antibacterial behavior of this class of chemicals we determined the inhibitory effect of a selected number of them upon the growth of *Staphylococcus aureus*. With this we combined the determination of the status of viability of the germs after different times of exposure to the inhibitory concentrations, ascertaining thereby the concentrations and times at which the bacteria are still capable of development when brought under favorable conditions. In Table III we give a complete record of data obtained with 5-chloro-4,6-dimethyl-2-hydroxydiphenylmethane in order to illustrate the procedure.

This table shows that the growth of staphylococcus in nutrient broth is prevented by a concentration of 1:150,000 or 0.00066% of 5-chloro-4,6-dimethyl-2-hydroxydiphenylmethane. This result is apparent after twenty-four hours of incubation, and does not change on keeping the set of culture tubes at 37° for another two days. Nevertheless the microbes are not actually dead or incapable of growth for many hours after having been implanted in broth containing this or even stronger concentrations of the compound.

When a transfer to fresh media is made fifteen minutes after planting, the concentration of 1:40,000 appears to be actually germicidal, while one of 1:50,000 is not. The longer the time allowed to elapse between planting and transfer, the lower is the concentration which kills the bacteria. But even after long exposure to the minimum bacteriostatic concentration of 1:150,000, there seem to be individual organisms which when transferred to fresh media are capable of producing growth.

Thus the minimum bacteriostatic concentration for *Staphylococcus aureus* is about twice lower than the minimum bactericidal concentration (given in Table I). It is also noteworthy that by this method the minimum bactericidal concentration after fifteen minutes appears to be 1:40,000, while by the direct method a concentration of only 1:80,000 was found. Indubitably this is due to the presence in the broth of organic matter in the bacteriostatic test, which interferes with the antibacterial action of the chemical.

Similar tests were carried out with a series of four compounds, *viz.*, 5-chloro-2-hydroxydiphenylmethane, 4'-chloro-4-hydroxydiphenylmethane, 5-chloro-4[6]-methyl-2-hydroxydiphenylmethane and 5-chloro-4,6-dimethyl-2-hydroxydiphenylmethane. In Table IV, instead of the complete records only the minimum concentrations are given at which no growth has occurred, and the phenol coefficients of bacteriostatic action.

TABLE IV
BACTERIOSTATIC ACTION UPON *Staphylococcus Aureus*

Derivatives of inhibitory hydroxydiphenylmethane	Minimum inhibitory concentration (96 hrs.)	No growth in subcultures from the following concentrations after						Bacterio static phenol coefficient
		15 min.	1 hr.	6 hrs.	24 hrs.	48 hrs.	72 hrs.	
5-Chloro-2-	1: 70,000	1: 7,000	1:15,000	1:20,000	1: 30,000	1: 50,000	1: 70,000	230
4'-Chloro-4-	1: 50,000	1:10,000	1:15,000	1:20,000	1: 20,000	1: 30,000	1: 50,000	165
5-Chloro-4[6]-methyl-2-	1:100,000	1:30,000	1:30,000	1:50,000	1: 70,000	1:100,000	1:100,000	330
5-Chloro-4,6-dimethyl-2-	1:150,000	1:40,000	1:60,000	1:80,000	1:100,000	1:150,000	1:150,000	500
Brilliant green	1:2,000,000	1: 5,000	1:50,000	1:2,000,000	1:2,000,000	1:2,000,000	6600
Phenol	1:300	1:100	1:120	1:150	1:200	1:200	1:300	1

Table IV indicates that the bacteriostatic action upon *Staph. aureus* of the four compounds tested is symbat with their bactericidal action upon the same microorganism. Thus in both cases the presence of the halogen in the nucleus bearing the hydroxyl group makes a more effective bacteriostatic agent than its presence in the other nucleus. The presence of one methyl radical increases the inhibitory capacity while the second methyl group brings about a further increase to more than double the value of the non-alkylated compound.

A parallel test with brilliant green (tetraethyldiaminotriphenylmethane) was included in order to demonstrate that the compounds of the class under discussion are typical bactericidal rather than typical bacteriostatic agents. Thus in three cases the maximum bacteriostatic dilution is only three to five times greater than the bactericidal (in fifteen minutes), while in one case it is ten times greater. In contrast to this, the maximum inhibitory dilution of brilliant green is about four hundred times its maximum germicidal dilution (in fifteen minutes), *i. e.*, the divergence of bactericidal and bacteriostatic concentrations is very considerable; brilliant green is a typical bacteriostatic agent.

The interesting antibacterial properties of the compounds described in this communication have suggested an extension of our investigations to include the alkyl and other alipharyl derivatives of halogenated phenols, work on which is in progress at this time.

Experimental Part

(a) **Chemical.**—The two methods used in the preparation of the compounds under consideration are illustrated in the following two examples.

Method I. Preparation of 3-Chloro-4-hydroxydiphenylmethane, $\text{Cl}(3)\text{OH}(4)\text{-C}_6\text{H}_4\text{CH}_2\text{C}_6\text{H}_5$.—*o*-Chlorophenol (51.4 g.) is mixed with 50.6 g. of benzyl chloride and 10 g. of anhydrous zinc chloride is added. The mixture is heated with stirring to 60° and kept at this temperature for two hours, then the temperature is raised to 90° and heating discontinued. Water is added and the mixture shaken with ether. The aqueous portion is withdrawn and the ethereal solution washed with dilute hydrochloric acid and finally with water. The ethereal solution is then shaken repeatedly with dilute potassium hydroxide. The alkaline extracts are washed with ether, then combined and acidified with hydrochloric acid. An oil precipitates which is shaken out with ether, and washed free from acid and salt. After drying and evaporation of the solvent, the oil is subjected to repeated distillation *in vacuo*. The fraction distilling at $155\text{--}160^\circ$ at 5 mm. is isolated.

Besides zinc chloride, aluminum chloride and sulfuric acid were used as condensing agents with success in several instances.

Method II. (Claisen's Reaction) Preparation of 3-Chloro-2-hydroxydiphenylmethane, $\text{Cl}(3)\text{OH}(2)\text{C}_6\text{H}_4\text{CH}_2\text{C}_6\text{H}_5$.—*o*-Chlorophenol (128 g.) is dissolved in 500 cc. of toluene and added slowly with constant mechanical stirring to 23 g. of "bird-shot" sodium in 100 cc. of toluene. Violence of reaction may be reduced by occasional immersion of the flask in cold water. When all of the sodium has disappeared the mixture is

cooled to room temperature and benzyl chloride is added very slowly with stirring. The reaction is completed by heating slowly in an oil-bath to 110° and maintaining at this temperature for four hours. The solvent and any uncombined phenol and benzyl chloride are removed by steam-distillation. To the residue methyl alcoholic alkali is added and the mixture shaken repeatedly with petroleum ether. The alkaline extract is acidified and, after the usual treatment, the oil is purified by vacuum distillation. The fraction distilling at 144° at 4 mm. is isolated.

Satisfactory results were also obtained when the sodium compounds of the halo-phenols were prepared by means of sodium hydroxide and subsequent drying of the reaction product.

The following Table V gives the physical constants of the compounds studied; together with a statement of the method and of the initial materials used in their preparation.

The procedure described by Huston and Eldridge⁵ was followed in the preparation of 3,5-dichloro-2-hydroxydiphenylmethane. However, the compound was found to melt at 81° while these authors report a melting point of 77–77.5°.

3-Methyl-5-chloro-2-hydroxydiphenylmethane was obtained by chlorination with chlorine in carbon tetrachloride of the condensation product of the sodium compound of *o*-cresol with benzyl chloride, referred to in the papers of Schorigin⁶ and of Huston, Swartout and Wardwell.⁷

(b) **Bacteriological.**—The determination of the bactericidal action upon *E. typhi* and *Staph. aureus* was carried out according to the method used by the Food and Drug Administration of the U. S. Department of Agriculture.⁸ In the work with *E. paradysenteriae* the same methods of culturing and testing were used as with *E. typhi*. Streptococcus (a very resistant hemolytic strain) was grown for the test in meat infusion-peptone broth (glucose free) at a *P_H* 7.2–7.4; for subcultures beef extract broth containing 1% of glucose and adjusted to the same *P_H* was used.

In the preparation of solutions, varying proportions of alcohol were employed. Because of the efficacy of most of the compounds studied toward staphylococci and streptococci in extremely low concentrations, the antibacterial effect of the alcohol present may be regarded as negligible. In most cases the minimum germicidal concentrations for the cocci in Table I did not contain more than 3% of alcohol, with the following exceptions: the extremely insoluble 3,5-dichloro-2-hydroxydiphenylmethane called for 20 and 10% of alcohol, respectively, and 6-methyl-3-isopropyl-5-chloro-2-hydroxydiphenylmethane required 15% of alcohol in both cases. Larger proportions of alcohol were necessary in the tests with the Gram-negative *E. typhi* and *E. paradysenteriae* because of the higher concentrations employed against these more resistant germs than against the Gram-positive cocci. Accordingly in the tests with monohalogen (non-alkylated) derivatives the minimum germicidal concentrations required not more than 5% of alcohol, in those with the alkyl derivatives not more than 15% (except the 6-methyl-3-isopropyl derivative which called for 20%) while the greatest proportion of alcohol had to be used with the dihalogen derivatives: 3,5-dichloro-2-hydroxydiphenylmethane (20%), 3-chloro-4'-bromo-4-hydroxydiphenylmethane (15%) and 3,4'-dichloro-4-hydroxydiphenylmethane (18% in the test with *E. typhi*, but only 3% with *E. paradysenteriae*).

It was considered important, therefore, to attempt a more complete determination of the effect of alcohol in our experiments. It may be assumed that the addition of a small amount of alcohol, by improving the

⁸ G. L. A. Ruehle and C. M. Brewer, U. S. Dept. of Agriculture, Circular No. 198, Dec., 1931.

solubility of an antiseptic substance, will make the preparation of a concentration within the bactericidal range possible. On the other hand, a large proportion of alcohol may produce one of two effects: a sufficient alcohol concentration may be present to be germicidal *per se*, or the alcohol concentration may be insufficient to kill bacteria, but sufficient to reduce the effectiveness of the antiseptic substance through a shift of its distribution ratio in favor of the aqueous phase. The following experiments, therefore, were made to ascertain to what extent these assumptions were correct.

Although the antibacterial action of alcohol has been studied by previous investigators,⁹ it was deemed necessary to carry out an experiment with alcohol under the exact conditions obtaining in our regular tests. The following table illustrates the results.

TABLE VI
BACTERICIDAL ACTION OF ALCOHOL

	5 min.		10 min.		10 min.	
	Killed	Not killed	Killed	Not killed	Killed	Not killed
<i>Staph. aureus</i>	40 (34.5)	30 (25.9)	40 (34.5)	30 (25.9)	40 (34.5)	30 (25.9)
<i>Streptococcus (haemol.)</i>	40 (34.5)	30 (25.9)	40 (34.5)	30 (25.9)	30 (25.9)	25 (21.6)
<i>E. typhi</i>	25 (21.6)	20 (17.3)	20 (17.3)	15 (13.0)	20 (17.3)	15 (13.0)
<i>E. paradysesterae</i>	25 (21.6)	20 (17.3)	20 (17.3)	15 (13.0)	20 (17.3)	15 (13.0)

The figures without brackets give the alcohol concentrations in per cent. obtained by diluting 95% alcohol. The bracketed figures have been recalculated on the basis of the fact that the addition of 0.5 cc. of culture to 5 cc. of diluted alcohol brings about a further dilution of the latter; they represent the actual concentrations of alcohol (100%) in which the bacteria are suspended. It appears that *E. typhi* and *E. paradysesterae* are considerably more sensitive to alcohol than staphylococcus and streptococcus. The germicidal alcohol concentrations for the latter two microorganisms appear to be considerably above the alcohol concentrations used in the tests with the antiseptic substances while with *E. typhi* and *E. paradysesterae* some alcohol concentrations approach those employed in a few tests with the most insoluble antiseptics; thus in certain isolated instances an interfering influence of the alcohol may be counted with.

Another experiment therefore was run in which the dilutions of an antiseptic (5-chloro-2-hydroxydiphenylmethane) were made with diluted alcohol of different concentrations instead of water. The microorganisms used were *E. typhi* and *Staph. aureus*. The results obtained are given in Table VII.

This table shows the interesting fact that alcohol, if used in concentrations which by themselves are not germicidal, is capable of reducing the germicidal action of an antiseptic substance to a considerable extent

⁹ F. W. Tilley and J. M. Schaffer, *J. Agr. Res.*, **65**, 611 (1931).

TABLE VII

THE EFFECT OF DILUTED ALCOHOL ON THE BACTERICIDAL POTENCY OF 5-CHLORO-2-HYDROXYDIPHENYLMETHANE

40	All dilutions germicidal			All dilutions germicidal		

(particularly in the case of *Staph. aureus*), the intensity of the impairment depending upon the alcohol concentrations. The most probable reason for this is the shift of the partition equilibrium of the antiseptic substance between the microorganisms and the aqueous-alcoholic phase, in favor of the latter, owing to an increased solvent capacity for the antiseptic substance.

One finds occasionally in the literature that difficultly soluble phenols are brought into solution for the purpose of bacteriological tests by means of diluted alkalis. We ran a series of experiments with three compounds which permitted the preparation of such solutions, using 0.035% potassium hydroxide for the preparation of the initial 0.1% solutions; the further dilutions were made with water. The results given in Table VIII were obtained.

TABLE VIII

THE EFFECT OF ALKALI USED IN THE PREPARATION OF THE INITIAL SOLUTION UPON THE GERMICIDAL ACTION

Derivatives of hydroxy-diphenylmethane	<i>Staph. aureus</i>			Diff. of effectiveness, %	<i>E. typhi</i>			Diff. of effectiveness, %

3-Bromo-4-	1:11,000	1:11,000	1:12,000	-20	1:2,000	1:2,500	1:2,500	-15
5-Chloro-2-	1:14,000	1:16,000	1:18,000	-2	1:11,000	1:12,000	1:12,000	+9

This table indicates that the use of very diluted alkali in preparing solutions offers no advantage, as it produces no uniform effect. It also obscures the picture because of the change of P_H to which bacteria are known to be sensitive in varying degrees.

The determination of the bacteriostatic effect upon *Staphylococcus aureus* was carried out according to the following procedure. To nine cc. of broth (of the same composition as used in growing the germs for the tests on bactericidal action), one cc. of the antiseptic solution was added (containing ten times the concentration which appears in the table). A spiral loop (of five turns of 2.18 mm. inside diameter, wire gage 23 B. and S., and holding approximately 0.02 cc.) was used to plant the twenty-four hour

culture in this mixture previously warmed to 37°. The tubes were kept in the incubator for ninety-six hours. Transfers were made into fresh broth after fifteen minutes, 1, 2, 4, 6, 24, 48 and 72 hours with a loop of the same size. Readings of subcultures were made after forty-eight hours' incubation.

Our thanks are due to Mr. A. Grawehr of our laboratory staff, for valuable assistance rendered in the bacteriological phase of this work.

Summary

A number of mono- and di-halogen derivatives of 2- and of 4-hydroxydiphenylmethanes and their alkyl homologs have been synthesized, either by direct benzylation of halogen phenols or by halogenation of benzylated phenols. The benzyl group was directed into either the ortho or para position to the hydroxyl group by the choice of suitable condensing agents.

While all the compounds of this series were found to be potent bactericides, some derivatives showed an extraordinarily high efficacy toward the two Gram-positive cocci studied (*Staph. aureus* and *Streptococcus haemol.*). Certain regularities in the relation between the antibacterial action and the chemical composition of the compounds studied were found. Thus halogen in the para position to the hydroxyl group conditioned a greater antibacterial efficiency than halogen in ortho position. The 4'-chloro-2-hydroxydiphenylmethane was more effective than the 4'-chloro-4-hydroxydiphenylmethane against the Gram-positive cocci but less so against the two Gram-negative bacteria (*E. typhi* and *E. paradysenteriae*). The monobromo derivatives of both the 2- and the 4-hydroxydiphenylmethanes were less effective than the corresponding monochloro derivatives against the germs of typhoid and paradysentery but more so against staphylococcus and streptococcus. The dihalogen derivatives were also highly bactericidal.

The presence of one or two methyl groups was found to cause a considerable increase in germicidal potency toward the cocci but not toward the germs of typhoid and paradysentery. A methyl and an isopropyl group however, reduce the bactericidal action upon all four microorganisms.

Experiments were also carried out with several compounds to determine their capacity of inhibiting bacterial growth. While, as was to be expected, much lower concentrations were necessary to produce this effect, than to kill the microorganisms upon short exposure, this class of substances appears to show a typically bactericidal rather than a bacteriostatic behavior, when compared, *e. g.*, with bacteriostatic dyes.

Some attention was devoted also to the effect of alcohol used in the preparation of the solutions employed in the bacteriological tests. It was found that alcohol concentrations not germicidal *per se* impaired the antibacterial action of 5-chloro-2-hydroxydiphenylmethane; an explanation

for this was suggested on the basis of an assumed shift of the partition equilibrium of the dissolved substance between the bacteria and the aqueous-alcoholic phase. The effect of diluted alkali in the preparation of the solutions upon their germicidal action was also studied.

STUDIES IN THE PHENANTHRENE SERIES. II. PHENANTHRENE CARBOXYLIC ACIDS AND 9-BROMOPHENANTHRENE DERIVATIVES¹

BY ERICH MOSETTIG AND JACOB VAN DE KAMP

RECEIVED APRIL 1, 1932

PUBLISHED AUGUST 5, 1932

These investigations have been carried out in order to find a practicable way of preparing the phenanthrene carboxylic acids, whereby an adequate supply of starting material for further syntheses in this series would be assured.

Of the hitherto known preparative methods, that of Pschorr² is the best for the phenanthrene-9-carboxylic acid, while the -2- and -3-carboxylic acids were best prepared through the corresponding phenanthrene-2- and 3-sulfonic acids.^{3,4} Neither of these methods is suitable however for large scale preparation of the carboxylic acids.

Recently, Mosettig and van de Kamp⁵ found a way of preparing phenanthrene-2- and -3-carboxylic acids by oxidizing 2- and 3-acetylphenanthrenes, respectively, with sodium hypochlorite, a method which seemed much simpler than those hitherto employed because of the relatively easy separation of the acetylphenanthrenes on a large scale and the good yields obtained in their oxidation.

Liebermann and Zsuffa⁶ described the preparation of a phenanthrene carboxylic acid from phenanthrene with oxalyl chloride and aluminum chloride. These authors claimed for their acid the constitution of phenanthrene-9-carboxylic acid and mentioned that besides this acid another one, containing the carboxyl group "in the nucleus," was found in smaller quantities.

In consideration of the results which we obtained from the acetylation of phenanthrene,⁵ where it was shown that the acetyl group enters the

phenanthrene nucleus in the 2- and 3-positions, but not in any detectable degree in the 9-position, it seemed desirable to test Liebermann's results.

When phenanthrene was treated with oxalyl chloride in the presence of aluminum chloride in carbon disulfide solution, under certain conditions a mixture of phenanthrene-3-, -2- and -9-carboxylic acids was formed in an approximate ratio of 75:18:4. Besides these acids, an acid which might be a phenanthrene monocarboxylic acid was formed, whose structure has not as yet been determined because of the small amount obtained (yield about 2%). This acid was compared with a sample of the phenanthrene-1-carboxylic acid⁷ which Dr. L. F. Fieser kindly sent us for comparison. No agreement in properties was found, so the formula of the 1-carboxylic acid for our acid is excluded.

These facts are to some extent in accord with the results of the action of acetyl chloride on phenanthrene, where the 3-position is favored, and the 2-position is the next in order of preference. We may remark that nitrobenzene, which gave such good results in the acetylation of phenanthrene, did not prove to be so useful in the case of oxalyl chloride, apparently because of the fact that in this medium we could not run the reaction at the desired low temperature (-15°). Unfortunately it appeared that this interesting formation of the acids was not a practicable method of preparation, first because of the high cost of oxalyl chloride, and second because of the extremely complicated procedure necessary in separating the reaction mixture.

As was shown by Staudinger,⁸ oxalyl chloride decomposes in the presence of aluminum chloride into phosgene and carbon monoxide, so that the action of oxalyl chloride on hydrocarbons under these conditions may be considered essentially as the action of phosgene under the catalytic influence of aluminum chloride, whereby the acid chlorides are formed, which in turn are converted into the acids when the reaction mixture is decomposed. Therefore the direct action of phosgene and aluminum chloride on phenanthrene was investigated. The conditions of the experiment were exactly the same as those in the experiment involving oxalyl chloride and phenanthrene, but we did not succeed in isolating any of the expected phenanthrene carboxylic acids.

Phenanthrene, phosgene and aluminum chloride were allowed to react at -15° for twenty-four hours. Not a trace of acid could be isolated from this reaction. The phenanthrene had changed completely. The brown amorphous mass obtained from the reaction mixture could not be crystallized in any way, nor did a high vacuum distillation give a product which could be crystallized.

⁷ Prepared from phenanthrene-1-sulfonic acid (private communication from Dr. L. F. Fieser).

⁸ Staudinger, *Ber.*, **41**, 3558 (1908).

The action of cyanogen bromide and aluminum chloride, which gave good results with anthracene,⁹ gave practically no product in the case of phenanthrene. Under the most varied experimental conditions it was not possible to obtain the expected nitriles. At low temperature and short duration, no reaction took place, whereas with higher temperatures and longer time the phenanthrene was changed completely and only traces of nitrile could be detected (hydrolysis to the carboxylic acids).

It was found, however, that the reaction of Rosenmund,¹⁰ the replacement of nuclear halogen by the cyano group with potassium cyanide in the presence of a cuprous salt as catalyst, could be applied in the phenanthrene series with satisfactory results. We were greatly assisted here by E. I. du Pont de Nemours and Company, Wilmington, Del., who were so kind as to carry out this reaction on a large scale in a high pressure autoclave, and to whom we wish to express our sincere thanks. An even better method, and one requiring no autoclave, was found in the modification of the Rosenmund procedure, recently published by von Braun and Manz.¹¹ By heating 9-bromophenanthrene with the calculated amount of cuprous cyanide at 260° for six hours, phenanthryl-9-cyanide was obtained in a yield of 90–95% of the theoretical. Because of its simplicity, this method is especially adapted for the production of phenanthrene-9-carboxylic acid in large quantities.

This substitution of nuclear bromine by the cyano group probably can be accomplished also on other bromophenanthrenes, but is of particular advantage for the preparation of phenanthrene-9-carboxylic acid (from the easily accessible 9-bromophenanthrene), which until now has been prepared either by Pschorr's method¹² or through the difficultly obtainable phenanthrene-9-sulfonic acid.¹³

The 9,10-double bond in phenanthrene has a well-marked olefinic character, as is shown in the formation of a 9,10-dibromo addition product¹⁴ and an ether of 10-nitro-9,10-dihydrophenanthrol (-9).^{15,16} The polymerization of olefinic compounds which is caused by aluminum halides under certain conditions might account for the unsatisfactory yields of acids or acid chlorides, respectively, in the action of oxalyl chloride on phenanthrene with aluminum chloride. Therefore one might expect that the formation of polymerization products, which appear in the form of unpleasant non-crystallizable and tarry products, would be minimized when the ac-

tivity of the 9,10-double bond is decreased by the introduction of an appropriate substituent, like bromine,¹⁷ in the 9-position. We find, in fact, that when the Friedel-Crafts reaction is carried out on 9-bromophenanthrene with oxalyl chloride or with acetyl chloride¹⁸ in carbon disulfide solution with aluminum chloride, it gives exclusively crystalline compounds.

When oxalyl chloride reacts with 9-bromophenanthrene in carbon disulfide solution under the catalytic influence of aluminum chloride at -15° , the main product formed is a monobromo-monocarboxylic acid of m. p. $283-284^{\circ}$, which appears to be 9-bromophenanthrene-3(or 6)-carboxylic acid. Besides this acid at least two other acids which have not been identified are formed in small quantities. The yield of crystalline material in this reaction is from 90 to 95%. The structure of this monocarboxylic acid was proved by oxidizing its methyl ester with chromic acid in glacial acetic acid solution, whereby a substituted phenanthrene-9,10-quinone was formed, which proved to be identical with the known¹⁹ phenanthrene-9,10-quinone-3-carboxylic acid methyl ester. Furthermore, the bromine atom in the methyl ester of this acid could be replaced by hydrogen, catalyzed with palladium. The reduction resulted in phenanthrene-3-carboxylic acid methyl ester which, as well as the oxidation with chromic acid, shows that the carboxyl group has entered the molecule in the 3- or 6-position.

The reaction between 9-bromophenanthrene and acetyl chloride in carbon disulfide solution in the presence of aluminum chloride at -15° yielded a solid reaction mixture, free from tars and resins, which consisted mainly of 9-bromo-3(or 6)-acetylphenanthrene of melting point $150-151^{\circ}$. The position of the acetyl group was proved by the oxidation of this compound with chromic acid in glacial acetic acid solution, which yielded 3-acetylphenanthrene-9,10-quinone of melting point $217-218.5^{\circ}$, identical with the quinone obtained on oxidation of 3-acetylphenanthrene.⁵ The structure could also be demonstrated by oxidation with a 2% sodium hypochlorite solution, which gave an acid which was identical with the 9-bromophenanthrene 3(or 6)-carboxylic acid obtained from 9-bromophenanthrene and oxalyl chloride. Here likewise, besides this main product, at least one other ketone was formed.

The separation and purification of these by-products, as well as of the by-products from the reaction of 9-bromophenanthrene and oxalyl chloride, involved extreme difficulties, however, and were not pursued, and the

¹⁷ Cf. Ingold and Ingold, *J. Chem. Soc.*, 2354 (1931).

¹⁸ Although this reaction carried out in nitrobenzene solution on phenanthrene itself gives excellent yields of crystalline products, the same reaction, when run in carbon disulfide solution, leads chiefly to light yellow, heavy oils which could not be crystallized by any means. We hope to collect more experimental material to provide a satisfactory explanation for this remarkable difference in the influence of the solvents.

¹⁹ Fieser, *THIS JOURNAL*, 51, 3101 (1929).

question of the position taken by the new substituent (3 or 6) in the main reaction product was likewise left unsettled, since we were mainly interested in showing the quantitative effect of the 9-bromine atom on these two Friedel-Crafts reactions.

Experimental

Phenanthrene with Oxalyl Chloride

Phenanthrene-2-, -3- and -9-Carboxylic Acids.—Twenty-five grams of phenanthrene dissolved in 150 cc. of carbon disulfide in a 500-cc. flask fitted with a mercury-sealed stirrer and a calcium chloride tube was placed in a freezing mixture of ice and salt. Sixty grams of oxalyl chloride was slowly added and to the mixture which was vigorously stirred at -15° was added 12 g. of aluminum chloride in small portions in the course of one-half hour. Immediately after the addition of the aluminum chloride the reaction mixture turned dark green and a rapid stream of hydrogen chloride was liberated. After one-half hour 100 cc. of carbon disulfide and 25 g. of aluminum chloride were added in small portions over a period of forty-five minutes. The evolution of hydrogen chloride which was quite violent in the beginning of the reaction slowed down toward the end, and when the hydrogen chloride had practically ceased to escape (after fourteen hours' stirring at -15°), the dark green viscous reaction mixture was decomposed very cautiously and slowly on cracked ice (under the hood). Violent streams of hydrogen chloride and possibly of phosgene were liberated in the decomposition. The mixture was then treated with 25 cc. of concentrated hydrochloric acid.

In all, 100 g. of phenanthrene was so treated and the decomposed reaction mixtures combined afterward. The carbon disulfide solution of the decomposed reaction mixture had a dark red color. After separating the two layers and removing the carbon disulfide *in vacuo*, a dark brown, sticky, partly solidified residue was obtained. This residue was extracted with 10% sodium carbonate solution until practically no precipitate was obtained on acidifying the filtered alkaline extracts with hydrochloric acid. The precipitate of acids obtained from these extractions will be designated A.

As it appeared that the residue still contained a small amount of an acid in the form of an almost insoluble sodium salt, it was extracted several times by boiling with water. These aqueous extracts were also filtered and acidified and yielded a precipitate of acid, designated B.

The final residue was dissolved in ether and the ethereal solution dried over sodium sulfate. On evaporation of the ether, crystals separated which were filtered and washed with cold ether. After one crystallization from benzene a homogeneous product was obtained, yellow needles melting at $233-234^{\circ}$ (uncorr.), yield, 2.0 g. This product, which showed no acid properties, might have been a mono or diketone. The properties and analyses of this compound, however, do not confirm this.

Anal. Subs., 0.0822, 0.0760: CO_2 , 0.2618, 0.2421; H_2O , 0.0349, 0.0321. Calcd. for monoketone $\text{C}_{14}\text{H}_9\text{COC}_{14}\text{H}_9$: C, 91.06; H, 4.75; for diketone $\text{C}_{14}\text{H}_9\text{COCOC}_{14}\text{H}_9$: C, 87.77; H, 4.42. Found: C, 86.86, 86.88; H, 4.75, 4.73.²⁰

After this substance had been isolated from the ethereal solution, the latter was evaporated to dryness. Upon standing, the residue crystallized partly to a red cake. From it, by extraction with methyl alcohol, 27 g. of phenanthrene could be recovered, while the remainder consisted of a dark red viscous oil, weighing 16 g., sparingly soluble in most of the common organic solvents, with the exception of pyridine, from which, however, it could not be recrystallized. The investigation of this oil offered little pros-

²⁰ We did not succeed in the preparation of a quinoxaline derivative which would indicate the presence of an α -diketone.

pect of success and has not been carried further. (If the temperature in this reaction is not kept as low as -15° , the product consists almost entirely of this red oil, and hardly any acid is formed.)

The mixture of acids A consisted of a yellowish-brown flocculent precipitate. In order to purify this precipitate, it was treated with dilute sodium carbonate solution, and the small insoluble residue taken up in ether. The carbonate solution was extracted with ether until the ether came off colorless. The ether extracts contained more of the red oil mentioned above. On acidification of the sodium carbonate solution, a slightly yellow precipitate was obtained which after being filtered, washed with water and dried in air weighed 52 g.

Space does not permit a description of the exact method of working up the mixture of acids, since for the complete separation of the mixture a division into at least sixty fractions was necessary. Neither the solubilities of the acids nor those of their potassium or sodium salts were so different that one component could be easily removed completely. Nevertheless, advantage could be taken of the fact that phenanthrene-3-carboxylic acid is less soluble in xylene, glacial acetic acid or ethyl alcohol than the 2- and 9-isomers. Furthermore, the formation of characteristic micro-crystalline salts enabled us to follow the separation more or less and to identify under the microscope each fraction obtained. Besides these properties, the fact that phenanthrene-9-carboxylic acid methyl ester is much less soluble (and crystallizes much better) than the 2- and 3-isomers, proved to be of great advantage in this separation.

The 52 g. of A was extracted eight times by boiling with 250 cc. of xylene each time. From the last four fractions nearly colorless crystals of phenanthrene-3-carboxylic acid separated, which was purified through its potassium salt. Also the mother liquors of these fractions consisted almost entirely of the 3-acid (melting point $267-269^{\circ}$, melting point of the methyl ester, after one recrystallization, $95-95.5^{\circ}$; mixed melting point with the 3-acid or its methyl ester, obtained on oxidation of 3-acetylphenanthrene⁵ $267-269^{\circ}$ and $95-95.5^{\circ}$, respectively). The fourth fraction, which had a slight yellow color, also yielded some phenanthrene-3-carboxylic acid. Fractions I, II and III (dark brown) gave only a very small crystalline precipitate of this acid.

The xylene mother liquor of fraction IV was combined with the mother liquors of fractions I, II and III, evaporated to dryness in a vacuum and the remaining residue brought into solution with a little dilute sodium hydroxide solution. With an excess of concentrated sodium hydroxide solution (50%), a very sparingly soluble sodium salt was precipitated which was not homogeneous. Enough water was added therefore to dissolve it again and the mixture of acids was precipitated with hydrochloric acid. After drying, this mixture was esterified with methyl alcohol and concentrated sulfuric acid. In this esterification a resinous product separated out which caused a loss of 5 to 10% of the material. (As yet the cause of this resin formation is unknown. As the original product was entirely alkali-soluble, one may assume that only products of an acid character are present, which, however, can in no way be separated from the phenanthrene-carboxylic acids.)

The brown oily mixture of esters was saponified with a concentrated aqueous sodium hydroxide solution, whereupon the sparingly soluble sodium salt of phenanthrene-2-carboxylic acid separated in shining white leaflets. This salt was uniform and gave, after digesting with hydrochloric acid, pure phenanthrene-2-carboxylic acid, melting point $256-258^{\circ}$ (melting point of its methyl ester after one recrystallization from methyl alcohol $95.5-96^{\circ}$; mixed melting points with the 2-acid, or its methyl ester, obtained on oxidation of 2-acetylphenanthrene⁵ $257-259^{\circ}$ and $95.5-96^{\circ}$, respectively).

From the mother liquors of the sparingly soluble sodium phenanthrene-2-carboxylate the free acids were regenerated; these free acids were put into solution with the calculated

amount of dilute potassium hydroxide and by gradual addition of 50% potassium hydroxide solution, several fractions of potassium salts were precipitated. The first salt fractions consisted of practically pure potassium-3-carboxylate. The last fractions contained a small amount of the 3-acid and a mixture of some other acids, and were dissolved in water again and precipitated with hydrochloric acid. This precipitate was a yellowish-brown crystalline mass and weighed after drying 24 g. It was extracted with hot ethyl alcohol and yielded thus 4 g. of almost white, insoluble crystals. This appeared to be practically pure phenanthrene-3-carboxylic acid, which was further purified through the potassium salt in the usual way. The alcoholic mother liquor was evaporated to dryness and treated with alkali, giving a trace of phenanthrene-3-carboxylic acid in the form of the potassium salt. The remaining mixture was acidified, and the mixture of acids which separated esterified with methyl alcohol and sulfuric acid. A further purification by fractional crystallization of the ester mixture could not be effected. Therefore the mixture of esters was distilled in oil pump vacuum. The slightly yellow distillate was taken up in methyl alcohol, from which a small amount of white needles was deposited. These were collected and after one more distillation in oil pump vacuum melted at 114–115°; a mixed melting point with the methyl ester⁵ of phenanthrene-9-carboxylic acid (synthesized according to Pschorr²¹) showed no depression (yield, 1.5 g.).

From the mother liquors of this ester a homogeneous product could not be obtained by fractional crystallization. On saponification of these fractions with sodium hydroxide, a small amount of sodium phenanthrene-2-carboxylate could be collected, whereupon the residual alkaline mother liquors were acidified separately, and from each a yellow mixture of acids was obtained.

Some of these fractions of acid gave a potassium salt crystallizing in shining leaflets, which was purified by two recrystallizations from water. On acidification of its colorless aqueous solution a yellow oil precipitated which upon cooling solidified to yellow needles. After drying in a desiccator, the melting point of the acid was found to be between 70 and 75°. Apparently it contained water of crystallization; after drying at 100° in a vacuum and recrystallizing from benzene, the acid melted at 123–125°. ²² It was analyzed in the form of its potassium salt, which was dried at 100° in a vacuum.

Anal. Subs., 0.0586: K_2SO_4 , 0.0193. Calcd. for phenanthrene monocarboxylic acid potassium salt $C_{16}H_9O_2K$: K, 15.03. Found: K, 14.78.

The precipitate B consisted of practically pure phenanthrene-2-carboxylic acid, which was purified through its sodium salt; melting point of the acid 258–260°, of the methyl ester 95.5–96°.

Whether acids were formed in the oxalyl chloride reaction which could not be esterified or were unstable under the conditions of separation could not be determined. From the original mixture of 52 g. of acids, 22.5 g. of pure acids was obtained: 17 g. of phenanthrene-3-carboxylic acid, 4 g. of phenanthrene-2-carboxylic acid, 1 g. of phenanthrene-9-carboxylic acid and 0.5 g. of the yellow acid of m. p. 123–125°.

Preparation of Phenanthrene-9-carboxylic Acid from 9-Bromophenanthrene.—A mixture of 50 g. of 9-bromophenanthrene (m. p. 63°), 30 g. of cuprous cyanide, 75 g. of potassium cyanide, 100 cc. of methyl alcohol and 40 cc. of water was heated at 210° for eight hours in an autoclave of 500 cc. capacity. The autoclave was heated in a bath of refluxing nitrobenzene (205–210°). After the autoclave had cooled down to room temperature the excess pressure was released (strong odor of ammonia). The reaction mixture was removed from the autoclave by pouring the liquid part into water,

²¹ Pschorr, *Ber.*, **29**, 496 (1896).

²² The phenanthrene-1-carboxylic acid prepared by Dr. L. F. Fieser melts at 232° (private communication).

and washing out the solid crystalline cake with water. After evaporation of the alcohol the mixture was filtered. From the filtrate a small amount (10–15%) of phenanthrene-9-carboxylic acid could be thrown out and purified through its potassium salt. The precipitate on the filter was extracted with ether. After drying and evaporating the ether, the residue was hydrolyzed by boiling with a 25% methyl alcoholic potassium hydroxide solution, which yielded the 9-acid. The acid thus collected combined with the small amount already obtained weighed 36 g. (yield, 83% of the theoretical). Recrystallized from glacial acetic acid, the acid melted at 251–252°.

The following procedure, which does not necessitate the use of an autoclave, was found to be most convenient. Thirty grams of 9-bromophenanthrene was mixed with 12 g. (1 mole + 10%) of finely powdered cuprous cyanide and heated at 260° for six hours. The reaction mixture, which solidified entirely upon cooling to room temperature, was finely powdered and extracted with ethyl alcohol or with chloroform. On evaporation of the solvent and removal of the last traces in a vacuum, 22.1 g. of phenanthryl-9-cyanide was obtained, which after one recrystallization from alcohol melted at 103–104°; yield, 93% of the theoretical. This nitrile was hydrolyzed to phenanthrene-9-carboxylic acid by boiling with 25% methyl alcoholic potassium hydroxide; yield, 90% of the theoretical.

9-Bromophenanthrene with Oxalyl Chloride.—Fifteen grams of 9-bromophenanthrene in 125 cc. of carbon disulfide, 25 cc. of oxalyl chloride, and 25 g. of aluminum chloride were allowed to react in the way described above. After decomposition of the reaction mixture a slightly yellow crystalline mixture of acids resulted which was filtered and brought into solution with dilute alkali. The alkaline solution was extracted with ether to remove unchanged 9-bromophenanthrene, and the acids were precipitated with hydrochloric acid. After drying, 15.5 g. of a mixture of acids was obtained; yield, 85% of the theoretical. (Ten to twelve per cent. of bromophenanthrene was recovered.) In all, 85 g. of 9-bromophenanthrene was so treated. The separation of the mixture of acids was carried out through their methyl esters.

9-Bromophenanthrene-3(or 6)-carboxylic Acid Methyl Ester, $C_{14}H_9BrCOOCH_3$.—Thirty grams of the mixture of acids described above, 600 cc. of methyl alcohol and 45 g. of concentrated sulfuric acid were boiled for four hours. During this esterification, part of the esters crystallized out. The esterification mixture was worked up in the usual way. Because of its slight solubility in methyl alcohol the methyl ester of 9-bromophenanthrene-3(or 6)-carboxylic acid was easily isolated and purified as white needles of m. p. 155–155.5°, sparingly soluble in methyl alcohol and ether, more soluble in glacial acetic acid, dioxane and chloroform.

Anal. Subs., 0.0904, 0.0798: AgI, 0.0657, 0.0577. Calcd. for $C_{14}H_{11}O_2Br$: one methoxyl, 9.83. Found: 9.60, 9.55.

9-Bromophenanthrene-3(or 6)-carboxylic Acid, $C_{14}H_9BrCOOH$.—The ester was saponified to the acid with 25% methyl alcoholic potassium hydroxide; yield, quantitative. The acid is recrystallized from glacial acetic acid, in which it is sparingly soluble, as white needles of m. p. 283–284° (uncorr.).

Anal. Subs., 0.1492: AgBr, 0.0942. Calcd. for $C_{14}H_9BrO_2$: Br, 26.55. Found: Br, 26.87.

This acid forms well-crystallized potassium and sodium salts, which are only sparingly soluble in water.

By treating the 9-bromophenanthrene-3(or 6)-carboxylic acid methyl ester with chromic acid in the usual way, a quinone was obtained which after recrystallization from glacial acetic acid melted at 210–212°. The mixed melting point with phenanthrene-9,10-quinone-3-carboxylic acid methyl ester, obtained from phenanthrene-3-carboxylic acid methyl ester, gave no depression.

Debromination of 9-Bromophenanthrene-3(or 6)-carboxylic Acid Methyl Ester with Hydrogen.—To a suspension of 0.1 g. of palladous hydroxide–calcium carbonate catalyst (Pd content 1%) in a mixture of 3 cc. of ethyl alcohol and 1 cc. of water, 0.1 g. of 9-bromophenanthrene-3(or 6)-carboxylic acid methyl ester dissolved in a mixture of 10 cc. of ethyl alcohol and 5 cc. of pyridine was added under a stream of hydrogen. On shaking the mixture with hydrogen, the calculated absorption was reached in about twenty minutes. Upon filtering the reaction mixture from the palladium–calcium carbonate and pouring the filtrate into 250 cc. of 10% hydrochloric acid, phenanthrene-3-carboxylic acid methyl ester separated practically pure. After one recrystallization from methyl alcohol the melting point is 95–95.5°. A mixed melting point with a sample of ester prepared from 3-acetylphenanthrene showed no depression.

The separation of the mixture of methyl esters contained in the mother liquors of 9-bromophenanthrene-3(or 6)-carboxylic acid methyl ester was attempted by laborious fractional crystallization from several solvents. A uniform product could not be obtained.

9-Bromophenanthrene with Acetyl Chloride

9-Bromo-3(or 6)-acetylphenanthrene, $C_{14}H_9BrCOCH_3$.—Twenty-five grams of 9-bromophenanthrene in 200 cc. of carbon disulfide, 10 g. of acetyl chloride and 40 g. of aluminum chloride were allowed to react in the way described above. After decomposition of the reaction mixture a light yellow oil was obtained, which soon solidified to an almost white crystalline cake. Fractional crystallization of this cake from methyl alcohol yielded mainly 9-bromo-3(or 6)-acetylphenanthrene ($\approx 70\%$ yield), besides a small amount of unchanged bromophenanthrene and a mixture of other ketones. The 9-bromo-3(or 6)-acetylphenanthrene was purified by two more recrystallizations from methyl or ethyl alcohol (with animal charcoal), from which solvents it crystallizes in long white needles of m. p. 150–151°. It is easily soluble in dioxane or glacial acetic acid, sparingly soluble in ether, methyl or ethyl alcohol and chloroform.

Anal. Subs., 0.1610: AgBr, 0.1023. Calcd. for $C_{16}H_{11}OBr$: Br, 26.73. Found: Br, 27.04.

9-Bromo-3(or 6)-acetylphenanthrene Semicarbazone.—The semicarbazone which was prepared in the usual way was recrystallized from methyl alcohol in which it is very sparingly soluble; white needles of m. p. 265–265.5° (uncorr.).

Anal. Subs., 0.1351: 14.65 cc. of N (29°, 746 mm.). Calcd. for $C_{17}H_{14}ON_3Br$: N, 11.80. Found: N, 12.03.

9-Bromo-3(or 6)-acetylphenanthrene Oxime.—Recrystallized from methyl alcohol it forms white needles of m. p. 142.5–143° (uncorr.).

Anal. Subs., 0.1541: 6.5 cc. of N (28°, 746 mm.). Calcd. for $C_{16}H_{12}ONBr$: N, 4.46. Found: N, 4.70.

Oxidation with Sodium Hypochlorite.—One gram of 9-bromo-3(or 6)-acetylphenanthrene was oxidized with a 2% sodium hypochlorite solution.^{5,23} The acid obtained melted after one recrystallization from glacial acetic acid at 283–284°. A mixed melting point with the 9-bromophenanthrene-3(or 6)-carboxylic acid described above showed no depression; yield, almost quantitative. One-half gram of this acid esterified with methyl alcohol and sulfuric acid yielded a methyl ester of m. p. 155–155.5°. This methyl ester gave no depression in melting point with the methyl ester of 9-bromophenanthrene-3(or 6)-carboxylic acid described above.

Oxidation with Chromic Acid.—The oxidation with chromic acid of 9-bromo-3(or 6)-acetylphenanthrene was carried out in the usual way. The quinone obtained

²³ Graebe, *Ber.*, **35**, 2753 (1902).

melted after two recrystallizations from glacial acetic acid at 217–218.5°. A mixed melting point with the quinone obtained by oxidation of 3-acetylphenanthrene showed no depression.

Summary

1. The action of oxalyl chloride on phenanthrene described by Liebermann and Zsuffa has been shown to yield not phenanthrene-9-carboxylic acid as the main product, but phenanthrene-3-carboxylic acid, accompanied by smaller quantities of the 2- and 9-isomers and an acid of melting point 123–125° whose structure has not yet been determined.

2. A good preparative method for phenanthrene-9-carboxylic acid is described.

3. The influence of bromine substitution in the 9-position on Friedel-Crafts reactions in this series has been investigated.

4. 9-Bromophenanthrene-3(or 6)-carboxylic acid and 9-bromo-3(or 6)-acetylphenanthrene are described.

PRODUCTION OF BUTENES BY PYROLYSIS OF THE NORMAL MONOCHLOROBUTANES

BY PAUL E. WESTON¹ AND H. B. HASS

RECEIVED APRIL 4, 1932

PUBLISHED AUGUST 5, 1932

Introduction

In recent years normal butane has become available in large quantities at a low price. It is conceivable that this butane can be converted into more valuable substances through the butenes as intermediates, for example into *sec.*-butyl alcohol, by chlorination of the *n*-butane, splitting off hydrogen chloride from the monochlorobutanes, and hydration of the resulting butenes. In addition to the direct economic importance, this method of producing the butenes is of fundamental importance to the general chemistry of the olefins, for the butenes are the simplest substances in which it is possible to have the shifting of a hydrogen atom from one carbon atom to another (shifting of a double bond), stereomutation between *cis* and *trans* forms and shifting of a methyl group. A survey of the literature has shown that almost no information at all is available concerning the conditions governing these changes.² Lucas and his associates³ have been at-

tacking this problem through the pyrolysis of the butyl alcohols, while we have been attacking it through the pyrolysis of the monochlorobutanes.

The splitting off of hydrogen halides from ethyl, propyl, isobutyl, isoamyl, hexyl and heptyl halides to form olefins has been accomplished, using pumice, soda lime,⁴ bivalent metallic chlorides, and alumina as catalysts. The reactions are reversible, and therefore the hydrogen halide must be removed, or the products cooled quickly, to prevent recombination. The catalysts gradually lose their activity by the formation of a carbonaceous deposit on them.

We have found that the pyrolyses of 1-chlorobutane and 2-chlorobutane in a glass tube are homogeneous vapor phase reactions, 1-chlorobutane giving all 1-butene, and 2-chlorobutane giving a mixture of 1-butene, *cis*-2-butene, and *trans*-2-butene. When calcium chloride was used as a catalyst, 2-chlorobutane gave almost entirely the 2-butenes, and 2-chlorobutane gave very largely 2-butenes also.

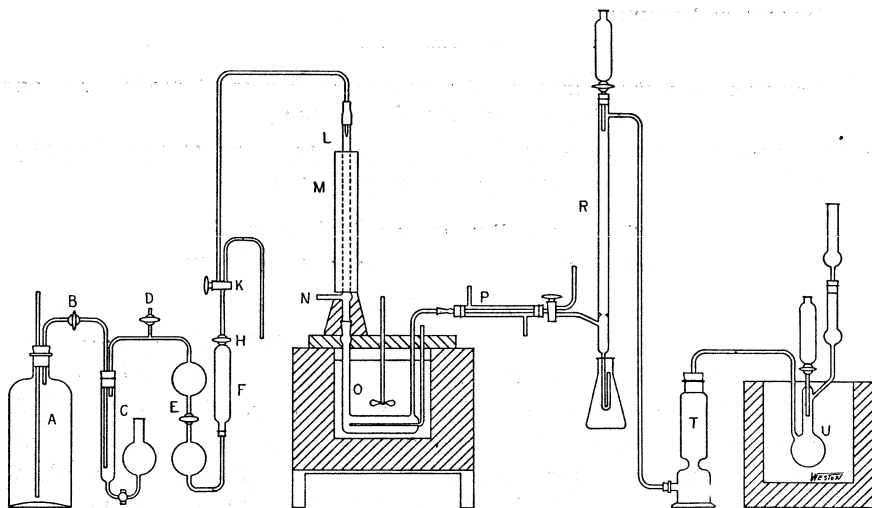

Fig. 1.—Apparatus for studying the pyrolysis of the monochlorobutanes.

Experimental Part

The apparatus is shown in Fig. 1. The parts A to L were designed to obtain a constant rate of flow of chlorobutane. Water from a source having a constant head (about 4.56 meters) flowed into the 2-liter bottle, A, compressing the air to a constant pressure. This air bubbled through mercury in C, and exerted pressure on some very viscous oil in the upper bulb of E. The rate of flow of oil could be adjusted by the stopcock, E. The oil displaced mercury in the lower bulb of E, which in turn displaced the chlorobutane from the graduated 50-ml. separatory funnel, F, into the vaporizer, M. As the mercury rose in F, the back pressure increased, and so to prevent a decrease in the

⁴ Hurd, "Pyrolysis of Carbon Compounds," Chemical Catalog Co., New York, 1929, p. 125; Faragher and Garner, *THIS JOURNAL*, **43**, 1715 (1921).

rate of flow, the pressure on the oil in E was increased by allowing an equivalent amount of mercury to escape from C. Since the oil had a high viscosity, the opening in the stop-cock had to be relatively large, and therefore small solid particles would not block the opening and alter the rate of flow, as would be the case if an attempt were made to control the flow of chlorobutane directly.

The chlorobutane was vaporized in the electrically heated tube, M. Indentations in the walls of the tube caused turbulent flow and better heating. The temperature of the vapor, as it entered the reaction tube, was about 100° as indicated by a thermometer inserted in the opening, N.

The reaction tube, O, of Pyrex glass, was immersed in an electrically heated bath of sodium nitrate and potassium nitrate. The temperature was kept uniform by stirring, and was controlled by a Leeds and Northrup potentiometer controller actuated by a thermocouple immersed in the bath. A well sealed into the reaction tube contained two thermocouples, one at each end. A loosely fitting glass plug placed in the entrance tube, O, caused the vapor to flow close to the hot walls and become heated quickly. The products were cooled quickly to reduce the extent of the reverse reaction by leading them through a capillary into the water cooler, P. The reaction tube could be removed by separating the ground joints.

The extent of reaction was determined by dissolving the hydrogen chloride in standard sodium hydroxide solution as it trickled over glass beads in the tower, R, and titrating the excess alkali. Unreacted chlorobutane which collected with the alkali did not react with it, or interfere with the titration in any way. From the moles of hydrogen chloride evolved and the moles of chlorobutane used, the extent of reaction was calculated. The exposure time, or duration of the reaction, was calculated from the rate of introduction of the chlorobutane, the volume of the reaction tube (53 ml.) and the mean of the entering and leaving volumes of gas, as calculated from the extent of reaction and the gas laws. This of course does not give the true reaction time.

The butenes were analyzed by converting them into the bromides and determining, for the bromides, the densities and reaction rates with potassium iodide in methanol, exactly as described by Dillon, Young and Lucas. The butenes were dried with calcium chloride in the tower, T, liquefied, and allowed to react with bromine in the bath, U, at -15 to -20° . The bromides were distilled under reduced pressure before being analyzed, to remove small amounts of chlorobutanes and butadiene tetrabromide.

Both 1-chlorobutane and 2-chlorobutane were prepared by the thermal chlorination of *n*-butane. Butane and chlorine were used in the ratio of 10:1 by volume, at a reaction temperature of 400 – 475° . The product consisted of 90.3% monochlorides and 9.7% polychlorides by weight. The monochlorides consisted of 63% 2-chlorobutane and 37% 1-chlorobutane. Unreacted butane was recycled. The chlorides were separated by rectification. The 1-chlorobutane used in this research had a boiling point of 77.6 – 77.7° at 743 mm., or 78.3 – 78.4° corrected to 760 mm.⁵ The 2-chlorobutane had a boiling point of 67.2 – 67.3° at 740 mm., or 68.0 – 68.1° corrected to 760 mm. If the butane used above contained any isobutane, the 2-chlorobutane made from it would have been contaminated with isobutyl chloride, for the boiling points of these isomers are only one degree apart; therefore some 2-chlorobutane was also prepared from the alcohol and hydrochloric acid. This 2-chlorobutane⁶ had a boiling point of 67.4° at 743 mm., or 68.0° corrected to 760 mm.

Discussion of the Rate of Reaction

The thermal decompositions of 1-chlorobutane at 550° and 2-chlorobutane at 500° in a glass tube are homogeneous vapor phase reactions.

⁵ "International Critical Tables," Vol. III, p. 246.

⁶ "Organic Syntheses," John Wiley and Sons, Inc., New York, Vol. V, 1925, p. 27.

The data to support this conclusion are given in Table I and Fig. 2. The reactions were run under three different conditions, namely, in a clean reaction tube (cleaned by burning the carbonaceous deposit with air), in a tube coated with the carbonaceous deposit which slowly formed from side reactions, and in a tube stuffed with glass wool. All of the points fit the curves equally well, indicating that the glass surface and the carbonaceous deposit did not alter the rate of reaction. In the table, two reaction temperatures are given, the first being the temperature at the entrance and the second at the exit of the reaction tube. Different temperatures were obtained at different rates of flow, and the temperatures inside the tube never equaled the temperature of the bath because these reactions are endothermic. The 2-chlorobutane from the alcohol reacted slightly, but definitely faster than the 2-chlorobutane from chlorination of butane, probably because the latter contained some isobutyl chloride, a primary chloride. It can be seen from the curves that 1-chlorobutane, a primary

chloride, reacted much more slowly than 2-chlorobutane, a secondary chloride. The amount of carbonaceous deposit which formed was very small, being only about 0.01 g. per 380 g. of chlorobutane decomposed.

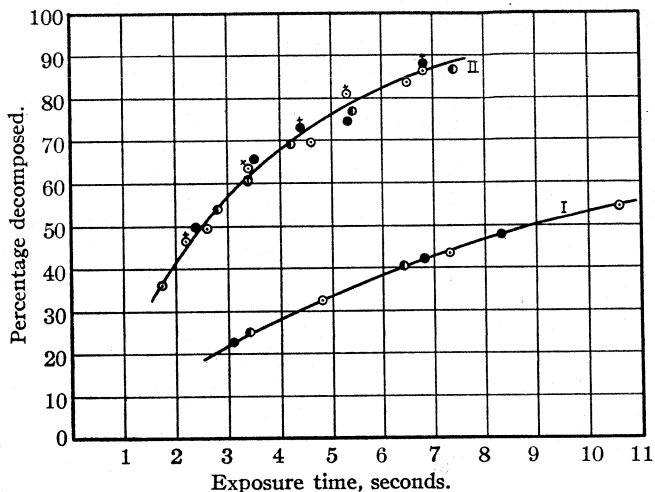

Fig. 2.—Rate of pyrolysis of the monochlorobutanes: I, 1-chlorobutane at 550°; II, 2-chlorobutane at 500°; ○, clean reaction tube; ●, carbonized reaction tube; ●, tube stuffed with glass wool; +, indicates that the 2-chlorobutane was made from the alcohol.

Discussion of the Composition of the Butenes

The compositions of the butenes obtained under various conditions are given in Table II. In the absence of a catalyst at 550°, 1-chlorobutane gave only 1-butene (Expt. 1), but 2-chlorobutane gave a mixture of all three normal butenes (Expt. 3). The butenes from 2-chlorobutane were about two-thirds 2-butenes, and of these, two-thirds was the lower-boiling isomer (*trans*). If the butenes were formed by the simple splitting off of a molecule of hydrogen chloride followed by rearrangement of the radical to a more stable form, it seems obvious that 1-chlorobutane should yield almost entirely 1-butene while 2-chlorobutane should yield a mixture of the isomers. The 1-butene does not rearrange easily under these conditions to 2-butenes, for in Expt. 2 the reaction time allowed was almost twice that in Expt. 1, but still 1-chlorobutane yielded all 1-butene. Under prolonged exposure, some of the 1-butene decomposed into butadiene, and the tetrabromide formed from the butadiene impaired the accuracy of the analysis, but even so, if there was a rearrangement of the 1-butene, it occurred to a very small extent.

The composition of the butenes did not change with the reaction temperature, for at 450, 490, 500 and 550° (Expts. 3 to 10) the mean composi-

tion was 1-butene $35 \pm 3\%$, *cis*-2-butene $22.5 \pm 3.5\%$, and *trans*-2-butene $43 \pm 4\%$, except No. 8, which was 6% low. In all of these experiments the results were the same with 2-chlorobutane prepared either from the alcohol or by chlorination of butane.

When anhydrous calcium chloride was used as a catalyst at 450° the butenes produced from both 1-chlorobutane and 2-chlorobutane were largely 2-butenes. Enough catalyst was used to fill the reaction tube entirely and the chlorobutanes were run slowly enough to obtain a high yield of butenes. The catalyst became covered with a dark gray deposit and lost most of its activity in two hours. Only 22% 1-butene was obtained from 1-chlorobutane with the catalyst compared to 100% 1-butene without a catalyst (Expts. 1 and 11), and only 13–16% 1-butene from 2-chlorobutane compared to 33% (Expts. 12, 13). At still lower temperatures, 400 and 250°, 2-chlorobutane gave almost no 1-butene at all when the catalyst was used (Expts. 14, 15). It is unknown whether the butenes rearranged in contact with the catalyst, or whether the catalyst caused the reaction to go in such a way that principally the 2-butenes were formed directly from the chlorobutanes, but Ipatiev and Zdzitovetsky⁷ state that zinc chloride does not cause rearrangement of either the *n*-butenes or isobutene. A study of the behavior of these butenes in contact with various catalysts would aid in explaining the results obtained by Dillon, Young and Lucas with the butyl alcohols, as well as these results with the chlorobutanes.

Summary

A study has been made of the thermal decomposition of 1-chlorobutane and 2-chlorobutane in the absence of a catalyst, and using anhydrous

⁷ Ipatiev and Zdzitovetsky, *Chem. Abstracts*, **2**, 259 (1908).

calcium chloride as a catalyst. The extent of reaction was determined by titrating the hydrogen chloride evolved, and the mixtures of butenes were analyzed by determining for their bromides, the densities and the reaction rates with potassium iodide in methanol.

In the absence of a catalyst, the decompositions of 1-chlorobutane at 550° and of 2-chlorobutane at 500° are homogeneous gaseous reactions. 1-Chlorobutane gave only 1-butene, but 2-chlorobutane gave a mixture of 1-butene, *cis*-2-butene and *trans*-2-butene. The composition of the product from 2-chlorobutane was the same at 450, 500 and 550°.

In the presence of the catalyst at 450°, both chlorobutanes gave mixtures of all three butenes, there being relatively little 1-butene, however.

It is unknown whether the butenes rearranged in contact with the catalyst, or whether the catalyst caused the reaction to go in such a way that principally the 2-butenes were formed directly from the chlorobutanes.

NATURAL AND SYNTHETIC RUBBER. X. CONSTITUENTS OF THE RUBBER HYDROCARBON

BY THOMAS MIDGLEY, JR., ALBERT L. HENNE AND MARY W. RENOLL

RECEIVED APRIL 6, 1932

PUBLISHED AUGUST 5, 1932

It has been shown in the seventh paper of this series,¹ that nitrogen-free rubber hydrocarbon can be prepared by fractional precipitation of natural rubber from a mixture of alcohol and benzene. This fractionation method is now applied to the rubber hydrocarbon itself to determine whether it is a single individual or a mixture of various components, and, in the last event, to isolate these constituents.

Some criterion is needed to follow the progress of any fractionation. The measurement of a well-defined physical property is best. In the present research, use is made of a standardized precipitation point (abbreviated to s. p. p. in the text), which is defined as follows. The standard precipitation point of a rubber specimen is the temperature at which a sudden increase of turbidity occurs in a slowly cooled solution of 0.85% rubber, 28.55% absolute alcohol and 70.60% benzene. The manner in which the s. p. p. is determined is described in the experimental part of this paper.

Procedure

Two hundred and fifty grams of crepe rubber was dissolved in benzene and fractionated into primary cuts. The method of fractionation was a duplication of that reported in the seventh paper. The technique, however, was improved to prevent alteration of the specimen by light or oxygen. The flasks containing the rubber solu-

¹ Midgley, Henne and Renoll, *THIS JOURNAL*, **53**, 2733 (1931).

tions were always completely covered with black cloth, frequently evacuated and filled with carbon dioxide. The solvents were removed by suction at room temperature. The rubber samples were stored in a bed of solid carbon dioxide. They were allowed to reach room temperature and exposed to atmospheric oxygen only during the short time required to take a sample for s. p. p. determinations.

Table I reports the results of this primary fractionation.

TABLE I
PRIMARY FRACTIONATION OF 250 G. OF CREPE RUBBER

Fractions	Amount, g.	Standard precipitation point (s. p. p.)	% based on 233.6 g.	
A ₁	44.8	33.0°	19.2	81.5%
A ₂	38.8	33.0°	16.6	
A ₃	46.5	34.9°	19.9	
A ₄	28.2	35.0°	12.1	
A ₅	31.9	35.3°	13.7	
B	43.4	Not obtained	18.6	
Total	233.6		100.1%	
Loss	16.4			

The loss of rubber during this separation amounts to 6.6% of the original 250-g. sample. This 16.4-g. loss includes an estimated amount of 12.5 g. of so-called "resins."

The tabulated results are shown on the chart, where the percentages are plotted against the s. p. p. They are represented by the solid line: the length of the horizontal lines measures the size of the fractions from

TABLE II
SECONDARY FRACTIONATION OF FRACTIONS A₁ TO A₅, viz., 81.6% OF THE RUBBER HYDROCARBON

Fractions	Amounts, g.	S. p. p.	% based on 190.2 g. = 81.5%
A ₁ Top ^a	11.0	32.1	5.4
Bottom ^a	29.8	34.2	14.7
A ₂ Top	9.8	32.5	4.8
Bottom	24.2	34.2	11.9
A ₃ Top	6.7	31.2	3.3
Bottom	30.7	34.8	15.1
A ₄ Top	4.2	31.2	2.1
Bottom	19.7	35.0	9.7
A ₅ Top	3.8	31.5	1.9
Bottom	25.7	35.1	12.6
Total	165.6		81.5
Loss	24.6		

The losses are almost entirely due to sampling for s. p. p. determinations.

^a "Bottom" is the rubber which settles out from a benzene-alcohol mixture held at 1° below its precipitation point. "Top" is the rubber chilled out from the supernatant liquid.

A₁ to A₅, in percentage of recovered rubber. Fraction B could not be shown on the chart since its s. p. p. could not be determined. It amounted to 18.6% of the total, and consequently the curve on the chart stops short of 100% by this amount, *viz.*, at 81.4%.

Each of the primary cuts, from A₁ to A₅ inclusive, amounting to 81.5% of the rubber recovered, was then resubjected to the same fractionation method. The only experimental detail altered was the lengthening of the time allowed for complete separation to fourteen hours. The results are given in Table II. These results appear on the chart.

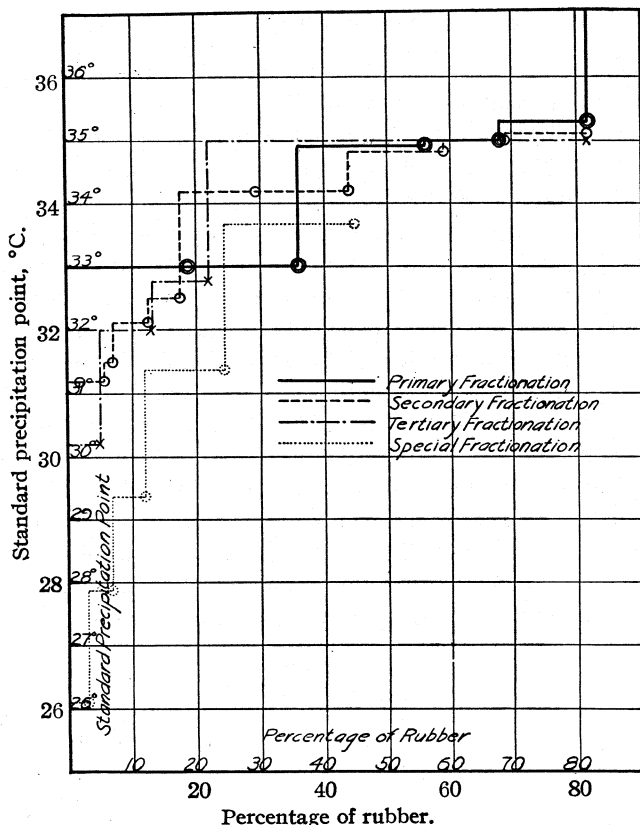

Fig. 1.

A third fractionation was then accomplished as follows. Cuts with an s. p. p. lower than 33° were put together, while cuts with an s. p. p. higher than 33° were united. The two fractions thus formed were separately fractionated as for the secondary fractionation, and the results shown in Table III were obtained. These results appear on the chart.

The third fractionation is only slightly better than the second one.

TABLE III

TERTIARY FRACTIONATION OF FRACTIONS A₁ TO A₅, OR 81.6% OF RUBBER HYDROCARBON

Fractions		Amounts, g.	S. p. p.	% based on 190.2 g. = 81.6%
Sum of tops	Top	8.5	30.2	4.7
	Bottom	15.7	32.8	8.8
Sum of bottoms	Top	14.4	32.0	8.1
	Bottom	107.3	35.0	59.9
Total		145.9		81.5
Loss		19.7		

The losses are almost entirely due to sampling.

It indicates that more than 50% of the initial material is no longer fractionated, *viz.*, the cut with an s. p. p. of 35°.

Since small amounts of the lower fractions were lost by solubility in the alcohol-benzene mixture, it was decided to investigate this lower portion by a somewhat modified technique.

A solution containing two hundred and fifty grams of crepe rubber was prepared and therefrom fractions A₁ and A₂ were obtained as before. After discarding the remainder of the rubber, these two fractions, A₁ and A₂, were redissolved in their original solvent, thus avoiding the loss of portions which were so soluble in the alcohol-benzene mixture that they could not be completely precipitated by chilling. These combined fractions were then treated by a procedure identical to the primary fractionation, and a fraction B₁ collected and stored. The supernatant liquid was then chilled. This precipitated some more rubber; one-half of the chilled liquid was then decanted and discarded. The chilled precipitate was then redissolved by warming in the retained half of the liquid. The whole procedure was repeated to give fractions B₂, B₃, etc. The results of this special fractionation are listed in Table IV and represented on the diagram.

TABLE IV
SPECIAL FRACTIONATION

Fractions	Amounts, g.	S. p. p.	% based on a total of 233 g. as 100%
B ₁	48.4	33.7	20.7
B ₂	29.2	31.4	12.5
B ₃	12.0	29.4	5.1
B ₄	9.4	27.9	4.0
B ₅	6.5	26.1	2.8

Results.—The diagram and the tables show that the present procedure separated a single component, characterized by an s. p. p. of 35.0%. The amount of this component exceeded 55% of the original rubber. A quantity of less than 20% of the original rubber was separated as a less soluble fraction, and was not investigated further; it probably still con-

tained an appreciable amount of the component s. p. p. 35°. The highly soluble part of the rubber, amounting to about 25%, was fractioned; it failed to reveal the presence of an important constituent, except more of the component s. p. p. 35°.

There was quite a difference in appearance between the high and low s. p. p. fractions. The rubber of s. p. p. 35.0° was very tough, non-tacky, and somewhat opaque. The lower fractions were soft, but white in color, showing no apparent signs of oxidation. The insoluble portion was yellow, in its fresh state, and darkened on standing. It had little elasticity and resembled horn more than rubber.

Conclusion.—It is therefore concluded that the original rubber specimen consisted of, (1) a soluble portion containing several individuals and totaling more than 20% of the specimen, (2) a single soluble component present in excess of 50% of the total, and (3) an insoluble portion amounting to less than 20% of the total.

Discussion.—The origin of the more soluble portions of rubber is obscure. Staudinger² suggests the possibility of forming such a portion by partial oxidation of the original molecule. Since precautions were taken to avoid oxidation during the course of the fractionation, it is suggested that the more soluble fractions were generated during the washing and sheeting of the original coagulate.

The present results bear a definite relation to two controversial points.

(1) Staudinger² has advanced the view that rubber is made up of a series of polymer homologs of many different lengths. It is now shown that though such a series may exist, to a limited extent, in the more soluble portions of rubber, the main constituent is one definite polymer.

(2) It is generally felt that in order to obtain a good grade of soft rubber goods, a two-phase system is required, implying that both sol and gel rubber should be present. Sol rubber, separated from gel, has been satisfactorily vulcanized, but the completeness of the separation was questioned. It is now found that pure sol rubber of s. p. p. 35° does give a satisfactorily vulcanized material (500% elongation and 4100 lb. tensile strength). That this sol rubber is of high purity is practically certain.

Experimental

Determination of the Standard Precipitation Point.—A 1.288-g. sample of the rubber (free from solvent) is placed in a 250-cc. Erlenmeyer flask. One hundred cc. of c. p. benzene is added. The flask is set away in the dark, under carbon dioxide, until complete solution is obtained. To this solution, warmed to about 50°, is added a hot mixture of 27 cc. of benzene and 56 cc. of absolute alcohol, and the whole is stirred and intermittently warmed until entirely clear. A calibrated thermometer reading tenth degrees is placed in it and it is allowed to cool. When the mixture becomes suddenly turbid, the temperature is read. This is the experimental precipitation point. It is

² Staudinger and Bondy, *Ann.*, [2] 488, 153 (1931).

reproducible to $\pm 0.1^\circ$. After checking the point, the flask is equipped with a bent tube carrying a water jacket on its downward branch. This branch delivers into a 250-cc. receiver cooled in ice; the receiver is in turn connected to a second one cooled in a mixture of carbonic snow and acetone, to ensure the recovery of all solvents during distillation. Atmospheric moisture is kept out of the system by means of a calcium chloride tube. While passing a slow stream of purified carbon dioxide through the system, the solvents are distilled with a steam-bath. The distillate is weighed, and its refractive index is measured in a Pulfrich refractometer, at 20.0° . From a previously constructed curve, the composition of the distillate is read. The rubber sample is weighed as soon as the distillation is finished, and its increase in weight, regarded as benzene, is added to the amount of benzene in the distillate. The percentages of alcohol and benzene are thus determined with accuracy; they can be duplicated to 0.1%. By means of the chart, Fig. 2, paper VII, the experimental precipitation point is then corrected to standard conditions, *viz.*, 28.55% alcohol and 0.85% rubber. This is the s. p. p. Including experimental errors and corrections, the s. p. p. determination is correct within $\pm 0.2^\circ$.

Summary

1. Fractional precipitation has been used to determine and isolate the constituents of the rubber hydrocarbon.
2. A "standard precipitation point" has been devised and its use advanced as a physical constant of rubber.
3. The presence of a single component, amounting to more than 50% and characterized by a standard precipitation point of 35° , has been demonstrated.
4. The presence of highly soluble portions, of indeterminate s. p. p., has been shown.

[CONTRIBUTION FROM THE SCHOOL OF CHEMISTRY OF THE UNIVERSITY OF MINNESOTA] THE OXIDATION OF SYMMETRICAL TRIBROMOANILINE BY CHROMIC ANHYDRIDE IN ACID SOLUTION. II. MECHANISM¹

BY W. H. HUNTER AND CARYL SLY

RECEIVED APRIL 11, 1932

PUBLISHED AUGUST 5, 1932

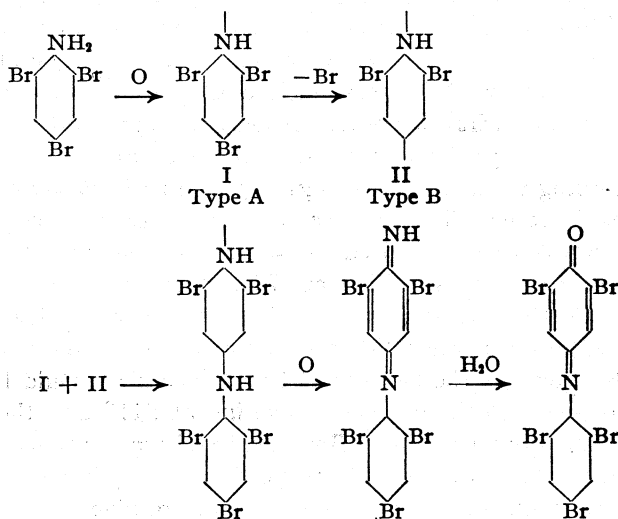

In some unpublished work performed in this Laboratory by A. G. Mayers (now deceased), it was found that symmetrical tribromoaniline, dissolved in a mixture of acetic and dilute sulfuric acids, on oxidation with chromic anhydride gave a compound with the molecular formula $C_{12}H_4ONBr$, and the structural formula

¹ Abstracted from a thesis submitted by Caryl Sly to the Graduate Faculty of the University of Minnesota, in partial fulfilment of the requirements for the degree of Doctor of Philosophy, August, 1927. The manuscript was written by the junior author after the death of Dr. Hunter.—L. I. SMITH.

Brominated *N*-phenylquinoneimines have been prepared by Smith and Orton² by first brominating *p*-hydroxydiphenylamine and then oxidizing with chromic anhydride. However, no reference could be found relative to the formation of such compounds by the oxidation of halogenated anilines.

Consideration of the probable mechanism for the formation of the above compound by oxidation of symmetrical tribromoaniline led to two widely divergent views of the reaction. Goldschmidt³ has shown in the oxidation of anilines that a radical of the type $C_6H_5NH\cdot$ is first formed, which may react as such or be further oxidized to the type $C_6H_5N\cdot$. This latter radical in his opinion was responsible for the formation of azobenzene and quinone diimine by the oxidation of aniline. The radical $C_6H_5NH\cdot$ is the nitrogen analog of the type A radicals which result during the oxidation of *sym*.-trihalogenated phenols.⁴ Using the type A and type B radicals pre-dicated in the case of the halogenated phenols the reaction becomes

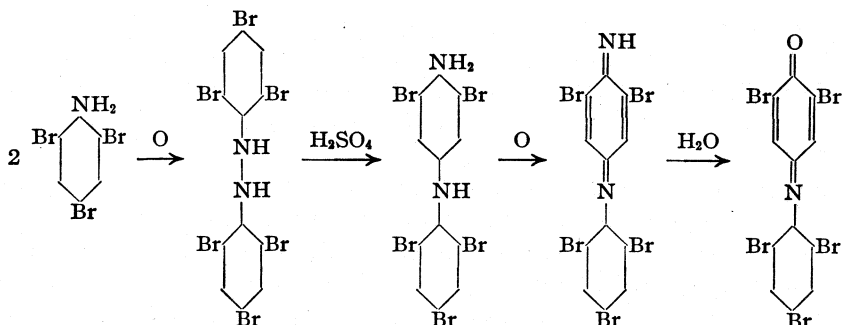

The alternative mechanism assumed the formation of *sym*.-hexabromohydrazobenzene, a *p*-semidine rearrangement of this derivative with the loss of a bromine atom, oxidation to the quinonediimine and finally hydrolysis to the quinoneimine.

In order to choose between these mechanisms an attempt was made to prepare the pentabromoquinoneimine from *sym*.-hexabromohydrazobenzene. The preparation of hexabromohydrazobenzene presented consider-

able difficulty despite the fact that it had been previously reported by Pechmann and Nold.⁵

Production of the desired hydrazo derivative from *sym.*-tribromonitrobenzene was not successful because at least one bromine was lost in alkaline reduction, a condition already observed by other workers.⁶ Eventually 2,4,6,2',4',6'-hexabromoazobenzene was prepared by oxidizing *sym.*-tribromoaniline in pyridine solution with potassium permanganate.

In the light of our work it is extremely doubtful if Pechmann and Nold had the hexabromohydrazobenzene. Instead, it is probable they had the 2,4,2',4'-tetrabromohydrazobenzene, since the reduction of hexabromoazobenzene according to their directions gave as the main product this tetrabromohydrazobenzene. The fact that we had the tetrabromohydrazo derivative was not at first recognized because Zincke⁷ had reported the corresponding azo compound as melting at 179°, as compared with a melting point of 211° for the oxidation product of our compound. The identity of the substance, however, was established by analysis, by reduction to 2,4-dibromoaniline, and by the fact that 2,4-dibromoaniline could be oxidized with permanganate to the compound melting at 211° and then reduced back to the 2,4-dibromoaniline. Both the hexabromoazobenzene and the tetrabromoazobenzene were readily reduced to the hydrazo state by zinc dust and acetic acid, the former without loss of bromine.

All of our attempts to cause the benzidine or semidine rearrangement of the hexabromoazobenzene or hexabromohydrazobenzene met with failure. Using the azo derivative, Jacobson's method⁸ or Witt's method⁹ gave only reduction products. With the hydrazo derivative, concentrated hydrochloric acid or 65% sulfuric acid¹⁰ caused only oxidation and reduction to

the azo compound and the substituted aniline. Tauber's method¹¹ of treating the hydrazo compound with a reducing agent and a mineral acid gave only reduction to the aniline. Similar results were obtained in the case of the tetrabromoazobenzene and tetrabromohydrazobenzene. The usual tests¹² for *o*- and *p*-semidine rearrangement products were negative.

As a final test for the formation of pentabromoquinoneimine from *sym*.-hexabromohydrazobenzene, the hydrazo compound was added to the reaction mixture which had oxidized *sym*.-tribromoaniline to the pentabromoquinoneimine. Here the only reaction was one of oxidation to hexabromoazobenzene.

In view of these results it seems probable that the oxidation of *sym*.-tribromoaniline in acid solution with chromic anhydride involves the same reaction mechanism as that previously postulated for the oxidation of symmetrically halogenated phenols, with the intermediate formation of the N analogs of the type A and type B radicals.

Experimental Part

2,4,6,2',4',6'-Hexabromoazobenzene.—Twenty grams of *sym*.-tribromoaniline was dissolved in a mixture of 90 cc. of pyridine and 46 cc. of water and the solution heated to 75°. To this solution 40 g. of finely pulverized potassium permanganate was added in small portions, shaking after each addition until the permanganate color had disappeared. The copious precipitate of manganese dioxide was filtered off, washed with cold water, dried and thoroughly extracted with chloroform. The chloroform solution was evaporated to dryness, and the resulting solid suspended in 100 cc. of acetic acid held at 80°. The insoluble purple precipitate was pure hexabromoazobenzene, m. p. 212–213° (uncorr.); yield, 40%.

A 20% yield was obtained by heating 1 g. of *sym*.-tribromoaniline, 5 cc. of pyridine and 1 cc. of 17% sodium hypochlorite solution, diluting with 50 cc. of water and treating the insoluble precipitate as above.

Pechmann and Nold⁵ described the compound as red needles, but in every case our product was a dull violet color, although solutions of it were red. The substance is readily soluble in hot chloroform or benzene, moderately soluble in these solvents cold and practically insoluble in either hot or cold alcohol, acetic acid, ether, and acetone.

Anal. Calcd. for $C_{12}H_4N_2Br_6$: Br, 73.17, N, 4.27. Found: Br, 73.17; N, 4.29.

2,4,2',4'-Tetrabromoazobenzene.—Using the same procedure described for the hexabromo derivative, 20 g. of 2,4-dibromoaniline dissolved in a mixture of 40 cc. of pyridine and 40 cc. of water was treated with 40 g. of potassium permanganate. The dried mixture of manganese dioxide and azo derivative was extracted with 200 cc. of benzene until no further coloration of the benzene resulted. On cooling the benzene solution a considerable portion of the azo compound crystallized as red needles. These were filtered off, the mother liquor evaporated to 50 cc. and 100 cc. of hot 95% alcohol added; yield, 40%; m. p. 211° (uncorr.).

Fifty to sixty per cent. yields were also obtained by reducing *sym*.-hexabromoazobenzene suspended in alcohol with zinc dust and ammonium chloride and then oxidizing the product thus formed in acetic acid with chromic anhydride.

¹¹ Tauber, *Ber.*, **25**, 1022 (1892).

The substance crystallizes in red needles from benzene, is very soluble in either hot chloroform or benzene, slightly soluble in hot acetic acid and practically insoluble in alcohol.

Anal. Calcd. for $C_{12}H_6N_2Br_4$: Br, 64.26; N, 5.62. Found: Br, 63.74, 63.61; N, 5.63, 6.03.

2,4,2',4'-Tetrabromohydrazobenzene.—Two and one-half grams of tetrabromohydrazobenzene dissolved in a boiling mixture of 40 cc. of benzene and 5 cc. of acetic acid was stirred vigorously with 1 to 3 g. of zinc dust, added in small portions. The excess zinc was filtered from the colorless solution and the filtrate evaporated to 5 cc. One cc. of water and 5 cc. of acetic acid were added, and the solution chilled, giving colorless needles of m. p. 123–124° (uncorr.); yield, 80%. Reduction with stannous chloride gave 2,4-dibromoaniline.

Anal. Calcd. for $C_{12}H_8N_2Br_4$: Br, 64.00; N, 5.60. Found: Br, 63.70; N, 5.99.

N,N'-Diacetyl-2,4,2',4'-tetrabromohydrazobenzene.—One gram of tetrabromohydrazobenzene was added to 25 cc. of cold acetic anhydride and the mixture allowed to stand for two days, then heated to 40° and cooled. The azo derivative which had formed was filtered off and the excess acetic anhydride destroyed with hot water. The insoluble material after treatment with water was recrystallized from dilute alcohol as colorless crystals, m. p. 178–179°C. (uncorr.); yield, 40%.

Anal. Calcd. for $C_{16}H_{12}O_2N_2Br_4$: Br, 54.80. Found: Br, 54.22.

Rearrangement Experiments.—All of our attempts to rearrange either the hexabromohydrazobenzene or the tetrabromohydrazobenzene met with failure. Mineral acids without a reducing agent present and at elevated temperatures gave only the azo

derivative and the aniline, while in the cold, stannous chloride in the presence of hydrochloric acid gave the aniline along with the unchanged hydrazobenzene.

The tables indicate the conditions of attempted rearrangement and the products isolated.

Summary

1. A study of the properties of *sym.*-hexabromohydrazobenzene has shown that it cannot be responsible for the formation of a pentabromoquinoneimine obtained by the oxidation of *sym.*-tribromoaniline in acid solution with chromic anhydride. It is, therefore, probable that N analogs of the type A and type B radicals postulated in the oxidation of *sym.*-halogenated phenols play the important role.

2. *Sym.*-hexabromohydrazobenzene and 2,4,2',4'-tetrabromohydrazobenzene do not undergo the benzidine type of rearrangement. Instead they oxidize and reduce to the corresponding azo and aniline derivatives in the presence of a mineral acid without a reducing agent; in the presence of a reducing agent they are split to the anilines.

3. A method for the preparation of azo compounds is described.

THE INTERACTION OF PHENYLARSINES WITH PHENYLHALOARSINES¹

BY F. F. BLICKE AND L. D. POWERS

RECEIVED APRIL 13, 1932

PUBLISHED AUGUST 5, 1932

Several years ago it was announced by Steinkopf and Smie² that phenyldichloroarsine and diphenylarsine react to form triphenylchlorodiarsyl.

Since we wished to prepare triphenylhydroxydiarsyl,^{2a} hydrolysis of the corresponding chloro compound suggested itself as a preparative procedure. Phenyldichloroarsine and diphenylarsine were allowed to react in the proportions used by the above-mentioned investigators but instead of triphenylchlorodiarsyl, arsenobenzene and diphenylchloroarsine were obtained in yields which correspond closely to those calculated from equation A.³

¹ This paper represents one part of a dissertation submitted to the Graduate School by L. D. Powers in partial fulfillment of the requirements for the degree of Doctor of Philosophy in the University of Michigan.

² Steinkopf and Smie, *Ber.*, **59**, 1459 (1926).

^{2a} It is of interest to note that Wieland and co-workers [*Ber.*, **44**, 898 (1911); *ibid.*, **48**, 1118 (1915)] were unable to obtain the corresponding nitrogen analog $\text{R}_2\text{N}-\text{NR}(\text{OH})$.

³ The very unsharp melting point (164–179°) of the "triphenylchlorodiarsyl" obtained by Steinkopf and Smie indicates that these investigators really had a mixture of compounds. The identity of the material obtained by them was based on the result

The reaction between diphenylarsine, as well as phenylarsine, and each of the following compounds was then investigated: phenyldichloroarsine, phenyldi-iodoarsine, diphenylchloroarsine and diphenyliodoarsine.

It has been shown in separate experiments that two molecular equivalents of phenyldichloroarsine and four equivalents of diphenylarsine yield arsenobenzene and tetraphenyldiarsyl (B), that equivalent amounts

of phenyldichloroarsine and tetraphenyldiarsyl react to form diphenylchloroarsine and arsenobenzene (C) and that no reaction takes place at ordinary temperature between diphenylchloroarsine and arsenobenzene or between diphenylarsine and arsenobenzene.

When phenyldi-iodoarsine is allowed to react with diphenylarsine in the ratio shown in formulation F diphenyldi-iododiarsyl and diphenyliodoarsine are formed. The di-iododiarsyl is produced in this instance

due to the fact that phenyldi-iodoarsine, unlike phenyldichloroarsine, reacts at ordinary temperature with arsenobenzene.⁴ The mechanism of this reaction may, possibly, be explained on the basis of reactions D and E since these reactions have been established by separate experiments.

Steinkopf and Smie⁵ mixed phenyldi-iodoarsine and diphenylarsine in the ratio expressed in formulation D and stated that phenyliodoarsine, $C_6H_5As(I)H$, and diphenyliodoarsine were produced. The "phenyliodoarsine" described by them was, undoubtedly, diphenyldi-iododiarsyl. Furthermore, these investigators stated⁶ that one molecular equivalent of phenyldi-iodoarsine and two equivalents of diphenylarsine react to form pentaphenyltriarsine, $(C_6H_5)_2As-As(C_6H_5)-As(C_6H_5)_2$; neither melting point nor any other property of this compound was recorded. The nature of the reaction product was merely deduced from the fact that treatment of the reaction product with iodine yielded phenyldi-iodoarsine and diphenyliodoarsine in a certain ratio. The experimental data yield of a chlorine analysis and on the fact that phenylarsonic acid and diphenylarsinic acid were obtained upon oxidation of the reaction product. Obviously, the same data would be obtained from a mixture which consisted of arsenobenzene and twice the molecular quantity of diphenylchloroarsine.

⁴ Blicke and Smith, *THIS JOURNAL*, **52**, 2942 (1930).

⁵ Ref. 2, p. 1460.

⁶ Ref. 2, p. 1461.

little or no evidence in favor of the contention that pentaphenyltriarsine was formed in this reaction.

Diphenylchloroarsine and diphenylarsine, dissolved in ether, yielded tetraphenyldiarsyl and the interaction of these substances represents a satisfactory method for the preparation of the diarsyl.

Diphenyliodoarsine and diphenylarsine, dissolved in alcohol, also react to form tetraphenyldiarsyl.

Phenyldichloroarsine reacts with phenylarsine to form arsenobenzene.

Phenyldi-iodoarsine and phenylarsine yield the same reaction product when they are mixed in equivalent amounts. However, if three molecular equivalents of the di-iodo compound react with one equivalent of phenylarsine diphenyldi-iododiarsyl is formed.

When diphenylchloroarsine and phenylarsine are allowed to react in the ratio expressed in the following equation arsenobenzene and tetraphenyldiarsyl are produced. If the above-mentioned compounds are mixed in equimolecular quantities arsenobenzene and tetraphenyldiarsyl are again formed as reaction products. Steinkopf and Smie⁷ stated that diphenylchloroarsine and phenylarsine react to form triphenyldiarsyl, $(C_6H_5)_2As-As(H)C_6H_5$. These investigators merely analyzed their reaction product, which was not characterized by a melting point, and considered the arsenic analysis and the fact that a mixture of phenylarsonic and diphenylarsinic acids was obtained upon oxidation of their product with nitric acid sufficient proof for the claim that triphenyldiarsyl had been formed. The data published by Steinkopf and Smie would be almost identical with that obtained from a mixture which consisted of one equivalent of arsenobenzene and two equivalents of tetraphenyldiarsyl.

Diphenyliodoarsine and phenylarsine, mixed in the proportion given below, yield arsenobenzene and tetraphenyldiarsyl.

Experimental Part

Since phenylarsine, diphenylarsine and many of the reaction products absorb oxygen with great rapidity, it was necessary to carry out all experiments in an inert atmosphere. The apparatus used for this purpose is shown in the accompanying sketch. By manipulation of the stopcocks the free radical bulb, as well as the buret above it, was evacuated and filled with dry, oxygen-free nitrogen. This operation was repeated several times until all air had been removed from the system. The arsine was introduced

⁷ Ref. 2, p. 1458.

into the buret from the reservoir⁸ and allowed to flow into the evacuated radical bulb. The walls of the buret were then washed free from arsine by the introduction of ether, benzene or alcohol from the dropping funnel. After the radical bulb had been filled with nitrogen, it was disconnected and the substance added with which the arsine was

to react.⁹ In the event that pressure developed in the bulb the side arm of the latter was connected to the mercury trap shown in the lower left-hand corner of the diagram or photograph.

All solvents were saturated with nitrogen prior to use and only the absolute grades of alcohol and ether were employed. A dextrin-mannitol-glycerol stopcock lubricant¹⁰ was found to be very satisfactory when ether or benzene was used as a solvent. The melting points of compounds which absorb oxygen were determined in a sealed tube filled with nitrogen. The reaction mixtures were shaken for at least twenty-four hours. Absorption experiments were carried out in bromobenzene solution.

Phenyldichloroarsine and Diphenylarsine (A, B).—Six and ninety-two hundredths grams (5.32 cc., 0.030 mole) of diphenylarsine¹¹ was added to 8.50 g. (0.038 mole) of phenyldichloroarsine, dissolved in 50 cc. of ether. After a short time a heavy, crystalline precipitate had formed. The ether was decanted into a second radical bulb and the precipitate, which proved to be arsenobenzene, washed with ether a number of times until it was entirely free from halogen compounds;¹² mixed m. p. 210–212°. The material was recrystallized from xylene for analysis.

Anal. Calcd. for $C_{12}H_{10}As_2$: As, 49.31.
Found: As, 49.23, 49.38.

The yield was 3.96 g. or 87% of the calcd. amount.

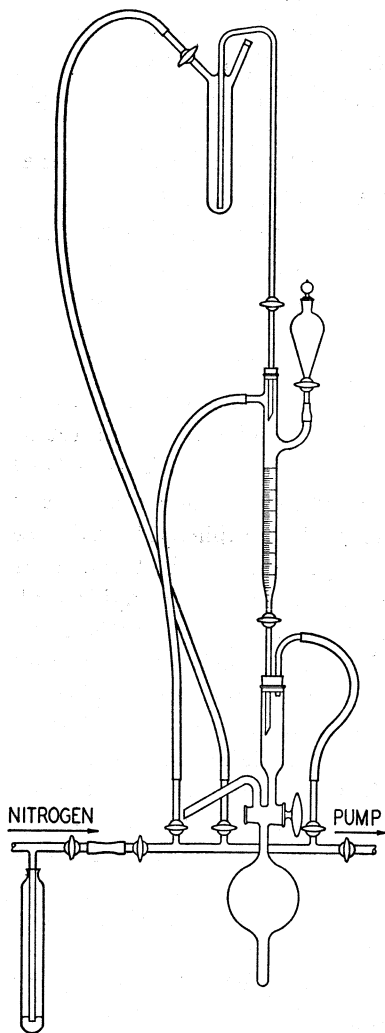

Fig. 1.

¹⁰ The directions for the preparation of this lubricant were furnished us by C. C. Meloche and W. G. Fredrick.

¹¹ The following constants were determined for diphenylarsine: d_4^{25} 1.30; b. p. 158–160° under 16 mm. pressure.

¹² Arsenobenzene absorbs oxygen rapidly unless it is washed free from all traces of halogen compounds.

⁸ After each arsine had been prepared it was distilled directly into a reservoir of the type shown through the short side arm. In such containers the arsines can be protected from oxidation for a long time.

⁹ In some instances the arsine was introduced after the other component of the reaction had been placed in the radical bulb.

The ether layer from the reaction mixture, which contained diphenylchloroarsine and unchanged phenyldichloroarsine, was treated with alkali in order to convert the chlorides into oxides. Phenylarsine oxide dissolved in the aqueous layer while 6.78 g. or 95% of the calcd. amount of tetraphenyldiarsyl oxide was isolated from the ether layer. The latter oxide, after it had been washed with petroleum ether (30–60°), melted at 94–95°.

Mixed in the ratio shown in formulation B, 4.6 g. (3.5 cc., 0.02 mole) of diphenylarsine reacted with 2.2 g. (0.01 mole) of phenyldichloroarsine, dissolved in 25 cc. of ether, to form a bulky, crystalline precipitate. In order to expel the hydrogen chloride formed¹³ the ether was removed by distillation, the residue treated with 25 cc. of ether and the solvent again expelled. After the product had been dried for two hours under 15 mm. pressure the mixture was extracted a number of times with ether in order to remove tetraphenyldiarsyl; about 500 cc. of ether was used for this purpose. The tetraphenyldiarsyl obtained melted at 125–129°;¹⁴ 0.887 g. of the material absorbed 43 cc. (N. T. P.) of oxygen, which is the calculated amount. The arsenobenzene, which remained as a residue, weighed 1.3 g.; calcd. amount 1.5 g.; mixed m. p. 209–211°.

Phenyldichloroarsine and Tetraphenyldiarsyl (C).—Two and forty-five hundredths grams (0.005 mole) of tetraphenyldiarsyl was allowed to react with 1.2 g. (0.005 mole) of phenyldichloroarsine, dissolved in 100 cc. of ether. About three-fourths of the solvent was then removed by distillation and after some time a precipitate of arsenobenzene was obtained. The supernatant liquid was decanted and the arsenobenzene washed free from chlorine compounds with ether. There was isolated 0.22 g. of the arseno compound which melted at 196–206°. The ether washings were exposed to air and the residue obtained after evaporation of the solvent was treated with a mixture of ether and low-boiling petroleum ether; 0.92 g. of diphenylchloroarsine, m. p. 41–42°, was obtained.

Phenyldi-iodoarsine and Diphenylarsine (D, F).—Diphenyldi-iododiarsyl precipitated almost immediately when 4.06 g. (0.01 mole) of phenyldi-iodoarsine, dissolved in 100 cc. of ether, was mixed with 2.30 g. (0.01 mole) of diphenylarsine. After twenty-four hours the solvent was completely removed by distillation and the residue, a mixture of diphenyldi-iododiarsyl and tetraphenyldiarsyl, dried for two hours under diminished pressure in order to expel hydrogen iodide. The mixture was extracted four times with 50-cc. portions of ether and the ether layers, which contained tetraphenyldiarsyl, decanted into a second radical bulb. The residue of diphenyldi-iododiarsyl weighed 2.43 g.; calcd. amount 2.79 g.; m. p. 176–179°.¹⁵

The combined ether extracts were shaken with alkali to remove traces of iodine compounds and the solvent then removed. An oil was obtained which was treated with 25 cc. of alcohol; after the solvent had been partially removed by distillation tetraphenyldiarsyl separated in crystalline form. After recrystallization from absolute alcohol, 1.3 g. of material was obtained which melted at 128–130°.

Anal. Calcd. for $C_{24}H_{20}As_2$: As, 32.73. Found: As, 32.58, 32.28.

From the alcoholic mother liquor 0.4 g. more of the diarsyl was obtained. The calcd. yield is 2.29 g. Upon exposure to oxygen, 0.587 g. of the compound absorbed 30 cc. (N. T. P.) of the gas; calcd. amount 29 cc.

In accordance with formulation F 2.30 g. (0.01 mole) of diphenylarsine was added to 8.11 g. (0.02 mole) of phenyldi-iodoarsine, dissolved in 50 cc. of ether. A copious

¹³ Removal of the hydrogen chloride seems to facilitate the quantitative isolation of arsenobenzene and also prevents oxidation of the latter.

¹⁵ Blicke and Smith, *THIS JOURNAL*, 52, 2943 (1930).

yellow precipitate of diphenyldi-iododiarsyl formed immediately. The ether layer was decanted, the precipitate washed a number of times with ether and then dried at 50° under 15 mm. pressure for two hours. The product melted at 177–178°; yield 5.32 g.; calcd. yield 5.57 g. From the ether mother liquor an oil was obtained which solidified in the form of a yellow crystalline mass when cooled; m. p. 39–41°. This material, diphenyliodoarsine, weighed 3.76 g. in the crude state; calcd. yield 3.55 g.

Phenyldi-iodoarsine and Tetraphenyldiarsyl (E).—Four and one-tenth grams of phenyldi-iodoarsine was added to about 2 g. of tetraphenyldiarsyl, dissolved in benzene. Diphenyldi-iododiarsyl soon precipitated from the mixture; after it had been washed with ether it melted at 175–177° and weighed 1.4 g. The benzene mother liquor and ether washings were combined and shaken with alkali in order to convert the halides to oxides. The diphenyliodoarsine was isolated, therefore, as tetraphenyldiarsyl oxide; yield 1.4 g. Eight-tenths of a gram of phenylarsine oxide was also obtained as the result of hydrolysis of the excess phenyldi-iodoarsine used.

Diphenylchloroarsine and Diphenylarsine (G).—To 3.4 g. (0.015 mole) of diphenylarsine there was added 4.4 g. (0.016 mole) of diphenylchloroarsine, dissolved in 50 cc. of ether. After two hours the solution was concentrated to a volume of about 10 cc., whereupon tetraphenyldiarsyl precipitated. The ether mother liquor was decanted, a small quantity of fresh ether added and the ether suspension shaken a number of times with water until all hydrochloric acid had been removed. The ether was then removed by distillation and the material dried under diminished pressure; m. p. 124–127°. The yield was 6.0 g.; calcd. yield, 6.8 g.

Diphenyliodoarsine and Diphenylarsine.—Tetraphenyldiarsyl precipitated instantly when 3.56 g. of diphenyliodoarsine, dissolved in 50 cc. of alcohol, was added to 2.30 g. of diphenylarsine. The diarsyl was purified in the manner described above; m. p. 129–130°. The yield was 3.4 g.; calcd. amount, 4.6 g.

Phenyldichloroarsine and Phenylarsine (H).—A mixture prepared from 3.34 g. (0.015 mole) of phenyldichloroarsine, 2.30 g. (0.015 mole) of phenylarsine and 65 cc. of ether was shaken for twenty-four hours. The ether layer was decanted from the crystalline material into a second radical bulb and the solid product washed with ether until it was completely free from hydrogen chloride. The material, which was arsenobenzene, weighed 1.94 g.; m. p. 209–211°. From the ether layer 2.20 g. more of arsenobenzene was obtained. The total yield was 4.14 g.; calcd. amount, 4.56 g.

Phenyldi-iodoarsine and Phenylarsine (I).—No apparent reaction took place after 2.30 g. (0.015 mole) of phenylarsine had been shaken with 1.68 g. (0.01 mole) of phenylarsine oxide, dissolved in benzene, for twenty-four hours.¹⁶ There was then added 12.2 g. (0.03 mole) of phenyldi-iodoarsine, dissolved in benzene. Diphenyldi-iododiarsyl precipitated immediately; m. p. 178–180°. The yield was 14.3 g.; calcd. yield, based on 0.04 mole of phenyldi-iodoarsine, 14.8 g.

Diphenylchloroarsine and Phenylarsine (J).—When 12 g. (0.045 mole) of diphenylchloroarsine was added to 2.97 g. (0.019 mole) of phenylarsine, dissolved in 100 cc. of ether, there was no visible sign of reaction. Twenty-five cubic centimeters of alcohol was then added, whereupon a crystalline precipitate soon began to form. After twelve hours the solvents were removed by distillation and the residue dried for two hours under 15 mm. pressure in order to remove hydrogen chloride completely. One hundred cubic centimeters of ether was added to the residue, the mixture shaken for several hours and the ether solution of tetraphenyldiarsyl decanted into a second radical bulb. This

¹⁶ These compounds were mixed in order to determine whether or not they reacted under the given experimental conditions. The hydrogen iodide, formed subsequently as a result of the interaction of phenylarsine and phenyldi-iodoarsine, converted the phenylarsine oxide into phenyldi-iodoarsine.

process was repeated until a test portion of the ether extract left no residue upon evaporation of the solvent; about 500 cc. of ether was required. From the ether solutions there was obtained 9.08 g. of tetraphenyldiarsyl; m. p. 123–127°; calcd. yield 9.16 g. When 0.915 g. of the compound was exposed to oxygen, 47 cc. of the gas was absorbed; calcd. absorption, 45 cc. The residue after extraction of the reaction mixture with ether was pure arsenobenzene; m. p. 210–211°. The yield was 2.70 g.; calcd. yield, 3.04 g.

Anal. Calcd. for $C_{12}H_{10}As_2$: As, 49.31. Found: As, 49.57, 49.23.

In the following experiment the compounds were allowed to react in amounts which are practically equimolecular. To 5.29 g. (0.020 mole) of diphenylchloroarsine, dissolved in 100 cc. of alcohol, there was added 3.24 g. (0.021 mole) of phenylarsine; an oil precipitated which soon became crystalline. The alcohol layer was decanted into a second bulb and after complete removal of hydrogen chloride and unchanged arsine the tetraphenyldiarsyl was extracted with ether; m. p. 123–130°. The yield was 2.33 g.; calcd. yield, 4.58 g. One and fifty-four hundredths grams of arsenobenzene, m. p. 207–210°, was left as a residue; calcd. amount, 1.52 g.

The alcoholic solution which had been decanted contained the remainder of the diarsyl; the latter was allowed to oxidize in air. The alcohol was removed, the mixture of diphenylarsinic acid and tetraphenylarsyl oxide treated with sulfur dioxide and hydriodic acid in the presence of hydrochloric acid and the diphenylhaloarsines hydrolyzed to tetraphenylarsyl oxide; yield, 1.93 g.; m. p. 92–95°.

Any pentaphenyltriarsine or triphenyldiarsyl which might have been formed in this reaction would have been present in the decanted alcoholic solution and upon oxidation would have been converted into tetraphenylarsyl oxide and phenylarsine oxide; only a trace of the latter was found to be present in the oxidized solution.

Diphenyliodoarsine and Phenylarsine (K).—No apparent reaction took place when 8.50 g. (0.024 mole)¹⁷ of diphenyliodoarsine was mixed with 1.08 g. (0.007 mole) of phenylarsine in 100 cc. of ether. Upon the addition of 25 cc. of alcohol a precipitate soon formed. After forty-eight hours the supernatant liquid was decanted into a second bulb and the precipitated arsenobenzene washed six times with 50-cc. portions of ether; m. p. 200–204°. The yield was 0.93 g.; calcd. yield, 1.07 g.

The ether-alcohol layer which had been decanted contained tetraphenyldiarsyl and the excess diphenyliodoarsine. The solution was concentrated to about 15 cc., whereupon tetraphenyldiarsyl and some diphenyliodoarsine precipitated. The mother liquor was decanted and the product washed a number of times with petroleum ether (30–60°) in order to remove the iodoarsine. The yield of tetraphenyldiarsyl was 1.40 g.; m. p. 129–130°; calcd. amount, 3.21 g.

Each of the following compounds, dissolved in ether, was shaken with arsenobenzene for three days at ordinary temperature: phenyldichloroarsine, diphenylchloroarsine, diphenyliodoarsine, diphenylarsine and phenylarsine. In the case of each mixture at least 90% of each component was recovered unchanged. Furthermore, it was found that neither phenylarsine nor diphenylarsine reacts with tetraphenyldiarsyl at ordinary temperature.

Summary

The interaction of phenylarsine, as well as diphenylarsine, and each of the following compounds has been investigated: phenyldichloroarsine, phenyldiiodoarsine, diphenylchloroarsine and diphenyliodoarsine. Substances such as tetraphenyldiarsyl, diphenyldiiododiarsyl and arsenobenzene have been obtained as reaction products.

¹⁷ This quantity represents an excess over that demanded by the formulation.

It seems that compounds such as phenyliodoarsine, triphenyldiarsyl, triphenylchlorodiarsyl and pentaphenyltriarsine are not produced by interaction of the above-mentioned arsines although the formation of these substances has been reported by other investigators.

RESEARCHES ON NITROGENOUS GLYCOSIDES. I. THE UTILIZATION OF GLYCOSE ISOCYANATES FOR GLYCOSIDE SYNTHESSES

BY TREAT B. JOHNSON AND WERNER BERGMANN¹

RECEIVED APRIL 14, 1932

PUBLISHED AUGUST 5, 1932

So far as the writers are aware, only one sugar isocyanate derivative has been described in the chemical literature, namely, tetraacetyl-*d*-glycose-*l*-isocyanate, $C_{14}H_{19}O_9NCO$. This interesting compound was described by Emil Fischer in a paper entitled "Synthese neuer Glycoside," in 1914² but since this publication, apparently no attention has been paid to its chemistry. Fischer obtained this sugar derivative by the action of silver cyanate on tetraacetobromoglycose, but the chief product of this reaction was an amorphous substance having the same composition as the glycose isocyanate but whose constitution was not established by Fischer.³

We have now repeated Fischer's preliminary experiments in order to obtain his isocyanate derivative for new glycoside syntheses. We find that silver cyanate interacts with tetraacetyl bromoglycose in xylene solution to give, besides resinous substances, three definite compounds which have been identified, namely, two modifications of the glycose isocyanate (A and B), melting at 120 and 92°, respectively, and the amorphous substance previously described by Fischer as a product of this reaction. We conclude that this amorphous material is without doubt impure *sym*.-octaacetyl-*d*-diglycose urea, which is formed by the interaction of tetraacetyl glycose isocyanate with water. It can be purified easily to give a beautiful crystalline substance melting at 160–161°. That this is octaacetyl-glycose urea is not only established by the results of our analyses, but also by its characteristic behavior toward aqueous ammonia. By treatment with this reagent it is transformed by hydrolysis smoothly into *sym*.-*d*-diglycose urea. The

¹ Sterling Research Assistant in Organic Chemistry, 1931–1932.

² E. Fischer, *Ber.*, **47**, 1377 (1914).

³ Fischer also examined the behavior of silver isothiocyanate toward tetraacetyl bromoglycose and observed the smooth formation of the corresponding glycose-isothiocyanate derivative, $C_{14}H_{19}O_9NCS$. Here also practically no attention has been paid to the chemistry of this mustard oil since Fischer's work in 1914. The results of a new research dealing with specific reactions of this interesting compound will be discussed in a future paper from this Laboratory by Miss Katherine Haring.

latter glycoside proved to be identical with the diglycose urea prepared recently by Helferich and Kosche⁴ by the action of aqueous ammonia on octabenzoyldiglycose urea.

Tetraacetyl-*d*-glycose-*l*-isocyanate is characterized by its behavior toward ammonia and alcohol. By the action of aqueous ammonia it is converted smoothly into the glycose urea previously described by Schoorl.⁵ The lower melting modification of the glycose isocyanate is unstable and rearranges on heating into Fischer's original glycose isocyanate, melting at 120°. The behavior toward alcohol is also characteristic of the isocyanate structure. We observed that *n*-amyl alcohol and ethylene chlorohydrin both interact smoothly at the boiling point of the respective alcohols, giving the corresponding urethans. A complete description of these various compounds and their preparation is given in the experimental part of this paper.

Tetraacetyl-*d*-glycose-*l*-isocyanate promises to be a fruitful starting point for the development of several new and important syntheses of biochemical interest. Our future program calls for coupling with various amino acids and peptide combinations leading to the formation of important glycosido-ureide constructions.⁶

Experimental Part

Tetraacetyl-*d*-glycose-*l*-isocyanate, $C_{14}H_{19}O_9NCO$ (A).—To a solution of 33 g. of tetraacetobromoglycose in 120 cc. of xylene, dried over sodium, 12 g. of freshly prepared, dried and pulverized silver cyanate is added. The reaction flask is connected with a rubber stopper fitted with a calcium chloride tube and heated on the steam-bath with frequent shaking. The silver cyanate soon turns yellow due to the formation of silver bromide. After one-half and one hour, respectively, 6 g. of silver cyanate is added and the mixture is finally heated for one hour more. The liquid is then filtered by suction and the insoluble silver salts are once more extracted with 80 cc. of xylene. The united liquids are then poured into 200 cc. of petroleum ether (30–60°), whereby a slightly yellow resin is precipitated. The mother liquor is at once decanted from the resin, mixed with 100 cc. more petroleum ether and allowed to stand overnight. One thus obtains a crystalline product, which consists of two distinctly different forms of crystals, needles and blocks. The yield of crystalline material is about 16–17 g. The melting point fluctuates between 80 and 110°, according to the proportion of needles or blocks which is obtained. The crystalline material is filtered and washed with petroleum ether.

This reaction product is extracted several times with anhydrous ether, when the needle form dissolves. The fraction insoluble in ether is dissolved in anhydrous chloroform, and ether then finally added until a separation of crystals begins. Under these conditions the beautiful crystalline glycose isocyanate "A" is obtained which melts sharply at 120°.

Anal. Calcd. for $C_{14}H_{19}O_9N$: C, 48.24; H, 5.13; N, 3.75. Found: C, 48.37;

⁴ Helferich and Kosche, *Ber.*, **59**, 69 (1926).

⁵ Schoorl, *Rec. trav. chim.*, **22**, 63 (1903).

⁶ We have observed also that silver cyanide and tetraacetylbromoglycose interact to give a beautiful crystalline isonitrile. The study of this substance will receive our attention later.

H, 5.19; N, 3.72. *Optical Rotation*. 0.8345 g. subs. in 25 cc. of CHCl_3 ; $l = 2$ dm.; $\alpha = -0.55^\circ$; $[\alpha]_D^{18} -8.3^\circ$.

These analytical results, and the fact that the product is readily dissolved in concentrated ammonia giving *d*-glycose-urea, are conclusive evidence that the compound is the tetraacetyl-*d*-glycose-*l*-isocyanate previously described by E. Fischer.²

Tetraacetyl-*d*-glycose-*l*-isocyanate, $\text{C}_{14}\text{H}_{19}\text{O}_9\text{NCO}$ (B).—The ether solution of the above-mentioned needles is diluted with petroleum ether until cloudy. After some time, needles separate which are filtered off, dissolved in anhydrous ether and reprecipitated with petroleum ether. After repeating this precipitation again, well-developed needle-like crystals were obtained melting at 92° .

Anal. Calcd. for $\text{C}_{14}\text{H}_{19}\text{O}_9\text{N}$: C, 48.24; H, 5.13; N, 3.75. Found: C, 48.26; H, 5.24; N, 3.84.

In all its reactions this glycose isocyanate modification "B" behaves like Fischer's compound "A." It rearranges into Fischer's isocyanate "A" if it is heated at its melting point. After cooling the fused mass and then reheating in a capillary tube, it melted at $115\text{--}120^\circ$. If a solution of the glycose isocyanate "B" in ether is mixed with petroleum ether, at first needles of this isocyanate will separate, but these slowly undergo a transformation, on standing, into the characteristic blocks of the isocyanate "A." During each recrystallization of the isocyanate "B" some of the isomeric modification "A" is always formed, which leads the authors to the conclusion that the modification "B" has not yet been obtained entirely pure and free from Fischer's glycose isocyanate.

Experience has shown that the highest yield of the isomer "B" is obtained if one filters the original xylene solution from the silver salts directly into a large excess of petroleum ether. At first a colorless amorphous mass separates, which soon takes on a crystalline form. This usually melts between $80\text{--}90^\circ$ and probably consists of about 80% of the lower melting isomer.

Sym.-Octaacetyl-*d*-diglycose Urea, $(\text{C}_{14}\text{H}_{19}\text{O}_9)\text{NHCONH}(\text{C}_{14}\text{H}_{19}\text{O}_9)$.—The amorphous precipitate first obtained during the preparation of the tetraacetylglycose isocyanate is dissolved in xylene and carefully reprecipitated with petroleum ether, when it deposits again in the amorphous form. This product is then dissolved in ethyl acetate and reprecipitated several times by addition of ether and finally recrystallized from hot alcohol. On cooling this alcohol solution, needles were finally obtained which melted at 164° . This octaacetyl-diglycose urea is easily soluble in ethyl acetate, benzene, warm alcohol, acetone, difficultly soluble in hot water and insoluble in ether and petroleum ether. Large quantities of this urea may also be obtained easily by digesting the crude tetraacetyl-*d*-glycose-*l*-isocyanate in aqueous acetone and then precipitating the urea with water.

Anal. Calcd. for $\text{C}_{28}\text{H}_{40}\text{O}_{18}\text{N}_2$: C, 48.04; H, 5.56. Found: C, 48.04; H, 5.72. *Optical Rotation*. 0.0615 g. subs. in 3.2 cc. of CHCl_3 ; $l = 1$ dm.; $\alpha = -0.07^\circ$; $[\alpha]_D^{26} -3.7^\circ$.

Preparation of Sym.-*d*-diglycose Urea, $(\text{C}_6\text{H}_{11}\text{O}_5)\text{NHCONH}(\text{C}_6\text{H}_{11}\text{O}_5)$.—The octaacetyl-*d*-glycose urea is suspended in ten times its weight of concentrated aqueous ammonia and the solution allowed to stand for three days. The urea finally dissolves completely. The solution is then concentrated in a vacuum, leaving behind an oily residue which easily dissolves in water. On adding alcohol to this aqueous solution the diglycose urea separates in a crystalline condition. It is purified by crystallization from dilute alcohol. When heated in a capillary tube this urea begins to turn brown at about 205° , and decomposes when heated above 230° .

Anal. Calcd. for $\text{C}_{12}\text{H}_{24}\text{O}_{11}\text{N}_2$: C, 40.61; H, 6.30. Found: C, 40.46; H, 6.16. *Optical Rotation*. 0.06633 g. subs. in 3.12 cc. of H_2O ; $l = 1$ dm.; $\alpha = 0.73^\circ$; $[\alpha]_D^{26} -25.4^\circ$.

This urea agrees in all its properties with the *d*-diglycose urea already described by Helferich.⁴

Tetraacetyl-*d*-glycose-*n*-amyl Urethan, $(C_4H_9O)_4NHCOOC_5H_{11}$.—Tetraacetyl-*d*-glycose-*l*-isocyanate is dissolved in 20 cc. of *n*-amyl alcohol and the solution heated to boiling for thirty minutes. After concentration *in vacuo*, an oil is obtained which dissolves in ether completely with the exception of a small amount of octaacetyl-*d*-diglycose urea present as an impurity. Dilution of this ether solution with petroleum ether (30–60°) precipitates an oil which soon crystallizes when chilled to a low temperature. By repeated recrystallizations from a mixture of ether and petroleum ether or from dilute alcohol, the amyl urethan is obtained in the form of well-developed prismatic crystals melting at 88°. This urethan is easily soluble in ethyl acetate, alcohol, chloroform, and ether, and is insoluble in petroleum ether and water.

Anal. Calcd. for $C_{20}H_{31}O_{11}N$: C, 52.04; H, 6.77; N, 3.03. Found: C, 51.90; H, 6.70; N, 2.95. *Optical Rotation.* 0.0775 g. subs. in 3.2 cc. of ether; $l = 1$ dm.; $\alpha = -0.16$; $[\alpha]_D^{26} -6.61^\circ$.

Tetraacetyl-*d*-glycose-chlorethyl Urethan, $(C_4H_9O)_4NHCOOCH_2CH_2Cl$.—Tetraacetyl-*d*-glycose-*l*-isocyanate and an excess of ethylene chlorohydrin are heated to boiling for ten minutes, and the solution concentrated *in vacuo*. An oil was obtained which dissolved immediately in cold ether. Dilution of this ether solution with petroleum ether led to the separation of needles which melted after repeated crystallizations at 110°. Recrystallization of this substance from dilute alcohol gave a product melting very sharply at 82–83° and containing solvent of crystallization. After drying *in vacuo* at 80° the melting point was raised to 114°.

Anal. Calcd. for $C_{17}H_{24}O_{11}NCl$: C, 44.98; H, 5.33; Cl, 7.81. Found: C, 45.05; H, 5.36; Cl, 8.01. *Optical Rotation.* 0.0551 g. subs. in 3.2 cc. of ether; $l = 1$ dm.; $\alpha = -0.20^\circ$; $[\alpha]_D^{26} -11.6^\circ$.

Summary

1. Tetraacetyl-bromoglycose interacts with silver cyanate in xylene solution to give three products, namely, two isomeric modifications of tetraacetyl-*d*-glycose-*l*-isocyanate melting at 92 and 120° and octaacetyl-*d*-diglycose urea.

2. The lower melting modification of the glycose isocyanate melting at 92° is rearranged by heating into the higher melting isomer (120°).

3. Tetraacetyl-*d*-glycose-*l*-isocyanate reacts with ammonia to form *d*-glycose urea and with *n*-amyl alcohol and ethylene chlorohydrin to form the corresponding urethans.

REDUCTION OF ALIPHATIC SULFONIC ACID SALTS WITH
PHOSPHORUS PENTABROMIDE AND PHOSPHORUS
TRIBROMIDE¹

BY W. H. HUNTER AND B. E. SORENSON

RECEIVED APRIL 18, 1932

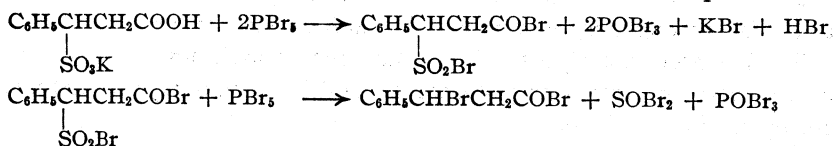

PUBLISHED AUGUST 5, 1932

In an attempt to prepare tribromobenzene sulfonyl bromide from the sodium salt of the sulfonic acid and phosphorus pentabromide, it was found that the reaction took a different course from that anticipated. Instead of the expected sulfonyl bromide, hexabromodiphenyl disulfide² was obtained. Further investigation showed that this reaction was quite general for salts of aromatic sulfonic acids.

The present work is an extension of this investigation to include the salts of the aliphatic sulfonic acids.

The sodium or potassium salts of methyl-, ethyl-, butyl-, isoamyl and benzylsulfonic acids, and the potassium salt of β -sulfo- β -phenylpropionic acid were prepared and treated with phosphorus bromides. In general this was carried out as follows: one mole of the salt was treated with one mole of phosphorus pentabromide (to form the sulfonyl bromide) and the reaction mixture was then further treated with two and one-half moles of phosphorus tribromide to bring about the reduction. In some cases this procedure was varied by allowing phosphorus pentabromide alone to react upon the sulfonate, and in one case the sulfonyl bromide was isolated and treated with phosphorus tribromide.

All the salts mentioned gave the corresponding disulfides when treated with *mixed* phosphorus bromides, except β -potassium sulfo- β -phenylpropionic acid, which gave β -bromo- β -phenylpropionic acid by the replacement of the SO_3K group by bromine as represented in the equations

This is similar to the action of phosphorus pentachloride on sulfonyl chlorides,³ except that it takes place at a lower temperature.

When phosphorus pentabromide was used alone, in sufficient quantities to cause reduction to occur, according to the reaction postulated in the

¹ The work described in this paper formed part of a thesis submitted to the Graduate Faculty of the University of Minnesota by B. E. Sorenson in partial fulfillment of the requirements for the degree of Doctor of Philosophy, June, 1927. The manuscript was written by the junior author after the death of Dr. Hunter.—L. I. SMITH.

first paper of this series,² the product isolated was usually the disulfide, but in some cases the sulfonyl bromide or the alkyl bromide resulted. Substitution of hydrogen by bromine also took place in several cases. Thus, β -potassium sulfo- β -phenylpropionic acid gave α,β -dibromophenylpropionic acid.

The results are summarized in Table I.

^a The sodium salt was made by oxidizing 50 g. of isoamyl disulfide with 20 cc. of nitric acid (sp. gr. 1.42).

Alkyl Sulfonyl Bromides.—One-tenth mole of potassium alkyl sulfonate and 0.35 mole of phosphorus pentabromide were heated for forty minutes at 70–80°, poured into 400 g. of crushed ice and stirred continuously until about 60 cc. of clear liquid remained undissolved. The lower layer was separated and shaken in a separatory funnel with 200 g. of ice for two minutes. The lower layer was separated, dried with calcium chloride and fractionated.

⁴ Muspratt, *Ann.*, 65, 261 (1848).

TABLE III
 PROPERTIES OF ALKYL SULFONYL BROMIDES

Sulfonyl bromide	Yield, %	Boiling point, °C.	d_4^{25}	Analyses, %		S	Found,		M. p. of sulfonamide, °C.
				S	Br		S	Br	
Ethyl ^a	41	103-106 (40 mm.) ^b		18.50		20.44	20.30		57-58
<i>n</i> -Butyl	66	101-102 (11 mm.)	1.5109	15.94	39.75	15.58	15.51	40.03	39.93

^a *J. prakt. Chem.*, [2] **26**, 384 (1880).

^b Cherbuliez and Schnauder [*Helv. Chim. Acta*, **6**, 249 (1923)] give 80° (13 mm.).

Alkyl Disulfides.—One-third mole of finely ground potassium alkyl sulfonate was mixed with 0.33 mole of phosphorus pentabromide, after which the reaction flask was fitted with a calcium chloride tube and heated on a steam-bath for fifteen minutes. After cooling to 80°, 0.8 mole of phosphorus tribromide was added and the temperature maintained at 70–80° for forty minutes. The red reaction mixture was transferred to a 1-liter flask, cooled in an ice-bath and dissolved in 250 cc. of ether. The halides of phosphorus were hydrolyzed by adding water slowly until the ether formed a separate layer, and then the solution was steam distilled. The ether layer of the distillate was separated, washed once with water, then with 5% sodium carbonate solution and finally with water. After drying with calcium chloride, it was filtered and fractionated, using a Clarke flask with column attached.

 TABLE IV
 PROPERTIES OF ALKYL DISULFIDES

Disulfide	Yield, %	Boiling point, °C.	d_4^{20}	Analyses		Sulfur	AgNO ₃ double salt

Preparation of *n*-Butyl Disulfide by a Known Method.—Since *n*-butyl disulfide was not described in the literature, it was made by refluxing an alcoholic solution of sodium disulfide with *n*-butyl chloride. The alcohol and excess butyl chloride were distilled off at atmospheric pressure and enough water added to dissolve the sodium chloride. The oily upper layer was separated, dried and fractionated at reduced pressure. *n*-Butyl disulfide was water white and had the following properties: b. p. 93-94° (7 mm.) or 226-229° (740 mm.), d_4^{25} 0.9329.

Anal. Calcd. for C₈H₁₈S₂: S, 35.95. Found: S, 36.64, 36.50.

n-Butyl trisulfide, the by-product, was pale yellow and had the following properties: b. p. 119-121° (6 mm.) and d_4^{25} 1.0117.

Anal. Calcd. for C₈H₁₈S₃: S, 45.73. Found: S, 46.50, 46.62.

Preparation of Benzyl Bromide from Sodium Benzyl Sulfonate.—Benzyl bromide was obtained in 70% yield when fifteen grams of sodium benzyl sulfonate and 93 g. of phosphorus pentabromide were heated at 85-90° for fifteen minutes. The mixture,

which fused and gave off hydrogen bromide, was dissolved in 100 cc. of ether, and water was added until the ether layer separated. The ether solution was separated, washed once with water and dried with calcium chloride. After evaporating the ether, the residual liquid was fractionated at 18 mm., and redistilled at atmospheric pressure; b. p. 195–197° (740 mm.).

Anal. Calcd. for C_7H_7Br : Br, 46.73. Found: Br, 48.64, 48.33.

Preparation of β -Bromo- β -phenylpropionic Acid.—Eighteen grams of β -potassium sulfo- β -phenylpropionic acid (made from cinnamic acid and potassium sulfite by the method of Valet [*Ann.*, 154, 63 (1870)] and purified by washing with benzene and recrystallizing from alcohol), 58 g. of phosphorus pentabromide and 45 g. of phosphorus tribromide were heated at 85–90° with occasional shaking until the phosphorus pentabromide was dissolved. The reaction mixture was cooled and dissolved in 125 cc. of ether. The ether solution was treated with water to hydrolyze the phosphorus bromides, dried, filtered and evaporated to dryness. This gave 12 g. (80%) of crude gray β -bromo- β -phenylpropionic acid, which was crystallized twice from benzene to give a colorless material, m. p. 135–137°. An authentic sample of β -bromo- β -phenylpropionic acid melted at 137°; mixed m. p. 135.5–137°. ⁵

Preparation of α,β -Dibromo- β -phenylpropionic Acid.—Nineteen grams of β -potassium sulfo- β -phenylpropionic acid and 125 g. of phosphorus pentabromide were mixed and heated at 100° until the evolution of hydrogen bromide ceased (about one hour). The reaction product was isolated in the same way as the β -bromo- β -phenylpropionic acid. The crude product was crystallized once from benzene, giving 13.2 g. (62%) of α,β -dibromo- β -phenylpropionic acid, m. p. 188–195° (with decomposition). It was recrystallized and melted at 197° (when heated rapidly near the melting point). ⁶

Anal. Calcd. for $C_9H_8O_2Br_2$: Br, 51.94. Found: Br, 51.60, 51.80.

Summary

1. Several salts of aliphatic sulfonic acids were reduced to the corresponding disulfides with a mixture of phosphorus pentabromide and phosphorus tribromide.
2. Phosphorus pentabromide alone gave the same disulfides in some cases. In other cases the sulfonic acid group was replaced by bromine.
3. The sulfonyl bromide group is more easily replaced by bromine (by means of phosphorus pentabromide) when attached to an aliphatic radical than when attached to an aromatic nucleus.
4. The presence of a phenyl radical on the carbon holding the sulfonyl bromide group facilitates the replacement of the latter by bromine.

MINNEAPOLIS, MINNESOTA

⁵ Bodwig, *Ber.*, 12, 538 (1874).

⁶ Sudborough and Thompson [*J. Chem. Soc.*, 83, 670 (1903)] give the melting point as 197° (when heated rapidly).

THE MECHANISM OF THE REDUCTION OF SULFONYL BROMIDES WITH PHOSPHORUS TRIBROMIDE¹

BY W. H. HUNTER AND B. E. SORENSON

RECEIVED APRIL 18, 1932

PUBLISHED AUGUST 5, 1932

Kohlhase² discovered that many aromatic sulfonyl bromides could be easily and conveniently reduced to disulfides by phosphorus tribromide. Hunter and Sorenson³ showed that the reaction could be applied with equal success to sulfonyl bromides of the aliphatic series. These earlier papers were concerned largely with the preparative aspects of the new reaction. Attention was logically next devoted to the mechanism of the change.

In order to elucidate the mechanism of the reaction, two methods of attack are possible: attempts could be made to isolate intermediate products of the reduction, or possible intermediate products could be synthesized by other means, and the action of phosphorus bromides upon these substances studied. Since the first procedure is attended with great difficulty and uncertainty under the conditions necessary for these reductions, we chose the latter method of attack.

For this purpose it was first assumed that the reaction took place in steps which might be represented as

Examples of each of these possible intermediate products were prepared and subjected to the action of phosphorus tribromide as described in this paper.

No sulfinyl bromides were described in the literature; therefore, *p*-toluene sulfinyl chloride⁴ was chosen for the first experiments. This sulfinyl chloride was reduced very readily by phosphorus tribromide, although it gave a slightly lower yield of *p*-toluene disulfide than *p*-toluene sulfonyl bromide which was also reduced as a control.⁵

¹ This article is an abstract of part of a thesis submitted by B. E. Sorenson to the Faculty of the Graduate School of the University of Minnesota, in partial fulfillment of the requirements for the degree of Doctor of Philosophy, in June, 1927. The manuscript was written by the junior author after the death of Dr. Hunter.—L. I. SMITH.

² Kohlhase, *THIS JOURNAL*, **54**, 2441 (1932).

³ Hunter and Sorenson, *ibid.*, **54**, 3364 (1932).

⁴ Hilditch and Smiles, *Ber.*, **41**, 4115 (1908).

⁵ The comparison between the *p*-toluene sulfinyl chloride and the sulfonyl bromide was not entirely logical, but since previous work² has shown that sulfonyl chlorides are not reduced by phosphorus tribromide whereas sulfonyl bromides are readily reduced, it seems probable that the sulfinyl bromide would be reduced at least as easily as the sulfinyl chloride.

Otto and Rössing⁶ also found that sodium benzene sulfinate was reduced to the disulfide by phosphorus trichloride according to the equation

If the first product of this reaction is the sulfinyl chloride it indicates that this is reduced by the phosphorus trichloride. Since sulfonyl bromides are not reduced by phosphorus trichloride,² this can be adduced as further evidence that sulfinyl bromides are more easily reduced than sulfonyl chlorides. This ease of reduction of the sulfinyl bromides very likely accounts for the fact that sulfinyl bromides do not appear as intermediate products.

o-Nitrophenyl sulfur bromide⁷ was chosen for the next experiments as it was well known and quite stable. This sulfur bromide did not react rapidly with phosphorus tribromide. However, when it was allowed to stand for several days in dry ether with phosphorus tribromide it gave some *o*-nitrophenyl disulfide. Under similar conditions the sulfur bromide alone in dry ether also gave some *o*-nitrophenyl disulfide but not as much as when phosphorus tribromide was present. These phenomena may be explained by assuming that the sulfur bromide dissociates reversibly into bromine and the disulfide, and that phosphorus tribromide may upset the equilibrium by combining with the bromine thus liberated.

When *o*-nitrophenyl disulfide was treated with an excess of phosphorus pentabromide, *o*-nitrophenyl sulfur bromide was formed, thus proving that the above reaction is in fact reversible. An attempt was made to prepare tribromobenzene sulfur bromide from the disulfide and bromine according to the general method of Zincke and Farr⁷ but it could not be isolated. As soon as the solvent and excess bromine were removed the reaction was completely reversed to give back the disulfide.

o-Nitrophenylsulfonyl bromide was reduced by phosphorus tribromide at low temperatures. The products were the disulfide and the sulfur bromide when the reaction products were isolated in the absence of water. When the reaction mixture was dissolved in ether and hydrolyzed by adding water, *o*-nitrophenyl disulfide and *o*-nitrothiophenol were obtained.

Thionaphthol² was previously isolated in this type of reduction and was assumed to be formed in accordance with the equations

This mechanism was tested by mixing *o*-nitrophenyl disulfide and phosphorus tribromide, but no thiophenol resulted. The next postulate was

⁶ Otto and Rössing, *Ber.*, **24**, 3883 (1891).

⁷ Zincke and Farr, *Ann.*, **391**, 67 (1912).

that the thiophenol resulted from the further reduction of the sulfur bromide when water was added to the ether solution. However, none of the reducing agents present in the reaction mixture, such as phosphorus acid and hydrobromic acid, reduced the sulfur bromide to the thiophenol in the presence of water and ether. However, pure *o*-nitrophenyl sulfur bromide and phosphorus tribromide in ether solution gave almost a quantitative yield of thiophenol when water was added. From this it was concluded that the thiophenol resulted from the hydrolysis of a molecular compound first formed from the sulfur bromide and phosphorus tribromide.

A freezing point method was devised to determine if evidence of the formation of a molecular compound could be obtained. Phosphorus tribromide or *o*-nitrophenyl sulfur bromide alone gave normal freezing point depressions in benzene. Likewise, the mixture gave a normal freezing point depression in benzene showing that no molecular compound was formed in this solvent. However, when a solution of the two in benzene was hydrolyzed (as was done with the ether solution) *o*-nitrophenyl disulfide was formed instead of the thiophenol obtained in ether. No direct proof of the presence of a molecular compound in the ether solution could be observed, but the different results obtained in ether and in benzene strengthened our opinion that some such explanation was probably correct.

On the basis of all the evidence we are able to postulate definitely that the steps in the reduction of sulfonyl bromides to disulfides are the following:

Experimental

Preparation of *p*-Toluenesulfinyl Chloride.—*p*-Toluenesulfinyl chloride was made by treating *p*-toluenesulfinic acid with an excess of thionyl chloride according to the method of Hilditch and Smiles.⁸ The material obtained was a liquid at room temperature. The above authors give the melting point as 54–58°.

Reaction between *p*-Toluenesulfinyl Chloride and Phosphorus Tribromide.—(a) Four grams (1 mole) of *p*-toluenesulfinyl chloride and 10 g. (1.5 moles) of phosphorus tribromide were mixed in a 50-cc. flask. The mixture became so hot that free bromine was given off and phosphorus pentabromide sublimed on the neck of the flask. When the reaction mixture became cool it was dissolved in 30 cc. of ether and water was added to hydrolyze the halides of phosphorus. The ether layer was separated, washed with sodium carbonate solution and dried. The ether was evaporated and the residual red oil allowed to solidify. This gave 1.5 g. (54% of the theoretical quantity) of crude *p*-

⁸ Ref. 4, p. 4114.

toluene disulfide. This was crystallized from alcohol and gave a colorless product of m. p. 44–45°. *p*-Toluene disulfide melts at 46°.⁹

Anal. Subs., 0.1190: BaSO₄ (Carius) 0.2308. Calcd. for C₁₄H₁₄S₂: S, 26.06. Found: S, 26.62.

Reaction between *p*-Toluenesulfonyl Bromide and Phosphorus Tribromide.—Three grams (1 mole) of *p*-toluenesulfonyl bromide¹⁰ was heated with 8.7 g. (2.5 moles) of phosphorus tribromide at 80–90° for twenty minutes. The *p*-toluene disulfide was isolated as in the previous experiment, and weighed 0.9 g. (56% of the theoretical). The recrystallized disulfide melted at 44–45°, and showed no depression when mixed with a sample prepared as in the previous experiment.

The Action of Phosphorus Tribromide on *o*-Nitrophenyl Sulfur Bromide in Ether.—One-half gram of *o*-nitrophenyl sulfur bromide was dissolved in 20 cc. of dry ether. To this 2.8 g. of phosphorus tribromide was added. The flask was stoppered and allowed to stand for five days. After several hours the solution became cloudy and in about eight hours a precipitate began to separate. This was filtered off after twenty-four hours and washed with benzene to remove a small amount of a green amorphous material. The disulfide weighed 0.05 g. (15%), m. p. 193–194°; mixed melting point with known *o*-nitrophenyl disulfide, 193–194.5°. The known disulfide melted at 195°. In a check experiment a yield of 5% of the disulfide was obtained.

The Action of Phosphorus Pentabromide on *o*-Nitrophenyl Disulfide in Dry Ether.—In a flask were placed 2 g. (1 mole) of *o*-nitrophenyl disulfide, 7 g. (3 moles) of phosphorus pentabromide and 50 cc. of dry ether. The *o*-nitrophenyl disulfide dissolved completely after about two hours. The ether solution was decanted from a small amount of a heavy red oil and evaporated at reduced pressure until a precipitate started to form. It was then treated with 50 cc. of ligroin and stirred until the precipitate was pale yellow. The solution was filtered and the precipitate washed several times with petroleum ether and dried. There resulted 1.2 g. (40%) of *o*-nitrophenyl sulfur bromide. The product melted at 78–81° after crystallization from benzene. Mixed with known *o*-nitrophenyl sulfur bromide it melted at 78–83°. The known product melted at 83–84°.

Attempt to Prepare Tribromophenyl Sulfur Bromide from Hexabromodiphenyl Disulfide and Bromine.—2.7 g. of hexabromodiphenyl disulfide was suspended in a mixture of 20 cc. of carbon tetrachloride and 4 cc. of bromine. The disulfide dissolved slowly and after twelve hours was all in solution. The carbon tetrachloride was evaporated in a vacuum desiccator. The solid which remained melted at 215–217°. The original disulfide melted at 215–217°; mixed m. p. 215–217°.

Preparation of *o*-Nitrophenylsulfonyl Bromide.—This compound was prepared by a modification of the process of Zincke and Farr⁷ for the preparation of sulfonyl chlorides.

Fifteen grams of *o*-nitrophenyl disulfide was suspended in 100 cc. of glacial acetic acid. To this was added 20 cc. of bromine dissolved in 100 cc. of glacial acetic acid. The mixture was heated at 50–60° until the disulfide dissolved. Water was added slowly until the total volume of the solution was about 500 cc. If the first addition of water caused a yellow bulky precipitate to form, it was necessary to heat the reaction mixture until this redissolved. The crude sulfonyl bromide which separated as a pink or colorless precipitate was filtered off, washed with water and dissolved in a small amount of ether without drying. The water was separated from the ether solution and after concentrating the ether to a volume of 35 cc. the sulfonyl bromide was precipitated by adding ligroin. The sulfonyl bromide was filtered off, washed once with ligroin and dried. The yield was 20 g. (79%); m. p. 62.5–63.5°. Recrystallized once from equal parts of benzene and benzine, a colorless product was obtained, m. p. 63–64° (uncorr.).

⁹ *J. prakt. Chem.*, [2] 41, 190 (1890).

¹⁰ *Otto, Ann.*, 142, 98 (1867).

Anal. Subs., 0.2488, 0.2215: AgBr (Carius), 0.1766, 0.1560. Calcd. for $C_6H_4O_2-NBrS$: Br, 30.04. Found: Br, 30.24, 29.97.

For further identification, the sulfonyl bromide was converted to the sulfonamide by saturating a ligroin-benzene solution with dry ammonia. The amide melted at 190.5–191.5° after recrystallizing from water. *o*-Nitrophenylsulfonamide¹¹ melts at 190–191°.

The Action of Phosphorus Tribromide on *o*-Nitrophenylsulfonyl Bromide.—Three grams (1 mole) of *o*-nitrophenylsulfonyl bromide was placed in a 100-cc. flask fitted with a dropping funnel. The flask was cooled in an ice-bath and 7.6 g. (2.5 moles) of phosphorus tribromide was added slowly through the dropping funnel. The reaction mixture was then agitated with 20 cc. of ligroin until only a flocculent yellow precipitate and a small amount of tarry material on the bottom of the flask remained undissolved. The crude yellow *o*-nitrophenyl sulfur bromide was filtered and the tar extracted with hot benzene. The crude sulfur bromide was crystallized from benzene and gave 1.1 g., m. p. 79–82°; mixed m. p. with known *o*-nitrophenyl sulfur bromide (m. p. 83–84°) was 80–83°.

Anal. Subs., 0.1242, 0.1214: AgBr (Carius), 0.0985, 0.0963. Calcd. for $C_6H_4O_2-NBrS$: Br, 34.14. Found: Br, 33.68, 33.75.

The residue which did not dissolve in the benzene in the second crystallization was extracted with the benzene used to extract the original residue in the flask. The solution was filtered and evaporated to a volume of 4 cc. The precipitate which formed on cooling was filtered, washed with dilute sodium hydroxide solution and dried. There was obtained 0.3 g. of crude *o*-nitrophenyl disulfide. It was recrystallized from benzene and melted at 192.5–193.5°. *o*-Nitrophenyl disulfide¹² melts at 195°. Mixed with known disulfide it melted at 193–194°.

If instead of isolating the reaction products as described above, the reaction mixture was dissolved in ether and hydrolyzed by adding water slowly, the products were *o*-nitrothiophenol and *o*-nitrophenyl disulfide. These were separated by extracting with normal sodium hydroxide solution. After filtration the thiophenol was reprecipitated by adding dilute hydrochloric acid. The crude disulfide was purified by recrystallizing from benzene. The *o*-nitrophenyl disulfide melted at 194–195°. The *o*-nitrothiophenol melted at 54–55°. Mixed with known *o*-nitrothiophenol (m. p. 56–56.5°) it melted at 54–55°.

The Action of Phosphorus Tribromide on *o*-Nitrophenyl Disulfide in Ether.—One gram of *o*-nitrophenyl disulfide was suspended in 15 cc. of ether. To this was added 3 cc. of phosphorus tribromide. The phosphorus tribromide was hydrolyzed by adding water slowly without cooling. When 15 cc. of water had been added the mixture was allowed to stand at room temperature until the ether evaporated. The precipitate which resulted was filtered off, washed with water and dried. This gave 0.95 g. of *o*-nitrophenyl disulfide, m. p. 194–195°. The original disulfide melted at the same temperature.

The Action of Phosphorus Tribromide on *o*-Nitrophenyl Sulfur Bromide in Ether and in Benzene.—(a) In ether: 0.5 g. of *o*-nitrophenyl sulfur bromide was dissolved in 2.8 g. of phosphorus tribromide. The solution was diluted with 10 cc. of ether; 10 cc. of water was added to the ether solution drop by drop without cooling, and the mixture was allowed to stand until the ether layer evaporated. The crystals which formed were filtered, washed with cold water and dried. This gave 0.3 g. (93%) of crude *o*-nitrothiophenol; m. p. 49–51°. It was dissolved in normal sodium hydroxide solution,

¹¹ Ekbohm, *Ber.*, **35**, 657 (1902).

¹² Wohlfahrt, *J. prakt. Chem.*, **66**, 553 (1902).

reprecipitated with hydrochloric acid, filtered, washed with water and dried. The purified thiophenol melted at 56–56.5°. *o*-Nitrothiophenol¹³ melts at 56°.

Anal. Subs. 0.1415: BaSO₄, 0.2070. Calcd. for C₆H₄O₂NS: S, 20.20. Found: S, 20.09.

(b) **In Benzene:** One-half gram of *o*-nitrophenyl sulfur bromide was dissolved in 2.8 g. of phosphorus tribromide. To this 10 cc. of benzene was added. The reaction mixture was hydrolyzed as in part (a). The crystals formed were stirred with sodium hydroxide solution, filtered, washed with water and dried. This gave 0.25 g. (92% of theoretical) of *o*-nitrophenyl disulfide; m. p. 192–194°; no depression when mixed with known *o*-nitrophenyldisulfide (m. p. 195°). The sodium hydroxide filtrate was acidified with hydrochloric acid but no *o*-nitrothiophenol separated.

Determination of Freezing Points

***o*-Nitrophenyl Sulfur Bromide in Benzene.**—Sample 0.4995; benzene 17.40; depression 0.600°. Calcd. for C₆H₄O₂NBrS: mol. wt. 234. Found: 239.

Phosphorus Tribromide and *o*-Nitrophenyl Sulfur Bromide in Benzene.—The experiment was carried out in the same way as molecular weight determinations by the cryoscopic method. The phosphorus tribromide was added to the benzene first and the freezing point depression noted. An equivalent weight of *o*-nitrophenyl sulfur bromide was added to this in three portions and the freezing point observed after each addition.

Substance added	Freezing point, °C.
Pure benzene	4.920
0.5920 g. phosphorus tribromide	4.306
0.1280 g. <i>o</i> -nitrophenyl sulfur bromide	4.147
0.3840 g. <i>o</i> -nitrophenyl sulfur bromide	3.835

Calcd. mol. wt. of PBr₃: 271. Found: 277. Calcd. mol. wt. of C₆H₄O₂NBrS: 234. Found: 233.

Summary

1. *p*-Toluene-sulfinyl chloride was reduced readily to *p*-toluene disulfide by phosphorus tribromide.

2. *o*-Nitrophenyl sulfur bromide was slowly reduced by phosphorus tribromide to give the corresponding disulfide in poor yield. The presence of phosphorus tribromide increased the yield of disulfide.

3. Phosphorus pentabromide reacted with *o*-nitrophenyl disulfide to give *o*-nitrophenyl sulfur bromide.

4. *o*-Nitrophenyl sulfonyl bromide was reduced to *o*-nitrophenyl sulfur bromide by phosphorus tribromide.

5. The action of water on an ether solution of *o*-nitrophenyl sulfur bromide and phosphorus bromide gave *o*-nitrothiophenol.

6. It is therefore postulated that the course of the reduction of a sulfonyl bromide by phosphorus tribromide is as follows: sulfonyl bromide → sulfinyl bromide → sulfur bromide ⇌ disulfide + Br₂. Sulfur

¹³ Mayer, *Ber.*, **42**, 3059 (1909).

bromide + PBr_3 (in ether) \longrightarrow addition compound \longrightarrow thiophenol (on hydrolysis).

THE HYDROLYSIS OF LIGNIN WITH 12% HYDROCHLORIC ACID

BY MAX PHILLIPS AND M. J. GOSS

RECEIVED APRIL 20, 1932

PUBLISHED AUGUST 5, 1932

Hägglund and Björkman¹ and later Hägglund and Rosenqvist² distilled lignin (isolated by the fuming hydrochloric acid method) with 12% hydrochloric acid and obtained a distillate which gave a precipitate with phloroglucinol, barbituric acid and with thiobarbituric acid. The substance present in the distillate was not definitely identified, but was shown to be neither furfural, methylfurfural nor hydroxymethylfurfural.

Freudenberg and Harder³ distilled lignin (isolated from wood by a method similar to that used by Urban⁴) with 12% hydrochloric acid and identified the volatile hydrolytic product as formaldehyde. In a subsequent paper, Freudenberg, Harder and Markert⁵ advanced the hypothesis that the formaldehyde arises from a methylene dioxide group ($-\text{O}-\text{CH}_2-\text{O}-$) present in the lignin molecule, as compounds containing the methylene dioxide group are known to yield formaldehyde when they are distilled with hydrochloric acid. However, this interpretation of the reaction involved has been questioned by Fuchs and Horn.⁶ They distilled with hydrochloric acid lignin, acetylated lignin and two oxidized acetylated lignin preparations and found that lignin itself gave a greater yield of formaldehyde-barbituric acid condensation product than the other three modified lignin preparations.

The present investigation was undertaken for the purpose of determining (1) whether lignin isolated from materials other than wood gives formaldehyde when distilled with 12% hydrochloric acid, and (2) whether the method employed for the isolation of the lignin has any effect on the formaldehyde-yielding component presumably present in lignin.

Experimental

The lignin used in these experiments was isolated from three different sources by the following different methods. The lignin was isolated from corn cobs by the alco-

⁶ Fuchs and Horn, *Ber.*, **62**, 2647 (1929).

holic⁷ and aqueous sodium hydroxide⁸ methods, by the fuming hydrochloric acid method of Willstätter and Zechmeister⁹ and by Urban's method⁴ as modified by Freudenberg and Harder.¹⁰ The lignin from oat hulls was isolated by the alcoholic and aqueous sodium hydroxide methods,¹¹ by the method of Willstätter and Zechmeister⁹ and by Freudenberg and Harder's modification¹⁰ of Urban's method. The lignin from spruce wood was prepared by the aqueous sodium hydroxide method and according to the procedure of Freudenberg and Harder.¹⁰

Distillation of the Lignin with 12% Hydrochloric Acid.—The distillation of the lignin with the 12% hydrochloric acid was carried out exactly as in the determination of pentosans by Tollens' method, as described in the official book of methods of the Association of Official Agricultural Chemists.¹² In all experiments, three grams of lignin was used for each distillation. The distillate was made up with water to a volume of 500 cc. in a volumetric flask. A portion of this solution was tested immediately for formaldehyde by the Schryver¹³ modification of the Rimini¹⁴ test. This test is specific for formaldehyde. Furfural, which might be expected to be present in some of the distillates, gives no reaction with the reagents employed in the formaldehyde test when the dilution reaches 1:100,000. When the concentration of the furfural is approximately 1:1000, or greater, an apricot-yellow color is formed which on addition of concentrated hydrochloric acid turns green and rapidly disappears. Formaldehyde, on the other hand, gives a fuchsin-like color which is quite permanent.

¹⁴ Rimini, *Bull. Soc. Chim. France*, [3] **20**, 896 (1898).

The formaldehyde in the distillates was determined quantitatively by the iodine titration method.¹⁵ The results obtained are given in Table I.

It will be observed from Table I that formaldehyde was obtained in appreciable quantity in the distillates from only two of the eight lignin preparations, namely, in that of the lignin from oat hulls prepared by the Freudenberg and Harder modification of Urban's method, and in the distillate of the lignin from spruce wood prepared by the same method. In the distillates from all the other lignin preparations, except one, no formaldehyde could be detected. In the distillate of the lignin from oat hulls prepared by the method of Willstätter and Zechmeister, the test for formaldehyde was so slight that it can be characterized only as a "trace." The percentage formaldehyde obtained from the lignin of spruce wood is in substantial agreement with that recorded by Freudenberg and Harder.¹⁶

It would appear from the data that the source of the lignin and the method employed for its isolation from the lignified plant materials are two factors which determine whether formaldehyde is obtained as an hydrolytic degradation product from lignin. Thus, lignin from oat hulls prepared by Freudenberg and Harder's modification of Urban's method, when hydrolyzed with 12% hydrochloric acid, yielded a quantity of formaldehyde equivalent to 0.61% of the weight of the lignin, whereas lignin isolated from corn cobs by the same method gave absolutely no test for formaldehyde when similarly hydrolyzed. On the other hand, the hydrolysate of the lignin from oat hulls prepared by the alcoholic sodium hydroxide method gave no test for formaldehyde and that from the lignin isolated from the same source by the method of Willstätter and Zechmeister contained only a trace of formaldehyde. The hydrolysate from the last-mentioned lignin preparation, however, gave a positive test for furfural so that in this case the minute quantity of formaldehyde may have originated from some carbohydrate impurity.

If we were to accept the explanation of Freudenberg, Harder and Markert⁵ that the formaldehyde arises from a methylene dioxide group present in the lignin molecule, the conclusion would have to be drawn that this group is present only in lignin isolated from certain plant materials. Furthermore, it is rather difficult to conceive how such a mild treatment as that employed in the isolation of lignin by the alcoholic sodium hydroxide method could bring about the removal of such a comparatively stable group as the methylene dioxide group. In this connection, attention is called to the fact that no formaldehyde was found in the distillate from the lignin fraction isolated from oat hulls by the alcoholic sodium hydroxide method, whereas in the distillate from the lignin isolated from the same source by Freudenberg and Harder's modification of Urban's method (where a solution comprising concentrated hydrochloric acid and sirupy phosphoric acid is employed for the removal of the cellulose and other carbohydrates) formaldehyde was obtained to the extent of 0.61% of the weight of the lignin. It would seem therefore, questionable whether the formaldehyde that is obtained in the hydrolysis of certain lignin preparations can be considered as a fission product of a methylene dioxide group.

Summary

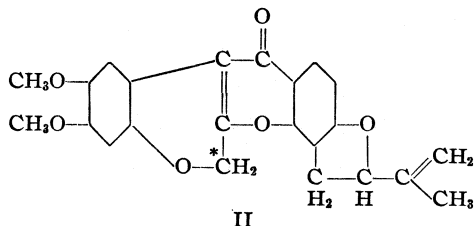

Lignin isolated from corn cobs, oat hulls and spruce wood by the method of Willstätter and Zechmeister, by the alcoholic and aqueous sodium hydroxide methods and by Freudenberg's modification of Urban's method, was distilled with 12% hydrochloric acid. Formaldehyde was obtained in appreciable quantity only in the distillate from the lignin isolated from oat

¹⁵ Smith, *THIS JOURNAL*, **25**, 1028 (1903).

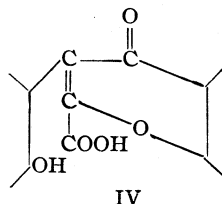

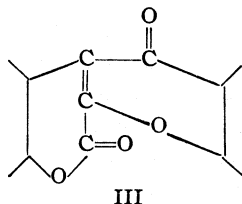

¹⁶ Ref. 3, page 585.

In a previous article⁴ we have described the oxidation of dihydro-rotenononic acid to dihydrotubaic acid, and also the reconversion of dihydrorotenononic acid to dihydrorotenonone. The last-mentioned reaction is best explained by the assumption that dihydrorotenonone and hence rotenonone are lactones.

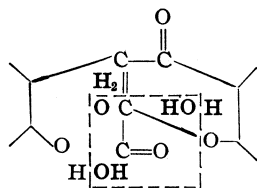

It is apparent from consideration of the formula of dehydrorotenone II

that a lactone would be formed on oxidation of the methylene group indicated by the asterisk. Consequently rotenonone would be represented by the formula III and rotenononic acid by IV.

A compound of formula III, like rotenone, might be expected to undergo alkaline hydrolysis with the formation of derritol. The experiment showed that this reaction does in fact take place. A small yield of derritol was obtained from rotenonone under the same conditions that were employed for the preparation of derritol from rotenone.⁵ The main product, however, was an acid which failed to crystallize.

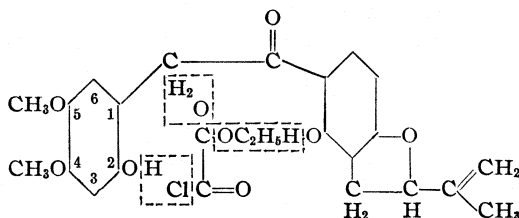

Rotenononic acid gives a positive test for phenol with ferric chloride and is easily methylated by dimethyl sulfate to the methyl ester of methyl-rotenononic acid, which separates in crystalline form from the alkaline solution. The corresponding acid is obtained from the ester. The ester is also easily hydrogenated to the tetrahydro derivative, which is alkali soluble.

Contrary to expectations, methyltetrahydrorotenononic acid is not cleaved by hydrogen peroxide to asaronic acid. The resistance of rotenononic acid toward strong alkali is also quite remarkable and indicates an unusual stability of the complex represented by formula IV.

⁴ LaForge and Smith, *THIS JOURNAL*, **52**, 3803 (1930).

⁵ LaForge and Smith, *ibid.*, **51**, 2574 (1929).

If formula III is a correct expression for rotenonone, it should be possible to effect the synthesis of rotenonone from derritol by substitution of the oxyalyl ethyl ester radical on the free phenol group in position 2 followed by saponification and dehydration, as in the formation of dehydrorotenone from derrisic acid. The reaction is represented below.

Derritol was therefore allowed to react with chloro-oxalyl ethyl ester in pyridine solution. It was expected that the oxalyl ethyl ester would result, which could subsequently be saponified and dehydrated to rotenonone. However, under the conditions of the experiment all three reactions took place spontaneously, and there resulted a nearly quantitative yield of rotenonone. In view of the small yield of rotenonone obtained by oxidation of rotenone, this method is probably the most convenient one for its preparation.

There can be no further doubt that rotenonone is represented by formula III.⁶

Experimental

Rotenononic Acid.¹—Two grams of rotenonone was added to a boiling solution of 2 g. of solid potassium hydroxide in 2 cc. of water to which 6 cc. of alcohol had been added. The solution was boiled for five minutes, then diluted with water and acidified. The amorphous precipitate crystallized directly, and the product was purified by dissolving in a large quantity of hot alcohol, filtering if necessary from a small residue of rotenonone and concentrating to a small volume. The compound crystallized slowly. The yield was about 1.7 g. It melted at 250°.

Methylrotenononic Acid Methyl Ester.—Four grams of rotenononic acid dissolved in 35 cc. of 5% potassium hydroxide was methylated with 7 g. of dimethyl sulfate. The reaction was carried out with mechanical stirring over a period of two hours.

The product separated crystalline and was recrystallized from methyl alcohol. It melted at 138°. The yield was 3.5 g.

Anal. Subs., g. 0.0790, 0.0207, 0.0198: CO₂, 0.1906; H₂O, 0.0386. Thiosulfate solution (1 cc. = 0.000520 CH₃O), 10.7, 10.15. Calcd. for C₂₆H₂₄O₈: C, 66.37; H, 5.32; 4CH₃O, 27.43. Found: C, 65.80; H, 5.43; CH₃O, 26.90; 26.68.

The corresponding acid was obtained by saponification of the ester. It was recrystallized from a small quantity of methyl alcohol. It melted at 179–180°.

Anal. Subs., 0.0777, 0.0272 g.: CO₂, 0.1864; H₂O, 0.0374. Thiosulfate (1 cc. =

⁶ An article by Butenandt and McCartney [*Ann.*, **494**, 17 (1932)] has just reached us, April 20, as the foregoing article is being submitted for publication in which the authors have expressed the formula for rotenonone by a formula identical with III.

0.000520 CH_3O), 11.00. Calcd. for $\text{C}_{24}\text{H}_{22}\text{O}_8$: C, 65.75; H, 5.02; $3\text{CH}_3\text{O}$, 21.23. Found: C, 65.43; H, 5.34; CH_3O , 21.04.

Tetrahydromethylrotenononic Acid.—Two grams of methylrotenononic acid methyl ester was reduced with platinum catalyst in acetic ester solution until the required four atoms of hydrogen were absorbed. The solution was extracted with cold dilute alkali, and, after standing for some time to allow the ester to saponify, the aqueous solution was acidified and the product recrystallized from dilute alcohol. A small sample was recrystallized from very little methyl alcohol. The melting point was $184\text{--}186^\circ$.

Anal. Subs., 3.542, 3.149 mg.: CO_2 , 8.495, 7.588; H_2O , 1.949, 1.712. Calcd. for $\text{C}_{24}\text{H}_{26}\text{O}_8$: C, 65.18; H, 5.88. Found: C, 65.42, 65.71; H, 6.11, 6.04.

Derritol from Rotenonone.—Three grams of rotenonone was boiled with zinc and alcoholic potassium hydroxide under the same conditions as for the preparation of derritol from rotenone.⁵

The solution was filtered and acidified, and the precipitate was dissolved in ether. The ether solution was extracted with aqueous carbonate solution, which removed a considerable quantity of an acid which was recovered by acidifying the solution and extracting with ether. The material remaining after evaporation of the ether represented by far the larger part of the reaction product, but it could not be made to crystallize.

The first ether solution was then extracted with dilute potassium hydroxide solution. The alkaline solution was acidified and extracted with ether. The ether solution gave on evaporation 0.06 g. of derritol. It was recrystallized and compared with an authentic sample by the mixed melting point and crystal form. It melted at 161° .

Anal. Subs., 2.989 mg.: CO_2 , 7.388; H_2O , 1.654. Calcd. for $\text{C}_{21}\text{H}_{22}\text{O}_6$: C, 68.07; H, 5.99. Found: C, 67.41; H, 6.15.

Synthesis of Rotenonone from Derritol.—Two grams of derritol was dissolved in 5 cc. of pyridine. The solution was cooled in an ice-bath and 2.5 g. of chloro-oxalyl ethyl ester⁷ was slowly added. The reaction mixture was allowed to stand for forty-eight hours, after which time the contents of the flask had become a semi-solid mass of fine yellow crystals. Alcohol was added and the solid material filtered off. The product was recrystallized by dissolving in chloroform and adding hot alcohol. It formed yellow needles and possessed all the characteristic properties of rotenonone. The melting point was 298° ; mixed melting point $298\text{--}300^\circ$. The yield was 1.6 g. of pure material.

Anal. Subs., 0.0257, 0.0249: thiosulfate (1 cc. = 0.000520 CH_3O) 7.30, 7.05. Calcd. for $\text{C}_{23}\text{H}_{18}\text{O}_7$: $2\text{CH}_3\text{O}$, 15.27. Found: CH_3O , 14.77, 14.69.

Summary

Rotenonone is partially converted into derritol by zinc alkali hydrolysis. Rotenononic acid is methylated by dimethyl sulfate to the methyl ester of methylrotenononic acid. Methylrotenononic acid is hydrogenated to a tetrahydro compound.

Rotenonone is the lactone corresponding to rotenononic acid.

The synthesis of rotenonone from derritol was accomplished by the substitution of the oxalyl ethyl ester groups on the reactive phenolic group in pyridine solution. Complete condensation to rotenonone took place in one operation with the formation of rotenonone.

NATURAL AND SYNTHETIC RUBBER. XI. CONSTITUENTS OF THE MILLED RUBBER HYDROCARBON

BY THOMAS MIDGLEY, JR., ALBERT L. HENNE AND MARY W. RENOLL

RECEIVED APRIL 22, 1932

PUBLISHED AUGUST 5, 1932

The tenth paper of this series¹ has shown that *unmilled* pale crepe rubber contains a single "sol" component, which constitutes more than one-half of the specimen, and a continuous series of undefined "sol" portions amounting to about 20% of the specimen. These results have been obtained by a fractional precipitation from a benzene-alcohol mixture.

The same method of investigation has now been applied to *thoroughly milled* pale crepe rubber, and the present paper shows that the whole specimen is made up of a continuous series of undefined "sol" components, in undefined proportions.

Procedure.—Pale crepe rubber was milled for one hour on cold rolls. A 250-g. specimen was dissolved in benzene, and fractionated into primary cuts, by the method described.¹ Although the principle of fractionation remained unchanged, minor experimental details were altered, as follows.

Milled rubber is much more soluble in a given benzene-alcohol mixture than unmilled rubber. To illustrate: the s. p. p.'s¹ of the rubber specimen used, before and after milling, were 35.4 and 27.7°, respectively. Consequently, in order to be able to carry out the fractionation at a convenient temperature, *viz.*, about 40°, the solvent was made richer in alcohol than previously reported. In all cases, the length of time allowed for separation was extended to fourteen hours. Chilling out was accomplished by letting the solutions stand (under vacuum) in a refrigerator at about -10° for six hours. Since the fractions obtained from milled rubber did not precipitate sharply from an alcohol-benzene mixture, the experimental precipitation point could not be duplicated closer than ±0.2°.

Table I shows the results of the primary fractionation.

TABLE I
PRIMARY FRACTIONATION OF 250 G. OF MILLED CREPE RUBBER

Fractions	Amounts, g.	Standard pre- cipitation point (s. p. p.) in degrees	% based on 233.4 g.	
A ₀	36.4	23.2	15.6	} 81.2
A ₁	66.4	23.4	28.4	
A ₂	68.5	24.3	29.3	
A ₃	30.3	24.9	13.0	
A ₄	24.5	24.9	10.5	
B	7.3	Not obtained	3.1	
Total	233.4		99.9	
Losses	16.6			

Fractions A₁ to B inclusive were obtained by the previously described method of operation.

¹ Midgley, Henne and Renoll, *THIS JOURNAL*, **54**, 3343 (1932).

Fraction A_0 was found in the supernatant liquid remaining after the separation of A_1 , in the following manner: the liquid was cooled to -10° and kept at that temperature until the lower half of the mixture (containing the rubber and benzene) had frozen. The upper half containing the so-called "resins" was decanted, and the rubber was precipitated from the benzene of the lower half with acetone.

The reported losses include an estimated amount of 12.5 g. of "resins," soluble in alcohol. Hence the actual losses amount only to 4 g., *viz.*, about 1.5%.

The tabulated results appear on the chart, where the percentages of rubber are plotted against the s. p. p. They are represented by the solid line. The length of the abscissa measures the size of fractions A_0 to A_4 inclusive. The s. p. p. of fraction B could not be determined, because it was insoluble. It was extracted with boiling benzene for several days, but the solvent removed only 1.1 g. of rubber. This B fraction was a nearly white, fibrous mass with a nitrogen content of 9.4%.

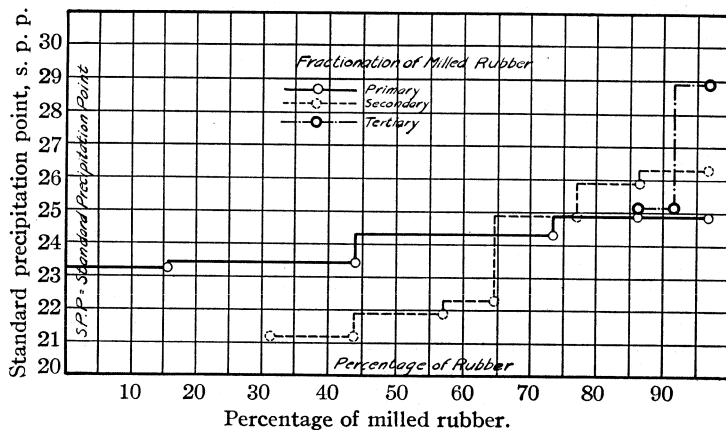

Fig. 1.—Fractionation of milled rubber.

Each of the primary cuts from A_1 to A_4 , (*viz.*, 81.2% of the rubber recovered) was refractionated. A_3 and A_4 were combined because they had the

TABLE II
SECONDARY FRACTIONATION OF FRACTIONS A_1 TO A_4 , *viz.*, 81.2% OF THE RUBBER RECOVERED

Fractions	Amount, g.	S. p. p. in degrees	% based on 81.2% = 189.7 g.
A_1 {	Top	21.2	12.2
	Bottom	24.9	11.6
A_2 {	Top	21.9	13.4
	Bottom	25.9	10.5
A_{3-4} {	Top	22.3	7.7
	Bottom	26.3	10.2
Total recovered	153.3		65.6
Remaining in solution	36.4		15.6
Total	189.7		81.2

same s. p. p. The refractionation was carried out at 50°; the results appear in Table II, and on the diagram.

The 36.4 g. of rubber remaining in solution could have been recovered in the manner used for A₀, in the primary fractionation; but this was considered superfluous for the present research.

The tables and diagram show that there is no indication of a single component, present in large proportion.

The fraction called "A₃₋₄ bottom," in Table II was then refractioned, to give the results shown in Table III.

TABLE III
TERTIARY FRACTIONATION OF A₃₋₄

Fractions	Amount, g.	S. p. p. in degrees	% based on 10.2% fractioned
A ₃₋₄ { Top	9.5	25.1	4.7
Bottom	11.3	28.9	5.5
Total	20.8		10.2

The efficiency of the separation method is illustrated as follows: a 10-g. specimen (s. p. p. 35°) obtained from *unmilled* rubber and a 10-g. sample (s. p. p. 28.9°) obtained from the fraction called [A₃₋₄, bottom], in Table III, were dissolved in the same batch of benzene, and separated by fractional precipitation. A single fractionation yielded 11.5 g. of s. p. p. 34.9° and 85. g. of s. p. p. 28.5°. This experiment demonstrates that the fractionation method separates with ease individual components.

The appearance of the various cuts was as follows. The fractions with low s. p. p. were almost colorless, transparent and very tacky. The higher s. p. p. fractions were less tacky, and they were yellow; in spite of the color, they did not have the appearance of oxidized rubber.

Conclusion.—Fractional precipitation shows that *milled* rubber is constituted of a continuous series of undefined components. Milling degrades the components of *unmilled* rubber into materials of lower s. p. p. without producing a single predominating component.

Summary

The composition of *milled* rubber has been investigated by a method based on fractional precipitation from a benzene-alcohol mixture. This has shown that milled rubber is made of a continuous series of undefined components, without a single predominating individual. The same method had previously shown that one single individual constituted more than one-half of unmilled rubber.

**SYNTHESES WITH TRIARYLVINYLMAGNESIUM BROMIDES.
 PENTAARYLALLYL ALCOHOLS**

By C. FREDERICK KOELSCH¹

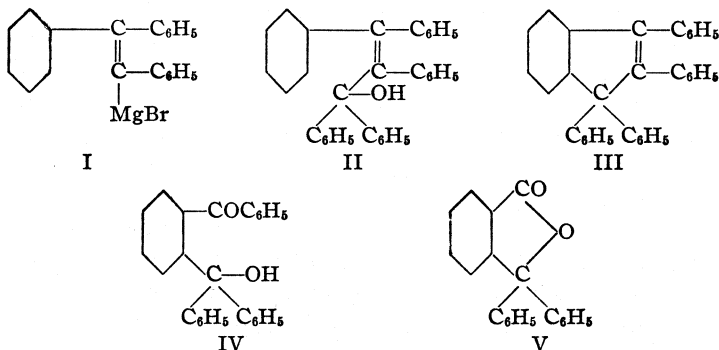

RECEIVED APRIL 27, 1932

PRINTED AUGUST 5, 1932

The interest attaching to compounds of trivalent carbon in which the methane carbon atom bears two aryl groups and one unsaturated aliphatic group has led to the investigation described in this paper. The object of this research has been to synthesize a pentaarylallyl radical, $R_2C=CR-CR_2$, and to compare the behavior of this substance with that of the less highly phenylated tetraarylallyl radicals, $R_2C=CH-CR_2$, of Ziegler. Although this object has not yet been attained, the present results are presented for their inherent interest.

It was reported previously² that triphenylvinylmagnesium bromide (I) reacted with benzophenone to form an addition product whose hydrolysis gave back the ketone and triphenylethylene. When, however, the reaction is carried out at an elevated temperature in toluene solution, it follows the normal course, yielding an $-OMgBr$ compound whose hydrolysis gives pentaphenylallyl alcohol (II).

In order to prepare a radical from pentaphenylallyl alcohol it is necessary to convert it first into a halide or an ether, but no means have yet been found for carrying out either of these reactions. When this alcohol is treated with any acidic reagent, even cold 1% alcoholic sulfuric acid, it loses water, forming a hydrocarbon $C_{33}H_{24}$. Since the oxidation of this hydrocarbon gives *o*-benzoyltriphenylcarbinol (IV) and benzoic acid, and further diphenylphthalide (V), it must be 1,1,2,3-tetraphenylindene (III).

The ease with which indene ring closure takes place in pentaphenylallyl alcohol results, at least in part, from the spatial arrangement of the atoms in the molecule. In Fig. 1 is shown a diagrammatic representation of the

¹ National Research Fellow in Chemistry.

² Koelsch, *THIS JOURNAL*, **54**, 2045 (1932).

arrangement of the part of the molecule involved in the reaction. In this diagram the assumptions are made that (1) all joined carbon atoms are at an equal distance a from each other; (2) the valence of the phenyl group extends radially; and (3) the valences of the aliphatic carbon atoms are inclined to the double bond at an angle of 109° . None of these assumptions is more than approximately true, but together they allow the calculation of the distance d between the o -position of the γ -phenyl group and the hydroxyl-bearing carbon atom. This distance is found to be $1.14a$.

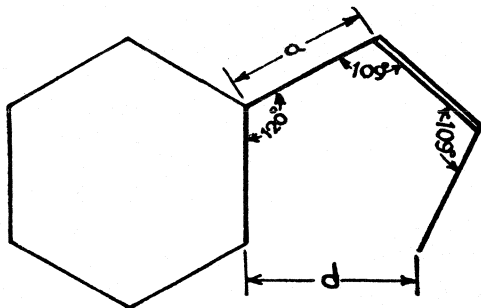

Fig. 1.—The spatial arrangement of penta-phenylallyl alcohol.

These steric considerations suggest a basis for synthesizing a pentaarylallyl alcohol unable to undergo indene ring closure. If the two phenyl groups on the γ -carbon atom are tied together, the conditions existing may be represented as in Fig. 2. Again, all joined carbon atoms are assumed to be at equal distances, and the pentagon involved in the structure is assumed to be regular. Here the distance d between the o -position of the γ -phenyl (ene) group and the hydroxyl-bearing carbon atom is calculated to be $1.86a$. Indene ring closure, since it involves the joining of these positions, should thus be impossible.

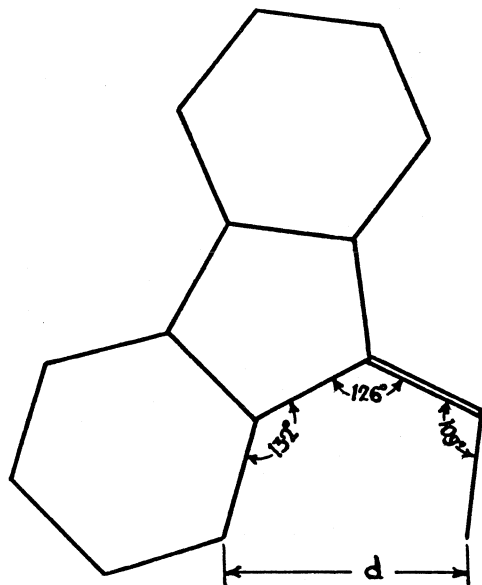

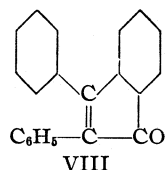

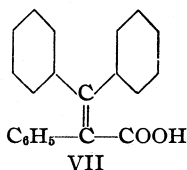

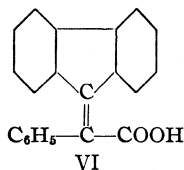

Fig. 2.—The spatial arrangement of α, α, β -triphenyl- γ -diphenyleneallyl alcohol.

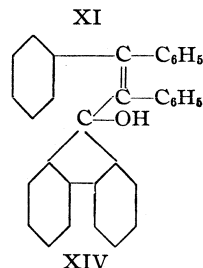

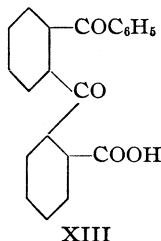

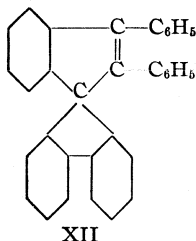

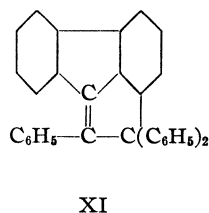

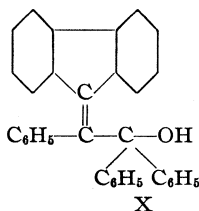

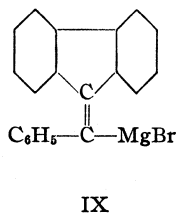

These calculations were experimentally verified using α -phenyl- β -diphenyleneacrylic acid (VI). This acid and its chloride are stable under conditions³ which lead to the formation of diphenylindone (VIII) or substituted diphenylindones from α, β, β -triphenylacrylic acid (VII) or its derivatives.

α -Phenyl- β -diphenylenevinylmagnesium bromide (IX) reacts with benzophenone to produce the expected α, α, β -triphenyl- γ -diphenyleneallyl

³ Koelsch, THIS JOURNAL, 54, 2487 (1932).

alcohol (X). Surprisingly, it was found that here, too, as in the case of pentaphenylallyl alcohol, even the mildest acidic reagents cause the elimination of water with the formation of a hydrocarbon $C_{33}H_{22}$. The oxidation of this hydrocarbon gives *o*-benzoylbenzophenone-*o*-carboxylic acid (XIII) and benzoic acid, showing that the "impossible" indene ring closure does not take place with the formation of (XI), but that an allylic rearrangement accompanies the dehydration, and that the hydrocarbon $C_{33}H_{22}$ is 1-diphenylene-2,3-diphenylindene (XII).

Finally, α -diphenylene- β,γ,γ -triphenylallyl alcohol (XIV), obtained from triphenylvinylmagnesium bromide and fluorenone, is distinctly different from its isomer (X), but treatment with an acidic reagent causes it to lose water with the formation of the same 1-diphenylene-2,3-diphenylindene (XII).

A subsequent paper will describe α,γ -bisdiphenylene- β -phenylallyl alcohol and its conversion into a radical.

Experimental

Benzalfluorene Dibromide.—A hot solution of 85 g. of benzalfluorene in 85 ml. of acetic acid is cooled rapidly to form a fine crystalline suspension, and at 20–35° (cooling) is added a solution of 55 g. of bromine in 55 ml. of acetic acid. On scratching and further cooling the dibromide separates. It is filtered off and washed with dilute acetic acid and with water; yield, 126 g. or 91%. The product melts at 116° with decomposition (literature⁴ 112°). Recrystallization is unnecessary and causes some decomposition.

⁴ Thiele and Henle, *Ann.*, **347**, 298 (1906).

α -Phenyl- β -diphenylenevinyl Bromide.—This compound can be prepared by the thermal decomposition of benzalfluorene dibromide, either in acetic acid or without a solvent, but the product thus obtained in a yield of 25–30% is difficult to purify. The decomposition in acetic acid in the presence of sodium acetate is likewise very unsatisfactory.

The following method gives a yield of 85–89%. A solution of 30 g. of potassium hydroxide in 15 ml. of water and 100 ml. of alcohol is added to a solution of 125 g. of benzalfluorene dibromide in 300 ml. of alcohol. The mixture is stirred vigorously and refluxed for twenty-five minutes on a water-bath. The solid product is filtered off after cooling, washed well with water and recrystallized from acetic acid (600–625 ml.). There is obtained 86 g. of pure bromide, and from the mother liquor by distilling to 50 ml. an additional 2.5 g. The product crystallizes in yellow prisms that melt at 127°.

Anal. Calcd. for $C_{20}H_{13}Br$: C, 72.0; H, 3.9. Found: C, 71.8; H, 3.9.

α -Phenyl- β -diphenylenevinylmagnesium Bromide (IX).—The Grignard reagent is prepared according to the usual procedure³ for triarylvinylmagnesium bromides. It separates as a green oil difficultly soluble in ether, or as yellow crystals.

Reaction with Benzoyl Chloride.—To the Grignard reagent from 5 g. of the bromide is added an ether solution of 2 ml. of benzoyl chloride. The product, α -phenyl- β -diphenyleneacrylophenone, is isolated in the usual way and crystallized from ethyl acetate. It forms small yellow plates that melt at 300–303°.

Anal. Calcd. for $C_{27}H_{18}O$: C, 90.5; H, 5.0. Found: C, 90.5; H, 5.1.

α -Phenyl- β -diphenyleneacrylic Acid (VI).—The Grignard reagent from 6.5 g. of α -phenyl- β -diphenylenevinyl bromide is carbonated in the usual way,³ and the product is crystallized from acetic acid. It forms fine needles that melt at 182–183°. It is soluble in cold concd. sulfuric acid, giving a pale green solution that becomes colorless on dilution with water.

Anal. Calcd. for $C_{21}H_{14}O_2$: C, 84.5; H, 4.7; neut. equiv., 298. Found: C, 84.0; H, 4.6; neut. equiv., 298.

Reaction with Thionyl Chloride.—Equal weights (0.5 g.) of α -phenyl- β -diphenyleneacrylic acid and thionyl chloride are refluxed together in 2 ml. of carbon tetrachloride for four hours. No red color appears. The solution is stirred into cold aqueous ammonia, the carbon tetrachloride is evaporated and the remaining solid is crystallized from alcohol. The yellow product, α -phenyl- β -diphenyleneacrylamide, melts at 128–129° and gives a test for nitrogen.

Anal. Calcd. for $C_{21}H_{16}ON$: C, 84.8; H, 5.0. Found: C, 85.0; H, 5.3.

Pentaphenylallyl Alcohol (II).—To the Grignard reagent from 10 g. of triphenylvinyl bromide is added 5 g. of benzophenone. Toluene is added and the mixture is distilled to 85°. It is refluxed until the bright red color has changed to light yellow (about four hours) and then it is allowed to stand for ten hours. The crystalline magnesium compound is filtered off, washed with dry ether and decomposed with iced ammonium chloride containing some ammonia. The oil is taken up in ether. This solution is dried with potassium hydroxide, distilled to a small volume under reduced pressure and mixed with petroleum ether. The product crystallizes very slowly; yield, 3.1 g.

The combined mother liquors from this preparation give 2.25 g. of tetraphenylindene on treatment with acid.

Pentaphenylallyl alcohol forms small white crystals that melt at 108–109°; its solution in acetic acid gives a green color with acetyl chloride or sulfuric acid that disappears immediately.

Anal. Calcd. for $C_{33}H_{24}O$: C, 90.4; H, 5.9. Found: C, 90.1; H, 6.0.

$\alpha,\alpha,\beta,\gamma,\delta,\delta$ -Hexaphenylbutadiene.—This hydrocarbon (0.4 g.) was isolated from the mother liquors of a preparation of pentaphenylallyl alcohol involving 20 g. of triphenylvinyl bromide. It can be prepared from triphenylvinylmagnesium bromide and cupric chloride⁵ in a 55% yield. It crystallizes from benzene and petroleum ether in faintly yellow needles that melt at 213–214°.

Anal. Calcd. for $C_{40}H_{30}$: C, 94.2; H, 5.8. Found: C, 93.9; H, 5.8.

α,α,β -Triphenyl- γ -diphenyleneallyl Alcohol (X).—To the Grignard reagent from 5 g. of α -phenyl- β -diphenylenevinyl bromide is added 2 g. of benzophenone. The mixture is refluxed for three hours and allowed to stand for twenty-four hours or until the original red-brown color has faded to a light tan. The solid magnesium compound is removed, washed with ether and decomposed with iced ammonium chloride. The crude solid is washed with alcohol containing a little ammonia, dried and crystallized from benzene and petroleum ether; yield, 1.75 g. The alcohol forms yellow prisms that melt at 217–219°; its solution in acetic acid gives no color with sulfuric acid; with hot concd. sulfuric acid the alcohol gives a green color which is permanent on dilution with water.

Anal. Calcd. for $C_{33}H_{24}O$: C, 90.9; H, 5.5. Found: C, 90.9; H, 5.6.

α -Diphenylene- β,γ,γ -triphenylallyl Alcohol (XIV).—Fluorenone (2 g.) is added to the Grignard reagent from 5 g. of triphenylvinyl bromide. The solution is treated and the product is isolated as described under α,α,β -triphenyl- γ -diphenyleneallyl alcohol. The product is crystallized from alcohol containing a little ammonia, and then from carbon tetrachloride and petroleum ether; yield, 1.35 g. α -Diphenylene- β,γ,γ -triphenylallyl alcohol forms colorless crystals that melt at 150–151°.

Anal. Calcd. for $C_{33}H_{24}O$: C, 90.9; H, 5.5. Found: C, 91.0; H, 5.5.

Dehydration of the Pentaaryllallyl Alcohols.—All of the alcohols described above lose water to form colorless indenenes when cold dilute alcoholic sulfuric acid is added to their solutions in methyl or ethyl alcohol. The indenenes are best prepared by warming an acetic acid solution of an allyl alcohol with a few drops of sulfuric acid, hydrochloric acid, or acetyl chloride. They can also be prepared by boiling the alcohols with undiluted acetyl chloride. The data concerning the indenenes recrystallized from acetic acid are summarized in Table I.

TABLE I
THE INDENES (III) AND (XII)

()-indene	M. p., °C.	Formula	Analysis			
			Calcd. C	Calcd. H	Found C	Found H
1,1,2,3-Tetraphenyl-	149–150	$C_{33}H_{24}$	94.2	5.8	94.0	5.8
1-Diphenylene-2,3-diphenyl-	^a 174–175	$C_{33}H_{22}$	94.7	5.3	94.5	5.3
	^b 174–175				94.5	5.3

^a From α,α,β -triphenyl- γ -diphenyleneallyl alcohol.

^b From α -diphenylene- β,γ,γ -triphenylallyl alcohol.

Oxidation of 1,1,2,3-Tetraphenylindene

(a) To *o*-Benzoyltriphenylcarbinol (IV).—To a solution of 1.85 g. of the hydrocarbon in acetic acid is added 5 g. of chromic acid in acetic acid and water. After refluxing for one hour the mixture is poured into water and extracted with ether. Sodium carbonate removes benzoic acid from the ether extract, and steam distillation gives 0.13 g. of benzophenone. Since the residue crystallizes with great difficulty, it is con-

⁵ Cf. Sakellarios and Kyrimis, *Ber.*, 57, 322 (1924).

verted into 9,9-diphenylanthrone by distillation.⁶ There is obtained 0.55 g. of the crude anthrone (m. p. 180–190°) which after crystallization from toluene and ligroin melts at 191–193° alone or mixed with a known sample of diphenylanthrone.⁷

(b) **To Diphenylphthalide (V).**—The oxidation is carried out as in (a) using 1.7 g. of tetraphenylindene and 9 g. of chromic acid. From the ether extract of the oxidation products is obtained 0.1 g. of benzoic acid. The oily residue left after the removal of the ether from the neutral part becomes crystalline on rubbing with alcohol, and after recrystallization from this solvent the product, diphenylphthalide, melts at 114–115° (mixed m. p.) and weighs 0.5 g.

Oxidation of 1-Diphenylene-2,3-diphenylindene.—The hydrocarbon (3.9 g.) in acetic acid is oxidized with 12 g. of chromic acid by refluxing for two hours. The solution is poured into water and extracted with ether. Sodium carbonate removes benzoic acid and *o*-benzoylbenzophenone-*o'*-carboxylic acid; the former (0.25 g.) is dissolved out with warm water, leaving 0.6 g. of the crude keto acid. This melts at 224–225° (literature⁸ 228°) and weighs 0.4 g. after recrystallization from acetic acid.

Anal. Calcd. for $C_{21}H_{14}O_4$: C, 76.3; H, 4.2. Found: C, 76.2; H, 4.3.

On treatment with ethereal diazomethane the acid gives the methyl ester, which melts at 162–163° (literature⁸ 165°); on heating with sulfuric acid, it gives the lactone of 9-*o*-carboxyphenyl-9-oxyanthrone-10 which melts at 235–237° (literature⁸ 239°).

The neutral substance not removed from the ether solution of the oxidation products by sodium carbonate is crystallized from acetic acid, distilled at 15 mm. and recrystallized. There is obtained 0.1 g. of a white compound⁹ crystallizing in needles that melt at 204–206°.

Anal. Calcd. for $C_{23}H_{18}O_3$: C, 83.6; H, 4.5. Found: C, 83.4; H, 4.5.

Summary

Triphenylvinylmagnesium bromide reacts with benzophenone and with fluorenone to give pentaarylallyl alcohols. On treatment with acids these alcohols lose water forming tetraarylindenes.

α -Phenyl- β -diphenylenevinylmagnesium bromide and carbon dioxide give α -phenyl- β -diphenyleneacrylic acid, which because of its steric arrangement cannot form an indone.

α, α, β -Triphenyl- γ -diphenyleneallyl alcohol, obtained from α -phenyl- β -diphenylenevinylmagnesium bromide and benzophenone, is prevented from forming an indene by its steric arrangement. However, acids cause it to undergo an allylic rearrangement, the resulting alcohol then losing water to form a tetraarylindene.

HEMI-ACETALS OF ALDEHYDO-GALACTOSE PENTAACETATE
AND THEIR OPTICAL PROPERTIES

BY M. L. WOLFROM AND WILLIAM M. MORGAN

RECEIVED APRIL 28, 1932

PUBLISHED AUGUST 5, 1932

The open-chain or aldehyde form of galactose pentaacetate forms a crystalline addition compound with one mole of ethyl alcohol.¹ Brigl and Muehlschlegel² have reported a similar compound for aldehyde-glucose pentabenzate. In the case of the galactose compound, we have produced evidence³ that the substance is a true hemi-acetal of unusual stability. Such a compound is thus the open-chain analog of the glycosides which are monocyclic acetals. In view of the great amount of research which has been done on the latter compounds, it was considered of interest to study the corresponding open-chain galactose compounds in somewhat more detail. Accordingly the hemi-acetals of aldehyde-galactose pentaacetate with a number of aliphatic alcohols will now be reported. That the carbonyl group in the sugar acetate used possesses the power of adding an alcohol of relatively large molecular weight is shown by the successful preparation of a compound with cyclohexanol.

The ethyl hemi-acetal showed a mutarotation curve in chloroform (alcohol-free) which passed through a minimum and was thus indicative of a three-membered equilibrium. This was explained³ by the following equation, the carbonyl carbon atom being asymmetric in the hemi-acetal and so existing in two forms

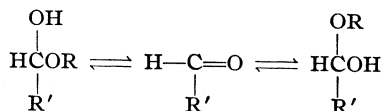

Figure 1 shows that a similar type of curve is obtained for the other hemi-acetals now prepared. It is to be noted that as the molecular weight of the alcohol increases, the dissociation in chloroform solution is more rapid, this being indicated by the steepness of the first part of the curve.

The investigation of the optical properties of these hemi-acetals has a direct bearing upon the theory of sugar mutarotation because the open-chain form of the sugar or its aldehydrol is postulated as the most probable intermediate in this reaction.⁴ From the standpoint of organic structural theory, the mutarotation of an aldehyde hemi-acetal in its own alcohol is

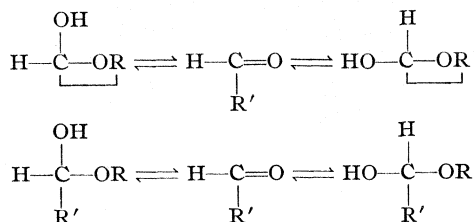

¹ Wolfrom, *THIS JOURNAL*, **52**, 2464 (1930).

⁴ Lowry, "Rapports sur les Hydrates de Carbone. Dixième Conférence de l'Union International de Chimie," Liège, 1930, p. 79.

quite analogous to the mutarotation of a sugar (a cyclic hemi-acetal) in water as the following formulas show

Of the hemi-acetals prepared, only the methanol compound possessed a solubility in its corresponding alcohol suitable for polarimetric observation at room temperature. Figure 2 shows that this compound in methanol exhibits a typical sugar mutarotation curve and the data of Table I place the reaction as apparently monomolecular. In view of the low rotations and the long time involved, the slight deviation from constancy of the values obtained is within the limits of experimental error. The presence of the intermediate aldehyde in methanol solution is thus undetectable by polarimetric measurement, while in chloroform solution an intermediate form is easily detectable. It appears reasonable that the intermediate is the same in both cases but that the concentration of the intermediate form is much greater in the chloroform solution.

In the course of this work it was necessary to prepare considerable quantities of aldehydo-galactose pentaacetate and a somewhat simplified method of preparation for this substance was devised.

Experimental

Preparation of Aldehydo-galactose Pentaacetate.—The mercaptal groups were removed from galactose ethyl mercaptal with mercuric chloride in acetone solution to which had been added only 25 cc. of water for 50 g. of the acetylated mercaptal, the proportions of the other reagents being the same as previously reported.¹ The evapo-

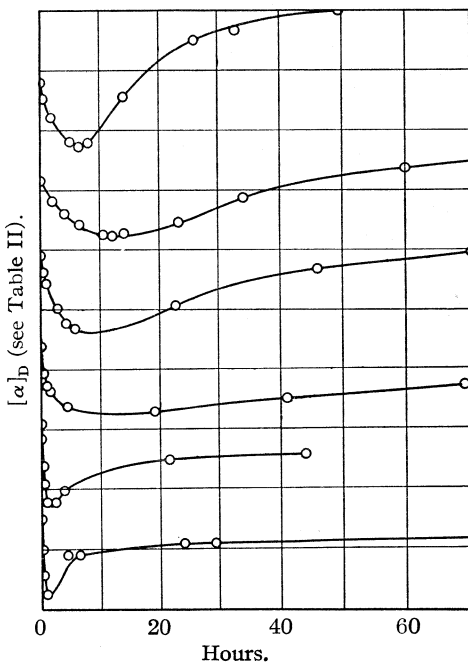

Fig. 1.—Mutarotation of several hemi-acetals of aldehydo-galactose pentaacetate in chloroform (alcohol-free). Order, from top to bottom: methyl, ethyl, *n*-propyl, isopropyl, isobutyl, cyclohexanol.

rated reaction mixture was dried by repeated additions of acetone followed by evaporation under reduced pressure. The residue was extracted with hot carbon tetrachloride, filtered hot and allowed to cool for the first crop of crystals. A second crop was obtained by evaporation of the mother liquor under reduced pressure. This crude product was

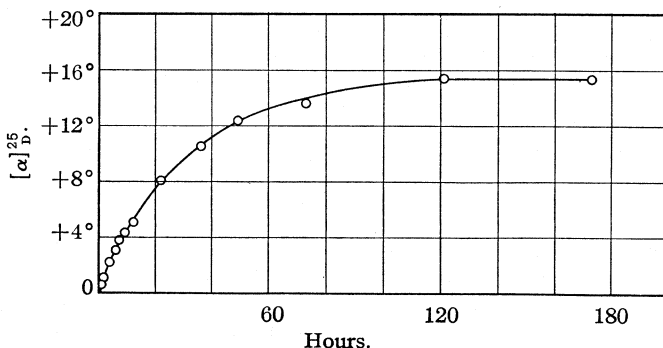

Fig. 2.—Mutarotation of the methyl hemi-acetal of aldehydo-galactose pentaacetate in methanol solution.

recrystallized by dissolving in a small amount of boiling acetone (carboraffin) cooled to room temperature and half the volume of alcohol-free ether added. Petroleum ether was then added until crystallization was initiated, an excess being avoided. After three crystallizations a yield of 11 g. of pure product (m. p. 120–121°) was obtained from 50 g. of the acetylated mercaptal. A much higher yield of slightly less pure product was

^b Hudson, THIS JOURNAL, 26, 1065 (1904).

readily obtainable, such material being satisfactory for the further synthetic experiments reported below.

Hemi-acetal Synthesis.—The hemi-acetals were prepared by recrystallization to constant melting point of aldehydo-galactose pentaacetate from the purified, anhydrous alcohols. For removal of the mother liquor, the filtered crystals were washed first with the cold alcohol and then with cold ether, the substances being insoluble in the latter solvent. In the case of the methyl hemi-acetal, the ether washing was omitted. A special procedure was required for the preparation of the cyclohexanol hemi-acetal. The aldehydo-galactose pentaacetate was dissolved in the least amount of cyclohexanol by warming to 80°. The solution was then quickly chilled by immersing the flask in ice water and was then treated with twice its volume of an equal mixture of absolute ethyl ether and petroleum ether. This procedure effected a good crystallization of the cyclohexanol compound. The filtered product was washed with a cold equal mixture of absolute ether and petroleum ether. The hemi-acetals prepared are shown in Table II, the ethyl compound having been reported previously. The mutarotation of the substances in alcohol-free chloroform is shown in Fig. 1.

TABLE II

HEMI-ACETALS OF ALDEHYDO-GALACTOSE PENTAACETATE, PROPERTIES AND ANALYSES

Hemi-acetal	M. p., °C.	[α] _D ²⁵ CHCl ₃ (alcohol-free)			Acetyl value (cc. 0.1 <i>N</i> NaOH per 100 mg. subs.)	
		Initial	Minimum	Final	Calcd.	Found
Methyl	123	+3.0	− 7.7	+15°	11.8	11.7
Ethyl	133	+1.5	− 7.5	+ 6	11.4	11.4

Cyclohexanol	136	0	− 12	− 3	10.2	10.4

The calculated acetyl value for aldehydo-galactose pentaacetate is 12.8 cc. of 0.1 *N* sodium hydroxide per 100 mg. A methoxyl (Zeisel) determination on the methyl hemi-acetal gave the following result: Subs., 0.3019: AgI, 0.1613. Calcd. for C₁₆H₂₂O₁₁·(OCH₃)₅: OCH₃, 7.35. Found: OCH₃, 7.06.

Summary

1. The following hemi-acetals of aldehydo-galactose pentaacetate have been synthesized in crystalline condition: methyl, *n*-propyl, isopropyl, isobutyl, cyclohexanol.

2. The optical properties of these compounds have been investigated and it has been shown that their behavior supports the open chain intermediate theory of sugar mutarotation.

RESEARCHES ON THIAZOLES. XVIII. THE SYNTHESIS OF 2-PHENYLBENZOTHIAZOLE-5-CARBOXYLIC ACID AND DERIVATIVES

BY MARSTON TAYLOR BOGERT AND HELEN G. HUSTED¹

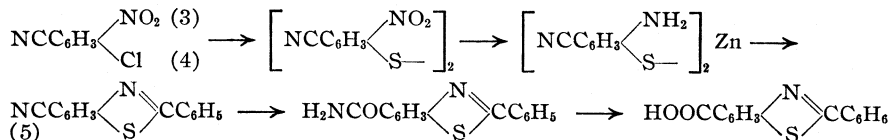

RECEIVED APRIL 29, 1932

PUBLISHED AUGUST 5, 1932

In the course of certain pharmacological experiments in the benzothiazole field with which we have been occupied lately, we had occasion to prepare some of the well-known benzothiazoles by new methods and some new compounds by old methods. For the benefit of other workers in this field, these experimental results are here recorded.

In place of the processes heretofore used, we found it most convenient to prepare *o*-aminophenyl mercaptan hydrochloride, $\text{HSC}_6\text{H}_4\text{NH}_2\text{HCl}$, by treating the zinc mercaptide with concentrated hydrochloric acid, and the 2-anilinobenzothiazole, $\text{C}_6\text{H}_4 \begin{smallmatrix} \text{S} \\ \diagup \quad \diagdown \\ \text{N} \end{smallmatrix} \text{CNHC}_6\text{H}_5$, from the *o*-aminophenyl disulfide and phenyl isothiocyanate.

From 3-nitro-4-chlorobenzonitrile, a series of new compounds was synthesized by the following steps

From the 2-phenyl-5-cyanobenzothiazole, a mononitro derivative was obtained, but the location of the nitro group was not determined. The methyl ester was prepared from the 2-phenylbenzothiazole-5-carboxylic acid. Both the acid and its methyl ester were too difficultly soluble to be used in our pharmacological experiments.

Experimental

From *o*-nitrochlorobenzene, there were prepared, as described in the literature and with similar results, *o*-nitrophenyl disulfide,² zinc *o*-aminophenyl mercaptide³ and *o*-aminophenyl disulfide.³

o-Aminophenyl mercaptan hydrochloride was obtained most conveniently by treating the zinc mercaptide (8.5 g.) with concentrated hydrochloric acid (sp. gr. 1.2) (75 cc.). The zinc salt dissolved with evolution of heat and of a trace of hydrogen sulfide. The warm solution was filtered through asbestos and the filtrate cooled in an ice pack. The hydrochloric acid salt separated rapidly in colorless needles, which were crystallized from concentrated hydrochloric acid, the crystals washed with ether, recrystallized from

¹ Ferguson Fellow, Columbia University, 1928-1929.

³ Bogert and Snell, *ibid.*, **46**, 1309 (1924).

water, and then melted with decomposition at 217° (corr.) in agreement with the literature;^{20,4} yield, 80.3%.

3-Nitro-4-chlorobenzonitrile was obtained, by nitration of *p*-chlorobenzonitrile, in a yield of 61% by the Mattaar⁵ method, m. p. $100-101^{\circ}$ (corr.). Mattaar recorded the m. p. as $99-100^{\circ}$. It formed odorless, colorless, lustrous spangles or fine needles, readily soluble in alcohol or toluene.

Anal. Calcd. for $C_7H_3O_2N_2Cl$: C, 46.03; H, 1.64; N, 15.34. Found: C, 46.60; H, 1.63; N, 15.17.

2-Nitro-4-cyanophenyl disulfide was prepared from 3-nitro-4-chlorobenzonitrile and sodium disulfide in essentially the same way as the *o*-nitrophenyl disulfide,² except that refluxing of the solution was not necessary, as the disulfide separated almost immediately in fine canary yellow needles or granules, which were thoroughly washed with boiling water and then with hot alcohol; yield, 86%. When heated, these crystals began to char around 235° , and liquefied at about 335° .

Anal. Calcd. for $C_{14}H_6O_4N_4S_2$: C, 46.65; H, 1.67; N, 15.64. Found: C, 46.92; H, 1.68; N, 15.56.

2-Amino-4-cyanophenyl Mercaptan (3-Amino-4-mercaptobenzonitrile).—The zinc salt was obtained by reduction of the corresponding nitro disulfide, as described by Bogert and Snell³ for *o*-aminophenyl mercaptan. Owing to the very slight solubility of the disulfide in hot glacial acetic acid, the reduction was carried out by intimately mixing (in a mortar) the finely pulverized disulfide with a very pure zinc dust (the purity of the zinc dust influenced the yield markedly), adding this mixture to the acid and refluxing for an hour. The product was pulverulent and pale cream colored; yield, 49%. When heated, it began to decompose at about 250° .

Anal. Calcd. for $C_{14}H_{10}N_4S_2Zn$: C, 46.28; H, 2.75. Found: C, 46.48; H, 3.39.

Benzothiazole.—*o*-Aminophenyl mercaptan hydrochloride was condensed with formaldehyde, as recorded by Claasz⁶ and by Bogert and Stull.²⁰

Considerable difficulty was encountered in purifying the crude thiazole satisfactorily by distillation. At atmospheric pressure, there was much decomposition, so that the distillation had to be conducted under reduced pressure, and then the maintenance of a fairly constant pressure proved troublesome even when all connections were carefully sealed.

The fraction (A) collected at $97-100^{\circ}$ at 18.6 mm. was used for some of the pharmacological experiments which will appear shortly in the *J. Pharmacol. and Exptl. Therapeutics*, and when tested by the Siwoloboff⁷ method showed a b. p. of 231° (corr.) at atmospheric pressure, in accordance with the figure given by Hofmann^{4a} and by Bogert and Stull.²⁰ From another run, the fraction (C) boiling at $87-91^{\circ}$ at 11 mm., 231° (corr.) at 760 mm. was used for pharmacological tests, some carried out by ourselves, and some by Professor S. W. Clausen, of the University of Rochester, in connection with his studies on experimental eczema.

The carefully purified material (b. p. 231° , corr.) showed the following constants: n_D^{24} , 1.6370; d_4^{25} 1.23.

Methiodide.—Fine colorless needles, melting with decomposition at 210° (corr.), in agreement with the literature.^{4a}

Anal. Calcd. for C_8H_8NSI : N, 5.06. Found: N, 5.08.

⁴ (a) Hofmann, *Ber.*, **20**, 2251 (1887).

⁵ Mattaar, *Rec. trav. chim.*, **41**, 24 (1922).

⁶ Claasz, *Ber.*, **49**, 1141 (1916).

⁷ Siwoloboff, *ibid.*, **19**, 795 (1886).

Nitrate.—Prepared as described by Mills,⁸ formed colorless crystals, but the aqueous solution of these crystals was too acidic to be suitable for our pharmacological experiments.

2-Anilinothiazole, $\text{C}_6\text{H}_4\begin{smallmatrix} \text{S} \\ \diagup \quad \diagdown \\ \text{N} \end{smallmatrix} \text{CNHC}_6\text{H}_5$.—A mixture of 0.01 mole of *o*-aminophenyl disulfide and 0.02 mole of phenyl isothiocyanate was heated for forty minutes at 100°, with or without 95% alcohol as solvent. A small amount of precipitate separated and some hydrogen sulfide was evolved. Evaporation of the alcohol and crystallization of the residue from toluene gave fine colorless needles; yield, 30%; m. p., 159.2° (corr.), as compared with the figure 159° recorded by Hofmann,⁹ and by Jacobson and Frankenbacher,¹⁰ who prepared it by other methods.

Anal. Calcd. for $\text{C}_{13}\text{H}_{11}\text{N}_2\text{S}$: C, 69.03; H, 4.43. Found: C, 68.88; H, 4.71.

2-Phenyl-5-cyanobenzothiazole.—When prepared by the Bogert and Snell³ method from the zinc aminocyanophenyl mercaptide (7.5 g.) and benzoyl chloride (12 cc.), crystallized from toluene in odorless silvery spangles, light and bulky, which melted at 197° (corr.). The yield was only 20%, as there was considerable loss in recrystallization.

Following the process of Bogert and Stull,^{2c} and using benzaldehyde (2 cc.) instead of benzoyl chloride upon the zinc mercaptide (2.55 g.), the yield of thiazole was 30% and its m. p. 196.6–197.7° (corr.).

Anal. Calcd. for $\text{C}_{14}\text{H}_8\text{N}_2\text{S}$: C, 71.18; H, 3.39; N, 11.86; S, 13.59. Found: C, 71.16; H, 3.52; N, 11.76; S, 13.42.

2-Phenylbenzothiazole-5-carbamide, $\text{H}_2\text{NCOC}_6\text{H}_5\begin{smallmatrix} \text{S} \\ \diagup \quad \diagdown \\ \text{N} \end{smallmatrix} \text{CC}_6\text{H}_5$.—When the above nitrile (3 g.) was suspended in 75% sulfuric acid (80 cc.), the mixture heated for about forty-five minutes at 80°, then cooled and the brown solution poured into 900 cc. of ice water, a copious white precipitate separated which was decolorized and crystallized repeatedly from 95% alcohol. There were thus obtained colorless small needles, m. p. 247.2° (corr.), insoluble in *N* sodium hydroxide solution; yield, 23%.

Anal. Calcd. for $\text{C}_{14}\text{H}_{10}\text{ON}_2\text{S}$: N, 11.02; S, 12.59. Found: N, 10.91; S, 12.15.

Nitro-2-phenyl-5-cyanobenzothiazole.—2-Phenyl-5-cyanobenzothiazole (0.5 g.) was warmed for eighteen hours at 25° with fuming nitric acid (20 cc. of sp. gr. 1.6), and the cooled solution then poured slowly upon cracked ice. The curdy pale yellow precipitate was purified by dissolving it in a large volume of boiling 95% alcohol and adding water to incipient turbidity. The product was a colorless pulverulent solid, m. p. 256° (corr.); yield, 10%.

Anal. Calcd. for $\text{C}_{14}\text{H}_7\text{O}_2\text{N}_3\text{S}$: C, 59.78; H, 2.49. Found: C, 59.66; H, 2.71.

Not enough of this derivative was obtained to enable us to ascertain the location of the nitro group.

2-Phenylbenzothiazole-5-carboxylic Acid.—When 2-phenyl-5-cyanobenzothiazole (0.51 g.) was heated at 80° for fifteen minutes with sulfuric acid (10 cc. of a mixture of three parts by weight of concentrated acid to one of water) and then for fifteen minutes at 205°, the nitrile was saponified and on dilution with ice the thiazole acid separated. It crystallized from 95% alcohol as an odorless, colorless microcrystalline powder, and from ether in minute colorless silky needles which began to decompose around 250° and melted at about 273° (corr.); yield, 80%.

⁸ Mills, *J. Chem. Soc.*, **121**, 460 (1922).

⁹ Hofmann, *Ber.*, **13**, 12 (1880).

¹⁰ Jacobson and Frankenbacher, *ibid.*, **24**, 1410 (1891).

Anal. Calcd. for $C_{14}H_9O_2NS$: C, 65.88; H, 3.53; N, 5.49. Found: C, 65.76; H, 3.60; N, 5.55.

It was practically insoluble in water and only slightly soluble in hot alcohol, but dissolved readily in ether or in caustic alkali solutions.

The same product was obtained by digesting 0.29 g. of the corresponding amide with 10 cc. of hydrochloric acid (sp. gr. 1.19) for a few minutes. The acid separated in crystalline form. It was removed, washed thoroughly with water, dissolved in aqueous sodium hydroxide solution, reprecipitated by sulfuric acid, this solution and reprecipitation being repeated several times and the purified acid then decolorized and crystallized from 95% alcohol, and finally from absolute alcohol; yield, 80%. The carboxyl content was determined by a Pregl micro-titration with *N*/100 sodium hydroxide solution.

Anal. Calcd. for $C_{12}H_8NSCOOH$: COOH, 17.6. Found: COOH, 18.0

Methyl Ester.—The silver salt was prepared by treating the sodium salt with silver acetate in aqueous solution. The solution was made faintly acid with nitric acid, the silver salt filtered out, washed with water, then with alcohol, dried, suspended in a methyl alcohol solution of methyl iodide, the mixture refluxed for ten minutes, diluted with methyl alcohol, the silver iodide filtered out of the hot solution, the filtrate concentrated and cooled. The methyl ester which separated was purified by recrystallization from methyl alcohol. The crystals were colorless and finely granular, m. p. 171–172° (corr.), with some previous sintering; yield, 5%.

Anal. Calcd. for $C_{16}H_{11}O_2NS$: N, 5.20. Found: N, 5.38.

Attempts to prepare the ester directly from the nitrile by the action of hydrochloric acid and methyl alcohol were unsuccessful, the original nitrile being recovered unaltered.

Summary

1. 2-Phenyl-5-cyanobenzothiazole has been synthesized from *p*-chlorobenzonitrile, by nitration of the latter, reduction of the nitrochloro compound, through the disulfide, to the 3-amino-4-mercaptobenzonitrile and the condensation of the zinc salt of the latter with either benzoyl chloride or benzaldehyde.

2. This cyanobenzothiazole has been hydrolyzed to the corresponding amide and acid, and some derivatives prepared from the latter.

3. The work was incidental to pharmacological studies which will appear elsewhere.

[A COMMUNICATION FROM THE LABORATORY OF ORGANIC CHEMISTRY OF THE UNIVERSITY OF WISCONSIN]

REARRANGEMENT AND HYDROGENATION OF CERTAIN METAL ALKYL

BY WALTER H. ZARTMAN AND HOMER ADKINS

RECEIVED APRIL 29, 1932

ACCEPTED AUGUST 5, 1932

During the course of the study of another problem, catalytically active nickel was found to exert a profound influence upon the decomposition under hydrogen of tetra alkyl and aryl lead compounds. For example, diphenyl was formed almost quantitatively (reaction 1) when tetraphenyllead was heated at 200° with a nickel catalyst for six hours under a pressure of 100 atmospheres of hydrogen. The reaction proceeded so smoothly that the product obtained directly from the reaction had practically the same melting point as purest diphenyl. Both a catalyst and hydrogen are essential for the

rearrangement indicated above, since tetraphenyllead was quite stable under 100 atmospheres of nitrogen or hydrogen at 200°, or under 100 atmospheres of nitrogen and in the presence of nickel.¹

Tetra-*p*-tolyllead underwent a similar transformation and was converted almost quantitatively into 4,4'-dimethyldiphenyl. The reaction is not limited to tetraaryllead compounds but is also manifested by tetra-*n*-heptyllead. However, in this case the conversion was not as high, for a yield of only 62% of the theoretical amount of *n*-tetradecane was obtained. (The real yield was probably higher as mechanical losses were relatively large in this experiment.) A small amount (6%) of heptene, as determined by a bromine titration of the solvent methylcycloheptane, and presumably some *n*-heptane were produced. There was no evidence of any product boiling higher than tetradecane.

The behavior of the tetra alkyl and aryl lead compounds in the presence of catalytically active nickel is in marked contrast to that of similar compounds observed by Ipatiev, Razuvaev and Bogdanov,¹ who studied the action of hydrogen in the absence of a catalyst. These investigators found that tetramethyl-, tetraethyl- and tetraphenyllead were converted into lead and the hydrocarbon corresponding to the alkyl group as indicated in equation 2.

¹ The data presented in Table I would indicate that tetraphenyllead, for example, is stable at somewhat higher temperatures than would be concluded from the results obtained by Ipatiev, Razuvaev and Bogdanov [*Ber.*, **63B**, 335 (1930), and preceding papers in the *J. Russ. Phys.-Chem. Soc.*]. However, the discrepancy may well be due to the fact that we used a copper and not a glass reaction vessel, and to other differences in equipment, temperature control and purity of materials.

^a M. p. 225–226°. Gilman and Robinson, *This Journal*, **49**, 2315 (1927). ^b M. p. 239–240°. The method was analogous to that used for preparation of tetraphenyllead, except that *p*-bromotoluene was used in place of bromobenzene and toluene in place of benzene: *c* B. p. 70–72° (8 mm.). Noller, *This Journal*, **51**, 594 (1929). ^d Noller, *ibid.*, **53**, 635 (1931). The analysis for the amount of (C₆H₅)₂Mg in solution was made by means of titration with standard acid. ^e M. p. 56°. "Organic Syntheses," John Wiley and Sons, New York, 1927, Vol. VII, p. 80. ^f Unless otherwise noted the reaction proceeded almost quantitatively. ^g Methylcyclohexane. ^h Absolute ethyl ether. ⁱ M. p. 121°. Zincke, *Ber.*, **4**, 396 (1871). ^j B. p. 252° (760 mm.). Kraft, *ibid.*, **15**, 1700 (1882). ^k Heptene and heptene have approximately the same boiling points as the solvent, so that the amount of heptane could not be determined, while the heptene was determined by titration of the methylcyclohexane solution with bromine. ^l Ether containing 15 to 20% dioxane. ^m Amount determined by titration with standard acid. ⁿ Adkins and Covert, *J. Phys. Chem.*, **35**, 1684 (1931). ^o Adkins and Connor, *This Journal*, **53**, 1091 (1931). ^p Experimental methods and apparatus were essentially the same as previously reported. Adkins and Cramer, *ibid.*, **52**, 4349 (1930). ^q The hydrogen absorption in each of two hydrogenations was approximately 400 millimoles and no cyclohexane was formed. This indicates that a compound of magnesium and hydrogen was formed. This magnesium compound was exceedingly reactive with air and water.

However, in the present work it was found that di-*n*-butyl zinc in the presence of nickel and hydrogen reacted almost entirely in the sense of equation 2, *i. e.*, zinc and butane were formed. There was only a 3 or 4% yield of octane. Di-*n*-butyl zinc reacted at a somewhat lower temperature than did tetraheptyl lead. It was stable at 130° in the presence of nickel and hydrogen but reacted rapidly at 160°.

Diphenylmagnesium behaved similarly to dibutyl zinc, that is, it was converted into benzene and what was apparently magnesium hydride. Triphenylstibene, on the contrary, was recovered unchanged after it had been subjected to the action of hydrogen and active nickel for seven and one-half hours at 200°.

It seems worth noting that the order of increasing stability of the metallic alkyls toward hydrogen in the presence of catalytically active nickel, appears to be magnesium, zinc, lead and antimony, which is the order of decreasing metallic character. With regard to the mechanism of the reaction attention should be called to the observations of Paneth and co-workers,² who believe that they have demonstrated that tetraethyllead decomposes into lead and ethyl radicals. The formation of diphenyl from tetraphenyllead and of benzene from diphenylmagnesium could be explained as involving in the one case the addition of two phenyl radicals and in the second case of a phenyl radical and a hydrogen atom. However, there is no apparent reason why a difference in the metal from which the phenyl radical has separated should determine the subsequent manner of combination of the radicals. There seems no justification for going beyond the conception that hydrogen and metal alkyl were in combination with the metal surface and there suffered rearrangement. A summary of the experimental results is given in Table I.

The authors are indebted to Dr. George Calingaert of the Ethyl Gasoline Corporation for the tetraheptyllead used in this investigation. Dr. Calingaert in a private communication has informed the authors that several years ago he obtained a 40% yield of *n*-butane (accompanied by ethylene and ethane) as the result of passing tetraethyllead over heated pumice. Taylor and Jones reported that when tetraethyllead is decomposed at 250–300° in the presence of hydrogen and ethylene there were produced unsaturated gaseous and liquid hydrocarbons.³

Summary

Nickel catalyzes a synthetic reaction whereby tetraphenyllead is converted quantitatively into diphenyl. A similar reaction occurs with tetra-*p*-tolyl- and tetraheptyllead and to a very limited extent with dibutyl

SOME ANALYTICAL REACTIONS OF ALKYL SULFIDES IN BENZENE AND PURIFIED NAPHTHA SOLUTIONS¹

JOHN R. SAMPEY,² KENNETH H. SLAGLE² AND E. EMMET REID³

RECEIVED APRIL 29, 1932

PUBLISHED AUGUST 5, 1932

In a study of possible agents for the removal of alkyl sulfides from hydrocarbons either by adsorption or by a chemical reaction an analytical method for the determination of sulfides, either alone or mixed with other sulfur compounds,⁴ was required. Reliability and rapidity were of more importance than extreme accuracy. As the most of our work on sulfur compounds has been done, for the sake of reproducibility, in benzene this hydrocarbon was used as the solvent in this investigation. The method devised has been found to be applicable to solutions in a naphtha such as purified "Skellysolve" but, unfortunately, cannot be used when unsaturates are present.

Alkyl sulfides have usually been estimated by precipitation with mercury salts. Mabery and Smith⁵ separated sulfides from Ohio petroleum by agitation of the naphtha with aqueous or alcoholic mercuric chloride. Thierry⁶ used the same method to identify several sulfides from Persian oil. Faragher, Morrell and Monroe⁷ recommend "normal" mercurous nitrate, $\text{HgNO}_3 \cdot \text{H}_2\text{O}$, to precipitate sulfides quantitatively from naphtha solutions.

¹ Presented in part before the Petroleum Division at the 81st Meeting of the American Chemical Society, Indianapolis, Ind., March 30 to April 3, 1931 under the title, The Analysis of Mixtures of Sulfides, Disulfides and Mercaptans. This paper contains results obtained in an investigation of "Reactions of a Number of Selected Sulfur Compounds" listed as Project 28 of the American Petroleum Institute Research. Financial assistance in this work has been received from a research fund of the American Petroleum Institute donated by John D. Rockefeller. This fund is being administered by the Institute with the coöperation of the Central Petroleum Committee of the National Research Council.

⁶ Thierry, *J. Chem. Soc.*, **127**, 2756 (1925).

⁷ Faragher, Morrell and Monroe, *Ind. Eng. Chem.*, **19**, 1281 (1927).

More recently Faragher, Morrell and Comay⁸ have made a comprehensive investigation of the interaction of alkyl sulfides and salts of mercury.

While the mercury salt method has been applied successfully to petroleum distillates, it is not applicable to the estimation of alkyl sulfides dissolved in benzene, for the complexes formed by the action of various mercury salts on the sulfides are too soluble in this solvent to give quantitative separations.

In a search for a method of analysis which might apply to benzene solutions, the action of bromine on sulfides gave some promise. G. Patein⁹ observed that the bromine addition product of methyl sulfide hydrolyzed readily according to the equation $(\text{CH}_3)_2\text{SBr}_2 + \text{H}_2\text{O} = (\text{CH}_3)_2\text{SO} + 2\text{HBr}$. He determined that the hydrolysis went to completion by titration of the hydrobromic acid with caustic potash solution. It remained to be shown that the bromine addition product could be formed quantitatively from sulfides dissolved in a hydrocarbon solvent.

Method of Analysis

The procedure adopted for the analysis of alkyl sulfides in low concentration in benzene as the solvent is as follows.

A saturated solution of bromine water is added drop by drop to a mixture of 50 cc. of distilled water and exactly 50 cc. of a benzene solution of the alkyl sulfide in a 250-cc. glass-stoppered Erlenmeyer flask. The flask is shaken during the bromine treatment, and the addition is continued slowly until the color of bromine persists in the solution. Not more than two drops excess of the bromine water should be added, and this should not be permitted to remain longer than one-fourth of a minute before it is removed by the addition of a slight excess of a saturated solution of potassium iodide. The liberated iodine is then reduced with a saturated sodium thiosulfate solution. The aqueous layer is separated from the benzene layer, and the hydrobromic acid in the latter is extracted three times with 20-cc. portions of distilled water; these extracts are added to the original solution, and the hydrobromic acid content is determined by titration with *n*/20 sodium hydroxide solution, using brom cresol purple or a purified litmus solution as indicator.

Attention is invited to two precautions and one correction factor to be applied to the method. The excess bromine must be removed completely by the potassium iodide solution, for otherwise the bromine water will attack the thiosulfate solution and cause the formation of two strong acids according to the equation¹⁰

The second precaution is similar. The iodine liberated from the potassium iodide must be removed completely by the thiosulfate solution to prevent it from acting upon the sodium hydroxide. The Erlenmeyer flask must be shaken vigorously, therefore, after the addition of the excess potassium iodide solution, and again after the introduction of the thiosulfate solution.

The correction factor which must be applied arises from the acid present in the bromine water. The exact amount of bromine water used during the oxidation must be

⁸ Faragher, Morrell and Comay, *THIS JOURNAL*, **51**, 2774 (1929).

noted, and its acid content determined by shaking a like amount, dissolved in 50 cc. of water and 50 cc. of benzene, with excess potassium iodide and thiosulfate solutions, and titrating the acid. The figure thus obtained must be subtracted from the total number of cubic centimeters of alkali used in the estimation of the sulfide.

Results of Analyses

The results of the analyses with several different alkyl sulfides, and with varying concentrations of *n*-butyl sulfide, are given in Tables I and II. The solutions in Table I were prepared by weighing out in a stoppered weighing bottle the calculated amount of sulfide to give a liter of solution of 0.0500% sulfur by weight; 50-cc. portions of these solutions were pipetted for the bromine water treatment into 250-cc. glass-stoppered flasks. The samples of alkyl sulfides were supplied by Dr. L. M. Ellis, Jr.

TABLE I

ACTION OF BROMINE WATER ON ALKYL SULFIDES

Sulfide	S present, %	S found, %	Error, %
Ethyl	0.0500	0.0498	-0.4
	.0500	.0499	-0.2
Isopropyl	.0500	.0504	+0.8
	.0500	.0503	+0.6
<i>n</i> -Propyl	.0500	.0495	-1.0
	.0500	.0495	-1.0
Isobutyl	.0500	.0496	-0.8
	.0500	.0496	-0.8
<i>n</i> -Butyl	.0500	.0497	-0.6
	.0500	.0496	-0.8

The first three solutions in Table II were prepared by making up weighed quantities of the sulfide to one liter. The fourth solution (0.0045% S) was made by pipetting 5 cc. of the 0.0500% S solution into 50 cc. of benzene.

TABLE II

CHANGE IN CONCENTRATION OF *n*-BUTYL SULFIDE

S present, %	S found, %	Error, %	S present, %	S found, %	Error, %
0.2000	0.2002	+0.1	0.0500	0.0497	-0.6
.2000	.2004	+0.2	.0500	.0496	-0.8
.1000	.1002	+0.2	.0045	.0045	0.0
.1000	.1000	0.0	.0045	.0046	+2.2

Application to a Naphtha Solution Free from Unsaturated Hydrocarbons.—As was to be expected, alkyl sulfides cannot be estimated by the bromine water method when unsaturated hydrocarbons are present. An attempt was made to analyze a benzene solution of *n*-butyl sulfide in the presence of amylene. Twenty-five cc. of benzene containing about one per cent. of β -*n*-amylene (Eastman) was added to 25 cc. of a benzene solution of *n*-butyl sulfide (0.0500% S). This solution decolorized several times as much bromine water as that required for the oxidation of the sulfide.

The bromine water method was found applicable to a naphtha solution of *n*-butyl sulfide which was free from unsaturated hydrocarbons. "Skellysolve C," essentially normal heptane, boiling range 90 to 100°, of water white color, and sulfur free (Doctor Test), purchased from the Skelly Oil Company, was freed from a small amount of unsaturated hydrocarbons by prolonged agitation with concentrated sulfuric acid; the acid was washed out, and the naphtha steam distilled and dried. Twenty-five cc. of this purified naphtha was added to 25 cc. of a benzene solution of *n*-butyl sulfide containing 0.1000% sulfur. Duplicate analyses by the bromine water method gave results which were 0.2 and 0.4% higher than those obtained in the benzene solution alone.

Summary

1. A method has been devised for the estimation of alkyl sulfides dissolved in benzene.
2. The method is applicable to a naphtha solution free from unsaturated hydrocarbons.

SOME ANALYTICAL REACTIONS OF ALKYL MERCAPTANS IN BENZENE SOLUTION¹

BY JOHN R. SAMPEY² AND E. EMMET REID³

RECEIVED APRIL 29, 1932

PUBLISHED AUGUST 5, 1932

It has been customary to estimate mercaptans by an iodimetric method.⁴ In an examination of this method as applied to dilute solutions in benzene, it has been found that the time allowed for the oxidation is an important factor. The present paper describes also a study of two additional methods for the estimation of mercaptans in dilute concentrations in hydrocarbon solvents. One of these methods involves the titration of the hydriodic

¹ Presented in part before the Petroleum Division at the 81st Meeting of the American Chemical Society, Indianapolis, Ind., March 30 to April 3, 1931, under the title "The Analysis of Mixtures of Sulfides, Disulfides and Mercaptans." acid formed by the oxidation of the mercaptan with iodine. The second method is based upon the estimation of the hydrochloric acid produced by the action of an aqueous solution of mercuric chloride on the mercaptan.

Estimation of Mercaptans by Iodimetry.—In a study of the time required for the oxidation of mercaptans by iodine a peculiar phenomenon was observed. When exactly 50 cc. of a benzene solution of *n*-butyl mercaptan (0.0500% S) and 50 cc. of an approximately *n*/40 iodine solution were allowed to stand for twenty minutes and then titrated with a standard solution of sodium thiosulfate until the aqueous layer gave no color reaction with starch solution, it was found that less thiosulfate was required than corresponded to complete oxidation of the mercaptan to disulfide; based upon the amount of iodine apparently consumed, the calculation gave 105.9% of mercaptan oxidized. The benzene layer, however, was strongly colored with iodine, and while it was not possible to decolorize it even upon vigorous shaking with a few drops excess of thiosulfate, after several minutes the purple color appeared again in the aqueous layer, with a decrease in the intensity of the iodine color in the benzene layer. The addition of a few drops of thiosulfate solution caused only the aqueous layer to become colorless again, and to remain so for several minutes of shaking. The addition of thiosulfate was continued in small amounts until both the benzene and the aqueous layers were colorless; a calculation from the total thiosulfate consumed in the several titrations gave 99.9% oxidation to the disulfide.

In a second series of experiments an attempt was made to follow more closely the reaction between iodine and mercaptan. The same concentrations of iodine and mercaptan were used, but the titrations with thiosulfate were begun immediately, and continued at stated intervals; just enough thiosulfate was added each time to decolorize the aqueous starch layer after vigorous agitation. The results of one series of titrations are expressed in Table I.

TABLE I
RATE OF OXIDATION OF MERCAPTAN WITH IODINE

Time, min.	Thiosulfate consumed, cc.	Time, min.	Thiosulfate consumed, cc.
0	7.0	30	16.2
5	8.0	40	17.5
10	11.5	60	19.0
15	12.8	80	20.5
20	14.0	1200 (20 hrs.)	24.3

The final titration at the end of twenty hours corresponded to 99.8% oxidation of the mercaptan present. These results suggest the formation of an intermediate addition compound between the iodine and the mercaptan. This problem is being investigated further.

From a purely analytical point of view, however, it was of more impor-

tance to determine the time required for the reaction to go to completion than to follow its course in the early stages. In order to determine the minimum length of time required for the oxidation, the same concentrations of *n*-butyl mercaptan and iodine as used above were permitted to stand for forty minutes before titration; under these conditions the oxidation was 98.8% complete. From a number of analyses on the normal mercaptans from ethyl through nonyl it was found that three hours was long enough for the reaction to go to completion. Several of the secondary mercaptans, however, were discovered to oxidize much slower; for example, 50 cc. of secondary nonyl mercaptan (0.0500% S) was only 91.2% oxidized in three and one-half hours by 50 cc. of *n*/40 iodine solution. Whenever a long-chained secondary mercaptan was present, it was found best to permit twenty-four hours for the oxidation; during this period the solutions were kept in the dark to prevent the formation of iodine from the hydriodic acid produced during the oxidation.

Modification of the Iodine Method.—Two acidimetric processes for the estimation of mercaptans have been studied. The first of these involved the titration of the hydriodic acid formed during the oxidation of the mercaptan in the iodimetric method. In the second method, the hydrochloric acid liberated by the action of mercuric chloride on the mercaptan is estimated. The procedure for the estimation of the hydriodic acid may be described briefly as follows.

Exactly 50 cc. of a benzene solution of the mercaptan is allowed to stand in a glass-stoppered flask with an excess of the iodine solution until the oxidation is complete. The excess iodine is then removed with thiosulfate solution. The aqueous and benzene layers are separated, and the latter is washed with 60 cc. of water in three portions in order to free it from any hydriodic acid. The washings are added to the main aqueous layer, and the hydriodic acid is titrated with *n*/40 sodium hydroxide solution, using brom cresol purple or a purified litmus solution as indicator.

The accuracy of this method is seen in Tables II and III, where the same samples were used for the estimation of the mercaptan by the iodine and the hydriodic acid methods; the sodium hydroxide titration on each sample was performed as soon as the excess standard iodine solution had been titrated with thiosulfate solution, and the benzene layer separated and washed. The hydriodic acid method is not as accurate as the iodine method, but it was developed in the expectation that it would prove useful where the other would not apply, *e. g.*, in the estimation of mercaptans in mixtures containing unsaturated hydrocarbons.

The solutions used in Tables II and III were prepared by weighing out in a small stoppered weighing bottle the calculated amounts of mercaptans to give a liter of the specified concentration. Fifty-cc. portions of these were pipetted into glass-stoppered flasks for the analyses. The samples of the pure mercaptans were prepared by Dr. L. M. Ellis, Jr.⁵

Limitations of the Iodine and Hydriodic Acid Methods in the Presence of Naphthas and Unsaturated Hydrocarbons.—No complications were encountered in the determination of mercaptans in naphtha solution ("Skellysolve C") which had been freed from unsaturated hydrocarbons.⁶ In the presence of amylene, however, neither the iodine nor the hydriodic acid method was applicable. An attempt was made to analyze 25 cc. of a benzene solution of *n*-butyl mercaptan (0.1000% S) to which had been added 25 cc. of a 1% amylene solution (in benzene). After this solution had stood for twenty-four hours with 50 cc. of *n*/40 iodine solution, the thiosulfate titration of the excess iodine gave an apparent sulfur content of 0.1077% due to addition of the iodine to the double bond of amylene. From the titration of the hydriodic acid only 0.0992% S was indicated. A duplicate analysis gave 0.1028% S from the iodine titration, and 0.0881% S from the hydriodic acid titration.

Mercuric Chloride Method for the Estimation of Mercaptans.—Mercaptans dissolved in benzene may be estimated rapidly through the use of an aqueous solution of mercuric chloride. Individual mercaptans have often been identified by the melting points of the salts formed from the

⁶ Sampey, Slagle and Reid, *THIS JOURNAL*, **54**, 3401 (1932).

action of an aqueous or alcoholic solution of mercuric chloride upon a naphtha solution of the mercaptan. From the equation for the reaction

it is seen that one mole of acid is liberated for each mole of mercaptan. The method of analysis based upon the titration of the acid may be indicated as follows.

Fifty cc. of a benzene solution of the mercaptan (0.0500% S) is shaken vigorously for three minutes with 25 cc. of a 1% aqueous solution of mercuric chloride; the amount of the mercury salt which precipitates varies with the individual mercaptan; the higher secondary mercaptans give salts which are completely soluble in the 50 cc. of benzene. In the event no precipitation takes place, or only a slight precipitate is formed, the two layers are separated and the hydrochloric acid is washed from the benzene with three 25-cc. portions of water; the acid in the aqueous layer and the washings is titrated with $n/40$ sodium hydroxide, using methyl orange or methyl red as indicator. When a heavy precipitate is formed by the mercuric chloride it is better not to attempt a separation of the two layers, but to add the alkali to the mixture slowly with frequent shakings; methyl orange must be used in this case, for methyl red dissolves in the benzene and becomes orange colored even when there is acid in the aqueous layer; since methyl orange is more soluble in the aqueous layer, and the white precipitate of RSHgCl remains in the benzene layer, the end-point is almost as sharp as when the layers are separated.

Calculations from the preliminary titrations gave results which were low. This was to be expected since both methyl orange and methyl red change color on the acid side. It was necessary to use this type of indicator, however, in order to prevent the formation of $\text{Hg}(\text{OH})_2$. It was found possible to apply a correction factor by standardizing against $n/40$ hydrochloric acid a volume of sodium hydroxide approximately the same as that required in the titration after the mercuric chloride treatment of the mercaptan. The values obtained in the standardization with hydrochloric acid when methyl orange and methyl red were the indicators were 0.4 to 0.5 cc. lower than the results when brom cresol purple and purified litmus were the indicators.

Table IV gives the results of the analyses of benzene solutions of mercaptans.

TABLE IV
MERCURIC CHLORIDE METHOD FOR THE ESTIMATION OF MERCAPTANS

Mercaptan	S present, %	S found, %
Ethyl	0.0500	0.0503
Isopropyl	.0500	.0498
<i>n</i> -Butyl	.0500	.0499
<i>n</i> -Butyl	.1000	.1003
<i>n</i> -Butyl	.2000	.2006
<i>Sec.</i> -butyl	.0500	.0501
<i>n</i> -Heptyl	.0500	.0496
<i>Sec.</i> -nonyl	.0500	.0503

Limitations of the Mercuric Chloride Method in the Presence of Naphthas and Unsaturated Hydrocarbons.—The mercuric chloride

method was applied without difficulty to *n*-butyl mercaptan in a naphtha ("Skellysolve") which was free from unsaturated hydrocarbons. In the presence of the latter, however, the method failed. Hofmann and Sand⁷ were the first to discover that mercuric chloride liberates hydrochloric acid when shaken with an unsaturated hydrocarbon of the olefin series. Several cubic centimeters of alkali was required to neutralize the acid when a 1% mercuric chloride solution was shaken for three minutes with a 1% solution of amylene in benzene.

Summary

1. The iodimetric method for the estimation of mercaptans has been applied to benzene solutions.

2. Two acidimetric methods for the estimation of mercaptans are given: in one the hydriodic acid formed in the iodimetric oxidation is titrated; in the second method, the hydrochloric acid liberated by the action of mercuric chloride on the mercaptan is estimated.

THE PROPERTIES OF *d*-MANNURONIC ACID LACTONE

BY WILLIAM L. NELSON AND LEONARD H. CRETCHER

RECEIVED MAY 2, 1932

PUBLISHED AUGUST 5, 1932

Since the publication of our paper on the isolation and identification of *d*-mannuronic acid lactone from *Macrocystis pyrifera*,¹ the lactone has been obtained in this Laboratory by hydrolysis of alginic acid from *Fucus serratus* and *Laminaria saccharina*.² As a result of our further work, we have discovered the mutarotation of the lactone which escaped our observation because of the small amount of the substance available in our earlier experiments.

The lactone was isolated through the cinchonine salt as previously described.¹ The melting point and optical rotation of the cinchonine salt from *Fucus serratus* and *Laminaria saccharina* agreed with the values reported for the salt from *Macrocystis pyrifera*.³ Under different conditions of hydrolysis, however, Schmidt and Vocke,⁴ Miwa⁵ and Bird and Haas⁶ have obtained salts with different properties.

¹ Nelson and Cretcher, *THIS JOURNAL*, **52**, 2130 (1930).

² We are indebted to Dr. E. J. Allen, Director of the Marine Biological Station, Plymouth, England, for his kindness in supplying us with these algae.

⁶ Bird and Haas, *Biochem. J.*, **25**, 403 (1931).

TABLE I
CINCHONINE SALTS OF URONIC ACIDS FROM ALGIN

		M. p., °C.	$[\alpha]_D$
Nelson and Cretcher	<i>Macrocystis pyrifera</i>	152	+113.6°
	<i>Fucus serratus</i>	153	+114.3°
	<i>Laminaria saccharina</i>	152	+111.2°
	From crystalline mannuronic lactone	154	+113.3°
Schmidt and Vocke	<i>Fucus serratus</i>	204	
Miwa	<i>Ulopteryx pinnatifidia</i> and other algae	174	+140.3°
Bird and Haas	<i>Laminaria</i>	195-197	+112.8°
		161	+154°

These discrepancies seem to indicate the presence of more than one uronic acid in alginic acid⁷ but we believe it is more probable that they are due to differences in degree of hydrolysis. The presence of glucuronic acid has been suggested^{4,8} but has never been established. We have prepared cinchonine mannuronate from crystalline mannuronic lactone and have found that the melting point and specific rotation of this preparation closely check these properties of the cinchonine salt obtained by us after hydrolysis of alginic acid.

The preparation of the cinchonine salt of mannuronic acid after hydrolysis of alginic acid is a matter of considerable trouble. This salt is not a suitable derivative for the characterization of mannuronic acid. The cinchonidine and brucine salts are more easily crystallized and their properties are described in the experimental part.

The separation of the barium salts of the products of hydrolysis of alginic acid by fractional precipitation with alcohol is a convenient method of isolating mannuronic acid. Schoeffel and Link⁹ have recently applied this method in their study of the preparation of mannuronic lactone.¹⁰

Experimental Part

Preparation of *d*-Mannuronic Lactone.—Hydrolysis of alginic acid from *Macrocystis pyrifera*, *Fucus serratus* and *Laminaria saccharina* with 80% sulfuric acid and the subsequent steps in the preparation of the lactone were accomplished with few changes from our previously described procedure.^{1,3} Among these was the method of removing sul-

⁷ It has been established that alginic acid is a uronic acid polymer exclusively.³

⁸ Atsuki and Tomodo, *J. Soc. Chem. Ind. (Japan)*, **29**, 509 (1926).

⁹ Schoeffel and Link, *J. Biol. Chem.*, **95**, 213 (1932).

¹⁰ Schoeffel and Link state that they obtained a "pure" barium salt after precipitation of polymers with alcohol. The barium content of their preparation was between 26 and 27% (calcd. 26.26%). Without an intimation that their salt was not pure barium mannuronate it may be stated that within the limits of analysis given the presence of a considerable amount of polymers is possible. Conclusions as to the purity of the barium salt may better be based on determination of its reducing power. It has been shown¹ that the lactone is abnormal in its reaction with iodine in alkaline solution (Willstätter-Schudell), but recent determinations in this Laboratory show that it is possible to obtain satisfactory estimations of the lactone with Benedict's solution.

furic acid after hydrolysis. In order to reduce decomposition of the uronic acid, it was found advisable to remove most (90%) of the inorganic acid with barium hydroxide at room temperature and the remainder with an excess of barium carbonate from the hot solution. The solution was concentrated and cooled to remove the more insoluble barium salts and the cinchonine salt was prepared from the filtrate. At times the cinchonine salt was difficult to crystallize. Several extractions of the aqueous solution with chloroform were found to be indispensable. Then the solution was evaporated to a thick sirup and allowed to crystallize in a cooler. The solid mass of salt was broken up and washed with 95% alcohol and filtered on a Büchner funnel.

The crystallization of the lactone from glacial acetic acid was sometimes attended with difficulty. Frequently a gummy substance precipitated while the acetic acid extract of the lactone was cooling. In these cases the crystalline lactone was obtained by decanting the mother liquor and concentrating to a small volume in a vacuum desiccator containing sodium hydroxide. The maximum yield of lactone recovered from the cinchonine salt was 35% of the theoretical. Improvements in the process, particularly the use of other alkaloids, will be investigated in this Laboratory.

The pure lactone is white, without the pink tinge of color usually apparent in the product from the first crystallization. The lactone is deposited from glacial acetic acid in dense clusters at the border of which may be seen, under a high power lens, the projecting ends of crystals of not easily recognizable form. The lactone obtained from *Macrocystis pyrifera*, *Laminaria saccharina* and *Fucus serratus*, after one recrystallization from glacial acetic acid, possessed the same melting point, 139°, which did not change on three further recrystallizations, and (within the limit of experimental error) the same maximum rotation

$$[\alpha]_D^{22} + 93.8^\circ \text{ (Macrocystis pyrifera)}$$

$$[\alpha]_D^{20} + 93.8^\circ \text{ (Laminaria saccharina)}$$

$$[\alpha]_D^{20} + 93.6^\circ \text{ (Fucus serratus)}$$

In all cases the mutarotation was of the character described in the following paragraph.

Mutarotation of *D*-Mannuronic Acid Lactone.—The lactone obtained from *Macrocystis pyrifera* was recrystallized four times from glacial acetic acid as follows. The lactone was dissolved in the minimum amount of solvent heated in a boiling water-bath. The solution was allowed to cool until there was a slight precipitate, quickly filtered on a vacuum filter and allowed to crystallize overnight. After the final crystallization, the lactone was washed several times with absolute alcohol and anhydrous ether and dried. The following table shows the rotation of 0.1892 g. of the recrystallized lactone in 10.08 cc. of aqueous solution. A 1-dm. tube was used. The first recorded specific rotation (three minutes after solution) was $[\alpha]_D^{22} + 79.9^\circ$. The rotation increased rapidly to the maximum, $[\alpha]_D^{22} + 93.8^\circ$, twenty-eight minutes after solution and then slowly decreased. The stoppered tube (with a drop of toluene on the surface of the solution) was allowed to stand at room temperature for 864 hours, at which time the rotation was not constant.

TABLE II
MUTAROTATION OF *D*-MANNURONIC LACTONE

Hours	α_D	$[\alpha]_D$	Hours	α_D	$[\alpha]_D$
0.05	+1.50	+79.9	24	1.74	92.7
.13	1.65	87.9	168	1.66	88.4
.22	1.72	91.6	336	1.58	84.2
.30	1.74	92.7	504	1.44	76.7
.38	1.75	93.2	672	1.30	69.3
.47	1.76	93.8	864	1.16	61.8

The rapid initial increase is probably due to attainment of equilibrium between the α and β forms of the aldehyde and the subsequent decrease is due to the formation of mannuronic acid. It was found by titration that the solution contained 39.1% acid and 60.9% lactone when the specific rotation was $+61.8^\circ$. Using these data for an approximate calculation of the equilibrated rotation of *d*-mannuronic acid gives $[\alpha]_D +12.0^\circ$. It may be noted that this value is close to the equilibrium rotation of *d*-mannose, $[\alpha]_D +14.6^\circ$.

The equilibrium ratio of acid and lactone was determined by heating solutions of the lactone at 80° . The percentages of acid and lactone, respectively, were 59.6 and 40.4 after 19.5 hours at 80° . Longer heating did not change this ratio appreciably, but caused a decrease of the optical rotation. Decomposition was evident after heating for thirty-five hours, when the solution became yellow.

Cinchonine Mannuronate.—0.110 g. of mannuronic lactone was dissolved in 20 cc. of 50% alcohol and heated with a slight excess of cinchonine in a water-bath at 80° for two hours. The solution was evaporated under reduced pressure to remove alcohol. Water was added and the solution was filtered to remove a small amount of cinchonine, extracted twice with chloroform and evaporated under reduced pressure to a thick sirup. The salt crystallized before cooling. It was dissolved in 80% alcohol and crystallized by evaporation in a desiccator under reduced pressure to a small volume. After washing with cold 80% alcohol, absolute alcohol and ether, it was dried over phosphorus pentoxide under reduced pressure. 0.106 g. of pure white salt was obtained. The salt crystallizes in sheaves of slender rectangular plates and when dry is quite insoluble in cold water. The melting point was 154° , with decomposition. 0.0285 g. in 3.017 cc. of aqueous solution gave an observed rotation of $+1.07^\circ$ in a 1-dm. tube; $[\alpha]_D^{24} +113.3^\circ$.

Cinchonidine Mannuronate.—Prepared in the same manner as the cinchonine salt and crystallized twice from 95% alcohol. After washing with absolute alcohol and ether, it was dried in a vacuum over phosphorus pentoxide. From 0.090 g. of lactone 0.140 g. of pure white salt was obtained. The compound crystallizes in small clusters of radiating needles and melts with decomposition at 154° .

0.0393 g. in 3.017 cc. of aqueous solution gave an observed rotation of -1.02° in a 1-dm. tube; $[\alpha]_D^{24} -78.3^\circ$.

Anal. (Micro Dumas). Calcd. for $C_{25}H_{32}O_8N_2$: N, 5.73. Found: N, 5.42, 5.43.

Brucine Mannuronate.—Prepared in the same manner as the cinchonine salt and crystallized twice from 80% alcohol. 0.070 g. of buff colored salt was obtained from 0.080 g. of lactone. The compound crystallizes in irregular masses of small needles and melts at 147° with decomposition. 0.0352 g. in 3.017 cc. of aqueous solution gave an observed optical rotation of -0.27° in a 1-dm. tube; $[\alpha]_D^{24} -23.1^\circ$.

Anal. (Micro Dumas). Calcd. for $C_{33}H_{36}O_{11}N_2$: N, 4.76. Found: N, 4.42, 4.47.

Summary

d-Mannuronic lactone has been isolated for the first time from the alginic acid of *Laminaria saccharina* and *Fucus serratus*. Data on the mutarotation of the lactone are presented and an approximate value for the rotation of the equilibrated mixture of α - and β -forms of the free acid has been calculated. The preparation and properties of the cinchonine and the more easily crystallized brucine and cinchonidine salts of *d*-mannuronic acid are described.

THE SYNTHESIS OF 2-IMIDAZOLONE-4-CARBOXYLIC ACID AND 2-IMIDAZOLONE

BY GUIDO E. HILBERT

RECEIVED MAY 5, 1932

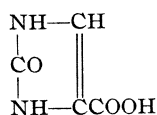

PUBLISHED AUGUST 5, 1932

Davidson and Baudisch¹ have utilized the von Pechmann reaction² for a novel synthesis of uracil by treating malic acid and urea with fuming sulfuric acid. More recently, Hilbert³ in a similar manner prepared uracil-4-acetic acid from citric acid and urea. This method for the synthesis of cyclic ureides by condensing urea with a derivative of formylacetic acid, which is formed by the action of sulfuric acid on an α -hydroxy- α,β -dicarboxylic acid, is practical only when the hydroxy acid is easily available. One other analog, tartaric acid, immediately suggests itself and the study of the product prepared from it and urea in sulfuric acid is the subject of this investigation.

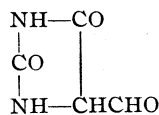

The initial product formed in a reaction between tartaric and sulfuric acids would be expected to be α,β -dihydroxyacrylic acid (I) (formylglycolic acid)

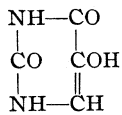

which upon subsequent reaction with sulfuric acid would yield glyoxal. The reaction of the degradation product of tartaric acid with urea can theoretically lead to a number of products. The condensation of urea with the α - and β -hydroxy groups of (I) would be expected to yield 2-imidazolone-4-carboxylic acid (II) and the combination with either the α - or β -hydroxy and the carboxyl group would be expected to produce 5-formylhydantoin (III) and isobarbituric acid (IV), respectively. A reaction between glyoxal and urea would yield acetylenediureide (V).

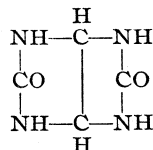

(II)

(III)

(IV)

(V)

Because of the presence of the additional α -hydroxy group, it is difficult to predict which product will be formed. The cases, involving malic and citric acids are much simpler since each can yield only one cyclic nitrogen compound.

¹ Davidson and Baudisch, *THIS JOURNAL*, **48**, 2379 (1926).

² Von Pechmann, *Ber.*, **17**, 936 (1884); *Ann.*, **264**, 261 (1891).

³ Hilbert, *THIS JOURNAL*, **54**, 2076 (1932).

The action of fuming sulfuric acid upon tartaric acid and urea actually leads to the formation of only one product which, considering the experimental conditions, is obtained in a satisfactory yield. It melts with decomposition at 261° , is insoluble in organic solvents, and slightly soluble in boiling water. The analytical results indicate that the empirical formula is $C_4H_4O_3N_2$ which is that required by the isomers (II), (III), and (IV), and which definitely eliminates (V) from consideration. The possibility that the product is isobarbituric acid is excluded by the wide difference in the decomposition points and by the fact that the product neither responds to the Wheeler-Johnson color test⁴ nor gives the characteristic blue color⁵ with ferric chloride. Of the two remaining, 2-imidazolone-4-carboxylic acid (II) was shown to be more probable since the product is easily soluble in an aqueous solution of potassium carbonate.

The experimental evidence obtained by degradation and by conversion into derivatives definitely shows that the product is 2-imidazolone-4-carboxylic acid. It has a neutral equivalent of 121 (calcd. 128) and on appropriate treatment with sulfuric acid and alcohol forms an ester. Oxidation with chromic acid leads to the formation of parabanic acid, which is excellent evidence for the original presence of the imidazole ring.⁶ Methylation with dimethyl sulfate in aqueous sodium hydroxide yields 1,3-dimethyl-2-imidazolone-4-carboxylic acid (decomp. $229-230^{\circ}$), which, by a comparison of the properties, appears to be similar to that prepared by the hydrolysis of 7,8-dimethyldihydrouric acid (decomp. 220°)⁷ and by the hydrolysis of 1,3-dimethyl-5-aminouracil-4-carboxylic acid (decomp. $224-225^{\circ}$).⁸ In order to obtain additional evidence that the methylated imidazolone carboxylic acid is the same as that reported by Biltz and Bülow, their work on the decarboxylation was repeated. The properties of the resulting 1,3-dimethyl-2-imidazolone are quite similar to those previously described.

2-Imidazolone-4-carboxylic acid reacts with acetic anhydride and yields a crystalline product which does not melt at 300° . As it is either sparingly soluble or insoluble in all ordinary solvents it is impossible to determine its molecular weight. The empirical formula is either $C_6H_4O_3N_2$ or a multiple of this. Its striking behavior toward alkali indicates that it

⁴ Wheeler and Johnson, *J. Biol. Chem.*, **3**, 183 (1907).

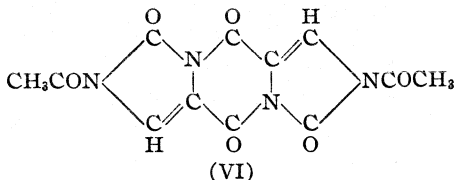

⁵ Behrend and Roosen, *Ann.*, **251**, 235 (1889).

⁶ The formation of parabanic acid by oxidation does not always necessarily indicate the original presence of an imidazole ring; see for example the oxidation of 1,4-dimethyluracil by Henkel, *Ann.*, **378**, 170 (1911), to 1-methylparabanic acid. A similar alteration in the ring is impossible in the present case since the presence of one of the carbon atoms in a carboxyl group does not allow a sufficient number to remain to form a pyrimidine ring.

⁷ Biltz and Bülow, *Ann.*, **457**, 117 (1927).

⁸ Beythien, *ibid.*, **389**, 214 (1912).

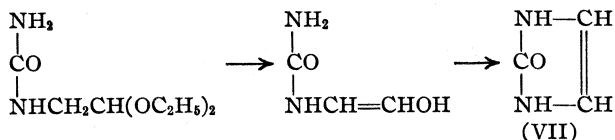

may be the diketopiperazine (VI). On treatment with potassium hydroxide the acetyl groups are removed and a crystalline canary yellow potassium salt forms, which analyzes well for $C_8H_2N_4O_4K_2$.

The condensation of urea with the hydroxyl groups of α,β -dihydroxyacrylic acid, in preference to a reaction involving the carboxyl group, is very interesting and not without analogy. Certain rare rearrangements of pyrimidines to imidazolones seem to undergo a similar reaction. Beythien^{8,9} for example, prepared 1,3-dimethyl-2-imidazolone-4-carboxylic acid from 1,3-dimethyl-5-aminouracil-4-carboxylic acid, and Johnson and Hadley¹⁰ noted the transformation, on alkaline treatment, of 4-(α -hydroxyl ethyl)-uracil to 4,5-dimethyl-2-imidazolone. These pyrimidines are apparently hydrolyzed to form the open-chain urea derivatives in which the hydroxyl group combines with the amino radical to yield the imidazolone.

It is unfortunate that there is no method for the reduction of a lactam such as occurs in 2-imidazolone-4-carboxylic acid. All efforts toward this end resulted in failure. A successful means of reduction would have considerable significance as it would allow an easy method of entrance into the important imidazoline series of compounds.

The Synthesis of 2-Imidazolone.—The synthesis of 2-imidazolone has been reported twice in the literature. The properties of the product obtained, however, were quite different. Marckwald¹¹ by the hydrolysis of acetalylurea with dilute sulfuric acid isolated a product to which he assigned the structure of 2-imidazolone (VII).

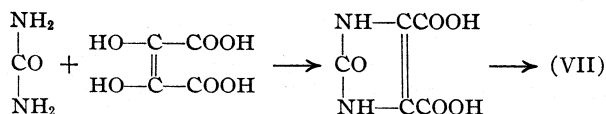

It was reported to be a semi-crystalline substance which did not melt at the boiling point of sulfuric acid. All attempts to convert this into some derivative were unsuccessful. Later Fenton and Wilks¹² by the condensation of dihydroxymaleic acid with urea obtained a crystalline product which decomposed at 245° and yielded a monoacetyl derivative.

⁹ See also Bremar, *ibid.*, 378, 188 (1911).

¹⁰ Johnson and Hadley, *THIS JOURNAL*, 39, 1715 (1917).

¹¹ Marckwald, *Ber.*, 25, 2357 (1892).

¹² Fenton and Wilks, *J. Chem. Soc.*, 95, 1329 (1909).

The analytical results and the molecular weight determination agreed well for 2-imidazolone. A direct comparison of this with Marckwald's compound definitely showed that they were different. Since Marckwald's substance was made by a more direct method, Fenton and Wilks apparently believed that he had obtained the true 2-imidazolone and accordingly named theirs "iso-imidazolone."

In order to throw further light on this question, 2-imidazolone-4-carboxylic acid was decarboxylated. This was effected by heating the acid at a temperature of 220° in a vacuum. The 2-imidazolone sublimed on the cooler parts of the vessel in the form of pyramidal crystals that decomposed at 250–251°. It had all the properties of the compound described by Fenton and Wilks, with the exception that it did not give a Weidel color reaction. The similarity of the chemical and optical properties and the fact that it also yielded an acetyl derivative melting at the same temperature as that of "iso-imidazolone" would seem to warrant the conclusion that these substances are identical and that Fenton and Wilks were the first to have obtained 2-imidazolone. The carbon and hydrogen values obtained by Fenton and Wilks for the acetyl derivative led them to believe that it was 1-acetyl-2-imidazolone. The product obtained in the present investigation, however, has been definitely shown to be 1,3-diacetyl-2-imidazolone.

I am indebted to Dr. David Davidson for a discussion concerning this work. The analytical results recorded were kindly carried out by Dr. Reid T. Milner and Mrs. Mildred S. Sherman.

Experimental Part

Preparation of 2-Imidazolone-4-carboxylic Acid.—A series of experiments run under varying conditions was carried out and the following procedure was found to be the best. To a 2-liter three-necked flask fitted with a stirrer was added 400 cc. of 13% fuming sulfuric acid. After cooling this to 0°, 112 g. of finely powdered anhydrous tartaric acid was added at such a rate that the temperature did not rise above 10°—this required ten minutes. The ice-bath was removed and 100 g. of urea added. The temperature during this operation rose rapidly and was finally held with the aid of a burner at 80° for thirty minutes. A vigorous reaction ensued with the concomitant evolution of carbon monoxide and carbon dioxide; the reaction mixture rapidly turned black. After completion of the reaction the contents of the flask were cooled and poured on 1200 g. of ice. An amorphous chocolate colored precipitate immediately separated. This, having stood in the ice box overnight, was filtered; yield of crude dry product, 35 g. It was decolorized by boiling a water solution with large portions of bone black and finally recrystallizing from water from which it separated as colorless nodules; it melted with vigorous effervescence at 261°. 2-Imidazolone-4-carboxylic acid was slightly soluble in boiling water and insoluble in organic solvents.

Anal. Calcd. for $C_4H_4O_4N_2$: C, 37.50; H, 3.15; N, 21.88. Found: C, 37.95; H, 3.28; N, 21.98, 21.85.

The acid was dissolved in an excess of standardized sodium hydroxide and titrated back with standardized hydrochloric acid using phenolphthalein as the indicator.

Neutral equivalent. Subs., 0.1164, 0.0489: 14.06, 5.78 cc. of 0.0694 *N* NaOH. Calcd. for $C_4H_4N_2O_4COOH$: 128. Found: 119.3, 121.9.

On treating the acid with Tollens' reagent it formed a silver mirror. The same result was obtained by heating it with an ammoniacal solution of silver nitrate. A water solution of the acid yielded a dark brown color when treated with aqueous ferric chloride. It did not give a Weidel color reaction.

In order to obtain evidence concerning the structure of 2-imidazolone-4-carboxylic acid, its action toward various reagents was studied. The following did not yield satisfactory results. A water solution of the acid was treated with bromine. The water was removed and a pale yellow sirup resulted which did not crystallize on standing, and was not further investigated. Treatment of the imidazolone with phosphorus oxychloride led to complete decomposition. On evaporation to dryness with fuming hydrochloric acid a gummy residue resulted that was not amenable to the isolation of a homogeneous product.

Isobarbituric acid was shown neither to be an intermediate in the formation of the imidazolone nor to be susceptible to rearrangement. It was heated with both dilute and concentrated sulfuric acid, 12% fuming sulfuric acid, 48% hydrobromic and 20% sodium hydroxide and in every case was recovered unaltered.

Oxidation of 2-Imidazolone-4-carboxylic Acid to Parabanic Acid.—To a suspension of 1 g. of 2-imidazolone-4-carboxylic acid in 20 cc. of water was added 1 g. of sodium dichromate and 3 g. of concentrated sulfuric acid. A vigorous evolution of carbon dioxide took place. After this had slowed down the green reaction mixture was boiled for fifteen minutes, another gram of sodium dichromate added, and the heating continued on a steam-bath for an hour; the imidazolone gradually dissolved. After cooling, the solution was thoroughly extracted with 4 portions of 40 cc. of ether. The ether extract was washed with a small amount of water and dried with calcium chloride. The ether was removed by distillation and the parabanic acid remained as a colorless crystalline cake; yield, 0.28 g. After recrystallization from 2 cc. of water, from which it separated in the form of curved thin plates, it decomposed at 247° with effervescence. It was shown to be identical with an authentic specimen of parabanic acid.¹³

Ethyl-2-imidazolone-4-carboxylate.—The usual method of esterification, in which the acid is treated with alcohol in the presence of a small quantity of sulfuric acid, was unsuccessful in this case probably because of the insolubility of the imidazolone in alcohol.

The following procedure was found to give the best results. Seven grams of 2-imidazolone-4-carboxylic acid was dissolved in 17 cc. of concd. sulfuric acid by heating in an oil-bath to 115°. Upon adding 40 cc. of absolute ethyl alcohol, the dark brown solution was heated at 100° for three hours, allowed to stand overnight, and poured on 80 g. of ice. A pale yellow flocculent solid separated immediately. The mixture was cooled in an ice-salt bath and filtered. The ester was recrystallized several times from

¹³ From a survey of the literature the simplest method for the preparation of parabanic acid appears to be that of Michael, *J. prakt. Chem.*, [2] 35, 457 (1887). This involves the condensation of urea with ethyl oxalate in the presence of sodium ethylate. A white precipitate immediately forms which was reported to be the sodium salt of parabanic acid (no analysis given). This reaction has been reinvestigated and definitely shown not to yield parabanic acid.

95% alcohol, from which it separated as colorless glistening plates, melting at 255°; yield, 50% of the theoretical. It was slightly soluble in boiling alcohol and insoluble in water.

Anal. Calcd. for $C_6H_8O_3N_2$: C, 45.84; H, 5.13; N, 17.95. Found: C, 46.14, 46.06; H, 5.17, 5.46; N, 18.13, 17.95.

Attempts to reduce the double bond in this compound by the Adams-Shriner method were unsuccessful.

1,3-Dimethyl-2-imidazolone-4-carboxylic Acid.—Five grams of 2-imidazolone-4-carboxylic acid was dissolved in a solution of 10 g. of sodium hydroxide in 30 cc. of water. This was cooled in an ice bath and 15 g. of dimethyl sulfate slowly added with stirring. A vigorous reaction took place with the evolution of heat. After this had practically ceased, the reaction mixture was made strongly alkaline with 20% sodium hydroxide and warmed on the steam-bath for one hour. It was filtered from a small amount of black flocculent material and then acidified with hydrochloric acid. On cooling, a mass of colorless needles separated which melted at 207–215°. It was impossible to raise the melting point by recrystallization. As the product was obviously still impure it was again subjected to methylation. This time, after decolorizing with bone black and recrystallizing from water, it separated as long colorless needles and melted sharply at 229–230° with effervescence; yield 4 g.

Anal. Calcd. for $C_8H_{10}O_3N_2$: C, 46.14; H, 5.17; N, 17.95. Found: C, 46.39; H, 5.05; N, 17.84, 17.95.

Conversion of 1,3-Dimethyl-2-imidazolone-4-carboxylic Acid to 1,3-Dimethyl-2-imidazolone.—One gram of 1,3-dimethyl-2-imidazolone-4-carboxylic acid was heated at its melting point until effervescence ceased. The colorless liquid on cooling and scratching solidified to a mass of dendritic crystals. The product was very hygroscopic, making it difficult to get either a good melting point or an analysis. It had all the properties of the substance reported by Biltz and Bülow, with the exception that it did not give the initial violet color reaction upon treatment with bromine. A water solution of the product obtained in this work immediately decolorized bromine water without undergoing any intermediate color change. It is possible that Biltz's product was slightly contaminated with an impurity.

Treatment of 2-Imidazolone-4-carboxylic Acid with Acetic Anhydride.—To 200 cc. of acetic anhydride was added 1.8 g. of the imidazolone and the mixture refluxed. After heating for one hour, a pale yellow solution resulted. On cooling and standing overnight, star-like clusters of colorless prisms separated; these were removed by filtration. The filtrate on concentration deposited a finely divided pale brown solid which proved to be identical with the above crystalline material. It was very slightly soluble in boiling acetic acid and acetic anhydride and insoluble in other organic solvents; it did not melt at a temperature of 300°. The product for analysis was boiled with acetic acid, filtered and well washed.

Anal. Calcd. for $C_{12}H_8O_6N_4$: C, 47.35; H, 2.65; N, 18.43. Found: C, 47.49, 47.49; H, 2.91, 2.72; N, 18.08, 18.24 (Kjeldahl).

The most striking property of this substance was that on treatment with a solution of potassium hydroxide or potassium carbonate, it was converted into a yellow potassium salt. Recrystallization from water, in which it was quite soluble, yielded yellow needle-like blades that charred at a temperature considerably above 300°.

Anal. Calcd. for $C_8H_2N_4O_4K_2$: C, 32.41; H, 0.68; N, 18.91; K, 26.40. Found: C, 32.46, 32.69; H, 1.31, 1.00;¹⁴ N, 18.45, 18.52; K, 26.04.

¹⁴ The percentage of hydrogen is so low that the values obtained are probably not very significant.

A water solution of the salt on acidification with hydrochloric acid precipitated a colorless solid which did not melt at 300° .

2-Imidazolone.—The application of the usual methods for the decarboxylation of an acid to 2-imidazolone-4-carboxylic acid was unsuccessful. Direct heating at atmospheric pressure was impractical owing to the fact, as later found out, that the acid melted with decomposition above the decomposition point of 2-imidazolone. The experiments in which the acid was heated in some medium such as diphenylmethane led to an amorphous brown product from which nothing crystalline could be isolated. It was finally found that heating the acid in a vacuum yielded a generous amount of 2-imidazolone. Under these conditions, the imidazolone, as soon as it was formed, sublimed to the cooler part of the flask and thus was removed from the heated zone.

One gram of finely powdered 2-imidazolone-4-carboxylic acid in a round-bottomed flask with a long wide neck was heated in an oil-bath at 220° for six hours at 2 mm. pressure. Glistening crystals were gradually deposited on the neck of the flask; yield, 0.45 g. It was recrystallized from 1 cc. of boiling water from which it separated as dendrites of pyramidal crystals. 2-Imidazolone colors at 225° and decomposes to a red liquid at 250 – 251° (corr.).

Anal. Calcd. for $C_4H_4ON_2$: C, 42.84; H, 4.80; N, 33.33. Found: C, 42.89; H, 5.08; N, 33.18.

It gives the dark red color reaction with aqueous ferric chloride previously described by Fenton and Wilks. It does not, however, give the Weidel color reaction. As this test is very sensitive and as it has never before been reported to be given by imidazolones, it would appear that the observation of the English investigators was probably due to the presence of a small amount of an impurity. The pink color reaction with hydrochloric acid and hydrogen peroxide, also described by Fenton and Wilks, is extremely faint, so faint that it can hardly be classified as being a significant property of 2-imidazolone.

Fenton and Wilks reported the results of a crystallographic examination of their crystals. A cursory examination of the crystals obtained by the decarboxylation of 2-imidazolone-4-carboxylic acid indicated that they were apparently uniaxial, optically negative and highly birefringent. They possibly have a lower symmetry than that of the tetragonal system, and appear to be identical with those described by Fenton and Wilks.

1,3-Diacetyl-2-imidazolone.—The acetyl derivative was made in the same manner as described by Fenton and Wilks. The easiest method of purification was that of sublimation. It occurs as long silky needles melting at 105 – 106° .

Anal. Calcd. for $C_8H_6O_4N_2$: C, 49.98; H, 4.80; N, 16.67. Found: C, 49.92, 49.71; H, 4.72, 4.74; N, 16.75, 16.61.

Fenton and Wilks reported a melting point of 106° . The percentages of carbon and hydrogen found by them were 48.07 and 5.00 (calcd. 47.62 and 4.76), respectively. Unfortunately the analysis for nitrogen, which would have been more significant, was not made. It seems reasonable to believe that Fenton and Wilks were dealing with the diacetyl derivative and that their analysis for carbon was somewhat low.

Summary

1. Urea and tartaric acid in fuming sulfuric acid yield 2-imidazolone-4-carboxylic acid. Its structure was proved and a number of derivatives prepared.

2. The synthesis of 2-imidazolone was effected by the decarboxylation of 2-imidazolone-4-carboxylic acid. It is probably identical with the "iso-imidazolone" of Fenton and Wilks.

WASHINGTON, D. C.

[A COMMUNICATION FROM THE LABORATORY OF ORGANIC CHEMISTRY, UNIVERSITY OF WISCONSIN]

ALCOHOLYSIS AND HYDROLYSIS OF 1,3-DIKETONES AND BETA-KETO ESTERS

BY RALPH CONNOR AND HOMER ADKINS

RECEIVED MAY 9, 1932

PUBLISHED AUGUST 5, 1932

A 1,3-diketone such as diacetylmethane does not undergo alcoholysis, as indicated in equation I, at temperatures obtainable in the liquid phase at atmospheric pressure unless a catalyst is used.

Hydrogen chloride and sodium ethoxide are active in bringing about this reaction but it is necessary to use high concentrations of the so-called catalyst in order to obtain a reasonably rapid rate of alcoholysis. For example, one hundred hours were required at 60° in order to completely cleave diacetylmethane even when the ratio of hydrogen chloride to diketone was 1 to 3.¹ The necessity for these high concentrations of catalyst indicates very clearly that hydrogen chloride as well as sodium ethoxide form compounds with the diketone or ester or both, to such an extent that the course of the cleavage may be profoundly modified. That the course of the reaction is modified by the environment during cleavage is further evidenced by the variation in the ratio of the two alternative modes of cleavage of an unsymmetrical 1,3-diketone as indicated in equations II and III.²

These considerations, in conjunction with the fact that no conditions were found under which β -keto esters underwent alcoholysis in the presence of hydrogen chloride, led to a search for conditions under which 1,3-diketones and β -ketonic esters would undergo alcoholysis even in the absence of any added catalyst. Conditions suitable for such an alcoholysis were suggested by the finding³ that dehydroacetic acid showed a 70% alcoholysis at 190° after two hours, the product being acetoacetic ester (not acetoacetic acid as indicated in the table on p. 5195 of the paper just cited). Since dehydroacetic acid is a 1,3-diketone as well as a di- β -keto ester, this result suggests what is now known to be true, *i. e.*, that the diketones may be split under conditions which leave β -keto esters unaffected.

Alcoholysis of 1,3-Diketones.—The alcoholysis of diacetyl- and dibenzoylmethanes and of five unsymmetrical acetylmethanes (*i. e.*, *n*-valeryl, isovaleryl, trimethylacetyl, cyclohexanoyl and benzoyl) has been

³ Adkins, Connor and Cramer, *ibid.*, **52**, 5194 (1930).

studied at 150–250° under about 100 atmospheres' pressure, using (1) alcohol which had been dried over lime and sodium ethoxide, (2) alcohol which had been dried over lime only and (3) alcohol which contained 0.2% of aluminum ethoxide. A summary of the results has been given in Table I along with the results obtained by Kutz² in the alcoholysis of the same diketones using hydrogen chloride as a catalyst at 60° and atmospheric pressure.

TABLE I

ALCOHOLYSIS OF 1,3-DIKETONES^a

Diketone	EtOH (Dry) ^b		EtOH (Moist) ^c		EtOH + Al(OEt) ₃ ^d		EtOH + HCl ^e	
	% Alco- holysis	% CH ₃ CO	% Alco- holysis	% CH ₃ CO	% Alco- holysis	% CH ₃ CO	% Alco- holysis	% CH ₃ CO
Acetyl- <i>n</i> -valeryl- methane	27	50	100	53	100	61

	9 (150°)		34 (150°)					
Diacetylmethane	13	...	100	100	...
	25 (250°)							

^a The experimental conditions for alcoholysis unless noted otherwise were as follows: 37.5 and 187.5 millimoles of diketone and ethanol, respectively, 200°, eight hours and 120 ± 30 atmospheres' pressure. ^b The ethanol was dried twice over lime. ^c The ethanol was dried over lime and aluminum ethoxide. ^d The ethanol contained 0.2% aluminum ethoxide. ^e These data were previously reported by Kutz and Adkins for alcoholysis at 60° for 100–150 hours.

The outstanding facts that emerge from these data are:

(1) Alcohol which has been dried with aluminum ethoxide was quite inactive for the alcoholysis of 1,3-diketones. For example, diacetylmethane was cleaved to the extent of only 25% after eight hours at 250°.

(2) Alcohol which contained the few tenths of one per cent. of water which was not removed by drying it twice with a good quality of lime was a rather active reagent for the cleavage of 1,3-diketones. For example, diacetylmethane was 100% cleaved after eight hours at 200° when this moist ethanol was used. This fact taken in conjunction with the inactivity of ethanol dried over aluminum ethoxide renders it open to question whether ethanol completely free of water would react at all with diketones.

(3) Aluminum ethoxide was a very active catalyst for the alcoholysis of 1,3-diketones. For example, the amount of alcoholysis, of acetylisovaleryl-

methane was more than four times as great for a given length of time in the presence of aluminum ethoxide as it was in dry ethanol.

(4) Dibenzoylmethane which was resistant to alcoholysis in the presence of hydrogen chloride at 60° and atmospheric pressure was readily cleaved at 200° either with dry ethanol or ethanol containing aluminum ethoxide. In fact the order of rate of cleavage of dibenzoyl-, acetylbenzoyl- and diacetylmethane in dry ethanol at 200° is the reverse of that previously found for the relative rates of cleavage of the three diketones at 60° in ethanol containing hydrogen chloride.

(5) Branching of the chain adjacent to one carbonyl group decreased the rate of alcoholysis with dry ethanol just as it did with ethanol containing hydrogen chloride.

(6) The ratio of the products formed in the cleavage of an unsymmetrical 1,3-diketone was a function of the experimental conditions under which alcoholysis occurred. For example, acetylbenzoylmethane which gave only ethyl acetate and acetophenone when it was cleaved with dry ethanol or with ethanol and hydrogen chloride gave a 20% yield of ethyl benzoate and acetone when it was cleaved with moist ethanol or with ethanol containing aluminum ethoxide. In every case the acetyl cleavage was less with dry ethanol and with ethanol containing aluminum ethoxide than it was with ethanol and hydrogen chloride.

Alcoholysis of β -Keto Esters.—A study of the alcoholysis of β -keto esters is considerably more complicated than is one of the 1,3-diketones. This results from the greater stability of the keto esters and from the fact that such a keto ester may undergo condensation to compounds of the dehydroacetic acid type as well as cleavage. The cleavage reactions with water and ethanol are formulated as

There is recorded in Table II a summary of experimental results obtained in subjecting various β -keto esters to the action of ethanol and butanol.

The data in Table II show clearly certain facts in regard to the alcoholysis of β -keto esters.

(1) Ethanol which has been dried over aluminum ethoxide was not an active reagent for the cleavage of β -keto esters. For example, from 51 to 68% of benzoylactic, benzylacetoacetic and acetoacetic esters were recovered from a reaction mixture after eight to nine hours at 250°, while the remainder had chiefly undergone hydrolysis and condensation.

(2) Ethanol dried twice over lime and so containing a few tenths of one per cent. of water was an active reagent and brought about almost identically the same amount of reaction IV (acetone) as of reaction V (ethyl acetate), although of course twice as many moles of ethyl acetate as of acetone were produced.

TABLE II
 ALCOHOLYSIS OF β -Keto Esters

Ester Name	m. mole	Reagent name ^a	m. mole	Time, hrs.	Temp., °C.	Hy-	Alco-	Con-	Unre-	(Loss, %)

Benzoylactic	200	EtOH ^d	1000	8	250	36	47	16	0	3	0
Benzoylactic	83	EtOH ^b	633	9	250	29	2	0	64	5	0
Malonic	319	EtOH ^d	1545	8	250	..	20	9	61	8	2

^a Terms in this column have the same significance as in Table I. It should be noted that the hydrogen introduced into the bomb was moist, and when it was allowed to escape through dehydrite the latter gained 0.86 g. in weight.

(3) Aluminum ethoxide was an active catalyst for alcoholysis. Since by its presence it reduces, if it does not eliminate, water from the sphere of reaction, there occurs little hydrolysis of the keto ester.

(4) Acetoacetic ester did not undergo alcoholysis at all readily at 200° even with moist alcohol, so that a temperature of 250° was required for the ready cleavage of the keto ester.

(5) *n*-Butanol was a more effective reagent for the alcoholysis of acetoacetic ester than was ethanol, apparently because butanol was more easily and more completely dried.

(6) Dimethylacetoacetic ester was found to be more resistant to alcoholysis than was the parent keto ester, there being only 12% cleavage after eight hours at 250°.

(7) The two monosubstituted (methyl and benzyl) acetoacetic esters underwent alcoholysis at least as readily as the parent ester, giving good yields of the esters of acetic and propionic, and of acetic and β -phenylpropionic acids, respectively.

(8) Benzoylactic ester even in the presence of aluminum ethoxide gave a high percentage of hydrolysis to acetophenone as well as alcoholysis to ethyl acetate and benzoate.

Hydrolysis of 1,3-Diketones and β -Keto Esters.—There is recorded in Table III a summary of the data obtained in subjecting various keto esters and acetylbenzoylmethane to hydrolysis. The important con-

clusions that may be drawn from the data in Table III would appear to be:

(1) The method of cleaving β -keto esters with water or with water containing a base at 200° gave excellent yields of the corresponding ketones, with little or no acid formation. Meerwein⁴ subjected certain β -keto esters to hydrolysis at 200° in a sealed glass tube. He obtained a 73% yield of acetophenone from benzoylacetate, an 88% yield of 4-phenylbutanone-2 from α -benzylacetoacetate and unstated amounts of ketones from five other esters which were reported as completely hydrolyzed.

TABLE III
HYDROLYSIS OF β -KETO ESTERS AND 1,3-DIKETONES

Compound		Reagents		Time, hrs.	Temp., °C.	Yield (%) of product(s)
Name	Milli-moles	Name	Milli-moles			
Acetoacetic ester	385	Water	1945	9 ^b	200	97% acetone
Benzylacetoacetic ester	114	Water	1390	8 ^b	200	97% 4-phenylbutanone-2
Diethylacetoacetic ester	168	EtOH ^a	860	11	250	No cleavage

Ethyl α, α -diethyl- β -hydroxybutyrate	53	Water	1060	8	250	No hydrolysis
Acetylbenzoylmethane	37.5	Water ^c	188	8	200	76% acetic acid; 24% benzoic acid

^a Ethanol used as a solvent to ensure contact of reactants. ^b The time intervals are no doubt much longer than necessary for complete reaction as 385 m. moles of acetoacetic ester was completely hydrolyzed by 400 m. moles of water within one hour at 200°. ^c Cleavage was not complete after eight hours at 200°, so 555 m. moles of water was added and the mixture kept at 250° for five and one-half hours. ^d The amount of ethanol used rendered the isolation of the ketone more difficult and probably materially reduced the yield of ketone obtained.

(2) The dimethyl- and diethylacetoacetic esters were quite resistant to hydrolysis even at 250°. The diethyl ester showed no trace of hydrolysis after repeated attempts at 250°. This resistance to hydrolysis of trisubstituted acetic acids is not limited to keto esters but was also manifested by trimethylacetic ester and especially by α, α -diethyl- β -hydroxybutyric ester, which showed no hydrolysis after eight hours at 250°. The inactivity of these esters would appear to be the result of steric hindrance. The resistance to hydrolysis at atmospheric pressure of the dialkylacetoacetic esters, especially those containing alkyl groups larger than methyl, was observed by Michael⁵ and utilized by him in purifying dialkylacetoacetic esters.

⁴ Meerwein, *Ann.*, **398**, 242 (1913).

⁵ Michael, *Ber.*, **38**, 2083 (1905).

(3) The ratio of cleavage products in the hydrolysis of acetylbenzoylmethane with water at 250° was similar to that obtained with moist ethanol.

Experimental Part

All of the experiments on the alcoholysis of diketones and keto esters reported in this paper were carried out in the apparatus recently described⁶ in glass or copper containers under a pressure of 90–150 atmospheres of hydrogen. The diketones were from the same preparation as those used by Kutz and the reaction products, with the exceptions noted below, were analyzed as described by him.⁷ The exceptions were made in that no phenylhydrazine was used if alcoholysis was complete as evidenced by a test with ferric chloride, and in that 2,4-dinitrophenylhydrazine and benzyl alcohol were used instead of phenylhydrazine and butanol in the determination of the extent of cleavage of dibenzoylmethane.

The method of analysis of the reaction products of the alcoholysis of β -keto esters and the calculation of the yields is best presented in describing a specific experiment. Seventy-five grams (0.58 mole) of acetoacetic ester and 132.7 g. (2.88 moles) of ethanol containing 0.26 g. of aluminum ethoxide were heated for twelve hours at 250°. The reaction products after removal from the bomb weighed 197.5 g. The loss (10.2 g.) was in part mechanical and in part due to the escape of carbon dioxide. The latter was identified by bubbling the gas from the bomb through a solution of barium chloride. The bomb and liner were washed out with ethanol and the combined liquid reaction products (which showed no enol test) distilled through a Widmer column having a spiral 25 cm. in length. All except 17.0 g. distilled below 79°. The mixture of acetone, ethanol and ethyl acetate was then analyzed for acetone by the sodium sulfite method⁸ and for the ester by saponification. The acid used in the analysis for acetone had been standardized against solutions of acetone containing ethanol and ethyl acetate.⁹ These analyses showed 5.86 g. of acetone (0.101 mole) and 51.9 g. of ethyl acetate (0.59 mole). The ketone was identified by the preparation of its 2,4-dinitrophenylhydrazone (m. p. 127–128°) and the determination of a mixed melting point (126–128°) with an authentic sample of the hydrazone of acetone. The percentages of hydrolysis and alcoholysis were calculated on the basis of equations IV and V directly from the amounts of acetone and ethyl acetate as found by analysis. The percentage conversion of acetoacetic ester to condensation products of b. p. above 45° (16 mm.) was calculated on the basis of its weight (17.0 g.) and the assumption that it was molecularly equivalent to acetoacetic ester. The amount of carbon dioxide (equation V) was calculated from the amount of acetone found and deducted from the 10 g. loss found on opening the bomb. This reduced the mechanical loss to 3% and left 5% of the acetoacetic ester unaccounted for.

This procedure for the study of the products from the alcoholysis was modified in some experiments as noted below. (1) If any unchanged keto ester remained after alcoholysis it was separated from the other products by fractionation. (2) Duclaux values were obtained upon the acids from the alcoholysis of α -methyl acetoacetic

⁶ Adkins and Cramer, *THIS JOURNAL*, **52**, 4349 (1930); see also *Ind. Eng. Chem., Anal. Ed.*, **4**, 342 (1932).

ester and indicated that both propionic and acetic acids were formed. (3) The alcoholysis of α -benzylacetoacetic ester gave ethyl acetate, ethyl β -phenylpropionate and 4-phenylbutanone-2. The ethyl acetate was obtained as in the alcoholysis of acetoacetic ester but the higher boiling ester and the ketone were obtained in a fraction 104–105 (9 mm.). In general the ester was determined by saponification and the ketone by difference. In one run the analytical procedure was checked by the isolation of the ketone. (4) The alcoholysis of benzoylacetic ester also gives a mixture of esters and ketone which were determined as in the case of α -benzylacetoacetic ester, except that in this case the mixture of ester and ketone boiled at 90–95° (12 mm.).

The acetone and acetic acid obtained by the hydrolysis of acetoacetic ester were determined by titration. 4-Phenylbutanone-2 resulting from the hydrolysis of α -benzylacetoacetic ester was extracted with ether, dried over potassium carbonate and 16.4 g. distilled at 110.5–111° (13 mm.). Ethyl α,α -diethylacetoacetate after attempted hydrolysis was recovered unchanged to the extent of 95.3%.

The products from the hydrolysis of α,α -dimethylacetoacetic ester (25.5 g.) were extracted with ether, dried over sodium sulfate and fractionated. After the removal of the solvent the following fractions were obtained: (1) 75–85°, 5.3 g.; (2) 85–169° 1.9 g.; (3) 169–181° (mostly 170–179°) 9.3 g.; (4) residue, 4.2 g. A good yield of a semicarbazone of m. p. 111–112° was obtained from fraction 1; this corresponds with the melting point (112°) of the semicarbazone of methyl isopropyl ketone. The above figures indicate that approximately one-half of the keto ester was hydrolyzed to the ketone with no evidence for the formation of acids.

The product from the alkaline hydrolysis of α,α -dimethylacetoacetic ester was acidified with sulfuric acid, heated on a steam-bath to complete the expulsion of carbon dioxide, extracted with ether, dried over sodium sulfate and fractionated. Fraction (1) 35–75°, 1.96 g.; (2) 75–85°, 5.49 g.; (3) 85–93° (mostly 91–93°) 4.40 g.; (4) residue, 2.57 g. The residue was no more than the normal amount of liquid held back by the fractionating column and flask used. It contained 0.015 mole of acid. It thus appears that all except approximately 5% of the keto ester was converted to the ketone. The procedure in working up the product from the alkaline hydrolysis of diethylacetoacetic ester was essentially the same as that just described.

Summary

The alcoholysis and hydrolysis of a number of 1,3-diketones and β -keto esters at 150–250° under pressures in the vicinity of 100 atmospheres have been investigated. Ethanol which had been dried over aluminum ethoxide was found to be a rather inactive reagent for the alcoholysis of 1,3-diketones and β -keto esters, while ethanol containing a few tenths of one per cent. of water was a very much more active reagent. Aluminum ethoxide was found to be quite an active catalyst for alcoholysis. The keto esters were much more resistant to alcoholysis than were the diketones, the reaction of the latter proceeding approximately as rapidly at 150° as did the alcoholysis of the keto esters at 250°. α -Methyl- and α -benzylacetoacetic esters underwent alcoholysis approximately as rapidly as did the parent ester, while the dimethyl and diethylacetoacetic esters were very resistant to cleavage. Excellent yields of ketones were obtained by the hydrolysis at 200° of several β -keto esters. Dialkyl substituted β -keto esters were quite stable toward water at 200° so that they may be freed of

monoalkyl substituted β -keto esters by such a treatment. The hydrolysis of these dialkyl β -keto esters necessitates the use of alkali at 250°. The ratio of the products formed in the cleavage of unsymmetrical 1,3-diketones varied greatly with variation in the environment during cleavage.

THE USE OF KETENE IN THE PREPARATION OF SIMPLE AND MIXED ACID ANHYDRIDES

BY CHARLES D. HURD AND MALCOLM F. DULL

RECEIVED MAY 13, 1932

PUBLISHED AUGUST 5, 1932

Mixed acid anhydrides, $R-CO-O-CO-CH_3$, are generally made¹ either by refluxing the acid, $RCOOH$, with acetic anhydride or by the interaction² of any acyl chloride and sodium acetate or by reaction of the acid with acetyl chloride and pyridine. A purification procedure is essential in all of these cases. Such anhydrides as acetic propionic anhydride or acetic isovaleric anhydride are sufficiently stable to be distilled under diminished pressure, but the tendency of mixed anhydrides to disproportionate into the two symmetrical anhydrides often makes the isolation of the mixed anhydride difficult or impossible.

Ketene is an acetylating agent but it has never been considered for use in preparing mixed acetic anhydrides. Ketenes which have been added to acids to convert them into mixed anhydrides are diphenylketene and carbon suboxide.³ Van Alphen's is the only account⁴ of the reaction of ketene itself with acids. He used phenolic acids and observed acetylation of the phenolic group. No mention was made of the production of mixed anhydrides.

In the present work it has been found that ketene readily attaches itself to aliphatic or aromatic acids giving rise to mixed acetic anhydrides

Since nothing else is formed, the purification procedure is greatly simplified. Thus, using ketene, acetic acid was quantitatively changed into acetic anhydride, *n*-butyric acid into acetic butyric anhydride, benzoic acid into acetic benzoic anhydride and furoic acid into acetic furoic anhydride.

Distillation of acetic benzoic anhydride or of acetic furoic anhydride, both of which were oils, gave rise to benzoic anhydride and furoic anhydride,

both solids, in excellent yields. Disproportionation was evident also with acetic butyric anhydride. Thus, this use of ketene serves to produce not only mixed acetic anhydrides, but also symmetrical acid anhydrides by pyrolysis of the mixed anhydrides. The reaction should be a perfectly general one for acids which possess no interfering groups such as hydroxyl or amino.

With aniline, acetic benzoic anhydride is converted into benzoic acid and acetanilide

and not into acetic acid and benzanilide. This agrees with Béhal's finding that ammonia reacted with the mixed anhydride to give benzoic acid and acetamide almost exclusively. If the mixed anhydride was left for twenty-four hours before adding the aniline, both of the anilides and both acids were formed indicating the gradual transformation of the mixed anhydride into benzoic anhydride and acetic anhydride.

Acetic furoic anhydride behaved analogously in its reaction with aniline. The only anilide formed was acetanilide. In the case of acetic butyric anhydride, both anilides were produced but the yield of butyranilide exceeded that of acetanilide.

This behavior of aniline toward the mixed acetic anhydrides is predictable on the basis of the generally recognized greater electron attraction of aryl radicals than alkyl and the slightly greater attraction of methyl than *n*-propyl inasmuch as the molecule of the mixed anhydride is entirely symmetrical except for the terminal groups. The electronic configuration for benzoic acetic anhydride which expresses these factors is

That the absorption of ketene by acids is not limited to organic acids was demonstrated by a few preliminary experiments with sulfuric and phosphoric acids. Ketene was quantitatively absorbed, presumably with the formation of acetylsulfuric acid and acetylphosphoric acid. The utility of the method with other inorganic acids, for example, in the synthesis of acetyl nitrate, is also evident.

Experimental Part

Ketene was prepared from acetone⁵ by pyrolysis. Instead of distilling the acetone into the reaction tube it was dropped in directly from a separatory funnel. In this way, such a rapid flow of acetone was maintained that the extent of decomposition at 700° was limited to 5-6%. Thus, from 108 g. of acetone 102 g. was recovered in an experiment lasting thirty minutes. The other 6 g. gave rise to a 72% yield of ketene since 10 g. of acetanilide was produced from it (*via* aniline + ketene).

Acetic Acid⁶ and Ketene.—Slightly more than the theoretical quantity of ketene

⁵ Hurd, "Organic Syntheses," John Wiley and Sons, New York, 1924, Vol. IV, p. 40.

⁶ Compare Hurd and Martin, *THIS JOURNAL*, 51, 3614 (1929).

was bubbled into acetic acid. From 20 cc. of this which was distilled, 17 cc. was collected between 136–138°. Thus, the conversion of acetic acid into acetic anhydride is nearly quantitative.

***n*-Butyric Acid and Ketene.**—Two grams of butyric acid (b. p. 161–163°) was treated with the calculated quantity of ketene. Any admixed acetone was evaporated off *in vacuo* and the residual acetic butyric anhydride was analyzed. Whitford's method of analysis⁷, which was developed for acetic anhydride, was found to apply with the mixed acetic anhydride. In it, the anhydride reacts with dry oxalic acid and pyridine to liberate carbon monoxide and carbon dioxide which are collected.

Anal. Subs., 0.2166, 0.2112; calcd. cc. of gas for $\text{CH}_3\text{COOCOC}_3\text{H}_7$, 72.9, 72.7; found, cc., 72.0, 72.1; per cent. of $\text{C}_6\text{H}_{10}\text{O}_3$, 98.7, 99.1.

The acetic butyric anhydride was found to boil⁸ at 147–160°, above which the boiling point rose abruptly to that of butyric anhydride itself. At 18 mm. the mixed anhydride boiled at 70–85°. With aniline it reacted vigorously, yielding butyranilide and a smaller quantity of acetanilide. The butyranilide crystallized first and was removed but the acetanilide crystallized almost immediately thereafter. After recrystallization from water the former melted at 89–90° and the latter at 110–112°.

Inasmuch as there was no sharp boiling fraction for the mixed anhydride in the above experiment, it was repeated on a larger scale. Twenty grams of redistilled *n*-butyric acid (b. p. 161–162°) was treated with ketene until addition of anhydrous sodium carbonate failed to result in an evolution of carbon dioxide. The crude product was allowed to stand over anhydrous sodium carbonate for two hours, after which the excess solvent (anhydrous ether and some acetone which had carried over) was removed by evacuating for half an hour with a water pump. A portion, treated with aniline, resulted in the formation of both acetanilide and butyranilide, the latter predominating.

The crude material (30 g.) was then fractionated at 7 mm. pressure. The first fraction of 15.5 g. was collected at 41–60°, the second of 10.5 g. at 60–66°, and the third of about 3 g. at 66–67°. The third fraction was butyric anhydride, for it yielded only butyranilide on treatment with aniline. The first fraction produced acetanilide and butyranilide with acetanilide in excess. The fraction was evidently a mixture of acetic anhydride and acetic butyric anhydride. Redistillation of this fraction failed to produce a constant boiling fraction. It distilled at 41–62°.

The second fraction (10.5 g.) gave rise to both butyranilide and acetanilide with the latter in considerably smaller amounts. On redistillation, it came over almost entirely at 63–64.5°. A fraction was thus obtained weighing 9.5 g. which, with aniline, again yielded both butyranilide and acetanilide. Much of both anilides was lost in the steps of purification but it was certain that more butyranilide was obtained than acetanilide.

Benzoic Acid.—(a) Ketene was passed through a tower which contained powdered benzoic acid. Some ketene escaped but some reacted as witnessed by a heat of reaction and by a gradual liquefaction of the solid acid into the liquid benzoic acetic anhydride. Accumulation of this mixed anhydride was slow by this method. Furthermore, the heat of reaction seemed to cause a partial disproportionation into benzoic anhydride.

(b) Using ether as a solvent, the reaction was more rapid and the temperature was kept under control. Ketene was passed into a solution of twenty grams of benzoic acid in 100 cc. of ether. To follow the reaction a stirring rod was dipped occasionally into the solution and withdrawn. Evaporation of the solvent left a solid at the start

⁷ Whitford, THIS JOURNAL, 47, 2939 (1925).

⁸ Autenrieth, *Ber.*, 34, 177 (1901), gave 155–175° as the b. p.

but only an oil at the conclusion of the reaction. After evaporation of the ether, 31–32 g. of benzoic acetic anhydride remained which is a quantitative yield.

Identification of Benzoic Acetic Anhydride

(a) **Analysis**, using dry oxalic acid and pyridine.

Anal. Subs. 0.2131, 0.2213; calcd. cc. of gas for $\text{CH}_3\text{COOCOC}_6\text{H}_5$, 58.2, 60.4; found, cc., 57.5, 59.3; per cent. of $\text{C}_9\text{H}_8\text{O}_4$, 98.8, 98.2.

(b) **Disproportionation to Benzoic Anhydride**.—The 31.5 g. of oil was distilled at 18 mm., giving 13 g. of acetic anhydride (collected below 210°) and 18.5 g. of benzoic anhydride which boiled at 210 – 210.5° . The latter solidified and melted at 41.5° . The 18.5 g. represents a 96% yield of benzoic anhydride.

In another run, two 25-g. portions of benzoic acid (each in 125 cc. of ether at room temperature) were connected in series to a stream of ketene. (The two were interchanged when the first portion was nearly converted.) In this run the acetone was dropped in the furnace at a rate of 4.5 cc. per minute. The time for the entire 50 g. to be changed to the mixed anhydride was 135 minutes. Distillation of the mixed anhydride gave 42 g. of benzoic anhydride (m. p. 42°) or a 93% yield.

(c) **Reaction with Aniline**.—To 10 g. of benzoic acetic anhydride (similar preparation from another experiment), 5.5 g. of aniline was added. Much heat was evolved and on cooling the mass solidified. By extraction with diluted sodium carbonate and subsequent acidification 6.5 g. of benzoic acid was obtained as compared with a theoretical yield of 7.4 g. The residue of acetanilide was dissolved in boiling water, whereupon 6.8 g. (calcd. is 8.2 g.) precipitated after filtering and cooling. About 0.3 g. of benzanilide, m. p. 163° , resisted solution in the water.

If the 10 g. of mixed anhydride was left for twenty-four hours before mixing it with aniline, there was considerable disproportionation as evidenced by the formation of 3.3 g. of benzoic acid, 4.1 g. of acetanilide and 4.2 g. of benzanilide.

Furoic Acid.—Ketene was passed into a solution of 25 g. of furoic acid in 150 cc. of ordinary ether. The details of this reaction were similar to those given with benzoic acid in ether solution. This run was completed in seventy-five minutes. On evaporation of the solvents, an oil remained which was furoic acetic anhydride. The yield was quantitative.

Anal. Subs. 0.1987, 0.2016; calcd. cc. of gas for $\text{CH}_3\text{COOCOC}_4\text{H}_5\text{O}$, 57.8, 58.6; found, cc., 56.7, 57.1. Per cent. of $\text{C}_7\text{H}_6\text{O}_4$, 98.1, 97.4.

Reaction with Aniline.—The mixed anhydride reacted vigorously with aniline. The exclusive products of the reaction were acetanilide (m. p. 113 – 114°) and furoic acid (m. p. 129 – 131°) which were separated and purified by crystallization from water.

Vacuum Distillation of Furoic Acetic Anhydride.—The mixed anhydride from 10 g. of furoic acid was distilled at 5 mm. Eleven grams of an almost odorless distillate was collected at 109 – 110° , and 2.7 g. at 150 – 152° . The latter quickly solidified (m. p. 71°) and was identified as furoic anhydride.⁹ The eleven grams of liquid distillate was largely unchanged furoic acetic anhydride. Considerable disproportionation of the mixed anhydride occurred when the distillation was performed at 22 mm., the furoic anhydride distilling at 196 – 197° . Using atmospheric pressure for the distillation, there was complete and rapid pyrolysis to the symmetrical anhydrides.

Summary

Mixed acetic anhydrides, RCO—O—COCH_3 , may be prepared very smoothly by interaction of ketene with acids. The mixed anhydrides

⁹ Baum, *Ber.*, **34**, 2505 (1901).

were analyzed, using dry oxalic acid and pyridine. The reaction with aniline was investigated. The disproportionation induced by heat was found to be a convenient method for synthesizing symmetrical acid anhydrides.

NEOPENTYL ALCOHOL AND ITS REARRANGEMENT PRODUCTS¹

BY FRANK C. WHITMORE AND HENRY S. ROTHROCK²

RECEIVED MAY 17, 1932

PUBLISHED AUGUST 5, 1932

The literature on neopentyl alcohol (*tert.*-butylcarbinol) and the related halides³ is unsatisfactorily incomplete, especially in view of the fact that these substances represent the simplest case in which removal of the alcoholic hydroxyl results in complete or nearly complete rearrangement of the carbon skeleton.⁴

The present study fills some of the gaps in our knowledge of this interesting group of substances. Neopentyl alcohol is stable to heat. Seven weeks at 230–240° gives no change. Heating to similar temperatures with iodine, anhydrous potassium carbonate or traces of hydrogen chloride gives little or no change. It dissolves in cold concentrated sulfuric acid with the formation of an acid ester from which the original alcohol can be recovered.

The preparation of halides from neopentyl alcohol is extraordinarily difficult. Its reactivity is much less than that of *n*-butyl alcohol. Dry hydrogen bromide very slowly forms an oxonium salt with neopentyl alcohol. This is stable at 40° but is slowly converted at 65° to a mixture of amyl bromides containing approximately 72% tertiary amyl bromide, 8% of a secondary bromide, probably secondary isoamyl bromide and 20% of one or more primary bromides. The composition of this mixture is not changed by heating at 105°.

The problem of the neopentyl halides and their rearrangements is being intensively studied in this Laboratory.

Experimental

The neopentyl alcohol used in this research was prepared from *tert.*-butylmagnesium chloride and formaldehyde by R. W. Beattie, of the Intermediate Laboratory of the Public Health Institute of Chicago.

Stability of Neopentyl Alcohol on Heating.—The relatively high melting point of

⁴ See p. 3279.

the alcohol (52°) was used in detecting any change due to the action of heat or reagents. This method was rendered more delicate by the large freezing point constant of the alcohol. This was found to be 11.0 ± 0.2 as compared with 5.1 for benzene and 1.86 for water. Thus 5% of water in the alcohol renders it liquid at room temperature.

A sample of neopentyl alcohol of m. p. 50° was sealed in a Pyrex tube filled with carbon dioxide, and heated at 230–240° for fifteen hours. The tube was then cooled and the melting point determined without opening the tube. The m. p. was 44–46°. The heating at 230–240° was then continued for forty-eight days, at the end of which time the m. p. was still 44–46°.

The Action of Reagents with Neopentyl Alcohol

(a) **Iodine.**—A sample of the alcohol (m. p. 50°) was sealed in a Pyrex tube with a crystal of iodine and heated at 230–240° for fifteen hours. A slight charring occurred and the m. p. dropped to 41–43°. After heating again for forty-eight days the m. p. was still 41–43°.

(b) **Anhydrous Potassium Carbonate.**—A sample of alcohol (m. p. 52°) was heated in a sealed tube with an equal weight of freshly dehydrated potassium carbonate at 225° for ten hours. The m. p. was 49°. After heating again for seven days at 225° the m. p. was 48–49°.

(c) **Traces of Hydrogen Chloride.**—Approximately 5 cc. of dry hydrogen chloride gas was passed into 4.5 g. of neopentyl alcohol (m. p. 51°) in a Pyrex tube. The tube was sealed and heated for thirty-four hours at 175°. The m. p. was 43–45°. The material was slightly pink. The tube was heated for two days more at 175°, three days at 200° and finally two weeks at 200° without any further change in the m. p. after each of these periods.

(d) **Cold Concentrated Sulfuric Acid.**—A mixture of 5 g. of neopentyl alcohol (m. p. 50°) and 5 cc. of c. p. sulfuric acid was prepared at 0°. About ten minutes' shaking was required to effect complete solution. The mixture was poured on 50 g. of finely ground ice. After the ice had melted, the solution was made barely alkaline with 25% sodium hydroxide solution and saturated with solid potassium carbonate. An upper layer (2 g.) separated which was neopentyl alcohol, m. p. 40–42°. The aqueous layer was extracted with ether, the ether solution dried with potassium carbonate and the ether removed by distillation. The residue reacted with phenyl isocyanate to give 3 g. of the phenyl urethan of neopentyl alcohol, m. p. 108–110°. This corresponded to 1.5 g. of the alcohol. Since the above experiment was carried out in such a way as to avoid mechanical loss of the alcohol and yet only 3.5 g. was recovered of the 5 g. used, it appeared that some other product was formed. This proved to be a stable acid ester of the alcohol, according to the following experiment.

A solution of neopentyl alcohol in c. p. sulfuric acid was allowed to stand at 20°. The solution first turned red and began to deposit crystals after twenty-four hours. After six days the entire mass was solid with crystals. The crystals were soluble in water, alcohol, benzene and ether. When the crystals were refluxed with water and steam distilled, neopentyl alcohol was recovered and identified as the phenyl urethan, m. p. 110–111°. Attempts to make a crystalline barium salt of the acid ester failed.⁵ Treatment of tertiary amyl alcohol with sulfuric acid under the same conditions gave only a red viscous liquid from which the alcohol was recovered on dilution.

Formation of Halides from Neopentyl Alcohol

1. **Action of Hydrogen Chloride.**—All attempts to repeat the work of Tissier and of Richard³ failed to give any chloride. Only one experiment will be described. Twenty-eight grams of neopentyl alcohol in a tube cooled to –10° was saturated with dry

⁵ Cf. Tissier, *Compt. rend.*, **112**, 1065 (1891).

hydrogen chloride gas and sealed. The tube was heated for 206 hours at 62–65°. The contents turned deep red-brown. Only one layer was present at any time. When the tube was cooled and opened, a violent evolution of hydrogen chloride occurred. The contents of the tube dissolved completely in 100 cc. of concentrated hydrochloric acid, indicating the absence of appreciable amounts of chlorides. Extraction with ether gave 10 g. of unchanged neopentyl alcohol. No trace of chloride was detected.

2. **Action of Thionyl Chloride.**—The method of Darzens,⁶ modified until it gave over 30% yields of *n*-butyl chloride from *n*-butyl alcohol, was applied to neopentyl alcohol. Twenty grains of neopentyl alcohol, 21 g. of dry pyridine and 22 cc. of dry ether were placed in a flask provided with a stirrer and a dropping funnel. The mixture was cooled to 0° and a solution of 29 g. of thionyl chloride in 27 cc. of dry ether was added slowly with vigorous stirring and cooling. After twenty-four hours the mixture was worked up in the usual way. This gave 16 g. of neopentyl alcohol, b. p. 108–112°, m. p. 41–43°, but no detectable chloride.

3. **Action of Phosphorus Tribromide.**—Twenty-nine grams of neopentyl alcohol, cooled to 0°, was treated slowly with 30 g. of phosphorus tribromide. After standing at room temperature for eight days, the mixture was poured into a large volume of ice water. A layer lighter than water separated. Most of this was unchanged alcohol, as shown by its solubility in concd. sulfuric acid. The total yield of bromide was 7 g. or 14%. A similar experiment with *n*-butyl alcohol gave a 50% yield.

4. **Action of 48% Hydrobromic Acid.**—Twenty grams of neopentyl alcohol was treated with 150 cc. of 48% hydrobromic acid in an all-glass reflux apparatus. On heating to 50°, the mixture turned black. The mixture was refluxed for twenty-five minutes and allowed to stand overnight. It was then distilled. A fraction passed over at 78–90°. This separated into two layers. The lower layer was water and the upper layer was completely soluble in concd. sulfuric acid, showing the absence of organic bromides. *n*-Butyl alcohol in a similar experiment gave an 80% yield of the bromide.

5. **Action of Dry Hydrogen Bromide.**⁷ (a) **At 40°.**—The work of Tissier³ could not be repeated. Eleven grams of neopentyl alcohol was saturated at –10° with dry hydrogen bromide prepared from bromine and boiling tetralin and purified by red phosphorus and phosphorus pentoxide. Even after this mixture was heated at 40° in a sealed tube for weeks, no separation into layers occurred.

(b) **At 65°.**—Only one of several experiments will be described. This used 188 g. (2.1 moles) of neopentyl alcohol, m. p. 48–50°. When dry hydrogen bromide was passed over the alcohol, the temperature rose rapidly to 50°. Hydrogen bromide was then passed through the liquid and cooling was applied. When it was saturated at 10°, 69 g. of the calculated quantity of 172 g. of hydrogen bromide had been absorbed. The reaction flask was capped with a stopper carrying two toy balloons coated inside with liquid paraffin. After standing for eight days the pressure of hydrogen bromide had dropped although no separate layers had appeared. The mixture was again saturated with hydrogen bromide, this time at 4° with a gain in weight of 37 g. After one day at room temperature, the mixture was again saturated with hydrogen bromide, now at –5°, with a gain in weight of 34 g. At further intervals of six and thirteen days 27 g. and 10 g. of hydrogen bromide were added at –10°. It thus required twenty-eight days to introduce slightly more than the calculated amount of hydrogen bromide. No layers separated.

In order to determine whether or not a stable bromide had been formed, two weighed samples were treated as follows. (1) Dry nitrogen was passed through until no more

⁶ Darzens, *Compt. rend.*, **152**, 1314, 1601 (1911).

⁷ This work was checked and extended by P. A. Krueger, while working in this Laboratory, under a Grant-in-aid from the National Research Council.

hydrogen bromide was driven out. The loss in weight was 49%. The residue smelled like neopentyl alcohol but did not solidify at -20° . It gave a qualitative test for an organic bromide. (2) Shaking for ten minutes with cold water removed 43% of the weight of the mixture as hydrogen bromide, which was determined as silver bromide.

Seventy-eight grams of the mixture containing 40 g. of neopentyl alcohol and 38 g. of hydrogen bromide was sealed in a 300-cc. Pyrex tube and heated at 65° . After twenty days no visible change had occurred. It was opened and saturated with hydrogen bromide at -20° . After five days more at 65° , a few drops separated on top. After two days more, the tube was opened, saturated again at -20° and heated at 65° . Four days later the two layers were about equal in volume. The upper layer increased in volume for nine days more. The upper layer then consisted of 61.5 g. of bromides and the lower layer of 20.1 g. of concd. hydrobromic acid. It thus took forty days at 65° to complete the conversion to bromides.

The bromide layer lost only 1.7 g. when washed with 21.3 g. of 40% hydrobromic acid. It was dried for nineteen hours at 0° over anhydrous calcium bromide. It was then distilled at 23–25 mm. at $22-32^{\circ}$. About 90% distilled at $22-24^{\circ}$ at this pressure. Only 1 cc. of residue was left. The distillate was water-white, of an organic bromide odor and free from hydrogen bromide, yield 53.0 g. A second tube treated in a similar way gave 47.5 g. of bromides distilling at $22-30^{\circ}$ at 25 mm.

Anal. Calcd. for $C_4H_{11}Br$: Br, 52.9. Found: Br, 53.2.

Nature of the Halides from Neopentyl Alcohol

1. **Freezing Point Studies.**⁸—The measurements were made by means of a Leeds and Northrup Type K potentiometer and a chromel-copel thermocouple standardized at the freezing points of pure *n*-heptane (-90.7°) and pure 2,2,4-trimethylpentane (-107.7°). The distilled samples of the bromides from neopentyl alcohol froze from -94 to -104° at which point complete solidification prevented stirring. Check determinations were made repeatedly with both preparations. Most of the material froze at -94 to -99° . Since the neopentyl halides reported in the literature are said to rearrange on heating, a sample was heated for nine hours at 105° . A slight darkening occurred. The bromide was subjected to a pressure of 20 mm. for a few seconds to allow any hydrogen bromide or olefin to boil out. The freezing point was then found to be unchanged, showing that the proportion of various bromides in the mixture had not been changed by heating.

Tertiary amyl alcohol, b. p. $101-101.5^{\circ}$ (735 mm.), was treated with constant boiling hydrobromic acid to form tertiary amyl bromide, b. p. $106.5-107^{\circ}$ (735 mm.). This froze at -82 to -85° . Addition of tertiary amyl bromide to the bromides from neopentyl alcohol raised the m. p. about 2 and 7° , respectively, for the addition of 2 cc. and 5 cc. of the tertiary amyl bromide to 5-cc. portions of the bromides from neopentyl alcohol. It was found that an equimolar solution of pure tertiary amyl bromide and pure ethyl bromide froze about 30° lower than the tertiary amyl bromide. Since the bromides from neopentyl alcohol froze about 10° lower than the tertiary bromide and had their freezing points raised by the addition of the latter, they must contain tertiary amyl bromide with about one-third of a mole of isomeric bromides for each mole of the tertiary bromide. The isomeric bromides were not converted to tertiary bromide by heating at 105° for nine hours.

2. **Analysis for Primary, Secondary and Tertiary Bromides.**—The method of Michael and Zeidler⁹ was used.

⁸ The mixture was studied by means of freezing point measurements because of the supposed instability of the mixture and its tendency to rearrange during chemical reactions.^{3,5}

⁹ Michael and Zeidler, *Ann.*, **385**, 271 (1911).

(a) A weighed sample (about 0.2 g.) of the bromide was shaken vigorously for twenty-five minutes on a mechanical shaker with 10 cc. of distilled water. The solution was then analyzed by the Volhard method, carefully avoiding the presence of any appreciable excess of silver nitrate. In this way 38.2% of bromine was found. Thus 72% of the total bromine in the mixture was removed by hydrolysis with cold water in twenty-five minutes, indicating the presence of approximately that amount of tertiary halide. When an excess of the standard silver nitrate solution (about 0.1 *N*) was shaken with a sample of the bromide, an additional 4.2% of bromine was removed, thus indicating the presence of about 8% of secondary bromide in the mixture. The remaining 20% of bromide in the mixture is undoubtedly primary bromide and accounts for the nitrolic acid test for primary bromides obtained by Tissier.^{3,5} The small amount of the mixture of secondary and primary bromides obtained distilled at 100–115° (secondary isoamyl bromide, b. p. 114°, *sec.*-butylcarbonyl bromide, b. p. 116–118°). Attempts to prepare a Grignard compound from the primary bromide failed. Studies on the primary bromide obtained from neopentyl alcohol are being continued.

Summary

1. The inactivity of neopentyl alcohol to heat and reagents has been demonstrated.

2. The composition of the bromide mixture obtained from neopentyl alcohol has been further studied and found to consist mainly of rearrangement products.

cally active migrating group in the latter case has been assumed to be due to a stable positive radical or carbonium ion, it can be explained equally well on the basis of a stable negative radical.⁷

In the present study it has been found that the amide of tertiary butylacetic acid reacts with sodium hypobromite to give a quantitative yield of neopentylamine and none of the tertiary amylamine which would be formed by a rearrangement of the migrating fragment. This marked difference in the behavior of the neopentyl group in different classes of compounds is best pictured on the basis that when the neopentyl group is deprived of an electron pair, it rearranges and when it is not so deprived it does not rearrange. The break in the molecules may be represented as follows

Experimental Part

Rearrangement of Tertiary Butylacetamide to Neopentylamine.—Two and four-tenths cc. of bromine was added dropwise to a stirred solution of 7.2 g. of sodium hydroxide in 60 cc. of water cooled to 0°. To the clear yellow solution was added immediately 3.50 g. of *tert.*-butylacetamide, m. p. 131°, and stirring was continued at 0° for an hour after the amide had dissolved. Then the reaction mixture was allowed to warm slowly. At room temperature a yellow turbidity appeared; at about 50° the solution became colorless and an oily layer separated. After adding 100 cc. of water the reaction mixture was distilled until no more oil came over. The distillate was collected in dilute hydrochloric acid, giving a yellow solution which became colorless on heating and yielded neopentylamine hydrochloride as a white crystalline residue on evaporation. This was taken up in absolute alcohol, evaporated to dryness and washed with ether. After keeping *in vacuo* until constant weight was obtained, the product weighed 3.60 g. (theoretical yield, 3.76 g.) and melted with decomposition *ca.* 273°. Freund and Lenze⁹ give the melting point of neopentylamine hydrochloride as *ca.* 275°.

Neopentylamine was identified by preparing the several derivatives described below. The melting points are uncorrected.

Sym.-Neopentylphenylthiourea.—The free amine liberated from 0.63 g. of its hydrochloride by adding excess dilute sodium hydroxide was extracted with ether, dried over anhydrous sodium sulfate and mixed with 0.60 g. of phenyl isothiocyanate. After concentrating, the thiourea was precipitated by adding petroleum ether. The product weighed 0.86 g. (theoretical yield 0.98 g.) and melted, without recrystallization, at 134.5°. Freund and Lenze¹⁰ give the melting point of *sym.*-neopentylphenylthiourea as 136°.

Sym.-Neopentylphenylurea was prepared in an analogous manner. The melting point was 155°. Freund and Lenze give 155°.

⁷ Private communication from E. S. Wallis.

⁸ See THIS JOURNAL, p. 3431.

⁹ Freund and Lenze, *Ber.*, **24**, 2156 (1891).

¹⁰ Freund and Lenze, *ibid.*, **23**, 2868 (1890); **24**, 2158 (1891).

Benzoylneopentylamine was prepared from the amine hydrochloride by the Schotten-Baumann method. After recrystallization from petroleum ether it melted at 112–113°.

Rearrangement of Ethyldimethylacetamide.—It was desired to prepare *tert.*-amylamine and its derivatives for purposes of comparison with the neopentylamine. The Hofmann rearrangement of 3.50 g. of ethyldimethylacetamide, m. p. 103°, was carried out as described above. The distillate yielded 2.75 g. of *tert.*-amylamine hydrochloride, m. p. *ca.* 225°. Extraction of the residue in the distilling flask with ether and recrystallization of the product from alcohol gave 0.85 g. of *sym.*-(di-*tert.*-amyl)-urea which sublimed at about 220°.

The urea was identified by fusing with phthalic anhydride¹¹ to give *tert.*-amylphthalimide. After two recrystallizations from dilute alcohol it melted at 190°. *Tert.*-amylphthalimide was also prepared from the free amine. The melting point was 187–188° and a mixed melting point showed no depression.

Benzoyl-*tert.*-amylamine was prepared from the amine hydrochloride by the Schotten-Baumann method. After recrystallization from petroleum ether it melted at 92–93°. A mixture of this compound (2.2 mg.) with benzoylneopentylamine (2.7 mg.) melted at 77–100°.

Sym.-*tert.*-amylphenylthiourea prepared by the method described above melted at 117–118°. A mixture of this thiourea (2.5 mg.) with *sym.*-neopentylphenylthiourea (2.1 mg.) melted at 95–99°.

Sym.-*tert.*-amylphenylurea melted at 130–131°. A mixture of this urea (1.8 mg.) with *sym.*-neopentylphenylurea (2.1 mg.) melted at 100–112°.

Summary

1. *Tert.*-butylacetamide yields neopentylamine quantitatively by the Hofmann rearrangement.
2. The failure of the migrating neopentyl group to rearrange to a *tert.*-amyl group is discussed in its bearing on the mechanism of rearrangements.
3. Apparently a “negative” neopentyl group is stable whereas a “positive” neopentyl group undergoes rearrangement to a *tert.*-amyl group and related compounds.

THE ACTION OF NITROUS ACID WITH TRIMETHYLACETAMIDE¹

BY FRANK C. WHITMORE AND D. P. LANGLOIS

RECEIVED MAY 17, 1932

PUBLISHED AUGUST 5, 1932

The established fact² of the rearrangement of neopentyl alcohol and of neopentylamine when the hydroxyl and amino groups are removed in chemical reactions, caused us to study the corresponding reactions with trimethylacetic acid and its derivatives. The relation of the two sets of compounds is as follows:

in which X may be OH, NH₂ or halogen. The entire trimethylacetyl series has been prepared.³ The literature gives no indication of rearrangement during any of these preparations but also gives no yields.

Nitrous acid reacts with acid amides to give a quantitative yield of nitrogen.⁴ No reference to the amount of organic acid formed has been found in the literature.

In the present work, acetamide is shown to give a quantitative yield of acetic acid.

If the action of trimethylacetamide with nitrous acid gave a similar rearrangement to that of neopentylamine, the products might be (CH₃)₂-C(OH)COCH₃,⁵ CH₂=C(CH₃)COCH₃.⁶ No such products were found. Trimethylacetamide (2 moles) was treated with nitrous acid at 30–35°. The products included 1.61 moles of nitrogen, 1.62 moles of trimethylacetic acid and 0.2 mole of unreacted amide. No other products were found.

The absence of rearrangement in reactions involving the trimethylacetyl group is further indicated by the fact that the changes, acid → acid chloride → acid amide → original acid, gave an over-all yield of 79% or an average of 93% for each step. Moreover, these reactions all take place with the greatest ease and at relatively low temperatures. The obvious explanation of these facts is that the initial step in each reaction is an addition to the carbonyl group of the trimethylacetyl, giving intermediate products such as

¹ Presented by D. P. Langlois in partial fulfilment of the requirements for the Ph.D. degree at the Pennsylvania State College.

⁶ Beilstein, "Handbuch," 4th ed., Vol. I, p. 733.

which then become RCOCl , RCONH_2 and RCOOH , respectively. No one of these changes gives an intermediate ion which might cause a re-arrangement.

On the other hand, reactions of neopentyl compounds must take place either through an initial ionization (Meerwein) or, more probably, through compound formation (oxonium or ammonium) with the hydroxyl or amino group attached to the neopentyl system. At the instant this oxonium or ammonium compound changes to give a stable inorganic molecule such as water or nitrogen, the neopentyl group is left with only 30 valence electrons and is consequently unstable.⁷

Experimental

Preparation of Trimethylacetamide.—Trimethylacetic acid was made according to "Organic Syntheses" (Vol. VIII, 1928, p. 104). Two moles (204 g.) of the acid was warmed on a steam-bath under a reflux condenser with 138 g. (50% excess) of phosphorus trichloride. Very little hydrogen chloride escaped. Two layers separated. After heating for one and a half hours, the mixture was cooled in ice. The acid chloride was decanted from the sirupy bottom layer and added to 1 liter of concentrated aqueous ammonia cooled to 0°. The white amide was filtered off and dried *in vacuo* over sulfuric acid. It was heated with 600 cc. of ethyl acetate and filtered hot to remove ammonium chloride. The solution was evaporated until crystals began to appear and 1200 cc. of petroleum ether was added. The mixture was heated to give a clear solution and then allowed to cool slowly. It was finally cooled in a refrigerator and filtered. The trimethylacetamide melted at 155–157°; yield 176.5 g. or 87% of the calculated amount based on the trimethylacetic acid used. Further crystallization did not change the melting point.

Action of Nitrous Acid on Acetamide.—One-half mole (29.5 g.) of acetamide (dried over phosphorus pentoxide) and 34.5 g. (0.5 mole) of sodium nitrite were dissolved in 350 cc. of water. The mixture was placed in an open flask fitted with a stirrer and a dropping funnel. To the mixture was added slowly with constant stirring 15 cc. of concentrated sulfuric acid in 100 cc. of water. After the addition of the acid another 34.5 g. of sodium nitrite was added and another 15 cc. of sulfuric acid in 100 cc. of water was added slowly. The mixture was stirred for six hours after all of the acid had been added. The temperature was kept at 50–60° during the addition of the acid and at 30–35° during the final stirring. The mixture was then heated for half an hour at 80° to drive off the excess nitrogen oxides and then distilled until no more acetic acid came over. The distillate was diluted to 1 liter in a volumetric flask and the acetic acid titrated, using 10-cc. portions; 10 cc. of the acid required 19 cc. of 0.2700 *N* base. Hence the acid was 0.513 *N*, and 0.51 mole of acid was obtained from 0.50 mole of acetamide.

Action of Nitrous Acid on Trimethylacetamide.—One mole of sulfuric acid was diluted to 2 liters and 2 moles of trimethylacetamide (202 g.) was dissolved in it. The mixture was warmed to 60° to effect solution. It was placed in a three-necked 5-liter flask and cooled. The flask was fitted with a mercury-sealed stirrer, a dropping funnel and an exit tube for gases. This tube was connected with an absorption train, consisting

⁷ See p. 3279.

of two ordinary wide-mouthed bottles fitted with bubblers and a Friedrich absorption tower, and a gas meter for measuring the gas evolved. The absorption train was filled with a saturated solution of potassium permanganate about 0.5 *N* in sulfuric acid. This was to remove any nitrogen oxides formed during the reaction, thus leaving pure nitrogen to be measured.

When the solution in the flask had cooled to 35°, stirring was started and a solution of 2 moles (138 g.) of sodium nitrite in 1 liter of water was run in at the rate of 1 cc. per minute. After this addition another half mole of sulfuric acid was run in and another mole of sodium nitrite (69 g.) in 500 cc. of water was added as before. The entire addition required about forty-eight hours. Stirring was continued another forty-eight hours as long as gas was evolved. An oily layer of trimethylacetic acid separated. The nitrogen evolved occupied 44 liters at an average temperature of 30° and an average pressure of 743 mm., thus amounting to 1.61 moles.

The contents of the reaction flask were poured out and the two layers separated. The water layer was extracted with four 250-cc. portions of ether, and the ether extracts combined with the acid layer. The water layer was reserved (1). The ether solution was extracted with three 150-cc. portions of 20% sodium hydroxide and the ether residue was reserved (2). The sodium hydroxide extract was heated to distil off the ether and any other volatile organic product. The distillate was reserved (3).

The sodium hydroxide solution was then cooled and acidified with sulfuric acid. A layer of trimethylacetic acid separated and was drawn off. The water layer was distilled until no more oily drops came over. The distillate was saturated with salt and the layer of acid drawn off. This water residue was then distilled until no more oily drops came over and the distillate was saturated with salt. The layer of acid was drawn off and all three lots of acid were combined. Twenty cc. of ether was added to the acid and the mixture was dried over sodium sulfate in the refrigerator. The solution was then distilled.

Fraction	B. p., °C.	Press., mm.	Weight
1	35- 55	743	15 cc.
2	55-162	743	1.5 g.
3	162-163	743	165 g.
4	Very little solid residue		

The 165 g. of the acid obtained is 1.62 moles.

The water layer (1) was made strongly alkaline with sodium hydroxide and cooled. It was extracted with six 200-cc. portions of ethyl acetate. The ethyl acetate was evaporated on a water-bath and 12 g. of a dry solid was obtained, m. p. 155-156° (unreacted trimethylacetamide). No other product could be detected.

The ether residue (2) was distilled on a water-bath. All of the volatile material came over at 35-55°, leaving 8 g. of a dry white solid, m. p. 155-157° (unreacted trimethylacetamide). No other product could be detected.

The distillate (3) was again distilled. Ether came over at 35°. There was then a gradual rise in temperature, more rapid toward the last, until it reached 98°, where it remained constant until all had distilled. Apparently it contained nothing but ether and water.

Summary

1. Trimethylacetamide reacts with nitrous acid to give over 90% of the calculated amounts of nitrogen and trimethylacetic acid.
2. The reactions of derivatives of trimethylacetyl give no rearrange-

ments. This is in marked contrast to the rearrangements of the analogous neopentyl derivatives.

3. The significance of this absence of rearrangement in relation to the mechanism of rearrangements is discussed.

REARRANGEMENTS INVOLVED IN THE ACTION OF NITROUS ACID WITH NORMAL-BUTYLAMINE¹

BY FRANK C. WHITMORE AND D. P. LANGLOIS

RECEIVED MAY 17, 1932

PUBLISHED AUGUST 5, 1932

The recorded data² on the reaction of nitrous acid and primary aliphatic amines make it of the utmost importance in the theory of rearrangements.³ For instance, it can hardly be argued that a primary amine undergoes an "ionization" into R^+ and NH_2^- similar to that which is sometimes assumed as part of the mechanism of the rearrangement of carbinols (Meerwein). Moreover, this reaction results in the formation of olefins under conditions which would not cause the dehydration of even a tertiary alcohol.

n-Propylamine reacts with nitrous acid to give *n*-propyl alcohol, isopropyl alcohol and propylene.⁴ Isobutylamine gives tertiary butyl alcohol⁵ and isobutylene. No other organic products are mentioned. *n*-Butylamine is reported to give *n*-butyl alcohol and isobutyl alcohol.⁶ Other workers report *n*-butyl alcohol, secondary butyl alcohol, *n*-butenes and dibutyl nitrosamine but *no* isobutyl alcohol.⁷

Neopentylamine gives only the rearrangement product, tertiary amyl alcohol.⁸

n-Butylamine was chosen for the present study because of the simplicity of its molecule and the disagreement in the literature regarding its behavior with nitrous acid. The amine was prepared from very pure *n*-butyl bromide obtained from highly purified *n*-butyl alcohol. The yields of products of the action of nitrous acid were as follows

¹ Presented by D. P. Langlois in partial fulfilment of the requirements for the Ph.D. degree at the Pennsylvania State College.

No trace of isobutyl alcohol, tertiary butyl alcohol or isobutylene was detected. The formation of the *n*- and *sec.*-butyl chlorides was unexpected. Their formation represents a new reaction in aliphatic chemistry and gives added evidence for the momentary existence of R^+ as an intermediate in the reaction, since it is most improbable that the alcohols were first formed and then were converted to chlorides in the bare acid solution. To get additional evidence on this new reaction, *n*-butylamine in calcium chloride solution was treated with calcium nitrite and hydrochloric acid. The increased concentration of chloride ion raised the yields of *n*- and *sec.*-butyl chlorides to 9.5 and 6.3%, respectively. The fact that the *n*-butyl chloride predominates indicates that the *n*-butenes are not intermediates in the process. Moreover, it is hardly conceivable that *n*-butenes could add hydrogen chloride under the conditions of the experiment. Further, the *n*-butenes could not have been formed by dehydration of the *n*- and *sec.*-butyl alcohols under the conditions of the experiment. The alcohols, halides and olefins are products of simultaneous reactions and are not formed from each other. Thus all evidence points to the validity of the suggested mechanism for the reaction of *n*-butylamine with nitrous acid.

The formation, from the amine nitrite, of a molecule of nitrogen, one of water, and an hydroxyl ion, each with its necessary number of electrons, leaves the end carbon of the *n*-butyl group with only six electrons. Such a product is capable of only momentary existence.⁹ It unites with ions from the solution giving the observed products, *n*-butyl alcohol, chloride and nitrite. It also changes monomolecularly by (a) losing a proton to give butene-1, and (b) undergoing a shift of an electron pair and its proton to form a positive *sec.*-butyl group. This unites with ions from the solution forming *sec.*-butyl alcohol, chloride and nitrite. It also loses protons to give butene-1 and butene-2. The *sec.*-butyl ion could undergo a shift of an electron pair with a methyl to give an isobutyl ion, which could unite with ions to give isobutyl alcohol, etc., or could give isobutylene. Since no forked four-carbon products were formed, it is evident that the shift of a

⁹ See p. 3277.

methyl does not take place under the conditions of these experiments. It is interesting, however, that Linnemann and Zotta, and Ray and Rakshit found such forked compounds when working at higher temperatures.

Experimental

Distillation of *n*-Butyl Alcohol.—Forty-five liters of the best commercial grade of *n*-butyl alcohol¹⁰ was distilled through an adiabatic packed column, 8.3 meters high and 7.6 cm. in diameter.¹¹ At the start a reflux ratio of about 80:1 was used. After 1300 cc. of the alcohol had distilled, the refractive index became constant (n_D^{20} 1.3990). The reflux ratio was then dropped to 50:1 for the next 10 liters of distillate. The refractive index rose only 0.0001. Then 25 liters was distilled with the ratio 10:1 without any change in the refractive index. The residue of 7.5 liters was slightly brown. In all, fifty fractions were collected. The middle fractions were used in the present studies. They boiled at 116.2–116.4° (744 mm.) (Cottrell) and showed n_D^{20} 1.3991.

Preparation and Purification of *n*-Butyl Bromide.—The methods of "Organic Syntheses" [Vol. I, 1921, p. 5] were used. A 48-mole run of the purified *n*-butyl alcohol gave an 86% yield of crude *n*-butyl bromide all boiling at 95–100° (735 mm.). The crude bromide was distilled through a 150 × 2 cm. column¹² using a reflux ratio of 30:1. Three low fractions were obtained, 190 g. at 95–99°, 178 g. at 99–99.5° and 425 g. at 99.5–100°. The first two contained water. The main fraction consisted of 4.2 kg. boiling at 100° (741 mm.), n_D^{20} 1.4395. The residue was 190 g.

Preparation and Purification of *n*-Butylamine.—Two 12-liter flasks were fitted with stirrers and 8 liters of 90% alcohol placed in each. Ammonia was run in with constant stirring until the flasks had gained about 300 g. in weight. Into each flask was run 0.5 mole (68.5 g.) of *n*-butyl bromide. A slow stream of ammonia was allowed to pass through the flasks during the reaction to ensure complete saturation so that the ratio of ammonia to bromide was kept high. Altogether 11 moles of the bromide was added at the rate of 0.5 mole to each flask every four hours. This varied slightly during the night. At the end of the addition the mixture was stirred for two days longer until no bromide could be detected. It was then distilled to remove the alcohol. After about 8 liters of alcohol had been removed from the combined flasks, ammonium bromide separated and was filtered off. Eight more liters of alcohol solution was distilled off and more ammonium bromide filtered off. A total of 378 g. was obtained. About 2 liters of solution remained in the flask. To this was added 2 liters of water. The mixture was distilled to remove the last traces of alcohol. This was repeated until no alcohol remained.

Without cooling the solution there was added 12 moles of sodium hydroxide in 2 liters of water and the mixture was distilled until the lower boiling substance had come over. It was then allowed to cool. The distillate was dried over fused potassium hydroxide.

The two layers in the reaction flask were separated and the oily amine layer was dried over fused potassium hydroxide. More sodium hydroxide was added to the water layer but no more amine separated. Since extraction of a small portion of the water layer with ether showed only very small amounts of the amine, it did not seem advisable to extract the whole water layer of over 4 liters.

¹⁰ Through the courtesy of C. L. Gabriel of the Commercial Solvents Corporation a middle cut was obtained from a batch distillation of 30,000 gallons of *n*-butanol.

¹¹ The construction and operation of this column have been described in detail by Fenske, Quiggle and Tongberg, *Ind. Eng. Chem.*, **24**, 408 (1932).

¹² See p. 3451.

The amine was fractionated through the 150-cm. glass-packed column.¹³ Nothing came over below 76.5°, then 383.5 g. distilled at 76.5° (742 mm.). At this point the amine ceased to distil. By heating the column and increasing the heat on the flask more amine was forced up the column but the temperature began to climb rapidly, indicating the presence of dibutylamine. The yield of pure *n*-butylamine was 47%; n_D^{20} 1.4008.

Reaction of *n*-Butylamine with Nitrous Acid.—The following is a typical run. *n*-Butylamine (1 mole) was dissolved in 1 liter of water and neutralized with the calculated quantity of 6 *N* hydrochloric acid. This was placed in a round-bottomed flask fitted with a mercury-sealed stirrer, a dropping funnel and an outlet tube for gas. A solution of three moles of sodium nitrite in a minimum quantity of water was added to the cold amine hydrochloride solution. No reaction occurred in the cold.

The outlet tube was connected with the following train: a spiral condenser with a receiver cooled in an ice-bath to remove the condensable materials; two calcium chloride and one phosphorus pentoxide drying towers; a series of three 250-cc. absorption bottles containing absolute alcohol for the absorption of butenes; an absorption tower containing alkaline permanganate solution (50 g. of potassium permanganate and 20 g. of potassium hydroxide per liter) for the absorption of nitrogen oxides; and finally a large graduated carboy for collecting and measuring the nitrogen evolved. The dropping funnel of the apparatus was filled with 1 *N* hydrochloric acid.

After sealing the apparatus, the stirrer was started and the flask slowly heated until the solution boiled. A rather rapid evolution of gas occurred and considerable volatile material collected in the receiver. Heating was continued until the volume of nitrogen increased only slowly. The reaction was then stopped. A very slow stream of 1 *N* hydrochloric acid was added during the reaction to prevent the solution from becoming alkaline due to the hydrolysis of the sodium nitrite. Samples of gas were removed during the reaction from various positions along the train to test the completeness of absorption of the butenes and nitrogen oxides.

The condensed material which consisted of an oily layer and a water layer was saturated with sodium chloride and a few cc. of 1 *N* hydrochloric acid was added to remove any amine which had distilled over. The two layers were separated and the water layer extracted with ether. The ether was removed and the residue added to the oily layer, which was dried over anhydrous potassium carbonate. The amine was recovered by making the water layer alkaline with sodium hydroxide and extracting with ether. The dried oily layer was fractionated through a partial condensation column 90 × 1.2 cm.¹⁴

The butenes were recovered by running the alcoholic solution into warm water and collecting the evolved gas.

Reaction 1.—A total of 3.5 moles (255.5 g.) of *n*-butylamine was treated with 10.5 moles (724.5 g.) of sodium nitrite by the procedure indicated. A fractionation of the condensed material gave the following fractions.

Fraction	B. p., °C.	Pressure, mm.	n_D^{20}	Wt., g.
1	66–68	744	1.3981	7
2	68–76	744		0.5
3	76–80	744	1.4085	13
4	80–97.6	744		1.1
5	97.6–98.4	742	1.3970	26.3
6	98.4–114.6	742		1.3
7	114.6–116.2	742	1.3991	50.0
8	Higher boiling material			15.0

¹³ See p. 3451.

¹⁴ See p. 3453.

Fraction 1 was chiefly *sec*.-butyl chloride. It was identified by the method of Johnson,¹⁵ yielding an anilide, m. p. 106–108°; mixed melting point with a pure sample of methylethylacetanilide prepared from *sec*.-butyl bromide, 106–108°. Some *sec*.-butyl nitrite was present (odor) but it was impossible to separate it by distillation since the two boiling points are so close together. A small amount of the material was refluxed for an hour with potassium carbonate solution and the aqueous solution gave a distinct test for nitrite ion.

Fraction 3 was chiefly *n*-butyl chloride. It was also identified by the method of Johnson,¹⁵ yielding an anilide, m. p. 58–59°; mixed melting point with a pure sample of *n*-valerianilide 58–61°. The chlorine analysis of the fraction indicated the presence of some substance besides *n*-butyl chloride. Found: 33.1% Cl; calcd. for C_4H_9Cl , 38.8%. The index of refraction was high for *n*-butyl chloride. *n*-Butyl nitrite was present. Boiling some of the material with potassium carbonate solution gave nitrite ion. The odor of an organic nitrite was always obtained from material in Fractions 1 and 3.

Fraction 5 had the boiling point and index of refraction of *sec*.-butyl alcohol.

Fraction 7 was *n*-butyl alcohol. It had the correct boiling point and index of refraction. With 3,5-dinitrobenzoyl chloride it gave an ester melting at 62–64°, mixed melting point with a sample of pure *n*-butyl 3,5-dinitrobenzoate 62–64°.

Fraction 8 was unidentified but may have been the same as the dibutylnitrosamine obtained by v. Meyer.¹⁶

Butenes.—25.2 liters of butenes at 24° and 727 mm. was obtained from Reaction 1. Calculated to standard conditions, this gives 22.1 liters or 55.2 g.

In order to test for the presence of isobutene in the gas the method of analysis of Marcowitch and Moore¹⁷ was used. This method depends on the relative rate of absorption of isobutene and the *n*-butenes in 68% sulfuric acid. No attempt was made to distinguish between the *n*-butenes.

The apparatus consisted of an Orsat absorption pipet and a gas-measuring buret. The rate of absorption was determined by measuring the decrease in volume of the gas standing in contact with the acid for five-minute periods.¹⁸

Samples of isobutene and the *n*-butenes were prepared according to the method of Davis¹⁹ and the rate of absorption of a 50% mixture of each gas with air was determined. The result is plotted on Fig. 1. The isobutene is quantitatively absorbed in twenty minutes while only 15% of the *n*-butenes is absorbed in the same time. Synthetic mixtures of isobutene with the *n*-butenes were then prepared and the rate of absorption determined as before. These results are also plotted on Fig. 1. The curves for the mixtures show a rapid absorption for the first five or ten minutes and then a sharp decrease in the rate until a final slow constant rate is obtained. From a consideration of the curves for the pure butenes it is evident that the final slow rate of absorption is due to the *n*-butenes and that they have been absorbed at this constant rate from the beginning. We can then calculate the percentage of isobutene in the mixture by taking the total absorption and subtracting from it the quantity of *n*-butenes absorbed. This latter factor is obtained by taking the amount of gas absorbed in five minutes as indicated by the final slope of the line and multiplying by the number of five-minute intervals. This may be read directly from the graph by extending the straight line portion of the curve until it intersects the ordinate axis, taking the percentage of isobutene to be that corresponding to the intersection on the axis. In this manner results with a precision of

¹⁸ Fresh acid was introduced after every third run.

¹⁹ See *THIS JOURNAL*, **50**, 2778 (1928).

about 1% can be obtained. The following results were calculated for the curves in Fig. 1.

Curve	Gas mixture		Isobutene taken, %	Isobutene calcd., %
	<i>n</i> -Butenes, cc.	Isobutene, cc.		
2	78.1	3.7	4.9	5.2
3	48.0	4.0	7.7	7.6
4	86.0	12.6	12.8	13.2
5	51.7	22.7	30.5	29.8
6	60.1	29.1	32.6	30.7

Figure 2 represents the absorption curve of the butenes obtained from Reaction 1. It is practically identical with the curve for *n*-butenes given in Fig. 1. There is a slightly

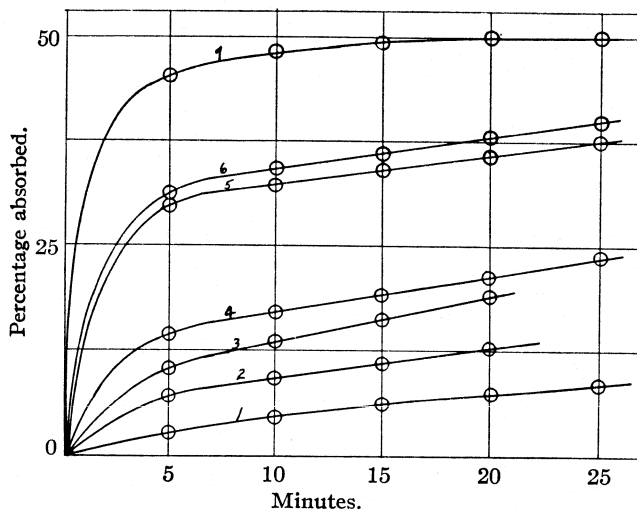

Fig. 1.—1, 50% *n*-butenes, 50% air; 2, 4.9% isobutene; 3, 7.7% isobutene; 4, 12.8% isobutene; 5, 30.5% isobutene; 6, 32.6% isobutene; 7, 50% isobutene, 50% air. 2-6, isobutene + *n*-butenes = 100%.

greater absorption during the first five minutes than during the subsequent five-minute intervals which amounts to about 0.5%. This behavior is also shown by the curve for

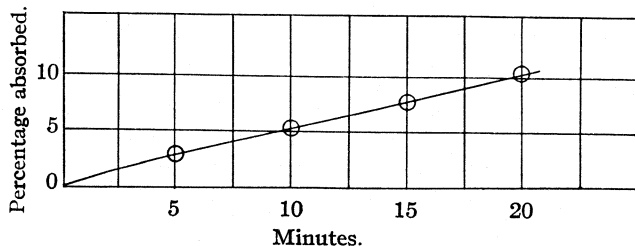

Fig. 2.—79% butenes, 21% air.

the *n*-butenes, so that it is evident that isobutene is not present in amounts greater than 1% in the gas from Reaction 1.

The dibromide was prepared by passing the butene into bromine in carbon tetrachloride. The product was fractionated through a 62 × 2.3 cm. packed total reflux column.²⁰ Only one fraction was obtained boiling at 153–158° at 728 mm. Apparently no isobutylene dibromide (b. p. 148°) was present.

No tertiary butyl alcohol, isobutyl alcohol or isobutylene could be detected.

Reaction 2.—This reaction was carried out in the presence of a higher concentration of chloride ion. One mole of *n*-butylamine in a solution of 1.5 moles of calcium chloride was treated with 1 mole of calcium nitrite. (The latter was used instead of sodium nitrite to prevent the precipitation of part of the chloride ion as sodium chloride.) The usual procedure was used and the products of reaction were separated and identified as in Reaction 1.

	Weight, g.	Yield based on amine consumed, %
<i>n</i> -Butyl chloride	4.4	9.5
<i>Sec.</i> -butyl chloride	2.9	6.3
Mixture of <i>n</i> - and <i>sec.</i> -butyl alcohols	14.7	39.6
<i>n</i> -Butenes	10.5	37.6
		<hr/> 93.0

Unreacted amine recovered, 36.1 g. (0.5 mole). No isobutyl alcohol, *tert.*-butyl alcohol or isobutylene was detected.

Reaction 3.—This reaction was carried out in the presence of freshly precipitated copper. Half a mole of *n*-butylamine (36.5 g.) in the presence of 60 g. of moist freshly precipitated copper was treated with 1.5 moles of sodium nitrite by the usual procedure. The copper reacted readily to give cuprous chloride but most of the amine was recovered unchanged.

Oily material	5.4 g.	
<i>n</i> -Butenes	5.32 g.	(43.6% yield based on amine consumed)
Unreacted amine recovered	21 g.	(0.29 mole)

Summary

1. *n*-Butylamine reacts with nitrous acid to give the alcohols and chlorides and traces of nitrites of *n*- and *sec.*-butyl together with butene-1 and -2. No branched chain butyl compounds have been detected.
2. The relation of these facts to the mechanism of rearrangements is discussed.

THE ABSENCE OF REARRANGEMENT OF THE ISOBUTYL GROUP DURING THE FORMATION OF ISOBUTYLMAGNESIUM BROMIDE AND ITS RELATION TO THE THEORY OF REARRANGEMENTS¹

BY FRANK C. WHITMORE AND ALBERT R. LUX

RECEIVED MAY 17, 1932

PUBLISHED AUGUST 5, 1932

The ready change of isobutyl compounds to tertiary butyl compounds has long been known. The interconversion of the bromides has been thoroughly studied.² The results of these studies indicate that (1) rearrangement of isobutyl bromide to tertiary butyl bromide at high temperatures in the *vapor phase* may occur by way of dissociation and addition of hydrogen bromide (Brunel) but (2) this rearrangement takes place more readily in the liquid phase and at temperatures at which there is no dissociation into hydrogen bromide and olefin. Heating the *vapor* of isobutyl bromide at 140° for fourteen hours produces no rearrangement while heating the *liquid* at the same temperature for *one* hour gives a 55% conversion to the tertiary bromide (Michael). The isobutyl "ions" readily rearrange by the transfer of an electron pair and its proton.³

Other isobutyl compounds undergo similar rearrangements. Isobutyl iodide reacts with silver acetate in the absence of a solvent to give isobutyl acetate while the presence of acetic acid as a solvent makes tertiary butyl acetate the chief product.⁴ Similar results are obtained with silver cyanate.⁵ With silver oxide in the presence of acetic acid, isobutyl bromide yields tertiary butyl alcohol and tertiary butyl acetate (Linnemann). An even more interesting example of this transformation is the conversion of isobutyl iodide to tertiary butyl chloride by the action of iodine monochloride (Linnemann). This reaction apparently occurs as follows

The two ions left are peculiar in that each is the result of a "chemical reaction" rather than of an ordinary "ionization." Each is present only in

small concentrations. This apparently favors the monomolecular rearrangement.

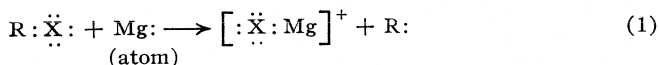

The literature contains no definite indication regarding a rearrangement of the isobutyl group during the formation or reaction of the Grignard reagent.⁶ This reaction was interesting to us because of the following relations:

If the hydroxyl is removed with the octet of the oxygen complete, the carbon to which it was attached must at some instant have only six electrons.⁷ Similarly

In each case the R^+ may undergo rearrangement before combining with a negative ion from the reaction mixture. (3) On the other hand, if RX is treated with an electrically neutral *element* such as magnesium or sodium, the possible intermediate products are more varied. Thus

In each case the pictured intermediate products can combine to form RMgX . A consideration of the three possible processes in detail is instructive. The first could give no rearrangement, since the organic radical has its full complement of electrons. Since there is no source of protons present, it can only combine with the MgX^+ . The free $\text{R} \cdot$ radicals formed according to (2) might combine to give $\text{R} : \text{R}$ or might disproportionate.

The R^+ could merely lose a proton to the $\text{R} \cdot$ or it could first rearrange and then lose a proton. In all cases studied to date, these two possible processes give the same product. Cases in which different products could be formed are being studied in this Laboratory in connection with both the Grignard and Wurtz reactions. If the third picture is correct, the R^+ should rearrange at least in part and the rearranged product could then give the corresponding Grignard reagent.

⁶ Gilman and Heck, *Bull. soc. chim.*, [4] **45**, 1095 (1929). Other rearrangements involving the Grignard reagent are recorded in the literature as follows: Richard, *Ann., chim. phys.*, [8] **21**, 342 (1908); Tiffeneau and Delange, *Compt. rend.*, **139**, 573 (1903); Gilman and Kirby, *THIS JOURNAL*, **51**, 3475 (1929); **54**, 345 (1932); Gilman and Harris, *ibid.*, **53**, 3541 (1931); Austin and Johnson, *ibid.*, **54**, 647 (1932).

⁷ This is on the simple assumption that the subtraction of eight electrons from the fourteen electrons originally associated with the carbon and its attached oxygen leaves only six with the carbon.

In the present study isobutyl bromide (5 moles) containing less than 0.5% of tertiary bromide was converted to 3.7 moles of Grignard reagent and 0.8 mole of gas consisting mainly of isobutylene and isobutane.⁸ The Grignard solution was diluted with dry ether and treated with oxygen at 0°. The resulting ROMgBr product was decomposed by ammonium sulfate solution and the resulting alcohol was fractionally distilled through special columns and tested for tertiary butyl alcohol by procedures found effective with mixtures containing 2% of tertiary butyl alcohol in isobutyl alcohol. No tertiary butyl alcohol was detected. When the Grignard solution from tertiary butyl chloride was similarly treated, an 80% yield of the alcohol was obtained.

These experiments practically eliminate process (3) from consideration. This study is being continued.

Experimental

Preparation of Isobutyl Bromide.—In a 3-liter three-necked flask provided with an efficient stirrer, a thermometer and a dropping funnel, was placed 1036 g. (14 moles) of isobutyl alcohol, b. p. 107–108°. After cooling to –4°, 1390 g. (5.1 moles) of phosphorus tribromide was added during six hours, with vigorous stirring and below –1° at all times. The cooling bath was removed and the mixture was allowed to stand for twelve hours. The mixture was then distilled through a short column using the vacuum of a water pump. The bromide was not heated above 50°. Much hydrogen bromide was evolved during the distillation. The crude bromide was shaken with 50 g. of anhydrous potassium carbonate and allowed to stand for two days with 25 g. of freshly calcined potassium carbonate. The latter was removed and the bromide was distilled under reduced pressure through an 85 × 2 cm. packed column of the total condensation, adjustable take-off type (Fig. 1). The isobutyl bromide was collected at 41.5–42.2° (137 mm.), yield 1060 g. (55% of the theoretical amount).

Analysis of Isobutyl Bromide for Tertiary Butyl Bromide.—The method of Michael and Leupold² was used. It depends on the fact that cold distilled water will hydrolyze *tert.*-butyl bromide but will not react with the isobutyl compound. The hydrogen bromide formed is conveniently determined by the Volhard method.

The isobutyl bromide prepared above was found to contain about 0.6% of tertiary bromide.

Further Purification of Isobutyl Bromide.—About 1 kg. of this isobutyl bromide was stirred with 300 cc. of distilled water for five hours. After washing with a fresh portion of distilled water, the bromide layer was dried over potassium carbonate and fractionated through the 85 × 2 cm. column. Over 80% of the bromide was recovered at 41.8–42.5° (135 mm.); d_4^{20} 1.266, n_D^{20} 1.4363.

Anal. Calcd. for C₄H₉Br: Br, 58.3. Found: Br, 58.5, 58.2; tertiary bromide, 0.37, 0.29%.

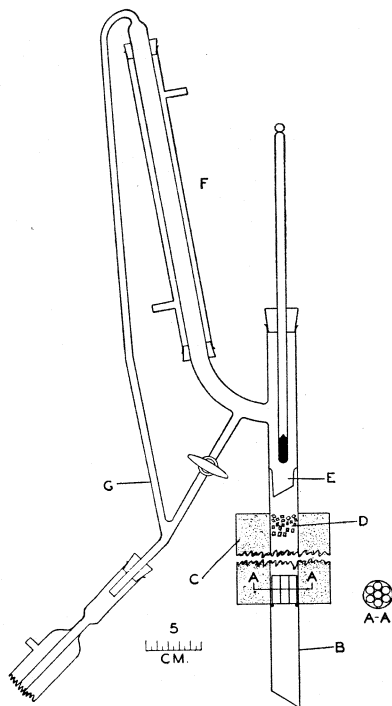

Preparation of Isobutylmagnesium Bromide.—A 2-liter three-necked flask was fitted with a mercury-sealed stirrer; a thermometer, an efficient reflux condenser and a 500-cc. dropping funnel. The condenser was connected to two traps, the first cooled with ice and the second with solid carbon dioxide and acetone.

To 120 g. of magnesium turnings and a crystal of iodine was added a small amount

⁸ The exact composition of this gas and the effect of varying conditions on its composition are being studied in relation to the theory of the Grignard reaction.

of the purified isobutyl bromide in dry ether. As soon as the reaction started, 250 cc. of dry ether was added and the rest of a solution of 685 g. (5 moles) of the highly purified isobutyl bromide in 625 cc. of dry ether was added as follows. Half of the solution was added during seven and a half hours. Then the remaining half was diluted with 375 cc. of dry ether and added during six and a half hours. The temperature of the reaction mixture was at all times below 50° . The trapped material amounted to 46 g. (0.8 mole) and was mainly isobutane and isobutylene. Titration of an aliquot part of the clear Grignard solution with standard acid showed that 3.7 moles of butylmagnesium bromide had been formed.

Fig. 1.—Several columns of this type were used in this study and in the researches described in the accompanying papers. A, A mat for holding up the packing in the column. It is made of several short pieces of glass tubing fused together, and rests on small indentations in the column. B, The column, of 20 mm. inside diameter Pyrex tubing measuring 100 cm. from the bottom to E, and about 115 cm. over-all. C, Magnesite pipe insulation. In some of the columns this was supplemented or replaced by electric heating coils (see Fig. 2). D, Packing made from 6-mm. glass tubing cut in 6-mm. lengths. This was kindly supplied by the du Pont Co. at cost. E, Drip indicator made by sealing a 15-mm. tube inside the column. F, Condenser made of 15-mm. Pyrex tubing with a jacket 25 cm. long. In some columns an internal condenser was used. In these, the drip indicator, E, was usually omitted as the reflux ratio could be calculated by counting the drops from the tip of the internal condenser instead of from E. G, Pyrex tubing 8 mm. in diameter with a stopcock having a 2-mm. bore. The take-off is adjusted by this stopcock. The tube G makes possible the use of the column under reduced pressure. Thus the ordinary disadvantages of distillations from Claisen flasks under reduced pressures are avoided.

Treatment of the Grignard Solution with Oxygen.—The solution was filtered through glass wool into a 5-liter flask equipped with a mercury-sealed stirrer, a thermometer, an inlet tube and an efficient reflux condenser attached to a mercury trap having a head of about 2.5 cm. of mercury.

The solution was diluted with 2250 cc. of ether, the inlet tube was adjusted to reach to about 2 cm. above the solution and stirring was started. After the solution had been cooled to -2° by an ice-salt mixture, dry oxygen was passed over the stirred cold solution at such a rate that none escaped through the mercury trap. The temperature was kept below 0° at all times. After about eight hours, the temperature dropped sharply and oxygen bubbled through the mercury trap. The treatment with oxygen at 0° or lower was continued for three hours.

The solution was added to a mixture of 1.5 kg. of cracked ice and 1.3 kg. of ammonium sulfate. The ether layer was separated and washed twice with 500-cc. portions of water which was added to the water layer. The water layer was extracted 10 times with 300-cc. portions of ether. The combined ether extracts were washed with water. The ether solutions were dried with 500 g. of anhydrous potassium carbonate. The ether was then removed by distillation through the 85×2 cm. column using a high reflux ratio. The residue was then carefully fractionated through a similar 38×1.8 cm. packed column as follows.

Fraction	Bar., mm.	B. p., °C.	Reflux ratio	Wt., g.
A1	742	60-67	15:1	0.7
2		67-81	8:1	2.5
3		85-90	60:1	13.0
4	745	90-95	60:1	17.0
5		95-100	60:1	2.0
6		100-106	60:1	2.5
7		106-107.2	60:1	7.0
8	742	107.2-107.4	60:1	78.5
9		107.4-107.8	60:1	90.5
10		107.8-107.9	60:1	21.0
11		Residue		8.5

Fractions A7-9 represent a 74% yield of isobutyl alcohol based on the Grignard reagent used. Fractions A2-4 were redistilled through a 55×0.8 cm. Vigreux column, bar. 743 mm.

Fraction	B. p., °C.	Reflux ratio	Wt., g.
Starting with fractions A2, 3			
B1	60-79	2:1	0.5
2	79-85	2:1	1.0
3	85-89	5:1	
Fraction A4 added			
	85.5-87	5:1	23.5
4	87-90	5:1	0.5
5	Residue		4.0

Fractions A5, 6, 7 and B2, 3, 4 were combined and distilled through a 90×1.2 cm. adiabatic column of the *partial* condensation type (Fig. 2), bar., 729-731 mm.

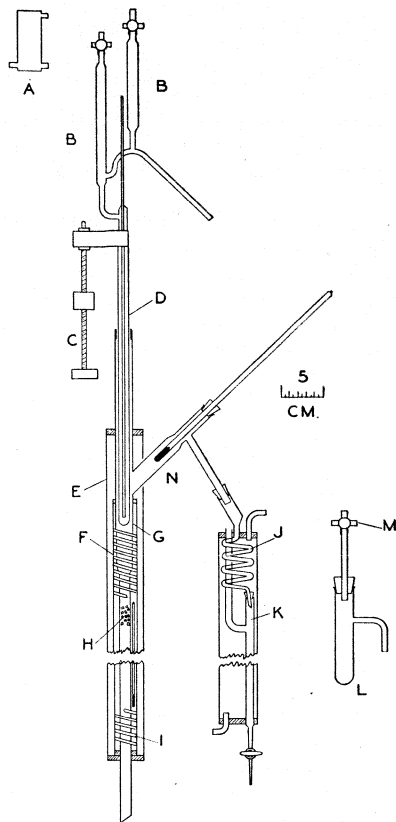

Fraction	B. p., °C.	Reflux ratio	Wt., g.	n_D^{20}
C1	84.6-85	46:1	0.5	
2	85-87	12:1	2.5	
3	87-89	20:1	12.0	1.4214

At this point it was found that the distillate contained halogen (Beilstein test and sodium ethylate test). The distillation was then completed in the small Vigreux column.

3a	90-96	2:1	2.5	1.4032
4	96-105	2:1	1.5	
5	105-106.2	20:1	7.5	

Fractions C3, 3a were redistilled through the Vigreux column. Bar., 734 mm.

Fig. 2.—This column was designed by M. R. Fenske and constructed by Franklin Johnston for the separation of smaller amounts of liquids than those which can be separated by means of columns of the total condensation, partial take-off type (Fig. 1). A, A one-gallon can arranged to supply a constant head of water to the inside tube of the condenser D. The outlet of the condenser is connected to the drop indicator L and the flow of water through the condenser is regulated by the screw clamp M. B, Air traps to take air bubbles out of the line leading from the condenser to the drop indicator. If these traps are omitted, air bubbles prevent the accurate adjustment of the flow of condenser water which is necessary in careful separations. C, A brass screw 15 cm. long arranged to make possible the accurate raising and lowering of the condenser within the enlarged top of the column. D, Condenser 39×1 cm. The cooling water from the constant level device enters the middle tube of the condenser. The condenser can be raised or lowered inside the column by means of the screw C. At the start of a distillation, the condenser is lowered until no vapor passes through the side arm N. After the column has reached equilibrium, the condenser is raised to allow a slow stream of vapor to pass through N to the condenser J. If this stream of vapor is very slow, the readings of the thermometer are not significant. The course of the distillation is then followed by

taking the refractive indices of the fractions. E, An insulating jacket consisting of a Pyrex tube 123 cm. long and 4.3 cm. inside diameter. F, A Pyrex tube, 115 cm. long and 2.7 cm. inside diameter, carrying the heating ribbon I. G, Column consisting of a Pyrex tube 29 cm. long and 2.1 cm. inside diameter sealed to the top of a Pyrex tube 113×1.2 cm. H, Packing consisting of Lessing rings, 5×5 mm., made of 50-mesh copper screen. Packed space, 90 cm. long. I, Heating ribbon. The jacket F is wrapped with 42 ft. (125 turns) of Chromel resistance ribbon, $\frac{1}{16} \times 0.005$ in., having a resistance of 1.68 ohms per ft.; total resistance, 70 ohms. A fixed outside resistance of 61 ohms and a variable resistance of 45 ohms with a capacity of 3.1 amp. are arranged to give the maximum flexibility in heating the column. The temperature of the column is given by a thermometer between the tubes F and G. J, A copper condenser consisting of 45 cm. of tubing 5 mm. outside diameter. K, A 10-cc. buret connected to the copper condenser. The buret and condenser are in a glass jacket through which cold water runs. L, Drop indicator connected to the outlet from the condenser D. This is used to measure the flow of cooling water through this condenser. M, Screw clamp used to regulate the flow of cooling water. By proper adjustment of the flow of water and the height of the condenser D in the column, the flow of vapor through N can be very accurately controlled. N, Side arm of column to convey the vapors which pass the partial condenser D to the total condenser J. The distance from the column to the second side arm is 9 cm.

D1	86.5-87	8:1	2.5	
2	87-89	8:1	7.0	1.4200
3	89-89.5	6:1	2.5	
4	Residue		1.0	

Analysis of Fraction D2.⁹ Calcd. for C_4H_9Br : Br, 58.3. Found: Br, 45.3, 44.5; tertiary bromide, 0.3. No fraction corresponding to *tert*-butyl alcohol was detected.

Separation of a Known Mixture Containing 98% Isobutyl Alcohol and 2% Tertiary Butyl Alcohol.—A mixture of 4 g. of *tert*-butyl alcohol (m. p. 25°) and 196 g. of isobutyl alcohol (b. p. 107-108°) was fractionated through a 38 × 1.8 cm. packed column with total condenser and variable take-off.

Fraction	B. p., °C.	Reflux ratio	Wt., g.
E1	99.9-101	60:1	12
2	101-105.5	60:1	11.5
3	105.5-107	60:1	14
4	Residue		160

Fractions E1, 2, 3 were combined and fractionated through the 90 × 1.2 cm. partial condensation column (Fig. 2).

Fraction	B. p., °C.	Reflux ratio	Wt., g.
F1	78	26:1	1.3
2	81.2-85.8	26:1	1.5

Fraction F1 did not freeze at -10° but F2 had a m. p. of +6°. The two fractions were mixed with concentrated hydrochloric acid (16 cc.) and an oily layer separated. This was dried with potassium carbonate and then had the correct b. p. for tertiary butyl chloride, 50-50.5°.

Preparation of Tertiary Butyl Alcohol from Tertiary Butylmagnesium Chloride.—The Grignard reagent was prepared from one mole each of tertiary butyl chloride and magnesium in the usual way, yield 60%. The solution was diluted with more ether, making a total of 600 cc. of ether, and treated with oxygen below 0°. The mixture was poured on ice. The ether layer was distilled in the usual way, the alcohol fractions being distilled through the 38 × 1.4 cm. column.

Fraction	B. p., °C.	Reflux ratio	Wt., g.	M. p., °C.
G1	62-78	30:1	6	- 8
2	78-81.8	30:1	24	+ 8
3	Residue		4	+21

Summary

1. No rearrangement to tertiary butyl compounds is found when pure isobutyl bromide is converted to the Grignard compound and then to isobutyl alcohol by the action of oxygen.

2. The possible relation of these facts to the theoretical consideration of rearrangements and of the Grignard reaction is indicated.

NOTE

The Oxidation of Optochin

By C. C. VERNON AND H. U. RESCH

Introduction.—Attempts have been made to reduce the toxicity of optochin¹ by altering the structure of its molecule,² since the drug has been shown to have certain desirable properties,³ and has given promise of being a specific for pneumococci.⁴ During such a study in this Laboratory it was necessary to prepare 6-ethoxyquinoline-carboxylic acid-4. In order that there might be no question as to structure, it was proposed to prepare this compound by direct oxidation of optochin. This should be a reliable method, because optochin (ethyl hydrocupreine) closely resembles quinine (methyl cupreine) in structure and chemical properties.⁵ Skraup⁶ has prepared quininic acid (6-methoxyquinoline-carboxylic acid-4) by the oxidation of quinine, in much the same fashion as described in this article.

Experimental

A solution containing 10 g. (0.029 mole) of optochin and 30 g. (0.328 mole) of sulfuric acid in 200 g. of water was heated to boiling in a flask fitted with a reflux condenser and dropping funnel. A cold saturated solution of chromic oxide in water, containing 20 g. (0.132 mole) in all, was slowly added to the boiling solution, over a period of ninety minutes. Boiling was continued for thirty to sixty minutes, and then sufficient ethyl alcohol was added to reduce the remaining oxidizing agent. The cooled reaction mixture was treated with a solution of 90 g. of potassium hydroxide dissolved in 500 cc. of water, and the gelatinous mass of chromium hydroxide filtered out. The filtrate was exactly neutralized with sulfuric acid, and concentrated to a volume of not more than 300 cc. An equal volume of 95% ethyl alcohol was added and the precipitated potassium sulfate removed by filtration. The alcohol was recovered from the filtrate by distillation and the remaining solution concentrated to approximately 50 cc. over a water-bath. Any precipitate appearing at this point was discarded, and 3 g. (7.1 cc. of a 36% solution) of hydrochloric acid added. After fifteen minutes' heating over a water-bath, yellow needles formed in this solution upon cooling to room temperature. Several crops of these crystals were secured by further concentration of this solution before the residue became so saturated with tarry materials that further treatment was useless.

⁶ Skraup, *Ber.*, **12**, 1104 (1879).

The product so prepared melted at 231–233°. It was insoluble in ether, chloroform, ethyl acetate and benzene. It crystallized from hot 95% ethyl alcohol in beautiful lemon yellow needles having a final melting point of 288.5°.

Anal. Qualitative: C, H, N, +; S, Cl, –. Calcd. for $C_{12}H_{11}O_3N$: C, 66.35; H, 5.07. Found: C, 66.32; H, 5.00.

The yield of the product melting at 231–233°, as shown in three separate runs, averaged slightly below 20%. The yield of the product melting at 288.5° was approximately 12% of the theoretical. This low yield was believed to be due to the retention of much of the product in the precipitated chromium hydroxide, which was difficult to filter out, and almost impossible to wash.

Summary.—Optochin has been oxidized with chromic oxide in an acid solution. The analysis of the product, and its method of preparation, indicated that it was 6-ethoxyquinoline-carboxylic acid-4.

COMMUNICATIONS TO THE EDITOR

THE POTENTIAL OF THE $Ag(s)$, $AgCl(s)$, $KCl(aq)$, $AgCl(s)$, $Ag(s)$ CELL, SHOWING THE EFFECT OF FLOWING THE ELECTROLYTE OVER ONE ELECTRODE ONLY

Sir:

Carmody, in a recent note [THIS JOURNAL, 52, 210 (1932)], states that when the electrolyte is flowing over a $Ag(s)$, $AgCl(s)$ electrode, there is a difference of 0.006 volt positive to a $Ag(s)$, $AgCl(s)$ electrode at equilibrium with the cell solution [p. 191]. This note was written because the value obtained for the Pb , Pb^{++} potential by Randall and Cann [THIS JOURNAL, 52, 589 (1930)] was 0.1203 v. whereas Carmody [THIS JOURNAL 51, 2905 (1929)] had obtained the value 0.1263 v. The difference in values was attributed by Carmody to the fact that Randall and Cann had allowed the electrolyte to flow over the $Ag(s)$ – $AgCl(s)$ electrode.

Because of this apparent discrepancy the authors investigated the cell $Ag(s)$, $AgCl(s)$, $KCl(aq)$, $AgCl(s)$, $Ag(s)$, using an H-cell, set up according to Fig. 1, keeping the electrolyte on one side stationary, and allowing it on the other side to be in motion, entering the cell at I and leaving it at II. The $Ag(s)$ – $AgCl(s)$ electrodes were prepared in precisely the same way as had been done previously by Randall and Cann, care being taken to free them from adsorbed gas. The electrodes were white because they were protected from all light. Every operation was performed in containers painted black on the outside. Two cells were made, one containing 0.025 *M* KCl and the other 0.05 *M* KCl . All measurements were made with a Type K potentiometer, using an oil-bath regulated at 25°.

Analysis of the results reveals the following facts. First, readings were always taken with the electrolyte on both sides of the cell stationary. In each case a period of at least twenty-four hours was allowed for this equilibrium to be obtained. After the flow of the electrolyte was started, a period of about twenty minutes was allowed to elapse before any readings were taken, in order to permit the cell to come to equilibrium under the new conditions. When the electrolyte was flowing, the potentials were always negative to those obtained when the electrolyte was stationary.

More than forty readings were taken on Cell A and about fifteen on Cell B. With Cell A the readings varied from the lowest values of -0.00023 v. to the highest of -0.00162 v. With Cell B the lowest reading was -0.00072 v. and the highest -0.00190 v. The average of the differences from the mean in Cell A was 0.00038 , and the average deviation of the average differences was 0.000078 . The average of the differences from the mean in Cell B was 0.00031 and the average deviation of the average differences was 0.0001 .

It might seem that the greater the rate of flow the more negative the difference becomes. A large variety of different rates of flow was examined, but apparently no definite relationship exists between rate of flow and difference of potential. Also, readings of the barometer were invariably taken, but the variations in this value, a maximum of eight millimeters, appeared to have no effect. The average difference in potential due to the flowing of the electrolyte in Cell A was -0.00074 v., and that in Cell B was -0.00100 v.

These results indicate that Carmody is correct in his contention that there is a drop of potential when electrolyte is flowing over the Ag(s) , AgCl(s) electrode. But the value obtained by us, using potassium chloride as the electrolyte, is much less than that suggested by Carmody, who used hydrochloric acid as the electrolyte. Our values of -0.00074 and

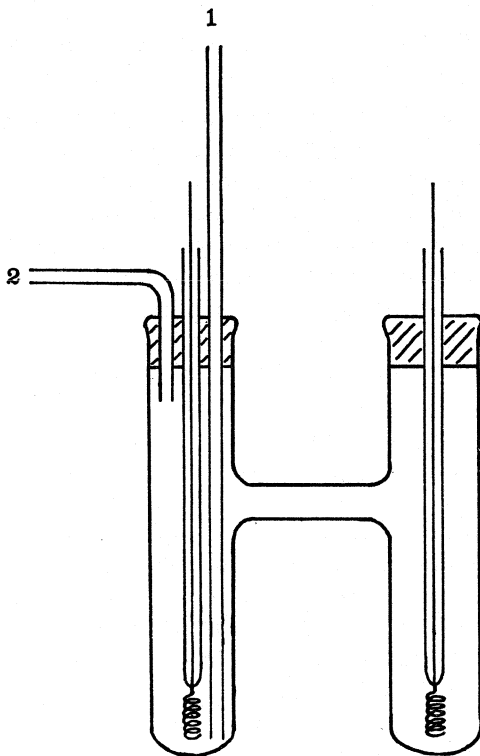

Fig. 1.

-0.00100 are not sufficient to account for the discrepancy between the values of 0.1203 v. for the Pb, Pb⁺⁺ electrode as obtained by Randall and Cann and the value of 0.1263 v. as obtained by Carmody.

THE CONSTITUTION OF BORNYL ANILINE

Sir:

In a recent publication, P. Lipp and G. Stutzinger [*Ber.*, **65**, 241 (1932)] presented evidence purporting to establish the identity of the so-called "bornyl aniline" of Ullmann and Schmidt [*ibid.*, **43**, 3202 (1910)] with the secondary amine obtained by the condensation of aniline with camphene in the presence of aniline hydrochloride and also with the amine resulting from the reduction of camphor anil with hydrogen and platinum. These findings have duplicated in part investigations well under way in this Laboratory, on which a preliminary report was presented by the authors at the recent Fall Meeting of the American Chemical Society at Buffalo, N. Y., under the title "The Fixation of Aniline by Hydrocarbons of the Terpene Series." The results of our experiments confirm the statement of L. and S. as to the identity of the camphene-aniline condensate with "bornyl aniline," but appear to be at variance with regard to the amine obtained from camphor anil by reduction. We performed the reduction of the anil with sodium and aniline as the reducing medium, obtaining a secondary amine whose acetyl derivative melted at 112-113° while L. and S. report 123° as the melting point of their product. The behavior of these amines, and also one obtained by the condensation of aniline with α -pinene in the presence of aniline hydrochloride are under investigation in this Laboratory in a further attempt to establish their structures by exhaustive methylation. The bornyl aniline of Ullmann and Schmidt and also that obtained from camphene have been found to yield camphene nearly quantitatively, while those obtained from α -pinene and reduced camphor anil exhibit behavior on exhaustive methylation which is similar to that of bornyl amine.

We expect to publish a complete account of this investigation in the near future.

THE HEAT CAPACITY OF SOME HYDROGEN HALIDES AT HIGH TEMPERATURES AS CALCULATED FROM RAMAN SPECTRA

Sir:

The existing data on the heat capacity of the hydrogen halides in gaseous form are very meager and are on the whole unsatisfactory as Eastman [*Bur. Mines, Tech. Paper* 445 (1929)] has pointed out in his critical summary of the specific heats of gases. Experimental evidence on HBr, HI and HF is entirely lacking, while such data as are available for HCl leave something to be desired. Since the heat capacities of N₂ and HCl are practically identical in so far as one can tell from the fragmentary evidence on the latter, and since the energy of the lower levels in the molecules of HCl, HBr and HI is not very different from that of the corresponding level in N₂, Eastman assigned to the three halide gases the heat capacity of N₂, which is known with reasonable accuracy. This assumption, which admittedly introduces some error, was nevertheless the best one that could be made under the circumstances.

Since the methods heretofore employed in making heat capacity measurements at high temperatures have involved a difficult technique and have led in a great many cases to questionable results, it seems not unlikely that for a polar molecule calculations based on the well-known Planck-Einstein specific heat equation may in the end be more satisfactory than direct observations, in spite of the fact that such factors as the increases in potential energy due to stretching of the molecule are neglected.

Reliable values of the fundamental frequency of vibration of HCl, HBr and HI have recently been derived by Salant and Sandow [*Phys. Rev.*, **37**, 373 (1931)] from Raman spectra. Using their results (HCl, $\Delta^1/\lambda = 2886 \text{ cm.}^{-1}$, HBr, $\Delta^1/\lambda = 2558 \text{ cm.}^{-1}$, HI, $\Delta^1/\lambda = 2233 \text{ cm.}^{-1}$) it is possible to calculate the heat capacity of these gases with an accuracy apparently somewhat greater than that of the values selected by Eastman, which are probably the best of the existing data.

Such a calculation has been made and the results, expressed as C_p ($C_p = C_v + R$), are shown in the accompanying table. The single set of

TABLE I
HEAT CAPACITY OF HYDROGEN HALIDES

Temp., °K.	C_p HCl as calcd.	C_p HBr calcd.	C_p HI calcd.	C_p Eastman's best value
600	7.07	7.13	7.26	7.17
800	7.28	7.44	7.58	7.33
1000	7.54	7.71	7.86	7.50
1200	7.78	7.94	8.10	7.67
1400	7.98	8.12	8.28	7.86
1600	8.14	8.28	8.42	8.06
1800	8.28	8.40	8.53	8.27
2000	8.38	8.48	8.59	8.49

values chosen by Eastman as representing the heat capacity of all three halide gases has been included for comparison.

It will be seen that the agreement between Eastman's selected figures and the calculated values for HCl is satisfactory, the maximum deviation being approximately 1.5%. It is perhaps worth noting that above 2000° Eastman's values run higher than the calculated ones and that this is the same direction in which Eastman's values deviate from the best of the experimental observations.

For HBr and HI differences as great as 5% exist between the results of the calculations and the data of Eastman. Unfortunately there appear to be no experimental observations on which to check the calculations but in view of the agreement found with HCl it seems probable that the calculated values are not much in error and almost certainly give a closer description of the true heat capacity of these gases than is obtained by assigning the same figure to all.

THE CHLORINATION OF NEOPENTANE

Sir:

All recorded methods of making neopentane failed to give appreciable yields except that of Lwow [*Z. Chem.*, 520 (1870)] involving dimethyl zinc and a tertiary butyl halide. The iodide, bromide and chloride gave 42, 46 and 51% yields, respectively. The hydrocarbon froze and boiled at approximately -20 and $+10^{\circ}$, respectively.

The chlorination of neopentane was very easy. At room temperature in diffused light the color of chlorine disappeared in fifteen minutes. The chloride boiled at 24° (80 mm.) and froze at -20° . The analysis for chlorine was 1.5% low for an amyl chloride. Tertiary amyl chloride showed b. p. 23.5° (8 mm.) and m. p. -73° . A small amount of a dihalide, b. p. 35° (8 mm.), was also obtained. The monochloride when shaken with cold water for thirty minutes showed the presence of 6% of tertiary halide (Michael). The amount of tertiary halide was increased only slightly, if at all, by heating the chloride at 140° for one and one-half hours. All known methods of converting a halide to a Grignard reagent failed. These facts indicate that the halide obtained is neopentyl chloride.

Neopentane is being prepared in larger amounts to make possible a more thorough study of its chlorination in relation to the mechanism of rearrangements. The limited amount of tertiary amyl chloride formed and the surprising stability of the neopentyl chloride carry implications of great

significance in this field [Whitmore, *THIS JOURNAL*, **54**, 3274 (1932); Whitmore and Rothrock, *ibid.*, **54**, 3431 (1932)].

DEHYDRATION OF DIETHYLCARBINOL

Sir:

By dehydrating diethylcarbinol in a flow reactor at 40 lb. pressure and at 365–410° with a phosphoric acid catalyst on silica gel we have obtained a mixture of olefins of b. p. 65–70° which on ozonolysis gives formaldehyde, acetaldehyde, propionaldehyde and butyraldehyde. The first two were identified by the resorcinol-sulfuric acid test and as acetaldehyde-ammonia, respectively. The last two were converted to the 2,4-dinitrophenylhydrazones, which were identified by melting point and mixed melting point determinations. Small amounts of impure 2,4-dinitrophenylhydrazones probably corresponding to methyl ethyl ketone and diethyl ketone were also obtained. These results show that the dehydration of diethylcarbinol gives both the normal and rearranged products. This study is to be continued on a larger scale in an endeavor to determine quantitatively the various modes of dehydration.

THE REACTION OF ACID IODIDES WITH ETHERS

Sir:

In a recent paper by Meerwein and Maier-Hüser [*J. prakt. Chem.*, **134**, 51 (1932)] on the cleavage of ethers by acid halides and anhydrides in the presence of catalysts, these workers have called attention to the isolated observation of Kishner [*J. Russ. Phys.-Chem. Soc.*, **41**, 651–659 (1909); *Chem. Zentr.*, II, 1132 (1909)] that benzoyl iodide is capable of splitting primary aliphatic ethers at 100° without the presence of a catalyst, giving alkyl iodides and benzoates. This work has not previously received the further study which its suggestive character would indicate.

With the hope that aliphatic acid iodides might prove more reactive, permitting the cleavage of ethers at ordinary temperatures, we have investigated the behavior of acetyl iodide and the chloro substituted acetyl iodides with a number of aliphatic ethers, thio ethers and oxides. This

study has shown that the cleavage reaction between acid iodides and ethers proceeds in all probability through a preliminary formation of an oxonium compound between the ether and the acid iodide.

Secondary ethers have been found to be much more readily cleaved into alkyl iodides and esters than are primary ethers. The substitution of chlorine in the α -position in aliphatic acid iodides has been found to diminish their ability to cleave ethers. The tendency of acetyl iodide, chloroacetyl iodide and dichloroacetyl iodide to split primary ethers was found to be diminished by increasing substitution of chlorine. Trichloroacetyl iodide showed no tendency to cleave either primary or secondary ethers at ordinary temperatures even in the presence of zinc iodide as a catalyst, though evidence of the formation of an oxonium compound was obtained. Similarly, substitution of chlorine in the α -position in aliphatic ethers greatly increased their resistance to cleavage by acid iodides.

IS THE NUTRILITE FOR "GEBRÜDE MAYER" YEAST OF UNIVERSAL BIOLOGICAL IMPORTANCE?

Sir:

We have obtained a considerable body of evidence that a single unknown hydroxy acid with molecular weight about 200 is the responsible agent for a remarkable growth stimulation of "Gebrüde Mayer" yeast.¹ Furthermore, what appears to be this same acid has been found universally in a great variety of living tissues.

The tissues extracted include (1) rice polish (Spermatophyta), (2) *Aspergillus niger* (Fungi), (3) *Spirogyra* and *Oscillatoria*, mixed (Algae), (4) *Bacillus subtilis* (Schizophyta), (5) Planarian worms (Plathylminthes), (6) Earthworms (Annulata), (7) Oysters (Mollusca), (8) Sea urchin eggs (Echinodermata), (9) Crabs eggs (Arthropoda), (10) Beef liver (Chordata), (11) Milk (Chordata). Not only was a growth stimulating substance present in every extract but on fractional electrolysis in an eight-compartment cell the activity in each case migrated under our experimental conditions to a cell with P_H value of about 4 and was usually completely removed from cells having a P_H of 5 or more.

¹ The criticism of Richards [*J. Biol. Chem.*, **96**, 416 (1932)] that our results may have been due to inorganic materials is not valid inasmuch as the article cited [*THIS JOURNAL*, **53**, 4171 (1931)] states that the activity was lost on ignition (p. 4176). Yeast nutrition like mammalian nutrition is undoubtedly affected by traces of elements of less frequent occurrence, but the effect of unknown organic materials is of entirely different order of magnitude and operates over an incomparably larger range.

The diffusion constant of the active substance (using rice polish and beef liver as sources) indicates that its molecular weight is about 200. The acid (rice polish was the source) has no primary or secondary amino group (nitrous acid anhydride treatment). It has been esterified with both methyl and ethyl alcohols. The esters are not basic (fractional electrolysis), hence the acid is not amphoteric. The presence of several hydroxy groups is indicated by (1) complete destruction of the active substance by treatment with dimethyl sulfate in the cold, (2) complete non-volatility of the methyl ester at a pressure of 10^{-3} mm., (3) solubility of the esters in water and comparatively slight solubility in ether. The activity is not destroyed by hydrogenation following the methods of Roger Adams *et al.*, indicating that the substance is not olefinic and contains no aldehyde nor ketone group nor aromatic nucleus.

The possibility of the universal occurrence of a single acid substance of the character we have indicated opens up some very interesting questions. There is fragmentary evidence that the same acid may function in the growth stimulation of certain bacteria, molds and mushrooms and that it is one of the substances involved in the growth stimulation of other yeasts such as Wildiers' and No. 578 (American Type Culture Collection). The presence of this acidic substance in soils and composts suggests the possibility that it may function in the stimulation of the growth of green plants. It is synthesized by the mold *Aspergillus niger*, and seems to be more widely and evenly distributed in tissues than any known vitamin.

Because of their rather far reaching interest we wish at present to emphasize the tentative character of our conclusions [THIS JOURNAL, 53, 4171 (1931)].

NEW BOOKS

- Quantitative Chemical Analysis. An Intermediate Textbook.** By FRANK CLOWES and J. BERNARD COLEMAN. Revised by D. STOCKDALE and J. DEXTER. Thirteenth edition. P. Blakiston's Son and Co., Inc., 1012 Walnut St., Philadelphia, Pa., 1931. xiv + 605 pp. Illustrated. 14.5×23 cm.
- Analytical Factors and their Logarithms.** By EARLE RADCLIFFE CALEY, M.Sc., Ph.D., Assistant Professor of Chemistry in Princeton University. John Wiley and Sons, Inc., 440 Fourth Ave., New York, 1932. v + 112 pp. 13×20 cm. Price, \$2.00.

The first of these volumes, originally published forty-one years ago as a laboratory textbook, is now a rather complete manual on the art of quantitative analysis. The book is divided into eight parts: (I) (65 pages) general processes; (II) (58 pages) simple gravimetric estimations; (III)

(93 pages) volumetric analysis; (IV) (38 pages) miscellaneous methods of analysis; (V) (216 pages) general quantitative analysis; (VI) (32 pages) organic analysis and determination of molecular weights; (VII) (43 pages) gas analysis; (VIII) (60 pages) tables of reference and a table of four place logarithms.

Despite its size the book is designed primarily for student use. Not only are the directions for carrying out the various analyses admirably clear and complete but the arrangement of the experiments is, in general, one of progressive complexity and difficulty. Parts I–III cover the ground of the elementary first course in quantitative analysis as it is usually given in this country. However, instead of the few typical experiments there is described a variety of experiments of the same type. Thus, for example, in Part II directions are given for about forty simple gravimetric determinations. Part IV contains descriptions of electrolytic determinations, electrometric measurements with the hydrogen electrode and by oxidation–reduction methods, colorimetric measurements, and a bare mention of spectrum and x-ray analysis. The remainder of the book—slightly more than half—is devoted to standard methods of analysis which are essentially technical in character. To illustrate the nature of this section, some of the material included in Part V may be mentioned: analysis of ores and coal, water analysis, food analysis, and the estimation of oils and fats.

The broad scope and viewpoint of the book together make it particularly well suited to the requirements of the advanced student or graduate who has frequent occasion to refer to standard methods of analysis with which he is not familiar. For this purpose especially the book can be highly recommended.

The second of the volumes listed above is a collection of tables planned to meet the needs of the analytical chemist. The tables of gravimetric factors which occupy the first two-thirds of the book comprise factors for metallo-organic as well as inorganic precipitates, and also, briefly, factors necessary for the more common indirect weighings, indirect analyses, and weight conversions. A serviceable feature of these tables is the inclusion of the correct temperatures for the drying or ignition of the various precipitates. Furthermore, for most of the metallo-organic precipitates reference is given to leading papers bearing on their use. The last third of the book is given over to tables of volumetric factors, a “convenient generic term” which is employed to denote, “in general, the grams of substance present in a cubic centimeter of normal solutions of the elements or compounds listed.” These factors include those elements and substances which can be determined by standard methods of volumetric analysis. At the end of the book is a table of five place logarithms and a series of explanatory notes indicating the use and possibilities of the different tables.

The tables are quite comprehensive and are very conveniently arranged. The book, as the reviewer already has had the opportunity to discover, will be practically valuable as a time saver in the analytical laboratory.

ARTHUR F. SCOTT

Microchemical Laboratory Manual. By FRIEDRICH EMICH. With a Section on Spot Analysis by Dr. FRITZ FEIGL. Translated by FRANK SCHNEIDER, Sc.M. John Wiley and Sons, Inc., 440 Fourth Avenue, New York, 1932. xvi + 180 pp. 88 figs. 15.5×23.5 cm. Price, \$2.75.

The appearance of Emich's admirable little text in English will meet with a ready welcome. This book is intended as an introduction to microchemical practice and presents sufficient material for a course of one semester. While many will not agree with the translator's prefatory statement regarding "the lack of an adequate text on the subject in English" in view of Chamot and Mason's excellent manual (to which Emich repeatedly refers in the text), there is ample room in this rapidly growing field for fresh points of view. The translation has an easy, readable style and the translator deserves credit for making the book available in English.

LAWRENCE T. FAIRHALL

Colloids. By ERNEST S. HEDGES, M.Sc., Ph.D. (Manchester), D.Sc.(London), A. I. C. Longmans, Green and Co., 55 Fifth Ave., New York, 1931. vii + 272 pp. Illustrated. 14×22 cm. Price, \$4.50.

Hedges has produced a fresh and distinctive treatment of the subject of Colloids which takes its place with the other introductions to that important field. The book is based to a large extent upon recent papers which have attracted the author's interest, although there is a refreshing number of references to important papers in the older literature. It is remarkable for its studious avoidance of quantitative formulations. The attempt is made rather to give a vivid mental image of the structure and behavior of colloidal systems, an object which is eminently desirable. Indeed if pushed still further it would help in the logical discrimination between confused or conflicting conceptions. In other words, the development of colloid science would benefit greatly from the setting up of models as working hypotheses and there is a much greater probability of such models possessing permanent validity than those used in the elucidation of atomic structure.

If the author had only pursued this method more consistently he would not have stated (p. 5) that "colloidal gold is a physical system composed of water and of gold in a certain state of subdivision," when from certain later pages it is evident that the author is aware that there is likewise an essential, partly dissociated, stabilizing agent present. The author has rightfully emphasized the properties of gels "because natural colloids

appear more often in the form of gels than sols." His description faithfully reflects the muddled state of the subject, which may be summarized in his opening sentence on the structure of gels (p. 207), "There is still considerable divergence of opinion about the structure of gels, but several of the accepted views approximate closely to the same thing when studied seriously."

The book is attractive, with good print and diagrams. Although many statements are debatable, Hedges' introductory presentation may be warmly recommended as being modern, stimulating, and original in its selection of subject matter.

JAMES W. MCBAIN

Annual Review of Biochemistry. Volume I. Edited by JAMES MURRAY LUCK, Stanford University. Stanford University Press, Stanford University, California, 1932. vii + 724 pp. 15.5 × 23 cm. Price, \$5.00.

The extremely rapid development of most of the sciences since the beginning of the century has brought along with it an enormous increase in the periodical literature pertaining thereto. This is conspicuously true of the so-called "borderline" sciences, like biochemistry, that present overlapping fields of interest to their devotees. The day has long since passed when even the most assiduous student could be expected to become familiar at first hand with the thousands of pages contributed each year to the scientific journals concerned with research in his department of knowledge. The development of abstract journals and reviews has thus become both inevitable and highly essential.

The newly launched enterprise, *The Annual Review of Biochemistry*, sponsored so vigorously by Professor J. M. Luck and his colleagues: C. L. Alsberg, D. R. Hoagland and C. L. A. Schmidt, on the Pacific coast, is not entirely a novelty in its conception. It surpasses most of the other review journals or books in breadth of scope and in the noteworthy success with which so many collaborators of unusual competence have been secured. The new volume gives evidence of the never-to-be-forgotten fact that science transcends the boundaries of nations. Thus there are critical essays by R. Wurmser of France; I. Smedley-MacLean, L. J. Harris, E. G. Holmes, J. Needham and M. Stephenson, of England; R. Hoeber, A. Windaus and H. Fischer of Germany; J. K. Parnas of Poland; E. Waldschmidt-Leitz of Czechoslovakia; N. N. Ivanoff of Russia; H. D. Kay and J. B. Collip of Canada; P. Karrer and L. Ruzicka of Switzerland; in addition to fourteen reviews by American experts. This truly represents an international endeavor.

It would be futile to attempt any really critical comments in the confines of this necessarily brief notice of these very useful—and for the most part readable—seven hundred pages. To single out individual essays for special

mention seems presumptuous when so many masters of research have summarized the recent development in the domains of their own endeavors. A few themes have been treated somewhat scantily; but subsequent volumes are promised to remedy such temporary omissions. One can imagine the surprise awakened in some of the early contributors to another pioneer effort in reviewing the literature of physiological chemistry—Maly's *Jahresbericht ueber die Fortschritte der Thierchemie*—if they were to study this latest volume portraying the current state of the science. There would be vitamins and hormones and immunochemistry to perplex those older chemists by the utter novelty of the topics. The chemistry of muscle would give new meanings to old observations. The animal and plant pigments would present surprises of a new order. The physical chemistry of protoplasm would reveal old facts in new interpretations. *Tempora mutantur!*
